$$\begin{cases} \mathbf{g}^{\varepsilon}_{r,z} = \Big(e^{-ik\hat{\mathbf{R}}_1\cdot z}\Delta(\mathbf{R}_1)\cdot\overrightarrow{\gamma}_1,\dots,e^{-ik\hat{\mathbf{R}}_1\cdot z}\Delta(\mathbf{R}_1)\cdot\overrightarrow{\gamma}_{d_r},\dots, \\ \qquad\qquad e^{-ik\hat{\mathbf{R}}_{n_r}\cdot z}\Delta(\mathbf{R}_{n_r})\cdot\overrightarrow{\gamma}_1,\dots,e^{-ik\hat{\mathbf{R}}_{n_r}\cdot z}\Delta(\mathbf{R}_{n_r})\cdot\overrightarrow{\gamma}_{d_r}\Big)^T, \\ \mathbf{g}^{\varepsilon}_{t,z} = \Big(e^{-ik\hat{\mathbf{r}}_1\cdot z}\Delta(\mathbf{r}_1)\cdot\overrightarrow{\beta}_1,\dots,e^{-ik\hat{\mathbf{r}}_1\cdot z}\Delta(\mathbf{r}_1)\cdot\overrightarrow{\beta}_{d_t},\dots, \\ \qquad\qquad e^{-ik\hat{\mathbf{r}}_{n_t}\cdot z}\Delta(\mathbf{r}_{n_t})\cdot\overrightarrow{\beta}_1,\dots,e^{-ik\hat{\mathbf{r}}_{n_t}\cdot z}\Delta(\mathbf{r}_{n_t})\cdot\overrightarrow{\beta}_{d_t}\Big)^T, \\ \mathbf{g}^{\mu}_{r,z} = \Big(e^{-ik\hat{\mathbf{R}}_1\cdot z}\Lambda(\mathbf{R}_1)\cdot\overrightarrow{\gamma}_1,\dots,e^{-ik\hat{\mathbf{R}}_1\cdot z}\Lambda(\mathbf{R}_1)\cdot\overrightarrow{\gamma}_{d_r},\dots, \\ \qquad\qquad e^{-ik\hat{\mathbf{R}}_{n_r}\cdot z}\Lambda(\mathbf{R}_{n_r})\cdot\overrightarrow{\gamma}_1,\dots,e^{-ik\hat{\mathbf{R}}_{n_r}\cdot z}\Lambda(\mathbf{R}_{n_r})\cdot\overrightarrow{\gamma}_{d_r}\Big)^T, \\ \mathbf{g}^{\mu}_{t,z} = \Big(e^{-ik\hat{\mathbf{r}}_1\cdot z}\Lambda(\mathbf{r}_1)\cdot\overrightarrow{\beta}_1,\dots,e^{-ik\hat{\mathbf{r}}_1\cdot z}\Lambda(\mathbf{r}_1)\cdot\overrightarrow{\beta}_{d_t},\dots, \\ \qquad\qquad e^{-ik\hat{\mathbf{r}}_{n_t}\cdot z}\Lambda(\mathbf{r}_{n_t})\cdot\overrightarrow{\beta}_1,\dots,e^{-ik\hat{\mathbf{r}}_{n_t}\cdot z}\Lambda(\mathbf{r}_{n_t})\cdot\overrightarrow{\beta}_{d_t}\Big)^T. \end{cases}$$

The MSR matrix $\mathbf{A}\in\mathbb{C}^{d_rn_r\times d_tn_t}$ admits the decomposition (22), where in the definition (20) the vectors $\mathbf{g}^{\varepsilon}_{p,z},\mathbf{g}^{\mu}_{p,z},p=r,t$, are given by (23).

4. The location search algorithm. Recall that MUSIC is essentially based on characterizing the range of the MSR matrix $\mathbf{A}$, forming projections onto its null spaces, and computing its singular value decomposition. In the next subsection, we give some useful results on the eigenvalue structure of matrices of the form (22).

4.1. Some preliminaries. Let $N,N_1,N_2\in\mathbb{N}$. Suppose $N\le\min\{N_1,N_2\}$. Define the matrix $\mathbf{A}\in\mathbb{C}^{N_1\times N_2}$ as

$$\mathbf{A}=\mathbf{g}_r\,\mathbf{M}\,\mathbf{g}_t^T, \tag{24}$$

where the matrices $\mathbf{g}_r\in\mathbb{C}^{N_1\times N}$, $\mathbf{g}_t\in\mathbb{C}^{N_2\times N}$, and the matrix $\mathbf{M}\in\mathbb{C}^{N\times N}$ is symmetric and nonsingular.

Let the matrix $\mathbf{g}_r$ have rank $k_r\le N$ and let $\mathbf{g}_t$ have rank $k_t\le N$. Then the matrices G_r and $G_t\in\mathbb{C}^{N\times N}$ defined by

$$G_r=\mathbf{g}_r^*\mathbf{g}_r,\quad G_t=\mathbf{g}_t^*\mathbf{g}_t$$

have rank k_r and k_t, respectively. Here, $\mathbf{g}^*=\overline{\mathbf{g}}^T$.

Suppose $k_r=k_t=N$. The matrices G_r and G_t are invertible. The polar decompositions of the matrices $\mathbf{g}_r$ and $\mathbf{g}_t$ are written as

$$\mathbf{g}_r=U_r(G_r)^{\frac12},\quad \mathbf{g}_t=U_t(G_t)^{\frac12},$$

where $(G_r)^{\frac12}$ and $(G_t)^{\frac12}$ are positive definite, and the matrices $U_r\in\mathbb{C}^{N_1\times N}$ and $U_t\in\mathbb{C}^{N_2\times N}$ have orthonormal columns, i.e., $U_r^*U_r=U_t^*U_t=\mathbf{I}_N$. Here $\mathbf{I}_N$ is the identity matrix in $\mathbb{R}^{N\times N}$. Therefore, U_r and U_t are uniquely determined by the formulae

$$U_r=\mathbf{g}_r(G_r)^{-\frac12},\quad U_t=\mathbf{g}_t(G_t)^{-\frac12}. \tag{25}$$

From (24) we have

$$\mathbf{A}=\mathbf{g}_r\,\mathbf{M}\,\mathbf{g}_t^T=U_r\,\underbrace{(G_r)^{\frac12}\,\mathbf{M}\,(\overline{G_t})^{\frac12}}_{\Xi}\,U_t^T=U_r\,\Xi\,U_t^T,$$

with $\Xi \in \mathbb{C}^{N\times N}$. Let the singular value decomposition (SVD) of the matrix Ξ be given by $\Xi = U_\Xi\, \Sigma_\Xi\, W_\Xi^*$. Then $\mathbf{A}$ can be written as

$$\mathbf{A} = U_r U_\Xi\, \Sigma_\Xi\, (\overline{U_t} W_\Xi)^*. \tag{26}$$

Therefore, the nonzero singular values of $\mathbf{A}$ are the diagonal elements of $\Sigma_\Xi = \mathrm{diag}(\sigma_{\Xi,1}, \ldots, \sigma_{\Xi,N})$. The first N left singular vectors of $\mathbf{A}$ are the columns of the matrix $U_r U_\Xi$ and form an orthonormal left basis for the space of $\mathbf{A}$, denoted by $\mathbf{U}_S$; the first N right singular vectors of $\mathbf{A}$ are the columns of the matrix $\overline{U_t} W_\Xi$ and form an orthonormal right basis for the space of $\mathbf{A}$, denoted by $\mathbf{W}_S$. From (25) and (26) it follows that for any vector $\mathbf{a} \in \mathbb{R}^N \setminus \{0\}$ the vector $\mathbf{g}_r \cdot \mathbf{a}$ is in the range, $\mathcal{R}(\mathbf{A}\mathbf{A}^*)$, of $\mathbf{A}\mathbf{A}^*$, and for any vector $\mathbf{b} \in \mathbb{R}^N \setminus \{0\}$ the vector $\overline{\mathbf{g}_t} \cdot \mathbf{b}$ is in the range, $\mathcal{R}(\mathbf{A}^*\mathbf{A})$, of $\mathbf{A}^*\mathbf{A}$.

The orthogonal projection onto the left null space of $\mathbf{A}$ is given by

$$\mathbf{P}_r = \mathbf{I}_{N_1} - \mathbf{U}_S \mathbf{U}_S^* = \mathbf{I}_{N_1} - U_r U_\Xi (U_r U_\Xi)^* = \mathbf{I}_{N_1} - U_r U_r^* = \mathbf{I}_{N_1} - \mathbf{g}_r (G_r)^{-1} \mathbf{g}_r^*,$$

while the orthogonal projection onto the right null space of $\mathbf{A}$ is given by

$$\mathbf{P}_t = \mathbf{I}_{N_2} - \mathbf{W}_S \mathbf{W}_S^* = \mathbf{I}_{N_2} - \overline{U_t} W_\Xi (\overline{U_t} W_\Xi)^* \mathbf{I}_{N_2} - \overline{U_t} {U_t}^T = \mathbf{I}_{N_2} - \overline{\mathbf{g}_t} (\overline{G_t})^{-1} {\mathbf{g}_t}^T.$$

Suppose now that $k_r \le k_t < N$. The matrices G_r and G_t are singular. Suppose throughout this subsection that the ranges of the matrices

$$\mathbf{g}_r = [g_{r,1}, \ldots, g_{r,k_r}, g_{r,k_r+1}, \ldots g_{r,N}] \text{ and } \mathbf{g}_t = [g_{t,1}, \ldots, g_{t,k_t}, g_{t,k_t+1}, \ldots, g_{t,N}]$$

are spanned by the matrices' first k_r and k_t columns denoted by $\mathbf{g}_{r,S} \in \mathbb{C}^{N_1\times k_r}$ and $\mathbf{g}_{t,S} \in \mathbb{C}^{N_2\times k_t}$, respectively. Then

$$g_{r,j} = \sum_{i=1}^{k_r} \alpha_{i,j} g_{r,i}, \quad j = k_r+1, \ldots, N, \quad \text{and} \quad g_{t,l} = \sum_{i=1}^{k_t} \beta_{i,l} g_{t,i}, \quad l = k_t+1, \ldots, N,$$

where $\{\alpha_{i,j}\}$ and $\{\beta_{i,l}\} \in \mathbb{C}$. Now the matrix $\mathbf{A}$, defined by (24), can be rewritten as

$$\mathbf{A} = \mathbf{g}_{r,S}\, \mathbf{M}_S\, \mathbf{g}_{t,S}^T,$$

where $\mathbf{M}_S \in \mathbb{C}^{k_r\times k_t}$. The elements of $\mathbf{M}_S$ depend on the elements of the matrix $\mathbf{M}$ and the coefficients $\{\alpha_{i,j}\}$ and $\{\beta_{i,l}\}$.

Suppose $k_r = k_t = k < N$. The square matrix $\mathbf{M}_S$ is nonsingular but not always symmetric. The calculation of the SVD of $\mathbf{A}$ is similar to the case where $k_r = k_t = k = N$. It can be proved that for any vector $\mathbf{a} = (a_1, \ldots, a_N)^T \in \mathbb{R}^N \setminus \{0\}$ such that $\mathbf{g}_r \cdot \mathbf{a} \neq 0$, the vector $\mathbf{g}_r \cdot \mathbf{a}$ is in the range of $\mathbf{A}\mathbf{A}^*$. Analogously, for any vector $\mathbf{b} = (b_1, \ldots, b_N)^T \in \mathbb{R}^N \setminus \{0\}$ such that $\overline{\mathbf{g}_t} \cdot \mathbf{b} \neq 0$, the vector $\overline{\mathbf{g}_t} \cdot \mathbf{b}$ is in the range of $\mathbf{A}^*\mathbf{A}$. Here

$$\mathbf{g}_r \cdot \mathbf{a} = \mathbf{g}_{r,S} \cdot \mathbf{a}_r, \quad \overline{\mathbf{g}_t} \cdot \mathbf{b} = \overline{\mathbf{g}_{t,S}} \cdot \mathbf{b}_t, \tag{27}$$

where

$$\mathbf{a}_r = \left(a_1 + \sum_{j=k+1}^{N} a_j\, \alpha_{1,j}, \ldots, a_k + \sum_{j=k+1}^{N} a_j\, \alpha_{j,k} \right)^T \in \mathbb{C}^k,$$

$$\mathbf{b}_t = \left(b_1 + \sum_{j=k+1}^{N} b_j\, \beta_{1,j}, \ldots, b_k + \sum_{j=k+1}^{N} b_j\, \beta_{j,k} \right)^T \in \mathbb{C}^k.$$

Suppose $k_r < k_t \leq N$. Then

$$\mathbf{A} = \mathbf{g}_{r,S}\,\mathbf{M}_S\,\mathbf{g}_{t,S}^T = \mathbf{g}_{r,S}\,(\mathbf{g}_{t,S}\,\mathbf{M}_S^T)^T = \mathbf{g}_{r,S}\,\mathbf{f}_{t,S}^T,$$

with $\mathbf{f}_{t,S} = \mathbf{g}_{t,S}{\mathbf{M}_S}^T \in \mathbb{C}^{N_2\times k_r}$. Again, define

$$\mathbf{g}_{rS} = U_{r,S}(\mathbf{g}_{r,S}^*\mathbf{g}_{r,S})^{\frac{1}{2}} = U_{r,S}(G_{r,S})^{\frac{1}{2}}, \quad \mathbf{f}_{t,S} = U_{t,S}\,(F_{t,S})^{\frac{1}{2}},$$

where the matrix

$$F_{t,S} = \overline{\mathbf{M}_S}\,\mathbf{g}_{t,S}^*\,\mathbf{g}_{t,S}{\mathbf{M}_S}^T = \overline{\mathbf{M}_S}\,G_{t,S}{\mathbf{M}_S}^T$$

has rank k_r. Then $U_{r,S}$ and $U_{t,S}$ are uniquely determined by

$$U_{r,S} = \mathbf{g}_{r,S}(G_{r,S})^{-\frac{1}{2}}, \quad U_{t,S} = \mathbf{f}_{t,S}(F_{t,S})^{-\frac{1}{2}}, \tag{28}$$

and the matrix $\mathbf{A}$ becomes

$$\mathbf{A} = U_{r,S}\,\underbrace{(G_{r,S})^{\frac{1}{2}}(F_{t,S})^{\frac{1}{2}}}_{\Xi = U_\Xi\,\Sigma_\Xi\,W_\Xi^*}\,U_{t,S}^T = U_{r,S}U_\Xi\,\Sigma_\Xi\,(\overline{U_{t,S}}\,W_\Xi)^*. \tag{29}$$

Once again, the first N left singular vectors of $\mathbf{A}$ are the columns of the matrix $U_{r,S}U_\Xi$; the first N right singular vectors of $\mathbf{A}$ are the columns of the matrix $\overline{U_{t,S}}W_\Xi$. From (27), (28), and (29) it follows that for any vector $\mathbf{a} \in \mathbb{R}^N \setminus \{0\}$ such that $\mathbf{g}_r \cdot \mathbf{a} \neq 0$, the vector $\mathbf{g}_r \cdot \mathbf{a}$ is in the range of $\mathbf{A}\mathbf{A}^*$, but the vector $\overline{\mathbf{g}_t} \cdot \mathbf{a}$ does not belong to the range of $\mathbf{A}^*\mathbf{A}$.

The orthogonal projection onto the left null space of $\mathbf{A}$ is given by

$$\mathbf{P}_r = \mathbf{I}_{N_1} - U_{r,S}U_\Xi(U_{r,S}U_\Xi)^* = \mathbf{I}_{N_1} - U_{r,S}U_{r,S}^* = \mathbf{I}_{N_1} - \mathbf{g}_{r,S}(G_{r,S})^{-1}\mathbf{g}_{r,S}^*,$$

while the orthogonal projection onto the right null space of $\mathbf{A}$ is given by

$$\begin{aligned}\mathbf{P}_t &= \mathbf{I}_{N_2} - \overline{U_{t,S}}W_\Xi(\overline{U_{t,S}}W_\Xi)^* = \mathbf{I}_{N_2} - \overline{U_{t,S}}{U_{t,S}}^T = \mathbf{I}_{N_2} - \overline{\mathbf{f}_{t,S}}(\overline{F_{t,S}})^{-1}{\mathbf{f}_{t,S}}^T \\ &= \mathbf{I}_{N_2} - \overline{\mathbf{g}_{t,S}}\mathbf{M}_S^*(\mathbf{M}_S\,\overline{G_{t,S}}\mathbf{M}_S^*)^{-1}\,\mathbf{M}_S\mathbf{g}_{t,S}^T.\end{aligned}$$

If $k_t < k_r \leq N$, we consider $\mathbf{A}^T$ instead of $\mathbf{A}$.

Finally, since the matrix $\mathbf{M}$ is nonsingular, the rank of $\mathbf{A}$ (the number of nonzero singular values of $\mathbf{A}$) depends only on the rank of the matrices G_r and G_t. Denote by $\hat{G}_r$ (and $\hat{G}_t$) a matrix of k_r (and k_t) linearly independent rows of G_r (and G_t), respectively. Suppose that the matrix $\hat{G}_r\mathbf{M}\hat{G}_t^T$ has rank $\min\{k_r, k_t\} \leq N$. Then $\operatorname{rank}(\mathbf{A}) = \min\{k_r, k_t\}$.

We have established the following result.

PROPOSITION 4.1. $\mathbf{A} = \mathbf{g}_r\,\mathbf{M}\,\mathbf{g}_t^T \in \mathbb{C}^{N_1\times N_2}$, $\mathbf{g}_r \in \mathbb{C}^{N_1\times N}$ $\mathbf{g}_t \in \mathbb{C}^{N_2\times N}$ $N \leq \min\{N_1, N_2\}$ $\mathbf{M} \in \mathbb{C}^{N\times N}$ $(\mathbf{g}_r) = k_r \leq N$ $(\mathbf{g}_t) = k_t \leq N$ $\hat{\mathbf{g}}_r$ $\hat{\mathbf{g}}_t$ k_r k_t $\mathbf{g}_r$ $\mathbf{g}_t$ $\hat{\mathbf{g}}_r\,\mathbf{M}\,\hat{\mathbf{g}}_t^T$ $\min\{k_r, k_t\}$ $\mathbf{A}$ $\min\{k_r, k_t\} \leq N$

- $k_r = k_t \leq N$ $\mathbf{a}, \mathbf{b} \in \mathbb{R}^N \setminus \{0\}$ $\mathbf{g}_r \cdot \mathbf{a} \neq 0$ $\overline{\mathbf{g}_t} \cdot \mathbf{b} \neq 0$ $\mathbf{g}_r \cdot \mathbf{a} \in \mathcal{R}(\mathbf{A}\mathbf{A}^*)$ $\overline{\mathbf{g}_t} \cdot \mathbf{b} \in \mathcal{R}(\mathbf{A}^*\mathbf{A})$.
- $k_r < k_t \leq N$ $\mathbf{a} \in \mathbb{R}^N \setminus \{0\}$ $\mathbf{g}_r \cdot \mathbf{a} \neq 0$, $\mathbf{g}_r \cdot \mathbf{a} \in \mathcal{R}(\mathbf{A}\mathbf{A}^*)$.
- $k_t < k_r \leq N$ $\mathbf{b} \in \mathbb{R}^N \setminus \{0\}$ $\overline{\mathbf{g}_t} \cdot \mathbf{b} \neq 0$ $\overline{\mathbf{g}_t} \cdot \mathbf{b} \in \mathcal{R}(\mathbf{A}^*\mathbf{A})$

4.2. MUSIC characterization of the multistatic response matrix. Now we return to the decomposition (22) of the MSR matrix $\mathbf{A} \in \mathbb{C}^{d_r n_r \times d_t n_t}$ and remember that we are considering separately the three (electromagnetic) cases.

Let $\min(d_r n_r, d_t n_t) \geq 3$ (cases 1 and 2) and $\min(d_r n_r, d_t n_t) \geq 6$ (case 3). For any $z \in \mathbb{R}^3 \setminus \{\mathbf{r}_1, \ldots, \mathbf{r}_{n_t}, \mathbf{R}_1, \ldots, \mathbf{R}_{n_r}\}$ (or $z \in \mathbb{R}^3$ for the far-field regime) define

$$G_{p,z} = \overline{\mathbf{g}_{p,z}}^T \mathbf{g}_{p,z}, \quad p = r, t,$$

where $\mathbf{g}_{p,z}$ is given by (20) with $\mathbf{g}^{\varepsilon}_{p,z}, \mathbf{g}^{\mu}_{p,z}, p = r, t$, defined by either (19) or (23). The matrix $G_{p,z}$ has rank k_p, where

$$\begin{aligned}
&\text{case 1:} \quad G_{p,z} = G^{\varepsilon}_{p,z} = \overline{\mathbf{g}^{\varepsilon}_{p,z}}^T \mathbf{g}^{\varepsilon}_{p,z}, \quad \operatorname{rank}(G^{\varepsilon}_{p,z}) = k^{\varepsilon}_p = k_p \leq 3,\\
&\text{case 2:} \quad G_{p,z} = G^{\mu}_{p,z} = \overline{\mathbf{g}^{\mu}_{p,z}}^T \mathbf{g}^{\mu}_{p,z}, \quad \operatorname{rank}(G^{\mu}_{p,z}) = k^{\mu}_p = k_p \leq 3,\\
&\text{case 3:} \quad G_{p,z} = G^{\mu,\varepsilon}_{p,z} = \overline{[\mathbf{g}^{\mu}_{p,z}, \mathbf{g}^{\varepsilon}_{p,z}]}^T [\mathbf{g}^{\mu}_{p,z}, \mathbf{g}^{\varepsilon}_{p,z}],\\
&\qquad\quad \operatorname{rank}(G^{\mu,\varepsilon}_{p,z}) = k^{\mu,\varepsilon}_p = k_p \leq 6, \quad p = t, r.
\end{aligned} \tag{30}$$

Moreover, in case 3, we have $k^{\mu,\varepsilon}_p = k^{\mu}_p + k^{\varepsilon}_p$.

For the far-field pattern, it is easy to see that the following proposition holds since $\overline{G_{p,z}}^T G_{p,z}$ is z-independent.

PROPOSITION 4.2. [illegible] $G_{p,z}$ [illegible] (30) [illegible] $z \in \mathbb{R}^3$

Propositions 4.1 and 4.2 together with (22) yield that the maximal rank of $\mathbf{A}$ is $m \min(k_r, k_t)$.

For the near-field regime, the rank k_p depends on the configuration (transmitter and receiver arrays), the polarizations, and the position z. If we suppose that the transmitter and receiver arrays are planar, then by the far-field expansion of the Green's function we can see that the claim in Proposition 4.2 holds for z far enough from the set of points $\{\mathbf{r}_1, \ldots, \mathbf{r}_{n_t}, \mathbf{R}_1, \ldots, \mathbf{R}_{n_r}\}$. See section 5.

The following is a MUSIC characterization of the locations of the electromagnetic inclusions [32, 21] and is valid if the numbers n_r and n_t are sufficiently large. See Appendix B for the statement of some technical assumptions which are necessary to rigorously prove the following proposition.

PROPOSITION 4.3. [illegible] $\min(d_r n_r, d_t n_t) \geq m \min(k_r, k_t)$ [illegible] k_r, k_t [illegible] (30)

- [illegible] $k_r = k_t$ [illegible] $\mathbf{a} \in \mathbb{R}^N \setminus \{0\}$ [illegible] $\mathbf{g}_{r,z} \cdot \mathbf{a} \neq 0$ [illegible] z [illegible]

$$\mathbf{g}_{r,z} \cdot \mathbf{a} \in \mathcal{R}(\mathbf{A}\mathbf{A}^*) \quad \text{for} \quad z \in \{z_1, \ldots, z_m\}.$$

[illegible] $\mathbf{b} \in \mathbb{R}^N \setminus \{0\}$ [illegible] $\overline{\mathbf{g}_{t,z}} \cdot \mathbf{b} \neq 0$ [illegible] z [illegible]

$$\overline{\mathbf{g}_{t,z}} \cdot \mathbf{b} \in \mathcal{R}(\mathbf{A}^*\mathbf{A}) \quad \text{for} \quad z \in \{z_1, \ldots, z_m\}.$$

- [illegible] $k_r < k_t$ [illegible] $\mathbf{a} \in \mathbb{R}^N \setminus \{0\}$ [illegible] $\mathbf{g}_{r,z} \cdot \mathbf{a} \neq 0$ [illegible] z [illegible]

$$\mathbf{g}_{r,z} \cdot \mathbf{a} \in \mathcal{R}(\mathbf{A}\mathbf{A}^*) \quad \text{for} \quad z \in \{z_1, \ldots, z_m\}.$$

• [illegible] $k_t < k_r$ [illegible] $\mathbf{b} \in \mathbb{R}^N \setminus \{0\}$ [illegible] $\overline{\mathbf{g}_{t,z}} \cdot \mathbf{b} \neq 0$ [illegible] z

$$\overline{\mathbf{g}_{t,z}} \cdot \mathbf{b} \in \mathcal{R}(\mathbf{A}^*\mathbf{A}) \quad \text{for} \quad z \in \{z_1, \ldots, z_m\}.$$

[illegible] N [illegible] $\mathbf{a}$ [illegible] $\mathbf{b}$ [illegible] 3 [illegible] 1 [illegible] 2 [illegible] 6 [illegible] 3

Note that, in view of Proposition 4.2, if a vector $\mathbf{a} \in \mathbb{R}^N \setminus \{0\}$ satisfies $\mathbf{g}_{p,0} \cdot \mathbf{a} \neq 0$, then $\mathbf{g}_{p,z} \cdot \mathbf{a} \neq 0$ for any point z (in the searching domain).

4.3. The MUSIC-type algorithm. Let the SVD of the matrix $\mathbf{A}$ be defined by $\mathbf{A} = \mathbf{U}\Sigma\mathbf{W}^*$. From Proposition 4.3, $\mathbf{A}$ has rank $m\,(\min(k_r, k_t))$. Then, as has been said, the first $m\,(\min(k_r, k_t))$ columns of $\mathbf{W}$ provide an orthonormal right basis for the image space of $\mathbf{A}$ which is denoted by $\mathbf{W}_S$, and the rest of the matrix $\mathbf{W}$ provides the basis for the right null space of $\mathbf{A}$, denoted by $\mathbf{W}_N$. Then the best rank approximation for $\mathbf{A}$ is $(\mathbf{W}_S\mathbf{W}_S^*)\mathbf{A}$ with error $E = \mathbf{A} - (\mathbf{W}_S\mathbf{W}_S^*)\mathbf{A}$. See [3, 4].

The orthogonal projections onto the left and right null space of $\mathbf{A}$ are given by $\mathbf{P}_r = \mathbf{I} - (\mathbf{U}_S\mathbf{U}_S^*)$ and $\mathbf{P}_t = \mathbf{I} - (\mathbf{W}_S\mathbf{W}_S^*)$. If $k_r = k_t$, a test point z coincides with one of the positions z_j if and only if $\mathbf{P}_r(\mathbf{g}_{r,z} \cdot \mathbf{a}) = 0$ and $\mathbf{P}_t(\overline{\mathbf{g}_{t,z}} \cdot \mathbf{a}) = 0$; if $k_r < k_t$, then a test point z coincides with one of the positions z_j if and only if $\mathbf{P}_r(\mathbf{g}_{r,z} \cdot \mathbf{a}) = 0$; if $k_t < k_r$, then a test point z coincides with one of the positions z_j if and only if $\mathbf{P}_t(\overline{\mathbf{g}_{t,z}} \cdot \mathbf{a}) = 0$.

Thus we can form an image of $z_j, j = 1, \ldots, m$, by plotting, at each point z, the following quantities:

- if $k_r = k_t$: $W_r(z) = 1/||\mathbf{P}_r(\mathbf{g}_{r,z} \cdot \mathbf{a})||$, or $W_t(z) = 1/||\mathbf{P}_t(\overline{\mathbf{g}_{t,z}} \cdot \mathbf{a})||$, or $W_{r,t}(z) = 1/||\mathbf{P}_r(\mathbf{g}_{r,z} \cdot \mathbf{a}_r) + \mathbf{P}_t(\overline{\mathbf{g}_{t,z}} \cdot \mathbf{a}_t)||$;
- if $k_r < k_t$: $W_r(z) = 1/||\mathbf{P}_r(\mathbf{g}_{r,z} \cdot \mathbf{a})||$;
- if $k_t < k_r$: $W_t(z) = 1/||\mathbf{P}_t(\overline{\mathbf{g}_{t,z}} \cdot \mathbf{a})||$.

We shall emphasize the fact that this algorithm can be used to recover the location of m well-separated electromagnetic inclusions provided that $\min(d_r n_r, d_t n_t) > m\,(\min(k_r, k_t))$. The obtained images do not depend on the shape of the inclusions.

Note also that once the location z_0 of the inclusion is found, we can approximate its polarization tensor. In the simplest case, $k_r = k_t = N$ ($N = 3$ in cases 1 and 2 and $N = 6$ in case 3), $m = 1$, and

$$\mathbf{M} = (G_{r,z_0})^{-1}(\mathbf{g}_{r,z_0})^*\, \mathbf{A}\, \overline{\mathbf{g}_{t,z_0}}\, (\overline{G_{t,z_0}})^{-1}.$$

In the case of multiple inclusions, if $z_1, \ldots, z_m$ are the reconstructed locations, then

$$\mathbf{M} = \operatorname{diag}(\mathbf{M}_1, \ldots, \mathbf{M}_m) = (G_{r,z_1,\ldots,z_m})^{-1}(\mathbf{g}_{r,z_1,\ldots,z_m})^*\, \mathbf{A}\, \overline{\mathbf{g}_{t,z_1,\ldots,z_m}}\, (\overline{G_{t,z_1,\ldots,z_m}})^{-1}.$$

We can represent and visualize the inclusion by means of an ellipsoid with the same polarization tensor which is the only geometric information of real interest that could be reconstructed from the MSR matrix. It is also worth mentioning that the polarization tensor yields information about the size and orientation of the inclusion. However, this information is a mixture of the electromagnetic parameters and the volume. See [9] for details.

5. Analysis of the eigenvalue structure of the multistatic response matrix. Suppose that the array of transmitters is in the plane $z = z_a$ and is symmetric about the ξ and η axes (see Figure 5.1). We make the same assumption for the array of receivers (not necessarily the same plane $z = z_a$ of the transmitters; the array of receivers can be in the plane $x = x_a$ or $y = y_a$).

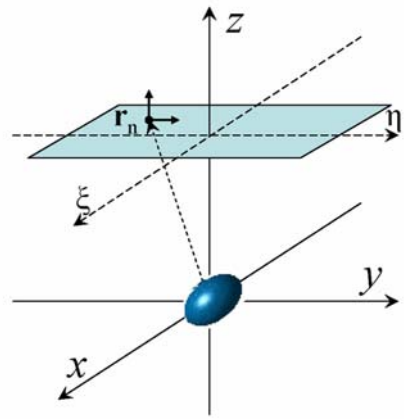

FIG. 5.1. *The planar array of transmitters.*

Suppose that the inclusions are ellipsoids. Then, as already noted,

$$\mathbf{M}^{\varepsilon} = R \begin{bmatrix} m_1^{\varepsilon} & 0 & 0 \\ 0 & m_2^{\varepsilon} & 0 \\ 0 & 0 & m_3^{\varepsilon} \end{bmatrix} R^T, \quad \mathbf{M}^{\mu} = R \begin{bmatrix} m_1^{\mu} & 0 & 0 \\ 0 & m_2^{\mu} & 0 \\ 0 & 0 & m_3^{\mu} \end{bmatrix} R^T,$$

where $m_i^{\varepsilon}, m_i^{\mu} \in \mathbb{C}$, $i = 1, 2, 3$, and $R \in \mathbb{R}^{3\times 3}$ is a rotation matrix. Note that $R = \mathbf{I}_3$ if the ellipsoid is aligned with the coordinate axes. See [34, 26, 9].

5.1. Case of a single dielectric inclusion. We first consider the case of a single dielectric inclusion ($m = 1$ and $\mu_1 = \mu_0$). Suppose that this inclusion is centered at the point z, so it is of the form αB, where B is an ellipsoid. Then

$$\mathbf{A} = \mathbf{g}_{r,z}^{\varepsilon} \mathbf{M}^{\varepsilon} (\mathbf{g}_{t,z}^{\varepsilon})^T,$$

and the positive semidefinite matrix $G_{r,z}^{\varepsilon}$ is given, for the near-field regime, by

$$G_{r,z}^{\varepsilon} = (\overline{\mathbf{g}_{r,z}^{\varepsilon}})^T \mathbf{g}_{r,z}^{\varepsilon} = \sum_{l=1}^{d_r} \sum_{j=1}^{n_r} \overline{\mathbf{G}(z, \mathbf{R}_j)} \, (\overrightarrow{\gamma}_l \, \overrightarrow{\gamma}_l^T) \, \mathbf{G}(\mathbf{R}_j, z),$$

where

$$\mathbf{G}(\mathbf{r}, \mathbf{r}') = \frac{e^{ik|s|}}{4\pi|s|} \left(\mathbf{I}_3 - \hat{s}\hat{s}^T + \frac{i}{k|s|} \left(\mathbf{I}_3 - 3\,\hat{s}\hat{s}^T \right) - \frac{1}{k^2|s|^2} \left(\mathbf{I}_3 - 3\,\hat{s}\hat{s}^T \right) \right), \quad s = \mathbf{r} - \mathbf{r}'.$$

If $|z| \to +\infty$, then using the far-field expansion of the Green's function $\mathbf{G}$ we obtain that $G_{r,z}^{\varepsilon}$ can be approximated by

$$G_{r,\infty}^{\varepsilon} = \sum_{l=1}^{d_r} \sum_{j=1}^{n_r} \Delta(\mathbf{R}_j) \, (\overrightarrow{\gamma}_l \, \overrightarrow{\gamma}_l^T) \, \Delta(\mathbf{R}_j),$$

which does not depend on the point z.

In the limit that the number of array elements becomes large and the spacing between elements small, the inner products can be replaced with integrals over the

aperture of the array [19]. Consider, for example, the far-field expansion of $G^{\varepsilon}_{r,z}$; we have

$$G^{\varepsilon}_{r,\infty} = \sum_{l=1}^{d_r} \int_{S_r} \Delta(\xi,\eta)\,(\overrightarrow{\gamma}_l\,\overrightarrow{\gamma}_l^{T})\,\Delta(\xi,\eta)\,d\xi\,d\eta, \tag{31}$$

where S_r and S_t are the aperture of the arrays of transmitters and receivers, respectively.

Writing $G^{\varepsilon}_{r,\infty} = \sum_{j=1}^{d_r} G^{\varepsilon,j}_{r,\infty}$, we have

$$\overrightarrow{\gamma}_1 = \mathbf{e}_z: \quad G^{\varepsilon,1}_{r,\infty} = \int_{S_r} \frac{1}{r^4} \begin{bmatrix} \xi^2 z_a^2 & \xi\eta z_a^2 & \xi z_a(z_a^2 - r^2) \\ \xi\eta z_a^2 & \eta^2 z_a^2 & \eta z_a(z_a^2 - r^2) \\ \xi z_a(z_a^2 - r^2) & \eta z_a(z_a^2 - r^2) & (z_a^2 - r^2)^2 \end{bmatrix} d\xi d\eta, \tag{32}$$

$$\overrightarrow{\gamma}_2 = \mathbf{e}_y: \quad G^{\varepsilon,2}_{r,\infty} = \int_{S_r} \frac{1}{r^4} \begin{bmatrix} \xi^2\eta^2 & \xi\eta(\eta^2 - r^2) & \xi\eta^2 z_a \\ \xi\eta(\eta^2 - r^2) & (\eta^2 - r^2)^2 & \eta z_a(\eta^2 - r^2) \\ \xi\eta^2 z_a & \eta z_a(\eta^2 - r^2) & \eta^2 z_a^2 \end{bmatrix} d\xi d\eta, \tag{33}$$

$$\overrightarrow{\gamma}_3 = \mathbf{e}_x: \quad G^{\varepsilon,3}_{r,\infty} = \int_{S_r} \frac{1}{r^4} \begin{bmatrix} (\xi^2 - r^2)^2 & \xi\eta(\xi^2 - r^2) & \xi z_a(\xi^2 - r^2) \\ \xi\eta(\xi^2 - r^2) & \xi^2\eta^2 & \xi^2\eta z_a \\ \xi z_a(\xi^2 - r^2) & \xi^2\eta z_a & \xi^2 z_a^2 \end{bmatrix} d\xi d\eta, \tag{34}$$

where $r = \sqrt{\xi^2 + \eta^2 + z_a^2}$. We conclude that for a symmetric array of receivers (symmetric in ξ and η) the matrices $G^{\varepsilon,j}_{r,\infty}$, $j = 1,2,3$, are diagonal with positive elements on the diagonal, which implies that $\operatorname{rank}(G^{\varepsilon}_{r,\infty}) = 3$. Or, equivalently,

$$G^{\varepsilon}_{r,\infty} = \begin{bmatrix} G^{\varepsilon}_{r,11} & 0 & 0 \\ 0 & G^{\varepsilon}_{r,22} & 0 \\ 0 & 0 & G^{\varepsilon}_{r,33} \end{bmatrix},$$

where $G^{\varepsilon}_{r,ij} = (\overline{\mathbf{g}^{\varepsilon,i}_{r,\infty}})^T \mathbf{g}^{\varepsilon,j}_{r,\infty}$, $i,j = 1,2,3$, and the orthogonal vectors $\mathbf{g}^{\varepsilon,j}_{r,\infty} \in \mathbb{C}^{d_r n_r}$ are the column vectors of the matrix $\mathbf{g}^{\varepsilon}_{r,\infty} \in \mathbb{C}^{d_r n_r \times 3}$, which is the leading-order term in the far-field expansion of $\mathbf{g}^{\varepsilon}_{r,z}$.

With the same notation, the same result holds for the matrix $G^{\varepsilon}_{t,z}$: if the array of receivers is symmetric and planar, then we have

$$G^{\varepsilon}_{t,\infty} = \begin{bmatrix} G^{\varepsilon}_{t,11} & 0 & 0 \\ 0 & G^{\varepsilon}_{t,22} & 0 \\ 0 & 0 & G^{\varepsilon}_{t,33} \end{bmatrix},$$

where $G^{\varepsilon}_{t,ij} = (\overline{\mathbf{g}^{\varepsilon,i}_{t,\infty}})^T \mathbf{g}^{\varepsilon,j}_{t,\infty}$, $i,j = 1,2,3$. Here the vectors $\mathbf{g}^{\varepsilon,j}_{t,\infty} \in \mathbb{C}^{d_t n_t}$ are the column vectors of the matrix $\mathbf{g}^{\varepsilon}_{t,\infty} \in \mathbb{C}^{d_t n_t \times 3}$.

We conclude that the matrices $G^{\varepsilon}_{r,\infty}$ and $G^{\varepsilon}_{t,\infty}$ are positive definite and diagonal.

For finite $|z|$, the same results as for $|z| \to +\infty$ hold if the inclusion is centered at the origin. However, if the inclusion is located at a point $z \neq 0$, the matrices $G^{\varepsilon}_{r,z}$ and $G^{\varepsilon}_{t,z}$ are positive definite but not diagonal. By the Taylor expansion of the scalar Green's function $g(\mathbf{r},z) = e^{ik|\mathbf{r}-z|}/(4\pi|\mathbf{r}-z|)$ for $|z|/|\mathbf{r}| < 1$, we can approximate the matrices $G^{\varepsilon}_{p,z}, p = r,t$, to find that they are symmetric with strictly dominant diagonals, which implies that they are invertible.

Now, once the rank of the matrices $G^{\varepsilon}_{r,z}$ and $G^{\varepsilon}_{t,z}$ is known, we can compute the SVD of $\mathbf{A}$ following subsection 4.1. Let $k^{\varepsilon}_r = k^{\varepsilon}_t = 3$. If the inclusion is centered at the origin ($z = 0$) or if $|z|$ is large enough, we have

$$U_r = \mathbf{g}^{\varepsilon}_{r,0}(G^{\varepsilon}_{r,0})^{-\frac{1}{2}}, \quad U_t = \mathbf{g}^{\varepsilon}_{t,0}(G^{\varepsilon}_{t,0})^{-\frac{1}{2}};$$

i.e., the columns of U_r and U_t are normalized column vectors of $\mathbf{g}^{\varepsilon}_{r,0}$ and $\mathbf{g}^{\varepsilon}_{t,0}$, respectively. The nonzero singular values of $\mathbf{A}$ are the singular values of

$$\Xi = (G^{\varepsilon}_{r,0})^{\frac{1}{2}}\mathbf{M}^{\varepsilon}(G^{\varepsilon}_{t,0})^{\frac{1}{2}} = U_{\Xi}\,\Sigma_{\Xi}\,W^{*}_{\Xi}$$

with corresponding singular vectors $U_r U_{\Xi} = \mathbf{g}^{\varepsilon}_{r,0}(G^{\varepsilon}_{r,0})^{-\frac{1}{2}}U_{\Xi}$ and provide an orthonormal left basis of $\mathbf{A}$. The singular vectors $\overline{U_t}W_{\Xi} = \overline{\mathbf{g}^{\varepsilon}_{t,0}}(G^{\varepsilon}_{t,0})^{-\frac{1}{2}}W_{\Xi}$ provide an orthonormal right basis of $\mathbf{A}$.

If our inclusion is an ellipsoid located at the origin with $R = \mathbf{I}_3$, writing $m^{\varepsilon}_j = |m^{\varepsilon}_j|e^{i\theta_j}$ we obtain that

$$\sigma_{\Xi,j} = |m^{\varepsilon}_j|\,(G^{\varepsilon}_{r,0,jj})^{\frac{1}{2}}(G^{\varepsilon}_{t,0,jj})^{\frac{1}{2}},\ j = 1,2,3, \quad U_{\Xi} = \mathrm{diag}(e^{i\theta_1}, e^{i\theta_2}, e^{i\theta_3}), \quad W_{\Xi} = \mathbf{I}_3.$$

It is worth noticing that for the imaging procedure, which can be developed independently of the nature (and geometry) of the inclusions and does rely on the MUSIC-type approach, we do not need to compute the rank of the matrices $G^{\varepsilon}_{r,z}$ and $G^{\varepsilon}_{t,z}$. We shall distinguish between the analysis of the main ingredients of the MSR matrix, which enables us to better understand what to expect from the imaging procedure, and the imaging procedure itself.

5.2. Case of a single permeable inclusion. If we consider the case of a single magnetic inclusion ($m = 1$ and $\varepsilon_1 = \varepsilon_0$), then

$$\mathbf{A} = \mathbf{g}^{\mu}_{r,z}\mathbf{M}^{\mu}(\mathbf{g}^{\mu}_{t,z})^{T},$$

and the matrix $G^{\mu}_{r,z}$ is given by

$$G^{\mu}_{r,z} = (\overline{\mathbf{g}^{\mu}_{r,z}})^{T}\mathbf{g}^{\mu}_{r,z} = \sum_{l=1}^{d_r}\sum_{j=1}^{n_r} -\overline{\nabla{\times}\mathbf{G}(z,\mathbf{R}_j)}\,(\overrightarrow{\gamma}_l\,\overrightarrow{\gamma}_l^{T})\,\nabla'{\times}\mathbf{G}(\mathbf{R}_j,z),$$

where

$$\nabla{\times}\mathbf{G}(\mathbf{r},\mathbf{r}')\cdot\mathbf{a} = \left(ik - \frac{1}{|s|}\right)\frac{e^{ik|s|}}{4\pi|s|}\,\Lambda(s)\cdot\mathbf{a}, \quad s = \mathbf{r}-\mathbf{r}'.$$

If $|z| \to +\infty$, then $G^{\mu}_{r,z}$ can be approximated by

$$G^{\mu}_{r,\infty} = -\sum_{l=1}^{d_r}\sum_{j=1}^{n_r}\Lambda(\mathbf{R}_j)\,(\overrightarrow{\gamma}_l\,\overrightarrow{\gamma}_l^{T})\,\Lambda(\mathbf{R}_j).$$

Again, in the limit that the number of array elements becomes large and the spacing between elements small, the inner products can be replaced with integrals over the aperture of the array. Similarly to the previous subsection, if we consider the far-field expansion of $G^{\mu}_{r,z}$ and write

$$G^{\mu}_{r,\infty} = \sum_{l=1}^{d_r} G^{\mu,l}_{r,\infty},$$

then

$$\overrightarrow{\gamma}_1 = \mathbf{e}_z: \quad G^{\mu,1}_{r,\infty} = \int_{S_r} \frac{1}{r^2} \begin{bmatrix} \eta^2 & -\xi\eta & 0 \\ -\xi\eta & \xi^2 & 0 \\ 0 & 0 & 0 \end{bmatrix} d\xi d\eta,$$

$$\overrightarrow{\gamma}_2 = \mathbf{e}_y: \quad G^{\mu,2}_{r,\infty} = \int_{S_r} \frac{1}{r^2} \begin{bmatrix} z_a^2 & 0 & -z_a\xi \\ 0 & 0 & 0 \\ -z_a\xi & 0 & \xi^2 \end{bmatrix} d\xi d\eta,$$

$$\overrightarrow{\gamma}_3 = \mathbf{e}_x: \quad G^{\mu,3}_{r,\infty} = \int_{S_r} \frac{1}{r^2} \begin{bmatrix} 0 & 0 & 0 \\ 0 & z_a^2 & -z_a\eta \\ 0 & -z_a\eta & \eta^2 \end{bmatrix} d\xi d\eta,$$

where $r = \sqrt{\xi^2 + \eta^2 + z_a^2}$. We can see that for a symmetric array and for any two (nonparallel) directions $\overrightarrow{\gamma}$ the matrix $G^{\mu}_{r,\infty}$ is diagonal with $\operatorname{rank}(G^{\mu}_{r,\infty}) = 3$. The diagonal elements are the squares of the norms of the orthogonal column vectors of the matrix $\mathbf{g}^{\mu}_{r,\infty}$, which is the leading-order term in the far-field expansion of $\mathbf{g}^{\mu}_{r,z}$. The same results hold for the matrix $G^{\mu}_{t,\infty}$.

Now, analogously to the previous subsection, we can estimate the rank of the matrices $G^{\mu}_{r,\infty}$. Thus, for a permeable inclusion located far enough from the set of the points $\{\mathbf{R}_1, \ldots, \mathbf{R}_{n_r}\}$, the matrix $G^{\mu}_{r,\infty}$ has rank 3 for any $d_r \geq 2$ directions $\overrightarrow{\gamma}$ and has rank 2 for any single direction $\overrightarrow{\gamma}$, $\overrightarrow{\gamma} \in \{\mathbf{e}_z, \mathbf{e}_y, \mathbf{e}_x\}$. Moreover, if $z = 0$, then the vector columns of $\mathbf{g}^{\mu}_{r,0}$ are orthogonal. The same conclusion holds for a transmitter array.

Hence, the singular values and the singular vectors of the matrix $\mathbf{A}$ can be found analogously to the case of a single dielectric inclusion.

5.3. Case of a single dielectric and permeable inclusion or perfectly conducting inclusion. In this case,

$$\mathbf{A} = [\mathbf{g}^{\mu}_{r,z}, \mathbf{g}^{\varepsilon}_{r,z}] \mathbf{M}^{\mu,\varepsilon} [\mathbf{g}^{\mu}_{r,z}, \mathbf{g}^{\varepsilon}_{r,z}]^T,$$

and the matrix $G^{\mu,\varepsilon}_{r,z}$ is given by

$$G^{\mu,\varepsilon}_{r,z} = [\overline{\mathbf{g}^{\mu}_{r,z}, \mathbf{g}^{\varepsilon}_{r,z}}]^T [\mathbf{g}^{\mu}_{r,z}, \mathbf{g}^{\varepsilon}_{r,z}] = \begin{bmatrix} G^{\mu}_{r,z} & H_{r,z} \\ H^*_{r,z} & G^{\varepsilon}_{r,z} \end{bmatrix}, \tag{35}$$

where

$$H_{r,z} = (\overline{\mathbf{g}^{\mu}_{r,z}})^T \mathbf{g}^{\varepsilon}_{r,z} = \sum_{l=1}^{d_r} \underbrace{\sum_{j=1}^{n_r} \overline{\nabla \times \mathbf{G}(z, \mathbf{R}_j)} \, (\overrightarrow{\gamma}_l \, \overrightarrow{\gamma}_l^T) \, \mathbf{G}(\mathbf{R}_j, z)}_{:= H^l_{r,z}} \sum_{l=1}^{d_r} H^l_{r,z}.$$

In the limit $|z| \to +\infty$,

$$H^l_{r,\infty} = \sum_{j=1}^{n_r} \Lambda(\mathbf{R}_j) \, (\overrightarrow{\gamma}_l \, \overrightarrow{\gamma}_l^T) \, \Delta(\mathbf{R}_j).$$

Computing $H^l_{r,\infty}$ for each direction $\overrightarrow{\gamma}_l$, $l = 1, \ldots, 3$, for the receiver array $\{\xi, \eta, z_a > 0\}$ which is symmetric about ξ and η axes, we obtain

$$H^1_{r,\infty} = \begin{bmatrix} 0 & -H^1_{r,12} & 0 \\ H^1_{r,21} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad H^2_{r,\infty} = \begin{bmatrix} 0 & -H^2_{r,12} & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad H^3_{r,\infty} = \begin{bmatrix} 0 & 0 & 0 \\ H^3_{r,21} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

where $H^l_{r,jk} > 0$, $l = 1,2,3$, $j,k = 1,2$. Here the elements of $H_{r,\infty}$ are the inner products of the column vectors of the matrices $\mathbf{g}^{\mu}_{r,\infty}$ and $\mathbf{g}^{\varepsilon}_{p,\infty}$. On the other hand, for any $d_r \geq 2$ directions $\overrightarrow{\gamma} \in \{\mathbf{e}_z, \mathbf{e}_y, \mathbf{e}_x\}$ the matrix $H_{r,0}$ has the following form:

$$H_{r,0} = \begin{bmatrix} 0 & -H_{r,12} & 0 \\ H_{r,21} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

By computing the nonzero elements of the matrix $G^{\mu,\varepsilon}_{r,\infty}$, for the receiver array $\{\xi, \eta, z_a\}$, which is symmetric about the ξ and η axes, we conclude that for any $d_r \geq 1$ direction $\overrightarrow{\gamma} \in \{\mathbf{e}_z, \mathbf{e}_y, \mathbf{e}_x\}$, the rank of the matrix $G^{\mu,\varepsilon}_{r,\infty}$ is the sum of the ranks of $G^{\mu}_{r,\infty}$ and $G^{\varepsilon}_{r,\infty}$.

For finite $|z|$ and $z \neq 0$, the analysis is more complicated. Fortunately, the elements of the matrix $H_{r,z}$ can be approximated analogously to the previous subsections. Therefore, for a dielectric and permeable or perfectly conducting inclusion located at $z \in \mathbb{R}^3$ far enough from the set of the points $\{\mathbf{R}_1, \ldots, \mathbf{R}_{n_r}\}$ the rank of the matrix $G^{\mu,\varepsilon}_{r,z}$ is the sum of the rank of $G^{\mu}_{r,z}$ and $G^{\varepsilon}_{r,z}$ for any $d_r \geq 1$ direction $\overrightarrow{\gamma}$, $\overrightarrow{\gamma} \in \{\mathbf{e}_z, \mathbf{e}_y, \mathbf{e}_x\}$. The same conclusion holds for a planar transmitter array.

To estimate the singular values and singular vectors of $\mathbf{A}$ we refer to subsection 4.1.

If $k^{\varepsilon}_r = k^{\mu}_t = 3$ and $z = 0$, then the matrix $G^{\mu,\varepsilon}_{r,0}$ of the form of the matrix given by (C.6) has rank 6. Thus, the matrices $G^{\mu,\varepsilon}_{r,0}$ and $G^{\mu,\varepsilon}_{t,0}$ are nonsingular, which implies that

$$U_r = [\mathbf{g}^{\mu}_{r,0}, \mathbf{g}^{\varepsilon}_{r,0}](G^{\mu,\varepsilon}_{r,0})^{-\frac{1}{2}}, \quad U_t = [\mathbf{g}^{\mu}_{t,0}, \mathbf{g}^{\varepsilon}_{t,0}](G^{\mu,\varepsilon}_{t,0})^{-\frac{1}{2}},$$

and

$$\Xi = (G^{\mu,\varepsilon}_{r,0})^{\frac{1}{2}}\, \mathbf{M}^{\mu,\varepsilon}\, (\overline{G^{\mu,\varepsilon}_{t,0}})^{\frac{1}{2}}.$$

Suppose that the inclusion is an ellipsoid centered at the origin and is aligned with the coordinate axes ($R = I$); then $\mathbf{M}^{\mu,\varepsilon}$ is diagonal and $\Xi\Xi^*$ is of the form of (C.6). The eigenvalues and eigenvectors of $\Xi\Xi^*$ are given by (C.7) and (C.8), respectively.

5.4. Case of multiple inclusions. Recall that the matrix $\mathbf{A}$ in the case of multiple inclusions is given by (22) and

$$G_{p,z_1,\ldots,z_m} = (\mathbf{g}_{p,z_1,\ldots,z_m})^* \mathbf{g}_{p,z_1,\ldots,z_m}, \quad p = r, t,$$

where $\mathbf{g}_{p,z_1,\ldots,z_m}$ is defined by (20) with $\mathbf{g}^{\varepsilon}_{p,z}, \mathbf{g}^{\mu}_{p,z}$ given by (19). Set

$$G^{\varepsilon}_{r,z_j,z_l} = (\overline{\mathbf{g}^{\varepsilon}_{r,z_j}})^T\, \mathbf{g}^{\varepsilon}_{r,z_l} = \sum_{q'=1}^{d_r} \sum_{q=1}^{n_r} \overline{\mathbf{G}(z_j, \mathbf{R}_q)}\, (\overrightarrow{\gamma}_{q'}\, \overrightarrow{\gamma}^T_{q'})\, \mathbf{G}(\mathbf{R}_q, z_l),$$

$$G^{\mu}_{r,z_j,z_l} = (\overline{\mathbf{g}^{\mu}_{r,z_j}})^T\, \mathbf{g}^{\mu}_{r,z_l} = -\sum_{q'=1}^{d_r} \sum_{q=1}^{n_r} \overline{\nabla\times\mathbf{G}(z_j, \mathbf{R}_q)}\, (\overrightarrow{\gamma}_{q'}\, \overrightarrow{\gamma}^T_{q'})\, \nabla'\times\mathbf{G}(\mathbf{R}_q, z_l),$$

$$H_{r,z_j,z_l} = (\overline{\mathbf{g}^{\mu}_{r,z_j}})^T\, \mathbf{g}^{\varepsilon}_{r,z_l} = \sum_{q'=1}^{d_r} \sum_{q=1}^{n_r} \overline{\nabla\times\mathbf{G}(z_j, \mathbf{R}_q)}\, (\overrightarrow{\gamma}_{q'}\, \overrightarrow{\gamma}^T_{q'})\, \mathbf{G}(\mathbf{R}_q, r_l),$$

$$G^{\mu,\varepsilon}_{r,z_j,z_l} = [\overline{\mathbf{g}^{\mu}_{r,z_j}, \mathbf{g}^{\varepsilon}_{r,z_j}}]^T [\mathbf{g}^{\mu}_{r,z_l}, \mathbf{g}^{\varepsilon}_{r,z_l}] = \begin{bmatrix} G^{\mu}_{r,z_j,z_l} & H_{r,z_j,z_l} \\ H^*_{r,z_j,z_l} & G^{\varepsilon}_{r,z_j,z_l} \end{bmatrix}, \quad j,l = 1,\ldots,m. \tag{36}$$

The same definition holds for the emitting array. Then

$$G_{p,z_1,\dots,z_m} = \{G_{p,z_j,z_l}\}_{j,l=1}^{m}, \quad p = r, t,$$

where

$$G_{p,z_j,z_l} = \begin{cases} G^{\varepsilon}_{p,z_j,z_l} \in \mathbb{C}^{3\times 3} & \text{in case 1,} \\ G^{\mu}_{p,z_j,z_l} \in \mathbb{C}^{3\times 3} & \text{in case 2,} \\ G^{\mu,\varepsilon}_{p,z_j,z_l} \in \mathbb{C}^{6\times 6} & \text{in case 3.} \end{cases}$$

For $j = l$, $j, l = 1, \dots, m$, we are in the case of a single inclusion centered at the point z_j, and the matrix $G_{p,z_j,z_j} = G_{p,z_j}$ is studied in the previous subsections.

Let $j \neq l$, $j, l = 1, \dots m$. Define

$$F_p(z_j, z_l) = \begin{cases} \displaystyle\sum_{n=1}^{n_r} \frac{e^{-ik|R_n - z_j|}}{|R_n - z_j|} \frac{e^{ik|R_n - z_l|}}{|R_n - z_l|}, & p = r, \\ \displaystyle\sum_{n=1}^{n_t} \frac{e^{-ik|r_n - z_j|}}{|r_n - z_j|} \frac{e^{ik|r_n - z_l|}}{|r_n - z_l|}, & p = t. \end{cases}$$

Similarly to previous sections, the inner product can be replaced with the integrals over the aperture of the array, and in the limit $|z| \to +\infty$ we can write the following:

$$F_p(z_j - z_l) = \int_{S_p} \frac{\exp\left(ik \frac{\xi z^1_{jl} + \eta z^2_{jl} + L_p z^3_{jl}}{\sqrt{\xi^2+\eta^2+L_p^2}}\right)}{\xi^2 + \eta^2 + L_p^2} d\xi d\eta, \quad z_l - z_j = \begin{bmatrix} z^1_{jl} \\ z^2_{jl} \\ z^3_{jl} \end{bmatrix} \in \mathbb{R}^3. \tag{37}$$

Here $S_p =]-A_p, A_p[\times]-B_p, B_p[$, $p = r, t$, and $z = L_p$ is the plane of the array of transmitters or receivers.

Then from (36) we have

$$G^{\mu}_{p,z_j,z_l} = -\sum_{h=1}^{d_p} \left[\nabla\times\mathbf{I}_3(\overrightarrow{\gamma}_h \overrightarrow{\gamma}_h^T)\nabla\times\mathbf{I}_3\right] F_p(z_j - z_l),$$

$$G^{\varepsilon}_{p,z_j,z_l} = \sum_{h=1}^{d_p} \left[\left(\mathbf{I}_3 + \frac{\nabla\nabla}{k^2}\right)(\overrightarrow{\gamma}_h \overrightarrow{\gamma}_h^T)\left(\mathbf{I}_3 + \frac{\nabla\nabla}{k^2}\right)\right] F_p(z_j - z_l),$$

$$H_{p,z_j,z_l} = \sum_{h=1}^{d_r} \left[\nabla\times\mathbf{I}_3(\overrightarrow{\gamma}_h \overrightarrow{\gamma}_h^T)\left(\mathbf{I}_3 + \frac{\nabla\nabla}{k^2}\right)\right] F_p(z_j - z_l).$$

Set $z^3_{jl} = 0$ in (37). If $|A_p|, |B_p| \gg L_p$ and if the inclusions are well separated, then from (D.10) we can approximate

$$G_{p,z_j,z_l} = \mathbf{0} \quad \forall j \neq l, \;\; j, l = 1, \dots, m.$$

Consequently, the columns of the matrix $\mathbf{g}_{p,z_1,\dots,z_m}$ are orthogonal and our problem is partitioned into m independent problems as follows:

$$\mathbf{A}_j = \mathbf{g}_{r,z_j}\, \mathbf{M}_j\, \mathbf{g}^T_{t,z_j}, \quad j = 1, \dots, m.$$

Thus, each inclusion can be imaged independently from the others.

If the values of the matrices G_{r,z_j,z_l} and G_{t,z_j,z_l}, $j \neq l$, $j,l = 1,\ldots,m$, are not very small, then the problem becomes more complicated (we have superposition of m problems). In this case, a priori we do not know which set of singular vectors corresponds to which inclusion. Thus, we can also plot for each right singular vector $\mathbf{w}_j$ and left singular vector $\mathbf{u}_j$ the quantities ${\mathbf{g}_{t,z,l}}^T\mathbf{w}_j$ for the transmitter array and ${\mathbf{g}_{r,z,l}}^*\mathbf{u}_j$ for the receiver array, where $\mathbf{g}_{t,z,l}$ and $\mathbf{g}_{r,z,l}$ are the basis column vectors of the matrices $\mathbf{g}_{t,z}$ and $\mathbf{g}_{r,z}$, respectively. Here $l = 1,\ldots,k_t$ or k_r. Let $z_l = (z_l^1, z_l^2, z_l^3)$, then under the condition $|A_p|, |B_p| \gg L_p$, the spatial resolution is compared to $\lambda/2$ in the plane $z = z_l^3$.

6. Numerical examples of MUSIC reconstructions. As discussed in the theoretical part of the paper the nature (dielectric and/or magnetic) of the inclusions with respect to the one of the embedding medium is essential to the results expected, as are the particular geometrical configuration and electromagnetic polarization of the transmitter and receiver arrays (or plane waves) which one is considering. Below, we display and briefly analyze a small number of numerical results acquired from synthetically generated data in order to illustrate a few features of the method, no attempt being made to cover the diversity of situations that should be encountered in practice. It is worth mentioning that in all the numerical results presented in this section the data are generated from the derived asymptotic expansions and may be affected by adding a white noise. Moreover, the error in the asymptotic expansion is smaller than the added white noise. The magnitudes of the equivalent point sources used in the asymptotic expansion are of order 10^{-3}.

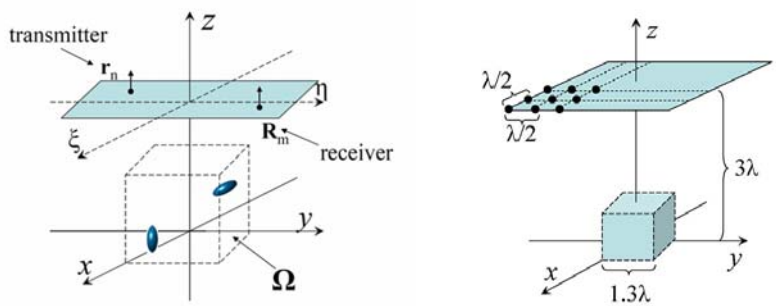

FIG. 6.1. *Sketch of the configuration under numerical study.*

The configuration of interest is schematized in Figure 6.1. We are considering two coincident transmitter and receiver arrays centered within the plane $z = z_a = 5$ and covering a square area of side 10, both consisting of $n_t = n_r = 13^2$ vertical electric dipoles ($\overrightarrow{\beta} = \mathbf{e}_z$) radiating or receiving with unit amplitudes Il and operated at circular frequency $\omega = 4$—the corresponding wavelength in the embedding free space, with as usual unit permittivity and permeability value ($\varepsilon_0 = \mu_0 = 1$), is $\lambda = \pi/2$. The position of the nth transmitter or receiver element is specified by $\mathbf{r}_n = \mathbf{R}_n = (\xi_i, \eta_j, z_a)$, where $n = i + 13(j-1)$ and $\xi_i = -5 + \frac{10}{12}(i-1)$, $\eta_j = -5 + \frac{10}{12}(j-1)$, $i,j = 1,\ldots,13$. Two identical prolate spheroidal inclusions D_1 and D_2 (needle-like, the length of the longest semiaxis being 3 times the ones of the other two semiaxes) with size parameter $\alpha = 0.1$ and orthogonal orientations (the longest semiaxis of D_1 is orientated along ⌣, the longest one of D_2 along ') are to be retrieved within a cubical box $\Omega = [-1,1]^3 \subset \mathbb{R}^3$ assumed situated below the arrays. The said inclusions are,

respectively, characterized by shape equations

$$D_1: \quad (x-0.6)^2+(y+0.6)^2+\frac{(z+0.1)^2}{9}=1,$$
$$D_2: \quad \frac{(x+0.6)^2}{9}+(y-0.6)^2+(z-0.7)^2=1.$$

Their dielectric permittivities are set to $\varepsilon_1=5$, $\varepsilon_2=2$, and their magnetic permeabilities to $\mu_1=5$, $\mu_2=2$; if one is tackling purely dielectric cases, the permeabilities are set to 1 and vice versa for the permittivities whenever tackling purely magnetic cases, the general dielectric magnetic situation involving the full set of nonunit values.

Let us notice that in terms of the probing wavelength, as is also indicated in Figure 6.1, the array step size is about $\lambda/2$, i.e., the traditional half-a-wavelength sampling step. As for the sought inclusions, they are about 1.3λ apart, at about 3.2λ from the center of the array. In short, the inclusions lie in the near field of the array, only strongly aspect-limited data (with view angles of 45 degrees or less) are available, and we are facing the rather severe hypothesis of single polarization electric field data, a good amount of noise being added to them also. However, as detailed below, we appear to be able to number, locate, and further characterize (via singular analysis) inclusions far smaller than the usual half-a-wavelength resolution of imaging procedures.

So, within the above setting, the retrieval involves the calculation of the SVD, $\mathbf{A}=\mathbf{U}\Sigma\mathbf{W}^*$, of the MSR matrix $\mathbf{A}\in\mathbb{C}^{169\times 169}$. Let $\mathbf{a}=(1,1,1)^T\in\mathbb{R}^3$ and $\mathbf{c}=(1,1,1,1,1,1)^T\in\mathbb{R}^6$. Then, for each discrete location $z\in\Omega$ (the sampling step is henceforth chosen as $h=0.06$), the identifiers of interest are

- dielectric inclusions: $W_{r,t}(z)=1/||(\mathbf{P}_r\,\mathbf{g}^{\varepsilon}_{r,z}+\mathbf{P}_t\,\overline{\mathbf{g}^{\varepsilon}_{t,z}})\cdot\mathbf{a}||$,
- permeable inclusions: $W_{r,t}(z)=1/||(\mathbf{P}_r\,\mathbf{g}^{\mu}_{r,z}+\mathbf{P}_t\,\overline{\mathbf{g}^{\mu}_{t,z}})\cdot\mathbf{a}||$,
- dielectric and permeable inclusions:

$$W_{r,t}(z)=1/||(\mathbf{P}_r\,\mathbf{g}^{\mu,\varepsilon}_{r,z}+\mathbf{P}_t\,\overline{\mathbf{g}^{\mu,\varepsilon}_{r,z}})\cdot\mathbf{c}||$$

and

$$W_{r,t}(z)=1/||(\mathbf{P}_r\,\mathbf{g}^{\varepsilon}_{r,z}+\mathbf{P}_t\,\overline{\mathbf{g}^{\varepsilon}_{t,z}})\cdot\mathbf{a}||,$$

which are calculated within Ω. Notice that we are operating herein with coincident transmitter and receiver arrays, which simplifies the formulation of the identifiers. Plots of $z\to W_\cdot(z)$ illustrate the results achieved. Other accompanying results displayed consist of the singular values of the MSR matrix $\mathbf{A}$, shown using a standard log scale.

6.1. Dielectric inclusions. In this purely dielectric case, the singular values are displayed in Figure 6.1.1 (left). In good accord with sections 5.1 and 5.4, six singular values emerge from the 163 others within the noise subspace. Maps of identifier $W_{r,t}(z)=1/||(\mathbf{P}_r\,\mathbf{g}^{\varepsilon}_{r,z}+\mathbf{P}_t\,\overline{\mathbf{g}^{\varepsilon}_{t,z}})\cdot\mathbf{a}||$ in cross-sectional planes $z=\{-0.1,0.7\}$, $x=\{-0.6,0.6\}$, and $y=\{-0.6,0.6\}$ are displayed in Figure 6.1.2, and corresponding three-dimensional (3D) plots are displayed in Figure 6.1.1 (right), the surfaces shown being associated to values of half the peak magnitude.

6.2. Permeable inclusions. In this purely permeable case, the singular values of the matrix $\mathbf{A}\in\mathbb{C}^{169\times 169}$ are displayed in Figure 6.2.1. Again in good accord with previous theoretical material, only four singular values now emerge from the noise,

the lack of multiply polarized data implying, for magnetic inclusions and electric fields, the reduction of that number from their maximal number of six. Maps of identifier $W_{r,t}(z) = 1/||(\mathbf{P}_r\, \mathbf{g}^{\mu}_{r,z} + \mathbf{P}_t\, \overline{\mathbf{g}^{\mu}_{t,z}}) \cdot \mathbf{a}||$ in cross-sectional planes $z = \{-0.1, 0.7\}$, $x = \{-0.6, 0.6\}$, and $y = \{-0.6, 0.6\}$ are displayed in Figure 6.2.2, and corresponding 3D plots are displayed in Figure 6.2.1 (right).

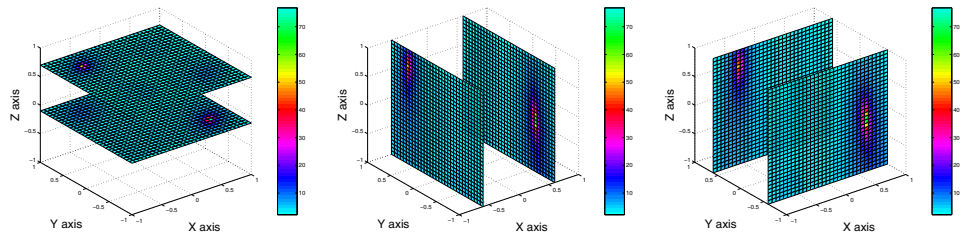

FIG. 6.2.2. *(Permeability contrasts only): color maps of* $W_{r,t}(z)$ *in cross-sectional planes* $z = \{-0.1, 0.7\}$, $x = \{-0.6, 0.6\}$, *and* $y = \{-0.6, 0.6\}$ *in the case of noisy data with* $20dB$ *signal-to-noise ratio (refer to Figure* 6.2.1*).*

6.3. Dielectric and permeable inclusions. In this example, both permittivity and permeability differ from those of the embedding free space. The first 25 singular values of the matrix $\mathbf{A} \in \mathbb{C}^{169\times 169}$ are displayed in Figure 6.3.1 (left); in the case of noisy data the full set is shown in Figure 6.3.1 (right). So, if ten of them (six associated to the dielectric features, four to the magnetic features, as expected from the previous analysis in the case of single polarization) emerge in the absence of noise, this is far less clear cut in the case of a good amount of noise on the data, since the two or three singular values of lesser magnitude are confounded with those outside the signal subspace.

Maps of identifier $W_{r,t}(z) = 1/||(\mathbf{P}_r\, \mathbf{g}^{\mu,\varepsilon}_{r,z} + \mathbf{P}_t\, \overline{\mathbf{g}^{\mu,\varepsilon}_{t,z}}) \cdot \mathbf{c}||$ and $W_{r,t}(z) = 1/||(\mathbf{P}_r\, \mathbf{g}^{\varepsilon}_{r,z} + \mathbf{P}_t\, \overline{\mathbf{g}^{\varepsilon}_{t,z}}) \cdot \mathbf{a}||$ in the cross-sectional planes $z = \{-0.1, 0.7\}$, $x = \{-0.6, 0.6\}$, and $y = \{-0.6, 0.6\}$ are displayed in Figures 6.3.2(a) and (b), respectively, and corresponding 3D plots are displayed in Figure 6.3.3.

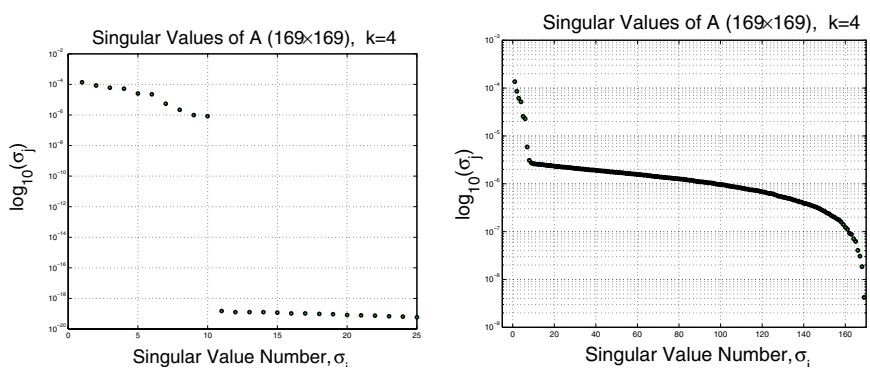

FIG. 6.3.1. *(Dielectric and permeability contrasts): distribution of the first* 25 *singular values of* $\mathbf{A}$ *or* 13^2 *singly polarized dipolar transmitters and receivers in the absence of noise (left) and distribution of the full set in the case of noisy data with* $20dB$ *signal-to-noise ratio (right).*

The singular values of the matrix A and corresponding 3D plots of $W_{r,t}$ are displayed in Figures 6.3.4–6.3.7 in the case of noisy data (white Gaussian noise) with 20dB signal-to-noise ratio.

Finally, we show examples of single inclusions so that the reader can see that, indeed, the number of significant singular values doubles when there are two inclusions.

To conclude this section, we make a remark. If the quantity of data (the dimension of the multistatic response matrix) is not enough to detect multiple inclusions, then,

from the numerical results above, it is clear that our inversion procedure of MUSIC type may miss some of these inclusions or wrongly determine their nature.

7. Conclusion. We have designed a MUSIC-type algorithm for imaging a collection of small 3D inclusions of arbitrary shape and electromagnetic nature. The inclusions are illuminated by an array of electric and/or magnetic dipoles with given polarizations and the resulting electric and/or magnetic field is collected by another array, not necessarily the same as the emitting one. This yields the MSR matrix. By examining the eigenvalue structure of this matrix at a given frequency of operation, we have efficiently located the inclusions and characterized their electromagnetic nature. The polarization tensors, which yield information about the size and orientation (the parameters of equivalent ellipsoids) of the inclusions, can be reconstructed as well. However, the information from these polarization tensors is a mixture of the electromagnetic parameters and the volume. In the case of a single ellipsoidal inclusion with arbitrary electromagnetic parameters and location with respect to the source and receiver arrays, we have provided the single vectors and values in a closed form.

We should emphasize that our approach holds for near-field regimes, as soon as the transmitters and receivers are far enough from the inclusions, and that it easily extends to bona fide far-field data using asymptotic expansions of the Green's functions, as we have done here. Also, the transmitter and receiver arrays can be constituted by electric dipoles (as is the case in the numerical examples) or by magnetic dipoles from application of duality, with one or more of the possible orthogonal polarizations. Conditions for full rank of the multistatic matrix have been spelled out, two orthogonal polarizations being the least number needed for magnetic inclusions while a single polarization suffices in the purely dielectric case.

Furthermore, in the present investigation, we have introduced the configuration when two or more inclusions are close to one another, which are now seen as two equivalent triaxial ellipsoids, one dielectric and one magnetic, through weighted-in electromagnetic and geometric parameters and combined polarization tensors—the case of one inclusion close to the interface could be derived in similar fashion via a multiscale approach.

Finally, the situation of two half-space media, and per extension of any kind of planarly stratified embedding medium, could easily be handled in similar fashion once we have introduced the proper Green's functions of this medium, using known transverse electric/ transverse magnetic spectral representations—this is expected to be true for cylindrical and spherical stratified media as well.

In brief, it appears that the so-called DORT method and 3D time-reversal analysis in electromagnetics are fully encompassed by the present investigation.

We expect that a multifrequency analysis of the MSR matrix will improve the signal-to-noise ratio in cluttered environments and enhance electromagnetic imaging. We also expect that by including higher-order polarization tensors, which in this case might be contributing significantly to scattering, the results given in this paper hold for larger inclusions; see [7]. We intend also to pursue the present investigation in the diffusive regime of electromagnetics (e.g., for eddy-current nondestructive testing and low-frequency subsoil probing), and to extend it to ultrasonic scattering and linear elasticity.

Appendix A. Derivation of the asymptotic formula (10). Since the points $z_j \in \mathbb{R}^3$, $j = 1, \ldots, m$, that determine the location of the inclusions are assumed to satisfy $|z_j - z_l| \geq d_0 > 0$, for all $j \neq l$, and since α, the common order of magnitude of the diameters of the inclusions, is small enough compared to d_0, it suffices to consider

only one inclusion $z + \alpha B$. For simplicity we denote the electric permittivity and magnetic permeability inside $z + \alpha B$ by ε_* and μ_*, respectively.

The asymptotic expansions of $\mathbf{E}_\alpha^{(n)}$ and $\mathbf{H}_\alpha^{(n)}$ are constructed by the method of matched asymptotic expansions for α small, as done in [10, 11]. To reveal the nature of the perturbations in the electric and magnetic fields, we introduce the local variables $\xi = (\mathbf{r} - z)/\alpha$ and set the field $\mathbf{e}_\alpha^{(n)}(\xi) = \mathbf{E}_\alpha^{(n)}(z + \alpha\xi)$ and $\mathbf{h}_\alpha^{(n)}(\xi) = \mathbf{H}_\alpha^{(n)}(z + \alpha\xi)$. We expect that $\mathbf{E}_\alpha^{(n)}(\mathbf{r})$ and $\mathbf{H}_\alpha^{(n)}(\mathbf{r})$ will differ appreciably from $\mathbf{E}_0^{(n)}(\mathbf{r})$ and $\mathbf{H}_0^{(n)}(\mathbf{r})$, respectively, for $\mathbf{r}$ near z, but they will differ little from $\mathbf{E}_0^{(n)}(\mathbf{r})$ and $\mathbf{H}_0^{(n)}(\mathbf{r})$ for $\mathbf{r}$ far from z. Therefore, in the spirit of matched asymptotic expansions, we shall represent each of the fields $\mathbf{E}_\alpha^{(n)}$ and $\mathbf{H}_\alpha^{(n)}$ by two different expansions, an inner expansion for $\mathbf{r}$ near z, and an outer expansion for $\mathbf{r}$ far from z. The outer expansion must begin with $\mathbf{E}_0^{(n)}$ and $\mathbf{H}_0^{(n)}$, respectively, so we write the outer expansions as

$$\begin{aligned} \mathbf{E}_\alpha^{(n)}(\mathbf{r}) &= \mathbf{E}_0^{(n)}(\mathbf{r}) + \alpha^{\tau_1}\mathbf{E}_1^{(n)}(\mathbf{r}) + \alpha^{\tau_2}\mathbf{E}_2^{(n)}(\mathbf{r}) + \cdots, \\ \mathbf{H}_\alpha^{(n)}(\mathbf{r}) &= \mathbf{H}_0^{(n)}(\mathbf{r}) + \alpha^{\tau_1}\mathbf{H}_1^{(n)}(\mathbf{r}) + \alpha^{\tau_2}\mathbf{H}_2^{(n)}(\mathbf{r}) + \cdots \end{aligned} \tag{A.1}$$

for $|\mathbf{r} - z| \gg O(\alpha)$, where $0 < \tau_1 < \tau_2 < \cdots$, and $(\mathbf{E}_j^{(n)}, \mathbf{H}_j^{(n)}), j = 1, 2, \ldots$, are to be found.

We write the inner expansions as

(A.2)

$$\begin{aligned} \mathbf{E}_\alpha^{(n)}(z + \alpha\xi) &= \mathbf{e}_\alpha^{(n)}(\xi)\mathbf{e}_0^{(n)}(\xi) + \alpha\mathbf{e}_1^{(n)}(\xi) + \alpha^2\mathbf{e}_2^{(n)}(\xi) + \cdots, \quad \text{for } |\xi| = O(1), \\ \mathbf{H}_\alpha^{(n)}(z + \alpha\xi) &= \mathbf{h}_\alpha^{(n)}(\xi) = \mathbf{h}_0^{(n)}(\xi) + \alpha\mathbf{h}_1^{(n)}(\xi) + \alpha^2\mathbf{h}_2^{(n)}(\xi) + \cdots, \quad \text{for } |\xi| = O(1), \end{aligned}$$

where $(\mathbf{e}_j^{(n)}, \mathbf{h}_j^{(n)})$, $j = 0, 1, \ldots$, are to be found.

In order to determine the functions $\mathbf{E}_i^{(n)}(\mathbf{r}), \mathbf{H}_i^{(n)}(\mathbf{r}), \mathbf{e}_i^{(n)}(\xi)$, and $\mathbf{h}_i^{(n)}(\xi)$ we have to equate the inner and the outer expansions in some "overlap" domain within which the stretched variable ξ is large and $\mathbf{r} - z$ is small. In this domain the matching conditions are as follows:

(A.3)

$$\begin{aligned} &\mathbf{E}_0^{(n)}(\mathbf{r}) + \alpha^{\tau_1}\mathbf{E}_1^{(n)}(\mathbf{r}) + \alpha^{\tau_2}\mathbf{E}_2^{(n)}(\mathbf{r}) + \cdots \sim \mathbf{e}_0^{(n)}(\xi) + \alpha\mathbf{e}_1^{(n)}(\xi) + \alpha^2\mathbf{e}_2^{(n)}(\xi) + \cdots, \\ &\mathbf{H}_0^{(n)}(\mathbf{r}) + \alpha^{\tau_1}\mathbf{H}_1^{(n)}(\mathbf{r}) + \alpha^{\tau_2}\mathbf{H}_2^{(n)}(\mathbf{r}) + \cdots \sim \mathbf{h}_0^{(n)}(\xi) + \alpha\mathbf{h}_1^{(n)}(\xi) + \alpha^2\mathbf{h}_2^{(n)}(\xi) + \cdots. \end{aligned}$$

Define the stretched coefficients $\varepsilon(\xi)$ and $\mu(\xi)$ by

$$\varepsilon(\xi) = \begin{cases} \varepsilon_0, & \xi \in \mathbb{R}^3 \setminus \overline{B}, \\ \varepsilon_*, & \xi \in B, \end{cases}$$

$$\mu(\xi) = \begin{cases} \mu_0, & \xi \in \mathbb{R}^3 \setminus \overline{B}, \\ \mu_*, & \xi \in B. \end{cases}$$

If we substitute the inner expansions (A.2) into the Maxwell's equations (4) and formally equate coefficients of α^{-1} we get from use of the first matching condition in (A.3) that

$$\begin{cases} \nabla \times \mathbf{e}_0^{(n)}(\xi) = 0 \quad \text{in } \mathbb{R}^3, \\ \nabla \cdot (\varepsilon(\xi)\mathbf{e}_0^{(n)}(\xi)) = 0 \quad \text{in } \mathbb{R}^3, \\ \mathbf{e}_0^{(n)}(\xi) \to \mathbf{E}_0^{(n)}(z) \quad \text{as } |\xi| \to +\infty, \end{cases} \tag{A.4}$$

and

$$\text{(A.5)}\qquad \begin{cases} \nabla \times \mathbf{h}_0^{(n)}(\xi) = 0 \quad \text{in } \mathbb{R}^3, \\ \nabla \cdot (\mu(\xi)\mathbf{h}_0^{(n)}(\xi)) = 0 \quad \text{in } \mathbb{R}^3, \\ \mathbf{h}_0^{(n)}(\xi) \to \mathbf{H}_0^{(l)}(z) \quad \text{as } |\xi| \to +\infty. \end{cases}$$

Therefore,

$$\begin{aligned} \mathbf{e}_0^{(n)}(\xi) &= \nabla v^{\varepsilon}(\xi)(\mathbf{E}_0^{(n)}(z)), \\ \mathbf{h}_0^{(n)}(\xi) &= \nabla v^{\mu}(\xi)(\mathbf{H}_0^{(n)}(z)), \end{aligned}$$

where the function v^q, for $q(\xi) = \varepsilon(\xi)$ or $\mu(\xi)$, is defined by (7).

Define the polarization tensors by (8). Inserting the inner expansions into the Lippman–Schwinger integral representation formula (6) for $\mathbf{E}_\alpha^{(n)}$ we arrive at (10).

Appendix B. Proof of Proposition 4.3. This proof directly follows from [32]. We sketch it for the reader's convenience.

We consider only the first case (permittivity contrast only) and suppose that $k_r = k_t$. The proof in all the other cases is similar. To see the correspondence of $\mathcal{R}(\mathbf{A}\mathbf{A}^*)$ with the different inclusions, we introduce the operator $\Lambda : \mathbb{C}^m \to \mathbb{C}^{d_r}$:

$$(\Lambda\lambda)(\mathbf{r}) := \sum_{j=1}^{m} \lambda_j \left((\mathbf{G}(z_j, \mathbf{r}) \cdot \vec{\gamma}_1) \cdot \mathbf{a}, \dots, (\mathbf{G}(z_j, \mathbf{r}) \cdot \vec{\gamma}_{d_r}) \cdot \mathbf{a} \right)^T$$

for $\mathbf{r} \in \mathbb{R}^3 \setminus \{z_1, z_2, \dots, z_m\}, \lambda \in \mathbb{C}^m, \mathbf{a} \in \mathbb{R}^3 \setminus \{0\}$. We then show that Λ is one-to-one. Let $\lambda \in \mathbb{C}^m$ with $(\Lambda\lambda)(\mathbf{r}) = 0$ for all $\mathbf{r} \in \mathbb{R}^3 \setminus \{z_1, z_2, \dots, z_m\}$. Letting $\mathbf{r}$ tend to one of the points z_j yields that $\lambda_j = 0$ for every $j = 1, \dots, m$.

Assume, without any loss of generality, that the receiver array is in the plane $\{z = 0\}$ and consider $\{\mathbf{R}_p\}_{p\in\mathbb{N}} \subset \{z = 0\}$ to be a countable set of positions with the property that any analytic function which vanishes in $\mathbf{R}_p$ for all $p \in \mathbb{N}$ vanishes identically on $\{z = 0\}$.

Next we show the existence of $n_0 \in \mathbb{N}$ such that the operator

$$\lambda \mapsto ((\Lambda\lambda)(\mathbf{R}_1), \dots, (\Lambda\lambda)(\mathbf{R}_n))^T$$

from $\mathbb{C}^m$ to $\mathbb{C}^{n_r \times d_r}$ is one-to-one for $n_r \geq n_0$. If there existed no such n_0, then there would exist sequences $\{n_l\}_{l\in\mathbb{N}}$ in $\mathbb{N}$ and $\{\lambda^{(l)}\}_{l\in\mathbb{N}}$ in $\mathbb{C}^m$ with $\sum_{j=1}^m |\lambda_j^{(l)}| = 1$ and $(\Lambda\lambda^{(l)})(\mathbf{R}_p) = 0$ for all $p = 1, \dots, n_l$. The sequence $\{\lambda^{(l)}\}_{l\in\mathbb{N}}$ has accumulation points. Without loss of generality we assume that $\lambda^{(l)} \to \lambda$, $l \to \infty$, with $\sum_{j=1}^m |\lambda_j| = 1$. For any $n \in \mathbb{N}$ and l with $n_l \geq n$ we estimate by the triangle inequality

$$\begin{aligned} |(\Lambda\lambda)(\mathbf{R}_p)| &\leq |\Lambda(\lambda - \lambda^{(l)})(\mathbf{R}_p)| + \underbrace{|(\Lambda\lambda^{(l)})(\mathbf{R}_p)|}_{=0} \\ &\leq \sum_{j=1}^{m} |\lambda_j - \lambda_j^{(l)}||\mathbf{G}(z_j, \mathbf{R}_p)| \leq C \sum_{j=1}^{m} |\lambda_j - \lambda_j^{(l)}| \end{aligned}$$

for some constant C independent of l, and this converges to zero as l tends to infinity. Therefore, $(\Lambda\lambda)(\mathbf{R}_p) = 0$ for every $p \in \mathbb{N}$. Since $\Lambda\lambda$ is analytic we conclude that $\Lambda\lambda$

vanishes on all of $\mathbb{R}^3 \setminus \{z_1, z_2, \ldots, z_m\}$, which yields $\lambda = 0$ by the first part of the proof. This contradicts the fact that $\sum_{j=1}^{m} |\lambda_j| = 1$. The proof of the proposition is complete.

Appendix C. Expressions for eigenvalues and eigenvectors. Let $A \in \mathbb{C}^{6\times 6}$ be a matrix of the following form:

$$A = \begin{bmatrix} a_{11} & 0 & 0 & 0 & a_{15} & 0 \\ 0 & a_{22} & 0 & a_{24} & 0 & 0 \\ 0 & 0 & a_{33} & 0 & 0 & 0 \\ 0 & a_{42} & 0 & a_{44} & 0 & 0 \\ a_{51} & 0 & 0 & 0 & a_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & a_{66} \end{bmatrix}. \tag{C.6}$$

Then the eigenvalues are given by

$$\begin{aligned} \lambda_{1,5} &= \frac{1}{2}\left(a_{11} + a_{55} \pm \sqrt{(a_{11} - a_{55})^2 + 4a_{15}a_{51}}\right), \\ \lambda_{2,4} &= \frac{1}{2}\left(a_{22} + a_{44} \pm \sqrt{(a_{22} - a_{44})^2 + 4a_{24}a_{42}}\right), \\ \lambda_3 &= a_{33}, \quad \lambda_6 = a_{66}, \end{aligned} \tag{C.7}$$

and are associated to the eigenvectors

$$\begin{aligned} u_{1,5} &= \frac{1}{\sqrt{a_{15}^2 + (a_{11} - \lambda_{1,5})^2}}\left(a_{15}\mathbf{e}_1 - (a_{11} - \lambda_{1,5})\mathbf{e}_5\right), \\ u_{2,4} &= \frac{1}{\sqrt{a_{24}^2 + (a_{22} - \lambda_{2,4})^2}}\left(a_{24}\mathbf{e}_2 - (a_{22} - \lambda_{2,4})\mathbf{e}_4\right), \\ u_3 &= \mathbf{e}_3, \quad u_6 = \mathbf{e}_6, \end{aligned} \tag{C.8}$$

where $\mathbf{e}_j$, $j = 1, \ldots, 6$, is an orthogonal basis in $\mathbb{R}^6$.

Appendix D. Useful identities to estimate the resolution. Recall the well-known identity

$$\frac{\sin(2\pi a r)}{r} = 2\pi \int_0^\infty J_0(2\pi r x) \frac{\Pi(x/(2a))}{\sqrt{a^2 - x^2}}\, x\, dx, \tag{D.9}$$

where $\Pi(x)$ (rectangular function) is a function that is 0 outside the interval $[-1/2, 1/2]$ and unity inside it.

Let L be fixed. For any point $z = (z_1, z_2, z_3 = 0)^T \in \mathbb{R}^3$, it follows from (D.9) that

(D.10)

$$\begin{aligned} \frac{1}{2\pi ik}\frac{\partial}{\partial z_3}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} dxdy\, \frac{\exp\left(ik\,\frac{xz_1 + yz_2 + Lz_3}{\sqrt{x^2+y^2+L^2}}\right)}{x^2 + y^2 + L^2} &= \frac{L}{2\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} dxdy\, \frac{\exp\left(ik\,\frac{xz_1 + yz_2}{\sqrt{x^2+y^2+L^2}}\right)}{(x^2 + y^2 + L^2)^{3/2}} \\ &= \frac{\sin(k|z|)}{k|z|}. \end{aligned}$$

Appendix E. Some extensions.

E.1. Closely spaced inclusions. Suppose that the set of inclusions $\mathcal{I}_\alpha = \bar{z} + \alpha \cup_{j=1}^m B_j$, where $\overline{B}_j$'s are mutually disjoint, and the electromagnetic parameters of B_j are ε_j and μ_j.

For any $\mathbf{r}$ away from $\mathbf{r}_n$ and $z_j,\ j = 1, \ldots, m$, we can prove that

(E.11)
$$\begin{aligned}\mathbf{E}_\alpha^{(n)}(\mathbf{r}) &= \mathbf{E}_0^{(n)}(\mathbf{r}) \\ &\quad + \alpha^3 \Bigg[- i\omega\mu_0 \, \nabla' \times \mathbf{G}(\mathbf{r}, \bar{z}) \cdot \mathbf{M}\left(\frac{\mu_1}{\mu_0}, \ldots, \frac{\mu_m}{\mu_0}; B_1, \ldots, B_m\right) \mathbf{H}_0^{(n)}(\bar{z}) \\ &\quad + k^2 \, \mathbf{G}(\mathbf{r}, \bar{z}) \cdot \mathbf{M}\left(\frac{\varepsilon_1}{\varepsilon_0}, \ldots, \frac{\varepsilon_m}{\varepsilon_0}; B_1, \ldots, B_m\right) \mathbf{E}_0^{(n)}(\bar{z}) \Bigg] + O(\alpha^4),\end{aligned}$$

where

$$\mathbf{M}\left(\frac{\mu_1}{\mu_0}, \ldots, \frac{\mu_m}{\mu_0}; B_1, \ldots, B_m\right) = \left(\sum_{j=1}^m \left(\frac{\mu_j}{\mu_0} - 1\right) \int_{B_j} \partial_{y_l} v_{l'}^{\mu}(y) \, dy \right)_{ll'},$$

and

$$\mathbf{M}\left(\frac{\varepsilon_1}{\varepsilon_0}, \ldots, \frac{\varepsilon_m}{\varepsilon_0}; B_1, \ldots, B_m\right) = \left(\sum_{j=1}^m \left(\frac{\varepsilon_j}{\varepsilon_0} - 1\right) \int_{B_j} \partial_{y_l} v_{l'}^{\varepsilon}(y) \, dy \right)_{ll'}.$$

Here $\varepsilon(y)$ and $\mu(y)$ are defined by

$$\varepsilon(y) = \begin{cases} \varepsilon_0, & y \in \mathbb{R}^3 \setminus \overline{\cup_{j=1}^m B_j}, \\ \varepsilon_j, & y \in B_j, j = 1, \ldots, m, \end{cases}$$

$$\mu(y) = \begin{cases} \mu_0, & y \in \mathbb{R}^3 \setminus \overline{\cup_{j=1}^m B_j}, \\ \mu_j, & y \in B_j, j = 1, \ldots, m. \end{cases}$$

Next, we define the overall electric permittivity $\bar{\varepsilon}$, the overall magnetic permeability $\bar{\mu}$, and the centers of mass $\bar{z_\varepsilon}$ and $\bar{z_\mu}$ of $B := \cup_{j=1}^m B_j$ as follows:

$$\frac{\bar{\varepsilon} - \varepsilon_0}{\bar{\varepsilon} + \varepsilon_0} \sum_{j=1}^m |B_j| = \sum_{j=1}^m \frac{\varepsilon_j - \varepsilon_0}{\varepsilon_j + \varepsilon_0} |B_j|, \quad \frac{\bar{\mu} - \mu_0}{\bar{\mu} + \mu_0} \sum_{j=1}^m |B_j| = \sum_{j=1}^m \frac{\mu_j - \mu_0}{\mu_j + \mu_0} |B_j|,$$

$$\frac{\bar{\varepsilon} - \varepsilon_0}{\bar{\varepsilon} + \varepsilon_0} \bar{z_\varepsilon} \sum_{j=1}^m |B_j| = \sum_{j=1}^m \frac{\varepsilon_j - \varepsilon_0}{\varepsilon_j + \varepsilon_0} \int_{B_j} x \, dx, \quad \frac{\bar{\mu} - \mu_0}{\bar{\mu} + \mu_0} \bar{z_\mu} \sum_{j=1}^m |B_j| = \sum_{j=1}^m \frac{\mu_j - \mu_0}{\mu_j + \mu_0} \int_{B_j} x \, dx.$$

We can represent and visualize the multiple inclusions $\cup_{j=1}^m B_j$ by means of two ellipsoids, $\mathcal{E}_\varepsilon$ and $\mathcal{E}_\mu$, of centers $\bar{z}_\varepsilon$ and $\bar{z}_\mu$ with the same polarization tensors. We call $\mathcal{E}_\varepsilon$ (resp., $\mathcal{E}_\mu$) the equivalent purely electric (resp., purely magnetic) ellipsoid of $\cup_{j=1}^m B_j$. If we consider the problem of determining the collection of the closely spaced small inclusions $\mathcal{I}_\alpha$, the only information of real interest that could be reconstructed is exactly the sum $\mathcal{E}_\varepsilon + \mathcal{E}_\mu$.

The decomposition of the MSR matrix associated with closely spaced inclusions reduces to the case of a single inclusion, where only the form of the polarization tensor must be changed. And by our MUSIC algorithm we can find the position $\bar{z}$.

E.2. Magnetic field-magnetic dipole. By the duality principle [22],

$$\mathbf{E} \to \mathbf{H}, \quad \mathbf{H} \to \mathbf{E}, \quad \mu \to -\varepsilon, \quad \varepsilon \to -\mu, \quad \mathbf{J} \to -\mathbf{M}, \tag{E.12}$$

where $\mathbf{M}$ is the magnetic current density. The incident magnetic field $\mathbf{H}_0^{(n)}$ in a homogeneous medium that is due to the magnetic dipole $\mathbf{M}_0^{(n)}(\mathbf{r}) = -i\omega\mu_0\,\delta(\mathbf{r} - \mathbf{r}_n)\,\overrightarrow{\beta}\,IA$, at the position $\mathbf{r}_n$ and directed in the $\overrightarrow{\beta}$ direction, is given by

$$\mathbf{H}_0^{(n)}(\mathbf{r}) = \omega^2\varepsilon_0\mu_0\,IA\,\mathbf{G}(\mathbf{r},\mathbf{r}_n)\cdot\overrightarrow{\beta} = k^2\,IA\,\mathbf{G}(\mathbf{r},\mathbf{r}_n)\cdot\overrightarrow{\beta},$$

where IA is the magnetic moment. The electric field is given by

$$\mathbf{E}_0^{(n)}(\mathbf{r}) = i\omega\mu_0\nabla\times IA\,\mathbf{G}(\mathbf{r},\mathbf{r}_n)\cdot\overrightarrow{\beta} = i\omega\mu_0 IA\,\nabla g(\mathbf{r},\mathbf{r}_n)\times\overrightarrow{\beta}.$$

Analogously to (10), for any $\mathbf{r}$ away from $\mathbf{r}_n$ and z_j, $j = 1,\dots,m$, the perturbation of the magnetic field due to the presence of the collection of small electromagnetic inclusions $\mathcal{I}_\alpha$ which is illuminated by the magnetic dipole $\mathbf{M}_0^{(n)}$ is approximated by

$$\begin{aligned}\mathbf{H}_\alpha^{(n)}(\mathbf{r}) - \mathbf{H}_0^{(n)}(\mathbf{r}) = \alpha^3\sum_{j=1}^{m}\Bigg[&i\omega\,(\varepsilon_j-\varepsilon_0)\,\nabla'\times\mathbf{G}(\mathbf{r},z_j)\cdot\mathbf{M}\left(\frac{\varepsilon_j}{\varepsilon_0};B_j\right)\mathbf{E}_0^{(n)}(z_j)\\ &+\omega^2\varepsilon_0\,(\mu_j-\mu_0)\,\mathbf{G}(\mathbf{r},z_j)\cdot\mathbf{M}\left(\frac{\mu_j}{\mu_0};B_j\right)\mathbf{H}_0^{(n)}(z_j)\Bigg]+O(\alpha^4).\end{aligned} \tag{E.13}$$

The duality principle also applies to decompose the MSR matrix $\mathbf{A}$. After multiplying the right-hand side of (18) by $i\omega\mu_0$, the duality principle shows that the decomposition (22) for the MSR matrix $\mathbf{A}$ holds where

$$\begin{gathered}\mathbf{g}_{r,z}^{\varepsilon} \to \mathbf{g}_{r,z}^{\mu}, \quad \mathbf{g}_{e,z}^{\varepsilon} \to \mathbf{g}_{e,z}^{\mu},\\ \mathbf{g}_{r,z}^{\mu} \to \mathbf{g}_{r,z}^{\varepsilon}, \quad \mathbf{g}_{e,z}^{\mu} \to \mathbf{g}_{e,z}^{\varepsilon},\\ \mathbf{M}^{\varepsilon} \to i\omega\mu_0\mathbf{M}^{\mu}, \quad \mathbf{M}^{\mu} \to i\omega\mu_0\mathbf{M}^{\varepsilon},\end{gathered}$$

and the analysis of the MSR matrix and the design of a MUSIC-type reconstruction algorithm are parallel to the ones provided in this paper.

Acknowledgments. Thorough discussions with D. H. Chambers, made possible by the CNRS Math-STIC program, have been very helpful to the authors. Work led by S. Gdoura for her 2005 master's thesis is acknowledged.

CONVERGENCE IN BACKWARD ERROR OF RELAXED GMRES*

L. GIRAUD†, S. GRATTON‡, AND J. LANGOU§

Abstract. This work is the follow-up of the experimental study presented in [A. Bouras and V. Frayssé, *SIAM J. Matrix Anal. Appl.*, 26 (2005), pp. 660–678]. It is based on and extends some theoretical results in [V. Simoncini and D. B. Szyld, *SIAM J. Sci. Comput.*, 25 (2003), pp. 454–477; J. van den Eshof and G. L. G. Sleijpen, *SIAM J. Matrix Anal. Appl.*, 26 (2004), pp. 125–153]. In a backward error framework we study the convergence of GMRES when the matrix-vector products are performed inaccurately. This inaccuracy is modeled by a perturbation of the original matrix. We prove the convergence of GMRES when the perturbation size is proportional to the inverse of the computed residual norm; this implies that the accuracy can be relaxed as the method proceeds which gives rise to the terminology "relaxed GMRES." As for the exact GMRES we show under proper assumptions that only happy breakdowns can occur. Furthermore, the convergence can be detected using a byproduct of the algorithm. We explore the links between relaxed right-preconditioned GMRES and flexible GMRES (FGMRES). In particular, this enables us to derive a proof of convergence of FGMRES. Finally, we report results of numerical experiments to illustrate the behavior of the relaxed GMRES monitored by the proposed relaxation strategies.

Key words. GMRES, backward error analysis, relaxed GMRES

1. Introduction.

We consider the solution of a linear system of equations $Ax = b$ using the GMRES [12] iterative method, where A is a nonsingular $n \times n$ matrix. In some applications, performing inexact matrix-vector products in this method may be interesting as long as the convergence of GMRES is maintained. Many situations in scientific computing may benefit from such a scheme. For instance, a natural application of this idea occurs in computational electromagnetics, where the fast multipole method provides approximations of the matrix-vector product within a user-defined accuracy; the less accurate the matrix-vector, the faster the computation. The key point is then to design a criterion to control the accuracy of the matrix-vector product so that the iterates achieve a satisfactory convergence level. Another example arises in nonoverlapping domain decomposition where the matrix-vector involving the Schur complement can be approximated.

In [4], a criterion is proposed for general systems and its numerical behavior is illustrated on a large set of numerical experiments. This work is based on some heuristic considerations and the approach is referred to as a relaxation strategy because the perturbation size can grow as the inverse of the residual norm. We denote by "relaxed GMRES" an inexact GMRES that implements a relaxation strategy. The relaxation strategy proposed in [4] attempts to ensure the convergence of the GMRES iterates

x_k within a relative normwise backward error

$$\begin{aligned}\eta_{A,b}(x_k) &= \min_{\Delta A,\Delta b}\{\tau > 0 : \|\Delta A\| \le \tau\|A\|,\ \|\Delta b\| \le \tau\|b\| \\ &\qquad \text{and } (A+\Delta A)x_k = b + \Delta b\} \\ &= \frac{\|Ax_k - b\|}{\|A\|\|x_k\| + \|b\|}, \end{aligned} \tag{1.1}$$

less than a prescribed quantity $\varepsilon > 0$. A significant number of numerical experiments are presented that illustrate the merits of the strategy but also reveal its lack of robustness; for a few examples the convergence at ε is not obtained. Nevertheless, based on [4], similar strategies have been successfully applied to the solution of heterogeneous diffusion problems using domain decomposition [3], to the preconditioning of a radiation diffusion problem [20], to the solution of electromagnetic problems [11], in lattice quantum chromodynamics [5], and in an ocean circulation model for steady barotropic flow [18]. A significant step toward a theoretical explanation of this observed behavior is proposed in [15, 19]. In these latter works, important justifications are brought to the fact that under some assumptions relaxed GMRES converges in residual norm.

The convergence of iterative solvers is often based on normwise backward error criteria [2, 6, 9]. In this paper we propose criteria to control the accuracy of the matrix-vector products and show that they ensure the convergence of GMRES with respect either to $\eta_{A,b}(x_k)$ defined in (1.1) or to

$$\begin{aligned}\eta_b(x_k) &= \min_{\Delta b}\{\tau > 0 : \|\Delta b\| \le \tau\|b\| \text{ and } Ax_k = b + \Delta b\} \\ &= \frac{\|Ax_k - b\|}{\|b\|}. \end{aligned} \tag{1.2}$$

We mention that $\eta_{A,b}$ and η_b are recommended in [2] when the concern related to the stopping criterion is discussed.

The forthcoming development shows that deriving a sufficient convergence condition of relaxed GMRES for the stopping criterion $\eta_b(x_k) \le \varepsilon$ is far simpler than for $\eta_{A,b}(x_k) \le \varepsilon$. However, we believe that both stopping criteria are of practical interest. Both may be used to account for data uncertainties. It is problem and application dependent to decide whether these uncertainties come chiefly from the right-hand side, when η_b must be used, or from the matrix and the right-hand side, when $\eta_{A,b}$ must be used.

The paper is organized as follows. In section 2 we study the convergence of relaxed GMRES. We first recall and discuss in section 2.1 some theoretical results established in [15, 19]. Section 2.2 is devoted to the convergence proofs. In particular, we show that under suitable assumptions only happy breakdowns can occur and we explain how the perturbation size can be monitored to ensure the convergence of relaxed GMRES with respect to either $\eta_{A,b}$ or η_b. We provide a stopping criterion that uses only byproducts of the algorithm and does not require an exact product by A to compute the backward errors. Numerical experiments that illustrate these theoretical results are given in section 2.3. In section 3, we study the situation when the preconditioner is perturbed. This might happen, for instance, when the application of the preconditioner is obtained by solving iteratively an auxiliary linear system. We also exploit the links between relaxed preconditioned GMRES and flexible GMRES (FGMRES) [13], and we derive a straightforward proof of convergence of FGMRES. In section 4

we consider the use of these strategies in a restarted framework. Finally, we conclude with some comments in section 5.

In this paper, the 2-norm of a vector x is denoted by $\|x\|$, and the spectral 2-norm of a matrix A is denoted by $\|A\|$. We use the notation $\sigma_{\max}(A)$ ($\sigma_{\min}(A)$) for the smallest (resp., the largest) singular value of A. The spectral condition number of a matrix is $\kappa(A) = \|A\|\|A^{-1}\| = \sigma_{\max}(A)/\sigma_{\min}(A)$.

2. GMRES with inexact matrix-vector.

2.1. Background and existing results. The GMRES method is based on the Arnoldi recursion $AV_k = V_{k+1}\bar{H}_k$, where $V_k = [v_1, \ldots, v_k]$ is an orthogonal matrix, and $\bar{H}_k$ is a $(k+1) \times k$ upper-Hessenberg matrix. We assume that we are given an initial guess x_0 for the solution $x^\star$ of the system. In this paper, we suppose $x_0 \neq x^\star$. The GMRES algorithm generates a sequence of iterates $\{x_k\}_{k=1,2,\ldots}$ such that x_k realizes the minimum of the 2-norm of the residual $r_k = b - Ax_k$ over the space $x_0 + \mathcal{K}_k(A, v_1)$. The Krylov subspace $\mathcal{K}_k(A, v_1)$ is defined by $\mathcal{K}_k(A, v_1) = \mathrm{span}(v_1, Av_1, \ldots, A^{k-1}v_1)$, where $\beta v_1 = r_0$ and $\beta = \|r_0\| \neq 0$. From the unitary invariance of the 2-norm, we obtain $x_k = x_0 + \delta x_k$, where $\delta x_k = V_k y_k$ and y_k is the solution of the linear least-squares problem $\min_y \|\bar{H}_k y - \beta e_1\|$, e_1 being the first vector of the canonical basis.

We assume that it is possible to monitor the accuracy of the matrix-vector product Av of the Arnoldi procedure. From a mathematical point of view, the inaccuracy can be modeled by introducing a perturbation matrix E, depending possibly on v, such that $(A + E)v$ is the quantity actually computed. At step k of this perturbed Arnoldi algorithm, the vector $w = (A + E_k)v_k$ is orthogonalized against the vectors v_j, $j = 1, \ldots, k$, so that the following relation holds:

$$[(A + E_1)v_1, \ldots, (A + E_k)v_k] = [v_1, \ldots, v_k, v_{k+1}]\bar{H}_k. \tag{2.1}$$

Note that this matrix perturbation approach was taken in [4, 15]. In [19] the inaccuracies are modeled by introducing the vector f_k such that $w = Av_k + f_k$. We took the former approach because it generalizes to the latter ones by setting $E_k = f_k v_k^T$ since $v_k^T v_k = 1$. In the above equality (2.1), referred to as the [illegible] in [15], $V_k = [v_1, \ldots, v_k]$ is an orthogonal matrix and $\bar{H}_k$ is a $(k+1) \times k$ upper-Hessenberg matrix. We first assume (as in [15, 19]) that the matrix-vector product occurring in the initial residual computation is exact, so that $r_0 = b - Ax_0$ and $\beta = \|b - Ax_0\|$. We define the kth iterate of the inexact method by $x_k = x_0 + \delta x_k$, where $\delta x_k = V_k y_k$ and y_k is the solution of the linear least-squares problem $\min_y \|\bar{H}_k y - \beta e_1\|$. Introducing the perturbation matrix $G_k = [E_1 v_1, \ldots, E_k v_k]$ the inexact Arnoldi relation can also be written [19] as an exact Arnoldi relation $\widetilde{A}_k V_k = (A + G_k V_k^T)V_k = V_{k+1}\bar{H}_k$, with $\widetilde{A}_k = A + G_k V_k^T$. This last equality shows that the quantities $\delta x_i, \bar{H}_i$, and v_i for $i \leq k$ generated by the inexact GMRES on $A\,\delta x = r_0$ until step k are the same as those generated by the first k steps of exact GMRES applied to the linear system $\widetilde{A}_k\,\delta x = r_0$. Using classical results on GMRES [14] this observation implies by induction that the norm of the residual $r_0 - \widetilde{A}_k\,\delta x_i$ is monotonically decreasing as i grows, where $i \leq k$. Furthermore, $\widetilde{A}_k\,\delta x_i = \widetilde{A}_i\,\delta x_i$, because $\widetilde{A}_k\,\delta x_i = (A + G_k V_k^T)V_i y_i = (A + G_i V_i^T)V_i y_i = \widetilde{A}_i\,\delta x_i$. Therefore, the norm of the [illegible] $\tilde{r}_k = r_0 - \widetilde{A}_k\,\delta x_k$ decreases with k. Let us denote by r_k the residual $r_0 - A\,\delta x_k$ and let us define $\tilde{r}_0 = r_0$. The inexact Arnoldi recursion can also be written

$$\widetilde{A}_k V_k = V_k H_k + h_{k+1,k} v_{k+1} e_k^T.$$

Using an analogy with the terminology used for the exact GMRES algorithm, we say that a [illegible] occurs at step m if $h_{m+1,m} = 0$. It is important to notice that, because of the orthogonality of V_k, similarly to the exact GMRES framework, such a breakdown [illegible] for $m \leq n$. In what follows, we denote by m the step where the breakdown occurs. At each step the residual gap is defined by $r_k - \tilde{r}_k = (A - \widetilde{A}_k)\,\delta x_k = G_k y_k = \sum_{i=1}^{k} y_{k,i} E_i v_i$, where $y_k = (y_{k,1}, \ldots, y_{k,k})^T \in \mathbb{R}^k$. Let ϵ be a positive real number. Assuming that the inexact method can be run until step ℓ without breakdown, it is shown in [15, Theorem 5.3] that if

$$\|E_k\| \leq \frac{\sigma_{\min}(\bar{H}_\ell)}{\ell} \frac{\epsilon}{\|\tilde{r}_{k-1}\|} \tag{2.2}$$

for $k \leq \ell$ then $\|r_\ell - \tilde{r}_\ell\| \leq \epsilon$.

This important result is easily derived from $r_\ell - \tilde{r}_\ell = \sum_{k=1}^{\ell} y_{\ell,k} E_k v_k$, $|y_{\ell,1}| \leq \|y_\ell\| = \|\bar{H}_\ell^\dagger \beta e_1\| \leq \|\bar{H}_\ell^\dagger\| \|r_0\| = \|\bar{H}_\ell^\dagger\| \|\tilde{r}_0\|$ and

$$|y_{\ell,k}| = |e_k^T \bar{H}_\ell^\dagger \beta e_1| = \left| e_k^T \bar{H}_\ell^\dagger \left(\beta e_1 - \bar{H}_\ell \begin{pmatrix} y_{k-1} \\ 0 \end{pmatrix} \right) \right| \leq \|\bar{H}_\ell^\dagger\| \|\tilde{r}_{k-1}\|,$$

where $1 < k \leq \ell$. Because the norm of the computed residual, $\|\tilde{r}_k\|$, is monotonically decreasing as k grows, $k \leq \ell$, the inequalities (2.2) and

$$\|r_k\| \leq \|r_k - \tilde{r}_k\| + \|\tilde{r}_k\| \tag{2.3}$$

ensure that the residual norm satisfies at step ℓ

$$\|r_\ell\| \leq \epsilon + \|\tilde{r}_\ell\|. \tag{2.4}$$

However, it can be seen that there is an implicit relation in (2.2) linking all the E_k's, $k \leq \ell$, together. The E_k's depend on $\bar{H}_\ell$ which itself depends on the E_k's. This means that it is not possible to implement (2.2) in an algorithm.

Another interesting feature would also be to monitor $\|\tilde{r}_\ell\|$ in (2.4) so that it can be less than any prescribed value for large enough ℓ. In this way, the residual norm $\|r_\ell\|$, which is a key ingredient of the backward errors $\eta_{A,b}(x_\ell)$ and $\eta_b(x_\ell)$, would also be controlled through (2.4). It turns out that contrary to the exact GMRES, $\|\tilde{r}_\ell\|$ is not necessarily zero at the breakdown of the inexact algorithm. For example, for $A = \mathrm{diag}(1, 2)$, $b = (1/\sqrt{2}, 1/\sqrt{2})^T$, and $x_0 = (0, 0)^T$, if we take $E_1 = 0$ and $E_2 = \mathrm{diag}(-2, 0)$, the inexact Arnoldi relation reads

$$[(A + E_1)v_1, (A + E_2)v_2] = [v_1, v_2] \begin{pmatrix} 3/2 & 3/2 \\ 1/2 & 1/2 \end{pmatrix}.$$

We therefore have a breakdown of the inexact GMRES method, but $\|\tilde{r}_1\| = \|\tilde{r}_2\| = 1/\sqrt{10}$. Note that H_2 is singular, and consequently, the linear least-squares problem $\min_y \|\bar{H}_2 y - \beta e_1\|$ is rank deficient. This means that there is an infinite number of solutions to the linear least-squares problem and neither y_2 nor x_2 is well defined.

The purpose of the next section is to fix the problems related to the control of $\|\tilde{r}_\ell\|$ and to the possible singularity of H_m as well as to remove the implicit relation linking all the E_k's, $k \leq \ell$, together. We shall see that this will enable us to design a relaxed GMRES algorithm that is guaranteed to converge with the backward error stopping criteria $\eta_b \leq \varepsilon$ or $\eta_{A,b} \leq \varepsilon$ for any prescribed tolerance ε.

2.2. Theoretical results. We first design a strategy that ensures the convergence of the inexact GMRES iterates so that η_b can be made smaller than any prescribed tolerance; this theoretical result is closely related to the work of [15, 19]. We consider the splitting

$$\eta_b(x_k) \leq \frac{\|r_k - \tilde{r}_k\|}{\|b\|} + \frac{\|\tilde{r}_k\|}{\|b\|}$$

and set accordingly

$$\varepsilon = \varepsilon_g + \varepsilon_c, \tag{2.5}$$

where ε_g (resp., ε_c) is the targeted tolerance for the scaled residual $\frac{\|r_k - \tilde{r}_k\|}{\|b\|}$ (resp., the relative residual norm $\frac{\|\tilde{r}_k\|}{\|b\|}$).

In the framework of the inexact GMRES the situation where the computed residual $\tilde{r}_m$ is zero at the breakdown is referred to as a . Such a situation is of interest because it ensures that $\frac{\|\tilde{r}_k\|}{\|b\|}$ can be made smaller than any prescribed ε_c provided that k is large enough. The following theorem shows a possible way to control the E_k's such that only a happy breakdown eventually occurs.

THEOREM 1 (breakdown in inexact GMRES). m

1. $r_0 \neq 0$ $k \leq m$ H_k $\tilde{r}_k$ $h_{k+1,k}$ $k = m$
2. $0 < c < 1$ $k \leq m$ $\|E_k\| \leq c\frac{\sigma_{\min}(A)}{n}$ $\bar{H}_k$ $(1-c)\sigma_{\min}(A) \leq \sigma_{\min}(\bar{H}_k)$ H_m m happy $\tilde{r}_m = 0$

1. Owing to the inexact Arnoldi relation (2.1), if $h_{k+1,k} = 0$, then we have $\tilde{r}_k = r_0 - \widetilde{A}_k V_k y_k = V_k(\beta e_1 - H_k y_k)$, where y_k minimizes $\|\beta e_1 - H_k y_k\|$. Because H_k is nonsingular, the minimum value is zero, and consequently $\tilde{r}_k = 0$.

On the other hand, suppose, for the purpose of establishing a contradiction that $\tilde{r}_k = 0$, that $h_{k+1,k} \neq 0$. The inexact Arnoldi relation (2.1) implies that $\tilde{r}_k = r_0 - \widetilde{A}_k V_k y_k = V_{k+1}(\beta e_1 - \bar{H}_k y_k)$. Then $\bar{H}_k(2:k+1, 1:k)$ is a square nonsingular upper-triangular matrix. From $\tilde{r}_k = 0$ it follows that $\|\beta e_1 - \bar{H}_k y_k\| = 0$, which in turn implies that $H_k(2:k+1, 1:k)y_k = 0$. Therefore, $y_k = 0$, since $\bar{H}_k(2:k+1, 1:k)$ is nonsingular. Now $\|\tilde{r}_k\| = \|\beta e_1 - \bar{H}_k y_k\| = \beta$, which contradicts $\tilde{r}_k = 0$.

2. The orthogonality of the V_k's and the relaxed Arnoldi relation read $V_{k+1}\bar{H}_k = (A + G_k V_k^T)V_k$, from which it follows, using the variational characterization of singular values, that

$$\sigma_{\min}(A + G_k V_k^T) \leq \sigma_{\min}(\bar{H}_k).$$

Assuming that there exists a constant c, $0 < c < 1$, such that

$$\|E_k\| \leq c\frac{\sigma_{\min}(A)}{n}, \tag{2.6}$$

we get

$$\|G_k V_k^T\| = \left\| \sum_{i=1}^{k} E_i v_i v_i^T \right\| \leq \sum_{i=1}^{k} \|E_i v_i v_i^T\| \leq c\sigma_{\min}(A), \tag{2.7}$$

and inequality $\sigma_{\min}(A) - \|G_k V_k^T\| \leq \sigma_{\min}(A + G_k V_k^T)$ (see [1, Theorem 3.3.16]) implies that $0 < (1-c)\sigma_{\min}(A) \leq \sigma_{\min}(\bar{H}_k)$. This inequality indicates that $\bar{H}_k$ has full rank. In particular, this is true at breakdown, which shows that H_m is nonsingular. The conclusion follows from 1. ∎

The next theorem gives a sufficient condition for the convergence of relaxed GMRES for η_b.

THEOREM 2 (convergence of relaxed GMRES for η_b). [illegible] m [illegible] c [illegible] $0 < c < 1$ [illegible] ε_c [illegible] ε_g [illegible] $k \leq m$ [illegible]

$$\|E_k\| \leq \frac{1}{n}\sigma_{\min}(A) \min\left(c, \frac{(1-c)\|b\|}{\|\tilde{r}_{k-1}\|}\varepsilon_g\right). \tag{2.8}$$

[illegible] ℓ $0 < \ell \leq m$ [illegible]

$$\|\tilde{r}_\ell\| \leq \varepsilon_c \|b\| \tag{2.9}$$

[illegible]

$$\eta_b(x_\ell) \leq \varepsilon_c + \varepsilon_g.$$

[illegible]. Inequality (2.2) holds with $\epsilon = \varepsilon_g \|b\|$, and it follows that, for all $k \leq m$, $\frac{\|r_k - \tilde{r}_k\|}{\|b\|} \leq \varepsilon_g$. It follows from the second statement of Theorem 1 that, for some $\ell \leq m$, $\|\tilde{r}_\ell\| \leq \varepsilon_c \|b\|$. The bound on $\eta_b(x_\ell)$ then follows from (2.3). The step ℓ can be, for instance, the step where the (happy) breakdown occurs. ∎

[illegible] 1. The stopping criterion (2.9) is based on $\|\tilde{r}_k\| = \|\bar{H}_k y_k - \beta e_1\|$ which is a byproduct of the algorithm and does not require any additional matrix-vector product [7]. Similarly the control on $\|E_k\|$ involves only some constants of the problem (n, $\sigma_{\min}(A)$, $\|b\|$) and the byproduct $\|\tilde{r}_k\|$. Finally, the constant c can be any value between zero and one.

We now show a similar result for a prescribed accuracy on the backward error $\eta_{A,b}$. In a first step, using the same technique as for Theorem 2, we obtain in the following lemma a control that ensures the convergence with respect to $\eta_{A,b}$.

LEMMA 1. [illegible] m [illegible] ε_c [illegible] ε_g [illegible] ℓ $0 < \ell \leq m$ [illegible] $k \leq \ell$ $\tilde{r}_{k-1} \neq 0$ [illegible]

$$\|E_k\| \leq \frac{\sigma_{\min}(\bar{H}_\ell)}{n} \frac{\|A\|\|x_\ell\| + \|b\|}{\|\tilde{r}_{k-1}\|}\varepsilon_g. \tag{2.10}$$

[illegible] $\|\tilde{r}_\ell\| \leq \varepsilon_c \|A\|\|x_\ell\|$ [illegible]

$$\eta_{A,b}(x_\ell) \leq \varepsilon_c + \varepsilon_g.$$

[illegible]. Substituting $(\|A\|\|x_\ell\| + \|b\|)\,\varepsilon_g$ for ϵ in (2.2) yields $\frac{\|r_\ell - \tilde{r}_\ell\|}{\|A\|\|x_\ell\| + \|b\|} \leq \varepsilon_g$. The conclusion follows from (2.3) and $\|\tilde{r}_\ell\| \leq \varepsilon_c \|A\|\|x_\ell\| \leq \varepsilon_c\,(\|A\|\|x_\ell\| + \|b\|)$. ∎

The above result is not implementable because of the forward reference to the quantities $\|x_\ell\|$ and $\sigma_{\min}(\bar{H}_\ell)$. The next lemma shows that the control ensuring a happy breakdown $\|\tilde{r}_m\| = 0$, i.e., $\|E_k\| \leq c\frac{\sigma_{\min}(A)}{n}$, also enables us to derive a lower-bound on $\|x_\ell\|$ when $\|\tilde{r}_\ell\| \leq \varepsilon_c \|A\|\|x_\ell\|$ is satisfied. This lower bound is expressed in terms of c, ε_c, and some constants of the problem.

LEMMA 2. [illegible] m [illegible] c x_0 $x^\star$ [illegible] $2c\|x_0\| \leq \|x^\star\|$ $0 < c < 1$ [illegible] $\ell > 0$ [illegible] $k \leq \ell$ $\|E_k\| \leq c\frac{\sigma_{\min}(A)}{n}$ $\|\tilde{r}_\ell\| \leq \varepsilon_c\|A\|\|x_\ell\|$. [illegible]

$$\frac{\|x^\star\|}{4 + 2\varepsilon_c\kappa(A)} \leq \|x_\ell\|. \tag{2.11}$$

[illegible]. Starting from the definition of $\tilde{r}_\ell$ and from $x_\ell = x_0 + \delta x_\ell$, we get

$$\begin{aligned}\tilde{r}_\ell &= b - Ax_0 - (A + G_\ell V_\ell^T)\,\delta x_\ell \\ &= A(x^\star - x_\ell) - G_\ell V_\ell^T x_\ell + G_\ell V_\ell^T x_0,\end{aligned}$$

which shows that

$$x^\star - x_\ell = A^{-1}\tilde{r}_\ell + A^{-1}G_\ell V_\ell^T x_\ell - A^{-1}G_\ell V_\ell^T x_0. \tag{2.12}$$

From the assumptions $\|E_\ell\| \leq c\frac{\sigma_{\min}(A)}{n}$ and $0 < c < 1$ it follows as in (2.7) that $\|G_\ell V_\ell^T\| \leq c\sigma_{\min}(A)$. Using $\|\tilde{r}_\ell\| \leq \varepsilon_c\|A\|\|x_\ell\|$ and $\|A^{-1}\|\sigma_{\min}(A) = 1$ and taking norms in (2.12) yield

$$\|x^\star - x_\ell\| \leq (c + \varepsilon_c\kappa(A))\|x_\ell\| + c\|x_0\|.$$

Since $\|x^\star\| - \|x_\ell\| \leq \|x^\star - x_\ell\|$, we get

$$\|x^\star\| - c\|x_0\| \leq (1 + c + \varepsilon_c\kappa(A))\|x_\ell\| \leq (2 + \varepsilon_c\kappa(A))\|x_\ell\|,$$

where we have used that $c < 1$. The conclusion follows from the assumption $2c\|x_0\| \leq \|x^\star\|$ that implies $\|x^\star\| - c\|x_0\| \geq \|x^\star\|/2$. ∎

We note that the assumption $2c\|x_0\| \leq \|x^\star\|$ is not very stringent as it is satisfied for $x_0 = 0$. The next theorem gives a sufficient convergence condition for the stopping criterion $\eta_{A,b}$. Similarly as for Theorem 2 (see Remark 1) the control on $\|E_k\|$ and the stopping criterion involved in relaxed GMRES are based on byproducts of the algorithm and some constants of the problem. Provided that the above constants are available or easily estimated, this result can be used in a practical implementation.

THEOREM 3 (convergence of relaxed GMRES for $\eta_{A,b}$). [illegible] m [illegible] c x_0 $x^\star$ [illegible] $2c\|x_0\| \leq \|x^\star\|$ $0 < c < 1$ [illegible] ε_c [illegible] ε_g [illegible] $k \leq m$

$$\|E_k\| \leq \frac{1}{n}\sigma_{\min}(A)\min\left(c, (1-c)\frac{\gamma^\star}{\|\tilde{r}_{k-1}\|}\varepsilon_g\right), \tag{2.13}$$

[illegible] $\gamma^\star = \frac{1}{4+2\varepsilon_c\kappa(A)}\|A\|\|x^\star\| + \|b\|$. [illegible] ℓ $\ell \leq m$ [illegible]

$$\|\tilde{r}_\ell\| \leq \varepsilon_c\|A\|\|x_\ell\| \tag{2.14}$$

[illegible]

$$\eta_{A,b}(x_\ell) \leq \varepsilon_c + \varepsilon_g.$$

. We first observe that $\|E_k\| \leq \frac{c}{n}\sigma_{\min}(A)$ implies (see Theorem 1) that a breakdown will necessarily occur; therefore, for some ℓ, $\ell \leq m$, $\frac{\|\tilde{r}_\ell\|}{\|A\|\|x_\ell\|} \leq \varepsilon_c$. Furthermore, from (2.13) it follows that

$$\|E_k\| \leq \left(\frac{(1-c)\sigma_{\min}(A)}{n}\right)\left(\frac{1}{4+2\varepsilon_c\kappa(A)}\|A\|\|x^\star\|+\|b\|\right)\frac{\varepsilon_g}{\|\tilde{r}_{k-1}\|}. \tag{2.15}$$

The first factor in the right-hand side of (2.15) can be bounded above by $\frac{\sigma_{\min}(\bar{H}_\ell)}{n}$, because $\|E_k\| \leq \frac{c}{n}\sigma_{\min}(A)$ and the second statement of Theorem 1 applies. Using the conclusions of Lemma 2, the second factor is bounded above by $\|A\|\|x_\ell\| + \|b\|$ because of (2.11). Therefore, we have $\|E_k\| \leq \frac{\sigma_{\min}(\bar{H}_\ell)}{n}\frac{\|A\|\|x_\ell\|+\|b\|}{\|\tilde{r}_{k-1}\|}\varepsilon_g$. Consequently the conditions of Lemma 1 hold, which concludes the proof. ∎

2. As illustrated in the forthcoming numerical experiments, it might be noticed that at the drawback of smaller perturbations one can derive a control that does not require the knowledge of $\|x^\star\|$ (or of a lower bound). If we replace $\gamma^\star$ by $\gamma^b = \|b\| < \gamma^\star$ in Theorem 3, the theorem is still valid.

So far, similarly to [15, 19], we have considered that the initial residual involved in the inexact algorithm is computed exactly: $r_0 = b - Ax_0$. We now provide an extension to these results which additionally accounts for inaccuracies in the very first matrix-vector product Ax_0. Such a result is crucial when only approximations of the matrix-vector product are available. This is the case, for instance, when A is a Schur complement matrix in domain decomposition where the local systems are solved iteratively [3].

THEOREM 4 (convergence of relaxed GMRES with inexact initial residual). m ε_A ε_b r_0 $\tilde{r}_0 = b+\Delta b-(A+\Delta A)x_0$ $\|\Delta A\| \leq \varepsilon_A\|A\|$ $\|\Delta b\| \leq \varepsilon_b\|b\|$ 3 ℓ $\ell \leq m$ (2.14)

$$\eta_{A,b}(x_\ell) \leq \varepsilon_c + \varepsilon_g + (1+\varepsilon_c+\varepsilon_g)\left(\varepsilon_A\frac{\|x_0\|}{\|x_\ell\|}+\varepsilon_b\right).$$

. We consider the following two algorithms:

- (A_1) is inexact GMRES with the approximated residual $\tilde{r}_0$ as in the theorem's assumption and with initial guess x_0.
- (A_2) is inexact GMRES without any initial perturbations on A or b for the solution of $Ax = b + \Delta b - \Delta A x_0 = \tilde{b}$ with same initial guess x_0.

If the same perturbations E_k are used for both algorithms (A_1) and (A_2), these two algorithms generate the same matrices V_k and H_k. This follows from writing $\tilde{r}_0 = (b+\Delta b)-(A+\Delta A)x_0 = (b+\Delta b-\Delta A x_0)- Ax_0$ (which shows that both algorithms share the same initial residual norm β) and from the fact that the perturbations E_k are the same.

Using Theorem 3 on (A_2) leads to $\frac{\|Ax_\ell-\tilde{b}\|}{\|A\|\|x_\ell\|+\|\tilde{b}\|} \leq \varepsilon_c+\varepsilon_g$. Furthermore, we have

$$\begin{aligned}
\frac{\|Ax_\ell-b\|}{\|A\|\|x_\ell\|+\|b\|} &\leq \frac{\|Ax_\ell-\tilde{b}\|}{\|A\|\|x_\ell\|+\|b\|} + \frac{\|\Delta b-\Delta A x_0\|}{\|A\|\|x_\ell\|+\|b\|} \\
&\leq \frac{\|Ax_\ell-\tilde{b}\|}{\|A\|\|x_\ell\|+\|\tilde{b}\|}\frac{\|A\|\|x_\ell\|+\|\tilde{b}\|}{\|A\|\|x_\ell\|+\|b\|} + \frac{\|\Delta b-\Delta A x_0\|}{\|A\|\|x_\ell\|+\|b\|} \\
&\leq (\varepsilon_c+\varepsilon_g)\left(1+\frac{\|\Delta b-\Delta A x_0\|}{\|A\|\|x_\ell\|+\|b\|}\right) + \frac{\|\Delta b-\Delta A x_0\|}{\|A\|\|x_\ell\|+\|b\|} \\
&\leq (\varepsilon_c+\varepsilon_g) + (1+\varepsilon_c+\varepsilon_g)\frac{\|\Delta b-\Delta A x_0\|}{\|A\|\|x_\ell\|+\|b\|}.
\end{aligned}$$

The fact that

$$\frac{\|\Delta b-\Delta A x_0\|}{\|A\|\|x_\ell\|+\|b\|} \leq \frac{\|\Delta b\|+\|\Delta A\|\|x_0\|}{\|A\|\|x_\ell\|+\|b\|} \leq \frac{\|\Delta b\|}{\|b\|} + \frac{\|\Delta A\|}{\|A\|}\frac{\|x_0\|}{\|x_\ell\|}$$

concludes the proof. ∎

2.3. Numerical experiments. In this section we report on numerical experiments performed with MATLAB and machine precision $\psi \sim 2.10^{-16}$. They illustrate that the theoretical results established in exact arithmetic in the previous section do ensure the convergence of the relaxed GMRES even in the presence of round-off errors. For those experiments we consider only the strategies related to the convergence with respect to $\eta_{A,b}(x_k)$. Consequently the stopping criterion implemented by the algorithm is defined by (2.14). For those experiments we set x_0, ε_A, and ε_b to zero. The matrices E_k are obtained using random matrices (MATLAB function `rand`) multiplied by a relevant scalar to match the upper bound of the corresponding strategies. We set $c = 1/4$, $\varepsilon_c = \varepsilon_g = \varepsilon/2$. We therefore consider the two strategies defined as follows.

1. Strategy $S^\star$:

$$\|E_k\| = \frac{\sigma_{\min}(A)}{4n}\min\left(1, \frac{3\gamma^\star}{2\|\tilde{r}_{k-1}\|}\varepsilon\right).$$

2. Strategy S^b:

$$\|E_k\| = \frac{\sigma_{\min}(A)}{4n}\min\left(1, \frac{3\gamma^b}{2\|\tilde{r}_{k-1}\|}\varepsilon\right).$$

Note that S^b is derived from Remark 2. The strategy S^b is interesting, because it does not require the knowledge of $\|x^\star\|$, but it enables only perturbations smaller than $S^\star$. The two strategies rely on the knowledge of $\sigma_{\min}(A)$, and $S^\star$ relies on the knowledge of the solution norm $x^\star$. In our experiments, we set $b = Ax^\star$, so that $x^\star$ is known, and $\sigma_{\min}(A)$ is computed using the `svd` MATLAB command. Further research is needed to establish similar convergence results while replacing these quantities by others that are simpler to estimate. Finally, for the sake of completeness we depict in Algorithm 1 the details of the implementation of the relaxed GMRES algorithm.

Typical behaviors are presented for the linear system $Ax = b$ in Figure 1, where A is the matrix `PDE225` preconditioned using the incomplete LU factorization (i.e., ILU(t) [14]) with threshold $t = 10^{-1}$ (i.e., we run the algorithms on

Algorithm 1. Relaxed GMRES with strategy S.

Choose a convergence threshold $\varepsilon = \varepsilon_c + \varepsilon_g$
Choose an initial guess x_0
$r_0 = b - Ax_0$; $\beta = \|r_0\|$
$v_1 = r_0/\|r_0\|$;
for $k = 1, 2, \ldots$ **do**
  $z = (A + E_k)v_k$, E_k being such that strategy S holds
  for $i = 1$ `to` k **do**
    $h_{i,k} = v_i^T z$
    $z = z - h_{i,k}v_i$
  end for
  $h_{k+1,k} = \|z\|$
  $v_{k+1} = z/h_{k+1,k}$
  Solve the least-squares problem $\min \|\beta e_1 - \bar{H}_k y\|$ for y_k
  if $\|\tilde{r}_k\| = \|\beta e_1 - \bar{H}_k y_k\| \leq \varepsilon_c \|A\| \|x_k\|$ **then**
    Set $x_k = x_0 + V_k y_k$
    Exit
  end if
end for

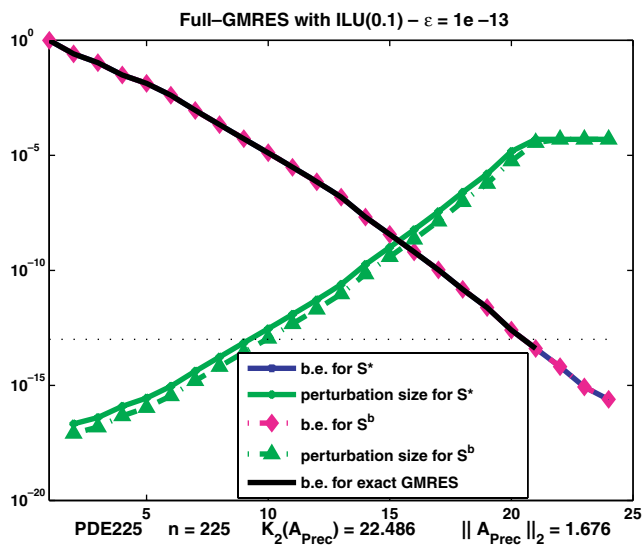

FIG. 1. *Relaxed GMRES with strategy $S^\star$ and S^b,* `PDE225`*, $\varepsilon = 10^{-13}$.*

$A = U^{-1}L^{-1}A_{PDE225}$). The right-hand side b is such that $x^\star = (1, \ldots, 1)^T$ is the solution of $Ax = b$. In this figure, we plot the convergence history, that is, the backward errors $\eta_{A,b}(x_k)$ along the iterations. The line without any tip is the convergence curve with the exact full GMRES; the line with $\diamond$ (resp., $+$) is the convergence of relaxed GMRES with strategy $S^\star$ (resp., S^b). Notice that the three curves perfectly overlap. The dashed horizontal line corresponds to the targeted backward error $\varepsilon = 10^{-13}$, and the line with $\triangle$ (resp., *) is the relative norm of the perturbation $\frac{\|E_k\|}{\|A\|}$ associated

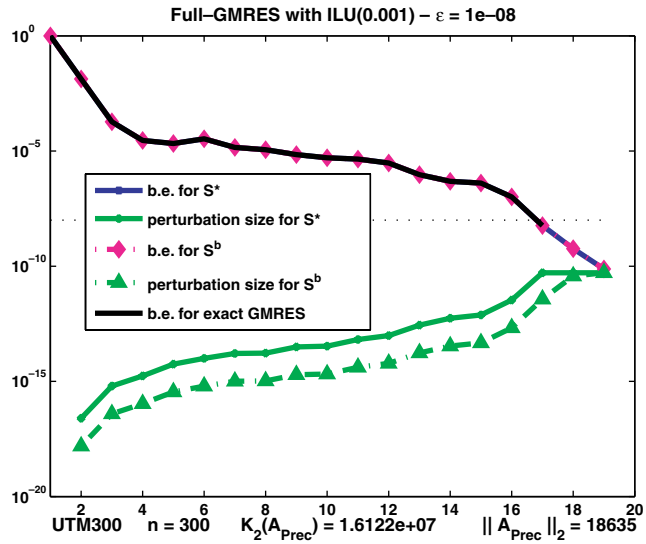

FIG. 2. *Relaxed GMRES with strategy $S^\star$ and S^b,* `UTM300`*, $\varepsilon = 10^{-8}$.*

with strategy $S^\star$ (resp., S^b). It can be seen that as relaxed GMRES converges the accuracy of the matrix-vector product is significantly relaxed without preventing relaxed GMRES from converging to the targeted backward error. We also see that one extra relaxed GMRES iteration is performed before the convergence is detected while $\eta_{A,b}(x_k)$ is already below ε. This delay is due to the stopping criterion implemented in the inexact algorithm that relies on an upper bound for $\eta_{A,b}$ based on (2.3).

In Figure 2, we display the same results for the matrix `UTM 300` preconditioned by ILU(10^{-3}). Again it can be seen that the accuracy of the matrix-vector product can be relaxed without preventing the convergence to occur. However, in that sort of extreme case, the perturbation size is smaller than ψ in the first iterations. This does not make much sense in finite precision calculation because the perturbation below ψ cannot be represented in finite precision. Finally, the example with matrix `UTM 300` better illustrates that S^b is more conservative than $S^\star$.

2.4. Design and behavior of some relaxation heuristics. It is established in [6] that the classical (unperturbed) GMRES algorithm implemented using reliable orthogonal transformation is a backward stable method in finite precision. This means that the quantity $\eta_{A,b}(x_k)$ is of the order of machine precision for some step ℓ, $\ell \leq n$. Let us use this result for a machine precision $\psi = \varepsilon$. Provided that all the operations occurring in the GMRES algorithm are performed with machine precision ε, a backward error $\eta_{A,b}(x_k) \sim C\,\varepsilon$ can be reached, where C depends on the problem size and on the details of the arithmetic. In that context we can define three heuristics that are closely related to the strategies studied in the previous section. They are simply derived by thresholding the norm of the perturbations and preventing them from becoming smaller than ε.

This leads to the definition of the following three heuristics.

1. Heuristic $S^\star(\varepsilon)$:

$$\|E_k\| = \max\left(\varepsilon\|A\|, \frac{\sigma_{\min}(A)}{4n}\min\left(1, \frac{3\gamma^\star}{\|\tilde{r}_{k-1}\|}\varepsilon_g\right)\right).$$

TABLE 2.1
Number of iterations of GMRES with various strategies.

BFW398A	398	10^{-1}	10^{-08}	40	40	41	41

2. Heuristic $S^b(\varepsilon)$:

$$\|E_k\| = \max\left(\varepsilon\|A\|, \frac{\sigma_{\min}(A)}{4n}\min\left(1, \frac{3\gamma^b}{\|\tilde{r}_{k-1}\|}\varepsilon_g\right)\right).$$

3. Heuristic $S(\varepsilon)$:

$$\|E_k\| = \varepsilon\|A\|.$$

The latter heuristic is related to exact GMRES run in a floating point arithmetic with machine precision ε.

In Table 2.1 we report on the number of iterations of exact GMRES and relaxed GMRES with the three heuristics on a set of matrices from Matrix Market. In that table we display the size of the matrix n, the threshold used for the $ILU(t)$ preconditioner, and the targeted accuracy ε for $\eta_{A,b}$; the number of exact GMRES iterations is N_{ex}, and the number of relaxed GMRES iterations with heuristic $S(\varepsilon)$ ($S^\star(\varepsilon)$ and $S^b(\varepsilon)$) is N_ε (resp., $N_\varepsilon^\star$ and N_ε^b). For the inexact GMRES the stopping criterion is defined by (2.14). The right-hand side b is such that $x^\star = (1, \ldots, 1)^T$ is the solution of $Ax = b$, where A stands again for the left-preconditioned matrix. We first see that the three variants of inexact GMRES always converge to the targeted accuracy. Even though not displayed for those examples the convergence histories with the three heuristics perfectly overlap the one of exact GMRES along the iterations for all the matrices. We observed this behavior for all the right-hand sides we have considered—not only for $b = A(1, \ldots, 1)^T$. Thus the reason the number of iterations for $S(\varepsilon)$ is sometimes smaller than for $S^\star(\varepsilon)$ and $S^b(\varepsilon)$ solely resides in the stopping criterion which induces a short delay in the convergence detection.

The only example we have encountered that behaves differently is the GRCAR matrix with $b = e_1$ and $\varepsilon \geq 10^{-8}$ (also considered in [15]); in Figure 3 we display for that example the convergence history of $\eta_{A,b}(x_k)$. We see in this peculiar case that exact GMRES converges quickly; that is, the solution lies in a low dimensional Krylov subspace. If inexact matrix-vector products are used, this low dimensional invariant space is not captured as quickly and the convergence is significantly delayed. We mention that this behavior disappears if a smaller value of ε (a larger Krylov space is required) is selected but still exists for larger ε (even smaller "invariant" space). It also disappears for other right-hand sides such as $b = A(1, \ldots, 1)^T$.

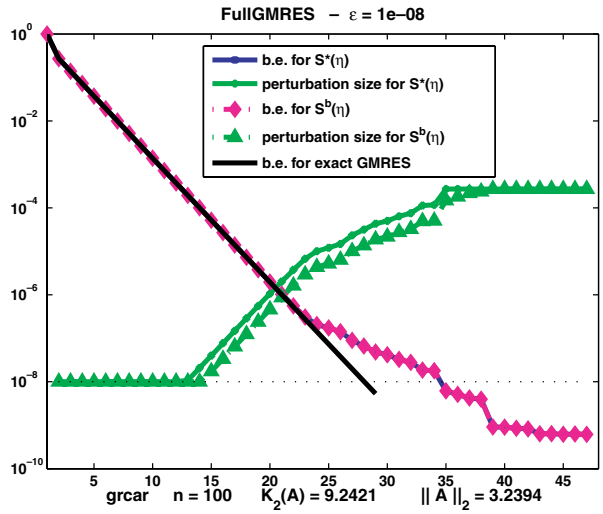

FIG. 3. *Convergence history of the inexact GMRES on* GRCAR *with* $b = e_1$.

3. GMRES with relaxed right-preconditioning. In practice GMRES is very often used with a preconditioner. When the preconditioner is used on the right, we solve the linear system $AM^{-1}u = b$ and we recover the solution by $x^\star = M^{-1}u^\star$. An important class of preconditioners, often referred to as implicit preconditioners, tries to approximate the matrix A and then solves the linear system associated with M (M is chosen such that this operation is much easier with M than with A). We are interested in the case where the application of the preconditioner is inexact: the system $Mz = v$ involved in the preconditioned GMRES is not solved exactly. This happens, for instance, when block preconditioners are used. Examples are Schwarz preconditioners in domain decomposition [17] or, more simply, block Jacobi preconditioners where each block is solved approximately using an iterative scheme. In this case, we assume that the matrix-vector product by A is performed exactly, but we have $Mz = v + p$, where p is the residual associated with the preconditioning operation. Our aim is to find a strategy to monitor $\|p\|$ in such a way that the convergence of GMRES reaches a backward error ε. A related study is developed in [15], where the focus is on the residual norm and the issue related to the recovery of x_ℓ from u_ℓ by the preconditioning $Mx_\ell = u_\ell + p_\ell$ is not addressed.

The inexact Arnoldi relation now reads

$$AM^{-1}V_k + AM^{-1}P_k = (AM^{-1} + AM^{-1}P_kV_k^T)V_k = V_{k+1}\bar{H}_k, \tag{3.1}$$

where $P_k = [p_1, \ldots, p_k]$, p_k being the residual associated with the kth preconditioning operation $Mz_k = v_k + p_k$. We present here results obtained for an unperturbed initial residual r_0. These results extend easily to cover the case where r_0 is perturbed, at the cost of much heavier notation as in Theorem 4. The following theorem, which is a direct application of Theorem 3 on the linear system $AM^{-1}u = b$, shows a possible control of $\|p_k\|$ so that the convergence of the relaxed right-preconditioned GMRES occurs.

THEOREM 5 (convergence of right-preconditioned GMRES for $\eta_{AM^{-1},b}$).

m c u_0 $u^\star$ $2c\|u_0\| \le \|u^\star\|$ $0 < c < 1$

ε_c , ε_g , , ,

TABLE 3.1
GMRES with relaxed right preconditioner.

ρ	$\eta_{A,b}(x_\ell)$	Upper bound
10^{-14}	$4 \cdot 10^{-14}$	$6 \cdot 10^{-14}$
10^{-11}	$3 \cdot 10^{-12}$	$1 \cdot 10^{-11}$
10^{-08}	$3 \cdot 10^{-09}$	$1 \cdot 10^{-08}$
10^{-05}	$3 \cdot 10^{-06}$	$1 \cdot 10^{-05}$
10^{-01}	$7 \cdot 10^{-04}$	$3 \cdot 10^{-03}$

We present a numerical illustration for Theorem 6 in order to demonstrate the effect of the last preconditioning operation on the backward error of the computed solution x_ℓ. We consider the matrix E05R0000 with an $ILU(10^{-2})$ as right-preconditioner and a targeted backward error on the preconditioned system $\eta_{AM^{-1},b}(u_\ell) \leq 10^{-10}$. To recover the unpreconditioned solution we perform a final preconditioning step $Mx_\ell = u_\ell + p$, where a random vector p is chosen such that $\|p\|$ is equal to a prescribed quantity ρ. We report in Table 3.1 the backward errors $\eta_{A,b}(x_\ell)$ obtained at the end of the process (inexact right-preconditioned GMRES and the final preconditioned step $Mx_\ell = u_\ell + p$) and the associated upper bound presented in Theorem 6. We see that the upper bound is tight on this example and that the backward error on x_ℓ strongly depends on the accuracy of the final $Mx_\ell = u_\ell + p$ as monitored by the quantity $\rho = \|p\|$.

REMARK 3. We mention that similar results can be derived for inexact left-preconditioning. In that context, the quantity ε_b from Theorem 4 enables us to account for the inaccuracy in the first preconditioning step to build the right-hand side of the preconditioned system.

REMARK 4. We consider FGMRES with a varying preconditioner satisfying $Mz_k = v + p_k$, where p_k is the residual vector whose norm is used to control the convergence of the algorithm. FGMRES is very close to the inexact right-preconditioned GMRES in the sense that the same Arnoldi relation (3.1) holds, which can be rewritten $AZ_k = V_{k+1}\bar{H}_k$. Contrary to the inexact GMRES framework, [14, Proposition 9.3] shows that when a breakdown occurs at step m in FGMRES and if the associated H_m is nonsingular, not only is $\tilde{r}_m$ zero but also $x_m = Z_\ell y_m = A^{-1}b$. In other words, the nonsingularity of H_m yields that, at the breakdown, x_m is the solution to $Ax = b$. Theorem 1 and (3.2) show that the nonsingularity of H_m is guaranteed if $\|p_k\| \leq \frac{c}{n\kappa(AM^{-1})}$.

Theorem 6 mainly emphasizes the role played by the last preconditioning step. Its use in real applications would deserve additional efforts to find reasonable estimates of the quantities involved in the control such that $\kappa(AM^{-1})$ or $\|AM^{-1}\|$.

4. Some remarks on inexact restarted GMRES. In this paper we are interested in relaxation techniques for which theoretical convergence of GMRES can be established. This is the main reason why we have considered only strategies in the context of full GMRES. There is a clear interest in practice to use the restarted GMRES(m) algorithm [12]. Unfortunately, no general theoretical result exists on the convergence of restarted GMRES. Establishing such a result is probably the first step before studying an inexact restarted algorithm. Nevertheless, we mention that some heuristic strategies [4, 8, 16] as well as those described in this paper enable the convergence of the inexact restarted algorithm in practice.

As previously in this paper we focus on provable convergence theory. In that respect, we consider a variant of restarted GMRES where the restart is not governed by the dimension of the Krylov space affordable in term of memory but rather by a targeted backward error η. We study this variant of restarted GMRES as a fixed point iteration scheme, where at each restart (i.e., each fixed point iteration) the residual can be inaccurately computed. This fixed point iteration is summarized in Algorithm 2, where the function *solve* involved in step 5 is any function ensuring that $\eta_{A,r_k}(s_k) \leq \eta$. If *solve* is exact full GMRES we end up with what we denote by GMRES(η). Notice, that Algorithm 2 differs from classical GMRES(m) in that the calculation of s_k is stopped when the associated backward error is less than η rather than on a memory limit. We define the normwise condition number of the linear system [10, p. 121] by $\kappa(A,b) = \frac{\|A^{-1}\|}{\|x^\star\|}(\|A\|\|x^\star\| + \|b\|)$.

Algorithm 2. Fixed point scheme.

1: Let ε_A, ε_b, and η be positive.
2: Choose an initial guess x_0
3: **for** $k = 1, 2, \ldots$ **do**
4: Compute $r_k = (b + \Delta b_k^{res}) - (A + \Delta A_k^{res})x_k$
5: $s_k = solve(A, r_k, \eta)$
6: $x_{k+1} = x_k + s_k$
7: **end for**

where s_k is such that $\eta_{A,r_k} \leq \eta$ with $\|\Delta A_k^{res}\| \leq \varepsilon_A\|A\|$ and $\|\Delta b_k^{res}\| \leq \varepsilon_b\|b\|$.

THEOREM 7. [illegible] $\{x_k\}$ [illegible] 2 [illegible] $\varepsilon_A\kappa(A) < 1/7$ [illegible] $\eta\kappa(A) < 1/7$ [illegible] $\varepsilon_A = \varepsilon_b = 0$ $\lim_{k\to+\infty} x_k = x^\star$ [illegible] $\max(\varepsilon_A, \varepsilon_b) > 0$ [illegible]

$$\frac{\|x_k - x^\star\|}{\|x^\star\|} \leq 5\kappa(A,b)\max(\varepsilon_A, \varepsilon_b)$$

[illegible] k [illegible] s_k [illegible] 2.2 [illegible]. Let us consider the fixed point iteration

$$x_{k+1} = x_k + s_k.$$

Since $s_k = solve(A, r_k, \eta)$, there exists q_k such that

$$As_k = r_k + q_k, \text{ where } \|q_k\| \leq \eta\left(\|A\|\|s_k\| + \|r_k\|\right). \tag{4.1}$$

We set $e_k = x_k - x^\star$, which yields $e_{k+1} = e_k + s_k$. Taking norms in $r_k = b + \Delta b_k^{res} - (A + \Delta A_k^{res})x_k$ leads to

$$\begin{aligned}\|r_k\| &= \|b + \Delta b_k^{res} - (A + \Delta A_k^{res})(x^\star + e_k)\| \\ &= \|\Delta b_k^{res} - \Delta A_k^{res}x^\star - (A + \Delta A_k^{res})e_k\| \\ &\leq \max(\varepsilon_b, \varepsilon_A)(\|b\| + \|A\|\|x^\star\|) + (1 + \varepsilon_A)\|A\|\|e_k\|\end{aligned}$$

and to

$$\|q_k\| \leq \eta \max(\varepsilon_b, \varepsilon_A)(\|b\| + \|A\|\|x^\star\|) + \eta(2+\varepsilon_A)\|A\|\|e_k\| + \eta\|A\|\|e_{k+1}\|. \tag{4.2}$$

Using $e_{k+1} = e_k + s_k$, multiplying (4.1) by A^{-1}, and using the definition of r_k yield

$$\begin{aligned}\|e_{k+1}\| &\leq \|e_k + A^{-1}b + A^{-1}\Delta b_k^{res} - A^{-1}(A + \Delta A_k^{res})(x^\star + e_k)\| + \|A^{-1}\|\|q_k\| \\ &= \|A^{-1}\Delta b_k^{res} - A^{-1}\Delta A_k^{res}(x^\star + e_k)\| + \|A^{-1}\|\|q_k\| \\ &\leq \max(\varepsilon_b, \varepsilon_A)\|A^{-1}\|(\|b\| + \|A\|\|x^\star\|) + \varepsilon_A\kappa(A)\|e_k\| + \|A^{-1}\|\|q_k\|.\end{aligned}$$

Under the assumption $\eta\kappa(A) < 1/7$, we have $(1 - \eta\kappa(A)) > 0$ and inequality (4.2) yields

$$\|e_{k+1}\| \leq \frac{(1+\eta)\max(\varepsilon_b, \varepsilon_A)}{1 - \eta\kappa(A)}\|A^{-1}\|(\|b\| + \|A\|\|x^\star\|) + \frac{2\eta + \varepsilon_A + \eta\varepsilon_A}{1 - \eta\kappa(A)}\kappa(A)\|e_k\|.$$

Suppose that $\eta\kappa(A) < 1/7$ and $\varepsilon_A\kappa(A) < 1/7$; then

$$\|e_{k+1}\| \leq 4/3 \max(\varepsilon_b, \varepsilon_A)\kappa(A, b)\|x^\star\| + 2/3\|e_k\|.$$

If $\varepsilon_A = \varepsilon_b = 0$, $\lim_{k\to+\infty} x_k = x^\star$; else we have

$$\limsup_{k\to\infty} \|e_k\| \leq 4 \max(\varepsilon_b, \varepsilon_A)\kappa(A, b)\|x^\star\|,$$

which concludes the proof. ∎

The above theorem shows that for a large enough k the forward error is bounded by five times the product of a backward error by the normwise condition number $\kappa(A, b)$. This is reasonable from a perturbation theory point of view.

The calculation of s_k by the function *solve* in Algorithm 2 can be implemented by relaxed GMRES. This latter variant is referred to as relaxed GMRES(η). In Figure 4 we display the convergence history of relaxed GMRES(η) for $\eta = 10^{-4}$ and for two different values of ε_A and ε_b. The curves with $\times$ represent the norm of the perturbations involved in the relaxed GMRES. The curves with + represent the backward error $\eta_{A,b}(x_k)$ at each iteration of relaxed GMRES that implements *solve*. In the experiments we did not implement any stopping criterion; we display the first seven outer iterations that result in 45 iterations of relaxed GMRES. It can be observed that the final backward error reached by the algorithm is related to the perturbation size $\max\{\varepsilon_A, \varepsilon_b\}$ imposed on the residual r_k of step 4 of Algorithm 2. Remarkably the perturbations involved in relaxed GMRES of step 5 are significantly larger than $\max\{\varepsilon_A, \varepsilon_b\}$. The spikes observed in the perturbation size curves correspond to the restarts in relaxed GMRES(η).

5. Conclusion. In this paper we are interested either in relaxation techniques for which theoretical convergence of relaxed GMRES can be established or in heuristics that are closely related to the backward stability of the GMRES algorithm with reliable orthogonalization schemes. The proposed strategies ensure the convergence in backward error $\eta_{A,b}$ or η_b down to a prescribed accuracy ε. Finally, our strategies rely on the knowledge of $\sigma_{\min}(A)$, the solution norm that might be difficult to estimate. Further research is needed to establish similar convergence results while replacing these quantities by others that are simpler to estimate.

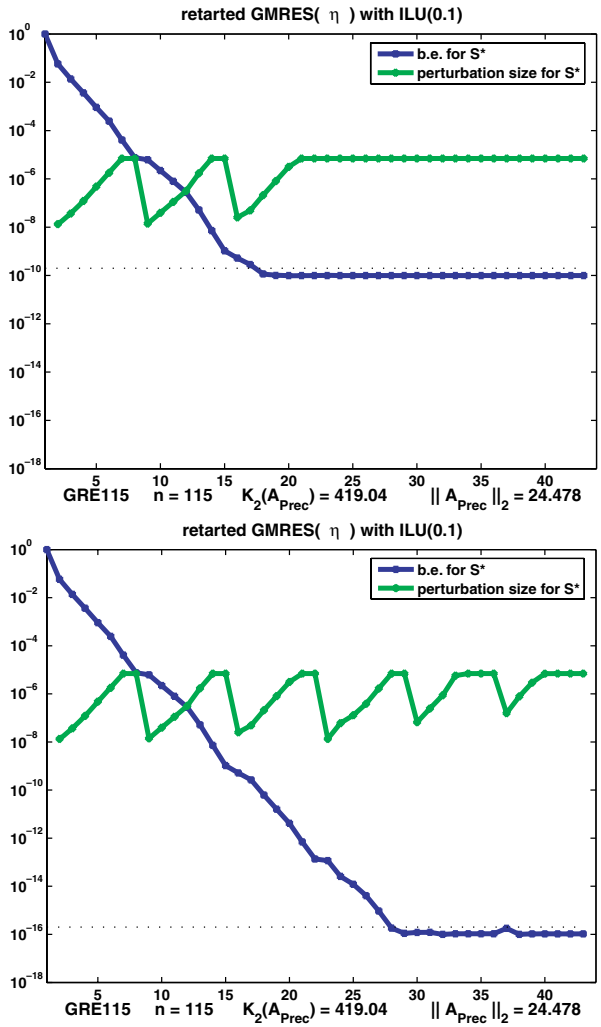

FIG. 4. *Restarted GMRES(ε) with inexact matrix-vector products,* `GRE115`*, with* $\varepsilon_A = \varepsilon_b = 10^{-10}$ *(top), and* $\varepsilon_A = \varepsilon_b = 10^{-16}$ *(bottom).*

Acknowledgments. We would like to thanks the anonymous referees for their valuable remarks, questions, and comments that enabled us to substantially improve this paper. We also express our gratitude to Anne Greenbaum for her continuous encouragement.

LIAPUNOV–SCHMIDT REDUCTION AND CONTINUATION FOR NONLINEAR SCHRÖDINGER EQUATIONS*

S.-L. CHANG†, C.-S. CHIEN‡§, AND B.-W. JENG‡¶

Abstract. We study the bifurcation scenario of nonlinear Schrödinger equations (NLS). The Liapunov–Schmidt reduction is applied to show that the simple bifurcations of a single NLS are pitchfork. The pitchfork bifurcation can be subcritical or supercritical, depending on the coefficient of the cubic term we choose. We also describe numerical methods so that the Liapunov–Schmidt reduction can effectively handle a corank-2 bifurcation point. Next, we apply numerical continuation methods to trace solution curves and surfaces of the NLS, where the system is discretized by the centered difference approximations. Numerical results on two- and three-dimensional M-coupled NLS are reported, where the physical properties such as the effect of trapping potentials, isotropic and nonisotropic trapping potentials, mass conservation constraints, and strong and weak repulsive interactions are considered in our numerical experiments.

Key words. Bose–Einstein condensates, time-independent system, bifurcation, mode interactions, mass conservation

1. Introduction.

The M-coupled nonlinear Schrödinger equations (MCNLS) are governed by

$$\begin{aligned} \mathbf{i}\frac{\partial}{\partial t}\Phi_j &= -\Delta\Phi_j + V_j(x)\Phi_j + \mu_j|\Phi_j|^2\Phi_j + \sum_{i\neq j}\beta_{ij}|\Phi_i|^2\Phi_j \\ &\qquad \text{for } x\in\mathbf{R}^n,\ n\le 3,\ t>0, \\ \Phi_j &= \Phi_j(x,t)\in\mathbf{C}, \quad j=1,\dots,M, \\ &\qquad \Phi_j(x,t)\to 0 \text{ as } |x|\to+\infty, \quad t>0. \end{aligned} \tag{1.1}$$

Here $V_j(x)$ is the trapping potential, which usually is harmonic and can be expressed as $V_j(x)=\frac{1}{2}(\alpha_{j,1}x_1^2+\cdots+\alpha_{j,n}x_n^2)$ with $\alpha_{j,1},\dots,\alpha_{j,n}>0$, $j=1,\dots,M$; $\mu_j>0$ being positive constants; and β_{ij} being coupling constants. The trapping potentials are said to be isotropic if $\alpha_{j,1}=\cdots=\alpha_{j,n}$ for $j=1,\dots,M$. Otherwise they are nonisotropic. Equation (1.1) describes a physical model in which M-species Bose–Einstein condensates (BEC) [1, 2, 3] come from ultracold dilute bosonic atoms in a magnetically trapped gas. The solution Φ_j in (1.1) also represents the jth component of the beam in Kerr-like photorefractive media with self-focusing parameter μ_j in nonlinear optics

[4]. Equation (1.1) is also known in BEC as the Gross–Pitaevskii equations [5, 6]. Let $\Phi_j(x,t) = e^{-\mathbf{i}\lambda_j t}u_j(x)$ in (1.1); then the time-independent MCNLS can be expressed as

$$
\begin{aligned}
&-\Delta u_j - \lambda_j u_j + V_j(x)u_j + \mu_j u_j^3 + \sum_{i\neq j}\beta_{ij}u_i^2 u_j = 0 \quad \text{in } \mathbf{R}^n,\ n \le 3,\\
&u_j > 0 \quad \text{in } \mathbf{R}^n,\ j = 1,\dots,M,\\
&u_j(x) \to 0 \quad \text{as } |x| \to +\infty.
\end{aligned}
\tag{1.2}
$$

In recent years the BEC has become one of the most popular research areas in experimental and theoretical physics [7, 8, 9, 10], as well as in applied and computational mathematics [11, 12, 13, 14, 15]. In particular, Bao and Tang [11] and Bao, Jaksch, and Markowich [13] studied the numerical solutions of (1.1) for $M = 1$. Hall et al. [16] reported the first experimental results concerning the dynamics of a two-component system of BEC in the different spin states of ^{87}Rb. Then Pu and Bigelow [17] studied the numerical solutions of the one-dimensional two-component BEC using centered difference approximations. Recent research articles concerning numerical solutions of (1.1) and (1.2) for $M > 1$ can be found in [18, 19].

Recently, the authors [20] studied numerical solutions of the steady state MCNLS, $M = 2, 3$, including ground and bound state solutions using continuation methods [21, 22], where the chemical potentials λ_j were treated as the continuation parameter. For $M = 2$ it was shown numerically that the first bifurcation point is pitchfork, which is supercritical if $\beta > 0$ and subcritical if $\beta < 0$. On the other hand, Kuo, Lin, and Shieh [14] studied the local bifurcation behavior of two-coupled nonlinear Schrödinger equations (NLS) by minimizing the potential energy of the system, where the coupling parameter β was used as the continuation parameter. From the viewpoint of numerical continuation, it is more natural to treat the eigenvalues or chemical potentials λ_j as the continuation parameters, since the bifurcation points of the system can easily be determined if $V_j(x) = 0$ for all $j = 1 : M$.

The purpose of this paper is twofold. First, we wish to indicate that the numerical continuation method described in [20] can be used to solve (1.2) with $M = 1$ under the normalization [12],

$$
\int_\Omega |u(x)|^2 dx = 1, \tag{1.3}
$$

where Ω is a subset of $\mathbf{R}^n$. Equation (1.3) means that we are concerned only with mass conservation of the physical system. Starting from the trivial solution curve of the discrete problem, i.e., with $\|u\|_2 = 0$, we numerically trace the nontrivial solution curve, say, branching from the first bifurcation point of (1.2). We stop if $\|u^{(k)}\|_2 = 1$ is reached, where k denotes the kth continuation step and $(u^{(k)}, \lambda^{(k)}, \mu)$ is the desired solution. Note that we may vary the value of μ as we wish. The numerical continuation method can also be used to solve (1.2) for $M > 1$ with the constraints

$$
\int_\Omega |u_j(x)|^2 dx = 1, \quad j = 1,\dots,M. \tag{1.4}
$$

However, as we may see from our numerical result for $M = 2$, we can obtain only

$$
\|u_2(x)\|_2 < \|u_1(x)\|_2 = 1
$$

if the coupling coefficient $\beta < 0$. On the other hand, if $\beta > 0$, then both $u_1(x)$ and $u_2(x)$ satisfy (1.4) but for different values of λ. We may explain this phenomenon as "phase separation."

Next, we will apply the Liapunov–Schmidt reduction [23, Chapters 1 & 7] to study the bifurcation scenario of a single NLS at simple eigenvalues. The Liapunov–Schmidt reduction has been widely used to analyze local bifurcation behavior of bifurcation problems. In [24] Böhmer proposed a numerical Liapunov–Schmidt method for studying the local bifurcation scenario of operator equations. Then Böhmer and Mei [25] used the numerical Liapunov–Schmidt method to compute the solution manifolds bifurcating at a singular zero point of an operator equation. The method was then applied to calculate reduced equations at Hopf bifurcations of the two-dimensional Brusselator equations on a square with Neumann and Dirichlet boundary conditions [26]. It is interesting to see that the Liapunov–Schmidt reduction process is also used in [15] to prove the existence of a bound state solution of (1.2).

In this paper, we consider (1.2) defined in $(0,1)^n,\ n \leq 3$. We show that the first bifurcation of a single NLS is pitchfork. The pitchfork bifurcation can be supercritical or subcritical, depending on the coefficient of the cubic term we choose. For two- and three-dimensional cases the second bifurcation points are of corank-2 and corank-3, respectively. We show that a double bifurcation of a single NLS can be split into two simple ones if the trapping potential is nonisotropic. To the best of our knowledge, the Liapunov–Schmidt reduction cannot be used to treat multiple eigenvalues; see, e.g., [23, Chapter 7, p. 326]. To overcome this difficulty, we describe some numerical methods so that the Liapunov–Schmidt reduction can be effectively applied. Nevertheless, the Liapunov–Schmidt reduction can give only qualitative properties of the system. In order to investigate the quantitative behavior, we need to apply the numerical continuation methods for curve-tracking. We will see how the solutions affect each other using numerical methods. Theoretical study of three-coupled NLS can be found, e.g., in [15].

The bifurcation scenario of the coupled NLS is getting more complicated. We show that mode interactions of the two-coupled NLS cannot occur. It is possible to use the modified Liapunov–Schmidt method described in [27] to investigate the local bifurcation behavior of the two-coupled NLS. But we will not go into detail.

This paper is organized as follows. In section 2 we briefly review the Liapunov–Schmidt reduction for bifurcation problems. Since a single NLS is odd with respect to the state variables, the computations in the Liapunov–Schmidt reduction can be effectively simplified. Moreover, it becomes clear that the bifurcations of a single NLS in one dimension are pitchfork. We give a detailed analysis for the bifurcation scenario of a single NLS in section 3. We also show that the bifurcation scenario is invariant under the effect of linear potentials. In particular, we discuss mode interactions for the coupled one-dimensional NLS. Additionally, we show how the Liapunov–Schmidt reduction can be used to treat a corank-2 bifurcation of the two-dimensional problem. The same techniques also can be used in the three-dimensional case. In section 4 we study the centered difference approximations for MCNLS. We describe a two-grid centered difference discretization algorithm which can compute the first few eigenpairs of the coupled nonlinear Schrödinger equations to the desired accuracy. The normalized eigenvector can be used as the tangent vector at the bifurcation for branch-switching. Furthermore, we indicate that the numerical continuation methods can be used to solve the MCNLS with the normalization constraints (1.4). Our numerical results are reported in section 5. The test problems

include two- and three-dimensional cases, where solution curves branching from the first simple bifurcation point and a corank-2 bifurcation point are numerically traced. Additionally, the physical properties of the NLS are considered in our numerical experiments, including the effect of trapping potentials, strong and weak repulsive interactions, and mass conservation constraints. Finally, some conclusions are given in section 6.

2. A brief review of the Liapunov–Schmidt reduction. To study the local bifurcation scenario of the MCNLS, we need some basic concepts from Golubitsky and Schaeffer [23]. Let $\mathcal{E}_{x,\lambda}$ be the space of all functions $g : \mathbf{R}^2 \to \mathbf{R}$ that are defined and C_∞ on some neighborhood of the origin. We identify any two functions in $\mathcal{E}_{x,\lambda}$ which are equal as germs. Let $g, h : \mathbf{R}^2 \to \mathbf{R}$ be any two smooth mappings that are defined near the origin. We say that g and h are strongly equivalent if there exist functions $X(x,\lambda)$ and $S(x,\lambda)$ such that the relation $g(x,\lambda) = S(x,\lambda)h(X(x,\lambda),\lambda)$ holds near the origin. In this definition we require that $X(0,0) = 0$, $X_x(x,\lambda) > 0$, $S(x,\lambda) > 0$. We refer to [23, p. 95] for the following proposition.

PROPOSITION 2.1. [illegible] $g \in \mathcal{E}_{x,\lambda}$ [illegible] $\alpha x^k + \beta\lambda x$ [illegible] $(x,\lambda) = (0,0)$

(2.1)
$$g = \frac{\partial}{\partial x}g = \cdots = \left(\frac{\partial}{\partial x}\right)^{k-1} g = \frac{\partial}{\partial \lambda}g = 0 \quad [\text{illegible}] \quad \alpha = \operatorname{sign}\left(\frac{\partial}{\partial x}\right)^k g, \quad \beta = \operatorname{sign}\frac{\partial}{\partial \lambda}\frac{\partial}{\partial x}g.$$

Thus if $k = 3$ in Proposition 2.1, then $g(x,\lambda)$ is strongly equivalent to the normal form $\pm x^3 \pm \lambda x = 0$. We say that (2.1) solves the recognition problem for this normal form. Moreover, the bifurcation problem $g(x,\lambda) = x^3 - \lambda x = 0$ is supercritical since the nontrivial solution lies entirely to the right of the bifurcation point $(0,0)$. On the other hand, $x^3 + \lambda x = 0$ is subcritical because the nontrivial solutions lies entirely to the left of the bifurcation point.

Let $\Phi : X \times \mathbf{R}^{k+1} \to Y$ be a smooth mapping between Banach spaces X and Y. We will solve

$$\Phi(u,\alpha) = 0, \tag{2.2}$$

where $u \in X$ and $\alpha = (\alpha_0, \alpha_1, \ldots, \alpha_k) \in \mathbf{R}^{k+1}$. We use α_0 as the continuation parameter and fix $\alpha_1, \ldots, \alpha_k$, say $\alpha_0 = \lambda$. Let L be the differential of Φ with respect to $(u,\lambda) = (0,0)$, i.e., $L = (d\Phi)_{0,0} = \Phi_u(0,0)$. Assume that the differential operator $L : X \to Y$ is Fredholm operator of index 0. The Liapunov–Schmidt reduction is briefly described as follows [23, Chapter 7].

[illegible] 1. Decompose

$$\text{(a) } X = \ker L \oplus M \quad \text{and} \quad \text{(b) } Y = N \oplus R(L), \tag{2.3}$$

where $\ker L$ and $R(L)$ denote the kernel and the range, respectively, of L. For simplicity we assume that $\ker L = \operatorname{span}\{v_0\}$. The discussion given below can be generalized to the case $\dim \ker L \geq 2$.

[illegible] 2. Split (2.2) into an equivalent pair of equations:

$$\text{(a) } E\Phi(u,\lambda) = 0, \quad \text{(b) } (I - E)\Phi(u,\lambda) = 0, \tag{2.4}$$

where $E : Y \to R(L)$ is the projection associated with the splitting.

3. Use (2.3a) to write $u = v + w$, where $v \in \ker L$ and $w \in M$. Define a map $G : \ker L \times M \times \mathbf{R} \to R(L)$ from (2.4a) by

$$G(v, w, \lambda) = E\Phi(v + w, \lambda). \tag{2.5}$$

The differential of G with respect to w at the origin is

$$EL = L.$$

Since the operator L is Fredholm, $R(L)$ is closed. Therefore

$$L : M \to R(L)$$

is invertible. Apply the implicit function theorem to solve (2.4a) for w as a function of v and λ. This leads to a function W, $W : \ker L \times \mathbf{R} \to M$ such that

$$E\Phi(v_0 + W(v_0, \lambda), \lambda) = 0. \tag{2.6}$$

4. Define $\phi : \ker L \times \mathbf{R} \to N$ by

$$\phi(v_0, \lambda) = (I - E)\Phi(xv_0 + W(xv_0, \lambda), \lambda). \tag{2.7}$$

Note that the vector in (2.6) is replaced by xv_0, $x \in \mathbf{R}$, in (2.7).

5. Choose a basis v_0^* for $(R(L))^\perp$. Define $g : \mathbf{R} \times \mathbf{R} \to \mathbf{R}$ by

$$g(x, \lambda) = \langle v_0^*, \Phi(xv_0 + W(xv_0, \lambda), \lambda) \rangle, \tag{2.8}$$

where $\langle r, s \rangle = \int_\Omega r(\xi) s(\xi)\, d\xi$ with Ω the domain of the smooth mapping Φ. The outcome of the Liapunov–Schmidt reduction can be summarized as follows. (See [23, p. 294].)

PROPOSITION 2.2. [illegible] (2.2) [illegible] (2.2) [illegible] $g(x, \lambda) = 0$ [illegible] g [illegible] (2.8)

If the mapping Φ is odd with respect to u, then we have $g_x = g_{xx} = g_\lambda = 0$. Thus if the bifurcation of (2.2) is pitchfork, then we need to compute only

$$\begin{aligned} &\text{(a) } g_{xxx} = \left\langle v_0^*, d^3\Phi(v_0, v_0, v_0) \right\rangle, \\ &\text{(b) } g_{\lambda x} = \left\langle v_0^*, d\Phi_\lambda \cdot v_0 \right\rangle. \end{aligned} \tag{2.9}$$

We refer to [23, Chapter 1] for details.

3. Local bifurcation analysis. We will give a detailed analysis for the local bifurcation behavior of a single NLS. The bifurcation scenario of the MCNLS will be briefly discussed.

3.1. Simple bifurcations of a single NLS. We consider the following equation:

$$\begin{aligned} -\Delta u - \lambda u + \mu u^3 &= 0 \qquad \text{in } \Omega = (0,1)^N,\ N = 1, 2, 3, \\ u &= 0 \qquad \text{on } \partial\Omega. \end{aligned} \tag{3.1}$$

It is well known that the eigenpairs of the linear eigenvalue problem

$$\begin{aligned} -\Delta u + \lambda u &= 0 \quad \text{in } \Omega = (0,1)^N, \\ u &= 0 \quad \text{on } \partial\Omega, \end{aligned} \tag{3.2}$$

for $N = 1$ are

$$\begin{aligned} u_m(x) &= \sin m\pi x, \\ \lambda_m &= m^2\pi^2, \end{aligned} \qquad m = 1, 2, \dots, \tag{3.3}$$

for $N = 2$ are

$$\begin{aligned} u_{m,n}(x, y) &= \sin m\pi x \cdot \sin n\pi y, \\ \lambda_{m,n} &= (m^2 + n^2)\pi^2, \end{aligned} \qquad m, n = 1, 2, \dots, \tag{3.4}$$

and for $N = 3$ are

$$\begin{aligned} u_{m,n,p}(x, y, z) &= \sin m\pi x \cdot \sin n\pi y \cdot \sin p\pi z, \\ \lambda_{m,n,p} &= (m^2 + n^2 + p^2)\pi^2, \end{aligned} \qquad m, n, p = 1, 2, 3, \dots. \tag{3.5}$$

THEOREM 3.1. [illegible] (3.1) [illegible] $\mu > 0$ [illegible] $\mu < 0$ [illegible]. Let $\Phi : X \times \mathbf{R} \to C^0(\bar{\Omega})$ be the mapping defined by

$$\Phi(u, \lambda) = -\Delta u - \lambda u + \mu u^3 = 0,$$

where $X = \{u \in C^2(\Omega) : u = 0 \text{ on } \partial\Omega\}$. First we consider the one-dimensional case. The linear operator $L = (d\Phi)_{0,\lambda} = -\Delta - \lambda$ is singular at $\lambda = \lambda_1$, and $\ker L = \operatorname{span}\{u_1 = \sin \pi x\}$ with $\dim(\ker L) = 1$. Since the linear operator L is self-adjoint, $\ker L^* = \ker L = \operatorname{span}\{u_1\}$. It is obvious that the mapping Φ is odd with respect to u, i.e., $\Phi(-u, \lambda) = -\Phi(u, \lambda)$. Therefore, when $u = 0$ we have $(d^2\Phi)_{0,\lambda} = 0$. We need to compute

$$g_{xxx} = \left\langle u_1, (d^3\Phi)_{0,\lambda_1}(u_1, u_1, u_1) \right\rangle \quad \text{and} \quad g_{\lambda x} = \left\langle u_1, (d\Phi_\lambda)_{0,\lambda_1} \cdot u_1 \right\rangle.$$

Since $\Phi_\lambda(u, \lambda) = -u$, we have $\Phi_\lambda(0, \lambda) = 0$. By definition,

$$(d\Phi_\lambda)_{0,\lambda} \cdot u_1 = \lim_{h \to 0} \frac{\Phi_\lambda(0 + hu_1, \lambda) - \Phi_\lambda(0, \lambda)}{h} = -u_1 = -\sin \pi\xi.$$

Thus, $g_{\lambda x} = \langle u_1, -u_1 \rangle = -\int_0^1 \sin^2 \pi\xi \, d\xi = -\frac{1}{2} < 0$. Next, we compute $(d^3\Phi)_{0,\lambda}(u_1, u_1, u_1)$. By definition,

$$\begin{aligned} d^3\Phi(0, \lambda)(u_1, u_1, u_1) &= \frac{\partial}{\partial t_1}\frac{\partial}{\partial t_2}\frac{\partial}{\partial t_3}\Phi(0 + t_1u_1 + t_2u_1 + t_3u_1, \lambda)\Big|_{(t_1,t_2,t_3)=0} \\ &= 6\mu \cdot \sin^3 \pi\xi. \end{aligned}$$

Since $\int_0^1 \sin^4 \pi\xi \, d\xi = \frac{3}{8}$, we have $(\frac{\partial}{\partial x})^3 g(0, \lambda_1) = \frac{9}{4}\mu$. It follows that the normal form is $\operatorname{sign}(\mu)x^3 - \lambda x = 0$. Thus the pitchfork bifurcation is supercritical if $\mu > 0$, and subcritical if $\mu < 0$. For $N = 2$ we replace u_1 by $u_{1,1} = \sin \pi x \cdot \sin \pi y$ in the proof given above. Note that $\int_0^1 \int_0^1 (\sin \pi\xi \cdot \sin \pi\eta) \, d\xi d\eta = \frac{9}{64}$. The result follows immediately. For $N = 3$, the proof is straightforward. □

COROLLARY 3.2. [illegible] $N = 1$ [illegible] (3.1) [illegible] $\mu > 0$ [illegible] $\mu < 0$ [illegible]. We replace $\sin \pi\xi$ by $\sin m\pi\xi$ in the proof of Theorem 3.1. The result follows immediately. □

Now we impose the term $V(x)u(x)$ on the left-hand side of (3.1) and obtain a single NLS,

$$\begin{aligned} -\Delta u(x) - \lambda u(x) + V(x)u(x) + \mu u^3(x) &= 0 \qquad \text{in } \Omega = (0,1)^N, \\ u &= 0 \qquad \text{on } \partial\Omega. \end{aligned} \tag{3.6}$$

It is clear that the bifurcations of (3.6) are located at the eigenvalues of the Schrödinger eigenvalue problem

$$\begin{aligned} -\Delta u + V(x)u(x) &= \lambda u(x) \qquad \text{in } \Omega = (0,1)^N,\ N = 1,2,3, \\ u &= 0 \qquad \text{on } \partial\Omega. \end{aligned} \tag{3.7}$$

We will show that the bifurcation scenario of (3.6) is the same as that of (3.1).

THEOREM 3.3. [illegible] (3.6) [illegible] $\mu > 0$ [illegible] $\mu < 0$ [illegible]. Let $F : X \times \mathbf{R} \to C^0(\Omega)$ be the mapping defined by

$$F(u,\lambda) = -\Delta u + Vu - \lambda u + \mu u^3,$$

where $X = \{u \in C^2(\Omega) : u = 0 \text{ on } \partial\Omega\}$. Note that the linear operator $L = (dF)_{0,\lambda} = -\Delta + V - \lambda$ is singular at $\lambda = \lambda_1$, and it has a one-dimensional kernel spanned by u_1, where u_1 is the eigenvector corresponding to the first minimum eigenvalue of (3.7). Since $F(-u,\lambda) = -F(u,\lambda)$ for all $\lambda \in \mathbf{R}$, the reduced function g at the bifurcation $(0,\lambda_1)$ satisfies $g = g_x = g_{xx} = g_\lambda = 0$. To prove that the first bifurcation of (3.6) is pitchfork, we only need to compute

$$g_{xxx} = \left\langle u_1,\ (d^3F)_{0,\lambda_1}(u_1,u_1,u_1) \right\rangle \quad \text{and} \quad g_{\lambda x} = \left\langle u_1,\ (dF_\lambda)_{0,\lambda_1} \cdot u_1 \right\rangle.$$

By definition,

$$\begin{aligned} &(d^3F)_{0,\lambda_1}(u_1,u_1,u_1) \\ &= \frac{\partial}{\partial t_1}\frac{\partial}{\partial t_2}\frac{\partial}{\partial t_3} F(0 + t_1u_1 + t_2u_1 + t_3u_1, \lambda_1)\Big|_{t_1=t_2=t_3=0} \\ &= 6\mu u_1^3. \end{aligned}$$

Thus,

$$g_{xxx} = \left\langle u_1, 6\mu u_1^3 \right\rangle = 6\mu \int_\Omega u_1^4 \neq 0 \quad \text{when } \mu \neq 0.$$

Similarly, $F_\lambda(u,\lambda) = -u$, and we have

$$(dF_\lambda)_{0,\lambda_1} \cdot u_1 = \frac{d}{dt} F_\lambda(0 + tu_1, \lambda_1)\Big|_{t=0} = -u_1.$$

Thus,

$$g_{\lambda x} = \langle u_1, -u_1 \rangle = -\int_\Omega u_1^2 < 0.$$

From this it follows that the reduced function g is equivalent to the normal form $\alpha x^3 - \lambda x = 0$, where $\alpha = \operatorname{sign}(\mu)$. Thus the first bifurcation of (3.6) is pitchfork. Moreover, the pitchfork bifurcation is supercritical if $\mu > 0$, and subcritical if $\mu < 0$. □

3.2. Multiple bifurcations of a single NLS in two dimensions. Consider the following semilinear elliptic eigenvalue problem:

$$\begin{aligned} G(u,\lambda) = \Delta u + \lambda f(u) = 0 \quad & \text{in } \Omega = (0,1)^2, \\ u = 0 \quad & \text{on } \partial\Omega, \end{aligned} \tag{3.8}$$

where $f : \mathbf{R} \to \mathbf{R}$ is a smooth odd function which satisfies $f'(0) \neq 0$ and $f'''(0) \neq 0$. A corank-2 bifurcation point of

$$\begin{aligned} -\Delta u - \lambda u + \mu u^3 = 0 \quad & \text{in } \Omega = (0,1)^2, \\ u = 0 \quad & \text{on } \partial\Omega \end{aligned} \tag{3.9}$$

has the form $\{(0, \lambda_{m,n}) \mid \lambda_{m,n} = (m^2+n^2)\pi^2, m \neq n\}$. It is clear that (3.9) satisfies the assumptions of (3.8). For convenience we assume $m = 1$, $n = 2$, and let $u_1 = \sin \pi x \sin 2\pi y$, $u_2 = \sin 2\pi x \sin \pi y$. The kernel of the linear differential operator L in (3.9) is $\ker L = \operatorname{span}\{u_1, u_2\}$. Another choice is $\ker L = \operatorname{span}\{u_1 + u_2, u_1 - u_2\}$. There are four nontrivial solution curves of (3.9) branching from $(0, \lambda_{1,2})$. Solution curves corresponding to $\operatorname{span}\{u_1, u_2\}$ are called rectangular solutions, and those corresponding to $\operatorname{span}\{u_1 + u_2, u_1 - u_2\}$ are called triangular solutions. The multiplicity of solution curves of (3.9) depends on the symmetry of the domain Ω, which we briefly discuss as follows.

Let $C_0^2(\Omega) := \{u \in C^2(\Omega) \mid u|_{\partial\Omega} = 0\}$ and $X = \left(C_0^2(\Omega)\right)^2$, $Y = (C(\Omega))^2$. If we also consider λ as the auxiliary continuation parameter, then $\Phi : X \times \mathbf{R} \to Y$ defined by $\Phi(u, \lambda) = -\Delta u - \lambda u + \mu u^3$ is a smooth mapping. Let $Z_2 := \{1, -1\}$, and let $D_4 := \{S_1, S_2; S_1', S_2', 1, R, R^2, R^3\}$ be the dihedral group of the unit square Ω. Here R denotes a counterclockwise rotation by $\frac{\pi}{2}$, and S_1 and S_2 are reflections about $x = \frac{1}{2}$ and $y = x$, respectively, which are defined by

$$S_1 \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} 1-x \\ y \end{bmatrix}, \qquad S_2 \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} y \\ x \end{bmatrix} \quad \forall\ (x,y) \in \Omega.$$

Moreover, $S_1' = R^2 S_1$, $S_2' = R^2 S_2$, and we separate the generators of D_4 by " ; ". Note that Φ is an odd function with respect to the state variables u. Since (3.2) is autonomous, we define $\Gamma := Z_2 \times D_4 = \{\pm S_1, \pm S_2; \pm S_1', \pm S_2', \pm 1, \pm R, \pm R^2, \pm R^3\}$ and consider the group action of Γ on the space Y by $\gamma u = \pm u(\delta^{-1}(x,y))$ for all $\gamma = \pm\delta \in \Gamma$, $\delta \in D_4$, and $u \in Y$. It is clear that the spaces X and Y are Γ-invariant. That is, $u \in X$ (respectively, Y) implies $\gamma u \in X$ (respectively, Y) for all $\gamma \in \Gamma$, $u \in X$ (respectively, Y). Note that the mapping Φ is Γ-equivariant; i.e., $\Phi(\gamma u, \lambda) = \gamma \Phi(u, \lambda)$ for all $\gamma \in \Gamma$; $u \in X$, $\lambda \in \mathbf{R}$.

Mei [28] used the group concept to classify the solution curves of (3.8) with their symmetries. In particular, solution curves branching from $(0, \lambda_{m,n})$ with $(m, n) =$ (odd,odd), (odd,even), and (even,even) can be numerically traced on a subdomain of Ω. However, to the best of our knowledge, the Liapunov–Schmidt reduction cannot be used to derive normal forms at a corank-2 bifurcation; see, e.g., [23, pp. 326–328].

To overcome the difficulty, we replace the unit square in Ω by a rectangular domain, say $\Omega_1 = (0, \ell) \times (0, 1)$, $\ell \neq 1$. Then the eigenpairs are

$$\begin{aligned} u_{m,n}(x,y) &= \sin\left(m\pi \frac{x}{\ell}\right) \sin(n\pi y), \\ \lambda_{m,n} &= \left(\frac{m^2}{\ell^2} + n^2\right)\pi^2, \end{aligned} \qquad m, n = 1, 2, 3, \ldots . \tag{3.10}$$

TABLE 1
The first six eigenvalues and residuals of the corresponding eigenvectors of (3.7) *in two dimensions with various choices of* $V(x)$.

	$V(x_1,x_2)=0$		$V(x_1,x_2)=\frac{x_1^2+x_2^2}{2}$		$V(x_1,x_2)=\frac{2x_1^2+x_2^2}{2}$	
	Eigenvalue	Residual	Eigenvalue	Residual	Eigenvalue	Residual
1	19.7382179255601	0.76[-9]	20.0203333007527	0.10[-9]	20.1608349571284	0.12[-8]

6	98.6554245154581	0.42[-9]	98.9603839634474	0.48[-9]	99.1243848025148	0.50[-9]

From (3.10) we have

$$\lambda_{1,2}=\left(\frac{1}{\ell^2}+4\right)\pi^2\neq\lambda_{2,1}=\left(\frac{4}{\ell^2}+1\right)\pi^2.$$

That is, the double eigenvalue $\lambda_{1,2}=\lambda_{2,1}$ in the domain Ω is split into two simple ones, $\lambda_{1,2}\neq\lambda_{2,1}$. Accordingly, the corank-2 bifurcation $(0,\lambda_{1,2})$ of (3.9) will be split into two simple bifurcations $(0,\lambda_{1,2})$ and $(0,\lambda_{2,1})$, which are called perturbed bifurcations. In this case the two triangular solution curves of (3.9) branching from the corank-2 bifurcation point $(0,\lambda_{1,2})$ in the domain $\Omega=(0,1)^2$ disappear automatically because of the domain perturbation. Actually, $\operatorname{span}\{u_{1,2}\pm u_{2,1}\}$ belongs to a two-dimensional subspace in the perturbed domain. The above-mentioned technique was discussed in [29] and was used, e.g., in [30]. In this case the Liapunov–Schmidt reduction can be used to treat the perturbed bifurcation again.

REMARK 3.4. It is obvious from [31, p. 459] that if we choose $\Omega=(0,1)^2$ in our numerical computations but with nonsquare grid points on Ω, then the discrete eigenvalues $\lambda_{1,2}$ and $\lambda_{2,1}$ are distinct. Thus the Liapunov–Schmidt reduction can be applied to treating solution curves bifurcating at $\lambda_{1,2}$ and $\lambda_{2,1}$ of the discrete problem as well.

We are ready to study the bifurcation scenario of (3.6) with $N=2$ again. In general, the eigenvalues of (3.7) are obtained by numerical methods. Our numerical results show that if the trapping potential is isotropic, then the second minimum eigenvalue of (3.7) corresponding to the counterpart of (3.2), namely $\lambda_{1,2}$, is still double. However, if a nonisotropic trapping potential is imposed on (3.7), then the double eigenvalues will be separated into two clustered ones. The distance of the clustered eigenvalues is proportional to that of the two coefficients α_1 and α_2 of $V(x)$. Table 1 lists the first six eigenvalues of (3.7) with various choices of $V(x)$, where the eigenvalues were computed using the two-grid centered difference discretization scheme described in [32] with coarse grid size $\widetilde{h}=\frac{1}{8}$ and fine grid size $h=\frac{1}{128}$. We conclude that the Liapunov–Schmidt reduction can be used to analyze the bifurcation scenario of (3.6) if the trapping potential is nonisotropic. For $N=3$ the bifurcations of (3.8) are of corank-1, 3, or 6. There are $13=\frac{(3^3-1)}{2}$ and $264=\frac{(3^6-1)}{2}$ nontrivial solution curves branching from a corank-3 and a corank-6 bifurcation point, respectively. Tracing solution curves bifurcating at a high corank bifurcation point becomes complicated; we refer to [33] for a numerical study of this subject. However, we still can apply the Liapunov–Schmidt reduction to investigate the local bifurcation behavior of the three-dimensional MCNLS. The technique is similar to the discussion described above and is omitted here.

3.3. Mode interactions of the two-coupled NLS. As we pointed out in section 1, the MCNLS is a nonlinear system involving multiple parameters. The parameters of cubic terms disappear as we evaluate the differential of Φ at $w = (u, v) = (0, 0)$. We will show that mode interactions cannot occur in the two-coupled NLS. We consider

$$\begin{aligned} -\Delta u - \lambda_1 u + \mu_1 u^3 + \beta u v^2 &= 0 \\ -\Delta v - \lambda_2 v + \mu_2 v^3 + \beta u^2 v &= 0 \qquad \text{in } \Omega_1 = (0,\ell)^N,\ N = 1, 2, 3, \\ u &= 0 \qquad \text{on } \partial\Omega_1. \end{aligned} \tag{3.11}$$

For convenience we consider $N = 1$ in (3.11). A change of variable $x = \ell\widetilde{x}$ transforms the domain Ω_1 in (3.11) back to $\Omega = (0, 1)$ again. By using the same notation as before, we can express (3.11) as

$$\begin{aligned} -\frac{1}{\ell^2}\frac{d^2}{dx^2}u - \lambda_1 u + \mu_1 u^3 + \beta u v^2 &= 0 \\ -\frac{1}{\ell^2}\frac{d^2}{dx^2}v - \lambda_2 v + \mu_2 v^3 + \beta u^2 v &= 0 \qquad \text{in } \Omega = (0, 1), \\ u(0) = u(1) = v(0) = v(1) &= 0. \end{aligned} \tag{3.12}$$

Now we consider the case $\lambda_1 = \lambda_2 = \lambda$. Let $X = (C_0^2(\Omega))^2$, $Y = (C(\Omega))^2$, and $w = (u, v)$. The linearization of Φ evaluated at $w = (0, 0)$ is

$$L = (d_w\Phi)_{(0,0,\lambda)} = \begin{pmatrix} -\dfrac{1}{\ell^2}\dfrac{d^2}{dx^2} - \lambda & 0 \\ 0 & -\dfrac{1}{\ell^2}\dfrac{d^2}{dx^2} - \lambda \end{pmatrix}, \tag{3.13}$$

where $L : X \times \mathbf{R} \to Y$.

To examine the spectrum of L, we observe that the direct sum

$$X = \sum_{k=1}^{\infty} \oplus X_k, \quad X_k := \left\{ \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} \sin k\pi x \mid c_1, c_2 \in \mathbf{R} \right\}, \quad k \in \mathbf{N}, \tag{3.14}$$

holds under the $L^2(\Omega)$-product. It is clear from (3.13) that the linear operator L maps X_k into itself. The restriction of L in the subspace X_k is a 2×2 matrix

$$M_k(\lambda, \ell) := L\Big|_{X_k} = \begin{pmatrix} \dfrac{k^2\pi^2}{\ell^2} - \lambda & 0 \\ 0 & \dfrac{k^2\pi^2}{\ell^2} - \lambda \end{pmatrix}, \quad k = 1, 2, \ldots . \tag{3.15}$$

The eigenvalues of L consist of those of $M_k \in \mathbf{R}^{2\times 2}$, $k = 1, 2, \ldots$. A stationary bifurcation occurs on the solution curve $w = 0$ at $\lambda = \lambda_0$ if and only if there exists at least one integer $k \in \mathbf{N}$ such that $\det M_k(\lambda_0, \ell) = 0$.

The eigenvectors associated with simple eigenvalues of the operator L are called modes. It is well known that a nonlinear system with multiple bifurcation parameters will have multiple modes. Therefore, secondary bifurcations may arise in the system. This process is called mode interaction [34, pp. 412–414]. Now the operator involves two parameters, namely ℓ and λ. We will show that steady/steady mode interactions cannot occur in (3.12).

THEOREM 3.5.

. We choose λ^* and ℓ_0 such that

$$\det M_k(\lambda^*, \ell_0) = 0 \quad \text{and} \quad \det M_m(\lambda^*, \ell_0) = 0, \quad k \neq m. \tag{3.16}$$

For mode interactions to occur we must have $\lambda^* = \frac{(k^2+m^2)\pi^2}{2\ell_0^2}$. However, λ^* cannot satisfy $\det M_k = 0$ and $\det M_m = 0$ simultaneously unless $k = m$. □

Böhmer and Mei [27] studied mode interactions of second order semilinear elliptic systems using a modified Liapunov–Schmidt reduction and symmetries. The technique described in [27] was applied to studying the local bifurcation behavior of the Brusselators in [35]. It is possible to apply the same technique to the MCNLS. However, we will not go into detail. Detailed discussions concerning mode interactions can be found in [34, Chapters 19 and 20].

4. Centered difference approximations and numerical continuation.

4.1. Centered difference approximations. Without loss of generality, we consider the three-coupled nonlinear Schrödinger equations (TCNLS)

$$\begin{aligned} -\Delta u_1 - \lambda_1 u_1 + \mu_1 u_1^3 + \beta_{12} u_1 u_2^2 + \beta_{13} u_1 u_3^2 &= 0 \\ -\Delta u_2 - \lambda_2 u_2 + \mu_2 u_2^3 + \beta_{21} u_2 u_1^2 + \beta_{23} u_2 u_3^2 &= 0 \qquad \text{in } \Omega = (0,1)^2, \\ -\Delta u_3 - \lambda_3 u_3 + \mu_3 u_3^3 + \beta_{31} u_3 u_1^2 + \beta_{32} u_3 u_2^2 &= 0 \\ u_1 = u_2 = u_3 &= 0 \qquad \text{on } \partial\Omega. \end{aligned} \tag{4.1}$$

Let $B = (\beta_{ij})$ with $\beta_{ii} = \mu_i$ be the coefficient matrix associated with the cubic terms in (4.1). We assume that the matrix B is symmetric. For simplicity we also assume that $\lambda_1 = \lambda_2 = \lambda_3 = \lambda$ is the continuation parameter and that the other parameters are fixed. Let $\mathbf{u} = (u_1, u_2, u_3)$, $X = (C_0^2(\Omega))^3$, and $Y = (C^0(\Omega))^3$. Then the system (4.1) can be expressed as

$$F(\mathbf{u}, \lambda) = \begin{bmatrix} -\Delta u_1 + f_1(u, \lambda) \\ -\Delta u_2 + f_2(u, \lambda) \\ -\Delta u_3 + f_3(u, \lambda) \end{bmatrix} = 0, \tag{4.2}$$

where $F : X \times \mathbf{R} \to Y$ is a smooth mapping. In our numerical experiments we will also consider the cases $\lambda_1 \neq \lambda_2 \neq \lambda_3$ and $\lambda_1 = \lambda_2 \neq \lambda_3$.

Differentiating F with respect to $\mathbf{u}$ at the homogeneous equilibrium $\mathbf{u}_0 = 0$, we obtain the linearization L of F, where

$$\begin{aligned} L := D_{\mathbf{u}} F(\mathbf{u}_0, \lambda) &= \begin{bmatrix} -\Delta + \frac{\partial f_1}{\partial u_1}(0,\lambda) & \frac{\partial f_1}{\partial u_2}(0,\lambda) & \frac{\partial f_1}{\partial u_3}(0,\lambda) \\ \frac{\partial f_2}{\partial u_1}(0,\lambda) & -\Delta + \frac{\partial f_2}{\partial u_2}(0,\lambda) & \frac{\partial f_2}{\partial u_3}(0,\lambda) \\ \frac{\partial f_3}{\partial u_1}(0,\lambda) & \frac{\partial f_3}{\partial u_2}(0,\lambda) & -\Delta + \frac{\partial f_3}{\partial u_3}(0,\lambda) \end{bmatrix} \\ &= \begin{bmatrix} -\Delta - \lambda I & 0 & 0 \\ 0 & -\Delta - \lambda I & 0 \\ 0 & 0 & -\Delta - \lambda I \end{bmatrix}. \end{aligned} \tag{4.3}$$

We discretize (4.2) by the centered difference approximations with uniform meshsize $h = \frac{1}{N+1}$ on the x- and y-axes. The centered difference analogue of (4.2) can be

expressed as

$$F(U,\lambda)=\begin{cases} A_1U_1-\lambda U_1+\mu_1U_1^3+\beta_{12}U_1\circ U_2^2+\beta_{13}U_1\circ U_3^2=0,\\ A_1U_2-\lambda U_2+\mu_2U_2^3+\beta_{21}U_2\circ U_1^2+\beta_{23}U_2\circ U_3^2=0,\\ A_1U_3-\lambda U_3+\mu_3U_3^3+\beta_{31}U_3\circ U_1^2+\beta_{32}U_3\circ U_2^2=0. \end{cases} \tag{4.4}$$

Here $A_1\in\mathbf{R}^{N^2\times N^2}$ is the coefficient matrix associated with the discretization of the Laplacian $-\Delta$, $U_i\in\mathbf{R}^{N^2}$, $i=1,2,3$; $U_i\circ U_j$ denotes the Hadamard product of U_i and U_j; and $U_i^r=U_i\circ\cdots\circ U_i$ stand for the r-times Hadamard products of U_i. It is obvious that $F:\mathbf{R}^K\times\mathbf{R}\to\mathbf{R}^K$ is a smooth mapping with $K=3N^2$. We denote the Jacobian matrix of the mapping F in (4.4) by

$$DF=[D_UF,D_\lambda F]\in\mathbf{R}^{(K+1)\times K}, \tag{4.5}$$

where

$$D_UF=\begin{bmatrix} A_1+\operatorname{diag}(S_1) & \operatorname{diag}(2\beta_{12}U_1\circ U_2) & \operatorname{diag}(2\beta_{13}U_1\circ U_3)\\ \operatorname{diag}(2\beta_{21}U_2\circ U_1) & A_1+\operatorname{diag}(S_2) & \operatorname{diag}(2\beta_{23}U_2\circ U_3)\\ \operatorname{diag}(2\beta_{31}U_3\circ U_1) & \operatorname{diag}(2\beta_{32}U_2\circ U_3) & A_1+\operatorname{diag}(S_3) \end{bmatrix},$$

with $S_1=-\lambda+3\mu_1U_1^2+\beta_{12}U_2^2+\beta_{13}U_3^2$, $S_2=-\lambda+3\mu_2U_2^2+\beta_{21}U_1^2+\beta_{23}U_3^2$, and $S_3=-\lambda+3\mu_3U_3^2+\beta_{31}U_1^2+\beta_{32}U_2^2$, is symmetric and

$$D_\lambda F=\begin{bmatrix} -U_1\\ -U_2\\ -U_3 \end{bmatrix}.$$

The discrete operator corresponding to the linear operator L in (4.3) is denoted by

$$A=\begin{bmatrix} A_1-\lambda I & 0 & 0\\ 0 & A_1-\lambda I & 0\\ 0 & 0 & A_1-\lambda I \end{bmatrix}\in\mathbf{R}^{K\times K}. \tag{4.6}$$

The eigenvalues and corresponding eigenvectors of A_1 are (see [31])

$$\begin{aligned} \lambda_{p,q}&=4(N+1)^2\left(\sin^2\frac{p\pi}{2(N+1)}+\sin^2\frac{q\pi}{2(N+1)}\right),\quad 1\le p,q\le N,\\ U_{p,q}(x_j,y_k)&=\sin\frac{jp\pi}{N+1}\sin\frac{kq\pi}{N+1},\quad 1\le j,k,p,q\le N, \end{aligned} \tag{4.7}$$

for $(x_j,y_k)=(\frac{j}{N+1},\frac{k}{N+1})$. Equations (4.6) and (4.7) show that the bifurcation points of the discrete TCNLS are located at $(U,\lambda)=(0,\lambda_{p,q})$, $1\le p,q\le N$.

4.2. Numerical continuation. We denote a solution curve c of (4.4) by

$$c=\{y(s)=(U(s),\lambda(s))\mid F(y(s))=0,s\in I\}.$$

Here I is any interval in $\mathbf{R}$. Assume that a parameterization via arc length is available on c. Let $y_i=(U^{(i)},\lambda^{(i)})\in\mathbf{R}^{K+1}$ be a point which has been accepted as an approximating point for the solution curve c. In the predictor-corrector continuation method, the predicted point is obtained either by the Euler predictor or the higher order Taylor predictor. Perhaps the simplest one is the Euler predictor

$$z_{i+1,1}=y_i+\delta_it_i.$$

Here $\delta_i > 0$ is the step length, and t_i is the unit tangent vector at y_i, which is obtained by solving

$$\begin{bmatrix} D_U F(y_i) & D_\lambda F(y_i) \\ & r_i^T \end{bmatrix} \cdot t_i = \begin{bmatrix} \overline{0} \\ 1 \end{bmatrix} \tag{4.8}$$

for some constraint vector $r_i \in \mathbf{R}^{K+1}$. The accuracy of the predicted point $z_{i+1,1}$ to the solution curve c must be improved via a corrector process. In general one uses Newton's method with constraints, solving

$$\begin{bmatrix} D_U F(z_{i+1,j}) & D_\lambda F(z_{i+1,j}) \\ & t_i^T \end{bmatrix} \cdot w_j = \begin{bmatrix} -F(z_{i+1,j}) \\ 0 \end{bmatrix}, \quad j = 1, 2, \dots , \tag{4.9}$$

and then setting $z_{i+1,j+1} = z_{i+1,j} + w_j$, $j = 1, 2, \dots$. The constraint vector t_i in (4.9) is the solution to the system (4.8). If y_i lies sufficiently near c, then Newton's method will converge if the step size δ_i is small enough. Equations (4.8) and (4.9) can be expressed as

$$\begin{bmatrix} B & p \\ q^T & r \end{bmatrix} \begin{bmatrix} x \\ \lambda \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix}, \tag{4.10}$$

where $p, q, f \in \mathbf{R}^K$ and $r, g \in \mathbf{R}$. A well-known numerical method for solving (4.10) is the block elimination algorithm in [22, Chapter 4], where we have to solve linear systems of the form $D_U F \cdot y = b$. Since $D_U F$ is symmetric, the preconditioned Lanczos method with iterative refinement described in [36] can be used as a linear solver for the TCNLS. A more stable numerical method for solving the bordered linear system (4.10) is the mixed block elimination [37, Chapter 3].

4.3. Testing for the bifurcation points. In numerical continuation methods we have to detect bifurcation points along the solution curve of a nonlinear system of equations. For the coupled NLS (4.1), the primary bifurcation points on the trivial solution curve $\{(0, \lambda) \mid \lambda \geq 0\}$ are located at $(0, \lambda_{p,q})$, where $\lambda_{p,q}$ are defined in (4.7). The discrete bifurcation points of the system (4.4) can be obtained by solving the coupled Schrödinger eigenvalue problem. It is evident that the two-grid discretization scheme described in [32] can be used to compute the first few eigenpairs of the coupled Schrödinger eigenvalue problems. We briefly describe the process as follows.

We express the coupled Schrödinger eigenvalue problem as an operator equation of the following form:

$$F(w, \lambda) = (f_1(u_1, \lambda), f_2(u_2, \lambda), f_3(u_3, \lambda)) = 0, \tag{4.11}$$

where $f_i(u_i, \lambda) = -\Delta u_i + V_i(x)u_i - \lambda u_i = 0$, $i = 1 : 3$, and $w = (u_1, u_2, u_3)$. Let $\widetilde{h}, h \in (0, 1)$ be chosen so that $h = O(\widetilde{h}^2)$. Suppose that (4.11) is discretized, say by the centered difference approximations with uniform meshsizes $\widetilde{h} = \frac{1}{\widetilde{N}+1}$ and $h = \frac{1}{N+1}$ on the coarse and the fine grids $\Omega_{\tilde{h}}$ and Ω_h, respectively, where $\widetilde{N} < N$ are two positive integers. Let $F_{\tilde{h}}$ and F_h be the discrete operators corresponding to (4.11), $A_{\tilde{h}} \in \mathbf{R}^{\widetilde{N}^2 \times \widetilde{N}^2}$ and $A_h \in \mathbf{R}^{N^2 \times N^2}$ the coefficient matrices corresponding to the Laplacian $-\Delta$, and $B_{\tilde{h}}$ and B_h the coefficient matrices corresponding to the linear operator L in (4.3) on the coarse and the fine grids, respectively. The eigenvalues of $B_{\tilde{h}}$ and B_h are obtained by solving

$$(A_{\tilde{h}} + (D_i)_{\tilde{h}} - \lambda I)u = 0, \quad i = 1 : 3, \tag{4.12}$$

and

$$(A_h + (D_i)_h - \lambda I)u = 0, \quad i = 1:3, \tag{4.13}$$

respectively. Here $(D_i)_{\tilde{h}} \in \mathbf{R}^{\widetilde{N}^2 \times \widetilde{N}^2}$ and $(D_i)_h \in \mathbf{R}^{N^2 \times N^2}$ are diagonal matrices whose diagonal entries are the values of V_i at each coarse and fine grid point, respectively. The first bifurcation point of (4.1) is determined by computing the minimal eigenvalues of the two diagonal matrices of $B_{\tilde{h}}$ and B_h. Now the two-grid centered difference discretization algorithm in [32] can be generalized to compute the first few eigenpairs of the matrices $B_{\tilde{h}}$ and B_h. Let $I_{\tilde{h}}^h : \Omega_{\tilde{h}} \to \Omega_h$ be the linear interpolation from the coarse grid $\Omega_{\tilde{h}}$ to the fine grid Ω_h.

ALGORITHM 4.1.

1.

2.

$$(C_i)_h u_{i,h}^{(j)} = \lambda_{i,\tilde{h}}^{(j)} (I_{\tilde{h}}^h u_{i,\tilde{h}}^{(j)}), \quad i = 1:3, \ j = 1, \ldots, k,$$

3.

$$\lambda_{i,h}^{(j)} = \frac{(u_{i,h}^{(j)})^T (C_i)_h (u_{i,h}^{(j)})}{(u_{i,h}^{(j)})^T (u_{i,h}^{(j)})}, \quad i = 1:3, \ j = 1, \ldots, k.$$

4.

(i)

$$x_{i,0}^{(j)} = u_{i,h}^{(j)} / \|u_{i,h}^{(j)}\|_2, \qquad \mu_{i,0}^{(j)} = \lambda_{i,h}^{(j)}, \quad i = 1:3, \ j = 1, \ldots, k.$$

(ii) **For** $i = 1:3$
For $j = 1, \ldots, k$
For $l = 0, 1, 2, \ldots$

$$\left((C_i)_h - \mu_{i,l}^{(j)} I + x_{i,l}^{(j)} (x_{i,l}^{(j)})^T\right) y_{i,l+1}^{(j)} = x_{i,l}^{(j)}$$

$$z_{i,l+1}^{(j)} = y_{i,l+1}^{(j)} / (1 - (x_{i,l}^{(j)})^T y_{i,l+1}^{(j)})$$

$$x_{i,l+1}^{(j)} = z_{i,l+1}^{(j)} / \|z_{i,l+1}^{(j)}\|_2$$

$$\mu_{i,l+1}^{(j)} = (x_{i,l+1}^{(j)})^T (C_i)_h (x_{i,l+1}^{(j)})$$

$\|(C_i)_h x_{i,l+1}^{(j)} - \mu_{i,l+1}^{(j)} x_{i,l+1}^{(j)}\|_2 < \tau$

End
End
End

4.2. The coefficient matrix in (ii) of step 4 is a rank-1 update of the matrix $(C_i)_h$. The solution is obtained by using the Sherman–Morrison formula. We solve the perturbed linear system because the condition number of the coefficient matrix increases as the approximate eigenvalue approaches the exact one in the RQI; see [38] for a detailed discussion. In case the eigenvalue we wish to compute is multiple, we can apply Rayleigh–Ritz subspace iteration [39] to solve the linear systems in the RQI.

4.4. Branch-switching techniques. Numerical methods for switching branches at bifurcation points are well known; see, e.g., [22, Chapter 5]. Perhaps the simplest one is the perturbed bifurcation technique. That is, instead of solving (4.4), we solve the following perturbed system:

$$F(U,\lambda)+d=0, \tag{4.14}$$

where $d\in\mathbf{R}^{3N^2}$ is a perturbation vector yet to be determined. In general, one can choose d so that it has the same mode as the eigenvector in (4.7). This technique can be used to handle multiple bifurcations as well. The discussion in subsection 4.3 shows that the first few eigenpairs of the coupled Schrödinger eigenvalue problem can be accurately computed using Algorithm 4.1. It is clear that the normalized eigenvector can be used as tangent vector for branch-switching at the bifurcation point.

Recently, Chien and Jeng [40] developed some two-grid discretization schemes with two-loop continuation algorithms for tracing solution branches of second order semilinear elliptic eigenvalue problems. It is also possible to develop two-grid discretization schemes for reaction-diffusion systems, which also can be used to solve the coupled nonlinear Schrödinger equations. The details will be given elsewhere.

4.5. MCNLS with mass conservation constraints. So far we treat the time-independent or stationary state MCNLS as a parameter-dependent nonlinear system of equations. However, from the physical viewpoint it is more realistic to impose mass conservation constraints on the system. As an example, we consider the single NLS (see [12])

$$\begin{aligned}\mathbf{i}\varepsilon\Phi_t=-\frac{\varepsilon^2}{2}\Delta\Phi+V(x)\Phi+\mu|\Phi|^2\Phi,\quad t>0,\ x\in\Omega=(0,1)^N,\ N=1,2,3,\\ \Phi(x,t)=0,\quad x\in\partial\Omega,\ t\ge 0.\end{aligned} \tag{4.15}$$

We say that a condensate has strong repulsive interactions if $\varepsilon=o(1)$, and weak interactions if $\varepsilon=O(1)$. Two important invariants of (4.15) are the mass conservation constraint of the wave function

$$N(\Phi)=\int_\Omega|\Phi(x,t)|^2\,dx=1,\quad t\ge 0, \tag{4.16}$$

and the energy conservation

$$E_\mu(\Phi)=\int_\Omega\left[\frac{\varepsilon^2}{2}|\nabla\Phi(x,t)|^2+V(x)|\Phi(x,t)|^2+\frac{\mu}{2}|\Phi(x,t)|^4\right]dx,\quad t\ge 0. \tag{4.17}$$

Setting $\Phi(x,t)=e^{-\mathbf{i}\lambda t/\varepsilon}u(x)$ in (4.15), we obtain the following semilinear elliptic eigenvalue problem:

$$\begin{aligned}\lambda u(x)&=-\frac{\varepsilon^2}{2}\Delta u(x)+V(x)u(x)+\mu u(x)^3\quad\text{in }\Omega,\\ u(x)&=0\quad\text{on }\partial\Omega,\end{aligned} \tag{4.18}$$

for $u(x)$ under the normalization condition

$$\int_\Omega |u(x)|^2 \, dx = 1. \tag{4.19}$$

It is obvious that any eigenvalue λ can be computed from its corresponding eigenfunction $u(x)$ by

$$\begin{aligned} \lambda = \lambda_\mu(u) &= \int_\Omega \left[\frac{\varepsilon^2}{2} |\nabla u(x)|^2 + V(x)|u(x)|^2 + \mu |u(x)|^4 \right] dx \\ &= E_\mu(u) + \int_\Omega \frac{\mu}{2} |\phi(x)|^4 \, dx. \end{aligned} \tag{4.20}$$

We wish to indicate that it is a straightforward application of the continuation methods to solve (4.18) with constraint (4.19). As one may see from (4.20), the chemical potential λ is computed by using the eigenfunction $u(x)$ for some fixed parameter μ. Thus, in the context of continuation methods, we treat λ as the continuation parameter and keep the parameter μ fixed. Starting from the trivial solution curve $\{(0, \lambda) \mid \lambda > 0\}$, we will follow, say, the solution curve branching from the first bifurcation point $(0, \lambda_{1,1})$. Since we are interested only in the target point $(\widetilde{u}, \widetilde{\lambda})$ with $\|\widetilde{u}\|_2 = 1$, we may take a relatively large step size to follow the curve until $\|\widetilde{u}\|_2 = 1$ is reached, say at the kth continuation step. In practice, it is quite impossible that we will hit the target point exactly. Therefore we may use the bisection method or linear interpolation to get $(\widetilde{u}, \widetilde{\lambda})$. We can vary the value of μ as we wish. The techniques we describe above can be generalized to treat the MCNLS with mass conservation constraints.

5. Numerical results. The bifurcation scenario of the MCNLS can supply many interesting phenomena, because the system contains $3M$ parameters. We discretized the MCNLS by using centered difference approximations with various uniform meshsizes. In our numerical experiments, we traced solution curves of the MCNLS branching from $(0, \lambda_{1,1})$ and $(0, \lambda_{2,1})$. Our test problems include two- and three- dimensional cases. In particular, the physical properties of the NLS are considered in our numerical experiments, including the effect of linear potentials, strong and weak repulsive interactions, and mass conservation constraints. For simplicity we choose λ_1 as the continuation parameter and keep the other chemical potentials fixed. The accuracy tolerance of the linear solver as well as the Newton corrector is 10^{-11}. Our numerical experiments were executed on a Pentium 4 computer using the MATLAB language.

1. The effect of linear potentials, $M = 3$. We consider (4.1) under the effect of linear potentials, where $V_1(x) = \frac{3x_1^2+x_2^2}{2}$, $V_2(x) = \frac{5x_1^2+3x_2^2}{2}$, $V_3(x) = \frac{7x_1^2+5x_2^2}{2}$, and $\lambda_2 = 40.0$, $\lambda_3 = 30.0$, $\beta_{ij} = \beta = 10.0$, $\mu_1 = 10.0$, $\mu_2 = 15.0$, and $\mu_3 = 30.0$. Algorithm 4.1 was implemented to compute the first eigenpair $(U_1^{(0)}, \lambda_1^{(0)})$ of the first equation, where we chose $\widetilde{h} = \frac{1}{16}$ and $h = \frac{1}{64}$. Note that in implementing Algorithm 4.1 we should set $h = O(\widetilde{h}^2)$. However, because of the storage limitation of our computer, we only have to choose $h = \frac{1}{64}$. The coefficient matrices on the coarse and fine grids are of order 225×225 and 3969×3969, respectively. The normalized eigenvector $(U_1^{(0)}, 0, 0)$ is used as the tangent vector for branch-switching at the bifurcation point $(0, 0, 0, \lambda_1^{(0)})$. The solution curve of u_1 obtained in this way is displayed in Figure 1 with a dashed line, where the bifurcation point is detected

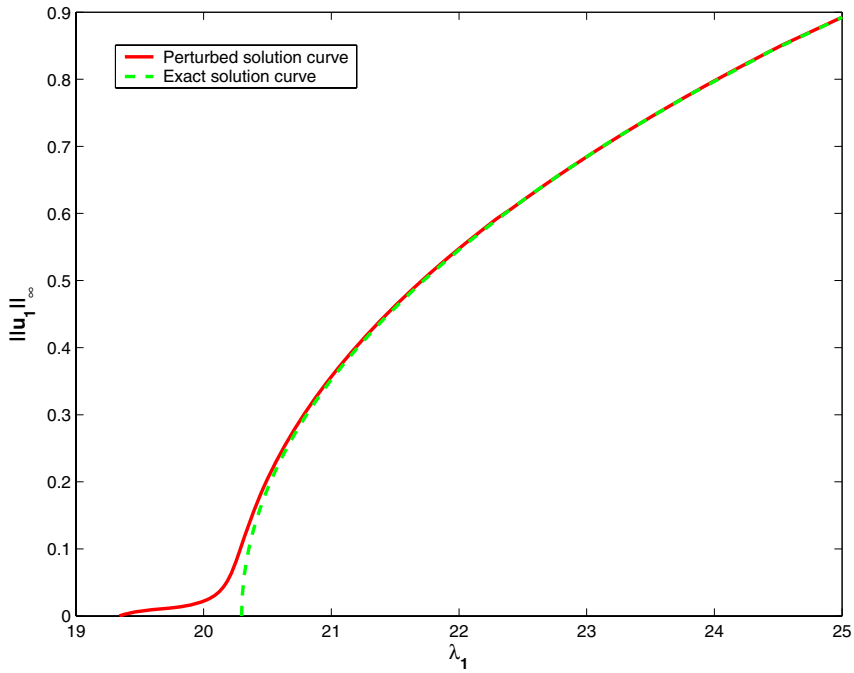

FIG. 1. *The solution curves of* u_1 *at* $\lambda_2 = 40.0$, $\lambda_3 = 30.0$, $\beta = 10.0$, $\mu_1 = 10.0$, $\mu_2 = 15.0$, *and* $\mu_3 = 30.0$.

at $(u_1^*, \lambda_1^*) \approx (0, 20.297808048)$. However, the solid line in Figure 1 is obtained by using the perturbed bifurcation technique, where the bifurcation point was detected at $(u_1^*, \lambda_1^*) \approx (0, 20.2208161)$. Next, we chose $V_1(x) = V_2(x) = V_3(x) = \frac{3x_1^2+x_2^2}{2}$, $\lambda_2 = 49.0$, $\lambda_3 = 30.0$, $\beta = -30.0$, and $\mu_1 = \mu_2 = \mu_3 = 0.1$. The bifurcation was detected at $(u_1^*, \lambda_1^*) \approx (0, 20.2792214)$. Figure 2 shows that a fold is detected at $(\lambda_1, \|u_1\|_\infty) \approx (20.2780507, 0.2655408)$. The contours of the solution curves of u_1 at $\lambda_1 = 10.8328$, -6.7886, -65.2619, and -463.7097 are displayed in Figure 3.

' . ,' 2. Double bifurcation, $M = 2$. We discretized the two-coupled NLS defined in $\Omega = (0, 1)^2$ with uniform meshsize $h = \frac{1}{50}$. The second bifurcation point is double and located at $(0, \lambda_{1,2}) = (0, \lambda_{2,1}) = (0, 5\pi^2)$. Figure 4 shows the two-dimensional contours of the solution curves $U_{1,2}$, $U_{1,2} + U_{2,1}$, $V_{1,2}$, and $V_{1,2} + V_{2,1}$ branching from $(0, \lambda_{1,2})$, where $\lambda_1 = 49.2619$, $\lambda_2 = 60.0$, $\beta = -30.0$, and $\mu_1 = \mu_2 = 0.1$. The contours of $U_{2,1}$, $U_{1,2} - U_{2,1}$, $V_{2,1}$, and $V_{1,2} - V_{2,1}$ can be obtained by rotating their counterparts in Figure 4 clockwise through ninety degrees. The three-dimensional contours of $U_{1,2}$, $V_{1,2}$ and $U_{1,2} + U_{2,1}$, $V_{1,2} + V_{2,1}$ at $\lambda_2 = 60.0$ and $\lambda_1 = 49.2619$, 49.4595, -22.0726, -1018.9563 are displayed in Figures 5 and 6, respectively. Next, we replace the unit square Ω by a rectangular domain $\Omega_1 = (0, \ell) \times (0, 1)$, where we choose $\ell = 0.96$. Thus, the corank-2 bifurcation $(0, \lambda_{1,2})$ of (3.9) is split into two simple bifurcations $(0, \nu_{1,2}) \approx (0, 50.7078)$ and $(0, \nu_{2,1}) \approx (0, 53.1176)$. The solution curves bifurcating at $(0, \nu_{1,2})$ and $(0, \nu_{2,1})$ in the domain Ω_1 and the second bifurcation curve at $(0, \lambda_{1,2})$ in Ω are shown in Figure 7.

' . ,' 3. Strong and weak repulsive interactions. We chose $\varepsilon = 0.1$, $\mu = 1.0$, and $\varepsilon = 1.0$, $\mu = 0.1$ for the former and the later, respectively. Equation (4.18) with $N = 3$ was discretized by the centered difference approximations with uniform

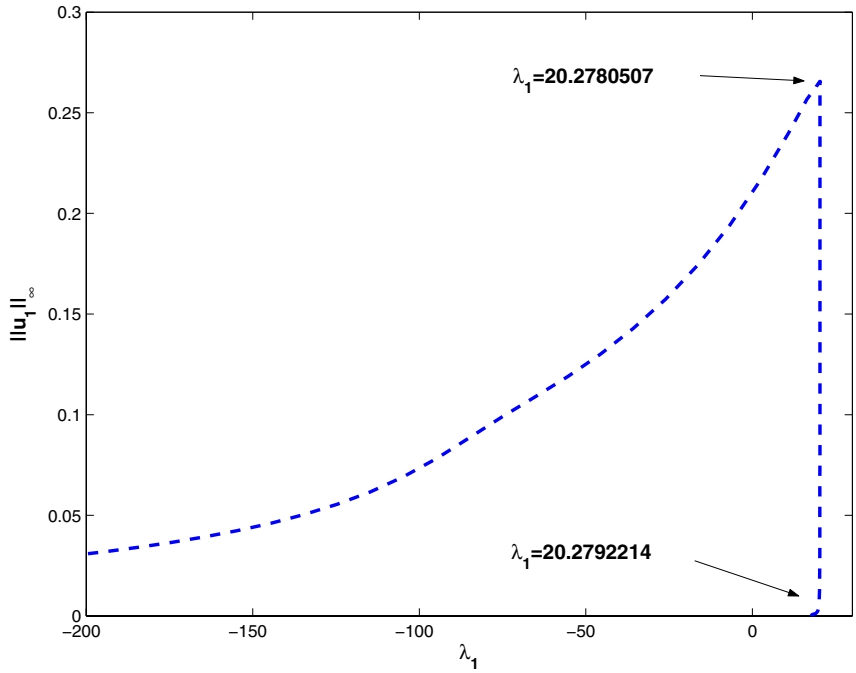

FIG. 2. *The solution curve of* u_1 *at* $\lambda_2 = 49.0$, $\lambda_3 = 30.0$, $\beta = -30.0$, *and* $\mu = 0.1$.

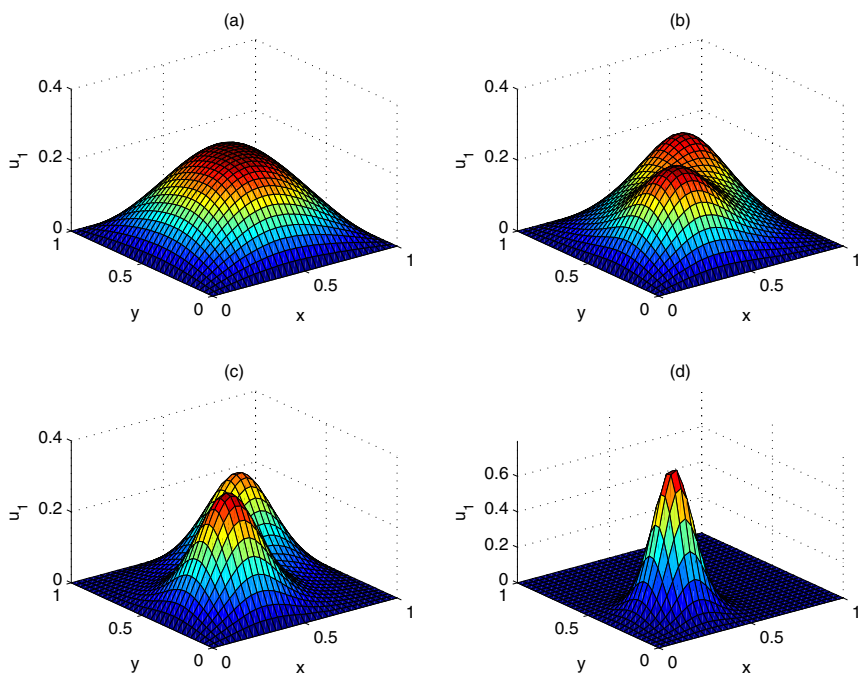

FIG. 3. *The contours of the solutions for* u_1 *at* (a) $\lambda_1 = 10.8328$, (b) $\lambda_1 = -6.7886$, (c) $\lambda_1 = -65.2619$, (d) $\lambda_1 = -463.7097$, *respectively, where* $\lambda_2 = 49.0$, $\lambda_3 = 30.0$, $\beta = -30.0$, *and* $\mu = 0.1$.

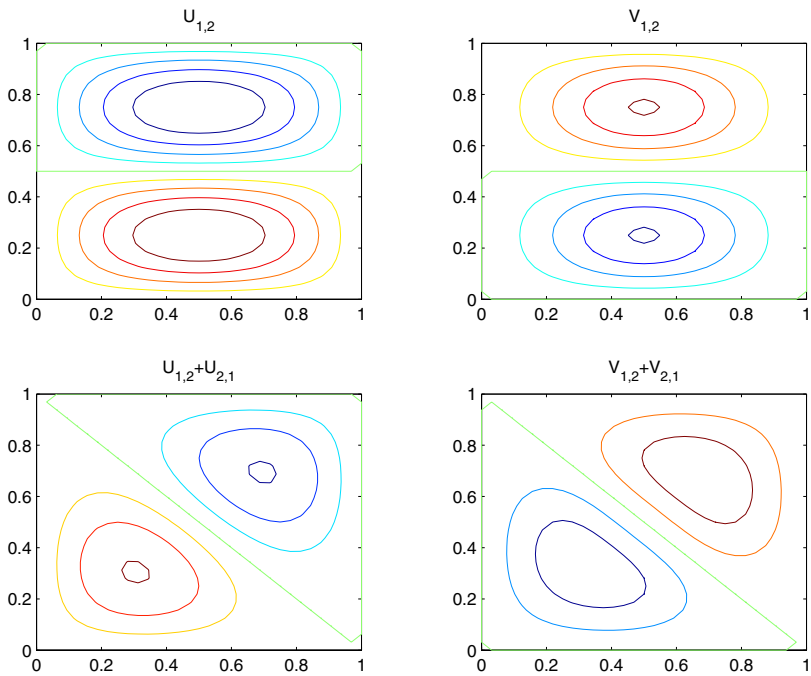

FIG. 4. *The contours of the solution curves bifurcating at* $(0, \lambda_{1,2})$*, where* $\lambda_1 = 49.2619$*,* $\lambda_2 = 60.0$*,* $\beta = -30.0$*, and* $\mu_1 = \mu_2 = 0.1$.

meshsize $h = \frac{1}{32}$, and $V(x) = \frac{1}{2}(x_1^2 + 4x_2^2 + 16x_3^2)$. Figures 8(a) and 8(b) show the solution curves for both cases, where the first bifurcation points were detected at $(0, \lambda^*) \approx (0, 0.977765)$ and $(0, 17.613727)$, respectively. Note that the first eigenvalue is approaching zero if ε is getting smaller.

4. Mass conservation constraints. We discretized (1.2) defined in $(0,1)^3$ with uniform meshsize $h = \frac{1}{20}$ under the normalization (1.3) for $M = 1$ and the constraints (1.4) for $M = 2, 3$. For $M = 1$, we choose $V(x) = \frac{1}{2}(x_1^2 + x_2^2 + x_3^2)$ and $\mu = 0.1$. The solution curve is shown in Figure 9, where the solution $\|u(x)\|_2 = 1$ is reached at the fifteenth continuation step. For $M = 2$, we choose $\lambda_2 = 30.0$, $\mu_1 = \mu_2 = 0.1$. The solution curves with $\beta = -300$ and $\beta = 300$ are displayed in Figures 10 and 11, respectively. In the former, only the component u satisfies (1.4), while in the latter, both u and v satisfy (1.4). For $M = 3$, we choose $\lambda_2 = 29.0$, $\lambda_3 = 50.0$, and $\mu_1 = \mu_2 = \mu_3 = 0.1$. The solution curves of $u_k, k = 1:3$, with $\beta_{ij} = \beta = -300$ and $\beta = 300$ are displayed in Figures 12 and 13, respectively. In the former, both u_1 and u_2 satisfy (1.4), while in the latter, the components u_1 and u_3 satisfy (1.4). For $M = 2$ and $M = 3$ we did not impose linear potentials on the system.

6. Conclusions. We have applied the Liapunov–Schmidt reduction to studying the local bifurcation behavior of a single NLS at simple eigenvalues. We show that the simple bifurcations of the NLS are pitchfork. The pitchfork bifurcation can be supercritical or subcritical, depending on the coefficient of the cubic term we choose. Next, we study how a double bifurcation of a single NLS can be split into two simple ones so that the Liapunov–Schmidt reduction can be applied as well. The methods involved in our study include domain perturbations, choosing nonsquare grid points on the

domain, and choosing nonisotropic potentials. A two-grid centered difference method is described for computing the extremum eigenpairs of the coupled linear Schrödinger eigenvalue problems. The normalized eigenvector can be used as the tangent vector at the bifurcation for branch-switching. In our numerical experiments, the effect of linear potentials, double bifurcations, strong and weak repulsive interactions, and the mass conservation constraints were considered. For $M = 2$ the numerical results show that both components of the condensates can reach the mass conservation requirements for different values of chemical potentials if $\beta > 0$, while only one component can reach the requirement if $\beta < 0$.

ANISOTROPIC MEASURES OF THIRD ORDER DERIVATIVES AND THE QUADRATIC INTERPOLATION ERROR ON TRIANGULAR ELEMENTS*

WEIMING CAO†

Abstract. The main purpose of this paper is to present a closer look at how the H^1- and L^2-errors for quadratic interpolation on a triangle are determined by the triangle geometry and the anisotropic behavior of the third order derivatives of interpolated functions. We characterize quantitatively the anisotropic behavior of a third order derivative tensor by its orientation and anisotropic ratio. Both exact error formulas and numerical experiments are presented for model problems of interpolating a cubic function u at the vertices and the midpoints of three sides of a triangle. Based on the study on model problems, we conclude that when an element is aligned with the orientation of $\nabla^3 u$, the aspect ratio leading to nearly the smallest H^1- and L^2-norms of the interpolation error is approximately equal to the anisotropic ratio of $\nabla^3 u$. With this alignment and aspect ratio taken, the H^1-seminorm of the error is proportional to the reciprocal of the anisotropic ratio of $\nabla^3 u$, the L^2-norm of the error is proportional to the $-\frac{3}{2}$th power of the anisotropic ratio, and both of them are insensitive to the internal angles of the element.

Key words. anisotropic mesh, quadratic interpolation, anisotropic ratio, aspect ratio, mesh alignment

1. Introduction.

In anisotropic mesh generation and refinement, elements or cells can be of different length scales in different directions in order to better fit the behavior of the interpolated functions or the properties of the PDEs to be solved. There are two anisotropic characters of a triangular element. One is the orientation, which is roughly the direction of its longest side. The other is the aspect ratio, which measures how long and thin the triangle is. For linear interpolation over triangular meshes, the error is determined by the Hessian $\nabla^2 u$ of the interpolated function u. There have been extensive studies on the optimal shape and orientation for minimizing the linear interpolation error in various norms. For instance, Nadler [16] studied the model problem of linear interpolation of quadratic functions and concluded that the optimal triangle for minimizing the L^2-error is an equilateral under the Hessian metric. Rippa [17] concluded that to minimize the L^p-error for linear interpolation, the triangular elements should be long and thin in the direction where the second order directional derivative of u is small. D'Azevedo and Simpson [11, 12] made similar conclusions for the maximum error and maximum derivative error in linear interpolation. They also developed several strategies for the anisotropic mesh generation and refinement based on $\nabla^2 u$ [11, 19]. Shewchuk [18] summarized various formulas for the linear interpolation error on a triangle in terms of its area and edge lengths. In [6] the author expresses the H^1- and L^2-errors for the linear interpolation of a quadratic function u on a triangle K in terms of the size, orientation, and aspect ratio of K, and

†Department of Mathematics, University of Texas at San Antonio, San Antonio, TX 78249 (wcao@math.utsa.edu).

the eigenvalues and eigenvectors of $\nabla^2 u$. It is identified that among all possible triangles of a fixed area, the smallest H^1-seminorm of the interpolation error is attained with the acute isosceles triangle that is aligned with the eigenvector (associated with the smaller eigenvalue) of $\nabla^2 u$, and has an aspect ratio $0.8|\lambda_2/\lambda_1|$, where $|\lambda_1| \leq |\lambda_2|$ are the eigenvalues of $\nabla^2 u$. For general triangular elements aligned with $\nabla^2 u$ without the restriction on the maximum internal angles, the best aspect ratio for the H^1-error is about $\sqrt{|\lambda_2/\lambda_1|}$. This is also the best aspect ratio for minimizing the L^2-error.

Meanwhile, there have been quite a few papers on generalizing the classical interpolation error estimates on quasi-uniform meshes to those on anisotropic meshes. For instance, Formaggia and Perotto [13], Huang [14], Huang and Sun [15], Chen, Sun, and Xu [8], and Chen and Xu [9] derived various estimates for the $W^{m,p}$-norm of the error for linear interpolation of general functions. They conclude similarly that the mesh leading to the smallest error bound is the one where all elements are aligned with the eigenvector of $\nabla^2 u$, and their aspect ratios are approximately equal to the square root of the ratio of the eigenvalues of $\nabla^2 u$. Chen, Sun, and Xu [8] further proved that their estimate of the L^p-error is optimal for the class of functions with positive Hessians.

In the case of quadratic interpolation, the understanding of the interplay between the geometric feature of elements and the anisotropic feature of interpolated functions has been mostly qualitative and crude [18]. As pointed by Apel in [1], a more precise understanding of their effects on the interpolation errors relies on "sufficiently fine description of the properties" of the interpolated functions. We introduced in [7] two quantities to measure the anisotropic characters of third order and higher derivative tensors. One is the orientation, along which the absolute value of the higher order directional derivative is about the smallest, while along its perpendicular direction it is about the largest. Another is the anisotropic ratio, which measures the strength of the anisotropic behavior, or how differently the directional derivative behaves in different directions. These measures are invariant under rotation and translation of the coordinates. We also derived an interpolation error estimate in terms of these anisotropic measures and identified the optimal alignment direction and aspect ratio which minimize an upper bounds of the error estimate; see [7] for details.

In this paper, we take a closer look at how the H^1- and L^2-errors for quadratic interpolation on a triangle are determined by the triangle geometry and the anisotropic features of $\nabla^3 u$. Since any smooth function can be approximated locally by a cubic function to a higher order accuracy than by a quadratic function, we simplify our local error analysis over an element by assuming the interpolated functions u are cubics. Unfortunately, unlike the case of linear interpolation studied in [6], a closed formula for the quadratic interpolation error in terms of the magnitude, orientation, and anisotropic ratio of $\nabla^3 u$ turns out to be too complicated. Nevertheless, for isosceles triangles that are aligned with $\nabla^3 u$, we are able to get some handy formulas for the H^1- and L^2-norms of the error. It is found from these formulas that when a triangle is aligned with the orientation of $\nabla^3 u$, the optimal aspect ratio for minimizing both H^1- and L^2-norms of the quadratic interpolation error is approximately equal to the anisotropic ratio of $\nabla^3 u$. This is true regardless of whether the element is an acute or an obtuse isosceles triangle. Therefore, in contrast to the case of linear interpolations, there seems to be no "superaccuracy" in favor of acute isosceles triangles for quadratic interpolations of general cubic functions; see [18]. For general triangle shape and orientations, we study numerically the effects of element alignment, aspect ratio, and internal angles on the H^1- and L^2-norms of the interpolation errors. It is found that

(i) the interpolation error is nearly the smallest when an element is aligned with the orientation of $\nabla^3 u$; (ii) when an element is aligned with $\nabla^3 u$, the optimal aspect ratio is about equal to the anisotropic ratio of $\nabla^3 u$. With this aspect ratio, the H^1-seminorm of the interpolation error is proportional to the magnitude of $\nabla^3 u$ and to the reciprocal of the anisotropic ratio of $\nabla^3 u$. The L^2-norm of the error is proportional to the magnitude of $\nabla^3 u$ and to the $-\frac{3}{2}$th power of the anisotropic ratio of $\nabla^3 u$. (iii) When proper alignment and proper aspect ratio are maintained, the H^1-error is insensitive to the internal angles of the element. Otherwise, it increases as the largest internal angle of the element increases. In this situation the maximum angle condition is essential. The L^2-error is always insensitive to the internal angles.

An outline of this paper is as follows: We first explain in sections 2 and 3 how to measure the orientation and aspect ratio of a triangle, and how to define the orientation and anisotropic ratio of $\nabla^3 u$. Then we derive in section 4 the exact formulas for the H^1- and L^2-norms of the error for quadratic interpolation of cubic functions on a triangle. In section 5 we study the special case with isosceles triangles that are aligned with the orientation of $\nabla^3 u$. In this case the H^1- and L^2-errors can be expressed in simple formulas, and optimal aspect ratios can be identified. For general triangular elements we present a numerical study in section 6 on the effects of the element shape and orientation. We conclude this paper with a few discussions.

2. Anisotropic character of a triangular element. We first recall the definitions of orientation and aspect ratio for a triangular element described in [6]. Let $\hat{K}$ be the standard element with vertices $\boldsymbol{\xi}_1 = (0,1), \boldsymbol{\xi}_2 = (-\frac{\sqrt{3}}{2}, -\frac{1}{2}), \boldsymbol{\xi}_3 = (\frac{\sqrt{3}}{2}, -\frac{1}{2})$. Let K be a general triangular element with vertices $\boldsymbol{x}_1, \boldsymbol{x}_2$, and $\boldsymbol{x}_3$. Let $\boldsymbol{x}_c = \frac{1}{3}(\boldsymbol{x}_1 + \boldsymbol{x}_2 + \boldsymbol{x}_3)$ be the center of K. The affine mapping from $\hat{K}$ to K can be expressed as $\boldsymbol{x} = F\boldsymbol{\xi} + \boldsymbol{x}_c$ with

$$F = \left(\frac{1}{\sqrt{3}}(\boldsymbol{x}_1 - \boldsymbol{x}_3), \boldsymbol{x}_2 - \boldsymbol{x}_c \right).$$

Denote by $F = U\Sigma V^*$ the singular value decomposition (SVD) of matrix F. Without loss of generality, we assume $\Sigma = \mathrm{diag}(\sigma_1, \sigma_2)$ with $\sigma_1 \geq \sigma_2 > 0$, and $U = R_{\phi_u}$ and $V = R_{\phi_v}$ are the matrices for rotation transform by angles ϕ_u and ϕ_v (counterclockwise), respectively.

The mapping $\boldsymbol{x} = F\boldsymbol{\xi}$ transforms $\hat{K}$ into a triangle centered at the origin. It also transforms the unit circle on the $\xi\eta$-plane into an ellipse on the xy-plane, with σ_1 and σ_2 being its semimajor and semiminor axes; see Figure 1. It is easy to see that ϕ_u determines the direction of the semimajor axis of the ellipse. We define this direction as the orientation of triangle K. We define the aspect ratio of K as $r = \frac{\sigma_1}{\sigma_2}$. These definitions are equivalent to the commonly used definition of orientation based on the longest side of K and the definition of aspect ratio based on the diameter of K and the radius of the inscribed circle of K. The angle ϕ_v in the SVD of mapping F determines the internal angles of K. In particular, K is an obtuse isosceles triangle when $\phi_v = 0$ and an acute isosceles triangle when $\phi_v = \pi/2$. If K is an obtuse/acute isosceles triangle, then its orientation is parallel/perpendicular to its base.

3. Anisotropic measures of third order derivatives. By Taylor's expansion, any smooth function u can be approximated locally by lower order polynomials,

$$u(x,y) = \sum_{j=0}^{m} \frac{1}{j!}[(\boldsymbol{x} - \boldsymbol{x}_c) \cdot \nabla]^j u(\boldsymbol{x}_c) + O(\|\boldsymbol{x} - \boldsymbol{x}_c\|^{m+1}).$$

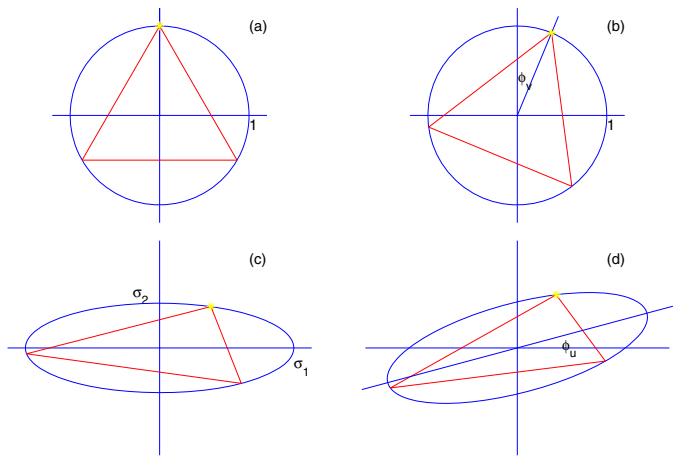

FIG. 1. (a) *standard element* $\hat{K}$; (b) $\hat{K}$ *under* $R^*_{\phi_v}$; (c) $\hat{K}$ *under* $\Sigma R^*_{\phi_v}$; (d) $\hat{K}$ *under* $F = R_{\phi_u}\Sigma R^*_{\phi_v}$.

Let Π_{m-1} be an interpolation operator that preserves the set of polynomials of total degree $\le m-1$. Then the leading term of the interpolation error $u - \Pi_{m-1}u$ is equal to the interpolation error for polynomial $\frac{1}{m!}((\boldsymbol{x}-\boldsymbol{x}_c)\cdot\nabla)^m u(\boldsymbol{x}_c)$, which is controlled by the partial derivative tensor $\nabla^m u(\boldsymbol{x}_c)$. To understand the local behavior of the interpolation error around $\boldsymbol{x}_c$, we need to measure the anisotropic behavior of $\nabla^m u$. Recall that there are three quantities, the area, orientation, and aspect ratio, to characterize the geometric features of a triangular element. We introduced in [7] three quantities to characterize the anisotropic behavior of $\nabla^m u$. The first one is its magnitude, which is equivalent to the Frobenius norm of $\nabla^m u$. The second is the orientation, along which direction the absolute value of the mth order directional derivative at $\boldsymbol{x}_c$ is about the smallest, while along its perpendicular direction it is about the largest. The third quantity is the anisotropic ratio, which measures the strength of the anisotropic behavior of $\nabla^m u$ at $\boldsymbol{x}_c$. These quantities are determined by the distribution of the mth order directional derivatives. They are invariant under the rotation and translation transforms of the independent variables of u. We describe below in detail these definitions in the cases of $m = 2, 3$.

3.1. Anisotropic measure of $\nabla^2 u$. We start from the case of $\nabla^2 u$, which will be needed for introducing the anisotropic measures of $\nabla^3 u$. Note that $\nabla^2 u(\boldsymbol{x}_c)$ is a 2×2 symmetric matrix; it admits the eigendecomposition

$$\nabla^2 u = R_\phi \begin{bmatrix} \lambda_1 & \\ & \lambda_2 \end{bmatrix} R_\phi^T, \tag{3.1}$$

where $|\lambda_1| \le |\lambda_2|$, and R_ϕ is the matrix for rotation with angle $\phi \in [-\frac{\pi}{2}, \frac{\pi}{2}]$ counterclockwise. The two eigenvectors of $\nabla^2 u$ are $\boldsymbol{v}_1 = [\cos\phi, \sin\phi]^T$ and $\boldsymbol{v}_2 = \boldsymbol{v}_1^\perp$, which are in the directions of angle ϕ and $\phi + \frac{\pi}{2}$ from the x-axis. When $|\lambda_1/\lambda_2|$ is small, the absolute value of the second order directional derivative is about the smallest along $\boldsymbol{v}_1$, and it is the largest along its perpendicular direction. We define $\boldsymbol{v}_1$ as the orientation of $\nabla^2 u$ at $\boldsymbol{x}_c$. Furthermore, we define the anisotropic ratio of $\nabla^2 u$ as

$$S(\nabla^2 u) \equiv S_2 \equiv \sqrt{\left|\frac{\lambda_2}{\lambda_1}\right|}$$

and define the magnitude of $\nabla^2 u$ as

$$|\nabla^2 u| \equiv D_2 \equiv \frac{1}{2}(|\lambda_1| + |\lambda_2|).$$

Clearly, $S_2 \geq 1$. The larger S_2 is, the stronger the anisotropic behavior of $\nabla^2 u$. Since $\frac{1}{2}|\lambda_2| \leq D_2 \leq |\lambda_2|$, the magnitude $|\nabla^2 u|$ is equivalent to the 2-norm, and hence the Frobenius norm, of $\nabla^2 u$.

The above definition of the orientation, anisotropic ratio, and magnitude for $\nabla^2 u$ can be interpreted geometrically in terms of the level curves of the following polynomial:

$$p_2(\xi, \eta) = \frac{1}{2}(\boldsymbol{\xi} \cdot \nabla)^2 u(\boldsymbol{x}_c),$$

where $\boldsymbol{\xi} = [\xi, \eta]^T$. For $\|\boldsymbol{\xi}\| = 1$, $p_2(\xi, \eta)$ is one half of the second order directional derivative along $\boldsymbol{\xi}$ for u at $\boldsymbol{x}_c$. We first consider the case $\lambda_1 \lambda_2 < 0$ (assume, more specifically, $\lambda_1 \geq 0$ and $\lambda_2 \leq 0$.) Let (r, t) be the polar coordinates of (ξ, η). Then by the eigendecomposition (3.1) for $\nabla^2 u$,

$$\begin{aligned} p_2(\xi, \eta) &= \tfrac{1}{2}(R_\phi^T \boldsymbol{\xi}) \cdot \begin{bmatrix} \lambda_1 & \\ & \lambda_2 \end{bmatrix} (R_\phi^T \boldsymbol{\xi}) \\ &= \tfrac{1}{2} r^2 [\lambda_1 \cos^2(t - \phi) + \lambda_2 \sin^2(t - \phi)]. \end{aligned} \tag{3.2}$$

Let $\alpha = \tan^{-1}(\sqrt{|\frac{\lambda_1}{\lambda_2}|})$. Then $\alpha \in [0, \frac{\pi}{4}]$ for $|\lambda_1| \leq |\lambda_2|$, and

$$\sin^2 \alpha = \frac{\lambda_1}{|\lambda_1| + |\lambda_2|}, \qquad \cos^2 \alpha = -\frac{\lambda_2}{|\lambda_1| + |\lambda_2|}.$$

Therefore,

$$\begin{aligned} p_2(\xi, \eta) &= \tfrac{1}{2} r^2 (|\lambda_1| + |\lambda_2|)\ [\sin^2 \alpha\ \cos^2(t - \phi) - \cos^2 \alpha\ \sin^2(t - \phi)] \\ &= \tfrac{1}{2} r^2 (|\lambda_1| + |\lambda_2|)\ \sin(\alpha + t - \phi) \cdot \sin(\alpha - t + \phi). \end{aligned}$$

Clearly, $p_2(\xi, \eta) = 0$ along the lines of angles $\phi + \alpha + k\pi$ and $\phi - \alpha + k\pi$ from the ξ-axis. Let $\beta_1 \leq \beta_2$ be the two angles among them that lie in $(-\pi/2, \pi/2]$. Then we can express p_2 as

$$\begin{aligned} p_2(\xi, \eta) &= \pm \tfrac{1}{2} r^2 (|\lambda_1| + |\lambda_2|)\ \sin(t - \beta_1)\ \sin(t - \beta_2) \\ &= \pm \tfrac{1}{2} r^2 (|\lambda_1| + |\lambda_2|)\ (\cos t\ \sin \beta_1 - \sin t\ \cos \beta_1) \cdot (\cos t\ \sin \beta_2 - \sin t\ \cos \beta_2) \\ &= \pm D_2\ \ell_1(\xi, \eta)\ \ell_2(\xi, \eta), \end{aligned} \tag{3.3}$$

where $D_2 = \frac{1}{2}(|\lambda_1| + |\lambda_2|)$, and

$$\ell_i(\xi, \eta) = \xi \sin \beta_i - \eta \cos \beta_i, \qquad i = 1, 2. \tag{3.4}$$

We are ready to see that the orientation of $\nabla^2 u$ is just the bisection direction of the smaller sector formed by the level-0 lines of $p_2(\xi, \eta)$; see Figure 2(a). The angle ϕ in (3.1) for this direction can be expressed as

$$\phi = \frac{1}{2}(\underline{\beta} + \bar{\beta}),$$

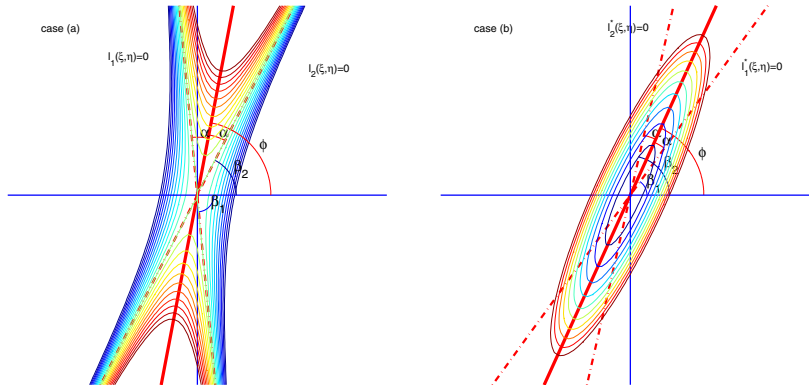

FIG. 2. *Contour lines of $p_2(\xi,\eta)$ and the orientation (bold line) of $\nabla^2 u$.* (a) *$p_2(\xi,\eta)$ has two linear factors. Here $\underline{\beta}=\beta_2$ and $\bar{\beta}=\beta_1+\pi$.* (b) *$p_2(\xi,\eta)$ does not change sign for all (ξ,η). ℓ_1^* and ℓ_2^* are the linear factors of the associated polynomial p_2^*. Here $\underline{\beta}=\beta_1$ and $\bar{\beta}=\beta_2$.*

where $[\underline{\beta},\bar{\beta}]$ is the smaller interval between $[\beta_1,\beta_2]$ and $[\beta_2,\beta_1+\pi]$. Furthermore, the anisotropic ratio $S(\nabla^2 u)=\sqrt{|\frac{\lambda_2}{\lambda_1}|}$ can be expressed in terms of the opening $\bar{\beta}-\underline{\beta}=2\alpha$ of the smaller sector as

$$S(\nabla^2 u)=\cot\alpha=\cot((\bar{\beta}-\underline{\beta})/2).$$

The magnitude $|\nabla^2 u|$ of $\nabla^2 u$ is just the coefficient D_2 in the factoring (3.3) of p_2.

Algebraically, $\lambda_1\lambda_2\le 0$ corresponds to the case where $p_2(1,z)$ has two real roots $z_i=\tan(\beta_i)$. Now we consider the case $\lambda_1\lambda_2>0$. In this case, $p_2(1,z)$ has two conjugate complex roots, and $p_2(\xi,\eta)$ does not change sign for all (ξ,η). In this case, we introduce matrix

$$\hat{H}=R_\phi\begin{bmatrix}\lambda_1 & \\ & -\lambda_2\end{bmatrix}R_\phi^T \tag{3.5}$$

and define an associated polynomial $p_2^*(\xi,\eta)=\frac{1}{2}(\boldsymbol{\xi}\cdot\hat{H}\boldsymbol{\xi})$; see Figure 2(b). Clearly, p_2^* can be factored into the product of two linear functions ℓ_1^* and ℓ_2^* as in (3.4). Since the magnitude, orientation, and anisotropic ratio of $\nabla^2 u$ are identical to those of $\hat{H}$, we can determine them equivalently by the level-0 lines for p_2^* as in the case with $\lambda_1\lambda_2<0$.

In summary, if $p_2(\xi,\eta)$ can be factored into the product of two linear functions, then the orientation and anisotropic ratio of $\nabla^2 u$ can be determined by the level-0 lines of $p_2(\xi,\eta)$. Otherwise, they can be determined equivalently by the level-0 lines of $p_2^*(\xi,\eta)$ defined by $\hat{H}$ in (3.5). In particular, the level-0 lines of p_2 or p_2^* are of angles $\pm\alpha=\pm\tan^{-1}(\sqrt{|\lambda_1/\lambda_2|})$ from the eigenvector $\boldsymbol{v}_1$ of $\nabla^2 u$.

3.2. Anisotropic measure of $\nabla^3 u$. To characterize the anisotropic behavior of $\nabla^3 u$ at a point $\boldsymbol{x}_c$, we study

$$p_3(\boldsymbol{\xi})=\frac{1}{3!}(\boldsymbol{\xi}\cdot\nabla)^3 u(\boldsymbol{x}_c).$$

For $\|\boldsymbol{\xi}\|=1$, $p_3(\boldsymbol{\xi})$ is one sixth of the third order directional derivative along $\boldsymbol{\xi}$ for u at $\boldsymbol{x}_c$. Since $p_3(\boldsymbol{\xi})$ is an homogeneous polynomial, we may write $p_3(\xi,\eta)=\xi^3 p_3(1,\eta/\xi)$,

with $p_3(1,z)$ being a real polynomial of degree ≤ 3. $p_3(1,z)$ can be factored into the product of linear polynomials and/or a positive quadratic polynomial of z. Therefore, we may factor $p_3(\xi,\eta)$ into either the product of three linear functions or the product of a linear function and a positive, homogeneous, quadratic function of ξ,η. We discuss the former case first. Assume

$$p_3(\xi,\eta) = D_3\ \ell_1(\xi,\eta)\ \ell_2(\xi,\eta)\ \ell_3(\xi,\eta), \tag{3.6}$$

where $D_3 \geq 0$, and each ℓ_i is a linear function of the form (3.4) with

$$-\frac{\pi}{2} < \beta_1 \leq \beta_2 \leq \beta_3 \leq \frac{\pi}{2}.$$

These factors can be easily determined by the roots of $p_3(1,z)=0$. Indeed, $\tan\beta_i$'s are just the roots of $p_3(1,z)=0$. Clearly, $\ell_i(\xi,\eta)=0$, $i=1,2,3$, are the level-0 lines of p_3. We define the magnitude of $\nabla^3 u$ as $|\nabla^3 u| = D_3$. This is an upper bound of all the third order directional derivatives at $\boldsymbol{x}_c$. It is not difficult to show that $|\nabla^3 u|$ is equivalent to the Frobenius norm of $\nabla^3 u$ [7]. Moreover, when all three level-0 lines of p_3 are close to a common direction, the absolute value of the third order directional derivative of u is about the smallest along this direction, while it is about the largest along its perpendicular direction. In this case, $\nabla^3 u$ is strongly anisotropic. To determine the common direction to which the level-0 lines are all close, we consider the three sectors formed by every other line of $\ell_i = 0$ for $i=1,2,3$; see Figure 3(a). The ranges of the central angle of these sectors are, respectively,

$$[\beta_1,\beta_3], \quad [\beta_2,\beta_1+\pi], \quad [\beta_3,\beta_2+\pi]. \tag{3.7}$$

Let $[\underline{\beta},\overline{\beta}]$ be the shortest interval among the three of (3.7). Clearly, $\overline{\beta}-\underline{\beta} \leq \frac{2\pi}{3}$. If $\overline{\beta}-\underline{\beta} \ll 1$, all the level-0 lines of $p_3(\xi,\eta)$ are close to the direction of angle $\phi = \frac{1}{2}(\underline{\beta}+\overline{\beta})$ from the ξ-axis. We define this direction as the orientation of $\nabla^3 u$. Furthermore, the smaller $\overline{\beta}-\underline{\beta}$ is, the stronger the anisotropic behavior of $\nabla^3 u$. Hence, we define the anisotropic ratio of $\nabla^3 u$ as

$$S_3 \equiv S(\nabla^3 u) \equiv \max(1, \cot((\bar{\beta}-\underline{\beta})/2)).$$

The artificial cutoff of $S(\nabla^3 u)$ at the value 1 reflects the fact that we consider only stretching an element in two perpendicular directions in anisotropic mesh refinements. When $\overline{\beta}-\underline{\beta} \geq \frac{\pi}{2}$, rescaling an element in two perpendicular directions (while keeping the area fixed) has little advantage in reducing the H^1-norm of the interpolation error; see Remark 2 in section 5 below. Therefore, we simply consider in this case that $\nabla^3 u$ is isotropic and its anisotropic ratio $S(\nabla^3 u)=1$.

Next we study the case where $p_3(\xi,\eta)$ is the product of a linear function and a positive, homogeneous, quadratic function. Assume

$$p_3(\xi,\eta) = \ell_3(\xi,\eta)\ q(\xi,\eta),$$

where $\ell_3(\xi,\eta)$ is in the form of (3.4), and $q(\xi,\eta) > 0$ for all $\|\boldsymbol{\xi}\| \neq \mathbf{0}$. We write $q = \frac{1}{2}\boldsymbol{\xi}^T Q \boldsymbol{\xi}$, where Q is the Hessian of q. Decompose Q into

$$Q = R \begin{bmatrix} \lambda_1 & \\ & \lambda_2 \end{bmatrix} R^T, \tag{3.8}$$

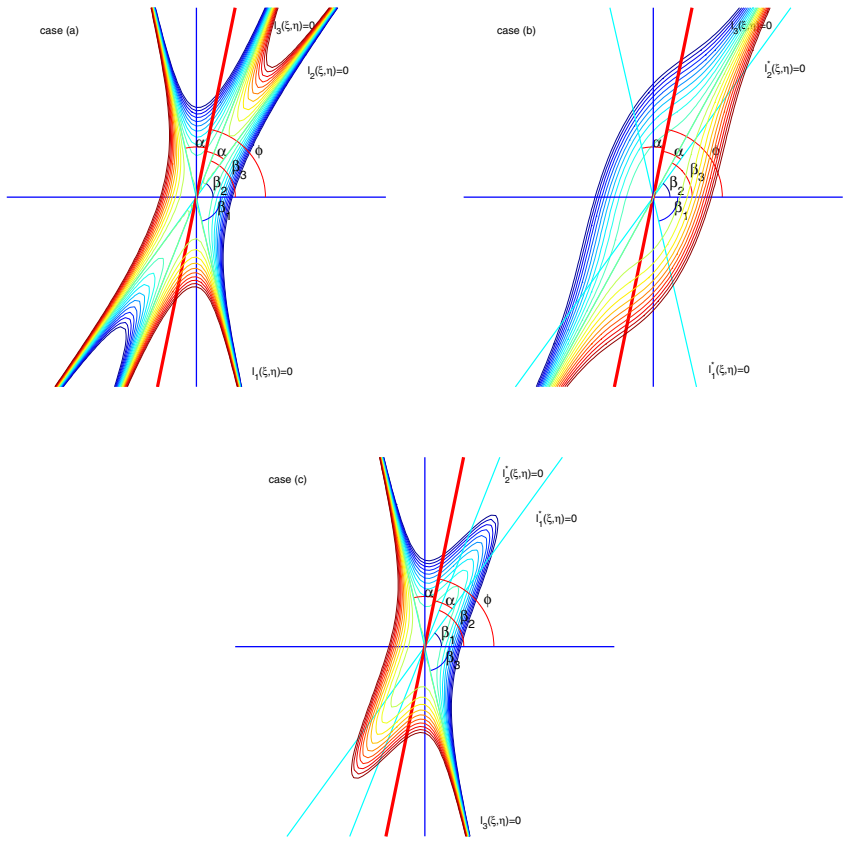

FIG. 3. *Contour lines of* $p_3 = \frac{1}{3!}(\boldsymbol{\xi} \cdot \nabla)^3 u$ *and the orientation (bold line) of* $\nabla^3 u$. (a) p_3 *has three linear (real) factors.* (b) p_3 *has a linear factor* $\ell_3(\xi, \eta)$ *and a positive quadratic factor* $q(\xi, \eta)$. $\ell_3 = 0$ *lies "inside" the level-*0 *lines of* $q^*(\xi, \eta)$. (c) p_3 *has a linear factor* $\ell_3(\xi, \eta)$ *and a positive quadratic factor* $q(\xi, \eta)$. $\ell_3 = 0$ *lies "outside" the level-*0 *lines of* $q^*(\xi, \eta)$.

where R is an orthogonal matrix, and $0 < \lambda_1 \leq \lambda_2$. As explained in the previous subsection, the anisotropic feature of $q(\xi, \eta)$ is identical to that of $q^*(\xi, \eta) = \frac{1}{2}\boldsymbol{\xi} \cdot \hat{Q}\boldsymbol{\xi}$, where

$$\hat{Q} = R \begin{bmatrix} \lambda_1 & \\ & -\lambda_2 \end{bmatrix} R^T. \tag{3.9}$$

Therefore, we define the magnitude, orientation, and anisotropic ratio of $\nabla^3 u$ based on

$$p_3^*(\xi, \eta) = \ell_3(\xi, \eta)\ q^*(\xi, \eta); \tag{3.10}$$

see Figure 3(b) and 3(c). Since $p_3^*(\xi, \eta)$ can be factored into the product of three linear functions ℓ_1^*, ℓ_2^*, and ℓ_3, these anisotropic measures can be determined by the position of the three level-0 lines of p_3^*.

An important feature about the above definitions of magnitude, anisotropic ratio, and orientation for $\nabla^3 u$ is that they are invariant under translation and rotation transforms of the independent variables of u.

1. The above definitions of the anisotropic measures can be generalized to the case of $\nabla^m u$ for $m > 3$; see [7]. Indeed, since $p_m(\xi, \eta) = \frac{1}{m!}(\boldsymbol{\xi} \cdot \nabla)^m u$ is

an homogeneous polynomial, we may write $p_m(\xi,\eta) = \xi^m p_m(1,\eta/\xi)$, with $p_m(1,z)$ being a real polynomial of degree $\le m$. By the fundamental theorem of algebra, $p_m(1,z)$ can be factored into the product of linear functions and/or positive quadratic functions of z. Therefore, $p_m(\xi,\eta)$ can be factored into the product of linear functions and/or positive, homogeneous, quadratic functions of ξ,η. We may convert each positive quadratic function $q(\xi,\eta)$ into $q^*(\xi,\eta)$. Then the magnitude, orientation, and anisotropic ratio of $\nabla^m u$ can be determined by the positions of the level-0 lines of $p_m^*(\xi,\eta)$.

3.3. Examples for anisotropic measures. We give several examples to demonstrate how to calculate the orientation and anisotropic ratio of $\nabla^3 u$. Assume ϵ is a small positive number.

1. $u(x,y) = y^3 + (\epsilon x)^3$. Here

$$p_3(\xi,\eta) = \frac{1}{3!}(\boldsymbol{\xi}\cdot\nabla)^3 u = \eta^3 + (\epsilon\xi)^3 = (\eta+\epsilon\xi)(\eta^2 - \epsilon\xi\eta + \epsilon^2\xi^2),$$

which is the product of a linear function and a positive quadratic function. Let $q(\xi,\eta) = \eta^2 - \epsilon\xi\eta + \epsilon^2\xi^2$. Then

$$\nabla^2 q = \begin{bmatrix} 2\epsilon^2 & -\epsilon \\ -\epsilon & 2 \end{bmatrix}.$$

The eigenvalues of $\nabla^2 q$ are

$$\begin{aligned} \lambda_1 &= (\epsilon^2+1) - \sqrt{\epsilon^4 - \epsilon^2 + 1} \quad \approx (\epsilon^2+1) - (1-\epsilon^2/2) \quad = 3\epsilon^2/2, \\ \lambda_2 &= (\epsilon^2+1) + \sqrt{\epsilon^4 - \epsilon^2 + 1} \quad \approx (\epsilon^2+1) + (1-\epsilon^2/2) \quad = 2+\epsilon^2/2. \end{aligned}$$

The eigenvector of $\nabla^2 q$, associated with the smaller eigenvalue λ_1, is $\boldsymbol{v}_1 = [1, (\epsilon^2 - 1 + \sqrt{\epsilon^4-\epsilon^2+1})/\epsilon]^T \approx [1, \epsilon/2]^T$. Note that the level-0 lines of $q^*(\xi,\eta)$ are along the angles $\phi \pm \alpha$ from the x-axis, where $\phi \approx \tan^{-1}(\frac{\epsilon}{2})$ is the angle of $\boldsymbol{v}_1$ and $\alpha = \tan^{-1}\sqrt{|\frac{\lambda_1}{\lambda_2}|}$. Thus in this case the two level-0 lines of $q^*(\xi,\eta)$ are along the angles $\tan^{-1}(\frac{\epsilon}{2}) \pm \tan^{-1}(\sqrt{\frac{3\epsilon^2}{4+\epsilon^2}}) \approx \frac{\epsilon}{2} \pm \frac{\sqrt{3}}{2}\epsilon$. Combining the direction of linear factor $y + \epsilon x = 0$, we have the three level-0 lines of $p_3^*(\xi,\eta)$ in approximately the directions of angle $-\epsilon$, $\frac{1-\sqrt{3}}{2}\epsilon$ and $\frac{1+\sqrt{3}}{2}\epsilon$, which implies $\underline{\beta} \approx -\epsilon$ and $\bar{\beta} \approx -\frac{1+\sqrt{3}}{2}\epsilon$. Therefore, the orientation of $\nabla^3 u$ is

$$\phi = \frac{1}{2}(\underline{\beta} + \bar{\beta}) \approx \frac{-1+\sqrt{3}}{4}\epsilon,$$

and the anisotropic ratio is

$$S(\nabla^3 u) = \cot(\tfrac{1}{2}(\bar{\beta} - \underline{\beta})) \approx \tfrac{4}{3+\sqrt{3}}\tfrac{1}{\epsilon}.$$

2. $u(x,y) = (x+y)^3 + \epsilon(x^3+y^3)$. Here

$$\begin{aligned} p_3(\xi,\eta) &= (\xi+\eta)^3 + \epsilon(\xi^3+\eta^3) \\ &= (\xi+\eta)\cdot[(1+\epsilon)\xi^2 + (2-\epsilon)\xi\eta + (1+\epsilon)\eta^2], \end{aligned}$$

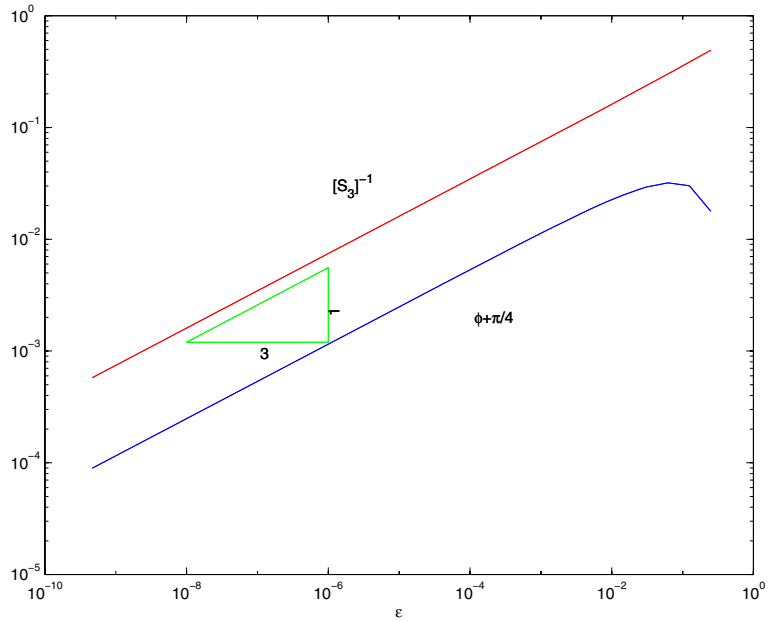

FIG. 4. *Example* 3*: The anisotropic ratio* S_3 *and orientation* $\phi + \frac{\pi}{4}$ *versus parameter* ϵ.

which is the product of a linear function and a positive quadratic function. Let $q(\xi, \eta) = (1+\epsilon)\xi^2 + (2-\epsilon)\xi\eta + (1+\epsilon)\eta^2$. Then

$$\nabla^2 q = \begin{bmatrix} 2+2\epsilon & 2-\epsilon \\ 2-\epsilon & 2+2\epsilon \end{bmatrix}.$$

Its two eigenvalues are 3ϵ and $4+\epsilon$, and the eigenvector associated with the smaller eigenvalue is $[1,-1]$. Therefore, the two level-0 lines of $q^*(\xi,\eta)$ are along angles $\tan^{-1}(-1) \pm \tan^{-1}\sqrt{\frac{3\epsilon}{4+\epsilon}}$. Together with the level-0 line $x+y=0$ due to the linear factor, we are ready to see that the orientation of $\nabla^3 u$ is along angle $\phi = \tan^{-1}(-1) = -\frac{\pi}{4}$, and the anisotropic ratio is $S(\nabla^3 u) = \cot\left[\tan^{-1}(\sqrt{\frac{3\epsilon}{4+\epsilon}})\right] \approx \frac{2}{\sqrt{3\epsilon}}$.

3. $u(x,y) = (x+y)^3 + \epsilon(x^3 - y^3)$. In this case, $p_3(\xi,\eta) = (\xi+\eta)^3 + \epsilon(\xi^3 - \eta^3)$, which is again the product of a linear function and a positive quadratic function. However, the asymptotic analysis for the level-0 lines of $p^*(\xi,\eta)$ is rather complicated. Instead we use a numerical method to determine the angles of the orientation and the anisotropic ratio; see Figure 4. It turns out that the orientation is still close to the line $y+x=0$, but the anisotropic ratio is of the magnitude $O(\sqrt[3]{\frac{1}{\epsilon}})$.

4. Quadratic interpolation error. In this section, we study the model problem of interpolating a cubic function by quadratic polynomials at the three vertices and the midpoints of three sides of a triangular element K. We derive the exact formulas for the H^1-seminorm and L^2-norm of the interpolation error. Let $\boldsymbol{x}_1, \boldsymbol{x}_2$, and $\boldsymbol{x}_3$ be the vertices of K (numbered counterclockwise), and let $\boldsymbol{\ell}_1 = \boldsymbol{x}_3 - \boldsymbol{x}_2, \boldsymbol{\ell}_2 = \boldsymbol{x}_1 - \boldsymbol{x}_3, \boldsymbol{\ell}_3 = \boldsymbol{x}_2 - \boldsymbol{x}_1$. Let $c_i(x,y)$, $i = 1,2,3$, be the barycentric coordinates of a point (x,y) in K. We call a triple index (i,j,k) in cyclic order if it is one of the

following three: $(1,2,3),(2,3,1),(3,1,2)$. For (i,j,k) in cyclic order, define

$$b_0 = c_1c_2c_3 \qquad \text{and} \qquad b_i = c_jc_k(c_j - c_k), \quad i = 1,2,3. \tag{4.1}$$

We are ready to see that b_i's are linearly independent. Let u be a cubic function, and let $\Pi_2 u$ be its quadratic interpolation at the vertices and side midpoints of K. Then the error $e = u - \Pi_2 u$ can be expressed as

$$e = \sum_{i=0}^{3} v_i b_i(x,y). \tag{4.2}$$

To determine the constants v_i, $0 \le i \le 3$, we first list a few basic formulas. Their proofs are elementary.

LEMMA 4.1. [illegible] $\boldsymbol{\tau}_i = \boldsymbol{\ell}_i/|\boldsymbol{\ell}_i|$ [illegible] $\boldsymbol{n}_i$ [illegible] $\boldsymbol{\ell}_i$ [illegible]

$$\nabla c_i = -\frac{|\boldsymbol{\ell}_i|}{2|K|}\boldsymbol{n}_i, \tag{4.3}$$

$$\boldsymbol{\tau}_i \cdot \nabla c_j = \begin{cases} 0 & \text{[illegible] } i = j, \\ \dfrac{-1}{|\ell_i|} & \text{[illegible] } (i,j) = (1,2),(2,3),(3,1), \\ \dfrac{+1}{|\ell_i|} & \text{[illegible] } (i,j) = (2,1),(3,2),(1,3). \end{cases} \tag{4.4}$$

LEMMA 4.2.

$$\begin{cases} \dfrac{\partial^3 b_i}{\partial \boldsymbol{\tau}_i^3} = \dfrac{12}{|\boldsymbol{\ell}_i|^3} & i = 1,2,3, \\ \dfrac{\partial^3 b_i}{\partial \boldsymbol{\tau}_j^3} = 0 & \forall i \ne j. \end{cases} \tag{4.5}$$

Note that $\Pi_2 u$ is of degree 2, and we get from the above two lemmas that

$$v_i = \frac{|\boldsymbol{\ell}_i|^3}{12}\frac{\partial^3 u}{\partial \boldsymbol{\tau}_i^3}, \qquad i = 1,2,3. \tag{4.6}$$

Next we determine the coefficient v_0. It is natural to consider the symmetric differentiation $\frac{\partial^3}{\partial \boldsymbol{\tau}_1 \boldsymbol{\tau}_2 \boldsymbol{\tau}_3}$ on both sides of (4.2). However, since

$$\frac{\partial^3 b_0}{\partial \boldsymbol{\tau}_1\boldsymbol{\tau}_2\boldsymbol{\tau}_3} = 0 \qquad \text{and} \qquad \frac{\partial^3 b_i}{\partial \boldsymbol{\tau}_1\boldsymbol{\tau}_2\boldsymbol{\tau}_3} = \frac{4}{|\boldsymbol{\ell}_1| \cdot |\boldsymbol{\ell}_2| \cdot |\boldsymbol{\ell}_3|}, \qquad i = 1,2,3, \tag{4.7}$$

this operation leads only to an identity

$$\frac{\partial^3 u}{\partial \boldsymbol{\tau}_1\boldsymbol{\tau}_2\boldsymbol{\tau}_3} = \frac{1}{3|\boldsymbol{\ell}_1|\,|\boldsymbol{\ell}_2|\,|\boldsymbol{\ell}_3|}\sum_{i=1}^{3} |\ell_i|^3 \frac{\partial^3 u}{\partial \tau_i^3}. \tag{4.8}$$

Therefore, we consider taking the following operation on both sides of (4.2):

$$\mathcal{L} = \frac{\partial^3}{\partial \boldsymbol{\tau}_1^2 \boldsymbol{\tau}_2} + \frac{\partial^3}{\partial \boldsymbol{\tau}_2^2 \boldsymbol{\tau}_3} + \frac{\partial^3}{\partial \boldsymbol{\tau}_3^2 \boldsymbol{\tau}_1}. \tag{4.9}$$

LEMMA 4.3. [illegible] (i,j,k) [illegible]

$$\begin{cases} \dfrac{\partial^3 b_0}{\partial \boldsymbol{\tau}_i^2 \boldsymbol{\tau}_j} = \dfrac{-2}{|\boldsymbol{\ell}_i|^2 \cdot |\boldsymbol{\ell}_j|}, & \dfrac{\partial^3 b_0}{\partial \boldsymbol{\tau}_i^2 \boldsymbol{\tau}_k} = \dfrac{+2}{|\boldsymbol{\ell}_i|^2 \cdot |\boldsymbol{\ell}_k|}, \\ \dfrac{\partial^3 b_i}{\partial \boldsymbol{\tau}_i^2 \boldsymbol{\tau}_j} = \dfrac{-6}{|\boldsymbol{\ell}_i|^2 \cdot |\boldsymbol{\ell}_j|}, & \dfrac{\partial^3 b_i}{\partial \boldsymbol{\tau}_i \boldsymbol{\tau}_j^2} = \dfrac{+2}{|\boldsymbol{\ell}_i| \cdot |\boldsymbol{\ell}_j|^2}, \\ \dfrac{\partial^3 b_i}{\partial \boldsymbol{\tau}_i^2 \boldsymbol{\tau}_k} = \dfrac{-6}{|\boldsymbol{\ell}_i|^2 \cdot |\boldsymbol{\ell}_k|}, & \dfrac{\partial^3 b_i}{\partial \boldsymbol{\tau}_i \boldsymbol{\tau}_k^2} = \dfrac{+2}{|\boldsymbol{\ell}_i| \cdot |\boldsymbol{\ell}_k|^2}, \\ \dfrac{\partial^3 b_i}{\partial \boldsymbol{\tau}_j^2 \boldsymbol{\tau}_k} = \dfrac{-2}{|\boldsymbol{\ell}_j|^2 \cdot |\boldsymbol{\ell}_k|}, & \dfrac{\partial^3 b_i}{\partial \boldsymbol{\tau}_j \boldsymbol{\tau}_k^2} = \dfrac{-2}{|\boldsymbol{\ell}_j| \cdot |\boldsymbol{\ell}_k|^2}. \end{cases}$$

We have from the above formulas that

$$\mathcal{L} b_0 = \frac{-2}{|\boldsymbol{\ell}_1|^2 |\boldsymbol{\ell}_2|} + \frac{-2}{|\boldsymbol{\ell}_2|^2 |\boldsymbol{\ell}_3|} + \frac{-2}{|\boldsymbol{\ell}_3|^2 |\boldsymbol{\ell}_1|} \tag{4.10}$$

and

$$\mathcal{L} b_i = \frac{-6}{|\boldsymbol{\ell}_i|^2 |\boldsymbol{\ell}_j|} + \frac{-2}{|\boldsymbol{\ell}_j|^2 |\boldsymbol{\ell}_k|} + \frac{+2}{|\boldsymbol{\ell}_k|^2 |\boldsymbol{\ell}_i|}, \qquad i = 1, 2, 3. \tag{4.11}$$

Now the coefficient v_0 can be solved from

$$\mathcal{L} u = v_0 \mathcal{L} b_0 + \sum_{i=1}^{3} v_i \mathcal{L} b_i,$$

which yields

$$v_0 = \left(\mathcal{L} u - \sum_{i=1}^{3} v_i \mathcal{L} b_i \right) / \mathcal{L} b_0. \tag{4.12}$$

Now we derive the formulas for the H^1-seminorm and L^2-norm of the interpolation error. Clearly,

$$\int_K |\nabla e|^2 \, dxdy = \boldsymbol{v} \cdot B_1 \boldsymbol{v}, \tag{4.13}$$

where $\boldsymbol{v} = [v_0, v_1, v_2, v_3]^T$, and $B_1 = \left(\int_K \nabla b_i \cdot \nabla b_j \, dxdy \right)$. By the identity [10]

$$\int_K (c_1)^{\alpha_1} (c_2)^{\alpha_2} (c_3)^{\alpha_3} \, dxdy = 2|K| \frac{\alpha_1! \alpha_2! \alpha_3!}{(\alpha_1 + \alpha_2 + \alpha_3 + 2)!},$$

we have

$$B_1 = \frac{1}{720|K|} \tag{4.14}$$

$$\begin{bmatrix} |\boldsymbol{\ell}_1|^2 + |\boldsymbol{\ell}_2|^2 + |\boldsymbol{\ell}_3|^2 & 2(|\boldsymbol{\ell}_3|^2 - |\boldsymbol{\ell}_2|^2) & 2(|\boldsymbol{\ell}_1|^2 - |\boldsymbol{\ell}_3|^2) & 2(|\boldsymbol{\ell}_2|^2 - |\boldsymbol{\ell}_1|^2) \\ & 4(2|\boldsymbol{\ell}_1|^2 - 3\boldsymbol{\ell}_2 \cdot \boldsymbol{\ell}_3) & -4\boldsymbol{\ell}_1 \cdot \boldsymbol{\ell}_2 & -4\boldsymbol{\ell}_1 \cdot \boldsymbol{\ell}_3 \\ & & 4(2|\boldsymbol{\ell}_2|^2 - 3\boldsymbol{\ell}_1 \cdot \boldsymbol{\ell}_3) & -4\boldsymbol{\ell}_2 \cdot \boldsymbol{\ell}_3 \\ & sym. & & 4(2|\boldsymbol{\ell}_3|^2 - 3\boldsymbol{\ell}_1 \cdot \boldsymbol{\ell}_2) \end{bmatrix}.$$

For the L^2-norm of the interpolation error, we similarly have

$$\int_K |e|^2 \, dxdy = \boldsymbol{v} \cdot B_0 \boldsymbol{v}, \tag{4.15}$$

where

$$B_0 = \left(\int_K b_i b_j \, dxdy \right) = \frac{|K|}{7!} \begin{bmatrix} 2 & 0 & 0 & 0 \\ & 6 & -2 & -2 \\ & & 6 & -2 \\ & sym. & & 6 \end{bmatrix}. \tag{4.16}$$

5. Optimal aspect ratios: A case study. Since error formulas (4.13) and (4.15) involve complicated interaction between the geometric features of K and the orientation and anisotropic ratio of $\nabla^3 u$, it is rather difficult, if not impossible, to decipher from them some quantitative guidelines for anisotropic mesh generation. In particular, among triangles that are of unit area and aligned with the orientation of $\nabla^3 u$, we would like to identify those which produce the smallest quadratic interpolation errors. We study this issue in the case when the triangle is an acute or obtuse isosceles triangle. Because the error is invariant under the rotation transform of the coordinates, we may assume the orientation of $\nabla^3 u$ is simply the x-axis. Furthermore, since we are mainly concerned with the local behavior of the error, we assume u is an homogeneous cubic function. In this case, $p_3(\boldsymbol{\xi}) = u(\boldsymbol{\xi})$ is either the product of three linear functions or the product of a linear function and a positive quadratic function. Suppose the anisotropic ratio of $\nabla^3 u$ is $\frac{1}{\epsilon}$. By the definition of the orientation and anisotropic ratio, u must be a multiple of one of the following three types of functions.

(i). u is the product of three linear functions. In this case u must be a multiple of

$$u_1(x, y) = \frac{1}{3!}(y - \delta x)(y^2 - \epsilon^2 x^2), \tag{5.1}$$

where $|\delta| \leq \epsilon$; see Figure 3(a).

(ii). u is the product of a linear function ℓ_3 and a positive quadratic function q, with the linear factor "lying inside" the quadratic factor (see Figure 3(b)). In this case, the orientation of $\nabla^3 u$ is determined by the directions of ℓ_1^* and ℓ_2^* in q^*. Hence, u is a multiple of

$$u_2(x, y) = \frac{1}{3!}(y - \delta x)(y^2 + \epsilon^2 x^2), \tag{5.2}$$

where $|\delta| \leq \epsilon$.

(iii). u is the product of a linear function ℓ_3 and a positive quadratic function q, with the linear factor "lying outside" the quadratic factor (see Figure 3(c)). In this case, the orientation of $\nabla^3 u$ is determined by the directions of ℓ_3 and one of the factors ℓ_1^* or ℓ_2^* in q^*. Therefore, u must be a multiple of

$$u_3(x, y) = \frac{1}{3!}(y - \epsilon x) q(x, y), \tag{5.3}$$

where

$$q(x, y) = (R_\gamma^T \boldsymbol{x}) \cdot \begin{bmatrix} \sin^2 \gamma & 0 \\ 0 & \cos^2 \gamma \end{bmatrix} (R_\gamma^T \, \boldsymbol{x}),$$

where R_γ is the matrix of rotation by angle γ, and $|\gamma| \le \tan^{-1}(\epsilon)$.

The magnitude of the first two types of functions is $(1+\epsilon^2)\sqrt{1+\delta^2}$, while for the third type it is $\sqrt{1+\epsilon^2}$. Under the assumption $\epsilon \ll 1$, we have for all three cases the magnitude being approximately 1.

We shall simplify the error formulas (4.13) and (4.15) for the first two types of functions when the element is an acute or obtuse isosceles triangle aligned with the $\nabla^3 u$. In this case, optimal aspect ratios leading to the smallest interpolation errors can be identified. The error formulas for the third type of function are still too complicated. For this case we study the optimal aspect ratio numerically in the next section.

5.1. H^1-seminorm of the interpolation error. First, we present the formula for the H^1-seminorm of the interpolation error for function (5.1). We first consider element K being an acute isosceles triangle aligned with the orientation of $\nabla^3 u$, i.e., $\phi_u = 0, \phi_v = \frac{\pi}{2}$. Denote by $|K|$ the area of K, and denote by r its aspect ratio. With the help of Maple, we have in this case

$$\boldsymbol{\ell}_1 = \sqrt{\frac{4|K|}{\sqrt{3}r}}\begin{bmatrix} 0 \\ -1 \end{bmatrix}, \quad \boldsymbol{\ell}_2 = \sqrt{\frac{|K|}{\sqrt{3}r}}\begin{bmatrix} \sqrt{3}r \\ 1 \end{bmatrix}, \quad \boldsymbol{\ell}_3 = \sqrt{\frac{|K|}{\sqrt{3}r}}\begin{bmatrix} -\sqrt{3}r \\ 1 \end{bmatrix},$$

and

$$B_1 = \frac{\sqrt{3}}{540}\begin{bmatrix} \frac{3}{2}(r+\frac{1}{r}) & 0 & \frac{3}{2}(r-\frac{1}{r}) & \frac{3}{2}(r-\frac{1}{r}) \\ & 5r+\frac{9}{r} & \frac{2}{r} & \frac{2}{r} \\ & & 6r+\frac{8}{r} & 3r-\frac{1}{r} \\ & sym. & & 6r+\frac{8}{r} \end{bmatrix}. \tag{5.4}$$

By using formulas (4.6)–(4.12) in section 4, we have the coefficients v_i, $0 \le i \le 3$, as

$$\begin{aligned} v_0 &= 0, \\ v_1 &= -\tfrac{2\sqrt[4]{3}}{9}|K|^{3/2} r^{-3/2}, \\ v_2 &= \tfrac{3^{3/4}}{108}|K|^{3/2}(3r^2\epsilon^2 - 1)(3\delta r - \sqrt{3})\ r^{-3/2}, \\ v_3 &= -\tfrac{3^{3/4}}{108}|K|^{3/2}(3r^2\epsilon^2 - 1)(3\delta r + \sqrt{3})\ r^{-3/2}, \end{aligned}$$

and the H^1-seminorm of the interpolation error $e = u - \Pi_2 u$ is

$$\begin{aligned} \|\nabla e\|^2_{L^2(K)} = \tfrac{|K|^3}{12960}[&r^2\epsilon^4(9+54\delta^2) + (7\epsilon^4 + 12\delta^2\epsilon^2 - 6\epsilon^2 + 16\delta^2) \\ &+ r^{-2}(33 + 6\delta^2 + 6\epsilon^2) + 15r^{-4}]. \end{aligned}$$

Now consider the optimal choice of the aspect ratio r for a given anisotropy ratio ϵ^{-1}. It is easy to verify that the minimum of $\|\nabla e\|_{L^2(K)}$ is attained when r solves the equation

$$(3 + 18\delta^2)r^6\epsilon^4 - (11 + 2\delta^2 + 2\epsilon^2)r^2 - 10 = 0.$$

Use the formula for roots of cubic polynomials, we have the only positive solution of the above equation,

$$r^2 = \frac{2}{3\epsilon^2}\sqrt{\frac{11 + 2\delta^2 + 2\epsilon^2}{1 + 6\delta^2}}\cos\left(\frac{\theta}{3}\right),$$

where

$$\theta = \cos^{-1}\left[45\epsilon^2\sqrt{\frac{1+6\delta^2}{(11+2\delta^2+2\epsilon^2)^3}}\right].$$

When $|\delta| \le \epsilon \ll 1$, we have $\theta \approx \frac{\pi}{2}$ and $r^2 \approx \sqrt{\frac{11}{3}}\epsilon^{-2}$. Therefore, the optimal aspect ratio r_* is approximately

$$r_* \approx \sqrt[4]{\frac{11}{3}}\,\epsilon^{-1} \approx 1.383\,\epsilon^{-1}.$$

With this aspect ratio, the interpolation error is

$$\|\nabla e_*\|^2_{L^2(K)} \approx (0.002196\epsilon^2 + 0.001235\delta^2)|K|^3.$$

Next we consider the case where K is an obtuse isosceles triangle aligned with the orientation of $\nabla^3 u$, i.e., $\phi_u = 0, \phi_v = 0$. Simplifying error formula (4.13), we end up with

$$\|\nabla e\|^2_{L^2(K)} = \tfrac{|K|^3}{12960}[15r^4\delta^2\epsilon^4 + r^2(33\delta^2\epsilon^4 + 6\epsilon^2\delta^2 + 6\epsilon^4) + (-6\epsilon^2\delta^2 + 16\epsilon^4 + 12\epsilon^2 + 7\delta^2) + r^{-2}(54 + 9\delta^2)].$$

The critical points of the right-hand side function are the solutions of

$$10r^6\delta^2\epsilon^4 + r^4(11\delta^2\epsilon^4 + 2\epsilon^2\delta^2 + 2\epsilon^4) - (18 + 3\delta^2) = 0.$$

Let $z = r^{-2}$; then z satisfies the cubic equation

$$z^3 - \frac{11\delta^2\epsilon^4 + 2\epsilon^2\delta^2 + 2\epsilon^4}{18 + 3\delta^2}z = \frac{10\delta^2\epsilon^4}{18 + 3\delta^2}.$$

By studying the positive solution of the above equation for all $|\delta| \le \epsilon \ll 1$, we conclude that the optimal value of the aspect ratio is in the range

$$1.047\epsilon^{-1} \le r_* \le 1.732\epsilon^{-1},$$

and the optimal interpolation error is in the range

$$0.003703|K|^3\epsilon^2 \le \|\nabla e_*\|^2_{L^2(K)} \le 0.007673|K|^3\epsilon^2.$$

We may study the H^1-error for the second type of function (5.2) in a similar way. The error formulas and the optimal aspect ratios are summarized in Table 5.1. A noticeable observation is that the optimal aspect ratio for both types of functions is proportional to the anisotropic ratio ϵ^{-1} of $\nabla^3 u$, and the H^1-seminorm of the error is proportional to ϵ. This is also true for the third type of function (5.3); see the numerical study of this case in the next section. Thus we conclude that when an element is aligned with the orientation of $\nabla^3 u$, the optimal aspect ratio that leads to the smallest H^1-seminorm of the quadratic interpolation errors is about cS_3, with $c \in (1.047, 1.732)$. With this direction and aspect ratio taken, the interpolation error $\|\nabla e\|^2_{L^2(K)}$ is of the magnitude $c(D_3)^2(S_3)^{-2}|K|^3$ for $c \in (0.001852, 0.007673)$. Here D_3 and S_3 are the magnitude and anisotropic ratio of $\nabla^3 u$ defined in section 3.

TABLE 5.1

H^1-seminorm of the quadratic interpolation error for functions (5.1) and (5.2) when element K is an isosceles triangle aligned with $\nabla^3 u$. $|K|$ and r are the area and aspect ratio of the triangle, respectively.

$u = \frac{1}{3!}(y - \delta x)(y^2 - \epsilon^2 x^2)$:

K = acute isosceles

$$\|\nabla e\|^2_{L^2(K)} = \tfrac{|K|^3}{12960}[r^2\epsilon^4(9 + 54\delta^2) + (7\epsilon^4 + 12\delta^2\epsilon^2 - 6\epsilon^2 + 16\delta^2) + r^{-2}(33 + 6\delta^2 + 6\epsilon^2) + 15r^{-4}],$$

$$r_* \approx 1.383\,\epsilon^{-1},$$

$$\|\nabla e_*\|^2_{L^2(K)} \approx (0.002196\epsilon^2 + 0.001235\delta^2)|K|^3.$$

K = obtuse isosceles

$$\|\nabla e\|^2_{L^2(K)} = \tfrac{|K|^3}{12960}[15r^4\delta^2\epsilon^4 + r^2(33\delta^2\epsilon^4 + 6\epsilon^2\delta^2 + 6\epsilon^4) + (-6\epsilon^2\delta^2 + 16\epsilon^4 + 12\epsilon^2 + 7\delta^2) + r^{-2}(54 + 9\delta^2)],$$

$$r_* \approx c\epsilon^{-1}, \text{ with } c \in (1.047, 1.732),$$

$$\|\nabla e_*\|^2_{L^2(K)} \approx c|K|^3\epsilon^2, \text{ with } c \in (0.003703, 0.007673).$$

$u = \frac{1}{3!}(y - \delta x)(y^2 + \epsilon^2 x^2)$:

K = acute isosceles

$$\|\nabla e\|^2_{L^2(K)} = \tfrac{|K|^3}{12960}[r^2\epsilon^4(9 + 54\delta^2) + (7\epsilon^4 - 12\delta^2\epsilon^2 + 6\epsilon^2 + 16\delta^2) + r^{-2}(33 + 6\delta^2 - 6\epsilon^2) + 15r^{-4}],$$

$$r_* \approx 1.383\,\epsilon^{-1},$$

$$\|\nabla e_*\|^2_{L^2(K)} \approx (0.003122\epsilon^2 + 0.001235\delta^2)|K|^3.$$

K = obtuse isosceles

$$\|\nabla e\|^2_{L^2(K)} = \tfrac{|K|^3}{12960}[15r^4\delta^2\epsilon^4 + r^2(33\delta^2\epsilon^4 - 6\epsilon^2\delta^2 + 6\epsilon^4) + (6\epsilon^2\delta^2 + 16\epsilon^4 - 12\epsilon^2 + 7\delta^2) + r^{-2}(54 + 9\delta^2)],$$

$$r_* \approx c\epsilon^{-1}, \text{ with } c \in (1.103, 1.743),$$

$$\|\nabla e_*\|^2_{L^2(K)} \approx c|K|^3\epsilon^2, \text{ with } c \in (0.001852, 0.004752).$$

Another important observation is that the optimal aspect ratio is about the same for both acute and obtuse isosceles triangles. This is in contrast to the case of linear interpolations, where a much higher accuracy can be achieved for acute isosceles triangles with a much larger aspect ratio than that for obtuse isosceles triangles. This phenomenon is termed as "superaccuracy" by Shewchuk in [18]. The study in this subsection indicates that there is no "superaccuracy" in favor of acute isosceles triangles for quadratic interpolation of general cubic functions.

5.2. L^2-norm of the interpolation error. For the L^2-norm of the interpolation error, we may study similarly the optimal choice of the aspect ratio r for the first two types of functions (5.1) and (5.2). The results are summarized in Table 5.2 for

TABLE 5.2

L^2-norm of the quadratic interpolation error for functions (5.1) *and* (5.2) *when element K is an isosceles triangle aligned with $\nabla^3 u$. $|K|$ and r are the area and aspect ratio of the triangle, respectively.*

$u = \frac{1}{3!}(y - \delta x)(y^2 - \epsilon^2 x^2)$:

K = acute isosceles

$$\|e\|^2_{L^2(K)} = \frac{\sqrt{3}|K|^4}{272160}[27\epsilon^4\delta^2 r^3 + 3(\epsilon^2 + 2\delta^2)\epsilon^2 r + (11\delta^2 - 10\epsilon^2)r^{-1} + 19r^{-3}],$$

$$r_* \approx c\epsilon^{-1}, \text{ with } c \in (0.9265, 1.732),$$

$$\|e_*\|^2_{L^2(K)} \approx c|K|^4\epsilon^3, \text{ with } c \in (0.00001959, 0.0003486).$$

K = obtuse isosceles

$$\|e\|^2_{L^2(K)} = \frac{\sqrt{3}|K|^4}{272160}[19\epsilon^4\delta^2 r^3 + (11\epsilon^2 - 10\delta^2)\epsilon^2 r + 3(\delta^2 + 2\epsilon^2)r^{-1} + 27r^{-3}],$$

$$r_* \approx c\epsilon^{-1}, \text{ with } c \in (1.079, 1.732),$$

$$\|e_*\|^2_{L^2(K)} \approx c|K|^4\epsilon^3, \text{ with } c \in (0.0001764, 0.0003486).$$

$u = \frac{1}{3!}(y - \delta x)(y^2 + \epsilon^2 x^2)$:

K = acute isosceles

$$\|e\|^2_{L^2(K)} = \frac{\sqrt{3}|K|^4}{272160}[27\epsilon^4\delta^2 r^3 + 3(\epsilon^2 - 2\delta^2)\epsilon^2 r + (11\delta^2 + 10\epsilon^2)r^{-1} + 19r^{-3}],$$

$$r_* \approx c\epsilon^{-1}, \text{ with } c \in (1.000, 2.517),$$

$$\|e_*\|^2_{L^2(K)} \approx c|K|^4\epsilon^3, \text{ with } c \in (0.00008092, 0.0004073).$$

K = obtuse isosceles

$$\|e\|^2_{L^2(K)} = \frac{\sqrt{3}|K|^4}{272160}[19\epsilon^4\delta^2 r^3 + (11\epsilon^2 + 10\delta^2)\epsilon^2 r + 3(\delta^2 - 2\epsilon^2)r^{-1} + 27r^{-3}],$$

$$r_* \approx c\epsilon^{-1}, \text{ with } c \in (1.000, 1.567),$$

$$\|e_*\|^2_{L^2(K)} \approx c|K|^4\epsilon^3, \text{ with } c \in (0.0001300, 0.0004073).$$

the cases $\phi_u = 0, \phi_v = \frac{\pi}{2}$ (aligned acute isosceles triangle) and $\phi_u = 0, \phi_v = 0$ (aligned obtuse isosceles triangle) separately. When the triangle is aligned with the orientation of $\nabla^3 u$, the aspect ratio leading to the smallest L^2-error is approximately equal to cS_3, with $c \in (0.9264, 2.517)$. With this aspect ratio, $\|e\|^2_{L^2(K)}$ is of the magnitude $c(D_3)^2(S_3)^{-3}|K|^4$ for $c \in (1.959 \times 10^{-5}, 4.072 \times 10^{-4})$.

It is interesting to note that when a triangle is aligned with $\nabla^3 u$, the optimal aspect ratios for both the H^1-seminorm and L^2-norm are close to the anisotropic ratio of $\nabla^3 u$. In practice, an aspect ratio $r \approx S(\nabla^3 u)$ can be used generally.

. . . 2. We emphasize the fact that the optimal aspect ratios listed in Tables 5.1 and 5.2 are derived under the assumption that K is aligned with the orientation of $\nabla^3 u$ defined in section 3. This orientation direction is only an estimate

of the direction along which the absolute value of third order directional derivative is about the smallest, while along its perpendicular direction it is about the largest. It is close to, but may not be exactly, the triangle orientation leading to the minimum interpolation error among all possible choices. Therefore, for elements aligned with the orientation of $\nabla^3 u$ we may expect only a nearly optimal interpolation error. Unlike the case of linear interpolation studied in [6], we do not know precisely in what alignment direction the quadratic interpolation error would be minimum (among all possible triangle shapes and orientations). Furthermore, it seems that the optimal choice of this direction is dependent on the norm used to measure the error. For instance, if we consider the L^2-norm of the interpolation error for function $u(x,y) = \frac{1}{6}xy^2$, then $\|e\|^2_{L^2(K)} = \frac{11\sqrt{3}}{272160}|K|^4 r^{-1}$ and $\frac{3\sqrt{3}}{272160}|K|^4 r^{-1}$ on an acute/obtuse isosceles triangle K aligned with the x-axis, respectively. In this case, the x-axis and a large r are good choices for the alignment and aspect ratio. On the other hand, if we consider the H^1-seminorm of the error for the above function, we have $\|\nabla e\|^2_{L^2(K)} = \frac{1}{12960}|K|^3(16 + 6r^{-2})$ and $\frac{1}{12960}|K|^3(7 + 9r^{-2})$ on an acute/obtuse isosceles triangle aligned with the x-axis, respectively. In this case, using triangles of high aspect ratios helps little to reduce the H^1-error. We may consider in this case $\nabla^3 u$ isotropic with no preferred alignment direction.

. . . 3. In a recent work studying mesh quality measures and variational mesh generation methods [14], Huang suggested use the following matrix to determine the element orientation and aspect ratio in the case of quadratic interpolation:

$$H(\nabla u) = |\nabla^2(\partial_x u)| + |\nabla^2(\partial_y u)|,$$

where $|A| = (A^T A)^{1/2}$ for a matrix A. More precisely, let $(\lambda_1, \boldsymbol{v}_1)$ and $(\lambda_2, \boldsymbol{v}_2)$ be the eigenpairs of $H(\nabla u)$. He suggested choosing the element length scale to be $1/\sqrt{\lambda_i}$ in the $\boldsymbol{v}_i$ direction, $i = 1, 2$, i.e., to use $\boldsymbol{v}_1$ as element orientation and $\sqrt{\lambda_2/\lambda_1}$ as element aspect ratio (assume $\lambda_1 \le \lambda_2$). We believe $H(\nabla u)$ cannot accurately characterize the anisotropic behavior of $\nabla^3 u$, and the guidelines based on $H(\nabla u)$ may not be helpful. While there is no numerical result in [14] for quadratic interpolation, we tested this choice for the function $u = y^3 + (\epsilon x)^3$, i.e., our Example 1 in section 3.3. In this case

$$H(\nabla u) = \begin{bmatrix} 6\epsilon^3 & 0 \\ 0 & 6 \end{bmatrix}.$$

Its eigenvalues are $\lambda_1 = 6\epsilon^3, \lambda_2 = 6$, and the corresponding eigenvectors are along the x-axis and y-axis. Suppose K is an isosceles triangle aligned with the x-axis and of aspect ratio r; then we may derive the exact formula of the interpolation error. Indeed, it is found that

$$\|\nabla e\|^2_{L^2(K)} = \frac{|K|^3}{12960}(33r^{-2} + 15r^{-4} + 54\epsilon^6 r^2),$$
$$\|e\|^2_{L^2(K)} = \frac{\sqrt{3}|K|^4}{272160}(19r^{-3} + 27\epsilon^6 r^3)$$

for acute isosceles triangle K and that

$$\|\nabla e\|^2_{L^2(K)} = \frac{|K|^3}{12960}[54r^{-2} + \epsilon^6(15r^4 + 33r^2)],$$
$$\|e\|^2_{L^2(K)} = \frac{\sqrt{3}|K|^4}{272160}(27r^{-3} + 19\epsilon^6 r^3)$$

for obtuse isosceles triangle K. If r is chosen as $\sqrt{\lambda_2/\lambda_1} = \epsilon^{-3/2}$ as determined in [14], then $\|\nabla e\|^2_{L^2(K)} = O(1) \cdot |K|^3$ for obtuse isosceles triangle K. This H^1-error is in the same magnitude as that over a shape regular triangle of the same area. In other words, using obtuse anisotropic elements with such an aspect ratio helps little to reduce the H^1-error. For the L^2-error, $r = \epsilon^{-3/2}$ leads to $\|e\|^2_{L^2(K)} = O(\epsilon^{3/2}) \cdot |K|^4$ for both acute and obtuse isosceles triangles K. They are a factor of $O(\epsilon^{-3/2})$ larger than with the choice suggested in this paper.

6. Effects of element orientation, aspect ratio, and internal angles: A numerical study. We present in this section a numerical study on the effects of the element alignment, aspect ratio, and internal angles in quadratic interpolations. Let K be a triangle of unit area but in general shape and orientation. Since, under rotation of the coordinates, any cubic function can be written as a multiple of the three types of functions (5.1)–(5.3), we study only the interpolation errors over K for these functions. Note that they are all of anisotropic ratio ϵ^{-1} and approximately of magnitude 1. We test with various values of ϵ in $(0, 1)$. We also experiment with different δ values for functions (5.1) and (5.2) and with various γ for $|\gamma| \le \tan^{-1}(\epsilon)$ for function (5.3).

We calculate exactly the H^1-seminorm and L^2-norm of the error $u - \Pi_2 u$ over K by a numerical quadrature for triangles based on 28 Fekete points described in [20]. This quadrature formula is exact for integrands of total degree up to 6, which is sufficient to evaluate precisely the H^1- and L^2-error for interpolation of cubic functions. We study mainly (1) the effects of the triangle aspect ratios when the element is aligned with $\nabla^3 u$; (2) the effects of the element alignments; and (3) the effects of the element internal angles. Because the numerical results for functions (5.1) and (5.2) are very similar, we report only those for (5.1). In particular, we report the results for (5.1) with $\delta = 0$ and $\delta = \epsilon$. The errors with general $|\delta| \le \epsilon$ are in between these two cases. Our main observations are the following:

(1) , , , r: If the triangle is aligned with the orientation of $\nabla^3 u$, then the optimal aspect ratios to produce the smallest interpolation error in both L^2- and H^2-norms are close to the anisotropic ratio of $\nabla^3 u$. We plot in Figure 5 the H^1-seminorm and L^2-, L^1-, and L^∞-norms of the error versus the aspect ratio of the element for test functions of different anisotropic ratios. The linear dependency of the optimal r on the anisotropic ratio ϵ^{-1} is clearly observed. In addition, with the optimal aspect ratio, the H^1-seminorm of the interpolation error is proportional to ϵ, and the L^2-, L^1-, and L^∞-norms are proportional to $\epsilon^{1.5}$.

(2) , , , ϕ_u: We study the effects of the element alignment by varying the angle ϕ_u in the SVD of the affine mapping for it; see section 2. We plot in Figure 6 the L^2-norm and H^1-seminorm of the error for test functions of various anisotropic ratios. In all the cases, the smallest interpolation error occurs when ϕ_u is close to 0, i.e., when the element is oriented in about the same direction of $\nabla^3 u$. Furthermore, this conclusion is true regardless of whether the element is an acute or obtuse isosceles triangle. It indicates that mesh alignment is crucial for minimizing the interpolation error.

(3) , , , ϕ_v: The internal angles of a triangular element are controlled by ϕ_v in the SVD of its affine mapping. When $\phi_v = m\pi/3$, the triangle is an obtuse isosceles triangle, and when $\phi_v = (2m + 1)\pi/6$, it is an acute isosceles triangle. We plot in Figures 7 and 8 the L^2- and H^1-errors versus ϕ_v for elements with $\phi_u = 0$ and $r = \epsilon^{-1}, 10\epsilon^{-1}$. When the aspect ratio $r = \epsilon^{-1}$, the L^2- and H^1-errors do not depend much on the value of ϕ_v, and thus the element internal angles have little

effect on the interpolation error. When the aspect ratio $r = 10\epsilon^{-1}$, which is far away from the optimal values, the H^1-seminorm of the error is about the smallest when $\phi_v = \pi/6, \pi/2, 5\pi/6$, which correspond to acute isosceles triangles, and the largest error occurs at $\phi_v = 0, \pi/3, 2\pi/3, \pi$, which correspond to obtuse isosceles triangles. The L^2-norm is still insensitive to the internal angles. Hence, we conclude that when proper aspect ratio $r \approx S(\nabla^3 u)$ is chosen and proper alignment is maintained, the H^1-seminorm of the interpolation error is insensitive to the element internal angles. If a much larger aspect ratio is used, then the H^1-error depends on the internal angles. The larger the maximum internal angle is, the larger the H^1-error. In this case, the maximum angle condition is essential [2]. The L^2-norm of the interpolation error is always insensitive to the internal angles.

7. Conclusion and discussions. In the previous sections we described how to measure the anisotropic behavior of the third order derivative $\nabla^3 u$ at a fixed point based on the distribution of the third order directional derivatives at the point. In particular, the orientation of $\nabla^3 u$ is defined as the direction along which the third order directional derivative is about the smallest, while along the perpendicular direction it is about the largest. The anisotropic ratio $S(\nabla^3 u)$ measures the strength of the anisotropic behavior of $\nabla^3 u$. These quantities are invariant under translation and rotation of the independent variables. Then we considered the model problem of quadratic interpolation of cubic functions over a triangular element. In particular, we studied the optimal choice of the aspect ratio for elements aligned with the orientation of $\nabla^3 u$. It turns out that (1) when an element is aligned with the orientation of $\nabla^3 u$, both the H^1-seminorm and L^2-norm of the error are about the smallest if its aspect ratio is approximately equal to $S(\nabla^3 u)$. This is true regardless of whether the element is an acute or an obtuse isosceles triangle. In practice, we may use the orientation of $\nabla^3 u$ for the mesh alignment direction and the anisotropic ratio $S(\nabla^3 u)$ for the element aspect ratio. Our study also indicates that unlike the case of linear interpolation [18, 6], there is no "superaccuracy" in favor of the acute isosceles triangles for quadratic interpolation in general. While there is no rigorous proof of it yet, we believe the reason is because $\nabla^3 u$ has richer geometric features than a triangle can capture. (Indeed, $\nabla^3 u$ has four degree of freedoms, while a triangle has only three: area, aspect ratio, and orientation.) (2) When an element is aligned with $\nabla^3 u$ and is of aspect ratio $S(\nabla^3 u)$, the H^1-seminorm of the error is proportional to $[S(\nabla^3 u)]^{-1}$, and the L^2-norm of the error is proportional to $[S(\nabla^3 u)]^{-3/2}$. Both of them are insensitive to the internal angles of the element. However, if the element aspect ratio is much larger than the anisotropic ratio of $\nabla^3 u$, the H^1-seminorm of the error increases greatly as the largest internal angle increases. The maximum angle condition is essential in this situation. The L^2-error is always insensitive to the internal angles.

The definitions of the orientation and the anisotropic ratio for $\nabla^3 u$ can be generalized to the case of $\nabla^m u$ for $m > 3$. It is also possible to derive more precise and coordinate independent error estimates for higher order interpolation based on these anisotropic measures; see [7]. These results can be used to better understand and improve the anisotropic mesh generation and local refinement. They can also be used for global mesh refinement strategies like the r-refinement or the moving mesh method. In these techniques, one typically needs to define a mesh metric (or monitor function) $M(\boldsymbol{x})$ and looks for a mesh that is quasi-uniform under the metric [3, 4, 5, 8, 9, 15]. For quadratic interpolation, one may choose the metric in the following form based on the anisotropic behavior of the third order derivatives of interpolated function u:

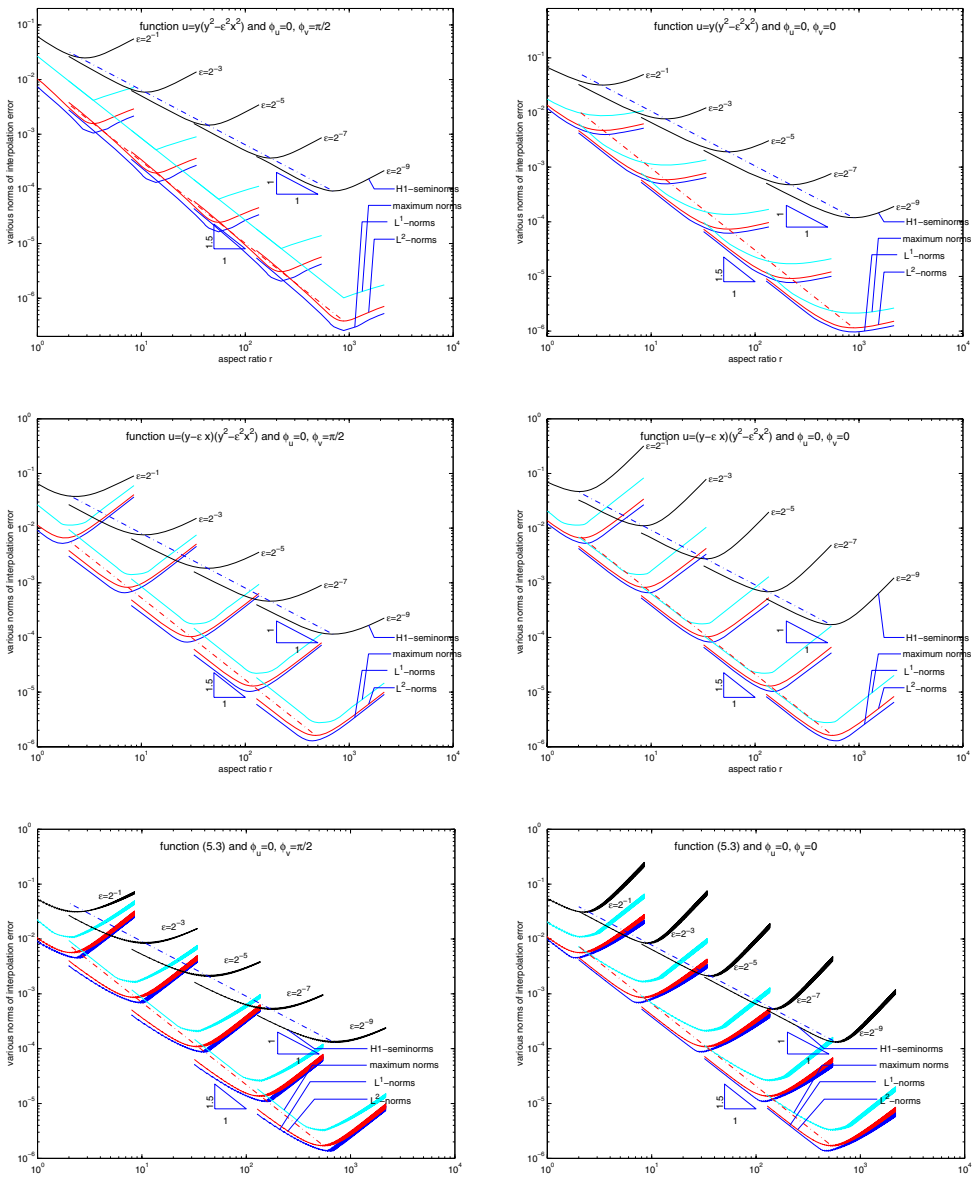

FIG. 5. *The H^1-seminorm and L^1-, L^2-, and maximum norms of the quadratic interpolation errors on an aligned element versus the element aspect ratio r.* (i) *Upper panel: for function $u = y(y^2 - \epsilon x^2)$;* (ii) *middle panel: for function $u = (y - \epsilon x)(y^2 - \epsilon^2 x^2)$;* (iii) *bottom panel: for function* (5.3) *with various $\gamma \in [0, \arctan(\epsilon)]$. The left panel is for the case $\phi_u = 0$ and $\phi_v = \pi/2$ (i.e., aligned acute isosceles triangle), and the right panel is for the case $\phi_u = 0$ and $\phi_v = 0$ (i.e., aligned obtuse isosceles triangle).*

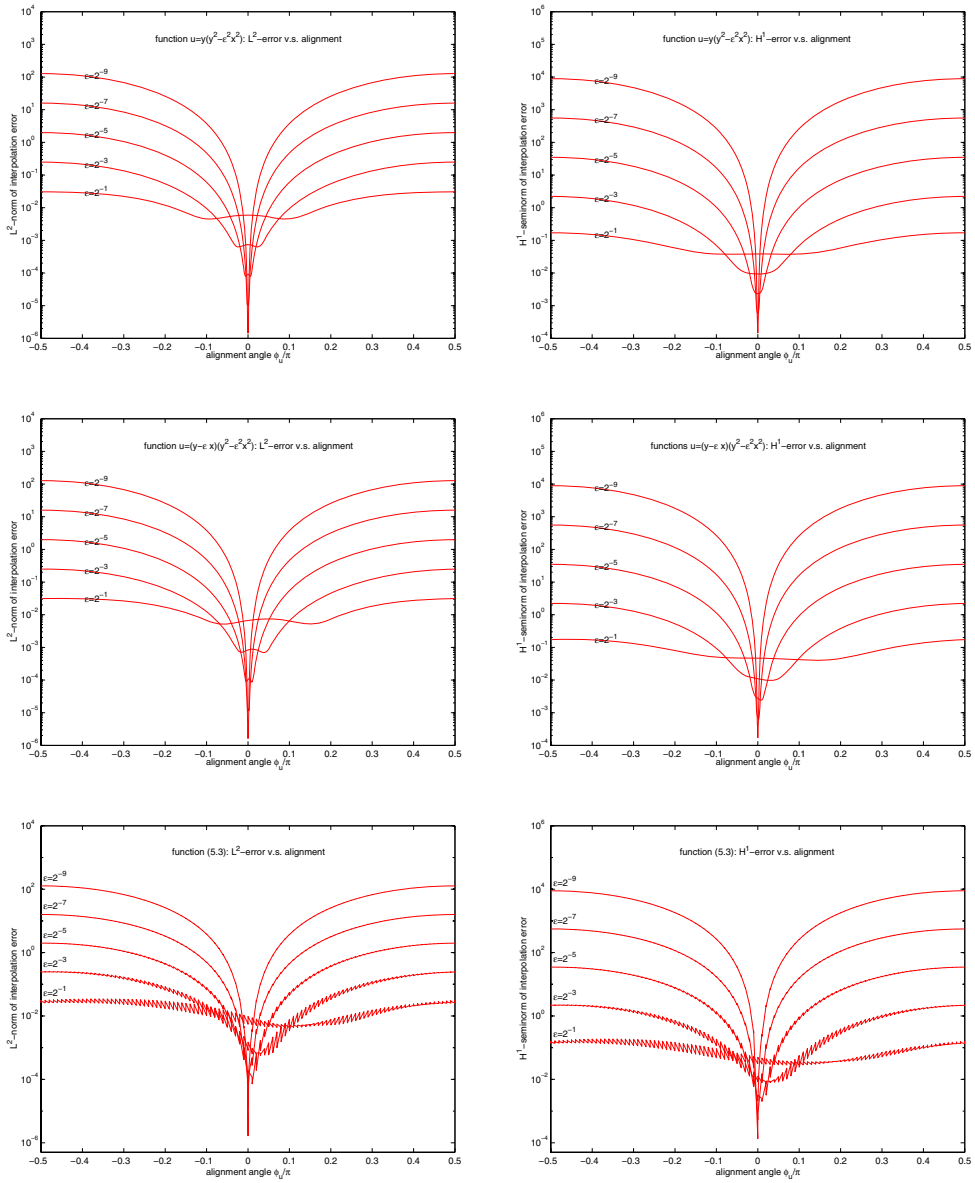

FIG. 6. *The L^2-norm (left) and H^1-seminorm (right) of the quadratic interpolation errors on an obtuse isosceles element (i.e., $\phi_v = 0$) versus its alignment angle ϕ_u/π for the case $r = \epsilon^{-1}$.* (i) *Upper panel: for function $u = y(y^2 - \epsilon x^2)$;* (ii) *middle panel: for function $u = (y - \epsilon x)(y^2 - \epsilon^2 x^2)$;* (iii) *bottom panel: for function* (5.3) *with various $\gamma \in [0, \arctan(\epsilon)]$.*

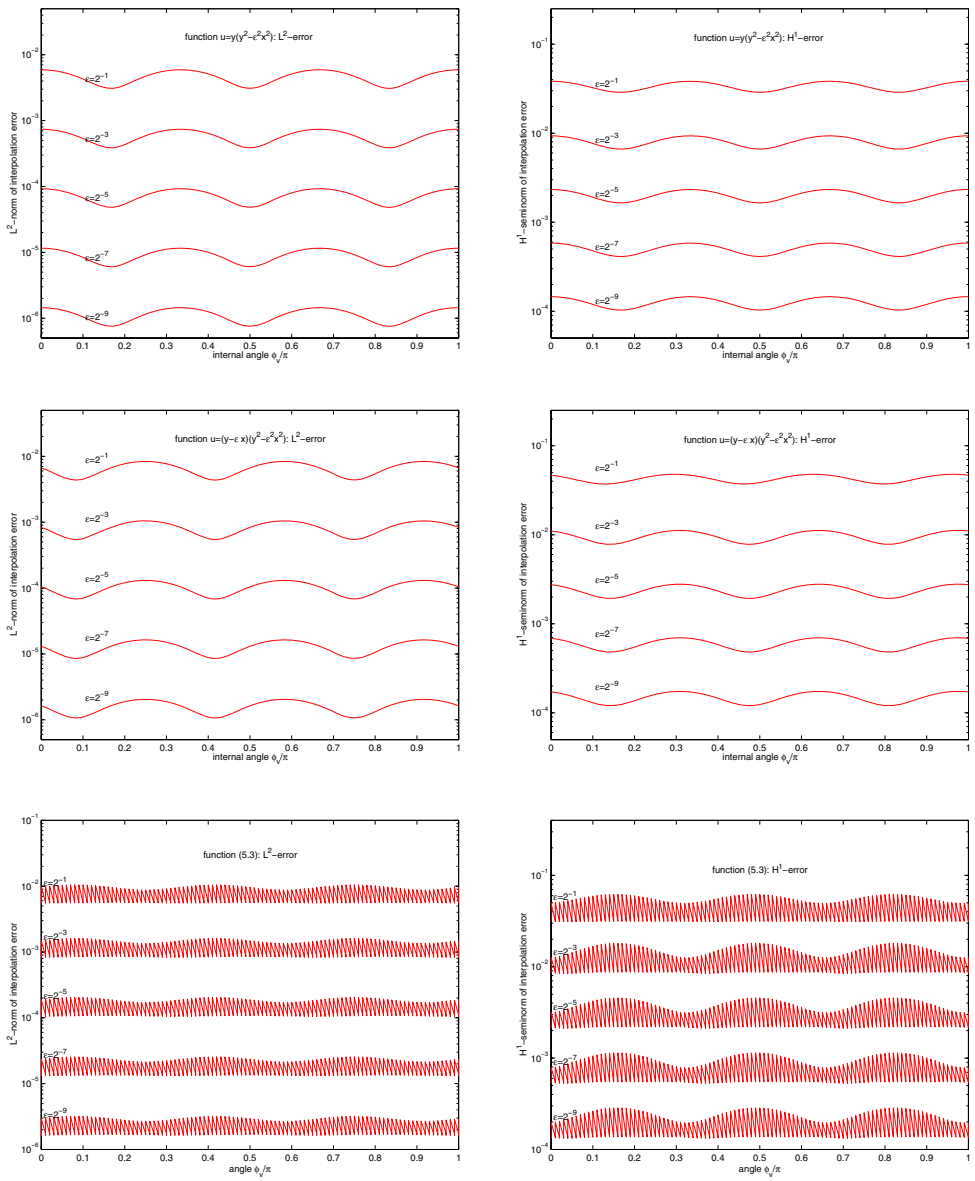

FIG. 7. *The L^2-norm (left) and H^1-seminorm (right) of the quadratic interpolation errors on an element versus the angle ϕ_v that controls the element internal angles. The element is always aligned with $\nabla^3 u$ (i.e., $\phi_u = 0$), and its aspect ratio is fixed as $r = \epsilon^{-1}$.* (i) *Upper panel: for function $u = y(y^2 - \epsilon x^2)$;* (ii) *middle panel: for function $u = (y - \epsilon x)(y^2 - \epsilon^2 x^2)$;* (iii) *bottom panel: for function* (5.3) *with various $\gamma \in [0, \arctan(\epsilon)]$.*

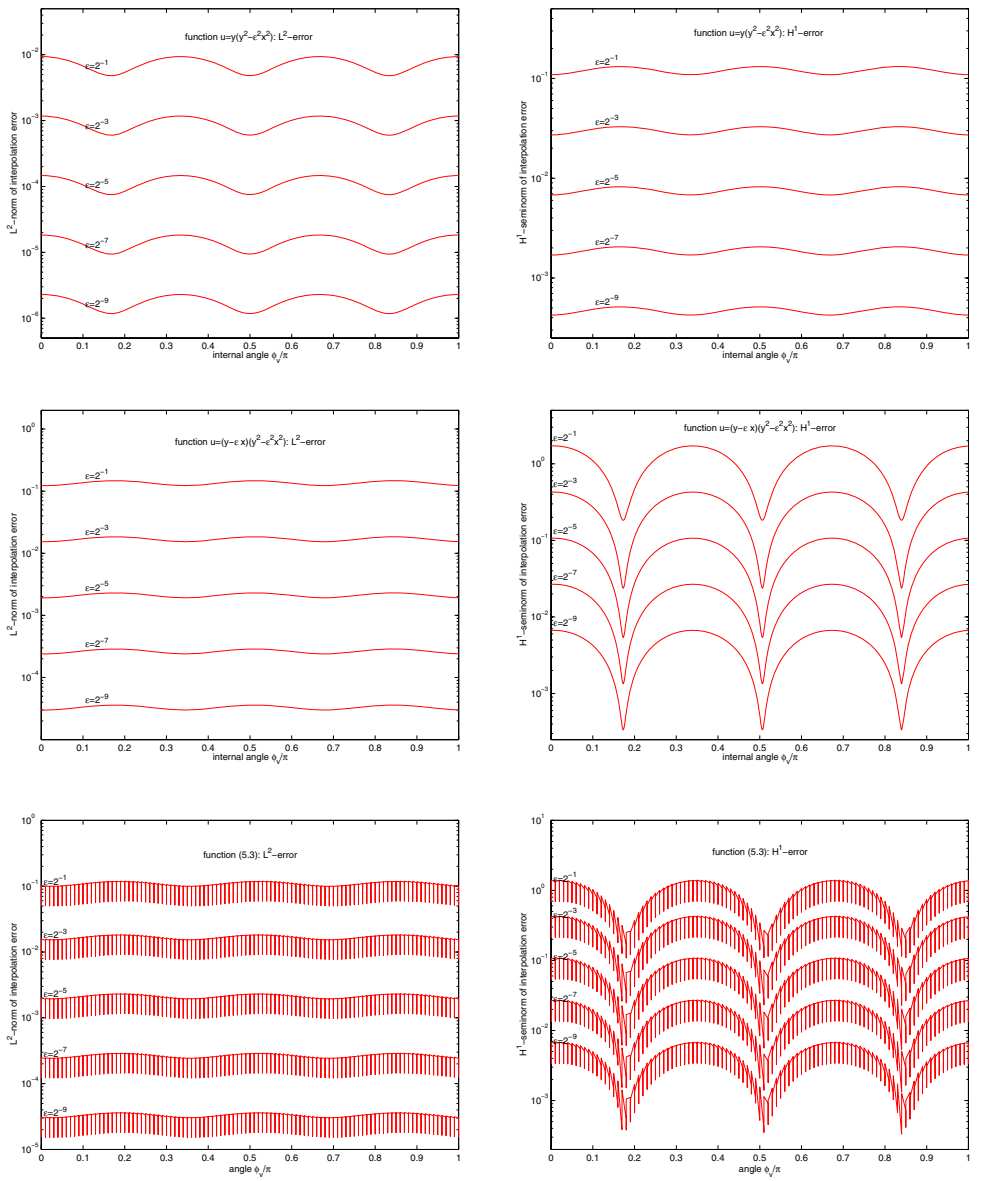

FIG. 8. *The L^2-norm (left) and H^1-seminorm (right) of the quadratic interpolation errors on an element versus the angle ϕ_v that controls the element internal angles. The element is always aligned with $\nabla^3 u$ (i.e., $\phi_u = 0$), and its aspect ratio is fixed as $r = 10\epsilon^{-1}$.* (i) *Upper panel: for function $u = y(y^2 - \epsilon x^2)$;* (ii) *middle panel: for function $u = (y - \epsilon x)(y^2 - \epsilon^2 x^2)$;* (iii) *bottom panel: for function* (5.3) *with various $\gamma \in [0, \arctan(\epsilon)]$.*

$$M(\boldsymbol{x}) = R_\phi \begin{bmatrix} \mu_1 & \\ & \mu_2 \end{bmatrix} R_\phi^T, \tag{7.1}$$

where ϕ is the angle (with the x-axis) of the orientation of $\nabla^3 u$,

$$\mu_1/\mu_2 \approx [S_3]^2, \tag{7.2}$$

and the determinant of $M(\boldsymbol{x})$ is taken as

$$\mu_1\mu_2 = \text{const} \cdot (D_3/S_3)^{4/3} \tag{7.3}$$

for minimizing the H^1-seminorm of the interpolation error and as

$$\mu_1\mu_2 = \text{const} \cdot D_3(S_3)^{-3/2} \tag{7.4}$$

for minimizing the L^2-norm of the interpolation error. Some modification is clearly needed when the function is almost unidirectional (i.e., the anisotropic ratio is ∞).

Finally, we would like to emphasize that the definition of orientation and anisotropic ratio for $\nabla^3 u$ described in [7] and here is only one possible way to characterize the anisotropic behavior of $\nabla^3 u$. Other definitions, possibly dependent on the norms used to measure the errors, can be introduced. In addition, when problems of multicomponents are considered, the anisotropic behavior of each variable should be carefully combined to produce an ideal direction for mesh alignment and an appropriate aspect ratio. These topics need further investigation.

AVERAGING TECHNIQUES FOR THE A POSTERIORI BEM ERROR CONTROL FOR A HYPERSINGULAR INTEGRAL EQUATION IN TWO DIMENSIONS*

CARSTEN CARSTENSEN† AND DIRK PRAETORIUS‡

Abstract. Averaging techniques or gradient recovery techniques are frequently employed tools for the a posteriori finite element error analysis. Their very recent mathematical justification for partial differential equations allows unstructured meshes and nonsmooth exact solutions. This paper establishes an averaging technique for the hypersingular integral equation on a one-dimensional boundary and presents numerical examples that show averaging techniques can be employed for an effective mesh-refining algorithm. For the discussed test examples, the provided estimator estimates the (in general unknown) error very accurately in the sense that the quotient *error/estimator* stays bounded with a value close to 1.

Key words. averaging techniques, ZZ error estimator, hypersingular integral equation, boundary element method, Galerkin method, a posteriori error estimate, adaptive algorithm

DOI. 10.1137/050623930

1. Introduction.

This paper is devoted to the numerical treatment of the hypersingular integral equation

$$Wu = f \quad \text{on } \Gamma \tag{1.1}$$

on the relatively open boundary piece Γ of $\partial\Omega \subseteq \mathbb{R}^2$ with the hypersingular integral operator

$$(Wu)(x) = \frac{1}{\pi}\frac{\partial}{\partial n_x}\int_\Gamma u(y)\,\frac{\partial}{\partial n_y}\log|x-y|\,ds_y. \tag{1.2}$$

Here, n_x, n_y denote the outer unit normal vectors in x and y, respectively, and ds_y denotes the surface integration on Γ with respect to the variable y. For finite element methods it has recently been shown that any averaging technique [ZZ] yields reliable error estimators [CB, AC, CFuI, CFuII, CFuIII, C2]. This paper establishes analogous results for the Galerkin boundary element method (BEM) for the hypersingular integral equation (1.1). The main idea, also employed in [HSWW], goes back at least to an Oberwolfach conference in the 1980s. The first application to integral equations provides an a posteriori error analysis for Symm's integral equation [CP]. Compared with [CP], the technical details in this paper—such as an approximation result in $H^{1/2}(\Gamma)$—are more involved; cf. Theorem 3.3 below. An overview of other types of a posteriori error estimates for the Galerkin BEM can be found in [CFa].

Let $\mathcal{H}$ denote the Hilbert space which allows the solution of (1.1) for a given $f \in \mathcal{H}^*$; see section 2 for the precise setting. Let $\mathcal{T}_H$ be a given triangulation of Γ with mesh-size H, and let $\mathcal{T}_h$ be obtained by uniform refinements of $\mathcal{T}_H$. We consider the discrete spaces $\mathcal{S}_0^1(\mathcal{T}_h)$ and $\mathcal{S}_0^2(\mathcal{T}_H)$ consisting of all globally continuous and $\mathcal{T}_h$-piecewise affine (resp., $\mathcal{T}_H$-piecewise quadratic) splines (with respect to the arclength) which are in $\mathcal{H}$. The corresponding Galerkin projections (with respect to the energy scalar product $\langle\!\langle \cdot\,, \cdot \rangle\!\rangle$; cf. (2.11)) are denoted with $\mathbb{G}_h$ and $\mathbb{G}_H$, respectively.

Let u denote the (in general, [illegible]) exact solution and $u_h = \mathbb{G}_h u \in \mathcal{S}_0^1(\mathcal{T}_h)$ be its Galerkin approximation, and consider the error estimator

$$\eta_M := |\!|\!| u_h - \mathbb{G}_H u_h |\!|\!| = \min_{v_H \in \mathcal{S}_0^2(\mathcal{T}_H)} |\!|\!| u_h - v_H |\!|\!|, \tag{1.3}$$

where $|\!|\!| v |\!|\!| := \langle\!\langle v\,, v \rangle\!\rangle^{1/2}$ denotes the energy norm. Then, Theorem 4.2 implies that

$$C_{\mathrm{eff}}\eta_M - \text{higher-order terms} \le |\!|\!| u - u_h |\!|\!| \le C_{\mathrm{rel}}\eta_M + \text{higher-order terms}, \tag{1.4}$$

where the higher-order terms depend only on the smoothness of the exact solution u. More precisely, (1.4) holds provided that u is $\mathcal{T}_H$-piecewise in $H^{2+\varepsilon}$ for some $\varepsilon > 0$. For the lower estimate in (1.4), we call the error estimator η_M [illegible]. For the upper estimate in (1.4), we say that η_M is [illegible].

[illegible] 1. In order to define spaces $H^m(\mathcal{T}_H)$ of all $\mathcal{T}_H$-piecewise H^m-functions, one has to assume further regularity of the boundary piece Γ provided that $m > 1$. For the analysis below, we restrict our discussion to polygonal boundary pieces.

In contrast to the L^2 norm on Γ, which satisfies $\|\cdot\|^2_{L^2(\Gamma)} = \sum_{\gamma \in \mathcal{T}_H} \|\cdot\|^2_{L^2(\gamma)}$, the energy norm is nonlocal. Thus, the error estimator η_M cannot be used directly for an adaptive mesh-refinement algorithm. Let H indicate the coarse triangulation $\mathcal{T}_H$ and associated quantities v_H, $\mathbb{G}_H$ as well as the (local) mesh-size as a weight in $L^2(\Gamma)$ norms, e.g., in (1.5) below. Replacing the (best approximation) operator $\mathbb{G}_H$ in the definition of η_M by an arbitrary averaging operator $\mathcal{A}_H$ onto $\mathcal{S}_0^2(\mathcal{T}_H)$, we obtain reliable error estimators $\eta_A := |\!|\!| u_h - \mathcal{A}_H u_h |\!|\!|$. By use of an inverse estimate provided in section 3.3, one verifies that

$$\mu_A := \|H^{1/2}(u_h - \mathcal{A}_H u_h)'\|_{L^2(\Gamma)} \le C_{\mathrm{inv}}\eta_A. \tag{1.5}$$

Here and throughout the paper, $(\cdot)' = \partial/\partial s$ denotes differentiation with respect to the arclengths along edges. In particular, this provides efficient error estimators

$$\mu_M := \|H^{1/2}(u_h - \mathbb{G}_H u_h)'\|_{L^2(\Gamma)} \quad \text{and} \quad \mu_\Pi := \|H^{1/2}(u_h' - \Pi_H u_h')\|_{L^2(\Gamma)}, \tag{1.6}$$

where Π_H denotes the L^2 projection onto $\mathcal{P}^1(\mathcal{T}_H)$, i.e., the $\mathcal{T}_H$-piecewise affine functions. Moreover, there also holds $\eta_M \le C\mu_M$ with some constant $C > 0$; i.e., μ_M is also reliable. Since the L^2 norm is local, the μ-estimators can be employed for an adaptive mesh-refinement.

The paper is organized as follows: Section 2 collects the preliminaries on the functional analytic setting of the hypersingular integral equation. Section 3 provides the necessary background on finite element approximation. We prove a local inverse estimate for the $H^{1/2}(\Gamma)$ norm and recall an approximation result from [C1] which is applied to the nodal interpolation operator. Section 4 is the core of this article and proves the reliability and efficiency results for the introduced error estimators. Section 5 provides details on the numerical implementation and the new adaptive mesh-refinement strategy. Four numerical experiments in section 6 conclude the work.

The examples cover a wide range, from an example with smooth solution (covered by the theory in section 4), to two examples with weak corner singularities, up to a final example on a slit which lacks almost any regularity. Even for this case, the proposed adaptive strategy recovers the optimal experimental convergence rate (in terms of number of elements).

2. Preliminaries on the functional analytic setting.

2.1. Fractional-order Sobolev spaces. Let Ω be a bounded domain in $\mathbb{R}^2$ with Lipschitz boundary $\partial\Omega$. Given $0 < \alpha \leq 1$, the Sobolev space $H^\alpha(\partial\Omega)$ is the set of all real-valued functions on $\partial\Omega$ which are the traces of functions in $H^{\alpha+1/2}(\mathbb{R}^2)$ to $\partial\Omega$,

$$H^\alpha(\partial\Omega) := \{u|_{\partial\Omega} \,:\, u \in H^{\alpha+1/2}(\mathbb{R}^2)\}. \tag{2.1}$$

Moreover, it is consistent to define $H^0(\partial\Omega) := L^2(\partial\Omega)$ and to define Sobolev spaces of negative order by duality:

$$H^{-\alpha}(\partial\Omega) := H^\alpha(\partial\Omega)^* := \text{ dual of } H^\alpha(\partial\Omega), \tag{2.2}$$

with corresponding norms and duality brackets $\langle\cdot\,,\cdot\rangle$ which extend the $L^2(\partial\Omega)$ scalar product. For the hypersingular integral equation on $\partial\Omega$, one considers the subspaces $H^\alpha_0(\partial\Omega)$ to factor the constant functions out:

$$H^\alpha_0(\partial\Omega) := H^\alpha(\partial\Omega)/\mathbb{R} = \{u \in H^\alpha(\partial\Omega) \,:\, \langle 1\,, u\rangle = 0\}, \tag{2.3}$$

where 1 denotes the constant function. For a (relatively) open subset $\omega \subseteq \Gamma$ and $\alpha \geq 0$, we define the fractional-order Sobolev space $H^\alpha(\omega)$ by extension:

$$H^\alpha(\omega) := \{u|_\omega \,:\, u \in H^\alpha(\partial\Omega)\}, \tag{2.4}$$

where the norm of $u \in H^\alpha(\omega)$ is defined as the minimal norm of an extension, i.e.,

$$\|u\|_{H^\alpha(\omega)} := \inf\{\|\widehat{u}\|_{H^\alpha(\partial\Omega)} \,:\, \widehat{u} \in H^\alpha(\partial\Omega) \text{ with } \widehat{u}|_\omega = u\}. \tag{2.5}$$

Furthermore, there are Sobolev spaces $\widetilde{H}^\alpha(\omega)$,

$$\widetilde{H}^\alpha(\omega) := \{u \in H^\alpha(\partial\Omega) \,:\, \operatorname{supp}(u) \subseteq \overline{\omega}\}, \tag{2.6}$$

associated with the usual $H^\alpha(\omega)$ norm. The corresponding spaces of negative order are again defined by duality:

$$H^{-\alpha}(\omega) = \widetilde{H}^\alpha(\omega)^* \quad \text{and} \quad \widetilde{H}^{-\alpha}(\omega) = H^\alpha(\omega)^*. \tag{2.7}$$

2. Note that $\widetilde{H}^\alpha(\partial\Omega) = H^\alpha(\partial\Omega)$. For $\omega \subsetneq \partial\Omega$, there holds only $\widetilde{H}^\alpha(\omega) \subseteq H^\alpha(\omega)$ with

$$\|u\|_{H^\alpha(\omega)} \leq \|u\|_{\widetilde{H}^\alpha(\omega)} \quad \text{for } u \in \widetilde{H}^\alpha(\omega). \tag{2.8}$$

3. Note that according to Sobolev's inequality in one dimension each function $u \in H^\alpha(\omega)$ with $\alpha > 1/2$ is continuous. Moreover, each function $u \in H^1(\omega)$ is absolutely continuous; i.e., there holds the fundamental theorem of calculus.

2.2. Hypersingular integral operator and energy norm. Let Γ be either the closed boundary $\Gamma = \partial\Omega$ or a (relatively) open boundary piece $\omega \subseteq \partial\Omega$. We recall the mapping properties of the hypersingular integral operator (1.2).

[illegible] 4. (a) For a closed surface $\Gamma = \partial\Omega$, the hypersingular integral operator is a bijective, linear, and bounded operator

$$W : H_0^\alpha(\partial\Omega) \to H_0^{\alpha-1}(\partial\Omega) \tag{2.9}$$

for all indices $0 \le \alpha \le 1$. It is elliptic for $\alpha = 1/2$.

(b) For an open surface $\Gamma \subsetneqq \partial\Omega$, the hypersingular integral operator is linear and bounded as operator

$$W : \widetilde{H}^\alpha(\Gamma) \to H^{\alpha-1}(\Gamma) \tag{2.10}$$

for all indices $0 \le \alpha \le 1$ and bijective provided that $0 < \alpha < 1$. For $\alpha = 1/2$, W is a bijective and elliptic operator.

To abbreviate the notation for the energy case $\alpha = 1/2$, we define the Sobolev space $\mathcal{H}$ to be either $H_0^{1/2}(\partial\Omega)$ in the case that $\Gamma = \partial\Omega$ is closed or $\widetilde{H}^{1/2}(\Gamma)$ provided that $\Gamma \subsetneqq \partial\Omega$ is an open arc. In both cases, $W : \mathcal{H} \to \mathcal{H}^*$ is bijective and elliptic, whence W induces a scalar product on $\mathcal{H}$,

$$\langle\!\langle u, v \rangle\!\rangle := \langle Wu, v \rangle \quad \text{for } u, v \in \mathcal{H}, \tag{2.11}$$

and the corresponding [illegible]

$$|\!|\!| u |\!|\!| := \langle\!\langle u, u \rangle\!\rangle^{1/2} \tag{2.12}$$

is an equivalent norm on $\mathcal{H} = H_0^{1/2}(\partial\Omega)$ and $\mathcal{H} = \widetilde{H}^{1/2}(\Gamma)$, respectively. According to the Lax–Milgram lemma, given $f \in \mathcal{H}^*$ there is a unique solution $u := W^{-1}f$ in $\mathcal{H}$ of (1.1).

3. Preliminaries on finite element approximation. This section recalls the Galerkin discretization of (1.1) in the Hilbert space $\mathcal{H}$ and provides some estimates for the discrete ansatz functions. Throughout we adopt the notation from the previous section.

3.1. Galerkin discretization. Let $\mathcal{T} = \{\Gamma_1, \dots, \Gamma_n\}$ be a triangulation of Γ. Each element Γ_j of the triangulation $\mathcal{T}$ is supposed to be a connected (affine) boundary piece. The set of all nodes of the triangulation $\mathcal{T}$ is denoted with $\mathcal{N}$. Let $h \in L^\infty(\Gamma)$ denote the local mesh-size $h|_{\Gamma_j} := h_j := \operatorname{diam}(\Gamma_j)$. For an integer $p \ge 0$, $\mathcal{P}_p(\mathcal{T})$ denotes the space of all piecewise polynomials of total degree $\le p$ (defined on a reference element $\Gamma_{\mathrm{ref}} = [0, 1]$). Furthermore, we define globally continuous splines $\mathcal{S}^p(\mathcal{T}) := \mathcal{P}_p(\mathcal{T}) \cap \mathcal{C}(\Gamma) \subseteq H^1(\Gamma) \subseteq H^\alpha(\Gamma)$. Finally, define $\mathcal{S}_0^p(\mathcal{T})$ to be either $\{v_h \in \mathcal{S}^p(\mathcal{T}) : \langle 1, v_h \rangle = 0\}$ provided that $\Gamma = \partial\Omega$ or $\{v_h \in \mathcal{S}^p(\mathcal{T}) : v_h|_{\partial\Gamma} = 0\}$ in case $\Gamma \subsetneqq \partial\Omega$. Here, $\partial\Gamma$ denotes the set of the two endpoints of Γ. The subspace $\mathcal{S}_0^p(\mathcal{T})$ satisfies $\mathcal{S}_0^p(\mathcal{T}) \subseteq \mathcal{H}$ and will be used for a Galerkin discretization.

If $\mathcal{S}$ is a finite dimensional subspace of $\mathcal{H}$, the discrete Galerkin approximation $u_h \in \mathcal{S}$ is uniquely determined by the linear system of equations

$$\langle\!\langle u_h, v_h \rangle\!\rangle = \langle f, v_h \rangle \quad \text{for all } v_h \in \mathcal{S}. \tag{3.1}$$

The Galerkin projection $\mathbb{G} : \mathcal{H} \to \mathcal{S}$, defined by $\mathbb{G}u \in \mathcal{S}$ with

$$\langle\!\langle G_u, v_h \rangle\!\rangle = \langle\!\langle u, v_h \rangle\!\rangle \quad \text{for all } v_h \in \mathcal{S}, \tag{3.2}$$

is the orthogonal projection onto $\mathcal{S}$ with respect to the energy norm.

3.2. Standard approximation estimate. Given a regular triangulation $\mathcal{T}$, real numbers $\alpha, m \in \mathbb{R}$ with $m \geq \alpha$, and an integer $p \geq 1$, define $\widehat{p} := \min\{p+1, m\} - 1/2$. Define the $\mathcal{T}$-piecewise Sobolev space

$$H^m(\mathcal{T}) := \{v \in L^2(\Gamma) : v|_{\Gamma_j} \in H^m(\Gamma_j) \text{ for all } \Gamma_j \in \mathcal{T}\}$$

with norm $\|v\|^2_{H^m(\mathcal{T})} = \sum_{j=1}^n \|v|_{\Gamma_j}\|^2_{H^m(\Gamma_j)}$. Let $\mathbb{G}$ denote the Galerkin projection onto $\mathcal{S}^p_0(\mathcal{T})$. Then, there exists some constant $C_1 > 0$ (depending only on Γ, α, m, and p) such that

$$|||v - \mathbb{G}v||| \leq C_1 h_{\max}^{\widehat{p}} \|v\|_{H^m(\mathcal{T})} \tag{3.3}$$

for all $v \in \mathcal{H} \cap H^m(\mathcal{T})$ and $h_{\max} := \max_{\Gamma_j \in \mathcal{T}} h_j$ [SaS, sections 4.1.9 and 4.1.11].

3.3. Local inverse estimate. This subsection establishes an inverse estimate in the energy norm (see Corollary 3.2), following the arguments from [GHS]. The proof uses the fact that the Sobolev spaces can be obtained from interpolation: $H^1(\Gamma)$ can equivalently be defined as the completion of the Lipschitz continuous functions $\mathrm{Lip}(\Gamma)$ with respect to the norm $\|u\|^2_{H^1(\Gamma)} = \|u\|^2_{L^2(\Gamma)} + \|u'\|^2_{L^2(\Gamma)}$. If one defines $\widetilde{H}^1(\Gamma)$ as the completion of $\{u \in \mathrm{Lip}(\Gamma) : u|_{\partial\Gamma} = 0\}$, the Sobolev spaces $H^\alpha(\Gamma)$ and $\widetilde{H}^\alpha(\Gamma)$ satisfy

$$H^\alpha(\Gamma) = [L^2(\Gamma); H^1(\Gamma)]_\alpha \quad \text{and} \quad \widetilde{H}^\alpha(\Gamma) = [L^2(\Gamma); \widetilde{H}^1(\Gamma)]_\alpha,$$

where the brackets $[\cdot]_\alpha$ denote complex interpolation with exponent $0 \leq \alpha \leq 1$ [BL, McL]. Note that interpolation leads to the same spaces $H^\alpha(\Gamma)$ and $\widetilde{H}^\alpha(\Gamma)$, respectively, but only to equivalent norms. We will use the symbol $\lesssim$ whenever an estimate holds up to a norm equivalence constant.

Remark 5. In the context of Sobolev spaces on domains $\omega \subseteq \mathbb{R}^d$, one writes $H^1_0(\omega)$ instead of $\widetilde{H}^1(\omega)$, but this would conflict with our definition of $H^1_0(\omega)$ in (2.3).

Proposition 3.1. [illegible] $C_2 > 0$ [illegible] α, p, Γ [illegible]

$$\|h^{1-\alpha} v_h'\|_{L^2(\Gamma)} \leq C_2 \|v_h\|_{H^\alpha(\Gamma)} \quad \text{[illegible] } v_h \in \mathcal{S}^p(\mathcal{T}). \tag{3.4}$$

[illegible] We first consider the case $\alpha = 0$. For an element $\Gamma_j \in \mathcal{T}$, there holds $\|v_h'\|_{L^2(\Gamma_j)} \leq C_3\, h_j^{-1} \|v_h\|_{L^2(\Gamma_j)}$ [GHS, Proposition 2.9]. The constant $C_3 > 0$ depends only on the degree p. The summation over all $\Gamma_j \in \mathcal{T}$ leads to

$$\|h v_h'\|_{L^2(\Gamma)} \leq C_3 \|v_h\|_{L^2(\Gamma)}. \tag{3.5}$$

The combination of (3.5) with the trivial estimate $\|v_h'\|_{L^2(\Gamma)} \lesssim \|v_h\|_{H^1(\Gamma)}$ allows an interpolation argument for the operator

$$T_\alpha : \big(\mathcal{S}^p(\mathcal{T}), \|\cdot\|_{H^\alpha(\Gamma)}\big) \to \big(\mathcal{P}_{p-1}(\mathcal{T}), \|h^{1-\alpha}(\cdot)\|_{L^2(\Gamma)}\big), v_h \mapsto v_h'. \tag{3.6}$$

T_0 is continuous with operator norm $\leq C_3$, and T_1 is continuous with operator norm $\lesssim 1$. In particular, T_α is well defined and continuous with operator norm $\lesssim C_3^{1-\alpha}$. Note that the interpolation space of $(L^2, \|h(\cdot)\|_{L^2(\Gamma)})$ and $(L^2, \|\cdot\|_{L^2(\Gamma)})$ for the index $0 \leq \alpha \leq 1$ is given by $(L^2, \|h^{1-\alpha}(\cdot)\|_{L^2(\Gamma)})$ [BL, section 5.4]. □

Remark 6. The given proof of the inverse estimate covers a wider range of problems: The same arguments hold for $d = 3$ (i.e., v_h' is replaced by the surface gradient ∇v_h) and arbitrary $1 \leq q \leq \infty$ instead of the Hilbert case $q = 2$.

For $\alpha = 1/2$, the norm equivalence on $\mathcal{H}$ and (2.8) prove the existence of local inverse estimates in the energy norm.

COROLLARY 3.2. [illegible] $C_{\rm inv} > 0$ [illegible] Γ [illegible] p [illegible]

$$\|h^{1/2} v_h'\|_{L^2(\Gamma)} \le C_{\rm inv} |\!|\!| v_h |\!|\!| \quad \text{[illegible]} \quad v_h \in \mathcal{S}_0^p(\mathcal{T}). \tag{3.7}$$

□

[illegible] 7. Since we will deal later with two discrete spaces, we are going to use superindices to indicate the mesh and the polynomial degree; e.g., $C_{\rm inv}^{h,p}$ denotes the constant in the inverse estimate (3.7) for $\mathcal{S}_0^p(\mathcal{T})$, where $\mathcal{T}$ is a mesh with (local) mesh-size $h \in L^\infty(\Gamma)$.

3.4. Local first-order approximation property. In this section we prove that the (slightly modified) nodal interpolation operator I_h onto $\mathcal{S}^1(\mathcal{T})$, for sufficiently smooth functions $v \in \mathcal{H}$, has a first-order approximation property with respect to the energy norm.

THEOREM 3.3 (see [C1]). [illegible] Ω [illegible] $\mathbb{R}^2$ $\Gamma = \partial\Omega$ [illegible] $\Gamma \subsetneqq \partial\Omega$ [illegible] $C_\alpha > 0$ [illegible] α [illegible] Γ [illegible]

$$C_4 := \begin{cases} C_\alpha & \text{[illegible]} \ \alpha \neq 1/2, \\ C_\alpha \, (\log(1+\kappa))^{1/2} & \text{[illegible]} \ \alpha = 1/2 \end{cases} \tag{3.8}$$

[illegible]

$$\kappa := \max\{h_j/h_k : \Gamma_j \text{ [illegible] } \Gamma_k\}, \tag{3.9}$$

[illegible]

$$\|v\|_{H^\alpha(\Gamma)} \le C_4 \, \|h^{1-\alpha} v'\|_{L^2(\Gamma)} \tag{3.10}$$

[illegible] $v \in H^1(\Gamma)$ [illegible] $\mathcal{T}$ □

For each node $z \in \mathcal{N}$, let $\phi_z \in \mathcal{S}^1(\mathcal{T})$ be the nodal basis function, i.e., $\mathcal{T}$-piecewise affine (with respect to the arclength) and globally continuous with $\phi_z(z) = 1$ and $\phi_z(z') = 0$ for $z' \in \mathcal{N} \backslash \{z\}$. Then, the [illegible] $\widehat{I}_h : \mathcal{C}(\Gamma) \to \mathcal{S}^1(\mathcal{T})$ is defined by

$$\widehat{I}_h v := \sum_{z \in \mathcal{N}} v(z) \phi_z. \tag{3.11}$$

In particular, $\widehat{I}_h v$ is well defined for any $v \in H^\alpha(\Gamma)$ and $\alpha > 1/2$. From this, we may define

$$I_h : \mathcal{C}(\Gamma) \to \mathcal{S}_0^1(\mathcal{T}), \quad I_h v := \begin{cases} \widehat{I}_h v & \text{for } \Gamma \subsetneqq \partial\Omega, \\ \widehat{I}_h v - |\Gamma|^{-1} \int_\Gamma \widehat{I}_h v \, ds & \text{for } \Gamma = \partial\Omega. \end{cases} \tag{3.12}$$

COROLLARY 3.4. [illegible] $v \in H_0^1(\Gamma)$ [illegible] $\Gamma = \partial\Omega$ [illegible] $v \in \widetilde{H}^1(\Gamma)$ [illegible] $\Gamma \subsetneqq \partial\Omega$ [illegible] $C_{\rm apx} \lesssim C_4$ [illegible] C_4 [illegible] (3.8)

$$|\!|\!| v - I_h v |\!|\!| \le C_{\rm apx} \|h^{1/2}(v - I_h v)'\|_{L^2(\Gamma)} \le C_{\rm apx} \|h^{1/2} v'\|_{L^2(\Gamma)}. \tag{3.13}$$

... $\Gamma \subsetneqq \partial\Omega$. Since $w := v - I_h v$ has a zero on each element, namely $w(z) = 0$ for all nodes $z \in \mathcal{N}$, we may apply Theorem 3.3 together with the continuity of $W : H^{1/2}(\Gamma) \to H^{-1/2}(\Gamma)$ to obtain

$$|||w||| \le C\|w\|_{H^{1/2}(\Gamma)} \le CC_4\|h^{1/2}w'\|_{L^2(\Gamma)}.$$

The second inequality is proved elementwise: Note that there holds $\int_{\Gamma_j} w'\,ds = 0$. Therefore, $(I_h v)' \in \mathcal{P}_0(\mathcal{T})$ satisfies $(I_h v)'|_{\Gamma_j} = (1/h_j)\int_{\Gamma_j} v'\,ds$. The elementwise L^2-orthogonality shows that

$$\|w'\|^2_{L^2(\Gamma_j)} = \|v'\|^2_{L^2(\Gamma_j)} - \|(I_h v)'\|^2_{L^2(\Gamma_j)} \le \|v'\|^2_{L^2(\Gamma_j)}.$$

A summation of these estimates over $\mathcal{T}_H$ concludes the proof:

$$\|h^{1/2}w'\|^2_{L^2(\Gamma)} = \sum_{j=1}^n h_j\|w'\|^2_{L^2(\Gamma_j)} \le \sum_{j=1}^n h_j\|v'\|^2_{L^2(\Gamma_j)} = \|h^{1/2}v'\|^2_{L^2(\Gamma)}. \qquad \square$$

... $\Gamma = \partial\Omega$. We define $w := v - I_h v \in H^1_0(\Gamma)$ and $\widehat{w} := w + (1/|\Gamma|)\int_\Gamma w\,ds$. Since $W1 = 0$ for the constant function 1, we have $|||w||| = |||\widehat{w}|||$. Because of $\int_\Gamma v\,ds = 0$, there holds $\widehat{w} = v - \widehat{I}_h v$. With $\widehat{w}' = w'$, we may thus apply the same arguments as in the case $\Gamma \subsetneqq \partial\Omega$ to prove (3.13). $\square$

COROLLARY 3.5. ... $\mathcal{S}$ ... $H^1_0(\Gamma)$ ... $\Gamma = \partial\Omega$ ... $\widetilde{H}^1(\Gamma)$ ... $\Gamma \subsetneqq \partial\Omega$ ... $\mathcal{S}^1_0(\mathcal{T}) \subseteq \mathcal{S}$ ... $\mathbb{G}_h$ ... $\mathcal{S}$ ...

$$|||v - \mathbb{G}_h v||| \le C_{\rm apx} \min\big\{\|h^{1/2}(v - \mathbb{G}_h v)'\|_{L^2(\Gamma)}, \|h^{1/2}v'\|_{L^2(\Gamma)}\big\} \tag{3.14}$$

... $v \in H^1_0(\Gamma)$ ... $v \in \widetilde{H}^1(\Gamma)$ ... $C_{\rm apx} > 0$ ... 3.4 ... According to the best approximation property of $\mathbb{G}_h$ and Corollary 3.4, there holds

$$|||v - \mathbb{G}_h v||| \le |||v - I_h v||| \le C_{\rm apx}\|h^{1/2}v'\|_{L^2(\Gamma)}. \tag{3.15}$$

Then $w := v - \mathbb{G}_h v$ satisfies $v - \mathbb{G}_h v = w - \mathbb{G}_h w$ from the idempotency of the projection $\mathbb{G}_h$. The application of (3.15) with v replaced by w yields $|||v - \mathbb{G}_h v||| \le C_{\rm apx}\|h^{1/2}w'\|_{L^2(\Gamma)}$. $\square$

4. A posteriori error control by averaging techniques. This section aims to provide a new class of error estimators for the hypersingular integral equation and states their reliability and efficiency.

4.1. Assumptions and notation. Let $\mathcal{T}_h = \{\Gamma_1, \dots, \Gamma_n\}$ and $\mathcal{T}_H = \{\gamma_1, \dots, \gamma_N\}$ be triangulations of Γ with (local) mesh-sizes h and H, respectively, and let $\mathcal{S}_h := \mathcal{S}^1_0(\mathcal{T}_h)$ and $\mathcal{S}_H := \mathcal{S}^2_0(\mathcal{T}_H)$ be defined in section 3.1. As in Corollary 3.4, let $I_h : H^1(\Gamma) \to \mathcal{S}_h$ denote the nodal interpolation operator onto $\mathcal{S}_h$ with approximation constant $C_{\rm apx} > 0$, and let $C^{H,2}_{\rm inv} > 0$ denote the constant in the inverse estimate (3.7) for $\mathcal{S}_H$. We assume that the mesh-size h is small enough when compared to H; more precisely,

$$C_{\rm apx}C^{H,2}_{\rm inv} \max_{\gamma_j \in \mathcal{T}_H} (\|h\|_{L^\infty(\gamma_j)}/H_j)^{1/2} =: L < 1. \tag{4.1}$$

Moreover, the analysis in the subsequent sections requires an additional regularity assumption on the exact solution $u \in \mathcal{H}$ of (1.1), namely,

$$u \in H^m(\mathcal{T}_H) \quad \text{for some } m > 2. \tag{4.2}$$

4.2. General results. Let $u \in \mathcal{H}$ denote the unique solution of (1.1), and let $u_h \in \mathcal{S}_h$ be its Galerkin approximation with respect to $\mathcal{S} = \mathcal{S}_h$ in (3.1). The Galerkin projection $\mathbb{G}_H$ onto $\mathcal{S}_H$ (i.e., the orthogonal projection onto $\mathcal{S}_H$ with respect to the energy norm) is compared with an [illegible] (not necessarily linear or continuous) operator

$$\mathcal{A}_H : L^2(\Gamma) \to \mathcal{S}_H. \tag{4.3}$$

The main results of this section are stated in Theorem 4.2 and Corollaries 4.3–4.5.

PROPOSITION 4.1. [illegible] (4.1) [illegible]

$$\|\!|u - u_h|\!\| \le \|\!|(\mathbb{1} - \mathbb{G}_H)(u - u_h)|\!\|/(1 - L). \tag{4.4}$$

[illegible] Define $\widetilde{h} \in \mathcal{P}_0(\mathcal{T}_H)$ by $\widetilde{h}|_{\gamma_j} := \|h\|_{L^\infty(\gamma_j)}$ for each element $\gamma_j \in \mathcal{T}_H$. For the Galerkin error $e := u - u_h$, the approximation property (3.13) of I_h yields

$$\|\!|(\mathbb{1} - I_h)\mathbb{G}_H e|\!\| \le C_{\rm apx}\|h^{1/2}(\mathbb{G}_H e)'\|_{L^2(\Gamma)} \le C_{\rm apx}\|\widetilde{h}^{1/2}(\mathbb{G}_H e)'\|_{L^2(\Gamma)}.$$

Now, we use the inverse estimate (3.7) for $\mathbb{G}_H e \in \mathcal{S}_H$ and infer that

$$\begin{aligned}\|\widetilde{h}^{1/2}(\mathbb{G}_H e)'\|_{L^2(\Gamma)} &\le \|(\widetilde{h}/H)^{1/2}\|_{L^\infty(\Gamma)}\|H^{1/2}(\mathbb{G}_H e)'\|_{L^2(\Gamma)}\\ &\le C_{\rm inv}^{H,2}\|(\widetilde{h}/H)^{1/2}\|_{L^\infty(\Gamma)}\|\!|\mathbb{G}_H e|\!\|.\end{aligned}$$

The combination with the best approximation property $\|\!|\mathbb{G}_H e|\!\| \le \|\!|e|\!\|$ shows that

$$\|\!|(\mathbb{1} - I_h)\mathbb{G}_H e|\!\| \le L\|\!|e|\!\|.$$

Using the Galerkin orthogonality and a Cauchy inequality, we obtain for $I_h\mathbb{G}_H e \in \mathcal{S}_h$

$$\langle\!\langle e, \mathbb{G}_H e\rangle\!\rangle = \langle\!\langle e, \mathbb{G}_H e - I_h\mathbb{G}_H e\rangle\!\rangle \le \|\!|e|\!\|\,\|\!|(\mathbb{1} - I_h)\mathbb{G}_H e|\!\| \le L\|\!|e|\!\|^2.$$

A further application of the Cauchy inequality concludes the proof:

$$\|\!|e|\!\|^2 = \langle\!\langle e, \mathbb{G}_H e\rangle\!\rangle + \langle\!\langle e, e - \mathbb{G}_H e\rangle\!\rangle \le \|\!|e|\!\|\,\big(L\|\!|e|\!\| + \|\!|(\mathbb{1} - \mathbb{G}_H)e|\!\|\big). \qquad \square$$

THEOREM 4.2. [illegible] (4.1) (4.2) [illegible]

$$\eta_M := \|\!|u_h - \mathbb{G}_H u_h|\!\|$$

[illegible]

$$\|\!|u - u_h|\!\| \le \big(\eta_M + \|\!|(\mathbb{1} - \mathbb{G}_H)u|\!\|\big)/\big(1 - L\big) \tag{4.5}$$

[illegible]

$$\eta_M \le \|\!|u - u_h|\!\| + \|\!|(\mathbb{1} - \mathbb{G}_H)u|\!\|. \tag{4.6}$$

[illegible] $\|\!|u - u_h|\!\|$ [illegible] η_M [illegible] $\|\!|(\mathbb{1} - \mathbb{G}_H)u|\!\|$ [illegible]

[illegible]. According to (3.3), the error in the energy norm is of order

$$\|\!|u - u_h|\!\| = O(h_{\rm max}^{\widehat{p}}) \quad \text{with} \quad \widehat{p} := \min\{2, m\} - 1/2 = 3/2.$$

Furthermore, for smooth u we have

$$|||(\mathbb{1}-\mathbb{G}_H)u||| = O(H_{\max}^{\widehat{q}}) \quad \text{with } \widehat{q} := \min\{3,m\} - 1/2 > 3/2.$$

Since $m > 2$, $|||(\mathbb{1}-\mathbb{G}_H)u|||$ is of higher order. The combination of Proposition 4.1 with a triangle inequality shows that

$$|||u-u_h||| \le \big(|||(\mathbb{1}-\mathbb{G}_H)u||| + |||(\mathbb{1}-\mathbb{G}_H)u_h|||\big)/\big(1-L\big).$$

This proves reliability. A simple triangle inequality,

$$\eta_M \le |||(\mathbb{1}-\mathbb{G}_H)(u-u_h)||| + |||(\mathbb{1}-\mathbb{G}_H)u||| \le |||u-u_h||| + |||(\mathbb{1}-\mathbb{G}_H)u|||,$$

shows efficiency since $(\mathbb{1}-\mathbb{G}_H)$ is an orthogonal projection with respect to the energy norm. □

Replacing the best approximation operator $\mathbb{G}_H$ by the operator $\mathcal{A}_H$, we immediately obtain the following corollary.

COROLLARY 4.3. $\eta_M \le \eta_A := |||u_h - \mathcal{A}_H u_h|||$ (4.1) (4.2) η_A □

To develop an adaptive mesh-refining algorithm, we have to provide an error estimator which can be localized. More precisely, we will estimate the nonlocal $\mathcal{H}$ norm by the (weighted) local H^1 seminorm, namely $\mu_M := \|H^{1/2}(u_h - \mathbb{G}_H u_h)'\|_{L^2(\Gamma)}$.

COROLLARY 4.4. $\mathcal{S}_0^1(\mathcal{T}_H) \subseteq \mathcal{S}_H$ $C_{\rm apx} > 0$ 3.4

$$\eta_M \le C_{\rm apx}\mu_M. \tag{4.7}$$

μ_M (4.1) (4.2)

. The proof follows immediately from the approximation property of the Galerkin projection (3.14). □

COROLLARY 4.5. $\mathcal{S}_H \subseteq \mathcal{S}^2(\mathcal{T}_h)$

$$\mu_A := \|H^{1/2}(u_h - \mathcal{A}_H u_h)'\|_{L^2(\Gamma)} \le C_5 C_{\rm inv}^{h,2}\eta_A \tag{4.8}$$

$C_5 := \max\{\|H\|_{L^\infty(\Gamma_j)}/h_j : \Gamma_j \in \mathcal{T}\}$ $C_{\rm inv}^{h,2} > 0$ $\mathcal{S}^2(\mathcal{T}_h)$ Π_H L^2 $\mathcal{P}^1(\mathcal{T}_H)$ μ_M $\mu_\Pi := \|H^{1/2}(u_h' - \Pi_H u_h')\|_{L^2(\Gamma)}$

$$\mu_\Pi \le \mu_M \le C_5 C_{\rm inv}^{h,2}\eta_M \tag{4.9}$$

(4.1) (4.2)

. The estimate (4.8) follows from the inverse estimate (3.7), and so does the second estimate in (4.9). Note that Π_H is the L^2 projection. This proves $\|u_h' - \Pi_H u_h'\|_{L^2(\gamma_j)} \le \|u_h' - (\mathbb{G}_H u_h)'\|_{L^2(\gamma_j)}$ for any $\gamma_j \in \mathcal{T}_H$. Summing the H-weighted L^2 norms over all elements $\gamma_j \in \mathcal{T}_H$, we prove (4.9). □

8. Note that the assumption $\mathcal{S}_H = \mathcal{S}_0^2(\mathcal{T}_H) \subseteq \mathcal{S}^2(\mathcal{T}_h)$ is quite weak and satisfied if $\mathcal{T}_h$ is obtained from $\mathcal{T}_H$ by some (local) refinements.

4.3. Reliability of μ_A for the L^2 projection. As proved in Corollary 4.5, there holds $\mu_A \le C_5 C_{\rm inv}^{h,2}\,\eta_A$ under weak assumptions on $\mathcal{T}_H$. To obtain the converse estimate $\eta_A \le C_6\,\mu_A$ with a constant C_6 which depends on neither the mesh-sizes nor the number of elements, one has to prove

$$|||v_h - \mathcal{A}_H v_h||| \le C_6 \|H^{1/2}(v_h - \mathcal{A}_H v_h)'\|_{L^2(\Gamma)} \quad \text{for all } v_h \in \mathcal{S}_h. \tag{4.10}$$

One then obtains the equivalence of the error estimators μ_A and η_A and, in particular, the reliability of μ_A under the assumptions (4.1)–(4.2). This is done for the L^2 projection $\mathcal{A}_H$ onto $\mathcal{S}_H$ in the following proposition.

PROPOSITION 4.6. [illegible] $\mathcal{A}_H$ [illegible] L^2 [illegible] $\mathcal{S}_H$ [illegible] 4.5, [illegible] μ_A [illegible] (4.8) [illegible]

$$C_6^{-1}\eta_A \le \mu_A \le C_5 C_{\mathrm{inv}}^{h,2}\,\eta_A. \tag{4.11}$$

[illegible] $\Gamma = \partial\Omega$. Since the L^2 projection $\mathbb{P}_H : H_0^1(\Gamma) \to \mathcal{S}^2(\mathcal{T}_H)$ satisfies

$$0 = \langle 1\,, (\mathbb{1} - \mathbb{P}_H)u_h\rangle = \langle 1\,, u_h\rangle - \langle 1\,, \mathbb{P}_H u_h\rangle = -\langle 1\,, \mathbb{P}_H u_h\rangle,$$

there holds $\mathbb{P}_H u_h \in \mathcal{S}_H$. Consequently, $\mathbb{P}_H u_h = \mathcal{A}_H u_h$ and $(\mathbb{1} - \mathcal{A}_H)u_h$ is L^2-orthogonal to $\mathcal{S}^2(\mathcal{T}_H)$. Let $\gamma_j \in \mathcal{T}_H$ be a coarse grid element with nodes $z, z' \in \mathcal{N}_H$. We define the bubble function $\beta_j(x) := \phi_{H,z}(x)\phi_{H,z'}(x)$ for $x \in \Gamma$ as the product of the corresponding hat functions. Then, $\beta_j \in \mathcal{S}^2(\mathcal{T}_H)$ is positive on the interior γ_j. With $v := (\mathbb{1} - \mathcal{A}_H)u_h$ there holds

$$0 = \langle \beta_j\,, v\rangle = \int_{\gamma_j} \beta_j v\, ds. \tag{4.12}$$

Therefore, v has at least one zero in γ_j so that Theorem 3.3 can be applied for $\mathcal{T}_H$. ∎

[illegible] $\Gamma \subsetneqq \partial\Omega$. The bubble functions vanish in all nodes $z \in \mathcal{N}_H$ and hence satisfy $\beta_j \in \mathcal{S}_H$ for all $1 \le j \le n$. Therefore, (4.12) holds and we can apply Theorem 3.3 again. ∎

[illegible] 9. The approximation argument in the proof of Proposition 4.6 works for sufficiently smooth $\widetilde{u} \in \mathcal{H}$ instead of $u_h \in \mathcal{S}_h$; e.g., u_h may be replaced by some $\widetilde{u}$ in $H_0^1(\Gamma)$ (resp., $\widetilde{H}^1(\Gamma)$).

In the case that $\Gamma \subsetneqq \partial\Omega$ is an open boundary piece, it is easy to construct operators which satisfy (4.10) since we only have to satisfy the zero boundary conditions for discrete functions at the endpoints of Γ.

[illegible] 10. Suppose that $\Gamma \subsetneqq \partial\Omega$. Let $\mathcal{A}_H$ be the pointwise interpolation operator satisfying

$$\mathcal{A}_H u_h \in \mathcal{S}^2(\mathcal{T}_H) \quad \text{and} \quad \mathcal{A}_H u_h(z) = u_h(z) \quad \text{for } z \in \{a_j, m_j, b_j\},$$

where a_j and b_j denote the nodes of γ_j and m_j denotes the element's midpoint. Note that $\mathcal{A}_H u_h$ vanishes at the endpoints of Γ. Therefore, $\mathcal{A}_H u_h \in \mathcal{S}_H$ and according to Theorem 3.3 there holds (4.10).

[illegible] 11. Suppose that $\mathcal{A}_H$ is idempotent; i.e., $\mathcal{A}_H^2 = \mathcal{A}_H$. Then, an elementary algebraic manipulation shows that (4.10) follows from the approximation estimate

$$\|\!|v_h - \mathcal{A}_H v_h|\!\| \le C_5 \|H^{1/2} v_h'\|_{L^2(\Gamma)}$$

for all $v_h \in \mathcal{S}_H$.

5. Numerical realization. As in the previous section, we write $\mathcal{S}_h = \mathcal{S}_0^1(\mathcal{T}_h)$ and $\mathcal{S}_H = \mathcal{S}_0^2(\mathcal{T}_H)$. The finer mesh $\mathcal{T}_h$ is obtained from the coarser $\mathcal{T}_H$ by uniform refinements; see section 5.5 for details. This ensures $\mathcal{S}_H = \mathcal{S}_0^2(\mathcal{T}_H) \subseteq \mathcal{S}^2(\mathcal{T}_h)$ as in Corollary 4.5.

5.1. Neumann problem and hypersingular integral equation. In the numerical experiments we consider examples where the right-hand side f in (1.1) comes from a Neumann problem

$$\Delta U = 0 \text{ in } \Omega \quad \text{and} \quad \partial U/\partial\nu = g \text{ on } \Gamma = \partial\Omega \tag{5.1}$$

with given Neumann data g on Γ (plus boundary conditions at infinity if Ω is unbounded) and the normal derivative $\partial U/\partial\nu$, where ν denotes the outer unit vector on $\partial\Omega$. This problem is equivalent to the hypersingular integral equation (1.1), where f takes the form

$$f = (\mathbb{1} - K^*)g \tag{5.2}$$

with the adjoint double-layer potential operator K^*, defined as Cauchy principal value by

$$(K^*g)(x) := -\frac{1}{\pi} \, \text{⨍}\!\!\!\!\!\!\int_\Gamma g(y) \, \frac{(y-x)\cdot\nu(x)}{|x-y|^2} \, ds_y \quad \text{for } x \in \Gamma. \tag{5.3}$$

Up to an additive constant, the exact solution of (1.1) is just the Dirichlet data $U|_\Gamma$ of U on the boundary Γ. More precisely, there holds $u = U|_\Gamma - \langle U|_\Gamma \, , 1\rangle/\langle 1 \, , 1\rangle$.

5.2. Computation of the discrete solution for $\Gamma = \partial\Omega$. The problem to solve (1.1) in the Hilbert space $H^\alpha_0(\Gamma)$ can equivalently be formulated as follows [CoS, CaS]: Given $(f, b) \in H^{\alpha-1}(\Gamma) \times \mathbb{R}$, find $(u, a) \in H^\alpha(\Gamma) \times \mathbb{R}$ such that

$$Wu + a = f \quad \text{and} \quad \langle 1 \, , u\rangle = b. \tag{5.4}$$

The corresponding discrete formulation reads as follows: Find $(u_h, a_h) \in \mathcal{S}^1(\mathcal{T}) \times \mathbb{R}$ such that

$$\langle Wu_h + a_h \, , v_h\rangle = \langle f \, , v_h\rangle \quad \text{for all } v_h \in \mathcal{S}^1(\mathcal{T}_h) \quad \text{and} \quad \langle 1 \, , u_h\rangle = b. \tag{5.5}$$

Notice that $\langle 1 \, , u - u_h\rangle = 0$, whence $u - u_h \in H^\alpha_0(\Gamma)$, and $\langle 1 \, , f - a_h\rangle = \langle 1 \, , Wu_h\rangle = 0$; i.e., $a_h = \langle f \, , 1\rangle/\langle 1 \, , 1\rangle$ and $f - a_h \in H^{\alpha-1}_0(\Gamma)$. In particular, for $b = 0$ and $f \in H^{\alpha-1}_0(\Gamma)$, the solution of (5.4) (resp., (5.5)) is just the solution of (1.1) (resp., (3.1)). The benefit of the generalized formulation is that we are allowed to consider the full discrete space $\mathcal{S}^1(\mathcal{T}_h)$ instead of $\mathcal{S}^1_0(\mathcal{T}_h)$. This simplifies the implementation since one can use the usual nodal hat functions instead of a basis of $\mathcal{S}^1_0(\mathcal{T}_h)$.

Let $\mathcal{N}_h$ denote the set of all nodes of $\mathcal{T}_h$ and, with $n := |\mathcal{N}_h|$, define the (symmetric) stiffness matrix $\mathbf{A}$ by

$$\mathbf{A}_{jk} = \langle\!\langle \phi_j \, , \phi_k \rangle\!\rangle \quad \text{for } 1 \le j, k \le n, \tag{5.6}$$

with $\phi_j, \phi_k \in \mathcal{S}^1(\mathcal{T}_h)$ denoting the hat functions corresponding to the jth and kth node, and

$$\mathbf{A}_{j,n+1} = \mathbf{A}_{n+1,j} = \langle 1 \, , \phi_j\rangle, \quad \mathbf{A}_{n+1,n+1} = 0. \tag{5.7}$$

With the right-hand side

$$\mathbf{b}_j = \langle f \, , \phi_j\rangle \quad \text{for } 1 \le j \le n, \tag{5.8}$$

the discrete solution u_h of (3.1) has the basis representation

$$u_h = \sum_{j=1}^{n} \mathbf{x}_j \phi_j, \tag{5.9}$$

where the coefficient vector $\mathbf{x} \in \mathbb{R}^{n+1}$ solves the linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ with $\mathbf{b}_{n+1} := 0$. Moreover, there holds $x_{n+1} = a_h$ with a_h from (5.5).

[illegible] 12. (a) The hypersingular integral operator (1.2) and the single-layer potential

$$(Vu)(x) := -\frac{1}{\pi} \int_\Gamma u(y) \log|x-y| \, ds_y \tag{5.10}$$

are linked through Nédélec's equation (recall $(\cdot)' = \partial/\partial s$)

$$\langle Wu \, , v \rangle = \langle Vu' \, , v' \rangle \quad \text{for all } u, v \in \mathcal{H}. \tag{5.11}$$

(b) According to (a), the entries of $\mathbf{A}$ in (5.6) can be computed analytically using (5.11) and exact integration for the single-layer potential; see [Ma].

5.3. Computation of the discrete solution for $\Gamma \subsetneqq \partial\Omega$. Let $\mathcal{K}_h := \mathcal{N}_h \backslash \partial\Gamma$ denote the set of all interior nodes of $\mathcal{T}$. Then, the implementation for an open curve is less involved since the hat functions ϕ_j with $j \in \mathcal{K}_h$ form the nodal basis of $\mathcal{S}^1_0(\mathcal{T}_h)$. With $n := |\mathcal{K}_h|$, we compute $\mathbf{A}$ and $\mathbf{b}$ as in (5.6) and (5.8), respectively. Then, the discrete solution u_h is represented as in (5.9) with $\mathbf{x} \in \mathbb{R}^n$ satisfying $\mathbf{A}\mathbf{x} = \mathbf{b}$.

[illegible] 13. For implementational reasons, the matrix $\mathbf{A}$ and the right-hand side $\mathbf{b}$ are computed for all hat functions, i.e., $\mathcal{N}_h$, and the resulting linear system is solved only on a subblock corresponding to $\mathcal{K}_h$.

5.4. Computation of the right-hand side for academic examples. If the exact solution $u \in \mathcal{H}$ is known, the entries for the right-hand side vector (cf. (5.8)), can easily be obtained by use of Remark 12: According to (5.11), there holds

$$\mathbf{b}_j = \langle f \, , \phi_j \rangle = \langle Wu \, , \phi_j \rangle = \langle u' \, , V\phi_j' \rangle.$$

Notice that the integrand $b(x) = u'(x)(V\phi_j')(x)$ may have logarithmic singularities. For the numerical experiments, we used the `quad` function implemented in MATLAB, which is based on an h-adaptive Simpson formula and Romberg extrapolation.

5.5. Adaptive algorithm. All mesh-refinements are performed with the following adaptive algorithm from [CP] based on the refinement indicators $\mu_{M,j}$, $\mu_{A,j}$, and $\mu_{\Pi,j}$ defined as follows: Given the coarse mesh $\mathcal{T}_H = \{\gamma_1, \dots, \gamma_N\}$ and the L^2 projections $\Pi^1_H : \mathcal{S}_h \to \mathcal{S}^1_0(\mathcal{T}_H)$ and $\Pi^2_H : \mathcal{S}_h \to \mathcal{S}^2_0(\mathcal{T}_H)$, we define, for $j = 1, \dots, N$,

$$\mu_{M,j} := H_j^{1/2} \| u_h' - (\mathbb{G}_H u_h)' \|_{L^2(\gamma_j)}, \tag{5.12}$$

$$\mu_{A,j} := H_j^{1/2} \| u_h' - (\Pi^2_H u_h)' \|_{L^2(\gamma_j)}, \tag{5.13}$$

$$\mu_{\Pi,j} := H_j^{1/2} \| u_h' - \Pi^1_H(u_h') \|_{L^2(\gamma_j)}, \tag{5.14}$$

i.e., $\mu_M = \big(\sum_{j=1}^N \mu_{M,j}^2\big)^{1/2}$, $\mu_A = \big(\sum_{j=1}^N \mu_{A,j}^2\big)^{1/2}$, and $\mu_\Pi = \big(\sum_{j=1}^N \mu_{\Pi,j}^2\big)^{1/2}$, respectively.

ALGORITHM 5.1. [illegible] $\mathcal{T}_H^{(0)}$ $k = 0$ $\ell \in \mathbb{N}_{\geq 2}$ $0 \leq \theta \leq 1$

(i) $\mathcal{T}_h^{(k)} = \{\Gamma_1, \dots, \Gamma_n\}$ $\mathcal{T}_H^{(k)} = \{\gamma_1, \dots, \gamma_N\}$
$\gamma_j \in \mathcal{T}_H^{(k)}$ ℓ
(ii) $u_h^{(k)}$ $\mathcal{T}_h^{(k)}$
(iii) η_M η_A $\mu_{M,j}$ $\mu_{A,j}$ $\mu_{\Pi,j}$
(iv) γ_j $\mu_{M,j} \geq \theta \max\{\mu_{M,1}, \dots, \mu_{M,N}\}$ $\mu_{M,j}$ $\mu_{A,j}$ $\mu_{\Pi,j}$
(v) $\gamma_j \in \mathcal{T}_H^{(k)}$ $\mathcal{T}_H^{(k+1)}$ (i)

14. The choice of $\theta = 0$ in Algorithm 5.1 leads to uniform mesh-refinement, whereas we used $\theta = 1/2$ for adaptive mesh-refinement in the subsequent numerical examples. The parameter $\ell \in \mathbb{N}_{\geq 2}$ is chosen between 2 and 4 and is empirically discussed later.

15. Since the local mesh-ratio $\kappa(\mathcal{T}_h^{(h)})$ defined in (3.9) enters the constant $C_{\rm apx}$ and thus affects the reliability of our estimators, we mark further elements for refinement to guarantee $\kappa(\mathcal{T}_H^{(k)}) \leq 2\kappa(\mathcal{T}_H^{(0)})$. Note that there holds $\kappa(\mathcal{T}_h^{(k)}) = \kappa(\mathcal{T}_H^{(k)})$.

5.6. Computation of the error estimators. Let $\phi_1, \dots, \phi_n$ be a basis of $\mathcal{S}_h$ and $\Phi_1, \dots, \Phi_N$ be a basis of $\mathcal{S}_H$ and define the matrices $\mathbf{A} \in \mathbb{R}^{n\times n}_{sym}$, $\mathbf{B} \in \mathbb{R}^{N\times N}_{sym}$, and $\mathbf{C} \in \mathbb{R}^{N\times n}$ by

$$\mathbf{A}_{jk} := \langle\!\langle \phi_j, \phi_k \rangle\!\rangle, \quad \mathbf{B}_{jk} := \langle\!\langle \Phi_j, \Phi_k \rangle\!\rangle, \quad \text{and} \quad \mathbf{C}_{jk} := \langle\!\langle \Phi_j, \phi_k \rangle\!\rangle. \tag{5.15}$$

Let $\mathbf{x} \in \mathbb{R}^n$ be the coefficient vector of $u_h \in \mathcal{S}_h$ and $\mathbf{y} \in \mathbb{R}^N$ the coefficient vector of $\mathbb{G}_H u_h \in \mathcal{S}_H$. Note that the vector $\mathbf{y}$ is the solution of the linear system $\mathbf{By} = \mathbf{Cx}$. Then, Galerkin orthogonality yields

$$\eta_M^2 = |\!|\!| u_h - \mathbb{G}_H u_h |\!|\!|^2 = |\!|\!| u_h |\!|\!|^2 - |\!|\!| \mathbb{G}_H u_h |\!|\!|^2 = \mathbf{x}\cdot\mathbf{Ax} - \mathbf{y}\cdot\mathbf{By} = \mathbf{x}\cdot(\mathbf{Ax} - \mathbf{C}^T\mathbf{y}).$$

The computation of the error estimator η_A involves the L^2 mass matrices $\widehat{\mathbf{B}} \in \mathbb{R}^{N\times N}_{sym}$ and $\widehat{\mathbf{C}} \in \mathbb{R}^{N\times n}$ defined by

$$\widehat{\mathbf{B}}_{jk} := \langle \Phi_j, \Phi_k \rangle \quad \text{and} \quad \widehat{\mathbf{C}}_{jk} := \langle \Phi_j, \phi_k \rangle. \tag{5.16}$$

If $\mathcal{A}_H$ denotes the L^2 projection onto $\mathcal{S}_H$, the coefficient vector $\widehat{\mathbf{y}} \in \mathbb{R}^N$ of $\mathcal{A}_H u_h$ is the solution of the linear system $\widehat{\mathbf{B}}\mathbf{y} = \widehat{\mathbf{C}}\mathbf{x}$. Then, η_A reads as

$$\eta_A^2 = |\!|\!| u_h - \mathcal{A}_H u_h |\!|\!|^2 = \mathbf{x}\cdot\mathbf{Ax} - \widehat{\mathbf{y}}\cdot(2\,\mathbf{Cx} - \mathbf{B}\widehat{\mathbf{y}}).$$

16. (a) In case $\Gamma = \partial\Omega$, it is convenient to extend $\mathbf{A}$, $\mathbf{B}$, and $\widehat{\mathbf{B}}$ by a side-constraint analogously to (5.7) and then to consider a basis of $\mathcal{S}^1(\mathcal{T}_h)$ and $\mathcal{S}^2(\mathcal{T}_h)$ instead of $\mathcal{S}_h$ and $\mathcal{S}_H$, respectively.

(b) The entries of $\mathbf{A}, \mathbf{B}, \mathbf{C}$ are computed analytically by use of Remark 12 for ϕ_j being a hat function in $\mathcal{S}^1(\mathcal{T}_h)$ and Φ_j being either a hat function in $\mathcal{S}^1(\mathcal{T}_H)$ or a bubble function in $\mathcal{S}^2(\mathcal{T}_H)$, i.e., the product of two hat functions with overlapping support.

(c) The entries of $\widehat{\mathbf{B}}$ are computed analytically by transforming the arising integrals to the reference element $[0, 1]$, where the hat functions are given by t and $1 - t$ and the corresponding bubble is $t(1 - t)$.

(d) The entries of $\widehat{\mathbf{C}}$ are easily computed since a fine grid element $\Gamma_j \in \mathcal{T}_h$ lies in precisely one coarse grid element $\gamma_k \in \mathcal{T}_H$. If we use the arclength parametrization of γ_k, Γ_j then corresponds to a subinterval $[a,b] \subseteq [0, H_k]$.

(e) The error estimators μ_M and μ_A are computed $\mathcal{T}_H$-elementwise as indicated in (5.12).

6. Numerical experiments. This section reports on four numerical experiments to study the accuracy of the introduced error estimators and the performance of the proposed adaptive strategy. All experiments have been conducted using MATLAB. All examples are academic in the sense that the exact solution is always known and we can compare the convergence of the error $E_h = |\!|\!| u - u_h |\!|\!|$ with the convergence of the error estimators. All experiments were performed with the parameter $\ell = 2, 3, 4$ in Algorithm 5.1. Since the numerical outcome looks similar, we restrict the presentation to the simplest case $\ell = 2$. The right-hand side for the Galerkin method is always computed as explained in section 5.4.

The first two examples are related to Neumann problems; cf. section 5.1. The solution for the example in section 6.1 is smooth and satisfies the regularity assumptions of section 4 so that the higher-order term in the error estimates satisfies $|\!|\!| u - \mathbb{G}_H u |\!|\!| = \mathcal{O}(h^{5/2})$. The solution for the example in section 6.2 corresponds to a classical finite element test problem on the (rotated) L-shaped domain which lacks H^2-regularity. For the generic corner singularity $U(r,\varphi) = r^\alpha \cos(\alpha\varphi)$ with $\alpha = 2/3$ for the reentrant corner $3\pi/2$, the corresponding Neumann data are (piecewise) smooth. In the example in section 6.3, we therefore consider the same example with $\alpha = 3/7$. Then, the Neumann data are singular at the reentrant corner and uniform mesh-refinement leads to a suboptimal convergence rate for the numerical solution of the hypersingular integral equation. This can be overcome by use of adaptive mesh-refinement. Finally, the example in section 6.4 considers a slit problem on the slit $\Gamma = [-1,1] \times \{0\}$. The right-hand side simplifies since the adjoint double layer potential vanishes; i.e., we do not have to deal with further quadrature errors to compute the right-hand side. The exact solution lies in $\widetilde{H}^{1-\varepsilon}(\Gamma)$ for any $\varepsilon > 0$.

6.1. Neumann problem with smooth solution. We consider the Neumann problem (5.1) on the halved unit square $\Omega = [0, 1/2]^2$ with exact solution

$$U(x,y) = \sinh(2\pi\, x)\, \cos(2\pi\, y) \tag{6.1}$$

and solve the corresponding hypersingular integral equation $Wu = f$ with right-hand side $f = (1 - K^*)g$ and $g = \partial U/\partial\nu$. Note that $\int_\Gamma U(x)\, ds_x = 0$. Therefore, the exact solution u of the hypersingular integral equation is just the trace on the boundary $u = U|_\Gamma$. The computation of the right-hand side for the Galerkin method is performed as shown in section 5.4 with the arclength derivative $u' = \nabla U(x) \cdot \tau(x)$ for the tangential vector $\tau(x)$ on Γ. Figure 1 shows initial mesh and the corresponding discrete solution u_h (for $\ell = 2$ in Algorithm 5.1) as a function of the arclength parameter $0 \le s \le 2$, where $s = 0$ corresponds to the point $(0,0)$ and counter-clockwise parametrization of the boundary $\Gamma = \partial\Omega$. The exact solution u is shown for comparison. Figure 2 shows the error

$$E_h := |\!|\!| u - u_h |\!|\!| = (|\!|\!| u |\!|\!|^2 - |\!|\!| u_h |\!|\!|^2)^{1/2},$$

where $|\!|\!| u |\!|\!| = 258.4278864$ (obtained from Aitkin's Δ^2 extrapolation of the sequence on uniformly refined meshes) as well as the introduced error estimators for uniform mesh-refinement. The values are plotted over the number $n^{(k)}$ of elements in the

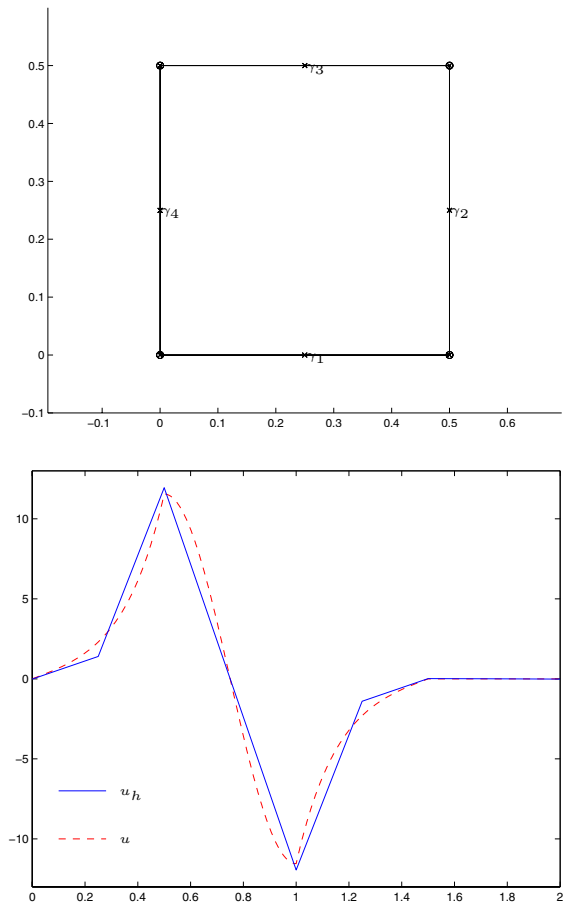

FIG. 1. *Initial coarse mesh* $\mathcal{T}_H^{(0)}$ *in the Neumann problem in section* 6.1 *with* $N = 4$ *elements (nodes indicated by* o*) (top) and the corresponding fine mesh* $\mathcal{T}_h^{(0)}$ *for* $\ell = 2$ *in Algorithm* 5.1*; i.e.,* $n = 8$ *(nodes indicated by* x*). The related discrete solution* u_h *on* $\mathcal{T}_h^{(0)}$ *(bottom) is plotted over the arclength* $s = 0, \dots, 2$ *of* Γ*. The exact solution* u *(i.e., the trace of* U *from* (6.1)*) is shown for comparison (bottom).*

kth fine grid $\mathcal{T}_h^{(k)}$. As is to be expected, uniform mesh-refinement leads to optimal experimental convergence rate

$$\kappa^{(k)}(E_h) := \log(E_h^{(k-1)}/E_h^{(k)}) \,/\, \log(n^{(k)}/n^{(k-1)}). \tag{6.2}$$

Here, $E_h^{(j)}$ denotes the error corresponding to the jth mesh (i.e., on the fine mesh in the jth step of Algorithm 5.1) with $n^{(j)}$ elements. The experimental convergence rate is visualized in Figure 2 through the slope of the interpolated values plotted in double-logarithmic scale. From the regularity of the exact solution $u = U|_\Gamma$ one expects convergence rate 3/2 for the error E_h and 5/2 for the error $E_H := |||u - \mathbb{G}_H u|||$ in a Galerkin scheme with $\mathcal{S}_0^2$ ansatz functions (cf. section 3.2), and this is in fact observed in Figure 2. Note that the assumptions of Theorem 4.2 are satisfied and η_M is an upper bound for the error E_h up to terms of higher order $\mathcal{O}(h^{5/2})$. We

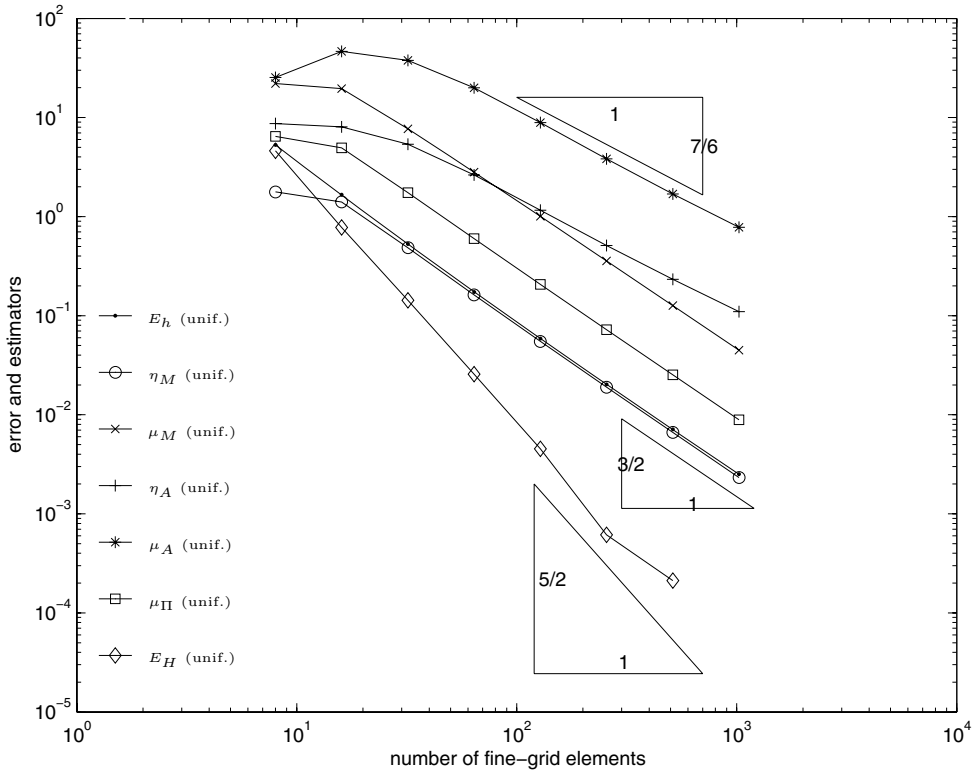

FIG. 2. *Error* $E_h = \|(\mathbb{1} - \mathbb{G}_h)u\|$ *and error estimators* η_M, μ_M, η_A, μ_A, *and* μ_Π *for* $\ell = 2$ *and uniform mesh-refinement in the Neumann problem in section* 6.1. *For comparison, we further show the* S_H*-error* $E_H = \|(\mathbb{1} - \mathbb{G}_H)u\|$ *which is of higher order: As expected from section* 3.2, *we observe* $\kappa(E_h) = 3/2$ *and* $\kappa(E_H) = 5/2$. *The estimators* η_A *and* μ_A *lack the efficiency, showing an experimental convergence rate less than* 3/2. *On the other hand, we observe reliability of* μ_Π. *Note that* η_M *is a very accurate estimator for* E_h *in the sense that both curves almost coincide.*

see that η_M is a very accurate estimate for E_h: The curves for E_h and η_M almost coincide. (See also Table 1, where we provide some numbers for $\ell = 1, \dots, 8$.) The error estimator μ_M is expected and observed to be reliable (for uniformly refined meshes) and efficient: The curve of μ_M is parallel to that of E_h and η_M. The same holds for the error estimator μ_Π which was only proved to be efficient in Corollary 4.5. The error estimators μ_A and η_A show reliability but obviously lack the efficiency: The curves for μ_A and η_A are parallel (as expected from Proposition 4.6) with slope 7/6. The failing efficiency estimate probably results from the lack of H^1 stability of the L^2 projection $\mathcal{A}_H : H^1(\Gamma) \to \mathcal{S}^2_0(\mathcal{T}) \subseteq H^1(\Gamma)$.

Figure 3 visualizes the error E_h and the error estimator μ_Π for uniform and adaptive mesh-refinement. As for uniform mesh-refinement, we obtain the experimental reliability of μ_Π: The curve of E_h and the corresponding curve of μ_Π are always parallel. Even for μ_A-adaptive mesh-refinement, where the error curve shows some zigzag behavior, this is imitated by the curve of μ_Π. All mesh-refining strategies recover the optimal convergence rate $\kappa(E_h) = 3/2$. Although adaptive mesh-refinement is not necessary for this example, the absolute values of E_h recommend the use of μ_M- or μ_Π-adaptive mesh-refinement. This is caused by the vanishing solution $u(x, y)$ for

TABLE 1

Index $\varrho = \|u-u_h\|/\eta_M$ for the Neumann problem in section 6.1 *with respect to the number $|\mathcal{T}_H|$ of coarse grid elements and the refinement parameter ℓ in Algorithm* 5.1. *One expects that ϱ tends to* 1 *for $\#\mathcal{T}_H, \ell \to \infty$ (cf. Theorem* 4.2*): In this case, the higher-order term $\|u - \mathbb{G}_H u\|$ tends to zero, and the constant $1/(1-L)$ tends to* 1. *Note that we used Aitkin's extrapolation rowwise to compute $\|u\|$ since the extrapolated value is affected by the quadrature errors to compute the right-hand side; cf. section* 5.4.

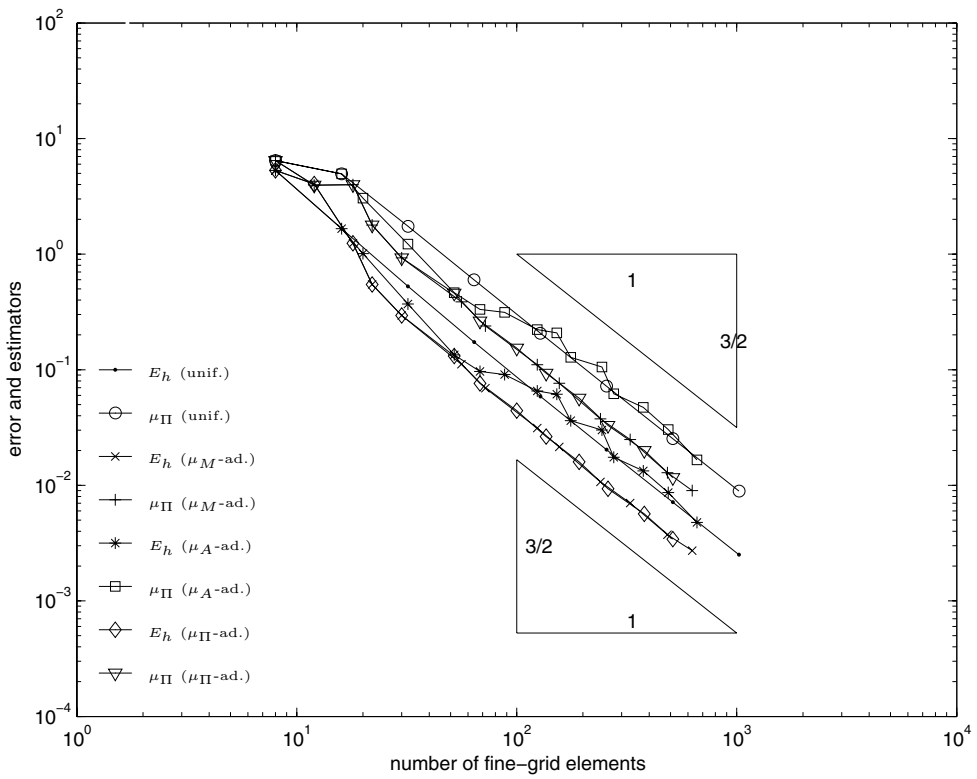

FIG. 3. *Error $E_h = \|(\mathbf{1} - \mathbb{G}_h)u\|$ and error estimator μ_Π in the example in section* 6.1 *for uniform (unif.) and adaptive (ad.) mesh-refinement and $\ell = 2$. Besides the efficiency of μ_Π proven in Corollary* 4.5 *one observes reliability of μ_Π: In all cases, the curves of E_h and μ_Π are parallel—even for μ_A-adaptive mesh-refinement.*

$x = 0$. We do not need any boundary elements there. The μ_A-adaptive mesh-refinement leads to absolute values of E_h which are even worse than the uniform mesh-refinement.

Some adaptively generated meshes are shown in Figure 4. For μ_M- and μ_Π-adaptive mesh-refinement, we see a strong refinement around the arclength parameter $s = 1/2$ and $s = 1$, where the exact solution has strong gradients; cf. Figure 1.

Finally, Figure 5 provides a comparison of the different estimators in dependence on the mesh-refining strategy. To make the subplots comparable we always print the outcome for uniform mesh-refinement. For all mesh-refining strategies, we see that η_A and μ_A are equivalent and reliable but lack the efficiency. The convergence rates for η_A and μ_A for adaptive mesh-refinement become even worse than for uniform mesh-refinement. On the other hand, we prove experimentally the reliability of μ_M (and μ_Π) even for non–quasi-uniform meshes.

6.2. Neumann problem with slightly singular solution. For a fixed parameter $\alpha > 0$, we consider the Neumann problem (5.1) on the L-shaped domain Ω shown in Figure 6 with exact solution

$$U(x) = \mathrm{Re}(x^\alpha) = r^\alpha \cos(\alpha\varphi) \quad \text{in polar coordinates} \quad x = r\,(\cos\varphi, \sin\varphi). \tag{6.3}$$

With the Dirichlet data $U|_\Gamma$, the exact solution u of (1.1) in $H^1_0(\partial\Omega)$ is given by $u = U|_\Gamma - \langle U|_\Gamma\,, 1\rangle/\langle 1\,, 1\rangle$. Numerical quadrature yields $\langle U|_\Gamma\,, 1\rangle/\langle 1\,, 1\rangle = 0.2095275$. The exact solution u is plotted over the arclength in Figure 6 for comparison with the discrete Galerkin solution. As in the previous section, the right-hand side in the Galerkin scheme is computed by use of the exact solution; cf. section 5.4. The gradient of $U(x)$ reads in polar coordinates as

$$\nabla U(x) = \alpha r^{\alpha-1} \begin{pmatrix} \cos(\varphi)\cos(\alpha\varphi) + \sin(\varphi)\sin(\alpha\varphi) \\ \sin(\varphi)\cos(\alpha\varphi) - \cos(\varphi)\sin(\alpha\varphi) \end{pmatrix}. \tag{6.4}$$

For the numerical experiment we choose $\alpha = 2/3$, which corresponds to the typical corner singularity at a reentrant corner with angle $3\pi/2$. The Neumann problem then leads to $U \notin H^2(\Omega)$. Nevertheless, the Dirichlet data are smooth as can be seen in Figure 6. Thus, we observe optimal experimental convergence rate 3/2 [in terms of number of elements] even for uniform mesh-refinement. Figure 7 visualizes the error E_h and the error estimators η_M and μ_Π for uniform and adaptive mesh-refinement. As in the example in section 6.1, we observe that both error estimators are reliable and efficient. μ_M- and μ_Π-adaptive mesh-refinement lead to optimal experimental convergence rate $\kappa(E_h) = 3/2$ and even the absolute values of E_h are superior to the values obtained from uniform mesh-refinement. The μ_A-adaptive mesh-refinement leads to a curve with absolute values E_h even worse than for uniform mesh-refinement.

Some adaptively generated meshes are shown in Figure 8 for comparison. The meshes generated by μ_M-related and μ_Π-related mesh-refinement are very similar. This can also be observed from the plot in Figure 7, where the curves corresponding to μ_M and μ_Π, respectively, almost coincide.

Independent of the mesh-refining strategy, the estimator η_M provides an accurate estimate for the error E_h: The curves for E_h and η_M, which are related to the same mesh-refinement, coincide.

6.3. Problem with singular solution. We consider the same example as in section 6.2 but now with $\alpha = 3/7$, which leads to a singular exact solution u. Figure 9 shows the discrete solution u_h on the initial mesh $\mathcal{T}_h^{(0)}$ and, for comparison, the Dirichlet data $U|_\Gamma$ (up to an additive constant). Note that we subtracted the constant $\langle U|_\Gamma\,, 1\rangle/\langle 1\,, 1\rangle = 0.4205278$ from the Dirichlet data to obtain the unique solution u

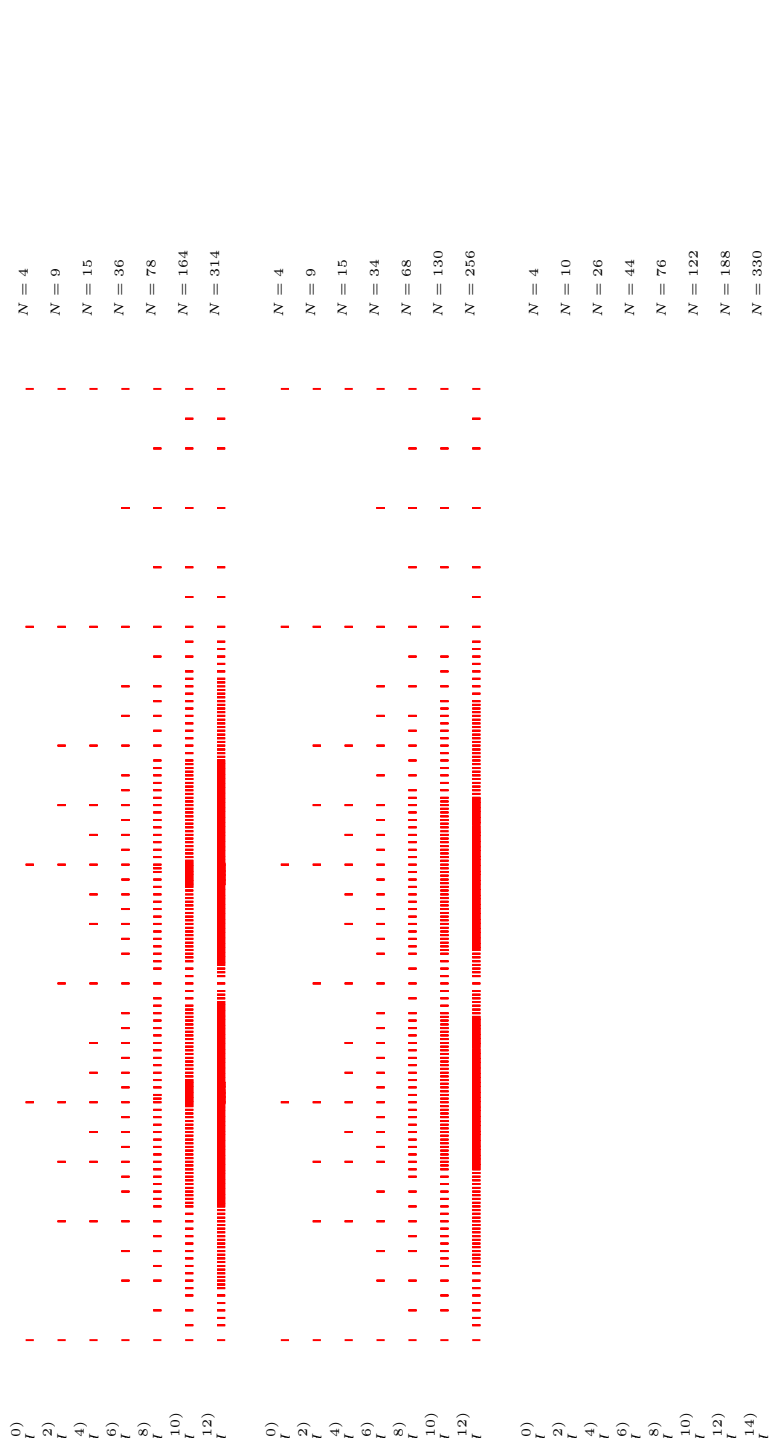

FIG. 4. *Adaptive mesh-refinement in the Poisson problem in section* 6.1 *with* $\ell = 2$ *related to the error estimator* μ_M *(top),* μ_Π *(middle), and* μ_A *(bottom), respectively.*

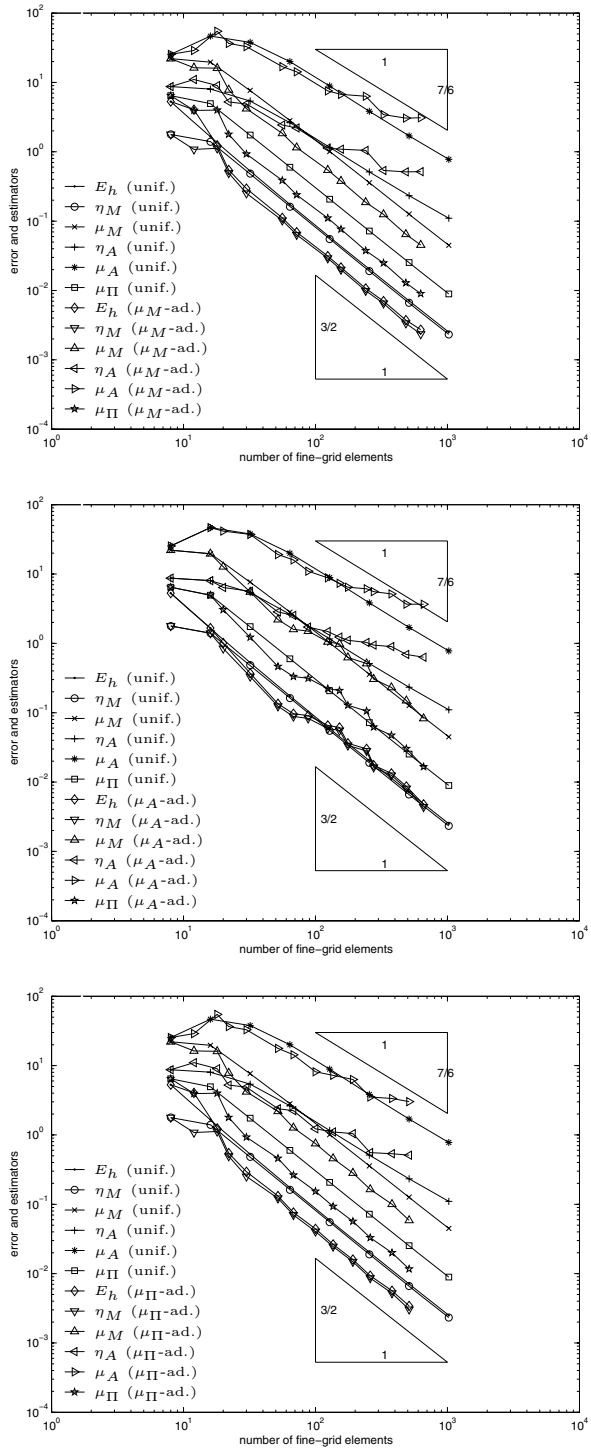

FIG. 5. *Error* $E_h = \|(\mathbf{1} - \mathbb{G}_h)u\|$ *and error estimator* μ_Π *in the example in section* 6.1 *for* $\ell = 2$ *and uniform (unif.) (resp., different adaptive (ad.)) mesh-refining strategies. In any case, we observe that the error estimators* η_M, μ_M, *and* μ_Π *are reliable and efficient. All mesh-refining strategies lead to optimal convergence rate* $\kappa(E_h) = 3/2$, *and* η_M *and* E_h *almost coincide. The error estimators* η_A *and* μ_A *lack the efficiency.*

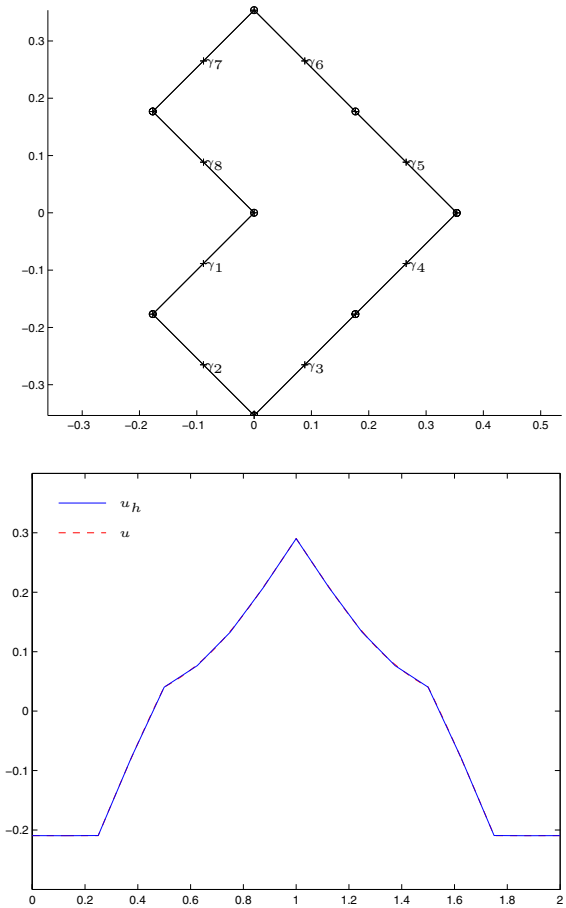

FIG. 6. *Initial coarse mesh* $\mathcal{T}_H^{(0)}$ *in the example in section* 6.2 *with* $N = 8$ *elements (nodes indicated by* ∘*) (top) and the corresponding fine mesh* $\mathcal{T}_h^{(0)}$ *for* $\ell = 2$ *in Algorithm* 5.1*, i.e.,* $n = 16$ *(nodes indicated by* +*). The related discrete solution* u_h *on* $\mathcal{T}_h^{(0)}$ *(bottom) is plotted over the arclength* $s = 0, \dots, 2$ *of* Γ*. The exact solution* u *is shown for comparison (bottom). of (1.1) in $H_0^1(\partial\Omega)$. As can be seen, the exact solution now yields a singularity at the reentrant corner at arclength $s = 0$ and $s = 2$, respectively.

Uniform mesh-refinement leads to a suboptimal experimental convergence rate of 3/7 for the error E_h. Figure 10 visualizes the error E_h as well as the error estimators η_M and μ_Π for uniform, and μ_M-, μ_A-, and μ_Π-adaptive, mesh-refinement. The μ_M- and μ_A-adaptive strategies recover the optimal convergence rate 3/2, which is experimentally obtained from the very start; i.e., there is no preasymptotic behavior as is normally observed for adaptive methods. The adaptively generated meshes, visualized in Figure 11, look very similar for both strategies, and the related E_h-curves coincide. This is very different for the μ_A-adaptive mesh-refinement. After a small preasymptotic phase (for $n \leq 40$) and compared with the uniform mesh-refinement, we observe an improvement of the experimental convergence rate. However, the μ_A-adaptive strategy does not seem to recover the optimal convergence rate. The μ_A-adaptively

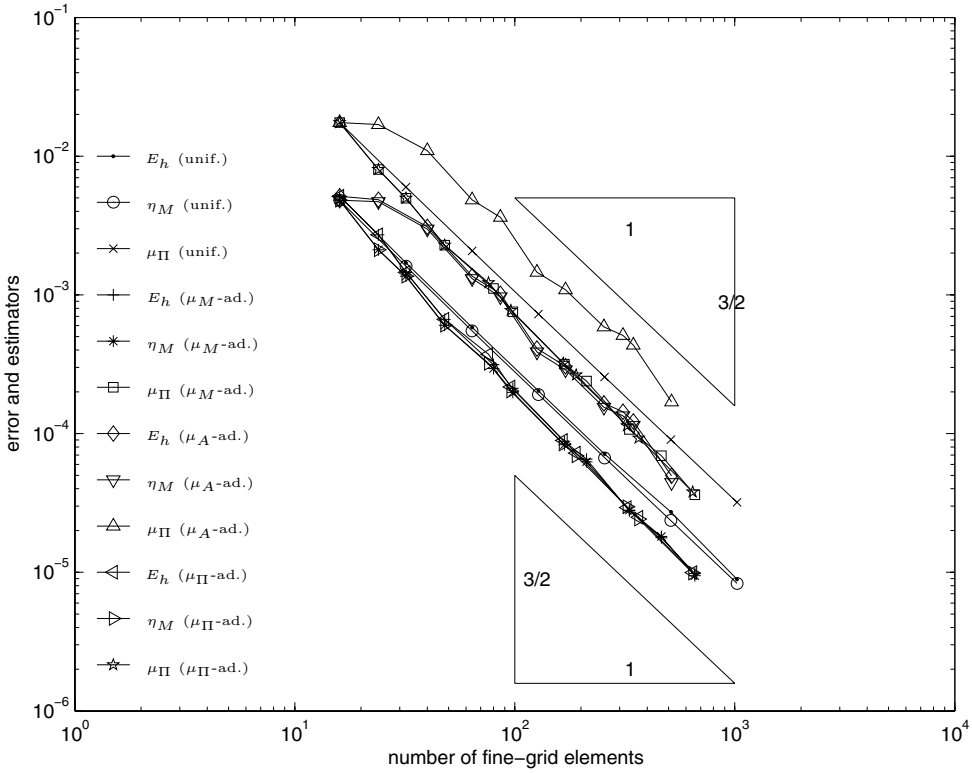

FIG. 7. *Error $E_h = \|(\mathbf{1} - \mathbb{G}_h)u\|$ and error estimator μ_Π in the example in section* 6.2 *for uniform (unif.) and adaptive (ad.) mesh-refinement and $\ell = 2$. Besides the efficiency of μ_Π proven in Corollary* 4.5 *one observes reliability of μ_Π. The error estimator η_M estimates E_h very accurately: The values almost coincide independent of the mesh-refining strategy. Whereas μ_M- and μ_Π-adaptive mesh-refinement lead to improved absolute values for the error E_h, the E_h-curve for μ_A-adaptive mesh-refinement is above the curve corresponding to uniform mesh-refinement; i.e., the absolute value of E_h for a fixed number of unknowns is even worse than for uniform mesh-refinement.*

generated meshes show some further mesh-refinement where the exact solution u has some local maxima (cf. Figures 9 and 11), which is not necessary when compared with the optimal results for μ_M- and μ_Π-adaptive mesh-refinement.

The error estimation by η_M is not as good as that observed in the preceding examples. This is probably due to the fact that the term $\|u - \mathbb{G}_H u\|$ now is a higher-order term.

6.4. Slit problem with exact solution. Our last example is concerned with the hypersingular integral equation (1.1) with constant right-hand side $f \equiv 1$ on the slit $\Gamma = [-1, 1] \times \{0\}$. The exact solution u is given by

$$u(x, 0) = \sqrt{1 - x^2} \quad \text{for } (x, 0) \in \Gamma. \tag{6.5}$$

There holds $u \in \widetilde{H}^{1-\varepsilon}(\Gamma)$ for all $\varepsilon > 0$, but $u \notin \widetilde{H}^1(\Gamma)$. The energy norm of u can be computed analytically, $\|u\| = \sqrt{\pi/2}$. Figure 12 shows the experimental results of our computations. As in the previous examples, the error estimators η_M, μ_M, and μ_Π show

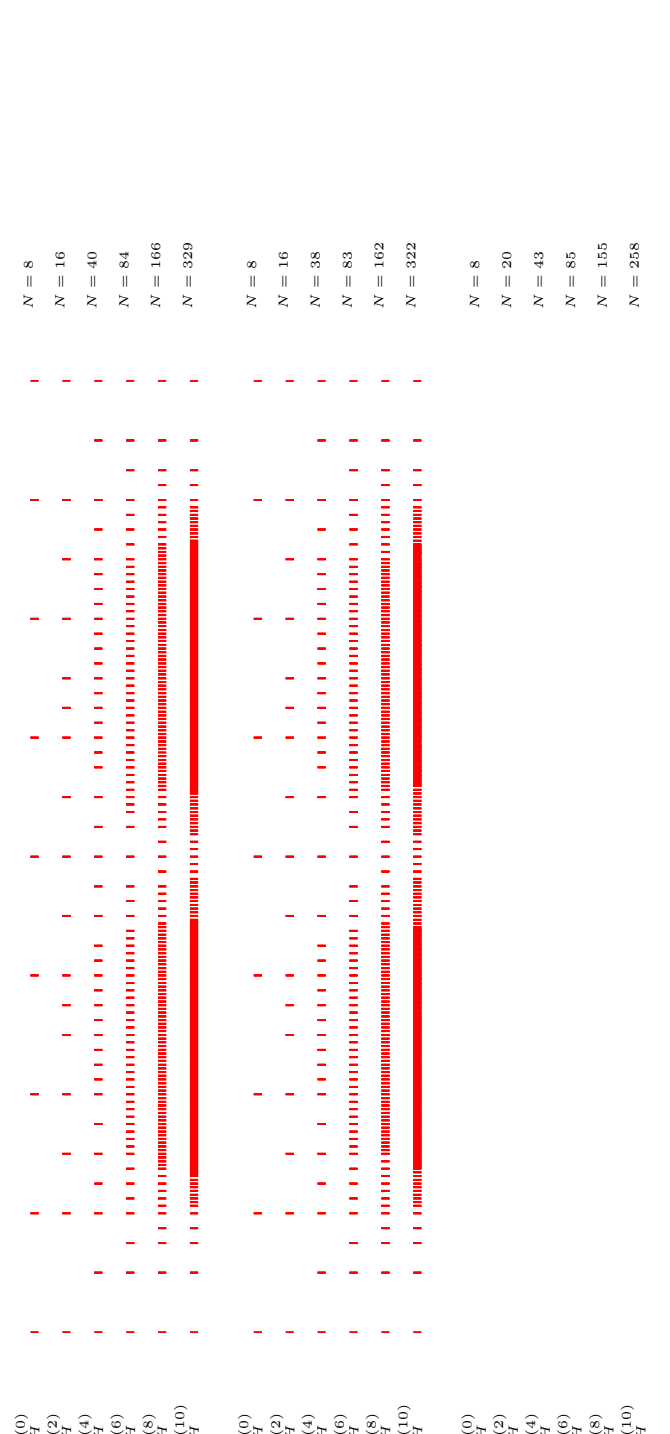

FIG. 8. *Adaptive mesh-refinement in the Poisson problem in section* 6.2 *with* $\ell = 2$ *related to the error estimator* μ_M *(top),* μ_Π *(middle), and* μ_A *(bottom), respectively. For the* μ_M*- and* μ_Π*-adapted meshes, we see a high mesh-refinement towards the reentrant corner, where* u *is slightly singular.*

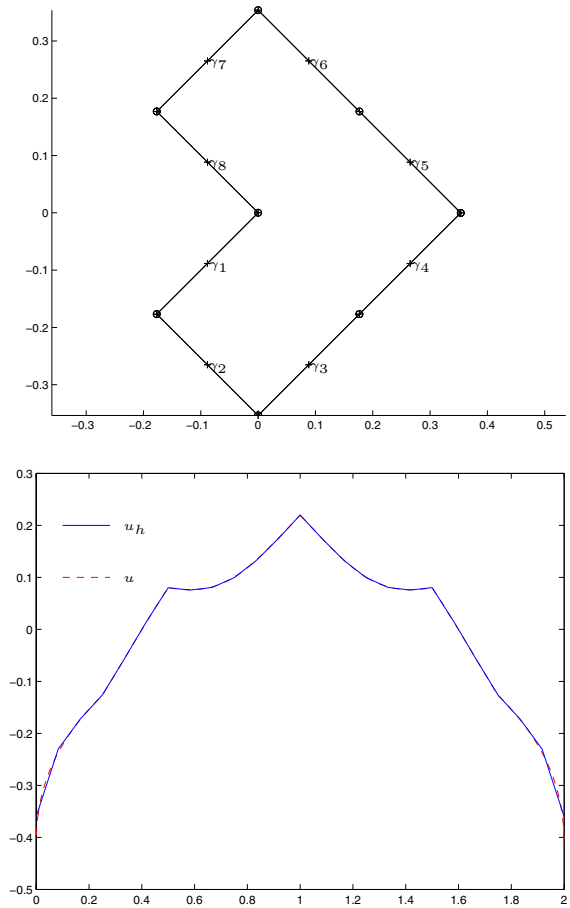

FIG. 9. *Initial coarse mesh* $\mathcal{T}_H^{(0)}$ *in the example in section* 6.3 *with* $N = 8$ *elements (nodes indicated by* ∘*) (top) and the corresponding fine mesh* $\mathcal{T}_h^{(0)}$ *for* $\ell = 2$ *in Algorithm* 5.1. *The related discrete solution* u_h *on* $\mathcal{T}_h^{(0)}$ *as well as the exact solution* u *is plotted over the arclength* $s = 0, \dots, 2$ *of* Γ *(bottom).*

efficiency and reliability independent of the mesh-refining strategy. Uniform mesh-refinement leads to a suboptimal experimental convergence rate $\kappa(E_h) = \mathcal{O}(h^{1/2})$. This can be improved by use of μ_M- and μ_Π-adaptive mesh-refinement. Both adaptive strategies recover the optimal convergence rate. As in the example in section 6.3, μ_A-adaptive mesh-refinement leads to an improved convergence rate of the error, but this is still suboptimal.

7. Conclusions.

7.1. Empirical results. The overall impressions of our numerical experiments, partly repeated from the preceding subsections, give us the subsequent empirical results.

(a) μ_Π is the most simple estimator (from the conceptual and implementational point of view); it is theoretically shown only to be efficient, but performs efficiently and reliably in our numerical examples.

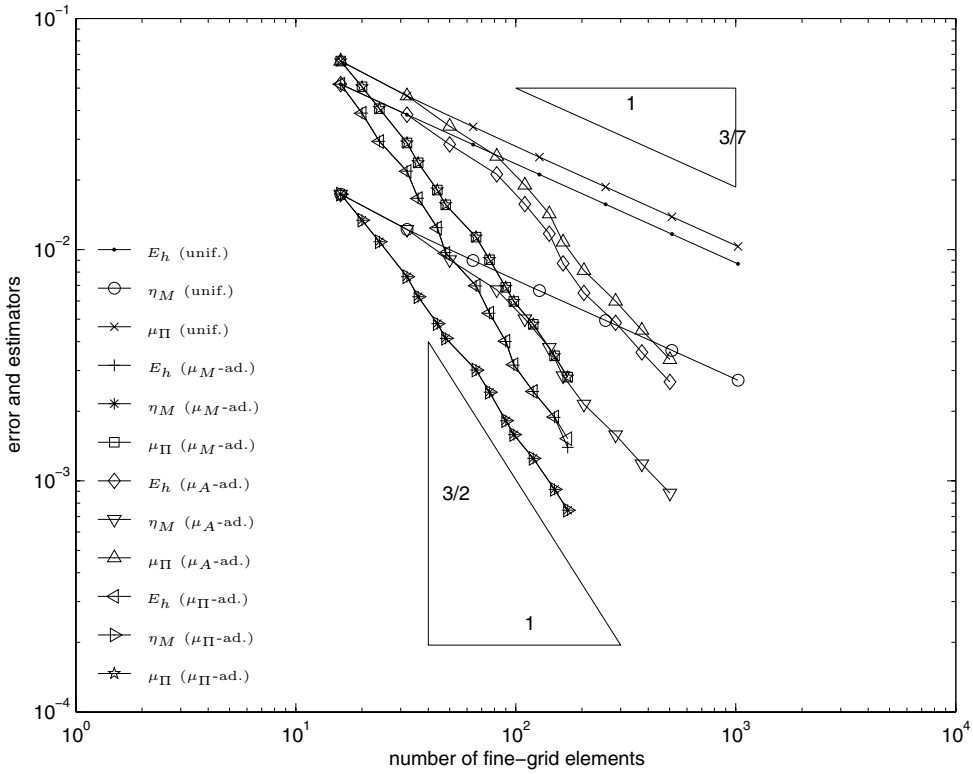

FIG. 10. *Error* $E_h = \|(\mathbf{1} - \mathbb{G}_h)u\|$ *and error estimators* η_M, μ_M, *and* μ_Π *for uniform (unif.),* μ_M*-adaptive (*μ_M*-ad.), and* μ_Π*-adaptive (*μ_Π*-ad.) mesh-refinement in the example in section* 6.3 *with* $\ell = 2$ *in Algorithm* 5.1.

(b) The error control of η_M is extremely accurate at least if the exact solution u has some regularity. The error estimation is far superior in comparison with the other error estimators.

(c) Algorithm 5.1 steered by the refinement indicators μ_M and μ_Π, respectively, leads to the optimal experimental convergence rate of the Galerkin method whenever the regularity of the exact solution leads to a reduced convergence order for uniform mesh-refinement.

(d) For $\mathcal{A}_H$, the L^2 projection onto $\mathcal{S}_H$, the error estimators η_A and μ_A lack the efficiency. Although μ_A-adaptive mesh-refinement leads to an improvement of the experimental convergence rate for the singular examples, this adaptive strategy does not regain the optimal convergence rate.

(e) The numerical outcome appears to be very sensitive with respect to implementational details. The estimators η_M, μ_M, and η_A involve stiffness matrices with respect to $\mathcal{S}_0^2$, while μ_Π relies on the much more robust L^2 projection.

7.2. Theoretical results. The heart of our analysis is Proposition 4.1 and, obtained from this, the efficiency and reliability of the error estimator $\eta_M = \|u_h - \mathbb{G}_H u_h\|$ up to terms of higher order. Those higher-order terms depend only on the regularity of the exact solution u which is in general unknown.

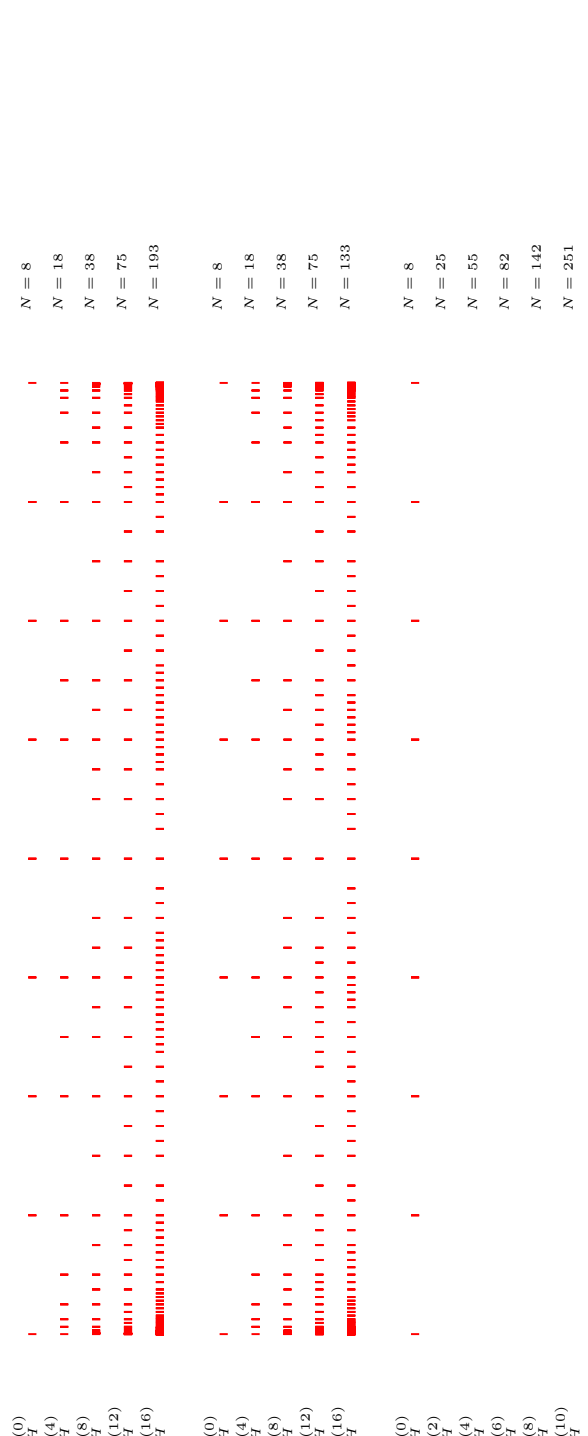

FIG. 11. *Adaptive mesh-refinement in the Poisson problem in section* 6.3 *with* $\ell = 2$ *related to the error estimator* μ_M *(top),* μ_Π *(middle), and* μ_A *(bottom), respectively.*

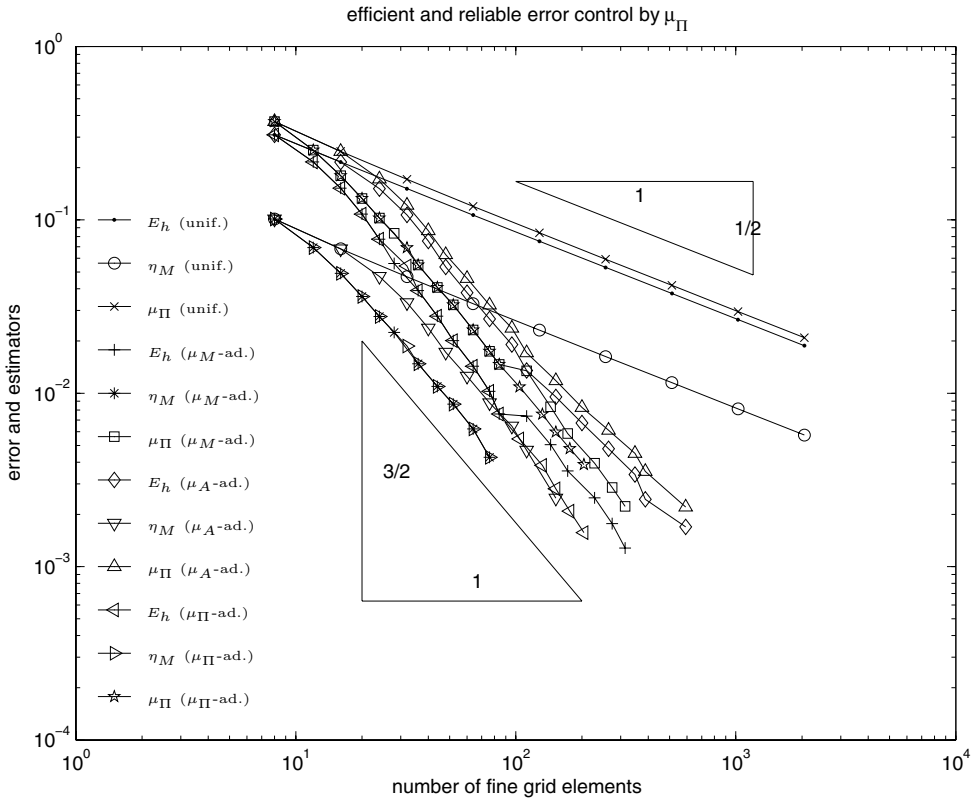

FIG. 12. *Error* $E_h = \|(\mathbf{1} - \mathbb{G}_h)u\|$ *and error estimators* η_M *and* μ_Π *for uniform (unif.) and adaptive (ad.) mesh-refinement in the example in section* 6.4 *with* $\ell = 2$ *in Algorithm* 5.1.

The proof of Proposition 4.1 has essentially two ingredients: first, an approximation operator $I_h : \mathcal{S}_H \to \mathcal{S}_h$ which has a local first-order approximation property, and second, a local inverse estimate in $\mathcal{S}_H$. Whereas we provided the inverse estimate for two- and three-dimensional problems, we did not provide the operator I_h in the latter case. For two dimensions, one can simply choose $I_h v_H$ to be the nodal interpolant. For three dimensions, one choice is (a slightly modified) Clément interpolation operator [FFP].

From the best approximation property of the Galerkin projection, one obtains that each averaging operator $\mathcal{A}_H : \mathcal{S}_h \to \mathcal{S}_H$ yields a reliable error estimator $\eta_A = \|u_h - \mathcal{A}_H u_h\|$.

Since the energy norm $\|\cdot\|$ is nonlocal, the obtained estimators cannot be employed for an adaptive mesh-refinement directly. We use localization in terms of the weighted H^1 seminorm $\mu_A = \|H^{1/2}(u_h - \mathcal{A}_H u_h)'\|_{L^2(\Gamma)}$. An inverse estimate shows the lower bound $C^{-1}\mu_A \leq \eta_A$. The verification of $\eta_A \leq C\,\mu_A$ needs some approximation property of $\mathcal{A}_H$ and holds, e.g., for the Galerkin projection $\mathcal{A}_H = \mathbb{G}_H$.

7.3. Future development. There remain several open questions for future research.

(a) From a comparison with the finite element method, the most natural error estimator is $\mu_\Pi = \|H^{1/2}(u_h' - \Pi_H u_h')\|_{L^2(\Gamma)}$ with Π_H the L^2 projection onto $\mathcal{P}^1(\mathcal{T}_H)$.

The proof of the reliability seems to need a different analytical technique, which is far beyond the scope of this paper.

(b) As for Symm's integral equation [CP], an analytical justification of Algorithm 5.1 would be desirable. The analytical verification of the introduced error estimators needs high regularity assumptions on u which are in general not satisfied and—according to our experiments—not necessary in praxis.

(c) The justification of η_M for the higher-order term $\|(\mathbb{1} - \mathbb{G}_H)u\|$ reads more precisely as follows, where $L < 1$ denotes the constant from (4.1): Provided that

$$\frac{1}{1-L}\,\frac{\|u - \mathbb{G}_H u\|}{\|u - u_h\|} =: \varrho_{hH} < 1, \tag{7.1}$$

Theorem 4.2 states that $\|u - u_h\| \le \frac{1}{1-L}\,\eta_M + \varrho_{hH}\|u - u_h\|$ and thus

$$\|u - u_h\| \le \frac{1}{(1-L)(1-\varrho_{hH})}\,\eta_M. \tag{7.2}$$

Sufficient smoothness of u (cf. (4.2)) justifies (7.1) for sufficiently small mesh-sizes h and H. However, singularities yield much poorer smoothness, e.g., $u \in H^s(\mathcal{T}_H)$ for $s \le \frac{3}{2} - \varepsilon$. Then, uniform meshes result in

$$\|u - u_h\| = C_7 h^\alpha + o(h^\alpha) \quad \text{and} \quad \|u - \mathbb{G}_H u\| = C_8 H^\alpha + o(H^\alpha)$$

for the same order of convergence $\alpha > 0$ as $h \to 0$. Then, there is no guarantee that

$$\varrho_{hH} = \frac{(H/h)^\alpha}{1-L}\,\frac{C_8}{C_7} + o(1)$$

satisfies $\varrho_{hH} < I$. However, because higher-order discrete spaces are better, one may expect that $C_8 < C_7$ so that there is room for (7.1). Since details depend on all the constants, a further analysis lies beyond the scope of this work.

(d) Three-dimensional experiments for Symm's integral equation and the hypersingular integral equation are postponed to a forthcoming paper [FFP].

ERROR ANALYSIS FOR OPERATIONS IN SOLID MODELING IN THE PRESENCE OF UNCERTAINTY*

LARS-ERIK ANDERSSON†, NEIL F. STEWART‡, AND MALIKA ZIDANI‡

Abstract. The problem of maintaining consistent representations of solids in computer-aided design and of giving rigorous proofs of error bounds for operations such as regularized Boolean intersection has been widely studied for at least two decades. One of the major difficulties is that the representations used in practice not only are in error but are fundamentally inconsistent. Such inconsistency is one of the main bottlenecks in downstream applications. This paper provides a framework for error analysis in the context of solid modeling, in the case where the data is represented using the standard representational method, and where the data may be uncertain. Included are discussions of ill-condition, error measurement, stability of algorithms, inconsistency of defining data, and the question of when we should invoke methods outside the scope of numerical analysis. A solution to the inconsistency problem is proposed and supported by theorems: it is based on the use of Whitney extension to define sets, called Quasi-NURBS sets, which are viewed as realizations of the inconsistent data provided to the numerical method. A detailed example illustrating the problem of regularized Boolean intersection is also given.

Key words. solid modeling, NURBS, regularized Boolean operations, Whitney extension

DOI. 10.1137/040604303

1. Introduction.

The problem of error analysis, in the context of representation and manipulation of solids (certain subsets of R^3), has generated a large literature over the last two decades—overviews can be found in [1] and [2]—but the fundamental problems have not yet been resolved. Indeed, Farouki [3] observes that inconsistent geometry is "... the key bottleneck in the use of CFD [Computational Fluid Dynamics] as a practical design tool" and, further, that the "... lack of a robust solution to the surface intersection problem is the culprit behind most problems in CAD data (e.g., gaps/overlaps between abutting surfaces, topological inconsistencies).... A satisfactory theory of how to approximate [edges and surfaces of represented solids] in a mutually consistent manner has failed to emerge." While certain solutions have been proposed [4, Chap. 20], in the setting considered here they do not provide the satisfactory theory referred to above.

In this paper we consider the case where a certain standard representation of solids is used and develop a framework for error analysis in this context. To establish the framework, the idea of Quasi-NURBS sets is introduced: these are regular-closed sets with boundary faces that are slight perturbations of nonuniform rational B-splines (NURBS) patches. Such sets will be viewed as realizations in R^3 of given representational data.

In the solid-modeling and computational-geometry literature our topic is called

"robustness." It is usually unclear, however, whether lack of robustness is related to [illegible] of the problem to be solved, to [illegible] of the methods used to implement operations on solids, to [illegible] in the underlying representations, or to some combination of these. Indeed, the distinction between ill-condition and instability [5, 6] is seldom made, and the possibility of uncertainty in the input data is often forgotten or eliminated by hypothesis. The fundamental inconsistencies mentioned may be due to the approximation of high-degree intersection curves by lower-degree curves, or to the use of floating-point arithmetic. Thus, standard methods for the representation of solids include multiple and inconsistent descriptions of geometric entities, and these descriptions will also be inconsistent with the specified topological information. This leads to the question of exactly which subset of R^3 is defined by the inconsistent representations of the input operands. We cannot prove rigorous theorems about, say, the computed union of two solids, until this has been specified.

Another serious shortcoming of much of the literature in this area is the lack of a metric permitting us to evaluate the quality of a computed result. In fact, robustness of a numerical method, in solid-modeling operations, is often taken to mean simply that the computer program does not "crash." Such a criterion is, of course, completely inadequate (for example, it can easily be satisfied by an algorithm that always outputs the unit cube, independently of its inputs).

In section 2 we describe the framework for error analysis. Section 3 describes the standard approach to representing solids and our method of specification of a well-defined subset of R^3 given well-formed data. Section 4 gives a specific proposal for the definition of a metric, and section 5 discusses, primarily, Boolean set operations. Section 6 concludes the paper.

2. Error analysis in the presence of uncertainty. A useful approach to error analysis, in the context of uncertain input operands, is to show that the numerical method produces a "slightly wrong solution to a slightly wrong problem" [7, sect. 4]. In particular, this idea was used with great success for methods in numerical linear algebra [5]. The fact that the data is uncertain permits us to associate all or part of the computational error with the problem itself, since we must in any case tolerate the error arising from the difference between the problem to be solved and the problem submitted to the numerical method. Thus, if we have performed an analysis of the sort suggested in the above quote, then the potential size of the error will be determined by the condition of the problem. If the problem is ill-conditioned (small perturbations of the input data may cause large changes in the solution), then the error may be large, even though the method has done as well as possible, and in this case we must be prepared to accept a large error in the solution, due to the combined effect of the uncertainty in the data and the ill-condition of the problem: improving the numerical method cannot guarantee a small error.

We will examine these ideas in the context of computing regularized[1] Boolean operations between [illegible] (i.e., compact, semialgebraic, regular-closed sets [8]).

2.1. Choice of metric. We will postpone the question of the choice of the metric d, to measure the distance between two solids, until section 4. For now we observe only that it may or may not be appropriate to include sameness of topological

[1]Boolean set operations in solid modeling are interpreted as operations in the algebra of regular-closed sets: $A \circ^* B = cl(int(A \circ B))$, $\circ = \cap, \cup$, or $\sim$ [8]. The r-sets, referred to here as *solids* or *objects*, have become a de facto standard for geometric modeling.

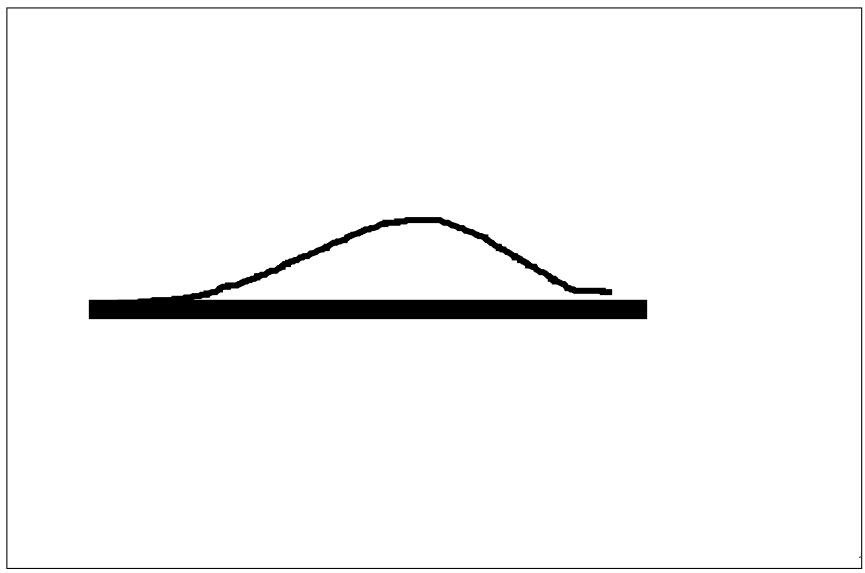

FIG. 1. *A springclip on a block: the set-union problem is ill-conditioned.*

form in the metric, depending upon the application.

The springclip shown in Figure 1 touches the block only at the left. If the block and the springclip are considered as separate objects, then there is no ambiguity about the topological form of the objects, notwithstanding possible inconsistencies in their representations: both are 3-balls, with boundaries that are 2-spheres. If these objects are submitted to a set-union algorithm, the topological form of the output is well defined, and if the algorithm does not produce an object with correct topological form (e.g., if it incorrectly joins the springclip to the block at the right end), then it has produced a wrong result. Furthermore, in a design application, the topological form of the result [illegible] to the user. Thus, it is often appropriate to include sameness of topological form [9, 10] in a metric that determines whether two objects are proximate. In contrast, in applications such as collision detection, use of the Hausdorff metric [11] may be sufficient.

2.2. Condition of the problem. Whether in the example of Figure 1 a computer program should be [illegible] to produce a result with the correct topological form is a completely different question. In fact, depending on the separation between the block and the right-hand end of the springclip, the problem submitted to the method may be ill-conditioned: small perturbations of the input data lead to a completely different answer (a set with the wrong topological form). This is relevant, because it is quite likely that there was uncertainty in the data defining the two original objects. For example, there may have been error in decimal-binary conversion or in the methods used to create or input the two original objects. In such circumstances, if the error metric requires sameness of topological form, then it is futile, for example, to apply exact arithmetic to obtain the exact result for the given input data.

Our second example illustrates the inevitability of uncertainty in the practical context of operations on solids. Let $S_0 = conv(\{(0,0,z),(1,0,z),(0,1,z) : z = 0,1\})$, $S_1 = conv(\{(0,0,z),(\sqrt{2},0,z),(\sqrt{2},\sqrt{2},z),(0,\sqrt{2},z) : z = 0,1\})$ (each of which has

a rectangular face with sides of length 1 and $\sqrt{2}$), and suppose that S_0 and S_1 are to be joined together by rotating and translating S_1 so that its vertices are $\{(1,0,z),(2,1,z),(1,2,z),(0,1,z),\ z=0,1\}$ and computing the set union of S_0 and S_1. In this set union, the rectangular faces mentioned above may or may not coincide: because of the uncertainty in the data defining S_1, due to the original approximation of $\sqrt{2}$ and to the error introduced by rotation and translation, the numerical set-union algorithm cannot tell. As in the case of the springclip, if sameness of topological form is required, then the set-union problem is [illegible]. Small perturbations of the input data could cause the union to be either a smooth connected object or two disjoint objects separated by a void corresponding to, say, a thin membrane or viscous fluid. The essential point is that the numerical method cannot possibly decide, using the information available, which answer is correct. An ideal set-union algorithm should not return either answer but should instead signal that it is unable to solve the problem, due to insufficient information. Possible approaches to resolving the ambiguity are outside the domain of numerical analysis. (They are, rather, in domains like human-computer interaction: for example, we might consider a "snap-to-grid" interface.) It is not the business of the numerical analyst to add clever tricks to the algorithm so that it happens to give a particular valid solid.

The above ideas may be illustrated by discussing what may be the most widely used test of the robustness of set-intersection algorithms in the solid-modeling literature. A well-formed cube and a slightly rotated version of the cube are presented to a set-difference algorithm; the smaller the angle of rotation that can be tolerated without the program "crashing," the more robust the algorithm is considered to be. First, as already suggested, this criterion gives no consideration to the accuracy of the result. Second, even if we introduce a stringent accuracy requirement, in the presence of uncertainty it is not appropriate to judge a method by the smallness of the angle for which it can produce accurate results for the [illegible] input solids. Once the angle and the data uncertainty preclude determination of the topological form of the difference set, an algorithm should not use expensive means to compute this difference; rather, it should signal that it is not possible to compute a reliable answer.

2.3. Requirements for a stability proof. We wish to provide rigorous error bounds for implementations of operations such as rigid motions or regularized Boolean operations. In the latter case, a typical problem is to compute $S_0 \cap^* S_1$, given solids S_0 and S_1. According to the prescription above, if S_c is the computed result, then we should show that

i. there exists S_0' and
ii. there exists S_1'

such that

1. $d(S_0', S_0)$ is small,
2. $d(S_1', S_1)$ is small, and
3. $d(S_0' \cap^* S_1', S_c)$ is small,

where d is the metric mentioned in section 2.1. A satisfactory value for "small" will depend on the uncertainty in the input data, but in the context of solid-modeling applications, relative errors as large as 1% are useful and appropriate.

There is, however, a fundamental difficulty: the representations of solids used in practice do not rigorously define regular-closed sets. The standard approach to representing such sets, widely used in commercial software [12] and in international standards [13], involves a finite collection of compact 2-manifolds-with-boundary in R^3 that are intended to fit together to form a topological 2-cycle and thus define the

boundary of a homogeneously three-dimensional subset of R^3 [8]. Unfortunately, the separate computations performed to obtain the boundary of each 2-manifold virtually ensure that manifolds which are indicated as being adjacent will not meet along the two evaluations of their common boundary. Moreover, there will typically be a third representation of the boundary between two patches, namely, an explicit boundary curve, which will be inconsistent with the other two; further, the endpoints of the boundary curve may be represented explicitly by points in R^3, inconsistently with the actual endpoints of the three curves approximating the patch boundary. The reasons for maintaining such redundant and almost certainly inconsistent information arise from the needs of various algorithms, such as graphical display.

As already mentioned, in order to prove theorems about operations on solids, we must define the actual subset S of R^3 defined by the inconsistent data Δ. This will be done in section 3.1: we will define conditions for [illegible] of Δ, which ensure that a corresponding subset S of R^3 is [illegible], and in this case we will say that S is the [illegible] of Δ, written $S \models \Delta$.

Since we want to consider only well-defined subsets of R^3, and since the distance d between two such subsets S_0 and S_1 will be defined (see section 4) in terms of their representations Δ_0 and Δ_1, we must revise the requirements given above. Suppose (S_0, Δ_0) and (S_1, Δ_1) are given with $S_0 \models \Delta_0$ and $S_1 \models \Delta_1$, and let Δ_c be the data representing the computed result. We wish to show that

i. there exist S_0' and Δ_0' such that $S_0' \models \Delta_0'$,
ii. there exist S_1' and Δ_1' such that $S_1' \models \Delta_1'$, and
iii. there exists S_c such that $S_c \models \Delta_c$

such that

1. $d(S_0', S_0)$ is small,
2. $d(S_1', S_1)$ is small, and
3. $d(S_0' \cap^* S_1', S_c)$ is small.

3. Well-formedness of Δ and well-definition of S.

3.1. The standard approach to representing r-sets. More formally, the representation Δ contains symbolic or [illegible], describing how the faces, edges, and vertices of the cellular decomposition of the boundary ∂S of S fit together. This data defines a topological 2-cycle.[2] Further, the representation contains [illegible]. Corresponding to each 2-cell in the topological data is an oriented (as specified by an outer normal $\boldsymbol{n}$) trimmed surface patch in R^3. Two of these, $\boldsymbol{F}[D] = \{\boldsymbol{F}(u,v) : (u,v) \in D \subseteq D_0\}$ and $\boldsymbol{F}'[D'] = \{\boldsymbol{F}'(u,v) : (u,v) \in D' \subseteq D_0\}$, are shown in Figure 2. Here, the mappings $\boldsymbol{F}$ and $\boldsymbol{F}'$ define NURBS surfaces[3] in R^3, defined over a (triangular [14] or rectangular [15]) domain D_0. The patches are called [illegible] NURBS patches because the spline function is restricted to a subset D of D_0, as delineated by certain curves (so called [illegible] [12]) in the parametric domain, which may arise, for example, from intersecting two surfaces used for the boundary of the solid.

[2] A topological 2-cycle is a collection of 0-cells, 1-cells, and 2-cells forming a closed boundary for which every 1-cell has an even number of incident 2-cells. This includes 2-manifolds (e.g., a torus) for which the even number of incident 2-cells is exactly 2, as well as nonmanifolds (e.g., two tetrahedra sharing a common edge). Surface patches are 2-manifolds-with-boundary that correspond to 2-cells, but the set $S \subseteq R^3$ is not necessarily a 3-manifold.

[3] In section 3, primes have been used to distinguish distinct faces within a single object. Elsewhere, primes denote perturbed versions of complete objects.

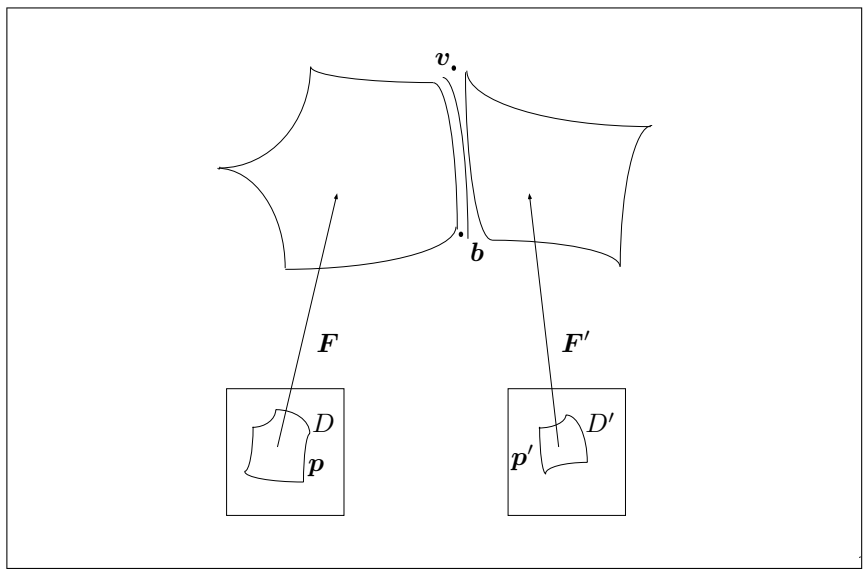

FIG. 2. *The geometric data includes adjoining trimmed NURBS patches.*

The actual boundaries of the trimmed patches are stored implicitly by their appropriate preimages (p-curves such as $\boldsymbol{p}$ and $\boldsymbol{p}'$). (Numerical algorithms [16, 17] compute these preimages as the output for an intersection of surfaces.) The data representation for each preimage is a collection of floating-point numbers, stored exactly, defining the control points (in (u-v)-space) for the p-curves, and it is easy to arrange that the p-curves interpolate their exactly stored endpoints [15]. There is an even number of p-curves corresponding to each 1-cell in the topological data, one associated with each adjacent face. There is also an explicit representation in R^3 of the boundary curve between $\boldsymbol{F}[D]$ and $\boldsymbol{F}'[D']$, denoted $\boldsymbol{b}(t)$, $t \in [0,1]$ (one such curve for each 1-cell). As shown in Figure 2, the curve $\boldsymbol{b}(t)$ does not usually coincide exactly with the corresponding edges of $\boldsymbol{F}[D]$ or $\boldsymbol{F}'[D']$. Finally, corresponding to each 0-cell in the topological data, there may also be stored an explicit corner-vertex $\boldsymbol{v}$, which in practice may not coincide exactly with the ends of the neighboring boundary curves, such as $\boldsymbol{b}(t)$, or with the exact corners of the trimmed patches $\boldsymbol{F}[D]$ and $\boldsymbol{F}'[D']$.

We would like to specify under what conditions such a representation is
and, when it is, exactly which subset of R^3 it represents.[4]

3.2. Specification of a well-defined r-set S. The question of whether to give precedence to the topological information or to the geometric information in Δ has been discussed often in the literature on robustness in solid modeling [18]. We will suppose that the topological information is correct and modify the geometric data slightly in order to bring them into agreement with each other and with the topological information.

In our context, it is easy to justify such slight modifications of the geometric

[4]Note that the purpose of introducing these well-defined sets is that we must agree on exactly which set is defined by the inconsistent data in Δ in order to prove rigorous theorems. There is no need to actually *compute* the well-defined set determined by a well-formed representation.

data.[5] First, the geometric data provided on input [illegible] be considered exact: the fact that, even for solids of very simple form, the edges of $\boldsymbol{F}[D]$ and $\boldsymbol{F}'[D']$ do not coincide shows that the geometric data is, patently, inexact. Second, suppose the user provides, say, a cylindrical surface as input. It may be important in practice that this surface be very nearly cylindrical, but the user does not believe that the eventually manufactured object will be an [illegible] mathematical cylinder. Such a user should be prepared to accept that the inconsistent data, provided in Δ, models an object with surfaces varying slightly from cylindrical. Third, in the case when there is uncertainty in the data provided, this uncertain data may correspond to uncertainty in the actual form of the object surfaces.

We now define the subset S of R^3 specified by the inconsistent data Δ. The boundary of S will be made up of slightly perturbed trimmed NURBS patches mutually consistent with the explicit vertices $\boldsymbol{v}$ and with slightly perturbed versions of the boundary curves $\boldsymbol{b}(t)$, and consistent with the topological information.

The collection of p-curves $\boldsymbol{p}^k(t)$ defining a domain $D \subseteq D_0$ will do so by specifying the boundary ∂D of D. Since D may have holes, ∂D is a collection of simple closed curves, each with segments that are p-curves. Each mapping $\boldsymbol{p}^k$ is supposed to be injective, each segment intersects its neighboring segments only at mutual endpoints, and distinct p-curves do not intersect. (These hypotheses can be easily verified in the case of Bézier curves [9].) We also suppose that if part of the boundary of the trimmed patch is defined by a line segment forming part of the edge of the u-v domain D_0, then there is an explicit p-curve that coincides with this line segment.

It will be desirable below that $\|\boldsymbol{b}^k(t) - \boldsymbol{F}(\boldsymbol{p}^k(t))\|$ be small, $0 \le t \le 1$, and at this point, if desired, a reparametrization [15, p. 241] of $\boldsymbol{b}^k(t)$ may be introduced to reduce the size of the difference just mentioned. This reparametrization need not be the same one that is used when other patches corresponding to $\boldsymbol{b}^k(t)$ are treated. Given the explicit endpoints $\boldsymbol{v}$ and $\boldsymbol{v}'$, corresponding to $t = 0$ and $t = 1$, respectively, we map the curves $\boldsymbol{b}^k(t)$ onto curves $\boldsymbol{\beta}^k(t)$, $t \in [0,1]$, for which $\boldsymbol{\beta}^k(0) = \boldsymbol{v}$ and $\boldsymbol{\beta}^k(1) = \boldsymbol{v}'$, using linear interpolation of the endpoint differences:

$$\boldsymbol{\beta}^k(t) = \boldsymbol{b}^k(t) + (1-t)[\boldsymbol{v} - \boldsymbol{b}^k(0)] + t[\boldsymbol{v}' - \boldsymbol{b}^k(1)], \quad 0 \le t \le 1,$$

so that $\|\boldsymbol{\beta}^k(t) - \boldsymbol{b}^k(t)\| \le \max\{\|\boldsymbol{v} - \boldsymbol{b}^k(0)\|, \|\boldsymbol{v}' - \boldsymbol{b}^k(1)\|\}$, $0 \le t \le 1$. It may be that $\boldsymbol{\beta}^k$ is identical to $\boldsymbol{b}^k$ (e.g., if $\boldsymbol{b}^k$ is a piecewise-linear curve obtained by "curve-tracing," or a NURBS curve interpolating its initial and final control points).

PROPOSITION 3.1. [illegible]

1. [illegible] $\boldsymbol{F}$ [illegible]
2. [illegible] k [illegible] $\boldsymbol{p}^k$ [illegible]
3. [illegible] k $\left\| \frac{\boldsymbol{b}^k(t) - \boldsymbol{b}^k(t')}{t - t'} \right\| > (\|\boldsymbol{v} - \boldsymbol{b}^k(0)\| + \|\boldsymbol{v}' - \boldsymbol{b}^k(1)\|)$, $t < t'$

[illegible] k [illegible] $\boldsymbol{F}(\boldsymbol{p}^k(t))) \to \boldsymbol{\beta}^k(t)$ [illegible] $(\boldsymbol{F}(\boldsymbol{p}^k(t)))$ [illegible] $(\boldsymbol{\beta}^k(t)))$ [illegible]. Since conditions 1 and 2 ensure that $\boldsymbol{F} \circ \boldsymbol{p}^k$ is injective on $[0,1]$ for each k, the mappings $\boldsymbol{F}(\boldsymbol{p}^k(t))) \to \boldsymbol{\beta}^k(t)$ are well defined. Condition 3 guarantees that for each k, $\boldsymbol{\beta}^k(t)$ is injective, and the mappings are therefore bijective. □

In order for condition 3.1 of Proposition 3.1 to be satisfied, $\boldsymbol{b}^k$ must itself be injective for each k. Since the mappings $\boldsymbol{p}^k = \boldsymbol{p}^k(t)$ are injective, and distinct p-

[5] In other applications, such as engineering analysis, deducing topology may be attempted, and in this case it may be appropriate to modify the topology to agree with the geometry.

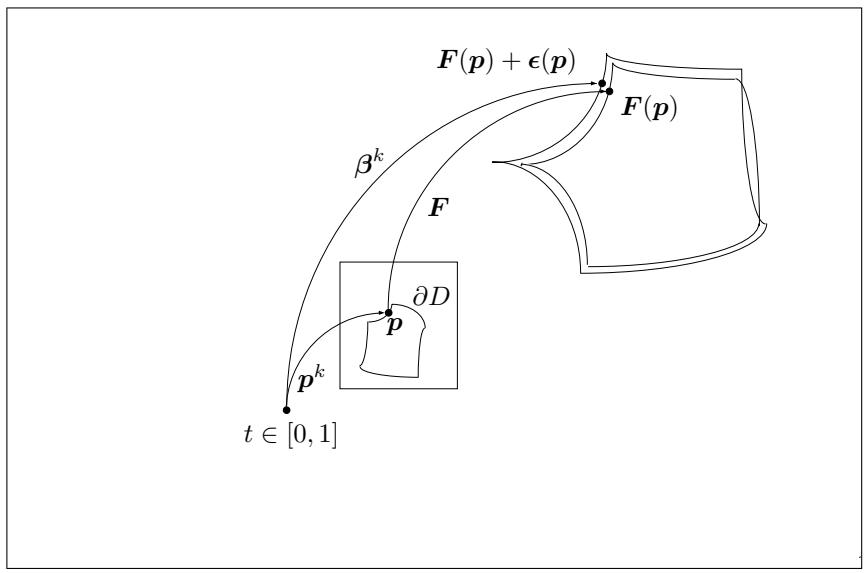

FIG. 3. *Defining the mapping* $\boldsymbol{\epsilon} = \boldsymbol{\epsilon}(\boldsymbol{p})$ *on* ∂D.

curves do not intersect, except at appropriate endpoints, we may define the mapping $\boldsymbol{\epsilon} : \partial D \to R^3$ by

$$\boldsymbol{\epsilon}(\boldsymbol{p}) = \boldsymbol{\beta}^k([\boldsymbol{p}^k]^{-1}(\boldsymbol{p})) - \boldsymbol{F}(\boldsymbol{p}), \quad \boldsymbol{p} \in \partial D, \tag{3.1}$$

where $[\boldsymbol{p}^k]^{-1}$ is the inverse [19] of the p-curve $\boldsymbol{p}^k$ for which $\boldsymbol{p}^k(t) = \boldsymbol{p}$ for some $t \in [0,1]$. Thus, $\boldsymbol{\epsilon}$ is the difference[6] between the edge of the trimmed patch $\boldsymbol{F}[D]$ and the curves $\boldsymbol{\beta}^k$, viewed as a function of $\boldsymbol{p} \in \partial D$ (see Figure 3).

We now extend $\boldsymbol{\epsilon}$ to all of D, in order to define a new trimmed patch

$$\boldsymbol{F}(\boldsymbol{p}) + \boldsymbol{\epsilon}(\boldsymbol{p}), \quad \boldsymbol{p} \in D,$$

that interpolates the modified boundary curves $\boldsymbol{\beta}$ at all points $\boldsymbol{p} \in \partial D$. These new trimmed patches will comprise the boundary of the Quasi-NURBS set S. (This defines "Quasi-NURBS set.")

Let $\epsilon(\boldsymbol{p})$ denote a component of the vector $\boldsymbol{\epsilon}(\boldsymbol{p})$, and define

$$L = \sup_{\boldsymbol{p}_1, \boldsymbol{p}_2 \in \partial D,\ \boldsymbol{p}_1 \neq \boldsymbol{p}_2} \frac{|\epsilon(\boldsymbol{p}_1) - \epsilon(\boldsymbol{p}_2)|}{\|\boldsymbol{p}_1 - \boldsymbol{p}_2\|} \quad . \tag{3.2}$$

We can extend ϵ to a continuous function on all of R^2 that satisfies a Lipschitz condition with the same Lipschitz constant L [20]. Define

$$l(\boldsymbol{p}) = \sup_{\boldsymbol{q} \in \partial D} \{\epsilon(\boldsymbol{q}) - L \cdot \|\boldsymbol{p} - \boldsymbol{q}\|\}, \quad \boldsymbol{p} \in R^2,$$

$$u(\boldsymbol{p}) = \inf_{\boldsymbol{q} \in \partial D} \{\epsilon(\boldsymbol{q}) + L \cdot \|\boldsymbol{p} - \boldsymbol{q}\|\}, \quad \boldsymbol{p} \in R^2,$$

[6]Depending upon how $\boldsymbol{b}(t)$ was obtained, it may be possible to obtain an estimate of $\boldsymbol{\epsilon}$ directly as a function of $\boldsymbol{p}$ (without examining the parametric forms) [15, p. 431], [16, sects. 4.29, 4.73].

and

$$a(\boldsymbol{p}) = \frac{1}{2}[l(\boldsymbol{p}) + u(\boldsymbol{p})], \quad \boldsymbol{p} \in R^2. \tag{3.3}$$

Any continuous function satisfying the Lipschitz condition on R^2 is bracketed by the [illegible], $l(\boldsymbol{p})$, and the [illegible], $u(\boldsymbol{p})$, and $l(\boldsymbol{p})$ and $u(\boldsymbol{p})$ are [21] themselves solutions to the extension problem, as is $a(\boldsymbol{p})$. Furthermore,

$$|a(\boldsymbol{p})| \leq \sup_{\boldsymbol{q} \in \partial D} |\epsilon(\boldsymbol{q})|, \quad \boldsymbol{p} \in R^2.$$

We will extend $\epsilon(\boldsymbol{p})$ to D using the method suggested by (3.3):

$$\epsilon(\boldsymbol{p}) = \frac{1}{2}[l(\boldsymbol{p}) + u(\boldsymbol{p})], \quad \boldsymbol{p} \in D. \tag{3.4}$$

Thus, the patch comprising the boundary of the set S differs (in each component) from the trimmed patch $\boldsymbol{F}[D]$, given as part of Δ, by no more than the error $\sup_{\boldsymbol{q} \in \partial D} |\epsilon(\boldsymbol{q})|$ in the original input data.

PROPOSITION 3.2. [illegible] $\epsilon(\boldsymbol{p})$ [illegible] (3.4) [illegible] D [illegible] (3.1) [illegible] ∂D [illegible] (3.4) [illegible] D [illegible] L [illegible] (3.2) [illegible]

$$|\epsilon(\boldsymbol{p})| \leq \sup_{\boldsymbol{q} \in \partial D} |\epsilon(\boldsymbol{q})|, \quad \boldsymbol{p} \in D.$$

The Lipschitz constants for each of the components of $\boldsymbol{\epsilon}$ can be used to define a Lipschitz constant for the vector-valued function $\boldsymbol{\epsilon}$.

We have now completed the task of defining a new patch $\boldsymbol{F}(\boldsymbol{p}) + \boldsymbol{\epsilon}(\boldsymbol{p})$, defined for all $\boldsymbol{p} \in D$, that interpolates the modified boundary curves $\boldsymbol{\beta}^k$ at all points $\boldsymbol{p} \in \partial D$, and if we apply the same process to each trimmed patch, they will fit together perfectly along the modified boundary curves. Furthermore, we have established bounds on the difference between $\boldsymbol{\beta}^k(t)$ and $\boldsymbol{b}^k(t)$, and bounds on the magnitude and rate of change of $\boldsymbol{\epsilon}(\boldsymbol{p})$ in terms of their values on ∂D.

3.3. Well-formedness of $\boldsymbol{\Delta}$. We summarize now the conditions thus far introduced, in order that Δ be well-formed. First, the topological data must define a topological 2-cycle. Second, the geometric data must include a trimmed patch corresponding to each 2-cell, an explicit boundary curve corresponding to each 1-cell, and an explicit corner point corresponding to each 0-cell. Furthermore, for each trimmed patch, there must be one p-curve corresponding to each 1-cell in the boundary of the 2-cell associated with the patch. Also, the geometric data must satisfy the conditions in the hypotheses of Proposition 3.1.

The remaining conditions, to be added now, ensure that the perturbed surface patches form an embedding of the 2-cycle in R^3: each perturbed patch

$$\boldsymbol{F}[D] + \boldsymbol{\epsilon}[D] = \{\boldsymbol{F}(\boldsymbol{p}) + \boldsymbol{\epsilon}(\boldsymbol{p}) : \boldsymbol{p} \in D\}$$

must not self-intersect, adjacent perturbed patches

$$\boldsymbol{F}[D] + \boldsymbol{\epsilon}[D] \text{ and } \boldsymbol{F}'[D'] + \boldsymbol{\epsilon}'[D']$$

may intersect only at a common corner point or along a common boundary curve, and nonadjacent perturbed patches must be disjoint. If all of the above conditions are satisfied, then S is well defined, and we write $S \models \Delta$.

In simple cases, it is possible to give a priori guarantees of non–self-intersection. If $\boldsymbol{q} = \boldsymbol{F}(\boldsymbol{p})$, the mapping $\boldsymbol{q} \mapsto \boldsymbol{q} + \boldsymbol{\epsilon}(\boldsymbol{p})$ is injective provided that the product of L and a Lipschitz constant for $\boldsymbol{F}^{-1}$ is less than 1, and, consequently, under the latter condition, injectiveness of $\boldsymbol{F}$ implies that $\boldsymbol{F}(\boldsymbol{p}) + \boldsymbol{\epsilon}(\boldsymbol{p})$ is injective in $\boldsymbol{p}$. For example, if $\boldsymbol{F}$ is a trimmed Bézier patch defined on a subset D that is contained in a triangular subset of the triangular domain D_0, then [9, Criteria 3.1 and 3.1*] and [22] can be used to guarantee injectiveness of $\boldsymbol{F}$ on D. On the other hand, adjacent patches sharing a common edge or vertex cannot be dealt with in this way. For this case and for self-intersection of single non-Bézier patches, it will be necessary to rely on a posteriori (computational) verification. Algorithms to verify non–self-intersection, based on properties of the surface normals, are available [23] (but note that care is required in applying such algorithms to composite patches [24]). If $\boldsymbol{F}$ is a rational tensor-product Bézier patch, then the Gauss map [25] of the patch can be computed by the methods of [26]. The problem of finding the Gauss map of $\boldsymbol{F} + \boldsymbol{\epsilon}$, given the Gauss map of $\boldsymbol{F}$, is discussed below.

4. Metrics for the measurement of error. Definition of a metric that adequately reflects our intuition, and practical requirements, in the context of solid modeling is not straightforward. For example, as mentioned in section 2.1, we must first decide whether the metric should require that two objects considered to be close have the same topological form, and if so, how demanding this requirement should be. A stringent requirement would be that the representations have equivalent topological data, and that the geometric objects be linked by an ambient isotopy.[7] The following is a possible definition.

Suppose $S \models \Delta$ and $S' \models \Delta'$ are given, that the 2-cycles associated with S and S' are isomorphic, and that there is an ambient isotopy linking S and S'. In this case, we define the penalty $\pi(S, S')$ to be zero; otherwise, it is infinite. Now, let $\boldsymbol{G}_i[D] = \boldsymbol{F}_i[D] + \boldsymbol{\epsilon}_i[D]$, $i = 1, \ldots, n$, be the embedded patches of S corresponding to the 2-cells in the topological 2-cycle, and let $\boldsymbol{G}'_i[D']$ be the corresponding patches of S'. Then the distance between S and S' may be defined by

$$d(S, S') = \max_{i=1,\ldots,n} \{d(\boldsymbol{G}_i[D], \boldsymbol{G}'_i[D'])\} + \pi(S, S'),$$

where the symbol d has also been used to denote the Hausdorff metric (no confusion should arise). In summary, for the distance between two representations to be small, they must define topologically equivalent embeddings, and the maximum Hausdorff distance between corresponding embedded patches must be small.[8]

We may envisage also the use of less demanding metrics: for example, the Hausdorff metric alone could be used to measure the distance between a true and a computed solution. Which problems are ill-conditioned depends strongly on the choice of metric. Thus, the example set-union problems discussed in section 2 are ill-conditioned

[7] In the case of objects defined by curvilinear complexes, not necessarily Bézier, sufficient conditions that perturbations of the control points should produce an object, linked to the original by an ambient isotopy, were given in [10].

[8] Even such a demanding metric is not always sufficient, however, to capture our intuitive idea of what constitutes closeness between solutions in the case of solid-modeling operations, since the Hausdorff metric is not sensitive to thin protrusions and cracks in an object [11].

if the metric requires equivalence of topological form, but well-conditioned if only the Hausdorff metric is used.

5. The example of set intersection or difference. A complete error analysis of the sort suggested by the requirements of section 2.3 is possible, at present, only for very simple representations and operations. Consider first an operation simpler than set intersection: suppose that an object is represented by a curvilinear Bézier complex (involving untrimmed triangular Bézier patches) [9] and that the operation is rigid motion. In this case, the representation of section 3.1 simplifies greatly. There are no p-curves other than the three boundaries of the triangular domain of each patch, and the images of the boundary segments of the parametric domain are Bézier curves; adjacent patches sharing an edge intersect in a common Bézier curve with common control points; the common curve can also play the role of $\boldsymbol{b}(t)$ and $\boldsymbol{\beta}(t)$; and, $\boldsymbol{\epsilon}(\boldsymbol{p}) \equiv \mathbf{0}$. The error introduced by applying the rigid motion to the control points of the Bézier mapping $\boldsymbol{F}$ defining each face, using finite-precision arithmetic, can be estimated by standard means [5]. Provided that $\boldsymbol{F}$ has no nearly critical points, these estimates can be used in conjunction with [9, 10] to verify that the computed solid (S_c, Δ_c) remains a well-formed Bézier complex, linked to the true transformed object by an ambient isotopy. The Hausdorff distance between the pairs of computed and true patches can also be computed. Thus, we can do a simple forward analysis: there is no need to associate any of the error with the problem data.

Even in the case of Bézier patches, however, the introduction of trimming complicates the problem greatly. The roundoff error incurred in the transformation of the control points of $\boldsymbol{F}$ can be taken into account in the application of the a priori self-intersection test described in section 3.3 (and in a similar way for tests of noninterference of disjoint patches) in order to verify that the computed set remains a well-formed Bézier complex. Verification of noninterference of adjacent patches would, however, depend on the use of computational methods [23, 24].

The [illegible] of two well-formed curvilinear objects, an operation that has occupied a central place in the robustness literature in solid modeling, is a vastly more difficult problem. We illustrate using the operations $\cap^*$ or $\sim^*$ with input solids that are modified versions of those in an example used by Hoffmann [2] to illustrate how Boolean algorithms can fail. The numerical results were obtained using the DT_NURBS software package [16].

The two ideal operands are shown in Figure 4. The first solid, denoted S_0, is a tetrahedron with four planar triangular faces: one horizontal, in the plane $z = 21$; another vertical, in the plane $x = 10/3$; and two others, partially hidden and separated by a heavy solid line partially visible in the figure. The extreme simplicity of this object means that the horizontal and vertical faces are exactly defined, in the representation of section 3.1, by their corner vertices, which respectively have third components equal to 21, or first components equal to (the floating-point representation of) 10/3. This permits use of a simple version of the Grandine–Klein algorithm, the planar-cut algorithm described in [17].

The second ideal mathematical solid shown in Figure 4, denoted S_1, has a curvilinear face defined by a Bézier mapping

$$\boldsymbol{F}(u,v) = \sum_{i=0}^{1}\sum_{j=0}^{3} \binom{1}{i}\binom{3}{j} u^i(1-u)^{1-i}v^j(1-v)^{3-j}\boldsymbol{P}_{ij}, \quad 0 \le u, v \le 1,$$

where $\boldsymbol{P}_{00} = (0,-10,0)$, $\boldsymbol{P}_{01} = (0,-10,40)$, $\boldsymbol{P}_{02} = (0,10,40)$, $\boldsymbol{P}_{03} = (0,10,0)$,

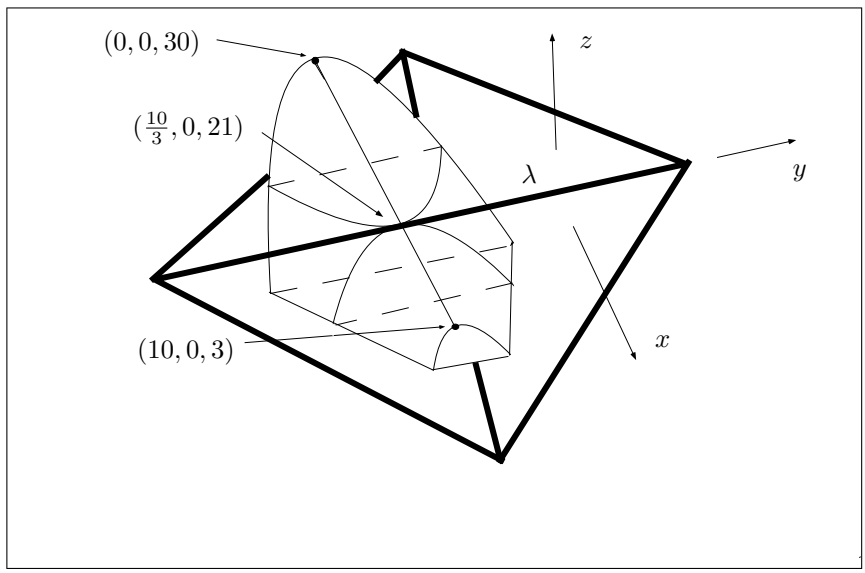

FIG. 4. *Two input objects (operands).*

and $\boldsymbol{P}_{10} = (10, -1, 0)$, $\boldsymbol{P}_{11} = (10, -1, 4)$, $\boldsymbol{P}_{12} = (10, 1, 4)$, $\boldsymbol{P}_{13} = (10, 1, 0)$. This face is symmetric with respect to the plane $y = 0$ and intersects each of the planes $z = 21$ and $x = 10/3$, as shown in Figure 4. There is a single point of intersection, namely $(10/3, 0, 21)$, between the curvilinear face and the line λ defined by $z = 21$ and $x = 10/3$. The other faces of this second object do not intersect the two rear triangular faces of S_0. For example, in the plane $x = 0$ there is a hidden face of S_1 with upper boundary defined by the Bézier curve $\sum_{j=0}^{3} v^j (1-v)^{3-j} \boldsymbol{P}_{1j}$, which has a maximum z value at $(0, 0, 30)$, and in the plane $x = 10$ there is a visible face of S_1 with upper boundary defined by the Bézier curve $\sum_{j=0}^{3} v^j (1-v)^{3-j} \boldsymbol{P}_{0j}$, which has a maximum z value at $(10, 0, 3)$.

The interesting region [2] for this example is the region near $(10/3, 0, 21)$. When the surface $\boldsymbol{F}$ is numerically intersected with the triangular face lying in the plane $z = 21$, the corresponding boundary curve may not intersect the plane $x = 10/3$ exactly once, as it theoretically should: it may intersect zero or two times. Similarly, when $\boldsymbol{F}$ is intersected with the triangular face lying in the plane $x = 10/3$, the corresponding boundary curve may intersect the plane $z = 21$ zero, one, or two times, depending on the surface-surface intersector. We used the routines D2PCUT and D2CLXT [16, sect. 4] with a tolerance of 10^{-7} to find fourth-order B-spline intersection curves $\boldsymbol{b}(t)$ lying in the $z = 21$ plane (see Figure 5) and the corresponding pair of p-curves in $(u$-$v)$-space. The two curves shown in Figure 5 can be viewed as parts of a single curve with a maximum x value approximately $3 \cdot 10^{-5}$ units beyond $(10/3, 0, 21)$ in the positive x direction. The intersections of $\boldsymbol{b}(t)$ with the line $x = 10/3$ are quite far (0.0022 units) from the true intersection $(10/3, 0, 21)$. This illustrates a major open problem in the analysis of regularized Boolean operations, namely, when and how various geometric entities, such as the two vertices indicated in Figure 5, should be merged. Commercial kernel systems [12] depend on the use of complicated (and partially undisclosed) systems of tolerances to decide these questions. The question of "topology resolution" of the boundary [17, 27] is related to this difficulty, and it is

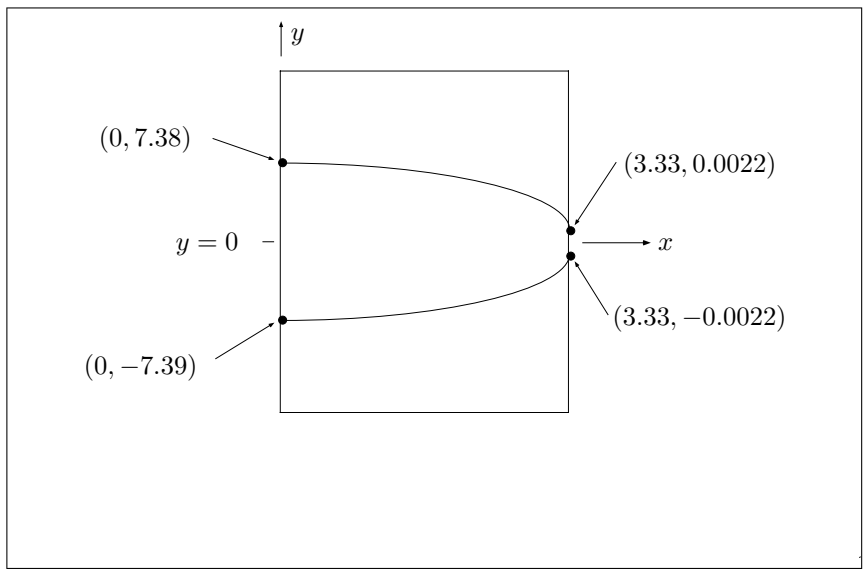

FIG. 5. *Two boundary curves in the plane* $z = 21$ *do not meet.*

aggravated by the use of finite-precision arithmetic.

Since ill-condition is possible in the case of $S_0 \sim^* S_1$, a backward error analysis will be appropriate ($S_0 \neq S_0'$ and $S_1 \neq S_1'$ in the notation of section 2.3). A promising first step in this direction has been made in [27], where it was shown, at least in special cases, how to perturb the control points of two input surfaces so that their exact intersection coincides with a given computed solution. In the context of regularized Boolean operations, however, the surface perturbations must take account of the simultaneous intersection of , , , pairs of surfaces, and the general problem remains open. To illustrate, we began with a pair of p-curves in (u-v)-space (see Figure 6), corresponding to the intersection between $\boldsymbol{F}$ and the plane $z = 21$. These p-curves (obtained by modifying the output of D2PCUT and D2CLXT) are quadratics. It was then possible to make perturbations in the third components of the $\boldsymbol{P}_{ij}$ which maintain the symmetry of $\boldsymbol{F}$ with respect to the plane $y = 0$ and for which the image of the p-curves is the , , intersection of the perturbed $\boldsymbol{F}$ and a perturbed version of the plane $z = 21$:

$$\begin{aligned}
\boldsymbol{P}^3_{0j} &\leftarrow \boldsymbol{P}^3_{0j} + 0.824\ldots, \quad j = 0, 3,\\
\boldsymbol{P}^3_{0j} &\leftarrow \boldsymbol{P}^3_{0j} - 0.747\ldots, \quad j = 1, 2,\\
\boldsymbol{P}^3_{1j} &\leftarrow \boldsymbol{P}^3_{1j} + 0.863\ldots, \quad j = 0, 3,\\
\boldsymbol{P}^3_{1j} &\leftarrow \boldsymbol{P}^3_{1j} + 0.654\ldots, \quad j = 1, 2.
\end{aligned}$$

The perturbed version of the plane $z = 21$ is a ruled surface: the perturbation is defined by a piecewise polynomial, where each polynomial is of degree 6 in a single parameter θ, $0 \leq \theta \leq 1$, and for each u the surface is constant as a function of v. The coefficients of the polynomials are bounded in magnitude by .00057.

The preimage of the intersection between $\boldsymbol{F}$ and the plane $x = 10/3$ is the straight line $u = \frac{1}{3}$ in (u-v)-space, and the first components of the $\boldsymbol{P}_{ij}$ can be perturbed (simultaneously with the perturbations of the third components, described above) in order to ensure that the image of the straight-line p-curve $u = u_o$, $u_o \cong \frac{1}{3} - 1.8 \cdot 10^{-5}$,

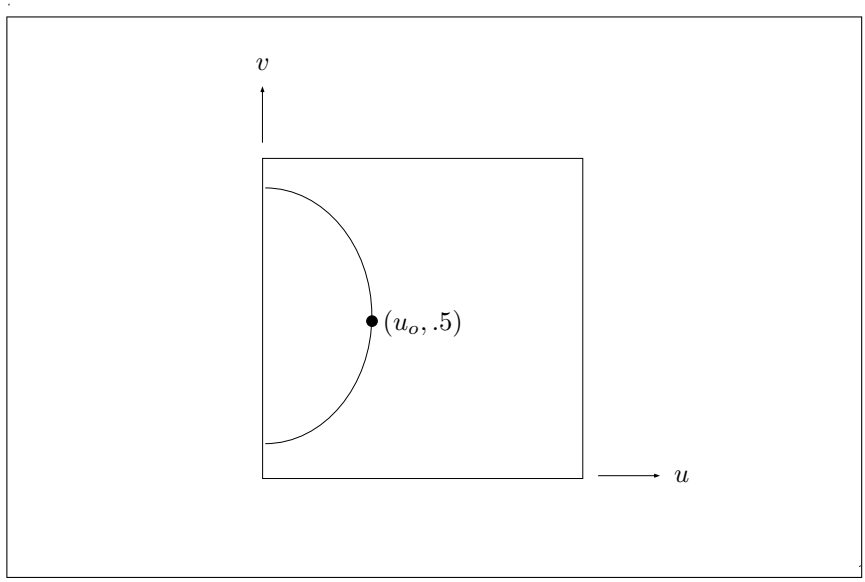

FIG. 6. *Preimage of the intersection with the plane* $z = 21$.

is the intersection of the perturbed $\boldsymbol{F}$ and a perturbed plane. In this case the perturbations are

$$\boldsymbol{P}^1_{0j} \leftarrow \boldsymbol{P}^1_{0j} + \frac{30u_o - 10}{3u_o - 3}, \quad \boldsymbol{P}^1_{1j} \leftarrow \boldsymbol{P}^1_{1j}, \quad j = 0, 1, 2, 3,$$

and the perturbed plane remains a perfect plane.

The simultaneous perturbations just described define sets S_0' and S_1' such that S_0' is close to S_0, S_1' is close to S_1, and the images of the p-curves in the parametric spaces define $S_0' \cap^* S_1'$. These sets S_0' and S_1' are, however, not necessarily sets such that $S_0' \models \Delta_0'$ and $S_1' \models \Delta_1'$, since we have not taken account of the computed intersection curves $\boldsymbol{b}(t)$. Nonetheless, note that the size of the Lipschitz constant obtained in the example ($L = 0.01114$) is promising, in the context of guaranteeing that perturbed versions $\boldsymbol{F} + \boldsymbol{\epsilon}$ and $\boldsymbol{F}' + \boldsymbol{\epsilon}'$ fit together seamlessly, as discussed at the end of section 3. To obtain such guarantees we need information about the Gauss map of $\boldsymbol{F} + \boldsymbol{\epsilon}$, given the Gauss map of $\boldsymbol{F}$.

Consider, for example, the case where $\boldsymbol{F}$ is a planar face and, for simplicity, suppose that the parametric domain is the plane itself:

$$\boldsymbol{F}(u, v) = Id(u, v),$$

and $\boldsymbol{F}(\boldsymbol{p}(t))$ is a simple closed planar curve $t \mapsto \boldsymbol{\alpha}(t)$. Suppose that we also have a similar curve, perturbed by $\boldsymbol{\epsilon}(t)$,

$$t \mapsto \begin{bmatrix} \boldsymbol{\alpha}(t) \\ 0 \end{bmatrix} + \boldsymbol{\epsilon}(t) \in R^3,$$

where it is known that $\|\boldsymbol{\epsilon}(t)\| \leq \epsilon_{max}$, and that for each component ϵ of $\boldsymbol{\epsilon}$,

$$|\epsilon(u_1, v_1) - \epsilon(u_2, v_2)| \leq L \cdot \|(u_1, v_1) - (u_2, v_2)\|$$

for (u_1, v_1), (u_2, v_2) on $t \mapsto \boldsymbol{\alpha}(t)$, as in section 3.2. Extending the mapping $(u, v) \mapsto \boldsymbol{\epsilon}(u, v)$, which is defined on the curve $t \mapsto \boldsymbol{\alpha}(t)$, to the region by $t \mapsto \boldsymbol{\alpha}(t)$, as described in section 3.2, we obtain a map $\boldsymbol{G} = \boldsymbol{F} + \boldsymbol{\epsilon}$:

$$\boldsymbol{G}(u, v) = \begin{bmatrix} u \\ v \\ 0 \end{bmatrix} + \boldsymbol{\epsilon}(u, v).$$

Assume that we have information about the normals of the patches adjacent to $\boldsymbol{F}$. In order to guarantee that $\boldsymbol{G}$ does not have extraneous intersections with any adjacent patch, we must bound the angle between the unit normal $\boldsymbol{n} = \boldsymbol{n}(u, v)$ of $\boldsymbol{G}$ and the unit normal $(0, 0, 1)$ of the planar surface $\boldsymbol{F}$.

We have $\frac{\partial \boldsymbol{G}}{\partial u} = (1, 0, 0) + \frac{\partial \boldsymbol{\epsilon}}{\partial u}$ and $\frac{\partial \boldsymbol{G}}{\partial v} = (0, 1, 0) + \frac{\partial \boldsymbol{\epsilon}}{\partial v}$. Computing $\frac{\partial \boldsymbol{G}}{\partial u} \times \frac{\partial \boldsymbol{G}}{\partial v}$ to obtain the surface normal of $\boldsymbol{G}$, normalizing it, and using $(1 + x)^{-\frac{1}{2}} = 1 - \frac{x}{2} + \frac{3}{8}x^2 + O(x^3)$, we obtain a vector $\boldsymbol{n}$ whose third component is no smaller than $1 - L^2 - O(L^3)$, since $\boldsymbol{\epsilon}$ is piecewise differentiable and each component of $\frac{\partial \boldsymbol{\epsilon}}{\partial u}$ and $\frac{\partial \boldsymbol{\epsilon}}{\partial v}$ is bounded by L. Taking $L = 0.01114$, this provides a lower bound of $1 - L^2 = 0.99987$ on the inner product between $\boldsymbol{n}$ and $(0, 0, 1)$ and an upper bound of $\sqrt{2}L = 0.0158$ radians on the angle between the two vectors.

The example illustrates that in order to obtain useful bounds precluding extraneous intersections between adjacent patches, it is important that the numerical method control not only the size of $\boldsymbol{\epsilon}$ but also the size of its derivative (and L).

6. Conclusion. In this paper a definition for the actual subset of R^3, defined by the solid-model representations that are used in practice, was proposed. Such representations are not only in error, they contain intrinsic inconsistencies. The proposed definition for the subset defined by such data, which was called a Quasi-NURBS set, produces patches that are perturbed by an amount smaller than the error already present along the boundaries of the given trimmed patches and are constrained by the same Lipschitz constants that describe the variation of the given trimmed patches along their boundaries.

The paper gave the basic results necessary to provide a framework for error analysis when using the representations referred to above. The discussion included the question of ill-condition and when it is appropriate to invoke methods outside the scope of numerical analysis. It also illustrated certain of the steps that must be taken to obtain a rigorous proof of stability for regularized Boolean operations on solids. The discussion and example (section 5) showed that much remains to be done to achieve this latter goal. On the other hand, other results may be more tractable. For example, the rigorous formulation of well-definition (section 3.2) may make it possible to prove that well-formedness (verified a posteriori, as discussed in section 3.3) is sufficient to guarantee the correctness of surface meshing algorithms, which are empirically very reliable when the underlying solid model does not contain errors [3]. Such a result would have significant practical importance.

Acknowledgments. The authors are grateful to T. J. Peters, who made many useful comments, and to J. Bisceglio, who provided many of the numerical results mentioned in section 5. Responsibility for any errors or omissions lies solely with the authors.

GEOMETRIC OPTIMIZATION OF THE EVALUATION OF FINITE ELEMENT MATRICES*

ROBERT C. KIRBY† AND L. RIDGWAY SCOTT‡

Abstract. This paper continues earlier work on mathematical techniques for generating optimized algorithms for computing finite element stiffness matrices. These techniques start from representing the stiffness matrix for an affine element as a collection of contractions between *reference tensors* and an element-dependent *geometry tensor*. We go beyond the complexity-reducing binary relations explored in [R. C. Kirby, A. Logg, L. R. Scott, and A. R. Terrel, *SIAM J. Sci. Comput.*, 28 (2006), pp. 224–240] to consider geometric relationships between three or more objects. Algorithms based on these relationships often have even fewer operations than those based on complexity-reducing relations.

Key words. finite element, variational form, optimized algorithm, graph theory

1. Introduction.

In our recent work, we have presented mathematical and computational techniques for the automatic generation of optimized code for evaluating local stiffness matrices for finite elements. These techniques are applicable to multilinear variational forms over affine elements using general basis functions. Beginning in [10], we suggested that the local evaluation of the stiffness matrix for multilinear forms for a single affine element could be written as contractions of a set of , with a single tensor encoding the geometry and coefficients.

This formulation allows us to generate code for the innermost part of a finite element computation. The FEniCS form compiler, FFC [11, 12], takes a variational form and approximating space as input. As output, it produces a function that maps the geometry and material coefficients for any element in an unstructured mesh to the element stiffness matrix. It also generates the higher-level code that loops over all elements in a mesh, computing the element stiffness matrices and inserting them into a global sparse matrix. The current implementation of FFC is fully functional for multilinear forms with arbitrary order Lagrange elements, and works for general unstructured meshes in one, two, or three space dimensions. In [12], we show how the technique can be applied to more general variational forms, curved elements, and $H(\mathrm{div})$ or $H(\mathrm{curl})$ elements. Although our techniques can be applied to quadrilateral or hexahedral meshes, spectral element techniques that work dimension by dimension are probably more effective.

The innermost computational kernel of the FFC-generated code is the collection of tensor contractions on each element of a mesh. Since this code is a single function executed over all elements of a mesh, it makes sense to find optimizations that allow us to perform the computations for an arbitrary element as efficiently as possible.

In [10], we noticed that relations exist between the reference tensors that allow one to perform all the contractions needed to compute a single element matrix in many fewer arithmetic operations than would otherwise seem necessary. Our rather crude heuristic for exploiting these dependencies allowed us to generate code that was notably faster than the standard method for forming local stiffness matrices on our test problems.

Then, in [13], we formalized part of the optimization process in [10] by introducing the concept of [illegible]. These are derived from metrics that model the cost of computing one of the tensor contractions once another contraction has been computed. This theory effectively translates optimizations based on pairwise dependencies between the reference tensors into a minimum spanning tree. While the strategy is quite effective at reducing the operation count for many variational forms, it does not address how to utilize relations between three or more reference tensors, such as when one reference tensor may be written as a linear combination of two others. In this paper, we study efficient algorithms for detecting such geometric relations and hence finding fast algorithms for building finite element stiffness matrices.

Our attempts to mechanize the optimization of evaluating finite element matrices bear strong resemblance to projects in other areas. In [2], a tool is developed for synthesizing high-performance FORTRAN code for high-dimensional structured tensor contractions arising in quantum chemistry. The authors search for ways of reducing operation counts by heuristics for common subexpression elimination. While our techniques seem to search for a wider class of arithmetic dependencies, their work pushes harder on data locality and other architecture and performance-related issues. Other attempts to mathematize the derivation of efficient numerical code include the FLAME project of van de Geijn and coworkers for dense linear algebra [8, 3] and the SMART project of Egner and Püschel in signal processing [6]. The latter project has developed a code that takes a (symbolic representation of) a matrix such as the discrete Fourier transform as input and factors it via representation theory into a short sequence of sparse structured matrices. Their techniques automatically replicate the Cooley–Tukey algorithm [4], but also find fast algorithms for other, more complicated, transforms. Many other projects, such as ATLAS [20] and SPIRAL [19], attempt to map a given algorithm as closely as possible to a given computer architecture.

We begin the remainder of this paper by reviewing the formulation of the local matrix computation as tensor contractions and stating the abstract computational problem to optimize in section 2. Then, we study our geometric optimization process in section 3. This includes both an expected quadratic-time algorithm for detecting coplanarity among a set of input vectors as well as using such relations to speed up the finite element computation. These ideas generalize readily to higher-dimensional dependencies, which we do at the end of this section. In section 4, we study the actual reduction of operation count generated by our algorithms. In many cases for both the Laplacian and weighted Laplacian, it gives reduction in arithmetic superior to that of complexity-reducing relations. This leads us to consider how the two approaches can be combined into a single optimization process. While we do not have a good answer to this yet, we discuss a simple heuristic and also phrase the issue as a combinatorial optimization problem in section 5. Throughout the paper, readers familiar with the subjects of finite linear spaces and ordered ternary relations may find many of the concepts somewhat familiar. To focus on the exposition of the algorithms and application to finite element computation, we defer these issues and make several remarks on these relationships in section 6.

2. Background. As in previous work, we let $\{V_i\}_{i=1}^r$ be a given set of finite-dimensional function spaces defined on a triangulation $\mathcal{T} = \{e\}$ of a domain $\Omega \subset \mathbb{R}^d$. We consider multilinear forms a defined on the product space $V_1 \times V_2 \times \cdots \times V_r$:

$$a : V_1 \times V_2 \times \cdots \times V_r \to \mathbb{R}. \tag{2.1}$$

In finite element methods, a is an integral of products of (derivatives) of its arguments.

We are interested in forming the element tensor A^K for each $K \in \mathcal{T}_h$. This element tensor depends on the basis chosen for each function space. We let $\{\varphi_i^1\}_{i=1}^{M_1}, \{\varphi_i^2\}_{i=1}^{M_2}, \ldots, \{\varphi_i^r\}_{i=1}^{M_r}$ be bases of $V_1, V_2, \ldots, V_r$ over K, and let $i = (i_1, i_2, \ldots, i_r)$ be a multi-index. The multilinear form a then defines a rank r tensor given by

$$A_i^K = a(\varphi_{i_1}^1, \varphi_{i_2}^2, \ldots, \varphi_{i_r}^r). \tag{2.2}$$

For affine elements such as triangles and tetrahedra, A^K is evaluated by mapping each K to a fixed reference element $\hat{K}$. As we have written extensively about this representation elsewhere, we recall the Laplacian as an example here. For other examples and a more general representation theorem for a class of variational forms, we refer the reader to [11, 12].

We let F_K be the affine map from $\hat{K}$ to K. We denote by x the coordinates on K and by X the coordinates on $\hat{K}$. We identify $\phi_i^j = \Phi_i^j \circ F_K^{-1}$, and by the chain rule we obtain

$$\begin{aligned} A_i^K &= \int_e \nabla\varphi_{i_1}^{e,1}(x) \cdot \nabla\varphi_{i_2}^{e,2}(x)\,\mathrm{d}x \\ &= \det F_e' \frac{\partial X_{\alpha_1}}{\partial x_\beta} \frac{\partial X_{\alpha_2}}{\partial x_\beta} \int_E \frac{\partial \Phi_{i_1}^1(X)}{\partial X_{\alpha_1}} \frac{\partial \Phi_{i_2}^2(X)}{\partial X_{\alpha_2}}\,\mathrm{d}X = A_{i\alpha}^0 G_e^\alpha. \end{aligned} \tag{2.3}$$

In [13], we abstracted the computation of A^K to the following scenario. Let $V \subset \mathbb{R}^d$ with $|V| = n < \infty$. By default, for any $g \in \mathbb{R}^d$, we may compute $\{v^t g : v \in V\}$ in nd multiply-add pairs (hence MAPs). However, the kinds of V that arise in finite element methods often possess special structure, so that the overall process may be performed on a general g in many fewer MAPs. In order to formalize an optimization procedure based on pairs of vectors in V, we introduced the notion of [illegible]. These are distance measures ρ such that if $\rho(u, v) = k$, then $u^t g$ may be computed using $v^t g$ in no more than k MAPs. For example, if u, v are colinear, then we may define $\rho(u, v) = 1$, since if $u = \alpha v$, then $u^t g = \alpha(v^t g)$. However, we left unstudied how to exploit relations between three or more members of V, such as when three vectors lie in a two-dimensional subspace.

The point of this work is to formalize and employ these geometric relations in optimizing the computation of element stiffness matrices. Throughout this work, we shall present illustrations of our geometric notions on a particular set of vectors. In this case, we will work with the vectors from the Laplacian reference tensor for cubic Lagrange elements over triangles. We will use the symmetry transformation described in [13] to map from $\mathbb{R}^4$ to $\mathbb{R}^3$ and work only with the triangular part of the matrix. A table of the vectors can be found in Table 2.1. In particular, we recall that many of the vectors are zero or else equal or colinear to other vectors. Hence, the number of vectors among which we need to consider coplanar relations is actually much smaller. In Table 2.2, we show the entries of the reference tensor after removing the zero entries and all but one of any collection of equal or colinear vectors.

3. Geometric relations. As with complexity-reducing relations, we will consider the following abstract problem. Suppose that $\{v_i\}_{i=1}^n \equiv V \subset \mathbb{R}^d$ is a finite collection of vectors. We desire to derive a process by which $\{v_i^t g\}_{i=1}^n$ may be constructed efficiently. This process must take an arbitrary $g \in \mathbb{R}^d$ as an input. Effectively, this corresponds to a matrix-vector multiplication Ag, where the elements of V form the rows of A. Such a process may then be encoded in some low-level C or FORTRAN program and used as the innermost computation for building finite element matrices. As finding such a process is a "compile-time" process that need only be performed once per variational form and set of basis functions, one may be willing to perform a relatively expensive computation to obtain it.

If any $u, v \in V$ are equal or colinear, then $u^t g$ may be computed in zero or one operation using $v^t g$. If such relations occur in V, we need only search for coplanarity among the noncolinear elements of V. Similarly, when we search for higher-dimensional dependencies, we will want to filter out coplanarity.

DEFINITION 3.1. $V \subset \mathbb{R}^d$ [illegible] $k+1 \leq |V| < \infty$ [illegible] k-independent [illegible] $k+1$ [illegible]

DEFINITION 3.2. [illegible] $U \subset V$ [illegible] k [illegible] U [illegible] k-maximal [illegible] $U \subset U'$ [illegible] U [illegible] U' [illegible]

It stands to reason that if there are many linear dependencies among the vectors, this should allow us to construct $\{v_i^t g\}_{i=1}^n$ efficiently, for if $w = \alpha u + \beta v$, then $w^t g$ may be computed in only two MAPs once $u^t g$ and $v^t g$ are known. In the rest of the section, we study a process to make thorough use of these dependencies. We first examine the case of two-dimensional dependencies, and then move on to present the general case.

Now, suppose that V is 1-independent (no two vectors are colinear or equal). Two issues must be resolved to make use of coplanar dependencies in computing the dot products. First, we must enumerate all of the 2-maximal subsets of V. Second, we must find a way to construct $\{v_i^t g\}_{i=1}^n$ in such a way that as many of the dot products are computed by using linear relations as possible. Equivalently, as few dot products as possible should be performed explicitly.

3.1. Search algorithms. The first step one might take in finding the 2-maximal sets is obvious; loop over all triples of vectors. This process runs in $O(n^3)$ time, and the innermost check for coplanarity will typically require $O(d^3)$ operations (for example, Gaussian elimination or singular value decomposition). It then remains to determine the 2-maximal sets from the coplanar triples. To do this, let (G, E) be a graph where $G = \{\{i, j, k\} : \dim \operatorname{span}\{v_i, v_j, v_k\} = 2\}$ and an edge is drawn between $\{i, j, k\}$ and $\{i', j', k'\}$ if $|\{i, j, k\} \cap \{i', j', k'\}| = 2$. Then the connected components of this graph encode the 2-maximal sets. Actually, the vertices of a connected component are a set of sets of vector labels; one must take the union of all sets of labels in each connected component.

The 2-maximal sets may be enumerated much more effectively. By assumption, each pair of elements in V spans a plane. If we consider two pairs of vectors (these pairs may share a common vector), then we should be able to determine whether they correspond to the same plane or not.

Rather than searching for equality among the planes themselves, we will work a [illegible] condition for equality, leading to Algorithm 1 below. Let $\Pi : \mathbb{R}^d \to \mathbb{R}^3$ be some full-rank linear transformation. We compute $\{\Pi v_i\}_{i=1}^n$. Then, if $\{v_i, v_j\}$ and $\{v_{i'}, v_{j'}\}$ encode the same two-dimensional subspace, then of necessity so do $\{\Pi v_i, \Pi v_j\}$ and $\{\Pi v_{i'}, \Pi v_{j'}\}$. Conveniently, each is a pair of vectors in $\mathbb{R}^3$, so its cross product provides a vector normal to the spanned plane. If $\{v_i, v_j\}$ and $\{v_{i'}, v_{j'}\}$ span the same plane, then $n_{i,j} = \Pi v_i \times \Pi v_j$ and $n_{i',j'} = \Pi v_{i'} \times \Pi v_{j'}$ must be colinear. We have already seen in [13] that we may search for colinearity among a set of vectors in expected linear time by using hash tables. We form a table T whose keys n are the unique normal vectors to the pairs of projected vectors and whose values are sets of vector indices. Consequently, this entire process runs in expected (thanks to hashing) $O(n^2)$ time and has a lower dependence on d than the brute force algorithm. Furthermore, this hash table maps the normal vector to the set of all vectors that lie in the projected plane, so we do not need to find connected components as above.

Of course, some information is lost when mapping vectors from $\mathbb{R}^d$ down to $\mathbb{R}^3$.

It is possible that the mappings of vectors are coplanar while the vectors themselves are not. The candidates for 2-maximal sets are table values $T[n]$ containing more than two indices. We must first verify that each set of vectors is indeed 2-dependent. If it is not, we may recur to find its 2-independent subsets by selecting a new Π. In practice, however, the size of these sets is much smaller than $|V|$, so even using brute force followed by connected components is effective.

ALGORITHM 1. One phase of projection-based algorithm for determining 2-maximal sets. This process finds candidates for 2-maximal sets, and we verify and possibly recur on each.

Given $\{v_i\}_{i=1}^n \subset \mathbb{R}^d$, $n < \infty$, 1-independent.
Compute $\Pi \in \mathbb{R}^{3,d}$, a full-rank transformation.
Let T be an (initially empty) hash table mapping vectors in R^3 to sets of integers in $[1, n]$.
for i=1 to n **do**
  Compute Πv_i
end for
for $i = 1$ to n **do**
  for $j = i + 1$ to n **do**
    $n_{i,j} = \Pi v_i \times \Pi v_j$
    Normalize $n_{i,j}$ to have the unit ∞-norm and first nonzero entry positive.
  end for
end for
for $i = 1$ to n **do**
  for $j = i + 1$ to n **do**
    if $n_{i,j}$ is a key of T **then**
      $T[n_{i,j}] \leftarrow T[n_{i,j}] \cup \{i, j\}$
    else
      $T[n_{i,j}] \leftarrow \{i, j\}$
    end if
  end for
end for
Output $T[n]$ for each key n of T such that $|T[n]| > 2$.

It is interesting to know how close to being optimal this algorithm is. To know this requires knowing just how many common planes there can be. Consider a set of vectors in three dimensions, for simplicity, in the positive orthant ($x \geq 0$, $y \geq 0$, $z \geq 0$). Now consider the projection of the vectors on the triangle T defined by

$$x + y + z = M, \quad x \geq 0, y \geq 0, z \geq 0, \tag{3.1}$$

where $M > 0$ could be arbitrary, but we will take it to be sufficiently large to simplify our notation. Three such vectors lie in a plane through the origin if and only if the projections onto T are collinear. We now construct a set of n points with $\mathcal{O}(n^2)$ common planes.

Let k be a positive integer, and consider the points in the rectangular lattice

$$(i, j), \quad i = 1, \ldots, 2k, \quad j = 1, 2, 3. \tag{3.2}$$

We see that for each point with $j = 0$ we can associate k lines going through three points, and thus there are at least $2k^2$ common planes. Figure 3.1 shows an example with $k = 4$ showing only four of the eight sets of four planes for $i = 1, 2, 3, 4$.

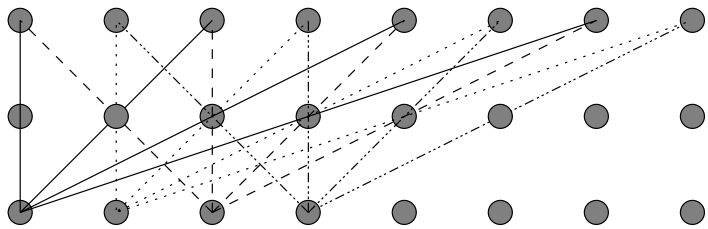

FIG. 3.1. *Example of lattice with $k = 4$. For each point on the lower line, there are exactly four planes. Only the planes for $i = 1, 2, 3, 4$ are shown.*

Since the number of planes to be determined is quadratic in the number of initial vectors, a quadratic algorithm for determining them is the best we would expect as a worst-case bound.

3.2. Generators. Now, let $\mathcal{P}$ be the set of all 2-maximal subsets of V. We would like to use V and $\mathcal{P}$ to infer an efficient process for computing $\{v_i^t g\}_{i=1}^n$ for arbitrary g. In order to do this, we will identify a (hopefully small) subset $S \subset V$ by which we may recursively construct the rest of the members of V via pairwise linear combinations. Once this construction is found, it will tell us how to efficiently compute the dot products. That is, we start with S and will compute $\{v^t g : v \in S\}$ by brute force. Then, we find all $v \in V - S$ with v in the span of two members of S. We then let S_1 be the union of all such v and S. This implies that we can compute each element of $\{v^t g : v \in S_1 - S\}$ in two MAPs. We then identify all $v \in V - S_1$ spanned by two members of S_1, letting S_2 be the union S_1 with all such v. Again, if $v \in S_2 - S_1$, then $v^t g$ may be computed in two MAPs. If S is chosen suitably, then this process will yield $S_i = V$ for some $i < \infty$. We will call such a set S a [illegible]. Then, the total arithmetic cost for computing $\{v_i^t g\}_{i=1}^n$ is no greater than $d|S|$ MAPs. The goal is then to find a generator with as few elements as possible.

THEOREM 3.3. [illegible] $g \in \mathbb{R}^d$ [illegible] $\{v_i^t g\}_{i=1}$ [illegible] $d|S| + 2|V - S|$ [illegible] S [illegible] V

We will initially develop these ideas geometrically rather than graph-theoretically, although later we will present the essential problem over a graph. However, our eventual goal for code generation is to find some sort of a [illegible] that tells us which vectors are constructed from which. The leaves (having no out-neighbors) are the members of S. All nodes not in S will have two out-neighbors. If v has two out-neighbors w, x, then $\{v, w, x\}$ must be 2-dependent; the computation of $v^t g$ will be performed using this linear relation rather than explicitly. A topological sorting of this graph such that each vertex follows its out-neighbors will allow all the dot products to be performed in an appropriate sequence. Straightline code for each dot product (corresponding to an entry of the element stiffness matrix) can then be generated. An example dependence graph is shown in Figure 3.2; this is for the vectors in Table 2.2 for the cubic Lagrange basis on triangles.

Without loss of generality, we will assume that every element of V is contained in at least one $P \in \mathcal{P}$. If some $v \in V$ does not lie in a plane with any two other items, then $v^t g$ must always be computed explicitly anyway. Such vertices are isolated points in a dependence graph, having no in- or out-neighbors.

We may refer to the above process of recursively taking linear combinations of S as a geometric [illegible].

DEFINITION 3.4. [illegible] $S \subset V$ [illegible] geometric 2-closure [illegible] S [illegible] $\bar{S}$ [illegible]

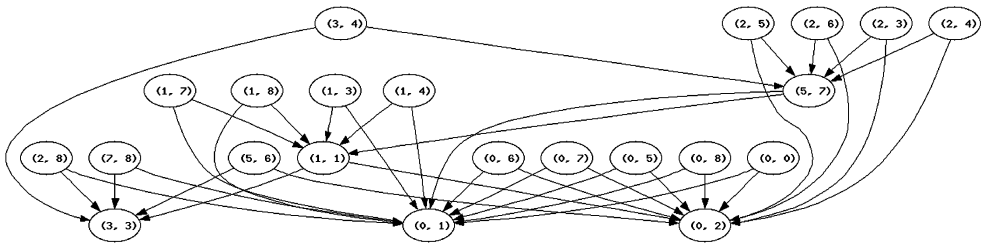

FIG. 3.2. *Generation graph for a* 1*-independent subset of vectors for the Laplacian using cubic Lagrange elements.*

$v \in S$ $v \in \bar{S}$ $v \in V$ $w, x \in \bar{S}$ $\{v, w, x\}$ 2 $v \in \bar{S}$

1. The term is appropriate, as the operation mapping S to its geometric 2-closure is an abstract closure operation. That is, the operation is increasing ($S \subseteq \bar{S}$), idempotent ($\bar{\bar{S}} = \bar{S}$), and monotone ($S \subseteq T \to \bar{S} \subseteq \bar{T}$).

DEFINITION 3.5. $\bar{S} = V$ S generates V generator $S' \subset S$ V S minimal generator S minimum generator

Our terminology here is intentionally analogous to the maximal and maximum independent set problems from algorithmic graph theory. An is a subset of a graph's vertices so that no two vertices are connected by an edge. A independent set is an independent set not contained in any larger independent set. A independent set is a maximal independent set with cardinality no less than any other maximal independent set. While simple efficient algorithms exist for finding a maximal independent set, finding a maximum independent set is NP-hard [9]. The algorithm we study below may have similar properties; while it might not always find a minimum generator, it finds a minimal one. The hardness of finding a minimum generator and the difference in size between the minimal generator that our algorithm finds and a minimum generator are all open questions; we will make an additional remark about this later.

Our algorithm is based on the of the 2-maximal sets.

DEFINITION 3.6. $\mathcal{P}$ 2 $\{v_i\}_{i=1}^n$ plane graph $(\mathcal{P}, E)$ 2 2 P_1 P_2 $|P_1 \cap P_2| = 1$

Equivalently, we may consider the plane graph to be a complete but weighted graph, where the edge weights indicate the number of items shared between two 2-maximal sets. This perspective will be more helpful in the next section, where we consider higher-dimensional geometric dependencies.

In certain simple circumstances, it is possible to infer or at least bound the size of a minimum generator based on properties of the plane graph. We present these results here.

THEOREM 3.7. $\mathcal{P}' \subseteq \mathcal{P}$ V $v \in V$ $P \in \mathcal{P}'$ V $2|\mathcal{P}'|$

. Let S contain two elements from each $P \in \mathcal{P}'$. Then clearly $\bar{S} = V$, since $\mathcal{P}'$ covers V. □

THEOREM 3.8. $\mathcal{P}' \subseteq \mathcal{P}$ V

V $1 + |\mathcal{P}'|$. Choose two elements $u, v \in P \in \mathcal{P}'$. Let $u, v \in S$. The closure of $\{a, b\}$ will contain all of P and one member of each neighbor of P. Select one additional member of each neighbor to add to S. Continue breadth first through the whole (connected) graph. □

These bounds are pessimistic; frequently much smaller generators can be found. It seems that the exact size depends not only on the connectivity of the plane graph, but also on how vectors are shared between planes. We leave this question aside and turn to algorithms for finding a generator.

3.3. Finding a minimal generator. Algorithm 2 is a simple greedy algorithm for finding a minimal generator. This works by assigning priorities to each 2-maximal set in $\mathcal{P}$. These priorities indicate how many items should be selected from that set to "close" it. Initially, these priorities will all be 2. When the priority of some P is two, then no vectors in it have been found by the process yet. If the priority is 1, then one vector has been found; selecting another allows the remainder of P to be added to the closure. At each step of our algorithm, we select a 2-maximal set P with minimal priority. Then, we add elements from P to build the generator set G. After updating the generator and what has been found, the priorities of neighboring planes are updated. Note that a simple modification of this algorithm builds a dependence graph. When items of a plane are selected as generators, they are added as roots of the dependence graph. The rest of the items of a plane are inserted with appropriate arrows.

ALGORITHM 2. Finding a minimal generator.

Given $V, \mathcal{P}$, and the plane graph
Let $G = \{\}$ be the (initially empty) generator.
Let Q be an empty priority queue.
Let $D = \{\}$ be the set of points generated by G.
for $P \in \mathcal{P}$ **do**
  $Q[P] \leftarrow 2$
end for
while Q not empty **do**
  Let P be an item from Q with minimal priority m.
  Remove P from Q.
  Select $\{v_{i_j}\}_{j=1}^{m}$ new generator elements from $P - D$.
  $G \leftarrow G \cup \{v_{i_j}\}_{j=1}^{m}$
  $D \leftarrow D \cup P$
  for P' adjacent to P in the plane graph **do**
    $Q[P'] \leftarrow \max(0, 2 - |P' \cap D|)$
  end for
end while

Algorithm 2 bears some similarity to some well-known algorithms. Like Dijkstra's [5] and Prim's [18] algorithms, it relies on a priority queue to make a locally optimal choice. However, it is not the vertices of the graph (the 2-maximal sets) but the members of those vertices that are of primary interest. Still, the similarity suggests that an optimality proof of this algorithm may be possible. On the other hand, we recall our remarks above regarding the similarity to maximum independent sets.

3.4. Exploiting higher-dimensional dependencies. The discussion of the earlier subsection readily generalizes to higher-dimensional dependencies. Interestingly, both Algorithms 1 and 2 are simple to extend. We explain both of these here.

To handle general k-dependencies, we assume as input a $(k-1)$-independent set. (The generator for a $(k-2)$-independent set is $(k-1)$-independent.) In practice, this means an iterative process by which we find a minimal generator for one order of linear dependence, remove the generated elements, and then proceed to the next higher order. Rather than pairs of vectors, we consider sets of k vectors, each of which spans a k-dimensional Euclidean space. We let $\Pi : \mathbb{R}^d \to \mathbb{R}^{k+1}$. Then we compute the generalized cross product that maps k elements of $\mathbb{R}^{k+1}$ to the unique (up to scaling) vector normal to the inputs. Equivalently, the full singular value decomposition could be used to find a normal vector. (It produces an orthonormal basis both for the column space of a matrix and its orthogonal complement.) Then these $O(n^k)$ normals are searched for colinearity via a hash table, and matches are verified and recurred upon as necessary.

The analogue of Algorithm 2 is likewise very similar. Instead of a plane graph, we make use of a "hyperplane graph" with edges weighted based on the length of intersection (between 0 and $k-1$, inclusive). The initial priorities are set to k rather than 2. The rest of the algorithm is exactly the same.

4. Empirical results. We present a study of using our geometric techniques for the Laplacian on tetrahedra, showing how many dependencies of each order we find. In Table 4.1, we report the number of vectors that are found to be equal or colinear to some other vector, and the number of vectors in the generator for each order

TABLE 4.1

Results of optimizing the evaluation of the Laplacian on tetrahedra using Lagrange elements of degrees two through four. For each degree k, the top portion of the table indicates the number of vectors (n), the length of each vector (d), the number of vectors that are zero (num zero), and the number of vectors removed from the search space because they were equal or colinear to another vector. The remaining three portions of the table describe the results of searching successively for linear dependencies of degrees two, three, and four. Each portion states the number of vectors with which the search process began, the number of vectors that have that order of dependency, the size of the generator (including independent elements), and the number of MAPs in the optimized algorithm. The final row indicates the number of MAPs in the algorithm generated using complexity-reducing relations, as described in [13].

of dependency. We also report the number of MAPs in the optimized algorithm. Comparing to the results in [13], we see that geometry can be at least as effective at reducing arithmetic as complexity-reducing relations. On triangles, however, the vectors are already so short that reducing the cost by geometric relations is much less practical.

We remark that, going from third- to fourth-order dependencies, the number of MAPs increases. This is due to the fact that a vector with one nonzero entry was written as a linear combination of four other vectors; greater care in a production-level implementation would prevent this.

We also consider the weighted Laplacian on triangles as in [13],

$$a_w(v,u) = \int_\Omega w(x)\nabla v(x)\cdot\nabla u(x)\,\mathrm{d}x, \tag{4.1}$$

with reference and geometric tensors given by

$$A^0_{i\alpha} = \int_E \Phi_{\alpha_1}(X)\frac{\partial\Phi_{i_1}(X)}{\partial X_{\alpha_2}}\frac{\partial\Phi_{i_2}(X)}{\partial X_{\alpha_3}}\,\mathrm{d}X \tag{4.2}$$

and

$$G^\alpha_e = w_{\alpha_1}\det F'_e\frac{\partial X_{\alpha_2}}{\partial x_\beta}\frac{\partial X_{\alpha_3}}{\partial x_\beta}, \tag{4.3}$$

respectively. In [13], we remarked that G_e is the outer product of the coefficient with the geometric tensor for the standard Laplacian ($(G^L)_e$). With this in mind, we could perform all of the contractions (of larger tensors) as in the constant coefficient case and search for geometric relations. However, in this case, , , geometric relations between vectors were discovered. This suggests that geometric optimization is likely not as good a default optimization strategy as complexity-reducing relations. On the other hand, we may also perform the computations in stages as in [13]. Here, we

consider the case

$$A_i^e = \left(A^0_{i,(\alpha_1,\alpha_2,\alpha_3)} w_{\alpha_1}\right) \left(G^L\right)_e^{(\alpha_2,\alpha_3)}, \tag{4.4}$$

in which case we consider contractions with the coefficient first. This may be optimized, but the subsequent stage of contracting with G^L is performed at full cost. Note that we obtain some benefit, finding vectors that are zero, equal, or colinear. We also compare to Table 4.8 in [13] to see that geometric optimization with second order dependencies leads to a slightly better result than complexity-reducing relations for quadratics and almost as good for cubics. We also see that substantial additional improvements are made by searching for third- and fourth-order dependencies for cubics. Third-order dependencies are also significant for quartics, but even with our efficient search algorithms, fourth-order search was beyond the capacities of our prototype Python implementation.

5. Combined optimization. In [13], we reduced the construction of an optimized algorithm based on binary relations to a well-known graph construction. In the geometric context, the problem is equivalent to finding a generator. It is natural to look for an effective way of using both binary and geometric relations to give a greater overall reduction of arithmetic than using either separately. Rather than describing an algorithm for finding the exact optimum, we describe first a combinatorial structure, which, if it were found, would be the optimum. Then we describe a heuristic modification of Prim's algorithm that outperforms binary relations alone. Finally, we pose the problem in terms of an optimization problem over all permutations of V.

Essentially, we want to construct a rooted, weighted tree or forest with all the vectors as nodes. Each node either will be a leaf node, if the corresponding dot product is performed explicitly, or will have one or more neighbors, depending on whether the corresponding computation is performed via a complexity-reducing relation or a linear combination. Each node is also assigned a weight based on the cost of using either explicit computation, a complexity-reducing relation, or a linear dependence. Of all possible spanning forests, we desire to find one with minimal weight.

While such a structure probably cannot be found efficiently, the idea appropriately generalizes both the dependence graph and the minimum spanning tree. If we neglect all the linear relations and focus only on a complexity-reducing relation, a (rooted) minimum spanning tree exactly solves the problem. On the other hand, if we were to neglect the complexity-reducing relation, we would wind up with a dependence graph (augmented slightly if we had found equality or colinearity among vectors). We have implemented a straightforward generalization of Prim's algorithm in which each time a vector v is added to the tree, if it and another member of the tree are coplanar with a vector w not already added in the tree, a labeled edge is drawn from v and w. While this approach finds (provably and in practice) more efficient algorithms than using complexity-reducing relations alone, the current naive implementation and search through coplanar relations at each step makes the code impractical for anything beyond very simple problems at the present time.

Finally, we may pose the optimal computation as a combinatorial optimization problem over all permutations of V. In effect, the exact solution to this problem allows any previous computation to be employed at each step. To each ordering $\{v_i\}_{i=1}^{|V|}$ of V we can assign a weight. This weight is a sum over weights for each v_i. The weight

of v_1 is always $w(v_1) = m$. For $i > 1$, we define

$$w_R(v_i) = \begin{cases} 2, & \exists j, k < i : R(\{v_i, v_j, v_k\}), \\ m, & \text{otherwise}, \end{cases} \tag{5.1}$$

to indicate whether v_i is linearly dependent on two of its predecessors, and also define

$$w_\rho(v_i) = \min_{j<i} \rho(v_i, v_j) \tag{5.2}$$

to indicate how expensive it is to compute $v_i^t g$ using the complexity-reducing relation ρ. Finally, define

$$w(v_i) = \min(w_{R,i}, w_{\rho,i}). \tag{5.3}$$

Let $\mathcal{V}$ be the set of all permutations of V. Our goal is to solve the minimization problem

$$\min_{\mathcal{V}} \sum_{i=1}^{|V|} w(v_i). \tag{5.4}$$

6. Related mathematics. Our present context seems to be related to many other mathematical structures, especially when we consider the 2-maximal sets on a 1-independent set of Euclidean vectors. We describe these relations here, restricting ourselves to this case.

6.1. Finite linear spaces. Most strikingly, the set of vectors V and the set of all planes spanned by them are an instance of a [illegible] [1]. Finite linear spaces are a logical precursor to finite geometries; they specify an incidence relation between [illegible] and [illegible] such that any two points lie on a unique line, and each line contains at least two points. In our situation, the vectors in V are the points, and the 2-maximal sets are lines. (Formally, we must also include with the set 2-maximal sets all pairs of vectors that do not already lie in some 2-maximal set.) The research literature on finite linear spaces seems focused on fundamental questions of structure and relationships, such as whether spaces with particular properties exist, or when they may be embedded into finite affine or projective planes; algorithms over finite linear spaces seem less studied. We have been unable to locate any notion of geometric closures or generators such as we have described above; the idea may be new.

On the other hand, we have found reference to the plane graph used in section 3. Finite linear spaces, and the weaker notion of [illegible] (in which any two points may or may not be colinear) are naturally interpreted as hypergraphs. In [14], Klein and Margraf restate the Erdős–Faber–Lovász conjecture (see [7]) that the chromatic index of a linear hypergraph on v points is at most v, in terms of properties of the [illegible] of the hypergraph. This graph is defined exactly in the same way as our plane graph.

6.2. Ternary relations. We may consider coplanarity in Euclidean space as an unordered ternary relation, R. Given a set of three vectors, $\{x, y, z\}$, R gives truth if they are linearly dependent and falsity otherwise. Other work has made use of [illegible] ternary relations. The theory of ordered ternary relations has been used to provide a notion of [illegible] for some time [15]. Recent applications have also appeared in [17], which is based on a technical report [16] that provides a historical

survey of the use of ordered ternary relations as a type of geometry, as does [15]. In [15], ternary relations associated with a metric d are studied. More precisely, one can define $T(x, y, z)$ to hold if and only if $d(x, y) + d(y, z) = d(x, z)$. If we take $d(x, y)$ to be the acute angle between the lines x and y, then $T(x, y, z)$ is the coplanarity relation we consider here. However, the fact that y can be viewed as [illegible] x and z plays no significant role for us, so we have not further explored the theory of ordered ternary relations.

6.3. Topology. Our notion of geometric closure is, at least on the surface, different from topological closure. The union of two 2-maximal sets need not be geometrically closed (indeed, this is even beneficial, as it makes the generator much smaller and hence the algorithm we find more efficient). Therefore, the geometrically closed sets (and hence geometric closure) cannot be used to define a topology through closed sets. It may be possible to define some kind of filter or neighborhood base, but we have not pursued this further.

6.4. Matroids. As we deal heavily with linear independence (and more particularly linear dependence) among a set of vectors, it seems that there should be some connection to matroids [21]. Matroids also provide a notion of [illegible]. For vector matroids, the closure involves anything that is linearly dependent on something in the set. On the other hand, our notion of closure requires a low-dimensional linear dependence; only linear dependence on two vectors in the set is allowed (recursively) rather than linear dependence on any number of items. It may be possible in the future to interpret our context as a nonstandard matroid. Doing so would likely open up new algorithmic perspectives on the issue.

7. Conclusions and future work. Searching for linear dependence among the entries of the reference tensor can be a powerful technique for optimizing the evaluation of finite element stiffness matrices. The potential for improving our current implementation, integrating them with tools such as FFC [12, 11], and combining geometric and binary optimization is great. On the other hand, we have left several open issues, both practical and theoretical.

On the practical side, a more efficient implementation of the geometric search algorithms in C++ would allow us to study more detailed forms. Providing an interface to FFC would allow these optimizations to be used in practice, much as complexity-reducing relations are now available. While these issues are fairly straightforward, finding ways of tackling (or reformulating) the combinatorial optimization problem discussed above will be much more challenging.

On the theoretical side, we lack understanding about the structure of the minimum generator problem. If our algorithm does not always find a minimum, is finding the minimum truly difficult? How well does our greedy algorithm approximate the minimum? Perhaps more light will be shed on this problem by better understanding exactly what mathematical structures we are dealing with. As we saw in section 6, there is tantalizing similarity to finite linear spaces and matroids, among other structures. Making a more precise connection to an appropriate mathematical structure would clarify optimal generators greatly.

EFFICIENT MOMENT COMPUTATION OVER POLYGONAL DOMAINS WITH AN APPLICATION TO RAPID WEDGELET APPROXIMATION*

F. FRIEDRICH†, L. DEMARET‡, H. FÜHR‡, AND K. WICKER‡

Abstract. Many algorithms in image processing rely on the computation of sums of pixel values over a large variety of subsets of the image domain. This includes the computation of image moments for pattern recognition purposes, or adaptive smoothing and regression methods, such as wedgelets. In the first part of the paper, we present a general method which allows the fast computation of sums over a large class of polygonal domains. The approach relies on the idea of considering polygonal domains with a fixed angular resolution, combined with an efficient implementation of a discrete version of Green's theorem. The second part deals with the application of the new methodology to a particular computational problem, namely wedgelet approximation. Our technique results in a speedup of $O(10^3)$ by comparison to preexisting implementations. A further attractive feature of our implementation is the instantaneous access to the full scale of wedgelet minimizers. We introduce a new scheme that replaces the locally constant regression underlying wedgelets by basically arbitrary local regression models. Due to the speedup obtained by the techniques explained in the first part, this scheme is computationally efficient and at the same time much more flexible than previously suggested methods such as wedgelets or platelets. In the final section we present numerical experiments showing the increase in speed and flexibility.

Key words. wedgelets, platelets, image approximation, image moments, polygonal domains, discrete Green's theorem, digital lines

DOI. 10.1137/050646597

1. Introduction.

This paper presents a new technique for the rapid computation of sums over varying image domains. The algorithms are particularly useful whenever sums of greyvalues over a large number of different image domains are needed for a fixed image. Techniques for this type of problem have been considered in the past mainly for the computation of image moments; see, e.g., [9, 10, 16, 13, 8]. These papers mostly deal with specific moments (such as geometric, Legendre, or Zernike moments), and often only for binary images; hence the algorithms usually depend on specific properties of the moments and cannot be directly adapted to our problem. However, a recurring theme in these papers which also plays a role here is the observation that the complexity of the algorithm may be reduced by appealing to a discrete version of Green's theorem. Recall that Green's theorem relates integration of a given function on a two-dimensional (suitably regular, connected, and simply connected) domain to the integration of associated functions over the boundary of the domain. In the discrete setting, one expects the reduction in dimension to result in a reduction of computational complexity.

Our approach is based on the simple observation that for [illegible], the integration step boils down to a summation over the vertices of the polygon, once certain auxiliary functions are known. The discretization of this scheme relies on precomputed functions containing integrals over suitably chosen domains. Basically, each auxiliary function corresponds to a possible angle of an edge with the standard coordinate axis. This way, the [illegible] of the polygons which may be treated after the precomputation step can be prescribed in a direct and convenient way, at linear cost, for both computational and memory requirements. As an example, discussed briefly in Remark 2.5 below, after computing the auxiliary functions for the angles 0 and $\pi/2$, integrals over arbitrary rectangles are computable in constant time.

Remark 2.5 illustrates that the use of Green's theorem for summation purposes is based on cancellation. To make this effect prevail in the discrete context, a careful treatment of discrete lines and polygons is necessary. The design and efficient treatment of these discrete lines turns out to be the keystone of our approach.

As a somewhat related collection of techniques, one could also mention the boundary element method (BEM; see e.g. [11]), in which the problem of discretization of the Green function is addressed. The main goal of BEM is to obtain numerical solutions for some classes of boundary integral equations, arising, for example, in the modeling of the mechanical behavior of materials in bounded domains. Observe that this method consists of approximating exact solutions of the considered problems by using discretizations at the boundary, thanks to the Green theorem in a continuous setting. In contrast to this, our method is designed in a fully discrete setting: our "discrete Green formula" is exact and valid for the specific case of discrete summations.

The second half of our paper deals with the application of our techniques to wedgelet approximations. We present an implementation of an algorithm suggested by Donoho [3], and demonstrate that our techniques result in a drastic speedup, by comparison to the only publicly available implementation as part of the package BeamLab [4]. In a sense we solve a problem that had been left open in [3]: Wedgelet approximations are piecewise constant approximations of an image, where the pieces—the [illegible]—are obtained by splitting dyadic squares along straight lines. Approximations which minimize a certain functional are of particular interest (see section 3 below for details). Donoho proposed an algorithm for the rapid computation of the minimizers, resting on an assumption that was not further addressed in [3]—nor, to our knowledge, anywhere else in the literature. The assumption was that constant regression over arbitrary wedges could be efficiently implemented. Since constant regression depends on image moments of order zero, it is obvious that our techniques can be brought to bear on this problem. Hence we obtain a very efficient and transparent implementation of Donoho's algorithm, again with a conveniently prescribable angular resolution at linear cost. This implementation is available at [6].

Moreover, our implementation allows us to discuss regression models other than piecewise constant functions. The observation that Donoho's model can be extended to include piecewise approximation by (e.g.) affine functions has already been made by Willett and Nowak [15]. Our discussion below includes a quite general discussion of such schemes. The reason we present this generalization, which in itself is quite straightforward and may be considered by some as being of purely theoretical interest, is that we want to point out the potential of wedgelet methodology combined with our techniques. While with BeamLab even piecewise constant approximation of moderate size images is rather time-consuming, the speedup due to our techniques allows us to design more involved models, which can also be implemented efficiently.

2. Discrete Green's theorem and rapid summation over polygonal domains. The use of discrete versions of Green's theorem for image analysis purposes can be traced back to Tang [14]. We first recall this theorem, and its application to our central problem, for the continuous setting. Mathematically speaking, the following sequence is not necessary to understand the rest of the paper.

2.1. The continuous case. We restrict the discussion to bounded domains contained in the positive quadrant $\mathcal{Q}^+ = \mathbb{R}^+ \times \mathbb{R}^+$; its boundary $\partial\mathcal{Q}^+ = (\{0\} \times \mathbb{R}^+) \cup (\mathbb{R}^+ \times \{0\})$ will also play a prominent role. Given a measurable function $F : \mathbb{R}^2 \to \mathbb{R}$, and continuously differentiable $\phi : [a, b] \to \mathbb{R}^2$ written as $\phi(t) = (\phi_1(t), \phi_2(t))$, let

$$\int_\phi F dx = \int_a^b F(\phi(t))\phi_1'(t)dt$$

and

$$\int_\phi F dy = \int_a^b F(\phi(t))\phi_2'(t)dt.$$

The definition extends to piecewise differentiable curves in the obvious way. The following version of Green's theorem (cf. [2]) is relevant to our purposes.

THEOREM 2.1. $\Omega \subset \mathcal{Q}^+$ $\partial\Omega$ $F \in \mathcal{C}^0(\overline{\Omega})$ $Q : \mathcal{Q}^+ \to \mathbb{R}$

$$Q(x, y) = \int_0^y F(x, t)dt. \tag{2.1}$$

$$\int_\Omega F(x, y)dxdy = \int_{\partial\Omega} Q dx. \tag{2.2}$$

For purposes of rapid integration methods, the key feature of Green's formula is that it reduces the dimension of the integration domain by one. Let us describe how the formula simplifies further in the case of polygonal domains. Assume from now on that $\partial\Omega$ is a polygon, with nodes $z_1, \ldots, z_n, z_{n+1} = z_1 \in \mathbb{R}^2$. As Ω is simply connected, the polygon does not intersect itself. Given $z, \widetilde{z} \in \mathbb{R}^2$, we let $[z, \widetilde{z}]$ denote the straight line segment from z to $\widetilde{z}$, parameterized by $t \mapsto z + t(\widetilde{z} - z), t \in [0, 1]$.

For an angle $\vartheta \in]-\pi/2, \pi/2]$, define $v_\vartheta = (\cos(\vartheta), \sin(\vartheta))$. The convention $-\pi/2 < \vartheta \leq \pi/2$ entails that v_ϑ points to the right. Given $z \in \mathcal{Q}^+$, let $I_\vartheta(z)$ denote the intersection of the halfline $z + v_\vartheta \cdot \mathbb{R}^- := \{z + \lambda \cdot v_\vartheta : \lambda \leq 0\}$ with $\partial\mathcal{Q}^+$.

We define an auxiliary function K_ϑ on $\mathcal{Q}^+$ by

$$K_\vartheta(z) = \int_{[I_\vartheta(z), z]} Q dx. \tag{2.3}$$

The following lemma is then easily verified.

LEMMA 2.2. $z, \widetilde{z} \in \mathcal{Q}^+$ $z - \widetilde{z} \in \mathbb{R} \cdot v_\vartheta$

$$\int_{[z,\widetilde{z}]} Q dx = \operatorname{sign}(\langle \widetilde{z} - z, v_\vartheta \rangle) \cdot (K_\vartheta(\widetilde{z}) - K_\vartheta(z)). \tag{2.4}$$

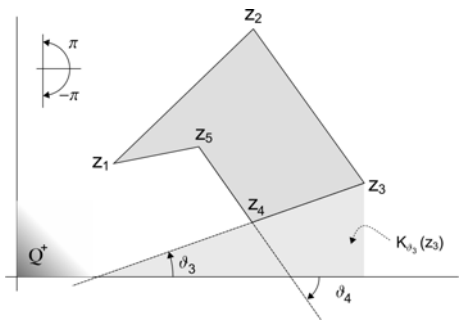

FIG. 2.1. *Illustration of polygon as used in Corollary* 2.3.

We note that for the degenerate case $\vartheta = \pi/2$, $K_\vartheta = 0$.

Plugging our definitions into Green's theorem yields the following result (observe the illustration in Figure 2.1).

COROLLARY 2.3. [illegible] Ω [illegible] $z_1, \ldots, z_n, z_{n+1} = z_1$ [illegible] $\vartheta \in]-\pi/2, \pi/2]$ [illegible] K_ϑ [illegible] (2.3). [illegible] ϑ_i [illegible] x [illegible] z_{i+1} [illegible] z_i [illegible]

$$\int\int_\Omega F(x,y)dxdy = \sum_{i=1}^{n} \operatorname{sign}(\langle z_{i+1} - z_i, v_{\vartheta_i} \rangle) \cdot (K_{\vartheta_i}(z_{i+1}) - K_{\vartheta_i}(z_i)) . \tag{2.5}$$

Note that the evaluation of the right-hand side involves $O(n)$ operations, [illegible] K_{ϑ_i} [illegible] This simple observation makes little sense in the continuous setting, but it contains the key to the algorithm which we will derive for the discrete setting.

A geometrically intuitive understanding of the corollary can be obtained by use of the following, easily verified, observation.

LEMMA 2.4. [illegible] $z \in \mathcal{Q}^+$ [illegible] $\vartheta \in]-\pi/2, \pi/2]$ [illegible] $\Omega_\vartheta(z)$ [illegible] $\partial\mathcal{Q}^+$ [illegible] $[I_\vartheta(z), z]$ [illegible] z [illegible]

$$K_\vartheta(z) = \int_{\Omega_\vartheta(z)} f(x,y)dxdy. \tag{2.6}$$

The lemma also covers the degenerate case $\vartheta = \pi/2$, as $\Omega_\vartheta(z)$ is then a line segment, a set of measure zero.

[illegible] 2.5. Using the lemma, we can recognize Green's theorem as an elegant and efficient way of handling cancellation: For illustration purposes, let us consider rectangles. Denote the four corners of the rectangular domain Ω by $p_1, \ldots, p_4$, numbered as in Figure 2.2. We claim that by the previous lemma,

$$\int_\Omega f(x,y)dxdy = K_0(p_2) - K_0(p_1) - K_0(p_3) + K_0(p_4). \tag{2.7}$$

To see this observe that Ω is obtainable by subtracting $\Omega_0(p_2) \cup \Omega_0(p_3)$ from $\Omega_0(p_1)$. However, by subtracting the integrals accordingly, the integral over the intersection $\Omega_0(p_2) \cap \Omega_0(p_3) = \Omega_0(p_4)$ is subtracted twice, and hence needs to be added again. On the other hand, observing that $K_{\pi/2} = 0$, we see that (2.7) is a special case of (2.5).

Naïvely one might expect that more complex—simply connected—domains could entail increasingly more complicated forms of cancellation. However, Corollary 2.3

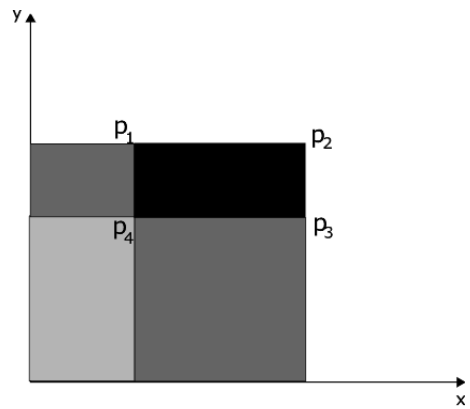

FIG. 2.2. *Illustration of the cancellation principle for the black rectangle, with use of* (2.7).

offers a simple and general way of handling all of them; in particular, the complexity is linear in the number of the vertices, regardless of the shape. The following section is dedicated to the description of a discrete analogue.

2.2. The discrete case. In this section we assume that $f : \mathcal{Q}^+ \cap \mathbb{Z}^2 \to \mathbb{R}$ is given, and describe versions of Green's theorem that allow the quick summation of function values over certain finite discrete domains $\Omega \subset \mathcal{Q}^+ \cap \mathbb{Z}^2$. In the following we restrict the presentation to [illegible] domains, which are defined in Definition 2.11. This restriction considerably simplifies the arguments and notation, while still covering the wedgelet case treated below. Note, however, that similar results can be formulated and proved for general simply connected domains (see [5]) and should also be useful in the general setting.

The key to an efficient discretization of the scheme described in the previous subsection consists of a suitable definition of straight lines, as follows.

DEFINITION 2.6. [illegible] $\alpha \in]-\pi/4, 3\pi/4]$ [illegible] $d_x := \cos\alpha$ [illegible] $d_y := \sin\alpha$ [illegible]

$$\delta_\alpha := \max\{|d_x|, |d_y|\} \qquad v_\alpha^\perp =: \begin{cases} (-d_y, d_x) & \text{[illegible] } |d_x| \geq |d_y|, \\ (d_y, -d_x) & \text{[illegible]} \end{cases}$$

[illegible] digital line through the origin in direction α [illegible]

$$L_\alpha^0 := \left\{ p \in \mathbb{Z}^2 : -\frac{\delta_\alpha}{2} < \langle p, v_\alpha^\perp \rangle \leq \frac{\delta_\alpha}{2} \right\}. \tag{2.8}$$

[illegible] L_α^n [illegible] $n \in \mathbb{Z}$ [illegible]

$$L_\alpha^n := \left\{ p \in \mathbb{Z}^2 : \left(n - \frac{1}{2}\right)\delta_\alpha < \langle p, v_\alpha^\perp \rangle \leq \left(n + \frac{1}{2}\right)\delta_\alpha \right\}. \tag{2.9}$$

[illegible] n [illegible] line number [illegible] L_α^n

In the following let the mapping $\text{Round} : \mathbb{R} \to \mathbb{Z}$ be defined by

$$\text{Round}(x) = \max\left\{ i \in \mathbb{Z} : i \leq x + \frac{1}{2} \right\}.$$

The particular choice $\alpha \in]-\pi/4, 3\pi/4]$ corresponds to all lines with positive horizontal or vertical main direction and leads to the following result.

LEMMA 2.7. [illegible] L_α^n [illegible]

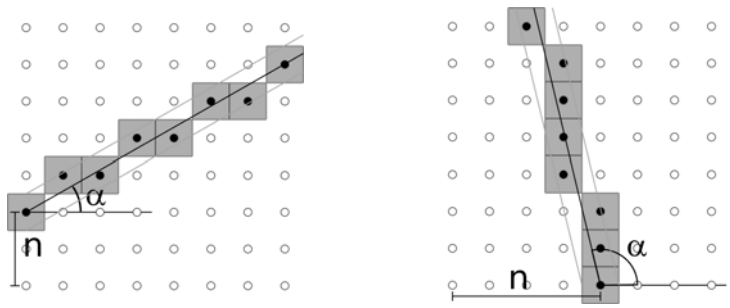

FIG. 2.3. *A flat and a steep discrete line.*

(a) flat line $d_x \geq d_y$ $y_\alpha(x) := \mathrm{Round}(x \cdot d_y/d_x)$

$$L_\alpha^n = (0,n) + \{(x, y_\alpha(x)) : x \in \mathbb{Z}\}, \tag{2.10}$$

(b) steep line $d_y > d_x$ $x_\alpha(y) := \mathrm{Round}(y \cdot d_x/d_y)$

$$L_\alpha^n = (n,0) + \{(x_\alpha(y), y) : y \in \mathbb{Z}\}. \tag{2.11}$$

. We prove (a) first. If $d_x \geq d_y$, then by $\alpha \in]-\pi/4, 3\pi/4]$ it holds that $|d_x| \geq |d_y|$, $d_x > 0$, and

$$\begin{aligned} L_\alpha^n &= \left\{(x,y) : \left(n - \frac{1}{2}\right) d_x < -d_y \cdot x + d_x \cdot y \leq \left(n + \frac{1}{2}\right) d_x\right\} \\ &= \left\{(x,y) : y \leq x \cdot \frac{d_y}{d_x} - n + \frac{1}{2} < y + 1\right\} \\ &= (0,n) + \left\{(x,y) : y \leq x \cdot \frac{d_y}{d_x} + \frac{1}{2} < y + 1\right\}. \end{aligned}$$

For (b) the proof can be done the same way. □

In other words, L_α^n is obtained by shifting L_α^0 by n in the vertical direction for flat lines and by shifts in the horizontal direction for steep line (see Figure 2.3). We remark that this definition of discrete lines is not new; it arises as output of the Bresenham algorithm used in computer graphics [1].

The following lemma notes the central property of digital lines: The digital lines corresponding to a fixed angle provide a partition of the image domain. In view of the observation, made in Remark 2.5, that Green's theorem—at least in the form discussed here—is primarily about cancellation, this simple fact will be crucial.

LEMMA 2.8. $\alpha \in]-\pi/4, 3\pi/4]$ $(L_\alpha^n)_{n\in\mathbb{Z}}$ $\mathbb{Z}^2$ $\mathbb{Z}^2 = \bigcup_{n\in\mathbb{Z}}^{\bullet} L_\alpha^n$

. The statement follows from (2.9), equivalently $L_\alpha^n = \{p \in \mathbb{Z}^2 : \langle p, v_\alpha^\perp\rangle \in](n-1/2)\delta_\alpha, (n+1/2)\delta_\alpha)]\}$, since the intervals $(](n-1/2)\delta_\alpha, (n+1/2)\delta_\alpha)])_{n\in\mathbb{Z}}$ form a partition of $\mathbb{R}$. □

We next want to define the discrete analogues of the auxiliary functions K_ϑ. For this purpose we number the points on a digital line L_α^n in such a way that following the points in ascending order, starting at the points numbered by zero, corresponds to going through L_α^n in direction (d_x, d_y), starting at a suitable element of $L_\alpha^n \cap \partial\mathcal{Q}^+$.

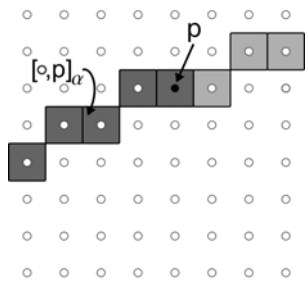

FIG. 2.4. *A line segment* $[\circ, p]_\alpha$.

Let $(x_0, y_0) \in \mathbb{Z}^2$, and let for flat lines the line number be given by $n = y_0 - y_\alpha(x_0)$ and for steep lines by $n = x_0 - x_\alpha(y_0)$; then $(x_0, y_0) \in L^n_\alpha$. Therefore the set of pixels on the line starting at $x = 0$ for flat lines and at $y = 0$ for steep lines and ending in $p = (x_0, y_0)$ is given by

$$[\circ, p]_\alpha := \begin{cases} (0, y_0 - y_\alpha(x_0)) + \bigcup_{x=0}^{x_0} \{(x, y_\alpha(x))\} & \text{if } d_x \geq d_y, \\ (x_0 - x_\alpha(y_0), 0) + \bigcup_{y=0}^{y_0} \{(x_\alpha(y), y)\} & \text{otherwise.} \end{cases}$$

In the following let the set of pixels below some pixel $p = (x_0, y_0)$ be given by $\mathcal{C}(p) := \{(x_0, y)\}_{y=0,\ldots,y_0}$. Moreover, consider the set of points between the line segment $[\circ, p]_\alpha$ (see Figure 2.4) and the x-axis defined by

$$\mathcal{W}_\alpha(p) := \bigcup_{q \in [\circ, p]_\alpha} \mathcal{C}(p).$$

Now for rectangular subsets $S = \{0, \ldots, w\} \times \{0, \ldots, h\}$ $(w, h \in \mathbb{N})$ of $\mathbb{Z}^2$, let [illegible] $f \in \mathbb{R}^S$, $f = (f(p))_{p \in S}$ be given. We denote the corresponding sum of values in columns below the point $p = (x_0, y_0)$ by $C(p) := \sum_{y=0}^{y_0} f((x_0, y))$, in rectangles left and below $p = (x_0, y_0)$ by $R(p) := \sum_{x=0}^{x_0} C((x, y_0))$, and below the piece of line $\mathcal{W}_\alpha(p)$ by

$$W_\alpha(p) := \sum_{q \in \mathcal{W}_\alpha(p)} f(q).$$

The following computation rules hold for columns and rectangles:

$$C((x, y+1)) = C((x, y)) + f((x, y+1)), \tag{2.12}$$

$$R((x+1, y)) = R((x, y)) + C((x+1, y)). \tag{2.13}$$

For the sums below a piece of line we obtain the following results. Let $p = (x, y) \in S$. For flat lines, i.e., $d_x \geq d_y$ with $p^+ = (x + 1, y - y_\alpha(x) + y_\alpha(x+1))$, it holds that

$$\mathcal{W}_\alpha(p^+) = \mathcal{W}_\alpha(p) \,\dot\cup\, \mathcal{C}(p^+),$$

and therefore, if $p^+ \in S$,

$$W_\alpha(p^+) = W_\alpha(p) + C(p^+). \tag{2.14}$$

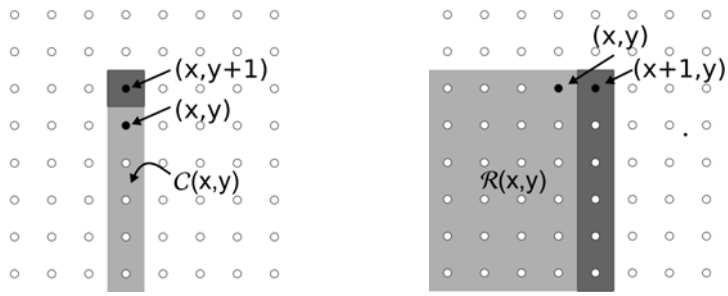

FIG. 2.5. *Summation rule for columns and rectangles.*

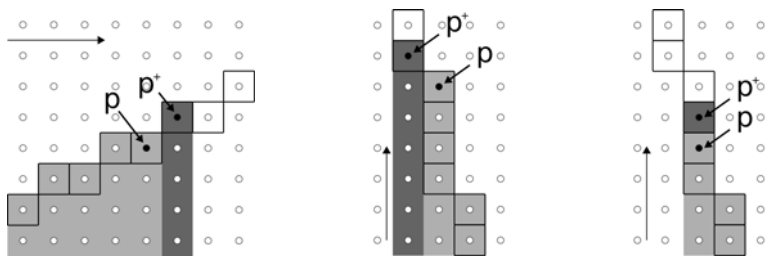

FIG. 2.6. *Summation rule for digital trapezes.*

For steep lines, i.e., $d_y > d_x$ with $p^+ = (x - x_\alpha(y) + x_\alpha(y+1), y+1)$, it holds that

$$\mathcal{W}_\alpha(p^+) = \mathcal{W}_\alpha(p) \,\dot\cup\, \begin{cases} \mathcal{C}(p^+) & \text{if } x_\alpha(y) \neq x_\alpha(y^+), \\ \{p^+\} & \text{if } x_\alpha(y) = x_\alpha(y^+), \end{cases}$$

and thus, if $p^+ \in S$,

$$W_\alpha(p^+) = W_\alpha(p) + \begin{cases} C(p^+) & \text{if } x_\alpha(y) \neq x_\alpha(y^+), \\ f(p^+) & \text{if } x_\alpha(y) = x_\alpha(y^+). \end{cases} \tag{2.15}$$

Note that the computation rules for the sums C and R are special cases of the one for W_α, namely the ones with $\alpha = \pi/2$ and $\alpha = 0$.

The computation rules for C, R, and W_α immediately lead to the following result.

LEMMA 2.9. [illegible] C R [illegible] W_α [illegible] $O(|S|)$ [illegible]. For the computation of C note that $C(p) = f(p)$ for all points p with $p^y = 0$. As illustrated by Figure 2.5, the rest of C can be computed using $C(x,y) = C(x,y-1) + f(x,y)$ in $O(|S|)$. Each line L^n_α that intersects S has at least one point on the lower or left boundary of S. Therefore there are at most $w + h$ such lines. For each line, the left or lower intersecting point p can be computed in $O(1)$; then $W_\alpha(p) = C(p)$. Using the rules (2.14) or (2.15), the values of W_α can then for each point on each line successively be computed in $O(1)$, as illustrated by Figure 2.6. Since the lines partition S this operation has to be performed $|S|$ times, and thus the computation of $W_\alpha(p)$ can be done in $O((w+h) + |S|) = O(|S|)$ steps. □

LEMMA 2.10. [illegible] $p, q \in \mathbb{Z}^2$ [illegible] $n \in \mathbb{Z}$ [illegible] $\alpha \in]-\pi/4, 3\pi/4]$ [illegible] $p, q \in L^n_\alpha$ [illegible]. For instance, we consider the angle α corresponding to $(d_x, d_y) = (q^x - p^x, q^y - p^y)$. We can restrict ourselves to the case of a flat line, the steep case being

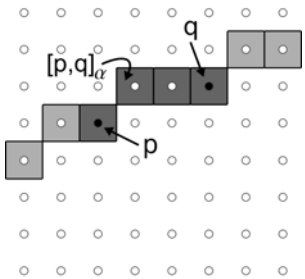

FIG. 2.7. *Segment* $[p,q]_\alpha$.

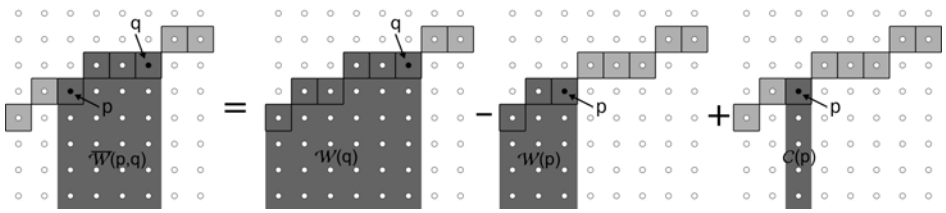

FIG. 2.8. *Summation over wedges.*

similar. Let r denote the point $(0, r^y) \in \mathbb{R}^2$ such that r lies on the continuous line through p and q. If we consider $n = Round(r_y)$, we have $n - r^y = y_\alpha(p^x) - p^x = y_\alpha(q^x) - q^x$; then $p, q \in L^n_\alpha$. □

Note that the discrete line L^n_α through two points p and q is in general not unique.

Let $p, q \in \mathbb{Z}^2$, $\alpha \in [-\pi/4, 3\pi/4[$ and $n \in \mathbb{Z}$ be given such that $p, q \in L^n_\alpha$. Assume that p is "before" q on the line; i.e., assume that $p^x \le q^x$ if $\alpha \in [-\pi/4, \pi/4[$, and that $p^y \le q^y$ if $\alpha \in]\pi/4, 3\pi/4]$. The discrete line segment between p and q, i.e., the set of points between p and q (including p and q) on the line L^n_α, is then given by

$$[p,q]_\alpha := [\circ, q]_\alpha \setminus [\circ, p]_\alpha \cup \{p\}.$$

(See Figure 2.7.) Accordingly, by $\overline{\mathcal{W}}_\alpha(p,q)$ we denote the [illegible] under $[p,q]_\alpha$, i.e., the set of points below this piece of line,

$$\overline{\mathcal{W}}_\alpha(p,q) = \bigcup_{r \in [p,q]_\alpha} \mathcal{C}(r).$$

As illustrated by Figure 2.8, for the sum over values of points below the piece $\overline{\mathcal{L}}_\alpha(p,q)$ it holds that

$$\sum_{r \in \overline{\mathcal{W}}_\alpha(p,q)} f(r) = W_\alpha(q) - W_\alpha(p) + C(p).$$

Now let two arbitrary points p, q on a line L^n_α, $\alpha \in]-\pi/4, 3\pi/4]$, be given. We denote the sum of values below the piece of line between p and q by

$$\overline{W}_\alpha(p,q) := \begin{cases} W_\alpha(q) - W_\alpha(p) + C(p) & \text{if } p^x \le q^x \text{ and } \alpha \in]-\pi/4, \pi/4], \\ W_\alpha(q) - W_\alpha(p) + C(p) & \text{if } p^y \le q^y \text{ and } \alpha \in]\pi/4, 3\pi/4], \\ W_\alpha(p) - W_\alpha(q) + C(q) & \text{otherwise.} \end{cases} \tag{2.16}$$

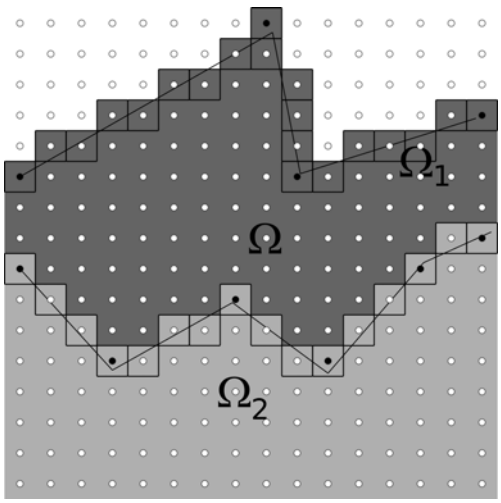

FIG. 2.9. *A simple polygonal domain.*

The next definition describes the class of domains to which we apply the summation techniques. In a first step, this is done by prescribing the upper boundary as a union of line segments and using the x-axis as lower boundary. More general lower boundaries can then be introduced by considering the set-theoretic difference of two such sets. See Figure 2.9 for an example.

DEFINITION 2.11. $p_0 \dots, p_n \in \mathcal{Q} \cap \mathbb{Z}^2$ $\alpha_1, \dots, \alpha_n \in]-\pi/4, 3\pi/4]$

1. $p_0^x < p_1^x < \cdots < p_n^x$
2. $1 \le i \le n$ $k_i \in \mathbb{Z}$ $p_{i-1}, p_i \in L_{\alpha_i}^{k_i}$
3. $[p_{i-1}, p_i]_{\alpha_i} \cap [p_i, p_{i+1}]_{\alpha_{i+1}} = \{p_i\}$ $1 \le i < n$

$\mathcal{D}(p_i, \alpha_i; i = 0, \dots, n)$

$$\mathcal{D}(p_i, \alpha_i; i = 0, \dots, n) = \bigcup_{i=1}^{n} \overline{\mathcal{W}}_{\alpha_i}(p_{i-1}, p_i). \tag{2.17}$$

$\Omega \subset \mathbb{N}^2$ simple polygonal domain of order n $\Omega_1 = \mathcal{D}(p_i, \alpha_i; i = 1, \dots, m)$ $\Omega_2 = \mathcal{D}(q_i, \vartheta_i; i = 1, \dots, k)$ $n = k+m$ $p_0^x = q_0^x$ $p_m^x = q_k^x$ $\Omega_2 \subset \Omega_1$ $\Omega = \Omega_1 \setminus \Omega_2$

Now the following discrete Green's theorem is easily proved.

THEOREM 2.12. Ω n $\Omega = \Omega_1(p_i, \alpha_i, i = 1, \dots, m) \setminus \Omega_2(q_i, \vartheta_i, i = 1, \dots, k)$

$$\sum_{r \in \Omega} f(r) = \sum_{i=1}^{m} \overline{W}_{\alpha_i}(p_{i-1}, p_i) - \sum_{i=1}^{m-1} C(p_i) - \sum_{i=1}^{k} \overline{W}_{\vartheta_i}(q_{i-1}, q_i) + \sum_{i=1}^{k-1} C(q_i). \tag{2.18}$$

. First, since $\Omega = \Omega_1 \setminus \Omega_2$ and $\Omega_2 \subset \Omega_1$,

$$\sum_{r \in \Omega} f(r) = \sum_{r \in \Omega_1} f(r) - \sum_{r \in \Omega_2} f(r).$$

Second, $\Omega_1 = \bigcup_{i=1}^{m} \overline{\mathcal{W}}_{\alpha_i}(p_{i-1}, p_i)$. By $p_i^x < p_{i+1}^x$ only neighboring line segments

intersect. It holds that

$$\overline{\mathcal{W}}_{\alpha_i}(p_{i-1},p_i) \cap \overline{\mathcal{W}}_{\alpha_{i+1}}(p_i,p_{i+1}) = \bigcup_{r\in[p_{i-1},p_i]_{\alpha_i}} \mathcal{C}(r) \cap \bigcup_{s\in[p_i,p_{i+1}]_{\alpha_{i+1}}} \mathcal{C}(s) = \mathcal{C}(p_i).$$

To see this observe that $[p_{i-1},p_i]_{\alpha_i} \cap [p_i,p_{i+1}]_{\alpha_{i+1}} = \{p_i\}$ for all $1 \le i < n$, and therefore $\mathcal{C}(p_i)$ is clearly contained in the intersection. If this inclusion were strict, then there would exist some $v \in \mathbb{Z}^2$ with $v^y > p_i^y$, $v^x = p_i^x$ with $v \in [p_{i-1},p_i]_{\alpha_i} \cap [p_i,p_{i+1}]_{\alpha_{i+1}}$, a contradiction to $[p_{i-1},p_i]_{\alpha_i} \cap [p_i,p_{i+1}]_{\alpha_{i+1}} = \{p_i\}$. Therefore

$$\sum_{r\in\Omega_1} f(r) = \sum_{i=1}^{m} \overline{W}_{\alpha_i}(p_{i-1},p_i) - \sum_{i=1}^{m-1} C(p_i).$$

The equivalent result holds for the sum concerning Ω_2. □

2.3. Implementation. We now summarize the results of the previous section with respect to implementation. Assume that we work on greylevel images $f \in \mathbb{R}^S$ defined over rectangular domains $S = [1,\dots,N_1] \times [1,\dots,N_2]$. We are interested in the computation of sums $\sum_{i\in\Omega} f(i)$ over simple polygonal domain Ω. To utilize Theorem 2.12 for a fast computation, we require the set of angles of Ω to stem from a finite set $\Theta \subset [-\pi/4, 3\pi/4]$. The main required ingredients are

(i) computation and storage of the auxiliary matrices C and $\overline{W}_\vartheta$ for all angles $\vartheta \in \Theta$,
(ii) determination of vectors $(p_{i-1},p_i,\vartheta_i)$, $1 \le i \le n$, defining the edges of the domain Ω,
(iii) use of formula (2.18) for the computation of $\sum_{i\in\Omega} f(i)$.

According to Lemma 2.9, step (i) has complexity $O(|S| \cdot |\Theta|)$, both in running time and memory consumption. Execution of step (ii) is required only if the parameters $(p_{i-1},p_i,\vartheta_i)$ $(1 \le i \le n)$ are not explicit. For example, in our applications of wedge divisions of a rectangle (cf. next section), we specify a wedge $\mathcal{W}$ by an intersection of a line $L_{n,\vartheta}$ with a rectangle R. To apply (iii) to the corresponding simple domain $\mathcal{W}$ the intersection points of R and $L_{n,\vartheta}$ on the boundary of R are required. According to Theorem 2.12, step (iii) requires no more than $2n$ additions, provided that the matrices from step (i) are known.

The following corollary summarizes the findings of this section.

COROLLARY 2.13. [illegible] $f : [1,\dots,N_1] \times [1,\dots,N_2] \to \mathbb{R}$ [illegible] $\Theta \subset]-\pi/4, 3\pi/4]$ [illegible] $O(|S| \cdot |\Theta|)$ [illegible]

$$\sum_{i\in\Omega} f(i)$$

[illegible] $O(n)$ [illegible] Ω [illegible] n [illegible] Θ

2.14. Note again that in practice the results of this section are useful only if the needed cumulative matrices W_{α_i} can be computed beforehand for all occurring polygons. This implies that a certain class of polygons are selected before computation of the integrals take place. In the next section we describe how such a class of polygons is implicitly selected by an arbitrary choice of angular resolution for wedgelets.

We close this section by pointing out that our scheme is [illegible]. Clearly, for large images and/or greyvalue ranges, overflow handling will have to be addressed, but the necessary length of the mantissa can easily be estimated.

3. Wedgelet approximations. In this section we apply the concepts described in section 2 to the specific case of wedgelet approximation. We are concerned first with the case of locally constant functions over dyadic wedgelet partitions. These were first proposed by Donoho [3], who derived approximation rates and showed asymptotic optimality of the wedgelet estimator, for functions of the horizon class and starlike domains. These functions are essentially characteristic functions of image subdomains with smooth boundary. It is also shown in [3] how the hierarchic structure of quad trees allows fast computation of minimizers.

Wedgelets may be viewed as a multiscale geometric dictionary for image representation. In recent years, several such constructions have been proposed (we refer the interested reader to [7]), containing a comparison of wedgelets, wavelets, and curvelets from a nonlinear approximation point of view.

To our knowledge, the only publicly available implementation of a wedgelet approximation algorithm can be found as part of BeamLab, a software package developed at Stanford University (see [4]). A runtime comparison of this implementation with ours can be found in section 5.2. A further source that deals with efficient wedgelet implementation is [12]. Here the central idea is to exploit a multiresolution structure of wedges: Wedges at one dyadic scale are the union of wedges at the next smaller scale, and one can use this in a way that is somewhat similar to our ideas.

However, the exposition in [12] is rather concise, and we have not been able to obtain an implementation of the described algorithms.

3.1. Dyadic square wedge partitions. In this subsection, we present the wedgelet partitions based on dyadic squares. For the sake of simplicity we restrict ourselves to discrete dyadic square domains of the form $S = [1, \dots, N] \times [1, \dots, N]$ with $N = 2^p$.

We adopt the standard definition for a [illegible] of the set S, as a set $\mathcal{P} = \{A_k\}_{k \in K}$, $A_k \subset S$, $\bigcup_{k \in K} A_k = S$, and $A_i \cap A_j = \emptyset$ if $i \neq j$. A subset $A_k \subset \mathcal{P}$ is called the atom of the partition.

The set of dyadic square partitions $\mathfrak{Q}$ can be defined with the following rules:

(1) $\mathcal{P}_0 = \{S\} \in \mathfrak{Q}$,

(2) if $\mathcal{P} \in \mathfrak{Q}$, $A \in \mathcal{P}$ and $|A| > 1$, then $\mathcal{P} \setminus \{A\} \cup_i \{A_i\} \in \mathfrak{Q}$,

where $A_i, i = 1, \dots, 4$, are formed by splitting A into four equally sized squares A_i. Since the image domain is a dyadic square, the atoms of a dyadic partition are also dyadic squares, of the form $[(k-1)2^i + 1, k2^i] \times [(l-1)2^i + 1, l2^i], i \in \{1, \dots, p\}, k, l \in \{1, \dots, 2^{p-i}\}$. Let $\mathcal{S}$ be the set of dyadic squares. Then $\mathcal{Q}$ consists of all partitions $\mathcal{P}$ of S such that $\mathcal{P} \subset \mathcal{S}$.

Now we introduce our [illegible]. This discretization scheme is a keystone for the development of efficient algorithms. The use of nonoverlapping lines allows an efficient implementation of discrete sums.

DEFINITION 3.1. [illegible] $A \in \mathcal{S}$ [illegible] L_ϑ^n [illegible] $(n, \vartheta) \in \mathbb{Z}^2 \times]-\pi/4, 3\pi/4]$ [illegible] $L_\vartheta^n \cap A \neq \emptyset$ $L_\vartheta^{n+1} \cap A \neq \emptyset$ [illegible] A [illegible] wedge [illegible] $\{W_{n,\vartheta}^1(A), W_{n,\vartheta}^2(A)\}$ [illegible]

$$W_{n,\vartheta}^1(A) = \bigcup_{k \leq n} L_\vartheta^k \cap A,$$

$$W_{n,\vartheta}^2(A) = \bigcup_{k > n} L_\vartheta^k \cap A.$$

Note that a wedge is a convex discrete polygon, which is a special case of simple domains in the sense of Definition 2.11, with at most five vertices. Indeed we can distinguish three cases: The wedge either has five vertices, or is a trapeze, or is a triangle. Thus the computation of one moment requires six auxiliary function values in the two first cases, and four function values in the triangular case.

It is now possible to properly define a

DEFINITION 3.2.

$$\{W^1_{n_k,\vartheta_k}(A_k), W^2_{n_k,\vartheta_k}(A_k)\},$$

$\vartheta_k \in]-\pi/4, 3\pi/4]$

3.2. Wedgelet approximation. Like in [3], we are interested in piecewise constant approximations of an image f over a class of dyadic wedge partitions. We follow a variational approach, with a balancing of segmentation complexity versus approximation accuracy. Here, we measure the complexity by the number of atoms in the partition.

More precisely, let $\mathfrak{W}$ be a set of dyadic wedgelet partitions of S. For $\lambda \in \mathbb{R}$ we select a partition $\hat{\mathcal{W}}_\lambda(f)$ from $\mathfrak{W}$ which satisfies

$$\hat{\mathcal{W}}_\lambda \in \operatorname*{argmin}_{\mathcal{W}\in\mathfrak{W}} \{\|f - \hat{f}_{\mathcal{W}}\|_2^2 + \lambda|\mathcal{W}|\}, \tag{3.1}$$

where $\hat{f}_{\mathcal{W}} = \sum_{W\in\mathcal{W}} \overline{f}_W$ and

$$\overline{f}_W = 1_W \frac{1}{|W|} \sum_{i\in W} f(i)$$

denotes the function equal to the average of f over the atom W (which is either a pure wedge or a square), and 0 elsewhere.

Note that the pair $(\hat{\mathcal{W}}_\lambda, f_{\hat{\mathcal{W}}_\lambda})$ minimizes $(\mathcal{W}, g) \mapsto \|f - g\|_2^2 + \lambda|\mathcal{W}|$, where a pair $(\mathcal{W}, g)$ is such that g is piecewise constant over $\mathcal{W}$. It is a particular property of the chosen functional that the minimization can be split up into a minimization over the partition class and (local) minimization on each segment. (Recall that $\overline{f}_W$ is the classical least squares local approximation of $\|f - g\|_2^2$ over W.)

3.3. Algorithm. Let us now describe the algorithm for efficient minimization of (3.1) for a given partition class $\mathfrak{W}$. As we manipulate huge sets $\mathfrak{W}$, finding the optimal partition among this set may lead to high computational costs. These costs are dramatically reduced by exploiting the recursive structure of the dyadic partitions. Nevertheless, still a huge number of sums ("moments") over polygonal domains have to be computed when minimizing over the class of dyadic wedge partitions. In order to handle this, we introduce an algorithm which employs the principles of section 2 for efficient moment computation on the wedge domains.

We work now with a finite set $\Theta \subset]-\pi/4, 3\pi/4]$ of angles. This means that the condition $\vartheta \in]-\pi/4, 3\pi/4]$ is replaced by the condition $\vartheta \in \Theta$. In order to treat the horizontal lines, it is required that $0 \in \Theta$. Since dyadic partitions are obtained by successive division of squares into four squares, each dyadic partition $\mathcal{P}$ can uniquely be mapped to a quad tree T. Each node N of the tree T corresponds to a dyadic square $Q \subset S$, and the four child-nodes of N (if any) correspond to the four squares

generated by a quad split of Q. Each terminal node of the tree T corresponds to a square in $\mathcal{P}$ and vice versa. Each quad tree is obtained as a pruning of the finest quad tree whose leaves correspond to the pixels of S; in implementation the pruning is coded by marking nodes as terminal.

The minimization of the functional consists of two steps: first, computation of the optimal wedge split for each dyadic square, i.e., for each node in the tree, and second, for a given parameter $\lambda \geq 0$ the computation of the minimizer $\hat{\mathcal{W}}_\lambda$ by recursively pruning the quad tree, using the optimal wedge splits obtained in the first step. Here, it is important to note that only the second step depends on λ, and, as will be seen below, its complexity does not depend on the number of angles used in the first step.

The heuristics for the second step can be explained as follows. Given $\lambda \geq 0$, there are three possible cases to consider for the optimal wedge partition $\hat{\mathcal{W}}_\lambda$:

1. $\hat{\mathcal{W}}_\lambda = \{S\}$,
2. $\hat{\mathcal{W}}_\lambda = \{W_1, W_2\}$ for the optimal two wedges W_1, W_2 stored at the root node,
3. $\hat{\mathcal{W}}_\lambda = \bigcup_{i=1,\dots,4} \hat{\mathcal{W}}^i_\lambda$, where each $\hat{\mathcal{W}}^i_\lambda$ is the optimal wedge partition of the dyadic subsquare Q_i, and $Q_1, \dots, Q_4$ are obtained by a quad split of S.

Hence a minimization algorithm consists of comparing the scores induced by the three cases; in the first case the score is local approximation error plus λ, in the second case it is local approximation error plus 2λ, and in the third case it is the sum of the four scores for $\hat{\mathcal{W}}^i_\lambda$, $i = 1, \dots, 4$. Observe that the third case requires a recursive application of the minimization algorithm.

In more precise terms the full minimization algorithm is described as follows:

1. Create empty tree. Initialize each node with approximation error $= \infty$.
2. Computation of optimal wedge splits:
   (a) Compute the vertical sum matrix C using (2.12) and $\overline{W}_0$ using (2.16).
   (b) For each $\vartheta \in \Theta$
      i. compute the auxiliary matrix $\overline{W}_\vartheta$ using (2.16),
      ii. for each dyadic square Q and each n compute the approximation error ε and associated mean values obtained by splitting Q along the line L^n_ϑ. If the induced approximation error is below the stored value at the corresponding node N, then store mean, error, angle ϑ, and line number n at node N.
3. Computation of the minimizer $\hat{\mathcal{W}}_\lambda$ and the associated score, for instance using a straightforward recursive implementation of the above procedure. For a bottom-up version of the algorithm, see [3]. In any case, the algorithm crucially relies on the availability of the optimal wedge splits of all dyadic squares, as provided by step 2.

The first step takes constant time. The complexity of step 2(a) is $O(4^p)$; the same for step 2(b)i, to be performed for each angle. The second step visits every wedge induced by the angles in Θ exactly once, and performs a constant time operation for each. Hence its complexity is linear in the number of wedges induced by Θ. Now, for each angle and each dyadic square q with sidelength 2^j, the number of possible wedge splits of q is less than or equal to $\frac{1}{2}$ the number of boundary pixels. Summing over all 4^{p-j} dyadic squares, all scales, and all angles, we obtain the total of $O(|\Theta| \sum_{j=0}^{p} 4^{p-j} 2^j) = O(|\Theta| 4^p)$ such wedges. The final step visits each dyadic square once, and thus requires $O(4^p)$ operations.

Moreover, we observe that the memory used for storing the lookup tables in step 2(b) can be reallocated; hence the overall memory requirement is only $O(4^p)$.

We have thus obtained the following result.

THEOREM 3.3. [illegible] f [illegible] $2^p \times 2^p$ [illegible] $\Theta \subset]-\pi/4, 3\pi/4]$ [illegible] (4.3) [illegible] $O(4^p \cdot |\Theta|)$ [illegible] $O(4^p)$

[illegible] 3.4. In some ways, our description of wedgelets deviates from Donoho's original exposition. The chief difference is in the parametrization of lines: In Donoho's paper they are parametrized by pairs of points on the boundary, and in our case by one point on the boundary and an angle. For the validity of certain approximation-theoretic results, Donoho requires that the spacing of the boundary points (and thus of the lines) become finer and finer as the resolution increases (see [3, Remark 9.1.1]).

It should be pointed out that our spacing of one pixel between two neighboring lines, as prescribed by Definition 2.6, contradicts this requirement. In principle, our methods can be adapted to this finer spacing, by suitable adjustment of the definition of digital lines; to some extent the finer spacing could also be approximated by simply increasing the set of admissible angles. In any case, it is not altogether clear to us whether this adjustment will actually provide a marked improvement in the approximation rate for digital images of a fixed resolution (of the kind investigated in section 5.2), since the subpixel precision requirement is mainly used to ensure good asymptotic behavior as the resolution tends to infinity.

4. Generalizations. In this section we show how the algorithm described in section 3 can easily be generalized to much larger classes of approximation models for which the computational complexity remains of the same order.

4.1. Wedge partitions with local regression models. The prototype model presented in section 3 was proposed first in a somewhat academic context: The goal was to get optimal approximations for some classes of piecewise constant functions with Hölder regular boundaries. For natural images, however, piecewise constant models lead to undesired block artifacts, especially for low resolutions, although these latter are often the target resolutions. Models based on richer local regression offer a first answer to this problem.

Instead of just considering optimal constant approximation on each atom of the dyadic wedge partition, we consider a finite set $\Phi = (\varphi_j)_{j \in R}$ of r linearly independent functions, $\varphi_j : S \to [0,1]$. Defining the set Φ globally and not locally is motivated by the computation of the moments on many overlapping atoms of several partitions. The functionalities are somewhat separated: The extraction of geometrical information is performed by the partitioning, whereas the local representation of the function is done by the regression on each atom. (We recall that, in our case, an atom consists merely of a wedge or of a square.) There is no theoretical restriction for the choice of Φ. In practice, however, discrete projections of some regular functions should be used. This requirement is connected to the the idea of piecewise smooth approximation.

If $\mathcal{W}$ is a dyadic wedge partition and $A \in \mathcal{W}$ an atom of this partition, we obtain the approximation $\hat{f}_{\Phi,\mathcal{W}}$ of the image as the sum of the projections of the local images f_A onto $\Phi_A = \mathrm{Span}\varphi_{j,A}$. The minimization problem now reads, for an image f and $\lambda \geq 0$,

$$\hat{\mathcal{W}}_{\lambda,\Phi}(f) = \operatorname*{argmin}_{\mathcal{W} \in \mathfrak{W}} \{\|f - \hat{f}_{\Phi,\mathcal{W}}\|_2^2 + \lambda |\mathcal{W}|\}. \tag{4.1}$$

Since $\mathcal{W}$ is a partition, $\hat{f}_{\Phi,\mathcal{W}}$ can be written as the sum of the solutions of the local regression minimization problems over each atom of $\mathcal{W}$,

$$\hat{f}_{\mathcal{W}} = \sum_{A \in \mathcal{W}} \hat{f}_A = \sum_{A \in \mathcal{W}} \sum_{j \in R} \hat{\alpha}_{A,j} \varphi_{A,j}.$$

For a given atom, this is a classical least squares minimization with some functions of the coordinates as regressing variables. The existence and uniqueness of the solution is then ensured, provided that the local family $(\varphi_{j,A})_{j\in R}$ is linearly independent. When it is not the case, uniqueness is forced by choosing a subset $\Phi' \subset \Phi$, so that the family $(\varphi_A)_{\varphi\in\Phi'}$ is linearly independent.

Thus the local minimization problem over A is performed by the solution of a linear system, which essentially requires the computation of the $\frac{r(r+1)}{2}$ local moments $\langle\varphi_i, \varphi_j\rangle_A$, and of the r additional moments $\langle f, \varphi_i\rangle_A$. Finally we also need the moment $\langle f, f\rangle_A$ in order to get the corresponding error measure

$$E_A(f) = \|f_A - \hat{f}_A\|^2. \tag{4.2}$$

The $r \times r$ linear system can be solved in $O(r^3)$ flops with a classical solution method for symmetrical linear systems. In practice, r should be small enough to maintain the advantage of very fast computation of the local regression parameters (typically smaller than 10), provided that the above-mentioned moments are given.

Finally, for step 2(b)ii of the algorithm described in subsection 3.3, it remains just to store the set of optimal parameters $(\alpha_j)_{j\in R}$ instead of the mean.

4.2. Locally adaptive regression models. The model described in the previous subsection allows rich classes of local approximating functions. It remains, however, limited by its global definition. Since a natural image can be viewed as a highly nonstationary signal, a further extension of our schemes consists of combining a finite number of local regression models in the same partition. In each atom an optimal model is selected according to its local relevance; i.e., it is the model for which the according reconstruction error is minimal. Formally, we consider a finite family $\mathcal{M}$ of regression models. If $\mathcal{W} \in \mathfrak{W}$ is a partition, for each atom $A \in \mathcal{W}$, let $\hat{\Phi}(A) \in \mathcal{M}$ denote an optimal local model, given by

$$\hat{f}_{\hat{\Phi}(A),A} = \min_{\Phi\in\mathcal{M}} \|f_A - \hat{f}_{\Phi,A}\|_2^2.$$

We can now define for any partition $\mathcal{W}$ the global approximation $\hat{f}_{W,\mathcal{M}}$, optimal according to the local models

$$\hat{f}_{\mathcal{W},\mathcal{M}} = \sum_{A\in\mathcal{W}} \hat{f}_{\hat{\Phi}(A),A}.$$

In this case, the minimization problem can be read as

$$\hat{\mathcal{W}}_{\lambda,\mathcal{M}} = \operatorname*{argmin}_{\mathcal{W}\in\mathfrak{W}} \|f - \hat{f}_{\mathcal{W},\mathcal{M}}\|_2^2 + \lambda \sum_{A\in\mathcal{W}} |\hat{\Phi}(A)|. \tag{4.3}$$

With regard to the algorithm of subsection 3.3, it should only be remarked that in step 2(b)ii, we now need to store for each dyadic square the index for the selected model in $\mathcal{M}$ and the error defined by

$$E_A = \min_{\Phi\in\mathcal{M}} E_{A,\Phi}.$$

Note that step 3 is unchanged, and hence the computational complexity of this step is independent of the size of the model. This ensures the real time access to every optimal solution to the locally adaptive regression problem, with varying λ, provided that the optimal local models have been computed (step 2).

4.3. General penalization functions. In functionals (3.1) or (4.1), the term $|\mathcal{W}|$ is merely the simplest example for penalizing the complexity of the model. In fact a larger class of suited penalization functions, describing the characteristics of our local approximation model, can be considered, to which our schemes can be applied. To fix the ideas, we treat the most general case of functional (4.3). We consider a function $g_{\mathcal{M}}$ defined for convenience on any subpartition of $\mathcal{W} \in \mathfrak{W}$. We require only that it is additive, which means that it satisfies

$$g_{\mathcal{M}}(\mathcal{W}) = g_{\mathcal{M}}(\mathcal{W}_1) + g_{\mathcal{M}}(\mathcal{W}_2) \text{ for any } (\mathcal{W}_1, \mathcal{W}_2) \quad \text{such that } \mathcal{W} = \mathcal{W}_1 \dot{\cup} \mathcal{W}_2.$$

An important example of such a function is the penalization according to the coding length required for each partition according to some coding scheme (or in practical cases an estimate of this length). This might take into account not only the size of a partition, but also, for instance, its depth or some correlation structure. Such a penalization function would enable rate-distortion optimization, for the purpose of compression schemes of images based on partition regression representations.

5. Experiments and results. This section presents some experimental results. They illustrate the efficiency of our scheme in terms of computational time, and show the flexibility allowed for the choice of the underlying approximation assumptions. The implementation of the algorithms described in the previous sections has been made in the Oberon programming language. Executable files of this implementation can be downloaded at [6].

5.1. Examples with locally adaptive models. In section 4.2, we treated the case where the optimal coefficients are selected locally, as well as the model itself. With the notation of this section, we present here some specific instances for the set of possible models $\mathcal{M}$.

An elementary set of models is formed by the set of bivariate polynomials of degree less than d, represented by their canonical basis $(x^i y^j)_{i+j \le d}$ and denoted by Φ_d. For d respectively equal to $0, 1, 2$, we obtain the so-called [illegible], and [illegible] regression models, with respective sizes $1, 3$, and 6. Consider the quadtree-wedgelet scheme with the set of models Φ_0, Φ_1, Φ_2. These models are nested ($\Phi_0 \subset \Phi_1 \subset \Phi_2$), and thus the computation of the moments reduces to those necessary for Φ_2. If we use the additional multiplicative properties (for example, $\langle x, y^2 \rangle = \langle xy, y \rangle$), we can even reduce our requirements to the computation of 22 moments instead of 28.

The previous models present a nice theoretical framework, leading to what could be called "discontinuous splines" over wedge partitioning. In practice, however, they may suffer from numerical instabilities, especially for big images and for d bigger than 2. This drawback mainly comes from the fact that orthogonality is not conserved by local projection over atoms A, and locally, the angles between some functions can be too small to guarantee numerical stability.

Other constructions, based on sinusoidal functions, present a much more stationary behavior, while still adapting locally to the image contents. Such functions avoid some blocking artifacts occurring, for example, with the use of a mere linear model. Heuristically, the aim of such a model is to combine a model for texture from the locally adaptive models with a pure geometrical method (optimal wedges) to detect the significant contours between patterns in the image. Consider, for instance, the set of parameterized models $\mathcal{M} = \Phi_{\vartheta_i, a_i} \cup \Phi_1$, where $\Phi_{\vartheta, a}$ is the local regression set composed of three functions defined by

$$\Phi_{\vartheta, a}(z) = (1, \cos(\langle z, v_\vartheta \rangle), \sin(\langle z, v_\vartheta \rangle)).$$

FIG. 5.1. *Barbara,* 256×256. *Quad tree with no wedges. Left: Linear model,* 14682 *coefficients, PSNR:* 25.96 *dB. Right: Linear model, combined with a generic sine model,* 14484 *coefficients, PSNR:* 28.97 *dB.*

FIG. 5.2. *Barbara,* 256×256. *Model with eight possible angles. Left: Linear model,* 14730 *coefficients, PSNR:* 27.79 *dB. Right: Linear model, combined with a generic sine model,* 14511 *coefficients, PSNR:* 33.29 *dB.*

Note that in order to keep coherence for nontextured areas, we still keep additionally the mode Φ_1, also consisting of three functions.

We applied this model to the standard image Barbara, which presents many textured areas. We performed this method with the following set of parameters: $(\vartheta, a) \in \{-\pi/4, 0, \pi/4, \pi/2\} \times \{1, 1/2, 1/4\}$. In Figures 5.1, 5.2, and 5.3, we compare, for a similar number of coefficients, an approximation provided by a simple linear model with an approximation provided by the set of models $\mathcal{M} = \Phi_{\vartheta_i, a_i}$. Although the comparison is not completely fair (for each piece an additional bit of information indicating the model selected locally has to be added), this shows the adaptivity of the scheme: With a set of models chosen in a heuristic way, it is possible to improve the approximation dramatically, both in terms of peak signal to noise ratio, PSNR (as displayed in Figure 5.4, and in terms of visual quality (rendering of the details, precision of the textured patterns).

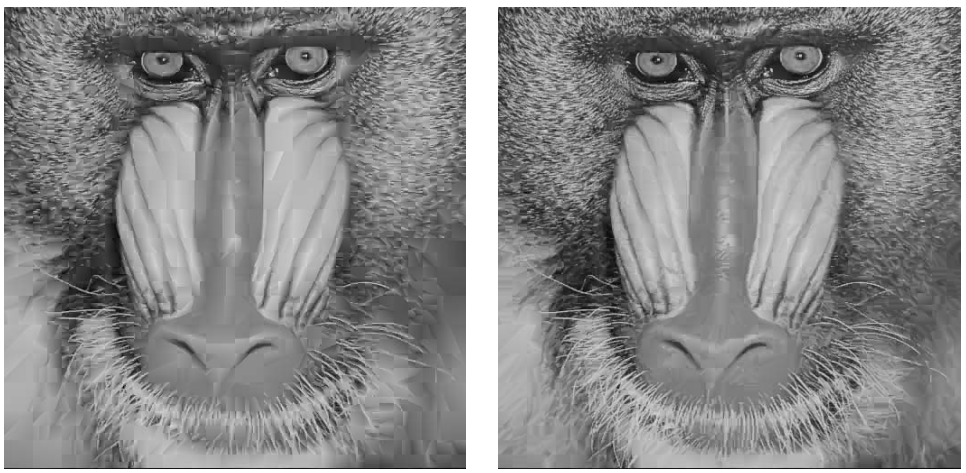

FIG. 5.3. *Baboon,* 512 × 512. *Model with eight possible angles. Left: Linear model,* 27150 *coefficients, PSNR:* 24.44 *dB. Right: Linear model, combined with a generic sine model,* 26574 *coefficients, PSNR:* 27.44 *dB.*

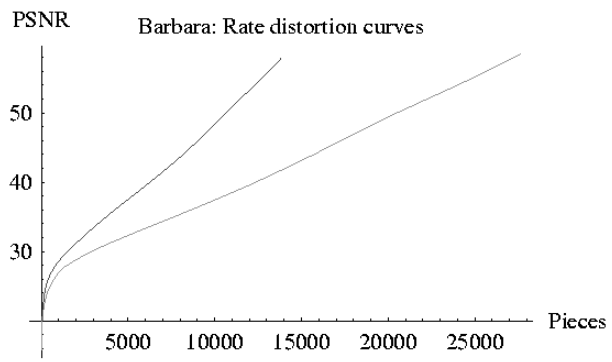

FIG. 5.4. *PSNR versus number of pieces of a linear model (lower line) and the model* $\mathcal{M}$ *(upper line).*

5.2. Influence of angular resolution. As already mentioned in the introduction, a major advantage of our approach is that the angular resolution can be chosen arbitrarily, allowing direct control of the trade-off between computation time and geometric accuracy. In [5, pp. 201–207] the effect of angular resolution is discussed in more detail. In particular, an adaptive choice of angular resolution is motivated there: As in the wedgelets approach in [3], the number of angles in a given dyadic square scales with the number of boundary points. We suggest taking $O(2^j)$ angles for dyadic intervals of size 2^j. PSNR plots in [5] provide evidence that this procedure yields results very similar to those that derive from taking the full set of angles in every dyadic scale. Moreover, the results provided by BeamLab and by our software are very comparable. The major differences between the results of BeamLab and those from our software stem from a different handling of the wedge boundaries. In our discrete approach pixels belong entirely to exactly one wedge, while in BeamLab a subpixel precision approach is used. In Figure 5.5 the effect of angular resolution and differences on BeamLab are illustrated with an example.

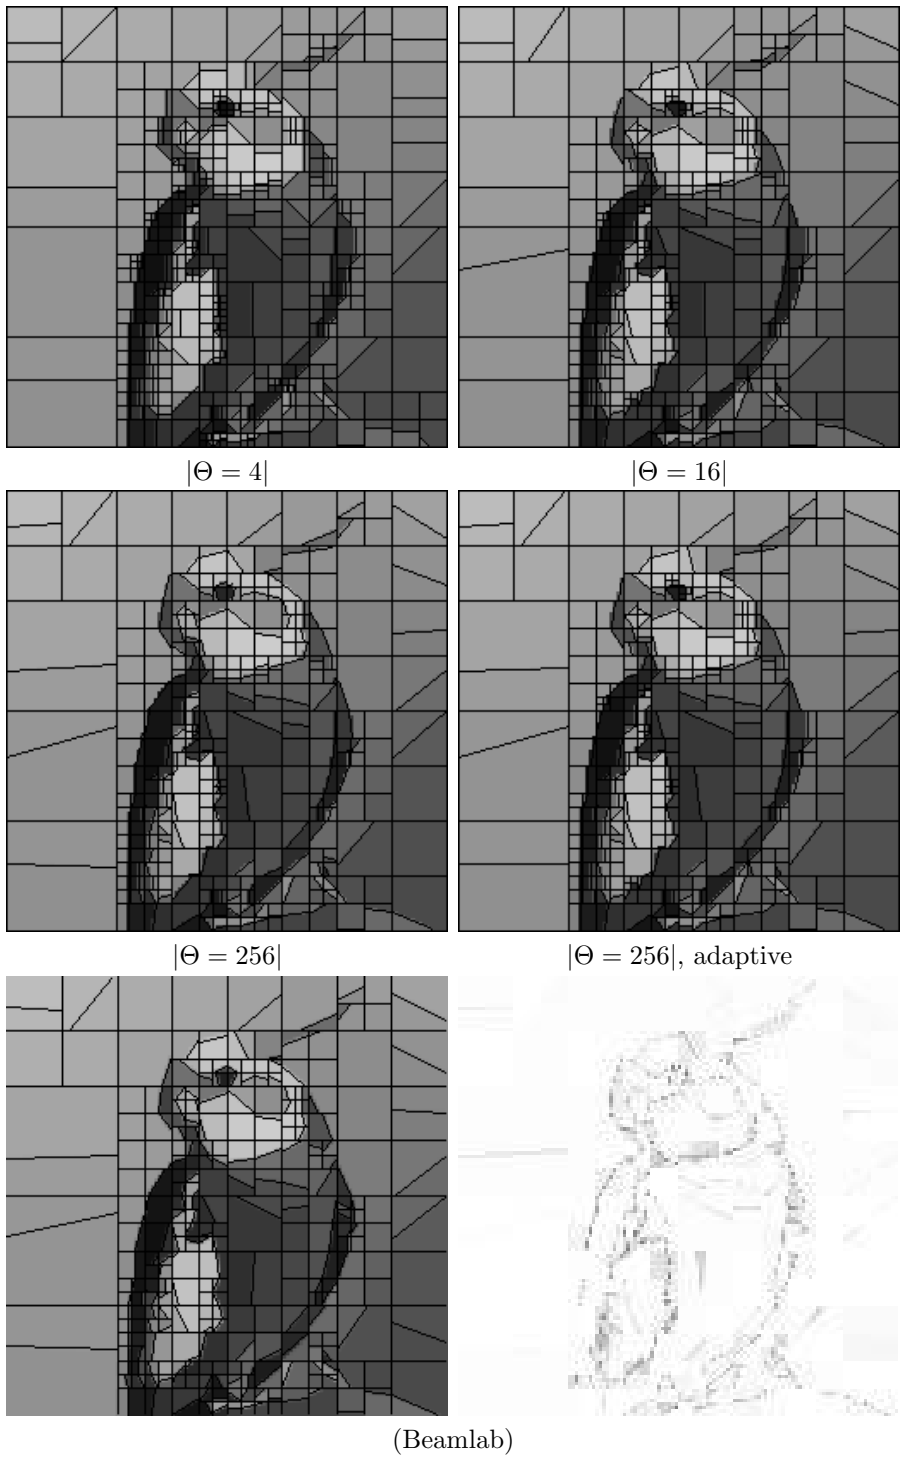

FIG. 5.5. *Wedgelet approximation of image "bird" (*128×128*) with* $\gamma = 0.1 \cdot |S|$ *with* 4, 16, 256 *angles and an adaptive resolution scheme. Lowermost row: wedgelet approximation performed with* BEAMLAB*, and image showing pixelwise* L^1 *distance (white is zero) to the adaptive approximation. Note that the differences mainly stem from different handling of the wedge boundaries.*

5.3. Runtime comparison. The very fast runtimes of our software can be shown by comparison with another library for computation of wedge segmentations, BeamLab [4]. BeamLab is a package running within MATLAB. It contains routines for constant wedgelet segmentations of images with exclusively dyadic dimensions. We used MATLAB version 6 and BeamLab as loaded from the webpage on June 8, 2004; see [4]. For the runtime comparison displayed in the following table, we used a 2.8 GHz Pentium IV machine. The displayed runtimes include all that is necessary to compute a wedgelet approximation of an image: preprocessing (computation of auxiliary matrices and local projection), minimization, and the reconstruction steps. We append approximate runtimes for a wedgelet model in our approach with different numbers of angles. An adaptive model removes half of the angles when entering the next depth in the quad tree. The "equivalent" model is an adaptive model with a number of 1024, 512, ... , 32 angles corresponding to image sizes 512×512, 256×256, ... , 16. This should be roughly equivalent to considering every wedgelet in the image.

Image size	16×16	32×32	64×64	128×128	256×256	512×512
BeamLab	6.72s	45.34s	330.41s $\approx$ 5.5min	2676.3s $\approx$ 44.6min	27918s $\approx$ 7h45min	$>$ 12h
Dyadic wedge equivalent	$<$ 0.02s	0.05s	0.2s	1.2s	8s	59s
Dyadic wedge 1024 angles	1s	2s	8s	37s	140s	722s
Dyadic wedge 180 angles	0.2s	0.3s	1.6s	6s	24s	120s
Dyadic wedge 4 angles	$<$ 0.01s	$<$ 0.01s	0.04s	0.2s	1s	10s
Dyadic square	$<$ 0.01s	$<$ 0.01s	$<$ 0.01s	0.04s	0.5s	6s

6. Conclusion. In this paper, we proposed a new efficient algorithm for rapid moment computation over polygonal domains. It provides a very efficient and flexible tool, enabling comparative experiments between many different bases on arbitrary adaptive local regression functions. A very useful property of our scheme is the ability to compute optimal solutions for many different parameters λ very rapidly: In particular, it enables computation of rate-distortion curves in very reasonable time. It also allows one to easily perform tests with diverse sets of parameterized models.

Acknowledgments. We thank Piyanut Pongpiyapaiboon for help with the implementation. We also thank the referees for their valuable comments.

MULTI-RESOLUTION-ANALYSIS SCHEME FOR UNCERTAINTY QUANTIFICATION IN CHEMICAL SYSTEMS*

O. P. LE MAÎTRE†, H. N. NAJM‡, P. P. PÉBAY‡, R. G. GHANEM§, AND O. M. KNIO¶

Abstract. This paper presents a multi-resolution approach for the propagation of parametric uncertainty in chemical systems. It is motivated by previous studies where Galerkin formulations of Wiener–Hermite expansions were found to fail in the presence of steep dependences of the species concentrations with regard to the reaction rates. The multi-resolution scheme is based on representation of the uncertain concentration in terms of compact polynomial multi-wavelets, allowing for the control of the convergence in terms of polynomial order and resolution level. The resulting representation is shown to greatly improve the robustness of the Galerkin procedure in presence of steep dependences. However, this improvement comes with a higher computational cost which drastically increases with the number of uncertain reaction rates. To overcome this drawback an adaptive strategy is proposed to control locally (in the parameter space) and in time the resolution level. The efficiency of the method is demonstrated for an uncertain chemical system having eight random parameters.

Key words. uncertainty quantification, chemical systems, polynomial chaos, multi-wavelets

1. Introduction.

Quantification of uncertainty in the modeling of chemical systems is necessary for analysis, design, and optimization purposes. It is also useful in the context of model validation with respect to experimental measurements that are generally imperfect and subject to systematic errors and noise. Numerical models aim to represent real physical processes, but are always approximations of the actual physics, involving both model and parametric uncertainties. Model uncertainty caused by modeling approximations will not be discussed here. Rather, we shall restrict ourselves to the uncertainty associated with the empirical physical parameters appearing in the simulation models (such as the reaction rate constants in chemical models). These physical parameters are usually extracted from (uncertain) experimental measurements, involving noise, by assuming an underlying chemical kinetic model. As a consequence, truly precise values are not available, and measured parameter values can strongly depend on the experimental conditions and the apparatus used for their

estimation. Thus, a probabilistic characterization (uncertainty bars, likelihood, etc.) of these parameters is more appropriate, and numerical techniques are called for to quantify the resulting uncertainties in the simulation output.

Often, Monte Carlo (MC) techniques are used for analysis of parametric uncertainties. This approach involves performing a (pseudo)random sampling of the parameter distributions, followed by a statistical treatment of the corresponding set of simulations, yielding estimates of the expectation, moments, and any desired statistics of the model output (see, for instance, [11, 15]. However, MC techniques are limited to simple models and/or rough estimates, due to the computational overhead required to solve the deterministic model multiple times. In fact, the large number of model realizations needed comes from the low convergence rate of the statistical estimates with regard to the size of the sample set. This fact strongly supports the use of deterministic techniques, as an alternative to MC sampling strategies. Among deterministic approaches, polynomial chaos (PC) expansions of the solution are attractive candidates, as they allow for a compact and convenient way of representing the functional dependences of the solution on the input random parameters.

PC methods have been the focus of many efforts within different fields of application (solid mechanics, thermal sciences, fluid flow, etc.) over the past decade, starting from the early work of Ghanem and Spanos [10]. The essence of these methods is the projection of the model output onto a subspace spanned by a basis of polynomial functions having for argument a denumerable set of independent random variables parameterizing the uncertain input data. For normalized Gaussian random variables one obtains the "classical" Wiener–Hermite expansion which has been generalized recently to other types of distributions by Xiu and Karniadakis [20]. First attempts to apply these techniques to the propagation of uncertainty in chemical and reacting flow models have been proposed in [7, 17, 18].

There are essentially two types of approaches for the determination of the spectral (projection) coefficients involved in the series expansion of the model output. In the first approach, orthogonality of the PC basis is exploited to perform a nonintrusive projection of the uncertain model solution: a sampling, either stochastic or deterministic, of the uncertainty range provides a set of model output values to be projected, i.e., to compute the correlation between model output and basis polynomials. The second approach makes use of the mathematical model to derive a new set of equations—the spectral problem—through a Galerkin procedure, to be solved for the projection coefficients. The first approach is termed nonintrusive as it requires solving the deterministic model only, but for different values of the uncertain parameters. The second approach, termed intrusive, requires a reformulation of the deterministic model solution algorithm to handle the spectral problem. While more complex than the nonintrusive approach, the intrusive construction is potentially more efficient. However, the intrusive approach does yield a larger (compared to the original one) system of equations and is particularly challenged by the nonlinearities involved in chemical models [8, 17]. In fact, as shown in [17], even for simple reaction mechanisms, the intrusive spectral approach may fail to yield the correct solution because of truncation errors and lack of robustness. These issues are the central focus of the current paper.

The lack of robustness in hitherto intrusive spectral simulations is essentially due to (1) the loss of the "double infinity" limit of the PC expansions because a single stochastic dimension is typically associated with each uncertain parameter and (2) the

decomposition of the solution using a basis of $\Gamma_{\ell}(\cdot,\cdot)$ polynomials, which appears to be inadequate when dealing with uncertain chemical systems. Given the nonlinearity of chemical models, sufficiently large parametric uncertainty levels can lead to solutions with significant uncertainties. Combined with necessary physical constraints (e.g., positivity of concentration values), this can lead to uncertain solutions having highly skewed probability density functions (PDFs). The requisite global PC order necessary for representation of such solutions can be very high, so that truncated spectral computations break down due to numerical instabilities and aliasing errors. For example, the oscillatory nature of the polynomials can result in PC expansions for concentrations that contain negative valued realizations with nonvanishing probability when truncated to finite order. Moreover, the use of high order expansions in spectral computations is not feasible in practice, due, first, to the emergence of numerical instability and, second, to the stiffness of the resulting system of equations whose time integration would require prohibitively small time steps [17]. To address these limitations, we propose here to substitute the PC representation of chemical kinetic models with a multi-resolution scheme based on the multi-wavelet (MW) construction of Alpert [3], following the methodology introduced in [12] for zero order or Wiener–Haar expansions and later extended to arbitrary polynomial order in [13]. These new representations have been designed to deal with steepness and bifurcations triggered by uncertainty; by allowing for discontinuous dependences and introducing the notion of localized decomposition and resolution level (scales), the MWs are expected to be better suited for nonlinear chemical systems than the usual PC expansion.

The paper is organized as follows. Section 2 presents the multi-resolution analysis (MRA) scheme and MW expansion. It starts with a short summary of the spectral stochastic formulation for uncertainty quantification in sections 2.1–2.2. Details on the MRA scheme and the construction method for the MW basis are then provided in sections 2.3–2.5. Section 2.6 offers a short discussion on the Galerkin derivation of the spectral problem and implementation details needed for the examples treated in the remaining sections. In section 3, we focus on the simple test-problem proposed in [17] for which the Wiener–Hermite (WHe) expansion was found ineffective. The causes for the WHe expansion failure are first analyzed in section 3.1. The results obtained using the MW expansion, for the same problem, are then presented in section 3.2, and a numerical inspection of the convergence of the MW representation is given. In the remaining sections, the MRA scheme is applied to a more complex chemical model. This model corresponds to the uncertain hydrogen oxidation mechanism described in [16] and briefly summarized in section 4. In section 5, the situation where only one of the reaction rate constants is uncertain is first considered. This reaction rate constant is selected as the one having the largest impact on the concentrations. Our objective here is to demonstrate the flexibility and robustness provided by the MW representation in adapting the polynomial order and resolution level to the actual solution of the problem. The results shown in section 5 are achieved at the cost of a significant enrichment of the expansion basis, which in turn directly translates into significant computational overhead. As a consequence, an adaptive strategy where a controlled local level of resolution applies is called for. Such a strategy is developed in section 6, based on an extension of the technique proposed in [13] for unsteady solutions. The effectiveness of the overall method (MRA plus adaptive scheme) is demonstrated for up to 8 uncertain reaction rate constants. Finally, major conclusions and proposed future developments and improvements are given in section 7.

2. Multi-resolution analysis and multi-wavelet basis.

2.1. Spectral stochastic representations. Consider a generic equation governing a function $\mathcal{P}$ that depends on space ($\mathbf{x}$), time (t), and an initial random event (θ):

$$\mathcal{O}(\mathcal{P}(\mathbf{x},t,\theta),\mathbf{x},t,\kappa(\theta))=0, \tag{2.1}$$

where $\mathcal{O}$ is a nonlinear operator with random parameters $\kappa(\theta)$. The spectral stochastic representations considered in this paper rely on an orthogonal Fourier-like decomposition of the solution process according to

$$\mathcal{P}(\mathbf{x},t,\theta)=\sum_i \mathcal{P}_i(\mathbf{x},t)\Psi_i(\boldsymbol{\xi}(\theta)), \tag{2.2}$$

where the $\mathcal{P}_i(\mathbf{x},t)$'s are the (yet-to-be-determined) spectral coefficients, $\{\Psi_i\}_{i\in\mathbb{N}}$ is the spectral basis, and $\boldsymbol{\xi}$ is a random vector having independent components. The orthogonality of the basis functions, as well as the equality in (2.2), holds in the mean square sense (for the sake of brevity, the dependence on θ is no longer made explicit):

$$(\forall (i,j)\in\mathbb{N}^2)\quad \langle \Psi_i(\boldsymbol{\xi})\Psi_j(\boldsymbol{\xi})\rangle = \delta_{ij}\left\langle \Psi_i^2(\boldsymbol{\xi})\right\rangle, \tag{2.3}$$

where the brackets denote the mathematical expectation. The expansion (2.2) is an orthogonal basis function representation of $\mathcal{P}$. This approach has lead to the concepts of homogeneous chaos and PC expansions [6, 10, 19] when $\boldsymbol{\xi}$ is a Gaussian vector with independent components, and the Ψ_i are multidimensional Hermite polynomials. It can also be extended to non-Gaussian measures [9, 20]. Due to the orthogonality of the basis functions, the spectral coefficients satisfy

$$(\forall i\in\mathbb{N})\quad \mathcal{P}_i=\frac{\langle \mathcal{P}\Psi_i(\boldsymbol{\xi})\rangle}{\langle \Psi_i(\boldsymbol{\xi})\Psi_i(\boldsymbol{\xi})\rangle}. \tag{2.4}$$

Several approaches can be used to compute the $\mathcal{P}_i$'s that determine the solution $\mathcal{P}$. A simple approach is to use MC sampling (e.g., [18]) or, alternatively, deterministic quadrature formulas (e.g., [14]) to solve (2.4). An alternative to MC and quadrature schemes is the Galerkin approach, where the expansion (2.2) is substituted into the governing equation (2.1) and orthogonal projections onto the basis functions are performed, resulting in the following system for the spectral coefficients:

$$(\forall j\in\mathbb{N})\quad \left\langle \mathcal{O}\left(\sum_i \mathcal{P}_i(\mathbf{x},t)\Psi_i(\boldsymbol{\xi}),\mathbf{x},t,\sum_k \kappa_k\Psi_k(\xi)\right)\Psi_j(\boldsymbol{\xi})\right\rangle = 0, \tag{2.5}$$

where $\sum_k \kappa_k\Psi_k$ is the spectral expansion of the random parameters; this expansion is known provided that the statistics of κ are prescribed. As indicated above, these global expansions can exhibit stability problems. In the following, we introduce an MW basis function expansion which overcomes this limitation. To simplify the presentation, we first focus on the case of a one-dimensional random vector ξ; generalization to the multidimensional case is then addressed in subsection 2.5.

2.2. Change of variable. Let $\mathrm{p}(\eta)$ denote the cumulative density function (CDF), giving the probability that $\xi\le\eta$. As in [12], we assume that $\mathrm{p}(\eta)$ is a continuous, strictly increasing function of η over the interval $[a,b]$, where $a<b$ are two real numbers, possibly infinite, and that $\mathrm{p}(a)=0$ and $\mathrm{p}(b)=1$. Based on these

properties of $\mathrm{p}(\eta)$, it follows that for all $r \in [0,1]$ there is a unique $\eta \in [a,b]$, such that $\mathrm{p}(\eta) = r$. In addition, if x is a uniformly distributed random variable on $[0,1]$, then $p^{-1}(x)$ is a random variable with values in $[a,b]$ having the same distribution as ξ [11]. Consequently, using the mappings $x = \mathrm{p}(\xi)$ and $\xi = \mathrm{p}^{-1}(x)$, we develop a representation of $\mathcal{P}$ in terms of $x = \mathrm{p}(\xi)$. To shorten the notation we shall write $x(\xi)$ (resp., $\xi(x)$) for $x = \mathrm{p}(\xi)$ (resp., $\xi = \mathrm{p}^{-1}(x)$).

2.3. Multi-resolution analysis. In this section, we recall some properties of the multi-wavelet bases introduced by Alpert [3] (see also [2]). The application to the representation of ODEs with random initial conditions is considered in section 2.4.

2.3.1. Vector spaces. For $\mathrm{N_o} = 0, 1, \ldots$ and $k = 0, 1, 2, \ldots$, we define the space $\mathbf{V}_k^{\mathrm{N_o}}$ of piecewise-continuous polynomials according to

$$\mathbf{V}_k^{\mathrm{N_o}} = \left\{ f : \mathrm{Supp}(f) = [0,1] \; \forall l \in \{0, \ldots, 2^k - 1\} \, f_{|_{]2^{-k}l, 2^{-k}(l+1)[}} \in \mathbb{R}_{\mathrm{N_o}}[X] \right\}, \tag{2.6}$$

where $\mathrm{Supp}(f)$ and $\mathbb{R}_{\mathrm{N_o}}[X]$, respectively, denote the support of f and the ring of degree $\mathrm{N_o}$ polynomials with real coefficients. In other words, the restriction of f to any interval $]2^{-k}l, 2^{-k}(l+1)[$ is such a polynomial function, and f vanishes outside of $[0,1]$. Thus, $\mathbf{V}_k^{\mathrm{N_o}}$ has dimension $2^k(\mathrm{N_o}+1)$ and $\mathbf{V}_0^{\mathrm{N_o}} \subset \mathbf{V}_1^{\mathrm{N_o}} \subset \cdots \subset \mathbf{V}_k^{\mathrm{N_o}} \subset \cdots$. Denoting by $\mathbf{V}^{\mathrm{N_o}}$ the union of all spaces $\mathbf{V}_k^{\mathrm{N_o}}$, $\mathbf{V}^{\mathrm{N_o}} = \overline{\bigcup_{k \geq 0} \mathbf{V}_k^{\mathrm{N_o}}}$ (see [3]), we remark that $\mathbf{V}^{\mathrm{N_o}}$ is dense in $L^2([0,1])$ with respect to the norm $\|f\| = \langle f, f \rangle^{1/2}$, where

$$\langle f, g \rangle = \int_0^1 f(x) g(x) \mathrm{d}x \tag{2.7}$$

is the standard inner product in $L^2([0,1])$. In addition, for any integer k, the subspace $\mathbf{W}_k^{\mathrm{N_o}}$, which we employ below as the MW subspace, is defined as the orthogonal complement of $\mathbf{V}_k^{\mathrm{N_o}}$ in $\mathbf{V}_{k+1}^{\mathrm{N_o}}$; we write

$$(\forall k \in \mathbb{N}) \quad \mathbf{V}_k^{\mathrm{N_o}} \oplus \mathbf{W}_k^{\mathrm{N_o}} = \mathbf{V}_{k+1}^{\mathrm{N_o}}, \quad \mathbf{W}_k^{\mathrm{N_o}} \perp \mathbf{V}_k^{\mathrm{N_o}}, \tag{2.8}$$

where $\oplus$ denotes the direct sum of vector spaces. From this construction we have

$$\mathbf{V}_0^{\mathrm{N_o}} \bigoplus_{k \in \mathbb{N}} \mathbf{W}_k^{\mathrm{N_o}} = L^2([0,1]). \tag{2.9}$$

2.3.2. Multi-wavelet basis. Let $\{\psi_0, \psi_1, \ldots, \psi_{\mathrm{N_o}}\}$ be an orthonormal basis of $\mathbf{W}_0^{\mathrm{N_o}}$, where the ψ_i's are piecewise polynomial functions of degree less than or equal to $\mathrm{N_o}$. From the orthonormality condition, we have

$$(\forall (i,j) \in \mathbb{N}^2) \quad \langle \psi_i(x), \psi_j(x) \rangle = \delta_{ij}. \tag{2.10}$$

Since $\mathbf{W}_0^{\mathrm{N_o}} \perp \mathbf{V}_0^{\mathrm{N_o}}$, the first $\mathrm{N_o}+1$ moments of the ψ_i vanish; i.e.,

$$(\forall (i,j) \in \mathbb{N}^2, \, i < j \leq \mathrm{N_o}) \quad \left\langle \psi_j, x^i \right\rangle = 0. \tag{2.11}$$

Equations (2.10) and (2.11) result in a system of polynomial equations which is solved, yielding the $(\mathrm{N_o}+1)$ ψ_i functions (see [3]). The space $\mathbf{W}_k^{\mathrm{N_o}}$, whose dimension is $2^k(\mathrm{N_o}+1)$, is spanned by the multi-wavelets, ψ_{jl}^k, which are images of the ψ_i's by translations and dilations. The ψ_{jl}^k are given by

$$(\forall (j,k,l) \in \mathbb{N}^3, \, j \leq \mathrm{N_o}, \, l < 2^k) \quad \psi_{jl}^k(x) = 2^{k/2} \psi_j(2^k x - l), \tag{2.12}$$

and their support is $\mathrm{Supp}(\psi_{jl}^k) = [2^{-k}l, 2^{-k}(l+1)]$. Due to the orthonormality of the ψ's, we have

$$\left\langle \psi_{im}^k, \psi_{jn}^l \right\rangle = \delta_{ij}\delta_{mn}\delta_{kl}. \tag{2.13}$$

A basis $\{\phi_0, \ldots, \phi_{k-1}\}$ for $\mathbf{V}_0^k$ is then constructed, using rescaled Legendre polynomials. Denoting L_i as the Legendre polynomial [1] of degree i, defined over $[-1, 1]$, we set

$$(\forall i \in \mathbb{N}, i \leq \mathrm{N_o}) \quad \phi_i(x) = \frac{L_i(2x-1)}{l_i}, \tag{2.14}$$

where l_i is a normalization factor selected such that

$$(\forall (i,j) \in \mathbb{N}^2,\, i \leq \mathrm{N_o},\, j \leq \mathrm{N_o}) \quad \langle \phi_i(x), \phi_j(x) \rangle = \delta_{ij}. \tag{2.15}$$

The space $\mathbf{V}_k^{\mathrm{N_o}}$, whose dimension is $2^k(\mathrm{N_o}+1)$, is spanned by the polynomials $\phi_{il}^k(x) = 2^{k/2}\phi_i(2^k x - l)$, for $i = 0, \ldots, \mathrm{N_o}$ and $l = 0, \ldots, 2^k - 1$, that are images of the ϕ_i's by translations and dilations.

2.3.3. MW expansion. A function $f \in L^2([0,1])$ can be arbitrarily well approximated using the MRA scheme constructed above. We denote by $f^{\mathrm{N_o},\mathrm{N_r}}$ the projection of f on $\mathbf{V}_{\mathrm{N_r}}^{\mathrm{N_o}}$; we have

$$f^{\mathrm{N_o},\mathrm{N_r}}(x) = \sum_{l=0}^{2^{\mathrm{N_r}}-1} \sum_{i=0}^{\mathrm{N_o}} \left\langle \phi_{il}^{\mathrm{N_r}}(x), f(x) \right\rangle \phi_{il}^{\mathrm{N_r}}(x) = \sum_{l=0}^{2^{\mathrm{N_r}}-1} \sum_{i=0}^{\mathrm{N_o}} \overline{f}_{il}^{\mathrm{N_r}} \phi_{il}^{\mathrm{N_r}}(x). \tag{2.16}$$

An alternative expression for $f^{\mathrm{N_o},\mathrm{N_r}}$, valid for all $\mathrm{N_r} \geq 1$, in terms of multi-wavelets is

$$f^{\mathrm{N_o},\mathrm{N_r}}(x) = f^{\mathrm{N_o},0} + \sum_{k=0}^{\mathrm{N_r}-1} \sum_{l=0}^{2^k-1} \left(\sum_{i=0}^{\mathrm{N_o}} \mathrm{d}f_{il}^k \psi_{il}^k(x) \right). \tag{2.17}$$

This expression, with $f^{\mathrm{N_o},0}(x)$ evaluated from (2.16), provides the sought-after expansion of $f^{\mathrm{N_o},\mathrm{N_r}}(x)$ in terms of Legendre polynomials overlaid with a specified number of MW details. The MW coefficients $\mathrm{d}f_{il}^k$ appearing in (2.17) are given by

$$\mathrm{d}f_{il}^k = \left\langle \left\{ f^{\mathrm{N_o},k+1} - f^{\mathrm{N_o},k} \right\}, \psi_{il}^k \right\rangle. \tag{2.18}$$

Denoting by $\delta_{\mathrm{N_o},\mathrm{N_r}}$ the L^2-norm of the approximation error of f on $\mathbf{V}_{\mathrm{N_r}}^{\mathrm{N_o}}$,

$$\delta_{\mathrm{N_o},\mathrm{N_r}} = \left\langle f - f^{\mathrm{N_o},\mathrm{N_r}}, f - f^{\mathrm{N_o},\mathrm{N_r}} \right\rangle, \tag{2.19}$$

convergence is characterized by $\delta_{\mathrm{N_o},\mathrm{N_r}} \to 0$ when the polynomial order $\mathrm{N_o}$ (p convergence) and the number of resolution levels $\mathrm{N_r}$ (h convergence) tend to ∞.

2.4. Expansion of a process. Consider an ODE governing $\mathcal{P}$ that depends on a random variable ξ satisfying the assumptions of section 2.2. Further, we assume that $\mathcal{P}(\xi)$ has a second order moment. Using the change of variables introduced in section 2.2, we express $\mathcal{P}(\xi)$ in terms of $x = \mathrm{p}(\xi)$ as

$$\mathcal{P}(\xi) = \mathcal{P}(\mathrm{p}^{-1}(x)) = \tilde{\mathcal{P}}(x(\xi)). \tag{2.20}$$

Introducing this change of variable, and taking into account that x is uniformly distributed on $[0,1]$, it is easy to show that $\tilde{\mathcal{P}}(x) \in L^2([0,1])$. Thus, $\tilde{\mathcal{P}}(x)$ can be expanded according to (2.17). This expansion can be recast through convenient indexing as (see [12])

$$\mathcal{P}(\xi) = \tilde{\mathcal{P}}(x(\xi)) = \sum_{\lambda \in \diamondsuit} \tilde{\mathcal{P}}_\lambda W_\lambda(x(\xi)), \quad \diamondsuit \equiv \triangle \cup \triangle_0, \tag{2.21}$$

where

$$\begin{cases} W_\lambda(x) = \psi_\lambda(x) & \text{for } \lambda \in \triangle \equiv \big\{\lambda : \lambda = (\mathrm{N_o}+1)(2^k + l - 1) + i, \\ & \qquad (i,j,k) \in \mathbb{N}^3,\ i \le \mathrm{N_o},\ j < 2^k\big\}, \\ W_\lambda(x) = \phi_{-1-\lambda}(x) & \text{for } \lambda \in \triangle_0 \equiv \{-\mathrm{N_o}-1, -\mathrm{N_o}, \ldots, -1\}. \end{cases} \tag{2.22}$$

The resolution level k for any $\lambda \in \triangle$ will be denoted by $|\lambda|$.

2.5. The multidimensional basis. Extension of the one-dimensional MW expansion to the $\mathrm{N_d}$-dimensional case is now considered. For simplicity, we focus on a vector $\boldsymbol{\xi}$ with random uncorrelated and independent components $\{\xi_1, \ldots, \xi_{\mathrm{N_d}}\}$:

$$\mathrm{pdf}(\boldsymbol{\xi}) = \prod_{d=0}^{\mathrm{N_d}} \mathrm{pdf}_d(\xi_d),$$

where pdf_d denotes the PDF of ξ_d. For each component ξ_d, we define the real numbers $a_d < b_d$ and assume that pdf_d satisfies the assumptions of section 2.2. Then for all $x_d \in [0,1]$ there is a unique $\xi_d \in [a_d, b_d]$, denoted for short as $\xi_d(x_d)$, such that $\mathrm{p}_d(\xi_d) = x_d$. Consistent with the one-dimensional case, we write for short $\boldsymbol{\xi}(\boldsymbol{x}) = (\xi_1(x_1), \ldots, \xi_{\mathrm{N_d}}(x_{\mathrm{N_d}}))$ and $\boldsymbol{x}(\boldsymbol{\xi}) = (x_1(\xi_1), \ldots, x_{\mathrm{N_d}}(\xi_{\mathrm{N_d}}))$. We now consider the multi-index $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_{\mathrm{N_d}})$ and define the sets

$$\Lambda_k = \left\{ \boldsymbol{\lambda} : \sum_{d=1}^{\mathrm{N_d}} |\lambda_d| = k \right\}, \quad \mathcal{W}_k = \left\{ \prod_{d=1}^{\mathrm{N_d}} W_{\lambda_d}(x_d) : \boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_{\mathrm{N_d}}) \in \Lambda_k \right\}. \tag{2.23}$$

$\mathcal{W}_k$ is the set of multidimensional multi-wavelets having resolution level k. Let $M_k = \mathrm{Card}(\Lambda_k)$, such that the MW expansion of $\tilde{\mathcal{P}}(\boldsymbol{x})$ can now be formally written as

$$\tilde{\mathcal{P}}(\boldsymbol{x}) = \sum_{i=1}^{M_0} c_i^0 \Gamma_i^0(\boldsymbol{x}) + \sum_{i=1}^{M_1} c_i^1 \Gamma_i^1(\boldsymbol{x}) + \sum_{i=1}^{M_2} c_i^2 \Gamma_i^2(\boldsymbol{x}) + \cdots, \tag{2.24}$$

where $\Gamma^k(\boldsymbol{x}) \in \mathcal{W}_k$ denotes a multidimensional multi-wavelet of resolution k. In practice, the MW expansion has to be truncated. For instance, we can choose to retain all multi-indices $\boldsymbol{\lambda}$ such that $|\boldsymbol{\lambda}| = \sum_{d=1}^{\mathrm{N_d}} |\lambda_d| \le \mathrm{N_r}$, where $\mathrm{N_r}$ is a prescribed resolution level. After truncation, the finite expansion may be rewritten in a single index form as

$$\mathcal{P}(\boldsymbol{\xi}) = \tilde{\mathcal{P}}(\boldsymbol{x}(\boldsymbol{\xi})) \approx \sum_{i=0}^{\mathrm{Nw}} \tilde{\mathcal{P}}_i \mathcal{M}_i(\boldsymbol{x}(\boldsymbol{\xi})), \tag{2.25}$$

where $\mathrm{Nw}+1 = \sum_{i=0}^{\mathrm{N_r}} M_i$ is the dimension of the truncated basis $\{\mathcal{M}_i, i = 0, \ldots, \mathrm{Nw}\}$. Further, we use the convention that the indexing is performed in such a way that the

first element of the basis is $\mathcal{M}_0 = 1$. With this convention, the mean and variance of $\mathcal{P}(\boldsymbol{\xi})$ are given, respectively, by

$$\langle \mathcal{P} \rangle = \tilde{\mathcal{P}}_0, \quad \sigma^2(\mathcal{P}) = \sum_{i=1}^{\mathrm{Nw}} \tilde{\mathcal{P}}_i^2.$$

2.6. Galerkin projection schemes. When an intrusive approach is used, the spectral coefficients appearing in the MW expansion of the process $\tilde{\mathcal{P}}(\boldsymbol{x})$ are determined using the Galerkin projection technique outlined in section 2.1. However, the projection of the governing equations on the spectral basis, as given by (2.5), may raise several difficulties depending on the nature of the nonlinear operator $\mathcal{O}$. For instance, in chemical systems, one has to deal with both polynomial and nonalgebraic functionals in the determination of the chemical source terms. The general spectral treatment of uncertain chemical source terms was extensively discussed in [17]. The nonlinearities appearing in the computational examples presented in the following, namely binary and ternary products of uncertain quantities, are treated by means of pseudospectral techniques (multiple application of the Galerkin product). For other types of nonlinearities (e.g., nonalgebraic terms such as exp, log, and square root), the reader should consult [7, 8, 17] since the methodologies readily extend to the MW expansions.

3. Comparison of WHe and MW expansions. The purpose of this section is to examine the efficiency and robustness of the MW representation, compared to a global WHe expansion [6, 10, 19]. To this end, a simple problem is used, namely, that proposed in [17]. This simple problem is designed as a "prototype" for the chemical problem discussed below. By construction, it involves nonlinearity and bifurcations, both being significant challenges with uncertainty quantification in chemical systems. This test problem is now introduced. Consider an uncertain system described by a state variable $X \in \mathbb{R}$ obeying

$$\left\{ \begin{array}{l} \dfrac{\mathrm{d}X}{\mathrm{d}t} = -X(X-B)(X-C), \\ X = X_0 \quad \text{for } t = 0, \end{array} \right. \tag{3.1}$$

where $B < 0$ and $C > 0$ are two real constants and the initial condition X_0 is uncertain. The system has three fixed-points, $X = 0$, B, and C, the first one being unstable. In the following, we set $B = -6$ and $C = 1$. While very simple, this problem is challenging for PC expansions whenever the initial condition is such that the set of possible realizations of X_0 overlaps the unstable point. In this case, the set of realizations splits into two parts, depending on the sign of X_0, leading to a discontinuous solution as time advances. This discontinuity in the solution is a source of breakdown of the spectral representation when using a global smooth basis.

3.1. Wiener–Hermite expansion. To start with, we consider the case where $X_0 \sim \mathcal{N}(\mu_0, \sigma_0^2)$; i.e., the distribution of X_0 is Gaussian with mean μ_0 and standard deviation σ_0, where $\mu_0 \geq 0$ and $\sigma_0 > 0$ are two arbitrary real constants. Hence, the parametric representation of X_0 in terms of a normalized Gaussian variable ξ is

$$X_0(\xi) = \mu_0 + \sigma_0 \xi, \quad \xi \sim \mathcal{N}(0,1). \tag{3.2}$$

Also, the solution $X(t,\xi)$ has a WHe PC expansion up to the order $\mathrm{N_o}$ given by

$$X(t,\xi) = \sum_{k=0}^{\mathrm{N_o}} X_k(t) \Psi_k^{(H)}(\xi),$$

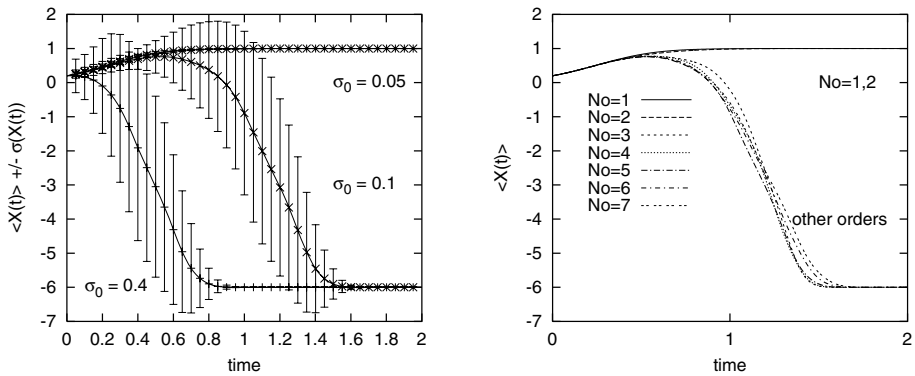

FIG. 3.1. *Time evolution of $X(t)$ for the test problem of section 3, using the WHe expansion and Gaussian initial condition $X_0 \sim \mathcal{N}(\mu_0, \sigma_0^2)$. Left: results for $\mu_0 = 0.2$, fifth order expansion and $\sigma_0 = 0.4$, 0.1, and 0.05; plotted are the mean of $X(t)$ and error bar extending to $\pm\sigma(X(t))$. Right: mean of $X(t)$ for $\mu_0 = 0.2$, $\sigma_0 = 0.1$ and different expansion orders $\mathrm{N_o} = 1, \ldots, 7$. Computations for $\mathrm{N_o} > 7$ are unstable.*

where the basis functions $\Psi_k^{(H)}(\xi)$ are the Hermite polynomials with respective degrees k [1]. To solve this problem, the Galerkin method is employed with a fourth order Runge–Kutta scheme using a time step $\Delta t = 10^{-3}$.

For a fixed order $\mathrm{N_o} = 5$, the numerical experiments presented in Figure 3.1 show that if the probability of $X_0 < 0$ is significant (for instance, for $\sigma_0 = 0.4$ and 0.1), then all the realizations identically (with unit probability) end up on the negative stable fixed-point. In contrast, if the probability of $X_0 < 0$ is small enough (for example, $\sigma_0 = 0.05$), one obtains $\lim_{t\to\infty} X(t) = C$. This result contradicts the exact expected behavior. Further, fixing $\mu_0 = 0.2$ and $\sigma_0 = 0.1$ and increasing the expansion order from $\mathrm{N_o} = 1$ to 7, we observe that the positive stable fixed-point is selected for $\mathrm{N_o} \leq 2$, while the solution goes to the negative fixed-point for $3 \leq \mathrm{N_o} \leq 7$; increasing $\mathrm{N_o}$ further leads to unstable computations.

To enforce a strictly positive initial condition, one often uses a log-normal rather than a Gaussian distribution; thus let us select $X_0(\xi) = \exp(\beta(\xi))$, where $\beta(\xi) = \mu_\beta + \sigma_\beta \xi \sim \mathcal{N}(\mu_\beta, \sigma_\beta^2)$. As a result, the initial condition has the following one-dimensional WHe expansion [9]:

$$X_0(\xi) = \exp\left(\mu_\beta + \frac{\sigma_\beta^2}{2}\right) = \sum_{k=0}^{\infty} \left\{ \frac{\sigma_\beta^k}{\left\langle {\Psi_k^{(H)}}^2 \right\rangle} \Psi_k^{(H)}(\xi) \right\}. \tag{3.3}$$

Even though the infinite series is positive with unit probability, truncation of (3.3) to a finite order $\mathrm{N_o}$ may again introduce a nonvanishing probability of having $X_0 < 0$. This issue was considered in [17]. In fact, if the expansion (3.3) does converge to the exact mapping of the log-normal distribution for increasing $\mathrm{N_o}$, oscillations of the left tail around $X_0 = 0$ can lead to negative realizations for X_0 for low μ_β and large σ_β. These oscillations are damped with increasing frequency as $\mathrm{N_o}$ increases and occur for lower values of ξ, so they are more unlikely. However these oscillations around the unstable point have a dramatic impact on the model robustness: each point where the mapping crosses the axis $X_0 = 0$ induces a discontinuity in the solution $\lim_{t\to\infty} X(t)$, and thus is a source for spectral breakdown. In other words,

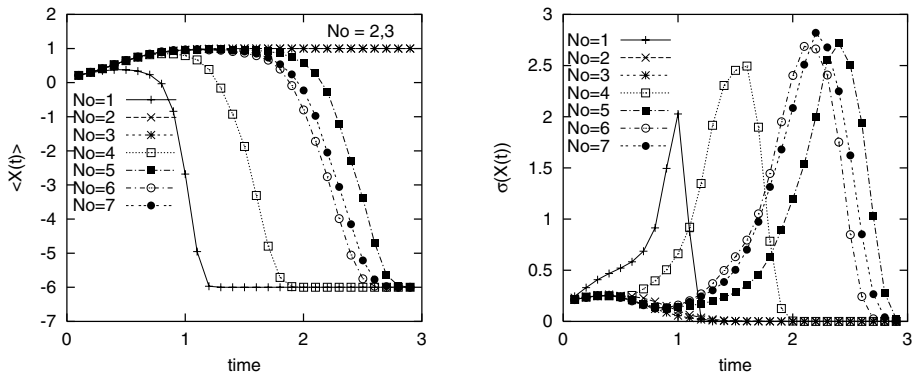

FIG. 3.2. *Time evolution of the computed mean (left) and standard deviation (right) of $X(t)$ for the test problem of section 3, using the WHe expansion with* $\mathrm{N_o} = 1, \ldots, 7$. *Log-normal initial condition with* $\mu_\beta = -2.5$ *and* $\sigma_\beta = 1.1$.

even though the probability of $X_0 < 0$ decreases for increasing $\mathrm{N_o}$, amplification of the higher order coefficients is expected because of the increasing number of zeros in the truncated mapping. This is shown in Figure 3.2, where the evolution of the mean and standard deviation of X with time are plotted, for different orders $\mathrm{N_o} = 1, \ldots, 7$ and $\mu_\beta = -2.5$, $\sigma_\beta = 1.1$. Again, the results contradict the expected behavior and were found unstable for $\mathrm{N_o} > 7$.

3.2. Multi-wavelet expansion. We repeat the experiments of the previous section using the MW expansion. The solution (and initial condition) are now expanded in terms of $x = \mathrm{p}(\xi)$, with $\xi \sim \mathcal{N}(0,1)$:

$$X(t,\xi) = \tilde{X}(t, x = \mathrm{p}(\xi)) = \sum_{i=0}^{\mathrm{Nw}} \tilde{X}_i(t)\mathcal{M}_i(x). \tag{3.4}$$

For these tests, we select the Gaussian distribution of the initial condition $X_0 \sim \mathcal{N}(\mu_0, \sigma_0^2)$ and rely on (3.2) to determine the spectral coefficients of the initial condition:

$$(\tilde{X}_0)_i = \left\langle (\mu_0 + \sigma_0 \mathrm{p}^{-1}(x)), \mathcal{M}_i(x) \right\rangle = \mu_0 \delta_{i0} + \sigma_0 \int_0^1 \mathrm{p}^{-1}(x)\mathcal{M}_i(x)\mathrm{d}x. \tag{3.5}$$

To compute the integral appearing in the right-hand side of (3.5), high order Gauss quadrature formulas [1] are used. However, since $\mathrm{p}^{-1}(x)$ is not a polynomial, $(\tilde{X}_0)_i$ cannot be exactly computed from a Gauss quadrature. To minimize the quadrature error, 32 Gauss-points were used to estimate these integrals.

Then, provided with the mapping of the initial condition, the governing equations for the MW coefficients are time integrated, still using the fourth order Runge–Kutta scheme with $\Delta t = 10^{-3}$, but employing the pseudospectral approximation of the ternary products. In Figures 3.3 and 3.4 we plot the time evolution of the computed mean and standard deviation of X, respectively, for $\mathrm{N_o} = 0, \ldots, 3$ and $\mathrm{N_r} = 1, \ldots, 6$. The results illustrate that, for fixed $\mathrm{N_o}$, both first and second order statistics converge for increasing $\mathrm{N_r}$. In contrast with the WHe computations, the statistics converge to their "exact" values (available by sampling) and not to spurious ones. In fact,

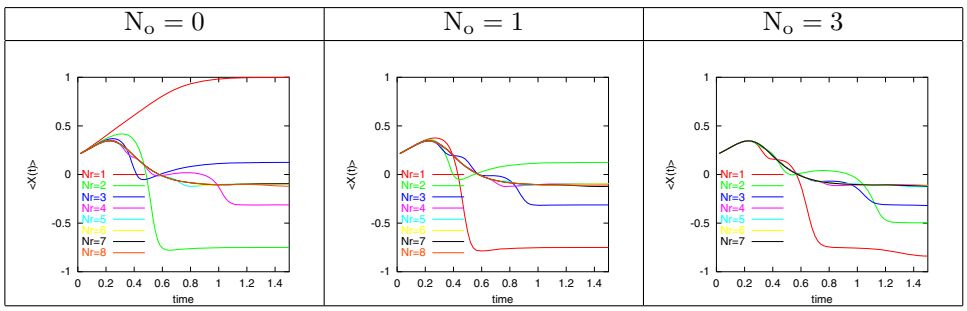

FIG. 3.3. *Time evolution of the computed mean of $X(t)$ for the MW expansions with N_o and N_r as indicated. The initial condition corresponds to the Gaussian distribution with $\mu_0 = 0.2$ and $\sigma_0 = 0.1$.*

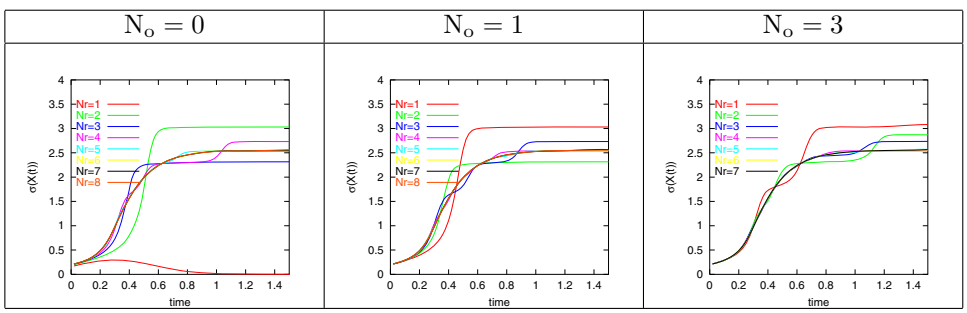

FIG. 3.4. *Time evolution of the computed standard deviation of $X(t)$ for the MW expansions with N_o and N_r as indicated. The initial condition corresponds to the Gaussian distribution with $\mu_0 = 0.2$ and $\sigma_0 = 0.1$.*

provided that the discretization order and resolution level are large enough, the co-existence of two stable fixed-points with respective attraction basins is captured by the MW expansion and appropriately measured with regard to the initial condition distribution. This behavior is clearly an improvement compared to the WHe case where computations, when stable, always predict vanishing standard deviation for a long time, meaning that only one stable fixed-point is recognized. Moreover, it is found that the minimal resolution level to be used to satisfactorily capture the dynamics of X is roughly $N_r = 4$ for $N_o = 1, 3$ and $N_r = 5$ when using $N_o = 0, 2$.

To further understand the behavior of the MW expansion, we provide in Figure 3.5 reconstructions of the response-surfaces $\tilde{X}(t, x)$ for $N_o = 0$ and $N_r = 1$, 2, and 6. It is shown that for $N_r = 1$, the model predicts that all realizations end up on the positive stable point. This is consistent with the mapping of the actual initial condition of the simulation which for this low resolution level is positive for all $x \in [0, 1]$. For $N_r = 2$, the probability of realizations having negative initial condition is, on the contrary, overestimated (the initial condition is negative for $x \in [0, 0.25]$ corresponding to a probability of 0.25 compared to the true probability equal to ≈ 0.159): the computed mean of $X(t)$ presented in Figure 3.3 reflects this fact, overpredicting the final negative mean, while the corresponding response-surface in Figure 3.5 illustrates how the MW expansion can actually split the set of realizations consistently with the approximation of the initial condition. When N_r is increased further, the approximation of the initial mapping becomes better and better, the discontinuity point is found with greater and

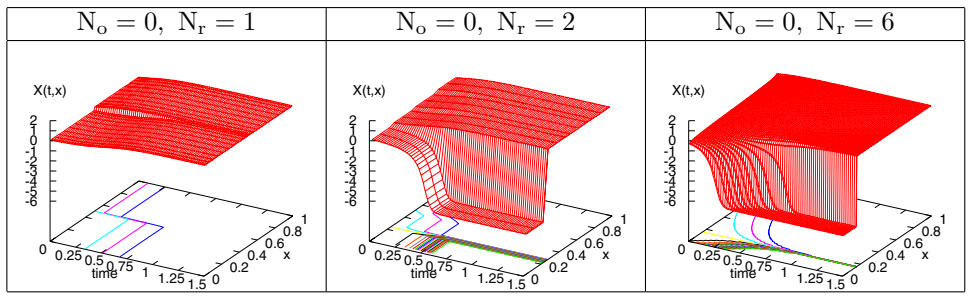

FIG. 3.5. *MW response-surfaces of* $\tilde{X}(t,x)$ *solution of the problem of section* 3 *and initial condition* $X_0 \sim \mathcal{N}(0.2, 0.1^2)$. *Plots were generated for* $N_o = 0$ *and* $N_r = 1, 2, 6$.

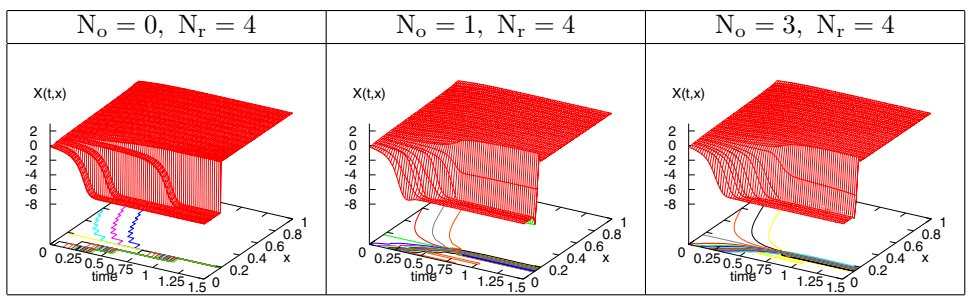

FIG. 3.6. *MW response-surfaces of* $\tilde{X}(t,x)$ *solution of the problem of section* 3 *and initial condition* $X_0 \sim \mathcal{N}(0.2, 0.1^2)$. *Plots were generated for* $N_o = 0$, 1, *and* 3 *with* $N_r = 4$.

greater precision, and the transient dynamics of individual realizations improve (see Figure 3.5).

Figure 3.6 depicts the response-surfaces computed for $N_r = 4$ and $N_o = 0$, 1, and 3. As explained above, this level of resolution provides quite an accurate estimate of the discontinuity location, but spurious oscillations in the solution are observed in the neighborhood of the discontinuity for $N_o > 0$, whose magnitudes increase with the polynomial order. These oscillations are in fact essentially due to Gibbs phenomena, characteristic of the representation of discontinuous solution using (even local) smooth polynomials. However, these oscillations are limited to the support overlapping the discontinuity and do not contaminate the full uncertainty range. Hence, the contribution of the spurious oscillations to the statistics of the process decreases exponentially when the resolution level N_r increases, explaining the convergence, for $N_o > 0$, of the first and second order moments reported in Figures 3.3 and 3.4. Clearly, these observations suggest that zero order polynomials should be used on supports overlapping discontinuities, and future work will focus on the adaptation of the local polynomial order with regard to the local behavior (smoothness) of the solution.

Repeating the experiment for the log-normal distribution of the previous subsection with the MW expansion (not shown) yields similar conclusions: correct long time solution for any resolution level and order, h and p convergence, and more robustness compared to the WHe expansion. To summarize the findings of the section, we stress that the MW expansion offers an attractive alternative to the WHe expansion in the context of chemical modeling, by providing more robustness and a better efficiency when dealing with steep or discontinuous processes. The MW expansion seems to be superior to WHe expansions when dealing with constrained problems, such as posi-

tivity of the solution, thanks to the local character of the representation. Moreover, by offering two ways of improving the predictions through increasing resolution level and polynomial order, the MW representation provides more flexibility than traditional global polynomial expansions with fixed dimension that can suffer from lack of robustness when increasing the representation order (recall, of course, that the general convergence of the PC representation is guaranteed only for increasing order dimensionality). These claims are further investigated in the following sections.

4. Chemical test problem.

4.1. Uncertainty parameterization. In this section, we present a short description of the chemical model used in the remainder of this paper. This model has been previously used as a test problem for uncertainty quantification in a chemical system in [16, 18], where spectral PC expansions were found to fail. The model is a reduced hydrogen oxidation mechanism involving seven species (OH, H, H_2O, H_2, O_2, HO_2, and H_2O_2) and the eight reactions listed in Table 4.1 (see [16] for more details). The initial temperature and pressure are defined to be at supercritical conditions, and the overall oxidation process is assumed to be isothermal. For this chemical system, uncertainties in the forward reaction rates, $k_{f,j}$, are present: from experimental data, these uncertainties have been characterized in [16] by their median values $\hat{k}_{f,j}$ and respective uncertainty levels UF_j. It is assumed that the actual forward rates are contained, with a 95% confidence level, within the lower and upper bounds $\hat{k}_{f,j}/UF_j$ and $\hat{k}_{f,j} \times UF_j$. Moreover, the forward reaction rates are modeled as independent random variables, and their probabilistic behaviors are modeled as log-normal distributions. It has to be noted that the assumption of independence is fairly strong but justified from the information theory point of view in the absence of any knowledge regarding the joint densities of the reaction rates: it yields a less informative probability law of the chemical model. From these assumptions, the eight forward rates can be parameterized using a set of eight independent normalized Gaussian variables $\boldsymbol{\xi} = (\xi_1, \ldots, \xi_8)$ according to

$$(\forall (i,j) \in \{1,\ldots,8\}^2) \quad \begin{cases} k_{f,j}(\xi_j) = \hat{k}_{f,j} \exp\left[\dfrac{\log(UF_j)}{1.96}\xi_j\right], \\ \xi_j \sim \mathcal{N}(0,1),\ \langle \xi_i \xi_j \rangle = \delta_{ij}, \end{cases} \tag{4.1}$$

where [17,18] the factor 1.96 ensures that the rate $k_{f,j}$ is in the range $[\hat{k}_{f,j}/UF_j, \hat{k}_{f,j} \times UF_j]$ with a probability equal to 0.95. The reverse rates are constructed from the equilibrium constants $K_{c,j}^{-1}$ of each of the eight reactions, which we presume to be known with unit probability. As a consequence, the reverse and forward rates are fully correlated and related by $k_{r,j}(\xi_j) = k_{f,j}(\xi_j) \times K_{c,j}^{-1}$. The equilibrium constants are computed using the expected values of the heats of formation reported in Table 2 of [16], neglecting any uncertainty therein, and are listed in Table 4.1. From this parameterization of the reaction rates using the Gaussian vector $\boldsymbol{\xi}$, we deduce their MW expansions in terms of the random vector $\boldsymbol{x} = (x_1, \ldots, x_8)$ with independent components, all being uniformly distributed on $[0, 1]$.

4.2. Solution method. The stochastic process to be modeled is then fully described by the time evolution of the state vector containing the species concentrations

$$\tilde{\mathcal{P}}(t, \boldsymbol{x}) = ([\mathrm{OH}](t, \boldsymbol{x}), [\mathrm{H}](t, \boldsymbol{x}), \ldots, [\mathrm{HO_2}](t, \boldsymbol{x}), [\mathrm{H_2O_2}](t, \boldsymbol{x}))^{\mathrm{T}}, \tag{4.2}$$

TABLE 4.1

all having MW expansions. The chemical system is governed by the following system of coupled ODEs:

$$\frac{\mathrm{d}\tilde{\mathcal{P}}(t,\boldsymbol{x})}{\mathrm{d}t} = \mathcal{R}(\tilde{\mathcal{P}}(t,\boldsymbol{x}),\boldsymbol{x}), \tag{4.3}$$

where the right-hand side vector $\mathcal{R}$ is a nonlinear functional of the uncertain species concentrations and reaction rates. Introduction of the MW expansions of the concentrations and reaction rates into the governing equations, followed by projection onto the spectral basis, yields a system of $7(\mathrm{Nw}+1)$ ODEs for the MW coefficients, where we recall that $\mathrm{Nw}+1$ is the dimension of the MW basis. Due to the broad spectrum of time scales involved in this chemical system, the deterministic system of equations resulting from the Galerkin projection is stiff, as for the deterministic case. In the following, we shall make use of the software package DVODE of Brown, Hindmarsh and Byrne, designed for the integration of systems of stiff ODEs [4, 5].

4.3. Initial conditions. To solve the chemical problem, initial conditions are needed. In this work, the initial concentrations are certain and set to

$$\begin{cases} [OH] = [H] = [HO_2] = [H_2O_2] = 0, \\ [H_2O] = 4.281\ 10^{-3}, \quad [H_2] = 2.06\ 10^{-6}, \quad [O_2] = 1.04\ 10^{-6}. \end{cases} \tag{4.4}$$

Since these initial conditions are certain, they correspond to the initial coefficients of the zero modes (associated to $\mathcal{M}_0$) of the solution while all other MW coefficients are initially vanishing.

5. One-dimensional MW modeling of supercritical hydrogen oxidation. We first restrict our attention to the case where only the seventh reaction rate constant is uncertain. Hence, the problem can be modeled with a single stochastic dimension, enabling intensive computations and analysis. Still, the uncertainty in $\tilde{k}_{f,7}$ and $\tilde{k}_{r,7}$ impacts the full set of species concentrations in a nontrivial way, as might be expected given the coupling of different species by the chemical source term. Since the mapping of the reaction rate in terms of the CDF $x(\xi)$ exhibits an infinite growth as $x \to 1$, significant resolution is required to properly represent the distribution for the highest values of $\tilde{k}_{f,7}$. However, while the convergence of the mapping with increasing number of resolution levels is quite slow for the zero order expansion, very few levels are needed when using higher order. These claims are verified in the following results.

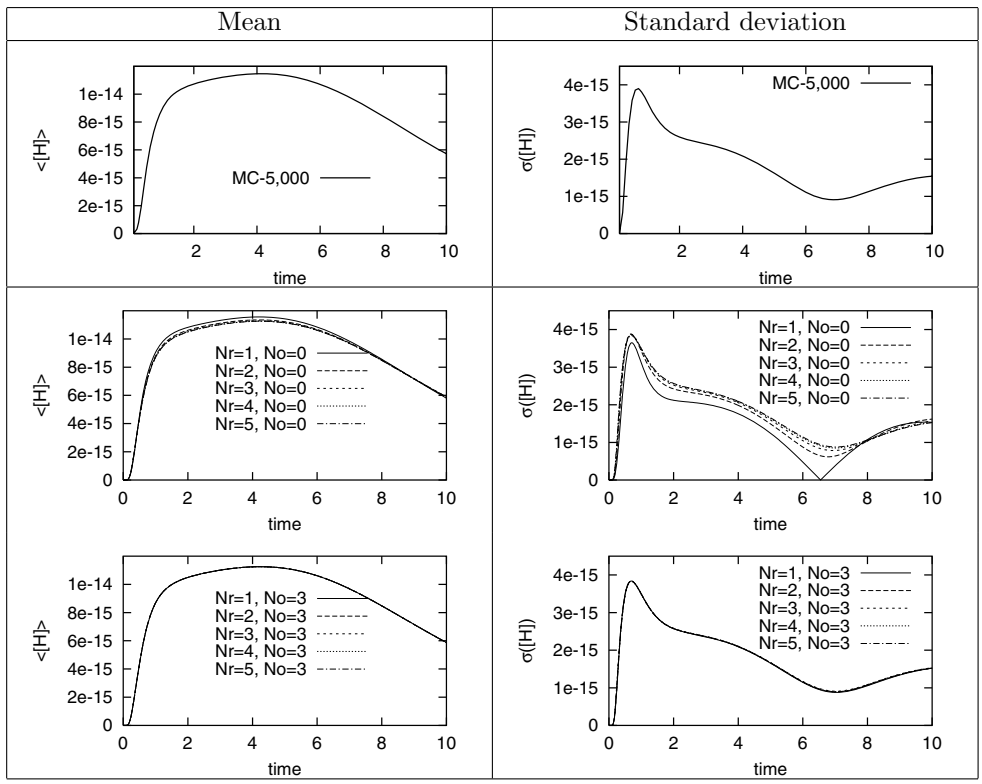

FIG. 5.1. *Mean (left) and standard deviation (right) of* H *concentration as a function of time. Top row: computations with MC sampling using a* 5000*-point sample. Bottom two rows: computations with MW expansions using* N_o *and* N_r *as indicated. Only the uncertainty in the seventh reaction (see Table* 4.1*) is considered, all other forward rates being taken equal to their median values.*

5.1. First order moments. In order to have a baseline against which the MW results can be compared, we provide approximations of the mean and standard deviation of H concentration (as functions of time) that we obtained using straightforward MC sampling, with a 5000-point sample of $\tilde{k}_{f,7}$. Note that the sole purpose of this calculation, whose results are shown in the first row of Figure 5.1, is to illustrate the correctness of the MW results at first and second (statistical) orders. In particular, we do not compare performance in terms of execution speed, since the following hold:

- Brute force MC sampling can be trivially implemented in an embarassingly parallel fashion; on the other hand, despite the fact that the MW algorithm (see section 6.1.2) uses mutually independent subdomains, further analysis must be conducted as to how a parallel implementation would scale.
- In order to achieve good approximations of higher order statistical moments using MC sampling, one typically has to increase the sample size as the order increases. However, this is not the case with the MW approach. Therefore, a fair comparison would require us to compare the advantages of the former method with respect to MC, which is not the purpose of this paper.

In this context, the plots of the last two rows in Figure 5.1 show the results obtained with the intrusive MW approach for $N_o = 0$ and 3 and $N_r = 1, \ldots, 5$.

Focusing first on the zero-order case, i.e., Wiener–Haar expansion, depicted on the top row in the figure, the convergence of the solution when N_r increases is clearly visible. In fact, for the mean of $[H](t)$, the solution obtained with $N_r = 1$ is slightly overestimated, but predictions for $N_r \geq 2$ are hardly distinguishable in the plot and are in excellent agreement with the higher order computation of the last row. For the standard deviation, the convergence appears to be slower with N_r, and the case with $N_r = 1$ significantly underestimates the statistical dispersion of the concentration induced by the uncertainty. It even predicts the absence of any uncertainty in the concentration for $t \approx 6.5$. Nonetheless, the convergence of the second order statistics, albeit slow, is still achieved for $N_o = 0$. Similar trends are reported when using $N_o = 1$ and 2 (not shown), but with more accurate predictions for $N_r = 1$ and a faster convergence rate. For $N_o = 3$, in the bottom row of Figure 5.1, even the prediction for $N_r = 1$ provides very accurate results, as far as these low order moments are concerned. Increasing the level of resolution does not seem to bring additional significant information into the uncertain process, even if the quality of the mapping appears fairly poor for $N_r = 1$ and $N_o = 3$. In fact, a closer analysis (see below) of the supplementary details introduced when increasing the resolution level indicates that they do improve the representation, although their impact on the low order statistics is negligible; a finer analysis of the predicted process distribution is necessary to assess the improvement resulting from increasing resolution. Last, but not least, we see a very good agreement between MC and MW results, agreement that improves as N_o increases.

To support the assertion that the MRA refinement essentially improves the higher order statistics, we show in the left-hand plot of Figure 5.2 the time evolution of the expected concentration in H with the $\pm$ one standard deviation bounding box ($\sigma([H])$). In addition, the deterministic solution corresponding to the median value of the forward rate (solid line) is also reported in the same plot. While one may have expected the deterministic median solution to remain roughly within the neighborhood of the expected solution, it appears that it actually departs significantly from the averaged realization, reaching the $+\sigma$ bound for $t \approx 6.5$. This behavior is characteristic of highly skewed processes, reflecting the nonlinearity of the chemical source term. To better appreciate the skewness of the uncertainty in the H concentration distribution, we provide in the right-hand plot of Figure 5.2 a set of 40 sample paths of $[H](t)$ for random realizations of $\tilde{k}_{f,7}$ following the prescribed log-normal distribution. These sample paths highlight the complex dependence of the concentration on the value of the seventh forward rate: it results in a skewed distribution of [H] with a sharp upper tail at $t > 5$. At this point, it should be clear that first and second order statistical moments are not enough to fully characterize the impact of the uncertainty in $k_{f,7}$ on the solution.

5.2. Analysis of concentration probability density functions. To stress further the need for accurate high order statistics in order to properly represent the impact of uncertainty on the chemical process under study, and to illustrate the improvement in this direction resulting from increasing the level of resolution in the MRA scheme, we now focus on the PDF of the species concentrations. To this end, we use for each species sp the time-dependent [illegible] $\mathcal{R}_{[\mathsf{sp}]}$ of species concentration, defined as follows:

$$(\forall t \in [0, 10]) \quad \mathcal{R}([\mathsf{sp}], t) = \frac{\mathrm{pdf}([\mathsf{sp}](t))}{\max_{[\mathsf{sp}]} \mathrm{pdf}([\mathsf{sp}](t))}. \tag{5.1}$$

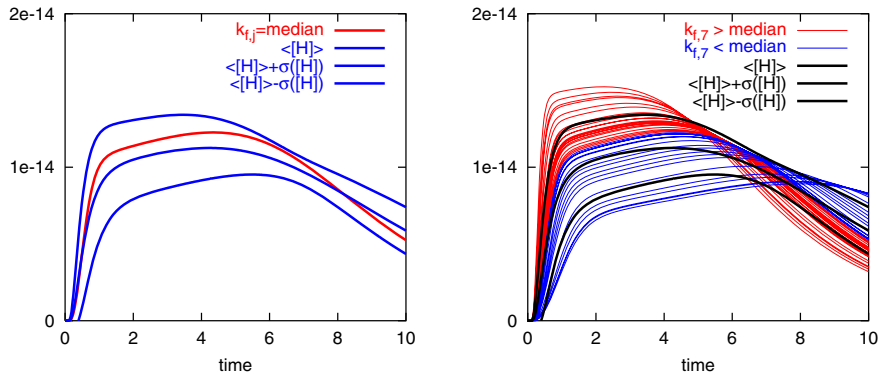

FIG. 5.2. *Left: mean of* $[\mathrm{H}](t)$ *with* $\pm\sigma([H])$ *box (blue lines) and deterministic* $[\mathrm{H}](t)$ *for* $\tilde{k}_{f,7}(x) = \hat{k}_{f,7}$ *(red line). Right:* 40 *deterministic samples of* $[\mathrm{H}](t)$*, corresponding to* $\tilde{k}_{f,7} > \hat{k}_{f,7}$ *(red lines) and* $\tilde{k}_{f,7} < \hat{k}_{f,7}$ *(blue lines), together with the computed expectation of* $[\mathrm{H}](t) \pm \sigma([\mathrm{H}])$ *(black). Mean and standard deviation of* $[\mathrm{H}](t)$ *were obtained using* $\mathrm{N_r} = 5$ *and* $\mathrm{N_o} = 3$.

Hence, one always has $\mathcal{R}([\mathsf{sp}], t) \in [0, 1]$, with equality to 1 if and only if $\mathrm{pdf}([\mathsf{sp}])$ is equal to the highest species PDF at time t; this is in particular the case for the maximum likelihood estimation of $[\mathsf{sp}]$, when it exists—with no guarantee of uniqueness. On the contrary, $\mathcal{R}([\mathsf{sp}], t)$ vanishes if and only if the PDF of $[\mathsf{sp}]$ at time t vanishes as well. The rescaling of the concentration PDF, with its local-time maxima, enables time-tracking of the concentration value with the highest PDF by removing the large fluctuations in magnitude of the absolute PDF. As with the PDF, however, a thin $\mathcal{R}$ for a given observable means a highly predictable concentration, while broad distributions or disperse peaks in $\mathcal{R}$ reflect large variability, possible unpredictability (at least unreliability), and a low confidence level in the predicted concentrations. In Figure 5.3, we have plotted the relative likelihood for two species concentrations: $[\mathrm{H}_2]$ and $[\mathrm{H}]$. The PDFs of the species concentrations were estimated using a set of one million samples for x, uniformly drawn on $[0, 1]$, and used to compute the corresponding concentration samples from their respective MW expansions.

The results in the figure clearly show the convergence of $\mathcal{R}([\mathrm{H}_2], t)$ and $\mathcal{R}([\mathrm{H}], t)$ (and thus of their respective PDFs) with increasing $\mathrm{N_r}$. The dominant features of the $\mathcal{R}([\mathrm{H}_2])$ time evolutions are largely converged for $\mathrm{N_r} = 3$, while low $\mathrm{N_r}$ artifacts in $\mathcal{R}([\mathrm{H}], t)$ are not eliminated until $\mathrm{N_r} = 5$. Further, while $\mathcal{R}([\mathrm{H}_2], t)$ exhibits generally smooth behavior, persistent sharp features are evident in $\mathcal{R}([\mathrm{H}], t)$ for $t > 4$. This suggests the role of implicit equilibrium constraints in the chemical system at late time (as equilibrium is approached) and the high sensitivity of the system to $[\mathrm{H}]$. The result is that a very narrow distribution in $[\mathrm{H}]$ is allowed for $t > 4$. Of course it is true that $[\mathrm{H}_2]$ also exhibits a narrowing distribution at late time, but of a clearly different qualitative nature. Note that the equilibrium state of the system is not uncertain, as it is determined by the thermodynamics of the mixture and not by the rate kinetics. Since uncertainty is only presumed here in one kinetic rate constant, it is expected that, for sufficiently large time, the residual distribution of $\mathcal{R}([\mathrm{H}_2])$ and $\mathcal{R}([\mathrm{H}])$ in the figure will approach peaked functions. Moreover, while $[\mathrm{H}_2]$ tends to zero at equilibrium and must remain positive, $[\mathrm{H}]$ tends to a nonzero limit and is skewed toward an upper limit (highest concentrations).

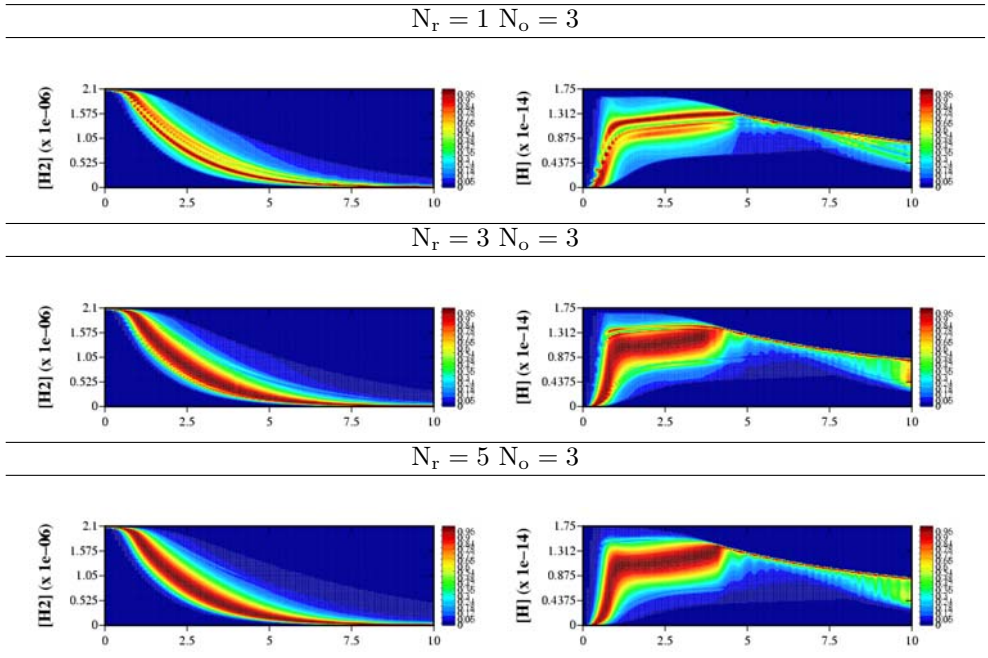

FIG. 5.3. *Color coded normalized PDFs* $\mathcal{R}([\mathrm{H}_2], t)$ *(left) and* $\mathcal{R}([\mathrm{H}], t)$ *(right) computed from their MW expansion using different levels of resolution as indicated, and polynomial order* $\mathrm{N_o} = 3$. *Dark red areas indicate concentrations of highest probability density of observation, while deep blue regions correspond to vanishing probability densities.*

6. Multidimensional process. Direct extension of the methodology of the previous section to the full uncertain problem is not feasible, because the size of the MW basis for given $\mathrm{N_r}$ and $\mathrm{N_o}$ exhibits a prohibitive rate of growth with the number of independent parameters. Also, if the uncertain process to be expanded is essentially smooth with regard to the parameter set, with only localized steep variations along only a few of the stochastic dimensions, one can expect that a large part of the MW coefficients have low magnitude, so that many can actually be neglected. However, the set of MW coefficients that could be removed from the expansion is not known a priori, and an adaptive strategy that dynamically selects the relevant coefficients is required in order to maintain an acceptable computational cost.

Although appealing, adaptive strategies based on coarsening/refinement of the set of MW coefficients are difficult to implement in multidimensional problems and not necessarily optimal from a CPU-load point of view, since any changes in the basis imply changes in the product tensors D_{ijk}, whose evaluation could be expensive if it were to be repeated many times during the simulation. Further, when the number of MW coefficients increases, the size of the set of nonvanishing elements in the binary and ternary products increases dramatically (see [13]) due to the overlapping supports of the MW at different resolution levels. This is a severe limitation for the use of MW expansions for $\mathrm{N_d} > 1$ because the binary product is the key operator in pseudospectral computations [8, 17].

These considerations lead us to the development of an alternative adaptive strategy in [13], which retains the fundamental feature of MRA, specifically the piecewise polynomial character of the expansion, while overcoming the issue of increasing com-

plexity of the binary product when the resolution level increases. The main ingredient of this adaptive scheme is the construction of an "analyzer-basis," involving multi-dimensional Legendre polynomials plus first resolution level one-dimensional details. This analyzer can be rescaled (to an arbitrary resolution level in each of the stochastic dimensions) and displaced (within the parameter space) to compute local expansions of the process. Within this framework, the aim of the adaptive strategy is to decide what is the minimal local level of resolution necessary to properly approximate the solution. In contrast with the algorithm presented in [13], where the resolution was held constant over the simulation time, we construct here a refinement that adaptively evolves with time. Below, we detail the construction of the adaptive scheme, which is then applied to the chemical test-problem.

6.1. Set partition of the parameter space and local basis. Let $\Omega = [a_1, b_1] \times \cdots \times [a_N, b_{\mathrm{N_d}}]$ be the space of random parameters. Let Ω^m, $m = 1, \ldots, \mathrm{N_b}$, be a finite set partition of Ω in $\mathrm{N_b}$ nonoverlapping subdomains:

$$\left\{ \begin{array}{l} \Omega^m = [a_1^m, b_1^m] \times \cdots \times [a_N^m, b_N^m], \\ \Omega = \bigcup_{m=1}^{\mathrm{N_b}} \Omega^m, \\ \Omega^m \cap \Omega^{m'} = \varnothing \quad \text{if } m \neq m'. \end{array} \right. \tag{6.1}$$

We define as follows the local PDF of $\boldsymbol{\xi}$ on each of the sub-domains Ω^m, denoted by $\mathrm{pdf}^m(\boldsymbol{\xi})$, using the independence of the random parameters:

$$\mathrm{pdf}^m(\boldsymbol{\xi}) = \prod_{d=1}^{\mathrm{N_d}} \mathrm{pdf}_d^m(\xi_d), \quad \mathrm{pdf}_d^m(\xi) = \frac{\mathrm{pdf}_d(\xi)}{\mathrm{p}_d(b_d^m) - \mathrm{p}_d(a_d^m)}. \tag{6.2}$$

Clearly, we have $\mathrm{pdf}^m(\boldsymbol{\xi}) > 0 \quad \text{for } \boldsymbol{\xi} \in \Omega^m$ and $\int_{\Omega^m} \mathrm{pdf}^m(\boldsymbol{\xi}) d\boldsymbol{\xi} = 1$. Moreover, defining $\mathrm{p}_d^m(\xi \in [a_d^m, b_d^m]) = \int_{a_d^m}^{\xi} \mathrm{pdf}_d^m(\xi') d\xi' \in [0,1]$, if x_d^m is uniformly distributed over $[0,1]$, then the random variable $(\mathrm{p}_d^m)^{-1}(x_d^m) \in [a_b^m, b_d^m]$ and has the same distribution as ξ_d^m. Thus, a second order stochastic process can be locally expanded on Ω^m, in terms of the random vector $\boldsymbol{x}^m$, having independent components $(x_1^m, \ldots, x_{\mathrm{N_d}}^m) \in [0,1]^{\mathrm{N_d}}$, with uniform distributions. Now let $\boldsymbol{\gamma}$ be the set of multidimensional indices

$$\boldsymbol{\gamma}(\mathrm{N_o}) = \left\{ (\gamma_1, \ldots, \gamma_{\mathrm{N_d}}) : \sum_{d=1}^{\mathrm{N_d}} \gamma_d \leq \mathrm{N_o} \right\}.$$

For $\boldsymbol{\xi} \in \Omega^m$, we build the local projection basis as

$$\mathcal{B}_p(\Omega^m, \mathrm{N_o}) = \left\{ \Phi^m_{\boldsymbol{\lambda} \in \boldsymbol{\gamma}(\mathrm{N_o})}(\boldsymbol{x}^m(\boldsymbol{\xi}^m)) = \prod_{d=1}^{\mathrm{N_d}} \phi_{\lambda_d}(x_d^m(\xi_d^m)) \right\},$$

and the details directional basis $\mathcal{B}_a^d(\mathrm{N_o})$, $d = 1, \ldots, \mathrm{N_d}$, as

$$\mathcal{B}_a^d(\Omega^m, \mathrm{N_o}) = \{\psi_i(x_d^m), i = 0, \ldots, \mathrm{N_o}\}.$$

The full local expansion basis will be the union of $\mathcal{B}_p$ and $\mathcal{B}_a^d$:

$$\mathcal{B}(\Omega^m, \mathrm{N_o}) = \mathcal{B}_p(\Omega^m, \mathrm{N_o}) + \bigcup_{d=1}^{\mathrm{N_d}} \mathcal{B}_a^d(\Omega^m, \mathrm{N_o}).$$

Finally, the multidimensional process $\mathcal{P}(\boldsymbol{\xi})$ will have for local expansion on Ω^m

$$\mathcal{P}(\boldsymbol{\xi}) = \tilde{\mathcal{P}}(\boldsymbol{x}^m(\boldsymbol{\xi})) \approx \sum_{\boldsymbol{\lambda}\in\boldsymbol{\gamma}} \tilde{\mathcal{P}}^m_{\lambda_1,\ldots,\lambda_N} \Phi_{\lambda_1,\ldots,\lambda_N}(\boldsymbol{x}^m(\boldsymbol{\xi})) + \sum_{d=1}^{\mathrm{N_d}} \sum_{i=0}^{\mathrm{N_o}} \tilde{\mathcal{P}}^m_{d,i} \psi_i(x^m_d), \tag{6.3}$$

where again, the equality holds in the mean-square sense. Note that the local basis $\mathcal{B}(\Omega^m, \mathrm{N_o})$, spanning the local expansion of $\mathcal{P}$ according to (6.3), is in fact the rescaled Legendre polynomial basis $(\mathcal{B}_p(\Omega^m, \mathrm{N_o}))$ augmented with the first-level detail basis, $\mathcal{B}^d_a$, $d = 1, \ldots, \mathrm{N_d}$. Thus, $\tilde{\mathcal{P}}(\boldsymbol{x})$ for $\boldsymbol{\xi}(\boldsymbol{x}) \in \Omega^m$, approximated by (6.3), is the local Wiener–Legendre projection of order $\mathrm{N_o}$, plus one-dimensional details. The local expectation of $\mathcal{P}$ is given by $\langle\mathcal{P}\rangle_{\Omega^m} = \mathcal{P}^m_{0,\ldots,0}$, and its local variance is

$$\sigma^2_{\Omega^m}(\mathcal{P}) \approx \left(\hat{\sigma}_{\Omega^m}\right)^2 + \sum_{d=1}^{\mathrm{N_d}} \left(\sigma^d_{\Omega^m}\right)^2,$$

where $\left(\hat{\sigma}_{\Omega^m}\right)^2 = \sum_{\boldsymbol{\lambda}\in\boldsymbol{\gamma}_p} (\mathcal{P}^m_{\boldsymbol{\lambda}})^2$, $\left(\sigma^d_{\Omega^m}\right)^2 = \sum_{i=0}^{\mathrm{N_o}} \left(\mathcal{P}^m_{d,i}\right)^2$, and we have denoted $\boldsymbol{\gamma}_p = \boldsymbol{\gamma} - \{(0,\ldots,0)\}$. The total expectation of the process is given by the volume-weighted summation of the local expectations:

$$\langle\mathcal{P}\rangle = \sum_{m=1}^{\mathrm{N_b}} \langle\mathcal{P}\rangle_{\Omega^m} \mathrm{Vol}^m, \tag{6.4}$$

where Vol^m is the Euclidean volume of Ω^m: $\mathrm{Vol}^m = \prod_{d=1}^{\mathrm{N_d}} (\mathrm{p}_d(b^m_d) - \mathrm{p}_d(a^m_d))$. Finally the total variance of the process is given by

$$\sigma^2(\mathcal{P}) = \sum_{m=1}^{\mathrm{N_b}} \left[\sigma^2_{\Omega^m}(\mathcal{P}) + \left(\mathcal{P}^m_{0,\ldots,0} - \langle\mathcal{P}\rangle\right)^2\right] \mathrm{Vol}^m. \tag{6.5}$$

6.1.1. Adaptive strategy. Assume that the current set partition of Ω involves $\mathrm{N_b}$ blocks; i.e., $\Omega = \bigcup_{m=1}^{\mathrm{N_b}} \Omega^m$. On each subdomain Ω^m, the process is expanded on the local basis $\mathcal{B}(\Omega^m, \mathrm{N_o})$, the spectral coefficients being computed through Galerkin projection methods as previously. To decide if a given block m needs more refinement and to determine which stochastic directions need such refinement, we consider the criterion

$$C_m(d) = \frac{\sigma^d_{\Omega_m}}{\sigma_{\Omega_m}} \geq \varepsilon_r, \tag{6.6}$$

and we refine the subdomain along the dth dimension if this inequality is satisfied. Here $\varepsilon_r < 1$ is a prescribed threshold. The test compares the "energy" of the one-dimensional details along the dth stochastic direction with the local variance of the solution. In other words, the one-dimensional detail coefficients are used as indicators of the quality of the representation along their respective stochastic directions. A new set partition of Ω is then constructed by splitting Ω^m into smaller subdomains. Specifically, if we assume the inequality (6.6) is satisfied for a single dimension d, then refinement of $\Omega^m = [a^m_1, b^m_1] \times \cdots \times [a^m_N, b^m_N]$ will give birth to two new subdomains $\Omega^{m'}$ and $\Omega^{m''}$ of equal volume, with common boundary at $(a^m_d + b^m_d)/2$. Then, local expansions of the process on the newly created subdomains are computed, before

being analyzed to determine whether additional refinement is needed. This sequence of analysis and refinement steps is repeated up to convergence. It is emphasized that, during refinement, computations are performed in newly created subdomains only, since the local solutions over other subdomains are unaffected. Note also that this methodology is well suited for parallel implementation, since local computations are independent of each other.

6.1.2. Application to chemical systems. We now provide the algorithm used to integrate the system of stochastic ODEs, with dynamical adaptation of the parameter space set partition. In order to minimize the computational load, we do not recompute the solution, starting from the initial time, for each refined subdomain, as in [13]. Instead, we advance the solution in time using equally spaced stages, where the correctness of the set partition with regard to the threshold function ϵ_r is verified. If the set partition at the end of a given stage k needs further refinement, then it is refined, and the solution over the created subdomains is computed from the initial conditions corresponding to the solution at the end of the stage $k-1$. A procedure is required to provide initial conditions for the new subdomains at the beginning of the current stage k. This is performed efficiently and without approximation using polynomial interpolations of the solution of the "parent" subdomain that has been split.

Suppose that we wish to integrate the system for $t \in [0, T_f]$. We denote by ΔT the time interval between successive analyses of the set partition. With this notation, the time-marching algorithm has the following structure:

1. **Initialization:**
   (a) Set times $t = 0$, $t_0 = 0$, and $t' = \Delta T$;
   (b) Initialize the set partition of Ω to $\Omega^1 = [0,1]^{\mathrm{N_d}}$, $\mathrm{N_b} = 1$;
   (c) Project the initial condition of the concentration on Ω^1;
   (d) Set subdomain flag $I(m = 1)$ to 1.
2. For each subdomain Ω^m of the set partition, $m = 1, \ldots, \mathrm{N_b}$, with $I(m) = 1$:
   (a) Set the local expansion of the forward and reverse reaction rates;
   (b) Set the local expansions for the concentrations at time t_0;
   (c) Perform the time integration between t_0 and t' of the local system of stochastic ODEs.
3. Set $\mathrm{N_b}' = \mathrm{N_b}$.
4. For each subdomain Ω^m of the set partition, $m = 1, \ldots, \mathrm{N_b}'$, with flag $I(m) = 1$:
   (a) Set subdomain flag to $I(m) = 2$;
   (b) Compute $C_m(d)$ given by (6.6), and retain highest value over the set of species concentrations;
   (c) If for all $d = 1, \ldots, \mathrm{N_d}$: $C_m(d) < \varepsilon_r$, then do:
      i. The subdomain is sufficiently refined, update flag to $I(m) = 0$;
      ii. Continue with the next subdomain in the list (step number (4)).
   (d) Else, for $d = 1, \ldots, \mathrm{N_d}$ do:
   If $C_m(d) \geq \varepsilon_r$, then do:
      i. For every subdomain $\Omega^{m' \leq \mathrm{N_b}}$ with $I(m') = 2$, do:
         - Store the solution S_0 at time t_0 over $\Omega^{m'}$;
         - Split (along the d-dimension) the subdomain $\Omega^{m'}$ into two subdomains with index m' and $m'' = \mathrm{N_b} + 1$: $\Omega^{m'} \to \Omega^{m'} \cup \Omega^{m''}$;
         - Set $I(m')$ and $I(m'')$ to 3 to make sure they are refined only once;

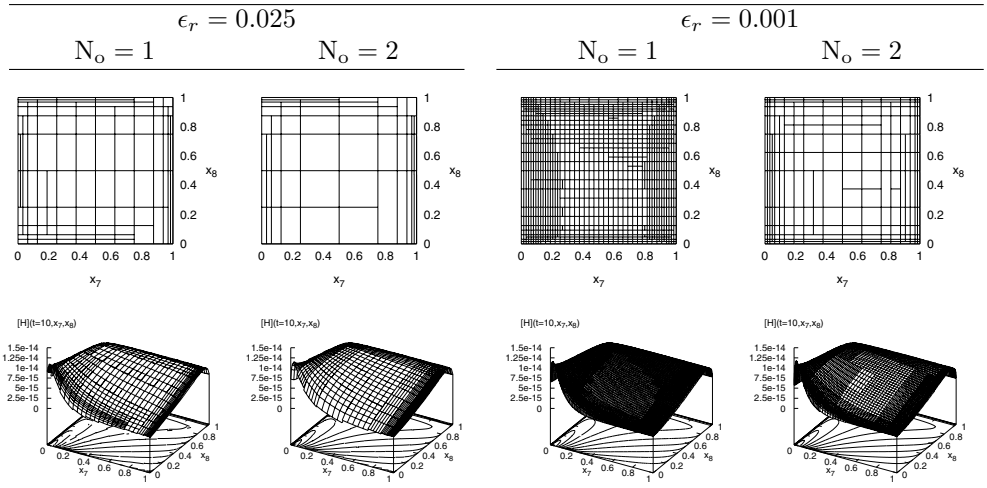

FIG. 6.1. *Results for the 2D problem considering uncertainty in the rates of reactions* 7 *and* 8. *Parameters are* $\epsilon_r = 0.025, 0.001$ *and* $\mathrm{N_o} = 1, 2$ *as indicated. The top row shows the partitioning of the* (x_7, x_8) *plane and its dependence on* ϵ_r *and* $\mathrm{N_o}$. *The bottom row shows the dependence of the* [H] *at* $t = 10$ *on* x_7 *and* x_8.

- Interpolate S_0 on $\Omega^{m'}$ and $\Omega^{m''}$;
- Update the set partition: $\mathrm{N_b} \leftarrow \mathrm{N_b} + 1$.

ii. Shift all subdomain flags with value 3 to $I = 2$, and proceed with the next dimension d in step (d).

(e) Refinement of the subdomain has been completed; set all flags $I = 2$ to $I = 1$ and proceed with the next subdomain in step (4).

5. If $\mathrm{N_b} > \mathrm{N_b}'$, new subdomains have been generated that need to be computed and further analyzed: continue from step (2).
6. The set partition satisfies the refinement criteria; then:
   (a) Record the set partition and the solutions over all subdomains at time $t = t'$, to be used as initial conditions in the next time interval;
   (b) If $t' < T_f$, then:
      i. Set $t_0 \leftarrow t'$, $t' \leftarrow t' + \Delta T$;
      ii. For $m = 1, \ldots, \mathrm{N_b}$ set $I(m) = 1$;
      iii. Continue from step (2).
7. End.

6.2. Test cases. We now present some test cases in order to illustrate the utility of our approach.

6.2.1. Two-dimensional tests. We consider uncertainty in the rates of reactions 7 and 8, and apply the adaptive scheme for three threshold values $\epsilon_r = 0.025$, 0.01, and 0.001. Tests are considered for the first and second order expansion.

In Figure 6.1, we plot the final ($t = 10$) set partitions and response-surfaces for $\epsilon_r = 0.025$, 0.001 and $\mathrm{N_o} = 1, 2$. The results highlight the dependence of the MW discretization and domain decomposition on ϵ_r and $\mathrm{N_o}$. The top row shows the partitioning of the (x_7, x_8) plane and its dependence on ϵ_r and $\mathrm{N_o}$. We note the more refined partitioning with decreasing ϵ_r and $\mathrm{N_o}$. For higher $\mathrm{N_o}$, less refinement of the (x_7, x_8) space is necessary for a given allowed directional block variance controlled by ϵ_r. The localization of the highly refined domain blocks at the $(0, 1)$ limits of x_7

and x_8 reflect both the variability of the rate constant mappings and the dependence of various elements of the solution on the (x_7, x_8) space. The dependence of [H] (at $t = 10$) on (x_7, x_8) is shown in the bottom row in Figure 6.1, again for the indicated ranges of ϵ_r and $\mathrm{N_o}$. The [H] response-surfaces exhibit strong variability with (x_7, x_8) in the vicinity of the origin, with generally smoother behavior elsewhere.

As it can be appreciated from the top row of Figure 6.1, the number of bins is significantly higher for $\mathrm{N_o} = 1$ than for $\mathrm{N_o} = 2$ to achieve the same threshold value. An optimal strategy ultimately requires suitable choices of $\mathrm{N_o}$ and ϵ_r for the problem at hand.

We note finally the relative insensitivity of the [H] response-surface shape to the choice of ϵ_r and $\mathrm{N_o}$ in the ranges considered in Figure 6.1. This is also evident in the mean and standard deviation profiles of [H] versus time (not shown). Any changes in these two moments over the specified range of ϵ_r and $\mathrm{N_o}$ is simply not observable in the profiles for all time.

6.2.2. High-dimensional tests. In this section the adaptive scheme is applied, considering all the reaction rates as uncertain. The simulation runs up to $t = 10$ as previously. The left-hand plot of Figure 6.2 displays the numbers of bins involved in the partitions as a function of time for different orders $\mathrm{N_o}$ and refinement threshold ϵ_r. It indicates that the number of bins quickly increases at the early stages of the simulation and then tends to level off. It may also be noticed that with $\epsilon_r = 0.05$ and $\mathrm{N_o} = 3$ the computations do not reach $t = 10$ because of numerical instabilities (even though the computations are stable for a longer period than with WHe expansions).

Clearly, the efficiency of the partitioning strategy depends on the capability of the algorithm to divide the parameter space into an optimal number of subdomains. To minimize this number of subdomains, the successive divisions have to be limited to the directions along which steep dependences are present, while avoiding division along smooth dimensions. To appreciate the capability of the algorithm to discriminate directions (uncertain reaction rates) requiring divisions from the smooth ones, we present in the right-hand plot of Figure 6.2 the frequency of successive divisions along the different dimensions of the parameter space for $\mathrm{N_o} = 1$ and $\epsilon_r = 0.05$. It is shown that no divisions are done along dimensions 1–4 and 6, denoting a smooth dependence of the concentrations with regard to the uncertainties in the corresponding reaction rates. On the contrary, reactions 5, 7, and 8 do require divisions, up to 3 successive ones in some areas of the parameter space. When ϵ_r is lowered to 0.005, more divisions are necessary along the previously divided directions to meet the refinement criteria, while some subdomains have now also been cut along directions 6 and 2, but with a significantly lower frequency (not shown).

It is seen from the results above that using a higher expansion order requires a lower number of subdomains to satisfy a fixed refinement criteria. However, the dimension of the local basis quickly increases with the order $\mathrm{N_o}$ such that a lower number of subdomains does not necessarily imply a lower computational cost. In fact, for given ϵ_r, the selection of the optimal order in terms of CPU cost remains an open question. Moreover, because the solutions over subdomains are fully independent and can be computed in parallel, the trade-off between number of subdomains and expansion order should account for memory requirement and data flow as well. Also, the optimal trade-off is certainly problem dependent so no general guidelines can be established. Another aspect that needs to be underlined is that different orders used with the same threshold value will not generally lead exactly to the same accuracy, although the same order of error is expected. This claim has been verified through

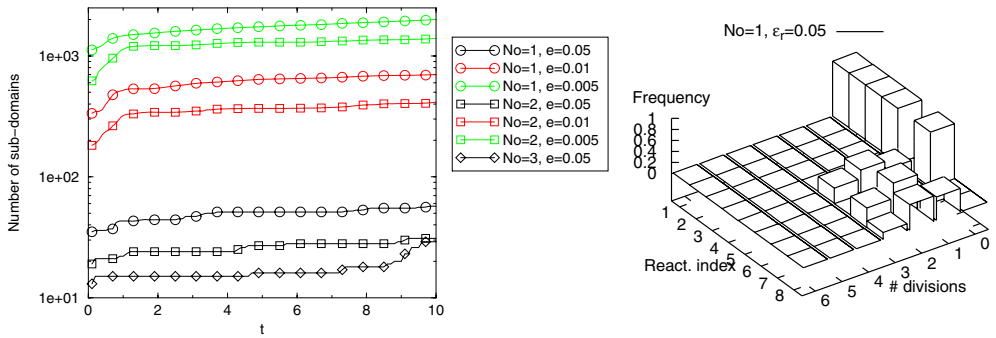

FIG. 6.2. *Left: evolution of the number of bins in the partitions as a function of time and for different expansion orders* N_o *and refinement threshold value* ϵ_r *as indicated. Right: relative frequency along each dimension of the parameter space (reaction indices) of the number of successive divisions. The graphs correspond to the partition at time* $t = 10$ *for* $N_o = 1$ *and threshold value* $\epsilon_r = 0.05$.

inspection of the time evolution of the expectations and standard deviations of the species concentrations when computed with different orders and threshold values. It is found that all predictions are in good agreement and appear to converge to the most refined and highest order solution.

Again, the tests suggest a fast convergence of the first moment with both the threshold value and the expansion order. However, if one is interested in a more complete statistical description of the solution, then the improvement in the prediction with decreasing ϵ_r and increasing expansion order are more visible. To illustrate this fact, we provide a quick analysis of the resulting pdfs of some species concentrations. Provided in Figure 6.3 are pdfs of [H] and [H_2] at different times, computed with $N_o = 1$ and $\epsilon_r = 0.005$ (other species exhibit similar pdfs). The plots indicate that the pdfs are smooth (except at the tails), denoting no significant discontinuities of the solution across subdomain boundaries. For less stringent refinement thresholds ($\epsilon_r = 0.1$) discontinuities are present (not shown). Also, the plots demonstrate the need for an adaptation of the partition, as the shapes of the pdfs drastically evolve with time. It is clear that such a complex uncertainty impact would have required a large order expansion if a global expansion is to be used (i.e., only one domain), but such a high order global expansion is numerically unstable, as shown in [17].

Finally, the numerical instabilities in the global spectral simulations reported in [17] were attributed to the spurious development of tails with negative concentrations in the solution expansion. Although the present computations are stable, it is

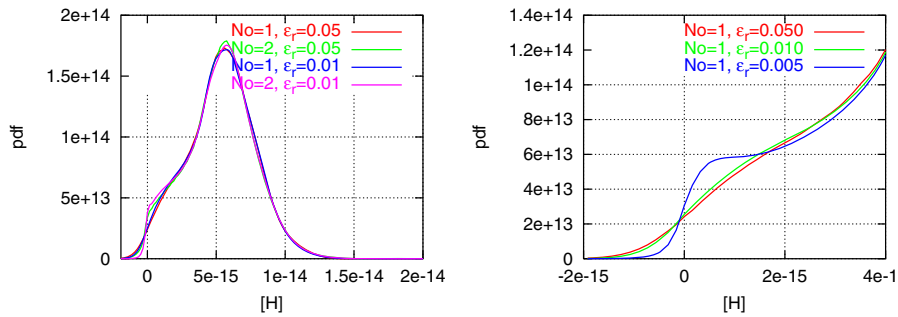

FIG. 6.4. *Left: pdfs of* [H] *for* $N_o = 1$, 2 *and* $\epsilon_r = 0.05$ *and* 0.01. *Right: details of the computed pdfs of* [H], *in the neighborhood of* [H] = 0, $N_o = 1$ *and decreasing refinement threshold as indicated.*

interesting to note that our simulations do not totally satisfy the positivity of the concentrations: the probability of all concentrations being positive is not exactly 0. This is illustrated in Figure 6.4, where pdfs of [H] are plotted at time $t = 10$ for different orders and threshold values. These plots show that the probability of [H] < 0 decreases with the order and the refinement criteria (similar behavior is observed for the other species). It can be concluded that the automatic partitioning of the parameter space stabilizes the computation by maintaining a low order expansion, valid locally, and dividing a subdomain whenever its local solution develops instability. This effect is further illustrated in the right-hand plot of Figure 6.4, which compares the computed pdfs of [H] in the neighborhood of [H] $= 0$ at $t = 10$ for a fixed order $N_o = 1$ and different refinement criteria.

7. Conclusions. In this paper, a multi-resolution analysis scheme for the quantification of parametric uncertainties in chemical systems has been developed. The impact of uncertainties is tackled using an orthogonal projection of the model solution on spectral bases composed of piecewise-continuous polynomial functions (multi-wavelets) of a set of random variables that represent the variability in the system parameters. This approach is designed to allow for local refinement of the representation in areas of the uncertain parameter space where it is needed. Such local refinements are required when the system dynamics exhibit complex and steep dependences on the random parameters (here the reaction rates). In fact, instead of using unnecessarily high order global PC expansions, a series of local low order expansions at controlled resolution levels are employed.

The main improvement of the proposed MRA scheme comes from the elimination of the numerical instability issues encountered with the original PC construction (using a global basis with noncompact support), particularly at higher PC orders. Thus, maintaining a low to moderate expansion order is crucial for the robustness of the computations, while convergence can still be controlled through the selection of an appropriate level of resolution. However, the fast increase of the basis dimension with the resolution level prevents the straightforward application of the MRA scheme to situations involving multiple independent random parameters, and calls for adaptive techniques. Consequently, an attempt toward the local adaptation of the resolution level is proposed. This adaptive technique makes use of the energy contained in the local correction at the next resolution level to decide if more resolution is needed. It naturally leads to an iterative partition of the parameter space, up to a prescribed tolerance, with the property that its computational cost is proportional to

the resulting number of subdomains in the partition and not a function of the basis dimension. Numerical experiments have demonstrated the validity of the proposed adaptive scheme but also highlight the need for an improvement of the methodology to include a coarsening strategy and ultimately a local adaptation of the expansion order too. In fact, the optimal trade-off, between refinement of the partition into smaller subdomains and/or an increase of the local expansion order to reduce the approximation error is problem dependent and needs further investigation; a possible way to determine such an optimal strategy could be based on a posteriori error estimators. Future developments will focus on this issue.

THEORETICAL AND COMPUTATIONAL ISSUES OF OPTIMAL CONTROL FOR DISTRIBUTED HOPFIELD NEURAL NETWORK EQUATIONS WITH DIFFUSION TERM*

QUAN-FANG WANG†

Abstract. This work investigates theoretical and computational issues of optimal control for distributed Hopfield neural network equations with diffusion term. Due to introducing a diffusion term in our model, a theoretical conclusion is deduced for the control of the nonlinear parabolic partial differential equation in the framework of variational methods (cf. [J. L. Lions, *Optimal Control of Systems Governed by Partial Differential Equations*, Springer-Verlag, Berlin, Heidelberg, New York, 1971]) by means of distributed control, boundary control, and initial control. Experimental demonstration is implemented via a semidiscrete numerical algorithm based on the finite element method. The theoretical results are verified using the proposed scheme.

Key words. Hopfield neural network equations, distributed control, boundary control, initial control, numerical approximation, finite element methods

DOI. 10.1137/050647943

1. Introduction.

The Hopfield neural networks (HNN) model has been extensively considered in various fields, such as the natural sciences (e.g., physics, chemistry), engineering (e.g., artificial intelligence), industry (e.g., signal processing), medicine (e.g., CT detection), and other areas. For related references see [7], [8], [9], [10], [11], [12], [13], [16], and [23]. An interesting topic arises at the viewpoint of biological science: How can we realize control for neural network systems (including about 100 hundred million neurons)? The control input may be language, laser pulse, electric current, or drug simulations, etc. In particular, how can we simulate the control process through experimental demonstration, and what results will be meaningful for the physics problem? That is the reason why we do this research. For more rational meaning in physics, a diffusion term is added to our model.

The goal of this work is to consider the theoretical and computational problems of optimal control for the HNN system with diffusion term by means of distributed, boundary, and initial controls. Physically, boundary control and initial control can be realized by practical methods, but how to realize distributed control (a kind of effect coming from another "neuron," or a kind of perturbation) is still a mystery. The spatial dimensional is restricted to the one-dimensional case in theoretical study for corresponding to numerical study.

Let $\Omega = (0, l)$ be an open bounded domain of $\mathbf{R}^1$ (the theoretical results for $\mathbf{R}^n$ refer to [17]), $T > 0$, and $Q = \Omega \times (0, T)$. Let $(x, t) \in Q$, $y_i = y_i(x, t)$ denote the activation potential of the ith neuron. The distributed HNN model with diffusion term of coupled n-numbers of neurons is described by

$$
(1.1)\qquad \begin{cases} \dfrac{\partial y_i}{\partial t} - d_i \Delta y_i = -a_i y_i + \displaystyle\sum_{j=1}^{n} c_{ij} F_j(y_j) + u_i \quad \text{in } (0,l)\times(0,T), \\ \dfrac{\partial y_i}{\partial \eta}(0,t) = v_i(0,t), \qquad \dfrac{\partial y_i}{\partial \eta}(1,t) = v_i(1,t), \\ y_i(0,x) = w_i(x) \text{ in } (0,l), \qquad i = 1,2,\dots,n. \end{cases}
$$

Here $d_i > 0$ are diffusion coefficients, $a_i > 0$ and c_{ij} are physical coefficients as explained in [13], u_i are respective distributed control variables, and $v_i(0,t)$ and $v_i(1,t)$ are boundary control variables at $x = 0$ and $x = 1$, respectively. w_i are initial control variables. $F_j : \mathbf{R} = (-\infty, \infty) \to (-1,1)$ are sigmoidal functions representing the effect coming from other neurons, e.g., $F_j(s) = \tanh s$.

Let $\mathcal{U}_i$, $\mathcal{V}_i^0$, $\mathcal{V}_i^1$, and $\mathcal{W}_i$ be the Hilbert spaces of control variables u_i, $v_i(0,t)$, $v_i(1,t)$, and w_i, respectively. Their product spaces are denoted by

$$
\mathcal{U} = \prod_{i=1}^{n} \mathcal{U}_i, \quad \mathcal{V}^0 = \prod_{i=1}^{n} \mathcal{V}_i^0, \quad \mathcal{V}^1 = \prod_{i=1}^{n} \mathcal{V}_i^1, \quad \mathcal{W} = \prod_{i=1}^{n} \mathcal{W}_i
$$

and $\mathbf{u} = (u_1, u_2, \dots, u_n)$, $\mathbf{v}(0) = (v_1(0,t), v_2(0,t), \dots, v_n(0,t))$, $\mathbf{v}(1) = (v_1(1,t), v_2(1,t), \dots, v_n(1,t))$, and $\mathbf{w} = (w_1, w_2, \dots, w_n)$. Set the product Hilbert space $\mathcal{C} = \mathcal{U} \times \mathcal{V}^0 \times \mathcal{V}^1 \times \mathcal{W}$ of control variables $\mathbf{c} = (\mathbf{u}, \mathbf{v}(0), \mathbf{v}(1), \mathbf{w}) \in \mathcal{C}$. Let $\mathbf{y} = \mathbf{y}(\mathbf{c}) = (y_1(\mathbf{c}), y_2(\mathbf{c}), \dots, y_n(\mathbf{c}))^T$ be the solution of the control system for a given $\mathbf{c} \in \mathcal{C}$. The attached cost function to system (1.1) is described by the terminal observation

$$
\begin{aligned} J(\mathbf{c}) = {} & \sum_{i=1}^{n} \int_{\Omega} |y_i(\mathbf{c},T) - z_{id}^T|^2 dx + \sum_{i=1}^{n} (u_i, u_i)_{\mathcal{U}_i} \\ & + \sum_{i=1}^{n} \|v_i(0,t)\|_{\mathcal{V}_i^0}^2 + \sum_{i=1}^{n} \|v_i(1,t)\|_{\mathcal{V}_i^1}^2 + \sum_{i=1}^{n} (w_i, w_i)_{\mathcal{W}_i} \quad \forall \mathbf{c} \in \mathcal{C}, \end{aligned} \tag{1.2}
$$

where $z_{id}^T \in L^2(\Omega)$ are desired values for $i = 1, 2, \dots, n$. Let $\mathcal{C}_{ad}$ be an admissible subset of $\mathcal{C}$. Without loss of generality, $\mathcal{C}_{ad} = L^2(Q)^n \times L^2(0,T)^n \times L^2(0,T)^n \times L^2(\Omega)^n$. The optimal control problem is to find and characterize an element $\mathbf{c}^* = (\mathbf{u}^*, \mathbf{v}^*(0), \mathbf{v}^*(1), \mathbf{w}^*) \in \mathcal{C}_{ad}$, called optimal control, such that

$$
\inf_{\mathbf{c} \in \mathcal{C}_{ad}} J(\mathbf{c}) = J(\mathbf{c}^*),
$$

where $\mathbf{u}^* = (u_1^*, u_2^*, \dots, u_n^*)$, $\mathbf{v}^*(0) = (v_1^*(0,t), v_2^*(0,t), \dots, v_n^*(0,t))$, $\mathbf{v}^*(1) = (v_1^*(1,t), v_2^*(1,t), \dots, v_n^*(1,t))$, and $\mathbf{w}^* = (w_1^*, w_2^*, \dots, w_n^*)$.

This paper is organized as follows. Section 2 states the basic results on the existence and uniqueness of weak solutions for state system (1.1) in the variational framework (cf. [6]). Section 3 proves the existence of an optimal control (distributed, boundary, and initial optimal control) for (1.2). In section 4, a semidiscrete numerical algorithm is proposed, based upon the finite element method. In section 5, numerical experiments are carried out to verify the obtained theoretical results and the efficiency of our proposed algorithm (cf. [2], [3], [4], [17], [19], [20], [21], [22]).

2. Existence and uniqueness of a weak solution. Assume that nonlinear function F_j satisfies the uniform Lipschitz continuity

$$
(2.1)\qquad \exists K > 0 : \quad |F_j(s) - F_j(r)| \le K|s - r|, \quad j = 1, 2, \dots, n.
$$

Introduce two Hilbert spaces $H = L^2(\Omega)$ and $V = H^1(\Omega)$ (cf. [1]) according to the Neumann boundary condition in (1.1). Those spaces are endowed with the usual inner products and norms denoted by $(\cdot,\cdot), |\cdot|, (\!(\cdot,\cdot)\!), \|\cdot\|$, respectively. The product Hilbert spaces $\mathcal{V} = H^1(\Omega)^n$, $\mathcal{H} = L^2(\Omega)^n$ have the inner products defined by

$$(\boldsymbol{\phi},\boldsymbol{\psi})_{\mathcal{H}} = \sum_{i=1}^{n}(\phi_i,\psi_i), \quad \boldsymbol{\phi} = (\phi_1,\phi_2,\dots,\phi_n)^T, \quad \boldsymbol{\psi} = (\psi_1,\psi_2,\dots,\psi_n)^T \in \mathcal{H},$$

$$(\boldsymbol{\phi},\boldsymbol{\psi})_{\mathcal{V}} = \sum_{i=1}^{n}(\!(\phi_i,\psi_i)\!), \quad \boldsymbol{\phi} = (\phi_1,\phi_2,\dots,\phi_n)^T, \quad \boldsymbol{\psi} = (\psi_1,\psi_2,\dots,\psi_n)^T \in \mathcal{V}.$$

Then $\mathcal{V}' = (V^n)'$ is the dual space of $\mathcal{V}$, and the dual pairing between $\mathcal{V}'$ and $\mathcal{V}$ is given by

$$\langle\boldsymbol{\phi},\boldsymbol{\psi}\rangle_{\mathcal{V},\mathcal{V}'} = \sum_{i=1}^{n}\langle\phi_i,\psi_i\rangle, \quad \boldsymbol{\phi} = (\phi_1,\phi_2,\dots,\phi_n)^T \in \mathcal{V}, \quad \boldsymbol{\psi} = (\psi_1,\psi_2,\dots,\psi_n)^T \in \mathcal{V}',$$

where $\langle\phi_i,\psi_i\rangle$ denotes the dual pairing between V and V'. The norms of $\mathcal{V}$ and $\mathcal{H}$ are denoted by $\|\boldsymbol{\psi}\|_{\mathcal{V}}$ and $|\boldsymbol{\psi}|_{\mathcal{H}}$, respectively. For the sake of simplicity, we introduce vectors and matrix representations:

$$\boldsymbol{\Delta}\mathbf{y} = \begin{bmatrix} \Delta y_1 \\ \Delta y_2 \\ \vdots \\ \Delta y_n \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} c_{11} & c_{12} & \cdots & c_{1n} \\ c_{21} & c_{22} & \cdots & c_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ c_{n1} & c_{n2} & \cdots & c_{nn} \end{bmatrix}, \quad \mathbf{F}(\mathbf{y}) = \begin{bmatrix} F_1(y_1) \\ F_2(y_2) \\ \vdots \\ F_n(y_n) \end{bmatrix},$$

$\mathbf{D} = \text{diag}\,\{d_1,d_2,\dots,d_n\}, \mathbf{A} = \text{diag}\,\{a_1,a_2,\dots,a_n\}$. Then the uncontrolled system is rewritten simply by

$$\begin{cases} \dfrac{\partial\mathbf{y}}{\partial t} - \mathbf{D}\boldsymbol{\Delta}\mathbf{y} = -\mathbf{A}\mathbf{y} + \mathbf{C}\mathbf{F}(\mathbf{y}) = \mathbf{g} \quad \text{in } Q, \\ \dfrac{\partial\mathbf{y}}{\partial\eta}(0,t) = \mathbf{k}(0,t), \quad \dfrac{\partial\mathbf{y}}{\partial\eta}(1,t) = \mathbf{k}(1,t), \\ \mathbf{y}(x,0) = \mathbf{y}_0(x) \quad \text{in } \Omega. \end{cases} \tag{2.2}$$

Here $\mathbf{g} = (g_1,g_2,\dots,g_n)^T$, $\mathbf{k}(0,t) = (k_1(0,t), k_2(0,t),\dots,k_n(0,t))^T$, $\mathbf{k}(1,t) = (k_1(1,t), k_2(1,t),\dots,k_n(1,t))^T$, and $\mathbf{y}_0 = (y_0^1, y_0^2,\dots,y_0^n)^T$, corresponding to distributed, boundary, and initial controls, respectively. The Hilbert space $W(0,T;\mathcal{V},\mathcal{V}')$ is called the solution space and is defined by

$$W(0,T;\mathcal{V},\mathcal{V}') = \{\phi \mid \phi \in L^2(0,T;\mathcal{V}),\ \phi' \in L^2(0,T;\mathcal{V}')\}.$$

Here ϕ' denotes the weak/distributed derivative of ϕ with respect to the time variable t. The inner product and norm in $W(0,T;\mathcal{V},\mathcal{V}')$ are defined respectively by

$$(\phi_1,\phi_2)_{W(0,T;\mathcal{V},\mathcal{V}')} = \int_0^T \{(\phi_1(t),\phi_2(t))_{\mathcal{V}} + (\phi_1'(t),\phi_2'(t))_{\mathcal{V}'}\}dt,$$

$$\|\phi\|_{W(0,T;\mathcal{V},\mathcal{V}')} = \left(\|\phi\|^2_{L^2(0,T;\mathcal{V})} + \|\phi'\|^2_{L^2(0,T;\mathcal{V}')}\right)^{\frac{1}{2}}.$$

The space $W(0,T;\mathcal{V},\mathcal{V}')$ is denoted by $\mathbf{W}(0,T)$ for brevity. Since $F_j : \mathbf{R} \to (-1,1)$, $j = 1,2,\ldots,n$, then $\mathbf{F} : \mathcal{H} \to \mathcal{H}$ and

$$\|\mathbf{F}(\boldsymbol{\psi})\|_{\mathcal{H}}^2 = \sum_{j=1}^{n} \int_0^l |F_j(\psi_j(x))|^2 dx \le nl \quad \forall \boldsymbol{\psi} \in \mathcal{H},$$

and by (2.1), $\mathbf{F}(\mathbf{y})$ satisfies the uniform Lipschitz continuity

$$\|\mathbf{F}(\boldsymbol{\phi}) - \mathbf{F}(\boldsymbol{\psi})\|_{\mathcal{H}} \le K\|\boldsymbol{\phi} - \boldsymbol{\psi}\|_{\mathcal{H}} \quad \forall \boldsymbol{\phi}, \boldsymbol{\psi} \in \mathcal{H}. \tag{2.3}$$

DEFINITION 2.1. [illegible] $\mathbf{y}$ [illegible] (2.2), $\mathbf{y} \in \mathbf{W}(0,T)$ [illegible]

$$\begin{cases} \langle \mathbf{y}', \upsilon\rangle_{\mathcal{V}',\mathcal{V}} + (\mathbf{D}\nabla\mathbf{y}, \nabla\upsilon)_{\mathcal{H}} = -(\mathbf{A}\mathbf{y}, \upsilon)_{\mathcal{H}} + (\mathbf{C}\mathbf{F}(\mathbf{y}), \upsilon)_{\mathcal{H}} + \langle \mathbf{g}, \upsilon\rangle_{\mathcal{V}',\mathcal{V}} \\ \qquad\qquad + (\mathbf{D}\mathbf{k}(0), \upsilon(0))_{\mathcal{V}^0} + (\mathbf{D}\mathbf{k}(1), \upsilon(1))_{\mathcal{V}^1} \\ \qquad\qquad \forall\ \upsilon \in \mathcal{V} \ \text{ in the sense of } \ \mathcal{D}'(0,T), \\ \mathbf{y}(0) = \mathbf{y_0} \in \mathcal{H}. \end{cases} \tag{2.4}$$

Here $\mathcal{D}'(0,T)$ denotes the space of distributions on $(0,T)$ (cf.[6]).

THEOREM 2.2. [illegible] $\mathbf{g} \in L^2(0,T;\mathcal{V}')$ $\mathbf{y_0} \in \mathcal{H}$, $\mathbf{k}(0) \in \mathcal{V}^0$ [illegible] $\mathbf{k}(1) \in \mathcal{V}^1$ [illegible] (2.2) [illegible] $\mathbf{y}$, $\mathbf{W}(0,T)$ [illegible] $C([0,T];\mathcal{H})$ [illegible]

$$\begin{aligned} &\|\mathbf{y}\|^2_{L^\infty(0,T;\mathcal{H})},\ \|\mathbf{y}\|^2_{\mathbf{W}(0,T)} \\ &\le C\big(1 + \|\mathbf{y_0}\|^2_{\mathcal{H}} + \|\mathbf{g}\|^2_{L^2(0,T;\mathcal{V}')} + \|\mathbf{k}(0)\|^2_{L^2(0,T)^n} + \|\mathbf{k}(1)\|^2_{L^2(0,T)^n}\big), \end{aligned} \tag{2.5}$$

[illegible] $C > 0$ [illegible] a_i c_{ij} [illegible] d_i [illegible] The proof of existence and uniqueness cites [17]. The regularity $\mathbf{y} \in C([0,T];\mathcal{H})$ is evident from $\mathbf{W}(0,T) \subset C([0,T];\mathcal{H})$.

3. Optimal control problem. The control system described by an HNN has a diffusion term in the form of

$$\begin{cases} \dfrac{\partial \mathbf{y}}{\partial t} - \mathbf{D}\boldsymbol{\Delta}\mathbf{y} = -\mathbf{A}\mathbf{y} + \mathbf{C}\mathbf{F}(\mathbf{y}) + \mathbf{u} \quad \text{in } Q, \\ \dfrac{\partial \mathbf{y}}{\partial \eta}(0,t) = \mathbf{v}(0,t), \quad \dfrac{\partial \mathbf{y}}{\partial \eta}(1,t) = \mathbf{v}(1,t), \\ \mathbf{y}(x,0) = \mathbf{w}(x) \ \text{ in } \Omega. \end{cases} \tag{3.1}$$

For any $\mathbf{u} \in L^2(0,T;\mathcal{V}')$, $\mathbf{v}(0) \in L^2(0,T)^n$, $\mathbf{v}(1) \in L^2(0,T)^n$, and $\mathbf{w} \in \mathcal{H}$, by virtue of Theorem 2.2, there exists a unique weak solution $\mathbf{y} = \mathbf{y}(\mathbf{c})$ of (3.1) in $\mathbf{W}(0,T)$. Hence a solution map $\mathbf{c} \to \mathbf{y}(\mathbf{c})$ can be defined from $\mathcal{C}$ into $\mathbf{W}(0,T)$, and $\mathbf{y}(\mathbf{c})$ will be called the state of control system (3.1).

The quadratic cost function associated with the control system (3.1) is given by (1.2) and can be written in compact form as

$$\begin{aligned} J(\mathbf{c}) = \|\mathbf{y}(\mathbf{c},T) - \mathbf{z}_d^T\|^2_{\mathcal{H}} + \|\mathbf{u}\|^2_{\mathcal{U}} + \|\mathbf{v}(0)\|^2_{\mathcal{V}^0} + \|\mathbf{v}(1)\|^2_{\mathcal{V}^1} + \|\mathbf{w}\|^2_{\mathcal{W}} \\ \forall \mathbf{c} = (\mathbf{u}, \mathbf{v}(0), \mathbf{v}(1), \mathbf{w}) \in \mathcal{C}, \end{aligned} \tag{3.2}$$

where $\mathbf{z}_d^T = (z_{1d}^T, z_{2d}^T, \ldots, z_{nd}^T)^t \in L^2(\Omega)^n$ are desired values.

3.1. Existence of optimal control. This subsection gives the existence theorem of the optimal control solution.

THEOREM 3.1. [illegible] $\mathcal{C}_{ad}$ [illegible] $\mathcal{C}$ [illegible] $\mathbf{c}^* = (\mathbf{u}^*, \mathbf{v}^*(0), \mathbf{v}^*(1), \mathbf{w}^*)$ [illegible] (3.1) [illegible] (3.2)

Set $J = \inf_{\mathbf{c}\in\mathcal{C}_{ad}} J(\mathbf{c})$. Since $\mathcal{C}_{ad}$ is nonempty, there is a sequence $\{\mathbf{c}_n\} = \{\mathbf{u}_n, \mathbf{v}_n(0), \mathbf{v}_n(1), \mathbf{w}_n\}$ in $\mathcal{C}_{ad}$ such that

$$\inf_{\mathbf{u}\in\mathcal{C}_{ad}} J(\mathbf{c}) = \lim_{n\to\infty} J(\mathbf{c}_n) = J.$$

Obviously, $\{J(\mathbf{c}_n)\}$ is bounded in $\mathbf{R}^+$. Since $\mathcal{U}_{ad}$ is bounded closed and convex, the subsequences $\{\mathbf{u}_m\}$, $\{\mathbf{v}_m(0,t)\}$, $\{\mathbf{v}_m(1,t)\}$, and $\{\mathbf{w}_m\}$ from $\{\mathbf{u}_n\}$, $\{\mathbf{v}_n(0,t)\}$, $\{\mathbf{v}_n(1,t)\}$, and $\{\mathbf{w}_n\}$ can be chosen, respectively, as

$$\begin{aligned}
&\mathbf{u}_m = \{u_{1m}, u_{2m}, \dots, u_{nm}\},\\
&\mathbf{v}_m(0,t) = \{v_{1m}(0,t), v_{2m}(0,t), \dots, v_{nm}(0,t)\},\\
&\mathbf{v}_m(1,t) = \{v_{1m}(1,t), v_{2m}(1,t), \dots, v_{nm}(1,t)\},\\
&\mathbf{w}_m = \{w_{1m}, w_{2m}, \dots, w_{nm}\}.
\end{aligned}$$

There exist $\mathbf{c}^* = \{\mathbf{u}^*, \mathbf{v}^*(0), \mathbf{v}^*(1), \mathbf{w}^*\} \in \mathcal{U}_{ad} \times \mathcal{V}^0_{ad} \times \mathcal{V}^1_{ad} \times \mathcal{W}_{ad}$ such that

$$\mathbf{u}_m \to \mathbf{u}^* \quad \text{weakly in } \mathcal{U} \text{ as } m \to \infty, \tag{3.3}$$

$$\mathbf{v}_m(0,t) \to \mathbf{v}^*(0,t) \quad \text{weakly in } \mathcal{V} \text{ as } m \to \infty, \tag{3.4}$$

$$\mathbf{v}_m(1,t) \to \mathbf{v}^*(1,t) \quad \text{weakly in } \mathcal{V} \text{ as } m \to \infty, \tag{3.5}$$

$$\mathbf{w}_m \to \mathbf{w}^* \quad \text{weakly in } \mathcal{W} \text{ as } m \to \infty. \tag{3.6}$$

For $\mathbf{y} = \mathbf{y}(\mathbf{c})$, the estimate (2.5) in Theorem 2.2 implies that

$$\|\mathbf{y}\|^2_{L^\infty(0,T;\mathcal{H})},\ \|\mathbf{y}\|^2_{\mathbf{W}(0,T)} \le C(1 + \|\mathbf{u}\|^2_{\mathcal{U}} + \|\mathbf{v}(0)\|^2_{\mathcal{V}^0} + \|\mathbf{v}(1)\|^2_{\mathcal{V}^1} + \|\mathbf{w}\|^2_{\mathcal{W}}). \tag{3.7}$$

The boundedness of $\mathcal{C}_{ad}$ and (3.7) show that $\{\mathbf{y}(\mathbf{c}_m)\}, \mathbf{c}_m = \{\mathbf{u}_m, \mathbf{v}_m(0), \mathbf{v}_m(1), \mathbf{w}_m\}$ is bounded in $\mathbf{W}(0,T)$. Hence a subsequence $\{\mathbf{y}(\mathbf{c}_{m_k})\}$ of $\{\mathbf{y}(\mathbf{c}_m)\}$ and a $\mathbf{z} \in \mathbf{W}(0,T)$ are extracted such that

$$\mathbf{y}(\mathbf{c}_{m_k}) \to \mathbf{z} \quad \text{weakly in } \mathbf{W}(0,T). \tag{3.8}$$

Denote $\mathbf{y}_{m_k} = \mathbf{y}(\mathbf{c}_{m_k})$ for simplicity. Since the embedding $\mathcal{V} \hookrightarrow \mathcal{H}$ is compact, we deduce from the Aubin–Lions–Temam compactness embedding theorem (cf. [18]) that

$$\mathbf{y}_{m_k} \to \mathbf{z} \quad \text{strongly in } L^2(0,T;\mathcal{H}). \tag{3.9}$$

The uniformly Lipschitz continuity (2.3) and (3.9) implies that

$$\mathbf{F}(\mathbf{y}_{m_k}) \to \mathbf{F}(\mathbf{z}) \quad \text{strongly in } L^2(0,T;\mathcal{H}). \tag{3.10}$$

Then (3.8) implies that

$$\begin{aligned}
\mathbf{y}'_{m_k} &\to \mathbf{z}' \quad \text{weakly in } L^2(0,T;\mathcal{V}'),\\
\nabla\mathbf{y}_{m_k} &\to \nabla\mathbf{z} \quad \text{weakly in } L^2(0,T;\mathcal{H}).
\end{aligned}$$

Hence by the definition of weak solutions we have

$$
\begin{aligned}
(3.11)\qquad & -\int_0^T \{\langle \mathbf{y}_{m_k}, \boldsymbol{\phi}'\rangle_{\mathcal{V}',\mathcal{V}} + (\mathbf{w}_{mk}, \boldsymbol{\phi})_{\mathcal{H}} + (\mathbf{D}\nabla \mathbf{y}_{m_k}, \nabla\boldsymbol{\phi})_{\mathcal{H}}\}dt \\
&= -\int_0^T \{(\mathbf{A}\mathbf{y}_{m_k}, \boldsymbol{\phi})_{\mathcal{H}} + (\mathbf{C}\mathbf{F}(\mathbf{y}_{m_k}), \boldsymbol{\phi})_{\mathcal{H}}\}dt + \int_0^T \langle \mathbf{u}_{mk}, \boldsymbol{\phi}\rangle_{\mathcal{V},\mathcal{V}'}dt \\
&\quad + (\mathbf{D}\mathbf{v}_{mk}(0), \boldsymbol{\phi}(0))_{\mathcal{V}^0} + (\mathbf{D}\mathbf{v}_{mk}(1), \boldsymbol{\phi}(1))_{\mathcal{V}^1} \quad \forall \boldsymbol{\phi} \in L^2(0,T;\mathcal{V}).
\end{aligned}
$$

Therefore, using (3.3)–(3.6) and (3.10), by taking $m_k \to \infty$ in (3.11), we obtain that

$$
\begin{aligned}
& -\int_0^T \{\langle \mathbf{z}, \boldsymbol{\phi}'\rangle_{\mathcal{V},\mathcal{V}'} + (\mathbf{w}^*, \boldsymbol{\phi})_{\mathcal{H}} + (\mathbf{D}\nabla \mathbf{z}, \nabla\boldsymbol{\phi})_{\mathcal{H}}\}dt \\
&= -\int_0^T \{(\mathbf{A}\mathbf{z}, \boldsymbol{\phi})_{\mathcal{H}} + (\mathbf{C}\mathbf{F}(\mathbf{z}), \boldsymbol{\phi})_{\mathcal{H}}\}dt + \int_0^T \langle \mathbf{u}^*, \boldsymbol{\phi}\rangle_{\mathcal{V},\mathcal{V}'}dt \\
&\quad + \int_0^T \mathbf{D}\mathbf{v}^*(0,t)\boldsymbol{\phi}(0) + \mathbf{D}\mathbf{v}^*(1,t)\boldsymbol{\phi}(1)dt,
\end{aligned}
$$

for all $\boldsymbol{\phi} \in L^2(0,T;\mathcal{V})$. Thus by standard manipulation we gain that the limit $\mathbf{z}$ satisfies

$$
\begin{aligned}
\langle \mathbf{z}, \boldsymbol{\phi}'\rangle_{\mathcal{V}',\mathcal{V}} + (\mathbf{D}\nabla \mathbf{z}, \nabla\boldsymbol{\phi})_{\mathcal{H}} &= -(\mathbf{w}^*, \boldsymbol{\phi})_{\mathcal{H}} + (\mathbf{A}\mathbf{z}, \boldsymbol{\phi})_{\mathcal{H}} + (\mathbf{C}\mathbf{F}(\mathbf{z}), \boldsymbol{\phi})_{\mathcal{H}} \\
&\quad + \langle \mathbf{u}^*, \boldsymbol{\phi}\rangle_{\mathcal{V},\mathcal{V}'} + (\mathbf{D}\mathbf{v}^*(0), \boldsymbol{\phi}(0))_{\mathcal{V}^0} + (\mathbf{D}\mathbf{v}^*(1), \boldsymbol{\phi}(1))_{\mathcal{V}^1}
\end{aligned}
$$

for all $\boldsymbol{\phi} \in \mathcal{V}$ in $\mathcal{D}'(0,T)$. Hence from the uniqueness of the weak solution for system (3.1), we have $\mathbf{z} = \mathbf{y}(\mathbf{c}^*)$. Then (3.8) and (3.9) imply that

$$
\begin{aligned}
\mathbf{y}(\mathbf{c}_{m_k}) &\to \mathbf{y}(\mathbf{c}^*) \quad \text{strongly in } L^2(Q)^n, \\
(3.12)\qquad \mathbf{y}(\mathbf{c}_{m_k}, T) &\to \mathbf{y}(\mathbf{c}^*, T) \quad \text{weakly in } \mathcal{H} = L^2(\Omega)^n.
\end{aligned}
$$

Since the norm $\|\cdot\|_{L^2(\Omega)^n}$ is lower semicontinuous in weak topology of $\mathcal{H} = L^2(\Omega)^n$, and using (3.12), we show that

$$
\liminf_{m_k\to\infty} \|\mathbf{y}(\mathbf{c}_{m_k}, T) - \mathbf{z}_d^T\|_{L^2(\Omega)^n} \geq \|\mathbf{y}(\mathbf{c}^*, T) - \mathbf{z}_d^T\|_{L^2(\Omega)^n}.
$$

On the other hand, the weak convergence (3.3)–(3.6) implies

$$
\begin{aligned}
&\liminf_{m_k\to\infty} (\mathbf{u}_{m_k}, \mathbf{u}_{m_k})_{L^2(Q)^n} \geq (\mathbf{u}^*, \mathbf{u}^*), \\
&\liminf_{m_k\to\infty} (\mathbf{v}_{m_k}(0,t), \mathbf{v}_{m_k}(0,t))_{L^2(0,T)^n} \geq (\mathbf{v}^*(0,t), \mathbf{v}^*(0,t)), \\
&\liminf_{m_k\to\infty} (\mathbf{v}_{m_k}(1,t), \mathbf{v}_{m_k}(1,t))_{L^2(0,T)^n} \geq (\mathbf{v}^*(1,t), \mathbf{v}^*(1,t)), \\
&\liminf_{m_k\to\infty} (\mathbf{w}_{m_k}, \mathbf{w}_{m_k})_{L^2(\Omega)^n} \geq (\mathbf{w}^*, \mathbf{w}^*).
\end{aligned}
$$

Since J is weakly lower semicontinuous, we have $J = \liminf_{m_k\to\infty} J(\mathbf{c}_{m_k}) \geq J(\mathbf{c}^*)$, and hence $J(\mathbf{c}^*) = \inf_{\mathbf{c}\in\mathcal{C}_{ad}} J(\mathbf{c})$. This proves that $\mathbf{c}^*(t) = \{\mathbf{u}^*, \mathbf{v}^*(0,t), \mathbf{v}^*(1,t), \mathbf{w}^*\}$ is an optimal control for cost (3.2), and completes the proof of Theorem 3.1.

3.2. Necessary optimality conditions. A first order necessary optimality condition for $\mathbf{c}^*$ is given by the variational inequality

$$
(3.13)\qquad J'(\mathbf{c}^*)(\mathbf{c} - \mathbf{c}^*) \geq 0 \quad \forall\ \mathbf{c} \in \mathcal{C}_{ad},
$$

where $J'(\mathbf{c}^*)$ denotes the Gâteaux derivative of $J(\mathbf{c})$ in (3.2) at $\mathbf{c}^*$.

PROPOSITION 3.2. [illegible] $\mathbf{y}_1$ [illegible] $\mathbf{y}_2$ [illegible] (3.1) [illegible] $\mathbf{c}_1 = \{\mathbf{u}_1, \mathbf{v}_1(0), \mathbf{v}_1(1), \mathbf{w}_1\}$ [illegible] $\mathbf{c}_2 = \{\mathbf{u}_2, \mathbf{v}_2(0), \mathbf{v}_2(1), \mathbf{w}_2\}$ [illegible] $t \in [0,T]$ $\mathbf{z} = \mathbf{y}_1 - \mathbf{y}_2$ [illegible]

$$
\begin{aligned}
&-\frac{1}{2}|\mathbf{z}|^2_{\mathcal{H}} + \frac{1}{2}|\mathbf{w}_1 - \mathbf{w}_2|^2_{\mathcal{H}} + \int_0^t (\mathbf{D}\nabla\mathbf{z}, \mathbf{z})|^2_{\mathcal{H}} dt \\
&= -\int_0^t (\mathbf{A}\mathbf{z}, \mathbf{z})_{\mathcal{H}} dt + \int_0^t (\mathbf{CF}(\mathbf{y}_1) - \mathbf{CF}(\mathbf{y}_2), \mathbf{z})_{\mathcal{H}} dt + \int_0^t ((\mathbf{u}_1 - \mathbf{u}_2), \mathbf{z})_{\mathcal{V}} dt \\
&\quad + \int_0^t (\mathbf{v}_1(0,t) - \mathbf{v}_2(0,t))\mathbf{z}(0) dt + \int_0^t (\mathbf{v}_1(1,t) - \mathbf{v}_2(1,t))\mathbf{z}(1) dt.
\end{aligned}
$$

PROPOSITION 3.3. [illegible] $\mathbf{c_0} \in \mathcal{C}$ [illegible]

$$
\lim_{\lambda \to 0} (\mathbf{y}(\mathbf{c} + \lambda \mathbf{c_0}) - \mathbf{y}(\mathbf{c})) = 0 \quad \text{strongly in} \quad C([0,T]; \mathcal{H}) \quad \text{and} \quad L^2(0,T; \mathcal{V}).
$$

The Gâteaux differentiability of solution map $\mathbf{c} \to \mathbf{y}(\mathbf{c})$ needs to assume $F_j \in C^1(\mathbf{R})$ and

$$
\exists K > 0 : \quad |F_j'(s)| \le K, \quad j = 1, 2, \ldots, n. \tag{3.14}
$$

Then for any $\mathbf{y} \in \mathcal{H}$, $\mathbf{F}$ is Gâteaux differentiable (cf. [17]).

THEOREM 3.4. [illegible] (3.14) [illegible] $\mathcal{C}$ [illegible] $\mathbf{W}(0,T)$ [illegible] $\mathbf{c} \to \mathbf{y}(\mathbf{c})$ [illegible] [illegible] $\hat{a}$ [illegible] $\mathbf{c}^* = \{\mathbf{u}^*, \mathbf{v}^*(0,t), \mathbf{v}^*(1,t), \mathbf{w}^*\}$ [illegible] [illegible] $\hat{a}$ [illegible] $\mathbf{z} = D\mathbf{y}(\mathbf{c}^*)(\mathbf{c} - \mathbf{c}^*) \in \mathbf{W}(0,T)$ [illegible] [illegible]

$$
\begin{cases}
\dfrac{\partial \mathbf{z}}{\partial t} - \mathbf{D}\boldsymbol{\Delta}\mathbf{z} = -\mathbf{A}\mathbf{z} + \mathbf{C}\partial_{\mathbf{y}}\mathbf{F}(\mathbf{y}(\mathbf{c}^*))\mathbf{z} + (\mathbf{u} - \mathbf{u}^*) \quad \text{in } Q, \\
\dfrac{\partial \mathbf{z}(0,t)}{\partial \eta} = \mathbf{v}(0,t) - \mathbf{v}^*(0,t), \quad \dfrac{\partial \mathbf{z}(1,t)}{\partial \eta} = \mathbf{v}(1,t) - \mathbf{v}^*(1,t), \\
\mathbf{z}(x,0) = \mathbf{w}(x) - \mathbf{w}^*(x) \quad \text{in } \Omega.
\end{cases} \tag{3.15}
$$

By Theorem 3.4, cost $J(\mathbf{u})$ is weakly Gâteaux differentiable, and optimality condition (3.13) is rewritten by

$$
\begin{aligned}
&J'(\mathbf{c}^*)(\mathbf{c} - \mathbf{c}^*) = (\mathbf{y}(\mathbf{c}^*, T) - \mathbf{z}_d^T, \mathbf{z}(T))_{\mathcal{H}} + (\mathbf{u}^*, \mathbf{u} - \mathbf{u}^*)_{\mathcal{U}} \\
&+ (\mathbf{v}^*(0), \mathbf{v}(0) - \mathbf{v}^*(0))_{\mathcal{V}^0} + (\mathbf{v}^*(1), \mathbf{v}(1) - \mathbf{v}^*(1))_{\mathcal{V}^1} + (\mathbf{w}^*, \mathbf{w} - \mathbf{w}^*)_{\mathcal{W}} \ge 0
\end{aligned}
$$

for all $\mathbf{c} = \{\mathbf{u}, \mathbf{v}(0), \mathbf{v}(1), \mathbf{w}\} \in \mathcal{C}_{ad}$ and $\mathbf{z}_d^T \in \mathcal{H} = L^2(\Omega)^n$.

THEOREM 3.5. [illegible] $\mathbf{c}^* = \{\mathbf{u}^*, \mathbf{v}^*(0), \mathbf{v}^*(1), \mathbf{w}^*\} \in \mathcal{C}_{ad}$ [illegible] (3.2) [illegible]

$$
\begin{cases}
\dfrac{\partial \mathbf{y}}{\partial t} - \mathbf{D}\boldsymbol{\Delta}\mathbf{y} = -\mathbf{A}\mathbf{y} + \mathbf{CF}(\mathbf{y}) + \mathbf{u}^* \quad \text{[illegible]} \quad Q, \\
\dfrac{\partial \mathbf{y}}{\partial \eta}(0,t) = \mathbf{v}^*(0,t) \ \dfrac{\partial \mathbf{y}}{\partial \eta}(1,t) = \mathbf{v}^*(1,t) \quad \text{[illegible]} \quad (0,T), \\
\mathbf{y}(x,0) = \mathbf{w}^*(x) \quad \text{[illegible]} \quad \Omega,
\end{cases}
$$

$$\begin{cases} -\dfrac{\partial \mathbf{p}(\mathbf{c}^*)}{\partial t} - \mathbf{D}\boldsymbol{\Delta}\mathbf{p}(\mathbf{c}^*) = -\mathbf{A}\mathbf{p}(\mathbf{c}^*) + \partial_{\mathbf{y}}\mathbf{F}(\mathbf{y}(\mathbf{c}^*))^*\mathbf{C}^*\mathbf{p}(\mathbf{c}^*) & \text{in } Q, \\ \dfrac{\partial \mathbf{p}(\mathbf{c}^*)}{\partial \eta}(0,t) = \dfrac{\partial \mathbf{p}(\mathbf{c}^*)}{\partial \eta}(1,t) = 0 & \text{in } (0,T), \\ \mathbf{p}(\mathbf{c}^*,T) = \mathbf{y}(\mathbf{c}^*,T) - \mathbf{z}_d^1 & \text{in } \Omega, \end{cases}$$

$$\begin{aligned} &\int_0^T\int_0^l \Big(\mathbf{D}^{-1}\mathbf{p}(\mathbf{c}^*(x,t)) + \mathbf{u}^*(x,t)\Big)(\mathbf{u}(x,t) - \mathbf{u}^*(x,t))dxdt \\ &+ \int_0^T \Big(\mathbf{D}^{-1}\mathbf{p}(\mathbf{c}^*(0,t)) + \mathbf{v}^*(0,t)\Big)(\mathbf{v}(0,t) - \mathbf{v}^*(0,t))dt \\ &+ \int_0^T \Big(\mathbf{D}^{-1}\mathbf{p}(\mathbf{c}^*(1,t)) + \mathbf{v}^*(1,t)\Big)(\mathbf{v}(1,t) - \mathbf{v}^*(1,t))dt \\ &+ \int_0^l \Big(\mathbf{D}^{-1}\mathbf{p}(\mathbf{c}^*(x,0)) + \mathbf{w}^*(x)\Big)(\mathbf{w}(x) - \mathbf{w}^*(x))dx \geq 0 \\ &\qquad\qquad \forall \mathbf{c} = (\mathbf{u}, \mathbf{v}(0), \mathbf{v}(1), \mathbf{w}) \in \mathcal{C}_{ad}. \end{aligned} \tag{3.16}$$

4. Numerical approach based on finite element methods. Let $0 = x_0 < x_1 < \cdots < x_N < x_{N+1} = l$ be a partition of interval $[0, l]$ into subinterval $I_e = [x_{e-1}, x_e]$ of length $h^e = x_e - x_{e-1}$ for $e = 1, 2, \ldots, N+1$. Let the following hold:

$$V_h = \left\{ b_i^e \;\middle|\; b_i^e \text{ is a quadratic function on } I_e \text{ and continuous on } [0,l], i = 1,2,3 \right\}.$$

Then $V_h \subset V$. The basis functions $b_i^e \in V_h$ are defined by quadratic interpolation functions

$$\begin{cases} b_1^e(x) = \left(1 - \dfrac{x - x_e}{h^e}\right)\left(1 - \dfrac{2(x - x_e)}{h^e}\right), \\ b_2^e(x) = \dfrac{4(x - x_e)}{h^e}\left(1 - \dfrac{x - x_e}{h^e}\right), \\ b_3^e(x) = -\dfrac{(x - x_e)}{h^e}\left(1 - \dfrac{2(x - x_e)}{h^e}\right). \end{cases}$$

Here x_e is the endpoint of the subinterval, and h^e is the length of the eth subinterval. Using quadratic basis functions, we construct the approximate solutions $y_{1h}, y_{2h}, \ldots, y_{nh}$ of $y_1, y_2, \ldots, y_n$ in the form of

$$\begin{cases} y_{1h}(t,x) = \displaystyle\sum_{e=1}^{N} y_{1h}^e(t,x) = \sum_{e=1}^{N}\sum_{i=1}^{3} \xi_{1i}^e(t) b_i^e(x), \\ y_{2h}(t,x) = \displaystyle\sum_{e=1}^{N} y_{2h}^e(t,x) = \sum_{e=1}^{N}\sum_{i=1}^{3} \xi_{2i}^e(t) b_i^e(x), \\ \qquad\qquad \vdots \\ y_{nh}(t,x) = \displaystyle\sum_{e=1}^{N} y_{nh}^e(t,x) = \sum_{e=1}^{N}\sum_{i=1}^{3} \xi_{ni}^e(t) b_i^e(x). \end{cases}$$

For each element, we set

$$\begin{aligned}
&\Psi^e = [(\psi^e_{ij})] = (b^e_i, b^e_j)^{j=1,2,3}_{i=1,2,3} \in M_{3\times 3}(\mathbf{R}),\\
&\Phi^e = [(\phi^e_{ij})] = (\bigtriangledown b^e_i, \bigtriangledown b^e_j)^{j=1,2,3}_{i=1,2,3} \in M_{3\times 3}(\mathbf{R}),\\
&\Xi^e_j(t) = [(\xi^e_j)] = [\xi^e_{j1}(t), \xi^e_{j2}(t), \xi^e_{j3}(t)]^T \in M_{3\times 1}(\mathbf{R}),\\
&F^e_j(t) = [(F^e_j)] = \begin{bmatrix} \left(F_j\left(\sum_{i=1}^{3}\xi^e_i(t)b^e_i(x)\right), b^e_1\right)\\ \left(F_j\left(\sum_{i=1}^{3}\xi^e_i(t)b^e_i(x)\right), b^e_2\right)\\ \left(F_j\left(\sum_{i=1}^{3}\xi^e_i(t)b^e_i(x)\right), b^e_3\right)\end{bmatrix} \in M_{3\times 1}(\mathbf{R}),\\
&U^e_j(t) = [(u^e_j)] = [(u_j(t), b^e_1), (u_j(t), b^e_2), (u_j(t), b^e_3)]^T \in M_{3\times 1}(\mathbf{R}),\\
&V^e_{0j}(t) = [(v^e_{0j})] = [(v_j(0,t), b^e_1), (v_j(0,t), b^e_2), (v_j(0,t), b^e_3)]^T \in M_{3\times 1}(\mathbf{R}),\\
&V^e_{1j}(t) = [(u^e_{1j})] = [(v_j(1,t), b^e_1), (v_j(1,t), b^e_2), (v_j(1,t), b^e_3)]^T \in M_{3\times 1}(\mathbf{R}),\\
&W^e_j = [(w^e_j)] = [(w_j, b^e_1), (w_j, b^e_2), (w_j, b^e_3)]^T \in M_{3\times 1}(\mathbf{R})
\end{aligned}$$

for $e = 1, 2, \ldots, N$ and $j = 1, 2, \ldots, n$. Referring to [21], Gauss–Legendre quadrature for six partitions is used to calculate numerical integration of the nonlinear term. $F^e_1(t)$, $F^e_2(t), \ldots, F^e_n(t)$ are calculated at $p^e_1, p^e_2, \ldots, p^e_6$ with weights $w^e_1, w^e_2, \ldots, w^e_6$ on $I_e = (x_e, x_{e+1})$. Then the approximations $\hat{F}^e_j(t)$ of $F^e_j(t)$ can be calculated as follows:

$$\hat{F}^e_j(t) = \begin{bmatrix} \hat{F}^e_{1j}\\ \hat{F}^e_{2j}\\ \hat{F}^e_{3j}\end{bmatrix} = \begin{bmatrix} \sum_{m=1}^{6} w^e_m F_j\left(\sum_{i=1}^{3}\xi^e_i\psi^e_i(p^e_m)\right)\psi^e_1(p^e_m)\\ \sum_{m=1}^{6} w^e_m F_j\left(\sum_{i=1}^{3}\xi^e_i\psi^e_i(p^e_m)\right)\psi^e_2(p^e_m)\\ \sum_{m=1}^{6} w^e_m F_j\left(\sum_{i=1}^{3}\xi^e_i\psi^e_i(p^e_m)\right)\psi^e_3(p^e_m)\end{bmatrix}$$

for $j = 1, 2, \ldots, n$. Therefore, (2.4) implies that

$$\begin{cases}
\Psi^e\Xi^{e\prime}_1(t) + d_1\Phi^e\Xi^e_1(t) = -a_1\Psi^e\Xi^e_1(t) + \sum_{j=1}^{n} c_{1j}F^e_j(t) + U^e_1(t) + V^e_{01}(t) + V^e_{11}(t),\\
\Psi^e\Xi^{e\prime}_2(t) + d_2\Phi^e\Xi^e_2(t) = -a_2\Psi^e\Xi^e_2(t) + \sum_{j=1}^{n} c_{2j}F^e_j(t) + U^e_2(t) + V^e_{02}(t) + V^e_{12}(t),\\
\qquad\qquad\qquad\qquad\vdots\\
\Psi^e\Xi^{e\prime}_n(t) + d_n\Phi^e\Xi^e_n(t) = -a_n\Psi^e\Xi^e_n(t) + \sum_{j=1}^{n} c_{nj}F^e_j(t) + U^e_n(t) + V^e_{0n}(t) + V^e_{1n}(t)
\end{cases} \tag{4.1}$$

with $\Psi^e\Xi^e_1(0) = W^e_1$, $\Psi^e\Xi^e_2(0) = W^e_2, \ldots, \Psi^e\Xi^e_n(0) = W^e_n$ for $e = 1, 2, \ldots, N$.

Taking into account $\xi^i_{j3} = \xi^{i+1}_{j1}$ for $j = 1, 2, \ldots, n$ and $i = 1, 2, \ldots, N$, the matrices and vectors globally are in the form of

$$\Psi_{2N+1} = \begin{bmatrix} \psi^1_{11} & \psi^1_{12} & \psi^1_{13} & & & & & & \\ \psi^1_{21} & \psi^1_{22} & \psi^1_{23} & & & & & & \\ \psi^1_{31} & \psi^1_{32} & \psi^1_{33}+\psi^2_{11} & \psi^2_{12} & \psi^2_{13} & & 0 & & \\ & & \psi^2_{21} & \psi^2_{22} & \psi^2_{23} & & & & \\ & & \psi^2_{31} & \psi^2_{32} & \psi^2_{33}+\psi^3_{11} & & & & \\ & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \\ & & 0 & & & & \psi^{N-1}_{33}+\psi^N_{11} & \psi^N_{12} & \psi^N_{13} \\ & & & & & & \psi^N_{21} & \psi^N_{22} & \psi^N_{23} \\ & & & & & & \psi^N_{31} & \psi^N_{32} & \psi^N_{33} \end{bmatrix},$$

and Φ_{2N+1} has the same structure instead of ψ^e_{ij} with ϕ^e_{ij}. Denote that

$$\Xi^i_{2N+1} = \begin{bmatrix} \xi_{i1} \\ \xi_{i2} \\ \xi_{i3} \\ \xi_{i4} \\ \xi_{i5} \\ \vdots \\ \xi_{i,2N-1} \\ \xi_{i,2N} \\ \xi_{i,2N+1} \end{bmatrix} = \begin{bmatrix} \xi^1_{i1} \\ \xi^1_{i2} \\ \xi^1_{i3}(=\xi^2_{i1}) \\ \xi^2_{i2} \\ \xi^2_{i3}(=\xi^3_{i1}) \\ \vdots \\ \xi^{N-1}_{i3}(=\xi^N_{i1}) \\ \xi^N_{i2} \\ \xi^N_{i3} \end{bmatrix}, \quad \hat{F}^i_{2N+1} = \begin{bmatrix} \hat{F}_{i1} \\ \hat{F}_{i2} \\ \hat{F}_{i3} \\ \hat{F}_{i4} \\ \hat{F}_{i5} \\ \vdots \\ \hat{F}_{i,2N-1} \\ \hat{F}_{i,2N} \\ \hat{F}_{i,2N+1} \end{bmatrix} = \begin{bmatrix} \hat{F}^1_{i1} \\ \hat{F}^1_{i2} \\ \hat{F}^1_{i3}+\hat{F}^2_{i1} \\ \hat{F}^2_{i2} \\ \hat{F}^2_{i3}+\hat{F}^3_{i1} \\ \vdots \\ \hat{F}^{N-1}_{i3}+\hat{F}^N_{i1} \\ \hat{F}^N_{i2} \\ \hat{F}^N_{i3} \end{bmatrix},$$

$$U^i_{2N+1} = \begin{bmatrix} U_{i1} \\ U_{i2} \\ U_{i3} \\ U_{i4} \\ U_{i5} \\ \vdots \\ U_{i,2N-1} \\ U_{i,2N} \\ U_{i,2N+1} \end{bmatrix} = \begin{bmatrix} u^1_{i1} \\ u^1_{i2} \\ u^1_{i3}+u^2_{i1} \\ u^2_{i2} \\ u^2_{i3}+u^3_{i1} \\ \vdots \\ u^{N-1}_{i3}+u^N_{i1} \\ u^N_{i2} \\ u^N_{i3} \end{bmatrix},$$

$$V^0_{i,2N+1} = \begin{bmatrix} V^0_{i1} \\ V^0_{i2} \\ V^0_{i3} \\ V^0_{i4} \\ V^0_{i5} \\ \vdots \\ V^0_{i,2N-1} \\ V^0_{i,2N} \\ V^0_{i,2N+1} \end{bmatrix} = \begin{bmatrix} v^{01}_{i1} \\ v^{01}_{i2} \\ v^{01}_{i3}+v^{02}_{i1} \\ v^{02}_{i2} \\ v^{02}_{i3}+v^{03}_{i1} \\ \vdots \\ v^{0,N-1}_{i3}+v^{0,N}_{i1} \\ v^{0,N}_{i2} \\ v^{0,N}_{i3} \end{bmatrix},$$

$$V^1_{i,2N+1}=\begin{bmatrix} V^1_{i1}\\ V^1_{i2}\\ V^1_{i3}\\ V^1_{i4}\\ V^1_{i5}\\ \vdots\\ V^1_{i,2N-1}\\ V^1_{i,2N}\\ V^1_{i,2N+1}\end{bmatrix}=\begin{bmatrix} v^{11}_{i1}\\ v^{11}_{i2}\\ v^{11}_{i3}+v^{12}_{i1}\\ v^{12}_{i2}\\ v^{12}_{i3}+v^{13}_{i1}\\ \vdots\\ v^{1,N-1}_{i3}+v^{1N}_{i1}\\ v^{1,N}_{i2}\\ v^{1,N}_{i3}\end{bmatrix},$$

$$W^i_{2N+1}=\begin{bmatrix} W_{i1}\\ W_{i2}\\ W_{i3}\\ W_{i4}\\ W_{i5}\\ \vdots\\ W_{i,2N-1}\\ W_{i,2N}\\ W_{i,2N+1}\end{bmatrix}=\begin{bmatrix} w^1_{i1}\\ w^1_{i2}\\ w^1_{i3}+w^2_{i1}\\ w^2_{i2}\\ w^2_{i3}+w^3_{i1}\\ \vdots\\ w^{N-1}_{i3}+w^N_{i1}\\ w^N_{i2}\\ w^N_{i3}\end{bmatrix}$$

for $i=1,2,\dots,n$. Hence by (4.1), the whole system on $(0,l)$ can be rewritten as

$$\text{(4.2)}\quad\begin{cases}\Psi_{2N+1}\Xi^{1\prime}_{2N+1}+d_1\Phi_{2N+1}\Xi^1_{2N+1}\\ \qquad=-a_1\Psi_{2N+1}\Xi^1_{2N+1}+\sum\limits_{j=1}^{n}c_{1j}\hat F^j_{2N+1}+U^1_{2N+1}+V^0_{1,2N+1}+V^1_{1,2N+1},\\ \Psi_{2N+1}\Xi^{2\prime}_{2N+1}+d_2\Phi_{2N+1}\Xi^2_{2N+1}\\ \qquad=-a_2\Psi_{2N+1}\Xi^2_{2N+1}+\sum\limits_{j=1}^{n}c_{2j}\hat F^j_{2N+1}+U^2_{2N+1}+V^0_{2,2N+1}+V^1_{2,2N+1},\\ \qquad\qquad\qquad\qquad\vdots\\ \Psi_{2N+1}\Xi^{n\prime}_{2N+1}+d_n\Phi_{2N+1}\Xi^n_{2N+1}\\ \qquad=-a_n\Psi_{2N+1}\Xi^n_{2N+1}+\sum\limits_{j=1}^{n}c_{nj}\hat F^j_{2N+1}+U^n_{2N+1}+V^0_{n,2N+1}+V^1_{n,2N+1}.\end{cases}$$

Using the notations of matrix and vectors, then

$$\Psi_{n(2N+1)}=\operatorname{diag}\{\Psi_{2N+1},\Psi_{2N+1},\dots,\Psi_{2N+1}\},$$
$$\Phi_{n(2N+1)}=\operatorname{diag}\{\Phi_{2N+1},\Phi_{2N+1},\dots,\Phi_{2N+1}\},$$
$$\Xi_{n(2N+1)}=\begin{bmatrix}\Xi^1_{2N+1}\\ \vdots\\ \Xi^n_{2N+1}\end{bmatrix},\qquad \hat F_{n(2N+1)}=\begin{bmatrix}\hat F^1_{2N+1}\\ \vdots\\ \hat F^n_{2N+1}\end{bmatrix},$$
$$U_{n(2N+1)}=\begin{bmatrix}U_{1,2N+1}\\ \vdots\\ U_{n,2N+1}\end{bmatrix},\qquad V^0_{n(2N+1)}=\begin{bmatrix}V^0_{1,2N+1}\\ \vdots\\ V^0_{n,,2N+1}\end{bmatrix},$$
$$V^1_{n(2N+1)}=\begin{bmatrix}V^1_{1,2N+1}\\ \vdots\\ V^1_{n,2N+1}\end{bmatrix},\quad W_{n(2N+1)}=\begin{bmatrix}W_{1,2N+1}\\ \vdots\\ W_{n,2N+1}\end{bmatrix}.$$

Let $D^i_{2N+1} = \operatorname{diag}\{d_i, d_i, \ldots, d_i\}$, $A^i_{2N+1} = \operatorname{diag}\{a_i, a_i, \ldots, a_i\}$ for $i = 1, 2, \ldots, n$; then

$$D_{n(2N+1)} = \operatorname{diag}\Big\{D^1_{2N+1}, D^2_{2N+1}, \ldots, D^n_{2N+1}\Big\},$$

$$A_{n(2N+1)} = \operatorname{diag}\Big\{A^1_{2N+1}, A^2_{2N+1}, \cdots, A^n_{2N+1}\Big\},$$

$$C_{n(2N+1)} = \begin{bmatrix} c_{11} & \cdots & c_{11} & & c_{1n} & \cdots & c_{1n} \\ \vdots & \cdots & \vdots & & \vdots & \cdots & \vdots \\ c_{11} & \cdots & c_{11} & & c_{1n} & \cdots & c_{1n} \\ \vdots & \cdots & \vdots & \ddots & \vdots & \cdots & \vdots \\ c_{n1} & \cdots & c_{n1} & & c_{nn} & \cdots & c_{nn} \\ \vdots & \cdots & \vdots & & \vdots & \cdots & \vdots \\ c_{n1} & \cdots & c_{n1} & & c_{nn} & \cdots & c_{nn} \end{bmatrix}.$$

Since $\Psi_{n(2N+1)}$ is invertible, one can convert (4.2) into a set of $n(2N+1)$-dimensional vector equations

$$\begin{aligned} (4.3)\quad & \Xi'_{n(2N+1)} + D_{n(2N+1)}\Psi^{-1}_{n(2N+1)}\Phi_{n(2N+1)}\Xi_{n(2N+1)} + A_{n(2N+1)}\Xi_{n(2N+1)} \\ & = C_{n(2N+1)}\Psi^{-1}_{n(2N+1)}\hat{F}_{n(2N+1)} + \Psi^{-1}_{n(2N+1)}(U_{n(2N+1)} + V^0_{n(2N+1)} + V^1_{n(2N+1)}). \end{aligned}$$

Here coefficient matrices $\Psi_{n(2N+1)}$ and $\Phi_{n(2N+1)}$ are given by (assume $h^e = h$),

$$\frac{h}{30}\begin{bmatrix} 16 & 2 & 0 & 0 & \cdots & 0 & 0 & & & & & & & \\ 2 & 8 & 2 & -1 & \cdots & 0 & 0 & & & & & & & \\ 0 & 2 & 16 & 2 & \cdots & 0 & 0 & & & 0 & & & & \\ 0 & -1 & 2 & 8 & \cdots & 0 & 0 & & & & & & & \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & & & & & & & \\ 0 & 0 & 0 & 0 & \cdots & 8 & 2 & & & & & & & \\ 0 & 0 & 0 & 0 & \cdots & 2 & 16 & & & & & & & \\ & & & & & & & \ddots & & & & & & \\ & & & & & & & & 16 & 2 & 0 & 0 & \cdots & 0 & 0 \\ & & & & & & & & 2 & 8 & 2 & -1 & \cdots & 0 & 0 \\ & & & & & & & & 0 & 2 & 16 & 2 & \cdots & 0 & 0 \\ & & & & 0 & & & & 0 & -1 & 2 & 8 & \cdots & 0 & 0 \\ & & & & & & & & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ & & & & & & & & 0 & 0 & 0 & 0 & \cdots & 8 & 2 \\ & & & & & & & & 0 & 0 & 0 & 0 & \cdots & 2 & 16 \end{bmatrix}$$

and

$$\frac{1}{3h}\begin{bmatrix}
16 & -8 & 0 & 0 & \cdots & 0 & 0 & & & & & & & \\
-8 & 14 & -8 & 1 & \cdots & 0 & 0 & & & & & & & \\
0 & -8 & 16 & -8 & \cdots & 0 & 0 & & & & & & & \\
0 & 1 & -8 & 14 & \cdots & 0 & 0 & & & 0 & & & & \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & & & & & & & \\
0 & 0 & 0 & 0 & \cdots & 14 & -8 & & & & & & & \\
0 & 0 & 0 & 0 & \cdots & -8 & 16 & & & & & & & \\
 & & & & & & & \ddots & & & & & & \\
 & & & & & & & & 16 & -8 & 0 & 0 & \cdots & 0 & 0 \\
 & & & & & & & & -8 & 14 & -8 & 1 & \cdots & 0 & 0 \\
 & & & & & 0 & & & 0 & -8 & 16 & -8 & \cdots & 0 & 0 \\
 & & & & & & & & 0 & 1 & -8 & 14 & \cdots & 0 & 0 \\
 & & & & & & & & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
 & & & & & & & & 0 & 0 & 0 & 0 & \cdots & 14 & -8 \\
 & & & & & & & & 0 & 0 & 0 & 0 & \cdots & -8 & 16
\end{bmatrix}.$$

We follow [21] to solve (4.3) by a fourth order Runge–Kutta method. Therefore, the approximate solution $y_{1h}, y_{2h}, \ldots, y_{nh}$ can be obtained on $(0,l)\times[0,T]$ numerically.

5. Numerical approach for optimal control.

5.1. Systems discretization. Let $\mathbf{c}_h = (\mathbf{c}_{1h}, \mathbf{c}_{2h}, \ldots, \mathbf{c}_{nh})$, $\mathbf{c}_{ih} = \{u_{ih}, v_{ih}(0), v_{ih}(1), w_{ih}\}$. The minimization problem for finite element approximation is formulated as follows: minimize the approximate cost functions

$$\begin{aligned}(5.1)\quad J(\mathbf{c}_h) &= \sum_{i=1}^{n}\int_0^l (y_{ih}(T)-z_{id}^T)^2dx + \sum_{i=1}^{n}\int_0^T (u_{ih}-u_i^d)^2dt \\ &+\sum_{i=1}^{n}\int_0^T (v_{ih}(0)-v_{0i}^d)^2dt + \sum_{i=1}^{n}\int_0^T (v_{ih}(1)-v_{1i}^d)^2dt + \sum_{i=1}^{n}\int_0^l (w_{ih}-w_i^d)dx\end{aligned}$$

with $y_{ih}\equiv y_i(\mathbf{c}_h)\in V_h$ satisfying

$$\begin{aligned}(5.2)\quad &\int_0^l \frac{dy_{ih}}{dt}\phi_h dx + d_i\int_0^l \nabla y_{ih}\nabla\phi_h dx = -\int_0^l a_i y_{ih}\phi_h dx + \sum_{j=1}^{n}\int_0^l F_j(y_{jh})\phi_h dx \\ &+\int_0^T\int_0^l u_{ih}\phi_h dxdt + \int_0^T v_{ih}(0)\phi_h dt + \int_0^T v_{ih}(1)\phi_h dt \qquad \forall\phi_h\in V_h.\end{aligned}$$

THEOREM 5.1. [illegible] 3.1 [illegible] [24] [illegible] (5.1)–(5.2)

Note that the Gâteaux derivative for the discrete solution y_{ih} at any direction ϕ_h is denoted by $y'_{ih}\phi_h$, satisfying (5.2) for all $\phi_h\in V_h$. For quadratic cost, let $p_{ih}\equiv p_i(\mathbf{c}_h)$, so that

$$\begin{aligned}J'(\mathbf{c}_h)\phi_h &= 2\sum_{i=1}^{n}\int_0^l p_i(\mathbf{c}_h)(x,T)\phi_h(x,T)dx + 2\sum_{i=1}^{n}\int_0^T\int_0^l u_{ih}(x,t)\phi_h(x,t)dxdt \\ &+2\sum_{i=1}^{n}\int_0^T v_{ih}(0,t)\phi_h(0,t)dt + 2\sum_{i=1}^{n}\int_0^T v_{ih}(1,t)\phi_h(1,t)dt + 2\sum_{i=1}^{n}\int_0^l w_{ih}(x)\phi_h(x,0)dx.\end{aligned}$$

Then necessary optimality condition (3.16) for optimal control pairing $u^*_{ih} \in U^i_{ad}$, $v^*_{ih}(0,t) \in V^0_{i,ad}, v^*_{ih}(1,t) \in V^1_{i,ad}, w^*_{ih} \in W^i_{ad}$ can be rewritten as

$$\begin{aligned}
&\sum_{i=1}^{n} \int_0^T \int_0^l (p_i(\mathbf{c}^*_h(x,t)) + u^*_{ih}(x,t))(u_{ih}(x,t) - u^*_{ih}(x,t))dxdt \\
&+ \sum_{i=1}^{n} \int_0^T (p_i(\mathbf{c}^*_h(0,t)) + v^*_{ih}(0,t))(v_{ih}(0,t) - v^*_{ih}(0,t))dt \\
&+ \sum_{i=1}^{n} \int_0^T (p_i(\mathbf{c}^*_h(1,t)) + v^*_{ih}(1,t))(v_{ih}(1,t) - v^*_{ih}(1,t))dt \\
&+ \sum_{i=1}^{n} \int_0^l (p_i(\mathbf{c}^*_h(x,0)) + w^*_{ih}(x))(w_{ih}(x) - w^*_{ih}(x))dx \geq 0,
\end{aligned}$$

for all $u_{ih} \in U^i_{ad}, v_{ih}(0) \in V^0_{i,ad}, v_{ih}(1) \in V^1_{i,ad}, w_{ih} \in W^i_{ad}$, where $\mathcal{U}^i_{ad}, V^0_{i,ad}, V^1_{i,ad}, W^i_{ad}$ are the admissible set of $\mathcal{U}^i, V^0_i, V^1_i, W_i$ for $i = 1, 2, \ldots, N$.

THEOREM 5.2. $\{\mathbf{c}^m_{ih}\} = \{u^m_{ih}, v^m_{ih}(0), v^m_{ih}(1), w^m_{ih}\}$ (5.1)–(5.2) $\mathbf{c}^m_h = \{\mathbf{c}^m_{1h}, \mathbf{c}^m_{2h}, \ldots, \mathbf{c}^m_{nh}\}$ $\mathbf{c}^{m_k}_h = \{\mathbf{c}^{m_k}_{1h}, \mathbf{c}^{m_k}_{2h}, \ldots, \mathbf{c}^{m_k}_{nh}\}$ $\{\mathbf{c}^m_i\}$ $\{\mathbf{c}^{m_k}_i\}$ $L^2(Q)^n \times L^2(0,T)^n \times L^2(0,T)^n \times L^2(0,l)^n$ (5.1)

The proof can be found in [24] and elsewhere.

5.2. Updated conjugate gradient method for minimization. Let m be the iteration times, and $J^m_{ih} = J_{ih}(\mathbf{c}^m_{ih})$; then

$$\mathbf{c}^{m+1}_{ih}(t) = \mathbf{c}^m_{ih}(t) - \beta^m_i \mathbf{P}^m_i(t) \quad \text{for} \quad i = 1, 2, \ldots, N \quad \text{and} \quad m = 1, 2, \ldots,$$

where $\beta^m_i(t)$ are searching step sizes in going from iteration m to iteration $m+1$, and $\mathbf{P}^m_i(t)$ are the directions of descent given by

$$\mathbf{P}^m_i(t) = J'^m_{ih}(t) + \gamma^m_i \mathbf{P}^{m-1}_i(t), \tag{5.3}$$

which are a conjugation of the gradient directions $J'^m_{ih}(t)$ at iteration m and the directions of descent $\mathbf{P}^{m-1}_i(t)$ at iteration $m-1$. The conjugate coefficients are determined from

$$\gamma^m_i = \frac{\varepsilon_1 \int_0^T (J'^m_{ih})^2 dt}{\varepsilon_2 \int_0^T (J'^{(m-1)}_{ih})^2 dt}, \quad \text{with} \quad \gamma^0_i = 0 \quad \text{and} \quad i = 1, \ldots, N. \tag{5.4}$$

Note that we can adjust $\varepsilon_1, \varepsilon_2$ to get proper γ^m_i. The stopping criterion is $J(\mathbf{c}^{m+1}_{ih}(t)) < \varepsilon$, where ε is a small specified number. The convergence of the above iteration procedure in minimizing the functional J_{ih} is guaranteed (cf. [14]).

5.3. The nonlinear minimization problem (5.1)–(5.2) can be solved by the nonlinear conjugate gradient method (CGM) consisting of (5.3) and (5.4). The updated CGM is a kind of efficient modification of the usual CGM.

5.3. Computation procedure. Suppose that $\mathbf{c}^k_{ih}(t)$ is available at iteration k, and $\mathbf{c}^k_{ih} = \{c^k_{ih}\}_{k=1}^{\infty}$ are minimizing sequences of $\{\mathbf{c}^k_{ih}\}$ such that the cost function (5.1) achieves minimization.

Step 0. Given $\mathbf{z}_d$ and $\mathbf{c}^k_{ih}(0) \in \mathcal{C}_{ad}$, use the approximate solution $\mathbf{y}_h = \sum_{e=1}^{N} \sum_{j=1}^{3} \xi^e_j(t) b^e_j(x)$ to solve the direct problems (5.2) for $\mathbf{y}_h$. Let $\mathbf{P}^k(t) := -\nabla J(\mathbf{c}(0))$; $k := 0$;

Step 1. By calculating the initial inputs $\mathbf{y}(\mathbf{c}_h, T) - \mathbf{z}_d^T$ of approximate adjoint solution $\mathbf{p}_h = \sum_{e=1}^{N} \sum_{j=1}^{3} \zeta_j^e(t) b_j^e(x)$, we can solve simultaneously equations consisting of (3.1) as in Step 0.

Step 2. Compute the search step size $\beta^k = (\beta_1^k, \beta_2^k, \ldots, \beta_n^k)$ such that

$$J_h(\mathbf{c}_h^k + \beta^k \mathbf{c}_h^k) = \min\{J_h(\mathbf{c}_h^k + \beta^k \mathbf{c}_h^k); \beta \geq 0\}.$$

Given $0 < \xi < \dfrac{1}{2}$, $0 < \tau < 1$. Let $\rho_i^0 = 1$, for $m = 0, 1, 2, \ldots$. If

$$J_h(\mathbf{c}_h^k - \rho_i^m \mathbf{P}^k) \leq J_h(\mathbf{c}_h^k) - \xi \rho_i^m J_h'(\mathbf{c}_h^k)^2,$$

then $\beta^n = \rho^m$; else $\rho^{m+1} = \tau \rho^m$.

Step 3. $\mathbf{c}_h^{k+1} := \mathbf{c}_h^k + \beta^k \mathbf{P}^k$;

Step 4. Computing the gradient of the functional J_h', one can obtain

$$\begin{aligned} J_h'(\mathbf{y}_h, \mathbf{c}_h^k)\boldsymbol{\phi}_h = {} & 2\varepsilon_3 \int_0^T \int_0^l (\mathbf{p}_h(x,t) + \mathbf{u}_h^k(x,t))\boldsymbol{\phi}_h(x,t)dxdt \\ & + 2\varepsilon_4 \int_0^T \Big(\mathbf{p}_h(0,t) + \mathbf{v}_h^k(0,t)\Big)\boldsymbol{\phi}_h(0,t)dt \\ & + 2\varepsilon_4 \int_0^T \Big(\mathbf{p}_h(1,t) + \mathbf{v}_h^k(1,t)\Big)\boldsymbol{\phi}_h(1,t)dt \\ & + 2\varepsilon_5 \int_0^T \Big(\mathbf{p}_h(x,0) + \mathbf{w}_h^k(x,0)\Big)\boldsymbol{\phi}_h(x)dx, \end{aligned} \tag{5.5}$$

for all $\boldsymbol{\phi}_h = (\phi_h^1, \phi_h^2, \ldots, \phi_h^n) \in V_h^n$. Citing the thought of Carleman weighted functions (cf. [5]), $\varepsilon_3, \varepsilon_4, \varepsilon_5$ will be considered to obtain available solutions in gradient calculation (5.5).

Step 5. Compute the conjugate coefficients $\gamma^k = (\gamma_1^k, \gamma_2^k, \ldots, \gamma_n^k)$ in (5.4);

Step 6. Compute direction of descent $\mathbf{P}^k(t) := J_h^{'k}(t) + \gamma^k \mathbf{P}^{k-1}(t)$ in (5.3); $k := k + 1$; return to Step 1, and so on.

5.4. Convergence of the nonlinear algorithm. We just need to prove the sequence $\{\mathbf{c}_h^k\}_{k=1}^{\infty}$ satisfying

$$J_h(\mathbf{c}_h^k - \beta^k \mathbf{P}^k) \leq J_h(\mathbf{c}_h^k) - \xi \rho^k J_h'(\mathbf{c}_h^k)^2$$

and $\mathbf{c}_h^{k+1} = \mathbf{c}_h^k - \beta^k \mathbf{P}^k$ such that cost function $J_h(\mathbf{c}_h^k) \to$ minimize. In fact, then

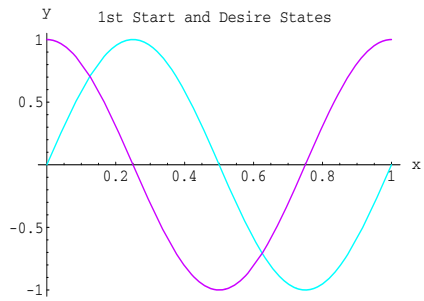
$$0 \leq \xi\{\rho^1 J_h'(\mathbf{c}_h^k)^2 + \rho^2 J_h'(\mathbf{c}_h^k)^2 + \cdots + \rho^n J_h'(\mathbf{c}_h^k)^2\} \leq J(\mathbf{c}_h^k) - J(\mathbf{c}_h^{k+1}) \leq J(\mathbf{c}_h^1).$$

Therefore, the series

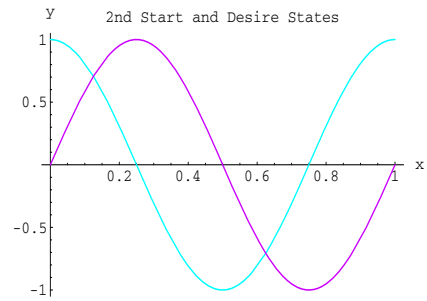
$$\rho^1 J_h'(\mathbf{c}_h^k)^2 + \rho^2 J_h'(\mathbf{c}_h^k)^2 + \cdots + \rho^n J_h'(\mathbf{c}_h^k)^2 + \cdots \to 0 \quad \text{as } k \to \infty.$$

For arbitrary k, there exists a ρ^* such that $\rho^k \geq \rho^* > 0$, and $J_h(\mathbf{c}_h)$ can be minimized by $\{\mathbf{c}_h^k\}$.

The convergence order can be easily obtained for approximate pairing $(\mathbf{y}_h, \mathbf{c}_h)$; it is clear that $\mathbf{c}_h$ moves towards $\mathbf{c}^*$ in the order of $O(h)$ as $h \to 0$.



$y_1(x,0), y_1(x,T)$



$y_2(x,0), y_2(x,T)$

6. Experimental demonstration. Consider distributed, boundary, and initial controls of two simultaneous systems:

$$\begin{cases} \dfrac{\partial y_1}{\partial t} - d_1\Delta y_1 = -y_1 + \beta_1(\tanh y_1 + \tanh y_2) + u_1(t,x) \ \text{ on } (0,1)\times[0,T], \\ \dfrac{\partial y_2}{\partial t} - d_2\Delta y_2 = -y_2 - \beta_2(100\tanh y_1 - 2\tanh y_2) + u_2(t,x) \ \text{ on } (0,1)\times[0,T], \\ y_{1x}(t,0) = v_1(0,t), y_{1x}(t,1) = v_1(1,t), y_{2x}(t,0) = v_2(0,t), y_{2x}(t,1) = v_2(1,t) \text{ in } [0,T], \\ y_1(0,x) = w_1(x), \quad y_2(0,x) = w_2(x) \ \text{ on } [0,1]. \end{cases}$$

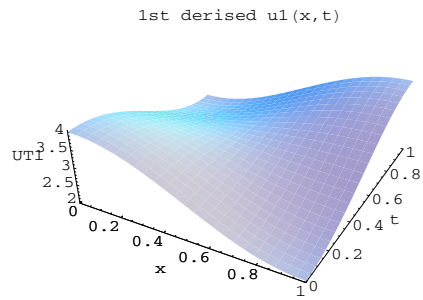
Let $h = 1/16$, $d_1 = d_2 = 0.0001$, and $\beta_1 = \beta_2 = 0.5$. The initial and desired state are given as follows.

$$\begin{aligned} y_1(x,0) &= \sin(2\pi x), \quad & z_{1d}^T &= 0.00001\sin(\pi x), \\ y_2(x,0) &= \cos(2\pi x), \quad & z_{2d}^T &= 0.00001\cos(\pi x). \end{aligned}$$

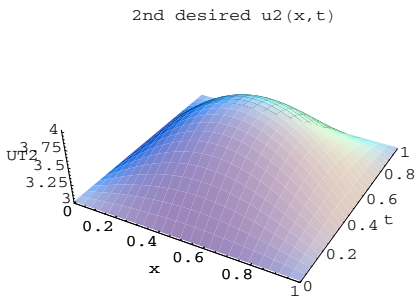
Figure 6.1 shows their graphs. The start and desired distributed controls:

$$\begin{aligned} u_1(x,t) &= 3 + 2\sin(2\pi t)\sin(2\pi x), \quad & u_1^d &= 3 + \cos(\pi t)\cos(\pi x), \\ u_2(x,t) &= 3 + 2\cos(2\pi t)\cos(2\pi x), \quad & u_2^d &= 3 + 2\sin(\pi t)\sin(\pi x). \end{aligned}$$

The graphs of the start controls are shown in Figure 6.2. The desired distributed controls are shown in Figure 6.3.



$u_1^d(x,t)$



$u_2^d(x,t)$

FIG. 6.3.

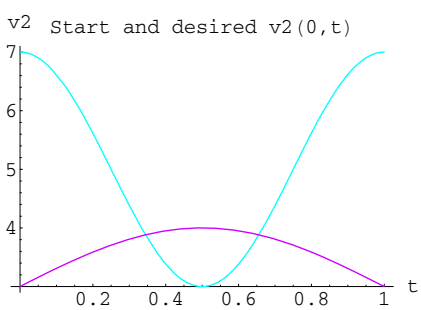
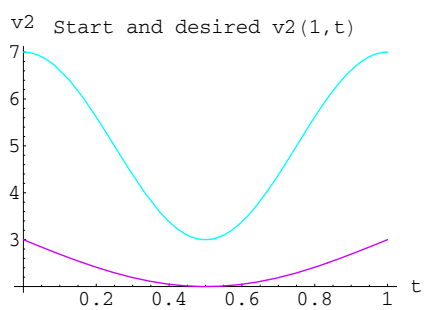
FIG. 6.4.



$v_2(0,t)$ at iteration $k=0$



$v_2(1,t)$ at iteration $k=0$

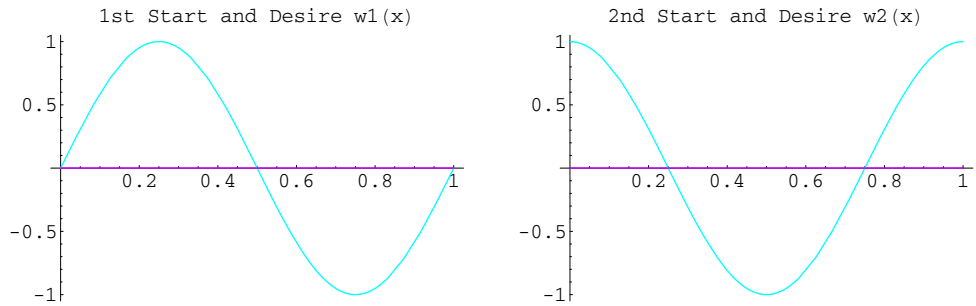
FIG. 6.5.

The first boundary controls are given by

$$v_1(0,t) = 5 + 2\sin(2\pi t), \quad v_{10}^d = 3 + 2\cos(\pi t),$$
$$v_1(1,t) = 5 + 2\sin(2\pi t), \quad v_{11}^d = 3 + 2\cos(\pi t).$$

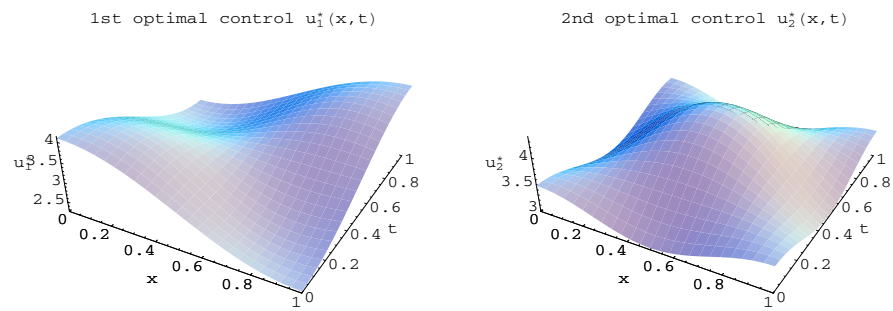
Their graphs are shown in Figure 6.4. The second boundary controls are given as follows, and plotted in Figure 6.5:

$$v_2(0,t) = 5 + 2\cos(2\pi t), \quad v_{20}^d = 3 + 2\sin(\pi t),$$
$$v_2(1,t) = 5 + 2\cos(2\pi t), \quad v_{21}^d = 3 + 2\sin(\pi t).$$



$w_1(x)$ at iteration $k = 0$ $\qquad$ $w_2(x)$ at iteration $k = 0$

FIG. 6.6.



$u_1^*(x,t)$ $\qquad$ $u_2^*(x,t)$

FIG. 6.7.

The initial controls are provided in the following form, and shown in Figure 6.6:

$$w_1(x) = \sin(2\pi x), \quad w_1^d = 0.00001\cos(\pi x),$$
$$w_2(x) = \cos(2\pi x), \quad w_2^d = 0.00001\sin(\pi x).$$

Optimal distributed control functions of two neurons can be obtained as follows:

$$u_1^*(t,x) = 3.19707 + 0.901467\cos[\pi t]\cos[\pi x] + 0.197066\sin[2\pi t]\sin[2\pi x];$$
$$u_2^*(t,x) = 3.23974 + 0.239738\cos[2\pi t]\cos[2\pi x] + 0.880131\sin[\pi t]\sin[\pi x].$$

Optimal distributed control graphs are displayed in Figure 6.7. The first optimal boundary controls are given by

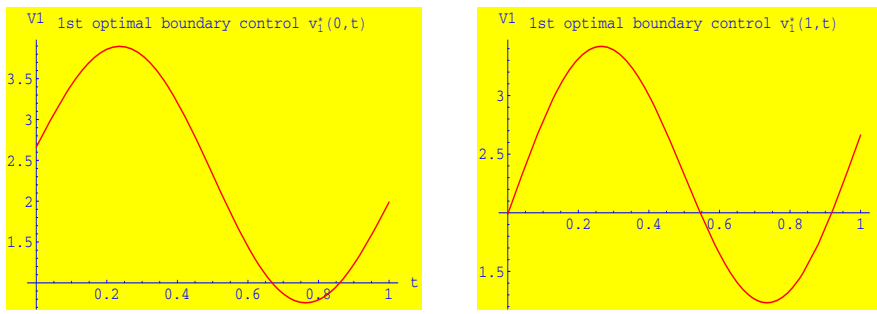
$$v_1^*(0,t) = 2.32593 + 0.33703\cos[\pi t] + 1.32593\sin[2\pi t];$$
$$v_1^*(1,t) = 2.32593 + 0.33703\cos[\pi(1+t)] + 1.32593\sin[2\pi(1+t)].$$

The graphs of first optimal boundary controls are given in Figure 6.8. The second optimal boundary controls are

$$v_2^*(0,t) = 2.26570 + 1.26561\cos[2\pi t] + 0.36719\sin[\pi t];$$
$$v_2^*(1,t) = 2.26570 + 1.26561\cos[2\pi(1+t)] + 0.36719\sin[\pi(1+t)].$$

The graphs of second optimal boundary controls are shown in Figure 6.9. The optimal initial controls are given by the following, and graphed in Figure 6.10:

$$w_1^*(x) = -4.23433 \times 10^{-7} + 3.3704110^{-6}\cos[\pi x] + 0.66296\sin[2\pi x];$$
$$w_2^*(x) = 0.00009 + 0.27130\cos[2\pi x] + 7.28697 \times 10^{-6}\sin[\pi x].$$



$v_1^*(0,t)$ $v_1^*(1,t)$

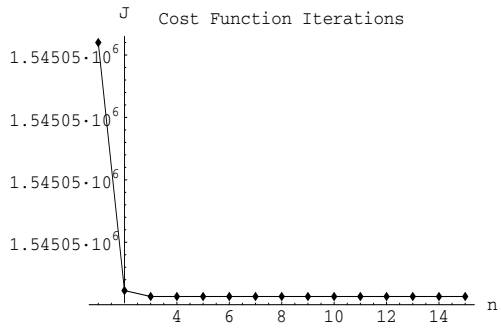
$w_1^*(x)$ $w_2^*(x)$

FIG. 6.10.

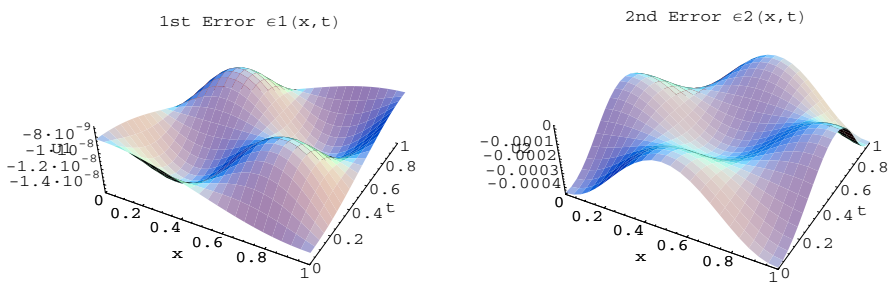
The optimal cost value $J[\mathbf{u}^*] = 1.54505 \times 10^6$; for the cost iterations, see Figure 6.11. Error estimates for cost function can be calculated step by step as

$$
\begin{array}{lll}
eJ[1] = - - -, & eJ[2] = 29158.8, & eJ[3] = 192.595, \\
eJ[4] = 0.459979, & eJ[5] = 0.517135, & eJ[6] = 0.587047, \\
eJ[7] = 0.663581, & eJ[8] = 0.747305, & eJ[9] = 0.838851, \\
eJ[10] = 0.938926, & eJ[11] = 1.04832, & eJ[12] = 1.16791, \\
eJ[13] = 1.29869, & eJ[14] = 1.44176, & eJ[15] = 1.59836.
\end{array}
$$



$J(\mathbf{y}, \mathbf{c})$

FIG. 6.11.



$\varepsilon_{u_1(x,t)}$ $\varepsilon_{u_2(x,t)}$

FIG. 6.12.

The L^2 error between optimal control and desired control is as follows:

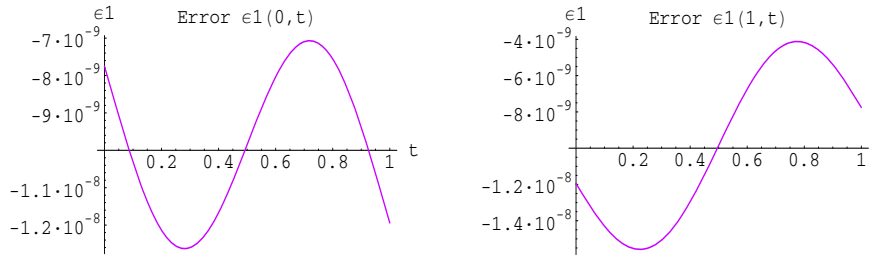
$$\begin{aligned}
&\|u_1 - u_1^T\|_{L^2(Q)} = 0, \qquad \|u_2 - u_2^T\|_{L^2(Q)} = 0,\\
&\|v_1(0) - v_1^T\|_{L^2(0,T)} = 0, \qquad \|v_1(1) - v_1^T\|_{L^2(0,T)} = 0,\\
&\|v_2(0) - v_2^T\|_{L^2(0,T)} = 0, \qquad \|v_2(1) - v_2^T\|_{L^2(0,T)} = 0,\\
&\|w_1 - w_1^T\|_{L^2(0,l)} = 0, \qquad \|w_2 - w_2^T\|_{L^2(0,l)} = 0.009977802.
\end{aligned}$$

For the error of the distributed control functions at the final iteration, see Figure 6.12. For the error of the boundary controls at the final iteration, refer to Figures 6.13–6.14. The error of the initial controls at the final iteration is shown in Figure 6.15.

Necessary optimality conditions can be checked numerically for control variables in each iteration step. Let N_C represent the left-hand side of the inequality in (3.16); then

$$\begin{aligned}
&N_C[1] = 8.99137 \times 10^9, \quad N_C[2] = 7.41451 \times 10^8, \quad N_C[3] = 1.73174 \times 10^7,\\
&N_C[4] = 1.58551 \times 10^7, \quad N_C[5] = 1.44051 \times 10^7, \quad N_C[6] = 1.29565 \times 10^7,\\
&N_C[7] = 1.15096 \times 10^7, \quad N_C[8] = 1.0064 \times 10^7, \quad N_C[9] = 8.62095 \times 10^6,\\
&N_C[10] = 7.17927 \times 10^6, \quad N_C[11] = 5.73944 \times 10^6, \quad N_C[12] = 4.30154 \times 10^6,\\
&N_C[13] = 2.86562 \times 10^6, \quad N_C[14] = 1.43175 \times 10^6, \quad N_C[15] = 0.
\end{aligned}$$

Clearly, the optimality necessary condition is valid.



$\varepsilon_{v_1(0,t)}$ $\varepsilon_{v_1(1,t)}$

FIG. 6.13.

Observing the experimental results on the control of neural network systems, in the viewpoint of biological science and medicine science, the methodology can be considered for controlling a large number of neurons by laser pulse input, language, or medicine drug technology. It would be useful to combine this approach with interdisciplinary research.

7. Conclusions. The optimal control for diffusion Hopfield neural networks was studied both in theoretical and numerical aspects. Based on the development of a variational method to the diffusion model, the optimal control problem has been investigated by the means of distributed, boundary, and initial control simultaneously. The minimization of quadratic criteria with terminal observation was solved by con-

structing a semidiscrete algorithm with a finite element approach. The study of the higher-dimensional case is interesting and will be considered in upcoming research.

AN INTERNAL STRUCTURE DEPENDENT RIEMANN SOLVER FOR REGULARIZATION-SENSITIVE SHOCK WAVES AND ITS APPLICATION TO FRONT TRACKING*

HYUN-CHEOL HWANG†

Abstract. We present an algorithm for the iterative Riemann solver for regularization-sensitive shock waves which constitute a codimension-one submanifold of the wave manifold. The algorithm uses the computation of the saddle-to-saddle type of connections in the state space using the multiple shooting method. This Riemann solver can be combined with front tracking methods to track these shock waves correctly if the physical internal structure is provided. Several numerical examples, such as transitional shock waves in the planar system and weak deflagration waves in combustion, are illustrated.

Key words. Riemann problem, hyperbolic conservation laws, front tracking, regularization-sensitive shock wave

AMS subject classifications. 35L65, 76L05, 65M06

DOI. 10.1137/040621715

1. Introduction. It is well known that certain types of shock waves are very sensitive to the regularization procedure. In the physical sense, the regularization procedure provides a discontinuous wave with a continuous internal structure on a small length scale [16], and mathematically it is a selection procedure for solutions satisfying certain mathematical properties. Usually internal structure of shock waves on a small length scale can be ignored; however, certain types of shock waves are highly dependent on the regularization procedure, not only in their internal structure, but also in their propagation speeds and limiting states. These waves, called [illegible], have been observed in numerical or real experiments, and occur in applications such as combustion [9], three-phase flow through a porous medium [3, 44], and magneto-hydrodynamics [54]. However, their exact physical meaning is not understood clearly, and the correct numerical method to handle these waves has rarely been studied.

In the mathematical structure, a regularization-sensitive shock wave differs from a classical shock wave in that fewer characteristic families impinge on the wave. Therefore the dynamical information carried into the wave along the characteristics is insufficient to determine the evolution of the wave. The missing information comes from the internal structure of the shock wave, implying that the internal structure strongly influences the wave propagation. Most numerical methods for shock waves rely on numerical diffusion for stability, and thus provide discontinuous waves with an artificial internal structure. Such methods are successful only if they are applied to waves that are insensitive to this numerical regularization. Difficulties will arise when they are used for regularization-sensitive waves: for example, excess diffusion can cause significant errors in detonation wave speeds [7], while the limiting states of a deflagration wave are sensitive to heat conduction and viscosity [9]. In order to

†Department of Mathematics and Information, Kyungwon University, Songnam 461-701, Korea (hchwang@kyungwon.ac.kr).

circumvent these difficulties, numerical methods must account for the true internal structure of discontinuities.

Our Riemann solver is conceived for this purpose. We consider the shock waves which constitute a codimension-one submanifold of the wave manifold, i.e., the case in which one piece of characteristic information is missing compared with classical shock waves. The Riemann solver for these waves utilizes the multiple shooting method to compute the viscous profile of the corresponding dynamical system; i.e., it constructs the exact internal structure of the wave corresponding to its physically correct viscous regularization. Equipped with this Riemann solver, the front tracking method can be used to accurately locate the position of the regularization-sensitive wave. Our method has been implemented for two different applications: quadratic models and reactive gas dynamics.

The paper consists of the following. In section 2, we briefly introduce mathematical preliminaries for the general system of hyperbolic conservation laws. We discuss the construction of Riemann solutions and regularization-sensitive waves. Our main algorithm for the Riemann solver is presented in the next section 3. The algorithm for solutions of Riemann problems near a regularization-sensitive shock wave is proposed for general $m \times m$ systems of conservation laws. This Riemann solver, which incorporates the information coming from the internal structure of a shock wave, is an essential component of the front tracking method. The complete front tracking algorithm is also presented.

In sections 4 and 5, the algorithm proposed in section 3 is applied to two applications: quadratic models, which are 2×2 systems of conservation laws having quadratic flux functions ($m = 2$), and weak deflagration waves in combustion ($m = 4$). Transitional waves, regularization-sensitive waves appearing in quadratic systems, are explained, and the Riemann solution near a transitional shock wave is obtained by applying our algorithm. Computational results using front tracking are also presented and compared with those using standard shock capturing methods. For the application to weak deflagration waves, the dynamical system for the internal structure of combustion waves is derived first, and then it is shown that deflagration waves are regularization-sensitive. The algorithm of the Riemann solver for solutions near a deflagration wave is developed, and computational results are presented. We conclude this paper in section 6.

2. Mathematical preliminaries. We consider solutions of general systems of conservation laws in one spatial dimension:

$$U_t + F(U)_x = 0, \tag{2.1}$$

$$U(x, 0) = U_0(x). \tag{2.2}$$

Here $U(x, t) \in \mathbf{R}^m$ is an m-dimensional vector of conserved quantities, $F : \mathbf{R}^m \to \mathbf{R}^m$ is a smooth function called the flux function, and U_0 is the initial data. It is well known that the uniqueness of solutions depends on the admissibility condition for selecting the physically correct solution from many possible weak solutions. The correct formulation of admissibility conditions is still a crucial issue, especially for a system of more than one equation. There are many different admissibility criteria, with their own domains of application. Throughout this work, we utilize the admissibility condition called the viscous profile criterion [14, 8], since we believe it to be most physically relevant.

The viscous profile criterion requires that a shock wave arise as the limit, as $\epsilon \to 0$, of a traveling wave solution to a parabolic equation associated with (2.1),

$$U_t + F(U)_x = \epsilon[D(U)U_x]_x. \tag{2.3}$$

Here $D(U)$ is the viscosity matrix, which models physical effects that have been neglected in (2.1). The viscosity matrix $D(U)$ is required to be positive definite. A traveling wave solution takes the form

$$U(x,t) = \hat{U}(\xi), \quad \xi := \frac{x - st}{\epsilon}, \tag{2.4}$$

where $\hat{U}(\xi) \to U_\pm$ as $\xi \to \pm\infty$ and s is the propagation speed. In order for U to satisfy (2.3), $\hat{U}$ must be a solution of the dynamical system

$$-s[\hat{U}(\xi) - U_-] + F(\hat{U}(\xi)) - F(U_-) = D(\hat{U}(\xi))\hat{U}'(\xi). \tag{2.5}$$

The limiting states U_- and U_+ are equilibria of this dynamical system, satisfying the Rankine–Hugoniot condition. If a solution of system (2.5) leads from U_- to U_+, then we say that the shock wave has a viscous profile. Only those shock waves having viscous profiles are accepted as admissible solutions; this is the viscosity profile criterion.

When this criterion is used, the admissibility of a shock wave might depend on the viscosity matrix $D(U)$. Certain shock waves admissible under the Lax criterion are also admissible under the viscous profile criterion, but there are other kinds of shock waves that are admissible under the viscous profile criterion but do not satisfy the Lax criterion. Such shock waves, undercompressive shock waves which have fewer entering characteristic curves than Lax shock waves and overcompressive shock waves which have more entering characteristics, play an important role in solving Riemann problems specifically in a system of nonstrictly hyperbolic or mixed type of conservation laws [38, 44, 46, 23, 11]. Overcompressive shock waves can be regarded as a combination of classical shock waves [38]. Such shock waves are the main concern of this work.

2.1. Construction of Riemann solution and regularization-sensitive shock waves. A Riemann problem is a particular Cauchy problem having piecewise constant initial data with a single discontinuity, i.e.,

$$U(x,0) = U_0(x) = \begin{cases} U_L & \text{if } x < 0, \\ U_R & \text{if } x > 0. \end{cases} \tag{2.6}$$

The solution of Riemann problems is important both analytically and numerically. A scale invariant solution of a Riemann problem, i.e., one depending only on x/t, describes the large-time asymptotic behavior of a stable wave pattern. Lax [28, 29] constructed the solution of Riemann problems when U_L is close to U_R under the assumptions of strict hyperbolicity (distinctness of the characteristic speeds) and of genuine nonlinearity within each mode. Under these hypotheses, at a given state U_L, there is a unique half of the shock curve stable under forward time evolution and a unique half of the rarefaction curve in other direction for the wave speed to increase along a curve. Hence two half curves join smoothly and define a [illegible] through U_R. There is one such curve for each characteristic mode, and the solution of a Riemann problem is constructed by connecting two initial states with the series of wave curves.

However, using only classical wave groups is not always sufficient for solving all Riemann problems for a systems of conservation laws. For example, when the strict hyperbolicity fails, the system has portions of state space that cannot be reached using classical waves. A nonclassical wave group, which does not correspond to a particular characteristic wave mode and is regularization-sensitive, fits between classical wave groups and fills these gaps.

The shock waves which we consider are different from classical Lax shock waves in that fewer characteristic families impinge on the wave. This difference has two main consequences. First, a regularization-sensitive wave is not associated with a unique characteristic family. It could appear as a wave family between two distinct wave families, say i and $(i+1)$. If we admit only Lax shock waves, then any wave has an associated family. Moreover, no wave can be preceded by a wave of a faster family, and two waves of the same family must belong to the same wave group. It follows that the solution of a Riemann problem contains at most m shock or rarefaction waves, where each is associated with a distinct family. However, if we allow nonclassical shock waves, then it is possible for the Riemann solution to contain more than m wave groups.

The other consequence is that less information enters into the wave from the surrounding flow. To compensate for this lack of information, information must come from the internal structure of the shock wave. Thus the internal structure of the shock wave strongly influences the propagation of the wave. From the dynamical systems viewpoint, its phase portrait is generally unstable. In the case of $m = 2$, this connection corresponds to a saddle-to-saddle connection. The structural instability of this connection requires that only special discontinuities, those in a codimension-one set, have viscous profiles [23, 39]. Moreover, the set of such shock waves generally varies with the viscosity matrix $D(U)$ in (2.3). In other words, not only is the internal structure sensitive to the precise form of the viscosity matrix, but the limiting states between the shock wave and the speed are also. Therefore, we say that these waves are regularization-sensitive.

3. Algorithm for Riemann solutions near a regularization-sensitive shock wave. We solve the Riemann problem defined by the states on either side. In general, solving a Riemann problem is extremely complicated. However, the Riemann problems that occur in numerical methods like front tracking usually have a simple feature: except for the tracked wave, all waves in the solution are weak. Indeed, the Riemann problem at a particular time level arises from the interaction, during the previous time step, of the tracked wave and the (usually) weak waves that have impinged on it. We say that a Riemann problem is near a certain wave type if its solution consists of a wave of this type together with small amplitude waves of other types. The algorithm we now describe works for a Riemann problem near a regularization-sensitive shock wave.

We consider the system of hyperbolic conservation laws (2.1) and its corresponding parabolic regularized equation (2.3). As we have shown in section 2, since the shock wave we consider is the limit of a traveling wave solution of (2.3) as $\epsilon \to 0$, U should be a solution of the dynamical system

$$U' = D(U)^{-1}[-s(U - U_M) + F(U) - F(U_M)] =: G(U, U_M, s), \tag{3.1}$$

where $U_M = U(-\infty)$ and $U_N = U(+\infty)$.

We shall solve the Riemann problem by finding a sequence of states $U_1, U_2, \ldots, U_m$ such that U_L is connected to U_1 by a 1-wave, U_1 is connected to U_2 by a 2-wave, ...,

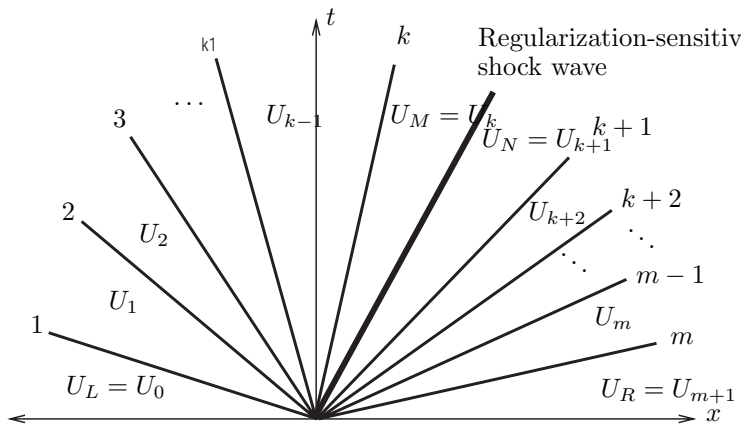

FIG. 1. *The solution of a Riemann problem near a regularization-sensitive wave which lies between k and $k+1$ waves as drawn in the (x,t)-plane.*

$U_k =: U_M$ is connected to $U_{k+1} =: U_N$ by a regularization-sensitive shock, and so on, with U_m connected to U_R by an m-wave. (See Figure 1.) Here the connecting wave from U_{i-1} to U_i can be either a shock wave or a rarefaction wave; thus U_i lies on the wave curve (either a shock curve or a rarefaction curve) from U_{i-1} in the state space.

Therefore, from U_L we can reach a one parameter family of states $U_1 = \mathcal{W}_1(U_L, \varepsilon_1)$ through a 1-wave. From U_1 we can reach another one parameter family of states $U_2 = \mathcal{W}_2(U_L, \varepsilon_1, \varepsilon_2)$ through a 2-wave. Continuing, we see that from U_L we can reach a k parameter family of states

$$U_M = \mathcal{W}_M(U_L, \varepsilon_1, \varepsilon_2, \ldots, \varepsilon_k). \tag{3.2}$$

Similarly, we can reach an $m-k$ parameter family of states

$$U_N = \mathcal{W}_N(U_R, \varepsilon_{k+1}, \varepsilon_{k+2}, \ldots, \varepsilon_m) \tag{3.3}$$

from U_R. Moreover, we know that if U_i lies on the ith family of wave curves through U_{i-1}, the wave curve is tangent to the ith eigenvector of $F'(U)$ at U_{i-1}. Thus when U_{i-1} and U_i are close enough, this curve can be approximated by a straight line. It gives the following formulations:

$$U_i = \begin{cases} \mathcal{W}_i(U_{i-1}, \varepsilon_i) \approx U_{i-1} + \varepsilon_i\, r_i(U_{i-1}) & \text{when } i = 1, 2, \ldots, k, \\ \mathcal{W}_i(U_{i+1}, \varepsilon_i) \approx U_{i+1} - \varepsilon_i\, r_i(U_{i+1}) & \text{when } i = k, k+1, \ldots, m. \end{cases} \tag{3.4}$$

Here $r_i(U)$ is the ith eigenvector of $F'(U)$ corresponding to the eigenvalue $\lambda_i(U)$, and U_0 and U_{m+1} are U_L and U_R, respectively.

The states U_M and U_N are also equilibria of dynamical systems (3.1), which satisfies the Rankine–Hugoniot condition for a regularization-sensitive shock wave:

$$G(U_N, U_M, s) = 0. \tag{3.5}$$

To calculate a viscous profile connection from U_M to U_N, we employ the multiple shooting method [49], as follows.

First, the ξ-axis is divided into the intervals $(-\infty, -T_1]$, $[-T_1, T_2]$, and $[T_2, \infty)$, where T_1 and T_2 are suitably large (see below); then the interval $[-T_1, T_2]$ is divided into n subintervals defined by the endpoints $\xi_0 := -T_1 < \xi_1 < \cdots < \xi_{n-1} < \xi_n := T_2$. State variables U_0^*, ..., U_n^* corresponding to points ξ_0, ..., ξ_n are introduced; U_M corresponds to $\xi = -\infty$, and U_N to $\xi = \infty$. The object is to have successive states joined by integral curves of the dynamical system (3.1).

Let the dimension of the unstable manifold at U_M be l. l could be any number between 0 and m, but its sum with the dimension of the stable manifold at U_N must be m since a regularization-sensitive wave constitutes the codimension-one submanifold of the wave manifold. The state U_0^* at $\xi = -T_1$ can then be approximated as

$$U_0^* = U_M + \tilde{\varepsilon}_m \tilde{r}_m(U_M) + \tilde{\varepsilon}_{m-1} \tilde{r}_{m-1}(U_M) + \cdots + \tilde{\varepsilon}_{m-l+1} \tilde{r}_{m-l+1}(U_M), \tag{3.6}$$

for some values of $\tilde{\varepsilon}_m, \ldots, \tilde{\varepsilon}_{m-l+1}$. Here $\tilde{r}_i(U_M)$ denotes an ith eigenvector of $G_U(U_M, s)$ corresponding to the positive eigenvalue $\mu_i(U_M), i = m, m-1, \ldots, m-l+1$; these eigenvectors form a basis for the tangent space of the unstable manifold at U_M. Similarly, the state U_n^* at $\xi = T_2$ is approximated as

$$U_n^* = U_N + \tilde{\varepsilon}_1 \tilde{r}_1(U_N) + \tilde{\varepsilon}_2 \tilde{r}_2(U_N) + \cdots + \tilde{\varepsilon}_{m-l} \tilde{r}_{m-l}(U_N) \tag{3.7}$$

because the dimension of stable manifold at U_N is $m-l$. Here $\tilde{r}_i(U_N)$ is the eigenvector of $G_U(U_N, s)$ corresponding to the negative eigenvalues $\mu_i(U_N), i = 1, 2, \ldots, m-l$. This linearized approximation also motivates choosing the values

$$T_1 = \frac{a}{\min_{m-l+1 \le i \le m} \mu_i(U_M)}, \quad T_2 = \frac{a}{\min_{1 \le i \le m-l} |\mu_i(U_N)|}, \tag{3.8}$$

where a is a dimensionless constant (taken to be 4 or 5 in the numerical experiments of later sections). For $i = 0, \ldots, n-1$, we let $H(U_i^*, s, U_L, \varepsilon_1, \ldots)$ denote the state obtained by numerically integrating the dynamical system (3.1) from $\xi = \xi_i$ to $\xi = \xi_{i+1}$ starting from the state U_i^*.

We have $mn + m + 1$ unknown quantities, namely,

$$\mathbf{x} := (\varepsilon_1, \ldots, \varepsilon_m, \tilde{\varepsilon}_1, \ldots, \tilde{\varepsilon}_m, s, U_1^*, \ldots, U_{n-1}^*)$$

(treating U_M, U_N, U_0^*, and U_n^* as given in these terms by the approximations described above), for which we require $mn+m+1$ equations. The mn matching conditions and the m Rankine–Hugoniot condition constitute $mn + m$ equations:

$$\begin{aligned}
H(U_0^*, s, U_L, \varepsilon_1, \ldots, \varepsilon_m) - U_1^* &= 0, \\
H(U_1^*, s, U_L, \varepsilon_1, \ldots, \varepsilon_m) - U_2^* &= 0, \\
&\vdots \\
H(U_{n-2}^*, s, U_L, \varepsilon_1, \ldots, \varepsilon_m) - U_{n-1}^* &= 0, \\
H(U_{n-1}^*, s, U_L, \varepsilon_1, \ldots, \varepsilon_m) - U_n^* &= 0, \\
G(U_N, U_M, s) &= 0.
\end{aligned} \tag{3.9}$$

There is one remaining degree of freedom, which reflects nonuniqueness of the solutions: since the dynamical system is autonomous, replacing t by $t +$ const. in one

solution yields another. To fix the solution uniquely, we impose the phase condition of [10], which requires that

$$\int_{-\infty}^{\infty} \langle G(U) - G(U_{\text{ref}}), G_U(U) \cdot G(U) \rangle \, d\xi = 0 \tag{3.10}$$

for some reference solution U_{ref}. (Here the arguments of G are suppressed, and the angle brackets denote the inner product.) We choose U_{ref} to be the solution calculated at the previous time level in the front tracking method, and we discretize the integral using the trapezoid rule. Now we have a complete set of equations, which we solve using a damped Newton method [49], with Broyden update of the Jacobian, to obtain the solution of the Riemann problem particularly U_M, U_N, and s.

. . .. 3.1 (derivation of the phase condition). The idea behind the phase condition (3.10) is that the solution should resemble the reference solution, in our case the previous computed orbit, as much as possible. We need to find the minimum distance orbit $U(t)$ among the one parameter family of solutions $\tilde{U}$ satisfying matching conditions and the Rankine–Hugoniot condition. Let $L(\sigma)$ denote the following distance between the orbit U_{ref} and the orbit $\tilde{U}(t+\sigma)$, as shifted by σ from which the current orbit is selected:

$$L(\sigma) = \int_{-\infty}^{\infty} \|\tilde{U}'(t+\sigma) - U'_{\text{ref}}(t)\|^2 dt, \tag{3.11}$$

where U_{ref} is a previous computed orbit. The necessary condition for a minimum distance is $\frac{dL}{d\sigma} = 0$. Let us define $U(t)$ as

$$U(t) := \tilde{U}(t + \sigma^*), \tag{3.12}$$

where σ^* satisfies $\frac{dL}{d\sigma}|_{\sigma=\sigma^*} = 0$. Then, the necessary condition for minimum distance is given as

$$\begin{aligned} \left.\frac{dL}{d\sigma}\right|_{\sigma=\sigma^*} &= \int_{-\infty}^{\infty} \langle U' - U'_{\text{ref}},\, U''(t) \rangle \, dt \\ &= \int_{-\infty}^{\infty} \langle G(U) - G(U_{\text{ref}}),\, G_U(U) \cdot G(U) \rangle \, d\xi \\ &= 0. \end{aligned} \tag{3.13}$$

. . .. 3.2 (damped Newton method with Broyden update). We solve the nonlinear system of equations by using a damped Newton method combined with line searches (to obtain a global convergence and to avoid trouble with U_M and U_N being in an elliptic region during iterations):

$$\mathbf{F}(\mathbf{x}) = 0, \quad \mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \lambda \delta \mathbf{x}, \tag{3.14}$$

where $\delta \mathbf{x} = -\mathbf{F}'(\mathbf{x}_{\text{old}})^{-1} \cdot \mathbf{F}$ is a Newton step. As a strategy to decide whether to accept the Newton step $\delta \mathbf{x}$, we require that the step decreases $|\mathbf{F}|^2 = \mathbf{F} \cdot \mathbf{F}$. This is the same requirement to minimize

$$f = \frac{1}{2} \mathbf{F} \cdot \mathbf{F}. \tag{3.15}$$

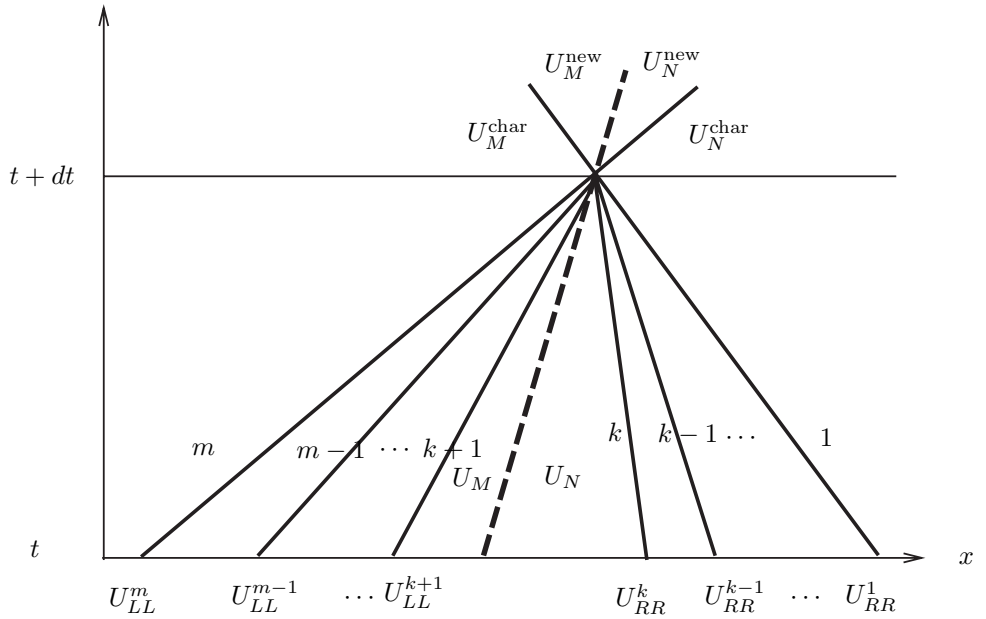

FIG. 2. *This figure shows the characteristic relation between a tracked regularization-sensitive shock wave and surrounding characteristic curves, drawn in the* (x, t) *plane.*

The aim is to find λ so that $f(\mathbf{x}_{\text{old}} + \lambda\delta\mathbf{x})$ has decreased sufficiently. We choose $\lambda = 1$ at first to make it be quadratic convergent when $\mathbf{x}$ is sufficiently close to the solution. However, if $f(\mathbf{x}_{\text{new}})$ does not decrease sufficiently, then choose λ so that $\mathbf{x}_{\text{new}}$ minimizes f in the Newton direction as a smaller value of λ. The criterion for accepting a step is to require the average rate of decrease of f to be at least some fraction α of the initial rate of decrease $\nabla f \cdot \delta\mathbf{x}$:

$$f(\mathbf{x}_{\text{new}}) \le f(\mathbf{x}_{\text{old}}) + \alpha\nabla f \cdot (\mathbf{x}_{\text{new}} - \mathbf{x}_{\text{old}}). \tag{3.16}$$

In computation, we choose α as a very small value: 10^{-4}.

If the step does not satisfy (3.16), we backtrack along the Newton direction by finding a suitable λ to satisfy (3.16). To do this, let

$$g(\lambda) \equiv f(\mathbf{x}_{\text{old}} + \lambda\delta\mathbf{x}). \tag{3.17}$$

Since we know $g(0), g'(0)$, and $g(1)$ which is a Newton step, we can approximate λ as a quadratic polynomial; thus we can have the exact form of λ which gives a minimum of $g(\lambda)$. If U_M and U_N is in an elliptic region in this procedure, then λ is reduced by half until they escape from an elliptic region. For details about Broyden the update, see [49].

3.1. Tracking algorithm. The algorithm to track the shock waves comprises four steps. (For the notation of states surrounding a tracked shock wave, see Figure 2.) Given the states U_L and U_R at time t, we do the following:

1. solve the Riemann problem and find U_M, U_N, and s;
2. find the states $U_{LL}^{k+1}, \ldots, U_{LL}^m$ and $U_{RR}^1, \ldots, U_{RR}^k$ at the feet of characteristics drawn from the new shock position;

3. calculate a characteristic correction, for improved accuracy, by solving the equations

$$l_i(U_M^{\text{char}})(U_M^{\text{char}} - U_M) = l_i(U_{LL}^i)(U_{LL}^i - U_L), \tag{3.18}$$

$$l_i(U_N^{\text{char}})(U_N^{\text{char}} - U_N) = 0, \quad i = k+1, k+2, \ldots, m, \tag{3.19}$$

$$l_j(U_N^{\text{char}})(U_N^{\text{char}} - U_N) = l_j(U_{RR}^j)(U_{RR}^j - U_R), \tag{3.20}$$

$$l_j(U_M^{\text{char}})(U_M^{\text{char}} - U_M) = 0, \quad j = 1, 2, \ldots, k, \tag{3.21}$$

for the states U_M^{char} and U_N^{char} at time $t + dt - 0$ (where $l_i(U)$ is an ith left eigenvector at U);

4. solve the Riemann problem with data U_M^{char} and U_N^{char} to obtain U_M^{new}, U_N^{new}, and s^{new} at time $t + dt + 0$, and revise the shock position using the average shock speed $\frac{1}{2}(s + s^{\text{new}})$.

4. Application to transitional shock waves in quadratic models. Quadratic models are nonlinear 2×2 systems of conservation laws having quadratic flux functions. Since a quadratic flux approximates a general flux near the neighborhood of a certain point, such models have been studied extensively as a prototype for the general 2×2 systems of conservation laws [41, 42, 45, 37, 38, 44, 40, 23, 24, 26, 19] just as the Burger's equation is studied in a scalar conservation law. Quadratic models are important for investigating special points, such as umblic points (isolated points at which the Jacobian is a multiple of the identity matrix). Inhomogeneous quadratic models are important as prototypes of mixed-hyperbolic/elliptic systems. For example, the existence of an umblic point or an elliptic region in some models of three-phase flow in porous media offers physical motivation for the study of Riemann problems for quadratic models [3, 43, 47, 1, 25].

Transitional shock waves are nonclassical shock waves which satisfy the viscosity profile criterion but are not admissible under the Lax criterion. In quadratic models, these waves are used to construct Riemann solutions near the elliptic region, where the Lax criterion fails to give solutions. Transitional waves are regularization-sensitive in the sense of the previous section. In this section, we apply our Riemann solver to these waves and the front tracking method for the correct numerical computation.

4.1. Transitional waves and quadratic models. We consider a general system of two conservation laws with $U = (u, v)^T$ and $F = (f, g)^T$ in (2.1), and for which f, g are quadratic functions of u and v:

$$f(u, v) = \frac{1}{2}\left(a_1 u^2 + 2b_1 uv + c_1 v^2\right) + d_1 u + e_1 v, \tag{4.1}$$

$$g(u, v) = \frac{1}{2}\left(a_2 u^2 + 2b_2 uv + c_2 v^2\right) + d_2 u + e_2 v. \tag{4.2}$$

Generally, such a model fails to be strictly hyperbolic; for example, for homogeneous models (when linear terms are absent), the characteristic speeds coincide at $U = 0$. Furthermore, an elliptic region, where characteristic speeds are not real, can occur. In the case of homogeneous models, Schaeffer and Shearer [37] found the nonsingular linear change of dependent variables that transforms (2.1) into a normal form which has two free parameters. Thus homogeneous quadratic models can be classified into four cases, I–IV, based on the structure of the integral curves through an origin in the

two parameter space. The first Riemann problem of this class, which was the symmetric case I, was solved by Shearer et al. [45]. In succession, other cases were solved [26, 38, 44, 24]. Most of these solutions were obtained under the Lax admissibility criterion. In [20], a Riemann problem is solved using the viscous profile criterion. This solution differs from that obtained using the Lax admissibility criterion, even though solutions exist and are unique for both criteria. With the viscous profile criterion, some nonlocal Lax shock waves are inadmissible; in their place, transitional waves appear in the wave patterns.

Transitional waves appear in wave groups located between the classical 1- and 2-family wave groups. A transitional shock wave from U_- to U_+ with speed s is a [illegible] in that

$$\lambda_1(U_-) < s < \lambda_2(U_-), \tag{4.3}$$

$$\lambda_1(U_+) < s < \lambda_2(U_+). \tag{4.4}$$

Thus all characteristic curves cross through the transitional shock wave. Transitional rarefaction waves appear when there exist special points at which two characteristic speeds coincide (the singularities of the rarefaction foliation). An integral curve from family 2 passes through this point and continues with an integral curve of family 1. This curve defines a transitional rarefaction wave. Transitional composite waves are also possible [23]. All of these kinds of transitional wave groups appear in the wave pattern located between the 1- and 2-wave groups.

4.2. Saddle-to-saddle connections. For a system of two conservation laws, the question of shock wave admissibility reduces to the study of planar dynamical systems (2.5) and their critical points, given a viscosity matrix $D(U)$. Let us first consider the situation where the viscosity matrix is the identity matrix. Then the eigenvalues at a critical point U_c of the dynamical system are

$$\mu_i = \lambda_i(U_c) - s, \quad i = 1, 2. \tag{4.5}$$

Therefore a shock wave satisfying the Lax admissibility condition [28] corresponds either to a connection from a repelling node to a saddle point, in the case of a 1-family wave, or to a connection from a saddle point to an attracting node, in the case of a 2-family wave. When $D(U)$ is not necessarily a multiple of the identity matrix, the node can be a spiral point, but the phase portrait is still generically stable, in that the sum of the dimensions of the unstable manifold of U_- and the stable manifold of U_+ is three.

In contrast, a transitional shock wave is a crossing discontinuity where the inequalities (4.4) hold, so that both characteristic families cross through the wave. Since $D(U)$ has a positive determinant, it follows that the eigenvalues of system (3.3) at U_- and U_+ satisfy $\mu_1(U_-)\,\mu_2(U_-) < 0$ and $\mu_1(U_+)\,\mu_2(U_+) < 0$, respectively. Therefore the viscous profile for a transitional wave connects two saddle points, and the phase portrait is generically unstable. (See Figure 3.)

In the special case of the quadratic model, there are two kinds of saddle-to-saddle connecting orbits possible: straight-line and curved. For dynamical systems that are quadratic gradients, Chicone [4] has shown that every saddle-saddle connection has a straight-line orbit. In [23], analytic formulae for Hugoniot curves and various bifurcation loci were given for quadratic models; in particular, all straight-line saddle-to-saddle connections were identified. This work has been extended [31, 21]. In section 4.4, we compare our numerical results with the answers obtained by this analytic work.

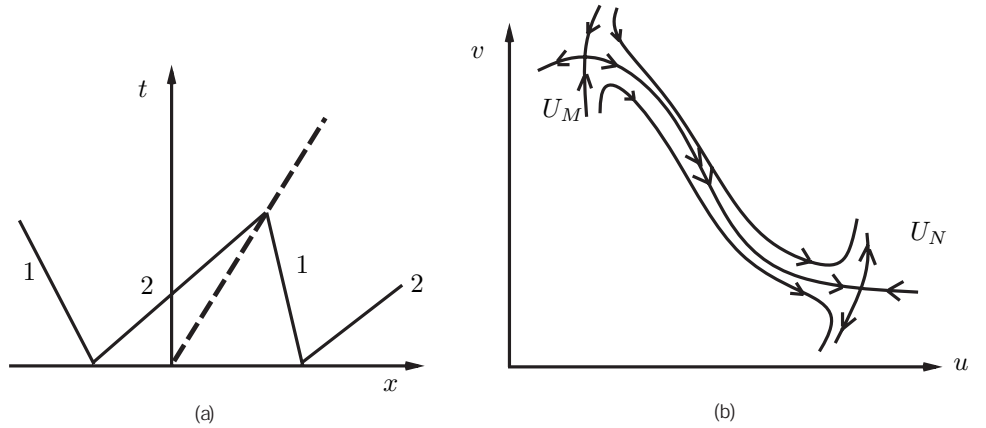

FIG. 3. *This picture shows a transitional shock wave in* (a) *the* (x,t) *plane and* (b) *the* (u,v) *plane.*

4.3. Numerical Riemann solver near a transitional shock wave. In this section we apply the algorithm of section 3 in the case $m = 2$. As illustrated in Figure 3, the solution of such a Riemann problem comprises a 1-wave from U_L to U_M, a transitional shock wave from U_M to U_N, and a 2-wave from U_N to U_R. Given U_L and U_R, we shall calculate U_M, U_N, and the speed s of the transitional wave.

Since U_M and U_N lie on the wave curves from U_L and U_R, they can be expressed as

$$U_M = \mathcal{W}_1^+(U_L, \varepsilon_L) \approx U_L + \varepsilon_L\, r_1(U_L), \tag{4.6}$$

$$U_N = \mathcal{W}_2^-(U_R, \varepsilon_R) \approx U_R + \varepsilon_R\, r_2(U_R), \tag{4.7}$$

where $\mathcal{W}_1^+$ (resp., $\mathcal{W}_2^-$) parameterizes the forward 1-family (resp., backward 2-family) wave curve in terms of the parameter ε_L (resp., ε_R). As indicated, we approximate the wave curves by straight lines, since U_M and U_N are close to U_L and U_R, but this approximation can easily be avoided. The states U_M and U_N are also saddle points of the dynamical system 3.1.

To calculate the saddle-to-saddle connection from U_M to U_N, we employ the multiple shooting method, as in section 3. The states U_0^* at $\xi = -T_1$ and U_n^* at $\xi = T_2$ can be approximated as

$$U_0^* \approx U_M + \varepsilon_M\, \tilde{r}_2(U_M), \tag{4.8}$$

$$U_n^* \approx U_N + \varepsilon_N\, \tilde{r}_1(U_N). \tag{4.9}$$

Then we have $2n + 3$ unknown quantities,$(\varepsilon_L,\ \varepsilon_R,\ \varepsilon_M,\ \varepsilon_N,\ s,\ U_1^*,\ \ldots,\ U_{n-1}^*)$, and we have $2n + 3$ equations to solve: $2n$ matching conditions, two Rankine–Hugoniot conditions, and a phase condition.

Figure 4 shows the convergence of a Riemann solver for examples of Riemann problems for a quadratic model with an elliptic region, whose coefficients are given as $a_1 = -1$, $b_1 = 0$, $c_1 = 1$, $d_1 = 0$, $e_1 = 0.23$, $a_2 = 0$, $b_2 = 1$, $c_2 = 0$, $d_2 = -0.23$, $e_2 = 0$ in (4.2). In this example, the saddle-to-saddle connections are curved connections. As described in section 3, our iterative solver adopts the line search technique to obtain a global convergence for different initial guesses. We use the straight line connection from U_L to U_R as an initial guess; however, a different initial guess could make a faster

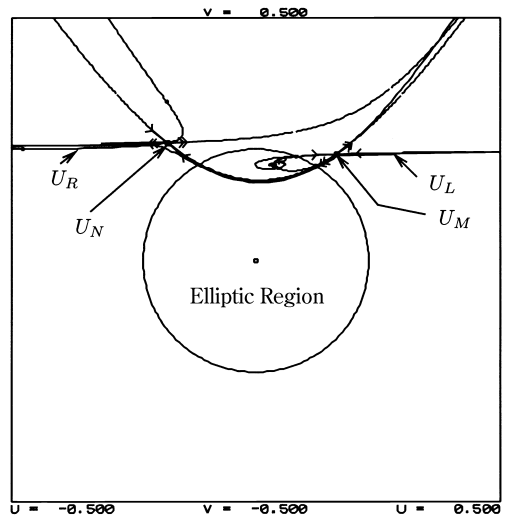

FIG. 4. *The (u, v)-plane. The region inside of the circle is the elliptic region, where the characteristic speeds are complex. convergence. Figure 4(a) is an exact solution obtained from the Riemann Problem Package of Isaacson, Marchesin, and Plohr [22] based on an analytic formulation for quadratic models, and the (b) is the computed result of the Riemann solver, which is exactly same as that in (a).

4.4. Computational results with front tracking and comparison to other methods. Equipped with the Riemann solver of the previous section, we are in a posi-

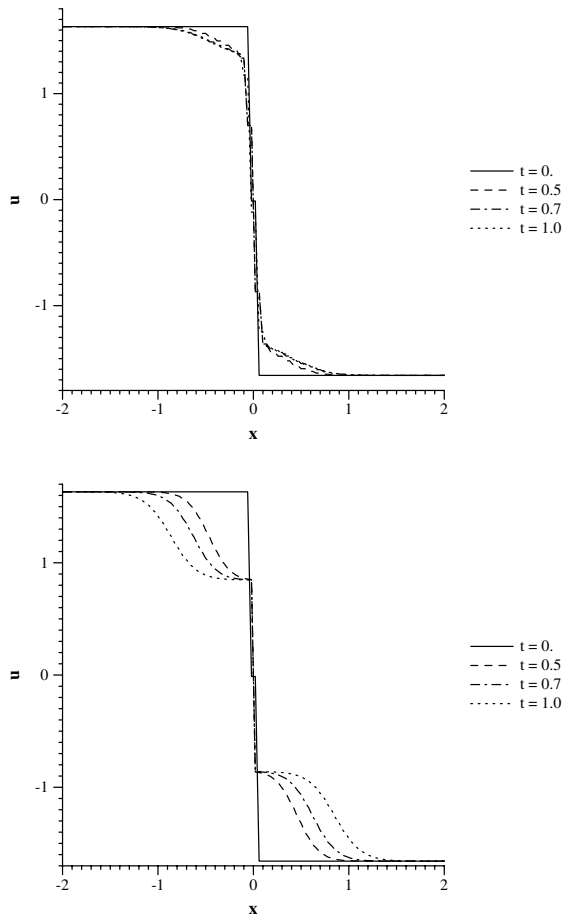

FIG. 5. *The case* II *model solved using the LF method without (top) and with (bottom) front tracking.*

tion to track a transitional shock wave using the front tracking method of section 3.1. We have implemented a front tracking method for pairs of conservation laws with quadratic flux functions of (4.2). In the following we describe some of the results of testing our tracking method. We also make comparisons to some commonly used shock capturing methods. We apply these methods to a homogeneous model in case II and to an inhomogeneous model for which the homogeneous quadratic part belongs to case I. In the first case, transitional shock waves have straight connections; in the latter case, we focus on curved connections.

For the homogeneous case II model, the coefficients are $a_1 = 0.5$, $b_1 = 0.2$, $c_1 = 1$, $d_1 = e_1 = 0$, $a_2 = 0.2$, $b_2 = 1$, $c_2 = d_2 = e_2 = 0$; the viscosity matrix is taken to be constant and diagonal, with diagonal entries 1 and 0.3. We solve the initial-value problem with Riemann data $U_L = (1.632, 1.278)$ and $U_R = (-1.658, -1.269)$. The exact solution comprises a 1-shock wave, a transitional wave, and a 2-shock wave [20]; the connecting orbit for the transitional wave lies along a line through the origin (a viscosity line) that can be determined analytically [23]. This solution is to be contrasted with the solution when $D(U)$ is a multiple of the identity matrix, or, more generally, a function of $F'(U)$: then the transitional wave lies along a different line

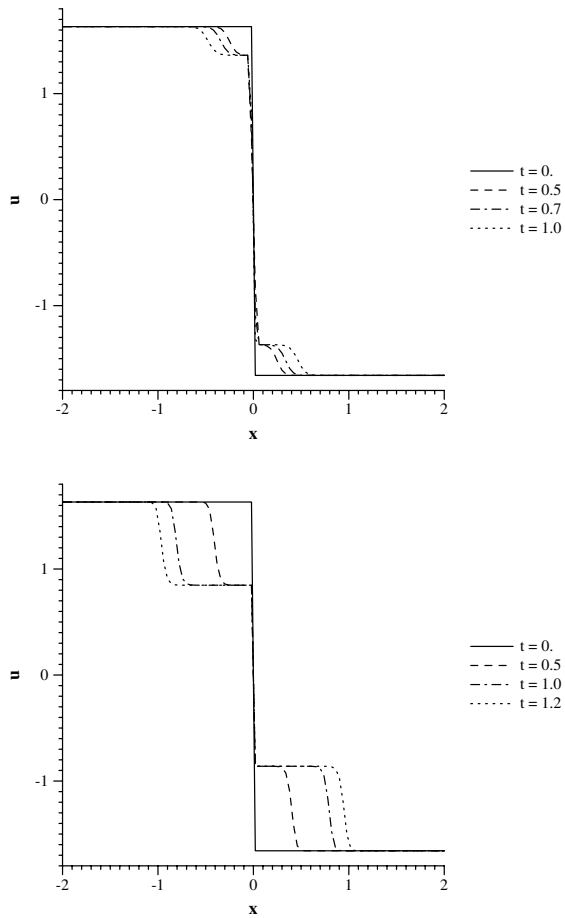

FIG. 6. *The case* II *model solved using the BCT method without (top) and with (bottom) front tracking.*

through the origin (a secondary bifurcation line).

Figures 5 and 6 show the results of using the Lax–Friedrichs (LF) [27] and Bell–Colella–Trangenstein (BCT) [2] methods with and without front tracking for comparison. Graphs of u plotted versus x for several time steps are shown superimposed. Graphs of v are omitted to save space but are similar to those of u. For both methods, the calculated solution shows the 1- and 2-family shock waves moving away from the tracked transitional wave; of course the untracked waves are sharper for the BCT method. Naturally, for these schemes, the transitional wave is less sharply defined, but more significantly, the limiting states of this wave are very different, leading to 1- and 2-family waves that are very different as well.

To compare these results with the exact solution, we have plotted the computed solutions in state space; see Figure 7. In the figure there are two sets of dashed lines: short-dashed lines are secondary bifurcation lines, whereas long-dashed lines are viscosity lines corresponding to the chosen viscosity matrix. These lines have been computed using the formulae in [23]. For the front tracking solutions, the orbit for the transitional wave lies along a viscosity line and thus approximates the exact solution well. For the untracked solutions, however, the orbit lies along a bifurcation

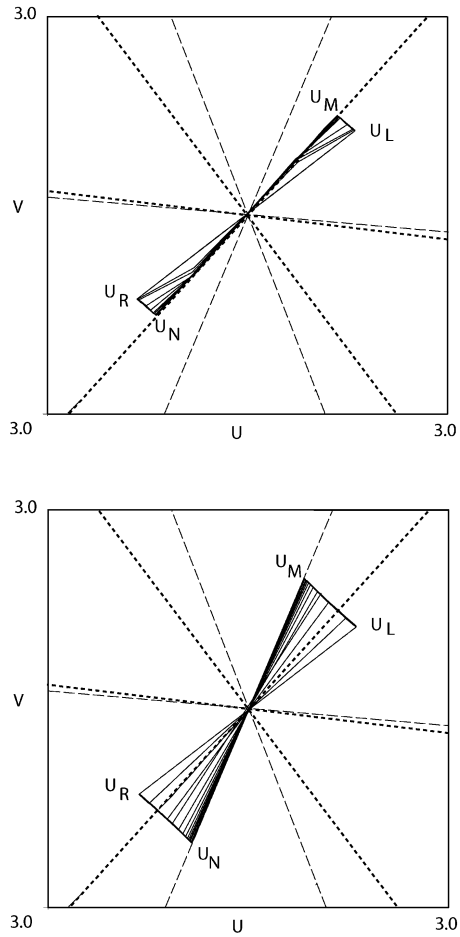

FIG. 7. *The case* II *model solved using the BCT method as shown in the* (u, v)*-plane. The top figure is computed without front tracking, and the bottom with front tracking.*

line; this is consistent with the fact that the numerical viscosity matrices for these schemes (i.e., the viscosity matrices for the corresponding modified equations) are functions of $F'(U)$.

The next set of figures shows the test results for the case I model. The coefficients for this model are $a_1 = -1$, $b_1 = 0$, $c_1 = 1$, $d_1 = 0$, $e_1 = 0.23$, $a_2 = 0$, $b_2 = 1$, $c_2 = 0$, $d_2 = -0.23$, $e_2 = 0$; the viscosity matrix is taken to be the identity matrix. This model has a elliptic region, the boundary of which is a circle shown in the state space Figure 4. The Riemann initial values are $U_L = (0.273, 0.182)$ and $U_R = (-0.246, 0.310)$. The exact solution, as computed using the Riemann Problem Package, comprises a 1-rarefaction wave, a transitional wave with a curved connecting orbit, and a 2-shock wave.

The results of using the front tracking method are shown in Figures 8, and 9. The underlying finite-difference schemes are the LF and the Lax–Wendroff (LW) [30] schemes; the LW scheme is modified by adding artificial viscosity [35]. For comparison, the results without front tracking are shown together. In the state space figures are drawn not only the solutions for several time steps but also the orbits of the dynami-

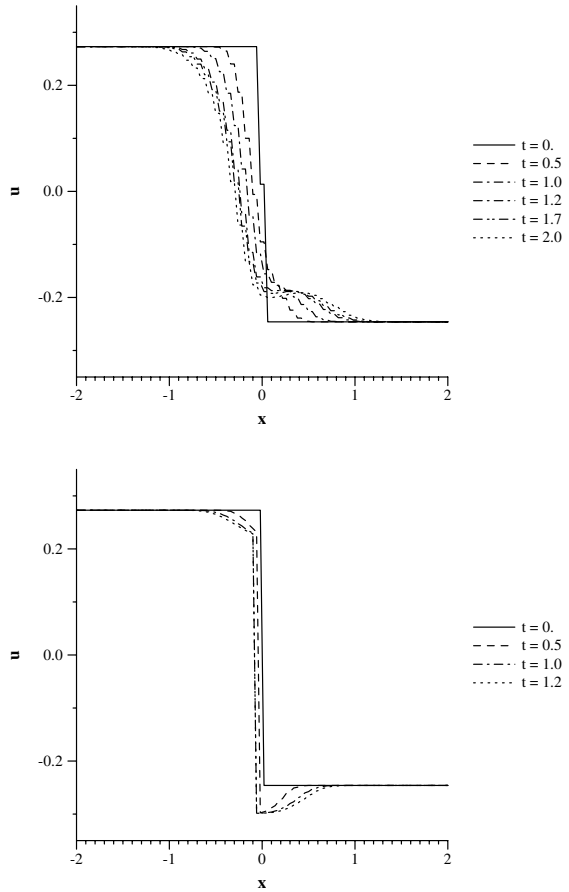

FIG. 8. *The case* I *model solved using the LF method without (top) and with (bottom) front tracking.*

cal system corresponding to the transitional shock wave (particularly the connecting orbit), the Hugoniot locus based at the point U_L, and the circle bounding the elliptic region. As seen in the state-space figures, the front tracking solution approximates the exact solution well, whereas the untracked solutions are significantly different.

5. Application to deflagration waves in combustion. In this section, we apply our algorithm for regularization-sensitive waves to deflagration waves appearing in combustion. Combustion is one of the most complex phenomena in nature, and it is extremely difficult to model numerically. Our standard approach is to assume that the reaction zone is infinitely thin. In this approach, all microscopic dissipative terms, such as viscosity, diffusion, and heat conductivity, which are dominated in the reaction zone are neglected. This assumption is motivated by their small sizes compared to a typical flow size, and by the short time for the chemical reactions compared to a typical flow time. Thus, combustion waves are treated as discontinuities in the resulting governing equations, which comprise a system of hyperbolic conservation laws. These discontinuities should be required to have viscous profiles, as in the previous section. The neglected microscopic dissipative terms play the the role of the vanishing viscosity matrix.

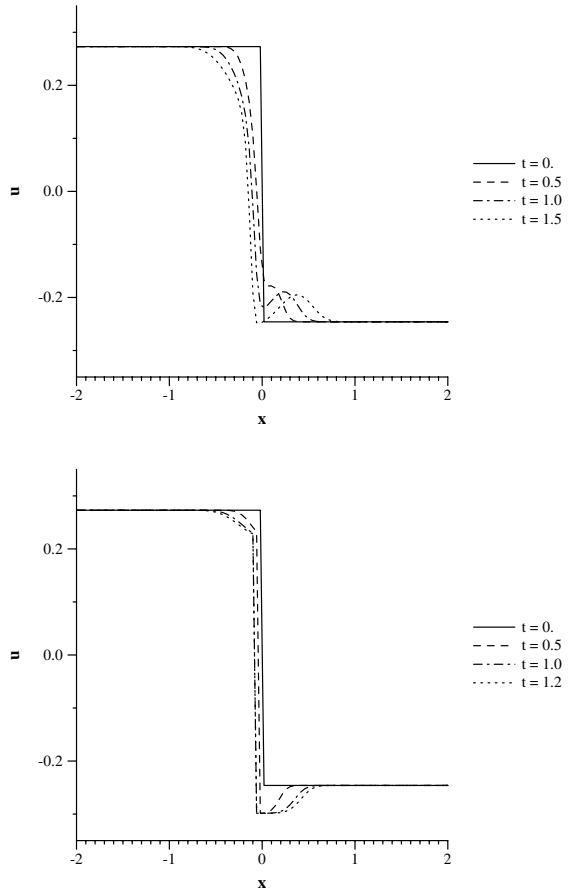

FIG. 9. *The case* I *model solved using the LW method without (top) and with (bottom) front tracking.*

In combustion, there are two kinds of waves in addition to standard gas dynamics waves. One is a detonation wave, and the other is a deflagration wave. Detonation waves have shock-like structures and are admissible under the Lax criterion. In contrast, deflagration waves violate the Lax criterion; i.e., fewer characteristics impinge on the wave than Lax shocks do. Thus its structure and propagation speed are sensitively dependent on the internal wave structure, which is, in turn, influenced by viscosity, diffusion, and heat conductivity.

This internal structure dependency implies difficulties in numerical computations. Excess diffusion can cause significant errors in calculating combustion wave speeds [7], and the naive use of standard numerical methods such as shock capturing schemes produces spurious results in the case of deflagration waves because of artificial viscosities.

In this section, we propose an algorithm for solving Riemann problems near a weak deflagration wave, the side states and speed of which depend on dissipation mechanisms.

5.1. Governing equations and viscous profiles of combustion waves. We consider the Navier–Stokes equations for a reacting gas in one space dimension. We assume the simple chemical reaction of one reactant that is converted to the product by a one-step exothermic reaction: $A \to B + \text{heat}$. Therefore we need only one variable

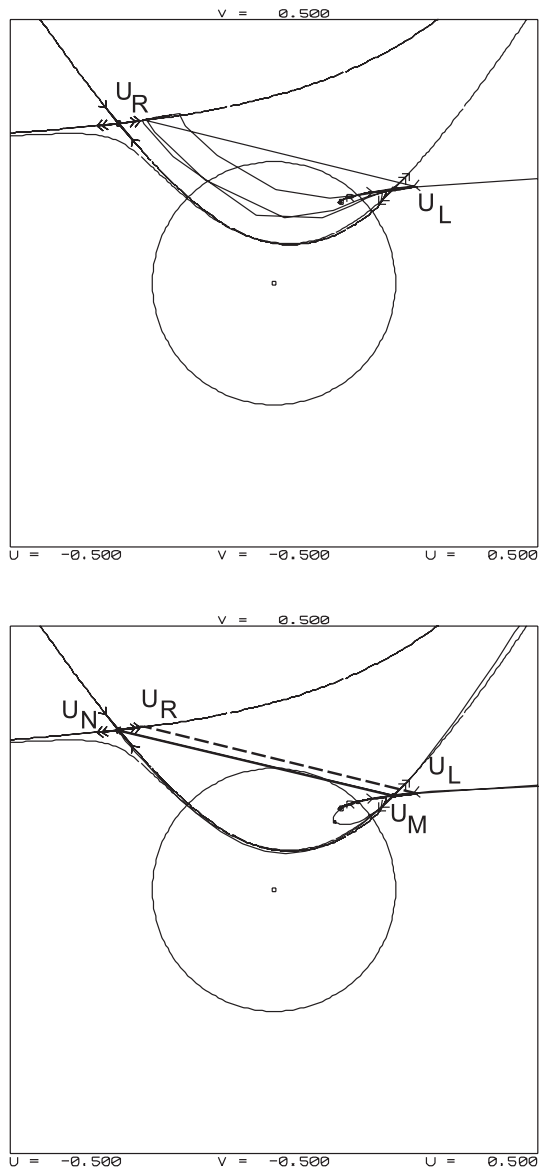

FIG. 10. *The case* I *model solved using the LW methods without (top) and with (bottom) front tracking, as shown in the* (u, v)*-plane.*

Y, which is the reactant mass fraction. More complicated reactions have a similar structure but more variables [13]. The governing equations are

$$\rho_t + (\rho u)_x = 0,$$

$$(\rho u)_t + (\rho u^2 + p)_x = (\mu u_x)_x,$$

$$\left[\rho\left(\frac{u^2}{2} + e\right)\right]_t + \left[\rho u\left(\frac{u^2}{2} + e\right) + pu\right]_x = (\lambda T_x)_x + (q\rho D Y_x)_x + (\mu u u_x)_x,$$

$$(\rho Y)_t + (\rho u Y)_x = (\rho D Y_x)_x - k\rho Y \phi(T). \tag{5.1}$$

Here, the variables ρ, u, p, e, T, and Y are respectively the mass density, velocity, pressure, specific energy, temperature, and reactant mass fraction of the gas. This last variable Y ranges from 0 to 1; $Y = 0$ means that gas is totally burned, and $Y = 1$ corresponds to an unburned gas. The constants μ, λ, and D are the viscosity, heat conductivity, and diffusion constants, respectively. Assuming a polytropic equation state, the specific energy e is given by

$$e = c_v T + qY = \frac{p}{\rho(\gamma - 1)} + qY, \tag{5.2}$$

where c_v is the specific heat at constant volume and q is the heat release parameter. For an exothermic reaction, q is positive, and the gas undergoes a chemical reaction in which energy q is released. In (5.1) we have also assumed a reaction rate

$$r = -k\rho Y \phi(T). \tag{5.3}$$

The function $\phi(T)$ is given by Arrhenius term of the form

$$\phi(T) = \begin{cases} \exp(-E_a/RT) & \text{if } T > T_i, \\ 0 & \text{otherwise,} \end{cases} \tag{5.4}$$

where E_a is an activation energy constant. To avoid the well-known cold boundary difficulty, we adapt the common mathematical remedy such that $\phi(T)$ vanishes identically for T below a certain ignition temperature T_i. The system (5.1) is a standard set of equations for a reactive gas flow [53].

If we neglect all dissipative effects, then (5.1) reduces to a system of hyperbolic conservation laws with a source term of a reaction rate, $-k\rho Y\phi(T)$, which is called the ZND model (named after Zeldovich, Neumann, and Döring).

A thorough analysis shows that the downstream gas velocity, relative to the wave, exceeds the sound velocity for weak detonations and strong deflagrations and is less than the sound velocity for strong detonations and weak deflagrations [9, 6]. These relations are known as [illegible]. From the the relations between characteristic speeds and speeds of deflagration waves, we can see that a weak deflagration wave is underdetermined.

Detonation and deflagration waves are traveling wave solutions of the Navier–Stokes equations (5.1) connecting an unburned state at $x = -\infty$ to burned state at $x = \infty$. To be admissible as physical solutions of corresponding hyperbolic conservation laws (5.5), these traveling waves must have viscous profiles, i.e., be the limits of solutions of (5.1) as the dissipation coefficients go to zero. The existence of combustion waves of system (5.1) has been analyzed by several authors under the simplifying assumptions such as certain fixed Prandtl and Lewis number [18] or very large activation energy [32]. However, the convergence of these solutions to solutions of the ZND model is not discussed by these authors. Recently, Wagner [52, 51] obtained the existence of viscous profiles for detonation and deflagration waves as ZND-limits under the assumption of certain fixed Prandtl and Lewis number. Gasser and Szmolyan [12] proved the same, using a geometric singular perturbation theory. In this section, we will derive the corresponding dynamical system for combustion waves and will show that the weak deflagration wave is regularization-sensitive in the sense described in previous sections.

5.2. Dynamical systems for combustion waves and linearization near an equilibrium point. Let us call m a conserved mass, i.e.,

$$(u - s)\rho = (u_0 - s)\rho_0 = -m, \tag{5.5}$$

and define a new variable

$$Z = Y + \rho D \frac{Y_x}{m}, \tag{5.6}$$

so that the third equation in (5.1) can be written as a first-order ordinary differential equation since Y_x vanishes at $x = \pm\infty$,

$$Z_1 = Y_1, \qquad Z_0 = Y_0. \tag{5.7}$$

Then we could obtain the following ordinary differential equations for the viscous profile of a combustion wave:

$$\begin{aligned}
\mu u_x &= -m(u-u_0) - mR\left(\frac{T}{u-s} - \frac{T_0}{u_0-s}\right),\\
\lambda T_x &= -mc_p(T-T_0) + \frac{m}{2}(u-u_0)^2 - mq(Z-Z_0)\\
&\quad + mR(u-s)\left(\frac{T}{u-s} - \frac{T_0}{u_0-s}\right),\\
DY_x &= (u-s)(Y-Z),\\
Z_x &= -k\frac{Y\phi(T)}{u-s},
\end{aligned} \tag{5.8}$$

after using the relation $c_p = c_v + R$.

To understand the solution of system (5.8), we first examine its equilibria. Let the state variables be denoted by $V = (u, T, Y, Z)$, setting the right-hand sides of (5.8) to zero; we find that the initial state V_0 and new state V_1 are related by the jump condition discussed in section 5.1. The ordinary differential equations for a shock profile in standard gas-dynamics correspond to the first two equations of (5.8) when q is zero, and it is easily shown that the equilibrium point is a saddle for a subsonic flow and a node (repeller or attractor) for a supersonic flow [15, 34]. A fast shock wave corresponds to a profile connecting an attractor to a saddle, and a slow shock wave to a profile from a saddle to a repeller. Recall that we are integrating from $x = \infty$ backwards. Thus the flow in the dynamical system is reversed.

A similar analysis can be performed for combustion waves. Let us linearize (5.8) near an equilibrium point V_c. Then, (5.8) may be expanded to first order to yield

$$\frac{d\tilde{V}}{dx} = \mathbf{J}\tilde{V}, \tag{5.9}$$

where

$$\tilde{V} = (\tilde{u}, \tilde{T}, \tilde{Y}, \tilde{Z}) = (u-u_c, T-T_c, Y-Y_c, Z-Z_c), \tag{5.10}$$

and $\mathbf{A}$ and $\mathbf{B}$ forming the Jacobian matrix $\mathbf{J} = \mathbf{B}^{-1}\mathbf{A}$ are

$$\mathbf{A} = \begin{bmatrix}
-m + m\dfrac{RT}{(u-s)^2} & -m\dfrac{R}{u-s} & 0 & 0\\
m(u-u_0) - m\dfrac{RT_0}{u_0-s} & -mc_v & 0 & -mq\\
Y-Z & 0 & u-s & -(u-s)\\
k\dfrac{Y\phi(T)}{(u-s)^2} & -k\dfrac{Y\phi'(T)}{u-s} & -k\dfrac{\phi(T)}{u-s} & 0
\end{bmatrix}, \tag{5.11}$$

$$\mathbf{B} = \begin{bmatrix} \mu & 0 & 0 & 0 \\ 0 & \lambda & 0 & 0 \\ 0 & 0 & D & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{5.12}$$

All matrix elements are evaluated at the equilibrium point.

Let us assume that the equilibrium point V_0 is an unburned state where $Y_0 = 1$ and $\phi(T_0) = 0$ since $T_0 < T_i$, and that the other critical point V_1 is a totally burned state, with $Y_1 = 0$. After some algebraic manipulation, we can find the signs of the eigenvalues at V_0 and V_1. At V_1, the eigenvalues μ_1, μ_2, μ_3, and μ_4 of $\mathbf{J}$ satisfy the following relations:

$$\mu_1 \cdot \mu_2 = -\frac{k\phi(T_1)}{D} < 0, \tag{5.13}$$

$$\mu_1 + \mu_2 = \frac{u_1 - s}{D}, \tag{5.14}$$

$$\begin{aligned} \mu_3 \cdot \mu_4 &= \frac{c_v \rho_1^2}{\lambda\mu}[(u-s)^2 - c_1^2] \\ &= \frac{c_v m^2}{\lambda\mu}\left(1 - \frac{1}{M_1^2}\right), \end{aligned} \tag{5.15}$$

$$\begin{aligned} \mu_3 + \mu_4 &= \frac{1}{\mu}\left[-m + \frac{mRT_1}{(u-s)^2}\right] - \frac{mc_v}{\lambda} \\ &= -\frac{m}{\mu}\left(1 - \frac{1}{\gamma M_1^2}\right) - \frac{mc_v}{\lambda}, \end{aligned} \tag{5.16}$$

where $M^2 = u^2/\gamma RT$ is the square of the Mach number. At an unburned state V_0, the analysis is simpler since $\phi(T_0) = 0$, and $\phi'(T_0) = 0$; the eigenvalues satisfy

$$\mu_1 = \frac{u_0 - s}{D}, \quad \mu_2 = 0, \tag{5.17}$$

$$\mu_3 \cdot \mu_4 = \frac{c_v m^2}{\lambda\mu}\left(1 - \frac{1}{M_0^2}\right). \tag{5.18}$$

As shown in section 5.1, the flow is subsonic both behind and ahead of a weak deflagration wave. Therefore two eigenvalues are positive and two eigenvalues are negative at both V_1 and V_0. In contrast, for a strong detonation wave, which is subsonic behind and supersonic ahead, there are three negative eigenvalues at V_0 and two positive eigenvalues at V_1.

To understand better the relative sizes and importance of variables terms in (5.8), we nondimensionalize them using some reference state V^*. Each nondimensional quantity, denoted by a tilde $\sim$, is obtained by dividing the corresponding dimensional quantity by its reference value. For a reference state, we choose a state from the ozone

decomposition reaction data in [7] and [33]. These values are summarized below (all data are CGS units):

$$R = 8.3143 \,\mathrm{x}\, 10^7,$$

$$\gamma = 1.4,$$

$$\rho_{\mathrm{atm}} = 1.29 \times 10^{-3},$$

$$p_{\mathrm{atm}} = 1.0135 \times 10^6,$$

$$\rho^* = 0.931\, \rho_{\mathrm{atm}},$$

$$p^* = 0.821\, p_{\mathrm{atm}},$$

$$T^* = \frac{\alpha p^*}{R\rho^*} \approx 267^\circ\mathrm{K},$$

where $\alpha = 36$ is a mole fraction.

5.3. Numerical Riemann solver near a deflagration wave. In this section, we apply the algorithm described in section 3 to solving a Riemann problem near a deflagration wave. The solution is essential for tracking a deflagration wave. As we have shown in section 5.1, a deflagration wave has fewer characteristics impinging on it; therefore, we need additional information to determine the evolution of the wave. Recently, Hilditch and Colella [17] tracked a deflagration flame, taking an experimental flame speed law for the additional information. The same strategy has been used also by Smiljanovski and Klein [48] except for a different tracking procedure. These authors all utilized the Riemann solution procedure of Teng, Chorin, and Liu [50] and used a phenomenological flame speed law to overcome the underdeterminacy. Our approach differs in that we construct the Riemann solution from the exact information coming from the internal structure of the flame. In particular, we do not use a phenomenological flame speed law.

Solving a Riemann problem near a deflagration wave means finding the flame speed s and the two states U_M and U_N in Figure 11 for given Riemann initial data U_L and U_R. We consider the dynamical system (5.8). For simplicity of notation, we drop the tildes from the scaled quantities. Then U_M and U_N are equilibrium points of a dynamical system

$$U' = G(U, s, U_N) = G(U, s, \varepsilon_R), \tag{5.19}$$

and these equilibria are connected by an orbit as we described in section 5.1.

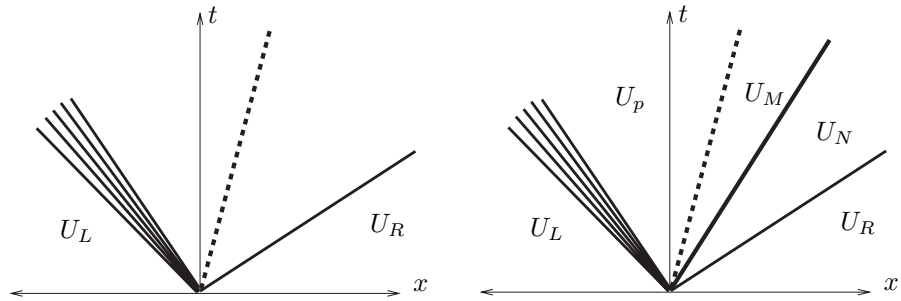
Since U_M is reached from U_L by a combination of weak 1- and 2-waves, it can be expressed as

$$U_M = \mathcal{W}_{1,2}^+(U_L, \varepsilon_L, \varepsilon_M) \approx U_L + \varepsilon_L\, r_1(U_L) + \varepsilon_M\, r_2(U_p). \tag{5.20}$$

Similarly, since U_N is reached from U_R by a weak 3-wave,

$$U_N = \mathcal{W}_3^-(U_R, \varepsilon_R) \approx U_R + \varepsilon_R\, r_3(U_R). \tag{5.21}$$

The algorithm for calculating a flame is the same as for a transitional shock wave except the number of parameters and the dimensions of stable and unstable manifolds.



(a) Gas dynamics (b) Weak deflagration

FIG. 11. *Riemann solution for gas dynamics (a), and for reactive gas with a right-facing weak deflagration (b). The waves between U_L and U_p, and between U_N and U_R, can be shock waves or rarefaction waves.*

The dimensions of the stable manifold at U_N and that of the unstable manifold at U_M are both two, as we have seen in section 5.2. The states U_0^* and U_n^* are approximated here as

$$U_0^* \approx U_M + \varepsilon_3 \tilde{r}_3(U_M) + \varepsilon_4 \tilde{r}_4(U_M), \tag{5.22}$$

$$U_n^* \approx U_N + \varepsilon_1 \tilde{r}_1(U_N) + \varepsilon_2 \tilde{r}_2(U_N), \tag{5.23}$$

where $\tilde{r}_i(U)$ is the ith eigenvector of $G'(U)$. Dividing the interval between U_0^* and U_n^* into n subintervals gives $4n-4$ unknown quantities, which are $U_1, \ldots, U_{n-1}$; thus we have a total of $4n+4$ unknowns, namely,

$$(\varepsilon_L, \varepsilon_M, \varepsilon_R, \varepsilon_1, \varepsilon_2, \varepsilon_3, \varepsilon_4, s, U_1^*, \ldots, U_{n-1}^*),$$

which require $4n+4$ equations. There are $4n$ matching conditions in the multiple shooting algorithm, three equations from the Rankine–Hugoniot relations, and one phase condition. Therefore we have a complete system of equations to solve.

5.4. Computational results with the Riemann solver. For testing the algorithm of section 5.3, we simplify (5.8) by neglecting the species diffusion effect; i.e., we set $D = 0$. Then $Y = Z$, and system (5.8) reduces to a 3×3 system of ordinary differential equations. The equations for U_M and U_N are still (5.20) and (5.21), but those for U_0 and U_n, (5.22) and (5.23), simplify to

$$U_0^* \approx U_M + \varepsilon_3 \tilde{r}_3(U_M), \tag{5.24}$$

$$U_n^* \approx U_N + \varepsilon_1 \tilde{r}_1(U_N) + \varepsilon_2 \tilde{r}_2(U_N). \tag{5.25}$$

This simplification leads to the system of $3n+4$ equations to solve for $3n+4$ unknown variables.

Figures 12 and 13 show the computational results for the solutions of Riemann problems near a deflagration wave. The values of the coefficients are taken from the ozone decomposition reaction data in [7] and [33] and are scaled for nondimensionalization using $\gamma = 1.4, T_i = 1.9, q = 2, E_a = 1.41, \mu = 0.4, \lambda = 0.3$. In this example, the initial data is $U_L = (0.26, -0.15, 1.57)$ and $U_R = (1.501, 0.45, 1.7)$, where $U = (\rho, u, p)$. The computed left and right states of a deflagration wave

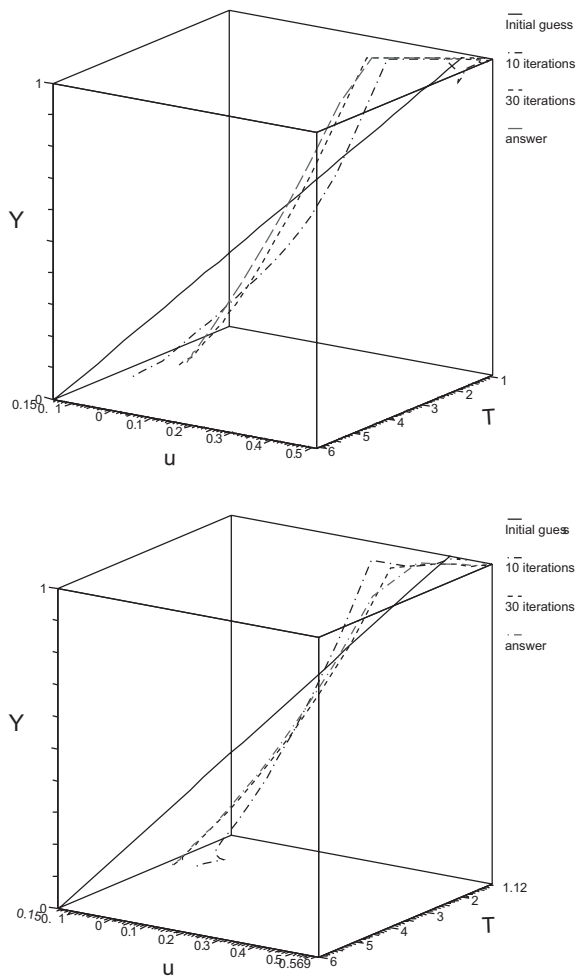


FIG. 12. *The top figure shows the convergence of the Riemann solver when* $\mu = 0.4$, $\lambda = 0.3$. *The Riemann initial data are* $U_L = (0.26, -0.15, 1.57)$ *and* $U_R = (1.501, 0.45, 1.7)$, *and the initial guess is a straight line connecting initial states. The final answer is a viscous profile connecting* U_M *and* U_N. *The bottom figure is when* $\mu = 0.5$, $\lambda = 0.4$; $U_M = (0.514279, -0.146324, 1.567224)$ *and* $U_N = (1.655849, 0.603822, 1.987245)$.

are $U_M = (0.501913, -0.092041, 1.526870)$ and $U_N = (1.538359, 0.489946, 1.770701)$. This result shows that the density and pressure decrease and the temperature increases ($T_{U_M} = 3.042099$) behind a deflagration wave. The temperature at U_N also increases towards temperature T_i. The flame speed obtained is $s = 0.773140$. In contrast, the experimental flame speed law used in the computations of Hilditch and Colella [17], Chorin [5], and Teng, Chorin, and Liu [50] is

$$s = u_0 + a \left(\frac{p_0}{\rho_0} \right)^b, \tag{5.26}$$

where $a = 0.1$ and $b = 0.2$ are determined by fitting experimental data to this equation. This law gives $s = 0.615809$.

In the next example, we change the values of viscosity and heat conductivity to

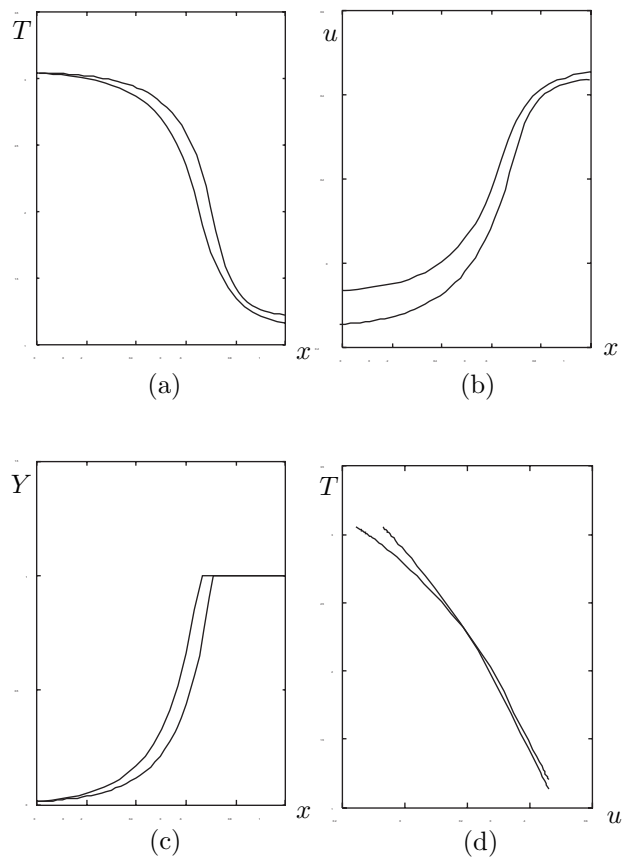

FIG. 13. *These figures show the different structure of the internal layer ($x = 0$ to $x = 1$) of a deflagration wave when μ and λ are given differently: ($\mu = 0.4$, $\lambda = 0.3$) and ($\mu = 0.5$, $\lambda = 0.4$).* (a) *velocity u versus x,* (b) *temperature T versus x,* (c) *mass fraction Y versus x, and* (d) *T versus u.*

$\mu = 0.5$ and $\lambda = 0.4$ and compute the Riemann solution, obtaining $U_M = (0.514279, -0.146324, 1.567224)$, $U_N = (1.655849, 0.603822, 1.987245)$, and $s = 0.941279$. This different solution illustrates the influence of the choice of regularization on wave propagation. Our Riemann solver has found a solution which correctly incorporates the information coming from the internal structure. Figure 12 shows converging approximations and the final computed viscous profiles in (u, T, Y)-space when initial guesses are taken as straight lines between U_L and U_R. Figure 13 illustrates the internal structures of waves resolved in our Riemann solver, drawn together with different viscosity and heat conductivity to demonstrate the effect of these internal coefficients.

6. Conclusion. The main purpose of this project has been to understand the mathematical structure of regularization-sensitive shock waves and to develop a numerical method that accurately captures their behaviors. We have devised a Riemann solver that directly accounts for the internal structure of such discontinuities, and have developed a front tracking algorithm based on this Riemann solver. By considering two applications of this method, we have demonstrated that our method accurately computes regularization-sensitive shock waves, in contrast to commonly used numerical methods, which fail to give correct solutions.

Our future plans include the extension of this algorithm to multiple space dimensions and its application to other physical systems. For the multidimensional algorithm, bifurcation cases must be handled; for example, regularization-sensitive shock waves can merge into classical shock waves. Another physical application is to multiphase flow through porous media, which is known to have regularization-sensitive waves. The physical meaning of these waves in physical applications remains a question that requires deeper understanding. We hope that our Riemann solver and front tracking algorithm will contribute to this understanding.

Acknowledgments. The author is grateful to Prof. Bradley Plohr at Los Alamos National Laboratories for his encouragement and for permisions to use his Riemann Problem Package , in exploring this interesting problem. Thanks also to Prof. James Glimm at Stony Brook University for his support and concern for this work.

TOWARDS A BLACK BOX ALGORITHM FOR NONLINEAR FUNCTION APPROXIMATION OVER HIGH-DIMENSIONAL DOMAINS*

ARTA A. JAMSHIDI† AND MICHAEL J. KIRBY†

Abstract. We propose an algorithm for constructing nonlinear models from high-dimensional scattered data. The algorithm progresses iteratively, adding a new function at each step to refine the model. The placement of the functions is driven by a statistical hypothesis test that reveals geometric structure when it fails. At each step the added function is fit to data contained in a spatio-temporally defined local region to determine the parameters, particularly the scale of the local model. Unlike currently available techniques for nonlinear function fitting over scattered data, the proposed method requires no ad hoc parameters. Thus, the number of basis functions required for an accurate fit is determined automatically by the algorithm. We illustrate the approach using several illustrative problems including modeling data on manifolds and the prediction of financial time-series. The algorithm is presented in the context of radial basis functions but in principle can be employed with other methods for function approximation, such as multilayer perceptrons.

Key words. algorithms for nonlinear functional approximation, radial basis functions, manifold learning, curve fitting

1. Introduction.

The problem of extracting nonlinear relationships in large high-dimensional scattered data sets is of central importance across fields of science, engineering, and mathematics. The beginnings of empirical data fitting may be traced to Gauss's work on using least squares to construct linear models. Over the last two decades we have seen a tremendous growth in this area, motivated by new ideas for computing nonlinear models; see, e.g., [10, 44, 39, 36, 37]. Today, diverse areas such as machine learning, optimal control, and mathematical modeling of physical systems often rely significantly on the ability to construct relationships from data. Subsequently there have been a multitude of applications including financial time-series analysis, voice recognition, failure prediction, and artificial intelligence, all of which provide evidence of the importance of nonlinear function approximation algorithms. Our interest in this problem relates to representing data on a manifold as the graph of a function [7, 8] and the reduction of dynamical systems [9].

A common element in empirical data fitting applications is that the complexity of the required model including the number and scale of representation functions is not known a priori and must be determined as efficiently as possible. A variety of approaches have been proposed to determine the number of model functions, i.e., the model order problem. A generally accepted measure of quality of such data

fitting algorithms is that the resulting models generalize well to testing data, i.e., data associated with the same process but that was not used to construct the model. This requirement is essentially that the data not be overfit by a model with too many parameters or underfit by a model with too few parameters.

One general approach to this problem is known as [illegible], i.e., fitting a smooth function through the data set using a modified optimization problem that penalizes variation [42]. A standard technique for enforcing regularization constraints is via cross-validation [17, 43]. Such methods involve partitioning the data into subsets of training, validation, and testing data; for details see, e.g., [18].

Additionally, a variety of model growing and pruning algorithms have been suggested, e.g., the upstart algorithm in [14], cascade correlation [13], optimal brain damage [12], and the resource allocating network (RAN) proposed by Platt [35]. Statistical methods have also been proposed that include, e.g., Akaike information criteria (AIC), Bayesian information criteria (BIC), and minimum description length (MDL) [41, 1] and Bayesian model comparison [28]. In [38, 30, 19] the issue of selecting the number of basis functions with growing and pruning algorithms from a Bayesian prospective has been studied. In [4], a hierarchical full Bayesian model for radial basis functions (RBFs) is proposed. The maximum marginal likelihood of the data has also been used to determine RBF parameters [33]. For a more complete list of references, the reader is referred to [21].

In general, model order determination via both regularization and growing and pruning algorithms can be computationally intensive and data hungry. More important, however, is that these algorithms do not explicitly exploit the geometric and statistical structure of the residuals during the training procedure. In addition, many algorithms in the literature require that anywhere from a few to a dozen ad hoc parameters be tuned for each data set under consideration.

This paper presents an approach for the model order determination problem free of ad hoc parameters. The algorithm is based on detecting any structure in the model residuals. As in the previous work [3, 2] on which this algorithm is based, such structure is quantified via a statistical hypothesis test to determine whether the residuals are independent and identically distributed (IID). The main contribution of this paper is the implementation of the algorithm over higher-dimensional domains using a spatio-temporal ball rather than a temporal window for constructing local training sets. This innovation is particularly critical if the data is periodic or quasi-periodic or, more generally, resides on a manifold. Further, a new initialization procedure is adopted that greatly accelerates the optimization algorithms. To illustrate the absence of ad hoc parameters, diverse data sets are fit without making any changes to the algorithm. In particular, no parameters are varied, or tuned, across data sets.

While we use RBFs to demonstrate the algorithms, the methodology holds for other function fitting problems. In particular, these methods may be applied directly to multilayer perceptrons. Also, we restrict the scope of the presentation to the case of batch data and will present extensions to the online algorithm elsewhere.

The organization of this paper is as follows. Section 2 reviews the RBF approach for multiscale approximation of scattered data. Section 3 develops the background for the hypothesis test for IID noise. Section 4 introduces the algorithm including the concept of spatio-temporal windowing and appropriate stopping criteria. Section 5 demonstrates the performance and robustness of the system using different data sets. Finally, section 6 provides some concluding remarks and discusses future work. For the purposes of keeping this paper self-contained we present some background details of the algorithm proposed in [3, 2] and [21].

2. Radial basis functions. RBFs were introduced for the function approximation problem as an alternative to multilayer perceptrons [10]. Part of their appeal is the variety of efficient algorithms available for their construction. In the extreme, the basis functions may be selected randomly (following the distribution of the data) with fixed scales. In this instance the resulting optimization problem is simply an overdetermined least squares problem to determine the expansion coefficients. One may improve on this approach at modest expense by employing a clustering algorithm to determine the basis function centers [31]. Furthermore, RBFs may be adapted with rank one updates or down-dates [32, 34]. Over the years RBFs have been used successfully to solve a wide range of function approximation and pattern classification problems [5, 21]. More recently, RBFs have been proposed as a tool for the simulation of partial differential equations; see, e.g., [48].

An RBF expansion is a linear summation of special nonlinear basis functions. In general, an RBF is a mapping $f : \mathbb{R}^n \longrightarrow \mathbb{R}^m$ that is represented by

$$f(x) = Ax + \alpha_0 + \sum_{k=1}^{K} \alpha_k \phi_k(\|x - c_k\|_W), \tag{2.1}$$

where x is an input pattern, ϕ_k is the kth radial basis function centered at location c_k, α_k denotes the weight for kth RBF, and A is an $m \times n$ matrix. The term W denotes the parameters in the weighted inner product

$$\|x\|_W = \sqrt{x^T W x}.$$

The term $Ax + \alpha_0$ affords an affine transformation of the data and is useful so that the nonlinear terms are not attempting to fit flat regions. More general polynomials may be used for this purpose [40]. As usual, the dimensions of the input n and output m are specified by the dimensions of the input-output pairs.

The general training problem for the RBF is the determination of the unknown parameters: $\{A, \alpha_i, c_k, W, K\}$. The focus of this paper is to determine an optimal value for K, i.e., the model order. Of course optimizing K depends on high quality values for the remaining parameters, and we propose algorithms for this purpose.

The requirements of the RBF expansion are the same as standard data fitting problems; i.e., given a set of L input-output pairs $\{(x_l, y_l)\}_{l=1}^L$, $\mathcal{X} = \{x_l\}_{l=1}^L$, and $\mathcal{Y} = \{y_l\}_{l=1}^L$, the goal is to find the underlying mapping f such that $y_l = f(x_l)$. In the standard situation we have more data than equations, so we cannot expect to satisfy each equation exactly. Thus the problem is to minimize the cost function

$$E(A, \alpha_i, c_k, W, K) = \frac{1}{2} \sum_{l=1}^{L} \| f(x_l) - y_l \|^2,$$

where now the metric $\| \cdot \|$ is generally the Euclidean inner product and is distinct from the W-weighted inner product used to compute the contributions of the basis functions.

One of the attractive features of RBFs is the variety of basis functions available for the expansion. In particular, these functions come in both local and global flavors and include

$$\phi(r) = \{\exp(-r^2), r, r^2 \ln r, r^3\}.$$

These functions satisfy the criteria of RBFs as described in [37], and the associated approximation theorem states that if $\mathcal{D}$ is a compact subset of $\mathbb{R}^d$, then every continu-

ous real valued function on $\mathcal{D}$ can be approximated uniformly by linear combinations of RBFs with centers in $\mathcal{D}$. In this study we restrict our attention to (local) Gaussian RBFs, i.e., $\phi(r) = \exp(-r^2)$, but the algorithm works in principle for any admissible RBF. We have also recently proposed several candidates for compact RBFs that have excellent conditioning properties associated with the overdetermined least squares problem [20].

We note that in function approximation problems one must distinguish whether the data for which a model is desired is available at the outset or whether the data becomes available as the model is being built. In keeping with standard terminology we refer to these problems as [illegible] and [illegible] training, respectively. In this paper we are specifically interested in learning input/output relationships from batch data.

3. Testing for structure in model residuals. As indicated earlier, one can infer essential information about an empirical model by examining its residuals. Following [3, 2], the proposed algorithm functions on the premise that if there is structure remaining in the residuals, then one or more additional basis functions should be added. On the other hand, if there is no discernible structure, then this is tantamount to a stopping criterion.

We seek to model data that may be viewed as the superposition of a signal and IID noise, observing that if data is noise-free, then one may simply add IID noise to employ this algorithm. In view of this, we may expect the model residuals to be IID, while the model itself represents the geometric structure of the data. Hence, an indication that an RBF model is unsatisfactory is the failure of the residuals to satisfy a hypothesis test for IID noise. This observation forms the basic idea for the stopping criterion used in this research work. The primary advantage of such a criterion is that the hypothesis test from which it stems does not involve any ad hoc parameters that require adjustment.

Now we outline the IID test for determining structure in the residuals and its associated algorithm.

3.1. Statistical background of test for IID noise. The model residual for the nth data point is defined as

$$e_n = y_n - f(x_n).$$

Following [2], we denote the set of residuals for a model of order K as

$$R^K = \{e_n\}_{n=1}^{L}, \tag{3.1}$$

where L is the cardinality of the training set. The standard definition for the sample autocorrelation function (ACF), $\widehat{\rho}(h)$, for a set of residuals $e_1, e_2, e_3, \ldots, e_L$ with sample mean $\bar{e}$ and lag h is defined as

$$\widehat{\rho}(h) = \frac{\widehat{\gamma}(h)}{\widehat{\gamma}(0)}, \tag{3.2}$$

where $-L < h < L$ and

$$\widehat{\gamma}(h) = \frac{1}{L} \sum_{i=1}^{L-|h|} \alpha(h, e_i). \tag{3.3}$$

As proposed in [3, 2], we decompose the ACF into its component terms

$$\alpha(h, e_i) = (e_{i+|h|} - \bar{e})(e_i - \bar{e}). \tag{3.4}$$

For a fixed lag h the quantity $\alpha(h, e_i)$ is the contribution of the ith residual to the ACF. Later we focus on this quantity α and will illustrate that it reveals critical information concerning where new basis functions should be placed. Given its importance, we refer to this term as the autocorrelation contribution, or ACC [3, 2].

3.2. IID hypothesis test. As indicated above, we seek to terminate the addition of new basis functions when the residuals appear to have no further structure. As a test for structure, we consider whether the residuals are IID. The relevant theorem from statistics states that for large L the sample autocorrelations of an IID sequence $U_1, U_2, \ldots, U_L$ with finite variance are approximately IID, with normal distribution with mean zero and variance $\frac{1}{L}$, $N(0, \frac{1}{L})$ [6, p. 222]. Hence, if $u_1, u_2, \ldots, u_n$ is a realization of such an IID sequence, then 95% of the sample autocorrelations should fall between the bounds

$$\frac{-1.96}{\sqrt{L}} < \widehat{\rho}(h) < \frac{1.96}{\sqrt{L}}. \tag{3.5}$$

Note that if the underlying model is known, there is a more accurate bound for this test, described in section 9.4 of [6]. Therefore, if one computes the sample autocorrelation up to lag h and finds that more than $0.05h$ of the samples fall outside the bound, or that one value falls far outside the bounds, the IID hypothesis is rejected. This test can equivalently be written in terms of χ^2 distribution. Given

$$Q = L\widehat{\rho}^T\widehat{\rho} = L\sum_{j=1}^{L-1}\widehat{\rho}^2(j),$$

it has been shown in [6] that Q has a χ^2 distribution with $L-1$ degrees of freedom. The adequacy of the model is therefore rejected at level α if

$$Q > \chi^2_{1-\alpha}(L-1).$$

3.3. Additional testing possibilities. To show rigorously that a sequence of random variables is truly IID, higher moments (if they exist) also need to be considered. In particular, if a sequence of random variables is IID, then any function of the random variables is also IID. Thus, the ACF of not only the sequence of random variables but also, e.g., squares, cubes, and the absolute values, must pass the above given test. For simplicity in this paper we only consider the ACF of the raw residuals. Although this limits our ability to conclude that the residuals are strictly IID, the results suggest that this test is already quite powerful. Note that the test as implemented does indeed provide a necessary and sufficient condition for a sequence to be white noise.

Finally, we remark that there are alternatives to the test described above based on the ACF for testing IID or white noise. Other such tests include the difference-sign test, the rank test, and a test based on turning point [6]. These tests might also be applied as stopping criteria individually, or in conjunction with the current test based on the ACF. Another route for improvement may be possible by considering the relationship between the data inputs and the residuals of the outputs [27].

4. RBF algorithm using a spatio-temporal ball. In this section we present the details of the proposed batch algorithm. The question of whether a new basis function should be added is answered by the IID test. We shall see that this test also

indicates where the new basis function should be added. We introduce the concept of a space-time ball for defining local regions.

Initially, the residuals of the model are equal to the original data. A step in this algorithm consists of evaluating the residuals and determining whether they indicate that a new basis function should be added. Pseudocode is provided in Algorithm 1, and we now proceed to describe the details.

Algorithm 1. RBF algorithm using spatio-temporal ball.

$ran_flag = 1$, $K = 0$
while $ran_flag = 1$ **do**
  evaluate the RBF on the training data set $\{f(x_n)\}_{n=1}^{L}$
  compute the model error $\{e_n\}_{n=1}^{L}$
  compute component contributions $\alpha(h, e_i) = (e_{i+|h|} - \bar{e})(e_i - \bar{e})$
  compute ACF for all $0 < h < L$
  if the autocorrelation test is rejected **then**
    compute h^* via equation $h^* = \arg\max \widehat{\gamma}(h), h > 0$, and
    compute $x^* = x_{i^*} = e^{-1}(e_{i^*})$, where $i^* = \arg\max_{i=1,\ldots,n-h^*} \alpha(h^*, e_i)$
    compute the ACC function, $\beta_i = \alpha(h^*, e_i)$, $i = 1, \ldots, n - h^*$
    optional: denoise the ACC function
    find the right and left local minimizers of i^*, i.e., l^* and r^*
    compute $d_l = d(x_{i^*}, x_{l^*})$, $d_r = d(x_{i^*}, x_{r^*})$, and $d_c = \max\{d_l, d_r\}$
    define the local ball as $\mathcal{X}_{local} = \{x \in \mathcal{X} : \|x - x^*\| \leq d_c\}$
    add a new RBF $h(x; v)$ with initial values $v = [c_0, \sigma_0, \alpha_0]^T$
    solve $E(v) = \min_{v} \| h(x; v) - y \|_2^2$, where $x \in \mathcal{X}_{local}$
    $K = K + 1$
  else
    $ran_flag = 0$
  end if
  compute confidence, RMSE, and $\gamma(h^*)$ of the current model on the training set
end while

4.1. Determining optimal locations of new RBFs. If the autocorrelation test indicates that the data is not IID, then the next requirement is to determine where the new basis function should be located to optimally reduce the structure in the model residuals. Following [3, 2], we look for the point in the domain that makes the largest contribution to the ACF. This is accomplished by observing that the residuals are associated with the data in the domain in a one-to-one manner; i.e., there is a mapping, say ψ, from a data point to its residual of the form

$$e_i = \psi(x_i).$$

Thus, by identifying the residual associated with the largest contribution to the ACF we may identify the location in the domain where the basis function should be added. Note that if the maximum contribution value to the ACF function is shared by more than one residual, a single basis function would be added, selected from the residuals at random. To actually find this point we first determine the exact lag for which the ACF $\widehat{\gamma}(h)$ reaches its maximum value h^*, i.e.,

$$h^* = \arg\max_{h>0} \widehat{\gamma}(h). \tag{4.1}$$

Note that we consider only lags $h > 0$. If we allowed $h = 0$, then the term $\alpha(0, e_i)$ would always have the maximum contribution (for some i) to the ACF, and the method would be similar to those that use maximum magnitude of residuals as a criterion to allocate new basis functions, critically losing the spatial component of the diagnostic.

Then, we find the point in the spatial domain that has the maximum contribution to the ACF for lag $h = h^*$ by solving

$$i^* = \arg \max_{i=1,\ldots,n-h} \alpha(h^*, e_i). \tag{4.2}$$

Thus the center for the new basis function is given by

$$x_{i^*} = \psi^{-1}(e_{i^*}),$$

where ψ^{-1} is the inverse of the function ψ. For simplicity, we will refer to this center location as x^*.

4.2. Spatio-temporal windowing. Now that the center of the new basis function has been found as described above, it is necessary to determine what data should be used to determine the scale and weight of the new RBF. Consider the function $\beta_i = \alpha(h^*, e_i)$. The index i is inherited from the data labels and, in the case of a time-series, corresponds to a time ordering. In practice, if we plot β_i as a function of i, we observe that the values of β_i decrease away from i^*, which is what one expects since this index was selected because it corresponded to a local maximum in (4.2). How quickly the values of β_i decrease for both $i > i^*$ and $i < i^*$ is a property of the scales of the data and the model.

For simplicity, we assume that β_i decreases monotonically for both increasing and decreasing values of i until local minima are reached at the indices $l^* < i^*$ and $r^* > i^*$; here we use l, r to indicate left and right, respectively. We now compute the distances

$$d_l = d(x_{i^*}, x_{l^*})$$

and

$$d_r = d(x_{i^*}, x_{r^*}),$$

as these indicate the size of the data ball around the center x^*. The subset of the data employed to update the added basis function is then

$$\mathcal{X}_{local} = \{x \in \mathcal{X} : \|x - x^*\| \leq d_c\},$$

where $\mathcal{X}$ is the entire training set. The distance d_c can be selected in a variety of ways, and here we select

$$d_c = \max\{d_l, d_r\}.$$

Note that $\mathcal{X}_{local}$ now may contain data whose indices have values that are substantially different from i^*, l^*, and r^*. For time-series data it is apparent that spatial neighbors may not be temporal neighbors. Hence, this spatial-temporal windowing has the potential to capture substantial training data that would otherwise be ignored. For periodic or quasi-periodic data we have found that space-time windowing is essential. As observed in [3, 2], if β_i does not decrease monotonically away from the peak, then a small amount of filtering can be employed to recover monotonicity. Note that while no smoothing of β_i was required to accurately determine $\mathcal{X}_{local}$ for the examples in this paper, it may be necessary in practice; see [3, 2, 21] for details.

4.3. Updating the model. We may write the RBF expansion as consisting of K adapted terms and one new term, i.e.,

$$f^{(K+1)}(x) = f^{(K)}(x) + h(x; v),$$

where $v = [c, \sigma, \alpha]^T$ is the vector of parameters to be optimized. The new term $h(x; v)$ is initialized as

$$h(x; v) = \alpha_0 \phi(\|x - c_0\|_W).$$

The initialization of the center c_0 is at the point of most structure according to our test, i.e., $c_0 = x^*$. The vector of widths σ is very effectively initialized using the diagonal elements of the covariance matrix of the local data,

$$\sigma_0 = \sqrt{\text{diag}(cov(\mathcal{X}_{local}))}. \tag{4.3}$$

Note here that $W = \text{diag}(\sigma_0)$, where the diagonal matrix W is the weighting term in the inner product and has its diagonal elements equal to the components in σ. This initialization of the weights has proven to be extremely valuable in accelerating the convergence of the conjugate gradient iteration. The initial value for the weight, α_0, is calculated via least squares using the initial values for center location and widths.

Once the data in $\mathcal{X}_{local}$ has been determined, the scale (width), weight, and center location of the new basis function are optimized using the conjugate gradient method with cost function

$$E(v) = \min_v \sum_{x \in \mathcal{X}_{local}} \| h(x; v) - y \|_2^2 .$$

We optimize only the parameters associated with the new RBF and keep the others fixed.

4.4. Stopping criteria. One of the most critical components of any growing algorithm is the stopping criterion. Once the optimization of the new term $h(x; v)$ is complete, a new set of residuals is computed over the entire training set. For an algorithm based on the IID test of the residuals the most natural stopping criterion to use is the 95% confidence level. Note that it is possible to interpret the level of confidence as a parameter, but we do not vary it. We present several examples in the section on numerical experiments which illustrate the effectiveness of this stopping criterion.

For all applications we have computed the root mean square error (RMSE)

$$RMSE = \sqrt{\frac{1}{T} \sum_{i=1}^{T} e_i^2}, \tag{4.4}$$

where T is the number of test points. To compare our results with other work we also compute two forms of the normalized prediction error (NPE), namely,

$$NPE_1 = \frac{\sum_{i=1}^{T} \mid e_i \mid}{\sum_{i=1}^{T} \mid y_i - \overline{y} \mid} \tag{4.5}$$

and

$$NPE_2 = \frac{\sum_{i=1}^{T} e_i^2}{\sum_{i=1}^{T} (y_i - \overline{y})^2}. \tag{4.6}$$

It is also interesting to note that the quantity $\hat{\gamma}(h^*)$, i.e., the total contribution to the ACF at lag h^*, monotonically decreases with the number of basis functions

and becomes very flat when the algorithm has converged. Hence, this quantity could be used as a sort of statistical no progress criterion. We have compared the usual criterion on the RMSE with the idea of a no progress criterion on $\hat{\gamma}(h^*)$ and have found the latter to be more robust. Although we did not need to use either as stopping criteria for our applications, it is possible that they could be useful for this purpose with other data sets. With this in mind, we will illustrate their behavior in the numerical experiments that follow.

5. Numerical examples. Here we present several applications to demonstrate the performance of the algorithm in higher-dimensional domains. The successful extension of this algorithm from one- to higher-dimensional domains requires the introduction of the notion of a space-time window. Here we illustrate the impact of this idea on several applications. Note that throughout all the following examples the same code was employed; in particular, there were no parameters that were adjusted or tuned to the data set. Applications to one-dimensional domains for a variety of noise levels and types have been explored in [21].

5.1. A simple manifold. In this example we illustrate the representation of data on a manifold as the graph of a function. We employ the data set (shown in Figure 5.1) named for its similarity to the boundary of a potato chip; see also [8, 7]. The task is to construct a mapping from an (x, y) value in the plane to its corresponding z value on the pringle. Thus, we are fitting the graph of a function from $\mathbb{R}^2$ to $\mathbb{R}$. Such graph fitting problems are at the center of the Whitney's manifold embedding theorem, where $2m + 1$ dimensional domains suffice (in general) to write m dimensional manifolds as graphs; see [8, 7] for a discussion.

This data set, as proposed in [9], can be generated as the solution to the following systems of ordinary differential equations:

$$\begin{aligned}
\frac{dx}{dt} &= y,\\
\frac{dy}{dt} &= -x - (x^2 + y^2 - 1)y,\\
\frac{dz}{dt} &= -\lambda z + 2(\lambda xy + \omega(x^2 - y^2)),
\end{aligned}$$

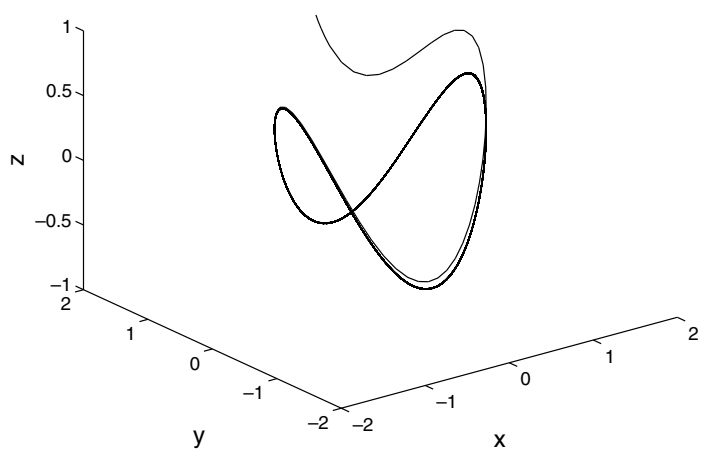

FIG. 5.1. *Plot of a typical pringle set with* $\lambda = 1$ *and* $\omega = 0.5$.

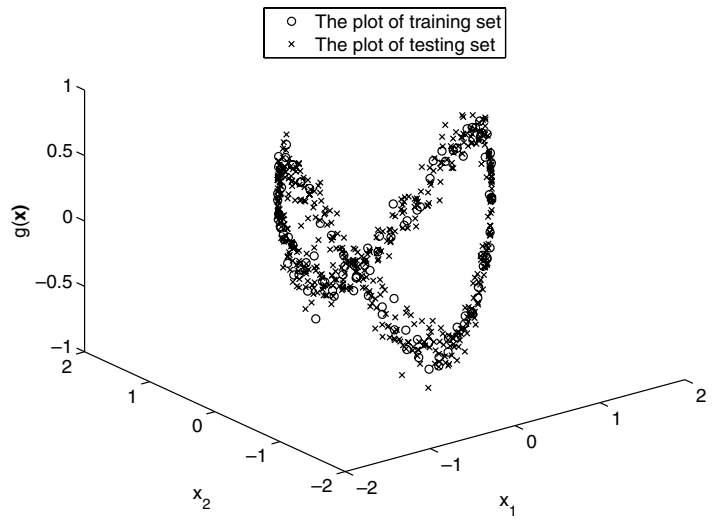

FIG. 5.2. *Plots of the training and testing data sets. The solution to the dynamical system is corrupted with Gaussian noise with standard deviation (STD) of* 0.1. *There are* 54 *data points in one cycle.*

where λ and ω are parameters. In Figure 5.1 a numerically integrated trajectory of an attracting cycle is shown. In this example, we are concerned only with fitting data on the limit cycle and ignore transients. Figure 5.2 shows the training set consisting of 101 points (almost two cycles) and testing data set consisting of 500 points, or almost 9 cycles. The fact that the solution is periodic will clearly illustrate the need for spatial as well as temporal windowing of the data. The system is capable of learning a specific part of the trajectory with a small amount of data, and generalizes well to the data that resides in the same region.

Figure 5.3 shows the ACC functions for the four major RBFs that capture the underlying structure of this data set. Again, the diamonds indicate the points in the ACC function that contribute to the RBF at that stage; i.e., they belong to $\mathcal{X}_{local}$. In Figure 5.3(a) we see that the spatio-temporal window collects data from two peaks, indicating that we have cycled through the data twice in that region. This example clearly illustrates the difference between spatio-temporal windowing and temporal windowing: [illegible]. We see the same effect in Figure 5.3(b), (c), and (d).

Figure 5.4 shows the location and shape of the four RBFs that are generated by the algorithm to model the data before the IID stopping criteria is satisfied. The training data and the RBFs are displayed together to illustrate how the algorithm has fit the RBFs to the data. Figure 5.5(a) shows the maximum value of the ACC function for each step in the training process. Figure 5.5(b) shows the performance of the model in the RMSE sense as the number of assigned RBFs increases, while Figure 5.5(c) shows the confidence level at each stage of training. We see that the first four basis functions are clearly the most significant. The four major RBFs model the data with RMSE of 0.1187, and 99% of points in the ACF reside in the 95% confidence bands. Note that neither the RMSE nor the values of $\gamma(h^*)$ provides reliable stopping criteria in this example. A plot of the output of the model and target values of the testing set are shown in Figure 5.6. We note that a similar experiment has been carried out for the noise-free pringle data set; see [21] for details.

5.2. Mackey–Glass time series. The Mackey–Glass time-delay equation

$$\frac{ds(t)}{dt} = -bs(t) + a\frac{s(t-\tau)}{1+s(t-\tau)^{10}} \tag{5.1}$$

generates a chaotic time series with short-range time coherence, where long time prediction is very difficult; it has become a standard benchmark for testing model fitting algorithms [35, 23, 46].

The time series is generated by integrating the equation with model parameters $a = 0.2$, $b = 0.1$, and $\tau = 17$ using the trapezoidal rule with $\Delta t = 1$, with initial conditions $x(t-\tau) = 0.3$ for $0 \le t \le \tau$ ($\tau = 17$). The initial 1000 data points corresponding to transient behavior are discarded. Then 4000 data points are reserved for the training set. The test set consists of 500 data points starting from point 5001. Note that not all 4000 training points collected were actually used for training the model. (These conditions are very similar to those in Platt [35].)

For purposes of comparison [47], the series is predicted with $\upsilon = 50$ samples ahead, using four past samples: s_n, s_{n-6}, s_{n-12}, and s_{n-18}. Hence, the nth input-output data for the network to learn are

$$x_{n+\upsilon} = [s_n, s_{n-6}, s_{n-12}, s_{n-18}]^T$$

with $y_n = s_n$, whereas the υ step-ahead predicted value at time n is given by $z_{n+\upsilon} = f(x_{n+\upsilon})$, where $f(x_{n+\upsilon})$ is the network output at time n. The υ step-ahead prediction

error is $\epsilon = s_{n+v} - z_{n+v}$. As such, this time series provides a good example for illustrating the construction of a nontrivial mapping from $\mathbb{R}^4$ to $\mathbb{R}$.

Figure 5.7(a) shows the initial ACF (computed on the training data), while Figure 5.7(b) shows the ACF of the residuals that indicates that the model fitting process should be terminated when a 95% confidence has been achieved. Figures 5.7(c) and (d) show the associated ACC functions, i.e., the point wise values β_i corresponding to the maximum value of the ACF in (a) and (b), respectively. From Figure 5.8 we see that it is sufficient to use only 76 centers to get the 95% confidence fit for the Mackey–Glass data set with a resulting RMSE of 0.0116. (See Figure 5.9.) The output of the 76 mode model for the testing data set appears to fit the target values very well. This example is interesting in that a large number of modes is required to attain the stopping criterion.

Our algorithm based on space-time balls provides a result similar to MRAN [46] (RMSE of 0.035) using 1500 data points with 21 centers. However, at this level of RMSE, both our algorithm (21 modes) and MRAN (24 modes and 4000 data points), produce sporadic but significant overshoots and undershoots of the function in regions of high gradient. These large pointwise errors are hidden to some degree by a relatively small RMSE. The IID test is, of course, point wise and reveals local unmodeled structure in the data, preventing the algorithm from terminating prematurely.

Yet, one might argue that stopping at 95% confidence and 76 modes is still premature stopping, as a slightly improved final RMSE value of 0.0090 on the test data

is achieved with 109 modes (but then does not improve with more). However, this example is for the special case of noise-free data. In such instances we recommend that the IID test be coupled with the RMSE test to draw optimal conclusions, unless, of course, one chooses to add noise artificially to the data. Given how close the RMSE errors are at 76 and 109 modes, one must seriously consider that even in this case the 95% confidence level is arguably superior.

5.3. Time series prediction using the exchange rate data set.[1] This data set consists of daily values of the Deutsche Mark/French Franc exchange rate over 701 days; see Figure 5.10. As mentioned in [29], this data set has irregular nonstationary components due to government intervention in the European exchange rate mechanism. Following [29], as there can be "day of week" effects in such data, a window of five previous values can be used as input, giving a data set of 696 patterns. Hence, this data set forms an interesting example of a mapping from $\mathbb{R}^5$ to $\mathbb{R}$.

The training data for this model was taken to be the first 600 data points. The test data set was taken to be the last 96 data points. Figure 5.11 shows the output of the resulting model (one-step prediction values) and the target (market) values for the test data. The modeling process terminated with a model of order three when the 95% confidence threshold was attained (actually 97.17%). The ACC and RMSE criteria are also in agreement with the model order of three; see Figure 5.12. The three mode model produces the RMSE value of 0.0043, $NPE_1 = 0.2760$, and $NPE_2 = 0.1033$. The model has centers at $(3.4933, 3.9292, 3.2870, 3.8574, 4.0983)$, $(3.2793, 3.3475, 3.3337, 3.18433.2718)$, and $(3.3666, 3.4187, 3.6620, 3.2056, 3.6457)$ with

[1]We would like to thank Dr. D. Lowe at Aston University for providing us with this data set.

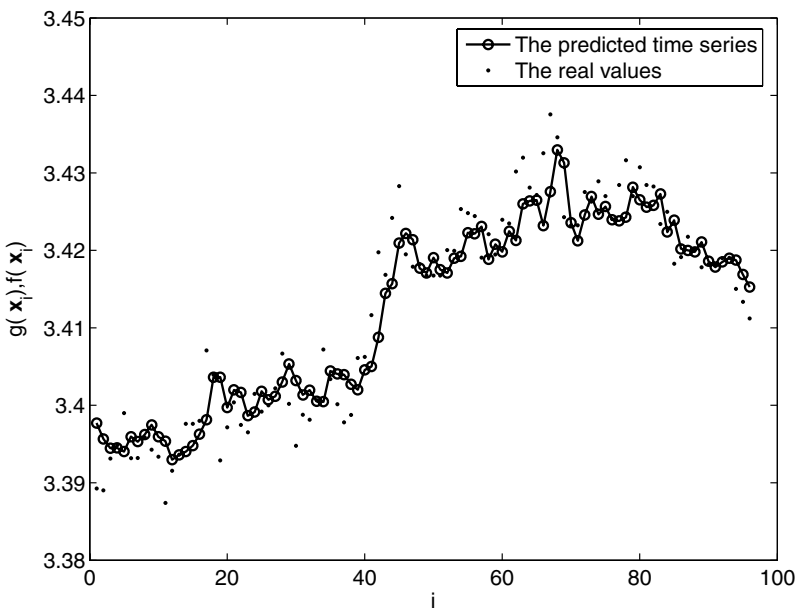

FIG. 5.11. *The one-step prediction of the exchange rate data using a three mode RBF constructed using spatio-temporal balls. The associated errors for this model are:* $RMSE = 0.0043$, $NPE_1 = 0.2760$, $NPE_2 = 0.1033$.

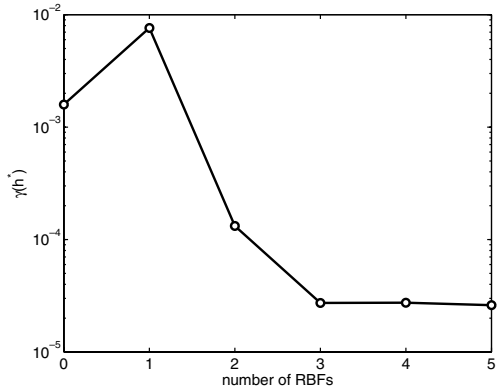
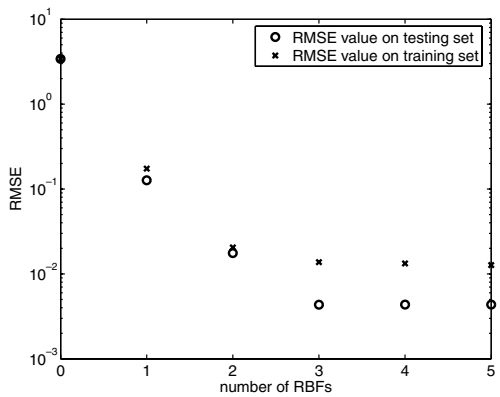
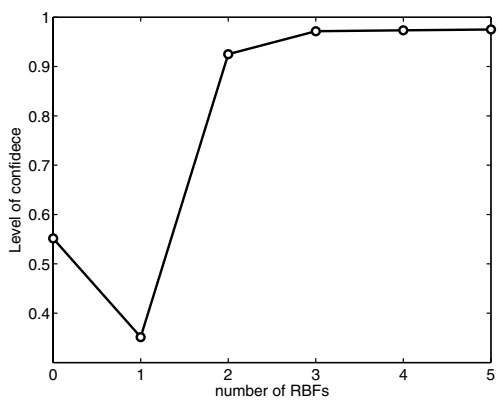
widths $(0.4501, 2.7037, 2.2175, 2.5672, 2.9234)$, $(0.1136, 0.1336, 8.5380, 0.6561, 0.5541)$, and $(0.0555, 0.0358, 0.1740, 0.1939, 0.4015)$, and weights 3.8595, 0.5751, and 1.3805, respectively.



(a) The log plot of $\gamma(h^*)$ as new basis functions are added to the model.



(b) The RMSE log plot of the model as new basis functions are added to the model.



(c) The confidence level of the fitted model as the new basis functions are added to the model.

FIG. 5.12. *The performance of the RBF fit on the exchange rate data set. Note: The confidence level is set at* 97.5% *so one can observe the behavior of the system beyond the* 95% *confidence. Also note that after adding three basis functions, the* 97.17% *of the residuals fall within the confidence bounds.*

The results for this exchange rate data reported in [29] show a model fit with 11 RBFs and the NPE_1 of 0.336. We note that in that study the data was assumed to be online so the results presented here do not compare directly. However, we have observed that the online performance of our algorithm was comparable to the batch mode for the exchange rate data.

Figure 5.13 highlights the patterns in the ACC functions associated with the maximum contributions of the ACFs in the process of adding the first three main RBFs. Note again the need for the spatio-temporal window as evidenced in Figure 5.13(b) and (c). Figure 5.13(b) shows two distinct time regions contributing to the local data., indicating either a periodic or quasi-periodic behavior. Figure 5.13(b) suggests that the remaining structure in the data is distributed across a preponderance of the data. A time-local windowing procedure would not capture this global structure in the data.

5.4. Overview of related work. In this section we review the work that is most similar in spirit to the algorithm presented here. It appears that the first paper to propose a growing algorithm for RBFs is [35]. In this paper, a new RBF is added to the model when the algorithm detects novelty in the input data. Briefly, the criteria for novelty include model error tolerance and the distance threshold between the input pattern and the nearest center. The new input pattern serves as the center of the new RBF, while the width of the RBF relates to a constant multiple of the distance between the new input and its closest center. If any of the criteria are not satisfied, the current model parameters are adjusted using the Widrow–Hoff LMS algorithm [45]. In attempt to achieve more compact networks, a new algorithm referred to as RAN-EKF has been introduced which uses the extended Kalman filter (EKF) instead of the LMS adaptation procedure [23]. Although RAN-EKF can produce more parsimonious models, it requires initialization of additional ad hoc parameters.

A minimal radial basis function neural network (MRAN) was proposed in [46]. MRAN adds a pruning strategy to RAN-EKF [23] that identifies RBFs that have negligible contribution to the overall model output over a number of consecutive inputs with respect to a threshold parameter. Also, MRAN includes an additional criterion that restrains the premature addition of new modes by smoothing the output error over a sliding window. A modified version of MRAN, called EMRAN, which utilizes an additional winner neuron strategy is proposed in [26]. Similarly, an algorithm that uses accumulated error information as a criterion for adding new RBFs is proposed in [15] and [16]. The diameter of the localized units is chosen based on the mutual distances of the RBFs. This modified method generates smaller networks with less training.

In an effort to reduce the number of required ad hoc parameters, a statistical test for adding new units to the network is proposed in [24]. This method, which uses EKF for training, is called incremental network (IncNet). In this model, if the prediction error does not fall within a certain level of confidence for the Z-statistic hypothesis test, then a new RBF will be added to the model.

More recently, a new RAN-EKF algorithm has been proposed that is applicable to both stationary and slowly varying nonstationary problems [29]. Here the novelty criterion involves testing whether the prediction error sequence corresponds to a zero mean Gaussian sequence at the 95% confidence level. A t-statistic is used to determine whether the sequence has zero mean, while the weighted sum squared residual (WSSR) statistic [11] tests the normality of the sequence.

The algorithms described above that employ the results of hypothesis tests to add modes are valid only if the residuals have Gaussian distribution. In addition, perhaps

TABLE 5.1
This table presents a comparison of related RBF algorithms. Note that the proposed algorithm is the only one that applies to the more general case of IID noise.

Algorithm	Noise type	Ad hoc parameters
Platt's RAN	-	7
RAN-EKF	Normal	9
MRAN	Normal	12
IncNet	Normal	5
RAN-WSSR	Normal	6
Full Bayesian	Normal	12
New algorithm	IID	None

more critically, all the algorithms mentioned in this section require careful adjustment of the ad hoc parameters for each data set to which they are applied. See Table 5.1 for a summary of these methods. For further details about the described algorithms and their ad hoc parameters, please see [21].

6. Conclusions. We propose an algorithm for approximating functions from scattered data and compare its performance to the leading algorithms in the literature. To illustrate the absence of ad hoc parameters, all the data sets presented in this paper were fit by exactly the same code. No adjustments were made based on the data set being fit. Hence, we claim that the proposed algorithm is approaching a black-box methodology for nonlinear function approximation. This feature will permit the advancement of a variety of other algorithms, e.g., the representation of data on manifolds as graphs of functions [7, 8], pattern classification [22, 25], as well as the low-dimensional modeling of dynamical systems [9].

It is assumed that the available data represents a functional relationship, or signal, with IID additive noise. Note that if the signal contains multiplicative noise, we can take the natural logarithm of the signal to make it additive. A hypothesis test is applied to the residuals at each step in the algorithm to determine whether a new basis function should be added, and if so, where it should be added. When it has been determined that this test has been passed using the 95% confidence criterion, one may infer that there is no geometric structure left in the residuals, and thus the model order has been found.

We extended previous work by employing a spatio-temporal window, i.e., space-time balls, for determining the local data to be used in updating the model. The examples suggest that this novelty is critical for approximating data over high-dimensional domains and in particular for data generated by dynamical systems. We have observed that significantly more data is located in the space-time balls than the temporal windows previously considered, resulting in the construction of significantly improved models.

In this paper we have assumed that the received signal is composed of additive IID noise, while prior algorithms based on statistical hypotheses are restricted to Gaussian noise. Despite the fact that the IID test provides only a necessary condition, it appears to generate low order models with small RMSE.

We have presented this algorithm for batch data. It is possible to extend this approach for data that arrives in a stream, i.e., online data. Our preliminary results show that this approach does not require the data to be seen repeatedly, as some "online" algorithms require. We will present these results in a companion study. Also, although the algorithm was presented here in the context of growing RBFs, in principle it can be employed with other architectures for fitting nonlinear functions such as feed-forward neural networks.

Acknowledgment. This work benefited from many early discussions with Markus Anderle.

PARALLEL MULTILEVEL RESTRICTED SCHWARZ PRECONDITIONERS WITH POLLUTION REMOVING FOR PDE-CONSTRAINED OPTIMIZATION*

ERNESTO E. PRUDENCIO† AND XIAO-CHUAN CAI‡

Abstract. We develop a class of V-cycle-type multilevel restricted additive Schwarz (RAS) methods and study the numerical and parallel performance of the new fully coupled methods for solving large sparse Jacobian systems arising from the discretization of some optimization problems constrained by nonlinear partial differential equations. Straightforward extensions of the one-level RAS to multilevel do not work due to the pollution effects of the coarse interpolation. We then introduce, in this paper, a pollution removing coarse-to-fine interpolation scheme for one of the components of the multicomponent linear system and show numerically that the combination of the new interpolation scheme with the RAS smoothed multigrid method provides an effective family of techniques for solving rather difficult PDE-constrained optimization problems. Numerical examples involving the boundary control of incompressible Navier–Stokes flows are presented in detail.

1. Introduction.

There are two major families of Newton techniques for solving nonlinear optimization problems: reduced space methods, characterized by the partition of the problem into smaller ones at each Newton step, and full space ones. As computers become more powerful in processing speed and memory capacity, full space methods become more attractive, as exemplified by the Lagrange–Newton–Krylov–Schur [3, 4] and one-level [illegible] [28] methods.

A key element of any successful full space approach is the Jacobian preconditioner, which needs to be able to simultaneously reduce the condition number and provide good parallel scalability [23]. In this paper, we focus on fully coupled Schwarz-type preconditioners in which all components of the linear system are treated equally; i.e., no variables are eliminated as in some Schur complement-type approaches. Among Schwarz-type preconditioners [32, 33], the recently introduced restricted versions [6, 9] seem to be more robust and computationally more efficient, especially for harder problems such as those indefinite, highly ill-conditioned, multicomponent systems arising from PDE-constrained optimizations. The extension of the one-level restricted additive Schwarz method (RAS) to multilevel using the multigrid V-cycle idea and standard coarse-to-fine interpolations is straightforward but may not work as expected due to the pollution effects of the interpolation. After many experiments with some flow control problems, we identified the source of the pollution at one of the three

components of the Jacobian system, namely the Lagrange multiplier. Using a pollution removing interpolation scheme we have then been able to restore the robust and fast convergence of RAS. We discuss only linear versions of Schwarz methods even though nonlinear versions can also be obtained [8, 13]. We refer to [2, 21, 31] for the analysis of some preconditioning techniques for optimal control problems and general saddle point problems.

In this paper we consider only optimization problems with equality constraints:

$$\left\{ \begin{array}{ll} \min\limits_{\mathbf{x}\in\mathbf{W}} & \mathcal{F}(\mathbf{x}) \\ \text{subject to} & \mathbf{C}(\mathbf{x}) = \mathbf{0} \in \mathbf{Y}. \end{array} \right. \tag{1.1}$$

Here $\mathbf{W}$ and $\mathbf{Y}$ are normed spaces, $\mathbf{W}$ is the space of optimization variables, $\mathcal{F} : \mathbf{W} \to \mathbb{R}$ is the objective functional, and $\mathbf{C} : \mathbf{W} \to \mathbf{Y}$. The associated Lagrangian functional $\mathcal{L} : \mathbf{W} \times \mathbf{Y}^* \to \mathbb{R}$ is defined as

$$\mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}) \equiv \mathcal{F}(\mathbf{x}) + \langle \boldsymbol{\lambda}, \mathbf{C}(\mathbf{x}) \rangle_{\mathbf{Y}} \quad \forall\ (\mathbf{x}, \boldsymbol{\lambda}) \in \mathbf{W} \times \mathbf{Y}^*,$$

where $\mathbf{Y}^*$ is the adjoint space of $\mathbf{Y}$, $\langle \cdot, \cdot \rangle_{\mathbf{Y}}$ denotes the duality pairing, and variables $\boldsymbol{\lambda}$ are called Lagrange multipliers or adjoint variables. In many cases it is possible to prove that if $\hat{\mathbf{x}}$ is a (local) solution of (1.1), then there exist Lagrange multipliers $\hat{\boldsymbol{\lambda}}$ such that $(\hat{\mathbf{x}}, \hat{\boldsymbol{\lambda}})$ is a critical point of $\mathcal{L}$. So, under sufficient smoothness assumptions, one proves that a solution has to necessarily solve a system of equations, called the Karush–Kuhn–Tucker (KKT) or optimality system.

For the numerical solution of (1.1) with PDE constraints, generally speaking, there are two families of approaches: [illegible] (OTD) and [illegible] (DTO). In OTD one usually works with constraints in the weak form, derives a KKT system containing both the original constraints and extra PDEs related to the Lagrange multipliers, and only then discretizes it, obtaining a finite dimensional system of nonlinear equations. In DTO one discretizes (1.1) to obtain a finite dimensional optimization problem and then derives the KKT system. The discrete KKT systems from both approaches are [illegible] necessarily the same, and no approach has a clear advantage over the other [18].

In this paper we follow the DTO approach, generating a mesh Ω_h of characteristic size $h > 0$ to obtain a finite dimensional optimization problem with $\mathbf{W} = \mathbb{R}^{n_h}$ and $\mathbf{Y} = \mathbb{R}^{m_h} = \mathbf{Y}^*$. The KKT system becomes $\nabla \mathcal{L}_h(\hat{\mathbf{x}}, \hat{\boldsymbol{\lambda}}) = \mathbf{0} \in \mathbb{R}^{n_h + m_h}$. Omitting symbols "$h$" and "$\hat{\ }$" and denoting $N \equiv n + m$ and $\mathbf{X} \equiv (\mathbf{x}, \boldsymbol{\lambda}) \in \mathbb{R}^N$, one has $\mathcal{L} : \mathbb{R}^N \to \mathbb{R}$ and an optimality system $\nabla \mathcal{L}(\mathbf{X}) = \mathbf{0} \in \mathbb{R}^N$, which we solve by the inexact Newton's method [15, 26] globalized by a line search, according to the heuristic explained in [28].

Let ξ be some real value and $\hat{\mathbf{x}}(\xi)$ denote the solution, if it exists, of the finite dimensional problem

$$\left\{ \begin{array}{lrcl} \min\limits_{\mathbf{x}\in\mathbb{R}^n} & \mathcal{F}(\mathbf{x}) & & \\ \text{subject to} & \mathbf{C}_1(\mathbf{x}) & = & 0, \\ & \vdots & & \\ & \mathbf{C}_{i-1}(\mathbf{x}) & = & 0, \\ & \mathbf{C}_i(\mathbf{x}) & = & \xi, \\ & \mathbf{C}_{i+1}(\mathbf{x}) & = & 0, \\ & \vdots & & \\ & \mathbf{C}_m(\mathbf{x}) & = & 0, \end{array} \right.$$

with arbitrarily fixed $1 \leqslant i \leqslant m$. Under appropriate assumptions, one can prove [16, 29]

$$\frac{\partial \mathcal{F}(\hat{\mathbf{x}}(\xi))}{\partial \xi} \bigg|_{\xi=0} = \lambda_i; \tag{1.2}$$

that is, the Lagrange multiplier λ_i indicates how sensitive the optimal value is to changes on the ith constraint. The module $|\lambda_i|$ gives a measure of how "effective" the corresponding constraint is. In the case of constraints corresponding to the discretized equations of boundary value problems, one might intuitively expect (1) different equations to have different effects on the objective function and (2) the "effectiveness" of a given original PDE constraint to have a "smooth behavior" throughout the domain over which the PDE acts. Such intuitive expectations match result (1.2). One less obvious symptom, however, is the potential discontinuity between those Lagrange multipliers related to PDEs governing the system behavior inside the problem domain and those Lagrange multipliers related to initial and boundary conditions. Indeed, we have observed such discontinuity in our test problems.

The rest of the paper is organized as follows. Section 2 explains multilevel restricted Schwarz preconditioners, and section 3 introduces the pollution removing interpolation. In section 4 we test the combination of both approaches on some boundary flow control problems. Final conclusions are given in section 5.

2. Multilevel restricted Schwarz preconditioners. Schwarz methods can be used in one-level or multilevel variants and, in each case, in combination with additive and/or multiplicative algorithms [33]. They can be also used as linear [14] and nonlinear preconditioners [8, 22].

In this section we introduce a multilevel version of the one-level RAS preconditioner initially studied in [6, 9]. The multilevel preconditioner is applicable to general linear systems arising from the discretized PDEs on a mesh using finite element or finite difference methods. Let $\Omega \subset \mathbb{R}^2$ be a bounded open domain on which a PDE is defined and a discretization is performed with a mesh Ω_h of characteristic size $h > 0$. To obtain the overlapping partition, we first divide Ω_h into nonoverlapping subdomains Ω_j, $j = 1, \ldots, N_S$. We then expand each Ω_j to $\Omega_j^{'}$, i.e., $\Omega_j \subset \Omega_j^{'}$. The overlap $\delta > 0$ is defined as the minimum distance between $\partial\Omega_j^{'}$ and $\partial\Omega_j$, in the interior of Ω. For boundary subdomains we simply cut off the part outside Ω. Let $H > 0$ denote the characteristic diameter of $\{\Omega_j\}$.

Let N and N_j denote the number of degrees of freedom associated to Ω and $\Omega_j^{'}$, respectively. Let $\mathbf{K}$ be a $N \times N$ sparse matrix of a linear system

$$\mathbf{K}\mathbf{p} = \mathbf{b} \tag{2.1}$$

that needs to be solved during the application of an algorithm for the numerical solution of the discretized differential equations. Let d indicate the number of degrees of freedom per mesh point. For simplicity let us assume that d is the same throughout the entire mesh. We define the $N_j \times N$ matrix $\mathbf{R}_j^{\delta}$ as follows: Its $d \times d$ block element $(\mathbf{R}_j^{\delta})_{l_1,l_2}$ is either (a) an identity block, if the integer indices $1 \leqslant l_1 \leqslant N_j/d$ and $1 \leqslant l_2 \leqslant N/d$ are related to the same mesh point and this mesh point belongs to $\Omega_j^{'}$, or (b) a zero block, otherwise. The multiplication of $\mathbf{R}_j^{\delta}$ with a $N \times 1$ vector generates a smaller $N_j \times 1$ vector by discarding all components corresponding to mesh points outside $\Omega_j^{'}$. The $N_j \times N$ matrix $\mathbf{R}_j^{0}$ is similarly defined, with the difference that its

application to a $N \times 1$ vector also zeros out all of those components corresponding to mesh points on $\Omega_j^{'} \setminus \Omega_j$. Let $\tilde{\mathbf{K}}_j$ be defined as

$$\tilde{\mathbf{K}}_j \equiv \mathbf{R}_j^{\delta}\, \mathbf{K}\, \left(\mathbf{R}_j^{\delta}\right)^T,$$

that is, as the $N_j \times N_j$ matrix related to a subdomain problem having zero Dirichlet boundary conditions at regions of $\partial\Omega_j^{'}$ not coinciding with $\partial\Omega$. We assume $\tilde{\mathbf{K}}_j$ to be nonsingular and denote by $\tilde{\mathbf{B}}_j^{-1}$ either the inverse of or a preconditioner for $\tilde{\mathbf{K}}_j$. The one-level classical, right restricted (r-RAS) and left restricted (l-RAS) additive Schwarz preconditioners for $\mathbf{K}$, respectively, are defined as [6, 9, 14]

$$\mathbf{B}_{\delta\delta}^{-1} = \sum_{j=1}^{N_s} \left(\mathbf{R}_j^{\delta}\right)^T \tilde{\mathbf{B}}_j^{-1} \mathbf{R}_j^{\delta}, \quad \mathbf{B}_{\delta 0}^{-1} = \sum_{j=1}^{N_s} \left(\mathbf{R}_j^{\delta}\right)^T \tilde{\mathbf{B}}_j^{-1} \mathbf{R}_j^{0}, \quad \mathbf{B}_{0\delta}^{-1} = \sum_{j=1}^{N_s} \left(\mathbf{R}_j^{0}\right)^T \tilde{\mathbf{B}}_j^{-1} \mathbf{R}_j^{\delta}.$$

When the distinction is not important, we will denote a Schwarz preconditioner simply by $\mathbf{B}^{-1}$. We refer to [17, 24, 25] for further analysis and examples of one-level restricted preconditioning techniques.

For the description of multilevel Schwarz preconditioners [34], let us use the index $i = 0, 1, \ldots, L-1$ to designate any of the $L \geqslant 2$ levels. All previously defined entities using the subindex "j" will now use double subindexes "i, j": $\mathbf{\Omega}_{i,j}$, $\mathbf{\Omega}_{i,j}^{'}$, $N_{i,j}$, $\mathbf{R}_{i,j}^{\delta}$, $\mathbf{R}_{i,j}^{0}$, $\tilde{\mathbf{K}}_{i,j}$, and $\tilde{\mathbf{B}}_{i,j}^{-1}$. All previously defined entities using no subindex will now use the subindex "i": h_i, N_i, $N_{S,i}$, H_i, δ_i, $\mathbf{B}_{i,\delta\delta}^{-1}$, $\mathbf{B}_{i,\delta 0}^{-1}$, $\mathbf{B}_{i,0\delta}^{-1}$, $\mathbf{B}_i^{-1}$, and $\mathbf{K}_i$, with the eventual notation $\mathbf{K}_{L-1} = \mathbf{K}$. The L meshes are not assumed to be either nested or structured. Let $\mathbf{I}_i$ denote the identity operator; for $i > 0$ let

$$\mathcal{I}_i^{i-1} : \mathbb{R}^{N_i} \to \mathbb{R}^{N_{i-1}}$$

denote a linear restriction operator from level i to level $i-1$, and let

$$\mathcal{I}_{i-1}^{i} : \mathbb{R}^{N_{i-1}} \to \mathbb{R}^{N_i}$$

denote a linear interpolation operator from level $i-1$ to level i. Given the iterate used for the computation of $\mathbf{K}_{L-1}$, the computation of coarse matrices $\mathbf{K}_i$ (i.e., $0 \leqslant i \leqslant L-2$) proceeds recursively from the finest coarse level $i = L-2$ until the coarsest level $i = 0$ by simply first restricting or injecting the finer iterate and then computing the Jacobian. Multilevel Schwarz preconditioners are obtained through the combination of one-level Schwarz preconditioners $\mathbf{B}_i^{-1}$ assigned to each level. Here we focus on multilevel preconditioners that can be seen as multigrid (MG) V-cycle algorithms [5] having Schwarz preconditioned Richardson working as the pre- and the postsmoother at each level $i > 0$, with $\mathbf{B}_{i,\mathrm{pre}}^{-1}$ preconditioning the $\mu_i \geqslant 0$ presmoother iterations and $\mathbf{B}_{i,\mathrm{post}}^{-1}$ preconditioning the $\nu_i \geqslant 0$ postsmoother iterations. In a general MG V-cycle algorithm with $L \geqslant 2$ levels, given the current iterate $\mathbf{p}^{(\ell)}$ for the solution of (2.1), the next iterate is computed as $\mathbf{p}^{(\ell+1)} = AlgV(\mathbf{b}, L, \mathbf{p}^{(\ell)})$, where the procedure

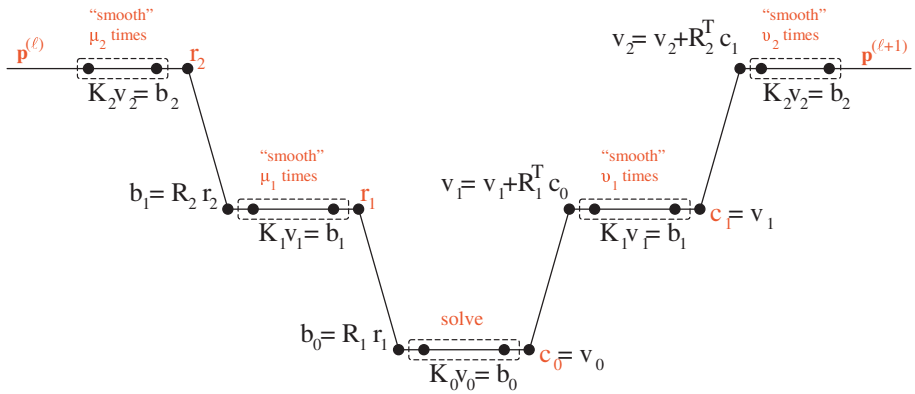

FIG. 2.1. *Graphical representation of a three-level MG V-cycle method:* $\mathbf{r}_1$ *and* $\mathbf{r}_2$ *denote residuals;* $\mathbf{c}_0$ *and* $\mathbf{c}_1$ *denote corrections.*

$\mathbf{v}_i = AlgV(\mathbf{b}_i, i, \mathbf{v}_i)$ consists of the following steps:

if $i = 0$
  Solve $\mathbf{K}_0\mathbf{v}_0 = \mathbf{b}_0$; /* Coarsest correction */
else
  Smooth μ_i times $\mathbf{K}_i\mathbf{v}_i = \mathbf{b}_i$: /* Presmoothing */
  $(\mathbf{b}_i - \mathbf{K}_i\mathbf{v}_i) = (\mathbf{I}_i - \mathbf{K}_i\mathbf{B}_{i,\text{pre}}^{-1})^{\mu_i}(\mathbf{b}_i - \mathbf{K}_i\mathbf{v}_i)$;
  $\mathbf{b}_{i-1} = \mathcal{I}_i^{i-1}(\mathbf{b}_i - \mathbf{K}_i\mathbf{v}_i)$; /* Residual restriction */
  $\mathbf{v}_{i-1} = AlgV(\mathbf{b}_{i-1}, i-1, 0)$; /* Recursivity */
  $\mathbf{v}_i = \mathbf{v}_i + \mathcal{I}_{i-1}^{i}\mathbf{v}_{i-1}$; /* Correction interpolation */
  Smooth ν_i times $\mathbf{K}_i\mathbf{v}_i = \mathbf{b}_i$: /* Postsmoothing */
  $(\mathbf{b}_i - \mathbf{K}_i\mathbf{v}_i) = (\mathbf{I}_i - \mathbf{K}_i\mathbf{B}_{i,\text{post}}^{-1})^{\nu_i}(\mathbf{b}_i - \mathbf{K}_i\mathbf{v}_i)$;
end

In this paper we consider multilevel Schwarz preconditioners with the coarsest correction computed as

$$\mathbf{v}_0 = \mathbf{B}_0^{-1}\mathbf{b}_0,$$

where $\mathbf{B}_0^{-1}$ might denote either a Schwarz preconditioner or an exact solver.

Then, as iterative methods for (2.1), with $\mathbf{r}^{(\ell)}$ denoting the residual at iteration $\ell = 0, 1, 2, \ldots$, such multilevel Schwarz procedures can be described in the case $L = 2$ as

$$\mathbf{r}^{(\ell+1)} = (\mathbf{I}_1 - \mathbf{K}_1\mathbf{B}_{1,\text{post}}^{-1})^{\nu_1}(\mathbf{I}_1 - \mathbf{K}_1\mathcal{I}_0^1\mathbf{B}_0^{-1}\mathcal{I}_1^0)(\mathbf{I}_1 - \mathbf{K}_1\mathbf{B}_{1,\text{pre}}^{-1})^{\mu_1}\mathbf{r}^{(\ell)}. \tag{2.2}$$

In the case of $L = 3$ and the usual choices of $\mathcal{I}_i^{i-1} = \mathbf{R}_i$ and $\mathcal{I}_{i-1}^{i} = \mathbf{R}_i^T$, for some $N_{i-1} \times N_i$ matrix $\mathbf{R}_i$, a graphical representation is given in Figure 2.1.

When classic Schwarz preconditioners are applied to symmetric positive definite systems arising from the discretization of elliptical problems defined in $H_0^1(\Omega)$, the condition number κ of the preconditioned system satisfies $\kappa \leqslant C\,(1 + H/\delta)\,/H^2$ for one-level methods and $\kappa \leqslant C\,(1 + H/\delta)$ for two-level methods, where C is independent of h, H, and δ. The factor $1/H^2$, associated to the number of subdomains on the fine level, relates itself to the increase on the number of iterations (needed for the exchange

of information among distant subdomains) with the increase in the total number of subdomains. The use of a coarse level helps the exchange of information. The necessity of information exchange among distant domain regions can be understood through the expression of the solutions of elliptic problems in terms of Green's functions: Although the solution value at a point strongly depends on surrounding values, there is weaker dependence w.r.t. the entire domain [32]. Regarding the application of two-level methods to indefinite model problems, the study in [10] suggests that the coarse mesh needs to be sufficiently fine for the two-level Schwarz preconditioner to perform well.

Theoretically, however, these results may not be directly applied to the case of symmetric indefinite KKT Jacobians. Let $\overline{\ell}$ be the average number of linear iterations per Newton step. We then look for the following more general properties when applying a two-level preconditioner:

(2.3) For fixed h and H/δ, $\overline{\ell}$ is not very sensitive to H decreasing;

(2.4) for fixed H and δ, $\overline{\ell}$ is not very sensitive to the mesh refinement.

Also, it might happen that a presumed "enhancement" of the preconditioner, aiming to cluster the eigenvalues around 1, eventually results in negative eigenvalues getting too close to 0. Although there is no necessary relationship between the eigenvalue distribution and ill-conditioning for general matrices [27], this process might qualitatively explain an eventual degradation of the linear convergence before it finally gets better [12, p. 199]. So,

(2.5) presumed enhancements of the preconditioner, e.g., an increase of H or δ, eventually result in a worse preconditioned Krylov convergence.

We report such temporary degradation in some of our numerical experiments in section 4.

3. Pollution removing interpolation. The motivation of including, additively or multiplicatively, coarse preconditioners to an existing fine mesh preconditioner is to make the overall preconditioner scalable w.r.t. the number of processors or the number of subdomains. In most cases, the addition of coarse preconditioners reduces the total number of iterations, as expected. However, for some classes of important problems, the unexpected happens: The number of iterations increases when a coarse preconditioner is involved. We refer to this phenomenon as coarse mesh pollution. To figure out the source of the pollution for a general problem is a highly nontrivial task. For the constrained optimization problems being considered we have discovered that the pollution is due to the coarse-to-fine mesh interpolation for one of the three types of variables (state variables, control variables, and Lagrange multipliers) of the problem, namely the Lagrange multipliers [29]. Due to the sharp jumps often encountered on the multiplier values over those regions of Ω where constraints are greatly affecting the behavior of the optimized system, we introduce a new interpolation for these particular components. Such modified interpolation constitutes, indeed, a key procedure in our proposed multilevel preconditioner. Although the evidence of this discontinuity property of Lagrange multipliers is just empirical in this paper, it is consistent with their interpretation (1.2): The value of a Lagrange multiplier at a mesh point gives the rate of change of the optimal objective function value w.r.t. to the respective constraint at that point.

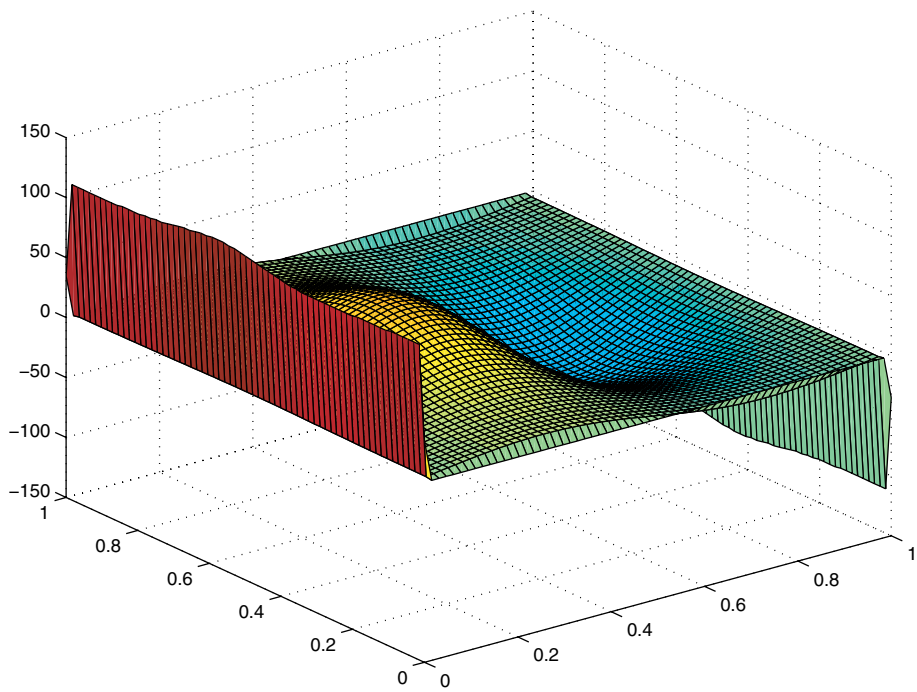

FIG. 3.1. *Lagrange multiplier* $\boldsymbol{\lambda}_1$ *related to the horizontal velocity* $\mathbf{v}_1$ *of a steady-state flow inside a unit square box with rigid slip walls.*

In the case of the problem corresponding to Figure 3.1, for instance, an external force causes the fluid to move clockwise, and the boundary consists of rigid slip walls (see Figure 4.1). The vertical walls greatly affect the overall vorticity throughout the domain, i.e., the value of the objective function, because they completely oppose the horizontal velocity component v_1. The values of λ_1 at the walls then reflect this situation. Similarly, λ_2 develops sharp jumps at the other two walls opposing v_2. In all of our experiments the discontinuities are located only across the boundary and not around it, even for very fine meshes. Common coarse-to-fine interpolation techniques will then smooth the sharp jumps present in coarse solutions, with a more gradual change, from interior mesh points towards boundary mesh points, appearing in those fine cells (elements, volumes) located inside coarse boundary ones, as represented in Figure 3.2(b). That is, the good correction information provided by the coarse solution is lost with a common interpolation. We refer to the smoothed jump as "pollution," in contrast to the "clean" sharp jump that is expected at the fine level as well.

We therefore propose a , , coarse-to-fine interpolation procedure that is based on a general and simple "removal of the pollution." Let $\mathcal{I}_{i-1}^{i}$ denote, as before, any unmodified interpolation operator, while

(3.1) $\boldsymbol{\mathcal{Z}}_i$ is the operator that zeros out, from a vector at level i, the Lagrange multipliers at all of those mesh points with equations that have a greater influence on the objective function.

For the case of PDEs describing physical systems, the number of such points can be expected to be relatively small. Our modified interpolation is then expressed by

$$\mathcal{I}_{i-1,\text{modif}}^{i} = \mathcal{I}_{i-1}^{i} - \boldsymbol{\mathcal{Z}}_i \mathcal{I}_{i-1}^{i} (\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}). \tag{3.2}$$

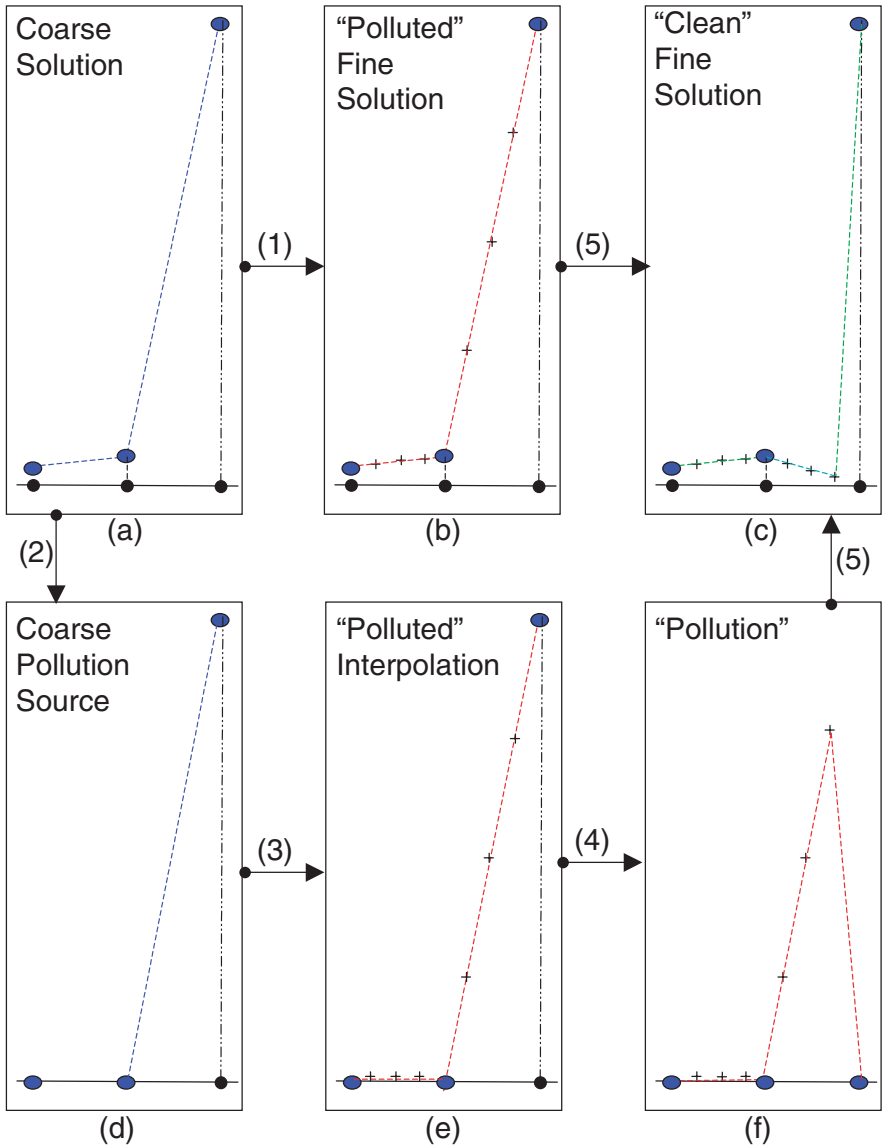

FIG. 3.2. *Representation of the modified coarse-to-fine interpolation* (3.2)*, with* (a) *input* $\boldsymbol{\varphi}_{i-1}$ *and* (c) *output* $\boldsymbol{\varphi}_i$*. The five steps are* (1) *interpolation* $\mathcal{I}_{i-1}^{i}\boldsymbol{\varphi}_{i-1}$*,* (2) *coarse jump values* $\tilde{\boldsymbol{\varphi}}_{i-1} = (\mathbf{I}_{i-1} - \mathcal{Z}_{i-1})\boldsymbol{\varphi}_{i-1}$*,* (3) *polluted* $\tilde{\boldsymbol{\varphi}}_i = \mathcal{I}_{i-1}^{i}\tilde{\boldsymbol{\varphi}}_{i-1}$*,* (4) *pollution isolation* $\mathcal{Z}_i\tilde{\boldsymbol{\varphi}}_i$*, and* (5) *pollution removal* $\boldsymbol{\varphi}_i = \mathcal{I}_{i-1}^{i}\boldsymbol{\varphi}_{i-1} - \mathcal{Z}_i\tilde{\boldsymbol{\varphi}}_i$*.*

This procedure removes the smoothed contributions due to the coarse discontinuities, maintaining, at the fine level, the sharp jumps originally present at the coarse level. It should be noted that the operator $\mathcal{I}_{i-1}^{i}$ is usually available for the coding of a multilevel procedure, and, once the locations where the operator $\boldsymbol{\mathcal{Z}}_i$ needs to act over are known, the implementation of (3.2) is extremely easy and can be performed on ' ' mesh in ' ' dimension, with ' ' number of components.

The Lagrange multipliers reflect an eventual "discontinuity" of the type of equations (or their physical dimensions) between equations in different regions of $\overline{\Omega}$. From

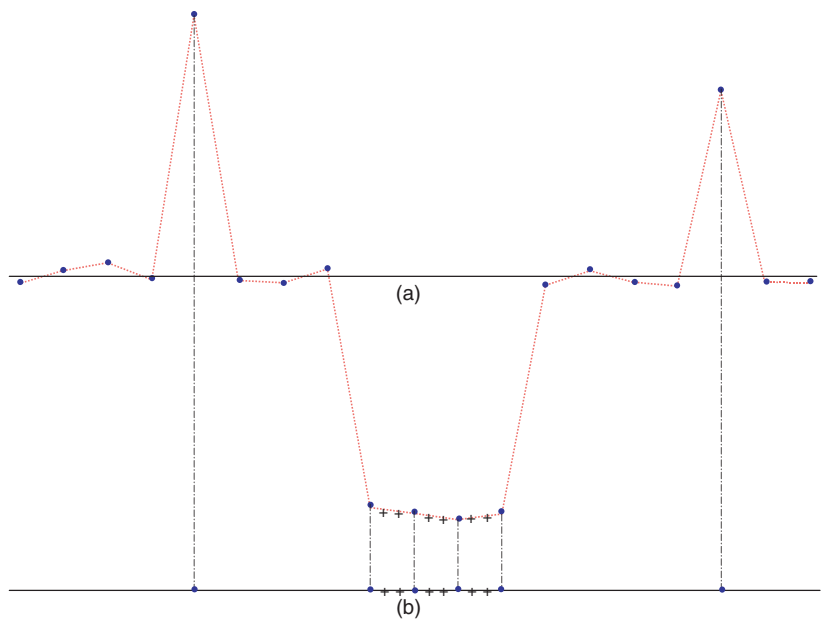

FIG. 3.3. (a) *A schematic example of a possible distribution of Lagrange multiplier components throughout a coarse mesh at level* $i-1$. (b) *The corresponding coarse (and fine) mesh points where the operator* $\mathcal{Z}_{i-1}$ *(and* $\mathcal{Z}_i$*) would act over. The plus sign refers to the fine mesh points where* $\mathcal{Z}_i$ *would act over as well.*

this point of view, it seems "natural" to apply different interpolations to the Lagrange multipliers depending on their location on $\overline{\Omega}$. In the case of the problems in section 4, for instance, a clear difference exists between those equations in Ω and those on $\partial\Omega$, that is, for those problems the operator $\boldsymbol{\mathcal{Z}}_i$ zeros the Lagrange multiplier components located at the boundary. A schematic representation of (3.2) for such a situation is then given in Figure 3.2 for the simpler case of a piecewise linear interpolation. However, the modified interpolation (3.1)–(3.2) is [illegible] at all restricted to situations where the discontinuities are located at the boundary. Figure 3.3(a) gives a schematic example where Lagrange multiplier discontinuities are spread throughout different regions of the domain. With the specification of the region where the operator $\boldsymbol{\mathcal{Z}}_i$ acts over, given by Figure 3.3(b), the pollution (smoothed jumps) created by the usual interpolation operators $\mathcal{I}_{i-1}^{i}$ will be removed in a way similar to the way exemplified in the simpler situation of Figure 3.2.

Whatever the shape of the Lagrange multipliers in the final solution of a PDE-constrained optimization problem, the eventual sharp jumps will tend to appear more on the first Newton steps and, at each Newton iteration, on the coarse corrections related to the first Krylov iterations. As both Newton and Krylov iterations progress towards the respective solutions, the steps and corrections will naturally shrink in magnitude. Nonetheless, even when sharp jumps are not involved anymore, the modified interpolation can still be applied with no harm: The interpolation of an eventual smooth coarse correction with small values on the Lagrange multiplier components will still present small values at the fine level. This fact facilitates the programming of (3.1)–(3.2), since the application of the modified interpolation is not conditional.

In our tests we apply the modified interpolation only for the Lagrange multiplier components of coarse corrections, while the optimization variables continue to be

interpolated with the unmodified process $\mathcal{I}_{i-1}^{i}$. Also, the restriction process remains $\mathcal{I}_{i}^{i-1}$ for all variables; i.e., (2.2) becomes

$$\mathbf{r}^{(\ell+1)} = (\mathbf{I}_1 - \mathbf{K}_1\mathbf{B}_{1,\text{post}}^{-1})^{\nu_1}(\mathbf{I}_1 - \mathbf{K}_1\mathcal{I}_{0,\text{modif}}^{1}\mathbf{B}_0^{-1}\mathcal{I}_1^0)(\mathbf{I}_1 - \mathbf{K}_1\mathbf{B}_{1,\text{pre}}^{-1})^{\mu_1}\mathbf{r}^{(\ell)}.$$

Three important aspects of our algorithm should be highlighted before we proceed. First, operator (3.2) is nonlinear, even for linear operators $\mathcal{I}_{i-1}^{i}$. The multilevel preconditioner is then nonlinear as well. The linearity of preconditioners is theoretically desired, because one can then guarantee the same solution when going from the original system (2.1) to the preconditioned one. In our tests, however, the same solution was obtained with both linear and nonlinear preconditioners.

Second, the application of the modification process to an already modified interpolation operator gives the same modified operator: Denoting

$$\mathcal{I}_{i-1,\text{modif,modif}}^{i} = \mathcal{I}_{i-1,\text{modif}}^{i} - \boldsymbol{\mathcal{Z}}_i\mathcal{I}_{i-1,\text{modif}}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}),$$

we have

$$\begin{aligned}
\boldsymbol{\mathcal{Z}}_i\mathcal{I}_{i-1,\text{modif}}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}) &= \boldsymbol{\mathcal{Z}}_i\left[\mathcal{I}_{i-1}^{i} - \boldsymbol{\mathcal{Z}}_i\mathcal{I}_{i-1}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1})\right](\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}) \\
&= \boldsymbol{\mathcal{Z}}_i\left[\mathcal{I}_{i-1}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}) - \boldsymbol{\mathcal{Z}}_i\mathcal{I}_{i-1}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1})^2\right] \\
&= \boldsymbol{\mathcal{Z}}_i\left[\mathcal{I}_{i-1}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}) - \boldsymbol{\mathcal{Z}}_i\mathcal{I}_{i-1}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1})\right] \\
&= \boldsymbol{\mathcal{Z}}_i(\mathbf{I}_i - \boldsymbol{\mathcal{Z}}_i)\mathcal{I}_{i-1}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}) \\
&= (\boldsymbol{\mathcal{Z}}_i - \boldsymbol{\mathcal{Z}}_i^2)\mathcal{I}_{i-1}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}), \\
&= (\boldsymbol{\mathcal{Z}}_i - \boldsymbol{\mathcal{Z}}_i)\mathcal{I}_{i-1}^{i}(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1}),
\end{aligned}$$

the null operator. This result might be important for eventual theoretical demonstrations of preconditioning properties.

Third, procedure (3.2) assumes that

(3.3) the neighborhood of the mesh points where operator $\boldsymbol{\mathcal{Z}}_i$ acts upon has Lagrange multipliers with values close to zero,

so that the term $(\mathbf{I}_{i-1} - \boldsymbol{\mathcal{Z}}_{i-1})$ reflects the true relative discontinuity between the Lagrange multiplier values at the points where operator $\boldsymbol{\mathcal{Z}}_i$ acts upon (acting points) and the Lagrange multiplier values at the neighboring points. If (3.3) is not valid, then operator $\boldsymbol{\mathcal{Z}}_{i-1}$ in (3.2) should be replaced by an operator $\boldsymbol{\mathcal{T}}_{i-1}$ that sets the Lagrangian multiplier values at the acting points equal to the neighboring values instead. In the case of OTD approaches, where explicit PDEs and boundary conditions are obtained for the Lagrange multipliers before discretization, the correct extension of values from the neighboring to the acting points might be known ahead of time; otherwise, the implementation of $\boldsymbol{\mathcal{T}}_{i-1}$ would be more difficult than that of $\boldsymbol{\mathcal{Z}}_{i-1}$. However, we expect (3.3) to be valid for many optimization problems of physical systems, e.g., (4.1)–(4.2) in section 4.

We remark that pollution removing is an efficient way of dealing with the potential discontinuity between Lagrange multipliers related to PDEs and Lagrange multipliers related to boundary constraints, and it does not assume that the latter constitute the traces of the former. In the case of DTO, the Lagrange multipliers are already finite dimensional vectors in their first appearance in the solution process, and so one does not need to deal with traces. Since the collection of mesh points associated to

a PDE and the collection of mesh points associated to the corresponding boundary conditions are disjoint and cover the entire mesh, it is convenient, for implementation purposes, to join Lagrange multipliers into a unique programming variable defined over the entire mesh and suitable for the application of pollution removing.

4. Numerical experiments. Our numerical experiments in this paper focus on optimal control problems [19], where the optimization space in (1.1) is generally given by $\mathbf{W}=\mathbf{S}\times\mathbf{U}$, with $\mathbf{S}$ being the state space and $\mathbf{U}$ the control space. More specifically, we treat the boundary control of two-dimensional steady-state incompressible Navier–Stokes equations in the velocity-vorticity formulation [20]: $\mathbf{v}=(v_1,v_2)$ is the velocity and ω is the vorticity. Let $\Omega\subset\mathbb{R}^2$ be an open and bounded smooth domain, $\Gamma=\partial\Omega$ its boundary, $\boldsymbol{\nu}$ the unit outward normal vector along Γ, and $\mathbf{f}$ a given external force defined in Ω. Let $L^2(\Omega)$ and $L^2(\Gamma_u)$ be the spaces of square Lebesgue integrable real functions in Ω and $\Gamma_u\subset\Gamma$, respectively. The control problems consist on finding $(\mathbf{s},\mathbf{u})=(v_1,v_2,\omega,u_1,u_2)\in\mathbf{S}\times\mathbf{U}=L^2(\Omega)^3\times L^2(\Gamma_u)^2$ such that the minimization

$$\min_{(\mathbf{s},\mathbf{u})\in\mathbf{S}\times\mathbf{U}}\mathcal{F}(\mathbf{s},\mathbf{u})=\frac{1}{2}\int_\Omega\omega^2\,d\Omega+\frac{c}{2}\int_{\Gamma_u}\|\mathbf{u}\|_2^2\,d\Gamma_u \tag{4.1}$$

is achieved subject to the constraints

$$\left\{\begin{array}{lcll}
-\Delta v_1-\dfrac{\partial\omega}{\partial x_2} & = & 0 & \text{in } \Omega,\\
-\Delta v_2+\dfrac{\partial\omega}{\partial x_1} & = & 0 & \text{in } \Omega,\\
-\Delta\omega+\text{Re } v_1\dfrac{\partial\omega}{\partial x_1}+\text{Re } v_2\dfrac{\partial\omega}{\partial x_2}-\text{Re curl } \mathbf{f} & = & 0 & \text{in } \Omega,\\
v_i-v_{D,i} & = & 0 & \text{on } \Gamma_{D,i},\quad i=1,2,\\
\dfrac{\partial v_i}{\partial\boldsymbol{\nu}}-v_{N,i} & = & 0 & \text{on } \Gamma_{N,i},\quad i=1,2,\\
\mathbf{v}-\mathbf{u} & = & \mathbf{0} & \text{on } \Gamma_u,\\
\omega+\dfrac{\partial v_1}{\partial x_2}-\dfrac{\partial v_2}{\partial x_1} & = & 0 & \text{on } \Gamma,\\
\int_\Gamma\mathbf{v}\cdot\boldsymbol{\nu}\,d\Gamma & = & 0, &
\end{array}\right. \tag{4.2}$$

where curl $\mathbf{f}=-\partial f_1/\partial x_2+\partial f_2/\partial x_1$ and, for $i=1,2$, $\Gamma=\Gamma_{D,i}\cup\Gamma_{N,i}\cup\Gamma_u$ and $\Gamma_{D,i}$ ($\Gamma_{N,i}$) is the part of the boundary where the velocity component v_i is specified through a Dirichlet (Neumann) condition with a prescribed velocity $v_{D,i}$ ($v_{N,i}$). The parameter $c>0$ is used to adjust the relative importance of the control norms in achieving the minimization, so indirectly constraining their sizes. The physical objective in (4.1)–(4.2) is the minimization of turbulence [18]. The last constraint is necessary for consistency with the physical law of mass conservation, making $m\neq n_s$ and causing the complexity of the parallel finite difference approximation of Jacobians to increase, since nonadjacent mesh points become coupled by the integral. An alternative formulation, that compromises between the physical law of mass conservation and the complex computation of Jacobians, eliminates the integral constraint but adds to the objective function the term $\tilde{c}\left[\int_\Gamma\mathbf{v}\cdot\boldsymbol{\nu}\,d\Gamma\right]^2/2$, with $\tilde{c}\gg 1$ [4]. We restrict our numerical experiments to [illegible] boundary control problems, i.e., $\mathbf{u}\cdot\boldsymbol{\nu}=0$ on Γ_u, and the velocity $\mathbf{v}$ is assumed to guarantee mass conservation along $\Gamma\setminus\Gamma_u$, so that $m=n_s$.

We consider rectangular domains $\Omega=(0,L_1)\times(0,L_2)$, $L_2\leqslant L_1$. We define $E_1=\{(x_1,0)\in\mathbb{R}^2:0<x_1<L_1\}$, $E_{1,a}=\{(x_1,x_2)\in E_1:0<x_1\leqslant L_2\}$, $E_{1,b}=$

$E_1 \setminus E_{1,a}$, $E_2 = \{(L_1, x_2) \in \mathbb{R}^2 : 0 < x_2 < L_2\}$, $E_3 = \{(x_1, L_2) \in \mathbb{R}^2 : 0 < x_1 < L_1\}$, $E_4 = \{(0, x_2) \in \mathbb{R}^2 : 0 < x_2 < L_2\}$, $E_{4,a} = \{(x_1, x_2) \in E_4 : \frac{L_2}{2} \leqslant x_2 < L_2\}$, and $E_{4,b} = E_4 \setminus E_{4,a}$, $C_1 = (0, 0)$. Two flow problems are considered: cavity and backward-facing step. In each case we consider both simulation problems and tangential boundary control problems. In the descriptions below we define only Γ_u and the velocity boundary conditions on $\Gamma \setminus \Gamma_u$, since all control problems seek the minimization of the objective function (4.1) with $c = 10^{-2}$ and have in common the three PDEs in Ω, the ω boundary condition on Γ, and the tangential boundary control on Γ_u. In the case of [illegible] flows, $L_1 = L_2 = 1$, $\Gamma_u = \Gamma$, and $\mathbf{f} = (f_1, f_2) = \big(-\sin^2(\pi x_1)\cos(\pi x_2)\sin^2(\pi x_2), \sin^2(\pi x_2)\cos(\pi x_1)\sin^2(\pi x_1)\big)$. In the case of [illegible] flows, $L_1 = 6$, $L_2 = 1$, $\Gamma_u = E_{4,b} \cup \{C_1\} \cup E_{1,a}$, and $\mathbf{f} = \mathbf{0}$. The velocity boundary conditions on $\Gamma \setminus \Gamma_u$ are $v_1 = 0$ on $E_{1,b} \cup \overline{E_3}$, $v_1 = 8(1 - x_2)(x_2 - 1/2)$ on $E_{4,a}$, $v_1 = x_2(1 - x_2)$ on $\overline{E_2}$, and $v_2 = 0$. All corresponding simulation problems, used for comparison with control problems, impose $\mathbf{v} \cdot \boldsymbol{\nu} = 0$ and $\partial \mathbf{v}/\partial \boldsymbol{\nu} = 0$ on Γ_u; i.e., Γ_u becomes a (set of) slip rigid wall(s).

4.1. Details of numerical approaches. We use a five-point second order finite difference method on a uniform nonstaggered mesh. We divide the horizontal edges on $N_{1,\mathrm{div}}$, equally spacing subintervals, and the vertical edges on $N_{2,\mathrm{div}}$, also equally spacing subintervals, generating a rectangular grid with a total of $N_g = (1+N_{1,\mathrm{div}})(1+N_{2,\mathrm{div}})$ points. We denote $h_1 = L_1/N_{1,\mathrm{div}}$ and $h_2 = L_2/N_{2,\mathrm{div}}$. Each grid point is assigned an integer index k and denoted $\mathbf{x}_k = (x_{1,k}, x_{2,k})$, $k \in K = \{k \in \mathbb{N},\ 0 \leqslant k < N_g\}$. K_b is the set of indexes related to the $N_b = 2(N_{1,\mathrm{div}} + N_{2,\mathrm{div}})$ grid points located at the boundary, l_k is the elementary boundary length surrounding a point $\mathbf{x}_k$, $k \in K_b$, and a_k is the elementary area surrounding a point $\mathbf{x}_k$, $k \in K$; that is,

$$l_k = h_1(\text{or } h_2),\ a_k = \frac{h_1 h_2}{2} \text{ for points on horizontal (or vertical) edges,}$$

$$l_k = \frac{h_1 + h_2}{2},\ a_k = \frac{h_1 h_2}{4} \text{ for points on corners,}$$

and $a_k = h_1 h_2$ for $k \in K \setminus K_b$. The total number of discrete state variables is $n_s = 3N_g$. For code implementation convenience, both discrete control components are defined everywhere in the domain; i.e., the total number of discrete control variables is $n_u = 2N_g$. There is no problem with such an approach since all control components not used as Dirichlet controls (i.e., not appearing in the constraints) are automatically forced to zero in the optimality system. The discrete state space is $\mathbf{S}_h = \mathbb{R}^{n_s}$, and the discrete control space is $\mathbf{U}_h = \mathbb{R}^{n_u}$. The discretized version of (4.1) then reads

$$\min_{(\mathbf{s},\mathbf{u}) \in \mathbf{S}_h \times \mathbf{U}_h} \mathcal{F}_h(\mathbf{s}, \mathbf{u}) = \frac{1}{2} \sum_{k \in K} \omega_k^2 a_k + \frac{c}{2} \sum_{k \in K_b} \|\mathbf{u}_k\|_2^2 l_k + \frac{c}{2} \sum_{k \in K \setminus K_b} \|\mathbf{u}_k\|_2^2 a_k.$$

All derivative terms in (4.2) are discretized with a second order scheme, including the ω boundary condition. For parallel performance reasons, only mesh points adjacent to the boundary are used by applying the definition $\omega = -\partial v_1/\partial x_2 + \partial v_2/\partial x_1$ at these points as well [28].

In order to form the algebraic system of nonlinear discretized equations, we need to order the unknowns and the corresponding functions. The unknowns are ordered mesh point by mesh point, in contrast to physical variable by physical variable as usually required by other methods. At each mesh point the unknowns are ordered as $v_1, v_2, \omega, u_1, u_2, \lambda_1, \lambda_2$, and λ_3. The mesh points are ordered subdomain by subdomain, for the purpose of parallel processing. The ordering of the subdomains is

not important, since we use, at each level other than the coarsest, additive methods whose performance has nothing to do with the subdomain ordering. In order to avoid pivoting during the sparse LU method (used in our experiments), the corresponding functions are ordered as $\nabla_{\lambda_1}\mathcal{L}$,$\nabla_{\lambda_2}\mathcal{L}$,$\nabla_{\lambda_3}\mathcal{L}$, $\nabla_{u_1}\mathcal{L}$,$\nabla_{u_2}\mathcal{L}$, $\nabla_{v_1}\mathcal{L}$,$\nabla_{v_2}\mathcal{L}$, and $\nabla_{\omega}\mathcal{L}$. Because the orderings for the unknowns and for the function components are different, the Jacobian matrix becomes nonsymmetric and so we use GMRES [30].

The Jacobian matrix is constructed approximately using a multicolored central finite difference method [11] with step size 10^{-5}. In problem (4.1)–(4.2), since there is no variable with power greater than two, central finite difference approximations of the Jacobian are exact up to roundoff errors. To solve the Jacobian systems we use restarted GMRES with an absolute (relative) tolerance equal to 10^{-8} (10^{-4}), a restart parameter equal to 90, and a maximum number of iterations equal to 5,000. When using left preconditioning, the GMRES tolerances are checked over preconditioned residuals. Regarding the one-level additive Schwarz preconditioner, the number of subdomains is equal to the number of processors, and the extended subdomain problems have zero Dirichlet interior boundary conditions and are solved with sparse LU. All subdomains Ω_j and $\Omega_j^{'}$ are rectangular and made up of an integral number of mesh cells. The computation of coarse matrices at each Newton iteration proceeds recursively from the finest coarse level until the coarsest level by simply first injecting the finer iterate and then computing the Jacobian. We use nested meshes, the redundant LU solver at the coarsest level (all processors construct and solve a full coarsest linear system by sending their local portions of the Jacobian and of the right-hand side to all other processors), and the interpolation is piecewise linear. Richardson smoothers are all used with a damping factor equal to 1. A line search is performed with an augmented Lagrangian merit function and cubic backtracking. For Newton iterations, the maximum allowed number is 100 and the absolute (relative) stopping tolerance is 10^{-6} (10^{-10}). Simulation problems are solved with Newton–Krylov–Schwarz [7]. We do not use Reynolds continuation in any of the algorithms.

If not stated otherwise, the modified interpolation process explained in section 3 is always used in multilevel tests.

4.2. Results of numerical experiments. We have performed tests on a cluster of Linux PCs and developed our parallel object-oriented software using the C++ programming language and the Portable, Extensible Toolkit for Scientific Computing (PETSc) from Argonne National Laboratory [1]. Since the cluster network is relatively slow and is shared with other processes, and since the redundant LU solver used at the coarsest level is not scalable in time w.r.t. the number of processors, our analysis focuses on the number of Newton and Krylov iterations, not on computing times.

4.2.1. Cavity flows. Figure 4.1(b) shows the controlled velocity field for the cavity flow with Re = 200: Although the fluid in the interior follows the clockwise direction imposed by the external force, the movement near the boundary is much less intense than in Figure 4.1(a). In fact, a zoom on the boundary velocity of Figure 4.1(b) shows the control acting in the counterclockwise way, making the integral of ω^2 on Ω decrease from the value of 55.4 for the simulation with slip walls to the controlled value of 32.5. Figure 3.1 shows the sharp jump of the Lagrangian multiplier function λ_1 at the boundary. The other two Lagrangian multipliers behave similarly, no matter how fine the mesh is.

Tables 4.1–4.4 show results for one-level preconditioners. In Tables 4.1–4.2 we fix the mesh size in 280×280 and the preconditioning side to , . Then, for Re = 200 and 300, respectively, we perform tests with 25 and 49 processors, varying the combi-

nations of Schwarz preconditioner type (ASM, l-RAS, or r-RAS) and relative overlap (1/8, 1/4, or 1/2). In Table 4.3, we do the same for $\mathrm{Re} = 300$, only fixing the preconditioning side to [illegible]. Most of the results in these first three tables are consistent with the behavior of one-level Schwarz preconditioners for positive-definite systems: The average number $\overline{\ell}$ of Krylov iterations per Newton iteration grows with the number N_p of processors and decreases as the overlap gets larger. Whenever some Newton step demanded 5,000 Krylov iterations to be computed, the overall test was considered to fail. This was the case in the six tests not reported in Tables 4.2 and 4.3.

The results in these first three tables suggest that the more robust combination is the [illegible] δ/H 1/2, which is then fixed for the next set of tests, shown in Table 4.4, with varying Re, mesh size, and number of processors, with the number of processors going up to 100 now. However, even with the pretty large relative overlap $\delta/H = 1/2$, the method fails for Re17 = 250 with 100 processors.

Clearly, then, some stabilization is needed. This stabilization is achieved with the use of a coarse mesh and the modified interpolation process explained in section 3. The

results so far suggest that one can focus on RAS preconditioners on the Richardson smoothers and not use ASM. We, however, made some experiments with an ASM preconditioned smoother, and in all cases the preconditioned GMRES diverged, with either left or right preconditioning. We also tried to avoid tests with $\delta = H/2$ as well, in order to check if the two-level method can be used with smaller and larger overlaps.

In Table 4.5 we fix the mesh size in 280×280 the preconditioning side to , , , and, for Re = 200 and 250, we test two-level Schwarz with 25 and 49 processors, varying the

combinations of Schwarz preconditioner type (l-RAS or r-RAS) and relative overlap (1/8 or 1/4). The method with left preconditioning diverges in many cases. The divergences were caused by the fact that the true linear residuals at the Newton steps did not decrease as much as the preconditioned linear residuals used for the Krylov stopping criteria. The overall algorithm then failed after some Newton iterations, either by computing steps that did not provide descent directions or by computing step lengths too small.

In Tables 4.6–4.8 we do basically the same as in Table 4.5, but now we fix the preconditioning side to $\mathcal{M}_{l,r}$ and test up to Re $= 300$ and 100 processors. In the case of Re $= 300$ (Table 4.8) the method demanded too many iterations for convergence with $\delta = H/8$, and so we report experiments with $\delta = H/2$.

It is interesting to observe in Tables 4.7 and 4.8 that, fixing the overlap, one of the RAS smoothers (l-RAS or r-RAS) causes the preconditioner to converge with a smaller average number of Krylov iterations for 25 subdomains, while the other RAS smoother contributes for a better average Krylov convergence in the case of 100 subdomains. That is, there is no concept such as a unique RAS version that is always the best smoother for all possible number of processors.

Based on the results of Tables 4.6–4.8, we perform the tests shown in Tables 4.9–4.11, where we fix the preconditioning side to $\mathcal{M}_{l,r}$ and vary Re, mesh size, and the

number of processors. Clearly, the two-level method performed in a very robust way, solving problems for which the one-level version has previously failed. In all three Tables 4.9–4.11, the average number $\overline{\ell}$ of Krylov iterations per Newton iteration is kept stable in the tested range of mesh size and number of processors. The results are consistent with predictions (2.3)–(2.4): In each column of the tables, $\overline{\ell}$ is not very sensitive to the increase in the number N_p of processors (prediction (2.3)), and, in each line of the tables, $\overline{\ell}$ is not too sensitive to mesh refinement (prediction (2.4)).

As intuitively expected, the Jacobian ill-conditioning gets worse as we increase Re and refine the mesh, demanding Schwarz preconditioning with bigger overlap and/or more smoothing iterations.

Many of the results reported so far, for both one-level and two-level Schwarz preconditioners, might be related to comment (2.5). Namely, the fact that the average number of Krylov iterations per Newton step gets eventually worse with an increase in the size H of subdomains or in the overlap δ. Such behavior is "strange" if we consider the literature results on the application of Schwarz preconditioners to the solution of positive definite systems. In the case of one-level tests, examples of strange results exist in Table 4.2, with 49 processors, and in Table 4.3, also with 49 processors. In the case of two-level tests, examples of strange results exist in Table 4.5, with Re $= 200$ and with Re $= 250$, a l-RAS preconditioner, and relative overlap $\delta/H = 1/4$, in Table 4.7, with a l-RAS preconditioner and relative overlap $\delta/H = 1/8$, and in Table 4.8, with a l-RAS preconditioner.

Figures 4.2(a) and 4.2(b) clearly show the stabilization on the average number of Krylov iterations provided by the two-level preconditioner with modified interpolation. The one-level preconditioner fails with 100 processors for Re = 250 and Re = 300.

Table 4.12 shows the efficacy of the modified interpolation process, which performs much better than the unmodified one, causing the two-level preconditioner to outperform the one-level preconditioner.

4.2.2. Backward-facing step flows. The numerical behavior observed in these problems is very different than the one observed in the cavity flows of the previous section. The backward-facing step problems demand more Newton iterations, but the

computation of each Newton step is easier. In fact, the one-level Schwarz preconditioner now works for problems with 100 processors for all three Re = 200, 250, and 300, the same happening for the two-level method with the polluted (unmodified) interpolation procedure. Also, similarly to the case of positive-definite systems, a left preconditioner now works better than a right preconditioner, as shown by Tables 4.13 and 4.14.

Nonetheless, the pollution-free two-level RAS preconditioner was the best choice, as exemplified by Table 4.15, where the use of the modified interpolation decreases the

average number of Krylov iterations by a further factor of two w.r.t. the unmodified interpolation. Figures 4.3(a) and 4.3(b) also show the stabilization on the average number of Krylov iterations provided by the preconditioner. Finally, as in the case of cavity flow control problems, Figure 4.3(b) is consistent with prediction (2.3).

5. Conclusions. We have developed a parallel multilevel Schwarz preconditioner that has shown a robust performance when tested on some tangential boundary flow control problems. With such a preconditioner we were able to extend the one-level Lagrange–Newton–Krylov–Schwarz presented in [28, 29] to a multilevel method.

Our algorithm works well for the discretize-then-optimize approach and has yet to be tested with an optimize-then-discretize approach.

In general, the success of Lagrange–Newton methods with a line search rests on four tasks: the computation of the Jacobian, the computation of a Newton step with descent direction, the choice of a penalty parameter in the merit function, and the computation of the step length. Although we addressed all of these issues in our work, our main contribution in this paper consists in the combination of a general multigrid V-cycle preconditioner with (1) RAS preconditioned Richardson smoothers and (2) a modified interpolation procedure that removes the pollution often generated by the application of common interpolation techniques to the Lagrange multipliers. Such a combination is the key for the successful application of the two-level Schwarz preconditioner in our experiments and the consequent improvement over the one-level method, handling flow control problems with higher Reynolds number, finer meshes, and more processors. Surprisingly, RAS preconditioners performed much better than the classical ones.

We expect multilevel pollution removing preconditioners to have a wide application in many scientific and engineering applications.

MIXED HIGHER ORDER SPECTRAL FINITE ELEMENTS FOR REISSNER–MINDLIN EQUATIONS*

G. COHEN† AND P. GROB‡

Abstract. We construct a class of high order numerical approximations for the Reissner–Mindlin plate model in the time domain, based on mixed spectral finite elements with mass lumping. In this way we obtain explicit time-stepping schemes. We first compare the Reissner–Mindlin model to three-dimensional (3D) solutions to validate our method. Then, we show the advantages of the schemes in terms of accuracy and computational time.

Key words. Reissner–Mindlin plate model, higher order spectral elements, mass lumping

Introduction. The study of vibrations of thin structures is important for many industrial applications. Each of these applications is concerned with numerical simulation on large frequency bandwidths. To avoid having to solve a large linear system for each frequency (which is very costly), it can be efficient to compute the solution in the time domain and to reconstitute the solution in the harmonic domain by an FFT method, for example. In this paper, we consider the Reissner–Mindlin–Naghdi (cf. [15], [17], [19], [20]) plate model in the time domain. This model is more general than that of Kirchhoff–Love (KL), which takes into account shear strain and makes it possible to treat the case of thick plates. Furthermore, we can use H^1-conforming finite elements, while the KL model a priori requires H^2-conforming finite elements. However, we have to deal with vectorial unknowns, and the shear strain terms induce numerical locking which is essentially bad convergence of the finite element method when the thickness tends to zero [1], [4], [6], [7]. To the best of our knowledge, the numerical analysis of the Reissner–Mindlin equations in the time domain is not well understood. We show in this paper the utility of using mixed spectral finite elements with mass lumping (cf. [9], [14]). This method is known to be robust and efficient for the linear elasticity system [10], [13]. We use a mixed formulation combined with the Piola transform [9] to avoid assembling the stiffness matrix and thus to have a very substantial gain in memory storage. Usually, the use of mixed finite elements (MFE) eliminates the problem of numerical locking. Our motivation for using MFEs is thus different. The outline of the article is as follows.

In section 1, we describe the equations that constitute the Reissner–Mindlin plate model. Then, we recall the energy identity, which ensures the well-posedness of the problem.

In section 2, we propose a mixed formulation for the problem and its discretization by mixed spectral finite elements with mass lumping. Mass lumping is obtained thanks to the use of the appropriate quadrature formula (Gauss–Lobatto). To our knowledge, the error analysis of such methods is not complete, particularly concerning the effect

of numerical integration. However, we give a short review of some known results in this direction.

In section 3, we propose and analyze a leapfrog scheme for the time discretization.

In section 4, we give several numerical results. First, we validate our method and our results using the fact that the plate model is asymptotic to the linear elasticity system: We compare our results with results given by a three-dimensional (3D) linear elasticity code. Then we show the advantages of the scheme in terms of accuracy and computational time. Finally, we address the question of numerical locking through a numerical experiment which shows that a low order (2 or 3) method is subject to a locking phenomena, while the higher order methods are little affected by this problem. To conclude, the aim of this paper is to propose a finite element method for the Reissner–Mindlin plate model in the time domain, that we claim to be robust, accurate, and high-performance in terms of computation time and memory storage. Some important aspects like boundary layer effects are not treated in this article.

1. The Reissner–Mindlin plate model.

1.1. Construction of the model by an asymptotic approach. In this paper, we define a plate as a parallelepipedic elastic material Ω with a dimension of thickness δ small compared to the other dimensions. The midsurface of the plate is Σ and the boundary is $\Gamma = \Gamma^+ \cup \Gamma^- \cup \Gamma^0$ (Figure 1.1), where

$$\Gamma^{\pm} = \Omega \cap \left\{ z = \frac{\pm\delta}{2} \right\}, \quad \Gamma^0 = \partial\Omega \setminus \Gamma^{\pm}.$$

We suppose that the plate is totally clamped along Γ_0 and is subjected to a loading force $\underline{g}$ on Γ^+ and that there are no internal forces in the plate. So, a displacement field

$$\underline{U}(x_1, x_2, x_3; t) = U_i(x_1, x_2, x_3; t)_{i=1,2,3}, \quad (x_1, x_2, x_3; t) \in \Sigma \times \left[-\frac{\delta}{2}, \frac{\delta}{2} \right] \times [0, T]$$

is characterized by the linear tensor of deformations

$$\underline{\underline{\varepsilon}}(\underline{U}) \stackrel{def}{:=} \underline{\underline{\varepsilon}}(\underline{U})_{i,j} = \frac{1}{2} \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right) \quad \forall\, (i,j) = \{1,2,3\}$$

and satisfies the linear elasticity system

$$\begin{cases} \rho \dfrac{\partial^2 \underline{U}}{\partial t^2} - \underline{\mathrm{Div}} \left(\underline{\underline{\tilde{C}}}\, \underline{\underline{\varepsilon}}(\underline{U}) \right) = 0 & \text{on} \quad \Omega, \\ \underline{\underline{\tilde{C}}}\, \underline{\underline{\varepsilon}}(\underline{U}) \underline{n} = \underline{g} & \text{on} \quad \Gamma^+, \\ \underline{\underline{\tilde{C}}}\, \underline{\underline{\varepsilon}}(\underline{U}) \underline{n} = 0 & \text{on} \quad \Gamma^-, \\ \underline{U} = 0 & \text{on} \quad \Gamma_0 \end{cases}$$

completed by zero initial data. In this system ρ is the density of the plate, $\underline{\underline{\tilde{C}}}$ is the stiffness tensor that arises in Hooke's law, and $\underline{n} = (0, 0, 1)$.

Then we can write the variational formulation of the elastic system

$$\frac{d}{dt^2} \int_\Omega \rho \underline{U} \cdot \underline{U}^*\, dx + \int_\Omega \underline{\underline{\tilde{C}}}\, \underline{\underline{\varepsilon}}(\underline{U}) : \underline{\underline{\varepsilon}}(\underline{U}^*)\, dx = \int_{\Gamma^+} \underline{g} \cdot \underline{U}^* d\gamma \quad \forall\, \underline{U}^* \in V_0, \tag{1.1}$$

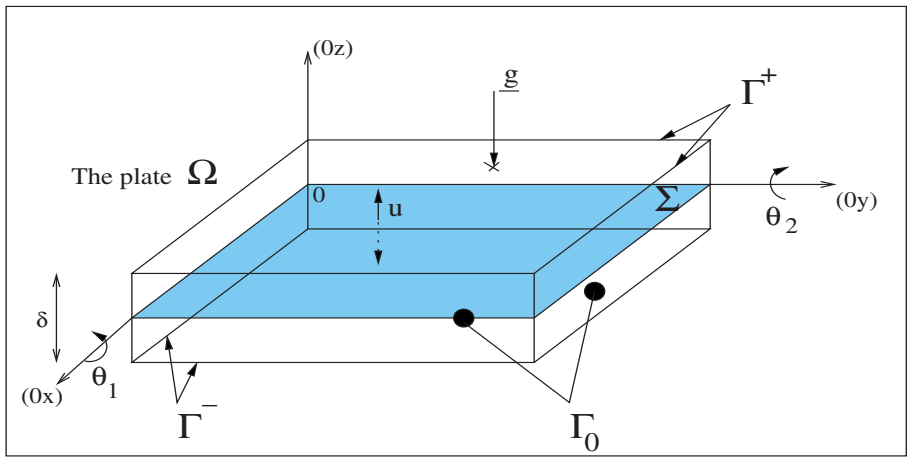

FIG. 1.1. *The plate model.*

where $V_0 = \{\underline{v} \in [H^1(\Omega)]^3,\ \underline{v} = 0 \quad \text{on } \Gamma^+\}$. The use of (1.1) and kinematical assumptions due to Reissner, Mindlin, and Nagdhi [17], [19], [20] on the admissible displacement profile permit us to describe the 3D displacement field $\underline{U}$ from two-dimensional (2D) displacement fields defined on Σ. We recall below the Reissner–Mindlin kinematical assumptions as given in [6].

ASSUMPTION 1.

$$U_\alpha(x_1, x_2, x_3; t) = u_\alpha(x_1, x_2; t) + x_3\theta_\alpha(x_1, x_2; t),\ \alpha = \{1, 2\}, \tag{1.2}$$

$$U_3(x_1, x_2, x_3; t) = u(x_1, x_2; t). \tag{1.3}$$

u_α u Σ $\underline{n}$ $x_3\theta_\alpha$ (Ox) (Oy)

1. In the case of a plate, the membrane displacement and the bending displacement are uncoupled. When there are no internal forces we can show that $u_\alpha = 0,\ \alpha = \{1, 2\}$.

We replace $\underline{U}$ by (1.2) and (1.3) in (1.1) and use test functions $\underline{U}^*$ of the same form. After making several hypotheses given in [6], [19] on the tensor $\underline{\underline{C}}$, and taking into account Remark 1, we can show that u and $\underline{\theta} = (\theta_1, \theta_2)$ satisfy the Reissner–Mindlin plate model,

$$\rho\frac{\delta^3}{12}\frac{\partial^2\underline{\theta}}{\partial t^2} - \frac{\delta^3}{12}\underline{\mathrm{Div}}\left(\underline{\underline{C}}\,\underline{\underline{\varepsilon}}(\underline{\theta})\right) + \delta\mu(\nabla u + \underline{\theta}) = 0 \quad \text{on } \mathcal{Q}_T, \tag{1.4}$$

$$\rho\delta\frac{\partial^2 u}{\partial t^2} - \delta\ \mathrm{div}[\mu(\nabla u + \underline{\theta})] = f \quad \text{on } \mathcal{Q}_T, \tag{1.5}$$

$$u = 0\ ,\ \underline{\theta} = 0 \quad \text{on } \mathcal{Q}_T, \tag{1.6}$$

completed by zero initial data. We have set $\mathcal{Q}_T = \Sigma \times [0, T]$. We denote by E the Young modulus, ν the Poisson coefficient, $\mu = E/[2(1+\nu)]$, and $\lambda = (E\nu)/(1-\nu^2)$.

Then, the new fourth-order stiffness tensor of the plate $\underline{\underline{C}}$ is given by

$$\begin{cases} c^{1111} = c^{2222} = \lambda + 2\mu, & c^{1122} = c^{2211} = \lambda, \\ c^{1221} = c^{2112} = c^{2121} = c^{1212} = \mu, & c^{\alpha\beta\lambda\mu} = 0 \text{ else.} \end{cases}$$

The loading force f is now scalar and depends on $\underline{g}$ and δ. The connection between the 3D model and the 2D model will be used in the validation of the method.

1.2. The well-posedness of the problem. Throughout the rest of the article, if $\xi(t,x)$ is defined on $\mathcal{Q}_T$, we use the notation $\xi(t) = \xi(t,.)$.

PROPOSITION 1.

$$\begin{aligned} E_m[\underline{\theta}(t), u(t)] = \rho\frac{\delta^3}{12}\left\|\frac{\partial\underline{\theta}(t)}{\partial t}\right\|^2_{L^2} + \rho\delta\left\|\frac{\partial u(t)}{\partial t}\right\|^2_{L^2} \\ + \frac{\delta^3}{12}\|\theta(t)\|^2_{\varepsilon,\Sigma} + \delta\,\mu\|(\nabla u + \underline{\theta})(t)\|^2_{L^2} \end{aligned} \tag{1.7}$$

$$\frac{1}{2}\frac{d}{dt}E_m[\theta(t), u(t)] = \int_\Sigma f(t)\frac{\partial u(t)}{\partial t}, \tag{1.8}$$

$\|\theta(t)\|^2_{\varepsilon,\Sigma} = \int_\Sigma \underline{\underline{C}}\,\underline{\underline{\varepsilon}}(\underline{\theta}(t)) : \underline{\underline{\varepsilon}}(\underline{\eta})$ $H^1_0(\Sigma)$. We multiply (1.4) by $\underline{\eta} \in [H^1_0(\Sigma)]^2$ and (1.5) by $v \in H^1_0(\Sigma)$, and we get

$$\begin{aligned} \rho\frac{\delta^3}{12}\frac{d^2}{dt^2}\int_\Sigma \underline{\theta}(t)\cdot\underline{\eta}\,dx - \frac{\delta^3}{12}\int_\Sigma \underline{\mathrm{Div}}\left[\underline{\underline{C}}\,\underline{\underline{\varepsilon}}(\underline{\theta}(t))\right] \\ \cdot\underline{\eta}\,dx + \delta\int_\Sigma \mu(\nabla u + \underline{\theta})(t)\cdot\underline{\eta}\,dx = 0, \end{aligned} \tag{1.9}$$

$$\rho\delta\frac{d^2}{dt^2}\int_\Sigma u(t)v\,dx - \delta\int_\Sigma \mathrm{div}\,[\mu(\nabla u + \underline{\theta})(t)]\,v\,dx = \int_\Sigma f(t)v\,dx. \tag{1.10}$$

By applying Green's formula to the stiffness terms, we get

$$-\int_\Sigma \underline{\mathrm{Div}}\left[\underline{\underline{C}}\,\underline{\underline{\varepsilon}}(\underline{\theta}(t))\right]\cdot\underline{\eta}\,dx = \int_\Sigma \underline{\underline{C}}\,\underline{\underline{\varepsilon}}(\underline{\theta}(t)) : \underline{\underline{\varepsilon}}(\underline{\eta})\,dx, \tag{1.11}$$

$$-\int_\Sigma \mathrm{div}[\mu(\nabla u + \underline{\theta})(t)]v\,dx = \int_\Sigma \mu(\nabla u + \underline{\theta})(t)\cdot\nabla v\,dx. \tag{1.12}$$

Using (1.6), we see that integrals over $\partial\Sigma$ are equal to 0. Then, we substitute (1.11) and (1.12) into (1.9) and (1.10), and by summing (1.9) and (1.10) we obtain

$$\begin{aligned} \rho\frac{\delta^3}{12}\frac{d^2}{dt^2}\int_\Sigma \underline{\theta}(t)\cdot\underline{\eta}\,dx \;+\; \rho\delta\frac{d^2}{dt^2}\int_\Sigma u(t)v\,dx + \frac{\delta^3}{12}\int_\Sigma \underline{\underline{C}}\,\underline{\underline{\varepsilon}}(\underline{\theta}(t)) : \underline{\underline{\varepsilon}}(\underline{\eta})\,dx \\ +\; \delta\int_\Sigma \mu(\nabla u + \underline{\theta})(t)\cdot(\nabla v + \underline{\eta})\,dx = \int_\Sigma f(t)v\,dx. \end{aligned} \tag{1.13}$$

Finally we choose $\underline{\eta} = \frac{\partial\underline{\theta}}{\partial t}(t)$ and $v = \frac{\partial u}{\partial t}(t)$ and we obtain (1.8). □

Then, this type of energy identity ensures the well-posedness of the problem via the Hille–Yosida theorem.

2. Approximation by mixed spectral finite elements.

2.1. The mixed formulation. In order to obtain a stiffness matrix independent of the mesh geometry and the physical coefficients of the problem, we propose in this section a mixed formulation for (1.4)–(1.6). This enables us to avoid assembling the stiffness matrix and thus to save on memory storage (the gains can be quite substantial). MFEs are more commonly used to prevent numerical locking (cf. [4], [6], [7]). As stated above, our motivation for using MFE is different. In the following, $(i,j) = \{1,2\}^2$.

First, we decompose the second-order operators in the stiffness part of (1.4) and (1.6) to get gradient- or divergence-type operators. Using the approach of Cohen–Fauqueux [10] we have the following lemma.

LEMMA 1.

$$\underline{\mathrm{Div}}(\underline{\underline{C}}\,\underline{\underline{\varepsilon}}(\theta))_i = \sum_{j=1}^{2} \mathrm{div}(A_{ij}\nabla\theta_j), \quad A_{ij} = \begin{pmatrix} c^{i1j1} & c^{i1j1} \\ c^{i2j1} & c^{i2j2} \end{pmatrix}.$$

The matrices introduced above are invertible, so by setting

$$\underline{\gamma}_{ij} = A_{ij}\nabla\theta_j \text{ and } \underline{Q} = \mu\,(\nabla u + \underline{\theta}) \quad \forall\, t \in [0,T]$$

and using Lemma 1, (1.4) and (1.6) lead to the following mixed formulation (with appropriated boundary and initial conditions):

$$\rho\frac{\delta^3}{12}\frac{\partial^2\theta_i}{\partial t^2} - \frac{\delta^3}{12}\sum_{j=1}^{2}\mathrm{div}(\underline{\gamma}_{ij}) + \delta\, Q_i = 0 \quad \text{on } \mathcal{Q}_T, \tag{2.1}$$

$$A_{ij}^{-1}\underline{\gamma}_{ij} = \nabla\theta_j \quad \text{on } \mathcal{Q}_T, \tag{2.2}$$

$$\rho\delta\frac{\partial^2 u}{\partial t^2} - \delta\,\mathrm{div}(\underline{\mathrm{Q}}) = \delta \mathrm{f} \quad \text{on } \mathcal{Q}_T, \tag{2.3}$$

$$\underline{Q} = \mu\,(\nabla u + \underline{\theta}) \quad \text{on } \mathcal{Q}_T. \tag{2.4}$$

In order to use a finite element method, we write a variational formulation for this system. We choose to integrate by parts the divergence-type operators. This induces the following space regularity for the four unknowns:

$$u(t) \in H_0^1(\Sigma),\ \underline{\theta}(t) \in [H_0^1(\Sigma)]^2,\ \underline{Q}(t) \in [L^2(\Sigma)]^2,\ \underline{\gamma}_{ij}(t) \in [L^2(\Sigma)]^2 \qquad \forall\, t \in [0,T].$$

Thanks to the Hille–Yosida theorem we can show that if $f \in C^1(0,T;L^2(\Sigma)$, then

$$(u(t),\underline{\theta}(t),\underline{\gamma}_{ij}(t),\underline{Q}(t)) \in C^1(0,T;H_0^1(\Sigma)) \times C^1(0,T;[H_0^1(\Sigma)]^2) \times C^1(0,T;[L^2(\Sigma)]^2) \times C^1(0,T;[L^2(\Sigma)]^2).$$

Then, the variational formulation is

$$\text{Find } (u(t),\underline{\theta}(t),\underline{\gamma}_{ij}(t),\underline{Q}(t)) \in H_0^1(\Sigma) \times [H_0^1(\Sigma)]^2 \times [L^2(\Sigma)]^2 \times [L^2(\Sigma)]^2 \quad \text{such that}$$

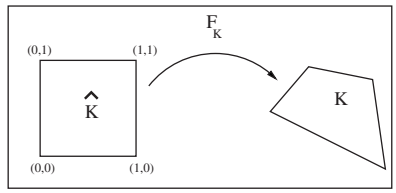

FIG. 2.1. F_K.

$$\rho\frac{\delta^3}{12}\frac{d^2}{dt^2}\int_\Sigma \theta_i(t)\eta_i\,dx + \frac{\delta^3}{12}\sum_{j=1}^{2}\int_\Sigma \underline{\gamma}_{ij}(t)\cdot\nabla\eta_i\,dx + \delta\int_\Sigma Q_i(t)\eta_i\,dx = 0, \tag{2.5}$$

$$\int_\Sigma A_{ij}^{-1}\underline{\gamma}_{ij}(t)\cdot\underline{\xi}_{ij}\,dx = \int_\Sigma \underline{\xi}_{ij}\cdot\nabla\theta_j(t)\,dx, \tag{2.6}$$

$$\rho\delta\frac{d^2}{dt^2}\int_\Sigma u(t)v\,dx + \delta\int_\Sigma \underline{Q}(t)\cdot\nabla v\,dx = \delta\int_\Sigma f(t)v\,dx, \tag{2.7}$$

$$\int_\Sigma \underline{Q}(t)\cdot\underline{q}\,dx = \int_\Sigma \mu\,(\nabla u(t) + \underline{\theta}(t))\cdot\underline{q}\,dx \tag{2.8}$$

for any test function $(v,\underline{\eta},\underline{\xi}_{ij},\underline{q}) \in H_0^1(\Sigma)\times[H_0^1(\Sigma)]^2\times[L^2(\Sigma)]^2\times[L^2(\Sigma)]^2$.

2.2. The choice of a finite element.

2.2.1. Objectives and main tools. Our objective here is to construct a class of higher-order numerical approximations in order to have very good precision, decrease numerical locking, and diminish computation time. Toward this end, we impose three conditions:

(i) To use an explicit time scheme. This is fundamental to decreasing computation time in the dynamic case.
(ii) To use a quadrature formula which keeps the order of the polynomial approximation.
(iii) To construct an approximation space for $[L^2(\Sigma)]^2$ with a "special" transformation in order to avoid the storage of the stiffness matrix.

To satisfy points (i) and (ii) we use the mass lumping principle and Gauss–Lobatto points. Concerning (iii), the use of the Piola transform will be the key point.

2.2.2. The finite element. We denote by $\widehat{K}$ the unit square, by K a quadrilateral, and by $\underline{F}_K$ the bilinear isomorphism between $\widehat{K}$ and K (Figure 2.1), and we consider $\mathcal{T}_h = \cup_{i=1}^{N_e} K_i$ a mesh of Σ consisting of N_e quadrilaterals. As stated above, we want to use a higher order numerical scheme, and so we choose to approximate the solution of the problem with polynomials in $\mathbb{Q}^r$, the set of polynomials of degree r in each variable. This leads us to use the finite element $\mathcal{Q}^r(\widehat{K}) = (\widehat{K},\mathbb{Q}^r,\Xi^2)$, where Ξ is the set of degrees of freedom given by $\Xi = \{\widehat{\xi}_1,\widehat{\xi}_2,\ldots,\widehat{\xi}_r,\widehat{\xi}_{r+1}\}$, where $\{\widehat{\xi}_i\}_{i=\{2,\ldots,r\}}$ are the Gauss–Lobatto points [5], [9], [21]. We have set $\widehat{\xi}_1 = 0$, $\widehat{\xi}_{r+1} = 1$.

REMARK 2. The finite element $\mathcal{Q}^r(\widehat{K})$ is the "tensor product" of the finite element $([0,1],\mathbb{P}^r,\Xi)$.

We will use the notation

$$\underline{\widehat{\xi}}_p = (\widehat{\xi}_m,\widehat{\xi}_n)\ \forall\, p\in\{1\ldots(r+1)^2\},\ \forall\, m\in\{1\ldots(r+1)\},\ \forall\, n\in\{1\ldots(r+1)\}.$$

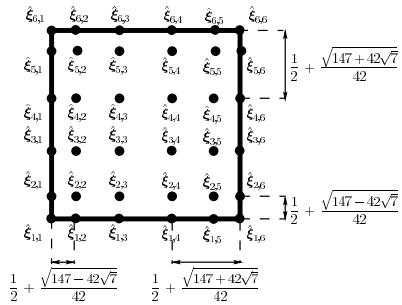

FIG. 2.2. *Example: Gauss–Lobatto points for* $r = 5$.

Even though it is well known, we briefly recall in the next lines what motivates the choice of the Gauss–Lobatto points (Figure 2.2). We have the following proposition [9], [21].

PROPOSITION 2. $\{\widehat{\omega}_i\}_{i\in\{1,\dots,r+1\}}$, $\widehat{\omega}_i > 0$

$$\forall p \in \mathbb{P}^{2r-1},\ \int_0^1 p(\widehat{x})\, d\widehat{x} = \sum_{m=1}^{r+1} \widehat{\omega}_m\, p(\widehat{\xi}_m).$$

Remark 2 and Proposition 2 yield the following corollary.

COROLLARY 1.

$$\forall p \in \mathbb{Q}^{2r-1},\ \int_{\widehat{K}} p(\widehat{x},\widehat{y})\, d\widehat{x}d\widehat{y} = \sum_{n=1}^{r+1}\sum_{m=1}^{r+1} \widehat{\omega}_n\, \widehat{\omega}_m\, p(\widehat{\underline{\xi}}_n, \widehat{\underline{\xi}}_m).$$

THEOREM 1. 1 [8] [5] (ii)

In the following we will use the notation for quadrature formula

$$\oint_K f(x)\, dx = \oint_{\widehat{K}} f(\widehat{x})|J_K(\widehat{x})|\, d\widehat{x} = \sum_{m=1}^{(r+1)^2} \widehat{\omega}_m\, f\circ F_K(\widehat{\underline{\xi}}_m)\, |J_K(\widehat{\underline{\xi}}_m)|.$$

3. This type of construction for our finite element is obviously inappropriate if we choose a triangular geometry. In this case it is difficult to construct a family of points that satisfies such a criterion of accuracy for arbitrary orders [8, 16].

Then, by the definition of $\mathcal{Q}^r(\widehat{K})$ we use the degrees of freedom as quadrature nodes, so we respect the mass lumping principle and satisfy (i).

2.3. The semidiscrete scheme.

2.3.1. Approximated spaces and variational formulation. We now introduce the following approximation spaces of $H_0^1(\Sigma)$ and $[L^2(\Sigma)]^2$, respectively:

$$U_{h,0}^r = \{\varphi \in C^0(\mathcal{T}_h) \text{ such that } \varphi_{|_K}\circ \underline{F}_K \in \mathbb{Q}_r(\widehat{K}) \text{ and } \varphi = 0 \text{ on } \partial\Omega\},$$

$$V_h^r = \{\underline{v} \in [L^2(\mathcal{T}_h)]^2 \text{ such that } |J_K| DF_K^{-1}\, \underline{v}_{|_K}\circ \underline{F}_K \in [\mathbb{Q}_r(\widehat{K})]^2\}.$$

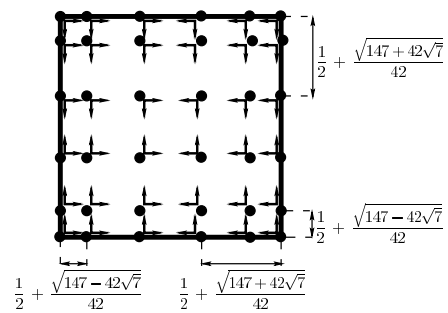

FIG. 2.3. *Example: Degrees of freedom for $r = 5$.*

In the next subsections we need a basis for these spaces. For now, we formally define

$$U_{h,0}^r = \mathrm{Vect}\{\varphi_n\}, \quad \dim(U_{h,0}^r) = n_h, \tag{2.9}$$

$$V_h^r = \mathrm{Vect}\{\underline{\psi}_m\}, \quad \dim(U_{h,0}^r) = m_h. \tag{2.10}$$

The space $U_{h,0}^r$ is a classical approximation of $H_0^1(\Sigma)$: $\varphi_K \in U_{h,0}^r$, defined on a quadrilateral K of the mesh; it is transformed into a function $\widehat{\varphi}$ defined on $\widehat{K}$ by the classical transformation

$$\varphi_K \circ F_K = \widehat{\varphi}. \tag{2.11}$$

The space V_h^r introduces a nonstandard approach: $\underline{\psi}_K \in V_h^r$, defined on a quadrangle K of the mesh, is transformed into a function $\underline{\widehat{\psi}}$ defined on $\widehat{K}$ by the [illegible]

$$\underline{\psi}_K \circ F_K = \frac{1}{|J_K|} DF_K \, \underline{\widehat{\psi}}. \tag{2.12}$$

[illegible] 4. Even if functions of V_h^r are discontinuous on the mesh, the Piola transform ensures that their normal components are continuous. It is in fact the condition to have an H(div)-conforming approximation.

Figure 2.3 shows that we have nodal continuous degrees of freedom at Gauss–Lobatto points for $U_{h,0}^r$ and vectorial discontinuous degrees of freedom at Gauss–Lobatto points for V_h^r. Using the previous spaces we consider the following semidiscrete variational problem.

Find $(u^h(t), \underline{\theta}^h(t), \underline{\gamma}_{ij}^h(t), \underline{Q}^h(t)) \in U_{h,0}^r \times [U_{h,0}^r]^2 \times V_h^r \times V_h^r$ such that

$$\rho \frac{\delta^3}{12} \frac{d^2}{dt^2} \oint_\Sigma \theta_i^h(t) \varphi_n \, dx + \frac{\delta^3}{12} \sum_{j=1}^{2} \oint_\Sigma \underline{\gamma}_{ij}^h(t) \cdot \nabla \varphi_n \, dx + \delta \oint_\Sigma Q_i^h(t) \, \varphi_n \, dx = 0, \tag{2.13}$$

$$\oint_\Sigma A_{ij}^{-1} \underline{\gamma}_{ij}^h(t) \cdot \underline{\psi}_m \, dx = \oint_\Sigma \underline{\psi}_m \cdot \nabla \theta_j^h(t) \, dx, \tag{2.14}$$

$$\rho\delta \frac{d^2}{dt^2} \oint_\Sigma u^h(t) \varphi_q^r \, dx + \delta \oint_\Sigma \underline{Q}^h(t) \cdot \nabla \varphi_n \, dx = \delta \oint_\Sigma f(t) \varphi_n \, dx, \tag{2.15}$$

$$\oint_\Sigma \underline{Q^h} \cdot \underline{\psi_m} \, dx = \mu \oint_\Sigma (\nabla u^h + \underline{\theta}) \cdot \underline{\psi_m} \, dx \tag{2.16}$$

for all indices $(n, m) \in \{1, \ldots, n_h\} \times \{1, \ldots, m_h\}$.

PROPOSITION 3. [illegible] (2.13)–(2.16) [illegible]

$$\rho\frac{\delta^3}{12}\frac{d^2}{dt^2}\oint_\Sigma \underline{\theta}_h(t)\cdot\underline{\eta}_h\,dx+\rho\delta\frac{d^2}{dt^2}\oint_\Sigma u_h(t)v_h\,dx+\frac{\delta^3}{12}\oint_\Sigma \underline{\underline{C}}\,\underline{\underline{\varepsilon}}(\underline{\theta}(t)):\underline{\underline{\varepsilon}}(\underline{\eta}_h)\,dx$$
$$+\delta\oint_\Sigma \mu(\nabla u_h+\underline{\theta}_h)(t)\cdot(\nabla v_h+\underline{\eta}_h)\,dx=\oint_\Sigma f(t)v_h\,dx \tag{2.17}$$

[illegible] $(v_h,\underline{\eta}_h)\in U_h^r\times[U_h^r]^2$

The proof is given in [18] for more general hyperbolic systems. Key points are the use of the same quadrature formulas and polynomial approximation for functions of U_h^r and V_h^r.

2.4. Matricial formulation. Now we give matrices of the bilinear forms which constitute the variational system (2.13)–(2.16). First, we deal with the mass matrices. Let

$$D:\quad (u_h,v_h)\longrightarrow \oint_\Sigma \rho u_h v_h \quad \text{in}\quad U_{h,0}^r\times U_{h,0}^r,$$
$$B:\quad (\underline{w}_h,\underline{w}_h)\longrightarrow \oint_\Sigma \underline{w}_h\cdot\underline{w}_h \quad \text{in}\quad V_h^r\times V_h^r,$$
$$M_{ij}:\quad (\underline{w}_h,\underline{w}_h)\longrightarrow \oint_\Sigma (A_{ij}\underline{w}_h)\cdot\underline{w}_h \quad \text{in}\quad V_h^r\times V_h^r.$$

These matrices have already been described in [13], [10] and we just recall their elementary terms which are useful for computation. Toward this end, we introduce some notation:

- q and p will be indices for local degrees of freedom: $(q,p)\in\{1,\dots,(r+1)\}^2$.
- Let A^K be the elementary matrix for the element K associated to a finite element matrix A.

PROPOSITION 4. [illegible] D, B [illegible] M_{ij} [illegible]

$$(D^K)_{q,q}=\widehat{\omega}_q\,|J_K(\widehat{\underline{\xi}}_q)|,$$
$$(B^K)_{q,q}=\frac{\omega_q}{|J_K(\widehat{\underline{\xi}}_q)|}\,DF_K^*(\widehat{\underline{\xi}}_q)\,DF_K(\widehat{\underline{\xi}}_q),$$
$$(M_{ij}^K)_{q,q}=\frac{\widehat{\omega}_q}{|J_K(\widehat{\underline{\xi}}_q)|}\,DF_K^*(\widehat{\underline{\xi}}_q)\,A_{ij}\,DF_K(\widehat{\underline{\xi}}_q).$$

[illegible] 5. We use the mass-lumping principle so D is diagonal. Furthermore, B and the M_{ij} are 2×2-block diagonal and do not need assembling because functions of V_h^r are discontinuous. Finally, the term DF_K appears in $\widehat{B}^K$ and $\widehat{M}_{ij}^K$ because of (2.12).

Now we deal with the stiffness matrix.

PROPOSITION 5. [illegible] R [illegible]

$$(u_h,\underline{w}_h)\in U_{h,0}^r\times V_h^r\longrightarrow \int_{\mathcal{T}_h}\underline{v}_h\cdot\nabla u_h\,dx.$$

[illegible] R [illegible] $\widehat{K}$

$$\forall\, K\in\mathcal{T}_h,\quad \int_K v_h\cdot\nabla u_h\,dx=\int_{\widehat{K}}\widehat{\underline{v}}_h\cdot\widehat{\nabla}\widehat{u}_h\,d\widehat{x}. \tag{2.18}$$

To give a proof we recall the algebraic identity

$$(\nabla\varphi)\circ F_K = DF_K^{*-1}\widehat{\nabla}\widehat{\varphi}. \tag{2.19}$$

For each element $K \in \mathcal{T}_h$ we have

$$\begin{aligned}\int_K v_h \cdot \nabla u_h \, d &= \int_{\widehat{K}} \underline{v}_h \circ F_K \cdot (\nabla u_h)\circ F_K |J_K| \, d\widehat{x} \\ &= \int_{\widehat{K}} \frac{1}{|J_K|} \, DF_K \underline{\widehat{v}}_h \cdot DF_K^{*-1}\widehat{\nabla}\widehat{u}_h \, |J_K| \, d\widehat{x} \quad \text{using (2.11), (2.12), (2.19),} \\ &= \int_{\widehat{K}} \underline{\widehat{v}}_h \cdot \widehat{\nabla}\widehat{u}_h \, d\widehat{x}. \qquad \square\end{aligned}$$

COROLLARY 2.

$$\forall\, K \in \mathcal{T}_h,\ R^K = R^{\widehat{K}} \qquad (R^K)_{q,p} = \widehat{\omega}_q \frac{\partial \widehat{\varphi}_p}{\partial x_l}(\widehat{\xi}_q)\delta_{2q+l,p} \qquad \forall\, l \in \{1,2\}.$$

Proposition 6 permits us to deduce an algorithm in which we avoid storing a stiffness matrix. More precisely, when we want to compute the product matrix vector $R\,U$, we do not assemble R but we compute directly the product from the storage of $R^{\widehat{K}}$. In fact we "assemble" the product $R\,U$. This method of computation is also possible in the harmonic or stationary case when we use an iterative algorithm to solve the associated linear system. It is obvious that the gain in terms of memory storage is quite substantial. Indeed, we just have to store an elementary matrix instead of the whole matrix. However, it is possible that this procedure penalizes the computation time. In fact, this algorithm also induces a gain in terms of computation time when we use elements with high enough order. When the order increases, the multiplicity of interactions of degrees of freedom also increases. Then a local computation of the product $R\,U$ with our algorithm is more efficient than a computation after assembling R. In Figure 2.4, we represent the computation time as a function of the order to compute $R\,U$ for a given number of degrees of freedom (at each order we have a mesh such that the number of degrees of freedom is constant). The standard formulation corresponds to the computation of $R\,U$ with the assembling of R.

To complete the definition of our matrices, we take into account in our model the shear strain which induces a coupling between u and $\underline{\theta}$ in the term $\underline{Q} = \mu(\nabla u + \underline{\theta})$. So it introduces a new coupling matrix.

PROPOSITION 6.

$$(\underline{u}_h, \underline{w}_h) \longrightarrow \oint_\Sigma \underline{u}_h \cdot \underline{w}_h \quad in\ [U_{h,0}^r]^2 \times V_h^r.$$

$(C^K)_{q,p} = \widehat{\omega}_q \, DF_K(\widehat{\xi}_q)\, \delta_{q,p}$.

We set $\overrightarrow{e}_1 = \binom{1}{0}$, $\overrightarrow{e}_2 = \binom{0}{1}$. From (2.9) we define a basis for $[U_{h,0}^r]^2$:

$$[U_{h,0}^r]^2 = \mathrm{Vect}\{\varphi_q \overrightarrow{e}_i\} \quad \forall i = \{1,2\},\ \forall n = \{1 \dots n_h\}.$$

Because functions of V_h^r are vectorial and discontinuous, $n_h = 2N_e(r+1)^2$ (we do not take into account Dirichlet conditions). So, instead of the formal basis given in (2.10) we use the enumeration

$$V_h^r = \mathrm{Vect}\{\underline{\psi}_{p,e,l}\} \quad \forall\,(p,e,l) \in \{1 \dots (r+1)^2\} \times \{1 \dots N_e\} \times \{1,2\},$$

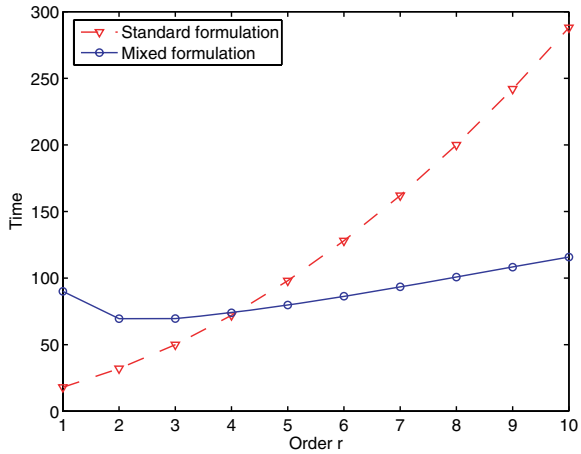

FIG. 2.4. *Compution time versus order for standard and mixed formulations.*

where p is still an index for local degrees of freedom, e is an index that describes elements, and l is an index that describes the vectorial components. Let K_e be the eth-element of the mesh. Then, the basis functions of V_h^r are constructed via the Piola transform and are given by the algebraic expression

$$\underline{\psi}_{p,e,l} \circ \underline{F}_{K_e} = \frac{\widehat{\varphi}_p}{|J_{K_e}|} DF_{K_e} \overrightarrow{e}_l. \tag{2.20}$$

With this notation we have

$$\begin{aligned} \oint_{K_e} \underline{\psi}_{p,e,l} \cdot \varphi_q \overrightarrow{e}_i \, dx &= \oint_{\widehat{K}} (\underline{\psi}_{p,e,l} \circ \underline{F}_{K_e}) \cdot (\varphi_q \circ \underline{F}_{K_e}) \overrightarrow{e}_i \, |J_{K_e}| \, d\widehat{x} \\ &= \oint_{\widehat{K}} \widehat{\varphi}_p \, \widehat{\varphi}_q \, (DF_{K_e} \overrightarrow{e}_l) \cdot \overrightarrow{e}_i \, d\widehat{x}; \end{aligned} \tag{2.21}$$

see (2.20). By applying a Gauss–Lobatto quadrature formula we get

$$\begin{aligned} \oint_{K_e} \underline{\psi}_{p,e,l} \cdot \varphi_q \overrightarrow{e}_i \, dx &= \sum_{m=1}^{(r+1)^2} \widehat{\omega}_m \, [DF_{K_e}(\widehat{\xi}_m) \overrightarrow{e}_l] \cdot \overrightarrow{e}_i \, \delta_{p,m} \, \delta_{q,m} \\ &= \widehat{\omega}_q \, [DF_{K_e}(\widehat{\xi}_q) \overrightarrow{e}_l] \cdot \overrightarrow{e}_q \, \delta_{p,q}. \qquad \square \end{aligned}$$

To write the semidiscrete system, we denote by, respectively, $U_h(t), \Theta_h(t), \Gamma_h^{ij}(t)$, and $\mathcal{Q}_h(t)$ the components of $u_h(t), \theta^h(t), \gamma_{ij}^h(t)$, and $\mathcal{Q}^h(t)$ in the appropriate basis. Using the definitions of the mass, stiffness, and coupling matrices, (2.13)–(2.16) lead to the matricial formulation

$$\frac{\delta^3}{12} D \frac{d^2 \Theta_h^i(t)}{dt^2} + \frac{\delta^3}{12} \sum_{j=1}^{2} R \, \Gamma_h^{ij}(t) + \delta \, C^i \mathcal{Q}_h^i(t) = 0, \tag{2.22}$$

$$M_{ij} \Gamma_h^{ij}(t) = R \, \Theta_h^j(t), \tag{2.23}$$

$$\rho\delta \, D \frac{d^2 U_h(t)}{dt^2} + \delta \, R^* \mathcal{Q}_h(t) = \delta \, F_h(t), \tag{2.24}$$

$$B \mathcal{Q}_h(t) = \mu \, [R U_h(t) + C^* \Theta_h(t)]. \tag{2.25}$$

In (2.22), the matrices C_i are related to C by the identity $C = [C_1\ C_2]$. The matrices B and M_{ij} being invertible, we can substitute $M_{ij}^{-1} R\ \Theta_h^j(t)$ and $\mu\ B^{-1}[RU_h(t) + C^*\Theta_h(t)]$ for the auxiliary unknowns $\Gamma_h^{ij}(t)$ and $\mathcal{Q}_h(t)$ (needed for the mixed formulation). To have a block expression we set

$$\mathcal{D} = \begin{pmatrix} D & 0 \\ 0 & D \end{pmatrix} \quad \text{and} \quad \mathcal{K} = \begin{pmatrix} R^*(M^{11})^{-1}R & R^*(M^{12})^{-1}R \\ R^*(M^{21})^{-1}R & R^*(M^{22})^{-1}R \end{pmatrix}.$$

So, the semidiscrete scheme that we propose the for Reissner–Mindlin plate equation is

$$\frac{\delta^3}{12}\,\mathcal{D}\frac{d^2\Theta_h(t)}{dt^2} + \frac{\delta^3}{12}\,\mathcal{K}\,\Theta_h(t) + \delta\ C\ B^{-1}\Big[R\,U_h(t) + C^*\Theta_h(t)\Big] = 0, \tag{2.26}$$

$$\delta D\frac{d^2U_h(t)}{dt^2} + \delta\ R^*B^{-1}\Big[R\,U_h(t) + C^*\Theta_h(t)\Big] = \delta\ F_h(t). \tag{2.27}$$

2.5. About error estimates and numerical integration. The error analysis of our method, in particular, the justification of the use of quadrature formula, is still an open question to our knowledge and will be the object of future research. Proposition 4 shows that we have to consider the analysis of a classical hyperbolic system of order 2 in space. We recall here some known results in this direction. There are two sources of error—the error due to the approximation of $H_0^1(\Sigma)$ that can be reduced to the study of interpolation error and the error related to numerical integration. One difficulty of the analysis is that our finite element subspaces are constructed from a space of reference shape functions which are then transformed to quadrilateral elements via the bilinear (and not affine) isomorphism F_K. The general theory of such finite elements is quite recent; however, in [2], [3], and [5] the authors give criteria on the mesh geometry to have the following estimates:

$$\inf_{v\in U_h^r} \|(u-v)(t)\|_{L^p(\Sigma)} \le Ch^{r+1}|u(t)|_{W^{p,r+1}}, \tag{2.28}$$

$$\inf_{v\in U_h^r} \|\nabla(u-v)(t)\|_{L^p(\Sigma)} \le Ch^{r}|u(t)|_{W^{p,r+1}}. \tag{2.29}$$

Then, using technical arguments given in [8] and [11] we prove the optimal error estimate for our finite elements method when the mass and stiffness matrices are computed exactly. Concerning quadratures formulas, using the approach in [8] we can show that the Gauss–Lobatto quadrature rule keeps the order of the polynomial approximation if we compute the stiffness matrix exactly. As far as we know, for general quadrilaterals the question of the influence of numerical integration is not solved because this case requires numerical integration on rational fractions. However, numerical experiments performed on the Helmholtz equation showed an optimal convergence with general quadrilateral meshes using the Gauss–Lobatto quadrature rule [12].

3. Time discretization and stability analysis.

3.1. The leapfrog scheme. Common software that solves the plate or shell equations uses, in the time domain, an implicit scheme for time discretization like the Newmark scheme. For our mass-lumped formulation, it is more suitable to use an explicit leapfrog scheme.

For $[0,T] \backsimeq \{t_n\} = n\Delta t\ ,\ \Delta t = \frac{T}{N}\ ,\ n \in [0,N]$, we set $U_h(t_n) = U_h^n,\ \Theta_h(t_n) = \Theta_h^n,\ \mathcal{Q}_h^n = \mathcal{Q}_h(t_n)$, and we consider the following scheme:

$$\frac{\delta^3}{12}\,\mathcal{D}\frac{\Theta_h^{n+1} - 2\Theta_h^n + \Theta_h^{n-1}}{\Delta t^2} + \frac{\delta^3}{12}\,\mathcal{K}\,\Theta_h^n + \delta\,C\mathcal{Q}_h^n = 0, \tag{3.1}$$

$$\rho\delta\,D\frac{U_h^{n+1} - 2U_h^n + U_h^{n-1}}{\Delta t^2} + \delta\,R^*\mathcal{Q}_h^n = \delta\,F_h^n, \tag{3.2}$$

$$B\,\mathcal{Q}_h^n = \mu\,(R\,U_h^n + C^*\Theta_h^n). \tag{3.3}$$

Remark 6. In practice (for the implementation) we use the leapfrog scheme for (2.26) and (2.27). For the stability analysis, we prefer to keep the unknown $\mathcal{Q}$ which justifies (3.3).

3.2. Stability results. Because of the mass-lumping principle, our time scheme is explicit. We prove in this section (by a classical technique using a discrete energy identity) that it is stable under a CFL condition. First, we introduce the notation

$$\left|\begin{array}{lcll} b_h : (X,Y) & \longrightarrow & (B\,X)\cdot Y, & \\ k_h : (X,Y) & \longrightarrow & (\mathcal{K}\,X)\cdot Y, & \\ (X,Y) & = & D\,X\cdot Y, & \text{and} \quad |X|^2 = (X,X) \end{array}\right.$$

for any vector $(X,Y) \in \mathbb{R}^{n_h}$. Then we define the discrete quantity at time $t_{n+\frac{1}{2}}$:

$$E_m^{n+\frac{1}{2}} = \frac{\delta^3}{12}\left|\frac{\Theta_h^{n+1} - \Theta_h^n}{\Delta t}\right|^2 + \delta\left|\frac{U_h^{n+1} - U_h^n}{\Delta t}\right|^2 + \frac{\delta^3}{12}k_h(\Theta_h^{n+1},\Theta_h^n) + \delta\,b_h(\mathcal{Q}_h^{n+1},\mathcal{Q}_h^n).$$

Proposition 7. [illegible] (3.1)–(3.3) [illegible]

$$\frac{E_m^{n+\frac{1}{2}} - E_m^{n-1/2}}{2\Delta t} = \delta\,F_h^n \cdot \frac{U_h^{n+1} - U_h^{n-1}}{2\Delta t}. \tag{3.4}$$

[illegible]. Multiplying (3.1) by $\frac{\Theta_h^{n+1} - \Theta_h^{n-1}}{2\Delta t}$ and (3.2) by $\frac{U_h^{n+1} - U_h^{n-1}}{2\Delta t}$ we get

$$\frac{\delta^3}{12}\left(\frac{\Theta_h^{n+1} - 2\Theta_h^n + \Theta_h^{n-1}}{\Delta t^2}, \frac{\Theta_h^{n+1} - \Theta_h^{n-1}}{2\Delta t}\right) + \frac{1}{2\Delta t}\frac{\delta^3}{12}\,[k_h(\Theta_h^n,\Theta_h^{n+1}) - k_h(\Theta_h^n,\Theta_h^{n-1})]$$
$$+ \frac{\delta}{2\Delta t}\,[C\mathcal{Q}_h^n\cdot\Theta_h^{n+1} - C\mathcal{Q}_h^n\cdot\Theta_h^{n-1}] = 0,$$

$$\delta\left(\frac{U_h^{n+1} - 2U_h^n + U_h^{n-1}}{\Delta t^2}, \frac{U_h^{n+1} - U_h^{n-1}}{2\Delta t}\right) + \frac{\delta}{2\Delta t}\,[R^*\mathcal{Q}_h^n\cdot U_h^{n+1} - R^*\mathcal{Q}_h^n\cdot U_h^{n-1}]$$
$$= \delta\,F_h^n\cdot\frac{U_h^{n+1} - U_h^{n-1}}{2\Delta t}.$$

Then we use the equality

$$(V^{n+1} - 2V^n + V^{n-1}, V^{n+1} - V^{n-1}) = |V^{n+1} - V^n|^2 - |V^n - V^{n-1}|^2 \qquad \forall V \in \mathbb{R}^{n_h}\ ,$$

and we obtain

(3.5)

$$\frac{\delta^3}{12}\left[\frac{1}{2\Delta t}\left|\frac{\Theta_h^{n+1}-\Theta_h^n}{\Delta t}\right|^2-\frac{1}{2\Delta t}\left|\frac{\Theta_h^{n}-\Theta_h^{n-1}}{\Delta t}\right|^2\right]+\frac{1}{2\Delta t}\frac{\delta^3}{12}[k_h(\Theta_h^n,\Theta_h^{n+1})-k_h(\Theta_h^n,\Theta_h^{n-1})]$$
$$+\frac{\delta}{2\Delta t}[\mathcal{Q}_h^n\cdot C^*\Theta_h^{n+1}-\mathcal{Q}_h^n\cdot C^*\Theta_h^{n-1}]=0,$$
$$\delta\left[\frac{1}{2\Delta t}\left|\frac{U_h^{n+1}-U_h^n}{\Delta t}\right|^2-\frac{1}{2\Delta t}\left|\frac{U_h^{n}-U_h^{n-1}}{\Delta t}\right|^2\right]+c\frac{\delta}{2\Delta t}[\mathcal{Q}^n\cdot RU_h^{n+1}-\mathcal{Q}^n\cdot RU_h^{n-1}]$$
$$=F_h^n\cdot\frac{U_h^{n+1}-U_h^{n-1}}{2\Delta t}.$$

We notice that

$$\mathcal{Q}^n\cdot C^*\Theta_h^{n+1}+\mathcal{Q}^n\cdot R\,U_h^{n+1}=\mathcal{Q}^n\cdot(R\,U_h^{n+1}+C^*\Theta_h^{n+1})=\mathcal{Q}^n\cdot B\mathcal{Q}^{n+1}=b_h(\mathcal{Q}^{n+1},\mathcal{Q}^n).$$

Since B is symmetric we show in the same way that

$$\mathcal{Q}^n\cdot C^*\Theta_h^{n-1}+\mathcal{Q}^n\cdot R\,U_h^{n-1}=b_h(\mathcal{Q}^n,\mathcal{Q}^{n-1}).$$

Finally, we use the symmetry of k_h : $k_h(\Theta_h^n,\Theta_h^{n+1})=k_h(\Theta_h^{n+1},\Theta_h^n)$, and by adding (3.5) and (3.5) we get (3.4). □

We now use this energy identity to write a condition of stability for the scheme (3.1)–(3.3).

1. Let

$$\mathcal{M}_h=\begin{pmatrix}\frac{\delta^3}{12}\mathcal{D} & 0\\ 0 & \delta D\end{pmatrix}\text{ and }\mathcal{S}_h=\begin{pmatrix}\frac{\delta^3}{12}\mathcal{K}+\delta\,C\,B^{-1}C^* & \delta\,C\,B^{-1}R\\ \delta\,R^*B^{-1}C^* & \delta\,R^*B^{-1}R^*,\end{pmatrix}.$$

Using the same substitution as that needed to obtain (2.26)–(2.27) the scheme (3.1)–(3.3) can be rewritten as

$$\mathcal{M}_h\frac{V_h^{n+1}-2V_h^n+V_h^{n-1}}{\Delta t^2}+\mathcal{S}_hV_h^n=\mathcal{F}_h^n\ ,\ V_h^n=\begin{pmatrix}\Theta_h^n\\ U_h^n\end{pmatrix},\ \mathcal{F}_h^n=\begin{pmatrix}\delta F_h^n\\ 0\end{pmatrix}.$$

With this notation, we can also write

$$E_m^{n+\frac{1}{2}}=\mathcal{M}_h\frac{V_h^{n+1}-V_h^n}{\Delta t}\cdot\frac{V_h^{n+1}-V_h^n}{\Delta t}+\mathcal{S}_hV_h^{n+1}\cdot V_h^n.$$

Using a discrete Gronwall lemma, (3.4) enables us to write the following proposition.

PROPOSITION 8.

$$\frac{\Delta t^2}{4}\sup_{V_h\in\mathbb{R}^{3n_h}}\frac{\mathcal{S}_hV_h\cdot V_h}{\mathcal{M}_hV_h\cdot V_h}<1.$$

We can show that a necessary condition to satisfy the condition in Proposition 8 is

$$\frac{\Delta t}{h}<\alpha,$$

where α depends on the highest eigenvalue of the matrix $\mathcal{M}_h^{-1}\mathcal{S}_h$. In practice we compute the limit of the sequence

$$\frac{\|X_{n+1}\|_{l^2}}{\|X_n\|_{l^2}},\ \text{where } X_n \text{ is given by } X_{n+1}=\mathcal{M}_h^{-1}\mathcal{S}_hX_n$$

to have an approximation of this eigenvalue.

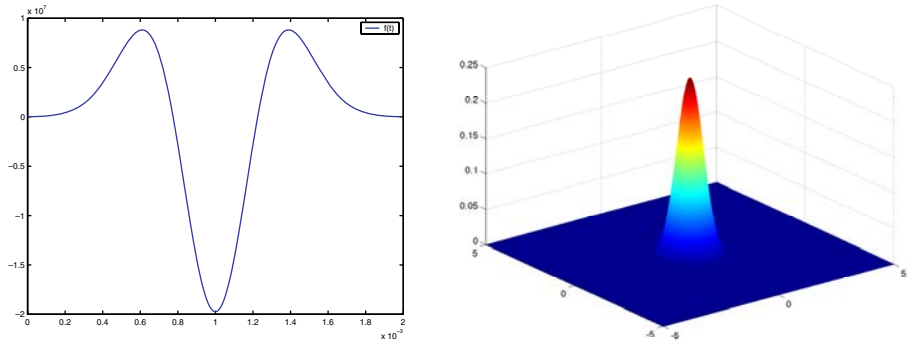

FIG. 4.1. *The loading force: on the left f_1, and on the right f_2.*

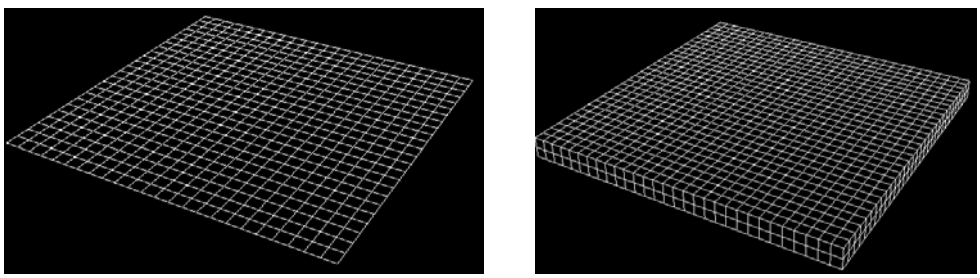

FIG. 4.2. 2D *and* 3D *meshes for the plate and the elastic media.*

4. Numerical results. In the following, the loading force $f(t,x) = f_1(t)f_2(x)$, where f_2 is a Gaussian-type function centered at x_0 with radius $r = 0.5$ and

$$f_1(t) = 2\pi^2 f_0^2(2\pi^2(f_0 t - 1)e^{-\pi^2(f_0 t-1)^2}$$

is a Ricker-type function with central frequency $f_0 = 1000$ Hz (Figure 4.1). We consider an aluminium plate, the physical coefficients of which are

$$\rho = 2700 kg.m^{-3}, \quad E = 7.4\ 10^{10} P_a, \quad \nu = 0.34.$$

The dimensions of the plate are $\Sigma = [-0.5; 0.5] \times [-0.5; 0.5]$, and we denote $x_0 = (0, 0)$ as its center. For all simulations, we consider the time interval $[0; T] = [0; 2e-2]$ which corresponds to many reflections of propagating waves in the plate.

4.1. A validation of the method. To the best of our knowledge, there is no analytical solution for the Reissner–Mindlin plate model. So, in order to validate our method and our results, we use the fact that the plate model is asymptotic to the linear elasticity system. We compute a 3D displacement field $U(t,x)$, solution of (1.1), with a code implemented from Cohen and Fauqueux's approach [10] and we compute $u(t,x)$ by our finite element method. Toward this end, we use a 3D mesh with two space steps in the thickness and a 2D mesh of the midsurface of the 3D mesh (Figure 4.2). We choose $\mathcal{Q}_5$ finite elements for the two computations. Then, taking into account relation (1.3), we compare the two quantities $U_3(t,x_0)$ and $u(t,x_0)$ as a function of time for different cases when the thickness goes to zero.

We can see in Figures 4.3, 4.4, and 4.5 that when the thickness goes to zero, the two solutions tend to be identical.

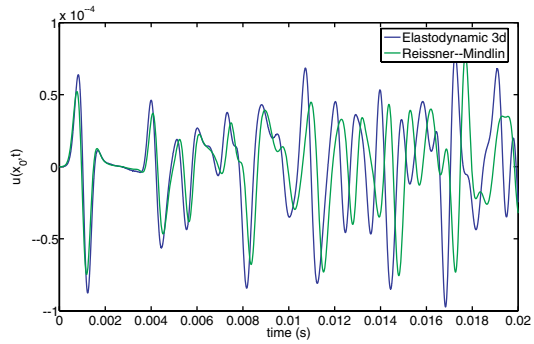

FIG. 4.3. *Comparaison with* $\delta = 1.4cm$.

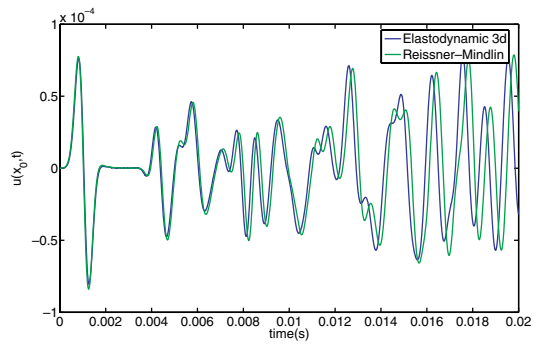

FIG. 4.4. *Comparaison with* $\delta = 0.5cm$.

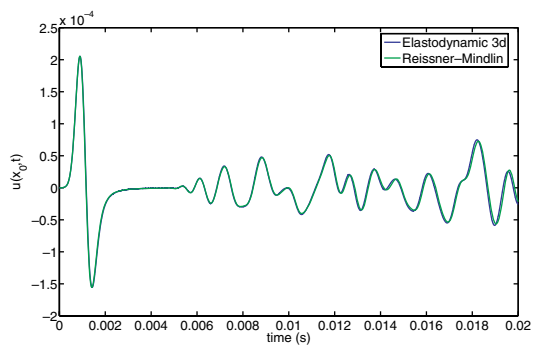

FIG. 4.5. *Comparaison with* $\delta = 0.01cm$.

4.2. Influence of the order of the method on CPU time and accuracy. In this section we want to show the advantages of our scheme in terms of accuracy and computational time. We fix $\delta = 1mm$ and we compute a reference solution with $\mathcal{Q}_7$-finite elements with an extremely fine mesh (5000 elements). Then, we compute the solution for orders $r = 2$ to $r = 7$ with a regular mesh with a space step h_r, such that the relative error (defined by (4.1)) of this solution compared to the reference solution is around 5%. For each case of computation, we take the optimal time step in terms of computation time, i.e., the maximum Δt authorized by the stability condition. In practice we compute the relative error e_h at the point x_0, so that our criterion of

accuracy is

$$e_h = \frac{\|u_h(x_0,t) - u_{ref}(x_0,t)\|_{l_2[0,T]}}{\|u_{ref}(x_0,t)\|_{l_2[0,T]}} \simeq 5\%. \tag{4.1}$$

The results we obtain are given in the following table:

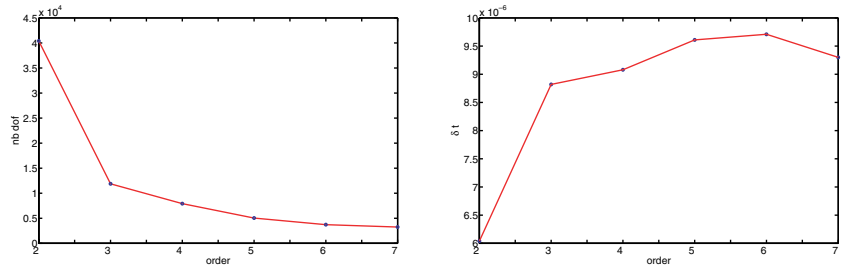
Order	Elements	Storage	Δt	CPU time(s)	$e_h(\%)$
2	10000	40401 dof	0.604e-5	556	5.2
3	1296	11881 dof	0.882e-5	84	5.4
4	484	7921 dof	0.908e-5	49	4.8
5	196	5041 dof	0.961e-5	26	4.9
6	100	3721 dof	0.971e-5	18	5.1
7	64	3249 dof	0.93e-5	16	5

The results of this table clearly illustrate the advantage of using higher order elements. The use of $\mathcal{Q}_7$-finite elements divides by 3 the computation time compared to $\mathcal{Q}_4$-finite elements, and divides by 35 the computation time compared to $\mathcal{Q}_2$-finite elements. We can also see the gain in terms of memory storage: Indeed, both the number of elements and the number of degrees of freedom needed to satisfy (4.1) decrease when we use higher orders.

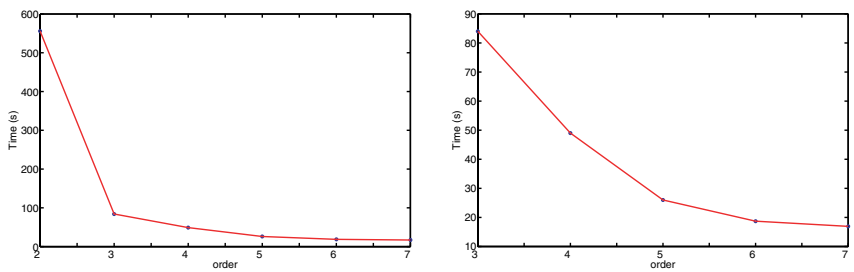
One can, however, notice a slower convergence for higher orders. This is due to the increase of the size of the discrete operators with the order, which finally balance and even overcome the gain realized by the use of larger elements. On the other hand, the step Δt remains approximately the same for orders from 4 to 7. Indeed, even if a high order enforces a smaller Δt than for low orders, we can use a less fine mesh to satisfy (4.1) and thus the CFL condition remains almost constant. All these comments are illustrated by Figure 4.6. Figure 4.6(a) represents the number of degrees of freedom as a function of the order to satisfy (4.1), Figure 4.6(b) represents the optimal step Δt as a function of the order, and Figure 4.6(c) represents the CPU time as a function of the order with a zoom at large orders in Figure 4.6(d).

4.3. Influence of the thickness in the finite element approximation. The previous table shows that for low orders (orders 2 and 3) the convergence is abnormally slow, and we need very many degrees of freedom (a very small space step) to be accurate. This is a locking phenomenon. Many papers [1], [4], [7] deal with this problem, which is not the subject of this paper. However, we were interested in this aspect. Figures 4.6 and 4.7 represent the number of degrees of freedom (and in some sense the size of the space step) needed to satisfy the criterion of accuracy (4.1) for different thicknesses. We can see that as the thickness goes to zero, the number of degrees of freedom needed to satisfy (4.1) becomes higher and higher for orders 2 and 3, while this is not the case from the order 4. For orders higher than 4, the influence of the thickness on the mesh is weak. Our conclusion is that a way to weaken locking phenomena is to use a finite element with a high enough order. Nevertheless we do not claim that this method eliminates numerical locking.

4.4. The case of a heterogeneous plate. To conclude we present some snapshots from a numerical simulation for a heterogeneous plate. The plate consists of three media. Medium 1 is plexiglass where the smallest velocity of propagating waves in the plate is 758 $m.s^{-1}$. Medium 2 is aluminium where the smallest velocity of propagating waves in the plate is 3097 $m.s^{-1}$, and medium 3 is cast iron where the smallest velocity of propagating waves in the plate is 3215 $m.s^{-1}$. So we have to construct a structured mesh that will be finer in the first media than in the two



(a) Degree of freedom/order (b) Δt/order



(c) CPU time/order (d) CPU time/order

FIG. 4.6. *Influence of the order on the performance of the method.*

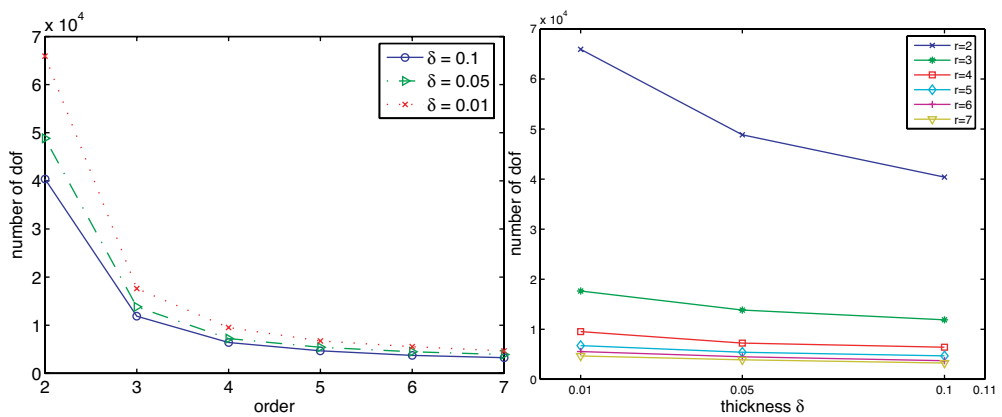


FIG. 4.7. *Numerical locking for low orders.*

others. Most of the software available gives appropriate triangular meshes. Then we obtain our quadrilateral mesh from a triangular mesh by cutting each triangle in three quadrilaterals. The mesh and the way to get the mesh are illustrated in Figure 4.8. We center the Gaussian function at the point $(-1, 0)$ in the medium 2.

Figure 4.9 brings to the fore that the plate equation is dispersive. The picture on the left shows the signal at the beginning of the simulation and the picture and the right shows the solution after a short time of propagation. We see the modification of the wave front during this time. We can see in Figure 4.10 that propagated waves are diffracted by the plexiglass because the velocity is slower than in the other media. We

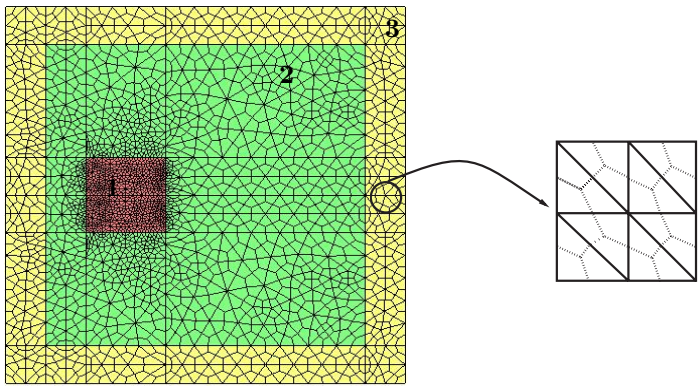

FIG. 4.8. *The mesh of the heterogeneous plate.*

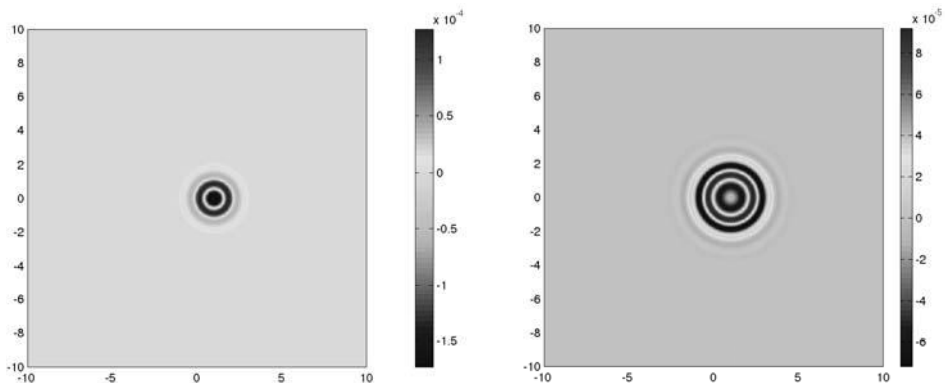

FIG. 4.9. *Snapshots of the bending displacement.*

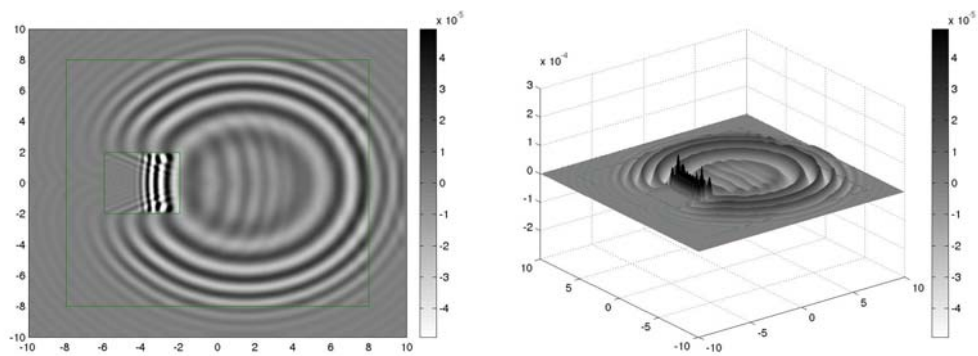

FIG. 4.10. *Snapshots of the bending displacement at the time* $t = 1.7 \times 10^{-4} s$.

do not see a similar phenomenon at the interface of aluminium and cast iron because the velocities are almost equal. To conclude, the amplitude of the displacement is higher in plexiglass than in aluminium and is higher in aluminium than in cast iron. This is consistent with the stiffness properties of each medium.

Conclusion. In this paper we have proposed a robust and accurate finite element method in the time domain for the Reissner–Mindlin plate model. This method is based on mixed spectral finite elements with mass lumping. A mixed formulation of the model has enabled us to construct an approximation space with the Piola transform to avoid the storage of the stiffness matrix which induces a very substantial gain in memory storage. Then we have proposed an explicit leapfrog scheme thanks to the mass-lumping principle, which induces a gain of CPU time. After a validation of our method with results of a 3D code, numerical experiments demonstrate the usefulness of high orders in terms of computation time, memory storage, and accuracy. Finally, we have brought to the fore that the use of high orders is a way to weaken locking phenomena.

ON THE VARIATIONAL APPROXIMATION OF COMBINED SECOND AND FOURTH ORDER GEOMETRIC EVOLUTION EQUATIONS*

JOHN W. BARRETT†, HARALD GARCKE‡, AND ROBERT NÜRNBERG†

Abstract. We present a variational formulation of combined motion by minus the Laplacian of curvature and mean curvature flow, as well as related flows. The proposed scheme covers both the closed curve case and the case of curves that are connected via triple or quadruple junction points or intersect the external boundary. On introducing a parametric finite element approximation, we prove stability bounds and compare our scheme with existing approaches. The presented scheme has very good properties with respect to the equidistribution of mesh points and, if applicable, area conservation.

Key words. surface diffusion, (inverse) mean curvature flow, surface attachment limited kinetics, nonlinear curve evolution, triple junctions, parametric finite elements, Schur complement, tangential movement

1. Introduction.

The motion of curves or surfaces driven by second or fourth order geometric evolution equations arises in many applications in materials science and, of course, in differential geometry. Well known is the mean curvature flow, where a hypersurface moves in the direction of its mean curvature vector. Also frequently arising are evolution laws where the normal speed of an evolving hypersurface is given as a function of mean curvature, in applications, such as image processing or mathematical physics. In mathematical physics the inverse mean curvature flow plays a role in the context of the positive mass conjecture. In materials science the motion of networks of curves or surfaces is also often important. The evolution of grain networks—arising in polycrystalline materials—is also given by mean curvature flow, where at junctions angle conditions have to hold.

Fourth order geometric evolution equations also frequently are found in geometry and materials science. The situation that the normal velocity of a hypersurface is given by minus the Laplacian of mean curvature is called surface diffusion. This evolution law arises in situations where the diffusion of material is restricted to interfacial regions; see, e.g., [36]. When many phases appear, networks also have to be taken into account. As the evolution law is of fourth order, additional conditions, which act as boundary conditions for the evolution law on the curves or surfaces, have to hold.

The goal of this paper is to propose and analyze a new approach to numerically solving geometric evolution laws of second and fourth order. The numerical method is variational and very flexible. In particular, it is possible to couple fourth and second order laws on the surfaces or at triple junctions in a straightforward way.

There exist numerous methods for numerically solving geometric evolution equations. Approaches are based on, e.g., the parametric formulation, the graph formulation, the level set method, or the phase field approach. We do not intend to give an outline of all these methods, but rather refer to [14] for a comprehensive recent review. Our approach makes use of a fundamental idea in [16], which used the identity

$$\Delta_s \, \vec{x} = \vec{\varkappa}, \tag{1.1}$$

where Δ_s is the surface Laplacian, $\vec{x}$ is the position vector, and $\vec{\varkappa}$ is the mean curvature vector, for the first time in order to design a finite element method for geometric partial differential equations and mean curvature flow; see also [17]. A second major idea stems from the paper [3], which came up with a splitting method and employed a Schur complement approach, in order to compute solutions of the surface diffusion law

$$\mathcal{V} = -\Delta_s \, \varkappa, \tag{1.2}$$

where $\varkappa$ is the sum of the principal curvatures of Γ and $\mathcal{V}$ is the normal velocity of the surface.

The approaches of Dziuk and of Bänsch, Morin, and Nochetto both require that the parameterization evolve only in the normal direction. In the recent paper [6], the present authors introduced a novel parametric finite element approximation for surface diffusion that also allowed for a tangential movement of mesh points, which of course does not change the geometry. This new approach has the advantage that the discretization has very good properties with respect to the equidistribution of mesh points. In the case of surface diffusion of curves, a semidiscrete version of this scheme, i.e., a scheme where one discretizes only with respect to space, leads to a precise equidistribution of mesh points. With the new ansatz it is also possible to formulate the rather complicated conditions that need to hold at triple junction points in a natural variational way. In this paper we want to demonstrate that the ideas developed in [6] can also be used to compute other geometric evolution laws of both second and fourth order. For instance, the inverse mean curvature flow and an evolution flow which couples mean curvature flow to surface diffusion at triple junctions (see, e.g., [12]) can be approximated in the spirit of the approach proposed in [6].

In this paper, we will consider evolution laws that couple fourth and second order geometric evolution laws. The coupling can be either through triple junctions or through a coupling that combines mean curvature flow and the fourth order surface diffusion flow via an appropriate interpolation; see [42] for applications of this flow in materials science. Let us introduce first the case of pure second order geometric evolution equations; that means in our context situations where the normal velocity is given by a function of mean curvature. For a closed hypersurface Γ in $\mathbb{R}^d$, mean curvature flow is given by

$$\mathcal{V} = \varkappa \tag{1.3}$$

or, more generally, we are also going to consider flows of the form

$$\mathcal{V} = f(\varkappa), \tag{1.4}$$

where $f : (a, b) \to \mathbb{R}$ with $-\infty \leq a < b \leq \infty$ is a strictly monotonically increasing continuous function, e.g.,

$$f(r) := |r|^{\beta-1} r, \quad \beta \in \mathbb{R}_{>0}\,; \tag{1.5}$$

see [35] and the references therein. For example, the evolution law (1.4), with (1.5) for $\beta = \frac{1}{3}$, has been studied in [1, 40, 2].

We will also consider computations for (1.4) with

$$f(r) := -r^{-1}, \tag{1.6}$$

i.e., the inverse mean curvature flow; see, e.g., [29, 32] for the origins of this flow in mathematical physics, and [31], and the references therein, for a consideration of this flow in differential geometry. To our knowledge, the only numerical results in the literature for (1.4) with (1.6) can be found in [38, 22], where a finite volume and a finite element approximation, respectively, of a regularized level set formulation of (1.4) with (1.6) are employed. We know of no direct approach for the approximation of the inverse mean curvature flow in the literature.

For a parameterization $\vec{x}(\rho, t) \in \mathbb{R}^d$ of Γ, (1.4) can be written as a second order equation:

$$\mathcal{V} := \vec{x}_t \,.\, \vec{\nu} = f(\varkappa), \qquad \varkappa\,\vec{\nu} = \Delta_s\,\vec{x}, \tag{1.7}$$

where $\vec{\nu}$ is a unit normal to Γ. Note that because the tangential component $\vec{x}_t - (\vec{x}_t \,.\, \vec{\nu})\,\vec{\nu}$ of the velocity $\vec{x}_t$ is not prescribed in (1.7), there exists a whole family of solutions $\vec{x}$, even though the evolution of Γ is uniquely determined by (1.3). Our numerical scheme will directly discretize (1.7), in contrast to the scheme considered by Dziuk (see [16, 17]), which discretizes $\vec{x}_t = \Delta_s\,\vec{x}$ and hence, on noting (1.1) and that $\vec{\varkappa} = \varkappa\,\vec{\nu}$, enforces a movement of the parameterization $\vec{x}$ in the normal direction only.

A version of (1.4) that preserves the enclosed volume is given by

$$\mathcal{V} = f(\varkappa) - \frac{\int_\Gamma f(\varkappa)\,\mathrm{d}s}{\int_\Gamma 1\,\mathrm{d}s}, \tag{1.8}$$

the so-called conserved mean curvature flow, also called surface attachment limited kinetics (SALK), if $f(r) := r$. An intermediate law between (1.4), with $f(r) := r$, and (1.2) is the following evolution law:

$$\mathcal{V} = -\Delta_s \left(\frac{1}{\alpha} - \frac{1}{\xi}\,\Delta_s\right)^{-1} \varkappa, \tag{1.9}$$

where $\alpha, \xi \in \mathbb{R}_{>0}$. The flow (1.9) interpolates between surfaces diffusion (1.2) and SALK, (1.8) with $f(r) := r$, and was first discussed in [42]; see also [20]. It is similar to (1.2) and (1.8) in that the enclosed volume is conserved while the area of the hypersurface decreases. We observe that for $\alpha \to \infty$ and $\xi = 1$ the solutions to (1.9) converge to solutions of (1.8) with $f(r) := r$, as has been shown in [21]. In the limit $\xi \to \infty$ and $\alpha = 1$ the solutions to (1.9) should converge to solutions of the law (1.2), although to our knowledge no rigorous proof exists. Given a parameterization $\vec{x}(\rho, t) \in \mathbb{R}^d$ of Γ, (1.9) can be written as a system of second order equations:

$$\vec{x}_t \,.\, \vec{\nu} = -\Delta_s\, y\,, \qquad \left(\frac{1}{\alpha} - \frac{1}{\xi}\,\Delta_s\right) y = \varkappa\,, \qquad \varkappa\,\vec{\nu} = \Delta_s\,\vec{x}. \tag{1.10}$$

Analogously surface diffusion can be rewritten as

$$\vec{x}_t \,.\, \vec{\nu} = -\Delta_s\,\varkappa, \qquad \varkappa\,\vec{\nu} = \Delta_s\,\vec{x}. \tag{1.11}$$

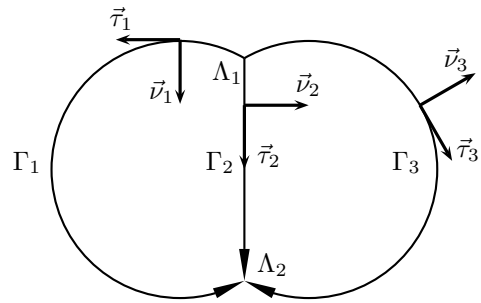

FIG. 1. *The setup of* $\Gamma = (\Gamma_1, \Gamma_2, \Gamma_3)$.

In section 2, we will consider a finite element approximation of a variational formulation of (1.11), as well as (1.7), (1.8), and (1.10), where throughout we will restrict our attention to the case $d = 2$, i.e., curves in the plane. In addition, we will compare our approximation of (1.3) with two other parametric approximations in the literature, namely, [17, 13].

A network of curves under motion by mean curvature with triple junctions can also be considered. In the example network in Figure 1, let Γ_1, Γ_2, Γ_3 be the given curves in $\mathbb{R}^d$, $d = 2$, that intersect at two triple junction points Λ_1 and Λ_2. Then the normal velocity for each curve is given by

$$\mathcal{V}_i = \sigma_i \, \varkappa_i, \qquad i = 1 \to 3, \tag{1.12}$$

where $\varkappa_i$ is the curvature of Γ_i and σ_i is the surface energy density of Γ_i. Let $\vec{\tau}_i \in \mathbb{R}^d$ be the unit tangent to Γ_i pointing away from the triple junction point Λ_1 and towards point Λ_2. The curvature is said to be positive if Γ_i is curved in the direction of the normal $\vec{\nu}_i \in \mathbb{R}^d$, which is the unique unit vector such that $(\vec{\tau}_i, \vec{\nu}_i)$ forms a positively orientated orthonormal system. For parameterizations $\vec{x}_i : [0,1] \times [0,T] \to \mathbb{R}^d$ of Γ_i, $i = 1 \to 3$, (1.12) can be written as a system of second order equations:

$$(\vec{x}_i)_t \, . \, \vec{\nu}_i = \sigma_i \, \varkappa_i, \qquad \varkappa_i \, \vec{\nu}_i = \Delta_s \, \vec{x}_i. \tag{1.13}$$

Then, in addition to (1.12), the following conditions have to hold at the triple junction points Λ_1 and Λ_2:

$$\text{the triple junction does not pull apart,} \tag{1.14a}$$

$$\sigma_1 \, \vec{\tau}_1 + \sigma_2 \, \vec{\tau}_2 + \sigma_3 \, \vec{\tau}_3 = \vec{0}. \tag{1.14b}$$

The condition (1.14a) is an attachment condition, and (1.14b) is Young's law, which is a balance-of-force equation at the triple junction. Young's law is equivalent to the angle condition $\frac{\sin\theta_1}{\sigma_1} = \frac{\sin\theta_2}{\sigma_2} = \frac{\sin\theta_3}{\sigma_3}$, where

$$\theta_1 = \sphericalangle(\vec{\tau}_2, \vec{\tau}_3), \quad \theta_2 = \sphericalangle(\vec{\tau}_3, \vec{\tau}_1), \quad \text{and} \quad \theta_3 = \sphericalangle(\vec{\tau}_1, \vec{\tau}_2)\,. \tag{1.15}$$

A variational formulation of (1.13) with (1.14a,b) will form the basis for the scheme that we present in section 2.

In most physical applications only triple junctions are of interest. However, in certain situations quadruple junctions are also possible. In the case that four interfaces meet at a quadruple junction the balance-of-force condition of the quadruple junction is

$$\sigma_1 \, \vec{\tau}_1 + \sigma_2 \, \vec{\tau}_2 + \sigma_3 \, \vec{\tau}_3 + \sigma_4 \, \vec{\tau}_4 = \vec{0}\,, \tag{1.16}$$

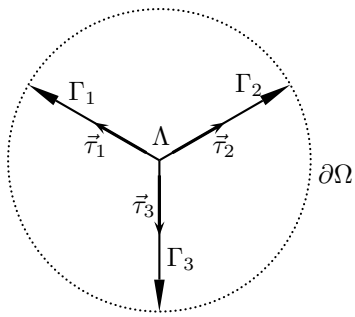

FIG. 2. *The second possible setup of* $\Gamma = (\Gamma_1, \Gamma_2, \Gamma_3)$.

where we use notation analogous to that in (1.14b); e.g., the four curves Γ_i, $i = 1 \to 4$, meeting at the quadruple junction are parameterized such that the tangent vectors point away from the junction. In this case the angles at the quadruple junction are not specified, and in fact there is one degree of freedom. For details we refer to [10, 11, 24].

In [6] the possibility of curve intersections with a fixed external boundary $\partial\Omega$, where Ω is a domain in $\mathbb{R}^d$, was not considered (see Figure 2 for an example). To state the necessary conditions that have to hold at an intersection with the external boundary we assume that $\partial\Omega$ is given by a function $F \in C^1(\mathbb{R}^d)$ such that

$$\partial\Omega = \{\vec{z} \in \mathbb{R}^d : F(\vec{z}) = 0\} \qquad \text{and} \qquad |\nabla F(\vec{z})| = 1 \quad \forall\ \vec{z} \in \partial\Omega\,.$$

Then, for three given curves Γ_i, $i = 1 \to 3$, evolving according to (1.12), the conditions (1.14a,b) need to hold only at the triple junction $\Lambda = \vec{x}_i(0)$, $i = 1 \to 3$, while at the boundary intersection points $\vec{x}_i(1)$, $i = 1 \to 3$, the following conditions have to hold:

(1.17a) the curve endpoint remains attached to $\partial\Omega$,

(1.17b) $$\vec{\tau}_i\,.\,[\nabla F(\vec{x}_i(1))]^\perp = 0,$$

where $\cdot^\perp$ denotes the clockwise rotation by $\frac{\pi}{2}$. The second condition, (1.17b), requires that forces at the outer boundary act only normal to the boundary, which is equivalent to a 90° angle condition. This is the case when the two phases that meet the external boundary have the same contact energy with the boundary. If this is not the case, then condition (1.17b) has to be replaced by the angle condition

(1.18) $$\vec{\tau}_i \cdot \vec{t} = \vec{\tau}_i \cdot [\nabla F(\vec{x}_i(1))]^\perp = \cos\alpha_i,$$

where $\vec{t}$ is a unit tangent to $\partial\Omega$. Condition (1.18) states that the curve Γ_i intersects the outer boundary with a given angle α_i; see, e.g., [23] for the physical background.

Before coupling fourth and second order geometric evolution equations at triple junctions, we now turn our attention to a network evolving according to surface diffusion. Using the same notation as above, we rewrite the evolution laws

(1.19) $$\mathcal{V}_i = -\sigma_i\,\Delta_s\,\varkappa_i, \qquad i = 1 \to 3,$$

as

(1.20) $$(\vec{x}_i)_t\,.\,\vec{\nu}_i = -\sigma_i\,\Delta_s\,\varkappa_i, \qquad \varkappa_i\,\vec{\nu}_i = \Delta_s\,\vec{x}_i.$$

These equations are coupled at triple junctions and have to fulfill boundary conditions at points that intersect the external boundary. At the triple junction we require in addition to (1.14a,b) the conditions

$$\sigma_1 \varkappa_1 + \sigma_2 \varkappa_2 + \sigma_3 \varkappa_3 = 0, \tag{1.21a}$$

$$\sigma_1 \vec{\tau}_1 \,.\, \nabla_s \varkappa_1 = \sigma_2 \vec{\tau}_2 \,.\, \nabla_s \varkappa_2 = \sigma_3 \vec{\tau}_3 \,.\, \nabla_s \varkappa_3, \tag{1.21b}$$

where $\nabla_s |_{\Gamma_i} \equiv \vec{\tau}_i \frac{\partial}{\partial s}$ with s being the arclength. Equation (1.21a) follows from the continuity of chemical potentials, and (1.21b) is a flux balance condition; see [28] for details. At an intersection with an external boundary we require (1.17a,b) and the following no-flux condition at the external boundary:

$$\nabla_s \varkappa_i = \vec{0}\,. \tag{1.22}$$

Finally, another possible setup is to require motion by mean curvature only on a subset of the given curves, while the remaining curves move by surface diffusion. This is of relevance, e.g., in thermal grooving [36], in interface motion in polycrystalline two-phase materials [10], and in the evolution of boundaries in the electromigration of intergranular voids [7]. For parameterizations $\vec{x}_i : [0,1] \times [0,T] \to \mathbb{R}^d$ of Γ_i, $i = 1 \to K_C$, this gives rise to the following system of equations:

$$\begin{aligned} &(\vec{x}_i)_t \,.\, \vec{\nu}_i = \sigma_i \varkappa_i, \quad i = 1 \to i_0, \qquad (\vec{x}_i)_t \,.\, \vec{\nu}_i = -\sigma_i \Delta_s \varkappa_i, \quad i = i_0 + 1 \to K_C, \\ &\varkappa_i \vec{\nu}_i = \Delta_s \vec{x}_i, \quad i = 1 \to K_C, \end{aligned} \tag{1.23}$$

subject to the triple junction conditions (1.14a,b). In addition, we require that at triple junctions

$$\sigma_i \vec{\tau}_i \,.\, \nabla_s \varkappa_i = \sigma_j \vec{\tau}_j \,.\, \nabla_s \varkappa_j \tag{1.24a}$$

for all interfaces $i, j \in \{i_0 + 1, \dots, K_C\}$ which are present at the junction. Further, we require that

$$\sum_{i \in T_{SD}} \sigma_i \varkappa_i = 0, \tag{1.24b}$$

where $T_{SD} \subset \{i_0 + 1, \dots, K_C\}$ are the interfaces present at the triple junction which move according to surface diffusion. We note that for practical applications of (1.23) only triple junctions, where one curve that moves by mean curvature flow and two curves moving by surface diffusion meet, are of interest. A variational formulation of (1.23) with the appropriate conditions at triple junctions and along the fixed external boundary will also be considered in section 2.

As for previous work on the approximation of curve networks, we refer to [9, 43, 37]. Also relevant is [8], where (1.12) and (1.14a,b) are derived from an Allen–Cahn system. A parametric finite element approximation of the mean curvature flow of a curve that intersects an external boundary was considered in [15]. A level set approach for mean curvature flow of curve networks has been considered in [34, 44, 41]. A phase field model for the combined motion of mean curvature flow and surface diffusion, as well as SALK, was considered in [7]. A phase field model for a mean curvature flow system is considered in [27], and a surface diffusion flow system in [4].

This paper is organized as follows. In section 2 we formulate a finite element approximation of problem (1.13) and derive stability bounds. Here we first introduce our

approximation for the simpler case of a closed curve, (1.7), and then generalize that scheme to cover (1.8), as well as (1.20) and (1.14a,b) in the case of a triple junction configuration, as in Figure 1. We indicate how to generalize the approach to a configuration as in Figure 2, as well as to an arbitrary setup of curves, triple junctions, and external boundary intersections. We will also indicate how to combine this approach with the algorithm presented in [6] to yield a scheme for combined mean curvature flow and surface diffusion. Finally, we consider the adaptation of our scheme to approximate (1.10). In section 3 we present a large number of numerical computations and compare our results, where possible, with those from other parametric algorithms in the literature.

2. Finite element approximation.

2.1. Closed curves. We introduce the following finite element approximation. Let $J := \mathbb{R}/\mathbb{Z} = \bigcup_{j=1}^{N} J_j$, $N \geq 3$, be a decomposition of J into intervals given by the nodes q_j, $J_j = [q_{j-1}, q_j]$. Let $h_j = |J_j|$ and $h = \max_{j=1\to N} h_j$ be the maximal length of a grid element. Then the necessary finite element spaces are defined as follows:

$$\underline{V}_0^h := \{\vec{\chi} \in C(J,\mathbb{R}^d) : \vec{\chi}|_{J_j} \text{ is linear } \forall\ j = 1 \to N\} =: [W_0^h]^d \subset H^1(J,\mathbb{R}^d), \tag{2.1}$$

where $W_0^h \subset H^1(J,\mathbb{R})$ is the space of scalar continuous (periodic) piecewise linear functions, with $\{\phi_l\}_{l=1}^N$ denoting the standard basis of W_0^h. Throughout this paper, we make use of the periodicity of J, i.e., $q_N \equiv q_0$, $q_{N+1} \equiv q_1$, and so on.

In addition, let $0 = t_0 < t_1 < \cdots < t_{M-1} < t_M = T$ be a partitioning of $[0,T]$ into possibly variable time steps $\tau_m := t_{m+1} - t_m$, $m = 0 \to M-1$. We set $\tau := \max_{m=0\to M-1} \tau_m$. Let $\vec{X}^m \in \underline{V}_0^h$ be an approximation to $\vec{x}(\cdot,t_m)$, and similarly $\kappa^m \in W_0^h$ for $\varkappa(\cdot,t_m)$.

For scalar and vector functions $u, v \in L^2(J,\mathbb{R}^{(d)})$ we introduce the L^2 inner product $\langle\cdot,\cdot\rangle_m$ over the current polygonal curve Γ^m, which is described by the vector function $\vec{X}^m \in \underline{V}_0^h$, as follows:

$$\langle u, v\rangle_m := \int_{\Gamma^m} u \,.\, v \,\mathrm{d}s = \int_J u \,.\, v\, |\vec{X}_\rho^m| \,\mathrm{d}\rho\,,$$

where, here and throughout, $\vec{X}_\rho^m$ denotes the derivative of $\vec{X}^m$ with respect to ρ, where $\rho \in [0,1]$ is the parameterization variable, and $\cdot^{(*)}$ denotes an expression with or without the superscript $*$, and similarly for subscripts. In addition, if u, v are piecewise continuous, with possible jumps at the nodes $\{q_j\}_{j=1}^N$, we define the mass lumped inner product $\langle\cdot,\cdot\rangle_m^h$ as

$$\langle u, v\rangle_m^h := \tfrac{1}{2} \sum_{j=1}^{N} |\vec{X}^m(q_j) - \vec{X}^m(q_{j-1})| \left[(u \,.\, v)(q_j^-) + (u \,.\, v)(q_{j-1}^+)\right], \tag{2.2}$$

where we define $u(q_j^\pm) := \lim_{\varepsilon \searrow 0} u(q_j \pm \varepsilon)$. Furthermore, we note that $\nabla_s u \,.\, \nabla_s v = \frac{u_\rho \,.\, v_\rho}{|\vec{X}_\rho^m|^2}$ and $\vec{\nu}^m = -\frac{(\vec{X}_\rho^m)^\perp}{|\vec{X}_\rho^m|}$.

We propose the following approximation to (1.7): Find $\{\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}_0^h \times W_0^h$ such that

$$\left\langle \frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m}, \chi\, \vec{\nu}^m \right\rangle_m^h - \langle f(\kappa^{m+1}), \chi\rangle_m^h = 0 \qquad \forall\ \chi \in W_0^h, \tag{2.3a}$$

$$\langle \kappa^{m+1}\, \vec{\nu}^m, \vec{\eta}\rangle_m^h + \langle \nabla_s \vec{X}^{m+1}, \nabla_s \vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}_0^h, \tag{2.3b}$$

where, as noted above, the inner products $\langle\cdot,\cdot\rangle_m^{(h)}$ as well as ∇_s depend on m.

In order to approximate (1.8), we adapt (2.3a) to

(2.4)
$$\left\langle \frac{\vec{X}^{m+1}-\vec{X}^m}{\tau_m}, \chi\,\vec{\nu}^m \right\rangle_m^h - \langle f(\kappa^{m+1}),\chi\rangle_m^h = -\frac{\langle f(\kappa^m),1\rangle_m^h}{\langle 1,1\rangle_m}\,\langle 1,\chi\rangle_m \qquad \forall\ \chi\in W_0^h,$$

where $\kappa^0\in W_0^h$ is suitably chosen; see section 3.

Remark 2.1. We note that in (2.3a,b), and throughout this paper, we use piecewise linear finite elements, e.g., as defined in (2.1). This is a sensible choice for the type of evolution equations in consideration, both from a theoretical and practical points of view. It is also in line with other approaches in the literature; see, e.g., [16, 17, 13, 15, 19, 3]. However, from a computational point of view, one could also choose to use higher order finite elements.

Before we can proceed to prove existence and uniqueness of (2.3a,b), we have to make the following very mild assumption.

($\mathcal{A}_0$) Let $|\vec{X}_\rho^m|>0$ for almost all $\rho\in J$. For $j=1\to N$, let $\vec{\nu}^m_{j-\frac12} := -\frac{(\vec{X}_\rho^m)^\perp}{|\vec{X}_\rho^m|}\,|_{J_j}$, and set

$$\vec{\omega}_j^m := \frac{|\vec{X}^m(q_j)-\vec{X}^m(q_{j-1})|\,\vec{\nu}^m_{j-\frac12}+|\vec{X}^m(q_{j+1})-\vec{X}^m(q_j)|\,\vec{\nu}^m_{j+\frac12}}{|\vec{X}^m(q_j)-\vec{X}^m(q_{j-1})|+|\vec{X}^m(q_{j+1})-\vec{X}^m(q_j)|}$$

$$= \frac{-[\vec{X}^m(q_{j+1})-\vec{X}^m(q_{j-1})]^\perp}{|\vec{X}^m(q_j)-\vec{X}^m(q_{j-1})|+|\vec{X}^m(q_{j+1})-\vec{X}^m(q_j)|}\,. \tag{2.5}$$

Then we further assume that $\dim \operatorname{span}\{\vec{\omega}_j^m\}_{j=1}^N = d = 2$.

Remark 2.2. We note that one can interpret $\vec{\omega}_j^m$ as a weighted normal defined at the node $\vec{X}^m(q_j)$ of the curve Γ^m, where in general $|\vec{\omega}_j^m|<1$. In addition, we note that ($\mathcal{A}_0$) is violated only in very rare occasions. For example, it always holds for curves without self intersections; see [6, Remark 2.2] for details.

THEOREM 2.3. [illegible] ($\mathcal{A}_0$) [illegible] $f:(a,b)\to\mathbb{R}$, [illegible] $-\infty\le a<0<b\le\infty$, [illegible] $f((a,b))=\mathbb{R}$ [illegible] $\{\vec{X}^{m+1},\kappa^{m+1}\}\in \underline{V}_0^h\times W_0^h$ [illegible] (2.3a,b) [illegible]. For later developments involving networks of curves, we first discuss the linear case when $f(r):=r$, and so existence follows from uniqueness. To investigate the latter, we consider the following system: Find $\{\vec{X},\kappa\}\in\underline{V}_0^h\times W_0^h$ such that

$$\langle\vec{X},\chi\,\vec{\nu}^m\rangle_m^h - \tau_m\,\langle\kappa,\chi\rangle_m^h = 0 \qquad \forall\ \chi\in W_0^h, \tag{2.6a}$$

$$\langle\kappa\,\vec{\nu}^m,\vec{\eta}\rangle_m^h + \langle\nabla_s\,\vec{X},\nabla_s\,\vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta}\in\underline{V}_0^h. \tag{2.6b}$$

Choosing $\chi=\kappa\in W_0^h$ in (2.6a) and $\vec{\eta}=\vec{X}\in\underline{V}_0^h$ in (2.6b) yields that

$$\langle\nabla_s\,\vec{X},\nabla_s\,\vec{X}\rangle_m + \tau_m\,\langle\kappa,\kappa\rangle_m^h = 0. \tag{2.7}$$

It follows from (2.7) that $\kappa\equiv 0$ and $\vec{X}\equiv\vec{X}^c\in\mathbb{R}^d$, and hence that

$$\langle\vec{X}^c,\chi\,\vec{\nu}^m\rangle_m^h = 0 \quad \forall\ \chi\in W_0^h. \tag{2.8}$$

Choosing $\chi=\phi_j$ in (2.8) yields that $\vec{X}^c\,.\,\vec{\omega}_j^m=0$ for all $j=1\to N$. It follows from assumption ($\mathcal{A}_0$) that $\vec{X}^c=\vec{0}$. Hence we have shown that (2.3a,b) with $f(r):=r$ has a unique solution $\{\vec{X}^{m+1},\kappa^{m+1}\}\in\underline{V}_0^h\times W_0^h$.

For a general function $f : (a,b) \to \mathbb{R}$ fulfilling the assumptions of the theorem, we can rewrite (2.3a,b), on noting (2.2) and (2.5), as: Find $\vec{X}^{m+1} \in \underline{V}_0^h$ such that

$$\langle \nabla_s \vec{X}^{m+1}, \nabla_s \vec{\eta} \rangle_m + \left\langle f^{-1}\left(\frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m} \,.\, \vec{\omega}^m \right), \vec{\eta} \,.\, \vec{\omega}^m \right\rangle_m^h = 0 \qquad \forall\ \vec{\eta} \in \underline{V}_0^h, \tag{2.9}$$

where $\vec{\omega}^m := \sum_{j=1}^N \vec{\omega}_j^m \phi_j$. Then $\kappa^{m+1} \in W_0^h$ is uniquely determined from

$$\kappa^{m+1}(q_j) = f^{-1}\left(\frac{\vec{X}^{m+1}(q_j) - \vec{X}^m(q_j)}{\tau_m} \,.\, \vec{\omega}_j^m \right), \qquad j = 1 \to N. \tag{2.10}$$

On noting our assumption $(\mathcal{A}_0)$, similarly as in the linear case above, it follows that (2.9) is the Euler–Lagrange variation of the strictly convex minimization problem

$$\min_{\vec{\eta} \in \underline{V}_0^h} \left[\tfrac{1}{2} \langle \nabla_s \vec{\eta}, \nabla_s \vec{\eta} \rangle_m + \tau_m \left\langle \Phi\left(\frac{\vec{\eta} - \vec{X}^m}{\tau_m} \,.\, \vec{\omega}^m \right), 1 \right\rangle_m^h \right],$$

where Φ is an antiderivative of f^{-1}. We note that $\Phi : \mathbb{R} \to \mathbb{R}$ is strictly convex with $\Phi'(f(0)) = f^{-1}(f(0)) = 0$, and hence we obtain that Φ is bounded from below and coercive. Therefore there exists a unique solution $\vec{X}^{m+1} \in \underline{V}_0^h$ to (2.9), and hence a unique solution $\{\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}_0^h \times W_0^h$ to (2.3a,b). ∎

The above proof immediately applies to the case when (2.3a) is replaced by (2.4). We remark also that we still obtain uniqueness for strictly increasing continuous functions $f : (a,b) \to \mathbb{R}$ with $-\infty \le a < b \le \infty$. This follows, since Φ defined as above is still strictly convex. Existence cannot be established as easily as above, because Φ is not coercive any longer. This discussion is relevant, e.g., for $f(r) = -r^{-1}$ with $r \in (0,\infty)$, which is the case of the inverse mean curvature flow if $\varkappa(\cdot,0) > 0$. In this case we obtain that $\Phi : (-\infty, 0) \to \mathbb{R}$ is defined as $\Phi(r) = \ln|r|$.

In addition, stability results for (2.3a,b) and the variants involving (2.4) can be established in certain cases; see Theorem 2.10, and the ensuing comment, below. For example, the term $\langle \kappa^{m+1}, \kappa^{m+1} \rangle_m^h$ in the analogue of (2.38) is replaced by $\langle f(\kappa^{m+1}), \kappa^{m+1} \rangle_m^h$, which once again is nonnegative if f is monotonically increasing with $f(0) = 0$. Of course, it may be computationally more convenient to consider a linearized version of (2.3a). For example, for (1.5) with $\beta \ge 1$ one could replace (2.3a) by

$$\left\langle \frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m}, \chi\, \vec{\nu}^m \right\rangle_m^h - \left\langle \frac{f(\kappa^m)}{\kappa^m}\, \kappa^{m+1}, \chi \right\rangle_m^h = 0 \qquad \forall\ \chi \in W_0^h,$$

with $\kappa^0 \in W_0^h$ suitably chosen. Once again, it is then straightforward to prove existence and uniqueness and to derive a stability result for this scheme.

In order to solve the (nonlinear) algebraic systems arising from (2.3a,b) and its generalizations, we apply a Schur complement approach. For later developments involving networks of curves, we describe it here for the linear case when $f(r) := r$. However, it easily caries over to nonlinear f; see (2.14a,b) below. Let $\vec{Id}_n \in (\mathbb{R}^{d\times d})^{n\times n}$ be the identity matrix, and similarly for $Id_n \in \mathbb{R}^{n\times n}$. We introduce also the matrices $\vec{N}_0 \in (\mathbb{R}^d)^{N\times N}$, $M_0 \in \mathbb{R}^{N\times N}$, and $\vec{A}_0 \in (\mathbb{R}^{d\times d})^{N\times N}$ with entries

$$[M_0]_{kl} := \langle \phi_k, \phi_l \rangle_m^h, \quad [\vec{N}_0]_{kl} := \int_{\Gamma^m} \pi^h[\phi_k\, \phi_l]\, \vec{\nu}^m \,\mathrm{d}s, \quad [\vec{A}_0]_{kl} := \langle \nabla_s \phi_k, \nabla_s \phi_l \rangle_m\, \vec{Id}_1\,, \tag{2.11}$$

where $\pi^h : C(J,\mathbb{R}) \to W_0^h$ is the standard interpolation operator at the nodes $\{q_j\}_{j=1}^N$. We can then formulate (2.3a,b) with $f(r) := r$ as: Find $\{\delta\vec{X}^{m+1}, \kappa^{m+1}\} \in (\mathbb{R}^d)^N \times \mathbb{R}^N$ such that

$$\begin{pmatrix} \tau_m M_0 & -\vec{N}_0^T \\ \vec{N}_0 & \vec{A}_0 \end{pmatrix} \begin{pmatrix} \kappa^{m+1} \\ \delta\vec{X}^{m+1} \end{pmatrix} = \begin{pmatrix} 0 \\ -\vec{A}_0\,\vec{X}^m \end{pmatrix}, \tag{2.12}$$

where, with an obvious abuse of notation, $\delta\vec{X}^{m+1} = (\delta\vec{X}_1^{m+1}, \dots, \delta\vec{X}_N^{m+1})^T$ and $\kappa^{m+1} = (\kappa_1^{m+1}, \dots, \kappa_N^{m+1})^T$ are the vectors of coefficients with respect to the standard basis for $\vec{X}^{m+1} - \vec{X}^m$ and κ^{m+1}, respectively. We can transform (2.12) into

$$\kappa^{m+1} = \frac{1}{\tau_m}\, M_0^{-1}\, \vec{N}_0^T\, \delta\vec{X}^{m+1}, \tag{2.13a}$$

$$\left(\vec{A}_0 + \frac{1}{\tau_m}\, \vec{N}_0\, M_0^{-1}\, \vec{N}_0^T\right) \delta\vec{X}^{m+1} = -\vec{A}_0\, \vec{X}^m. \tag{2.13b}$$

As (2.13b) is clearly symmetric and positive definite under our assumption $(\mathcal{A}_0)$, there exists a unique solution to (2.13b). Moreover, the solution to (2.13a,b) uniquely solves (2.3a,b) with $f(r) := r$.

For later purposes, we note that for the approximation (2.3a,b) with nonlinear f, the linear Schur system (2.13a,b) has to be replaced by the corresponding nonlinear system

$$\kappa^{m+1} = f^{-1}\left[\frac{1}{\tau_m}\, M_0^{-1}\, \vec{N}_0^T\, \delta\vec{X}^{m+1}\right], \tag{2.14a}$$

$$\vec{A}_0\, \delta\vec{X}^{m+1} + \vec{N}_0\, f^{-1}\left[\frac{1}{\tau_m}\, M_0^{-1}\, \vec{N}_0^T\, \delta\vec{X}^{m+1}\right] = -\vec{A}_0\, \vec{X}^m, \tag{2.14b}$$

where $f^{-1}(z) \in \mathbb{R}^N$ is defined by $[f^{-1}(z)]_i := f^{-1}(z_i)$, $i = 1 \to N$, for any $z \in \mathbb{R}^N$.

REMARK 2.4. In section 3, we will report on computations for our scheme (2.3a,b) and compare our results in the case of $f(r) := r$ with two other schemes in the literature. The first scheme is from [17] and can be formulated as: Find $\vec{X}^{m+1} \in \underline{V}_0^h$ such that

$$\left\langle \frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m}, \vec{\eta} \right\rangle_m^h + \langle \nabla_s\, \vec{X}^{m+1}, \nabla_s\, \vec{\eta} \rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}_0^h. \tag{2.15}$$

The system (2.15) is a discretization of the variational formulation of

$$\vec{x}_t = \vec{\varkappa}, \qquad \vec{\varkappa} := \varkappa\, \vec{\nu} = \Delta_s\, \vec{x}, \tag{2.16}$$

as opposed to (1.7) with $f(r) := r$. From (2.10), we see that our scheme (2.3a,b) with $f(r) := r$ can be rewritten as: Find $\vec{X}^{m+1} \in \underline{V}_0^h$ such that

$$\left\langle \frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m} \cdot \vec{\omega}^m, \vec{\eta} \cdot \vec{\omega}^m \right\rangle_m^h + \langle \nabla_s\, \vec{X}^{m+1}, \nabla_s\, \vec{\eta} \rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}_0^h\,, \tag{2.17}$$

which clearly highlights the key difference between the two schemes. The second scheme is from [13] and can be formulated as follows: Find $\vec{X}^{m+1} \in \underline{V}_0^h$ such that

$$\int_J |\vec{X}_\rho^m|^2\, \pi^h\left[\frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m} \cdot \vec{\eta}\right] \mathrm{d}\rho + \int_J \vec{X}_\rho^{m+1} \cdot \vec{\eta}_\rho\, \mathrm{d}\rho = 0 \qquad \forall\ \vec{\eta} \in \underline{V}_0^h\,, \tag{2.18}$$

or equivalently

$$\left\langle |\vec{X}^m_\rho| \, \frac{\vec{X}^{m+1}-\vec{X}^m}{\tau_m}, \vec{\eta} \right\rangle^h_m + \langle\, |\vec{X}^m_\rho| \, \nabla_s \vec{X}^{m+1}, \nabla_s \vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}^h_0\,.$$

We note that the scheme (2.15) changes the approximation of $\vec{x}$ predominantly in the normal direction (recall (2.16)), whereas the scheme (2.3a,b) proposed in this paper, as well as (2.18), also induce tangential changes. This is a crucial difference. Without movement in the tangential direction, clustering and coalescence of nodes can occur, which leads to a breakdown of the algorithm. In addition, we note that the schemes (2.15) and (2.18) do not easily generalize to the case of nonlinear f, in contrast to our scheme (2.3a,b). However, it should be noted that the numerical analysis of the schemes (2.15) and (2.18) is well developed, in that error bounds in the semidiscrete case have been derived; see [17, 13]. This is something that we hope to achieve for our scheme in the future.

REMARK 2.5. Similarly to [6, Remark 2.3], one can consider a continuous-in-time semidiscrete version of our scheme (2.3a,b). In particular, we let

$$\langle \vec{X}_t, \chi\, \vec{\nu}^h\rangle^h - \langle f(\kappa), \chi\rangle^h = 0 \qquad \forall\, \chi \in W^h_0, \tag{2.19a}$$

$$\langle \kappa\, \vec{\nu}^h, \vec{\eta}\rangle^h + \langle \nabla_s \vec{X}, \nabla_s \vec{\eta}\rangle = 0 \qquad \forall\, \vec{\eta} \in \underline{V}^h_0, \tag{2.19b}$$

where we always integrate over the current curve Γ^h, described by $\vec{X}$, and so $\vec{\nu}^h = -\frac{(\vec{X}_\rho)^\perp}{|\vec{X}_\rho|}$ and $\langle\cdot,\cdot\rangle^{(h)}$ is the same as $\langle\cdot,\cdot\rangle^{(h)}_m$ with Γ^m and $\vec{X}^m$ replaced by Γ^h and $\vec{X}$, respectively. It is then possible to show that the scheme (2.19a,b) will always equidistribute the nodes along Γ^h if the corresponding intervals are not locally parallel; see [6, Remark 2.4] for details. Although it does not appear possible to prove an analogue for the fully discrete scheme (2.3a,b), in practice we see that the nodes are moved tangentially so that they will eventually be equidistributed; see section 3 for details.

While the scheme (2.18) from [13] also induces a tangential movement of vertices, it does not appear possible to show an analogous result for that scheme.

2.1.1. Intermediate evolution laws. In this subsection we consider the intermediate motion (1.10). We introduce the following approximation to (1.10): Find $\{\vec{X}^{m+1}, Y^{m+1}, \kappa^{m+1}\} \in \underline{V}^h_0 \times [W^h_0]^2$ such that

$$\left\langle \frac{\vec{X}^{m+1}-\vec{X}^m}{\tau_m}, \chi\, \vec{\nu}^m \right\rangle^h_m - \langle \nabla_s Y^{m+1}, \nabla_s \chi\rangle_m = 0 \qquad \forall\ \chi \in W^h_0, \tag{2.20a}$$

$$\frac{1}{\xi}\,\langle \nabla_s Y^{m+1}, \nabla_s \chi\rangle_m + \frac{1}{\alpha}\,\langle Y^{m+1}, \chi\rangle^h_m - \langle \kappa^{m+1}, \chi\rangle^h_m = 0 \qquad \forall\ \chi \in W^h_0, \tag{2.20b}$$

$$\langle \kappa^{m+1}\, \vec{\nu}^m, \vec{\eta}\rangle^h_m + \langle \nabla_s \vec{X}^{m+1}, \nabla_s \vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}^h_0. \tag{2.20c}$$

REMARK 2.6. The scheme (2.20a–c) is close in concept to the approximation for (1.11) in [6]: Find $\{\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}^h_0 \times W^h_0$ such that

$$\left\langle \frac{\vec{X}^{m+1}-\vec{X}^m}{\tau_m}, \chi\, \vec{\nu}^m \right\rangle^h_m - \langle \nabla_s \kappa^{m+1}, \nabla_s \chi\rangle_m = 0 \qquad \forall\ \chi \in W^h_0, \tag{2.21a}$$

$$\langle \kappa^{m+1}\, \vec{\nu}^m, \vec{\eta}\rangle^h_m + \langle \nabla_s \vec{X}^{m+1}, \nabla_s \vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}^h_0. \tag{2.21b}$$

A semidiscrete version of (2.21a,b) enjoys exact area conservation and an equidistribution of vertices; see [6, Remarks 2.3 and 2.4] for the relevant details. We note that the same holds true for the semidiscrete analogue of (2.20a–c).

THEOREM 2.7. [illegible] $(\mathcal{A}_0)$ [illegible] $\{\vec{X}^{m+1}, Y^{m+1}, \kappa^{m+1}\} \in \underline{V}_0^h \times [W_0^h]^2$ [illegible] (2.20a–c) [illegible]

$$|\Gamma^k| + \frac{1}{\alpha} \sum_{m=0}^{k-1} \tau_m \, |\nabla_s \, Y^{m+1}|_m^2 + \xi \sum_{m=0}^{k-1} \tau_m \, |\kappa^{m+1} - \tfrac{1}{\alpha} \, Y^{m+1}|_{m,h}^2 \leq |\Gamma^0| \tag{2.22}$$

[illegible] $k = 1 \to M$ [illegible] $|\cdot|_{m(,h)}^2 := \langle \cdot, \cdot \rangle_m^{(h)}$ [illegible]. The uniqueness proof is a straightforward adaption of the proof of Theorem 2.3. As (2.20a–c) is linear, existence follows from uniqueness, and the latter is easily established for the relevant equations

$$\begin{aligned} \langle \vec{X}, \chi \, \vec{\nu}^m \rangle_m^h - \tau_m \, \langle \nabla_s \, Y, \nabla_s \, \chi \rangle_m &= 0 \qquad \forall \; \chi \in W_0^h, \\ \frac{1}{\xi} \, \langle \nabla_s \, Y, \nabla_s \, \chi \rangle_m + \frac{1}{\alpha} \, \langle Y, \chi \rangle_m^h - \langle \kappa, \chi \rangle_m^h &= 0 \qquad \forall \; \chi \in W_0^h, \\ \langle \kappa \, \vec{\nu}^m, \vec{\eta} \rangle_m^h + \langle \nabla_s \, \vec{X}, \nabla_s \, \vec{\eta} \rangle_m &= 0 \qquad \forall \; \vec{\eta} \in \underline{V}_0^h, \end{aligned}$$

on choosing $\chi = \frac{\alpha}{\xi} \, \kappa$, $\chi = \tau_m \, (\alpha \, \kappa - Y)$, and $\vec{\eta} = \frac{\alpha}{\xi} \, \vec{X}$, respectively. Combining yields that

$$\frac{\alpha}{\xi} \, \langle \nabla_s \, \vec{X}, \nabla_s \, \vec{X} \rangle_m + \frac{\tau_m}{\xi} \, \langle \nabla_s \, Y, \nabla_s \, Y \rangle_m + \frac{\tau_m}{\alpha} \, \langle \alpha \, \kappa - Y, \alpha \, \kappa - Y \rangle_m^h = 0 \, . \tag{2.23}$$

It follows from (2.23) that $\vec{X} = \vec{X}^c \in \mathbb{R}^d$, $Y = Y^c \in \mathbb{R}$, and $\kappa = \frac{Y^c}{\alpha} \in \mathbb{R}$, and hence, similarly to (2.8) on recalling assumption $(\mathcal{A}_0)$, that $\vec{X}^c = \vec{0}$ and $Y^c = 0$. Hence we have existence of a unique solution $\{\vec{X}^{m+1}, Y^{m+1}, \kappa^{m+1}\} \in \underline{V}_0^h \times [W_0^h]^2$ to the system (2.20a–c). Finally, choosing $\chi = \frac{\alpha}{\xi} \, \kappa^{m+1}$, $\chi = \tau_m \, (\alpha \, \kappa^{m+1} - Y^{m+1})$, and $\vec{\eta} = \frac{\alpha}{\xi} \, (\vec{X}^{m+1} - \vec{X}^m)$ in (2.20a–c) gives, similarly to (2.23), that

$$\langle \nabla_s \, \vec{X}^{m+1}, \nabla_s \, (\vec{X}^{m+1} - \vec{X}^m) \rangle_m + \frac{\tau_m}{\alpha} \, |\nabla_s \, Y^{m+1}|_m^2 + \xi \, \tau_m \left| \kappa^{m+1} - \frac{1}{\alpha} \, Y^{m+1} \right|_{m,h}^2 = 0 \, . \tag{2.24}$$

Combining (2.24) with the closed curve analogue of (2.40), below, yields (2.22). ∎

On recalling the definitions (2.11) and on similarly introducing the matrix $A_0 \in \mathbb{R}^{N \times N}$, we can reformulate (2.20a–c) as: Find $\{\delta \vec{X}^{m+1}, Y^{m+1} \, \kappa^{m+1}\} \in (\mathbb{R}^d)^N \times [\mathbb{R}^N]^2$ such that

$$\begin{pmatrix} 0 & \tau_m \, A_0 & -\vec{N}_0^T \\ -M_0 & \frac{1}{\xi} \, A_0 + \frac{1}{\alpha} \, M_0 & 0 \\ \vec{N}_0 & 0 & \vec{A}_0 \end{pmatrix} \begin{pmatrix} \kappa^{m+1} \\ Y^{m+1} \\ \delta \vec{X}^{m+1} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ -\vec{A}_0 \, \vec{X}^m \end{pmatrix}, \tag{2.25}$$

where, with obvious abuse of notation, $\delta \vec{X}^{m+1}$, Y^{m+1}, and κ^{m+1} are the vectors of coefficients with respect to the standard basis of $\vec{X}^{m+1} - \vec{X}^m$, Y^{m+1}, and κ^{m+1}, respectively. Introducing the inverse S_0 of A_0 restricted on the set $(\ker A_0)^\perp \equiv (\mathrm{span}\{1\})^\perp$, where $1 := (1, \ldots, 1)^T \in \mathbb{R}^N$, and noting that the first equation in (2.25)

implies that $1^T \vec{N}_0^T \, \delta\vec{X}^{m+1} = 0$, one can transform (2.25) to

$$Y^{m+1} = \frac{1}{\tau_m} \, S_0 \, \vec{N}_0^T \, \delta\vec{X}^{m+1} + \mu \, 1, \tag{2.26a}$$

$$\kappa^{m+1} = \frac{1}{\tau_m} \left(\frac{1}{\alpha} \, S_0 + \frac{1}{\xi} \, M_0^{-1} \right) \vec{N}_0^T \, \delta\vec{X}^{m+1} + \frac{\mu}{\alpha} \, 1, \tag{2.26b}$$

$$\begin{aligned} &\left(\vec{A}_0 + \frac{1}{\tau_m} \, \vec{N}_0 \left[\frac{1}{\alpha} \, S_0 + \frac{1}{\xi} \, M_0^{-1} \right] \vec{N}_0^T \right) \delta\vec{X}^{m+1} = -\vec{A}_0 \, \vec{X}^m - \frac{\mu}{\alpha} \, \vec{N}_0 1, \\ &\qquad (\delta\vec{X}^{m+1})^T \, \vec{N}_0 1 = 0, \end{aligned} \tag{2.26c}$$

where $\mu = \frac{1^T Y^{m+1}}{1^T 1} \in \mathbb{R}$ is unknown. We introduce also the orthogonal projection $\vec{\Pi}_0$ onto $\mathcal{R}_0^\perp := \{\vec{X} \in (\mathbb{R}^d)^N : \vec{X}^T \vec{N}_0 1 = 0\}$ by $\vec{\Pi}_0 := \vec{Id}_N - \frac{\vec{w}\,\vec{w}^T}{\vec{w}^T \vec{w}}$, where $\vec{w} := \vec{N}_0 1$. Then (2.26c), on noting that $\vec{\Pi}_0 \, \delta\vec{X}^{m+1} = \delta\vec{X}^{m+1}$, is replaced by

$$\vec{\Pi}_0 \left(\vec{A}_0 + \frac{1}{\tau_m} \vec{N}_0 \left[\frac{1}{\alpha} \, S_0 + \frac{1}{\xi} \, M_0^{-1} \right] \vec{N}_0^T \right) \vec{\Pi}_0 \, \delta\vec{X}^{m+1} = -\vec{\Pi}_0 \, \vec{A}_0 \, \vec{X}^m. \tag{2.27}$$

As (2.20a–c) has a unique solution, it is easily established that there exists a unique solution to (2.27). Moreover, the system (2.27) is symmetric and positive definite on $\mathcal{R}_0^\perp$. For details of a similar situation involving surface diffusion and triple junctions, we refer to [6, Theorem 2.4].

2.2. Triple junctions. In this section, we consider the case where a network of curves meeting at triple junction points moves under motion by mean curvature. Here the curves can meet at triple junction points or can intersect the external boundary $\partial\Omega$. For ease of exposition, from now on we consider the two cases of three curves $(\Gamma_1, \Gamma_2, \Gamma_3)$ with surface energies $\sigma := (\sigma_1, \sigma_2, \sigma_3)$ meeting either at two triple junction points Λ_1 and Λ_2, as in Figure 1, or meeting at a single triple junction point Λ and each intersecting the external boundary $\partial\Omega$, as in Figure 2. In particular, we note the stated choices of the direction of the unit tangents. We will outline also how the ideas presented for these cases can be carried over to an arbitrary setup of curves; see Remark 2.13 below.

We begin with the first setup. The main idea for the necessary trial ($\equiv$ test) spaces is to make sure that the conditions (1.14a,b) hold either essentially or weakly at the triple junctions. Here we will enforce condition (1.14a) explicitly through the trial space, whereas condition (1.14b) will be enforced weakly, similarly to a Neumann boundary condition for a standard second order elliptic PDE.

Let $I := [0,1]$ be the unit interval, and let $I = \bigcup_{j=1}^{N_i} I_j^i$, $i = 1 \to 3$, be decompositions of I into intervals $I_j^i = [q_{j-1}^i, q_j^i]$ based on the nodes $\{q_j^i\}_{j=0}^{N_i}$, $N_i \geq 2$. Let $h_j^i = |I_j^i|$ and $h = \max_{i=1\to 3} \max_{j=1\to N_i} h_j^i$ be the maximal length of a grid element. Let $\underline{V} := \{(\vec{\chi}_1, \vec{\chi}_2, \vec{\chi}_3) \in [C(I, \mathbb{R}^d)]^3 : \vec{\chi}_1 = \vec{\chi}_2 = \vec{\chi}_3 \text{ on } \partial I\}$ and $W_{\mathcal{M}} := \{(\chi_1, \chi_2, \chi_3) \in [C(I, \mathbb{R})]^3\}$. The appropriate finite element spaces are then defined by

$$\underline{V}^h := \{(\vec{\chi}_1, \vec{\chi}_2, \vec{\chi}_3) \in \underline{V} : \vec{\chi}_i\,|_{I_j^i} \text{ is linear } \forall\ j = 1 \to N_i,\ i = 1 \to 3\} \subset \underline{V} \tag{2.28}$$

and similarly for the space of scalar functions $W_{\mathcal{M}}^h \subset W_{\mathcal{M}}$.

Recall the time partitioning $\{\tau_m\}_{m=0}^{M-1}$, and let $\vec{X}^m \in \underline{V}^h$ be an approximation to $\vec{x}(\cdot, t_m) \equiv (\vec{x}_1, \vec{x}_2, \vec{x}_3)(\cdot, t_m)$, and similarly $\kappa^m \in W_{\mathcal{M}}^h$ for $\varkappa(\cdot, t_m)$. We introduce the σ weighted L^2 inner product $\langle \cdot, \cdot \rangle_m$ and the mass lumped inner product $\langle \cdot, \cdot \rangle_m^h$ over

the current surface $\Gamma^m := (\Gamma_1^m, \Gamma_2^m, \Gamma_3^m)$, which is described by the vector function $\vec{X}^m \in \underline{V}^h$, for scalar and vector functions $u, v \in [L^2(I, \mathbb{R}^{(d)})]^3$ as follows:

$$\langle u, v \rangle_m := \int_{\Gamma^m} u \,.\, v \,\mathrm{d}s := \sum_{i=1}^{3} \sigma_i \int_I u_i \,.\, v_i \, |(\vec{X}_i^m)_\rho| \,\mathrm{d}\rho,$$

(2.29)

$$\langle u, v \rangle_m^h := \sum_{i=1}^{3} \frac{\sigma_i}{2} \sum_{j=1}^{N_i} |\vec{X}_i^m(q_j^i) - \vec{X}_i^m(q_{j-1}^i)| \left[(u_i \,.\, v_i)([q_j^i]^-) + (u_i \,.\, v_i)([q_{j-1}^i]^+) \right].$$

In addition, we note that

$$(\nabla_s u \,.\, \nabla_s v)\,|_{\Gamma_i^m} = \frac{(u_i)_\rho \,.\, (v_i)_\rho}{|(\vec{X}_i^m)_\rho|^2}, \qquad \vec{\nu}^m\,|_{\Gamma_i^m} = -\frac{(\vec{X}_i^m)_\rho^\perp}{|(\vec{X}_i^m)_\rho|}, \qquad i = 1 \to 3.$$

We then propose the following approximation to (1.13) with (1.14a,b): Find $\{\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}^h \times W_{\mathcal{M}}^h$ such that

$$\left\langle \frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m}, \chi\, \vec{\nu}^m \right\rangle_m^h - \langle \sigma\, \kappa^{m+1}, \chi \rangle_m^h = 0 \qquad \forall\ \chi \in W_{\mathcal{M}}^h, \tag{2.30a}$$

$$\langle \kappa^{m+1}\, \vec{\nu}^m, \vec{\eta} \rangle_m^h + \langle \nabla_s \vec{X}^{m+1}, \nabla_s \vec{\eta} \rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}^h. \tag{2.30b}$$

Observe that (2.30a,b) was derived from (1.13) using integration by parts and the definition of the space $\underline{V}^h$. On noting that $(\nabla_s \vec{X}^{m+1})\,|_{\Gamma_i^m}$ approximates $\vec{\tau}_i\, \vec{\tau}_i^T$, $i = 1 \to 3$, we see that (2.30b) weakly approximates Young's law (1.14b) at the triple junction points Λ_1 and Λ_2.

An extension of the scheme (2.18) that incorporates intersections with an external boundary was given in [15]. The authors considered a setup where a single curve intersects a fixed external boundary, and, for their fully discrete scheme, introduced the following trial and test space: For a given $\vec{X}^m \in C(I, \mathbb{R}^d)$,

$$\widetilde{\underline{V}}(\vec{X}^m) := \{\vec{\chi} \in C(I, \mathbb{R}^d) : \vec{\chi} \,.\, \nabla F(\vec{X}^m) = 0 \ \text{ on } \partial I\}, \tag{2.31}$$

and in addition $\widetilde{\underline{V}}^h(\vec{X}^m) := \{\vec{\chi} \in \widetilde{\underline{V}}(\vec{X}^m) : \vec{\chi}\,|_{I_j^1} \text{ is linear } \forall\ j = 1 \to N_1,\} \subset \widetilde{\underline{V}}(\vec{X}^m)$. Then their fully discrete approximation can be formulated as: Find $\delta\vec{X}^{m+1} \in \widetilde{\underline{V}}^h(\vec{X}^m)$, where $\vec{X}^{m+1} := \vec{X}^m + \delta\vec{X}^{m+1}$ such that

$$\int_I |\vec{X}_\rho^m|^2\, \pi^h \left[\frac{\delta\vec{X}^{m+1}}{\tau_m} \,.\, \vec{\eta} \right] \mathrm{d}\rho + \int_I \vec{X}_\rho^{m+1} \,.\, \vec{\eta}_\rho \,\mathrm{d}\rho = 0 \qquad \forall\ \vec{\eta} \in \widetilde{\underline{V}}^h(\vec{X}^m). \tag{2.32}$$

We now adapt the definition (2.31) to the setup as depicted in Figure 2. For a given $\vec{X}^m \in [C(I, \mathbb{R}^d)]^3$, let

$$\underline{V}_\partial(\vec{X}^m) := \{(\vec{\chi}_1, \vec{\chi}_2, \vec{\chi}_3) \in [C(I, \mathbb{R}^d)]^3 : \vec{\chi}_1(0) = \vec{\chi}_2(0) = \vec{\chi}_3(0) \quad \text{and}$$
$$\vec{\chi}_i(1) \,.\, \nabla F(\vec{X}_i^m(1)) = 0 \quad \forall\ i = 1 \to 3\}.$$

The finite element space $\underline{V}_\partial^h(\vec{X}^m)$ is then defined accordingly, similarly to (2.28). Moreover, the system (2.30a,b) is then adapted to: Find $\{\delta\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}_\partial^h(\vec{X}^m) \times$

$W^h_{\mathcal{M}}$, where $\vec{X}^{m+1} := \vec{X}^m + \delta\vec{X}^{m+1}$, such that

$$\left\langle \frac{\delta\vec{X}^{m+1}}{\tau_m}, \chi\,\vec{\nu}^m \right\rangle^h_m - \langle \sigma\,\kappa^{m+1}, \chi\rangle^h_m = 0 \qquad \forall\ \chi \in W^h_{\mathcal{M}}, \tag{2.33a}$$

$$\langle \kappa^{m+1}\,\vec{\nu}^m, \vec{\eta}\rangle^h_m + \langle \nabla_s\,\vec{X}^{m+1}, \nabla_s\,\vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}^h_\partial(\vec{X}^m). \tag{2.33b}$$

Once again (2.33a,b) was derived from (1.13) using integration by parts and the definition of the space $\underline{V}^h_\partial(\vec{X}^m)$. On recalling that $(\nabla_s\,\vec{X}^{m+1})|_{\Gamma^m_i}$ approximates $\vec{\tau}_i\,\vec{\tau}_i^{\,T}$, $i = 1 \to 3$, we see that (2.33b) weakly approximates Young's law (1.14b) at the triple junction point Λ and (1.17b) at the boundary intersections. In order to approximate the general contact angle condition (1.18), we need to replace (2.33b) by

$$\begin{aligned} &\langle \kappa^{m+1}\,\vec{\nu}^m, \vec{\eta}\rangle^h_m + \langle \nabla_s\,\vec{X}^{m+1}, \nabla_s\,\vec{\eta}\rangle_m \\ &\quad = \sum_{i=1}^3 \sigma_i\,\frac{[\nabla F(\vec{X}^m_i(1))]^\perp}{|\nabla F(\vec{X}^m_i(1))|}\,.\,\vec{\eta}_i(1)\,\cos\alpha_i \qquad \forall\ \vec{\eta} \in \underline{V}^h_\partial(\vec{X}^m). \end{aligned} \tag{2.34}$$

Furthermore, the constraint $\delta\vec{X}^{m+1} \in \underline{V}^h_\partial(\vec{X}^m)$ weakly enforces (1.17a), as it is a linearized approximation of these constraints. In particular, for curved boundaries the equations $F(\vec{X}^{m+1}_i(1)) = 0$, $i = 1 \to 3$, are only approximately satisfied. Similarly to [15, p. 651] it formally follows, on assuming that $F(\vec{X}^0_i(1)) = 0$ for $i = 1 \to 3$, that

$$|F(\vec{X}^{m+1}_i(1))| \leq \sum_{k=0}^m |F(\vec{X}^{k+1}_i(1)) - F(\vec{X}^k_i(1))| = \mathcal{O}(\tau), \qquad i = 1 \to 3.$$

Hence, for small time steps the endpoints of the curve segments should stay close to $\partial\Omega$, and this is what one observes in practice; see section 3 for details. However, one could also employ a projection step that orthogonally projects $\vec{X}^{m+1}$ onto $\partial\Omega$ at every time step, which would have the advantage of satisfying (1.17a) exactly throughout the evolution. But this complicates the stability proof below; hence our preference for the approximation (2.33a,b). However, we do include numerical results using both approaches in section 3.

We remark that as the parameterization $\vec{X}^{m+1}$ does not "see" the boundary for $\rho < 1$, it is possible that the evolving curves touch the external boundary at some interior point, in which case the evolution is no longer described by the approximation. We note that for a convex domain this cannot happen for mean curvature flow; see [39]. However, in the surface diffusion case this can happen even for convex domains.

2.8. We note that, as stated in [15, p. 640], it is not clear how to naturally generalize the scheme (2.32) to triple junctions, as there are severe difficulties with how to approximate the condition (1.14b) within that scheme.

Before we can proceed to proving existence and uniqueness for (2.30a,b), we have to make the following very mild assumption, the analogue of $(\mathcal{A}_0)$ for a network of curves.

$(\mathcal{A})$ Let $|(\vec{X}^m_i)_\rho| > 0$ for almost all $\rho \in I$, $i = 1 \to 3$. Let

$$\vec{\nu}^m_{i,j-\frac12} := -\frac{(\vec{X}^m_i)^\perp_\rho}{|(\vec{X}^m_i)_\rho|}\,|_{I^i_j}, j = 1 \to N_i,$$

and set

$$\vec{\omega}^m_{i,j} := \frac{|\vec{X}^m_i(q^i_j) - \vec{X}^m_i(q^i_{j-1})|\,\vec{\nu}^m_{i,j-\frac{1}{2}} + |\vec{X}^m_i(q^i_{j+1}) - \vec{X}^m_i(q^i_j)|\,\vec{\nu}^m_{i,j+\frac{1}{2}}}{|\vec{X}^m_i(q^i_j) - \vec{X}^m_i(q^i_{j-1})| + |\vec{X}^m_i(q^i_{j+1}) - \vec{X}^m_i(q^i_j)|},$$
$$j = 1 \to N_i - 1, i = 1 \to 3.$$

Then we assume further that $\dim \operatorname{span}\{\{\vec{\omega}^m_{i,j}\}_{j=1}^{N_i-1}\}_{i=1}^3 = d = 2$.

The assumption $(\mathcal{A})$ basically assures that none of the curves Γ^m_i, $i = 1 \to 3$, is a "zig zagging" connection between the two triple junctions points Λ_1 and Λ_2. A sufficient condition for $(\mathcal{A})$ to hold is that at least one of the three curves is not a "saw tooth"-like curve, similar to the one in [6, Figure 3], where all the vertex normals $\vec{\omega}^m_{i,j}$, $j = 1 \to N_i - 1$, are linearly dependent.

THEOREM 2.9. $(\mathcal{A})$ $\{\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}^h \times W^h_{\mathcal{M}}$ (2.30a,b)

. As (2.30a,b) is linear, existence follows from uniqueness. To investigate the latter, we consider the system: Find $\{\vec{X}, \kappa\} \in \underline{V}^h \times W^h_{\mathcal{M}}$ such that

$$\langle \vec{X}, \chi\,\vec{\nu}^m\rangle^h_m - \tau_m\,\langle \sigma\,\kappa, \chi\rangle^h_m = 0 \qquad \forall\ \chi \in W^h_{\mathcal{M}}, \tag{2.35a}$$

$$\langle \kappa\,\vec{\nu}^m, \vec{\eta}\rangle^h_m + \langle \nabla_s\,\vec{X}, \nabla_s\,\vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}^h. \tag{2.35b}$$

Similarly to (2.6a,b), choosing $\chi = \kappa \in W^h_{\mathcal{M}}$ in (2.35a) and $\vec{\eta} = \vec{X} \in \underline{V}^h$ in (2.35b) yields that

$$\langle \nabla_s\,\vec{X}, \nabla_s\,\vec{X}\rangle_m + \tau_m\,\langle \sigma\,\kappa, \kappa\rangle^h_m = 0\,. \tag{2.36}$$

It follows from (2.36) that $\kappa \equiv 0$ and $\vec{X} \equiv \vec{X}^c = (\vec{X}^c_1, \vec{X}^c_2, \vec{X}^c_3)^T \in (\mathbb{R}^d)^3$ with $\vec{X}^c_1 = \vec{X}^c_2 = \vec{X}^c_3$, and hence

$$\langle \vec{X}^c, \chi\,\vec{\nu}^m\rangle^h_m = 0 \quad \forall\ \chi \in W^h_{\mathcal{M}}. \tag{2.37}$$

Similarly to (2.8), choosing $\chi = \varphi^i_j$ in (2.37) and noting that $\vec{X}^c_1 = \vec{X}^c_2 = \vec{X}^c_3$ yields that $\vec{X}^c_1 \cdot \vec{\omega}^m_{i,j} = 0$ for all $j = 1 \to N_i - 1$, $i = 1 \to 3$. Assumption $(\mathcal{A})$ then yields that $\vec{X}^c_1 = \vec{0}$, and hence $\vec{X}^c = \vec{0}$. Hence we have shown that (2.30a,b) has a unique solution $\{\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}^h \times W^h_{\mathcal{M}}$. ∎

The proof immediately carries over to the system (2.33a,b).

Furthermore, we can establish that our scheme is unconditionally stable.

THEOREM 2.10. $\{\vec{X}^m, \kappa^m\}_{m=1}^M$ (2.30a,b) $k = 1 \to M$

$$|\Gamma^k| + \sum_{m=0}^{k-1} \tau_m\,\langle \sigma\,\kappa^{m+1}, \kappa^{m+1}\rangle^h_m \le |\Gamma^0|\,, \tag{2.38}$$

$|\Gamma^k| := \int_{\Gamma^k} 1\,\mathrm{d}s \equiv \sum_{i=1}^3 \sigma_i\,|\Gamma^k_i|$ (2.29)

. Choosing $\chi = \kappa^{m+1} \in W^h_{\mathcal{M}}$ in (2.30a) and $\vec{\eta} = \frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m} \in \underline{V}^h$ in (2.30b) yields that

$$\langle \nabla_s\,\vec{X}^{m+1}, \nabla_s\,(\vec{X}^{m+1} - \vec{X}^m)\rangle_m + \tau_m\,\langle \sigma\,\kappa^{m+1}, \kappa^{m+1}\rangle^h_m = 0\,. \tag{2.39}$$

We now analyze the first term in (2.39), using the ideas in [18]. Let $\vec{h}_j^{\,i,m} := \vec{X}_i^m(q_{j+1}^i) - \vec{X}_i^m(q_j^i)$. Then it holds that

$$\begin{aligned}\langle \nabla_s \vec{X}^{m+1}, \nabla_s (\vec{X}^{m+1} - \vec{X}^m)\rangle_m &= \sum_{i=1}^{3} \sigma_i \int_{\Gamma_i^m} [\nabla_s \vec{X}^{m+1}] \,.\, [\nabla_s (\vec{X}^{m+1} - \vec{X}^m)] \,\mathrm{d}s \\ &= \sum_{i=1}^{3} \sigma_i \sum_{j=1}^{N_i-1} \left[\frac{|\vec{h}_j^{\,i,m+1}|^2 - \vec{h}_j^{\,i,m+1} \,.\, \vec{h}_j^{\,i,m}}{|\vec{h}_j^{\,i,m}|} \right] \\ &\geq \sum_{i=1}^{3} \sigma_i \sum_{j=1}^{N_i-1} \left[|\vec{h}_j^{\,i,m+1}| - |\vec{h}_j^{\,i,m}| \right] = |\Gamma^{m+1}| - |\Gamma^m| \,. \end{aligned} \tag{2.40}$$

Combining (2.39) and (2.40) yields that

$$|\Gamma^{m+1}| - |\Gamma^m| + \tau_m \int_{\Gamma^m} \sigma \, |\kappa^{m+1}|^2 \,\mathrm{d}s \leq 0. \tag{2.41}$$

Summing (2.41) for $m = 0 \to k-1$ yields the desired result. ∎

The proof above is written explicitly for (2.30a,b), but as it depends solely on a specific choice of test functions, it immediately carries over to (2.33a,b), as well as (2.3a,b) with the changes, in the case of nonlinear f, stated after Theorem 2.3.

Let $N := \sum_{i=1}^{3}(N_i + 1)$. We define the orthogonal projection $\vec{P} : (\mathbb{R}^d)^N \to \underline{\mathbb{X}} := \{(\vec{z}_1, \vec{z}_2, \vec{z}_3) \in (\mathbb{R}^d)^N : [\vec{z}_1]_0 = [\vec{z}_2]_0 = [\vec{z}_3]_0, [\vec{z}_1]_{N_1} = [\vec{z}_2]_{N_2} = [\vec{z}_3]_{N_3}\}$ onto the Euclidean space associated with $\underline{V}^h$.

In order to give a matrix formulation for (2.30a,b) we introduce the matrices $M^i \in \mathbb{R}^{(N_i+1)\times(N_i+1)}$, $\vec{N}^i \in (\mathbb{R}^d)^{(N_i+1)\times(N_i+1)}$, $A^i \in \mathbb{R}^{(N_i+1)\times(N_i+1)}$, and $\vec{A}^i \in (\mathbb{R}^{d\times d})^{(N_i+1)\times(N_i+1)}$, $i = 1 \to 3$, defined by

$$\begin{aligned} M_{kl}^i &:= \sigma_i \int_{\Gamma_i^m} \pi_i^h[\phi_k^i \, \phi_l^i] \,\mathrm{d}s, \qquad \vec{N}_{kl}^i := \sigma_i \int_{\Gamma_i^m} \pi_i^h[\phi_k^i \, \phi_l^i] \, \vec{\nu}^m \,\mathrm{d}s, \\ A_{kl}^i &:= \sigma_i \int_{\Gamma_i^m} \nabla_s \phi_k^i \,.\, \nabla_s \phi_l^i \,\mathrm{d}s, \qquad \vec{A}_{kl}^i := A_{kl}^i \, \vec{Id}_1 \,, \end{aligned} \tag{2.42}$$

where $\{\phi_l^i\}_{l=0}^{N_i}$ is the standard basis of $S_i^h := \{\chi \in C(I,\mathbb{R}) : \chi\,|_{I_j^i} \text{ is linear } \forall\ j = 1 \to N_i\}$ and $\pi_i^h : C(I,\mathbb{R}) \to S_i^h$ is the standard interpolation operator at the nodes $\{q_j^i\}_{j=0}^{N_i}$. Then on introducing the matrices

$$M := \begin{pmatrix} \sigma_1 M^1 & 0 & 0 \\ 0 & \sigma_2 M^2 & 0 \\ 0 & 0 & \sigma_3 M^3 \end{pmatrix}, \ \vec{A} := \begin{pmatrix} \vec{A}^1 & 0 & 0 \\ 0 & \vec{A}^2 & 0 \\ 0 & 0 & \vec{A}^3 \end{pmatrix}, \ \vec{N} := \begin{pmatrix} \vec{N}^1 & 0 & 0 \\ 0 & \vec{N}^2 & 0 \\ 0 & 0 & \vec{N}^3 \end{pmatrix}, \tag{2.43}$$

where $M : \mathbb{R}^N \to \mathbb{R}^N$, $\vec{A} : (\mathbb{R}^d)^N \to (\mathbb{R}^d)^N$, and $\vec{N} : \mathbb{R}^N \to (\mathbb{R}^d)^N$, the system of equations (2.30a,b) can be written as: Find $\{\delta\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{\mathbb{X}} \times \mathbb{R}^N$ such that

$$\begin{pmatrix} \tau_m M & -\vec{N}^T \vec{P} \\ \vec{P}\vec{N} & \vec{P}\vec{A}\vec{P} \end{pmatrix} \begin{pmatrix} \kappa^{m+1} \\ \delta\vec{X}^{m+1} \end{pmatrix} = \begin{pmatrix} 0 \\ -\vec{P}\vec{A}\vec{P}\,\vec{X}^m \end{pmatrix}. \tag{2.44}$$

Here, with an obvious abuse of notation as in (2.12), $\kappa^{m+1} = (\kappa_1^{m+1}, \kappa_2^{m+1}, \kappa_3^{m+1})^T$ with $\kappa_i^{m+1} = ([\kappa_i^{m+1}]_0, \ldots, [\kappa_i^{m+1}]_{N_i})$, $i = 1 \to 3$, and $\delta\vec{X}^{m+1} = (\delta\vec{X}_1^{m+1}, \delta\vec{X}_2^{m+1},$

$\delta\vec{X}_3^{m+1})^T$ with $\delta\vec{X}_i^{m+1} = ([\delta\vec{X}_i^{m+1}]_0, \ldots, [\delta\vec{X}_i^{m+1}]_{N_i})$, $i = 1 \to 3$, are the vectors of coefficients with respect to the standard basis $\{\{\phi_l^i\}_{l=0}^{N_i}\}_{i=1}^3$ of κ^{m+1} and $\vec{X}^{m+1} - \vec{X}^m$ in (2.30a,b), respectively.

As M is nonsingular, we can reformulate (2.44), similarly to (2.13a,b), as

$$\kappa^{m+1} = \frac{1}{\tau_m}\, M^{-1}\, \vec{N}^T \vec{P}\, \delta\vec{X}^{m+1}, \tag{2.45a}$$

$$\left(\vec{P}\vec{A}\vec{P} + \frac{1}{\tau_m}\, \vec{P}\vec{N}\, M^{-1}\, \vec{N}^T \vec{P}\right) \delta\vec{X}^{m+1} = -\vec{P}\vec{A}\vec{P}\, \vec{X}^m. \tag{2.45b}$$

THEOREM 2.11. [illegible] $\{\delta\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{\mathbb{X}} \times \mathbb{R}^N$ [illegible] (2.44) [illegible] $\delta\vec{X}^{m+1}$ [illegible] (2.45b) [illegible] (2.45b) [illegible]. The proof is straightforward. □

The system (2.45a,b) is easily adapted to cover the approximation (2.33a,b) of the setup displayed in Figure 2. In particular, we need to introduce the orthogonal projection $\vec{P}_\partial : (\mathbb{R}^d)^N \to \underline{\mathbb{X}}_\partial := \{(\vec{z}_1, \vec{z}_2, \vec{z}_3) \in (\mathbb{R}^d)^N : [\vec{z}_1]_0 = [\vec{z}_2]_0 = [\vec{z}_3]_0$ and $[\vec{z}_i]_{N_i} \,.\, \nabla F([\vec{X}_i^m]_{N_i}) = 0 \;\forall i = 1 \to 3\}$ onto the Euclidean spaces associated with $\underline{V}_\partial^h(\vec{X}^m)$. Then (2.45b) is readily replaced by

$$\left(\vec{P}_\partial\vec{A}\vec{P}_\partial + \frac{1}{\tau_m}\, \vec{P}_\partial\vec{N}\, M^{-1}\, \vec{N}^T\vec{P}_\partial\right) \delta\vec{X}^{m+1} = -\vec{P}_\partial\vec{A}\, \vec{X}^m. \tag{2.46}$$

We note that (2.13b) and (2.46) can easily be generalized to curve networks with an arbitrary number of triple junctions and external boundary intersections; see Remark 2.13 below for the relevant details.

2.2.1. Surface diffusion of curve networks. We recall the following approximation to (1.19), with (1.14a,b) and (1.21a,b), as proposed in [6]: Find $\{\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}^h \times W^h$ such that

$$\left\langle \frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m}, \chi\, \vec{\nu}^m \right\rangle_m^h - \langle \sigma\, \nabla_s\, \kappa^{m+1}, \nabla_s\, \chi\rangle_m = 0 \qquad \forall\ \chi \in W^h, \tag{2.47a}$$

$$\langle \kappa^{m+1}\, \vec{\nu}^m, \vec{\eta}\rangle_m^h + \langle \nabla_s\, \vec{X}^{m+1}, \nabla_s\, \vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}^h, \tag{2.47b}$$

where

$$W^h := \{(\chi_1, \chi_2, \chi_3) \in W : \chi_i|_{I_j^i} \text{ is linear } \forall\ j = 1 \to N_i,\ i = 1 \to 3\} \subset W \tag{2.48}$$

and $W := \{(\chi_1, \chi_2, \chi_3) \in [C(I, \mathbb{R})]^3 : \sigma_1\, \chi_1 + \sigma_2\, \chi_2 + \sigma_3\, \chi_3 = 0 \text{ on } \partial I\}$. We recall further that the system (2.47a,b) can be solved by applying a Schur complement approach and then solving for $\delta\vec{X}^{m+1} \in \underline{\mathbb{X}}$:

$$\vec{\Pi}\, \vec{P}\, \left(\vec{A} + \frac{1}{\tau_m}\, \vec{N} K\, S\, K \vec{N}^T\right)\, \vec{P}\, \vec{\Pi}\, \delta\vec{X}^{m+1} = -\vec{\Pi}\, \vec{P}\vec{A}\vec{P}\, \vec{X}^m. \tag{2.49}$$

Here $K : \mathbb{R}^N \to \mathbb{X} := \{(z_1, z_2, z_3) \in \mathbb{R}^N : \sum_{i=1}^3 \sigma_i\, [z_i]_0 = \sum_{i=1}^3 \sigma_i\, [z_i]_{N_i} = 0\}$ is the orthogonal projection onto $\mathbb{X}$, and S is the inverse of KAK, where A is defined similarly to (2.43) using A^i in (2.42), on the space $(\ker KAK)^\perp$. Also $\vec{\Pi} : (\mathbb{R}^d)^N \to \mathcal{R}^\perp$ is the orthogonal projection onto $\mathcal{R}^\perp$, where $\mathcal{R} := \text{span}\,\{\vec{P}\vec{N}K\, e_i : i = 1 \to 2\} \equiv$

$\{\vec{P}\vec{N}K\,v : v \in \ker KAK\} \subset \underline{\mathbb{X}}$ with $\{e_i\}_{i=1}^2$, $e_1 := (\frac{1}{\sigma_1}1^1, -\frac{1}{\sigma_2}1^2, 0) \in \mathbb{X}$ and $e_2 := (0, \frac{1}{\sigma_2}1^2, -\frac{1}{\sigma_3}1^3) \in \mathbb{X}$, where $1^i := (1,\dots,1)^T \in \mathbb{R}^{N_i+1}$, $i = 1 \to 3$, being a basis of the space $E = \ker A \cap \mathbb{X}$.

We now want to adapt the above scheme to include possible boundary intersections. Naturally in the case of (1.17b), (2.47a,b) is changed to: Find $\{\delta\vec{X}^{m+1}, \kappa^{m+1}\} \in \underline{V}_\partial^h(\vec{X}^m) \times W_\partial^h$ such that

$$\left\langle \frac{\delta\vec{X}^{m+1}}{\tau_m}, \chi\,\vec{\nu}^m \right\rangle_m^h - \langle \sigma\,\nabla_s\,\kappa^{m+1}, \nabla_s\,\chi\rangle_m = 0 \qquad \forall\ \chi \in W_\partial^h, \tag{2.50a}$$

$$\langle \kappa^{m+1}\,\vec{\nu}^m, \vec{\eta}\rangle_m^h + \langle \nabla_s\,\vec{X}^{m+1}, \nabla_s\,\vec{\eta}\rangle_m = 0 \qquad \forall\ \vec{\eta} \in \underline{V}_\partial^h(\vec{X}^m), \tag{2.50b}$$

where $W_\partial := \{(\chi_1,\chi_2,\chi_3) \in [C(I,\mathbb{R})]^3 : \sigma_1\,\chi_1(0)+\sigma_2\,\chi_2(0)+\sigma_3\,\chi_3(0) = 0\}$ and W_∂^h is defined similarly to (2.48). On defining the orthogonal projection $K_\partial : \mathbb{R}^N \to \mathbb{X}_\partial := \{(z_1,z_2,z_3) \in \mathbb{R}^N : \sum_{i=1}^3 \sigma_i\,[z_i]_0 = 0\}$ and using the projection $\vec{P}_\partial$ defined earlier, we can apply a Schur complement approach to yield

$$\vec{\Pi}_\partial\,\vec{P}_\partial\left(\vec{A} + \frac{1}{\tau_m}\,\vec{N}K_\partial\,S_\partial\,K_\partial\vec{N}^T\right)\vec{P}_\partial\,\vec{\Pi}_\partial\,\delta\vec{X}^{m+1} = -\vec{\Pi}_\partial\,\vec{P}_\partial\vec{A}\,\vec{X}^m, \tag{2.51}$$

where S_∂ is the inverse of $K_\partial AK_\partial$ on the space $(\ker K_\partial AK_\partial)^\perp$ and $\vec{\Pi}_\partial$ is the orthogonal projection from $\mathbb{R}^N$ onto $\mathcal{R}_\partial^\perp$ with $\mathcal{R}_\partial := \vec{P}_\partial\vec{N}K_\partial(\ker K_\partial AK_\partial)$. In fact, for the setup in Figure 2, $\vec{\Pi}_\partial \equiv \vec{\Pi}$. However, in general this is not always the case; see Remark 2.14 below. Of course, the above is extended to (1.18) by replacing (2.50b) by (2.34).

2.12. A possible definition for the projection $\vec{\Pi}$ is $\vec{\Pi} := \vec{Id}_N - \vec{Q}\,\vec{Q}^T$, where $\operatorname{im}\vec{Q} = \mathcal{R}$ and $\vec{Q}^T\vec{Q} = Id_2$. In other words, the columns of $\vec{Q} \in (\mathbb{R}^d)^{N\times 2}$ are an orthonormal basis of the subspace $\mathcal{R} \subset (\mathbb{R}^d)^N$ spanned by $\vec{P}\vec{N}Ke_i \equiv \vec{P}\vec{N}\,e_i$, where $e_i \in \mathbb{X}$, $i = 1 \to 2$, are the above mentioned null vectors of KAK. We note that the definitions of $\vec{P}$ and $\vec{N}$ yield that $\dim\mathcal{R} = 2$. Hence $\vec{\Pi}$ is the orthogonal projection from $(\mathbb{R}^d)^N$ onto $(\operatorname{im}\vec{Q})^\perp \equiv \mathcal{R}^\perp$.

2.13. The definitions of the spaces $\underline{V}$ and W can easily be generalized to a situation with K_B bubbles (enclosed areas), K_C curves, and K_T triple junction points. Note that Euler's formula yields that $6\,(K_B-1) = 2\,K_C = 3\,K_T$ in the absence of external boundary intersections. For example, $K_B = 2$, $K_C = 3$, and $K_T = 2$ in Figure 1. In particular, we would have that $\underline{V} := \{(\chi_1,\dots,\chi_{K_C}) \in [C(I,\mathbb{R}^d)]^{K_C} : \chi_{i_j}(p_{j,i_j}) = \chi_{1_j}(p_{j,1_j}),\ i = 2 \to 3,\ \forall j = 1 \to K_T\}$ and

$$W := \left\{(\chi_1,\dots,\chi_{K_C}) \in [C(I,\mathbb{R})]^{K_C} : \sum_{i=1}^3 (-1)^{p_{j,i_j}}\,\sigma_{i_j}\,\chi_{i_j}(p_{j,i_j}) = 0\ \ \forall j = 1 \to K_T\right\}. \tag{2.52}$$

Here $i_j \in \{1,\dots,K_C\}$, $i = 1 \to 3$, denotes the three curves meeting at triple junction j, while $p_{j,i_j} \in \{0,1\}$ denotes whether these curves start ($p_{j,i_j} = 0$) or end ($p_{j,i_j} = 1$) at the triple junction point j. That is, $|\{i_j : i = 1 \to 3\}| = 3$ for all $j = 1 \to K_T$, $|\{j : i_j = c\}| = 2$ for all $c = 1 \to K_C$, and $\sum_{j=1}^{K_T} p_{j,c} = 1$ for all $c = 1 \to K_C$.

The above definitions are easily generalized to the possible presence of external boundary intersections. Let K_B denote the number of bubbles (enclosed areas), K_T the number of triple junctions, K_C the number of curves, and K_I the number of

intersections with the external boundary. Then Euler's formula yields that $6\,(K_B - 1) = 2\,(K_C + K_I) = 3\,(K_T + K_I)$. (Note that the special case $K_I = 0$ corresponds to the formula given above.) For example, $K_B = 3$, $K_C = 3$, $K_T = 1$, and $K_I = 3$ in Figure 2. The corresponding precise definitions of the spaces $\underline{V}_\partial(\vec{X}^m)$ and W_∂ are straightforward, and we omit the details here.

Remark 2.14. The definition of $\vec{\Pi}$ can easily be adapted to a situation with K_B bubbles. In the case of no external boundary intersections, the subspace $E := \mathbb{X} \cap \ker A$ of the kernel of KAK has dimension K_B, and a possible basis consists of vectors that each "describe an admissible orientation of the boundary of a bubble" in terms of the given K_C curves. For example, if $K_B = 3$, one area is enclosed by curves $1, 2, 4$, and curve 2 is parameterized in the opposite direction to curves 1 and 4, then the corresponding eigenvector would be $(\frac{1}{\sigma_1}1^1, -\frac{1}{\sigma_2}1^2, 0, \frac{1}{\sigma_4}1^4, 0, 0)$. See the appendix in [6] for a more rigorous definition.

When boundary intersections are present, the subspace E has dimension $K_B - 1$, and a possible basis consists of vectors that each "describe an admissible orientation of the boundary of a bubble" (ignoring the boundary part of any bubble that is made up by the external boundary $\partial\Omega$) in terms of the given K_C curves. Similarly to [6, Appendix] one can show that it indeed holds that $\dim E = K_C - K_T = (K_C + K_I) - (K_T + K_I) = 3\,(K_B - 1) - 2\,(K_B - 1) = K_B - 1$.

One can interpret each set of basis vectors of E as a linearly independent collection of regions that preserve their areas. Then it is intuitive that the respective dimensions of E in the two described cases are K_B and $K_B - 1$.

2.2.2. Combined surface diffusion and mean curvature flow. We now adapt (2.47a,b) so that it approximates the evolution law (1.23), with (1.14a,b) and (1.24a,b). Choosing $\underline{V}^h$ based on $\underline{V}$, as defined in Remark 2.13, and $W_\star^h$ based on (recall (2.52)) $W_\star := \{(\chi_1, \ldots, \chi_{K_C}) \in [C(I, \mathbb{R})]^{K_C} : \sum_{i=1}^{3} \mathcal{H}_{\{i_0+1 \to K_C\}}(i_j)\,[(-1)^{p_{j,i_j}}\,\sigma_{i_j}\,\chi_{i_j}(p_{j,i_j})] = 0 \;\; \forall\; j = 1 \to K_T\}$, where $\mathcal{H}_{\mathcal{F}}$ is the indicator function for the set $\mathcal{F}$, yields the following approximation: Find $\{\vec{X}^{m+1},\, \kappa^{m+1}\} \in \underline{V}^h \times W_\star^h$ such that

$$\left\langle \frac{\vec{X}^{m+1} - \vec{X}^m}{\tau_m}, \chi\,\vec{\nu}^m \right\rangle_m^h - \langle \sigma\,\kappa^{m+1}, \chi \rangle_m^\star = 0 \qquad \forall\; \chi \in W_\star^h, \tag{2.53a}$$

$$\langle \kappa^{m+1}\,\vec{\nu}^m, \vec{\eta} \rangle_m^h + \langle \nabla_s\,\vec{X}^{m+1}, \nabla_s\,\vec{\eta} \rangle_m = 0 \qquad \forall\; \vec{\eta} \in \underline{V}^h, \tag{2.53b}$$

where $\langle \sigma\,\eta, \chi \rangle_m^\star := \langle \sigma\,\eta\,|_{\Gamma^{m,MC}}, \chi\,|_{\Gamma^{m,MC}} \rangle_m^h + \langle \sigma\,\nabla_s\,\eta\,|_{\Gamma^{m,SD}}, \nabla_s\,\chi\,|_{\Gamma^{m,SD}} \rangle_m$ for all $\eta,\, \chi \in W_\star^h$. Here $\Gamma^{m,MC} := \bigcup_{i=1}^{i_0} \Gamma_i^m$ and $\Gamma^{m,SD} := \bigcup_{i=i_0+1}^{K_C} \Gamma_i^m$. The above (weakly) approximates the correct conditions at the triple junctions, (1.14a,b) and (1.24a,b). Once again, it is a straightforward matter to derive an existence and uniqueness result and a stability result for (2.53a,b) under an appropriate mild assumption.

Using the natural extensions from the setup in Figure 1 to K_C curves of the matrices defined earlier, recalling (2.42) and (2.43), introducing $A_\star := \mathrm{diag}(\sigma_1\,M^1, \ldots, \sigma_{i_0}\,M^{i_0}, \sigma_{i_0+1}\,A^{i_0+1}, \ldots, \sigma_{K_C}\,A^{K_C})$, extending the associated operators, and introducing the orthogonal projection $K_\star$ onto the Euclidean space $\mathbb{X}_\star$ associated with $W_\star^h$, we can derive the following equations for the extended coefficient vectors:

$$\begin{pmatrix} \tau_m\,K_\star A_\star K_\star & -K_\star \vec{N}^T \vec{P} \\ \vec{P}\vec{N}K_\star & \vec{P}\vec{A}\vec{P} \end{pmatrix} \begin{pmatrix} \kappa^{m+1} \\ \delta\vec{X}^{m+1} \end{pmatrix} = \begin{pmatrix} 0 \\ -\vec{P}\vec{A}\vec{P}\,\vec{X}^m \end{pmatrix}. \tag{2.54}$$

Introducing the inverse $S_\star$ of $K_\star A_\star K_\star$ restricted on the set $(\ker K_\star A_\star K_\star)^\perp = \mathbb{X}_\star \cap \ker A_\star$, i.e., $S_\star\,K_\star A_\star K_\star\,v = K_\star A_\star K_\star\,S_\star\,v = v$ for all $v \in \mathbb{X}_\star \cap \ker A_\star$, we can employ

a Schur complement approach in order to transform (2.54) to

$$\kappa^{m+1} = \frac{1}{\tau_m}\, S_\star\, K_\star \vec{N}^T \vec{P}\, \delta\vec{X}^{m+1} + z, \qquad z \in \mathbb{X}_\star \cap \ker A_\star, \tag{2.55a}$$

$$\vec{\Pi}_\star \left(\vec{P}\vec{A}\vec{P} + \frac{1}{\tau_m}\, \vec{P}\vec{N} K_\star\, S_\star\, K_\star \vec{N}^T \vec{P} \right) \vec{\Pi}_\star\, \delta\vec{X}^{m+1} = -\vec{\Pi}_\star \vec{P}\vec{A}\vec{P}\, \vec{X}^m, \tag{2.55b}$$

where $\vec{\Pi}_\star : (\mathbb{R}^d)^N \to \mathcal{R}_\star^\perp$ is the orthogonal projection onto $\mathcal{R}_\star^\perp$ with $\mathcal{R}_\star := \vec{P}\vec{N} K_\star\, E_\star$ and $E_\star := \mathbb{X}_\star \cap \ker A_\star$.

Remark 2.15. A basis of $\mathcal{R}_\star$ can be found similarly to the pure surface diffusion case; see Remark 2.14. The corresponding basis of $E_\star$ is now made up of vectors that assign orientations for bubble boundaries to linear independent collections of curves Γ_i^m with $i > i_0$. Of course, one can extend the approximation (2.53a,b) to include external boundaries in the natural way. Although we omit the details here, some numerical results are given in section 3.

2.3. Quadruple junctions. A further generalization of the schemes (2.33a,b), (2.50a,b), and (2.53a,b) in this paper is the extension from triple junction points to quadruple junction points. This needs only a minor change to the introduced finite element spaces, and we omit the exact details here. However, numerical results for this practically interesting situation can be found in the next section.

3. Results. The Schur complement systems (2.13b), (2.26c), (2.45b), (2.46), (2.49), (2.51), and (2.55b) can be easily solved with a conjugate gradient solver. Where necessary, the solution of $KAK\, y = x$ and its variants in order to compute $S\, x$, $S_\partial\, x$, $S_\star\, x$, and $S_0\, x$, respectively, can be obtained with an (inner loop) CG solver without a projection, as the right-hand-side vector x always satisfies the necessary compatibility condition, e.g., $x \in (\ker KAK)^\perp$. See [30] for a justification for using a CG solver for a positive semidefinite system.

The system (2.14b), on the other hand, can be solved with an inexact Newton method. When f is given by (1.6), because of the singularity of $f^{-1} = f$ at the origin, the discrete system (2.14b) needs to be solved with a damped inexact Newton method, where as initial guess for the Newton iteration we choose $\delta\vec{X}^{m+1,0} := \vec{N}_0\, 1$. Moreover, we perform computations only for (1.7) with (1.6), where the evolution is well defined for all times, e.g., where the initial data $\vec{x}(\cdot,0)$ is such that that $\varkappa(\cdot,0) > 0$. In practice, the damped Newton method always converged in these cases and we always observed that $\kappa^m > 0$, $m = 0 \to M$. In addition, for the scheme (2.4), (2.3b) we will use the initial data $\kappa^0 := -(\vec{N}_0^{\,T} \vec{N}_0)^{-1} \vec{N}_0^{\,T} \vec{A}_0\, \vec{X}^0$, on noting that $\vec{N}_0^{\,T} \vec{N}_0$ is a diagonal matrix with strictly positive diagonal entries.

Throughout this section we use uniform time steps $\tau_m = \tau$, $m = 0 \to M-1$. For later purposes, we define $\vec{X}(t) := \frac{t-t_{m-1}}{\tau}\, \vec{X}^m + \frac{t_m - t}{\tau}\, \vec{X}^{m-1}$ for $t \in [t_{m-1}, t_m]$, $m \geq 1$.

3.1. Closed curves. Here we compare our scheme (2.3a,b) with $f(r) := r$, i.e., (2.17), with two other algorithms in the literature, namely the schemes (2.15) from [17] and (2.18) from [13]. As a first test, we repeat the computations for a true solution as given in [17, p. 604]. An exact solution to (1.7) with $f(r) := r$, so that the resulting $\Gamma(\cdot)$ solves (1.3), is given by

$$\vec{x}(\rho,t) = (1-2\,t)^{\frac{1}{2}}\, (\cos g(\rho), \sin g(\rho))^T, \quad \varkappa(\rho,t) = (1-2\,t)^{-\frac{1}{2}}, \quad t \in [0, \overline{T}),\ \overline{T} = 0.5, \tag{3.1}$$

where $g(\rho) = 2\pi\rho + 0.1\,\sin(2\pi\rho)$ in order to make the initial distribution of nodes nonuniform. We note that $\vec{x}_t \,.\, \vec{\tau} = 0$ for the solution (3.1). We compare our results from (2.17) to the schemes (2.15) and (2.18); see Table 1. We use $\tau = 0.5\,h^2$ and either $T = \frac{1}{2}\,\overline{T}$ or $T = \overline{T} - \tau$. Here and in what follows we always compute the error $\|\vec{X} - \vec{x}\|_{L^\infty} := \max_{m=1\to M} \|\vec{X}(t_m) - \vec{x}(\cdot, t_m)\|_{L^\infty}$, where $\|\vec{X}(t_m) - \vec{x}(\cdot, t_m)\|_{L^\infty} := \max_{j=1\to N} \min_{\rho\in J} |\vec{X}^m(q_j) - \vec{x}(\rho, t_m)|$ between $\vec{X}$ and the true solution on the interval $[0, T]$. We note that the experiments indicate that the convergence rate for the error away from the singularity is $O(h^2)$, and up to the singularity at time $\overline{T}$ is of order less than $O(h)$, for all three schemes, as is to be expected.

The next experiment is for a mild ellipse. The parameters were chosen as follows. $N = 128$, $\tau = 10^{-2}$, $T = 1.5$, and the initial curve is a $3:1$ ellipse with a unit semiminor axis. In order to highlight one difference between the three schemes in consideration, we plot for each of them the ratio $r := h_{\vec{X}^m}/\ell_{\vec{X}^m}$, where $h_{\vec{X}^m} := \max_{j=1\to N} |\vec{X}^m(q_j) - \vec{X}^m(q_{j-1})|$ and $\ell_{\vec{X}^m} := \min_{j=1\to N} |\vec{X}^m(q_j) - \vec{X}^m(q_{j-1})|$, over time. The evolution of our scheme (2.17) can be seen in Figure 3. Plots of the ratio r for the three schemes can be seen in Figure 4. One can clearly see that the ratio increases for scheme (2.15), while the tangential movement of vertices induced by the

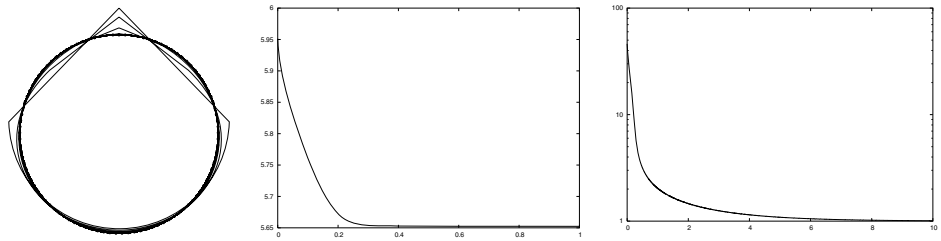

FIG. 5. *Plots of* $\vec{X}(t)$ *at* $t = 0, 0.1, \ldots, T = 10$, $|\Gamma(t)|$ *for* $t \in [0,1]$, *and* $\log r(t)$ *for* $t \in [0,T]$.

other two schemes, as discussed in Remark 2.5, results in a decrease of the ratio r, which approaches the optimal value 1. In order to underline this point further, we conducted an experiment for area preserving mean curvature flow, (1.8). The initial curve for our approximation (2.4), with $f(r) := r$, and (2.3b) consists of a semicircle and a single additional node on the periphery of the circle with unit radius. We used the parameters $N = 100$, $T = 10$, and $\tau = 10^{-3}$. In Figure 5 we show $\vec{X}(t)$ at different times, as well as a plot of $|\Gamma(t)|$ and $\log r(t)$ over time. One can clearly see that although an approximation to the true steady state, a circle, is reached very quickly (at around time $t = 0.6$), in the remaining time the vertices are continually moved tangentially, which results in a further decrease in the ratio r that eventually approaches the optimal value 1.

In addition, we computed (2.3a,b) with $f(r) := r$ for a self-intersecting curve that exhibits cusps during the evolution. The initial curve is taken from [13, Figure 1] and can be parameterized by $\vec{x}(\rho,0) = \cos(4\pi\,\rho)\,(\cos(2\pi\,\rho), \sin(2\pi\,\rho))^T$. We used the parameters $N = 100$, $\tau = 10^{-3}$, and $T = 0.09$. We see in Figure 6 that for this example the mesh points are clustered in regions where the curvature is high, due to the very fast evolution there. Of course this clustering decreases as the time step size τ is reduced in line with an equidistribution result for the semidiscrete scheme; recall Remark 2.5. Similarly to other parametric algorithms, our approximation jumps across the singularity in the evolution; see, e.g., [13, Figure 1] for (2.4) and [14, Figure 4.2] for (2.15).

For the first experiment for the nonlinear approximation (2.3a,b) we used the exact solution to (1.4) with (1.5):

$$\vec{x}(\rho,t) = (1-(\beta+1)\,t)^{\frac{1}{\beta+1}}\,(\cos g(\rho), \sin g(\rho))^T, \quad \varkappa(\rho,t) = (1-(\beta+1)\,t)^{-\frac{1}{\beta+1}}, \quad t \in [0,\overline{T}),$$

where $\overline{T} = \frac{1}{\beta+1}$ and g is given as in (3.1). We note once again that here $\vec{x}_t \,.\, \vec{\tau} = 0$. We report on a corresponding error table for $\beta = \frac{1}{2}$ and $\beta = \frac{1}{3}$ in Table 2, where we used $\tau = 0.5\,h^2$.

TABLE 2

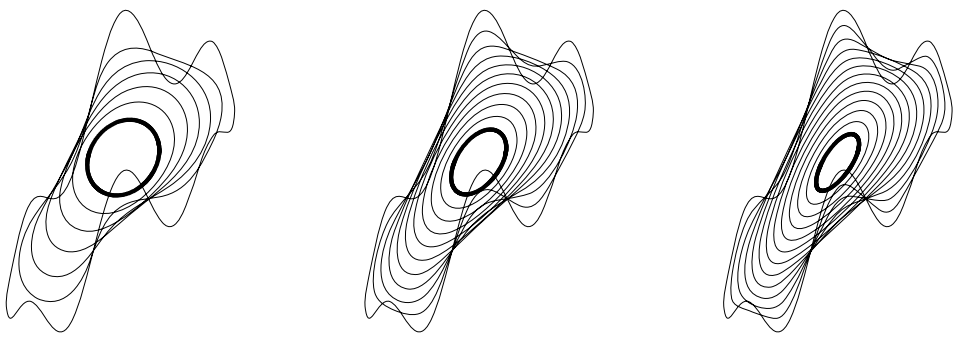

FIG. 7. $\mathcal{V} = \varkappa^\beta$, *with* $\beta = 1, \frac{1}{2}, \frac{1}{3}$. *We plot* $\vec{X}(t)$ *at times* $t = 0, 0.05, \ldots, T$, *with* $T = 0.3, 0.5$, *and* 0.6, *respectively.*

Next, we considered (2.3a,b) with (1.5) for the initial curve as given in [35, p. 1494] for the three different choices $\beta = 1, \frac{1}{2}, \frac{1}{3}$; i.e., we chose

$$\vec{x}(\rho, 0) = \Bigg(\cos g_0(\rho), \\ \frac{1}{2}\,\sin g_0(\rho) + \sin\left(\cos g_0(\rho)\right) + \sin g_0(\rho)\,\left[\frac{1}{5} + \sin g_0(\rho)\,\sin^2 g_0(3\,\rho)\right]\Bigg)^T,$$

where $g_0(\rho) = 2\pi\,\rho$, and set $\vec{X}^0 = \pi^h\,\vec{x}(\cdot, 0)$ for a uniform partitioning of J. The numerical results for the approximation (2.3a,b) can be seen in Figure 7, where we used $N = 256$ and $\tau = 10^{-3}$. It should be noted that in [35] a system of second order PDEs is derived to model (1.4), which introduces a tangential movement that locally equidistributes nodes under discretization by a finite difference approximation. However, the system and subsequent approximation is far more complicated than our simple approximation (2.3a,b).

3.1.1. Inverse mean curvature flow. Here we consider the flow (1.4) with (1.6). First, we performed a convergence test for the approximation (2.3a,b) with f given by (1.6). A true solution to (1.7) and (1.6) with $\vec{x}_t \,.\, \vec{\tau} = 0$ is given by

$$\vec{x}(\rho, t) = \exp(t)\,(\cos g(\rho), \sin g(\rho))^T, \quad \varkappa(\rho, t) = \exp(-t), \quad t \in [0, \infty),$$

where g is defined as in (3.1). We report on the corresponding errors for $\tau = 0.5\,h^2$ in the last column of Table 2. The evolution for $N = 256$ can be seen on the left

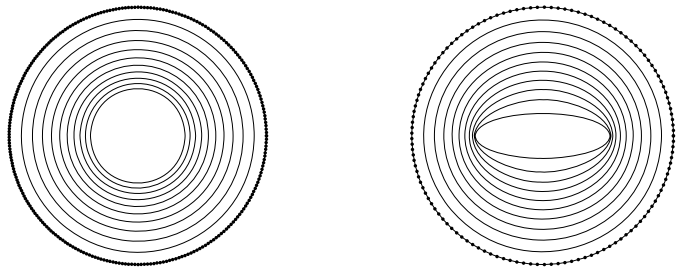

FIG. 8. $\vec{X}(t)$ *for* $t = 0, 0.1, \ldots, T = 1$ *for the inverse mean curvature flow of a circle (left) and an ellipse (right).*

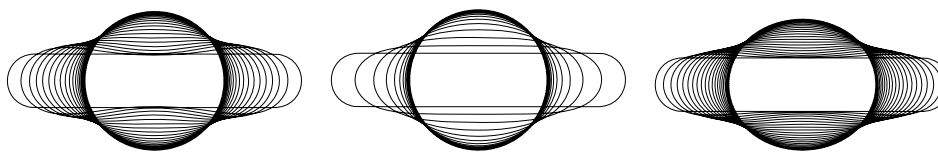

FIG. 9. *Different evolutions for surface diffusion, area preserving mean curvature flow, and the intermediate flow* (1.9)*, with* $\alpha = \xi = 1$*. In each case, we plot* $\vec{X}(t)$ *for* $t = 0, 1, \ldots, T = 20$*.*

of Figure 8. The next experiment is for a $3:1$ ellipse that expands to a circle. The discretization parameters are $N = 128$, $\tau = 10^{-3}$, and $T = 1$; see the right-hand side of Figure 8.

3.1.2. Intermediate evolution laws. In this subsection, we report on numerical results for our approximation (2.20a–c) of the intermediate evolution law (1.10). First, we compare the different evolutions of (1.2), (1.8) with $f(r) := r$, and (1.9) with $\alpha = \xi = 1$, for an initial curve that is given by an elongated tube of dimensions 10×1. As discretization parameters for the schemes (2.21a,b), (2.4) with (2.3b) and $f(r) := r$, and (2.20a–c) we used $N = 256$, $\tau = 10^{-3}$, and $T = 20$, and the corresponding results are shown in Figure 9. One can clearly see that while the curve that moves under area preserving mean curvature flow remains convex throughout the evolution, this is not the case for the other two evolution laws. The area losses for the respective schemes were 0.004%, 0.016%, and 0.002%. As noted before for $\alpha \to \infty$ and $\xi = 1$, the solutions to (1.9) converge to solutions of (1.8), while $\xi \to \infty$ and $\alpha = 1$ corresponds to the law (1.2). We now investigate this property numerically. To this end, we repeat the above experiments for (2.20a–c) with $\xi = 1$, $\alpha = 1000$ and $\xi = 1000$, $\alpha = 1$, respectively. The results, for which the respective area losses were 0.008% and 0.004%, can be seen in Figure 10. One can clearly see the similarity between these evolutions and their corresponding limits in Figure 9. We note also that the curve in the first evolution remains convex, while the curve for the second evolution does not.

3.2. Triple junctions. In the first experiment for triple junctions (see Figure 11) we simulate how two initially elliptic bubbles move under motion by mean curvature. Throughout, we assume equal surface energies, $\sigma_i = 1$, $i = 1 \to K_C$, unless stated otherwise. The plot on the left-hand side of Figure 11 shows the evolution

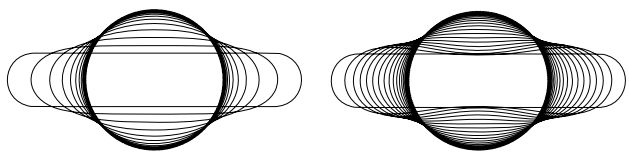

FIG. 10. *The flow* (1.9) *with* $\xi = 1$, $\alpha = 1000$ *(left) and* $\xi = 1000$, $\alpha = 1$ *(right). In each case, we plot* $\vec{X}(t)$ *for* $t = 0, 1, \ldots, T = 20$.

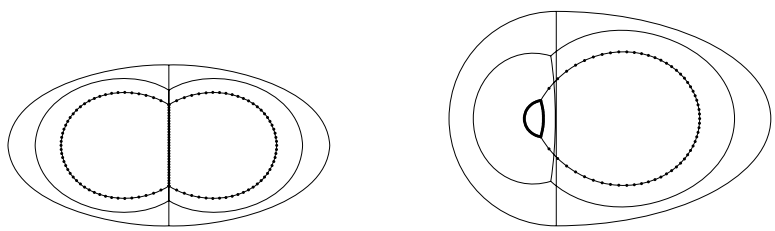

FIG. 11. $\vec{X}(t)$ *for* $t = 0, 0.2, T = 0.4$. *An equal area double bubble under mean curvature flow is shown on the left, and a nonequal area case on the right.*

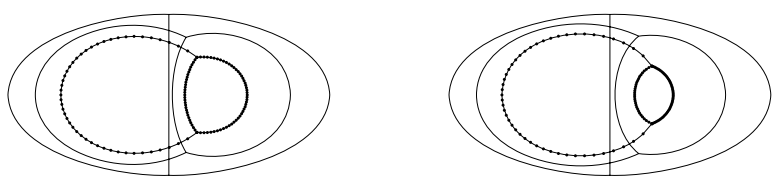

FIG. 12. $\vec{X}(t)$ *for* $t = 0, 0.2, T = 0.4$. *An equal area double bubble under mean curvature flow is shown for surface energies* $(1, 1, \frac{3}{2})$ *and* $(1, 1, \frac{7}{4})$, *respectively.*

for two equal area bubbles, while the nonequal area case is displayed on the right-hand side. The chosen parameters were $N = 128$, $\tau = 0.01$, and $T = 0.4$. The initial shapes are given by two segments of a $2:1$ ellipse with unit semiminor axis and a straight line, or a semicircle together with an elliptic segment from the above ellipse and a straight line, respectively. We repeated the experiment on the left-hand side of Figure 11 for different surface energies. The surface energies were chosen to be $(\sigma_1, \sigma_2, \sigma_3) = (1, 1, \frac{3}{2})$ and $(1, 1, \frac{7}{4})$. That means that the length of the curve Γ_3 is weighted more in the overall energy $|\Gamma|$, so that it will shorten faster during the evolution; see Figure 12.

The next experiment is for motion by surface diffusion. The initial setup, as depicted in Figure 13, consists of a segmentation of the $[-1, 1]^2$ square, with the middle segments having width 0.3. Our discretization parameters were $N = 256$, $\tau = 10^{-3}$, and $T = 0.04$. The evolution leads to one curve segment shrinking to a single point. Of course, our approximation cannot compute beyond that singularity. However, on the right-hand side of Figure 13 we show how, after a topological change, the evolution continues to a numerically steady state. This numerical result was

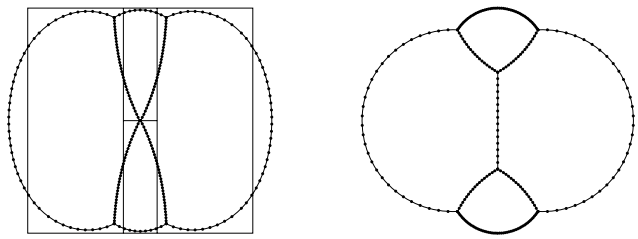

FIG. 13. *A curve shrinks to a point: $\vec{X}(t)$ for $t = 0, T$ (left). The eventual numerically steady state after a change of topology (right).*

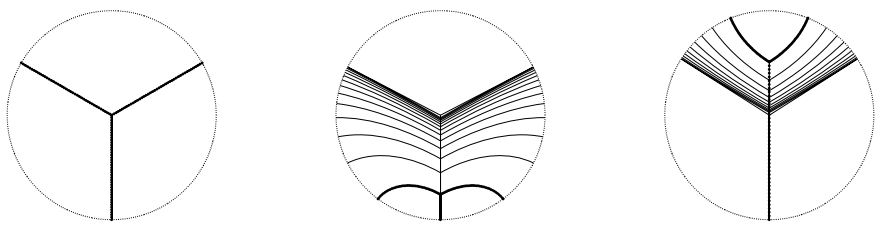

FIG. 14. *A triple junction inside the unit circle moving under mean curvature flow.*

obtained by restarting the computation from a curve network that was topologically equivalent to the steady state, and with enclosed regions having the same area as before, i.e., 0.7, 0.3, 0.7, and 0.3.

3.3. Boundary intersections. In the first experiment for curve networks with triple junctions and intersections with the external boundary (see Figure 14), we simulate how an initial "letter Y" inside the unit circle moves under motion by mean curvature. We varied the initial angle θ_3 between the two upper curves, which meet at the origin. Here and throughout, $\theta := (\theta_1, \theta_2, \theta_3)$ is defined as the angles formed by the three curve segments meeting at a triple junction, and θ_i, $i = 1 \to 3$, denotes the angle opposite the curve Γ_i at a triple junction; recall (1.15).

The values used for θ_3 are 120°, 125°, and 115° with $\theta_1 = \theta_2$. The first setup is a steady state for this law of motion, while the other two experiments show that the symmetric boundary intersections will either move up or down the unit circle. The chosen discretization parameters for (2.33a,b) were $N = 128$, $\tau = 0.01$, and $T = 1, 2.6$, and 2, respectively. The times shown in Figure 14 are $t = 0, 0.2, \ldots, T$. The maximum distance $d_{\partial\Omega} := \max_{i=1\to3} \operatorname{dist}(\vec{X}_i^M(1), \partial\Omega)$ of the curve endpoints at time T was $d_{\partial\Omega} = 0$, 8.6×10^{-3}, and 1.8×10^{-3}, respectively. Moreover, note that eventually the solution for the latter two experiments becomes either a single point (on the boundary $\partial\Omega$) or a single straight line.

We repeated the last experiment inside the square $[-1, 1]^2$. Note that in this case $F \notin C^1(\mathbb{R}^2)$, but as the points of the derivative discontinuities are never reached by the evolving curves, this has no effect on the evolution; this will always be true in all examples below for such F. Here no steady state solution exists for this law of motion. For the results see Figure 15, where we chose as angles $\theta_3 = 180°,\ 95°,\ 85°$ and integrated until time $T = 1.4,\ 2$, and 0.4, respectively. We observe that in the first two cases the solution exhibits a traveling wave character. In fact, an exact solution can be found for this setup; see [27, p. 313]. Let $\gamma(\rho, t) := \frac{6}{\pi} \ln(\cos(\frac{\pi}{6}(1-\rho))) - \frac{\pi}{6} t + 1$

and

(3.2)
$$\vec{x}_1(\rho,t) = \begin{pmatrix} -\rho \\ \gamma(\rho,t) \end{pmatrix}, \quad \vec{x}_2(\rho,t) = \begin{pmatrix} \rho \\ \gamma(\rho,t) \end{pmatrix}, \quad \vec{x}_3(\rho,t) = (1-\rho)\begin{pmatrix} 0 \\ \gamma(0,t) \end{pmatrix} + \rho \begin{pmatrix} 0 \\ -1 \end{pmatrix}.$$

Then $\vec{x} := (\vec{x}_1, \vec{x}_2, \vec{x}_3)$ is a solution to (1.12), (1.14a,b), and (1.17a,b). We used this exact solution to perform a convergence test for our approximation (2.33a,b). See Table 3, where we show the error $\|\vec{X}-\vec{x}\|_{L^\infty}$ on the time interval $[0,T]$ for $T = 3$ and $\tau = 0.5\,h^2$. Here $\|\vec{X}-\vec{x}\|_{L^\infty} := \max_{m=1\to M} \|\vec{X}(t_m) - \vec{x}(\cdot,t_m)\|_{L^\infty}$ with $\|\vec{X}(t_m) - \vec{x}(\cdot,t_m)\|_{L^\infty} := \max_{i=1\to 3} \max_{j=0\to N_i} \min_{\rho\in I} |\vec{X}_i^m(q_j^i) - \vec{x}_i(\rho,t_m)|$ is computed by employing a Newton method for the curved segments of the true solution. The evolution for $N = 128$ is shown on the right of Table 3.

3.3.1. Surface diffusion with boundary intersections. We repeated the above type of experiments for motion by surface diffusion, i.e., the approximation (2.50a,b) of the system (1.19)–(1.22) and (1.17a,b). In the first experiment we simulate how an initial "letter Y" inside the unit circle moves under motion by surface diffusion. We varied the initial angle θ_3 between the two upper curves at the origin with values 120°, 180°, and 45°. While the first setup is already a steady state for this law of motion, the other two experiments soon reach a steady state. The chosen parameters were $N = 128$, $\tau = 10^{-4}$, and $T = 0.05$. In Figure 16 we show $\vec{X}(t)$ at times $t = 0,\ T$. Note that the maximum distance of the curve endpoints to the external boundary $\partial\Omega$ at time T was $d_{\partial\Omega} = 0,\ 3\times10^{-5}$, and 8×10^{-5}, respectively. The results for the same experiments inside the domain $\Omega = [-1,1]^2$ can be found in Figure 17. We note that here $d_{\partial\Omega} = 0$ in each case, as the external boundary consists of straight lines.

We repeated the experiment on the left-hand side of Figure 16 for different surface energies. The surface energies were chosen to be $(\sigma_1,\sigma_2,\sigma_3) = (1,1,\frac{3}{2})$ and $(1,1,\frac{7}{4})$, respectively. We observe that as the length of the curve Γ_3 is weighted

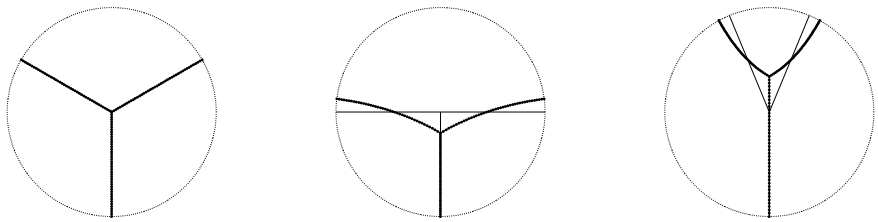

FIG. 16. *A triple junction inside the unit circle moving under motion by surface diffusion.*

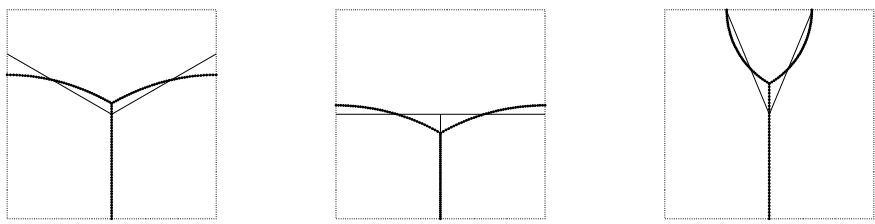

FIG. 17. *A triple junction inside the square* $[-1,1]^2$ *moving under motion by surface diffusion.*

more in the overall energy $|\Gamma|$, it shortens in comparison to the other two curves during the evolution; see Figure 18. The observed angles at the triple junction are $\theta = (138.4, 138.4, 83.2)$ and $\theta = (150.6, 150.6, 58.8)$. (Note that Young's law yields $\theta = (138.6, 138.6, 82.8)$ and $\theta = (151, 151, 57.9)$, respectively, for the exact solution.) Finally, we give the same evolution for the surface energies $(1,1,2)$ on the right-hand side of Figure 18. Here in the true steady state the curve Γ_3 has shrunk to a point on the boundary $\partial\Omega$, which, as it represents a change of topology, our approximation cannot compute. We give a plot of $\vec{X}(T)$ for $T = 0.5$, when the observed triple junction angles are $\theta = (178.2, 178.2, 3.7)$.

An example with only two enclosed areas can be seen in Figure 19. Here the initial curve is given by a straight line through the origin that forms an angle of 10° with the x-axis inside a 2:1 elliptic domain Ω with unit semiminor axis. The chosen parameters were $N = 128$, $\tau = 10^{-4}$, $T = 2$. On the left-hand side of Figure 19 we plot $\vec{X}(t)$ at times $t = 0, 0.05, \ldots, T = 2$. The right-hand side shows a similar experiment, where the initial curve goes through the point $(0, -\frac{1}{2})^T$. The parameters were $N = 32$, $\tau = 10^{-3}$, and $T = 10$, and we display $\vec{X}(t)$ at times $t = 0, 0.5, \ldots, T = 10$. In both cases the evolution finds the minimum of a corresponding partitioning problem in which the length of the interface between two phases is minimized subject to an area constraint for the phases.

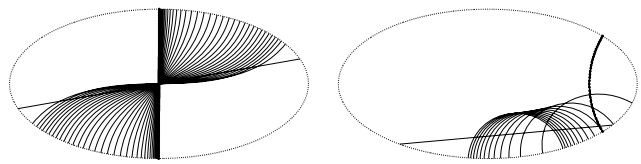

FIG. 19. *A curve inside an elliptic domain moving under motion by surface diffusion.*

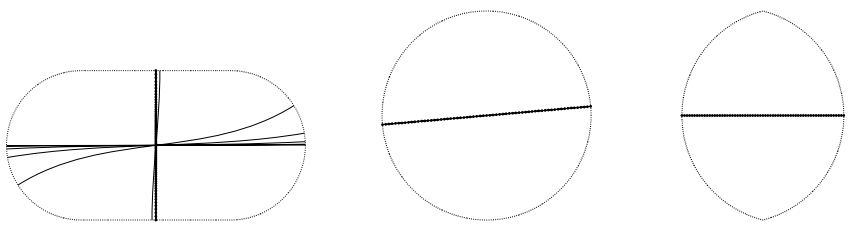

FIG. 20. *Initially straight lines that are unstable (left), neutral (middle), or stable (right). On the left,* $\vec{X}(t)$ *at times* $t = 0, 2, \ldots, 16$. *The remaining plots show* $\vec{X}(t)$ *at times* $t = 0, 6$.

Next, we investigate numerically the stability of some of the setups discussed in [25]. We start by considering a domain Ω that has a boundary with piecewise constant curvature. The analysis in [25, Figure 6] predicts that a straight line inside Ω is only stable if it is sufficiently short. In the situation considered in Figure 20, it must not exceed twice the radius of the two arcs. In the first experiment, the total dimensions of the domain are 4×2. The initial line has a slope of $0.1°$, and as the straight line on the x_1-axis is not stable, it evolves to a straight line on the x_2-axis. If, however, the dimensions of the domain are only $\frac{3}{2} \times 2$, then the straight line is stable, and this is seen in the corresponding experiment. The case where the domain is a circle is neutral, as any straight line through the origin is a steady state solution. As an example, we show an initially straight line with slope $5°$, which does not change under the surface diffusion flow. The final solutions depicted in Figure 20 are all numerically steady states.

The next experiment investigates the behavior for the setup in [25, Figure 7]. In each case, we use a domain where the lower boundary follows a sine shape. In particular, the lower boundary is given by $x_2 = -1 + \frac{1}{8}\sin(2\pi\, x_1)$. The initial profile is always a semicircle with radius 0.5. Depending on the sign of the curvature of the domain boundary, that solution is either stable or unstable. We investigate the stability numerically, by using $\vec{z} = (\mp 0.24, -1 \pm \frac{1}{8})$ as the center of the half-circle. Note that $\vec{z} = (\mp\frac{1}{4}, -1 \pm \frac{1}{8})$ corresponds to a steady state. The results are shown in Figure 21, where we also include the neutral case of a semicircle attached to a straight part of the boundary.

Next, we performed computations with three enclosed areas and two vertices on the external boundary $\partial\Omega$; see Figure 22. Starting with an initially circular area (with radius 0.75) that is connected by two straight lines to the external boundary inside a $2:1$ rectangular domain, we observe different steady state solutions depending on the chosen surface energies $\sigma = (\sigma_1, \sigma_2, \sigma_3, \sigma_4)$. We note that for a physically relevant setup $\sigma_1 = \sigma_4$, where Γ_1 and Γ_4 are the straight line curve segments. We used the

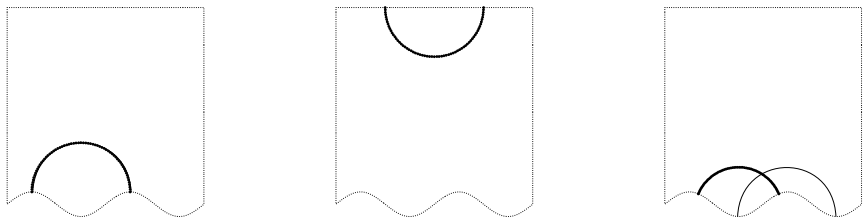

FIG. 21. *Stable (left) and unstable (right) setup. In the middle a neutral situation is shown. Each plot shows* $\vec{X}(t)$ *at times* $t = 0, 1$.

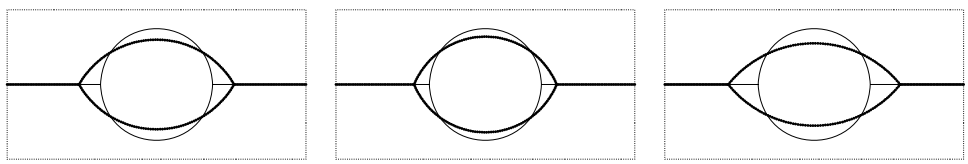

FIG. 22. *Steady state solutions for different angles* θ_1.

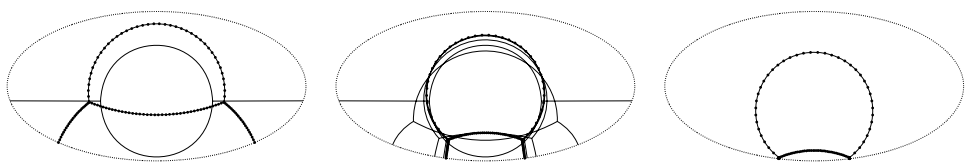

FIG. 23. *Solution for circular setup for pure surface diffusion (left) and combined mean curvature and surface diffusion inside an elliptic domain. In the middle* $\vec{X}^m(t)$ *at times* $t = 0, 0.5, \dots, 2$ *and on the right* $\vec{X}^m(T)$ *at* $T = 40$.

values $\sigma = (1, \lambda, \lambda, 1)$ with $\lambda = 1,\ \frac{\sqrt{7}}{2},\ (\frac{5}{8})^{\frac{1}{2}}$, corresponding to [7, Figures 3 and 8], so that the true triple junction angle is $\theta_1 = 120°,\ 135°,\ 102°$, respectively. The chosen discretization parameters for each experiment were $N = 256$, $\tau = 10^{-4}$, and $T = 0.2$. The observed angles inside the circular area were $\theta_1 = 118.6°$, $133.9°$, and $100.2°$, respectively.

For later purposes, we repeated the first experiment in Figure 22, but now inside a 2:1 elliptic domain and with the initial profile at the height $y = -0.2$. The chosen parameters were $N = 128$, $\tau = 10^{-3}$, and $T = 2$, by which time the numerical solution has reached a steady state. The results are shown on the left-hand side of Figure 23.

Next, we report on some experiments for (2.50a) and (2.34), i.e., for the surface diffusion of a curve network with specified contact angles α_i that the curves form with the external boundary $\partial\Omega$. Here we use as initial data a "letter Y" inside the unit circle, similarly to Figure 14. We varied the angle α_i, $i = 1 \to 3$, that the three curves form with the external boundary. In Figure 24 we show the solution $\vec{X}(t)$ at times $t = 0,\ T$ for the values $\alpha_1 = \alpha_2 = \alpha_3 = \alpha$ with $\alpha = 60°$, $30°$, and $5°$. The chosen discretization parameters were $N = 128$, $\tau = 10^{-3}$, and $T = 0.1$. The same experiments inside the square $[-1, 1]^2$, where the initial profile is now a "letter T,"

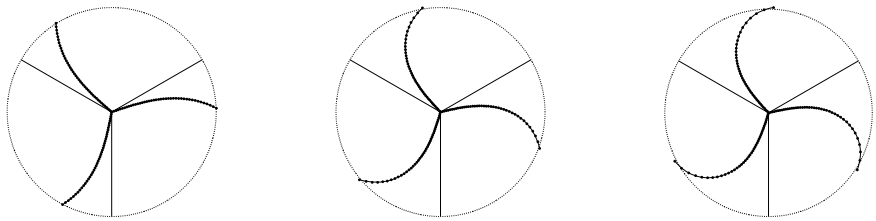

FIG. 24. *A triple junction inside the unit circle with different contact angles at* $\partial\Omega$.

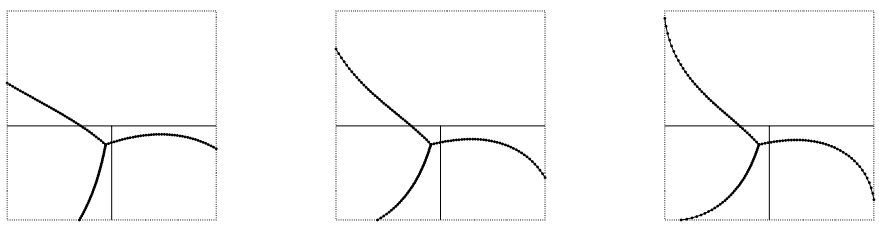

FIG. 25. *A triple junction inside the square* $[-1,1]^2$ *with different contact angles at* $\partial\Omega$.

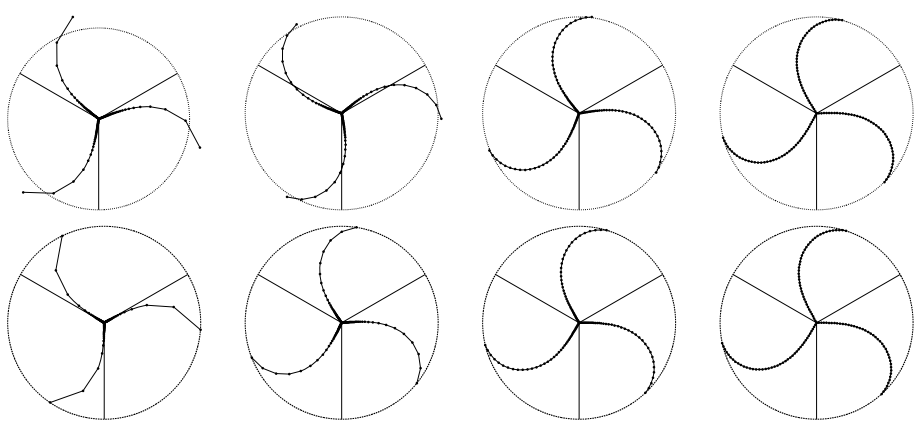

FIG. 26. *Tangential movement and boundary vertex mislocation for different time step sizes,* $\tau = 10^{-k}$, $k = 2 \to 5$. *Results for* (2.50a,b) *(top) and the corresponding scheme with a projection onto* $\partial\Omega$ *at each time step (bottom).*

can be seen in Figure 25.

We note that in practice we observe a tangential movement of mesh points away from the boundary intersection towards the triple junction. On the other hand, we have mentioned in Remark 2.5 that it was shown in [6] that for a semidiscrete in time approximation the vertices equidistribute along each curve Γ_i^h, $i = 1 \to 3$. Hence for τ sufficiently small, we expect the parameterizations $\vec{X}_i^m$ to become more and more uniform. We investigate this behavior with the following set of experiments. We repeat the last experiment in Figure 24 and integrate until time $T = 1$ for different choices of $\tau = 10^{-k}$, $k = 2 \to 5$. In the top row of Figure 26 we see clearly that the distribution of vertices improves as τ decreases. For comparison, we include the results for the same set of experiments for a version of our scheme, where one employs

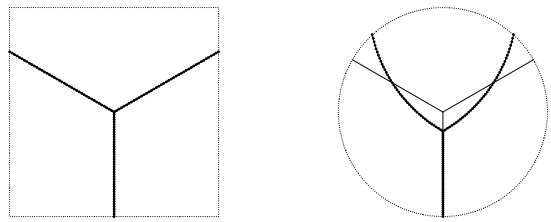

FIG. 27. *A steady state solution for given boundary contact angles inside the square* $[-1,1]^2$*, and the corresponding evolution inside the unit circle.*

a projection step that orthogonally projects the boundary vertices of $\vec{X}^{m+1}$ onto $\partial\Omega$ at every time step. As can be seen from the results in the bottom row of Figure 26, for small time step sizes the results are virtually indistinguishable, while for large time steps it can be beneficial to employ the described projection step.

Finally, we provide an experiment for a steady state inside the domain $\Omega = [-1,1]^2$. The chosen contact angles are $\alpha_1 = 60°$, $\alpha_2 = 120°$, and $\alpha_3 = 90°$, so that the initial "letter Y" is a true steady state solution. We confirm this with a numerical experiment for (2.50a) and (2.34) with $N = 128$, $\tau = 10^{-3}$, and $T = 0.5$; see Figure 27, where we complement this result with the corresponding evolution inside the unit circle.

3.3.2. Combined surface diffusion and mean curvature flow. In this subsection, we report on numerical results for the approximation (2.53a,b) of (1.23). First, we repeated the experiment reported on earlier, shown on the left-hand side of Figure 23, but now for a combined motion of surface diffusion and mean curvature flow. In particular, we prescribe surface diffusion on the two initially circular curves, while the initially straight-lined curves experience motion by mean curvature. See Figure 23 for the results, where we plot $\vec{X}^m(t)$ at different times. The chosen parameters were $N = 128$, $\tau = 10^{-3}$, and $T = 40$. One can clearly see the very different evolution compared to the pure surface diffusion flow, and note in particular that each of the two curves moving under motion by mean curvature now shrink to a single point (on the boundary $\partial\Omega$).

The next experiment is motivated by the considerations on a traveling wave solution to (1.23) that was first mentioned in [36] and which plays a major role in the study of grain boundary motion; see also [33] and [7, Figure 7]. The computations shown in Figure 28 start with three curves meeting at a single triple junction, of which the two horizontal ones experience motion by surface diffusion, while the third curve undergoes motion by mean curvature. As surface energies we chose $\sigma = (1, 1, \sigma_3)$ with $\sigma_3 = 1$ and $\sigma_3 = \frac{3}{2}$, respectively. Moreover, the evolution law for the curve moving under motion by mean curvature is here given by $\mathcal{V}_3 = \mu_3\,\sigma_3\,\varkappa_3$ in place of (1.12), where for the mobility we chose either $\mu_3 = 1$ or $\mu_3 = 2$. Note that our approximation (2.53a,b) can easily be adapted to this situation by replacing σ_3 with $\mu_3\,\sigma_3$ in (2.53a). The domain Ω is an 8×2 rectangle. The chosen discretization parameters were $N = 256$ and $\tau = 10^{-3}$.

3.4. Quadruple junctions. Here we consider a setup of three enclosed areas meeting at two triple junctions and one quadruple junction. A physical interpretation of this configuration is an alloy material with two grains and two phases, similar to the situation considered in [10, 26]. For the initial curves depicted in Figure 29 this

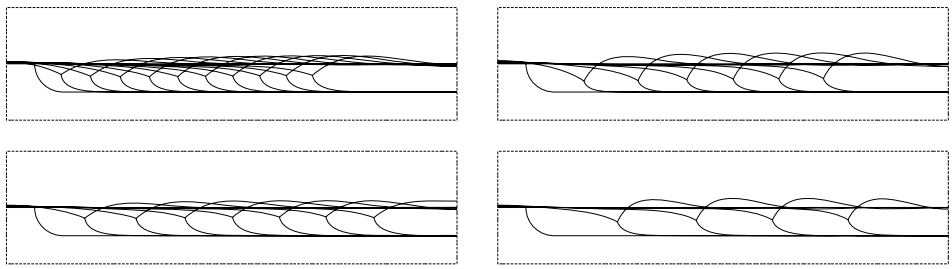

FIG. 28. *Traveling wave solutions* $\vec{X}^m(t)$ *at times* $t = 0, 0.1, \ldots, T$, *with* $T = 1,\ 0.6,\ 0.7$, *and* 0.4, *respectively. Surface energies are* $\sigma_3 = 1$ *(left) and* $\sigma_3 = \frac{3}{2}$ *(right), with mobilities* $\mu_3 = 1$ *(top) and* $\mu_3 = 2$ *(bottom).*

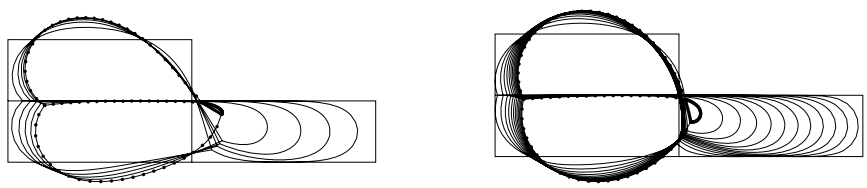

FIG. 29. $\vec{X}(t)$ *for* $t = 0, 0.1, \ldots, T$ *for a quadruple junction with* $\lambda = \frac{3}{2}$ *(left) and* $\lambda = \frac{2}{3}$ *(right).*

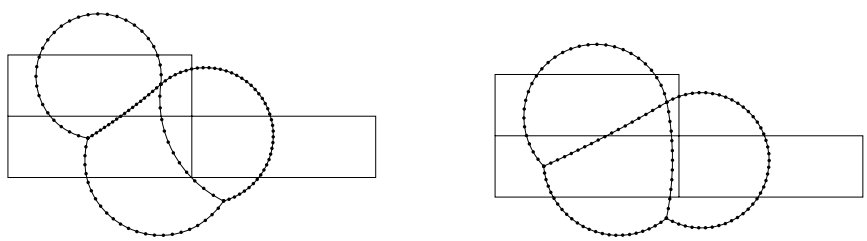

FIG. 30. $\vec{X}(t)$ *for* $t = 0, T$ *for a quadruple junction with* $\lambda = \frac{3}{2}$ *(left) and* $\lambda = \frac{2}{3}$ *(right).*

means that the two left enclosed areas represent phase B, while the rest of the plane is made up of phase A. Moreover, the lower two enclosed areas represent grain I, with the rest of the domain being grain II. Then we have motion by surface diffusion for the interfaces Γ_1 and Γ_3 separating the two phases, and mean curvature flow for the interfaces Γ_2 and Γ_4 between the two grains. The surface energies were chosen to be $\sigma_{SD} = 1$ for the curves moving by surface diffusion and $\sigma_{MC} = \lambda$ for the remaining curves. Two evolutions for $\lambda = \frac{3}{2}$ and $\lambda = \frac{2}{3}$, where the initial curves create a collection of $3:1$ rectangles, can be seen in Figure 29. The discretization parameters were $N = 128$, $\tau = 10^{-3}$, and $T = 0.49$ and $T = 1.2$, respectively. In both evolutions we can see that the two curves enclosing grain I in phase A eventually shrink to a point. The change of topology needed to continue the evolution is beyond the scope of our direct parametric approximation. We also give the corresponding numerical steady states for the pure surface diffusion flow version of this experiment in Figure 30. The discretization parameters were $N = 128$, $\tau = 10^{-3}$, and $T = 8$.

Finally, we remark that, on recalling $\sigma_{SD} = 1$ and $\sigma_{MC} = \lambda$, the balance of forces equation (1.16) becomes $(\vec{\tau}_1 + \vec{\tau}_3) + \lambda\,(\vec{\tau}_2 + \vec{\tau}_4) = \vec{0}$. It follows from this that $\theta_1 = \theta_3$ and $\theta_2 = \theta_4$, where $\theta_i := \sphericalangle(\vec{\tau}_i, \vec{\tau}_{i+1})$, $i = 1 \to 3$, and $\theta_4 := \sphericalangle(\vec{\tau}_4, \vec{\tau}_1)$, as adding the four vectors $\vec{\tau}_1, \lambda\,\vec{\tau}_2, \vec{\tau}_3, \lambda\,\vec{\tau}_4$ in the plane leads to a 4-polygon with two opposite sides having length 1 and two opposite sides having length λ. This implies that the 4-polygon is a parallelogram, and hence opposite angles in the parallelogram have to be equal. This fact can be seen clearly in the numerical computations. For example, on labeling the curves anticlockwise starting from the top most one, the angles observed in Figure 30 at the quadruple junction are $\theta = (133.1, 44.6, 133.7, 48.6)$ and $\theta = (107.5, 69.6, 105.8, 77.1)$, respectively; i.e., the stated angle condition is approximately satisfied.

4. Conclusions. We have presented a fully practical finite element approximation for the (combined) motion by mean curvature and motion by surface diffusion of curves in $\mathbb{R}^2$, as well as for other related second and fourth order geometric evolution equations. Our scheme can handle both triple and quadruple junction points between different curves, and intersections of curves with a fixed external boundary $\partial\Omega$. To our knowledge, this is the first such scheme in the literature. Moreover, the presented scheme intrinsically moves the vertices tangentially along the curves, so that no artificial redistribution of vertices is necessary in practice. Finally, we note that a generalization of the presented method to geometric flows of two-dimensional hypersurfaces in $\mathbb{R}^3$ will be considered in the forthcoming manuscript [5]. Moreover, extending our schemes for curves and hypersurfaces to include the case of fully anisotropic surface energies is the subject of our ongoing research in this area.

NEW ACYCLIC AND STAR COLORING ALGORITHMS WITH APPLICATION TO COMPUTING HESSIANS*

ASSEFAW H. GEBREMEDHIN†, ARIJIT TARAFDAR†, FREDRIK MANNE‡, AND ALEX POTHEN†

Abstract. Acyclic and star coloring problems are specialized vertex coloring problems that arise in the efficient computation of Hessians using automatic differentiation or finite differencing, when both sparsity and symmetry are exploited. We present an algorithmic paradigm for finding heuristic solutions for these two NP-hard problems. The underlying common technique is the exploitation of the structure of two-colored induced subgraphs. For a graph G on n vertices and m edges, the time complexity of our star coloring algorithm is $O(n\bar{d}_2)$, where $\bar{d}_k$, a generalization of vertex degree, denotes the average number of distinct paths of length at most k edges starting at a vertex in G. The time complexity of our acyclic coloring algorithm is larger by a multiplicative factor involving the inverse of Ackermann's function. The space complexity of both algorithms is $O(m)$. To the best of our knowledge, our work is the first practical algorithm for the acyclic coloring problem. For the star coloring problem, our algorithm uses fewer colors and is considerably faster than a previously known $O(n\bar{d}_3)$-time algorithm. Computational results from experiments on various large-size test graphs demonstrate that the algorithms are fast and produce highly effective solutions. The use of these algorithms in Hessian computation is expected to reduce overall runtime drastically.

1. Introduction.

The cost involved in computing a Jacobian or a Hessian matrix using automatic differentiation or finite differencing is proportional to the number of columns in the matrix. When the target derivative matrix A is sparse, huge savings in runtime can be attained by first computing a matrix B, where each column of B is a sum of several structurally "independent" columns of A, and then recovering the nonzero elements in A from B. Thus, an important component of the efficient computation of a sparse derivative matrix, whose sparsity pattern is known a priori, is the problem of partitioning the columns of the matrix into the fewest groups, each consisting of structurally independent columns.

The appropriate notion of structural independence—and the corresponding partitioning problem—depends on whether the derivative matrix to be computed is or , and on whether the nonzero entries are to be recovered from the compressed matrix or via . Conceptually, direct recovery corresponds to solving a diagonal system of equations, and recovery via substitution corresponds to solving a set of simple triangular systems of equations. Several previous studies have shown that these matrix partitioning problems can be modeled and effectively solved using specialized graph coloring problems and their algorithms [9, 12, 13, 14, 22, 27]. See our earlier work [17] for a comprehensive review.

This paper is concerned with the design and implementation of effective algorithms for [illegible] and [illegible] coloring, models for efficient computation of Hessians. In a star coloring, adjacent vertices receive distinct colors (distance-1 coloring), and every [illegible] (P_4) uses at least three colors. In an acyclic coloring, adjacent vertices receive distinct colors, and every [illegible] uses at least three colors. Coleman and Moré [13] showed that star coloring models the partitioning problem that occurs in the computation of a Hessian via a direct method; Coleman and Cai [9] showed that the corresponding model in a substitution-based computation is acyclic coloring. Both problems, whose objectives are to minimize the number of colors used, are known to be NP-hard [9, 13]. As we show in section 2, these problems are also hard to approximate.

Star coloring as a model for direct Hessian computation was preceded by two less accurate models: the [illegible] 2 coloring model due to McCormick [27] and the [illegible] coloring model due to Powell and Toint [28]. Similarly, acyclic coloring as a model for Hessian computation via substitution was preceded by a less accurate model, [illegible] coloring, due to Coleman and Moré [13]. These models and the interrelationships amongst them are discussed in detail in section 5.

In a previous work [17], we suggested a simple heuristic algorithm for the star coloring problem. In each step of that algorithm, the color of a vertex is determined by examining every P_4 starting at the vertex. The time complexity of the algorithm for a graph on n vertices is $O(n\bar{d}_3)$, where $\bar{d}_k$ denotes the average number of paths of length at most k edges starting at a vertex. A similar $O(n\bar{d}_2)$-time algorithm for restricted star coloring, originally due to Powell and Toint [28], exists. However, when used for solving the star coloring problem, the latter algorithm uses significantly more colors than the $O(n\bar{d}_3)$-time algorithm mentioned earlier.

Although Coleman and Cai [9] identified acyclic coloring as the model for computing a Hessian via a substitution method, the algorithm they suggested is an algorithm for triangular coloring. In their approach, first a graph G' is constructed by adding edges to the input graph G, and then a distance-1 coloring algorithm is applied on the graph G'. A similar approach for triangular coloring was taken earlier by Coleman and Moré [13]. An optimal solution for the triangular coloring problem is not necessarily an optimal solution for the acyclic coloring problem. Moreover, working with a denser graph G' is undesirable for large-scale problems, since the approach may require excessive storage space and lead to memory overflow. As for the acyclic coloring problem, we are not aware of any previous practically relevant algorithm.

In this paper, we present new algorithms for both the acyclic and the star coloring problems. The common paradigm underlying the two algorithms is the exploitation of the structure of [illegible]. In the acyclic coloring case, every subgraph induced by any two color classes is a collection of [illegible]; the corresponding structure in the star coloring case is a collection of [illegible]. In both cases, the two-colored induced subgraphs [illegible] the edge set of the input graph. Our algorithms are based on these observations.

The algorithms presented in this paper are [illegible]—they progressively extend a partial coloring by processing one vertex at a time. In each step, a vertex is assigned the [illegible] (assuming colors are positive integers) allowable color with respect to the current partial coloring, and the color assigned to the vertex remains unchanged during the course of the algorithm. Greedy coloring heuristics stand in contrast to [illegible] heuristics, where the color assigned to a vertex may change several times during the course of an algorithm in an attempt to ultimately

reduce the number of colors used. Greedy coloring heuristics are in general fast, which makes them attractive approaches for solving subproblems in scientific computing applications, such as the case in this paper. An important issue in greedy coloring algorithms is the order in which vertices are processed. We consider several effective ordering techniques in this paper.

A key component of our new algorithms is the efficient management of two-colored induced subgraphs. For the acyclic coloring case, the disjoint-set data structure is used for this purpose; for the star coloring case, a simpler data structure is shown to be sufficient. In addition, a few intricate techniques which yet use simple data structures are employed to avoid two-colored cycles in the acyclic coloring case, and two-colored P_4's in the star coloring case. The time complexity of the star coloring algorithm is $O(n\bar{d}_2)$, and that of the acyclic coloring algorithm is larger by a multiplicative factor involving the inverse of Ackermann's function. The space complexity of both algorithms is $O(m)$, where m denotes the number of edges in a graph. The acyclic coloring algorithm will be presented (in section 3) before the star coloring algorithm (in section 4) to reflect that the former in an algorithmic sense corresponds to the more general case.

We have implemented the new acyclic and star coloring algorithms presented in this paper as well as several previously known algorithms for related coloring problems; the latter algorithms will be discussed in section 6. Results from experiments carried out on various large-size test graphs show that the new algorithms are highly effective, both in terms of the number of colors used and in practical runtime. On the test graphs used, the number of colors used by the acyclic coloring algorithm is observed to be very close to (within a factor of two) the [illegible] of a graph—the number of colors used by a greedy distance-1 coloring algorithm that employs a [illegible] vertex ordering. The coloring number is an important graph parameter with close relationship to graph notions such as degeneracy, maximal core, and arboricity. The runtime of the acyclic coloring algorithm is observed to be nearly the same as that of a greedy distance-2 coloring algorithm. In comparison with our implementation of an algorithm for triangular coloring—the previously known approach for Hessian computation via a substitution method—the acyclic coloring algorithm runs faster, uses fewer colors, and requires less memory and storage space. In agreement with time complexity analyses, our new star coloring algorithm is observed to be significantly faster than our previous $O(n\bar{d}_3)$-time algorithm—it offers a relative speedup as high as ten on the test graphs used. Moreover, the new algorithm uses slightly fewer colors. In comparison with the restricted star coloring algorithm of Powell and Toint [28], which is of the same time complexity as the new star coloring algorithm proposed here, our algorithm significantly reduces the number of colors used. In terms of observed runtime, the new star coloring algorithm is slower than the restricted star coloring algorithm by only a small factor, typically two.

2. Background.

2.1. Preliminary concepts and notations. Throughout this paper, we consider simple, undirected graphs without loops or parallel edges. Two classes of (sub)graphs that we have need for are trees and stars. A [illegible] is a connected graph without any cycle, and a [illegible] is a collection of trees. A [illegible] is a complete bipartite graph in which one of the vertex sets consists of a single vertex. In a star with at least two edges, we call the vertex at which the edges meet the [illegible] of the star.

We denote an edge whose endpoints are the vertices v and w by vw. Two distinct vertices v and w are [illegible] k [illegible] if a shortest path connecting them consists

TABLE 2.1
Characterization of subgraphs induced by a pair of color classes. The coloring variants are listed in an increasing order of restrictiveness; correspondingly, the two-colored induced subgraphs get increasingly less connected as one goes from top to bottom in the table.

Coloring variant	A two-colored induced subgraph
Distance-1 coloring	A bipartite graph
Acyclic coloring	A collection of trees
Star coloring	A collection of stars
Distance-2 coloring	A distance-2 matching

of at most k edges. We denote the set of distance-k neighbors of a vertex v, excluding the vertex v itself, by $N_k(v)$. As usual, the [illegible] of a vertex is the number of edges incident on it. We extend this notion and define the [illegible] k of a vertex v, denoted by $d_k(v)$, to be the number of distinct paths of length at most k edges starting at v. (Two paths are [illegible] if they differ in at least one edge.) We denote the average degree-k in a graph by $\overline{d}_k$. Note that degree-1 is synonymous with degree, and that the degree-2 of a vertex v is equal to the number of edges that are incident either on v or on vertices adjacent to v. Note also that in general $d_k(v) \geq |N_k(v)|$.

A [illegible] of a graph $G = (V, E)$ is a mapping $\phi : V \to \{1, 2, \ldots, p\}$ such that whenever vertices v and w are distance-k neighbors, $\phi(v) \neq \phi(w)$. By definition, two distance-k neighboring vertices are distance-k' neighbors for $k' > k$, and a distance-k coloring is a distance-k'' coloring for $k'' < k$. The k[illegible] of a graph $G = (V, E)$ is the graph $G^k = (V, F)$, where $vw \in F$ whenever vertices v and w are distance-k neighbors in G. A mapping ϕ is a distance-k coloring of a graph G if and only if ϕ is a distance-1 coloring of the graph G^k. A [illegible] of a graph is a distance-1 coloring with the additional requirement that [illegible]. An [illegible] of a graph is a distance-1 coloring with the further restriction that [illegible]. In a distance-k, a star, an acyclic, or any other coloring variant on a graph, a [illegible] is a set of vertices that have received the same color.

The names star and acyclic coloring are due to the structures of subgraphs induced by any two color classes. In an acyclically colored graph, a subgraph induced by any two color classes is clearly a collection of trees, and thus acyclic. Similarly, in a star-colored graph, a subgraph induced by any two color classes is a collection of stars. It is easy to see that a two-colored connected induced subgraph here ought to be a star, for otherwise there would exist a two-colored path on four vertices, violating a condition of star coloring. These structures are used in the design of the acyclic and star coloring algorithms to be presented in the next two sections. Although not so useful for algorithm design, the structures of two-colored induced subgraphs in the cases of distance-1 and distance-2 coloring are also interesting. A coloring of a graph is a distance-1 coloring if and only if every two-colored induced subgraph is a bipartite graph. In the case of a distance-2 coloring, every two-colored induced subgraph is a set of edges in which a pair of edges is apart by a path of length at least two edges in the original graph, a structure appropriately called a [illegible] 2[illegible]. These observations on two-colored induced subgraphs are summarized in Table 2.1.

2.2. Complexity results. The objective of an optimization problem associated with each of the coloring variants we have introduced is to minimize the number of colors used. Lin and Skiena [26] proved that the distance-k graph coloring problem is NP-hard for every fixed integer $k \geq 1$. Coleman and Moré [13] showed that the

star coloring problem is NP-hard even if the graph is bipartite. The acyclic coloring problem was proven to be NP-hard by Coleman and Cai [9].

The distance-1 coloring problem is also known to be hard to approximate: for a graph on n vertices, there exists $\delta > 0$ such that approximating distance-1 coloring within $O(n^{\delta})$ is NP-hard (Corollary 10.1 in [5]). We use this to prove similar inapproximability results for acyclic and star coloring. We first introduce some notation. The [illegible] of a graph G, denoted by $\chi_k(G)$, is the least number of colors required to distance-k color G. The acyclic and star chromatic numbers are defined analogously, and are denoted by χ_a and χ_s, respectively.

THEOREM 2.1. [illegible] $\epsilon > 0$ [illegible] $\chi_a(G)$ [illegible] G [illegible] $O(n^{\epsilon})$ [illegible] n [illegible] G [illegible]. The reduction is from distance-1 coloring, and it is a small modification of the reduction for proving the NP-completeness of acyclic coloring in Coleman and Cai [9].

Assume that we are given a graph $G = (V, E)$ which we are required to distance-1 color; from G we create a new graph $H = (W, F)$ for acyclic coloring as follows. Let Δ denote the maximum degree of a vertex in G. Each edge $uv \in E$ is replaced by a subgraph (a gadget) in H consisting of vertices u', v', and Δ new vertices w_1, w_2, $\ldots$, w_{Δ}; and edges join vertices u' and v' to every one of the Δ vertices w_i.

We claim that G has a distance-1 coloring using p colors if and only if H has an acyclic coloring using p colors, where $3 \leq p \leq \Delta$.

Suppose G has a distance-1 coloring with p colors. In any edge $uv \in E$, the vertices u and v receive distinct colors. In the graph H, assign u' the same color as u, and v' the same color as v. Since each vertex w_i is adjacent only to the pair of vertices u' and v', it can be assigned any one of the $p-2$ colors distinct from the two colors that have been used for u' and v'; note that the quantity $p-2$ is positive (there exists a color for the vertex w_i) since p is assumed to be at least three. The coloring of H obtained by "processing" every edge in G in this fashion is acyclic. To see this, notice that every cycle in H contains one u' vertex, one v' vertex, and at least one w_i vertex from the gadget we created for some edge $uv \in E$, and these three vertices receive distinct colors in H. Hence every cycle in H uses at least three colors, and one direction of the claim follows.

Now consider an acyclic coloring of H with p colors, again where $3 \leq p \leq \Delta$.

We claim that the vertices u' and v' corresponding to an edge $uv \in E$ receive distinct colors. Suppose not. Then every pair of vertices w_i and w_j in this gadget would have to be colored with distinct colors, or else there would be a cycle u', w_i, v', w_j, u' which would be colored with two colors. But then this subgraph of H would need $\Delta + 1$ colors, contradicting the choice of p.

Thus in every gadget the vertices u' and v' receive distinct colors in the acyclic coloring, and these same colors can be assigned to the vertices u and v to obtain a distance-1 coloring of G using at most p colors.

There exists $\delta > 0$ such that approximating distance-1 coloring within $O(n^{\delta})$ is NP-hard [5], where $n = |V|$, the number of vertices in G. Let N denote the number of vertices in H. Then $N = n + \Delta|E| = O(n + n^3)$. Thus it follows that there exists an $\epsilon > 0$ such that approximating acyclic coloring within $O(N^{\epsilon})$ is NP-hard. □

Under stronger complexity conjectures ($NP \neq ZPP$, the class of problems with polynomial time zero-error randomized algorithms), we can prove that it is hard to approximate acyclic coloring within $O(n^{1/3-\epsilon})$, using a technique similar to that in

Agnarsson and Halldórsson [3].

We can also prove inapproximability results for star coloring, using the same gadget used in the acyclic coloring proof. We omit the details.

THEOREM 2.2. [illegible] $\epsilon > 0$ [illegible] $\chi_s(G)$ [illegible] G [illegible] $O(n^{\epsilon})$

2.3. Related work. Some of the coloring problems introduced in section 2.1 have been studied by other authors, from an application or a pure graph-theoretic point of view. Krumke, Marathe, and Ravi [24] studied the role of distance-2 coloring in channel assignment problems in radio networks. Kumar et al. [25] have undertaken a related study on scheduling problems in wireless networks. In these two studies, several approximation and distributed algorithms for distance-2 coloring of disk and other special classes of graphs have been suggested. Balakrishnan et al. [6] showed that the problem of maximizing concurrent transmissions in certain ad-hoc wireless networks can be modeled as a maximum cardinality distance-2 matching problem, a problem related to distance-2 coloring as discussed at the end of section 2.1. The distance-2 matching problem was first studied and shown to be NP-hard by Stockmeyer and Vazirani [29].

Agnarsson and Halldórsson [2] have studied distance-k coloring of planar graphs, and a similar study of chordal graphs is available in Agnarsson, Greenlaw, and Halldórsson [1]. Acyclic colorings were first defined and studied by Grünbaum [21], who asked whether the acyclic chromatic number $\chi_a(G)$ of a graph G satisfies the inequality $\chi_a(G) \leq \Delta + 1$. A negative answer to this question was given by Erdös, who proved probabilistically the existence of graphs where $\chi_a(G) \geq \Delta^{4/3-\epsilon}$ [23]. Borodin [7] proved that every planar graph can be acyclically colored using at most five colors. Star coloring has recently been studied by Albertson et al. [4], who showed that every acyclic coloring that uses q colors can be refined to a star coloring with at most $2q^2 - q$ colors. These authors also prove that planar graphs have star colorings with at most 20 colors, and they exhibit an example in which 10 colors are required. For more pointers to theoretical works on distance-k, acyclic, and star coloring, see the monograph by Jensen and Toft [23] and our earlier work [17]. The focus of this paper is on practical, fast, suboptimal algorithms for acyclic and star coloring.

3. The new acyclic coloring algorithm.

3.1. Overview. Suppose a subset $U \subset V$ of the vertices of a graph $G = (V, E)$ has been colored satisfying the two requirements of an acyclic coloring. As discussed in section 2.1, every subgraph of G induced by a set of vertices assigned any two colors is a forest. Furthermore, every edge in G both of whose endpoints are in the set U of colored vertices belongs to a unique tree (in a two-colored forest). Therefore, the union of all possible two-colored forests induced by the vertices in the set U is a collection of edge-disjoint trees. Our algorithm maintains such a collection of trees efficiently and extends the partial coloring by processing one vertex at a time.

We use the illustration in Figure 3.1 to provide an overview of the algorithm. The graph shown at the left is the input graph G which has been partially colored, and v is the only vertex that remains to be colored. The right half of Figure 3.1 shows two-colored forests induced by the rest of the vertices of the graph. The input graph currently uses four colors, red, blue, green, and yellow (to ease black-and-white viewing, each colored vertex in the figure has been labeled with a letter reflecting the color used). Thus there could exist at most six two-colored induced forests. Out of these, the subgraph induced by green and yellow vertices is a graph whose edge set

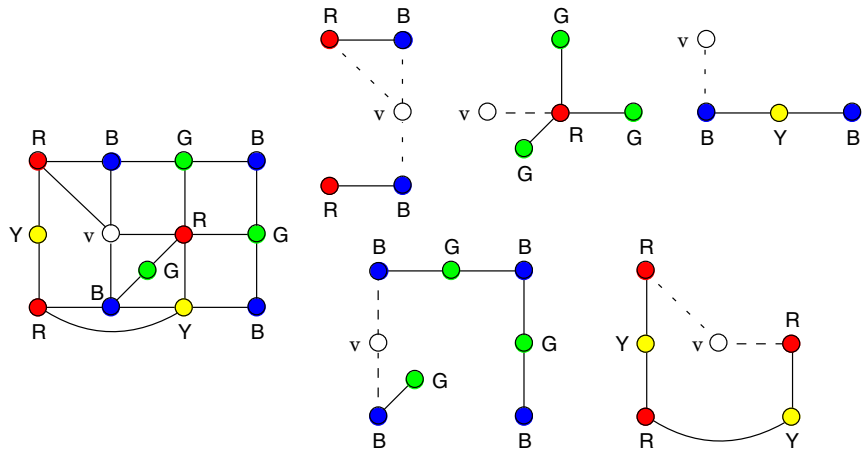

FIG. 3.1. *Left: A partial acyclic coloring of a graph; vertex v is the only vertex that remains to be colored. Every other vertex has been assigned one of the four colors red, blue, green, or yellow; the label on each vertex reflects the color used. Right: All of the nonempty, two-colored induced subgraphs; each subgraph is a forest.*

is empty. The remaining five forests are depicted in the figure. Each of the red-blue and blue-green forests consists of two trees, while each of the other forests consists of a single tree. In the example, all of the two-colored trees are incident on the vertex v.

The task of choosing a valid color for the vertex v can be divided into two natural parts. The first part involves excluding the colors of each of the distance-1 neighbors of v from its set of allowable colors. In our illustration, this results in the exclusion of the colors red and blue from the allowable set of colors for v. The second part involves ensuring that a color chosen for the vertex v does not lead to a two-colored cycle in the graph G. Since the vertex v (and, in general, any vertex in a graph) could be part of many, arbitrarily long cycles, the second part is more difficult than the first, which is confined to the distance-1 neighborhood of v in G.

The key point in our algorithm is the detection of a potential two-colored cycle that involves the vertex v in an efficient way. In particular, the cycle detection is done efficiently by examining two-colored trees incident on v, a task accomplished by visiting the distance-2 (and not any further) neighborhood of v once. Due to the distance-1 coloring requirement in an acyclic coloring, an odd cycle would necessarily use at least three colors. Thus in avoiding two-colored cycles, we will be concerned only with even cycles.

A two-colored cycle that involves the vertex v can arise only if the following two conditions are satisfied:

1. the vertex v is adjacent to , vertices in a two-colored tree, and
2. these adjacent vertices are of the , color.

Note that condition 2 restricts the concern to only even cycles, for if the vertex v is adjacent to two vertices with different colors in a two-colored tree, the corresponding cycle involving v is of odd length and thus uses three colors, posing no concern. For example, in Figure 3.1, though vertex v is adjacent to two vertices in the upper red-blue tree, v will not induce a cycle in that tree since the adjacent vertices have distinct colors.

Now let F_v denote a collection of two-colored trees that are incident on the vertex

v and satisfy the aforementioned two conditions. For each tree $T_v \in F_v$, let c_1 denote the color of the vertices adjacent to the vertex v, and let c_2 be the other color used in the tree T_v. Then, for each tree T_v, we exclude the color c_2 from the allowable set of colors for the vertex v, for otherwise v might be assigned the color c_2, creating a two-colored cycle involving v. In Figure 3.1 this process would lead to the exclusion of the color yellow from the allowable set of colors for the vertex v, for otherwise a two-colored cycle could arise in the red-yellow tree.

When both the first and the second tasks discussed above are completed for the vertex v, we know exactly the colors that cannot be assigned to v, and thus we can choose the smallest allowable color for v.

To complete the overview of the algorithm, we now need to update the collection of two-colored trees to reflect the fact that the vertex v has been colored. The update can be performed in two stages. In the first stage, edges vw that connect the vertex v and an already colored vertex w are grouped into two-colored stars. In the second stage, these stars are merged with existing two-colored trees as needed. A point that should be noted here is that the second stage of the update may cause previously disconnected trees in a two-colored forest to be connected. For example, if the vertex v in Figure 3.1 receives the color green, then the two (currently disconnected) trees in the green-blue forest need to be merged. Just as the task of choosing a color for the vertex v, we will show that the task of updating the collection of two-colored trees after v is assigned a color can be accomplished by visiting the distance-2 neighborhood of v once.

3.2. Detailed description. For an efficient implementation of the algorithm sketched in section 3.1, we use the disjoint-set data structure to maintain the collection of two-colored trees. For a discussion of the disjoint-set data structure, see, e.g., [15]. A set in our context corresponds to a two-colored tree, and an element of a set corresponds to an edge. The disjoint-set data structure supports three operations: MAKESET, FIND, and UNION. Operation MAKESET(e) creates a new set consisting of the element e. Operation FIND(e) returns the representative element of the set to which element e belongs, and operation UNION(e_1, e_2) merges the two sets $S(e_1)$ and $S(e_2)$ to which elements e_1 and e_2 belong.

Further, in our implementation of the sketched algorithm, we use the two arrays color and forbiddenColors for coloring purposes. The vertex-indexed array color is used to store the colors assigned to vertices. In particular, color$[u] = c$ indicates that the vertex u has been assigned the color c, a value that once set remains unchanged during the course of the algorithm. The color-indexed array forbiddenColors is used to mark the colors that are forbidden to a specific vertex. In particular, forbiddenColors$[c] = u$ indicates that the color c is impermissible for the vertex u; otherwise the color c is a candidate color for the vertex u. Unlike the array color, the value stored at a particular index in the array forbiddenColors varies during the course of the algorithm, an issue that will be clear in a moment.

3.2.1. The main routine. The driver routine in our acyclic coloring algorithm is outlined in Algorithm 3.1 and the current section is devoted to its discussion. The subroutines called by Algorithm 3.1 will be presented in section 3.2.2.

Leaving the initialization of various data structures in line 2 aside for a moment, the body of the outermost for-loop of Algorithm 3.1 consists of two parts. The first part (lines 4–10) is concerned with finding a color for the vertex v, the current vertex in the iteration over the vertex set V. The second part (lines 11–16) deals with updating the collection of two-colored trees incident on the vertex v.

ALGORITHM 3.1. Input: a graph G. Effect: finds an acyclic coloring of G.

```
1: procedure AcyclicColoring(G = (V, E))
2:     Initialize data structures
3:     for each v ∈ V do
4:         for each colored w ∈ N1(v) do
5:             forbiddenColors[color[w]] ← v
6:         for each colored w ∈ N1(v) do
7:             for each colored x ∈ N1(w) do
8:                 if forbiddenColors[color[x]] ≠ v then
9:                     preventCycle(v, w, x)
10:        color[v] ← min{i > 0, forbiddenColors[i] ≠ v}
11:        for each colored w ∈ N1(v) do      ▷ grow two-colored stars around the vertex v
12:            growStar(v, w)
13:        for each colored w ∈ N1(v) do
14:            for each colored x ∈ N1(w), x ≠ v do
15:                if color[x] = color[v] then
16:                    mergeTrees(v, w, x)   ▷ merge trees T1 ∋ vw and T2 ∋ wx if T1 ≠ T2
```

Pursuant to the first requirement of acyclic coloring, the for-loop in lines 4–5 marks the colors of the distance-1 neighbors of the vertex v as forbidden colors to v. The subsequent for-loop in lines 6–9 forbids additional colors that can result in two-colored cycles involving the vertex v, to enforce the second requirement of acyclic coloring. Here, a subset of the two-colored trees incident on the vertex v—through edges wx, where w is an already colored vertex adjacent to v and x is an already colored vertex adjacent to w—is examined. The routine preventCycle (to be discussed in section 3.2.2) checks whether the vertex v is connected to the two-colored tree containing the edge wx via two edges. If this turns out to be the case, the routine forbids the color of the vertex x from being a candidate color for the vertex v by updating the global array forbiddenColors. The if-test in line 8 ensures that a two-colored tree incident on the vertex v is investigated only if there is a potential for a two-colored cycle to arise in the same tree; recall that the upper red-blue tree in Figure 3.1 need not be examined while coloring the vertex v since it cannot lead to a two-colored cycle involving v. The if-test also avoids an unnecessary computation: once a color c in a two-colored tree T is forbidden to the vertex v to prevent a potential two-colored cycle C (that involves T and v), then the tree T need not be investigated any further in the determination of a color for the vertex v, for the existence of any other cycle C' (that also involves T and v) would only result in the exclusion of the same color c.

Once all the colors that are not allowed for the vertex v are marked in the array forbiddenColors, the array is scanned sequentially in search of the first index in which a value other than v is stored. This corresponds to the smallest allowable color for the vertex v and is chosen as the color for v (line 10). The array forbiddenColors is initialized at the beginning of the algorithm with some value outside the set V. This array can be used without being reinitialized while coloring another vertex, since in each iteration a unique vertex is colored (i.e., the identity of a vertex serves as a "time-stamp").

The remainder of Algorithm 3.1 is concerned with creating and updating two-colored trees incident on the vertex v. This

task is done in two stages, reflected by the two for-loops in lines 11–12 and lines 13–16. In the first stage (the first for-loop), two-colored trees consisting of edges incident on the vertex v are grown. More precisely, the structures grown are two-colored stars, and the hub of each star is the vertex v. To this end, for every edge vw that connects the vertex v with an already colored vertex w, (1) a new two-colored star consisting only of the edge vw is created, and (2) if there is already a similarly two-colored star S with one or more edges of the form vw' (hence $\mathsf{color}[w] = \mathsf{color}[w']$), then the newly created star (edge vw) is merged with S. Both of these items are achieved by the call to the routine GROWSTAR in line 12; the details of this routine will be discussed in section 3.2.2.

At the end of the for-loop in lines 11–12, every edge vw connecting v and an already colored vertex w has been placed in a star in the right two-colored forest. There may now be a need for another level of merges in a forest, constituting the second stage of the data structure update. Such merges involve stars grown at the current iteration, and trees grown in iterations prior to the coloring of v. The piece of code in lines 13–16 determines whether there is a need for such merges, and if so, updates the disjoint-set data structure appropriately. In particular, for each colored vertex w adjacent to v, and each colored vertex x adjacent to w with $\mathsf{color}[x] = \mathsf{color}[v]$, the routine MERGETREES is called in line 16 with the arguments v, w, and x. The routine checks whether the tree that contains the edge vw is the same as the tree that contains the edge wx; if the two trees turn out to be different, then they are merged.

To illustrate the points discussed in the previous two paragraphs without revealing the details of the routines GROWSTAR and MERGETREES, consider the example in Figure 3.1. Suppose the vertex v has been assigned the color green. At the end of the for-loop in lines 11–12, two stars are grown around the vertex v. These are the star (path) B–v–B and the star R–v–R, where B and R stand for a blue and a red neighbor of the vertex v, respectively. In the subsequent for-loop, the star R–v–R is merged with the only tree in the current red-green forest. In the same loop, the star B–v–B is first merged with one of the two disconnected trees in the current blue-green forest, and then the resulting tree is further merged with the other tree. As a result, the blue-green forest now becomes a single tree (to be more precise, a path on eight vertices).

3.2.2. The subroutines. Let us now take an inside look at the routines PREVENTCYCLE, GROWSTAR, and MERGETREES. In the discussion below, we will refer to the actions performed on the vertex v in lines 4–16 of Algorithm 3.1 as v.

The routine PREVENTCYCLE (see Algorithm 3.2) takes three vertices v, w, and x as input parameters: v is the vertex currently being processed, w is a colored vertex adjacent to v, and x is a colored vertex adjacent to w. The primary task of the routine is to forbid the color of the vertex x from being chosen as a color for the vertex v, if it could lead to a two-colored cycle in the input graph. This would happen if the vertex v is incident on the two-colored tree to which the edge wx belongs via two edges. An auxiliary task of the routine is to update an associated data structure.

To determine whether or not a vertex v is connected to a two-colored tree via two edges in an efficient way, we each two-colored tree containing an edge wx incident on the vertex v. While doing so, if a tree is marked twice, then we know that the vertex v is incident on the tree via two edges. We use an edge-indexed array called $\mathsf{firstVisitToTree}$ for this purpose. An index of the array $\mathsf{firstVisitToTree}$ is the

ALGORITHM 3.2. Input: the vertex v being colored, a colored neighbor w of v, and a colored neighbor x of w. Associated data structure: firstVisitToTree$[e] = (p, q)$ indicates that firstVisitToTree$[e]$ was last set when processing vertex p and at that time the tree represented by the edge e was *first* visited through the edge pq. Effect: (1) updates the array firstVisitToTree, or (2) excludes color$[x]$ from the allowable set of colors for v if it could otherwise lead to a two-colored cycle involving v.

```
1: procedure PREVENTCYCLE(v, w, x)
2:     e ← FIND(wx)        ▷ edge wx belongs to the 2-colored tree T represented by edge e
3:     (p, q) ← firstVisitToTree[e]
4:     if p ≠ v then                ▷ T is being visited from vertex v for the first time
5:         firstVisitToTree[e] ← (v, w)
6:     else if q ≠ w then           ▷ T is connected to vertex v via at least two edges
7:         forbiddenColors[color[x]] ← v
```

ID of the representative edge of a two-colored tree. A vertex pair (p, q) is stored at index e of the array to indicate that firstVisitToTree$[e]$ was last set when processing the vertex p, and at that time the two-colored tree whose representative edge is e was [illegible] visited through the edge pq. In firstVisitToTree and other similar data structures used elsewhere in this paper, the word [illegible] refers to the context in which the neighborhood of the vertex p being processed is visited. The array firstVisitToTree is globally declared and initialized at the beginning of Algorithm 3.1 with a pair of values not corresponding to any vertex. As in the array forbiddenColors, the "marker" vertex p in the array firstVisitToTree serves as a time-stamp. Hence, this array need not be reinitialized while processing another vertex.

The routine PREVENTCYCLE begins by getting the two-colored tree T to which the edge wx belongs. Let e be the representative edge of T returned by the FIND operation. In line 3, the vertex pair (p, q) stored at index e of the array firstVisitToTree is retrieved. If $p \neq v$, then the implication is that the tree T is being visited from the vertex v for the first time. To reflect this, the vertex pair (v, w) is stored at firstVisitToTree$[e]$. If, on the other hand, $p = v$, then there are two possibilities, corresponding to the cases $q = w$ and $q \neq w$. The case $q = w$ implies that the tree T has previously been visited from the vertex v, but the visit was through the same edge vw. This occurs if the vertex w is adjacent to at least two vertices (besides the vertex v) in the tree T, and does not cause the color of the vertex x to be a forbidden color for the vertex v. The second case, $q \neq w$, implies that the tree T has previously been visited from the vertex v through an edge other than vw. In this case, setting color$[v]$ = color$[x]$ would create a two-colored cycle, and therefore color$[x]$ is forbidden from being a color for the vertex v.

[illegible] As discussed earlier, the first stage of updating the collection of two-colored trees incident on the vertex v being processed involves growing two-colored stars around the vertex v. This is achieved by the calls GROWSTAR(v, w) made in line 12 of Algorithm 3.1 for each colored vertex w adjacent to the vertex v.

To achieve the desired merging of edges into two-colored stars in an efficient manner, we maintain a color-indexed array, firstNeighbor, in which we store pairs of vertices. The array is used to determine whether or not a particular color is encountered for the first time while visiting the distance-1 neighborhood of a particular vertex. Specifically, we let firstNeighbor$[c] = (p, q)$ to indicate that while processing the vertex p, the vertex q was the first-to-be-encountered neighbor having the color

ALGORITHM 3.3. Input: the vertex v being processed and a colored neighbor w of v. Associated data structure: $\mathsf{firstNeighbor}[c] = (p, q)$ indicates that the vertex q is the first-to-be-encountered neighbor of the vertex p having the color c. Effect: (1) creates a new two-colored tree T_{vw} consisting only of the edge vw, and (2) either updates the array firstNeighbor or merges the tree T_{vw} with a two-colored star being grown around v.

```
1: procedure GROWSTAR(v, w)
2:     MAKESET(vw)                          ▷ create a new tree T_vw consisting only of edge vw
3:     (p, q) ← firstNeighbor[color[w]]
4:     if p ≠ v then          ▷ a neighbor of v with color color[w] encountered for 1st time
5:         firstNeighbor[color[w]] ← (v, w)
6:     else                              ▷ merge T_vw with a two-colored star being grown around v
7:         e1 ← FIND(vw); e2 ← FIND(pq)
8:         UNION(e1, e2)
```

ALGORITHM 3.4. Input: the vertex v being processed, a colored neighbor w of v, and a neighbor x of w having the same color as v. Effect: merges the tree containing the edge vw with the tree containing the edge wx, if the two trees are distinct.

```
1: procedure MERGETREES(v, w, x)
2:     e1 ← FIND(vw); e2 ← FIND(wx)
3:     if e1 ≠ e2 then
4:         UNION(e1, e2)
```

c. As the array firstVisitToTree discussed earlier, the array firstNeighbor is globally declared and initialized in Algorithm 3.1, and can be used without reinitialization while iterating through the vertex set V.

The routine GROWSTAR (Algorithm 3.3) begins by creating a two-colored tree (star) consisting only of the edge vw, a task accomplished by the call MAKESET(vw). The routine then retrieves the vertex pair (p, q) stored at the index $\mathsf{color}[w]$ of the array firstNeighbor. If $p \neq v$, then the implication is that the color used by the vertex w is encountered for the first time while visiting the vertices adjacent to the vertex v. To signify this, the vertex pair (v, w) is stored at the index $\mathsf{color}[w]$ of the array firstNeighbor. Otherwise, if $p = v$, then the implication is that a vertex q (distinct from w) that has the same color as the vertex w has already been encountered while visiting the neighbors of the vertex v. In this case, the edge vw—the two-colored star just created—is merged with the (growing) two-colored star containing the edge pq.

The second stage of the update involves merging the two-colored stars just grown with existing two-colored trees as needed. This is achieved by the calls to MERGETREES made in line 16 of Algorithm 3.1. Each such call is made with the arguments v, w, and x, where v is the vertex currently being processed, w is a colored vertex adjacent to v, and x is a colored vertex adjacent to w with $\mathsf{color}[x] = \mathsf{color}[v]$. The routine MERGETREES (Algorithm 3.4) first queries for the representative edges e_1 and e_2 of the two-colored trees T_1 and T_2 to which the edges vw and wx, respectively, belong. If $e_1 \neq e_2$, then it means that the two trees T_1 and T_2 are distinct, and therefore they need to be merged. Otherwise no further action needs to be taken.

3.3. Complexity. The outermost for-loop in Algorithm 3.1 consists of $n = |V|$ iterations. In each iteration, the two visits to the distance-2 neighborhood of the vertex v being processed, i.e., the for-loops in lines 6–9 and 13–16, constitute the dominant part of the computation. On each visited neighbor, a constant number

of operations is performed. Thus, disregarding the time spent on updating and querying the disjoint-set data structure, the time complexity of the algorithm is $O(\sum_{v \in V} d_2(v)) = O(n\bar{d}_2)$.

The disjoint-set data structure in our context contains at most m distinct elements, the edges of G. Thus there can be at most $m-1$ UNION calls and m MAKESET calls. Further, there can be at most $m' = 2n \cdot \bar{d}_1 + 3n \cdot \bar{d}_2 \leq 5n \cdot \bar{d}_2$ FIND calls, since the routine FIND is called once in the procedure PREVENTCYCLE and twice in each of the procedures GROWSTAR and MERGETREES. In our implementation of the disjoint-set data structure, we use [illegible] for the FIND operation and [illegible] for the UNION operation to achieve the best runtime performance. When these techniques are used, the average time spent on each such operation is at most $\alpha(m', m)$, where α is the inverse of Ackermann's function [15]. Thus the overall time complexity of our acyclic coloring algorithm is $O(n\bar{d}_2 \cdot \alpha(m', m))$. Clearly, the space complexity of the algorithm is $O(m)$.

4. The new star coloring algorithm.

4.1. Overview. Our star coloring algorithm is based on the same idea as the acyclic coloring algorithm presented in section 3. Instead of managing a collection of edge-disjoint two-colored trees, we now manage a collection of edge-disjoint two-colored stars. Recall that the [illegible] of a star is the vertex at which the edges meet. The key difference between the acyclic and the star coloring algorithms stems from the following fact: An edge may be added to a tree at any vertex of the tree, whereas the only way an edge may be added to a star is at the hub of the star. A consequence of this fact is that the addition of an edge to a star does not lead to the merging of two existing stars. Hence, a simpler data structure than disjoint-set suffices. We use a one-dimensional array that maps edges to stars, and a similar array that maps stars to hubs, to manage the collection of two-colored stars.

Figure 4.1 provides an overview of the algorithm. Part (a) of the figure shows the input graph G where every vertex except v has been colored consistent with the requirements of a star coloring. The illustration uses the six colors red, blue, green, yellow, pink, and black (Bk). Parts (b) through (f) show a subset of the two-colored stars with nonempty edge sets that are incident on v.

Since a star coloring is also a distance-1 coloring, the set of colors used by vertices adjacent to the vertex v is impermissible for v. Enforcing this requirement is straightforward. In addition, any color that leads to a two-colored path involving v and three other vertices is impermissible for v. There are exactly two cases that need to be considered to identify and forbid a color of this type.

- [illegible] 1. If vertex v has two adjacent vertices w and x of the [illegible] color, then the color of every vertex adjacent to w, and the color of every vertex adjacent to x should be excluded from the allowable set of colors for v.
- [illegible] 2. If vertex v has exactly one adjacent vertex w of color c, and w belongs to a star S containing at least two edges but is not the hub of S, then the color used by the hub of S should be disallowed from being a candidate color for v.

Parts (b) and (c) of Figure 4.1 illustrate Case 1; neither the color blue nor the color green can be assigned to the vertex v. Similarly, parts (d) and (e) illustrate Case 2; the colors green and pink used by the hubs of the respective stars are not allowed for the vertex v. As illustrated in part (f), if the star S in a situation similar to Case 2 has only one edge, then it does not impose any additional color restriction on the vertex v. We say that the hub of such a star consisting of a single edge is [illegible].

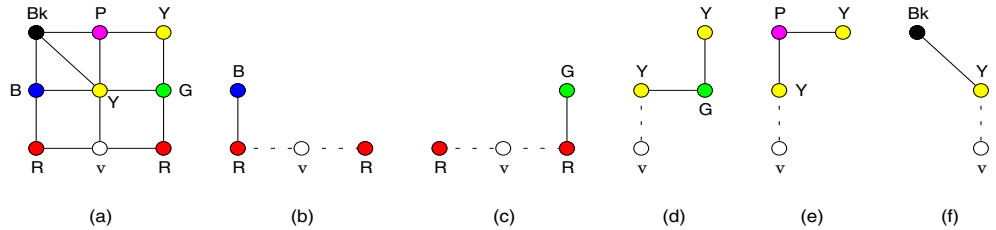

FIG. 4.1. (a): *A partial star coloring of a graph; vertex v is the only vertex that remains to be colored.* (b)–(f): *A subset of the two-colored induced subgraphs incident on the vertex v; each subgraph is a collection of stars. The illustration uses the six colors red, blue, green, yellow, pink, and black (Bk).*

The hub is defined later if and when another edge joins the star, in which case the point of incidence between the two edges becomes the hub.

Like the acyclic coloring algorithm, our star coloring algorithm iterates over the vertex set V in some order, coloring one vertex at a time. In the step where a vertex v is colored, the color used by each adjacent vertex and every additional color identified by checking Cases 1 and 2 is excluded from the allowable set of colors for v. Then the smallest permissible color is chosen and assigned to the vertex v. After this, every edge vw connecting the vertex v and an already colored vertex w is placed in the appropriate two-colored star. In particular, if an edge vw is incident on some (color$[v]$,color$[w]$)-star S, then the edge vw joins the star S; otherwise, the edge vw forms a star on its own with an undefined hub. Unlike the acyclic coloring algorithm in which the addition of an edge to a two-colored tree may result in the merging of two existing trees, the addition of an edge to a two-colored star does not lead to the merging of two existing stars.

4.2. Detailed description. To maintain the collection of two-colored stars effectively, we use an edge-indexed array, star, that maps edges to stars, and a star-indexed array, hub, that maps stars to hubs. In particular, star$[vw] = s$ signifies that the edge vw belongs to the star s, and hub$[s] = u$ indicates that the hub of the star s is the vertex u. We work with the two separate arrays, star and hub, in order to distinguish between stars consisting of at least two edges (having defined hubs) and stars consisting of a single edge (having undefined hubs). In addition, we make use of the two arrays color and forbiddenColors in just the same way as in section 3.

Our star coloring algorithm is outlined in Algorithm 4.1. The body of the outer for-loop has two parts. The first part, the piece of code in lines 4–16, is concerned with finding a color for the vertex v, the current vertex in the iteration over the vertex set. The second part deals with updating the collection of two-colored stars incident on the vertex v, and is achieved by the call to UPDATESTARS in line 17. Hereafter, we shall refer to the actions performed on the vertex v in lines 4–17 as [illegible] v.

[illegible] The for-loop in lines 4–15 of Algorithm 4.1 determines the colors that cannot be assigned to the vertex v. In line 5, the color used by a vertex w adjacent to the vertex v is marked as a forbidden color for v, since a star coloring is also a distance-1 coloring. To determine and forbid additional colors that lead to two-colored paths involving v and three other vertices, Cases 1 and 2 outlined earlier need to be checked. To detect Case 1 in an efficient manner, we use the color-indexed array firstNeighbor which stores pairs of vertices: firstNeighbor$[c] = (p, q)$ indicates

ALGORITHM 4.1. Input: a graph G. Associated data structure: $\mathsf{firstNeighbor}[c] = (p, q)$ indicates that the vertex q is the first-to-be-encountered neighbor of the vertex p having the color c; $\mathsf{treated}[y] = x$ indicates that the color of every vertex adjacent to the vertex y is already forbidden from being a color for the vertex x. Effect: finds a star coloring of G.

```
1:  procedure StarColoring(G = (V, E))
2:      Initialize data structures
3:      for each v ∈ V do
4:          for each colored w ∈ N1(v) do
5:              forbiddenColors[color[w]] ← v
6:              (p, q) ← firstNeighbor[color[w]]
7:              if p = v then                                   ▷ Case 1
8:                  if treated[q] ≠ v then
9:                      TREAT(v, q)                  ▷ forbid colors of neighbors of q
10:                     TREAT(v, w)                  ▷ forbid colors of neighbors of w
11:             else
12:                 firstNeighbor[color[w]] ← (v, w)
13:                 for each colored x ∈ N1(w), x ≠ v do
14:                     if x = hub[star[wx]] then                ▷ potential Case 2
15:                         forbiddenColors[color[x]] ← v
16:         color[v] ← min{i > 0, forbiddenColors[i] ≠ v}
17:         updateStars(v)
```

ALGORITHM 4.2. Input: the vertex v being processed and a colored vertex w adjacent to v. Effect: excludes the colors used by vertices adjacent to w from the allowable set of colors for v, and updates the array treated to reflect this.

```
1:  procedure TREAT(v, w)
2:      for each colored x ∈ N1(w) do
3:          forbiddenColors[color[x]] ← v
4:      treated[w] ← v
```

that when processing the vertex p, the vertex q was the first neighbor with color c to be encountered. (An array with the same name was used for a similar purpose in the acyclic coloring algorithm discussed in the previous section.) In line 6, a lookup in the table firstNeighbor at the index $\mathsf{color}[w]$ is made and the stored value is retrieved in the vertex pair (p, q).

If $p = v$, then the implication is that a vertex which is distinct from, but has the same color as, the vertex w—the vertex q—has already been encountered while visiting the distance-1 neighbors of the vertex v. This clearly corresponds to Case 1. The appropriate action to be taken is to forbid the colors used by the vertices adjacent to q and the colors used by the vertices adjacent to w. The calls to the subroutine TREAT (outlined in Algorithm 4.2) in lines 9 and 10 do precisely that. In connection with this case, we use the vertex-indexed array treated in which we store vertices; $\mathsf{treated}[y] = x$ indicates that the color of every vertex adjacent to the vertex y has already been marked as a forbidden color for the vertex x. The if-test in line 8 is performed to avoid unnecessary computation in the case where $\mathsf{color}[w]$ is encountered for a third time or later.

If, on the other hand, $p \neq v$, then the implication is that the color used by the vertex w is encountered for the first time while visiting the distance-1 neighborhood

ALGORITHM 4.3. Input: the vertex v being processed. Effect: adds edges vw, where w is colored, to appropriate two-colored stars.

```
1: procedure updateStars(v)
2:     for each colored w ∈ N1(v) do
3:         if ∃x ∈ N1(w) where x ≠ v and color[x] = color[v] then      ▷ vw, wx ∈ E
4:             hub[star[wx]] ← w                                      ▷ this may already be true
5:             star[vw] ← star[wx]
6:         else
7:             (p, q) ← firstNeighbor[color[w]]
8:             if (p = v) and (q ≠ w) then                            ▷ vw, vq ∈ E ∧ color[w] = color[q]
9:                 hub[star[vq]] ← v                                  ▷ this may already be true
10:                star[vw] ← star[vq]
11:            else                                                   ▷ vw forms a new star
12:                starID ← starID + 1
13:                star[vw] ← starID
```

of the vertex v. This information is recorded in line 12 for future use. The piece of code in the subsequent for-loop takes a proactive measure in anticipation of Case 2. In particular, the loop iterates over edges wx that belong to existing two-colored stars. For each star to which an edge wx belongs, if the star has a defined hub and the hub is the vertex x, then the color of x is forbidden from being a color for the vertex v (line 14). Potentially, this corresponds to Case 2; if the vertex v is later found to have a neighbor vertex $w' \neq w$ with the same color as w, then it reduces to Case 1. Recall that only stars containing at least two edges have defined hubs; for a star with only one edge the test in line 14 will fail and therefore will not impose an additional color restriction (cf. Figure 4.1 (f)).

At the end of the for-loop in lines 4–15, every color that is not allowed to be a color for the vertex v is marked in the array forbiddenColors. The smallest permissible color is then chosen and assigned to the vertex v in line 16.

As with the arrays used in section 3, in the arrays firstNeighbor and treated the marker vertex p serves as a time-stamp; it is used to determine whether the information stored in the data structures concerns the vertex currently being processed. These data structures are initialized at the beginning of Algorithm 4.1, and no reinitialization is required in the course of iteration over the vertex set.

The call to the routine updateStars (outlined in Algorithm 4.3) is made at line 17 to update the collection of two-colored stars to reflect the fact that the vertex v has been assigned a color. In Algorithm 4.3, each edge vw that joins the vertex v with an already colored vertex w is placed in an existing or a new two-colored star depending on the colors of the vertex v and its distance-2 neighbors. The edge vw joins an existing star if (1) there exists an edge wx and color$[v]$ = color$[x]$, or (2) there exists an edge vq and color$[w]$ = color$[q]$. The first case can be detected by looking at the distance-1 neighborhood of the vertex w; for the second case, the information in the array firstNeighbor, which is set in Algorithm 4.1, is utilized. Clearly, in the first case the vertex w becomes the hub of the resulting star (if it was not already so), and in the second case the vertex v becomes the hub (again, if it was not already so). If neither of cases (1) or (2) turns out to be positive, then the edge vw forms a new two-colored star on its own with an undefined hub. Notice that the definitions of the hubs in lines 4 and 9 are necessary, since the edges wx and

vq could be single-edge-stars with undefined hubs at the time the routine is called.

4.3. Complexity. Given a graph on n vertices and m edges, the computational work involved in each of the n iterations of the outer for-loop in Algorithm 4.1 is proportional to $d_2(v)$. Hence the overall time complexity of our star coloring algorithm is $O(n\bar{d}_2)$. Its space complexity is clearly $O(m)$.

5. Coloring models in Hessian computation. We have experimentally compared the new algorithms for acyclic and star coloring presented in this paper with previously suggested algorithms for these and other related coloring problems that occur in the computation of sparse Hessians. In this section, we briefly review such coloring models and discuss their interrelationships. In section 6, we will discuss corresponding greedy algorithms.

One step in an efficient computation of a sparse derivative matrix A using automatic differentiation (or finite differencing) is to use structural information about A to partition its n columns into p disjoint groups, with p as small as possible. This step can be posed as a problem of seeking an $n \times p$ matrix S whose (j,k) entry is defined as follows:

$$s_{jk} = \begin{cases} 1 & \text{if column } a_j \text{ belongs to group } k, \\ 0 & \text{otherwise.} \end{cases} \tag{5.1}$$

Since the matrix S specified by (5.1) corresponds to a partitioning of the columns of the matrix A, in every row r of the matrix S there exists exactly one column c in which the entry s_{rc} is equal to one. In the automatic differentiation literature, there exist approaches that use a seed matrix where a row-sum is not necessarily equal to one [19]. Such approaches are not partitioning-based as they allow a column of A to be placed in more than one group. In this paper we consider only seed matrices that define a partition.

The specific criteria used to define a seed matrix S depend on whether the entries of the matrix A are to be recovered from the compressed representation AS (by conceptually solving a diagonal system of equations) or via $A'S$ (by conceptually solving a set of triangular systems of equations). The criteria also depend on whether the derivative matrix A is Jacobian (nonsymmetric) or Hessian (symmetric). In general, a seed matrix S suitable for a direct method requires a larger p compared to one suitable for a substitution method. On the other hand, the recovery of entries via substitution incurs an additional, but affordable, computational cost.

5.1. Models for direct methods. Curtis, Powell, and Reid [16] observed that a structurally orthogonal partition of a Jacobian matrix A—a partition of the columns of A in which no two columns in a group share a nonzero at the same row index—gives a seed matrix S where the entries of A can be directly recovered from the compressed representation AS. Obviously, a structurally orthogonal partition could also be used in the context of computing a Hessian if one were to settle for not exploiting the available symmetry. Following this approach, McCormick [27] showed that a structurally orthogonal partition of a Hessian is equivalent to a star 2 of its adjacency graph.

The adjacency graph $G(A)$ of a Hessian A has a vertex for each column, and an edge joins column vertices a_i and a_j whenever the entry a_{ij}, $i \neq j$, is nonzero; the diagonal entries in A are assumed to be nonzero, and they are not explicitly represented by edges in $G(A)$. In the distance-2 coloring model for structurally orthogonal

partition as well as in other models discussed in this section, a set of vertices having the same color corresponds to a set of columns that belong to the same group in the induced partition. In other words, each column of the seed matrix corresponds to a color class.

Powell and Toint [28] were the first to suggest symmetry-exploiting partitions for both direct and substitution-based methods for computing Hessians. When translated to a coloring ϕ of the adjacency graph, the partition Powell and Toint suggested for a direct Hessian computation requires that (1) ϕ be a distance-1 coloring, and (2) in every path on three vertices $P_3 = v, w, x$, the vertices v and x receive different colors whenever $\phi(w) > \min\{\phi(v), \phi(x)\}$. We call a coloring that satisfies these two requirements a [illegible]. Notice that, unlike in a distance-2 coloring, in a restricted star coloring, the terminal vertices v and x in a path v, w, x are allowed to have the same color as long as the color of the middle vertex w is lower in value.

Coleman and Moré [13] generalized the approach of Powell and Toint and showed that a symmetrically orthogonal partition of a Hessian suffices for a direct recovery of its entries from a compressed representation. A partition of the columns of a Hessian matrix A is [illegible] if for every nonzero element a_{ij}, either (1) the group containing column a_j has no other column with a nonzero in row i, or (2) the group containing column a_i has no other column with a nonzero in row j. Coleman and Moré established that a symmetrically orthogonal partition of a Hessian is equivalent to a [illegible] of its adjacency graph.

5.2. Models for substitution methods. Based on the work of Powell and Toint [28], Coleman and Moré [13] found a coloring model for a partitioning of a Hessian matrix A that defines a seed matrix S such that the nonzero entries of A can be recovered from the compressed representation AS via a (restricted) substitution method. The recovery of the entries of the matrix A from the matrix AS requires solving a triangular system of equations, a system that heavily relies on the structure of A. Appropriately, Coleman and Moré called the model triangular coloring. Given a graph $G = (V, E)$, a mapping $\phi : V \to \{1, 2, \ldots, p\}$ is a [illegible] if there exists a vertex ordering π such that (1) ϕ is a distance-1 coloring, and (2) in every $P_3 = v, w, x$, the vertices v and x receive different colors whenever $\pi(w) > \max\{\pi(v), \pi(x)\}$. A vertex ordering π that is well suited for triangular coloring exists and will be discussed in section 5.3.

Triangular coloring exploits symmetry only to a limited extent. This limitation was later addressed by Coleman and Cai [9], who introduced a generalized notion of substitutable partitions for which they provided a simple graph-theoretic characterization. In particular, they proved that an [illegible] of the adjacency graph of a Hessian induces a substitutable partition of its columns. They also showed that, using an acyclic coloring, the nonzeros of the Hessian can be recovered from its compressed representation by considering [illegible] (groups of columns) at a time. The key difference between a partition induced by a triangular coloring and a partition induced by an acyclic coloring is the following. Triangular coloring induces a partition that defines one large, coupled triangular system of equations, whereas acyclic coloring induces a partition that defines several smaller, decoupled triangular systems of equations, each defined by a pair of color classes.

Table 5.1 summarizes the coloring models in Hessian computation discussed thus far. In the table, the coloring variants are listed in an increasing order of restrictiveness, with the least constrained variant at the top and the most constrained variant at the bottom. In the following subsection, we present results that make the interre-

TABLE 5.1

*Overview of coloring models used in Hessian computation. In each case, the adjacency graph $G = (V, E)$ of the underlying Hessian is used, and the mapping $\phi : V \rightarrow \{1, 2, \ldots, p\}$ defines a coloring. In addition to the input graph G, the definition of triangular coloring assumes the existence of a vertex ordering π. *Powell and Toint [28] stated these models using their equivalent matrix partitioning counterparts; the translations into graph colorings are due to Coleman and Moré [13].*

Name	Coloring conditions	Computation modeled
Acyclic	1. $vw \in E \Rightarrow \phi(v) \neq \phi(w)$	substitution
	2. every cycle uses ≥ 3 colors	Coleman and Cai [9]
Triangular	1. $vw \in E \Rightarrow \phi(v) \neq \phi(w)$	restricted substitution
	2. in every $P_3 = v, w, x$:	Powell and Toint [28]*
	$\pi(w) > \max\{\pi(v), \pi(x)\} \Rightarrow \phi(v) \neq \phi(x)$	Coleman and Moré [13]
Star	1. $vw \in E \Rightarrow \phi(v) \neq \phi(w)$	direct
	2. every P_4 uses ≥ 3 colors	Coleman and Moré [13]
Restricted	1. $vw \in E \Rightarrow \phi(v) \neq \phi(w)$	restricted direct
star	2. in every $P_3 = v, w, x$:	Powell and Toint [28]*
	$\phi(w) > \min\{\phi(v), \phi(x)\} \Rightarrow \phi(v) \neq \phi(x)$	Coleman and Moré [13]
Distance-2	1. $vw \in E \Rightarrow \phi(v) \neq \phi(w)$	direct (ignores symm.)
	2. $P_3 = v, w, x \in G \Rightarrow \phi(v) \neq \phi(x)$	McCormick [27]

lationships among these variations more precise.

5.3. Interrelationships. Recall that we denote specialized chromatic numbers by χ with an appropriate subscript. For example, $\chi_a(G)$ denotes the acyclic chromatic number of G. In Lemma 5.1, we relate the acyclic, star, and restricted star chromatic numbers of a graph. Similarly, in Lemma 5.2 we show the relationship among the acyclic, triangular, and restricted star chromatic numbers of a graph.

LEMMA 5.1. [illegible] G $\chi_a(G) \leq \chi_s(G) \leq \chi_{rs}(G)$

[illegible]. Let ϕ be a star coloring of a graph G. Observe that a cycle in G on three vertices uses three colors, since ϕ is also a distance-1 coloring of G. Moreover, a cycle on at least four vertices contains a P_4 and therefore uses at least three colors. Hence ϕ is an acyclic coloring of G, and the first inequality follows.

For the second inequality, we show that if ϕ is a restricted star coloring of G, then ϕ is also a star coloring of G. Let $P = v, w, x$ be a P_3 in G. Since ϕ is a restricted star coloring, $\phi(v) \neq \phi(w)$ and $\phi(w) \neq \phi(x)$. Furthermore, either $\phi(v) \neq \phi(x)$ or $\phi(v) = \phi(x) > \phi(w)$ holds. In the former case, in any P_4 in G that contains the path P, adjacent vertices have different colors, and the P_4 uses at least three colors, satisfying the requirements of a star coloring. To see that the latter case also fulfills the requirements of a star coloring, consider any $P_4 = v, w, x, y$ in G that extends the path P in one of its ends. (A similar argument would hold for a path u, v, w, x that extends P in the other end.) Again, since ϕ is a restricted star coloring, $\phi(y) \neq \phi(x)$. Moreover, the relationship $\phi(y) \neq \phi(w)$ holds, since otherwise the relationship $\phi(x) > \phi(w) = \phi(y)$ in the path w, x, y would hold, contradicting the fact that ϕ is a restricted star coloring. Hence, in the path v, w, x, y, adjacent vertices have different colors, and at least three colors are used. Therefore ϕ is a star coloring of G. □

LEMMA 5.2. [illegible] G $\chi_a(G) \leq \chi_t(G) \leq \chi_{rs}(G)$

[illegible]. Suppose ϕ is a triangular coloring of a graph G for a vertex ordering π. We show that ϕ is then an acyclic coloring of G. Consider any cycle C in G, and let

z be the vertex in C with the [illegible] index in the ordering π. Since C is a cycle, there exists a path $P = u, z, v$ in C for some vertices u and v. Further, since ϕ is a triangular coloring, $\phi(u) \neq \phi(v)$ by choice of z. Since ϕ is also a distance-1 coloring, both of these colors are distinct from $\phi(z)$. Hence, the cycle C uses at least three colors, and therefore ϕ is an acyclic coloring of G.

We now show the second inequality. Suppose ϕ is a restricted star coloring of a graph G on n vertices. Consider a vertex ordering $\pi = v_1, v_2, \ldots, v_n$ such that the sequence $\{\phi(v_i)\}$ is nondecreasing. In other words, the ordering π is such that vertices in the same color class are listed consecutively, and the color classes in turn are listed in increasing order. Consider any path $P = v, w, x$ on three vertices in G. Since ϕ is a restricted star coloring, a pair of adjacent vertices in the path P have different colors. There are two possibilities regarding the terminal vertices v and x in P: either $\phi(v) \neq \phi(x)$ or $\phi(v) = \phi(x) > \phi(w)$. In the former case, the path P trivially satisfies the requirements of a triangular coloring. Given the ordering π as defined in the proof, the path P in the latter case also satisfies the requirements of a triangular coloring, since $\pi(w) < \min\{\pi(v), \pi(x)\}$. Hence, the coloring ϕ and the ordering π together define a triangular coloring of G. □

The inequalities in Lemmas 5.1 and 5.2 can easily be extended in both ends. Clearly, $\chi_1(G) \leq \chi_a(G)$ holds, since an acyclic coloring is also a distance-1 coloring. In a distance-2 colored graph, the vertices in every P_3 use three distinct colors. Hence, a distance-2 coloring is also a restricted star coloring, implying the relationship $\chi_{rs}(G) \leq \chi_2(G)$. We summarize these relationships in Theorem 5.3.

THEOREM 5.3. [illegible] G [illegible]

$$\chi_1(G) \leq \chi_a(G) \leq \chi_t(G) \leq \chi_{rs}(G) \leq \chi_2(G) = \chi_1(G^2),$$

$$\chi_1(G) \leq \chi_a(G) \leq \chi_s(G) \leq \chi_{rs}(G) \leq \chi_2(G) = \chi_1(G^2).$$

The relationship between $\chi_t(G)$ and $\chi_s(G)$ is not clear. There are examples of star colorings where there does not exist a vertex ordering that makes a given star coloring a triangular coloring. An example would be a star coloring of a graph in which every vertex is the hub of a two-colored P_3. Conversely, there are examples of colorings that are triangular but not star. A simple example is a two-colored P_4 in which adjacent vertices have different colors. Thus the class $C_s(G)$ of star colorings of a graph G and the class $C_t(G)$ of triangular colorings of G are such that neither $C_t(G) \subseteq C_s(G)$ nor $C_s(G) \subseteq C_t(G)$ holds. However, the relationship $\chi_t(G) \leq \chi_s(G)$ might still hold. We leave settling the latter issue as an open problem.

The last equality in Theorem 5.3 follows from the fact that a distance-2 coloring of G is equivalent to a distance-1 coloring of the square graph G^2. In fact, most of the coloring variants on a graph $G = (V, E)$ listed in Table 5.1 can also be viewed as a distance-1 coloring of an appropriately defined "filled" graph $G' = (V, E \cup F)$.

When the original graph G is the adjacency graph of a Hessian, the filled graphs in the distance-2 and triangular coloring cases have interesting interpretations. The filled graph in the distance-2 coloring case (the square graph G^2) is the [illegible] of the underlying Hessian A. The column intersection graph of a matrix has a vertex for each column, and an edge between a pair of columns exists whenever the two columns share nonzero entries at some common row index. In the case of a triangular coloring for a given vertex ordering π, the filled graph G', in which each fill edge f is generated as per the specification

$$\forall P_3 = v, w, x \text{ in } G : \pi(w) > \max\{\pi(v), \pi(x)\} \Rightarrow f = vx, \tag{5.2}$$

is the column intersection graph of the [illegible] L_π of the permuted matrix P^TAP, where P is a permutation matrix defined by the ordering π. These relationships were observed and used by Coleman and Moré [13], who showed that a [illegible] (SL) vertex ordering as a choice for π is particularly well suited for triangular coloring.

Given a graph on n vertices, a vertex ordering $v_1, v_2, \ldots, v_n$ is an SL ordering if for all $1 \leq i \leq n$, the vertex v_i is a vertex with the [illegible] degree in the graph induced by vertices $v_1, \ldots, v_i$. Here is why an SL ordering is well suited for triangular coloring: Among the $n!$ possible orderings (permutations) π, an SL ordering minimizes the maximum number of nonzeros in a row in L_π. Thus, an SL ordering provides a lower bound on the triangular chromatic number, a result proven by Coleman and Moré [13].

Orthogonal to its role in triangular coloring, an SL ordering is also known to be one of the effective ordering techniques for reducing the number of colors used by a greedy coloring algorithm. The number of colors used by a greedy distance-1 coloring algorithm that employs an SL ordering to color a graph G is an important graph parameter. The parameter is known as the [illegible] $col(G)$ of G and is closely related to several other graph notions, including degeneracy, maximal core, and arboricity [17]. In our context, since an SL ordering can be computed in linear time in the number of edges, the coloring number is an easy-to-compute, nontrivial upperbound for the distance-1 chromatic number. As mentioned in the previous paragraph, the coloring number is also a lower bound for the triangular chromatic number. Theorem 5.4 summarizes these relationships.

THEOREM 5.4. [illegible] G $\chi_1(G) \leq col(G) \leq \chi_t(G)$

6. Previous algorithms. Coleman and Cai [9] accurately modeled the partitioning problem that occurs in substitution-based Hessian computation as the acyclic coloring problem. However, the algorithm they suggested is an algorithm for triangular coloring. Specifically, they suggested that a filled graph G' be explicitly constructed as described by the expression (5.2), using an SL vertex ordering for π, and then that G' be distance-1 colored. The same approach has been taken earlier by Coleman and Moré [13] and in the related software papers [10, 11]. However, as we will soon show in the current section, it is possible to achieve a triangular coloring of G by using a greedy algorithm that works directly on G. This section also discusses previously known greedy algorithms for star and distance-k coloring. All of the algorithms discussed in this section are included in our experiments.

In a previous work [17], we suggested an algorithm for star coloring that enforces the coloring requirements in a straightforward manner—by checking paths on four vertices. We refer to this algorithm here as NAIVESTARCOLORING (,). Powell and Toint [28] suggested an algorithm of the same spirit, formulated in the language of matrices, for the restricted star coloring problem. We will call this algorithm here RESTRICTEDSTARCOLORING (,).

Algorithms , and , are both greedy. In determining a set of forbidden colors for a vertex v, algorithm , consults the colors used by the distance-3 neighbors of v, whereas algorithm , checks the colors used by only the distance-2 neighbors. Once the set of forbidden colors is obtained, both algorithms choose the smallest color not included in the set as the color for the vertex v. In a similar fashion, one can design greedy algorithms for distance-1 coloring, distance-2 coloring, and triangular coloring for a given ordering π. We refer to such algorithms as DISTANCE1COLORING (1), DISTANCE2COLORING (2), and TRIANGULARCOLORING (π). The suffix in the

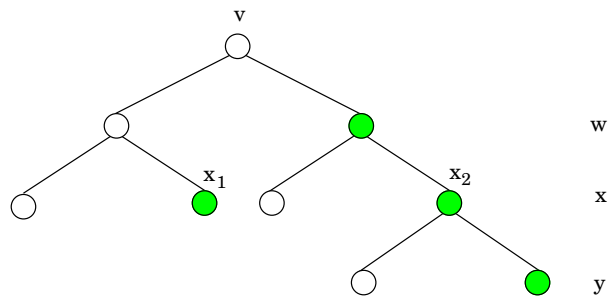

FIG. 6.1. *Visualizing a step in greedy coloring algorithms; v is the vertex currently being colored. Table 6.1 shows how the set of forbidden colors for v is determined in various cases.*

TABLE 6.1
Conditions under which a particular color is forbidden to v (see in conjunction with Figure 6.1). Here ϕ is a coloring, and π is a vertex ordering.

	w	x_1	x_2
$D1$	always		
$D2$	always	always	always
NS	always	always	only if $\phi(w) = \phi(y)$
RS	always	always	only if $\phi(w) > \phi(x)$
T-π	always	only if $\pi(w) > \max\{\pi(v), \pi(x)\}$	only if $\pi(w) > \max\{\pi(v), \pi(x)\}$

notation π signifies that a specific vertex ordering π is used by the algorithm.

We use Figure 6.1 in conjunction with Table 6.1 to illustrate how the set of forbidden colors for a vertex is determined by the various greedy algorithms in coloring a graph G on n vertices and m edges. The tree depicted in Figure 6.1 is not a subgraph of G, but rather a visualization of the classification of the neighborhood $N_k(v)$ of the vertex v being colored at the current step of the particular algorithm. The classification is based on whether a vertex in the set $N_k(v)$ is already colored or not. In the figure, the vertices of the graph G that are one, two, and three edges away from the vertex v are represented by the tree nodes at the levels w, x, and y, respectively. A shaded signifies already colored and an unshaded node signifies vertices not yet colored. The shaded nodes at level x are further labeled x_1 and x_2, to distinguish between the cases where a vertex w in a path v, w, x is already colored or not.

Table 6.1 summarizes the conditions under which a color used by a vertex in the scenario described in Figure 6.1 is forbidden to the vertex v for the various algorithms. Cases x_1 and x_2 correspond to distinct decisions in algorithms and . These two cases are indistinguishable in algorithms 2 and π and are irrelevant to algorithm 1. As column x_1 in Table 6.1 shows, in algorithms and , the color of vertex x in a path v, w, x where vertex w is not yet colored is immediately forbidden to the vertex v. This ensures that any extension v, w, x, y of the path v, w, x would end up using at least three colors, as desired, since in the step in which the vertex w is colored, the distance-1 coloring requirement guarantees that the vertex w gets a color distinct from the colors of vertices v and x. In contrast, in the case where vertex w is already colored (see column x_2 in the table), determining whether the color of vertex x should be forbidden to vertex v or not requires a further check. In algorithm , the check involves vertices w and y (note that y is three edges away from v). In

algorithm , the check involves vertices w and x. In each of the algorithms listed in Table 6.1, once the set of forbidden colors to the vertex v is determined, the smallest color not included in the set is chosen as the color for v.

The illustration should make it clear that the complexity of algorithm 1 is $O(n\bar{d}_1) = O(m)$, the complexity of each of algorithms 2, , , and π is $O(n\bar{d}_2)$, and the complexity of algorithm is $O(n\bar{d}_3)$.

7. Experimental results.

7.1. Setup. To demonstrate the performance of our new algorithms, we ran experiments on 29 graphs obtained from molecular dynamics applications [8, 30]. The test graphs were chosen because of their large size and irregular structure. The left half of Table 7.1 shows the number of vertices $|V|$, the number of edges $|E|$, the maximum degree Δ, and the average degree $\bar{d}_1$ in each test graph. The right half of the table shows certain computed values that we will discuss shortly. All of the algorithms used in our experiments were implemented in C++. The hardware used was a Linux machine equipped with Dual AMD Opteron Processor 244, 1.8 GHz, 2 GB memory, and 1 GB cache. The operating system was RHEL 3 and the compiler was GCC.

7.2. Algorithms compared and orderings used. In addition to the new acyclic and star coloring algorithms presented in sections 3 and 4—abbreviated henceforth as and —in this section, we report experimental results on the algorithms 1, 2, , , , and discussed in section 6. The suffix in the triangular coloring algorithm indicates that we used an SL vertex ordering as the ordering π to define the coloring, since this is optimal as discussed in the paragraph leading to Theorem 5.4. Algorithms 1 and 2 are included in our experiments primarily to serve as references against which quantities could be normalized.

The order in which vertices are colored in a greedy algorithm determines the number of colors used by the algorithm. As mentioned earlier, an SL ordering (more precisely, a distance-1 SL ordering) is one of the effective known ordering techniques for distance-1 coloring. As a natural extension, for algorithms such as 2, where the distance-2 neighborhood of a vertex is explored at each step, a distance-2 SL ordering (D2SL) can be defined and used to attain a similar benefit. Specifically, we define a D2SL ordering using the quantity $|N_2(v)|$ associated with each vertex v in a graph. Using linear-time sorting techniques, a D2SL ordering can be computed within the same order of time as a subsequent distance-2 coloring, i.e., in $O(n\bar{d}_2)$ time.

In our experiments (results to be presented in section 7.3), for each of the algorithms 1, 2, , , , , and , we used one of the orderings among natural (the order in which vertices appear in the input graph), D1SL, and D2SL orderings that led to the fewest colors on a majority of the test cases. For algorithm 1, this ordering was D1SL; for algorithms 2, , , , and , this was the D2SL ordering; and for algorithm , it was the natural ordering. We have also experimented with appropriately extended variants of and orderings [17]. The results we obtained using these are in general similar to or worse than the ones obtained using the SL orderings and hence are not reported here.

In a greedy algorithm for triangular coloring, vertex orderings arise in two different contexts: (1) as part of the definition of the coloring, and (2) as part of the coloring algorithm. In terms of an ordering (π) that defines the coloring, a D1SL ordering in the input graph G is optimal. The same ordering can be used while coloring the vertices sequentially, and that is what we did in algorithm . To (potentially) reduce the number of colors used, one could also use a D1SL coloring order based on

TABLE 7.1

*Test graph statistics (left half) and computed values (right half). Column col(G) lists the coloring number of each graph, and columns D1 and D2 list the runtime in seconds of algorithms D1 and D2. The last column shows the ratio of number of edges in a derived graph G′ to that in an original G; the graph G′ is obtained from the graph G as per the specification in expression (5.2) where π is an SL vertex ordering in G. The symbol *** indicates that a graph G′, being too large to fit in memory, could not be computed.*

vertex degrees in the filled graph G' derived from G according to the specification given by expression (5.2).

In a method they call , Coleman and Moré [13] construct such a filled graph G' using a D1SL ordering in G as π, and then distance-1 color the graph G' using a D1SL ordering in G' to obtain a triangular coloring of the original graph G. We have implemented this method as well; here we call it to reflect that it is a triangular coloring of the original graph. The last column of Table 7.1 shows the ratio of the number of edges in the derived graph G' to that in the original graph G. For 6 out of the 29 test graphs we used (the last six in Table 7.1), the graph G' could not be computed as it was too big to fit in the size of the available memory. The asterisks used in the corresponding entries in the last column of Table 7.1 indicate this.

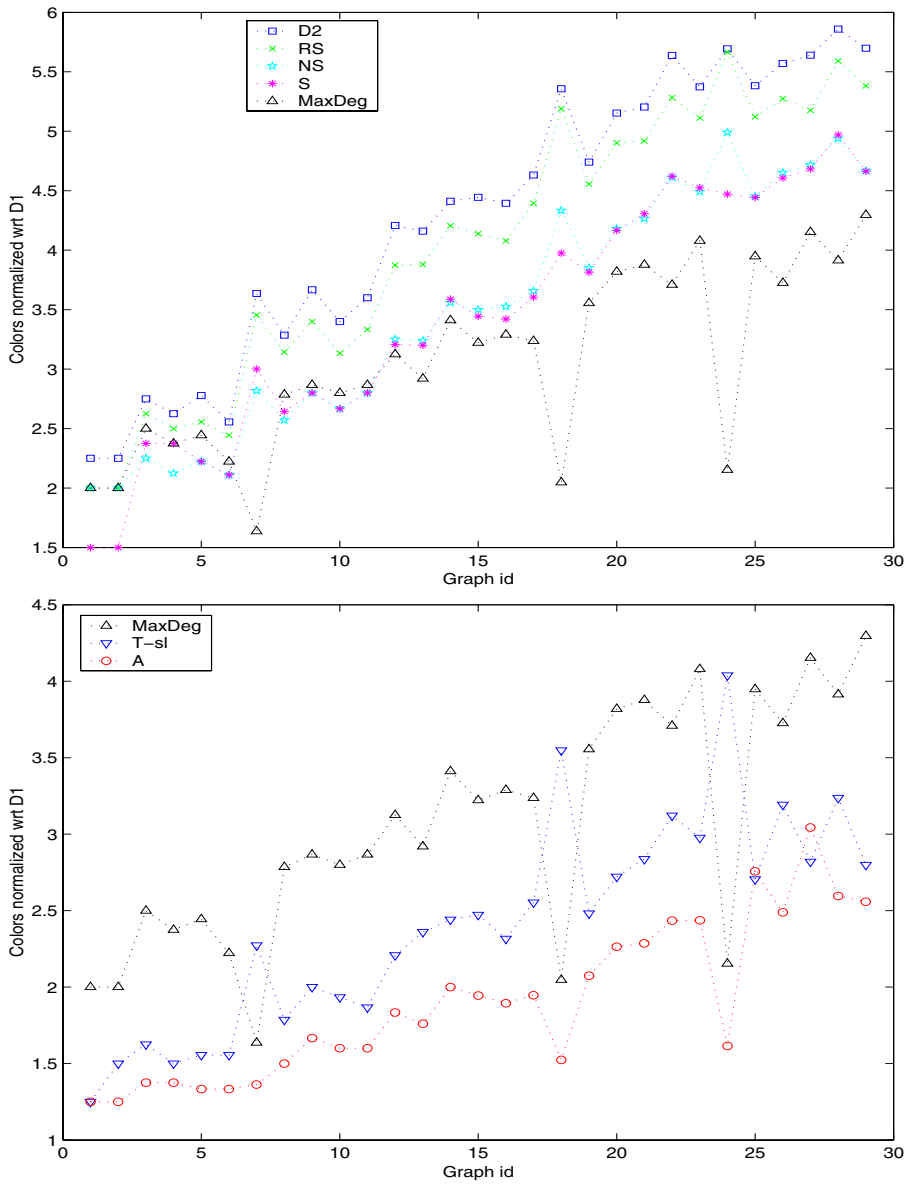

FIG. 7.1. *Normalized number of colors used by various greedy algorithms. In algorithm T-sl, a D1SL ordering of the vertices in G is used to both define and perform the coloring. Algorithm D1 uses a D1SL ordering for coloring. In algorithms D2, RS, NS, and S, vertices are colored in a D2SL ordering in G; in algorithm A, vertices are colored in the natural order they appear in G. The plots are normalized relative to the number of colors used by algorithm D1, i.e., the coloring numbers of the graphs. These numbers are listed in Table* 7.1.

7.3. Results. We will now describe a few figures and tables that show our experimental results. The figures will be discussed collectively in section 7.4.

The upper graph of Figure 7.1 displays plots of the number of colors used by algorithms $D2$, , , , , and , normalized relative to the number of colors used by algorithm $D1$, the coloring numbers of the graphs. The bottom graph shows analogous

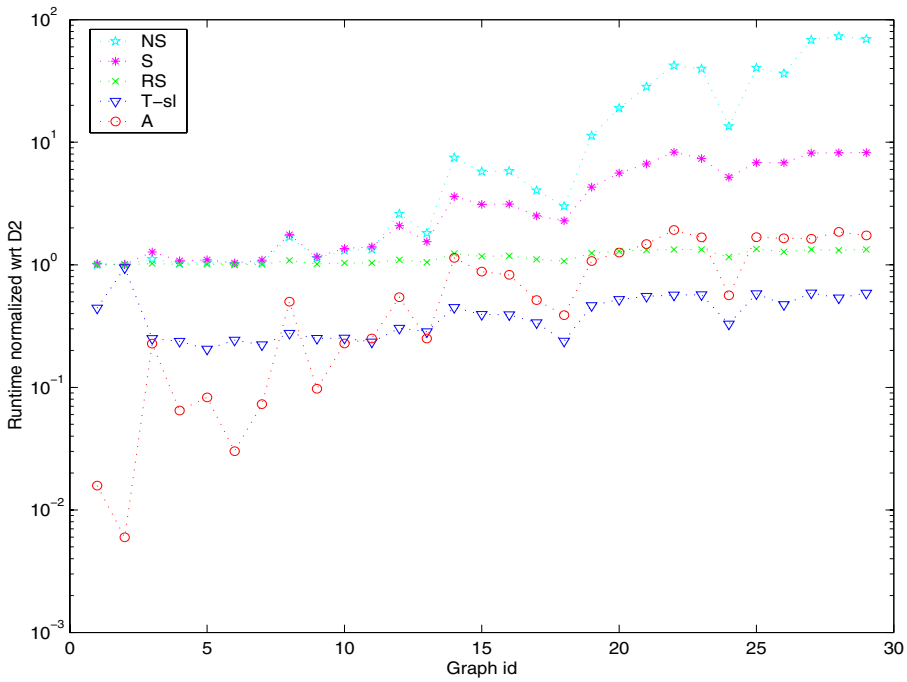

FIG. 7.2. *Execution time comparison. Vertices are colored in the orderings specified in Figure* 7.1. *The plots, in semilog scale, are normalized relative to the runtime of Algorithm D*2*, values listed under column D*2 *of Table* 7.1.

plots for algorithms and . The common curve in the two parts is the plot of the maximum degrees in the graphs, again normalized relative to the coloring numbers. The coloring numbers of the graphs, sorted in increasing order, are listed under column $col(G)$ in Table 7.1.

Figure 7.2 shows semilog plots of the runtimes of algorithms , , , , , , , and normalized relative to the runtime of algorithm $D2$, the values of which are listed in the column labeled $D2$ in Table 7.1. Column $D1$ in the same table shows the runtimes of algorithm $D1$. In these two columns as well as in execution times reported elsewhere in this section, the reported times include time spent on ordering, when applicable, but not time for reading test graph files from disk.

Figure 7.3 shows a comparison between algorithms and . The results reported in the figure concern the test graphs on which the latter could be run successfully, the first 23 of the 29 test graphs used.

Table 7.2 shows a summary of the results for the various algorithms; the upper row gives data summed over all test cases, and the lower row shows data summed over test cases on which algorithm was successfully run.

To show the reduction in number of colors that algorithms $D1$, $D2$, , , , and were able to get through their use of D1SL or D2SL orderings, we ran these algorithms with natural vertex ordering as well. Table 7.3 summarizes the results obtained. In addition to absolute figures, the table shows the savings in number of colors (as a percentage) and the relative time cost in comparison with a coloring that uses an appropriate SL ordering (data listed in Table 7.2).

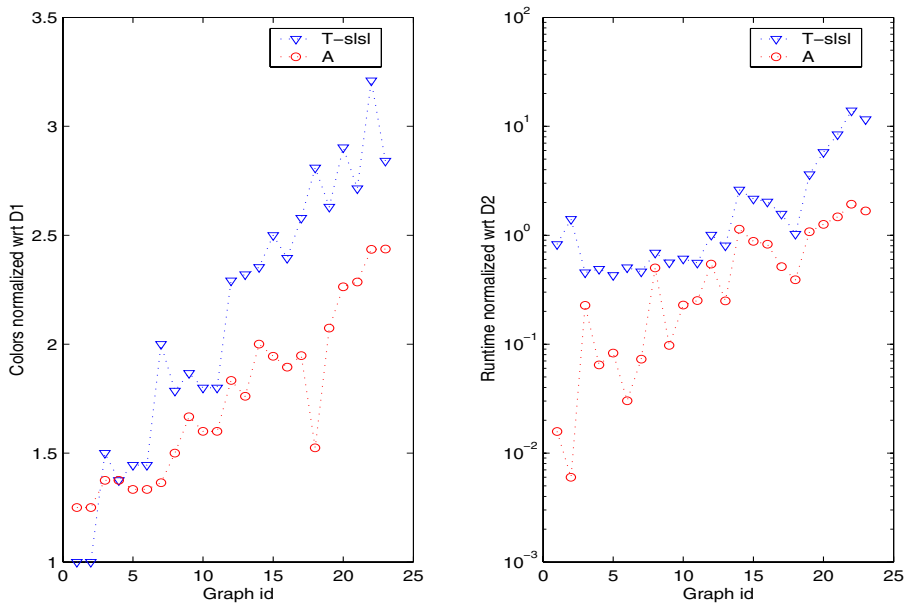

FIG. 7.3. *Comparison of normalized number of colors (left) and normalized runtimes (right) between algorithms A and T-slsl. The number of colors are normalized relative to that used by algorithm D1, and the runtimes are normalized relative to that of algorithm D2.*

TABLE 7.2

Top row: Total number of colors and runtime summed over all test graphs. Bottom row: Totals over test graphs on which algorithm T-slsl could be run successfully (i.e., graphs without asterisks in Table 7.1). The order in which vertices are colored is as specified in Figure 7.1.

	D2	*RS*	*NS*	*S*	*T-sl*	*T-slsl*	*A*	*D1*
Colors	9,240	8,749	7,636	7,558	5,065		4,110	1,757
Runtime (min)	28.2	34.4	930	162	12.4		32.5	0.04
Colors	3,951	3,734	3,207	3,191	2,189	2,149	1,709	823
Runtime (min)	9.6	11	128	34.5	3.8	41.8	7	0.02

TABLE 7.3

Top row: Total number of colors and runtime summed over all test graphs, when vertices are colored in their natural order in an input graph (Nat). Bottom row: Color savings and relative time cost in comparison with coloring using an appropriate SL ordering (numbers listed in Table 7.2).

	D2	*RS*	*NS*	*S*	*D1*
Colors	11,429	11,275	9,973	9,470	2,384
Runtime (min)	4.32	9.60	679	126	0.03
SL vs. Nat colors saved (%)	19	22	23	20	26
SL to Nat time ratio	6.5	3.6	1.4	1.3	1.3

7.4. Discussion. A reader can make several observations from Figures 7.1–7.3 and Tables 7.1–7.3. We highlight the following few points to supplement such observations in the context of Hessian computation.

- The advantage of exploiting sparsity using coloring cannot be overstated. If all of the Hessians (with the nonzero structures of the test graphs) were to be computed without exploiting sparsity or symmetry, the time required would be proportional to 1.5 million steps (the sum total of the vertices in Table 7.1).

If the strongest coloring model considered here—acyclic coloring—were to be used, all of these Hessians could be evaluated in about four thousand time steps (the number of colors, or compressed columns, in the column at the top half of Table 7.2). Moreover, in general, coloring constitutes only a small fraction (typically far less than 10%) of the overall computation time involved in obtaining numerical values in a derivative matrix [18, 19]. Note that the total coloring time required to acyclic-color of the test graphs, totaling over 88 million edges, is about 30 minutes.

- As the upper part of Figure 7.1 shows, among the three algorithms , , , and for direct Hessian computation where symmetry is exploited, algorithm uses the fewest colors. Algorithm uses slightly fewer colors than the symmetry-ignoring algorithm $D2$. The difference in the number of colors used by algorithms and is significant, whereas that between and is marginal.
- The maximum degree Δ in a graph is a lower bound for the distance-2 chromatic number; this fact is clearly reflected in Figure 7.1. One can also see that for a majority of our test graphs, algorithms , , and used more than Δ colors. However, there were cases, noticeably among the relatively sparse graphs of ID less than 10, where these algorithms used fewer than Δ colors.
- The more important advantage of algorithm over algorithm is its lower time complexity, a fact supported by the nearly sixfold reduction in observed running times, as Figure 7.2 and Table 7.2 attest. Algorithms and have the same theoretical complexity, and, in practice, algorithm is observed to be slower by a small factor.
- As the bottom graph of Figure 7.1 illustrates, the coloring algorithms for Hessian computation via substitution—algorithms and —use many fewer colors than the coloring algorithms for direct Hessian computation—algorithms , , , and . On the test graphs we used, our acyclic coloring algorithm consistently used fewer colors than the triangular coloring algorithm . Moreover, in of our test cases, algorithm used fewer than Δ colors, while for algorithm the statement holds true for a majority, but not all, of the test cases. Interestingly, the exceptions in the latter case are regular graphs (graphs 7, 18, and 24 in Table 7.1). Note that the reference against which the number of colors in Figures 7.1 and 7.3 are normalized is a lower bound for triangular coloring.
- As Figure 7.3 shows, our acyclic coloring algorithm also used fewer colors than algorithm . On the subset of the test cases on which algorithm could be run successfully, algorithm used 20% fewer colors than . In terms of runtime, algorithms and are comparable, whereas is much slower.
- In comparison with a natural ordering, an appropriate SL vertex (re)ordering for coloring reduced the number of colors used by algorithms $D1$, $D2$, , , and by roughly 20% (see Table 7.3). In contrast, the numbers listed in Table 7.2 show that the savings in number of colors rendered by algorithm compared to algorithm is only 1.8%, obtained at a cost of runtime that is larger by a factor of 11. The acyclic coloring algorithm did not benefit from an SL ordering.
- Disregarding time for computing vertex orderings, the practical runtimes of algorithms $D2$, , , , , and are expected to be similar since the time

complexity of each of these algorithms is nearly $O(n\bar{d}_2)$. In the observed runtimes in Figure 7.2, the plots for and for the most part lie below the line $y = 1$, which corresponds to the runtime of algorithm $D2$. This is mainly due to the variation in the orderings used: for algorithm $D2$ (as well as and) a D2SL ordering in G was used, for algorithm a D1SL in G was used, and for algorithm the natural ordering was used.

- Even when vertices were colored in natural order, the acyclic coloring algorithm was observed to be slightly faster than the star coloring algorithm . On the other hand, time complexity analyses of the two algorithms show to be slightly slower than . The most likely reason for being slower than in practice is that there are many more two-colored stars to be maintained in algorithm than there are two-colored trees to be maintained in algorithm , which in turn makes the former use more memory operations, and therefore more runtime.

8. Conclusion. We have presented new algorithms for star and acyclic coloring, models for efficient Hessian computation via direct and substitution methods. We experimentally demonstrated that the new algorithms outperform previously known methods. Our acyclic coloring algorithm runs faster, uses fewer colors, and requires less memory and storage space than the triangular coloring method of Coleman and Moré [13]. In comparison with our implementation of the triangular coloring algorithm—which unlike the original algorithm of Coleman and Moré works directly on an input graph G—the new acyclic coloring algorithm produces fewer colors at comparable runtime. Our new star coloring algorithm runs faster and uses fewer colors than our previous algorithm for the same problem [17]. In comparison with the previously known restricted star coloring algorithm, our new star coloring algorithm yields a significant reduction in number of colors at the cost of a slight increase in observed runtime.

Using an acyclic coloring, Coleman and Cai [9] showed that the nonzero entries of a Hessian can be evaluated via substitution by considering a pair of color classes at a time. Our new acyclic coloring algorithm has such structures (two-colored trees) in place, which facilitates an efficient implementation of a procedure for recovering a Hessian from a compressed representation. We have implemented such a routine. In collaboration with Andrea Walther at the Technical University of Dresden, our coloring and Hessian recovery codes have been incorporated in the automatic differentiation tool ADOL-C [20]. A paper that demonstrates the efficacy of the new star and acyclic coloring algorithms in the overall process of computing the Hessian of a given function using automatic differentiation has been submitted for publication elsewhere [18]. The results we obtained in our experiments using ADOL-C show that the new coloring algorithms render huge savings in overall runtime, and that Hessian computation via substitution using acyclic coloring is faster than a direct computation using star coloring, considering the overall process.

The underlying idea in the new algorithms, the exploitation of two-colored structures, can be extended to models in efficient computation of Jacobians [14]. We are currently working in this direction.

We conclude this paper by pointing out a few other directions for further work.

- As discussed in the paragraph immediately after Theorem 5.3, the relationship between the triangular and star chromatic numbers of a graph is not clear. Prove or disprove the claim $\chi_t(G) \leq \chi_s(G)$.

- The size of a largest clique in a graph is an obvious lower bound for the distance-1 chromatic number $\chi_1(G)$. Analogously, $\Delta + 1$ is a lower bound for the distance-2 chromatic number $\chi_2(G)$, since there exists a clique of that size in the square graph G^2. Finding nontrivial lower bounds for acyclic and star chromatic numbers is a worthwhile issue.
- Appropriate extensions of orderings such as [illegible] and [illegible] helped reduce the number of colors used by our star coloring algorithm, but not that of the acyclic coloring algorithm. It would be interesting to find orderings suitable for the latter algorithm.

Acknowledgments. We thank Jorge Moré for suggesting a comparison between acyclic and triangular coloring and for his helpful comments on a draft of this paper. We also thank Paul Hovland for making the test graphs available to us. Our sincere thanks go to the anonymous referees for their valuable comments on the content and presentation of this paper and for bringing related works in the literature to our attention.

OVERLAPPING SCHWARZ METHODS FOR FEKETE AND GAUSS–LOBATTO SPECTRAL ELEMENTS*

L. F. PAVARINO†, E. ZAMPIERI†, R. PASQUETTI‡, AND F. RAPETTI‡

Abstract. The classical overlapping Schwarz algorithm is here extended to the triangular/tetrahedral spectral element (TSEM) discretization of elliptic problems. This discretization, based on Fekete nodes, is a generalization to nontensorial elements of the tensorial Gauss–Lobatto–Legendre quadrilateral spectral elements (QSEM). The overlapping Schwarz preconditioners are based on partitioning the domain of the problem into overlapping subdomains, solving local problems on these subdomains, and solving an additional coarse problem associated with either the subdomain mesh or the spectral element mesh. The overlap size is generous, i.e., one element wide, in the TSEM case, while it is minimal or variable in the QSEM case. The results of several numerical experiments show that the convergence rate of the proposed preconditioning algorithm is independent of the number of subdomains N and the spectral degree p in case of generous overlap; otherwise it depends inversely on the overlap size. The proposed preconditioners are also robust with respect to arbitrary jumps of the coefficients of the elliptic operator across subdomains.

Key words. spectral elements, Fekete nodes, Gauss–Lobatto–Legendre nodes, overlapping Schwarz preconditioners

1. Introduction.

Spectral and *hp*-finite elements are among the most successful high-order methods for the numerical approximation of partial differential equations. These methods can achieve spectral convergence of the discrete solution by allowing both *h*-refinement of the elements mesh and *p*-refinement of the polynomial degree in each element. While hierarchical *hp*-finite elements employ modal basis functions (see [29, 27]), spectral element methods on quadrilateral elements (QSEM) employ a nodal approach based on the tensorial product of one-dimensional Gauss–Lobatto–Legendre (GLL) points (see, e.g., [1, 17, 7]). The need to extend spectral element formulations to complex geometries and unstructured meshes has recently led to the construction and study of triangular/tetrahedral spectral elements (TSEM); see, e.g., [15, 16, 31, 33, 12, 13] and the previous studies of interpolation nodes on triangles [5, 6, 14] and on *p*-version substructuring methods [2]. In this paper, we consider TSEM based on the Fekete nodes [3, 30], as in our previous works [19, 20, 21].

The discrete systems produced by these high-order methods are much more ill-conditioned than in the standard finite element or finite difference cases, and therefore the design and analysis of efficient iterative solvers is still a challenging research topic. In this paper, we construct and study overlapping Schwarz methods for Fekete–Gauss TSEM, obtaining solvers that are scalable (independent of the number of subdomains N) and optimal (independent of the spectral degree p). This last property holds because we employ generous overlap (at least one element wide) between subdomains. In the QSEM case it is possible to construct Schwarz preconditioners with minimal

overlap by extending each subdomain with a few rows of GLL nodes of the neighboring elements [4, 10, 11, 18], but the design of a similar technique in the TSEM case is still an open problem, since Fekete points are not distributed as a tensor product. The good convergence properties of our solver are retained also for heterogeneous problems with discontinuous coefficients across subdomain boundaries. Preliminary results with only one element per subdomain and constant coefficients have been reported in the conference paper [21]. A different approach involving preconditioners based on nonoverlapping methods of Neumann–Neumann type for TSEM has been recently studied in [22].

In the rest of the paper, we introduce the model elliptic problem and its QSEM and TSEM discretizations (section 2), the overlapping Schwarz preconditioners in additive and multiplicative form (section 3), and the results of several numerical experiments with the additive Schwarz preconditioners for TSEM and QSEM for homogeneous and heterogeneous problems (section 4).

2. The model problem and SEM formulation. Let $\Omega \in \mathbb{R}^d,\ d = 2, 3$, be a bounded Lipschitz domain with piecewise smooth boundary $\partial\Omega$. For simplicity, we consider a model elliptic problem in the plane ($d = 2$), with homogeneous Dirichlet boundary data, but the numerical methods and results presented in this paper can be applied equally well in three dimensions and to more general elliptic problems:

$$-\mathrm{div}(\alpha\,\mathbf{grad}\,u) + \beta u = f \quad \text{in } \Omega, \qquad u = 0 \quad \text{on } \partial\Omega, \tag{2.1}$$

where $\alpha,\ \beta > 0$ are piecewise constant in Ω and f is a given function in $L^2(\Omega)$. We denote by $L^2(\Omega)$ the space of square integrable measurable functions in Ω, and by $H^1(\Omega)$ the space of functions in $L^2(\Omega)$ whose gradient is in $[L^2(\Omega)]^2$. Then let V be the Sobolev space

$$V \equiv H^1_0(\Omega) = \{v \in H^1(\Omega) : v = 0 \text{ on } \partial\Omega\}.$$

The weak formulation of (2.1) reads (see, e.g., [26]): Find $u \in V$ such that

$$a(u, v) := \int_\Omega (\alpha \mathbf{grad} u \cdot \mathbf{grad} v + \beta\, u\, v)\, \mathrm{d}\mathbf{x} = (f, v) := \int_\Omega f\, v\, \mathrm{d}\mathbf{x} \quad \forall v \in V. \tag{2.2}$$

The variational problem (2.2) is discretized by the standard conforming spectral element method, either quadrilateral-based (QSEM) or triangle-based (TSEM). The method can be viewed as a nodal version of the *hp*-finite element method, which uses GLL points of the quadrilateral for the QSEM and the Fekete points of the triangle for the TSEM, and employs a discrete space consisting of continuous piecewise polynomials of degree p within each quadrilateral or triangular spectral element; see [1, 7, 17] for a general introduction and an analysis of the method. For the QSEM, let Q_{ref} be the reference square $(-1, 1)^2$ and let $\mathbb{Q}_p(Q_{\mathrm{ref}})$ be the set of polynomials on Q_{ref} of degree $\le p$ in each variable. Then, for the TSEM, let $T_{\mathrm{ref}} = \{(r, s) :\ -1 \le r, s,\ r + s \le 0\}$ be the reference triangle and let $\mathbb{P}_p(T_{\mathrm{ref}})$ be the set of polynomials on T_{ref} of total degree $\le p$. We assume that the original domain Ω is decomposed into K quadrilateral or triangular spectral elements T_k,

$$\overline{\Omega} = \bigcup_{k=1}^{K} \overline{T}_k.$$

This is a conforming finite element partition; in particular, the intersection between two distinct elements T_k is either the empty set or a common vertex or a common side.

We denote by h the maximum diameter of the elements T_k and by τ_h the associated finite element mesh. Each element T_k is the image of the reference square $Q_{\rm ref}$ or triangle $T_{\rm ref}$ by means of a suitable mapping $g_k,\ k = 1, \ldots, K$, i.e., $T_k = g_k(Q_{\rm ref})$ or $T_k = g_k(T_{\rm ref})$.

Finally, the space V is discretized by continuous piecewise polynomials of degree $\leq p$ in each variable for QSEM,

$$V_{K,p}^Q = \{v \in V : v|_{\Omega_k} \circ g_k \in \mathbb{Q}_p(Q_{\rm ref}),\ k = 1, \ldots, K\},$$

or of total degree $\leq p$ for TSEM,

$$V_{K,p}^T = \{v \in V : v|_{\Omega_k} \circ g_k \in \mathbb{P}_p(T_{\rm ref}),\ k = 1, \ldots, K\}.$$

The spectral element approximation of the variational elliptic problem (2.2) is obtained by replacing the L^2-inner product and the bilinear form defined in (2.2) with their approximations based either on GLL points for QSEM or on Gauss points for the Fekete–Gauss TSEM.

2.1. The GLL QSEM. We consider conforming QSEM based on GLL quadrature points, which also allows the construction of a tensor-product basis for $V_{K,p}^Q$. We denote by $\{\xi_j\}_{j=0}^p$ the set of GLL points of $[-1, 1]$ that are the $(p + 1)$ zeros of the polynomial

$$(1 - \zeta^2)\frac{\partial L_p(\zeta)}{\partial \zeta},$$

where L_p is the pth Legendre polynomial in $[-1, 1]$. Then we denote by σ_j the quadrature weight associated with ξ_j. Let $l_j(x)$ be the Lagrange interpolating polynomial of degree $\leq p$ which vanishes at all the GLL nodes except ξ_j, where it equals 1. The Lagrangian nodal basis functions on the reference square $Q_{\rm ref}$ are defined by building tensor products

$$l_j(x)l_\ell(y), \quad 0 \leq j, \ell \leq p.$$

Each function $u \in \mathbb{Q}_p(Q_{\rm ref})$ is expanded in this nodal GLL basis through its values at GLL nodes $u(\xi_j, \xi_\ell),\ 0 \leq j, \ell \leq p$, as

$$u(x, y) = \sum_{j=0}^{p}\sum_{\ell=0}^{p} u(\xi_j, \xi_\ell)l_j(x)l_\ell(y).$$

Then, on $Q_{\rm ref}$, the discrete L^2-inner product is

$$(u, v)_{Q_{\rm ref},p} = \sum_{j=0}^{p}\sum_{\ell=0}^{p} u(\xi_j, \xi_\ell)v(\xi_j, \xi_\ell)\sigma_j\sigma_\ell,$$

and in general on Ω,

$$(u, v)_{K,p}^Q = \sum_{k=1}^{K}\sum_{j,\ell=0}^{p} (u \circ g_k)(\xi_j, \xi_\ell)(v \circ g_k)(\xi_j, \xi_\ell)|J_k^Q|\sigma_j\sigma_\ell, \tag{2.3}$$

where $|J_k^Q|$ is the Jacobian of the mapping g_k. We then obtain the discrete variational problem: Find $u \in V_{K,p}^Q$ such that

$$a_{K,p}^Q(u, v) = (f, v)_{K,p}^Q \quad \forall v \in V_{K,p}^Q, \tag{2.4}$$

where $a^Q_{K,p}(\cdot,\cdot)$ is obtained by substituting each integral in (2.2) with the GLL quadrature rule (2.3).

The discrete problem (2.4) can be written equivalently in matrix form as a linear system $A_Q\mathbf{u} = \mathbf{b}$, where A_Q is here the assembled QSEM matrix, $\mathbf{b}$ is the load vector accounting for the contribution of f, and $\mathbf{u}$ is the vector of the unknown nodal values of the function u at the GLL nodes.

2.2. The Fekete–Gauss TSEM. For TSEM it is no longer possible to define spectral elements by tensor product as for QSEM. With $n = (p+1)(p+2)/2$, let $\{\psi_j\}_{j=1}^n$ be a polynomial basis of $\mathbb{P}_p(T_{\rm ref})$ for the usual $L^2(T_{\rm ref})$-inner product, e.g., the Koornwinder–Dubiner orthogonal basis [9]. The Fekete points on $T_{\rm ref}$ are defined as the points $\{\hat{\mathbf{x}}_i\}_{i=1}^n$ that maximize the determinant of the Vandermonde matrix V with elements

$$V_{ij} = \psi_j(\hat{\mathbf{x}}_i), \quad 1 \le i,j \le n,$$

and an algorithm to accurately solve the corresponding optimization problem is described in [30]. For TSEM introduced in [31], the Fekete points are used as approximation points; i.e., the Lagrange polynomials $\{\phi_i\}_{i=1}^n$ built on these points are used as basis functions. Among the main properties of Fekete points proved in [3, 30], we recall that for the cube, Fekete points and Gauss–Lobatto points coincide, thus providing a strong link with the usual QSEM.

Unlike GLL points, a quadrature formula based on Fekete points is exact only for integrands in $\mathbb{P}_p(T_{\rm ref})$. This fact has suggested for the TSEM that we might separate the sets of approximation and quadrature points, using the Fekete points $\{\hat{\mathbf{x}}_i\}_{i=1}^n$ for the first set and Gaussian points $\{\hat{\mathbf{y}}_i\}_{i=1}^m$ for the second set, obtained by imposing an exact integration of polynomials, e.g., in $\mathbb{P}_{2p}(T_{\rm ref})$; see [20]. Given the values of a polynomial $u_p \in \mathbb{P}_p(T_{\rm ref})$ at the Fekete points, one can set up interpolation and differentiation matrices to compute, at the Gauss points, the values of u_p and of its derivatives, respectively. For instance, denoting by $\underline{u}$ the vector of the $u_i = u_p(\hat{\mathbf{x}}_i)$, $1 \le i \le n$, and by $\underline{u}'$ that of the $u_p(\hat{\mathbf{y}}_i)$, $1 \le i \le m$, we have $\underline{u}' = V'V^{-1}\underline{u}$, where $V'_{ij} = \psi_j(\hat{\mathbf{y}}_i)$. On a generic triangle $T_k = g_k(T_{\rm ref})$, the same relation between $\underline{u}'$ and $\underline{u}$ holds true, provided that $u_i = (u_p \circ g_k)(\hat{\mathbf{x}}_i)$ and $u'_j = (u_p \circ g_k)(\hat{\mathbf{y}}_j)$. Similarly, in $T_{\rm ref}$ one has $(\underline{\partial u})' = W'V^{-1}\underline{u}$, with ∂ for differentiation with respect to any coordinates and where $W'_{ij} = \partial\psi_j(\hat{\mathbf{y}}_i)$. Then, using the chain rule, one can compute derivatives in the generic triangle.

The TSEM requires, of course, the use of highly accurate integration rules based on Gauss points, which are still an open subject of research, but in any case, we can use integration rules based on Gauss points for the quadrilateral and then map them to $T_{\rm ref}$; see [17]. On a generic triangle $T_k = g_k(T_{\rm ref})$,

$$(u,v)_{T_k,p} = \sum_{j=1}^m u'_j\, v'_j\, |J_k^T(\hat{\mathbf{y}}_j)|\, \omega_j,$$

where $\omega_j > 0$, $1 \le j \le m$, are the quadrature weights and $|J_k^T|$ is the Jacobian of the mapping g_k between $T_{\rm ref}$ and T_k, and in general on Ω,

$$(u,v)^T_{K,p} = \sum_{k=1}^K (u,v)_{T_k,p}. \tag{2.5}$$

As for (2.4), we obtain a discrete problem

$$a^T_{K,p}(u,v) = (f,v)^T_{K,p} \quad \forall v \in V^T_{K,p}, \tag{2.6}$$

which can be written in matrix form as a linear system $A_T\mathbf{u} = \mathbf{b}$. The TSEM matrix A_T is less sparse than the QSEM matrix A_Q and more ill-conditioned, since its condition number grows as $O(p^4h^{-2})$ rather than $O(p^3h^{-2})$ for $d = 2$ (see section 4).

3. Decomposition into subdomains and overlapping Schwarz preconditioners. We now apply some domain decomposition techniques and build some preconditioning techniques for the iterative solution of the QSEM or TSEM discrete systems $A\mathbf{u} = \mathbf{b}$ by the preconditioned CG (PCG) method, with $A = A_Q$ for QSEM or $A = A_T$ for TSEM. The preconditioner belongs to the family of overlapping Schwarz methods and is built from the solution of parallel independent local elliptic problems on overlapping subdomains, in addition to the solution of coarse problems on the coarse mesh, needed to ensure scalability. For a general introduction to domain decomposition methods and overlapping Schwarz preconditioners we refer to [8, 32, 28, 26] and the references therein.

Preliminary results on overlapping Schwarz preconditioners for Fekete TSEM have been reported in the conference paper [21], where we considered only the case of one spectral element per subdomain and constant coefficients in the elliptic operator. For the classical GLL QSEM case with only one element per subdomain, several works are available in the literature, both for the scalar and vector cases; see, e.g., [4, 10, 24, 25]. In this paper, we extend our investigation to the more general case where Ω is decomposed into subdomains Ω_i, which are in turn partitioned into spectral elements, for both the triangular and quadrilateral case. To this aim, we assemble the elements T_k, $k = 1, \ldots, K$, of the QSEM or TSEM partitions into N quadrilateral or triangular subdomains Ω_i, each consisting of K_i spectral elements T_k. With a local renumbering of the triangles we then have

$$\overline{\Omega}_i = \bigcup_{k=1}^{K_i} \overline{T}_k,$$

where $K = \sum_i K_i$ (see Figures 1–3 below for some examples). We assume also that the subdomain partition is conforming, i.e., that the intersection between two distinct subdomains is either the empty set or a common vertex or a common side, and we denote by H the maximum diameter of the subdomains Ω_i.

The coarse mesh τ_0 is defined to be either the subdomain mesh τ_H or the element mesh τ_h. Let τ_p be the fine discretization mesh determined by either the GLL or the Fekete nodes introduced in each element T_k in sections 2.1 and 2.2. We can define different discretizations and overlapping partitions, according to the spectral element domain decomposition of Ω and the set of nodes within each subdomain. In the special case where $H = h$, each element T_k coincides with a whole subdomain. When $H > h$, we associate groups of triangular or quadrilateral elements to each subdomain, and two different choices for the coarse problem are possible, one associated with the subdomain mesh τ_H, the other with the element mesh τ_h, and both using coarse basis functions with $p = 1$ polynomial degree. We will denote them as τ_H-coarse space and τ_h-coarse space.

The coarse triangulation τ_0 is given by quadrilateral subdomains Ω_i (resp., elements T_k) providing a coarse problem on $\tau_0 \equiv \tau_H$ (resp., $\tau_0 \equiv \tau_h$) with bilinear finite

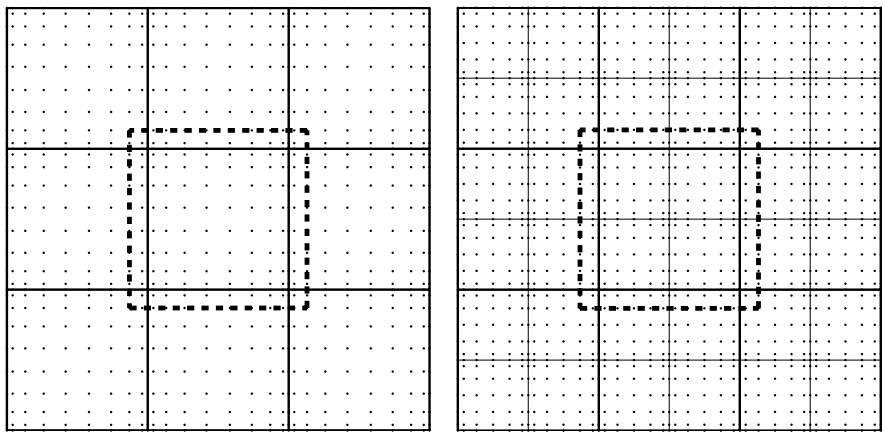

FIG. 1. *QSEM examples with $N = 3 \times 3$ subdomains Ω_i' corresponding to an overlap of $\delta = 2$ GLL points. The internal overlapping subdomain is depicted with thick dashed lines. Left: spectral degree $p = 9$ and $K_i = 1$; i.e., each subdomain consists of only one element. Right: spectral degree $p = 6$ and $K_i = 2 \times 2$; i.e., each subdomain consists of four elements.*

elements ($p = 1$ in each direction). Then the local fine discretization τ_p is determined by GLL nodes in each subdomain Ω_i, when we associate each quadrilateral finite element to a subdomain, or GLL nodes in each element T_k, when each subdomain Ω_i is in turn partitioned into K_i quadrilateral elements of smaller size h. We observe that τ_p is not shape-regular, because the distance between GLL points close to the endpoints of $[-1, 1]$ is on the order of $1/p^2$, while in the middle of the interval $[-1, 1]$ this distance is on the order of $1/p$ (see [1]).

We consider an overlapping partition of Ω by extending each subdomain Ω_i to a larger subdomain Ω_i', consisting of all GLL nodes of τ_p within a certain distance δ^* from Ω_i. Precisely, $\delta^* = \min_{i=1}^{N}\{\text{dist}(\partial\Omega_i, \partial\Omega_i')\}$. We also measure the size of the overlapping region by the number δ of GLL points extending Ω_i in each direction. For example, in the case of minimal overlap and a uniform partition of a square domain Ω, as in Figure 1, we have $\delta = 1$ and $\delta^* = (\xi_1 - \xi_0)h/2$, where ξ_0 and ξ_1 are respectively the first and second GLL node in $[-1, 1]$; in the case of generous overlap we have $\delta = p$ and $\delta^* = h$.

See Figure 1 (left) for a two-dimensional example on a square domain Ω corresponding to local polynomial degree $p = 9$ and one element per subdomain ($H = h$), and Figure 1 (right) for a two-dimensional example on a square domain Ω corresponding to local polynomial degree $p = 6$ and $K_i = 2 \times 2$ elements per subdomain ($H = 2h$). In both cases the original domain Ω is decomposed into $N = 3 \times 3$ subdomains, with overlap $\delta = 2$ GLL points.

The coarse triangulation τ_0 is given either by all quadrilateral or triangular subdomains Ω_i, providing a coarse problem on $\tau_0 \equiv \tau_H$ with, respectively, bilinear or linear finite elements ($p = 1$), or by all triangular elements T_k providing a richer coarse problem on $\tau_0 \equiv \tau_h$ with linear finite elements ($p = 1$). Then the local fine discretization τ_p is determined by Fekete nodes within each subdomain Ω_i in the first case, or within each element T_k in the second one. The overlapping partition of Ω is generated by extending each quadrilateral or triangle Ω_i to a large subdomain Ω_i' consisting of all triangular elements sharing with Ω_i either a vertex or an edge. See Figure 2 for a two-dimensional example on a square domain Ω corresponding to

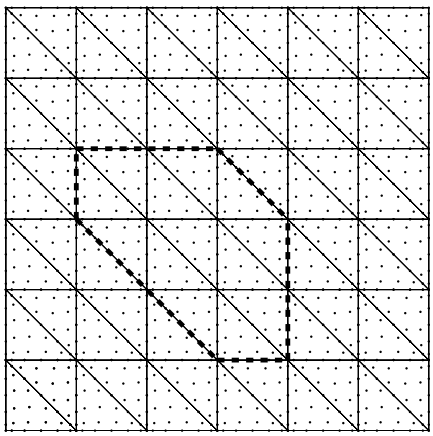

FIG. 2. *TSEM example with spectral degree* $p = 6$, $K = 6 \times 6 \times 2$ *triangular elements, and* $K_i = 1$*; i.e., each subdomain consists of only one element. In this case, an internal overlapping subdomain (depicted with thick dashed lines) consists of* 13 *elements.*

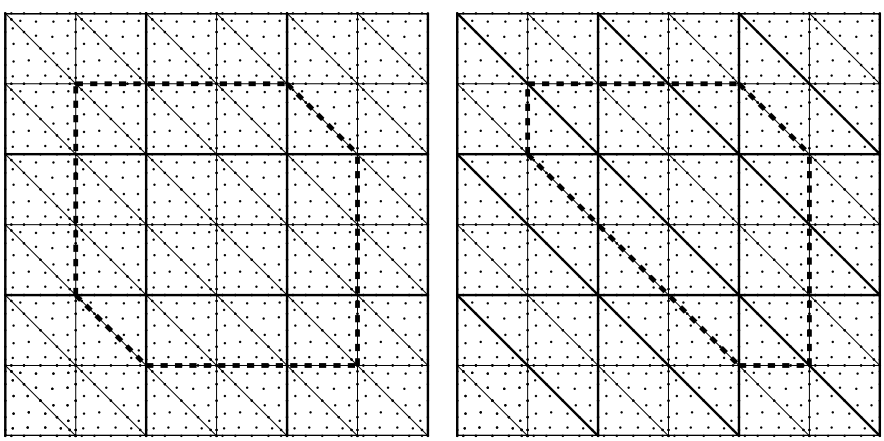

FIG. 3. *TSEM example with spectral degree* $p = 6$. *Left:* $N = 3 \times 3$ *square subdomains,* $K_i = 2 \times 2 \times 2$ *elements per subdomain; in this case, an internal overlapping subdomain (depicted with thick dashed lines) consists of* 30 *elements. Right:* $N = 3 \times 3 \times 2$ *triangular subdomains,* $K_i = 4$ *elements per subdomain; in this case, an internal overlapping subdomain (depicted with thick dashed lines) consists of* 22 *elements.*

$N = 6 \times 6 \times 2$ triangular subdomains ($H = 1/3$), polynomial degree $p = 6$, and one element per subdomain ($H = h$). Moreover, see Figure 3 (left) for a two-dimensional example corresponding to $N = 3 \times 3$ quadrilateral subdomains ($H = 2/3$), polynomial degree $p = 6$, and $K_i = 2 \times 2 \times 2$ triangular elements per subdomain, and Figure 3 (right) for a two-dimensional example corresponding to $N = 3 \times 3 \times 2$ triangular subdomains, polynomial degree $p = 6$, and $K_i = 2 \times 2$ triangular elements per subdomain. Overlapping techniques involving a smaller number of elements (e.g., sharing edges of T_k only) proved unsuccessful, whereas less generous overlapping partitions considering few nodes around Ω_i similarly to the QSEM case cannot be designed straightforwardly, since the internal Fekete nodes are not distributed regularly as in a tensor product.

Overlapping Schwarz methods can now be described either in matrix form or in terms of a space decomposition of the discrete spaces. Let us consider the matrix form first. The overlapping Schwarz preconditioner B^{-1} for A is based on the following:

(a) the solution of a coarse problem on the coarse mesh τ_0, with bilinear elements for QSEM and bilinear or linear ones for TSEM ($p = 1$);

(b) the solutions of local problems on the overlapping subdomains Ω_i'.

For the coarse solve, we need to define:

(a_1) a restriction matrix R_0; its transpose R_0^T interpolates coarse bilinear (resp., bilinear or linear) functions on τ_0 to spectral elements functions on the fine GLL (resp., Fekete) mesh τ_p;

(a_2) a coarse stiffness matrix $A_0 = R_0 A R_0^T$ needed for the solution of the coarse problem with $p = 1$ on τ_0.

For the local solves, we need to define the following:

(b_1) restriction matrices R_i (with 0,1 entries) returning only the degrees of freedom inside each subdomain Ω_i';

(b_2) local stiffness matrices $A_i = R_i A R_i^T$ needed for the solution of the ith local problem on Ω_i' with zero Dirichlet boundary conditions on $\partial\Omega_i'$.

Finally, we define

$$P_i = R_i^T A_i^{-1} R_i A, \qquad i = 0, 1, \ldots, N.$$

These are the building blocks of the proposed preconditioners. The additive form of the overlapping Schwarz preconditioner is

$$B_{add}^{-1} = R_0^T A_0^{-1} R_0 + \sum_{i=1}^{N} R_i^T A_i^{-1} R_i, \qquad \text{i.e.,} \quad P_{add} \equiv B_{add}^{-1} A = P_0 + \sum_{i=1}^{N} P_i, \tag{3.1}$$

while the multiplicative form is

$$B_{mul}^{-1} A = I - (I - P_N) \cdots (I - P_1)(I - P_0). \tag{3.2}$$

More general hybrid variants can be considered as well; see [28].

These preconditioners are associated with the space decomposition

$$V_{K,p} = V_0 + \sum_{i=1}^{N} V_i,$$

where either $V_{K,p} \equiv V_{K,p}^Q$ or $V_{K,p} \equiv V_{K,p}^T$. Here, V_0 is the subspace of $V_{K,p}$ consisting of piecewise bilinear or linear functions on the coarse mesh τ_0 and for QSEM

$$V_i = \{v \in V_{K,p}^Q : v = 0 \text{ at all the GLL nodes outside } \Omega_i' \text{ and on } \partial\Omega_i'\},$$

while for TSEM

$$V_i = \{v \in V_{K,p}^T : v = 0 \text{ at all the Fekete nodes outside } \Omega_i' \text{ and on } \partial\Omega_i'\}.$$

Defining the operators $T_i : V_{K,p} \longrightarrow V_i,\ i = 0, 1, \ldots, N$, by

$$a_{K,p}(T_i u, v) = a_{K,p}(u, v) \qquad \forall v \in V_i,\ i = 0, 1, \ldots, N,$$

where $a_{K,p} \equiv a^Q_{K,p}$ for QSEM and $a_{K,p} \equiv a^T_{K,p}$ for TSEM, it is then easy to check that $B^{-1}_{add}A$ given in (3.1) is exactly the matrix form of the additive Schwarz operator

$$T_{add} = T_0 + T_1 + \cdots + T_N. \tag{3.3}$$

Analogously, $B^{-1}_{mul}A$ given in (3.2) is the matrix form of the multiplicative Schwarz operator

$$T_{mul} = I - (I - T_N)\cdots(I - T_1)(I - T_0). \tag{3.4}$$

The spectral equivalence between the QSEM matrices (mass and stiffness) and the usual P_1 finite element matrices obtained when using the GLL nodal mesh (see Casarin [4]) allows us to transfer the main domain decomposition results from the finite element case to QSEM (see, e.g., Toselli and Widlund [32]).

THEOREM 3.1. $\kappa_2(T_{add}) = \lambda_{max}(T_{add})/\lambda_{min}(T_{add})$ T_{add}

$$\kappa_2(T_{add}) \le C\left(1 + \frac{H}{\delta^*}\right), \tag{3.5}$$

C p, H, h, δ^*

As in the standard finite element case, we cannot guarantee that in the case of QSEM this bound is independent of the coefficient jumps in the elliptic operator, in our case α, but the numerical experiments reported in the next section show that such independence holds.

The bound (3.5) implies that in case of minimal overlap $\delta = 1$ GLL points, i.e., $\delta^* \approx h/p^2$, we have

$$\kappa_2(T_{add}) \le C\left(1 + \frac{H}{h}p^2\right); \tag{3.6}$$

i.e., the number of iterations is expected to scale like p for fixed H/h, while it scales like $\sqrt{H/h}$ for fixed p. In case of generous overlap $\delta^* = h$, we have

$$\kappa_2(T_{add}) \le C\left(1 + \frac{H}{h}\right); \tag{3.7}$$

i.e., the number of iterations is expected to be independent of p and on the order of $\sqrt{H/h}$. This was already proved in Pavarino [23] for *hp*-finite elements and generous overlap. For unstructured *hp* elements on nontensorial elements, such as TSEM, the spectral equivalence used for QSEM in [4, 23] does not hold, and preconditioners with small overlap are not known. Nevertheless, we can build preconditioners with generous overlap as shown before, and the numerical results of the next section show that they are optimal and scalable. Hence we conjecture that a bound as in Theorem 3.1 also holds for TSEM.

We briefly examine here the computational costs of solving both the original TSEM discrete problem and the TSEM preconditioned problem in two dimensions on a serial computer. Analogous estimates can be derived in three dimensions and for QSEM.

We consider for simplicity the square domain $\Omega = (0,1)^2$ with a uniform subdivision in triangular elements as in Figure 3, where the total number of degrees of freedom

is $d_T = O(p^2 N K_i)$, since we have $O(p^2)$ degrees of freedom per element, K_i elements per subdomain, and N subdomains (in this geometry, we have $h^{-1} = \sqrt{NK_i/2}$ and $H^{-1} = \sqrt{N}$). The band of the stiffness matrix is $b_T = O(p^2\sqrt{NK_i})$, i.e., the number of degrees of freedom on one spectral element row (or column) of the square domain.

(a) The computational cost of solving the original TSEM system with a banded direct solver is $O(d_T b_T^2) = O(p^6 (NK_i)^2)$. The cost of solving the same system with a CG method would be proportional to the number of required CG iterations (i.e., the square root of the condition number $= O(p^2 h^{-1}) = O(p^2\sqrt{NK_i})$) times the cost of each CG iteration. The latter is dominated by the matrix-vector products, which for our banded matrix involve $O(d_T b_T) = O(p^4 (NK_i)^{3/2})$ operations. Hence the CG cost would be $O(p^6 (NK_i)^2)$, i.e., similar to the direct solver's one.

(b) The computational cost of solving the TSEM system with the Schwartz PCG is again given by the product of the required PCG iterations and the cost of each PCG iteration; see [28, Chapter 3.6]. From (3.7), the condition number of our two-level Schwarz preconditioner with generous overlap is $O(H/h) = O(\sqrt{K_i})$. Since H/h can be kept constant by decreasing h and H proportionally, we have that the PCG iterations are $O(1)$ (otherwise the extra cost would only be a factor $\sqrt{K_i}$). The cost per iteration is dominated by the matrix-vector products and the preconditioner solves. We assume that we have factored the local and coarse matrices before starting the iterations, so that the local and coarse solves are just banded back-substitutions, with band $b_i = O(p^2\sqrt{K_i})$ for the ith local matrix and band $b_0 = \sqrt{N}$ for the coarse matrix (linear elements on the coarse mesh $\tau_0 = \tau_H$). Denoting by $d_i = O(p^2 K_i)$ and $d_0 = O(N)$ the number of local and coarse degrees of freedom, we have that the cost of the local solves is $O(N d_i b_i) = O(p^4 N K_i^{3/2})$, while the cost of the coarse solve is $O(N^{3/2})$. The overlap costs amount to lower-order terms, since the factor $\sqrt{K_i}$ in the local band b_i is only increased by 1 (if the subdomain touches the domain boundary) or 2 (if the subdomain is internal), and similarly the local number of degrees of freedom d_i is only increased by a factor $O(p^2\sqrt{K_i})$ corresponding to the elements in the overlapping subregion Ω_i' outside subdomain Ω_i. Adding up the matrix-vector products and all the local and coarse solves of the preconditioner, we then estimate the total PCG cost as $O(p^4 (NK_i)^{3/2} + p^4 N K_i^{3/2} + N^{3/2})$. This cost is lower than the cost of solving the original TSEM system as estimated in (a). Better estimates could be obtained by considering better local and coarse solvers, matrix-vector products, etc. We remark that these serial estimates have a relative importance, since domain decomposition preconditioners should be considered on parallel architectures, where more involved complexity estimates need to include architecture-dependent quantities such as communication and memory costs (see [28, Chapter 3.6]), and are beyond the scope of this paper.

4. Numerical results. We tested the properties of the overlapping Schwarz preconditioned CG method for TSEM and QSEM partitions, by performing a p-, H-, and h-convergence study. We consider either a homogeneous or a heterogeneous material, given by the model problem (2.1) over the domain $\Omega = [-1, 1]^2$. The body force f is consistent with $u(x) = \sin(\pi x)\sin(\pi y)$ as an exact solution of (2.1). The discrete problems are solved by either the CG method or the PCG method, with zero initial guess and stopping criterion $\|\mathbf{r}^{(\nu)}\|_2 / \|\mathbf{b}^{(\nu)}\|_2 \leq 10^{-7}$, where $\mathbf{r}^{(\nu)}$ is the residual of the linear systems $A_T \mathbf{u} = \mathbf{b}$ or $A_Q \mathbf{u} = \mathbf{b}$ at the νth iterate. The Schwarz preconditioner is here applied in the additive version (3.1) without or with the coarse correction given by the term $R_0^T A_0^{-1} R_0$ in (3.1). We recall that the overlapping Schwarz preconditioners are built using generous overlap in the TSEM case and using minimal overlap ($\delta = 1$) in the QSEM case.

4.1. The homogeneous case: The Fekete–Gauss TSEM. In this section, we report the results of numerical experiments for the model problem (2.1) discretized with triangular TSEM using the Fekete and Gauss nodes. We consider a homogeneous material with $\alpha = \beta = 1$.

4.1.1. Case $K_i = 1$. We start with the simple choice of associating each triangular element with a subdomain (i.e., $H = h$, or equivalently, $N = K$). The mesh is obtained by first dividing Ω into M^2 identical squares and then by dividing each of them into two triangles, thus providing a partition of $N = 2M^2$ triangular subdomains. The overlapping partition is described in Figure 2. The grid-size parameter H is equal to $2/M$.

In Table 1, we report the iteration counts (It.), spectral condition number (κ_2), and extreme eigenvalues (λ_{max}, λ_{min}), fixing $p = 6$ and varying the parameter $1/h = 1/H$ from 2 to 7, i.e., varying the number of subdomains from $N = 2 \times 4 \times 4$ to $N = 2 \times 14 \times 14$.

Columns 2–3 refer to unpreconditioned CG, columns 4–7 to PCG without coarse problem, and columns 8–11 to PCG with coarse problem ($\tau_h = \tau_H$ in this case).

The same quantities are reported in Table 2, now fixing $h = H = 1/2$ ($N = 2{\times}4{\times}4$ subdomains) and varying the degree p from 3 to 18.

The condition numbers and extreme eigenvalues (not reported in the tables) of the unpreconditioned Fekete matrix are plotted in Figure 4 as a function of H (left) and p (right). These results show that the very ill-conditioned TSEM original matrix A_T has a condition number that grows as $O(p^4 h^{-2})$. The maximum eigenvalue λ_{max} grows as $O(p^2)$, and $1/\lambda_{min}$ grows as $O(p^2 h^{-2})$. The results also show that the overlapping Schwarz preconditioned operator with or without coarse solver is optimal in p, since all the quantities are bounded by constants independent of p (Table 2). Without the coarse problem the preconditioner loses its scalability (Table 1), since

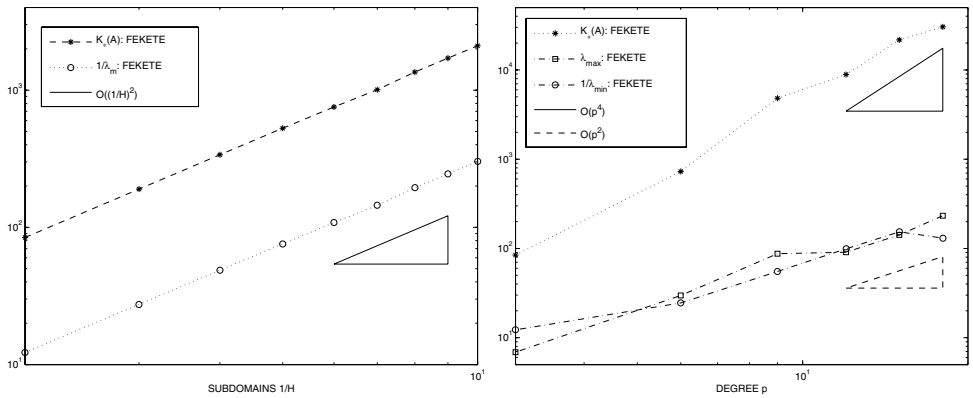

FIG. 4. *TSEM: log-log plot of the condition number of the unpreconditioned Fekete operator as a function of $h = H$ (left) and p (right) from the data of Tables* 1 *and* 2.

λ_{min} tends to 0 with increasing N, while the addition of a coarse problem seems to guarantee scalability (higher values of $1/H$ would be necessary in order to clearly asses scalability).

4.1.2. Case $K_i > 1$. We now consider the more general case where each subdomain Ω_i contains several triangular elements. The TSEM partition is built by first dividing the square computational domain Ω into $N = M^2$ identical square subdomains Ω_i, with $M = 2, \ldots, 6$. Then a fine local partition is considered within each subdomain, consisting of $2 \times 2, \ldots, 6 \times 6$ smaller squares, each of them being divided into two identical triangular elements, so that $K_i = 8, 18, \ldots, 72$. Each subdomain Ω_i is then extended into an overlapping subdomain Ω_i' by adding all the surrounding elements that intersect its boundary; see Figure 3(left). The numerical results with the overlapping Schwarz preconditioner are obtained with both the τ_h-coarse space and τ_H-coarse space.

First, we check the convergence properties of our TSEM preconditioners with respect to the number of subdomains, fixing $p = 6$ as total degree of the polynomials within each triangle and with $h = H/3$. The results are reported in Table 3 and plotted in Figure 5(left). As expected, one observes an increase of the condition number when no coarse solver is used. However, nice results are obtained when the preconditioner employs either one of the τ_h- or τ_H-coarse spaces, and the condition number appears to be bounded above by a constant of about 20.

Second, we vary the number K_i of triangular elements in each subdomain; i.e., we vary the ratio H/h. The results are reported in Table 4 and plotted in Figure 6(left). Again, one observes the efficiency of the overlapping Schwarz preconditioner, especially when a coarse solver is included. Here it should be remarked that the result is better than expected, since the condition number appears to be independent of H/h, i.e., K_i.

Third, we vary the TSEM polynomial degree p. The results are reported in Table 5 and plotted in Figure 7(left). Of course, the coarse solver has no influence here, and all the three preconditioners have slowly increasing condition numbers that seem to be bounded above by a constant independent of p. We note that such slow increase toward an upper bound was not observed in the case $K_i = 1$ (Table 2), where the independence of p was very clear.

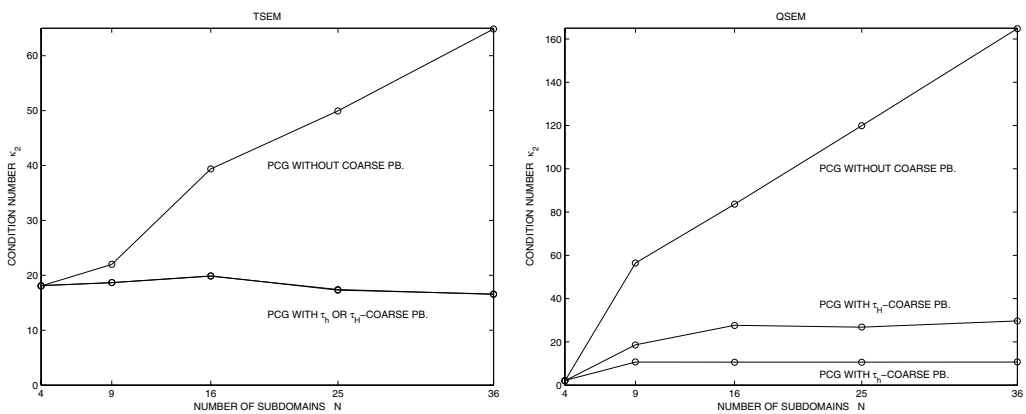

FIG. 5. *Condition number of PCG with and without coarse problem as a function of the number of subdomains N; TSEM data from Table 3 (left), QSEM data from Table 6 (right).*

These results show that the overlapping Schwarz preconditioner with a coarse problem is optimal and scalable also in the nontrivial case $H \neq h$, i.e., $K_i > 1$. The results are not as clear as in the trivial case with only one element per subdomain ($H = h$, i.e., $K_i = 1$), but we conjecture that numerical experiments with higher values of p and N would confirm these properties.

4.2. The homogeneous case: The GLL QSEM. Overlapping Schwarz methods for QSEM based on GLL points have been successfully applied to many elliptic and parabolic problems (see, e.g., [32, 7] and the references therein). Numerical results are usually carried out by considering the simpler choice $H = h$ with only one element per subdomain.

In this section, we report the results of numerical experiments with GLL QSEM for the same tests and model problem (2.1) of the previous section. We focus on the nontrivial case $H \neq h$ and perform analogous p-, H-, and h-convergence tests. The QSEM partition is built by dividing the square computational domain Ω into $N = M^2$ identical square subdomains Ω_i of characteristic diameter H. Then a local partition is considered within each subdomain, consisting of K_i square elements of

characteristic diameter h, and a tensorial GLL mesh is introduced in each element. We then extend each subdomain Ω_i to an overlapping subdomain Ω_i' with minimal overlap, consisting of just $\delta = 1$ layer of GLL nodes outside the boundary; see Figure 1(right) and section 3.

We first study the convergence properties of overlapping Schwarz preconditioners for QSEM with respect to the number of subdomains. We compare the overlapping Schwarz preconditioner operator based either on the τ_h- or the τ_H-coarse space. In Table 6 we report the same quantities of the previous section, and we plot them in Figure 5(right). We fix the local polynomial degree $p = 6$ and the number of elements per subdomain $K_i = 3 \times 3$, which corresponds to $H = 3h$, varying the number of subdomains from $N = 2 \times 2$ to $N = 6 \times 6$. While both unpreconditioned CG and PCG without coarse problem are not scalable, PCG with either the τ_h- or τ_H-coarse space is.

We then consider the convergence properties with respect to the number K_i of elements per subdomain in Table 7 and plot the results in Figure 6(right). We fix the local polynomial degree $p = 6$ and the number of subdomains $N = 3 \times 3$, varying the number of elements per subdomain from $K_i = 2 \times 2$ to $K_i = 6 \times 6$. In agreement

with the theoretical estimate of Theorem 3.1, the preconditioner with the τ_H-coarse space yields condition numbers that grow linearly with K_i. On the other hand, the τ_h-coarse space yields condition numbers that are independent of K_i.

We then study the convergence properties with respect to the polynomial degree p in Table 8 and plot the results in Figure 7(right). We fix the number of subdomains $N = 3 \times 3$, and the number of elements per subdomain $K_i = 3 \times 3$, varying the local polynomial degree from $p = 3$ to $p = 18$. In agreement with the bound of Theorem 3.1, all PCG iteration counts display a linear growth with p, corresponding to a quadratic growth of the condition number associated with a quadratic decay of λ_{min} (while λ_{max} has a constant value of about 4).

Finally, we consider the convergence properties of our preconditioner with respect to the overlap δ (number of GLL points extending Ω_i in each direction) in Table 9 and plot the same results with respect to the corresponding values of δ^* (size of the overlapping region) in Figure 8. We fix the number of subdomains $N = 3 \times 3$, the number of elements per subdomain $K_i = 2 \times 2$, the local polynomial degree $p = 9$, varying the overlap from $\delta = 1$ GLL points (minimal overlap) to $\delta = 9$ GLL

points (generous overlap). Again in agreement with the theory, the condition numbers improve with increasing δ because λ_{min} improves considerably. The improvement is large in going from $\delta = 1$ to $\delta = 2$ and 3, while it becomes rapidly marginal (or negative) for larger values of δ, due to the slight growth of λ_{max}.

4.3. The heterogeneous case: The Fekete–Gauss TSEM. To check the efficiency of the additive Schwarz preconditioner for TSEM, we vary the diffusion coefficient α in the elliptic operator of our model problem (2.1). The computations are done for the reference case with $p = 6$, $N = 3 \times 3$, and $K_i = 2 \times 3 \times 3$.

First, we use two different values of α, $\alpha_1 = 1$ in some subdomains and $\alpha_2 = 10^t$, with $t = -3, -2, \ldots, 3$ in the others. These two values are distributed in a checkerboard layout on the subdomains, starting with α_1 on the top left subdomain; see Figure 9(left). The results are reported in Table 10. We remark that the efficiency of the overlapping Schwarz preconditioner is not affected by the jump of α at the interfaces of the subdomains, while unpreconditioned CG greatly suffers the severe

ill-conditioning of the problems due to the increasing coefficient jumps.

We then consider a harder case with "random" distribution of α shown in Figure 9(right), and report the results in the last line of Table 10. Even in this very difficult case, where unpreconditioned CG does not seem to converge, the overlapping Schwarz preconditioner remains very efficient.

4.4. The heterogeneous case: The GLL QSEM. Analogous conclusions are obtained with GLL QSEM; see Table 11. Here the condition numbers of the preconditioned operator seem to even improve with increasing coefficient jumps, while their maximum is attained in absence of jumps for $t = 0$. For the difficult test case with the same random distribution of α, unpreconditioned CG again fails to converge, while the overlapping Schwarz preconditioner requires about the same iterations as in absence of jumps.

5. Conclusions. We have constructed and studied overlapping Schwarz preconditioners for the triangular/tetrahedral spectral element (TSEM) discretization of scalar elliptic problems based on Fekete nodes. The proposed preconditioners employ generous overlap among subdomains, since it is not currently know how to construct TSEM preconditioners with small overlap. We also compared the TSEM nontensorial

discretization with the classical Gauss–Lobatto–Legendre QSEM discretization, where it is possible to construct Schwarz preconditioners with variable overlap (from generous to minimal). In spite of the more severe ill-conditioning of the resulting TSEM discrete problem (where $\kappa_2 \approx O(p^4 h^{-2})$), the convergence rate of the proposed preconditioning algorithm is independent of the number of subdomains N when a coarse problem is employed and of the spectral degree p in case of generous overlap; otherwise it depends inversely on the overlap size. Moreover, the proposed preconditioners are robust with respect to arbitrary jumps across subdomains of the coefficients of the elliptic operator. Our results are limited to regular structured meshes in the plane. Future work will extend this study to three dimensions and to unstructured meshes for more general domains.

ON WELL-BALANCED FINITE VOLUME METHODS FOR NONCONSERVATIVE NONHOMOGENEOUS HYPERBOLIC SYSTEMS*

M. J. CASTRO DÍAZ†, T. CHACÓN REBOLLO‡, E. D. FERNÁNDEZ-NIETO§, AND CARLOS PARÉS†

Abstract. In this work we introduce a general family of finite volume methods for nonhomogeneous hyperbolic systems with nonconservative terms. We prove that all of them are "asymptotically well-balanced": they preserve all smooth stationary solutions in all the domain except for a set whose measure tends to zero as Δx tends to zero. This theory is applied to solve the bilayer shallow-water equations with arbitrary cross-section. Finally, some numerical tests are presented for simplified but meaningful geometries, comparing the computed solution with approximated asymptotic analytical solutions.

Key words. well-balanced finite volume method, upwinding, shallow water, source terms, two-layer flows

1. Introduction.

This work deals with finite volume solvers for nonhomogeneous hyperbolic systems with nonconservative terms. Our goal is to design numerical schemes that calculate with high accuracy the stationary solutions of the system.

The accurate computation of stationary solutions of hyperbolic systems with source terms has been found in recent years to be closely related to the accurate computation of transient solutions. Numerical schemes that do not solve steady solutions up to second order, at least, yield transient solutions that present large errors, unacceptable from the physical point of view. To avoid this difficulty, Bermúdez and Vázquez [1] introduced the so-called C-property in the context of shallow-water equations. They ask the numerical schemes to exactly calculate at grid nodes the stationary solution corresponding to water at rest. They also present some numerical evidence of the large errors presented by schemes that do not verify this property. In that work, the scheme of Roe (cf. [19]) is generalized to nonhomogeneous hyperbolic systems, in such a way that it verifies the C-property.

This property has given fruitful extensions to more general situations: numerical models, hyperbolic equations, and extensions of the condition itself.

For instance, an extension to kinetic schemes was introduced by Perthame and Simeoni in [17]. This type of scheme is based upon the discretization of an equation for the density of particles. Also, Kurganov and Levy in [14] introduced the central upwind schemes for shallow-water equations, characterized by including only scalar numerical diffusion. No upwinding matrix is needed. Both schemes ensure the

positiveness of the water height and verify the C-property.

The relevance of this property as a consistency condition was pointed out in the work of Perthame and Simeoni [18]. They prove the convergence, in the sense of distributions, of the numerical solution computed by a finite volume scheme for a nonhomogeneous equation under some hypothesis of consistency of the numerical scheme. This hypothesis is fulfilled if the numerical scheme preserves certain equilibrium states of the system.

An extension of the C-condition to a more general condition was introduced in Greenberg and Leroux [13]: the concept of a "well-balanced"scheme, as a scheme that preserves all equilibria of the system at grid nodes. In this work, a numerical scheme for nonhomogeneous scalar equations satisfying this condition was introduced.

An extension to a class of nonconservative hyperbolic system of equations was introduced in [2] by Castro, Macías, and Parés by means of a generalized Roe scheme. The systems considered include a nonconservative product with the structure $B(W)\frac{\partial W}{\partial x}$, where B is a matrix and W is the unknown. The numerical stability of this scheme is achieved by using upwinding matrices defined not only from the Jacobian of the flux, but also from the matrix B involved by the nonconservative terms. The scheme introduced is applied to the one-dimensional two-layer shallow-water system for channels with constant width. The scheme exactly computes water at rest. More recently, in [4] this Roe scheme has been extended to the more general case of channels with irregular geometry and not necessarily rectangular cross-section. This extended numerical scheme was applied to the simulation of the Strait of Gibraltar.

The derivation of systematic techniques to build numerical schemes satisfying the C-property is also a relevant issue, as this is far from being a straightforward condition to obtain. In [5] Chacón Rebollo, Domínguez Delgado, and Fernández-Nieto introduced the idea of separately compensating the centered and decentered components of the numerical flux by centered and decentered discretizations of the source terms. In [6] the same authors introduced the idea of adding an additional source term to the parabolic equivalent equation. This term is specifically designed to compensate for the first order error generated by the numerical diffusion term on steady solutions. Then centered discretizations automatically provide second order accurate approximations of all steady solutions.

In this work, we extend the preceding analysis by considering a general nonhomogeneous hyperbolic system of equations with nonconservative terms, which also depends upon the space variable. We derive a general class of numerical schemes that we prove to be "asymptotically well-balanced" in the following sense: they calculate, with at least order two, all stationary solutions of the system in all the domain except those on a set whose measure tends to zero as Δx tends to zero. One of the free parameters of this class is the diffusion matrix, so we include both flux-splitting and flux-difference or Roe methods as particular cases.

We also give general sufficient conditions under which the schemes exactly calculate a given stationary solution. These conditions may be read as meaning on one hand that the numerical flux of the scheme must compensate the centered part of the numerical source term, and on another hand that the numerical diffusion must compensate the decentered part of the numerical source term.

This paper is organized as follows: In section 2, a family of numerical schemes for a general nonhomogeneous hyperbolic systems of equations with nonconservative terms is introduced. In section 3, we introduce the concept of the "asymptotically well-balanced" scheme and prove that the introduced numerical schemes satisfy this

property. Section 4 is devoted to the construction of numerical diffusion matrices that ensure the stability of our schemes for linear systems, while ensuring the asymptotically well-balanced computation of all steady solutions. In section 5, we apply the theory developed to the bilayer shallow-water equations with arbitrary cross-sections to construct a family of asymptotically well-balanced numerical schemes. The Roe-type scheme introduced in [4] is a particular case. In section 6, we present some numerical tests for simplified geometries, where exact solutions can be determined. The purpose of these experiments is to compare the properties of the numerical schemes introduced here for the two-layer shallow water system. More precisely, we focus on the well-balanced property and the quality of the numerical approximations for smooth transitions and shocks. We present our conclusions in section 7. In particular we conclude that the use of pointwise adapted discretizations of the centered part of the numerical flux helps to construct accurate solvers for nonconservative equations.

2. Nonhomogeneous nonconservative hyperbolic systems. We shall consider the following system:

$$(1)\quad \begin{cases} \dfrac{\partial W(x,t)}{\partial t} + \dfrac{\partial}{\partial x}[F(x,W(x,t))] = G(x,W(x,t)) + B(x,W(x,t))\dfrac{\partial W(x,t)}{\partial x}, \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad x \in (0,L), \quad t \in (0,T); \\ \\ W(x,0) = W_0(x), \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad x \in (0,L), \end{cases}$$

where by $F : [0,L] \times \mathbf{R}^N \to \mathbf{R}^N$ we denote the physical flux function and by $G : [0,L] \times \mathbf{R}^N \to \mathbf{R}^N$ the source term, and where $B : [0,L] \times \mathbf{R}^N \to \mathbf{R}^N \times \mathbf{R}^N$ is a regular matrix function of x and W. We will suppose that F, G, and B are C^2 functions. By L we denote the length of the domain and by T the final time. We will complete (1) with appropriate boundary conditions that we set in each problem.

System (1) includes the nonconservative product

$$B(x,W)\frac{\partial W}{\partial x},$$

which is not a distribution if W is discontinuous. Its presence requires an adaptation of the usual concept of weak solutions: Across a discontinuity of W, the nonconservative product can be defined along paths connecting the two states, following Dal Masso, LeFloch, and Murat [8].

System (1) also includes a dependency upon the space variable of the flux F. Both characteristics appear in two-layer shallow-water equations in channels of variable breadth, as we shall see later on. However, these characteristics also appear in other flow models such as boiling flows and two-phase flows, among others (see Fowler [11]).

We suppose that the system (1) is hyperbolic in the sense that $\forall x \in [0,L]$ and $\forall W \in \mathbf{R}^d$ the matrix

$$(2)\qquad M(x,W) = A(x,W) - B(x,W)$$

can be diagonalized and all its eigenvalues are real and different, where $A(x,W) = \frac{\partial F}{\partial W}(x,W)$ is the Jacobian matrix of the flux function F.

We consider a partition $\{x_i\}_{i=0}^{M+1}$ of the interval $[0,L]$, and a partition $\{t^n\}_{n=0}^{m+1}$ of $[0,T]$. By W_i^n we define an approximation to the average of the solution in the control volume, $(x_{i-1/2}, x_{i+1/2})$ at $t = t^n$.

In this work, for the space discretization, we develop finite volume schemes that can be written in viscous form. For the homogeneous conservative system, these schemes are second order approximations in space of a parabolic equivalent system:

$$\frac{\partial W}{\partial t} + \frac{\partial}{\partial x} F(x, W) - \nu \frac{\partial}{\partial x} \left(\mathcal{D}(x, W) \frac{\partial}{\partial x} W \right) = 0,$$

where ν is equal to half of the space step ($\nu = \Delta x/2$) and $\mathcal{D}(x, W)$ is the numerical diffusion matrix: The term

$$-\nu \frac{\partial}{\partial x} \left(\mathcal{D}(x, W) \frac{\partial W}{\partial x} \right) \tag{3}$$

represents the numerical diffusion introduced by the scheme, stemming from the upwinding of the convection terms. The diffusion matrix $\mathcal{D}(x, W)$ must take into account that the effective transport term in system (1) is $M(x, W)\frac{\partial W}{\partial x}$, where M is the matrix defined by (2).

If a centered discretization of the remaining terms in the nonhomogeneous and nonconservative system (1) is performed, then the equivalent parabolic system is

$$\frac{\partial W}{\partial t} + \frac{\partial}{\partial x} F(x, W) - \nu \frac{\partial}{\partial x} \left(\mathcal{D}(x, W) \frac{\partial}{\partial x} W \right) = G(x, W) + B(x, W) \frac{\partial W}{\partial x}. \tag{4}$$

Notice that if $\bar{W}$ is a stationary solution of (1), then it verifies

$$\frac{\partial}{\partial x} [F(x, \bar{W}(x))] = G(x, \bar{W}(x)) + B(x, \bar{W}(x)) \frac{\partial \bar{W}(x)}{\partial x}. \tag{5}$$

So, it is clear that $\bar{W}$ is not a stationary solution of (4). There is a first order error due to the numerical diffusion term (3) that is not compensated.

In order to obtain numerical schemes that calculate up to a second order of accuracy all smooth stationary solutions, we propose compensating the numerical diffusion term by an additional source term, which we denote by $C(x, W)$ (correction term), that is, the numerical scheme must be a second order approximation of

$$\frac{\partial W}{\partial t} + \frac{\partial}{\partial x} \left[F(x, W) \right] - \nu \frac{\partial}{\partial x} \left(\mathcal{D}(x, W) \frac{\partial W}{\partial x} \right) = G(x, W) + B(x, W) \frac{\partial W}{\partial x} + C(x, W).$$

In order to define the term $C(x, W)$, we consider a smooth stationary solution $\bar{W}$ of (1). We want the identity

$$-\nu \frac{\partial}{\partial x} \left(\mathcal{D}(x, \bar{W}) \frac{\partial \bar{W}}{\partial x} \right) = C(x, \bar{W}) \tag{6}$$

to hold. As $\bar{W}$ verifies (5), then

$$\frac{\partial F}{\partial x}(x, \bar{W}(x)) + A(x, \bar{W}(x)) \frac{\partial \bar{W}}{\partial x}(x) = \frac{\partial}{\partial x} [F(x, \bar{W}(x))] = G(x, \bar{W}(x)) + B(x, \bar{W}(x)) \frac{\partial \bar{W}}{\partial x}.$$

Thus,

$$M(x, \bar{W}(x)) \frac{\partial \bar{W}}{\partial x}(x) = G(x, \bar{W}(x)) - F_x(x, \bar{W}(x)), \tag{7}$$

where $F_x(x,W) = \frac{\partial F}{\partial x}(x,W)$. Moreover, if $M(x,\bar{W})$ is nonsingular, we have

$$\frac{\partial \bar{W}(x)}{\partial x} = M^{-1}(x,\bar{W}(x))S(x,\bar{W}(x)),$$

where

$$S(x,W) = G(x,W) - F_x(x,W).$$

Therefore,

$$-\nu\frac{\partial}{\partial x}\left(\mathcal{D}(x,\bar{W}(x))\frac{\partial \bar{W}}{\partial x}(x)\right) = -\nu\frac{\partial}{\partial x}\left(\mathcal{D}(x,\bar{W}(x))M^{-1}(x,\bar{W}(x))S(x,\bar{W}(x))\right). \tag{8}$$

Comparing (8) with (6), we propose to define

$$C(x,W) = -\nu\frac{\partial}{\partial x}\left(\mathcal{D}(x,W)M^{-1}(x,W)S(x,W)\right) \quad \forall x \in [0,L],$$

$\forall W \in \mathbf{R}^N$ such that $M(x,W)$ is nonsingular. The equivalent system for the hyperbolic system with source term and nonconservative terms is

$$\begin{aligned}&\frac{\partial W}{\partial t} + \frac{\partial}{\partial x}F(x,W) - \nu\frac{\partial}{\partial x}\left(\mathcal{D}(x,W)\frac{\partial W}{\partial x}\right)\\ &= G(x,W) + B(x,W)\frac{\partial W}{\partial x} - \nu\frac{\partial}{\partial x}\left(\mathcal{D}(x,W)M^{-1}(x,W)S(x,W)\right).\end{aligned} \tag{9}$$

Every stationary solution of (1) is also a stationary solution of this system at points where $M(x,W(x))$ is nonsingular.

We conclude then that asymptotically well-balanced numerical schemes for the hyperbolic system (1) can be built by the use of approximations of second order in space of (9).

Notice that system (9) has a conservative structure when the original system (1) is conservative (i.e., $B = 0$). Indeed, it can be rewritten as

$$\frac{\partial W}{\partial t} + \frac{\partial}{\partial x}\left[F(x,W) - \nu\mathcal{D}(x,W)\left(\frac{\partial W}{\partial x} - M^{-1}S(x,W)\right)\right] = G(x,W) + B(x,W)\frac{\partial W}{\partial x}. \tag{10}$$

Based upon this structure, we propose general three-point schemes as follows:

$$\begin{aligned}&\frac{W_i^{n+1} - W_i^n}{\Delta t} + \frac{\phi_R^S(x_i,x_{i+1},W_i^n,W_{i+1}^n) - \phi_L^S(x_{i-1},x_i,W_{i-1}^n,W_i^n)}{\Delta x}\\ &= G_C(x_{i-1},x_i,x_{i+1},W_{i-1}^n,W_i^n,W_{i+1}^n),\end{aligned} \tag{11}$$

where

$$\phi_R^S(x_i,x_{i+1},W_i,W_{i+1}) = \phi^S(x_i,x_{i+1},W_i,W_{i+1}) - \frac{1}{2}\mathcal{B}_R(x_i,x_{i+1},W_i,W_{i+1})\,(W_{i+1}-W_i), \tag{12}$$

$$\phi_L^S(x_i,x_{i+1},W_i,W_{i+1}) = \phi^S(x_i,x_{i+1},W_i,W_{i+1}) + \frac{1}{2}\mathcal{B}_L(x_i,x_{i+1},W_i,W_{i+1})(W_{i+1}-W_i), \tag{13}$$

and

$$\begin{aligned}\phi^S(x_i,x_{i+1},W_i,W_{i+1}) &= F_C(x_i,x_{i+1},W_i,W_{i+1}) - \nu D(x_i,x_{i+1},W_i,W_{i+1})\\ &\times\left(\frac{W_{i+1}-W_i}{\Delta x} - \widetilde{M^{-1}}(x_i,x_{i+1},W_i,W_{i+1})S_D(x_i,x_{i+1},W_i,W_{i+1})\right).\end{aligned} \tag{14}$$

Here, $\mathcal{B}_L$ and $\mathcal{B}_R$ are approximations of B at $x = x_{i+1/2}$, respectively. Moreover, G_C is an approximation of $G(x,W)$ in $x = x_i$. By F_C, D, $\widetilde{M^{-1}}$, and S_D we denote the approximations of F, $\mathcal{D}$, M^{-1}, and S in $x = x_{i+1/2}$, respectively.

Let us suppose, for instance, that the singularities of M are concentrated on a continuous hypersurface $\gamma \subset \mathbf{R}^{n+1}$, where, say the jth eigenvalue λ_j vanishes. In this case, we define $\widetilde{M^{-1}}(x,y,U,V)$ as

$$\widetilde{M^{-1}}(x,y,U,V) = X((x+y)/2,\widetilde{W})\widetilde{\Lambda^{-1}}(x,y,U,V)X^{-1}((x+y)/2,\widetilde{W}), \tag{15}$$

where $\widetilde{W} = \widetilde{W}(x,y,U,V)$ is an intermediate state between U and V, by X we denote the matrix defined by the eigenvectors of $M((x+y)/2,\widetilde{W})$, and

$$\widetilde{\Lambda^{-1}}(x,y,U,V) = \mathrm{Diag}(\widetilde{\lambda_i^{-1}}(x,y,U,V), i = 1,\dots,N)$$

with

$$\widetilde{\lambda_i^{-1}} = \lambda_i^{-1} \quad \text{if } i \neq j$$

and

$$\widetilde{\lambda_j^{-1}} = \begin{cases} \lambda_j^{-1} & \text{if } L[(x,U),(y,V)] \subset \mathbf{R}^{N+1} \setminus \gamma,\\ 0 & \text{otherwise,}\end{cases} \tag{16}$$

where the λ_j are the eigenvalues of $M((x+y)/2,\widetilde{W})$ and $L[(x,U),(y,V)]$ is the closed segment in $\mathbf{R}^{N+1}$ that connects (x,U) and (y,V). It is straightforward to extend this definition to a more general case.

This definition of $\widetilde{M^{-1}}$ implies that when an eigenvalue vanishes, no upwinding of the source term is performed at the direction defined by the corresponding eigenvector. For nonhomogeneous scalar hyperbolic equations we may prove that this leads to stable schemes.

This definition of $\widetilde{M^{-1}}$ allows the schemes to be asymptotically well-balanced even for a class of stationary solutions for which matrix M is singular and, for convenient choices of the diffusion matrix D, for every stationary solution. We shall prove this in the next section.

. . . . 1. In [7] it is proved that for homogeneous conservative systems like (10) both flux-difference and flux-splitting schemes fit into the general structure of fluxes given by (12) and (13) with convenient choices of the centered numerical flux F_C and the numerical diffusion matrix D. We point out that for nonconservative systems, it makes no sense to consider flux-splitting schemes, as these are intrinsically based upon the conservative formulation. Indeed, these schemes use a splitting of the flux into (we assume $B = 0$)

$$F(W) = \mathcal{A}^*(W)\,W$$

for some matrix $\mathcal{A}^*$. However, in general we may use flux-difference schemes, as these are based upon the use of the velocities and speeds of propagation of the total flux, given by the matrix M.

In addition, other kind of schemes fit into the general framework set by the general structure (11). We shall introduce some of them in section 5.

3. Analysis of the "asymptotically well-balanced" property. The purpose of this section is to analyze the well-balanced property of the numerical schemes of the form (10)–(14). This analysis is performed by considering an arbitrary stationary solution and using Taylor expansions. As a consequence, the results are valid for every stationary solution (and not only for particular cases of "water at rest" solutions for the shallow-water equations), but we shall only be able to analyze the well-balanced property in terms of orders of accuracy, and not exactly at grid nodes.

Due to the lack of regularity of M^{-1} (and also to the low regularity of D, usually only Lipschitz continuous) we cannot hope to balance steady solutions of system (1) up to second order of accuracy in the whole domain $(0, L)$. However, we shall prove that this property holds on a subset of $(0, L)$ except for a subset whose measure tends to zero as Δx tends to zero for a large class of stationary solutions. We will say in this case that the numerical scheme is "asymptotically well-balanced."

Based upon these observations, we introduce the following definitions.

DEFINITION 1 (second order well-balanced schemes). [illegible] (11)–(14) [illegible] $W(x)$ [illegible] (1) [illegible] x_i [illegible] $(0, L)$

The following definition was introduced in [6].

DEFINITION 2 (asymptotically well-balanced schemes). [illegible] (11)–(14) [illegible] $W(x)$ [illegible] (1) [illegible] $\{K_n\}_n$ [illegible] $[0, L]$ [illegible]

(1) $\mu((0, L) \setminus \cup_n K_n) = 0$ [illegible] μ [illegible] $\mathbf{R}$

(2) [illegible] n [illegible] $\delta_n > 0$ [illegible], $0 < \Delta x < \delta_n$ [illegible] (1) [illegible] K_n

To perform our analysis, we will assume some hypotheses on the different elements defining the numerical scheme (11)–(14). Although these are somewhat cumbersome, this will allow us to extend the analysis to a rather large class of schemes:

HYPOTHESIS 1. (a) [illegible] C^1 2 [illegible] $F_1 : [0, L] \times \mathbf{R}^N \to \mathcal{L}(\mathbf{R}^{n+1}, \mathbf{R}^n)$ [illegible] $\forall U, V \in \mathbf{R}^N \quad \forall x, y \in [0, L]$

$$F_C(x, y, U, V) = F\left(\frac{x+y}{2}, \frac{U+V}{2}\right) + F_1\left(\frac{x+y}{2}, \frac{U+V}{2}\right)\begin{pmatrix} y-x \\ V-U \end{pmatrix} + o(|x-y|^2 + |U-V|^2).$$

(b) [illegible] C^1 3 [illegible] $B_{1,L}$ [illegible] $B_{1,R} : [0, L] \times \mathbf{R}^N \to \mathcal{L}(\mathbf{R}^{n+1}, \mathcal{L}(\mathbf{R}^n, \mathbf{R}^n))$ [illegible] $\forall U, V \in \mathbf{R}^N \quad \forall x, y \in [0, L]$

$$\mathcal{B}_{L/R}(x, y, U, V) = B\left(\frac{x+y}{2}, \frac{U+V}{2}\right) + B_{1,L/R}\left(\frac{x+y}{2}, \frac{U+V}{2}\right)\begin{pmatrix} y-x \\ V-U \end{pmatrix} + o(|x-y|^2 + |U-V|^2).$$

(c) $\forall x, y, z, \in [0, L] \quad \forall U, V, W \in R^N$

$$G_C(x, y, z, U, V, W) = G(y, V) + \mathcal{O}(|y - x|^2 + |z - y|^2 + |V - U|^2 + |W - V|^2).$$

(d) [illegible] C^1 [illegible] $S_1 : [0, L] \times \mathbf{R}^N \to \mathcal{L}(\mathbf{R}^{n+1}, \mathbf{R}^n)$ [illegible] $\forall x, y \in [0, L] \quad \forall U, V, \in \mathbf{R}^N$

$$S_D(x, y, U, V) = S\left(\frac{x+y}{2}, \frac{U+V}{2}\right) + S_1\left(\frac{x+y}{2}, \frac{U+V}{2}\right)\begin{pmatrix} y-x \\ V-U \end{pmatrix} + \mathcal{O}(|x-y|^2 + |V-U|^2).$$

(e) [illegible] $\gamma \subset \mathbf{R}^{N+1}$ [illegible] M [illegible] C^2 [illegible] $\mathbf{R}^{N+1} \setminus \gamma$ [illegible] 3 [illegible] $M_1 : \mathbf{R}^{N+1} \setminus \gamma \to \mathcal{L}(\mathbf{R}^{n+1}, \mathcal{L}(\mathbf{R}^n, \mathbf{R}^n))$ [illegible] C^1 [illegible] $\mathbf{R}^{N+1} \setminus \gamma$ [illegible]

$$\widetilde{M^{-1}}(x, y, U, V) = M^{-1}\left(\frac{x+y}{2}, \frac{U+V}{2}\right) + M_1\left(\frac{x+y}{2}, \frac{U+V}{2}\right)\begin{pmatrix} y-x \\ V-U \end{pmatrix} + \mathcal{O}(|x-y|^2 + |V-U|^2)$$

[illegible] (x, U) (y, V) [illegible] $L[(x, U), (y, V)] \subset \mathbf{R}^{N+1} \setminus \gamma$

(f) [illegible] $\widetilde{\gamma} \subset \mathbf{R}^{N+1}$ [illegible] 3 [illegible] $D_1 : \mathbf{R}^{N+1} \setminus \widetilde{\gamma} \to \mathcal{L}(\mathbf{R}^{n+1}, \mathcal{L}(\mathbf{R}^n, \mathbf{R}^n))$ [illegible] C^1 [illegible] $\mathbf{R}^{N+1} \setminus \widetilde{\gamma}$ [illegible] (x, U) (y, V) [illegible] $L[(x, U), (y, V)] \subset \mathbf{R}^{N+1} \setminus \widetilde{\gamma}$

$$D(x, y, U, V) = \mathcal{D}\left(\frac{x+y}{2}, \frac{U+V}{2}\right) + D_1\left(\frac{x+y}{2}, \frac{U+V}{2}\right)\begin{pmatrix} y-x \\ V-U \end{pmatrix} + \mathcal{O}(|y-x|^2 + |V-U|^2),$$

[illegible] E F $\mathcal{L}(E, F)$ [illegible]

Hypotheses (a), (b), and (c) state that F_C, $(\mathcal{B}_L + \mathcal{B}_R)/2\Delta x$, and G_C, respectively, are second order approximations of F, $B\partial W/\partial x$, and G. Hypothesis (e) formalizes the fact that M^{-1} presents singularities at points where one of its eigenvalues vanishes. Hypothesis (f) takes into account the fact that usually matrix D will present only Lipschitz regularity when one of its eigenvalues vanishes. A typical choice is, for example, $D = |M|$.

To state our main result, we need another technical definition.

DEFINITION 3. [illegible] $W : [0, L] \to \mathbf{R}^N$ [illegible] "W [illegible] (11)–(14) [illegible] $[0, L]$ [illegible]

$$\omega(W) = \{x \in (0, L) \text{ [illegible] } W(x) \in (\mathbf{R}^N \setminus \gamma) \cap (\mathbf{R}^N \setminus \widetilde{\gamma})\},$$

$$\sigma(W) = (0, L) \setminus \omega(W).$$

Then we have the following.

THEOREM 1. [illegible] $W : [0, L] \to \mathbf{R}^N$ [illegible] C^2 [illegible] (1) [illegible]

(a) [illegible] $M(x, W)$ [illegible] (11)–(14) [illegible] (1) [illegible] W [illegible]

(b) [illegible] W $\sigma(W)$ [illegible] (11)–(14) [illegible] (1) [illegible] W.

(c) [illegible] D [illegible] M [illegible] D [illegible] M [illegible] (11)–(14) [illegible] (1) [illegible] W

The proof of this result is given in the appendix, as it essentially uses Taylor expansions and finite-dimensional compactness arguments.

We also have the following result that yields sufficient conditions for the exact calculation of stationary solutions at grid points.

THEOREM 2. [illegible] W [illegible] (1) [illegible] F_C G_C S_D $\mathcal{B}_L$ $\mathcal{B}_R$ [illegible] W [illegible]

$$\frac{F_C(x_i, x_{i+1}, W_i, W_{i+1}) - F_C(x_{i-1}, x_i, W_{i-1}, W_i)}{\Delta x} = G_C(x_{i-1}, x_i, x_{i+1}, W_{i-1}, W_i, W_{i+1})$$

$$+ \frac{1}{2}\left(\mathcal{B}_L(x_{i-1}, x_i, W_{i-1}, W_i)\frac{W_i - W_{i-1}}{\Delta x} + \mathcal{B}_R(x_i, x_{i+1}, W_i, W_{i+1})\frac{W_{i+1} - W_i}{\Delta x}\right), \tag{17}$$

$$\frac{W_{i+1} - W_i}{\Delta x} = \widetilde{M^{-1}}(x_i, x_{i+1}, W_i, W_{i+1}) S_D(x_i, x_{i+1}, W_i, W_{i+1}). \tag{18}$$

[illegible] (11)–(14) [illegible] (1) [illegible] $D(x, y, U, V)$

To prove this theorem it is enough to verify that under these hypotheses the numerical scheme is reduced to $W_i^{n+1} = W_i^n$.

These results mean that the general structure of our schemes allows us to separately balance the numerical flux and the numerical diffusion terms, in a way largely independent of the discretization parameters appearing in each of them.

In fact, the role of the matrix D is mainly to give some stability to the scheme and not to contribute to the balancing of source terms. It remains, however, to construct matrices D that satisfy Hypothesis 1(f) of Theorem 1 in order to ensure the well-balanced property for all stationary solutions. The construction of such matrices is discussed in section 4.

[illegible] 2. The definition of $\widetilde{M^{-1}}$ given by (15) satisfies Hypothesis 1(e) if the intermediate state $\widetilde{W}$ satisfies for (x, U) and (y, V) close enough

$$\widetilde{W}(U, V) = \frac{U + V}{2} + \rho\left(\frac{U + V}{2}\right)(V - U) + \mathcal{O}(|V - U|^2), \tag{19}$$

where $\rho : \mathbf{R}^N \to \mathbf{R}$ is a C^1 function. Indeed, if $L[(x, U), (y, V)] \subset \mathbf{R}^{N+1} \setminus \gamma$, as $(\frac{x+y}{2}, \widetilde{W}(U, V)) \in \mathbf{R}^{N+1} \setminus \gamma$ and M^{-1} is C^2 in $\mathbf{R}^{N+1} \setminus \gamma$, we deduce

$$\widetilde{M^{-1}}(x, y, U, V) = M^{-1}\left(\frac{x + y}{2}, \widetilde{W}(U, V)\right) = M^{-1}\left(\frac{x + y}{2}, \frac{U + V}{2}\right)$$

$$+ \partial_W(M^{-1})\left(\frac{x + y}{2}, \frac{U + V}{2}\right)\left(\widetilde{W}(U, V) - \frac{U + V}{2}\right) + \mathcal{O}\left(\left|\widetilde{W}(U, V) - \frac{U + V}{2}\right|^2\right)$$

$$= M^{-1}\left(\frac{x + y}{2}, \frac{U + V}{2}\right) + \partial_W(M^{-1})\left(\frac{x + y}{2}, \frac{U + V}{2}\right)\rho\left(\frac{U + V}{2}\right)(V - U) + \mathcal{O}(|V - U|^2).$$

We thus obtain Hypothesis 1(e).

REMARK 3. Hypothesis 1(f) is also recovered if the diffusion matrix is defined similarly to $\widetilde{M^{-1}}$:

$$D(x,y,U,V) = X((x+y)/2, \widetilde{W})\widetilde{\Lambda}_D(x,y,U,V)X^{-1}((x+y)/2, \widetilde{W}),$$

where X denotes the matrix composed by the eigenvectors of $\mathcal{D}$, and

$$\widetilde{\Lambda}_D(x,y,U,V) = \mathrm{Diag}(\widetilde{d}_j(x,y,U,V), j = 1,\dots,N)$$

with

$$\widetilde{d}_j(x,y,U,V) = \begin{cases} d_j & \text{if } L[(x,U),(y,V)] \subset \mathbf{R}^N \setminus \gamma; \\ 0 & \text{if not,} \end{cases} \tag{20}$$

where d_j denotes the eigenvalues of $\mathcal{D}((x+y)/2, \widetilde{W})$. Notice that this is the usual way of defining the diffusion matrix.

REMARK 4. Property (19) is satisfied by intermediate states of usual solvers such as Van Leer's or Roe's for shallow-water equations.

REMARK 5. Equalities (17) and (18) are discrete versions of the identities

$$\frac{\partial}{\partial x}F(x,W(x)) = G(x,W(x)) + B(W(x))\frac{\partial W}{\partial x}$$

and

$$\frac{\partial W}{\partial x}(x) = M^{-1}(x,W(x)) \cdot S(x,W(x)).$$

4. Some possible choices of matrix D. In this section we discuss some possible choices of the diffusion matrix D with a double purpose: to ensure both the asymptotically well-balanced property for all steady smooth solutions and the stability of the numerical scheme at least for the linear homogeneous case.

To start with this last purpose, we consider the linear system

$$\frac{\partial W}{\partial t} + A\frac{\partial W}{\partial x} = B\frac{\partial W}{\partial x}, \tag{21}$$

where A and B are constant matrices. We suppose that the system is hyperbolic, that is, the matrix $M = A - B$ has N real different eigenvalues $m_j \in \mathbf{R}$, $j = 1,\dots,m$.

We study under which conditions the family of schemes previously introduced is L^2 stable. To do this, we observe that these schemes can be rewritten in viscous form, so the L^2 stability condition is given from the following result (cf. Godlewsky and Raviart [12])

THEOREM 3. [illegible] $d_j \in \mathbf{R}$ $j = 1,\dots,N$ [illegible] D [illegible] D [illegible] M [illegible]

$$\left(\frac{\Delta t}{\Delta x}m_j\right)^2 \le \frac{\Delta t}{\Delta x}d_j \le 1, \quad j = 1,\dots,N, \tag{22}$$

[illegible] ^{2} [illegible]

We look for choices of D satisfying the hypothesis of the previous theorem (and therefore those of statement (c) of Theorem 1 and Hypothesis 1(f)). Some possible choices of matrix D satisfying these conditions are the following:

If $M = X\Lambda X^{-1}$ with $\Lambda = \mathrm{diag}(m_j, j = 1, \ldots, N)$, then

$$D = X\Lambda_D X^{-1} \quad \text{with} \quad \Lambda_D = \mathrm{diag}(d_j, j = 1, \ldots, N)$$

and

- $d_j = |m_j|$,
- $d_j = \frac{\Delta t}{\Delta x} m_j^2$,
- $d_j = (1 - \varphi(r))|m_j| + \varphi(r)\frac{\Delta t}{\Delta x} m_j^2$, where $\varphi(r)$ is a flux-limiter (cf. [12], [15]).

Moreover, (22) gives the corresponding CFL condition to set the time step in terms of the solution and the space step.

. . . . 6. We observe that for previous definitions, the singularities of matrix $\widetilde{M^{-1}}$ and D are located at same points, so the hypersurfaces γ and $\widetilde{\gamma}$ coincide. Moreover, as matrices M and D have the same eigenvectors, we obtain

$$\widetilde{M^{-1}}(x, y, U, V) D(x, y, U, V) = X((x + y)/2, \widetilde{W})\, \Lambda(x, y, U, V)\, X^{-1}((x + y)/2, \widetilde{W})$$

with $\Lambda = \mathrm{Diag}(\widetilde{\lambda_j^{-1}}\, \widetilde{d}_j, j = 1, \ldots, N)$, where by (16) and (20) we have

$$\widetilde{\lambda_j^{-1}}\widetilde{d}_j(x, y, U, V) = \begin{cases} \lambda_j^{-1} d_j & \text{if } L[(x, U), (y, V)] \subset \mathbf{R}^N \setminus \gamma; \\ 0 & \text{if not.} \end{cases} \tag{23}$$

Finally, we also observe that in the last case we obtain a zero in the jth diagonal entry because $\widetilde{\lambda_j^{-1}} = 0$, and $\widetilde{d}_j = 0$. In practice, in this case we define directly $\widetilde{M^{-1}D}$ by (23).

5. Application to the two-layer shallow-water system. In this section we apply the general discretization technique previously introduced to the numerical solution of the one-dimensional two-layer shallow-water system for channels with arbitrary cross-sections. We start by describing the model equations. Next, we propose a family of numerical schemes by defining the different components of the general scheme (11)–(14) in such a way that Hypotheses 1(a)–(f) are satisfied. We also discuss some possible choices for the diffusion matrix D.

5.1. Equations. Let us consider the flow of a stratified fluid along an open channel. The channel is supposed to have a straight axis and be symmetric with respect to a vertical plane passing through its axis. The channel shape of cross-sections is given by the function $\sigma(x, z)$ and the bottom is given by the function $z_b(x)$. The fluid is assumed to be composed of two shallow layers of immiscible fluids of constant density, ρ_1 and ρ_2. Moreover, we assume that the flow is one-dimensional, i.e., at every layer the velocities $v_i(x, t)$, $i = 1, 2$, are uniform over the cross-section, and the thickness depends only on the x coordinate and the time. In the following sections, index 1 makes reference to the upper layer and index 2 to the lower one (see Figure 1).

Let r be the ratio of densities $r = \rho_1/\rho_2$. Let $Q_i(x, t) = v_i(x, t)A_i(x, t)$ be the discharge of the ith layer, with $A_i(x, t)$ the wetted cross-section of the ith layer at position x and time t. The thickness of layer i is given by $h_i(x, t)$. Therefore, A_i, $\sigma(x, z)$, h_i, and z_b are related through the equations

$$A_1 = \int_{z_b+h_2}^{z_b+h_2+h_1} \sigma(x, z)dz, \quad A_2 = \int_{z_b}^{z_b+h_2} \sigma(x, z)dz.$$

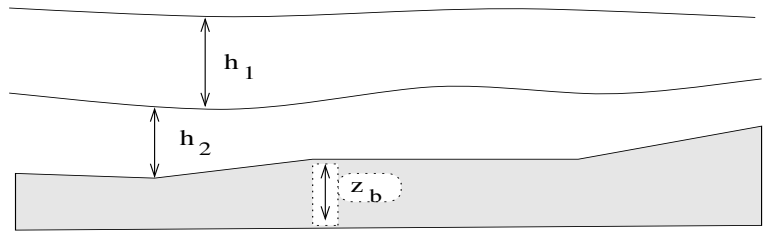

FIG. 1. *Sketch of a bilayer fluid.*

In [3] a PDE system modeling such a flow was deduced by imposing the mass and momentum conservations principles. Here, we consider the reformulation introduced in [4]:

$$\frac{\partial \mathrm{W}}{\partial t}(x,t) + \frac{\partial \mathrm{F}}{\partial x}(\varsigma(x,t), \mathrm{W}(x,t)) = G(x, \varsigma(x,t), \sigma^b(x), \mathrm{W}(x,t)) + B(\varsigma(x,t), \mathrm{W}(x,t))\frac{\partial \mathrm{W}}{\partial x} \quad \forall x \in (0,L),\ \ t \in (0,T), \tag{24}$$

where the unknowns are

$$\mathrm{W}(x,t) = \begin{bmatrix} W_1(x,t) \\ W_2(x,t) \end{bmatrix}, \quad W_j = \begin{bmatrix} A_j \\ Q_j \end{bmatrix}, \quad j = 1,2,$$

and $\varsigma = \left[\begin{smallmatrix} \sigma_1 \\ \sigma_2 \end{smallmatrix}\right]$, where σ_1 and σ_2 are defined by

$$\sigma_1(x,t) = \sigma(x, z_b(x) + h_1(x,t) + h_2(x,t)),$$

$$\frac{1}{\sigma_2(x,t)} = \frac{1-r}{\sigma_3(x,t)} + \frac{r}{\sigma_1(x,t)},$$

with

$$\sigma_3(x,t) = \sigma(x, z_b(x) + h_2(x,t)).$$

We also define

$$\sigma^b(x) = \sigma(x, z_b(x)).$$

The flux function, the coupling (nonconservative) terms, and the source terms are given, respectively, by

$$\mathrm{F}(\varsigma, \mathrm{W}) = \begin{bmatrix} F_1(\sigma_1, W_1) \\ F_2(\sigma_2, W_2) \end{bmatrix}, \quad F_j(\sigma_j, W_j) = \begin{bmatrix} Q_j \\ \dfrac{Q_j^2}{A_j} + \dfrac{g}{2\sigma_j} A_j^2 \end{bmatrix}, \quad j = 1,2,$$

$$B(\varsigma, \mathrm{W}) = \begin{bmatrix} 0 & B_1(\varsigma, W_1) \\ B_2(\varsigma, W_2) & 0 \end{bmatrix},$$

with

$$B_1(\varsigma, W_1) = \begin{bmatrix} 0 & 0 \\ -g\dfrac{1}{\sigma_1} A_1 & 0 \end{bmatrix}, \quad B_2(\varsigma, W_2) = \begin{bmatrix} 0 & 0 \\ -g\dfrac{r}{\sigma_1} A_2 & 0 \end{bmatrix},$$

and

$$G(x,\varsigma,\sigma^b,\mathrm{W}) = \mathrm{V}(\varsigma,\mathrm{W}) + \mathbf{S}(x,\varsigma,\sigma^b,\mathrm{W}),$$

with

$$\mathrm{V}(\varsigma,\mathrm{W}) = \begin{bmatrix} V_1(\sigma_1,W_1) \\ V_2(\sigma_2,W_2) \end{bmatrix}, \quad V_j(\sigma_j,W_j) = \begin{bmatrix} 0 \\ \dfrac{g}{2}\left(\dfrac{1}{\sigma_j}\right)_x A_j^2 \end{bmatrix}, \quad j=1,2.$$

We denote by $\mathbf{S}$ the source terms due to the variations of the geometry (depth and cross-section variations). If we define $\omega = z_b + h_1 + h_2$ and $\omega_r = z_b + h_2 + r\,h_1$, then $\mathbf{S}$ can be written

$$\mathbf{S} = \begin{pmatrix} 0 \\ g\dfrac{A_1}{\sigma_1}\dfrac{\partial}{\partial x}(A_1 + A_2 - \omega) \\ 0 \\ gA_2\dfrac{1}{\sigma_2}\dfrac{\partial A_2}{\partial x} + gA_2\dfrac{r}{\sigma_1}\dfrac{\partial A_1}{\partial x} - gA_2\dfrac{\partial \omega_r}{\partial x} \end{pmatrix}. \tag{25}$$

In order to easily describe the discretization of the terms V_j, we rewrite them as follows:

$$V_j(\sigma_j,W_j) = \begin{bmatrix} 0 \\ \dfrac{g}{2}\left(\dfrac{A_j^2}{\sigma_j}\right)_x - g\dfrac{A_j}{\sigma_j}(A_j)_x \end{bmatrix}, \quad j=1,2.$$

These terms appear due to the dependence of the flux F on the spatial variable x. In fact, $V = \partial_\varsigma F\ \partial_x \varsigma$. Therefore

$$G(x,\varsigma,\sigma^b,\mathrm{W}) - \mathrm{F}_\varsigma(\varsigma,\mathrm{W})\,\partial_x\varsigma(x) = \mathbf{S}(x,\varsigma,\sigma^b,\mathrm{W}).$$

It is easy to verify that this system can be written in matrix form as follows:

$$\frac{\partial W}{\partial t} + \mathcal{A}(\varsigma,\mathrm{W})\frac{\partial W}{\partial x} = \mathbf{S}(x,\varsigma,\sigma^b,\mathrm{W}), \tag{26}$$

where $\mathcal{A}$ is the 4×4 matrix whose expression is given by

$$\mathcal{A}(\sigma,\mathrm{W}) = J(\varsigma,\mathrm{W}) - B(\varsigma,\mathrm{W}),$$

with

$$J(\varsigma,\mathrm{W}) = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -\dfrac{Q_1^2}{A_1^2} + \dfrac{g}{\sigma_1}A_1 & 2\dfrac{Q_1}{A_1} & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -\dfrac{Q_2^2}{A_2^2} + \dfrac{g}{\sigma_2}A_2 & 2\dfrac{Q_2}{A_2} \end{bmatrix}.$$

The eigenvalues of $\mathcal{A}$ can be classified in two external and two internal eigenvalues. The external eigenvalues, $\lambda^{e\pm}$, are related to the propagation speed of barotropic

perturbations and the internal ones, $\lambda^{i\pm}$, to the propagation of baroclinic perturbations. In the case $r \cong 1$, first order approximations of the eigenvalues were given in [20]. In most of the applications to geophysical flows, one has $\lambda^{e-} < 0$ and $\lambda^{e+} > 0$. Therefore, the transitions depend on the sign of the internal eigenvalues: the flow is said to be [illegible] if the sign of the internal eigenvalues differs, [illegible] if one of them takes the value zero; otherwise the flow is called [illegible]. It can be deduced from the expression of the matrix $\mathcal{A}$ that critical, supercritical, and subcritical sections can be characterized by $G^2 = 1$, $G^2 > 1$, $G^2 < 1$, respectively, where

$$G^2 = F_1^2 + F_2^2 - (1-r)\frac{\sigma_2}{\sigma_3}F_1^2F_2^2 \tag{27}$$

and

$$F_1^2 = \frac{v_1^2}{g'\left(\frac{\sigma_2}{\sigma_3}\right)\left(\frac{A_1}{\sigma_1}\right)}, \quad F_2^2 = \frac{v_2^2}{g'\left(\frac{A_2}{\sigma_3}\right)}. \tag{28}$$

In these definitions, $g' = g(1-r)$ is the reduced gravity, and G and F_i, $i = 1, 2$, are the appropriate definitions for this case of the [illegible] and the [illegible], respectively.

The internal eigenvalues may become complex corresponding to the development of shear instabilities. Nevertheless, in the description of the numerical schemes only the case in which the matrix $\mathcal{A}$ has 4 different real eigenvalues is considered, i.e., the flow is supposed to be stable and the system strictly hyperbolic.

5.2. Discretization of the system. In this subsection we introduce a one-parameter numerical scheme to solve system (24), with the structure (11)–(14). In order to obtain asymptotically well-balanced schemes, we must define the different components of the numerical scheme to fit the general Hypotheses 1(a)–(f).

We will use the following notation:

$$\mathrm{W}_{i+\alpha} = (1-\alpha)\mathrm{W}_i + \alpha\mathrm{W}_{i+1}, \quad \alpha \in [0,1].$$

We also consider an analogous notation for ς:

$$\varsigma_{i+\alpha} = \begin{bmatrix} \sigma_{1,i+\alpha} \\ \sigma_{2,i+\alpha} \end{bmatrix},$$

with

$$\sigma_{1,i+\alpha} = (1-\alpha)\sigma_{1,i} + \alpha\sigma_{1,i+1}, \quad \sigma_{3,i+\alpha} = (1-\alpha)\sigma_{3,i} + \alpha\sigma_{3,i+1}$$

and $\sigma_{2,i+\alpha}$ defined by

$$\frac{1}{\sigma_{2,i+\alpha}} = \frac{1-r}{\sigma_{3,i+\alpha}} + \frac{r}{\sigma_{1,i+\alpha}}.$$

With this notation, following [7] we define the centered approximation of the flux function by

$$F_C(x_i, x_{i+1}, W_i, W_{i+1}) = \frac{F(\varsigma_{i+\alpha}, \mathrm{W}_{i+\alpha}) + F(\varsigma_{i+1-\alpha}, \mathrm{W}_{i+1-\alpha})}{2}, \tag{29}$$

with $\alpha \in [0,1]$. This approximation satisfies Hypothesis 1(a).

We propose to use this approximation of F_C due to our former experience with a similar one-parameter family of numerical schemes for solving the one-layer shallow-water system. In this case, a good choice of the parameter α allows us to correctly approximate solutions including sonic rarefaction waves without the use of entropy corrections. In particular, in [7] the value $\alpha = 1/8$ is proposed.

Matrix $\widetilde{M^{-1}}$ is defined by (15). In practice we set $\widetilde{\lambda_j^{-1}} = 0$ if the absolute value of λ_j is smaller than a certain ϵ nearly to zero. The decentered source terms $\mathcal{B}_L$ and $\mathcal{B}_R$ are given by

(30)
$$\mathcal{B}_L(x_{i-1}, x_i, W_{i-1}, W_i) = \alpha \mathbf{B}\left(\varsigma_{i-\alpha/2}, \mathrm{W}_{i-\alpha/2}\right) + (1-\alpha)\mathbf{B}\left(\varsigma_{i-(1-\alpha)/2}, \mathrm{W}_{i-(1-\alpha)/2}\right)$$

and

(31)
$$\mathcal{B}_R(x_i, x_{i+1}, W_i, W_{i+1}) = \alpha \mathbf{B}\left(\varsigma_{i+\alpha/2}, \mathrm{W}_{i+\alpha/2}\right) + (1-\alpha)\mathbf{B}\left(\varsigma_{i+(1-\alpha)/2}, \mathrm{W}_{i+(1-\alpha)/2}\right).$$

To complete the definition of ϕ_L^S and ϕ_R^S we must define a discretization of S in $x = x_{i+1/2}$, $S_D(x_i, x_{i+1}, W_i, W_{i+1})$, satisfying Hypothesis 1(c). We propose the following one:

(32)
$$\mathcal{S}_D(x_i, x_{i+1}, W_i, W_{i+1}) = \frac{1}{\Delta x}\begin{pmatrix} 0 \\ g\dfrac{A_{1,i+1/2}}{\sigma_{1,i+1/2}}(A_{1,i+1} + A_{2,i+1} - \omega_{i+1} - A_{1,i} - A_{2,i} + \omega_i) \\ 0 \\ g\dfrac{A_{2,i+1/2}}{\sigma_{2,i+1/2}}(A_{2,i+1} - A_{2,i}) + gr\dfrac{A_{2,i+1/2}}{\sigma_{1,i+1/2}}(A_{1,i+1} - A_{1,i}) \\ -gA_{2,i+1/2}(\omega_{r,i+1} - \omega_{r,i}) \end{pmatrix}.$$

We define a centered discretization of G in $x = x_i$, G_C:

$$G_C = \mathbf{S}_i + V_i,$$

where $\mathbf{S}_i$ and V_i are centered approximations of $\mathbf{S}$ and V at $x = x_i$, respectively. They are constructed as follows:

$$\mathbf{S}_i = \frac{1}{2}\Big(\mathbf{S}_{i,L} + \mathbf{S}_{i,R}\Big), \tag{33}$$

where, if we denote by $[\cdot]_j$ the jth component of the vector$[\cdot]$, then

$$[\mathcal{S}_{i,L}]_1 = 0, \tag{34}$$

$$\Delta x[\mathcal{S}_{i,L}]_2 = g\frac{A_{1,i-\alpha/2}}{\sigma_{1,i-\alpha/2}}(A_{1,i} + A_{2,i} - \omega_i - A_{1,i-\alpha} - A_{2,i-\alpha} + \omega_{i-\alpha})$$

$$+ g\frac{A_{1,i-(1-\alpha)/2}}{\sigma_{1,i-(1-\alpha)/2}}(A_{1,i} + A_{2,i} - \omega_i - A_{1,i-1+\alpha} - A_{2,i-1+\alpha} + \omega_{i-1+\alpha}), \tag{35}$$

$$[\mathcal{S}_{i,L}]_3 = 0, \tag{36}$$

and

$$\Delta x[\mathcal{S}_{i,L}]_4 = g\frac{A_{2,i-\alpha/2}}{\sigma_{2,i-\alpha 1/2}}(A_{2,i}-A_{2,i-\alpha}) + g\,r\frac{A_{2,i-\alpha/2}}{\sigma_{1,i-\alpha/2}}(A_{1,i}-A_{1,i-\alpha})$$
$$- gA_{2,i-\alpha/2}(\omega_{r,i}-\omega_{r,i-\alpha}) + g\frac{A_{2,i-(1-\alpha)/2}}{\sigma_{2,i-(1-\alpha)/2}}(A_{2,i}-A_{2,i-1+\alpha})$$
$$+ g\,r\frac{A_{2,i-(1-\alpha)/2}}{\sigma_{1,i-(1-\alpha)/2}}(A_{1,i}-A_{1,i-1+\alpha}) - gA_{2,i-(1-\alpha)/2}(\omega_{r,i}-\omega_{r,i-1+\alpha}). \tag{37}$$

$\mathcal{S}_{i,R}$ is given by

$$[\mathcal{S}_{i,R}]_1 = 0, \tag{38}$$

$$\Delta x[\mathcal{S}_{i,R}]_2 = g\frac{A_{1,i+\alpha/2}}{\sigma_{1,i+\alpha/2}}(A_{1,i+\alpha}+A_{2,i+\alpha}-\omega_{i+\alpha}-A_{1,i}-A_{2,i}+\omega_i)$$
$$+ g\frac{A_{1,i-(1-\alpha)/2}}{\sigma_{1,i-(1-\alpha)/2}}(A_{1,i+1-\alpha}+A_{2,i+1-\alpha}-\omega_{i+1-\alpha}-A_{1,i}-A_{2,i}+\omega_i), \tag{39}$$

$$[\mathcal{S}_{i,R}]_3 = 0, \tag{40}$$

and

$$\Delta x[\mathcal{S}_{i,R}]_4 = g\frac{A_{2,i+\alpha/2}}{\sigma_{2,i+\alpha/2}}(A_{2,i+\alpha}-A_{2,i}) + g\,r\frac{A_{2,i-\alpha/2}}{\sigma_{1,i-\alpha/2}}(A_{1,i+\alpha}-A_{1,i})$$
$$- gA_{2,i-\alpha/2}(\omega_{r,i+\alpha}-\omega_i) + g\frac{A_{2,i+(1-\alpha)/2}}{\sigma_{2,i+(1-\alpha)/2}}(A_{2,i+1-\alpha}-A_{2,i})$$
$$+ g\,r\frac{A_{2,i+(1-\alpha)/2}}{\sigma_{1,i+(1-\alpha)/2}}(A_{1,i+1-\alpha}-A_{1,i}) - gA_{2,i+(1-\alpha)/2}(\omega_{r,i+1-\alpha}-\omega_{r,i}). \tag{41}$$

The centered discretization of the term V at point $x = x_i$, V_i, is given by

$$V_i = \begin{bmatrix} \mathcal{V}_1 \\ \mathcal{V}_2 \end{bmatrix}, \tag{42}$$

with

$$[\mathcal{V}_j]_1 = 0 \quad \text{for} \quad j = 1,2 \tag{43}$$

and

$$2\Delta x[\mathcal{V}_j]_2 = g\frac{A_{j,i+\alpha}A_{j,i+\alpha}}{2\sigma_{j,i+\alpha}} - g\frac{A_{j,i-1+\alpha}A_{j,i-1+\alpha}}{2\sigma_{j,i-1+\alpha}}$$
$$+ g\frac{A_{j,i+1-\alpha}A_{j,i+1-\alpha}}{2\sigma_{j,i+1-\alpha}} - g\frac{A_{j,i-\alpha}A_{j,i-\alpha}}{2\sigma_{j,i-\alpha}}$$
$$- g\frac{A_{j,i+\alpha/2}}{\sigma_{j,i+\alpha/2}}(A_{j,i+\alpha}-A_{j,i}) - g\frac{A_{j,i+(1-\alpha)/2}}{\sigma_{j,i+(1-\alpha)/2}}(A_{j,i+1-\alpha}-A_i)$$
$$- g\frac{A_{j,i-\alpha/2}}{\sigma_{j,i-\alpha/2}}(A_i-A_{j,i-\alpha}) - g\frac{A_{j,i-(1-\alpha)/2}}{\sigma_{j,i-(1-\alpha)/2}}(A_{j,i}-A_{j,i-1+\alpha}) \tag{44}$$

for $j = 1,2$.

It remains to define a matrix D satisfying Hypothesis 1(f). This may be done as indicated in section 4. In all the numerical tests discussed in section 6, we have chosen $D = |M|$, where M is the Roe-type matrix introduced in [4]. With this choice, the numerical scheme proposed in [4] is the particular case of the previous one corresponding to $\alpha = 0$.

5.3. Balance properties. As the different components defining the numerical scheme verify Hypotheses 1(a)–(f), we can apply Theorem 1 and conclude the following result.

THEOREM 4. (1) [illegible] D [illegible] 4 [illegible] (11)–(14), (29)–(44) [illegible] (24) [illegible]

(2) [illegible] D [illegible] $W(x)$ [illegible] $M(x, W(x))$ [illegible] $\forall x \in [0, L]$ [illegible] $M(x, W(x))$ [illegible] (24) [illegible] $W(x)$

We can also apply Theorem 2 to the stationary solutions corresponding to water at rest:

$$\overline{W} = \begin{bmatrix} A_1 \\ 0 \\ A_2 \\ 0 \end{bmatrix}, \quad \text{with} \quad A_1 = \int_{\overline{h}_2}^{\overline{h}_2+\overline{h}_1} \sigma(x,z)dz, \quad A_2 = \int_{z_b}^{\overline{h}_2} \sigma(x,z)dz, \tag{45}$$

with $\overline{h}_1$ constant and $\overline{h}_2 = h_2 + z_b(x)$ with $\overline{h}_2$ constant. In this solution the free surface of the fluid, given by $\overline{h}_1 + \overline{h}_2 + z_b$, is constant, as well as the interface given by $\overline{h}_2 + z_b$.

We have the following result.

THEOREM 5. [illegible] (29)–(44) [illegible] (24) [illegible] (45) [illegible] α [illegible] D

To prove this theorem it is enough to verify conditions (17) and (18) on the stationary solution (45).

[illegible] 7. As we previously mentioned, solving the one-layer shallow-water system with centered numerical fluxes F_C as (29) with a good choice of the parameter α ($\alpha = 1/8$) allows us to correctly approximate sonic rarefaction waves without the need for entropy-correction techniques. Also, in the case of stationary shocks the best choice is given by $\alpha = 0$. This suggests that a better method can be obtained if the parameter α is replaced by a function $\alpha(x)$ taking the value 0 at intercells where a stationary shock develops and 1/8 elsewhere.

Taking in mind that transitions depend on the sign of the internal eigenvalues, a suitable approximation $\alpha_{j+1/2}$ to $\alpha(x_{j+1/2})$ can be given by

$$\begin{aligned} &\alpha_{j+1/2} = \min(\alpha^-_{j+1/2}, \alpha^+_{j+1/2}), \quad \text{with} \\ &\alpha^\pm_{j+1/2} = \begin{cases} \bar{\alpha} & \text{if } \operatorname{sgn}(\lambda^{i\pm}_j) = \operatorname{sgn}(\lambda^{i\pm}_{j+1}), \\ \bar{\alpha}(1 - 0.5(1 + \operatorname{sgn}(\lambda^{i\pm}_j - \lambda^{i\pm}_{j+1}))) & \text{otherwise,} \end{cases} \end{aligned} \tag{46}$$

where $\bar{\alpha}$ is a constant value ($\bar{\alpha} = 1/8$) and $\lambda^{i\pm}_j$ are the internal eigenvalues of the matrix $M(x_j, W_j)$.

In most applications, this numerically defined function $\alpha(x)$ will be constant in all the domain but for a set whose measure tends to zero (a bounded number of cells), so that the balance properties are preserved.

6. Numerical tests. In this section, some experiments illustrating the properties of the proposed family of numerical schemes are presented. The purposes of these experiments are mainly to validate the numerical schemes and to investigate the

influence of the parameter α when the numerical viscosity vanishes. For this reason in all our tests we have chosen a unique numerical diffusion matrix D, given by the simplest choice in section 4, i.e., $D = |M|$.

The first experiment has been designed to verify whether the still-water solution is exactly computed in practice, even for very irregular geometries. The second one provides a numerical study of the order of the numerical scheme. This study confirms the theoretical results. In section 6.3 the influence of the parameter α in smooth transitions is investigated: we observe that any positive value yields good results. Finally, the last test has been designed to analyze the influence of the parameter α for a nonsmooth solution. In this case we see that the best results are obtained if the constant parameter α is replaced by the function α defined in Remark 6.

6.1. Water at rest in a channel with irregular geometry. In this example, a numerical test is presented to verify how accurately the solution (45), in practice, is computed for a channel with very irregular geometry. To do this, we have considered a 4-meter long channel with rectangular cross-section and for which depth and breadth were randomly generated. The numerical scheme was applied for the values of the parameter $\alpha = 0$, $1/8$, $1/4$, and $3/8$ (only the values for $\alpha = 1/8$ are shown, because all results are very similar), taking as initial condition a steady solution representing water at rest. The CFL parameter is set to 0.95 and $\Delta x = 0.05$.

Figures 2(a) and 2(b) show the bottom topography and the channel breadth, respectively. Figures 2(c) and 2(d) depict the free surface and the water interface at the initial time and after 15 seconds of simulation. Finally, Figures 2(e) and 2(f) show the value of the discharge at each layer at the initial state and after 15 seconds of simulation, respectively. As predicted in Theorem 5, for any value of the parameter, the water elevation at the free surface and the interface as well as the discharges at each layer are accurately computed: only round-off errors are present, and they do not grow with time.

6.2. Well-balancing test. In this section, we test the order of the numerical scheme when it is applied to approach a stationary solution of the two-layer shallow-water system with constant breadth function. The regular stationary solutions of this system satisfy the following:

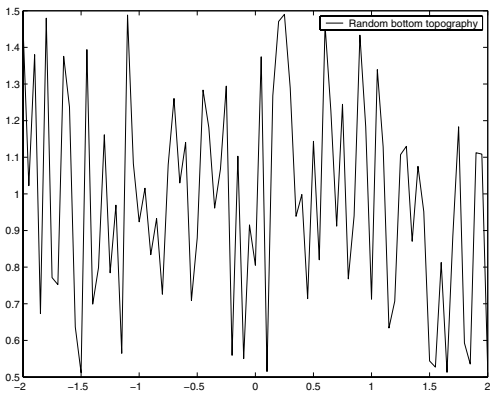
$$\begin{cases} Q_1 = \text{constant}, \\ \dfrac{v_1^2}{2} - \dfrac{v_2^2}{2} + g' h_1 = \text{constant}, \\ Q_2 = \text{constant}, \\ \dfrac{v_1^2}{2} + g(h_1 + h_2 + z_b) = \text{constant}, \end{cases} \tag{47}$$

where $g' = (1 - r)g$ is the reduced gravity.

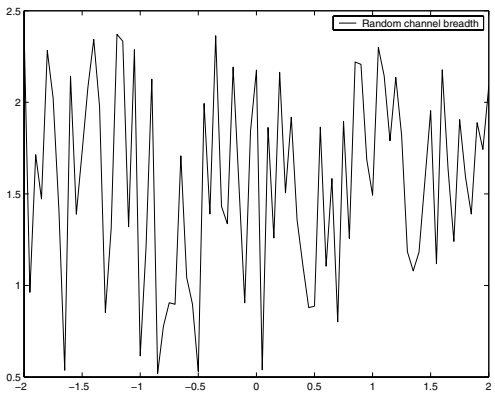
In this numerical test, we consider $\sigma(x, z) = 1.0$, $r = 0.98$, and the depth function

$$z_b(x) = 0.5e^{-x^2} - 2.0, \quad x \in [-3, 3].$$

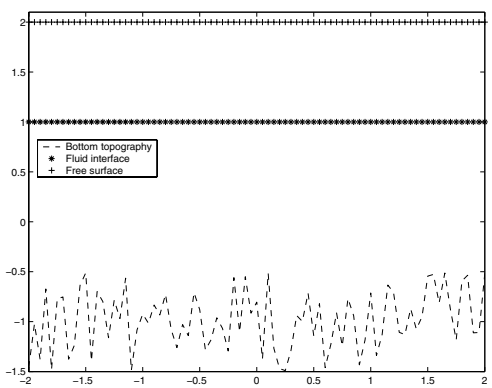
In order to obtain a particular stationary solution, we impose first its values at $x = -3$: $h_1(-3, 0) = 0.5$, $h_2(-3, 0) = z_b(-3) + 1.5$, $Q_1(-3, 0) = 0.15$, and $Q_2(-3, 0) = -0.15$. From these values, we compute the constants in (47). Once the constants are known,



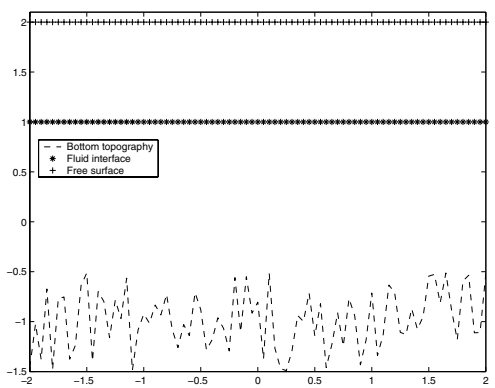
(a) Channel bottom topography (random).



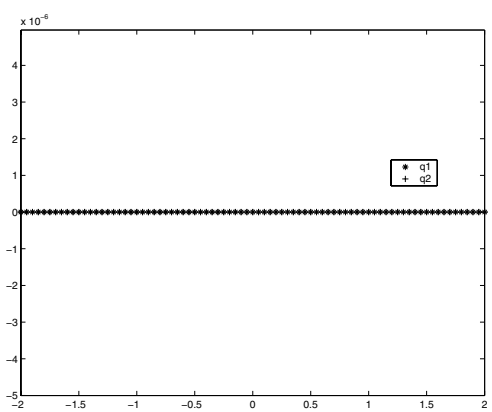
(b) Channel breadth (random).



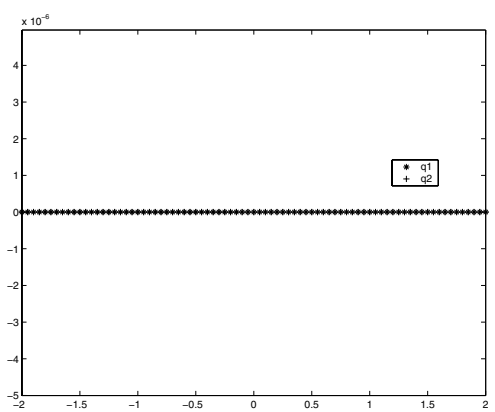
(c) Free surface and interface at initial state.



(d) Free surface and interface after 15s of simulation.



(e) Discharge at each layer at initial state.



(f) Discharge at each layer after 15s of simulation.

FIG. 2. *Water at rest in an irregular channel ($\alpha = 1/8$).*

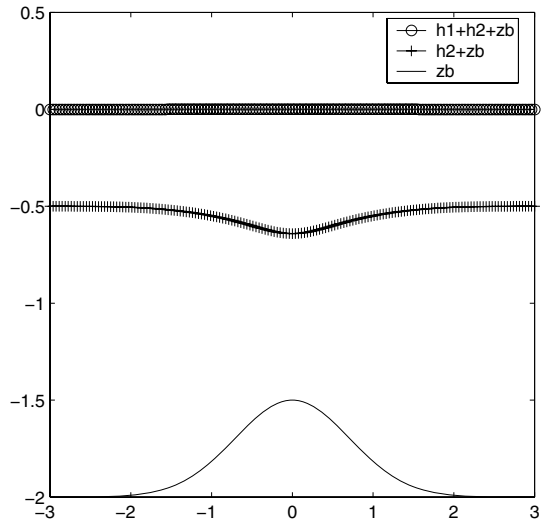


FIG. 3. *Stationary solution in the test case of section* 6.2. *Elevations* $\eta_1 = h_1 + h_2 + z_b(x)$, $\eta_2 = h_2 + z_b(x)$ *and bottom topography* $z_b(x)$.

the values of the solution at any point are obtained by solving (47). Figure 3 shows the computed elevations $\eta_1(x) = h_1(x) + h_2(x) + z_b(x)$ and $\eta_2(x) = h_2(x) + z_b(x)$ corresponding to this particular stationary solution.

In the numerical experiment, this stationary solution is taken as the initial condition. As the stationary solution chosen does not correspond to water at rest, the numerical scheme should be second order accurate.

We have applied the numerical scheme for different values of the parameter $\alpha = 0$, 1/8, 1/4, and 3/8 (only the values for $\alpha = 1/8$ are shown, because all results are very similar). The CFL coefficient has been taken as 0.9. The results obtained for $\alpha = 1/8$ are shown in Tables 1 and 2. As expected, the order obtained is 2.

6.3. Rectangular channel with a bump. The validation of numerical schemes for solving the two-layer shallow-water system with transcritical solutions is not a simple task, as exact solutions with smooth transitions cannot be easily obtained for this system. Nevertheless, Farmer and Armi introduced in [9], in the context of the study of exchange flows through channels, an asymptotic technique to obtain steady solutions for channels with simplified geometries. In this particular case, they consider a channel of uniform width with a sill on the floor, separating two broad and deep reservoirs.

Let us first briefly recall the main aspects of the theory developed by these authors. In their works, smooth steady state solutions are studied. The equations of the model are obtained by replacing the fourth equation in (47) by the ,,, , assumption:

$$h_1 + h_2 + z_b = \text{constant}. \tag{48}$$

The equations are first written in nondimensional form using some dimensionless variables Q_i', h_i', z_b' that are such that $h_1' + h_2' + z_b' = 1$ at the section of minimal depth. Then all the variables are expressed in terms of the internal Froude numbers, $F_i = v_i/\sqrt{(g' h_i)}$, $i = 1, 2$. Using the approximation $r = 1$ the following 2×2 nonlinear

system is obtained from the second equation of (47) with the assumption (48):

$$F_1^{-\frac{2}{3}} + \frac{1}{2}F_1^{\frac{4}{3}} - \frac{1}{2}q_r^{-\frac{2}{3}}F_2^{\frac{4}{3}} = \Delta H'(Q_1')^{-\frac{2}{3}}, \tag{49}$$

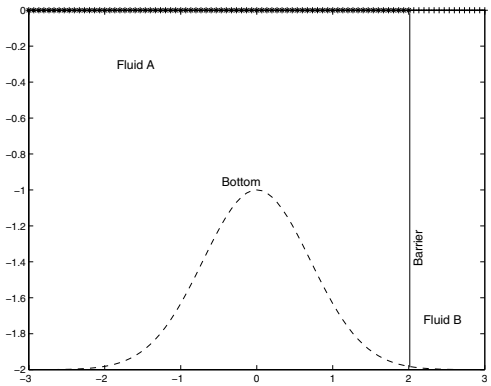
$$F_1^{-\frac{2}{3}} + q_r^{-\frac{2}{3}}F_2^{-\frac{2}{3}} = \left[\frac{Q_1'}{(1-z_b')^{\frac{3}{2}}}\right]^{-\frac{2}{3}}, \tag{50}$$

where $\Delta H'$ is a constant corresponding to the dimensionless energy difference between the two layers and $q_r = Q_1/Q_2$. Here, only the case $|q_r| = 1$ will be considered.

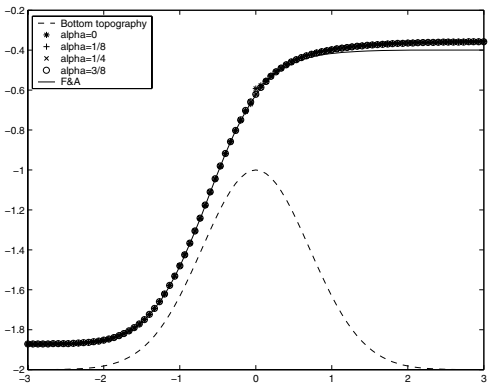
The solutions of the equations can be identified with the family of curves in the (F_1^2, F_2^2)-plane defined by (49). These curves have been plotted in detail in [9].

If the reservoirs are sufficiently deep, except in the neighborhood of the sill, the speed of the thicker layer is negligible away from the influence of the sill. In this case, the Froude numbers F_1 and F_2 have to be near zero far from the sill at the reservoir corresponding to water of densities ρ_1 and ρ_2, respectively. Observe that there is only one family of curves for which F_1 and F_2 are close to zero at the reservoir corresponding to water densities ρ_1 and ρ_2, respectively. Among the curves of this family, there is one for which the value of the exchanged flow Q_1' is maximal. This curve corresponds to $\Delta H' = 1.5$ and is called the [illegible] : it represents the steady state limit that occurs when the fluids are free to move in opposite directions across the sill. If the reservoir corresponding to water of density ρ_1 is placed to the left, this solution is critical at the section of minimal depth, subcritical to the right of this section, and supercritical to the left. If the condition $F_2 = 0$ is imposed at the exit section of the channel (that is, if the depth of the reservoir to the left is assumed to be infinity), the flow is critical again at this section.

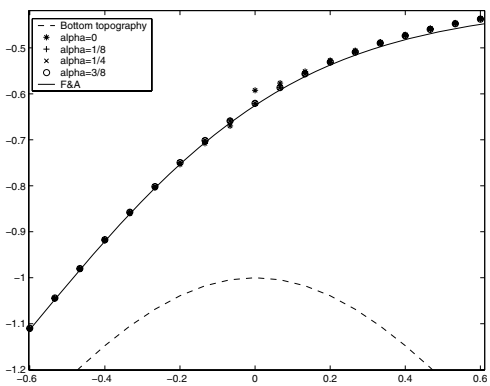
In the experiment, we consider a rectangular channel 1 meter wide and 6 meters long. Its bottom topography is defined by the function $z_b(x) = \exp(-x^2) - 2$, where $x \in [-3, 3]$. The ratio between fluxes is set to 1 and the ratio between densities is set



(a) Initial condition.



(b) Interface at the stationary state and comparison with F&A interface.



(c) Interface at the stationary state and comparison with F&A interface (zoom).

FIG. 4. *Maximal exchange flow through a rectangular channel with a single bump. Initial condition and comparison with F&A stationary interface* ($\bar{\alpha} = 0,\ 1/8,\ 1/4,\ 3/8$).

to $r = \rho_1/\rho_2 = 0.98$. In order to reproduce the maximal two-way exchange with the numerical model, we solve the classical [illegible]. This problem consists in taking as initial state the two fluids separated by a vertical "artificial barrier" that, in this case, is located at $x = 2$ (see Figure 4(a)). This barrier is dropped out at time $t = 0$ and the fluids are left to evolve until a stationary state is reached (see Figure 4(b)). The CFL parameter is set to 0.9 and $\Delta x = 1/15$.

The boundary conditions in this test have been designed to simulate the presence of the infinite reservoirs at both ends of the channel and the fact that $q_r = 1$: the two layers must be allowed to go out of the channel as freely as possible, with the only constraint $Q_1 = -Q_2$. To do this, we have modified the usual numerical treatment based on the introduction of two ghost cells and the duplication of states, which is used very often in practice to simulate open boundaries. The idea is as follows: let us suppose that, at the nth time iteration, the approximation obtained at the first cell is W_1^n. If the corresponding value of Q_2, $Q_{2,1}^n$, is equal to zero, the lower layer has not

yet reached the left boundary. In this case, the state is duplicated at the ghost cell,

$$\mathrm{W}_0^n = \mathrm{W}_1^n,$$

and the first cell is treated as an internal one during the calculation of the approximations at time t^{n+1}. If, instead, $Q_{2,1}^n$ is not equal to zero, then the state at the ghost cell is modified so that the relation $Q_1 = -Q_2$ holds. More precisely, we define

$$\mathrm{W}_0^n = \mathrm{W}_1^n - \frac{\Delta Q_1^n}{|Q_{1,1}^n| + |Q_{2,1}^n|} \begin{bmatrix} 0 \\ |Q_{1,1}^n| \\ 0 \\ |Q_{2,1}^n| \end{bmatrix},$$

with

$$\Delta Q_1^n = Q_{1,1}^n + Q_{2,1}^n.$$

Again, the first cell is treated as an internal one. A similar treatment is performed at the right boundary.

During the computations, complex eigenvalues appear. Following [10], when the appearance of complex eigenvalues is detected, a linear friction term is added to the momentum equations of both layers. Concretely, a source term of the form

$$-CQ_k, \quad k = 1, 2,$$

is added which is intended to simulate the loss of momentum induced by the instabilities in real flows. The local friction coefficient C is large enough to make the numerical scheme linearly stable. More precisely, we take $C = (\sqrt{1 + 2|m_2|\Delta t/\Delta x} - 1)/\Delta t$, where m_2 is the complex part of the eigenvalue. In [10] it has been shown that this choice ensures the L^2 stability in a simplified case.

Figures 4(b) and 4(c) show the interface at the steady state reached for the different values of the parameter $\alpha = 0$, 1/8, 1/4, and 3/8. These steady states are compared with the interface corresponding to the maximal two-way exchange obtained in [9] (in what follows, this solution will be called the F&A solution, after Farmer and Armi). To do this, once the value Q_1' has been calculated, the 2×2 nonlinear system (49)–(50) is solved numerically for every value of z_b' corresponding to the intercells of the mesh (the graphical study of the solutions performed in [9] gives the necessary hints about the adequate choice of the initial guess for the numerical algorithms).

Notice that all the numerical solutions differ slightly from the F&A solution at the right part of the channel (see Figure 4(b)). These differences are due mainly to the rigid-lid hypothesis. The main differences among the numerical solutions are located near the critical section, as expected. The parameter $\bar{\alpha}$ has practically no influence in regular zones, but it is important in transitions (regular or not). So, we focus only in a neighborhood of $x = 0$ ($x \in [-0.4, 0.4]$). Figure 4(c) shows the computed interfaces and the F&A interface in this zone. Notice that if the parameter α is set to 0, the numerical scheme corresponds to a Roe-type scheme and produces a nonentropy solution, as expected. Table 3 shows the L^∞ and L^1 errors corresponding to the comparison of the numerical interfaces with the analytical one. Observe that the values $\alpha = 1/8$, $\alpha = 1/4$, $\alpha = 3/8$ produce similar results.

The discharges computed by the model are $Q_1 = -Q_2 = 9.38\,10^{-2}$ m^3/s for $\alpha = 1/8$, 1/4, and 3/8, and $Q_1 = -Q_2 = 9.33\,10^{-2}$ m^3/s for $\alpha = 0$, while the F&A model gives $Q_1 = -Q_2 = 9.213\,10^{-2}$ m^3/s.

In order to test the convergence, a numerical stationary solution over a finer mesh of 11520 cells has been computed. The L^1 errors for the variables h_1, h_2, Q_1, and Q_2 are shown in Tables 4 and 5 for several meshes with increasing numbers of cells using the numerical scheme, with the parameter α replaced by the function $\alpha(x)$ defined in Remark 7 with $\bar{\alpha} = 1/8$. As expected, the order obtained is nearly 2. Notice that the computed stationary solutions are not expected to converge to the solution provided by F&A due to the rigid-lid assumption. In Table 6 we show the difference in L^1-norm between the F&A solution and the numerical solution corresponding to the mesh of 11520 cells.

6.4. Nonsmooth solution. The purpose of this numerical test is to compare the behavior of the numerical schemes in the neighborhood of a discontinuity. We consider the two-layer shallow-water system for channels with rectangular cross-section with constant breadth ($\sigma = 1$) and a flat bottom topography. In this case, the system

reduces to

$$\frac{\partial W}{\partial t} + \mathcal{A}(\mathrm{W})\frac{\partial W}{\partial x} = 0, \tag{51}$$

where $\mathcal{A}$ is the 4×4 matrix whose expression is given by

$$\mathcal{A}(\mathrm{W}) = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -\dfrac{Q_1^2}{A_1^2} + gA_1 & 2\dfrac{Q_1}{A_1} & gA_1 & 0 \\ 0 & 0 & 0 & 1 \\ rgA_2^2 & 0 & -\dfrac{Q_2^2}{A_2^2} + gA_2 & 2\dfrac{Q_2}{A_2} \end{bmatrix}.$$

The difficulty in defining a discontinuous solution of this system comes from the fact that the nonconservative products do not make sense within the distribution theory for such a solution. Nevertheless, there are several mathematical theories allowing us to make sense of these products in a weaker manner. In particular we consider here the definition of nonconservative products as Borel measures introduced by Volpert in [21]. This definition can be considered as a particular case of the concept of nonconservative products developed in [8]. In this latter work, the definition of the nonconservative product depends on the choice of a family of viscous paths. Volpert's definition is equivalent to the choice of the family of segments.

According to this definition, across a discontinuity with speed ξ a weak solution of the system must satisfy the generalized Rankine–Hugoniot condition

$$\int_0^1 \mathcal{A}\left(\mathrm{W}^- + s(\mathrm{W}^+ - \mathrm{W}^-)\right) \cdot (\mathrm{W}^+ - \mathrm{W}^-)\, ds = \xi(\mathrm{W}^+ - \mathrm{W}^-), \tag{52}$$

where W^-, W^+ are the left and right limits of the solution at the discontinuity.

In [16], a Roe-type numerical scheme for the two-layer shallow-water system was studied which is the particular case of the family introduced here that corresponds to the choice $\alpha = 0$. In this reference it was shown that this numerical scheme is consistent with the notion of weak solutions associated to Volpert's definition of nonconservative products in the following sense: Let us suppose that the approximations W_i^n and W_{i+1}^n obtained by the numerical scheme in two neighbor cells can be linked by a shock of speed ξ satisfying the jump condition (52). Then ξ is an eigenvalue of the intermediate matrix of the scheme, $\mathcal{A}_{i+1/2}$, and $\mathrm{W}_{i+1}^n - \mathrm{W}_i^n$ is an associated eigenvector. As a consequence, the solution of the linear approximate Riemann solver used by the numerical scheme to advance in time is equal to that of the exact Riemann problem. In particular, this implies that the numerical scheme solves exactly stationary shocks. In order to numerically verify this property, in [16] the authors proposed a test consisting in solving the system with values $g = 10$ and $r = 0.02$, and the initial condition

$$W(x,t) = \begin{cases} W_L & \text{if } x < 0, \\ W_R & \text{if } x > 0, \end{cases}$$

with

$$W_L = \begin{bmatrix} 1 \\ \sqrt{0.1} \\ 1 \\ \sqrt{20} \end{bmatrix}, \quad W_R = \begin{bmatrix} 0.3961560 \\ \sqrt{0.1} \\ 1.5820186 \\ \sqrt{20} \end{bmatrix}.$$

(c) Q_1 (d) Q_2

FIG. 5. *Internal hydraulic jump: water depths and discharges at each layer of fluid for* $\bar{\alpha} = 0$, $1/8$, $1/4$, *and* $3/8$.

These states satisfy the generalized jump condition (52) with an error of about 10^{-5}.

We have applied to this test problem the numerical scheme with values of the parameter $\alpha = 0$, $1/8$, $1/4$, and $3/8$. If the numerical schemes were consistent with the jump condition (52), they should obtain a stationary discontinuity placed at $x = 0$ with values of the unknowns close to the initial conditions. Figure 5 depicts the steady state solutions (water depths and discharges) for the different values of the parameter $\bar{\alpha}$ obtained with $\Delta x = 0.01$ and CFL $= 0.90$ for a rectangular channel 1 meter long. The errors are shown in Tables 7 and 8. Notice that in all the cases the numerical scheme behaves as expected: a stationary discontinuity placed at $x = 0$ and close to the initial condition is captured.

From Tables 7 and 8 and Figure 5 it is clear that the smallest errors correspond to $\alpha = 0$. For the other values an overshooting near the stationary shock occurs (see Figure 5), becoming larger for increasing values of $\bar{\alpha}$.

We have applied to the test problem the numerical scheme with the parameter α replaced by the function $\alpha(x)$ defined in Remark 7 with $\bar{\alpha} = 1/8$. Figure 6 depicts the steady state solution (water depths and discharges) obtained with again $\Delta x = 0.01$

and CFL = 0.90. It coincides with that obtained with $\alpha = 0$. In this case, once the stationary solution is reached the corresponding function $\alpha(x)$ takes the value 0 only at the intercell where the discontinuity stands and 1/8 at the others: Figure 7 shows the values of $\alpha(x)$ close to the discontinuity.

Finally, the L^1 errors for the variables h_1, h_2, Q_1, and Q_2 are shown in Tables 9 and 10 for several meshes with increasing numbers of cells using the numerical scheme with the function $\alpha(x)$ with $\bar{\alpha} = 1/8$. As expected, the order obtained is one, due to the presence of the stationary discontinuity.

7. Conclusion. We have addressed in this paper the accurate numerical solution of nonconservative nonhomogeneous hyperbolic systems in one space dimension by finite volume solvers. We have introduced a general class of schemes that we have proved to be "asymptotically well-balanced" in the sense that they calculate, with at least order two, all stationary solutions of the system in all the domain except those on a set whose measure tends to zero as Δx tends to zero. One of the free parameters of this class is the diffusion matrix, so we include both flux-splitting (for conservative equations) and flux-difference solvers as particular cases.

We also give general sufficient conditions under which the schemes exactly calculate a given stationary solution. These conditions may be read as meaning on one hand that the numerical flux of the scheme must compensate the centered part of the numerical source term, and on another hand that the numerical diffusion must compensate the decentered part of the numerical source term.

In the case of two-layer shallow-water flows, we finally have introduced a specific solver to deal with the numerical difficulties associated to nonconservative products combined with nonlinear convection and source terms effects. On one hand, this solver is able to exactly compute water at rest. On the other hand, it yields accurate computation of subcritical to supercritical transitions without need of entropy corrections, and also of nonsmooth solutions due to the presence of the nonconservative products. Our main technical innovation is an adaptive discretization of the centered part of the numerical flux which, in our opinion, may be extended to construct accurate solvers for more general nonconservative nonhomogeneous equations.

Appendix. Proof of Theorem 1. We consider first a regular stationary solution W of (1) and a compact set, $K \subset \omega(W)$.

Let T be the continuous operator appearing in system (1),

$$T(W) = \frac{\partial}{\partial x}[F(x,W)] - G(x,W) - B(x,W)\frac{\partial W}{\partial x},$$

and T_h the discrete operator appearing in the numerical scheme (11)–(14),

$$T_h(W) = \frac{\phi_R^S - \phi_L^S}{\Delta x} - G_C$$

(where we omit the arguments for brevity). We must prove that

$$T_h(W)(x_i) = T(W)(x_i) + \mathcal{O}((\Delta x)^2) \quad \forall x_i \in K.$$

The proof is based on identity (8):

$$\widetilde{T}(W) = \frac{\partial}{\partial x}\left[F(x,W) - \nu\mathcal{D}(x,W)\left(\frac{\partial W}{\partial x} - M^{-1}S(x,W)\right)\right] - G(x,W) - B(x,W)\frac{\partial W}{\partial x}.$$

It is enough to prove that every term appearing in T_h,

$$\begin{aligned} \alpha_i &= \frac{F_C(x_i, x_{i+1}, W_i, W_{i+1}) - F_C(x_{i-1}, x_i, W_{i-1}, W_i)}{\Delta x}, \\ \beta_i &= \nu\frac{D(x_i, x_{i+1}, W_i, W_{i+1})(W_{i+1} - W_i) - D(x_{i-1}, x_i, W_{i-1}, W_i)(W_i - W_{i-1})}{(\Delta x)^2}, \end{aligned} \tag{53}$$

$$\begin{aligned} \eta_i = \nu\frac{1}{\Delta x}\Big[&D(x_i, x_{i+1}, W_i, W_{i+1})\widetilde{M^{-1}}(x_i, x_{i+1}, W_i, W_{i+1})S_D(x_i, x_{i+1}, W_i, W_{i+1}) \\ &- D(x_{i-1}, x_i, W_{i-1}, W_i)\widetilde{M^{-1}}(x_{i-1}, x_i, W_{i-1}, W_i)S_D(x_{i-1}, x_i, W_{i-1}, W_i)\Big], \end{aligned} \tag{54}$$

$$\delta_i = G_C(x_{i-1}, x_i, x_{i+1}, W_{i-1}, W_i, W_{i+1}),$$

$$\lambda_i = \frac{1}{2\Delta x}\Big[\mathcal{B}_R(x_i, x_{i+1}, W_i, W_{i+1})\,(W_{i+1} - W_i) - \mathcal{B}_L(x_{i-1}, x_i, W_{i-1}, W_i)\,(W_i - W_{i-1})\Big],$$

balances up to second order the corresponding term in $T(W)$. We prove the case of the more complex term η_i. The proof is similar for the other terms.

We define

$$R(x,U) = \mathcal{D}(x,U)M^{-1}(x,U)S(x,U),$$

$$R_C(x,y,U,V) = D(x,y,U,V)\widetilde{M^{-1}}(x,y,U,V)S_D(x,y,U,V),$$

and we want to prove that

$$\begin{aligned}\Delta R_C(x_i) &= R_C(x_i, x_{i+1}, W_i, W_{i+1}) - R_C(x_{i-1}, x_i, W_{i-1}, W_i)\\ &= \Delta x \frac{\partial}{\partial x}[R(x, W(x))]_{|_{x=x_i}} + \mathcal{O}((\Delta x)^2). \qquad (55)\end{aligned}$$

As K is a compact set and $\mathbf{R}^{N+1} \setminus \gamma$ is an open set, there exists $\delta_K > 0$ such that if

$$|U - W(x)| + \Delta x < \delta_K,$$

then $(x + \Delta x, U) \subset \mathbf{R}^{N+1} \setminus \gamma \quad \forall x \in K$.

On the other hand, if $W_{i+\theta} = (1-\theta)W_i + \theta W_i$, then using the mean value theorem we prove

$$|W_{i+\theta} - W(x_{i+\theta})| \le \frac{\Delta x}{2}\left\|\frac{\partial W}{\partial x}\right\|_{L^\infty(K)} \qquad \forall\, x_i \in K.$$

So, if

$$\Delta x < \delta_K / \left(1 + \left\|\frac{\partial W}{\partial x}\right\| /2\right),$$

we obtain that $(x_{i+\theta}, W_{i+\theta}) \subset \mathbf{R}^{N+1} \setminus \gamma$ for $\theta \in [0,1]$. Then if Δx verifies the previous inequality, we obtain that $L[(x_i, W_i), (x_{i+1}, W_{i+1})] \subset \mathbf{R}^{N+1} \setminus \gamma \ \forall x_i \in K$. Then we can apply Hypotheses 1(c), (d), and (f) and conclude that

$$\begin{aligned}R_C(x_i, x_{i+1}, W_i, W_{i+1}) &= R\left(x_{i+1/2}, \frac{W_i + W_{i+1}}{2}\right)\\ &+ R_1\left(x_{i+1/2}, \frac{W_i + W_{i+1}}{2}\right)\begin{pmatrix} x_{i+1} - x_i \\ W_{i+1} - W_i \end{pmatrix} + \mathcal{O}(|x_{i+1} - x_i|^2 + |W_{i+1} - W_i|^2)\end{aligned}$$

for some C^1 matrix function R_1.

As W is of class C^2, we have that

$$\begin{aligned} R_1\left(x_{i+1/2}, \frac{W_i+W_{i+1}}{2}\right)\begin{pmatrix} x_{i+1}-x_i \\ W_{i+1}-W_i \end{pmatrix} - R_1\left(x_{i-1/2}, \frac{W_{i-1}+W_i}{2}\right)\begin{pmatrix} x_i-x_{i-1} \\ W_i-W_{i-1} \end{pmatrix} \\ = \Delta x \left[R_1(x_{i+1/2}, W(x_{i+1/2}))\begin{pmatrix} 1 \\ \dfrac{\partial W}{\partial x}(x_{i+1/2}) \end{pmatrix} \right. \\ \left. - R_1(x_{i-1/2}, W(x_{i-1/2}))\begin{pmatrix} 1 \\ \dfrac{\partial W}{\partial x}(x_{i-1/2}) \end{pmatrix}\right] + \mathcal{O}((\Delta x)^2) \\ = (\Delta x)^2 \frac{\partial}{\partial x}\left[R_1(x, W(x))\begin{pmatrix} 1 \\ \dfrac{\partial W}{\partial x} \end{pmatrix}\right]_{\Big|_{x=x_i}} + \mathcal{O}((\Delta x)^2) = \mathcal{O}((\Delta x)^2). \end{aligned} \tag{56}$$

Moreover,

$$\begin{aligned} R\left(x_{i+1/2}, \frac{W_i+W_{i+1}}{2}\right) - R\left(x_{i-1/2}, \frac{W_{i-1}+W_i}{2}\right) \\ = \Delta x \frac{\partial}{\partial x}\Big[R(x, W(x))\Big]_{\Big|_{x=x_i}} + \mathcal{O}((\Delta x)^2). \end{aligned} \tag{57}$$

From (56) and (57) we conclude that (55) is verified.

We can now prove statements (a) and (b) of Theorem 1:

(a) If W has no singular points, then $\omega(W) = (0, L)$, and it is enough to use the preceding argument for some compact set $K \subset \omega(W)$ containing all the internal nodes of the discretization.

(b) If $\mathrm{meas}(\sigma(W)) = 0$, since $\omega(W)$ is an open set, then we may find an increasing sequence of compact sets $\{K_n\}_{n\geq 1}$ such that $\cup_{n\geq 1} K_n = \omega(W)$. Then $\mathrm{meas}((0, L) \setminus \cup_{n\geq 1} K_n) = 0$. It is enough to use the preceding argument for each K_n.

To prove statement (c) let us remark that, by the previous argument, the scheme is asymptotically well-balanced in $\omega(W)$. Thus, it only remains to prove this property in $\sigma(W)$ when this set has nonzero measure.

Let us denote by $\mathrm{int}(\sigma(W))$ the interior of $\sigma(W)$. As

$$\mathrm{meas}(\sigma(W) - \mathrm{int}(\sigma(W))) = 0,$$

it is enough to prove the property in $\mathrm{int}(\sigma(W))$. And, as we shall see, this occurs because in $\mathrm{int}(\sigma(W))$ $\mathcal{D}$ and M^{-1} coincide with smooth functions.

For the sake of simplicity, we shall assume $N = 2$ and that the first eigenvalue of M vanishes in $\sigma(W)$.

Let us define the operator

$$\begin{aligned} \widetilde{T}(W) = \frac{\partial}{\partial x}\left[F(x, W) - \mathcal{H}(x, W)\left(\frac{\partial W}{\partial x} - \mathcal{C}(x, W)S(x, W)\right)\right] \\ - G(x, W) - B(x, W)\frac{\partial W}{\partial x}, \end{aligned}$$

where

$$\mathcal{H}(x, W) = X(x, W)\begin{pmatrix} 0 & 0 \\ 0 & d_2(x, W) \end{pmatrix} X^{-1}(x, W),$$

$$\mathcal{C}(x,W) = X(x,W) \begin{pmatrix} 0 & 0 \\ 0 & \lambda_2^{-1}(x,W) \end{pmatrix} X^{-1}(x,W).$$

By d_2 and λ_2 we denote the second eigenvalue of $\mathcal{D}$ and M, respectively.

As W is a steady solution of (1),

$$M(x,W)\frac{\partial W}{\partial x}(x) = S(x,W).$$

Then

$$\mathcal{C}(x,W)S(x,W) = \mathcal{C}(x,W)M(x,W)\frac{\partial W}{\partial x}(x).$$

But

$$\begin{aligned}
&\mathcal{C}(x,W)M(x,W)\frac{\partial W}{\partial x}(x) = X(x,W) \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} X^{-1}(x,W)\frac{\partial W}{\partial x}(x) \\
&= X(x,W)\left[\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \right] X^{-1}(x,W)\frac{\partial W}{\partial x}(x) \\
&= \frac{\partial W}{\partial x} - \left[X^{-1}(x,W)\frac{\partial W}{\partial x}(x) \right]_1 X_1(x,W),
\end{aligned}$$

where by $[\,\cdot\,]_1$ we denote the first component of a vector and by X_1 the first eigenvector of M.

Then, as X_1 is also the first eigenvector of $\mathcal{H}$,

$$\mathcal{H}(x,W)\left[\frac{\partial W}{\partial x}(x) - \mathcal{C}(x,W)S(x,W) \right] = \lambda_{\mathcal{H},1}(x,W)\left[X^{-1}(x,W)\frac{\partial W}{\partial x}(x) \right]_1 X_1(x,W) = 0,$$

as by construction the first eigenvalue $\lambda_{\mathcal{H},1}$ of $\mathcal{H}$ is zero.

We deduce that

$$\widetilde{T}(W) = T(W).$$

It is then enough to prove that for any compact set $K \subset \mathrm{int}(\sigma(W))$ there exists $\delta_K > 0$ such that if $0 < \Delta x < \delta_K$, then

$$T_h(W)(x_i) = \widetilde{T}(W)(x_i) + \mathcal{O}((\Delta x)^2) \quad \forall\, x_i \in K. \tag{58}$$

Let us assume

$$\delta_K \leq \mathrm{dist}(K, \partial\sigma(W)).$$

If $x_i \in K$, then $x_{i-1},\ x_{i+1} \in \mathrm{int}(\sigma(W))$ and we may ensure that $L[(x_i,W_i),(x_{i+1},W_{i+1})]$ cuts $\gamma = \widetilde{\gamma}$. Then, using our definition of $\widetilde{M^{-1}}$ and D, we have

$$\begin{aligned}
&\widetilde{M^{-1}}(x_i, x_{i+1}, W_i, W_{i+1}) \\
&= X(x_{i+1/2}, \widetilde{W}_{i+1/2}) \begin{pmatrix} 0 & 0 \\ 0 & \lambda_2^{-1}(x_{i+1/2}, \widetilde{W}_{i+1/2}) \end{pmatrix} X^{-1}(x_{i+1/2}, \widetilde{W}_{i+1/2}) \\
&= \mathcal{C}(x_{i+1/2}, \widetilde{W}_{i+1/2}),
\end{aligned}$$

where we denote $\widetilde{W}_{i+1/2} = \widetilde{W}(x_i, x_{i+1}, W_i, W_{i+1})$. Also,

$$\begin{aligned} &D(x_i, x_{i+1}, W_i, W_{i+1}) \\ &= X(x_{i+1/2}, \widetilde{W}_{i+1/2}) \begin{pmatrix} 0 & 0 \\ 0 & d_2(x_{i+1/2}, \widetilde{W}_{i+1/2}) \end{pmatrix} X^{-1}(x_{i+1/2}, \widetilde{W}_{i+1/2}) \\ &= \mathcal{H}(x_{i+1/2}, \widetilde{W}_{i+1/2}). \end{aligned}$$

Now, T_h can be written as in the previous case by replacing D by $\mathcal{H}$ and $\widetilde{M^{-1}}$ by $\mathcal{C}$ in the definitions of β_i, η_i, and the proof is similar. ∎

CONSERVATIVE COUPLING BETWEEN FINITE ELEMENTS AND RETARDED POTENTIALS. APPLICATION TO VIBROACOUSTICS*

P. GROB† AND P. JOLY‡

Abstract. The numerical simulation of vibroacoustics is concerned with the radiation of sound emitted by thin vibrating mechanical structures. We present a numerical method that combines boundary elements (integral equation) for the acoustic wave equation with standard finite elements for the mechanics. The originality of our work is that we consider the time domain problem and use retarded potentials for writing the integral equation. We establish a nonstandard variational formulation of this new problem, in space-time for the acoustic equation, and in space only for the mechanic equation. The basic ideas for the discretization are the following: (i) Space finite elements and finite differences with time step Δt (a θ-scheme, $0 \leq \theta \leq 1/2$) are used for the discretization of the mechanic equation. (ii) Space-time finite elements are used for the discretization of the acoustic equation, which is "projected" two times on two staggered time grids of time step $2\Delta t$. The use of staggered twice larger time grids for the discretization of the acoustic equation (see (ii) above) plays a key role in the cancellation of the "coupling terms" (between the two equations), which is crucial in the energy analysis.

Key words. coupling method, retarded potentials, stability

1. Introduction.

Vibroacoustics is the science that studies the radiation of sound emitted by thin vibrating mechanical structures (a membrane, a plate, or a shell). Under the assumption of small vibrations, usual mathematical models couple the standard acoustic wave equation with dynamic membrane, plate, or shell models. A lot of work has been devoted to the time harmonic problem [26]. In this work we are more specifically interested in the time dependent case. A first natural approach consists in coupling three-dimensional (3D) finite element approaches for the sound radiation with appropriate two-dimensional (2D) finite element approaches for the thin structure. In such a case, it is important to preserve the explicit nature of the time stepping procedure, especially for the acoustic part. This is what has been done, for instance, in [12], [16], and [14].

In the present work, we investigate an alternative approach which consists in coupling a finite element method for the thin structure with an integral equation method for the acoustics. This is made possible by the homogeneous structure of the surrounding fluid: the Green's function of the exterior problem is known explicitly. Such an approach has been extensively developed in the time harmonic case [8], [23], [34], and we investigate an extension to the time dependent case, This is more delicate especially because of the additional time discretization that may be the cause of some instability phenomena. The a priori advantages of the use of integral equations are quite clear and have already been largely investigated in the case of pure diffraction problems (which corresponds to the case where the thin structure does not vibrate):

(i) The calculations are restricted to the thin structure: one makes the economy of one space dimension.
(ii) One avoids the question of the truncation of the exterior domain (absorbing conditions, perfectly matched layers, etc.): the unboundedness of this domain is treated exactly.
(iii) One avoids (at least partially) the dispersion (propagation) errors induced by the discretization of the 3D wave equation.

The counterparts of these advantages are also well known:

(a) The time discretization of the integral equation may induce instability phenomena (this is of course the major question).
(b) One has to deal with full matrices, contrary to what happens with 3D finite elements. In particular, in the time domain, the resulting scheme cannot be completely explicit: a (full) band matrix has to be inverted.
(c) In the time domain, one needs to store the story of the solution in the past.

However, if point (c) cannot be overcome, the negative impact of points (a) and (b) is minimized by some recent progress of the research:

- Instability phenomena are essentially observed with collocation methods [28], [33]. The development of variational methods leads to the construction of unconditionally stable schemes [19], [22], [4], [6], [20], [21] (even though they appear to be more difficult to implement).
- A lot of progress has been made in the conception of rapid algorithms (multiple methods) for the evaluation of the product's matrix-vector for the matrices that appear after the discretization of integral equations. Initially developed for the time hamonic case [18], they are now also available for the time dependent case [17]. Coupled with iterative solvers, they permit us to efficiently solve large scale diffraction problems with integral equations.

With the coupling of time domain integral equations with finite elements, new difficulties appear, linked to the objective we wish to achieve:

- We want to couple the methods that would be naturally usually employed for discretizing the "uncoupled problem" made of the integral equation only (acoustic part of the problem, assuming that the structure does not vibrate) and the dynamic thin structure equation only (mechanic part of the problem). These are by nature different: one uses space-time finite elements for the acoustic part, and space finite elements and finite differences in time for the mechanic part.
- We want to find a robust coupling algorithm, namely, an algorithm that guarantees a priori, from the theoretical point of view, the stability of the resulting method, if possible without affecting the stability of the method in the uncoupled case.

It is difficult to find, in the mathematical literature, works that address these questions in a rigorous way. A first work in this direction can be found in [2] and [3] in the case of electromagnetism (Maxwell's equations), where retarded potentials are used as a transparent boundary condition for diffraction problems with locally heterogeneous media. One of the major differences from our work is that a space-time variational formulation is used for both the surfacic part and the volumic part of the equations, which leads to a nonstandard discretization, necessarily nonexplicit, of Maxwell's equations in the volume. From this point of view, our work is closer to some recent research in the engineering literature [33], [28], where finite differences are used for the mechanic part of the problem but where the central question of stability is not

treated.

The work we present in this paper has been precisely guided by the stability constraint, which has led us to propose a new method. The key idea is to ensure the stability via some discrete energy identity, which is a kind of equivalent of the classical energy conservation for the full coupled problem. In this sense, our method can be seen as a conservative coupling method in a sense similar to the one developed in [24] and used in [15], [5] for space-time mesh refinement methods. To get such a discrete energy identity, assuming that Δt is the time step for the discretization of the mechanic part of the problem, we are led to distinguish two staggered discretization grids, corresponding to even and odd instants, for the discretization of the acoustic part. These two grids are coupled only through the coupling with the mechanic part.

The outline of the article is as follows. The major part of the article (sections 2 to 6) is devoted to the presentation and the analysis of our method on the membrane problem that we present as our model problem in section 2. In section 3, we describe and give the main properties of the so-called Dirichlet to Neumann operator N_Σ. This operator is used to reduce our original 2D-3D problem into a 2D one posed only on the membrane (section 4). Sections 5 and 6 are the two main sections of this article. We describe our numerical method in section 5 and analyze its main properties in section 6, where the fundamental stability result (Theorem 6.2) is proven as a consequence of the energy identities of Theorem 6.1. In section 7, we explain how the formalism of sections can be extended to the vibrations of a plate of Kirchoff–Love type (section 7.1) or Mindlin–Reissner type (section 7.2). Finally, section 8 is devoted to the numerical results. We consider successively the vibrations of a membrane (section 8.1) and the vibrations of a Mindlin–Reissner plate (section 8.2). We validate our new method through a comparison with computations done with a full finite element code (coupling between 3D finite elements for the acoustics and 2D finite elements for the mechanics).

2. A model problem.

2.1. Notation. In what follows $\mathbf{x} = (x, x_3)$, with $x = (x_1, x_2) \in \mathbb{R}^2$ and $x_3 \in \mathbb{R}$, will denote the current point of $\mathbb{R}^3$, with associated canonic basis $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$. For simplicity, x will also denote the point $(x, 0)$ of $\mathbb{R}^3$. We consider the (small) vibrations of a membrane Σ located in the plane $x_3 = 0$ so that it can de identified to a bounded open or $\mathbb{R}^2$. This membrane is fixed along its boundary and coupled to a homogeneous fluid occupying the exterior domain $\Omega = \mathbb{R}^3 \setminus \Sigma$. For what follows, in particular, to define traces of functions in Ω, it will be useful to distinguish the two "lips" of Σ that we can define as $\Sigma^+ = \partial\Omega^+ \cap \Sigma$ and $\Sigma^- = \partial\Omega^- \cap \Sigma$, where $\Omega^\pm = \{\mathbf{x} = (x, x_3) \in \Omega \ / \ \pm x_3 > 0\}$. We shall define an "orientation" of Σ by defining the unit normal vector to Σ as $n = \mathbf{e}_3$, which points from Ω^- toward Ω^+ (see Figure 2.1). Finally, for any function $g : \Omega \mapsto \mathbb{R}$ sufficiently smooth (typically in $H^1(\Omega)$), we denote by $[g]$ its jump across Σ, defined in agreement with the above orientation, namely,

$$[g] = g_{|\Sigma_+} - g_{|\Sigma_-} \quad (\in H_{00}^{\frac{1}{2}}(\Sigma) \quad \text{if} \quad g \in H^1(\Omega)) \,. \tag{2.1}$$

We shall denote by Δ the 2D Laplacian operator (with respect to x) and by $\mathbf{\Delta} = \Delta + \partial^2/\partial x_3^2$ the 3D Laplacian operator. In the same way we shall denote ∇ and $\mathbf{\nabla}$, respectively, the 2D and 3D gradient operators.

2.2. Description of the model. The unknowns of our mathematical model will be as follows.

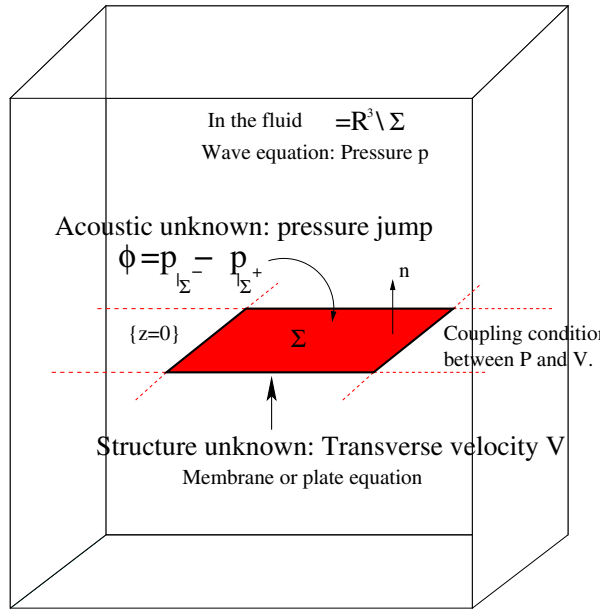

FIG. 2.1. *The problem geometry.*

- The pressure field distribution in the fluid:

$$p(\mathbf{x}, t), \quad \mathbf{x} \in \Omega, \quad t > 0.$$

- The distribution over the membrane of the normal velocity (as usual for membrane models, we assume that the deformation of the membrane can be described only with normal displacements in the x_3 direction):

$$v(x, t), \quad x \in \Sigma, \quad t > 0.$$

In what follows, we shall denote by ρ and c, respectively, the fluid density and sound speed, which are supposed to be positive constants (homogeneity of the fluid, a fundamental assumption). In the same way $\rho_m > 0$ will denote the surface density of the membrane and $T > 0$ its tension, so that the propagation velocity of waves along the membrane is $c_m = (\rho_m/\sigma)^{1/2}$. For simplicity, we shall also assume that these quantities are also constant, but this assumption is not essential here: we could consider a heterogeneous membrane. Finally, we assume that the membrane is submitted to a loading force described by its surfacic density $f(x, t), x \in \Sigma, t \geq 0$. The equations of the mathematical model are (we refer the reader to [9] for more physical insight)

$$\begin{cases} \rho_m \dfrac{\partial^2 v}{\partial t^2} - T\, \Delta v = f + \left[\dfrac{\partial p}{\partial t}\right], & x \in \Sigma, \quad t > 0, \\ \dfrac{1}{c^2}\dfrac{\partial^2 p}{\partial t^2} - \boldsymbol{\Delta} p \quad = 0, & \mathbf{x} \in \Omega, \quad t > 0, \end{cases} \tag{2.2}$$

coupled by the fluid structure interaction condition, that expresses in terms of our unknowns, the continuity across Σ of the transverse displacement (in the fluid and on the membrane)

$$\left.\frac{\partial p}{\partial n}\right|_{\Sigma_+} = \left.\frac{\partial p}{\partial n}\right|_{\Sigma_-} = -\rho \frac{\partial v}{\partial t}, \quad x \in \Sigma, \quad t > 0, \tag{2.3}$$

and completed by a boundary condition along $\partial\Sigma$,

$$v(x,t) = 0, \quad x \in \Sigma, \quad t > 0, \tag{2.4}$$

and homogeneous initial conditions:

$$\begin{cases} v(x,0) = \dfrac{\partial v}{\partial t}(x,0) = 0, & x \in \Sigma, \\ p(\mathbf{x},0) = \dfrac{\partial p}{\partial t}(\mathbf{x},0) = 0, & \mathbf{x} \in \Sigma. \end{cases} \tag{2.5}$$

2.3. A mathematical result. Let us first introduce a notation for spaces of functions of the variable $t \in [0,T]$, with values Hilbert space X, which are restrictions of functions in Sobolev spaces on $\mathbb{R}$ that have support in $\mathbb{R}^+$ (causal functions). More precisely, given $s \in \mathbb{R}^+$, we shall set

$$\begin{aligned} \mathcal{H}^s(0,T;X) = \{u \in L^2(0,T;X) \,/\, \exists\, \widetilde{u} \in H^s_+(\mathbb{R};X) \\ \text{such that } u(t) = \widetilde{u}(t) \text{ if } 0 \le t \le T\}, \end{aligned} \tag{2.6}$$

where by definition

$$H^s_+(\mathbb{R};X) = \{u \in H^s(\mathbb{R};X) \mid u(t) = 0 \text{ for } t < 0\}.$$

$\mathcal{H}^s(0,T;X)$ is a Hilbert space equipped with the norm

$$\|u\|_{\mathcal{H}^s(0,T;X)} = \inf_{u \in H^s(\mathbb{R};X),\, \widetilde{u}_{|[0,T]} = u} \|u\|_{H^s(\mathbb{R};X)}, \tag{2.7}$$

and we shall denote by $\mathcal{H}^{-s}(0,T;X)$ the dual of $\mathcal{H}^s(0,T;X)$.

Remark 1. Of course the lower bound 0 of the interval $[0,T]$ plays a special role. One can show, for instance [27], that

- for $0 \le s < \frac{1}{2}$, $\mathcal{H}^s(0,T;X) = H^s(0,T;X)$,
- for $s = \frac{1}{2}$, $\mathcal{H}^{\frac{1}{2}}(0,T;X) = \{u \in H^s(0,T;X) / \int_0^T \|u(t)\|^2_X \frac{dt}{t} < +\infty\}$,
- for $\frac{1}{2} < s < \frac{3}{2}$, $\mathcal{H}^s(0,T;X) = \{u \in H^s(0,T;X) / u(0) = 0\}$.

On the other hand, for $T_2 > T_1$, $\mathcal{H}^s(0,T_1;X)$ is nothing but the space generated by the restrictions to $]0,T_1[$ of functions in $\mathcal{H}^s(0,T_2;X)$.

Next, we state an existence and uniqueness result for the problem (2.2)–(2.5).

THEOREM 2.1.

$$f \in C^1(\mathbb{R}^+;L^2(\Sigma)) \tag{2.8}$$

(2.2)–(2.5) (v,p)

$$\begin{cases} v \in C^2(\mathbb{R}^+;L^2(\Sigma)) \cap C^1(\mathbb{R}^+;H^1_0(\Sigma)) \cap C^0(\mathbb{R}^+;H^2(\Sigma)), \\ p \in C^2(\mathbb{R}^+;L^2(\Omega)) \cap C^1(\mathbb{R}^+;H^1(\Omega)), \quad \Delta p \in C^0(\mathbb{R}^+;L^2(\Omega)). \end{cases} \tag{2.9}$$

The proof of the theorem is an exercise on the application of Hille–Yosida's theorem [35]. □

3. A Dirichlet to Neumann operator and its properties. In this section, we introduce an operator that maps functions defined on Σ onto functions defined on Σ and is of Dirichlet to Neumann nature. This operator will allow us (section 4) to reduce our problem to a new one posed only on Σ.

All the material of this section is essentially already known. It is, however, essential in understanding the rest of the paper. We choose to present it in a manner adapted to our purpose.

3.1. Formal definition of the operator. In this paragraph we shall be interested in the properties of a (very classical) intermediate problem which consists in solving the wave equation in Ω, with 0 initial data, with a prescribed jump φ across Σ, assuming that the normal derivative of the solution is continuous across Σ.

$$\begin{cases} \dfrac{1}{c^2}\dfrac{\partial^2 u_\varphi}{\partial t^2} - \Delta u_\varphi = 0 & \text{on } \Omega, \\ \left[\dfrac{\partial u_\varphi}{\partial n}\right] = 0, \quad [u_\varphi] = \varphi & \text{on } \Sigma, \\ u_\varphi(x,0) = \dfrac{\partial u_\varphi}{\partial t}(x,0) = 0. \end{cases} \tag{3.1}$$

Formally, we define the operator N_Σ by

$$N_\Sigma \varphi = \frac{\partial u_\varphi}{\partial n}|_\Sigma, \tag{3.2}$$

which is a well-defined quantity since $\frac{\partial u_\varphi}{\partial n}$ is continuous across Σ.

In the forthcoming subsections, we shall

- present a functional framework for the definition of $N_\Sigma\varphi$ (section 3.2),
- give its main properties (section 3.2), and
- give an explicit expression for $N_\Sigma\varphi$, useful for numerical computations (section 3.3).

3.2. Functional framework and properties of N_Σ. Our first objective is to give a functional framework in which the operator N_Σ can be defined rigorously. This subject has already been substantially investigated and it is not our purpose to present all the needed functional analysis. However, we wish to provide the minimum information in order to make our exposition self-contained.

The first step is to define precisely $N_\Sigma\varphi$ for sufficiently smooth φ. As usual, the notion of the Neumann boundary condition has to be understood in the weak sense. Using standard semigroup theory, it is easy to show that if

$$\varphi \in C^3(\mathbb{R}^+; H^{\frac{1}{2}}_{00}(\Sigma)), \tag{3.3}$$

the problem (3.1) admits a unique solution,

$$u_\varphi \in C^1(\mathbb{R}^+; H^1(\Omega)) \cap C^2(\mathbb{R}^+; L^2(\Omega)), \tag{3.4}$$

with, moreover,

$$\Delta u_\varphi \in C^0(\mathbb{R}^+; L^2(\Omega)). \tag{3.5}$$

By the trace theorem, one deduces that

$$\frac{\partial u_\varphi}{\partial n}|_{\Sigma^+} \equiv \frac{\partial u_\varphi}{\partial n}|_{\Sigma^-} = \frac{\partial u_\varphi}{\partial n}|_\Sigma \in C^0(\mathbb{R}^+; H^{\frac{1}{2}}_{00}(\Sigma)'). \tag{3.6}$$

This allows us to define an operator:

$$\left| \begin{array}{rccl} N_\Sigma : & C^3(\mathbb{R}^+; H^{\frac{1}{2}}_{00}(\Sigma)) & \longrightarrow & C^0(\mathbb{R}^+; H^{\frac{1}{2}}_{00}(\Sigma)'), \\ & \varphi & \longrightarrow & N_\Sigma\varphi = \dfrac{\partial u_\varphi}{\partial n}|_\Sigma. \end{array} \right. \tag{3.7}$$

The results (3.3) to (3.5) are far from optimal, in terms of the required regularity for φ and in terms of the resulting regularity of the solution u_φ. Sharper results can be obtained by Fourier–Laplace techniques. Such techniques naturally lead to results in weighted (in time) Sobolev spaces in $\Omega \times \mathbb{R}^+$ and $\Sigma \times \mathbb{R}^+$ [1], [19]. However, by truncation and causality arguments, these results can be translated into results over finite time intervals. This is the point of view that we shall adopt here. For a given $T > 0$, we denote $\mathcal{Q}_T = \Omega \times]0, T[$ and $\mathcal{S}_T = \Omega \times]0, T[$.

We introduce the functional space

$$V(\mathcal{S}_T) = L^2(0, T; H^{\frac{1}{2}}_{00}(\Sigma)) \cap \mathcal{H}^{\frac{1}{2}}(0, T; L^2(\Sigma)) \tag{3.8}$$

that we equip with its natural norms $\| \cdot \|_{V(\mathcal{S}_T)}$. Then, one can show that there exists a constant $C_T > 0$ such that

$$\forall\, \varphi \in C^3(\mathbb{R}^+; H^{\frac{1}{2}}_{00}(\Sigma)), \quad \|N_\Sigma \varphi\|_{V(\mathcal{S}_T)'} \leq C_T \, \|\varphi\|_{V(\mathcal{S}_T)}. \tag{3.9}$$

Remark 2. The estimate is valid for a general manifold Σ. In our case, since Σ is a part of a plane $x_3 = 0$, this estimate could be obtained using a Fourier–Laplace transform in time and a Fourier transform in space,

$$\widetilde{\varphi}(x, t) \longrightarrow \widehat{\varphi}(k, s), \quad k \in \mathbb{R}^2, \quad \mathcal{R}e\ s > 0,$$

where $\widetilde{\varphi}$ is the extension of φ by 0 outside Σ. One can compute (with obvious notation)

$$\widehat{\frac{\partial u_\varphi}{\partial n}}(k, s, x_3 = 0) = \frac{1}{2}\, (k^2 + s^2/c^2)^{\frac{1}{2}}\, \hat{\varphi}(k, s) \quad (\text{with } \mathcal{R}e\, (k^2 + s^2/c^2)^{\frac{1}{2}} > 0).$$

The conclusion follows from standard arguments (Plancherel's theorem, definition of Sobolev spaces via the Fourier–Laplace transform, and causality).

We refer the reader to [25] for a more thorough study of this operator.

As a consequence, by the density (modulo truncation to $]0, T[$) of $C^3(\mathbb{R}^+; H^{\frac{1}{2}}_{00}(\Sigma))$ in $V(\mathcal{S}_T)$), the operator N_Σ can be uniquely extended as an operator, still denoted N_Σ, such that

$$N_\Sigma \ \in \ \mathcal{L}(V(\mathcal{S}_T), V(\mathcal{S}_T)'), \tag{3.10}$$

and we shall denote by $b_T(\cdot, \cdot)$ the associated bilinear form

$$b_T(\varphi, \psi) \ = \ \langle N_\Sigma \varphi, \psi \rangle_{\mathcal{S}_T} \quad \forall\, (\varphi, \psi) \ \in \ V(\mathcal{S}_T)^2, \tag{3.11}$$

where $\langle \cdot, \cdot \rangle_{\mathcal{S}_T}$ denotes the usual duality pairing between $V(\mathcal{S}_T)$ and $V(\mathcal{S}_T)'$, which we can also rewrite as

$$b_T(\varphi, \psi) \ = \ \int_0^T \langle N_\Sigma \varphi(\cdot, t), \psi(\cdot, t) \rangle_\Sigma \, dt,$$

where $\langle \cdot, \cdot \rangle_\Sigma$ denotes the duality product between $H^{\frac{1}{2}}_{00}(\Sigma)'$ and $H^{\frac{1}{2}}_{00}(\Sigma)$.

Moreover, thanks to Remark 1 (second part), for any $t \leq T$ one can define

$$b_t(\varphi, \psi) = b_T(\varphi, \chi_t \psi) \quad \forall\, (\varphi, \psi) \ \in \ V(\mathcal{S}_T)^2.$$

Next, we state and prove a fundamental positivity property of N_Σ. For this, we introduce

$$W(\mathcal{S}_T) = \mathcal{H}^1(0, T; H^{\frac{1}{2}}_{00}(\Sigma)) \cap \mathcal{H}^{\frac{3}{2}}(0, T; L^2(\Sigma)). \tag{3.12}$$

Since $\partial/\partial t$ maps $W(\mathcal{S}_T)$ in $V(\mathcal{S}_T)$, we can introduce, for any $t \leq T$, the bilinear form

$$p_t(\varphi,\psi) \;=\; b_t\left(\varphi, \frac{\partial \psi}{\partial t}\right) \quad \forall\, (\varphi,\psi) \;\in\; V(\mathcal{S}_T)\times W(\mathcal{S}_T). \tag{3.13}$$

THEOREM 3.1. [illegible] $0 < t \leq T$ [illegible] $\varphi \in W(\mathcal{S}_T)$ [illegible]

$$|\varphi|^2_{N,\mathcal{S}_t} := p_t(\varphi,\varphi) \tag{3.14}$$

[illegible]

$$\varphi \;\in\; W(\mathcal{S}_T) \longrightarrow \|\varphi\|_{N,\mathcal{S}_T} := \int_0^T p_t(\varphi,\varphi)\, dt \equiv \int_0^T |\varphi|^2_{N,\mathcal{S}_t}\, dt \tag{3.15}$$

[illegible] $\|\cdot\|_{N,\mathcal{S}_T}$ [illegible] $W(\mathcal{S}_T)^2$ [illegible] α_T [illegible]

$$\|\varphi\|^2_{N,\mathcal{S}_T} \;\geq\; \alpha_T\, \|\varphi\|^2_{V(\mathcal{S}_T)}. \tag{3.16}$$

[illegible]. Obviously, it suffices to work with $\varphi \in C^3(0,T;H^{\frac{1}{2}}_{00}(\Sigma))$ and to conclude by density. First writing that

$$\iint_{\mathcal{Q}_t} \left(\frac{1}{c^2}\frac{\partial^2 u_\varphi}{\partial t^2} - \Delta u_\varphi \right) \frac{\partial u_\varphi}{\partial t}\, dxds = 0,$$

we easily deduce from Green's formula that

$$\int_0^t \left\langle \left[\frac{\partial u_\varphi}{\partial n}\right], \frac{\partial u_\varphi}{\partial t} \right\rangle_\Sigma ds = \frac{1}{2}\int_\Omega \left(\frac{1}{c^2}\left|\frac{\partial u_\varphi}{\partial t}\right|^2 + |\nabla u_\varphi|^2 \right)(x,t)\, dx,$$

that is, according to the definitions of N_Σ, $b_t(\cdot,\cdot)$, and $p_t(\cdot,\cdot)$,

$$p_t(\varphi,\varphi) = \int_0^t \left\langle N_\Sigma \varphi, \frac{\partial u_\varphi}{\partial t} \right\rangle_\Sigma ds = \frac{1}{2}\int_\Omega \left(\frac{1}{c^2}\left|\frac{\partial u_\varphi}{\partial t}\right|^2 + |\nabla u_\varphi|^2 \right)(x,t)\, dx,$$

which proves the first part of the theorem. Next, after time integration over $t \in [0,T]$ of the previous identity (in which T has been replaced by t), we get

$$\int_0^T p_t(\varphi,\varphi)\, dt = \frac{1}{2}\int_\Omega \left(\frac{1}{c^2}\left|\frac{\partial u_\varphi}{\partial t}\right|^2 + |\nabla u_\varphi|^2 \right) dxdt,$$

and the estimate (3.16) follows from the trace theorem in $H^1(\mathcal{Q}_T)$.

3.3. An explicit representation for N_Σ. The definition and properties of N_Σ as defined in section 3.2 remain valid in the case of nonconstant coefficients (for instance, with c a function of x). We can exploit the fact that we worked in a homogeneous medium (c is constant) by getting an explicit representation for N_Σ, based on the following integral representation (also called double layer representation) of the solution u_φ.

LEMMA 1. [illegible] u_φ [illegible] (3.1) [illegible]

$$u_\varphi(\mathbf{x},t) = -\int_\Sigma \frac{x_3}{|\mathbf{x}-y|}\left(\frac{\varphi(y,t-\tau(\mathbf{x},y))}{|\mathbf{x}-y|^2} + \frac{1}{c}\,\frac{\dot\varphi(y,t-\tau(\mathbf{x},y))}{|x-y|} \right) dy, \tag{3.17}$$

[illegible] $\tau(\mathbf{x},\mathbf{y}) = |\mathbf{x}-y|/c$ [illegible] $\ddot{\varphi}$ [illegible] φ [illegible]. One can find in [19] the general formula for any manifold Σ. Equation (3.17) is nothing but this formula specified to the case where Σ is a part of a plane. □

The evaluation of $N_\Sigma\varphi$ requires us to differentiate (3.17) with respect to x_3 and take the trace for $x_3 = 0$. This is made delicate by the presence of the singularity of the fundamental solution of the wave equation, since $|\mathbf{x} - y|$ may tend to 0 when $\mathbf{x}$ approaches Σ. The resulting formula is a so-called hypersingular integral whose meaning has to be precisely defined and which is not practical for numerical computation. This difficulty can be overcome by choosing to evaluate the bilinear form $b_T(\varphi,\psi)$ associated to N_Σ, at least for sufficiently smooth (φ,ψ). This is, moreover, the quantity that we need for finite element approximation. The main idea is to use integration by parts to transfer space derivatives from the Green's kernel to the test functions.

THEOREM 3.2. [illegible] $\varphi \in H^2(0,T;L^2(\Sigma)) \cap L^2(0,T;H_0^1(\Sigma))$ [illegible] $\varphi(x,0) = \frac{\partial\varphi}{\partial t}(x,0) = 0$

$$
\left|
\begin{aligned}
b_T(\varphi,\psi) &= \frac{1}{4\pi}\int_0^T \int_\Sigma\int_\Sigma \frac{\ddot{\varphi}(y,t-\tau(x,y))\;\psi(x,t)}{c^2|x-y|}\;dxdydt \\
&\quad + \frac{1}{4\pi}\int_0^T \int_\Sigma\int_\Sigma \frac{\nabla\varphi(y,t-\tau(x,y))\cdot\nabla\psi(x,t)}{|x-y|}\;dxdydt
\end{aligned}
\right. \tag{3.18}
$$

[illegible] $\psi \in V(\mathcal{S}_T)\cap L^2(0,T;H_0^1(\Sigma))$ $\ddot{\varphi}$ [illegible] φ

[illegible]. This is a well-known result. For completeness, we give a simple proof adapted to our particular case (plane geometry). Let $\widetilde{\varphi} \in H^1(\mathbb{R}^2\times\mathbb{R}) \cap H^2(\mathbb{R};L^2(\mathbb{R}^2))$ such that

$$\widetilde{\varphi}(x,t) = 0 \quad \forall\, x \notin \overline{\Sigma} \quad \text{and} \quad \widetilde{\varphi}(x,t) = \varphi(x,t) \quad \forall\, x \in \Sigma, \quad \forall\, t \in [0,T].$$

Let $\psi \in H^2(0,T;L^2(\Sigma)) \cap L^2(0,T;H_0^1(\Sigma))$ and $\widetilde{\psi}$ its extension (to $\mathbb{R}^2\times\mathbb{R}$) by 0 outside $\mathcal{S}_T$. We use successively the Fourier transform in time and the Fourier transform in space (each normalized such that the Fourier transform of the Dirac distribution is 1):

$$(\widetilde{\varphi},\widetilde{\psi})(x,t) \xrightarrow{\mathcal{F}_t} (\widehat{\Phi},\widehat{\Psi})(x,\omega) \xrightarrow{\mathcal{F}_x} (\widehat{\varphi},\widehat{\psi})(k,\omega.$$

By definition of $b_T(\cdot,\cdot)$, we can write, thanks to the regularity of φ and ψ,

$$b_T(\varphi,\psi) = \int_0^T\int_\Sigma \frac{\partial u_\varphi}{\partial n}(x,0,t)\;\psi(x,t)\;dxdt = \int_{\mathbb{R}}\int_{\mathbb{R}^2} \frac{\partial u_\varphi}{\partial n}(x,0,t)\;\widetilde{\psi}(x,t)\;dxdt.$$

On the other hand, one computes easily that

$$\widehat{\frac{\partial u_\varphi}{\partial n}}(k,\omega,x_3=0) = \frac{1}{2}\left(k^2 - \frac{\omega^2}{c^2}\right)^{\frac{1}{2}}\;\hat{\varphi}(k,\omega),$$

$$\text{with}\quad \left(k^2 - \frac{\omega^2}{c^2}\right)^{\frac{1}{2}} = \lim_{\varepsilon\longrightarrow 0}\left(k^2 - \frac{(\omega+i\varepsilon)^2}{c^2}\right)^{\frac{1}{2}}.$$

Thus, using Plancherel's theorem in x and t, we have

$$\begin{aligned} b_T(\varphi,\psi) &= \int_{\mathbb{R}}\int_{\mathbb{R}^2} (k^2-\omega^2/c^2)^{\frac12}\ \widehat{\varphi}\ \overline{\widehat{\psi}}\, dkd\omega \\ &= \int_{\mathbb{R}}\int_{\mathbb{R}^2} \frac{ik\widehat{\varphi}\ \overline{ik\widehat{\psi}}}{(k^2-\omega^2/c^2)^{\frac12}}\, dkd\omega + \frac{1}{c^2}\int_{\mathbb{R}}\int_{\mathbb{R}^2} \frac{(i\omega)^2\widehat{\varphi}\ \overline{\widehat{\psi}}}{(k^2-\omega^2/c^2)^{\frac12}}\, dkd\omega. \end{aligned}$$

Next, we use the fact that

$$\mathcal{F}_x^{-1}\left[\frac12\,(k^2-\omega^2/c^2)^{-\frac12}\right] = \frac{e^{-i\frac{\omega}{c}|x|}}{4\pi|x|}$$

so that, using the standard properties of the Fourier transform,

$$\mathcal{F}_x^{-1}\left(\frac{ik\widehat{\varphi}}{(k^2-\omega^2/c^2)^{\frac12}}\right) = \int_{\mathbb{R}^2} \frac{e^{-i\frac{\omega}{c}|x-y|}}{4\pi|x-y|}\,\nabla\Phi(y,\omega)\,dy.$$

Then, Plancherel's theorem in x (using that the functions have support in Σ) leads to

$$\int_{\mathbb{R}^2} \frac{ik\widehat{\varphi}\ \overline{ik\widehat{\psi}}}{(k^2-\omega^2/c^2)^{\frac12}}\, dk = \int_\Sigma\int_\Sigma e^{-i\frac{\omega}{c}|x-y|}\,\frac{\nabla\Phi(y,\omega)\,\overline{\nabla\Psi(x,\omega)}}{4\pi|x-y|}\,dxdy.$$

Next, we observe that

$$\mathcal{F}_t^{-1}\left[e^{-i\frac{\omega}{c}|x-y|}\ \Phi(y,\omega)\right] = \varphi(y,t-\tau(x,y))$$

so that Plancherel's theorem in the t variable (plus the fact that supp $\widetilde{\psi}\subset\overline{\Sigma}\times[0,T]$) leads to

$$\int_{\mathbb{R}}\int_{\mathbb{R}^2} \frac{ik\widehat{\varphi}\ \overline{ik\widehat{\psi}}}{(k^2-\omega^2/c^2)^{\frac12}}\, dkd\omega = \frac{1}{4\pi}\int_0^T\int_\Sigma\int_\Sigma \frac{\nabla\varphi(y,\tau(x,y,t))\cdot\nabla\psi(x,t)}{|x-y|}\,dxdydt.$$

In the same way

$$\int_{\mathbb{R}}\int_{\mathbb{R}^2} \frac{(i\omega)^2\widehat{\varphi}\ \overline{ik\widehat{\psi}}}{(k^2-\omega^2/c^2)^{\frac12}}\, dkd\omega = \frac{1}{4\pi}\int_0^T\int_\Sigma\int_\Sigma \frac{\ddot{\varphi}(y,\tau(x,y,t))\,\psi(x,t)}{|x-y|}\,dxdydt.$$

Then, summing the two last equations and using the inverse Fourier transform, we obtain 3.18. □

3. The integrals appearing in (3.18) are well defined because

$$(x,y)\longrightarrow |x-y|^{-1}\ \in\ L^2(\Sigma\times\Sigma).$$

The formula (3.18) also shows that $b_T(\varphi,\psi)$ is well defined with less regular ψ when

$$(\varphi,\psi)\in\mathcal{H}^2(0,T;H_0^1(\Sigma))\times L^2(0,T;H_0^1(\Sigma)).$$

Moreover, for any $t\le T$ one has the formula

$$b_t(\varphi,\psi) = b_T(\varphi,\chi^t\psi)\quad\forall\,(\varphi,\psi)\in\mathcal{H}^2(0,T;H_0^1(\Sigma))\times L^2(0,T;H_0^1(\Sigma)), \tag{3.19}$$

where χ^t denotes the characteristic function of the interval $[0,t]$.

4. There is a more general formula for a nonplane manifold Σ (see [30]),

$$b_T(\varphi,\psi) = \frac{1}{4\pi}\int_0^T \int_\Sigma \int_\Sigma \frac{\ddot{\varphi}(y,\tau(x,y,t))\ \psi(x)}{c^2|x-y|}\ d\gamma_x d\gamma_y dt + \frac{1}{4\pi}\int_0^T \int_\Sigma \int_\Sigma \frac{\overrightarrow{\mathrm{rot}}_\Sigma\ \varphi(y,\tau(x,y,t))\cdot \overrightarrow{\mathrm{rot}}_\Sigma\ \psi(x)}{|x-y|}\ d\gamma_x d\gamma_y dt,$$

where n_x denotes the unit vector to Σ at point x, $d\gamma$ the surfacic measure along Σ, and $\overrightarrow{\mathrm{rot}}_\Sigma$ the surface curl operator [31]. It is straightforward to recover (3.18) from the above formula.

4. Reduction to a problem on the surface.

4.1. An equivalent problem posed on Σ. Let $(v,p) \in W_v(\mathcal{Q}_T) \times W_p(\mathcal{Q}_T)$, where

(4.1)
$$\begin{cases} W_v(0,T) = C^2(0,T;L^2(\Sigma))\ \cap\ C^1(0,T;H_0^1(\Sigma))\ \cap\ C^0(0,T;H^2(\Sigma)), \\ W_p(0,T) = \{p \in C^2(0,T;L^2(\Omega))\ \cap\ C^1(0,T;H^1(\Omega))\ /\ \Delta p\ \in\ C^0(0,T;L^2(\Omega))\} \end{cases}$$

is the unique solution of (2.2)–(2.5) (see Theorem 2.1).

Let us introduce the new unknown function

$$\varphi := [p] \quad (\Sigma \times \mathbb{R}^+ \longrightarrow \mathbb{R}). \tag{4.2}$$

From the standard trace theorem in $H^1(\Omega)$, we deduce that

$$\varphi\ \in\ C^1(0,T;H_{00}^{\frac{1}{2}}(\Sigma)). \tag{4.3}$$

Assuming that $p \in \mathcal{H}^3(0,T;L^2(\Omega))$, the trace operator $p \mapsto [p]$ maps $\mathcal{H}^3(0,T;L^2(\Omega)) \cap \mathcal{H}^1(0,T;H^1(\Omega))$ into $\mathcal{H}^{\frac{3}{2}}(0,T;L^2(\Sigma))$. Therefore, we also have

$$\varphi\ \in\ \mathcal{H}^{\frac{3}{2}}(0,T;L^2(\Sigma)). \tag{4.4}$$

Finally, $p(x,0) = 0$ implies that

$$\varphi(x,0) = 0. \tag{4.5}$$

Then, it is straightforward to infer from (4.3), (4.4), and (4.5) that

$$\varphi\ \in\ W(\mathcal{S}_T). \tag{4.6}$$

Using (2.3) and the definition of N_Σ, one sees that $(v,\varphi) \in W_v(\mathcal{Q}_T) \times W(\mathcal{S}_T)$ is a solution of

(4.7)
$$\begin{cases} \rho_m \dfrac{\partial^2 v}{\partial t^2} - T\ \Delta v - \dfrac{\partial \varphi}{\partial t} = f, & x \in \Sigma, \quad t > 0, \\ N_\Sigma \varphi + \rho \dfrac{\partial v}{\partial t} = 0 & \text{in } V(\mathcal{S}_T), \\ v(x,0) = \dfrac{\partial v}{\partial t}(x,0) = 0, & x \in \Sigma. \end{cases}$$

More precisely, problems (2.2)–(2.5) and (4.7) are "equivalent" in the following sense.

THEOREM 4.1. [illegible] $(v,p) \in W_v(\mathcal{Q}_T) \times W_p(\mathcal{Q}_T)$ [illegible] (2.2)–(2.5) [illegible] 2.1 [illegible] $\varphi = [p]$ $(v,\varphi) \in W_v(\mathcal{Q}_T) \times W(\mathcal{S}_T)$ [illegible] (4.7).

[illegible] $(v,\varphi) \in W_v(\mathcal{Q}_T) \times W(\mathcal{S}_T)$ [illegible] (4.7) [illegible] $(v, p = u_\varphi$ [illegible] (3.1)) $\in W_v(\mathcal{Q}_T) \times W_p(\mathcal{Q}_T)$ [illegible] (2.2)–(2.5).

[illegible]. We have already proven the first part of the theorem. For the second claim, it is sufficient to prove the uniqueness result of (v,p) which is a consequence of Lemma 2 below. □

LEMME 2. [illegible] $(v,\varphi) \in W_v(\mathcal{Q}_T) \times W(\mathcal{S}_T)$ [illegible] (4.7), [illegible] $0 \le t \le T$

$$\frac{1}{2}\int_\Sigma \left(\rho_m \left|\frac{\partial v}{\partial t}\right|^2 + T\,|\nabla v|^2\right)(x,t)\,dx + \frac{1}{\rho}\,|\varphi|^2_{N,\mathcal{S}_t} = \iint_{\mathcal{S}_t} f(x,s)\frac{\partial v}{\partial t}(x,s)\,dxds. \tag{4.8}$$

[illegible]. We multiply the first equation of (4.7) by $\frac{\partial v}{\partial t}$ and integrate over $\mathcal{S}_t$ to obtain, thanks to Green's formula,

$$\frac{1}{2}\int_\Sigma \left(\rho_m \left|\frac{\partial v}{\partial t}|^2 + T\,\right|\nabla v|^2\right)\,dx - \iint_{\mathcal{S}_t} \frac{\partial \varphi}{\partial t}\,\frac{\partial v}{\partial t}\,dxds = \iint_{\mathcal{S}_t} f\,\frac{\partial v}{\partial t}\,dxds. \tag{4.9}$$

On the other hand, from the second equation of (4.7) (multiply by $\frac{\partial \varphi}{\partial t}$ and integrate over $\mathcal{S}_t$), we obtain, by definition of $b_t(\cdot,\cdot)$,

$$\frac{1}{\rho}\,b_t\left(\varphi, \frac{\partial \varphi}{\partial t}\right) + \iint_{\mathcal{Q}_t} \frac{\partial v}{\partial t}\frac{\partial \varphi}{\partial t}\,dxds = 0. \tag{4.10}$$

One concludes by summing (4.9) and (4.10) and employing (3.13) and (3.14). □

The identity (4.8) is fundamental in the sense that it not only leads to the uniqueness result but also to a priori estimates. Indeed, after time integration of (4.8), we get

$$\frac{1}{2}\iint_{\mathcal{S}_T} \left(\rho_m \left|\frac{\partial v}{\partial t}\right|^2 + T\,|\nabla v|^2\right)\,dxdt + \frac{1}{\rho}\|\varphi\|^2_{N,\mathcal{S}_T} = \iint_{\mathcal{Q}_T} (T-t)\,f\,\frac{\partial v}{\partial t}\,dxdt, \tag{4.11}$$

which yields, using in particular Theorem 3.1,

$$\begin{cases} \|v\|_{H^1(\mathcal{S}_T)} \le C_T\,\|f\|_{L^2(\mathcal{S}_T)}, \\ \|\varphi\|_{H^{\frac{1}{2}}(\mathcal{S}_T)} \le C_T\,\|f\|_{L^2(\mathcal{S}_T)}. \end{cases} \tag{4.12}$$

That is why the two identities (4.8) and (4.12) are the ones that we shall try to respect, at least in some sense, after discretization. This will allow us to prove a stability theorem.

4.2. A variational formulation. We give in this section a variational formulation of (4.7) which is preparatory to its discretization in space and time. This formulation is, as we shall see, somewhat hybrid and guided by the following remarks:

- If φ were considered as a given source term in the first equation of (4.7), then one would like to compute an approximation of v by using a finite element in space and finite differences in time, as this is standard for a pure membrane problem (see, for instance, [12]). That is why we shall make a variational formulation in space only on this equation.

- If v were considered as a given source term in the first equation of (4.7), then one would like to compute an approximation of φ by using space-time finite elements as we would do for a pure crack diffraction problem formulated with retarded potential (see, for instance, [22], [1], [4]). That is why we shall make a variational formulation of this equation in space and time.

Therefore, the variational formulation we shall work with is

(4.13)
$$\begin{cases} \text{Find } (v,\varphi) \in W_v(\mathcal{Q}_T) \times W(\mathcal{S}_T) \quad \text{such that} \quad \forall\, w \in H^1_0(\Sigma), \quad \forall\, \psi \in V(\mathcal{S}_T), \\ \\ \dfrac{d^2}{dt^2}(v(t),w) + a(v(t),w) - \displaystyle\int_\Sigma \frac{\partial \varphi}{\partial t}(x,t)\; w(x)\; dx = \int_\Sigma f(x,t)\; w(x)\; dx, \\ \\ \dfrac{1}{\rho}\; b_T(\varphi,\psi) + \displaystyle\iint_{\mathcal{S}_T} \frac{\partial v}{\partial t}\; \psi\; dxdt = 0, \\ \\ v(0) = \dfrac{dv}{dt}(0) = 0, \end{cases}$$

where we have set

(4.14)
$$\begin{cases} (v,w)_\rho = \displaystyle\int_\Sigma \rho_m\; v\; w\; dx \qquad \forall\, (v,w)\ \in\ L^2(\Sigma)^2, \\ \\ a(v,w) = \displaystyle\int_\Sigma T\; \nabla v \cdot \nabla w\; dx \quad \forall\, (v,w)\ \in\ H^1(\Sigma)^2. \end{cases}$$

REMARK 5. The solution (v,φ) of (4.7) is obviously a solution of (4.13). Proceeding as in Lemma 2, one shows the uniqueness of the solution of (4.13). Therefore, (4.7) and (4.13) are equivalent.

REMARK 6. Note that, in the second equation of (4.13), the space $W(\mathcal{S}_T)$ for test functions is different from the space $V(\mathcal{S}_T)$ in which the solution is searched.

5. The space-time discretization.

5.1. Space-time finite element spaces. The most nontrivial part of the approximation process is the construction of suitable finite element spaces for the approximation of the spaces $W(\mathcal{S}_T)$ and $V(\mathcal{S}_T)$ appearing in (4.13). In this goal, we introduce suitable notation.

Given some Hilbert space X and some time step $\Delta t = T/2N$, we introduce spaces of piecewise linear and piecewise constant functions of time with values in X:

(5.1)
$$\begin{cases} \mathcal{P}^1_{\Delta t}(0,T;X) = \{f \in C^0([0,T],H)\ /\ \forall\, n \le 2N-1,\ f\ |_{[t^n,t^{n+1}]} \in P^1(X)\}, \\ \\ \mathcal{P}^0_{\Delta t}(0,T;X) = \{f \in L^2([0,T],X)\ /\ \ \forall\, n \le 2N-1, f\ |_{[t^n,t^{n+1}]} \in P^0(X)\}, \end{cases}$$

where $t^n = n\Delta t$ and

(5.2)
$$\begin{cases} P^1(X) = \{\psi(t) = \psi_0 + t\psi_1, \quad (\psi_0,\psi_1) \in X^2\}, \\ \\ P^0(X) = \{\psi(t) = \psi_0, \quad \psi_0 \in X\}. \end{cases}$$

In what follows, we shall be led to distinguish two time grids of space step $2\Delta t$, respectively, the even grid associated to instants t^{2n} and the odd grid associated to

instants t^{2n+1}. This leads to a natural decomposition of the spaces $\mathcal{P}^k_{\Delta t}(0,T;X),\ k=0,1$, as

$$\mathcal{P}^k_{\Delta t}(0,T;X) = \mathcal{P}^{k,ev}_{\Delta t}(0,T;X) + \mathcal{P}^{k,od}_{\Delta t}(0,T;X), \quad k=0,1\ , \tag{5.3}$$

(5.4)
$$\begin{cases} \mathcal{P}^{k,ev}_{\Delta t}(0,T;X) = \{f\ \in\ \mathcal{P}^k_{\Delta t}(0,T;X)\ /\ \forall\ n \le N-1,\ f\ |_{[t^{2n},t^{2n+2}]} \in P^k(X)\}, \\ \mathcal{P}^{k,od}_{\Delta t}(0,T;X) = \{f\ \in\ \mathcal{P}^k_{\Delta t}(0,T;X)\ /\ \forall\ n \le N-1,\ f\ |_{[t^{2n-1},t^{2n+1}]} \in P^k(X)\}. \end{cases}$$

To the decomposition (5.3) for $k=1$, we associate two interpolation operators,

$$\Pi^{1,ev}_{\Delta t} : \mathcal{P}^1_{\Delta t}(0,T;X) \longrightarrow \mathcal{P}^{1,ev}_{\Delta t}(0,T;X), \quad \Pi^{1,od}_{\Delta t} : \mathcal{P}^1_{\Delta t}(0,T;X) \longrightarrow \mathcal{P}^{1,od}_{\Delta t}(0,T;X),$$

which are completely characterized by

$$\begin{cases} \left[\Pi^{1,ev}_{\Delta t}\ f\right](t^{2n}) = f(t^{2n}), & 0 \le n \le N-1, \\ \left[\Pi^{1,od}_{\Delta t}\ f\right](t^{2n+1}) = f(t^{2n+1}), & 0 \le n \le N-1. \end{cases} \tag{5.5}$$

In the same way, for k=0, we define the $L^2(0,T;X)$ projection operators

$$\Pi^{0,ev}_{\Delta t} : \mathcal{P}^0_{\Delta t}(0,T;X) \longrightarrow \mathcal{P}^{k,ev}_{\Delta t}(0,T;X), \quad \Pi^{0,od}_{\Delta t} : \mathcal{P}^0_{\Delta t}(0,T;X) \longrightarrow \mathcal{P}^{0,od}_{\Delta t}(0,T;X).$$

Assuming that $f_{n+\frac12}$ is the constant value of some $f \in \mathcal{P}^0_{\Delta t}(0,T;X)$, we simply have

$$\begin{cases} \left[\Pi^{0,ev}_{\Delta t}\ f(t)\right] = \frac{f_{2n+\frac12}+f_{2n+\frac32}}{2} & \text{if}\quad t^{2n} < t < t^{2n+2}, \qquad 0 \le n \le N-1, \\ \left[\Pi^{0,od}_{\Delta t}\ f(t)\right] = \frac{f_{2n+\frac12}+f_{2n-\frac12}}{2} & \text{if}\quad t^{2n-1} < t < t^{2n+1}, \quad 0 \le n \le N-1. \end{cases} \tag{5.6}$$

The effect of the interpolation and projection operators is illustrated in Figure 5.1. Next, we introduce a suitable family $(\mathcal{M}_h, h>0)$ of finite dimensional subspaces of $H^1_0(\Sigma)$, and we consider the finite element spaces for approximating $W(\mathcal{S}_T)$ and $V(\mathcal{S}_T)$:

$$\begin{cases} W_{h,\Delta t}(\mathcal{S}_T) = \{\varphi_{h,\Delta t} \in \mathcal{P}^1_{\Delta t}(0,T;\mathcal{M}_h)\ /\ \varphi_{h,\Delta t}(\cdot,0) = 0\ \}, \\ V_{h,\Delta t}(\mathcal{S}_T) = \mathcal{P}^0_{\Delta t}(0,T;\mathcal{M}_h). \end{cases} \tag{5.7}$$

These spaces can also be defined as follows. Let $w_n(t),\ n\ \in\ \mathbb{N}$, be the functions defined by

$$w_0(t) = 1 - \frac{|t|}{\Delta t} \quad \text{if } |t| \le \Delta t, \quad = 0 \text{ if not}, \quad w_n(t) = w_0(t-t_n). \tag{5.8}$$

Then $\varphi_{h,\Delta t} \in W_{h,\Delta t}(\mathcal{S}_T)$ if and only if there exists $(\varphi_1,\dots,\varphi_{2N}) \in \mathcal{M}_h^{2N}$ such that

$$\varphi_{h,\Delta t}(x,t) = \sum_{n=1}^{2N} \varphi_n(x)\ w_n(t). \tag{5.9}$$

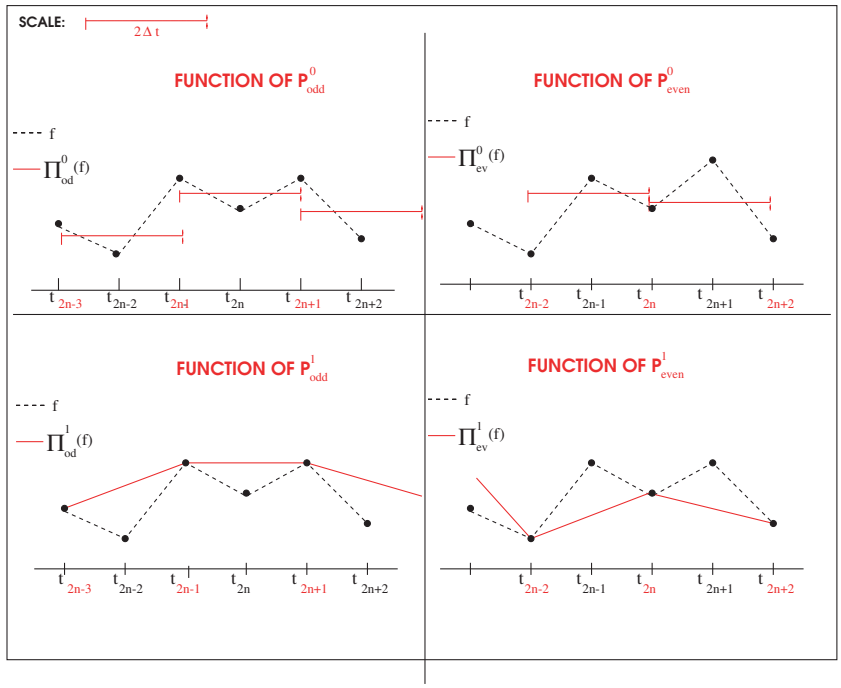

FIG. 5.1. *The interpolation and projection operators.*

In the same way, let $\zeta_n(t)$, $n \in \mathbb{N}^*$, be the functions defined by

$$\zeta_n(t) = 1 \quad \text{if } t \in [t_{n-1}, t_n], \quad = 0 \text{ if not.} \tag{5.10}$$

For any $\psi_{h,\Delta t} \in W_{h,\Delta t}(\mathcal{S}_T)$, there exists $(\psi_1, \ldots, \varphi_{2N}) \in \mathcal{M}_h^{2N}$ such that

$$\psi_{h,\Delta t}(x,t) = \sum_{n=1}^{2N} \psi_n(x)\, \zeta_n(t). \tag{5.11}$$

One can notice the following:

- The space $W_{h,\Delta t}(\mathcal{S}_T))$ is stable by "integer" truncation:

$$\forall\, n \le N, \quad \forall\, \psi_{h,\Delta t} \in W_{h,\Delta t}(\mathcal{S}_T), \quad \chi_{n\Delta t}\psi_{h,\Delta t} \in W_{h,\Delta t}(\mathcal{S}_T). \tag{5.12}$$

- The time derivative $\partial/\partial t$ maps $V_{h,\Delta t}(\mathcal{S}_T)$ into $W_{h,\Delta t}(\mathcal{S}_T)$.

Moreover, one easily checks the commutation property

$$\begin{aligned} \forall\, \varphi_{h,\Delta t} \in W_{h,\Delta t}(\mathcal{S}_T), \quad \Pi^0_{ev} \frac{\partial \varphi_{h,\Delta t}}{\partial t} &= \frac{\partial}{\partial t}\left[\Pi^1_{ev}\varphi_{h,\Delta t}\right], \\ \Pi^0_{od} \frac{\partial \varphi_{h,\Delta t}}{\partial t} &= \frac{\partial}{\partial t}\left[\Pi^1_{od}\varphi_{h,\Delta t}\right]. \end{aligned} \tag{5.13}$$

For the construction of our scheme, since $V_{h,\Delta t}(\mathcal{S}_T)$ (resp., $W_{h,\Delta t}(\mathcal{S}_T)$) is not a subspace of $V(\mathcal{S}_T)$ (resp., $W(\mathcal{S}_T)$), there is a problem, a priori, for defining $b_T(\varphi_{h,\Delta t}, \psi_{h,\Delta t})$ for $\varphi_{h,\Delta t}$ in $W_{h,\Delta t}(\mathcal{S}_T)$ and $\psi_{h,\Delta t}$ in $V_{h,\Delta t}(\mathcal{S}_T)$. Fortunately, this difficulty can be overcome as follows.

For any $0 < \varepsilon < 1/2$, let $w_0^\varepsilon \in C^2(\mathbb{R})$ such that

$$\begin{cases} w_0^\varepsilon(t) = w_0(t) \quad \text{if} \quad |t| \notin [0, \varepsilon\Delta t[\cup]\Delta t(1-\varepsilon), \Delta t(1+\varepsilon)[\,, \\ |w_0^\varepsilon(t)| \le 1 \quad \forall\, t \in \mathbb{R}. \end{cases} \tag{5.14}$$

We set $w_n^\varepsilon(t) = w_0^\varepsilon(t - t_n)$ and introduce the regularization operator

$$\begin{aligned} \varphi_{h,\Delta t} = \sum_{n=1}^{2N} \varphi_n(x)\, w_n(t) \;\in\; W_{h,\Delta t}(\mathcal{S}_T) &\longrightarrow J_\varepsilon \varphi_{h,\Delta t} \\ = \sum_{n=1}^{2N} \varphi_n(x)\, w_n^\varepsilon(t) &\in \mathcal{H}^2(0,T;\mathcal{M}_h). \end{aligned} \tag{5.15}$$

In particular, one can define (cf. Remark 3)

$$b_T(J_\varepsilon \varphi_{h,\Delta t}, \psi_{h,\Delta t}) \quad \forall \psi_{h,\Delta t} \in V_{h,\Delta t}(\mathcal{S}_T).$$

We state without proof the precise result. The main ingredients for the computation will be given in the proof of Lemma 4, which provides an explicit expression useful for numerical computations. The rigorous justification relies on Lebesgue's theorem.

LEMMA 3. [illegible] $(\varphi_{h,\Delta t}, \psi_{h,\Delta t}) \in W_{h,\Delta t}(\mathcal{S}_T) \times V_{h,\Delta t}(\mathcal{S}_T)$ [illegible]

$$b_T(\varphi_{h,\Delta t}, \psi_{h,\Delta t}) = \lim_{\varepsilon \to 0} b_T(J_\varepsilon \varphi_{h,\Delta t}, \psi_{h,\Delta t}), \tag{5.16}$$

[illegible] (6.12) [illegible] 4. [illegible] $\alpha_T > 0$ [illegible] (3.16)

$$\begin{aligned} \forall\, \varphi_{h,\Delta t} \in W_{h,\Delta t}(\mathcal{S}_T), \quad p_T(\varphi_{h,\Delta t}, \varphi_{h,\Delta t}) &\equiv b_T\left(\varphi_{h,\Delta t}, \frac{\partial \varphi_{h,\Delta t}}{\partial t}\right) \\ &\ge \alpha_T\, \|\varphi_{h,\Delta t}\|^2_{V(\mathcal{S}_T)}. \end{aligned} \tag{5.17}$$

[illegible] 7. The inequality (5.17) is obtained by passing to the limit in the inequality (3.16) applied to $J_\varepsilon\, \varphi_{h,\Delta t}$.

5.2. The numerical scheme. We consider a second family $\mathcal{V}_h$ of finite element subspaces of $H_0^1(\Sigma)$ for the approximation of the unknown v. Our approximate solution is

$$\begin{cases} v_{h,\Delta t} \in \mathcal{P}^1_{\Delta t}(0,T;\mathcal{V}_h), \text{ the approximation of } v, \text{ with } v_h^n = v_{h,\Delta t}(t^n), \\ \varphi_{h,\Delta t} \in W_{h,\Delta t}(\mathcal{S}_T), \text{ the approximation of } \varphi, \text{ with } \varphi_h^n = \varphi_{h,\Delta t}(t^n). \end{cases} \tag{5.18}$$

The way we approximate the first equation of (4.13) is completely standard. We use a Galerkin approximation in space (in $\mathcal{V}_h$) and a θ finite difference scheme in time, where θ denotes some parameter in $[0,1]$:

(5.19)

$$\begin{cases} \text{For any } w_h \in \mathcal{V}_h \quad \text{and} \quad n = 1, 2, \dots, 2N-1, \quad v_h^0 = v_h^1 = 0, \text{ and} \\ \left(\dfrac{v_h^{n+1} - 2v_h^n + v_h^{n-1}}{\Delta t^2}, w_h \right) + a(v_h^{n,\theta}, w_h \Big) - \displaystyle\int_\Sigma \frac{\varphi_h^{n+1} - \varphi_h^{n-1}}{2\Delta t}\, w_h\, dx = \int_\Sigma f^n\, w_h\, dx, \end{cases}$$

where

$$f^n = f(t^n) \quad \text{and} \quad v_h^{n,\theta} = \theta\, v_h^{n+1} + (1-2\theta)\, v_h^n + \theta\, v_h^{n-1}. \tag{5.20}$$

For the approximation of the second equation of (4.13), the most natural process would be

$$\frac{1}{\rho}\, b_T\Big(\varphi_{h,\Delta t}, \psi_{h,\Delta t}\Big) + \iint_{\mathcal{S}_T} \frac{\partial v_{h,\Delta t}}{\partial t}\, \psi_{h,\Delta t}\, dxdt = 0 \quad \forall\, \psi_{h,\Delta t} \in V_{h,\Delta t}(\mathcal{S}_T). \tag{5.21}$$

However, this choice does not allow us to guarantee the stability of the resulting method (at least, we did not find a proof—see also Remark 9) by ensuring a discrete equivalent of the identities (4.8) or (4.12).

To make this possible, it appears that a solution consists in writing the same type of equation after "projection" on the two (even and odd) time grids. More precisely, we write that

$$\begin{cases} \dfrac{1}{\rho}\, b_T\Big(\left[\Pi^1_{ev}\varphi_{h,\Delta t}\right], \Pi^0_{ev}\psi_{h,\Delta t}\Big) + \displaystyle\iint_{\mathcal{S}_T} \frac{\partial v_{h,\Delta t}}{\partial t}\ \Pi^0_{\mathrm{ev}}\psi_{h,\Delta t}\, dxdt = 0, \\ \dfrac{1}{\rho}\, b_T\Big(\left[\Pi^1_{od}\varphi_{h,\Delta t}\right], \Pi^0_{od}\psi_{h,\Delta t}\Big) + \displaystyle\iint_{\mathcal{S}_T} \frac{\partial v_{h,\Delta t}}{\partial t}\ \Pi^0_{\mathrm{od}}\psi_{h,\Delta t}\, dxdt = 0 \end{cases} \tag{5.22}$$

for any $\psi_{h,\Delta t} \in V_{h,\Delta t}(\mathcal{S}_T)$.

Remark 8. The reader will note that, in some sense, (5.22) amounts to writing two times (5.21) using two staggered time grids of time step $2\Delta t$.

The numerical method we propose is made of (5.18), (5.19), and (5.22).

6. Analysis of the numerical method. In this section, we first present the calculations that lead to the practical implementation of the method (subsection 6.1). Then we prove the main theoretical result of this paper, namely, the stability theorem, Theorem 6.1. This is the major step to the convergence analysis of the method and the derivation of error estimates, which are delayed to a future work.

6.1. Matrix formulation. Let us introduce a basis $\{\eta_j, 1 \le j \le N_h^v\}$ (resp., $\{\xi_j^h, 1 \le j \le N_h^m\}$) of $\mathcal{V}_h$ (resp., $\mathcal{M}_h$). We can decompose the discrete unknowns (5.18) as

$$v_h^n = \sum_{j=1}^{N_h^v} v_j^n\, \eta_j, \quad \varphi_h^n = \sum_{j=1}^{N_h^v} \varphi_j^n\, \xi_j, \quad 0 \le n \le 2N. \tag{6.1}$$

We are going to rewrite (5.19), (5.22) as a linear problem in the unknown vectors

$$V_h^n = \left(v_j^n\right)_{1\le j\le N_h^v} \in \mathbb{R}^{N_h^v}, \quad \Phi_h^n = \left(\varphi_j^n\right)_{1\le j\le N_h^m} \in \mathbb{R}^{N_h^m}, \quad n = 1, 2, \ldots, 2N. \tag{6.2}$$

We denote by $\mathbf{M}_h$ the $N_h^v \times N_h^v$ mass matrix defined by

$$\mathbf{M}_h = \left((\mathbf{M}_{ij})\right)_{1\le i,j\le N_h^v}, \quad \mathbf{M}_{ij} = (\eta_i, \eta_j), \tag{6.3}$$

by $\mathbf{A}_h$ the $N_h^v \times N_h^v$ stiffness matrix defined by

$$\mathbf{A}_h = \left((\mathbf{A}_{ij})\right)_{1\le i,j\le N_h^v}, \quad \mathbf{A}_{ij} = a(\eta_i, \eta_j), \tag{6.4}$$

and by $\mathbf{C}_h$ the $N_h^v \times N_h^m$ coupling matrix defined by

$$\mathbf{C}_h = ((\mathbf{C}_{ij}))_{1\le i\le N_h^v,\ 1\le j\le N_h^m}, \quad \mathbf{C}_{ij} = \int_\Sigma \eta_i\ \xi_j\ dx. \tag{6.5}$$

Then (5.19) is equivalent to

$$\mathbf{M}_h\ \frac{V_h^{n+1} - 2V_h^n + V_h^{n-1}}{\Delta t^2} + \mathbf{A}_h\ V_h^{n,\theta} - \mathbf{C}_h \frac{\Phi_h^{n+1} - \Phi_h^{n-1}}{2\Delta t} = F_h^n, \tag{6.6}$$
$$n = 1, 2, \dots, 2N-1,$$

where $F_h^n = \left(F_j^n\right)_{1\le j\le N_h^v}$, with $F_j^n = \int_\Sigma f(x,t^n)\ \eta_j\ dx$.

The matrix formulation of (5.22) is slightly more complicated. It is based on Lemma 4. To state this lemma, we need some notation. Let $\delta > 0$ (homogeneous to a time). We introduce the subdomains of $\mathbb{R}^4$:

$$\mathcal{C}_k(\delta) = \{\ (x,y) \in \Sigma^2\ /\ c\ k\delta \le |x-y| \le c\ (k+1)\delta\ \}, \quad k \ge 1. \tag{6.7}$$

Note that these are empty sets for k large enough:

$$k > 1 + \frac{diam\ \Sigma}{c\ \delta} \Longrightarrow \mathcal{C}_k(\delta) = \emptyset.$$

We then define the $N_h^m \times N_h^m$ matrices $\mathbf{P}_h^k(\delta)$ as

$$\mathbf{P}_{ij}^k(\delta) = \delta^2 \int_{C_k(\delta)} \frac{\xi_i(x)\xi_j(y)}{4\pi|x-y|}\ dxdy. \tag{6.8}$$

Next, setting

$$\sigma_k^\delta(x,y) = \frac{1}{2}(k\ - |x-y|/c\delta)^2 \ \text{ and } \ G_{ij}(x,y) = \frac{\nabla\xi_i(x)\cdot\nabla\xi_j(y)}{4\pi|x-y|}\ ,$$

we then define $N_h^m \times N_h^m$ matrices $\mathbf{Q}_h^k(\delta)$:

$$\left|\begin{array}{l} \mathbf{Q}_{ij}^k(\delta) = \delta^2 \displaystyle\int_{C_k(\delta)} G_{ij}\ dxdy - \delta^2 \int_{C_k(\delta)} G_{ij}\ \left[\ \sigma_k^\delta + \sigma_{k-1}^\delta\ \right]\ dxdy \\ \qquad\qquad + \delta^2 \displaystyle\int_{C_{k-1}(\delta)} G_{ij}\ \sigma_{k-2}^\delta\ dxdy\ + \delta^2 \int_{C_{k+1}(\delta)} G_{ij}\ \sigma_{k+1}^\delta\ dxdy. \end{array}\right. \tag{6.9}$$

Finally, we introduce the matrices $\mathbf{N}_h^k(\delta)$ defined by

$$\mathbf{N}_h^k(\delta) = \frac{\mathbf{P}_h^{k+1}(\delta) - 2\ \mathbf{P}_h^k(\delta) + \mathbf{P}_h^{k-1}(\delta)}{\delta^2} - \mathbf{Q}_h^k(\delta). \tag{6.10}$$

Note that the matrices $\mathbf{P}_h^{k+1}(\delta)$, $\mathbf{Q}_h^k(\delta)$, and $\mathbf{N}_h^k(\delta)$ are all symmetric.

LEMMA 4. [illegible] $(\varphi_{h,\Delta t}, \psi_{h,\Delta t}) \in W_{h,\Delta t}(\mathcal{S}_T) \times V_{h,\Delta t}(\mathcal{S}_T)$ [illegible] $\Phi^n = (\varphi_j^n)_{1\le j\le N_h^m}$ $\Psi^n = (\psi_j^n)_{1\le j\le N_h^m}$ [illegible] N_h^m [illegible]

$$\varphi_{h,\Delta t} = \sum_{n=0}^{2N} \varphi_j^n\ w^n \otimes \xi_j, \quad \psi_{h,\Delta t} = \sum_{n=0}^{2N} \psi_j^n\ \zeta^n \otimes \xi_j, \tag{6.11}$$

[illegible] $\Phi^0 = \Psi^0 = 0$ [illegible]

$$b_T(\varphi_{h,\Delta t}, \psi_{h,\Delta t}) = \sum_{n=0}^{2N} \sum_{m=0}^{n} \mathbf{N}_h^{n-m}(\Delta t)\ \Phi_h^m \cdot\ \Psi_h^n, \tag{6.12}$$

[illegible] $\Phi_h \cdot\ \Psi_h$ [illegible] $\mathbb{R}^{N_h^m}$.

[illegible] We sketch the proof by presenting the formal computations that lead to formulas and that can be rigorously justified (this is omitted here) according to Lemma 3.

By linearity, we have

$$\left| \begin{aligned} b_T(\varphi_{h,\Delta t}, \psi_{h,\Delta t}) &= \sum_{m=0}^{2N} \sum_{n=0}^{2N} \sum_{i=1}^{N_h^m} \sum_{j=1}^{N_h^m} b_T(w^m \otimes \xi_i\ ,\ \zeta^n \otimes \xi_j)\ \varphi_i^m\ \psi_j^n \\ &= \sum_{m=0}^{2N} \sum_{n=0}^{2N} \mathbf{B}_T^{m,n} \Phi_h^m \cdot\ \Psi_h^n, \end{aligned} \right. \tag{6.13}$$

where $\mathbf{B}_T^{m,n}$ is the matrix given by $(\mathbf{B}_T^{m,n})_{ij} = b_T(w^m \otimes \xi_i\ ,\ \zeta^n \otimes \xi_j)$.

Using formula (3.18), we have formally

$$\left| \begin{aligned} \mathbf{B}_T^{m,n} \quad &= \mathbf{B}_{T,1}^{m,n}\ +\ \mathbf{B}_{T,2}^{m,n}, \\ \left(\mathbf{B}_{T,1}^{m,n}\right)_{ij} &= \frac{1}{2\pi} \int_\Sigma \int_\Sigma \frac{\xi_j(y)\ \xi_i(x)}{c^2|x-y|}\ J_{mn}^1(x,y)\ dxdy, \\ \left(\mathbf{B}_{T,2}^{m,n}\right)_{ij} &= \frac{1}{2\pi} \int_\Sigma \int_\Sigma \frac{\nabla\xi_j(y) \cdot \nabla\xi_i(x)}{c^2|x-y|}\ J_{mn}^2(x,y)\ dxdy, \end{aligned} \right. \tag{6.14}$$

where

$$\begin{cases} J_{mn}^1(x,y) = \displaystyle\int_0^T \ddot{w}^m\big(t - \tau(x,y)\big)\ \zeta^n(t)\ dt, \\ J_{mn}^2(x,y) = \displaystyle\int_0^T w^m\big(t - \tau(x,y)\big)\ \zeta^n(t)\ dt. \end{cases}$$

In particular, since $\operatorname{supp} w^m(\cdot - \tau(x,y)) \subset [t_{m-1}, +\infty\,[$, one sees that

$$m > n \quad \Longrightarrow \quad J_{mn}^1(x,y) = J_{mn}^2(x,y) = 0 \quad \forall (x,y)\ \in\ \Sigma \times \Sigma \quad \Longrightarrow \quad \mathbf{B}_T^{m,n} = 0.$$

For $m \le n$, the integral J_{mn}^1 has to be understood in a generalized sense since one has, in the sense of distributions ($\delta(t-a)$ denoting the Dirac distribution at time $t = a$),

$$\ddot{w}^n = \frac{1}{\Delta t}\ [\delta(t - t^{n+1}) - 2\ \delta(t - t^n) + \delta(t - t^{n-1})]. \tag{6.15}$$

Therefore,

$$J_{mn}^1(x,y) = \frac{1}{\Delta t}\left[\zeta^m\big(t^{n+1} + \tau(x,y)\big) - 2\ \zeta^m\big(t^n + \tau(x,y)\big) + \zeta^m\big(t^{n-1} + \tau(x,y)\big)\right].$$

The reader will notice that the above expression makes sense for almost every $(x,y) \in \Sigma \times \Sigma$ (as soon as $\tau(x,y)$ is not a multiple of Δt). This is what makes the rigorous

justification of these computations possible. Substituting this expression in (6.14) allows us to show that (simply note that looking at the support of the functions $(x,y) \mapsto \chi^m\big(t^n + \tau(x,y)\big)$ leads us to introduce the domains $\mathcal{C}_k(\Delta t)$)

$$\mathbf{B}_{T,1}^{m,n} = \frac{\mathbf{P}_h^{n-m+1}(\Delta t) - 2\,\mathbf{P}_h^{n-m}(\Delta t) + \mathbf{P}_h^{n-m-1}(\Delta t)}{\Delta t^2}. \tag{6.16}$$

In the same way, rather tedious but simple computations show that

$$\mathbf{B}_{T,2}^{m,n} = -\mathbf{Q}_h^{n-m}(\Delta t). \tag{6.17}$$

One concludes by regrouping (6.13), (6.14), (6.16), and (6.17). ∎

Since our scheme (5.22) amounts to working with two staggered grids of space step $2\Delta t$ (see Remark 8), it is quite easy to deduce from Lemma 4 that (5.22) is equivalent to the following discrete convolution equations:

(6.18)
$$\begin{cases} \dfrac{1}{2\rho\Delta t}\displaystyle\sum_{m=0}^{n} N_h^{n-m}(2\Delta t)\ \Phi_h^{2m+2} + \ C_h^*\ \frac{V_h^{2n+2} - V_h^{2n}}{2\Delta t} = 0, \quad n = 0,1,\dots,N-1, \\ \dfrac{1}{2\rho\Delta t}\displaystyle\sum_{m=0}^{n} N_h^{n-m}(2\Delta t)\ \Phi_h^{2m+1} + \ C_h^*\ \frac{V_h^{2n+1} - V_h^{2n-1}}{2\Delta t} = 0, \quad n = 0,1,\dots,N-1. \end{cases}$$

Remark 9. The "natural" process (5.21) would have led to (instead of (6.18))

$$\frac{1}{\rho\Delta t}\sum_{m=0}^{n} N_h^{n-m}(\Delta t)\ \Phi_h^{m+1} + \ C_h^*\ \frac{V_h^{n+1} - V_h^n}{\Delta t} = 0, \quad n = 0,1,\dots,2N-1. \tag{6.19}$$

Looking at the two coupling terms in (6.6) and (6.18), one sees that the time derivative of v is discretized differently—with a time step Δt in (6.6) and a time step $2\Delta t$ in (6.18). This is what causes trouble for establishing a stability theorem.

6.2. The computational algorithm. In this section, we describe the algorithm that permits us to compute iteratively the solution (V_h^n, Φ_h^n) of (6.6), (6.18). This also gives a proof of the existence and uniqueness of the solution of the scheme (5.18), (5.19), (5.22).

Let us introduce, for each $n \geq 0$, the vector of dimension $N_h^m + N_h^r$:

$$U_h^n = (V_h^n, \Phi_h^n)^T. \tag{6.20}$$

Assuming that U_h^k has been computed up to $k = 2n$, we explain how to compute U_h^{2n+1} and U_h^{2n+2}. From (6.6), (6.18), it is easy to see that one has to solve successively two linear systems of the same nature, namely,

$$\mathbb{K}_h(\Delta t)\ U_h^{2n+1} = B_h^{2n}, \quad \mathbb{K}_h(\Delta t)\ U_h^{2n+2} = B_h^{2n+1}, \tag{6.21}$$

where the matrix $\mathbb{K}_h(\Delta t)$ is given by the block decomposition

$$\mathbb{K}_h(\Delta t) = \begin{pmatrix} (\mathbf{M}_h + \theta\Delta t^2 \mathbf{A}_h) & -\dfrac{\Delta t}{2}\mathbf{C}_h \\ \dfrac{\Delta t}{2}\mathbf{C}_h^* & \mathbf{N}_h^0(2\Delta t) \end{pmatrix},$$

where the right-hand sides B_h^{2n} and B_h^{2n+1} are known linear combinations (that we omit to develop here) of the previous U_h^k's. B_h^{2n} depends on V_h^{2n} and $\Phi_h^{2k}, k \leq N$, and

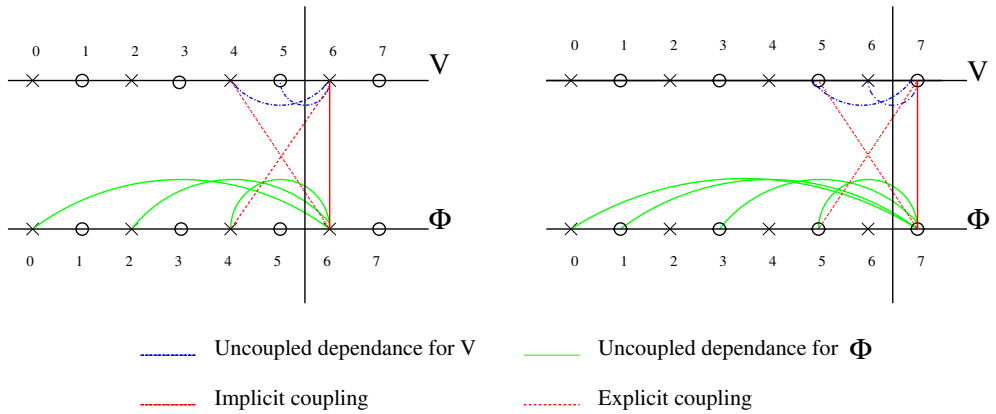

FIG. 6.1. *The computational algorithm.*

B_h^{2n+1} depends on V_h^{2n+1} and $\Phi_h^{2k+1}, k \leq N$. Let us mention that the $\mathbf{N}_h^k(2\Delta t)$'s for $k \geq 1$ appear only in the expressions of B_h^{2n} and B_h^{2n+1}.

The invertibility of S_h is ensured as soon as Δt is small enough (independently of h). Indeed, it is proven in [22] that, for small Δt, the matrix N_h^0 is symmetric positive definite. Figure 6.1 illustrates the computational algorithm.

6.3. Stability analysis. The stability analysis of the method relies on a discrete equivalent of the energy identity (4.11). In the following, we adopt the notation

$$|v|^2 = (v, v) \quad \text{and} \quad v_h^{n+\frac{1}{2}} := \frac{v_h^{n+1} + v_h^n}{2},$$

and we introduce the discrete energy of the membrane at time $t^{n+\frac{1}{2}}$:

(6.22)
$$E^{n+\frac{1}{2}} = \frac{1}{2}\left|\frac{v_h^{n+1} - v_h^n}{\Delta t}\right|^2 + \frac{1}{2}\, a(v_h^{n+\frac{1}{2}}, v_h^{n+\frac{1}{2}}) + \left(\theta - \frac{1}{4}\right)\, a\left(\frac{v_h^{n+1} - v_h^n}{\Delta t}, \frac{v_h^{n+1} - v_h^n}{\Delta t}\right).$$

This is nothing but a discrete equivalent of the continuous membrane energy (which appears as the first term in the left-hand side of the identity (4.8))

$$E(t) = \frac{1}{2}\int_\Sigma \left(\frac{1}{c_m^2}\left|\frac{\partial v}{\partial t}\right|^2 + |\nabla v|^2\right)(x,t)\, dx. \tag{6.23}$$

This discrete energy is the energy which is naturally associated to the θ-scheme for the membrane equation and one has the well-known identity

$$\begin{aligned}\frac{E^{n+\frac{1}{2}} - E^{n-\frac{1}{2}}}{\Delta t} &= \left(\rho_p \frac{v_h^{n+1} - 2v_h^n + v_h^{n-1}}{\Delta t^2}, \frac{v_h^{n+1} - v_h^{n-1}}{2\Delta t}\right) \\ &\quad + a\left(v_h^{n,\theta}, \frac{v_h^{n+1} - v_h^{n-1}}{2\Delta t}\right).\end{aligned} \tag{6.24}$$

The main result of this section is the following theorem.

THEOREM 6.1. [illegible] $(v_h^n, \varphi_{h,\Delta t})$ [illegible] (5.18), (5.19), (5.22) [illegible] n

$$E_h^{2n-\frac{1}{2}} + \frac{1}{2\rho}\left[\, |\Pi^1_{\mathrm{od}}\varphi_{\mathrm{h},\Delta\mathrm{t}}|^2_{\mathrm{N},\mathcal{S}_{\mathrm{t}2\mathrm{n}}} + |\Pi^1_{\mathrm{ev}}\varphi_{\mathrm{h},\Delta\mathrm{t}}|^2_{\mathrm{N},\mathcal{S}_{\mathrm{t}2\mathrm{n}-1}} \,\right] = \sum_{k=0}^{2n-1} \Delta t \int_\Sigma f^k \, \frac{v_h^{k+1} - v_h^{k-1}}{2\Delta t}\, dx, \tag{6.25}$$

$$E_h^{2n+\frac{1}{2}} + \frac{1}{2\rho}\left[\, |\Pi^1_{\mathrm{od}}\varphi_{\mathrm{h},\Delta\mathrm{t}}|^2_{\mathrm{N},\mathcal{S}_{\mathrm{t}2\mathrm{n}}} + |\Pi^1_{\mathrm{ev}}\varphi_{\mathrm{h},\Delta\mathrm{t}}|^2_{\mathrm{N},\mathcal{S}_{\mathrm{t}2\mathrm{n}+1}} \,\right] = \sum_{k=0}^{2n+1} \Delta t \int_\Sigma f^k \, \frac{v_h^{k+1} - v_h^{k-1}}{2\Delta t}\, dx. \tag{6.26}$$

[illegible]. We restrict ourselves to the proof of (6.25). The proof of (6.26) is almost identical.

Taking $w_h = \frac{v_h^{k+1} - v_h^{k-1}}{2\Delta t}$ in (5.19) (with $n = k$), and using identity (6.24), we obtain

$$\frac{E_p^{k+\frac{1}{2}}(v_h) - E_p^{k-\frac{1}{2}}(v_h)}{\Delta t} - \int_\Sigma \frac{\varphi_h^{k+1} - \varphi_h^{k+1}}{2\Delta t}\, \frac{v_h^{k+1} - v_h^{k-1}}{2\Delta t}\, dx = \int_\Sigma f^k \, \frac{v_h^{k+1} - v_h^{k-1}}{2\Delta t}\, dx.$$

After summation over k from 0 to $2n-1$, we get

$$\left|\begin{aligned} E_p^{2n-\frac{1}{2}}(v_h) &- \Delta t \sum_{k=0}^{n-1} \int_\Sigma \frac{\varphi_h^{2k+1} - \varphi_h^{2k-1}}{2\Delta t}\, \frac{v_h^{2k+1} - v_h^{2k-1}}{2\Delta t}\, dx \\ &- \Delta t \sum_{k=0}^{n-1} \int_\Sigma \frac{\varphi_h^{2k+2} - \varphi_h^{2k}}{2\Delta t}\, \frac{v_h^{2k+2} - v_h^{2k}}{2\Delta t}\, dx \\ &= \Delta t \sum_{k=0}^{2n-1} \int_\Sigma f^k \, \frac{v_h^{k+1} - v_h^{k-1}}{2\Delta t}\, dx. \end{aligned}\right. \tag{6.27}$$

Next, in the first equation of (5.22), we take $\psi_{h,\Delta t} = \chi^{2n\Delta t}\, \frac{\partial}{\partial t}\, \varphi_{h,\Delta t}$, which is possible since $\chi^{2n\Delta t}\, \partial/\partial t$ maps $W_{h,\Delta t}(\mathcal{S}_T)$ in $V_{h,\Delta t}(\mathcal{S}_T)$. Using the fact that

$$\Pi^0_{ev}\left[\chi^{2n\Delta t}\, \frac{\partial}{\partial t}\, \varphi_{h,\Delta t}\right] = \chi^{2n\Delta t}\, \frac{\partial}{\partial t}\, \Pi^1_{ev}\varphi_{h,\Delta t}$$

and the properties of the bilinear form $b_T(\cdot,\cdot)$ (see, in particular, (3.19)), we get

$$\left|\begin{aligned} b_T\Big(\left[\Pi^1_{ev}\varphi_{h,\Delta t}\right], \Pi^0_{ev}\left[\chi^{2n\Delta t}\, \tfrac{\partial}{\partial t}\, \varphi_{h,\Delta t}\right]\Big) &= b_T\Big(\left[\Pi^1_{ev}\varphi_{h,\Delta t}\right], \chi^{2n\Delta t}\, \tfrac{\partial}{\partial t}\, \Pi^1_{ev}\varphi_{h,\Delta t}\Big) \\ &= |\Pi^1_{ev}\varphi_{h,\Delta t}|^2_{N,\mathcal{Q}_{t2n}}. \end{aligned}\right. \tag{6.28}$$

On the other hand, one computes easily that

$$\int_{\mathcal{S}_T} \frac{\partial v_{h,\Delta t}}{\partial t} \cdot \chi^{2n\Delta t}\, \frac{\partial}{\partial t}\, \varphi_{h,\Delta t}\, dx\, dt = 2\Delta t \sum_{k=0}^{n} \int_\Sigma \frac{\varphi_h^{2k+2} - \varphi_h^{2k}}{2\Delta t}\, \frac{v_h^{2k+2} - v_h^{2k}}{2\Delta t}\, dx. \tag{6.29}$$

Finally, we obtain

$$\frac{1}{\rho\Delta t}\,|\Pi^1_{ev}\varphi_{h,\Delta t}|^2_{N,\mathcal{S}_{t^{2n}}} + 2\Delta t\sum_{k=0}^{n-1}\int_\Sigma \frac{\varphi_h^{2k+2}-\varphi_h^{2k}}{2\Delta t}\,\frac{v_h^{2k+2}-v_h^{2k}}{2\Delta t}\,dx = 0. \tag{6.30}$$

In the same way, substituting into the second equation of (5.22), $\psi_{h,\Delta t} = \chi^{(2n-1)\Delta t}\cdot\frac{\partial}{\partial t}\,\varphi_{h,\Delta t}$, we get

$$\frac{1}{\rho\Delta t}\,|\Pi^1_{od}\varphi_{h,\Delta t}|^2_{N,\mathcal{S}_{t^{2n-1}}} + 2\Delta t\sum_{k=0}^{n-1}\int_\Sigma \frac{\varphi_h^{2k+1}-\varphi_h^{2k-1}}{2\Delta t}\,\frac{v_h^{2k+1}-v_h^{2k-1}}{2\Delta t}\,dx = 0. \tag{6.31}$$

Finally, the combination (6.27) + $\frac{1}{2}$ (6.30) + $\frac{1}{2}$ (6.31) leads to the desired result. □

We are now in a position to state our main stability theorem.

THEOREM 6.2. [illegible] $\theta \geq 1/4$ [illegible]

$$\begin{cases} \displaystyle\sup_{t^{n+1}\leq T}\Big|\frac{v_h^{n+1}-v_h^n}{\Delta t}\Big| + \sup_{t^{n+1}\leq T}|\nabla v_h^{n+\frac{1}{2}}|_{L^2(\Sigma)} \;\leq\; C\,T\,\|f\|_{L^\infty(0,T;L^2(\Sigma))}, \\[2ex] \displaystyle\sup_{t^n\leq T}|\Pi^1_{ev}\varphi_{h,\Delta t}|_{S_{t^n}} + \sup_{t^n\leq T}|\Pi^1_{od}\varphi_{h,\Delta t}|_{S_{t^n}} \;\leq\; C\,T\,\|f\|_{L^\infty(0,T;L^2(\Sigma))}, \end{cases} \tag{6.32}$$

[illegible] C [illegible] Δt [illegible] $\theta < 1/4$ [illegible]

$$\exists\,\alpha<1,\quad \frac{\Delta t^2}{4}\,(1-4\theta)\,\|a_h\| \leq \alpha, \tag{6.33}$$

[illegible]

$$\|a_h\| = \sup_{v_h\in\mathcal{V}_h}\frac{a(v_h,v_h)}{|v_h|^2}. \tag{6.34}$$

[illegible] (4.12) [illegible] C [illegible] α [illegible]. We restrict ourselves to the case $\theta \geq 1/4$. The case $\theta < 1/4$ differs only in technical details. Due to $\theta \geq 1/4$, we have

$$\Big|\frac{v_h^{n+1}-v_h^n}{\Delta t}\Big|^2 \leq 2\,E_h^{n+\frac{1}{2}}.$$

Thus, from the two identities (6.25) and (6.26), we deduce the existence of a positive constant C (that depends only on σ) such that

$$\Big|\frac{v_h^{n+1}-v_h^n}{\Delta t}\Big|^2 \;\leq\; C\sum_{k=0}^{n-1}\|f^k\|_{L^2}\Big|\frac{v_h^{k+1}-v_h^{k-1}}{\Delta t}\Big|\,\Delta t.$$

Then, thanks to a discrete Gronwall lemma, we deduce

$$\Big|\frac{v_h^{n+1}-v_h^n}{\Delta t}\Big| \;\leq\; C\sum_{k=0}^{n}\|f^n\|_{L^2(\Sigma)}\,\Delta t \;\leq\; C\,t^n\,\|f\|_{L^\infty(0,T;L^2(\Sigma))}. \tag{6.35}$$

Using (6.35) in (6.25) and (6.26), we easily obtain

$$E_h^{n+\frac{1}{2}} \ \leq \ C \ (t^n)^2 \ \|f\|^2_{L^\infty(0,T;L^2(\Sigma))},$$

from which the first inequality of (6.32) follows immediately.

Next, (6.25) and (6.26) also lead to

$$|\Pi^1_{od}\varphi_{h,\Delta t}|^2_{N,\mathcal{S}_{t^n}} + |\Pi^1_{ev}\varphi_{h,\Delta t}|^2_{N,\mathcal{S}_{t^n}} \ \leq \ C \ (t^n)^2 \ \|f\|^2_{L^\infty(0,T;L^2(\Sigma))}$$

for any $t^n \leq T$. This yields the second inequality of (6.32). □

. . . . 10. The CFL condition is nothing but the standard CFL condition for the θ-scheme applied to the plate equation only.

7. Extension to the vibrations of a plate. We present the extension of the numerical method of section 4 to the vibrations of a plate, considering the two classical plate models: Kirchhoff–Love [10], [7] and Mindlin–Reissner [10], [32]. For simplicity, we shall assume that the material constituting the plate is an isotropic solid characterized by its Young modulus E and its Poisson's coefficient ν. However, the extension to the anisotropic case is straightforward (see [29], for instance). The surface density of the plate will be denoted ρ_p and its thickness will be denoted δ. What is important to notice is that, for both models, the normal velocity v is, as for the case of the membrane, one of the unknowns of the problems and, consequently, the kinematic coupling fluid-structure condition (2.3) is preserved. The changes of the models affect essentially the first equation of system (2.2): the wave equation has to be replaced by a plate equation. However, we show in this section how the coupled model can be put in the abstract variational framework (4.13) in such a way that the method of section (5) (and the results of section 6) can be applied directly. For the two models, the unknown φ has the same meaning as for the case of the membrane: it represents the pressure jump across Σ.

7.1. The case of a Kirchhoff–Love plate. In this case, the normal velocity is the only unknown of the mechanical model. The equations for the movement of the plate are

$$\begin{cases} \rho_p \ \delta \ \dfrac{\partial^2 v}{\partial t^2} + \dfrac{\delta^3 E}{12(1-\nu^2)} \ \Delta^2 v = f + \left[\dfrac{\partial p}{\partial t}\right], & x \in \Sigma, \quad t > 0, \\ v(x,t) = \dfrac{\partial v}{\partial \nu}(x,t) = 0, & x \in \partial\Sigma, \quad t > 0, \end{cases} \tag{7.1}$$

where f and $[p]$ have the same meaning as in section 2. We have considered the case of an isotropic plate, clamped along its boundary, which explains the boundary conditions in (7.1) ($\nu \in \mathbb{R}^2$ is the unit vector of the plane $z = 0$, normal to $\partial\Sigma$, outgoing with respect to Σ).

Proceeding as in section 4, it is not difficult to show that the problem (7.1) can be reduced in a problem of the form (4.13), where only the meanings of the inner product $(\cdot,\cdot)$, of the bilinear form $a(\cdot,\cdot)$, and of the space $\mathcal{V}$ are changed with respect to section 4. More precisely,

$$\begin{cases} \mathcal{V} = H^2_0(\Sigma), \\ (v,w) = \rho_p \ \delta \ \displaystyle\int_\Sigma v \ w \ dx & \forall \ (v,w) \ \in \ L^2(\Sigma)^2, \\ a(v,w) = \dfrac{\delta^3 E}{12(1-\nu^2)} \ \displaystyle\int_\Sigma \Delta v \ \Delta w \ dx & \forall \ (v,w) \ \in \ \mathcal{V}^2. \end{cases} \tag{7.2}$$

7.2. The case of a Mindlin–Reissner plate. The Mindlin–Reissner model is slightly more complicated than in the Kirchhoff–Love model in the sense that, in addition to the normal velocity v, a new unknown has to be introduced for the description of the movements of the plate, namely, the rotation vector

$$\theta = (\theta_x, \theta_y)^t. \tag{7.3}$$

The governing equation is a linear hyperbolic system of second order, namely,

(7.4)
$$\begin{cases} \rho_p\ \delta\ \dfrac{\partial^2 v}{\partial t^2} - \delta\ \mathrm{div}[\ G\ (\nabla v + \theta)\ ] & = f + \left[\dfrac{\partial p}{\partial t}\right], \quad x \in \Sigma, \quad t > 0, \\ \rho_p\ \dfrac{\delta^3}{12}\ \dfrac{\partial^2 \theta}{\partial t^2} - \dfrac{\delta^3}{12}\ \mathrm{Div}\left(\underline{\underline{C}}\ \underline{\underline{\varepsilon}}(\theta)\right) + \delta\ G\ (\nabla v + \theta) & = 0, \qquad x \in \Sigma, \quad t > 0, \\ v(x,t) = \theta(x,t) & = 0, \qquad x \in \partial\Sigma, \quad t > 0, \end{cases}$$

which depends on E and ν, where $\underline{\underline{\varepsilon}}$ is the linearized plane deformation tensor defined by

$$\underline{\underline{\varepsilon}}(\theta) := \underline{\underline{\varepsilon}}(\theta)_{i,j} = \frac{1}{2}\left(\frac{\partial \theta_i}{\partial x_j} + \frac{\partial \theta_j}{\partial x_i}\right) \quad \forall\ i,j = \{1,2\}.$$

$G = \frac{E}{2(1+\nu)}$ and $\underline{\underline{C}}$ is the stiffness tensor given by (the indices below belong to $\{1,2\}$ and $\delta_{\alpha\beta}$ is the usual Kronecker symbol)

$$C^{\alpha\beta\lambda\mu} = \frac{E}{2(1+\nu)}\left(\ \delta_{\alpha\lambda}\ \delta_{\beta\mu} + \delta_{\alpha\mu}\ \delta_{\beta\lambda} + \frac{2\nu}{1-\nu}\delta_{\alpha\beta}\ \delta_{\lambda\mu}\ \right). \tag{7.5}$$

After reduction to Σ, one can write a variational formulation of the type (4.13), provided that one has made the substitution

$$v \to (v, \theta), \quad w \to (w, \eta) \tag{7.6}$$

and one has defined

(7.7)
$$\begin{cases} \mathcal{V} = H_0^1(\Sigma) \times H_0^1(\Sigma) \quad \text{and for any } ((v,\theta),(w,\eta)) \text{ in } \mathcal{V}^2, \\ \big((v,\theta),(w,\eta)\big) = \rho_p\ \delta\ \displaystyle\int_\Sigma v\ w\ dx + \rho_p\ \frac{\delta^3}{12}\ \int_\Sigma \theta \cdot \eta\ dx, \\ a\big((v,\theta),(w,\eta)\big) = \dfrac{\delta^3}{12}\displaystyle\int_\Sigma \underline{\underline{C}}\ \underline{\underline{\varepsilon}}(\theta) : \varepsilon(\eta) + \delta \int_\Sigma G\ (\nabla v + \theta) \cdot (\nabla w + \eta). \end{cases}$$

8. Numerical results.

- Concerning the continuous model:
  - The sound speed in the fluid is $c = 1$.
  - The membrane (or plate) Σ is the square $[-5,5] \times [-5,5]$.
  - The loading force f is localized at the center of Σ and its time dependence is a Ricker-type function with a central frequency f_0:

$$\left|\begin{array}{l} f(t,x) = g(x)h(t), \\ h(t) = -2\pi^2 f_0^2\ [2\pi^2(f_0 t - 1)]\ e^{-\pi^2(f_0 t - 1)^2}, \\ g(x) = e^{-\pi^2 |x|^2} \quad \text{if } |x| < 1, \quad 0 \text{ if not.} \end{array}\right.$$

- Concerning the discretization:
  - For the discretization of the pressure jump φ, i.e., for the space $\mathcal{M}_h$, we use P_1 continuous Lagrange elements [11] associated with a triangular mesh of Σ.
  - The discretization grid for φ is constructed by partitioning Σ into equal $N \times N$ squares of size $h = 0.2 \Longleftrightarrow N = 50$ and dividing each small square via its diagonal into two square triangles.
  - We take $\Delta t = 0.07$ to have a CFL: $c\ (2\Delta t)/h = 0.7$ for the time discretization of retarded potentials.
  - For the 3D-2D computations, the computational box for the 3D part of the computation is a parallelepipedic box that surrounds Σ in a symmetric way. It is chosen large enough in order to be sure that the computation is not affected by the presence of the exterior artificial boundary for the duration of the experiment.

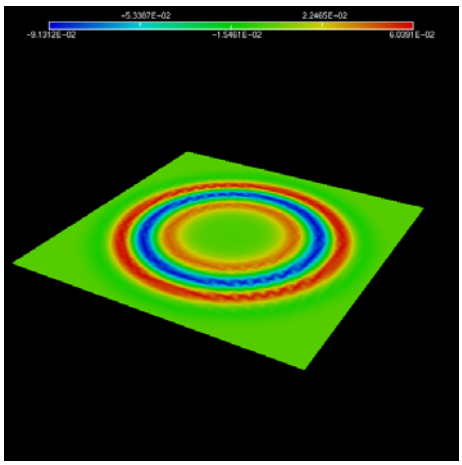
The numerical results that we present in this section are not supposed to reproduce realistic physical experiments but are essentially devoted to validate our numerical method by comparing the results of the computations with those obtained with another code based on the coupling between 3D and 2D finite elements. Such a code has already been validated for both cases of the membrane [9] and of the plate [7], [13]. We shall consider successively the case of the membrane (section 8.1) and of the Mindlin–Reissner plate (section 8.2). Both experiments will have common features. Moreover, in section 8.2, we shall also compute a reference solution computed with the 3D-2D method with very high accuracy (high order finite elements). This will allow us to compare the respective accuracy of the BEM-FEM and 3D-2D methods.

8.1. Vibrations of a membrane. We feature in this section some numerical results that illustrate the pressure jump $\varphi_{h,\Delta t}$ and the transverse velocity $v_{h,\Delta t}$, solutions of the system (5.19)–(5.22) where bilinear forms $(.,.)$ and $a(.,.)$ are given in (4.14). Toward this end, the speed velocity in the membrane is $c_m = 1$ and the central frequency f_0 is taken equal to 0.5 such that the central wavelength in each media is $\lambda = 2$. Parameters for the spatial discretization are well appropriated for this computation case.

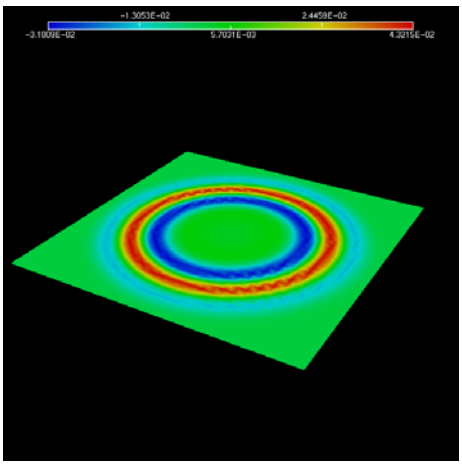
In order to illustrate the physical phenomenon we want to simulate, we represent in Figure 8.1 two snapshots of $\varphi_{h,\Delta t}$ and $v_{h,\Delta t}$ at times $t = 4.2s$ and $t = 8.4s$. Due to the fact that the two propagation velocities c and c_m are here equal and to the fact that the source is centered at the middle of the membrane, this phenomenon is particularly simple: propagation at velocity 1 along the membrane and reflection of the four boundaries in a symmetric way.

In Figures 8.2 and 8.3, we observe and compare $\varphi_{h,\Delta t}$ and $v_{h,\Delta t}$ as functions of the time at the center of the membrane during 30s. We have successively computed these solutions with our new BEM-FEM method and a 2D-3D finite element code. We can see that both solutions are very closed, which brings to the fore that our BEM-FEM method is stable and computes the good solution with a very good precision.

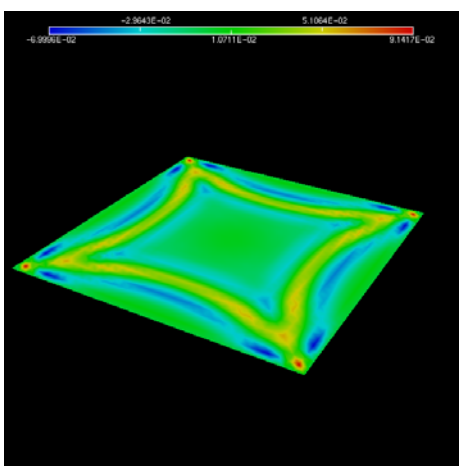
8.2. Vibrations of a plate. In this section, we consider a Reissner–Mindlin plate model instead of the membrane model. We feature here some results related to the pressure jump $\varphi_{h,\Delta t}$ and the transverse velocity $v_{h,\Delta t}$ that satisfy the system (5.19)–(5.22) where bilinear forms are given in (7.7). We have chosen to keep the same computational mesh as in the previous section (in particular to avoid recomputing the matrices $\mathbf{N}_h^M$—one of the more expensive steps of the computations). Consequently,



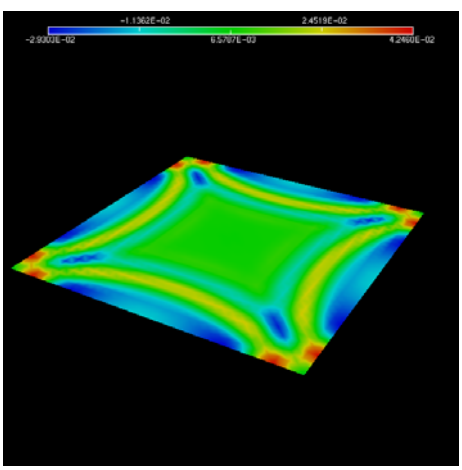
(a) Pressure jump at $t = 4.2s$



(b) Transverse velocity at $t = 4.2s$



(c) Pressure jump at $t = 8.4s$



(d) Transverse velocity at $t = 8.4s$

FIG. 8.1. *Snapshots of the solutions.*

we have chosen the following set of values for the physical parameters:

$$\rho_p = 1,\ E = 0.1297,\ \nu = 0.3,\ f_0 = 1,$$

and have been able to check numerically that, for this choice, our computational mesh is fine enough. Note that such parameters do not correspond to an existing physical material and are just used for an academic benchmark.

As in the previous subsection, we first give some snapshots (cf. Figure 8.4) that illustrate the involved physical phenomenon. As one can expect, this phenomenon is much more complex than for the membrane: in particular, the dispersive nature of the waves along the plate is clearly visible.

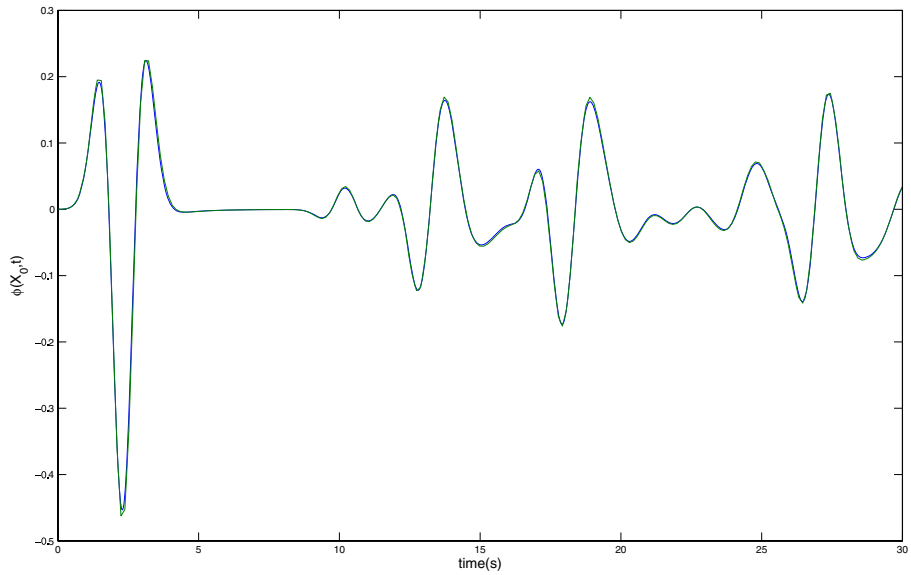


FIG. 8.2. *The pressure jump at the center of the plate. The solid line represents the* 2*D*-3*D method, and the dotted line represents the BEM-FEM method.*

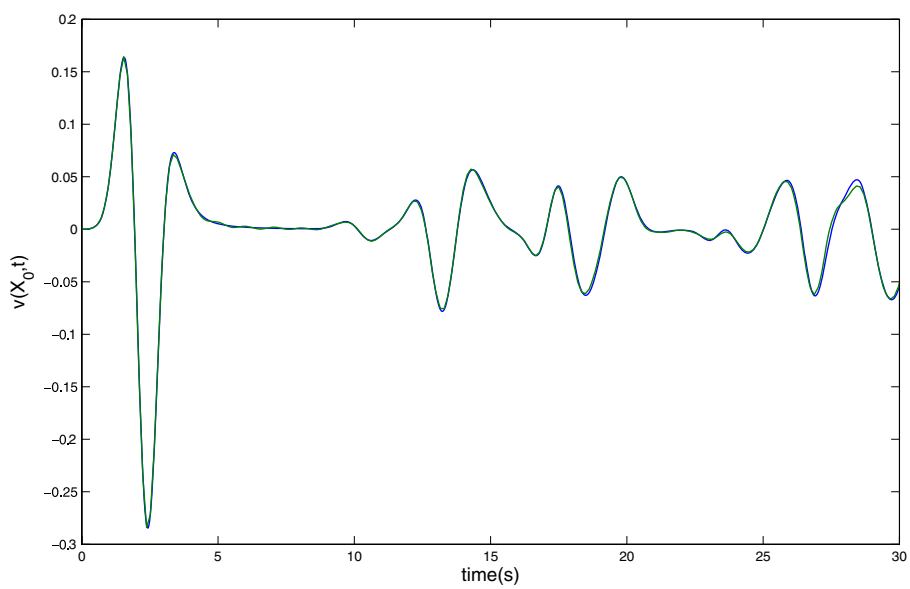

FIG. 8.3. *The transverse velocity at the center of the plate. The solid line represents the* 2*D*-3*D method, and the dotted line represents the BEM-FEM method.*

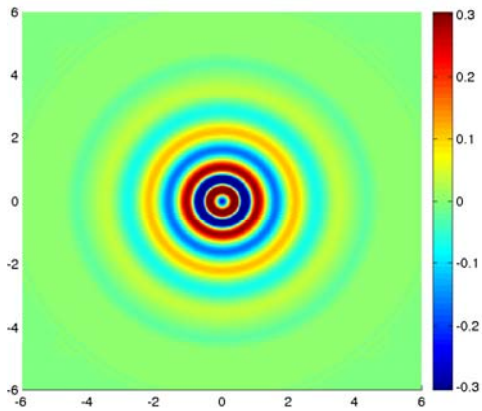
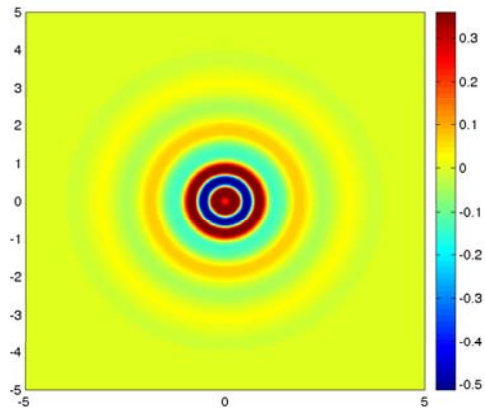
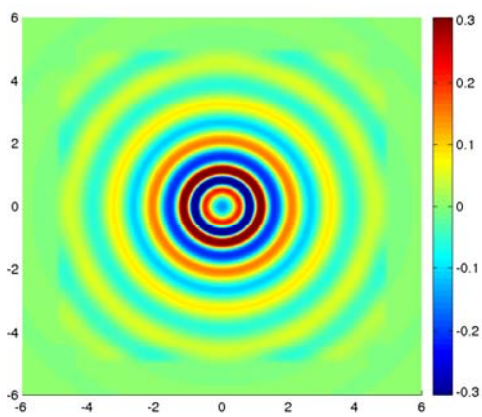


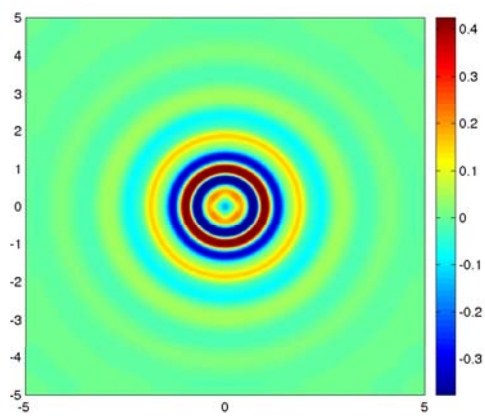
(a) Pressure jump at $t = 5s$



(b) Transverse velocity at $t = 5s$



(c) Pressure jump at $t = 7.5s$



(d) Transverse velocity at $t = 7.5s$

FIG. 8.4. *Snapshots of the solutions.*

Next we observe $\varphi_{h,\Delta t}$ and $v_{h,\Delta t}$ as functions of the time but at point $x_1 = (-2, 5, 0)$ (this is no longer the center of the plate), during 50s. Figures 8.5 and 8.6 show the comparison between the reference solution and the solution computed with our BEM-FEM method. The results are quite convincing with respect to the validation of our method.

Finally, in order to show the advantage of our BEM-FEM method in terms of accuracy (the use of retarded potential minimizes numerical dispersion), we show the transverse velocity and the pressure jump obtained with the 2D-3D finite element code with exactly the same parameters as for the spatial discretization. Figures 8.7 and 8.8 seem to acknowledge the fact that, with the same computational mesh, the BEM-FEM method is more accurate than the 2D-3D finite element one. Our interpretation is that this is probably due to the fact that the acoustic propagation is treated in a more exact way via retarded potentials: one eliminates the dispersion effects due to the discretization of the 3D wave equation.

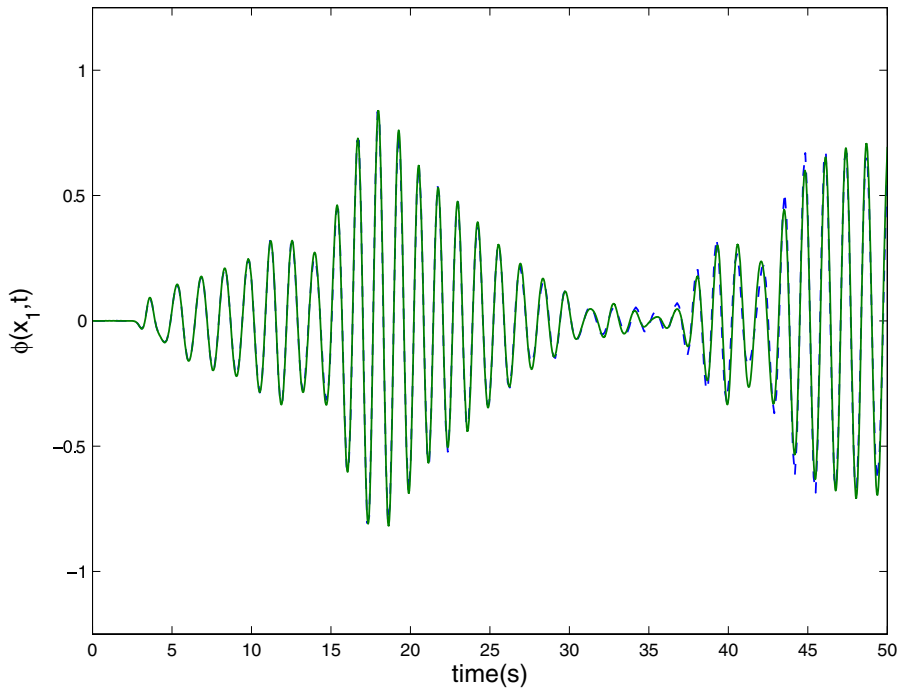


FIG. 8.5. *The pressure jump with the BEM-FEM method. The dashed line represents the BEM-FEM method, and the dotted line represents the reference solution.*

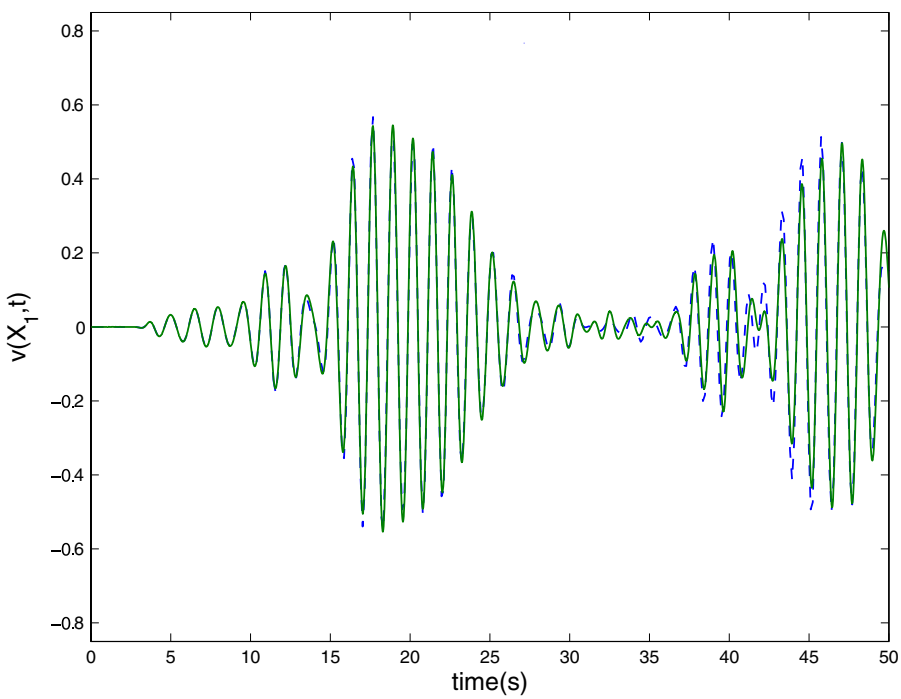

FIG. 8.6. *The transverse velocity with the BEM-FEM method. The dashed line represents the BEM-FEM method, and the dotted line represents the reference solution.*

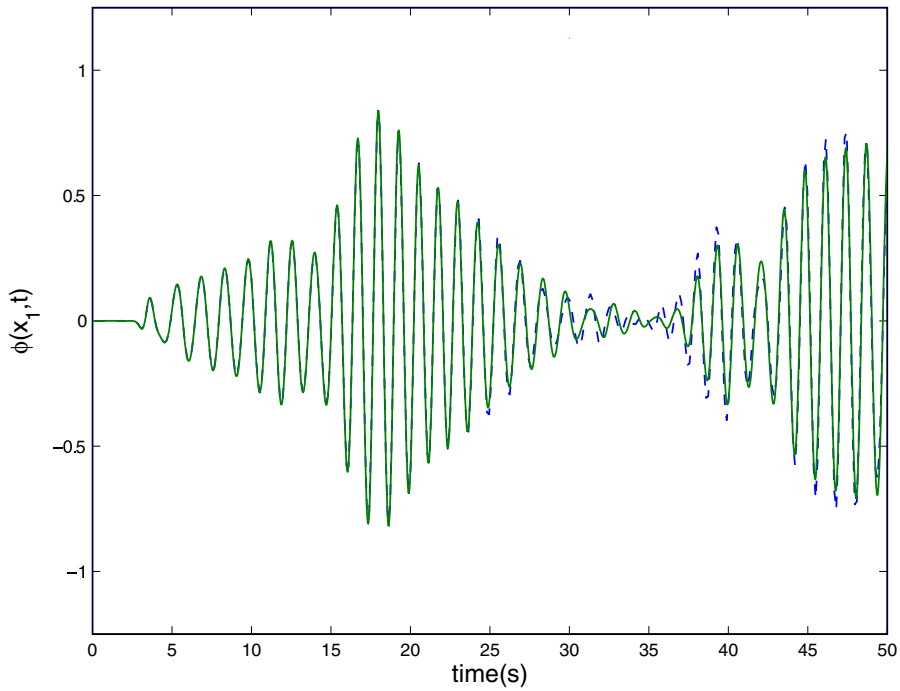

FIG. 8.7. *The pressure jump obtained with the 2D-3D finite element code. The dashed line represents the 2D-3D method, and the dotted line represents the reference solution.*

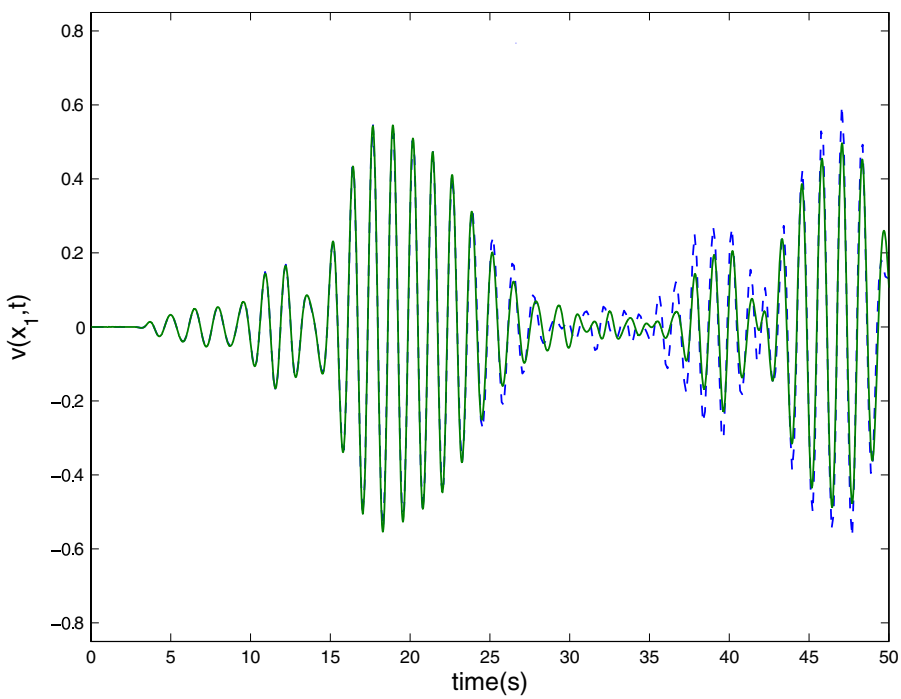

FIG. 8.8. *The transverse velocity obtained with the 2D-3D finite element code. The dashed line represents the 2D-3D method, and the dotted line represents the reference solution.*

Acknowledgments. The authors would like to thank Toufic Abboud, Eliane Bécache, and Isabelle Terrasse for stimulating discussions. They also thank Toufic Abboud for having provided the computations of the matrices $\mathbf{N}_h^m$.

AN ACCELERATED KERNEL-INDEPENDENT FAST MULTIPOLE METHOD IN ONE DIMENSION*

P. G. MARTINSSON† AND V. ROKHLIN‡

Abstract. A version of the fast multipole method (FMM) is described for charge distributions on the line. Previously published schemes of this type relied either on analytical representations of the potentials to be evaluated (multipoles, Legendre expansions, Taylor series, etc.) or on tailored representations that were constructed numerically (using, e.g., the singular value decomposition (SVD), artificial charges, etc.). The algorithm of this paper belongs to the second category, utilizing the matrix compression scheme described in [H. Cheng, Z. Gimbutas, P. G. Martinsson, and V. Rokhlin, SIAM J. Sci. Comput. 26 (2005), pp. 1389–1404]. The resulting scheme exhibits substantial improvements in the CPU time requirements. Furthermore, the scheme is applicable to a wide variety of potentials; in this respect, it is similar to the SVD-based FMMs. The performance of the method is illustrated with several numerical examples.

Key words. fast multipole method, fast summation, matrix interpolation, skeletonization

1. Introduction.

We consider the problem of rapidly evaluating the sum

$$u_m = \sum_{n=1}^{N} K(x_m, x_n)\, q_n, \qquad \text{for } m = 1, \ldots, N, \tag{1.1}$$

given a set of points $(x_n)_{n=1}^N$ in $\mathbb{R}$, a kernel K that is smooth away from the diagonal, and a set of real or complex numbers $(q_n)_{n=1}^N$. We refer to the numbers q_n as "sources," the numbers u_n as "potentials," and the points x_n as "source locations."

The sum (1.1) can be straightforwardly evaluated using $O(N^2)$ floating point operations. In many applications, this cost is prohibitively large, and a number of methods that reduce the cost to $O(N)$ or $O(N \log^\kappa N)$ have been developed, [2, 10]. In this paper, we describe an $O(N)$ method that is a development of the fast multipole method (FMM) [10, 9]. The changes introduced enable the application of the method to a large class of kernels and makes the method significantly faster than existing techniques for the case where the sum (1.1) has to be evaluated several times for a fixed set of locations $(x_n)_{n=1}^N$ (see section 6).

There are two principal differences between the method presented here and the original FMM of [10]. The first concerns the way sources and potentials are represented. While the FMM relies on analytic properties of the kernel, the method presented here relies on a precomputation step that adaptively constructs representations that are optimized for the given kernel and the given source locations. The second difference concerns the treatment of the interactions between adjacent subintervals on the finest level of subdivision. While the original FFM evaluates such

interactions directly, the representations used by the method of this paper enable the compression of such interactions.

The method presented here is similar to the methods of [8, 15, 25] in that they all rely on adaptively computed representations, and thus work for a wide range of kernels. While the methods of [8, 25] rely on the singular value decomposition (SVD) to compress the kernel and [15] relies on the QR-decomposition, this paper is based on a technique described in [5, 18, 17] that we refer to as "skeletonization." Similar techniques were previously used in [19, 20, 24]. We also note that the method presented here bears some similarity to the kernel-independent FMM of [26] (which can in turn be viewed as a development of [1, 16]). However, while the method of this paper relies only on certain smoothness properties of the kernel, the method of [26] requires the kernel to satisfy certain Green-type identities (as kernels associated with fundamental solutions of constant coefficient partial differential operators tend to do).

This paper is structured as follows: Section 2 lists some results from numerical linear algebra that will be of use. Section 3 describes the adaptive technique for the representation of sources and potentials that the current method relies on. Section 4 describes a fast summation scheme based on the same data structures as the original FMM, but using the representation described in section 3. Section 5 describes an additional acceleration of the method based on compressing interactions between [illegible] boxes, including adjacent ones. Section 6 reports the results of several numerical experiments, and section 7 summarizes the results.

[illegible] 1. This paper deals with the one-dimensional case. Extensions of the method to higher dimensions are under investigation and will be reported at a later date.

2. Preliminaries. The fast summation technique described in this paper achieves acceleration by approximating off-diagonal blocks of the matrix $[K(x_m, x_n)]_{m,n=1}^{N}$ in (1.1) by low-rank matrices. The particular matrix factorization we use to represent the low-rank matrix was described in [13] and [5]. The following lemma summarizes the facts needed for our purposes.

LEMMA 1. [illegible] A [illegible] $M \times N$ [illegible] k [illegible] $C_1, \ldots, C_N$ [illegible] $R_1, \ldots, R_M$ [illegible]

$$A = [C_1, \ldots, C_N] = \begin{bmatrix} R_1 \\ \\ R_M \end{bmatrix}.$$

[illegible]

$$A = A_{\text{col}} \circ \text{proj}, \tag{2.1}$$

[illegible] proj [illegible] $k \times N$ [illegible] $k \times k$ [illegible] A_{col} [illegible] $M \times k$ [illegible] k [illegible] A

$$A_{\text{col}} = [C_{n_1}, \ldots, C_{n_k}].$$

[illegible]

$$A = \text{eval} \circ A_{\text{row}}, \tag{2.2}$$

eval $M \times k$ $k \times k$
A_{row} $k \times N$ k A

$$A_{\text{row}} = \begin{bmatrix} R_{m_1} \\ \\ R_{m_k} \end{bmatrix}.$$

eval proj 1

2. Since the matrix proj contains a $k \times k$ identity matrix it can be applied to a vector using $k \times (N-k)$ multiplications and additions. Similarly, the matrix eval can be applied to a vector using $k \times (M-k)$ multiplications and additions.

3. As a direct consequence of Lemma 1, the condition number of proj is bounded by $\sqrt{1+k(N-k)}$ and the condition number of eval is bounded by $\sqrt{1+k(M-k)}$.

4. For simplicity, Lemma 1 is stated only for the case where the matrix A has exact rank k. Similar factorizations can be constructed for matrices of approximate rank k; see [5].

5. Methods for computing the factorizations in Lemma 1 are described in [5, 13]. The computational cost is typically $O(MNk)$ but can in rare cases be slightly higher.

3. Representation of functions via tabulation.

3.1. Outline. At the core of the original FMM is a technique for compactly representing sources and potentials. A source distribution inside a box is represented by a multipole expansion about the center of the box. From this expansion, the potential caused by the source distribution at distant target points can be evaluated. For a given accuracy, only a small number of terms in the expansion are needed, regardless of how many sources made up the original distribution. In the same way that source distributions are efficiently represented via multipole expansions, potentials are represented by giving the expansion coefficients in an expansion in harmonic polynomials.

In this section, we describe an alternative technique for representing sources and potentials. In order to describe the technique, we consider a simple model problem: Assume that we are given N source locations $(y_n)_{n=1}^N$ in a set b, M target locations $(x_m)_{m=1}^M$ in a set a, an interaction kernel $K(x,y)$, and that for a given vector of sources $q^b = (q_n)_{n=1}^N$, we wish to determine the vector of potentials $u^a = (u_m)_{m=1}^M$ given by

$$u^a = \text{direct}(a,b)\, q^b, \tag{3.1}$$

where $\text{direct}(a,b)$ is the $M \times N$ matrix with entries $K(x_m, y_n)$. We demonstrate that if the matrix $\text{direct}(a,b)$ has rank k (to within some precision ε), then it is possible to choose a subset of k source locations $(y_{n_j})_{j=1}^k$ with the property that the potential u^a can be replicated at all source points by placing some "proxy" sources on the points y_{n_j}. These proxy sources form the representation of the original source distribution. Similarly, it is possible to choose a subset of k target locations $(x_{m_i})_{i=1}^k$ with the property that if the potential is known at these k points, then it can be interpolated to all the remaining points. The potentials $(u_{m_i})_{i=1}^k$ form the representation for the potential u^a.

The representation technique described in this section has two principal advan-

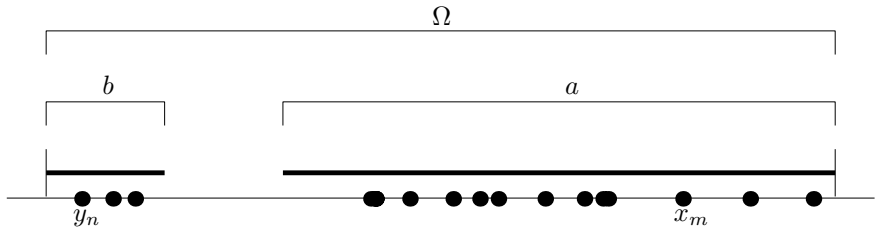

FIG. 1. *The computational domain described in section* 3.2.

tages over techniques based on analytic methods, such as multipole expansions: (1) It is cheaper to construct the proxy sources that represent a source distribution than it is to compute the corresponding multipole expansion (or any other similar representation). (2) The operator that maps a representation for a source distribution to a representation for a potential (sometimes called a "translation operator") is a submatrix of the original matrix of interaction direct(a, b). As a result, this operator need never be separately constructed or stored.

3.2. Notation. We assume that we are given a computational domain Ω, containing a number of source locations. For a given subset $b \subset \Omega$, we let $(y_n)_{n=1}^N$ denote the locations inside b, and we let $q^b = (q_n)_{n=1}^N$ denote a set of sources located at the points $(y_n)_{n=1}^N$. We let a denote the set of all points x that are [illegible] from b, meaning that $\text{dist}(x, b) \geq \text{diam}(b)$, where $\text{diam}(b) = \sup_{y,y' \in b} |y - y'|$. We let $(x_m)_{m=1}^M$ denote the locations inside a, and let $u^a = (u_m)_{m=1}^M$ denote the potential on a induced by the charges q^b (so that u^a and q^b satisfy (3.1)); see Figure 1.

3.3. Construction of the representation. We first consider the task of evaluating a potential in a caused by a set of charges in b. To this end, we form the $M \times N$ matrix $A = \text{direct}(a, b)$ with entries $K(x_m, y_n)$, we determine its ε-rank k, form a $k \times N$ matrix $\text{proj}(b)$, and an index vector $(n_j)_{j=1}^k$ such that, cf. (2.1),

$$A = A_{\text{col}} \circ \text{proj}(b) + O(\varepsilon),$$

where A_{col} is the $M \times k$ matrix whose jth column is the n_jth column of A. Then given any charge distribution q^b on b, we form the vector

$$\psi^b = \text{proj}(b)\, q^b \in \mathbb{C}^k. \tag{3.2}$$

The vector ψ^b has the property that the potential in a, caused by the charge distribution q^b, can within precision ε be reconstructed from ψ^b, since

$$u^a = A\, q^b = \big(A_{\text{col}} \circ \text{proj}(b) + O(\varepsilon)\big)\, q^b = A_{\text{col}}\, \psi^b + O(\varepsilon). \tag{3.3}$$

We say that ψ^b is the [illegible] of q^b, and that the points $(y_{n_j})_{j=1}^k$ form the [illegible] of b.

We next consider the task of evaluating a potential in b caused by a charge distribution in a. To this end, we form the $N \times M$ matrix $B = \text{direct}(b, a)$ with entries $K(y_n, x_m)$, we determine its ε-rank k, and form an $N \times k$ matrix $\text{eval}(b)$ and an index vector $(n_i)_{i=1}^k$ such that

$$B = \text{eval}(b) \circ B_{\text{row}} + O(\varepsilon),$$

where B_{row} is the $k \times M$ matrix whose ith row is the n_ith row of B. Then given any distribution q^a of charges on a, we form the vector

$$\phi^b = B_{\text{row}}\, q^a \in \mathbb{C}^k. \tag{3.4}$$

The vector ϕ^b has the property that the potential on b can within precision ε be reconstructed from ϕ^b only, since

$$u^b = B\, q^a = \big(\text{eval}(b) \circ B_{\text{row}} + O(\varepsilon)\big)\, q^a = \text{eval}(b)\, \phi^b + O(\varepsilon). \tag{3.5}$$

We say that ϕ^b is the [illegible] of u^b, and that the points $(y_{n_i})_{i=1}^k$ form the [illegible] of b.

[illegible] 6. The numbers in the vectors ψ^b and φ^b admit simple heuristic interpretations: Writing out equation (3.3) componentwise, we find that

$$u^a_m = \sum_{j=1}^{k} K(x_m, y_{n_j})\, \psi^b_j + O(\varepsilon), \qquad m = 1, \ldots, M. \tag{3.6}$$

In other words, the numbers ψ^b_j can be interpreted as charges that replicate the potential u^a when placed at the skeleton points y_{n_j}. Analogously, writing out (3.4) componentwise, we find that

$$\phi^b_i = \sum_{m=1}^{M} K(y_{n_i}, x_m)\, q^a_m + O(\varepsilon) = u^b_{n_i} + O(\varepsilon), \qquad i = 1, \ldots, k. \tag{3.7}$$

In other words, the number ϕ^b_i is simply the potential at the point y_{n_i}.

[illegible] 7. For many kernels it is possible to prove that when two sets a and b are separated by some finite distance, there exist basis functions $\{f_j\}_{j=1}^p$ and $\{g_j\}_{j=1}^p$ such that

$$\sup_{(x,y)\in a\times b} |K(x,y) - \sum_{j=1}^{p} f_j(x) g_j(y)| \leq \varepsilon, \tag{3.8}$$

where p tends to scale as a small power of $|\log \varepsilon|$ as $\varepsilon \to 0$. When (3.8) holds, the number p provides an upper bound on the numerical rank of the matrix of interaction direct(a, b), regardless of the number of target and source points and their locations. Moreover, when a formula like (3.8) can be constructed using analytical properties of the kernel, it can be used to accelerate the computation of proj and eval; cf. section 3.6.

[illegible] 8. In most environments, it is possible to construct the representations (3.3) and (3.5) in such a manner that the outgoing and the incoming skeletons are identical; see [5]. This causes only a minor increase in the number p.

3.4. Converting outgoing to incoming representations. In this section, we construct a matrix that converts the outgoing representation for a set of charges in one box, to an incoming representation for the potential induced by this set of charges in a different box.

Given two well-separated boxes a and b in Ω, suppose that we are given the outgoing representation $\psi^b = (\psi_j)_{j=1}^{k_b}$ for a charge distribution q^b in b, and that we wish to determine the incoming representation ϕ^a for the potential u^a induced by q^b.

We let $(x_m)_{m=1}^M$ and $(y_n)_{n=1}^N$ denote the locations in a and b, and we let $(x_{m_i})_{i=1}^{k_a}$ and $(y_{n_j})_{j=1}^{k_b}$ denote the corresponding skeletons. Then (3.7) implies that $\phi_i^a = u_{m_i}^a + O(\varepsilon)$, and (3.6) implies that $u_{m_i}^a = \sum_{j=1}^{k_b} K(x_{m_i}, y_{n_j})\, \psi_j^b + O(\varepsilon)$. In other words, letting $\mathrm{oi}(a,b)$ denote the $k_a \times k_b$ matrix with entries $K(x_{m_i}, y_{n_j})$, we find that

$$\phi^a = \mathrm{oi}(a,b)\, \psi^b + O(\varepsilon). \tag{3.9}$$

We refer to the matrix $\mathrm{oi}(a,b)$ as an [illegible] translation operator. This operator is a submatrix of $\mathrm{direct}(a,b)$. One ramification of this fact is that $\mathrm{oi}(a,b)$ need not be explicitly constructed. Since the kernel $K(x,y)$ is known, $\mathrm{oi}(a,b)$ is uniquely defined by the incoming and outgoing skeletons of a and b.

[illegible] 9. The matrix $\mathrm{direct}(a,b)$ is related to the matrices $\mathrm{eval}(a)$, $\mathrm{oi}(a,b)$, and $\mathrm{proj}(b)$ via the relation

$$\mathrm{direct}(a,b) = \mathrm{eval}(a) \circ \mathrm{oi}(a,b) \circ \mathrm{proj}(b) + O(\varepsilon). \tag{3.10}$$

To prove (3.10), we first note that $\mathrm{direct}(a,b)$ is defined by the relation

$$u^a = \mathrm{direct}(a,b)\, q^b. \tag{3.11}$$

Moreover, (3.5), (3.9), and (3.2) imply that

$$u^a = \mathrm{eval}(a)\, \phi^a + O(\varepsilon), \tag{3.12}$$

$$\phi^a = \mathrm{oi}(a,b)\, \psi^b + O(\varepsilon), \tag{3.13}$$

$$\psi^b = \mathrm{proj}(b)\, q^b, \tag{3.14}$$

respectively. Since (3.11) must hold for every q^b, the equations (3.11), (3.12), (3.13), and (3.14) together imply (3.10). (We remark that (3.10) is analogous to (3.1) in [5].)

3.5. Merging the representations of two boxes. In this section we describe a procedure for the construction of the outgoing representation of a set b if the outgoing representations are known for two sets b_1 and b_2 such that $b = b_1 \cup b_2$.

We let a denote the set of points that are well-separated from b, and for $j = 1, 2$, we similarly let a_j denote the set of points that are well-separated from b_j. It follows that $a \subseteq a_j$. Typically, a is strictly smaller than a_j.

We let u^a denote the potential induced on the locations $(x_m)_{m=1}^M \subset a$ by two given charge distributions in b_1 and b_2 with outgoing representations $\psi^{(1)}$ and $\psi^{(2)}$. Furthermore, we let $y^{(1)}$ and $y^{(2)}$ be the corresponding outgoing skeletons. (We recall that $y^{(1)}$ and $y^{(2)}$ are subsets of the original sets of locations in b_1 and b_2.) Merging these two pairs of vectors, we form $\hat{\psi} = [\psi^{(1)}, \psi^{(2)}]$ and $\hat{y} = [y^{(1)}, y^{(2)}]$. Since a is wholly contained in $a_1 \cap a_2$, (3.6) implies that

$$u_m^a = \sum_{j=1}^{k_1+k_2} K(x_m, \hat{y}_j)\, \hat{\psi}_j + O(\varepsilon) \qquad \text{for } m = 1, \ldots, M, \tag{3.15}$$

where k_1 and k_2 are the lengths of $\psi^{(1)}$ and $\psi^{(2)}$. We rewrite (3.15) as a matrix-multiplication by introducing the $M \times (k_1+k_2)$ matrix A with entries $A_{mj} = K(x_m, \hat{y}_j)$,

$$u^a = A\, \hat{\psi} + O(\varepsilon). \tag{3.16}$$

Equation (3.15) says that $\hat{\psi}$ is a valid outgoing representation for b with an associated outgoing skeleton $\hat{y}$. However, when a contains fewer target locations than $a_1 \cup a_2$ (which is typically the case), this representation is likely to be longer than necessary. To be precise, the length of an optimal representation equals the ε-rank of the matrix A in (3.16), which we denote by k. To obtain an optimal representation, we factor A as in (2.1),

$$A = \tilde{A}_{\text{col}} \circ Z + O(\varepsilon),$$

where Z is a $k \times (k_1 + k_2)$ matrix, and $\tilde{A}_{\text{col}}$ consists of k columns of A. We denote the indices of these by $(j_i)_{i=1}^k$. An optimal outgoing representation is then the vector $\psi^b = Z\,\hat{\psi}$; it is associated with the outgoing skeleton $(\hat{y}_{j_i})_{i=1}^k$. Letting $\text{oo}(b, b_1)$ denote the matrix formed by the first k_1 columns of Z and letting the remaining columns form $\text{oo}(b, b_2)$, we find that

$$\psi^b = \text{oo}(b, b_1)\,\psi^{(1)} + \text{oo}(b, b_2)\,\psi^{(2)}.$$

Analogously, we construct matrices $\text{ii}(b_1, b)$ and $\text{ii}(b_2, b)$ that construct the incoming representations $\phi^{(1)}$ and $\phi^{(2)}$ for b_1 and b_2 from the incoming representation of b via the formulas

$$\phi^{(1)} = \text{ii}(b_1, b)\,\phi^b \qquad \text{and} \qquad \phi^{(2)} = \text{ii}(b_2, b)\,\phi^b. \tag{3.17}$$

We refer to the matrix $\text{oo}(b, b_1)$ as an [illegible] translation operator, while the matrix $\text{ii}(b_1, b)$ is referred to as an [illegible] translation operator.

3.6. Efficient construction of translation operators. The techniques for constructing translation operators that were given in sections 3.3, 3.4, and 3.5 could potentially be quite expensive. For instance, when computing the operator $\text{proj}(b)$ in section 3.3, we considered the interaction between the set of locations in b and the set of all locations in Ω that are well-separated from b. The second set is typically very large. However, in most instances of practical interest, the process can be accelerated by replacing this very large set by a small set of predetermined locations in a that act as proxies for the actual charge locations. This acceleration technique works for kernels satisfying the following assumption.

Assumption I. [illegible] b [illegible] Ω [illegible] a [illegible] Ω [illegible] b [illegible] ε [illegible] $(z_i)_{i=1}^p \subset a$ [illegible] $(f_i)_{i=1}^p$ [illegible]

$$\sup_{x \in a} \sup_{y \in b} \left| K(x, y) - \sum_{i=1}^{p} f_i(x)\, K(z_i, y) \right| \leq \varepsilon. \tag{3.18}$$

[illegible] p [illegible]

$$p \leq C |\log \varepsilon|,$$

[illegible] $\varepsilon \to 0$ [illegible] $(w_i)_{i=1}^p \subset a$ [illegible] $(g_i)_{i=1}^p$ [illegible]

$$\sup_{x \in a} \sup_{y \in b} \left| K(y, x) - \sum_{i=1}^{p} K(y, w_i)\, g_i(x) \right| \leq \varepsilon. \tag{3.19}$$

REMARK 10. It is shown in [17] that Assumption I holds for any kernel that is separable in the sense described in Remark 7.

Suppose now that the kernel K satisfies Assumption I. Then for for any given set $b \subset \Omega$, one can quite inexpensively construct an outgoing representation that is valid for evaluating potentials at the points z_i. Assumption I then assures us that this representation is also valid at any other point that is well-separated from b, since the potential there can be interpolated locally from the potential at the z_i's. Incoming representations can be constructed analogously.

REMARK 11. In general, the cost of constructing the matrix $\text{proj}(b)$ and determining the outgoing skeleton $(y_{n_j})_{j=1}^{k}$ is $O(kNM)$, where k is the ε-rank of interaction, N is the number of points in b, and M is the number of locations that are well-separated from b. When the kernel K satisfies Assumption I, this cost can be reduced to $O(kNp)$ with no dependence on M.

3.7. Representations with extended domains of validity. For a given box b, we have so far constructed outgoing and incoming representations that are valid with respect to locations in the computational domain that are separated from a box b by at least the diameter of b. This requirement of a "buffer" zone is a standard feature of fast summation techniques. However, the particular technique for representing functions described in section 3.3 can also be used to compress the interaction between adjacent boxes. The resulting representations are very similar to the ones constructed for the interactions between separated boxes. However, the expansions are longer, and should not be used unless necessary. We call such unbuffered representations "rich representations," and denote the outgoing and the incoming rich representations by Ψ^b and Φ^b, respectively. The corresponding projection and evaluation operators are called Proj and Eval (capitalized), respectively, so that for a given box b

$$\Psi^b = \text{Proj}(b)\, q^b, \tag{3.20}$$

$$u^b = \text{Eval}(b)\, \Phi^b. \tag{3.21}$$

The representation Ψ^b in (3.20) can be used to compute the potential induced by q^b at any location outside b, while the representation Φ^b may be used to reconstruct any potential u^b induced by a distribution of charges at any of the locations outside b.

REMARK 12. In the original FMM and its variants, the existence of a buffer between source and target boxes was necessary to assure that the classical representations (multipole series, etc.) are valid and have controlled convergence rates. Here, we eliminate the need for the buffers by constructing the representations via numerical techniques (as opposed to using analytic properties of the kernel). Such representations are possible because they are not required to be valid everywhere in the boxes, but only at a finite number of source and target points.

REMARK 13. If for a given box b, we wish to compute both its rich and its regular outgoing representations, the most efficient way for doing so is to first compute the rich representation Ψ^b, and then compute the regular one, ψ^b, from it.

In order to construct the matrix that maps Ψ^b to ψ^b, we first construct the matrix A with entries $A_{mj} = K(x_m, y_j)$, where $(y_j)_{j=1}^{K}$ are the points in the rich skeleton and $(x_m)_{m=1}^{M}$ is a set of well-separated target points. Letting k denote the ε-rank of A, we factor A as in (2.1),

$$A = A_{\text{col}} \circ \overline{\text{proj}(b)} + O(\varepsilon),$$

where A_{col} is the $M \times k$ matrix consisting of the columns of A with indices $(j_i)_{i=1}^k$, and $\overline{\text{proj}(b)}$ is a $k \times K$ matrix. If Ψ^b is an outgoing representation associated with the rich outgoing skeleton $(y_j)_{j=1}^K$, then

$$\psi^b = \overline{\text{proj}(b)}\, \Psi^b$$

is a regular outgoing representation for b associated with the outgoing skeleton $(y_{j_i})_{i=1}^k$.

Analogously, we construct an operator $\overline{\text{eval}(b)}$ that constructs a rich incoming representation from a regular one:

$$\Phi^b = \overline{\text{eval}(b)}\, \phi^b. \tag{3.22}$$

Other types of translation operators involving rich representations can be constructed, but are not needed for the purposes of this paper.

4. A kernel-independent fast summation technique.

4.1. Problem formulation. In this section, we consider the problem of evaluating the sum

$$u_i = \sum_{j=1}^{N} K(x_i, x_j)\, q_j, \qquad i = 1, \ldots, N, \tag{4.1}$$

given a set of real numbers $(x_i)_{i=1}^N$, a set of real or complex numbers $(q_j)_{j=1}^N$, and a kernel $K(x, y)$. We call the numbers x_i "locations," the numbers q_i "charges," and the numbers u_i "potentials." The numbers x_i are all contained in an interval Ω called the "computational domain."

We focus on the situation where the potentials $(u_i)_{i=1}^N$ are to be evaluated for a sequence of charge distributions $(q_i)_{i=1}^N$ associated with a single set of locations $(x_i)_{i=1}^N$. In this environment, we spend a moderate amount of computational effort on optimizing the representations and the various translation operators used for the given set of locations. Once this has been done, each potential evaluation can be performed rapidly.

The summation technique presented in this section follows the same template as earlier versions of the fast multipole method [10, 11, 8, 6]. The only difference between these methods and the method presented in this section is that a different representation for potentials and sources is used. In section 5, a further acceleration of the method is described. This acceleration is obtained by compressing the interactions between adjacent regions.

4.2. Tree structure. Given a computational domain $\Omega = [x_{\text{left}}, x_{\text{right}}) \subset \mathbb{R}$ and a set of locations $(x_n)_{n=1}^N \subset \Omega$, we construct an adaptive partitioning of the domain into subintervals in such a way that no interval contains more than N_0 locations, for some given (small) integer N_0. We do this via a hierarchical subdivision process in which any interval holding more than N_0 points is split into two halves, and then the process is continued with each half that, in turn, contains more than N_0 points. If $a = [x^a_{\text{left}}, x^a_{\text{right}})$ is an interval resulting from this process, then

$$\begin{aligned} x^a_{\text{left}} &= x_{\text{left}} + (j-1)\, 2^{-l} \left(x_{\text{right}} - x_{\text{left}}\right), \\ x^a_{\text{right}} &= x_{\text{left}} + j\, 2^{-l} \left(x_{\text{right}} - x_{\text{left}}\right), \end{aligned}$$

for some number $l = 0, 1, 2, \ldots$, and some number $j = 1, 2, \ldots, 2^l$. The number l is called the "level" of the box a and denotes how many times Ω has been cut in half to reach a.

For every box a, we construct the following lists of other boxes:

$\mathrm{L}_{\mathrm{children}}(\mathrm{a})$: For a nonleaf box a, this is a list of all boxes b that are contained in a and that are separated from a by one level only. If $b \in \mathrm{L}_{\mathrm{children}}(a)$, we say that b is a "child" of a and that a is a "parent" of b. For a leaf box, $\mathrm{L}_{\mathrm{children}}(a)$ is empty.

$\mathrm{L}_{\mathrm{close}}(a)$: For a leaf-box a, this is a list of all leaf boxes b that are not well-separated from a. For a nonleaf box, $\mathrm{L}_{\mathrm{close}}(a)$ is empty.

$\mathrm{L}_2(a)$: The list of all boxes b on the same level as a that are well-separated from a, but whose parents are not separated from the parent of a. (This list is known as the "interaction list" in the original FMM.)

4.3. Outgoing and incoming representations. For any box a, we let the vector of charges inside the box be denoted by q^a, and with $\mathrm{proj}(a)$ the matrix defined in section 3.3, we let the vector

$$\psi^a = \mathrm{proj}(a)\, q^a \tag{4.2}$$

denote the outgoing representation of a. Similarly, we let u^a_{far} denote the potential on a caused by all charges that are well-separated from a. An incoming representation for a is a vector ϕ^a such that

$$u^a_{\mathrm{far}} = \mathrm{eval}(a)\, \phi^a + O(\varepsilon), \tag{4.3}$$

where the operator $\mathrm{eval}(a)$ is defined in section 3.3.

. . . . 14. In the original fast multipole method, the function of the vector ψ^a was performed by a vector of multipole coefficients representing q^a, and the function of ϕ^a was performed by a vector of expansion coefficients for u^a_{far} in a basis of harmonic polynomials.

4.4. Hierarchical construction of representations. Both the incoming and the outgoing representations can be computed recursively. Specifically, if a is any nonleaf box a, its outgoing representation can be computed from the outgoing representations of its children via the formula

$$\psi^a = \sum_{b \in \mathrm{L}_{\mathrm{children}}(a)} \mathrm{oo}(a, b)\, \psi^b, \tag{4.4}$$

where the matrices $\mathrm{oo}(a, b)$ are defined in section 3.5. Similarly, if a is any box other than the root box, the incoming representation ϕ^a (representing the potential u^a_{far} caused by charges in all boxes that are well-separated from a) can be constructed by combining the incoming potential of its parent b with the outgoing potentials of all boxes in the interaction list of a via the formula

$$\phi^a = \mathrm{ii}(a, b)\, \phi^b + \sum_{c \in \mathrm{L}_2(a)} \mathrm{oi}(a, c)\, \psi^c, \tag{4.5}$$

where the list $L_2(a)$ is defined in section 4.2, the matrix $\mathrm{ii}(a, b)$ is defined in section 3.5, and the matrices $\mathrm{oi}(a, c)$ are defined in section 3.4.

4.5. Precomputation. Given a set of locations $(x_n)_{n=1}^N$ and a kernel function $K(x,y)$, the precomputation stage consists of the following steps:

1. Divide the computational domain into a tree structure, as described in section 4.2.
2. Construct the lists described in section 4.2.
3. Loop over all leaf boxes. For each box a, construct the regular outgoing and incoming skeletons. Simultaneously, determine the matrices $\mathrm{proj}(a)$ and $\mathrm{eval}(a)$, described in section 3.3.
4. Loop over all nonleaf boxes, going from finer to coarser levels. For each box a, construct the regular outgoing and incoming skeletons by merging the skeletons of its children b_i. Simultaneously, determine the matrices $\mathrm{oo}(a,b_i)$ and $\mathrm{ii}(b_i,a)$, as described in section 3.5.
5. Loop over all boxes a, then over all elements b in the list $\mathrm{L}_2(a)$. For each such pair (a,b), construct the translation operator $\mathrm{oi}(a,b)$, as described in section 5.3.

The total cost of the steps described above depends on the kernel and on the charge distribution. If the kernel satisfies Assumption I in section 3.6, then the computational cost is typically either $O(N)$ or $O(N\log N)$, and the amount of storage required is typically $O(N)$; cf. Remark 15.

4.6. A general fast multipole method. We have now assembled the tools for computing the sum (4.1) through two passes through the hierarchical tree: one upwards and one downwards.

1. Sweep over all leaf boxes a. For each box, construct its outgoing representation from the values of the charges inside it; cf. (4.2):

$$\psi^a = \mathrm{proj}(a)\, q^a.$$

2. Sweep over all nonleaf boxes a, going from finer to coarser levels. For each box a, construct its outgoing representation by merging the outgoing representations of its children; cf. (4.4):

$$\psi^a = \sum_{b\in \mathrm{L}_{\mathrm{children}}(a)} \mathrm{oo}(a,b)\,\psi^b.$$

3. Set $\phi^r = 0$ for the root box r. Then loop over all boxes (including the root box), going from coarser to finer levels. For each box a, form its incoming representation by combining the incoming representation of its parent, box b, with the contributions from the boxes in $\mathrm{L}_2(a)$ (its "interaction list"); cf. (4.5):

$$\phi^a = \mathrm{ii}(a,b)\,\phi^b + \sum_{c\in \mathrm{L}_2(a)} \mathrm{oi}(a,c)\,\psi^c.$$

4. Sweep over all leaf nodes a. For each node, form the potential u^a by evaluating the incoming representation and directly adding the contributions from the charges inside a and in all boxes that are not well-separated from a; cf. (4.3):

$$u^a = \mathrm{eval}(a)\,\phi^a + \mathrm{direct}(a,a)\,q^a + \sum_{c\in \mathrm{L}_{\mathrm{close}}(a)} \mathrm{direct}(a,c)\,q^c.$$

For kernels satisfying Assumption I, the computational cost of the steps described in this subsection is typically $O(N)$.

15. It is possible to construct (highly nonuniform) charge distributions for which the computational cost of the steps described in sections 4.5 and 4.6 exceed $O(N)$. A discussion of this phenomenon, and a modification to the scheme that makes it always retain $O(N)$ complexity, can be found in [21].

5. An accelerated kernel-independent FMM.

5.1. Outline. In this section, we again consider the problem of rapidly evaluating the sum (4.1). We describe a technique for doing so that is similar to the technique described in section 4, but with the difference that even interactions between adjacent boxes are compressed. To enable this additional compression, we keep track of four representations for each leaf box: the regular outgoing and incoming ones described in section 3.3, and also the rich outgoing and incoming representations described in section 3.7. The rich representations are used exclusively for the purpose of evaluating interactions involving at least one leaf box.

The asymptotic cost for the algorithm described in this section scales in the same way with N as the cost for the algorithm described in section 4.6 (typically, $O(N \log N)$ for precomputation and $O(N)$ for evaluation). However, the constants involved are smaller.

5.2. Tree structure. The accelerated algorithm uses the same tree structure that was described in section 4.2. In addition to the lists described in that section, the accelerated algorithm also uses the following three lists:

$\mathrm{L}_1(a)$: For a leaf box a, this is a list of the leaf boxes that directly border a. For a nonleaf box, $\mathrm{L}_1(a)$ is empty.

$\mathrm{L}_3(a)$: For a leaf box a, this is a list of all boxes on finer levels than a that are separated from a but whose parents are not separated from the parent of a. For a nonleaf box a, $\mathrm{L}_3(a)$ is empty.

$\mathrm{L}_4(a)$: The dual of L_3. In other words, $b \in \mathrm{L}_4(a)$ if and only if $a \in \mathrm{L}_3(b)$.

5.3. Translation operators. The algorithm described in section 4.6 utilizes a single type of outgoing-to-incoming translation operator. This operator maps a regular outgoing representation ψ^a to a regular incoming representation ϕ^b for all pairs (a, b) such that $a \in \mathrm{L}_2(b)$. This translation operator is also used in the accelerated algorithm described in this section, we label it $\mathrm{oi}_2(a, b)$. The accelerated algorithm requires three additional outgoing-to-incoming translation operators: For each pair (a, b) such that $b \in \mathrm{L}_1(a)$, the operator $\mathrm{oi}_1(a, b)$ maps a rich representation to a rich representation. For each pair (a, b) such that $b \in \mathrm{L}_3(a)$, the operator $\mathrm{oi}_3(a, b)$ maps a regular representation to a rich representation. For each pair (a, b) such that $b \in \mathrm{L}_4(a)$, the operator $\mathrm{oi}_4(a, b)$ maps a rich representation to a regular representation. Each matrix $\mathrm{oi}_j(a, b)$ is the restriction of the original matrix of interaction $\mathrm{direct}(a, b)$ to the relevant outgoing and incoming skeletons for a and b, respectively.

5.4. Precomputation. The precomputation for the accelerated algorithm is very similar to the precomputation described in section 4.5. The difference is that for all leaf nodes, we compute both the regular and the rich skeletons (and the corresponding operators $\overline{\mathrm{eval}}$ and $\overline{\mathrm{proj}}$). We also determine the additional lists L_1, L_3, and L_4, as well as the corresponding translation operators oi_1, oi_3, and oi_4.

5.5. Potential evaluations. After the particle locations $(x_n)_{n=1}^N$ and the kernel $K(x, y)$ have been fixed, and the precomputation described in section 5.4 has been

completed, the following steps will compute the vector of potentials $(u_n)_{n=1}^N$ from a vector of charges $(q_n)_{n=1}^N$ cf. (4.1)) to within a precision of computations ε:

1. Loop over all leaf boxes. For each box a, compute Ψ^a and then ψ^a:

$$\Psi^a = \mathrm{Proj}(a)\, q^a \quad \text{and then} \quad \psi^a = \overline{\mathrm{proj}(a)}\, \Psi^a.$$

2. Loop over all nonleaf boxes, going from finer levels to coarser. For each box a, compute ψ^a by combining the outgoing representations of its children,

$$\psi^a = \sum_{b \in \mathrm{L}_{\mathrm{children}}(a)} \mathrm{oo}(a,b)\, \psi^b.$$

3. Loop over all leaf boxes. For each box a, add up the contributions from the boxes in $\mathrm{L}_1(a)$,

$$\Phi_1^a = \sum_{b \in \mathrm{L}_1(a)} \mathrm{oi}_1(a,b) \Psi^b.$$

4. Loop over all boxes. For each box a, add up the contributions from the boxes in $\mathrm{L}_2(a)$,

$$\phi_2^a = \sum_{b \in \mathrm{L}_2(a)} \mathrm{oi}_2(a,b) \psi^b.$$

5. Loop over all leaf boxes. For each box a, add up the contributions from the boxes in $\mathrm{L}_3(a)$,

$$\Phi_3^a = \sum_{b \in \mathrm{L}_3(a)} \mathrm{oi}_3(a,b) \psi^b.$$

6. Loop over all boxes. For each box a, add up the contributions from the boxes in $\mathrm{L}_4(a)$,

$$\phi_4^a = \sum_{b \in \mathrm{L}_4(a)} \mathrm{oi}_4(a,b) \Psi^b.$$

7. Set $\phi^r = 0$ for the root box r. Then loop over all nonleaf boxes (including the root box) from coarser levels to finer. For each box a, and for each child b of a, construct the incoming regular representations for b:

$$\phi^b = \phi_2^b + \phi_4^b + \mathrm{ii}(b,a)\, \phi^a.$$

8. Loop over all leaf boxes. For each box a, construct its rich incoming representation by adding the various contributions:

$$\Phi^a = \Phi_1^a + \Phi_3^a + \overline{\mathrm{eval}(a)}\, \phi^a.$$

9. Loop over all leaf boxes. For each box a, construct u^a by interpolating Φ^a and adding the contributions from q^a:

$$u^a = \mathrm{Eval}(a)\, \Phi^a + \mathrm{direct}(a,a) q^a.$$

16. The vectors ϕ_2^a, ϕ_4^a, Φ_1^a, and Φ_3^a are never stored; they are added directly to either ϕ^a or Φ^a as they are computed.

6. Numerical examples. The numerical algorithm described in section 5 has been implemented in FORTRAN 77 and tested on several model problems. In this section, we summarize the results from tests involving three different kernels.

1. This example involves the evaluation of the sum

$$u_m = \sum_{\substack{n=1 \\ n \neq m}}^{N} \left(\log |x_m - x_n| \right) q_n \qquad \text{for } m = 1, \ldots, N, \tag{6.1}$$

where the points $(x_n)_{n=1}^N$ were drawn from a uniform random distribution on the interval [0, 1].

2. This example involves the evaluation of the sum

$$u_m = \sum_{n=1}^{N} \frac{p_{k+1}(x_m)p_k(x_n) - p_k(x_m)p_{k+1}(x_n)}{x_m - x_n} q_n \quad \text{for } m = 1, \ldots, N, \tag{6.2}$$

where p_k is the kth Legendre polynomial and the points $(x_n)_{n=1}^N$ are the Gaussian nodes on the interval $[-1, 1]$. The sum (6.2) arises in evaluating orthogonal projections onto the space of order k polynomials in $L^2([-1, 1])$; see [14]. Similar sums are encountered in the construction of fast algorithms for the harmonic expansions on the sphere, in the FMM for the Helmholtz and Maxwell equations, etc.; see [4, 22]. In the numerical examples reported, k was one third of N (rounded to the nearest integer).

3. This example involves the evaluation of the sum

$$u_m = \sum_{n=1}^{N} \frac{\sin(a(x_m - x_n))}{x_m - x_n} q_n \qquad \text{for } m = 1, \ldots, N, \tag{6.3}$$

where $(x_n)_{n=1}^N$ are equispaced nodes in the interval $[-1, 1]$. Such sums occur frequently in signal processing and many other areas; see [3, 7, 23]. The parameter a was chosen so that there were 5 nodes per wavelength, i.e., $a = \pi N/5$.

The CPU times required for the accelerated matrix-vector multiplication in the three examples are given in Figure 2. The experiments were carried out on a 3.2GHz Pentium IV desktop with 2Gb of RAM. All calculations shown were carried out with a requested accuracy of $\varepsilon = 10^{-10}$. Detailed CPU time requirements are given in Tables 2, 3, and 4 in the appendix. These tables also report the memory requirements of the algorithm, as well as the time required for the precomputing step.

For comparison, Figure 2 also reports the CPU times required for uncompressed matrix-vector multiplies, both for the case where the matrix elements are precomputed and stored and the case where the matrix elements are computed on the fly. The break-even points obtained by extrapolating the lines in Figure 2 are given in Table 1. Finally, Figure 2 reports the CPU time requirement for a Fast Fourier Transform (FFT) of length N (with equispaced nodes). We note that for large problems, the matrix-vector multiply reported here is about one order of magnitude slower than an FFT.

In order to investigate the dependence of the CPU time requirement on the requested accuracy, the matrix-vector multiplication in Example 1 was carried out for $\varepsilon = 10^{-3.5}$, 10^{-7}, and 10^{-14}. The resulting CPU times are reported in Figure 3. This table also specifies the CPU times required for the precomputational stage. We remark that no attempt whatsoever was made to optimize this part of the code, and its CPU time requirements can be reduced dramatically.

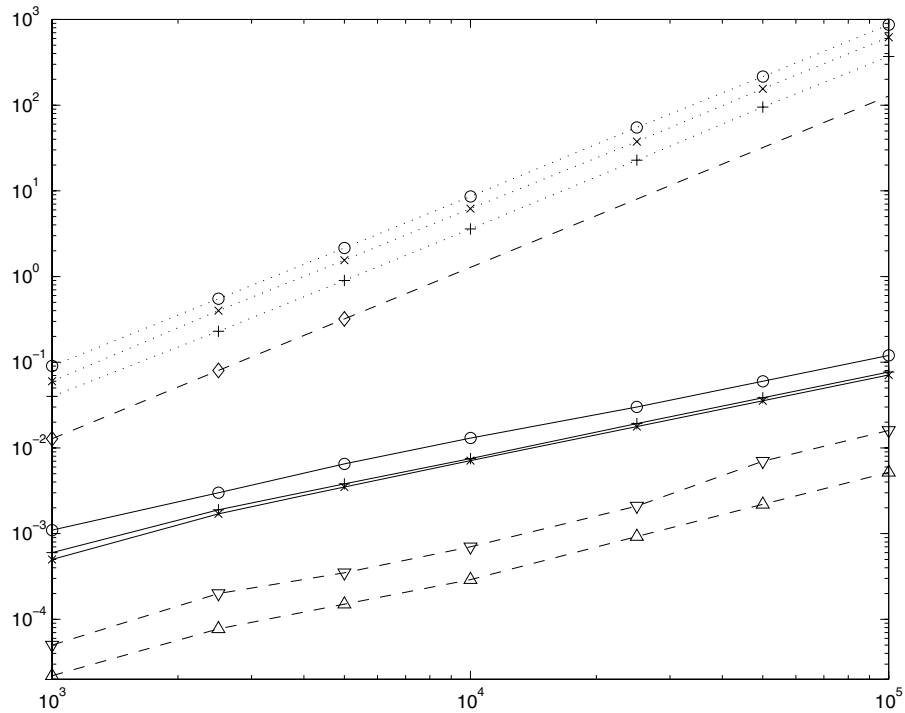

FIG. 2. *The CPU times (in seconds) required for evaluating the sums* (6.1), (6.2), *and* (6.3) *versus problem size* N. *The markers "×," "+," and "∘" label the three cases. The dotted lines mark the times required for uncompressed matrix-vector multiplies, the solid lines mark the times required for the algorithm of section* 5. *The times for a matrix-vector multiply with a stored matrix are marked with "◇" and the times for the FFT are marked "▽" for an FFTPACK implementation and "△" for an FFTW implementation.*

7. Conclusions. This paper describes an FFM for the rapid evaluation of sums of the form (1.1). In one and two dimensions, the computational complexity of this method is $O(N)$.

The method does not use any analytic expansions of the kernel; instead, it numerically compresses the kernel in a preprocessing stage whose computational cost is $O(N \log N)$. The combined cost of the precomputation, and a single potential evaluation using the present scheme, is larger than the cost of a single evaluation using some existing precomputation-free fast summation techniques. However, if the evaluation is to be performed for a sequence of different charge distributions (on a fixed set of charge locations), then the current method outperforms most existing methods, with the important exception of convolutional sums that can be evaluated using the FFT. Moreover, since the current scheme does not explicitly rely on analytical properties

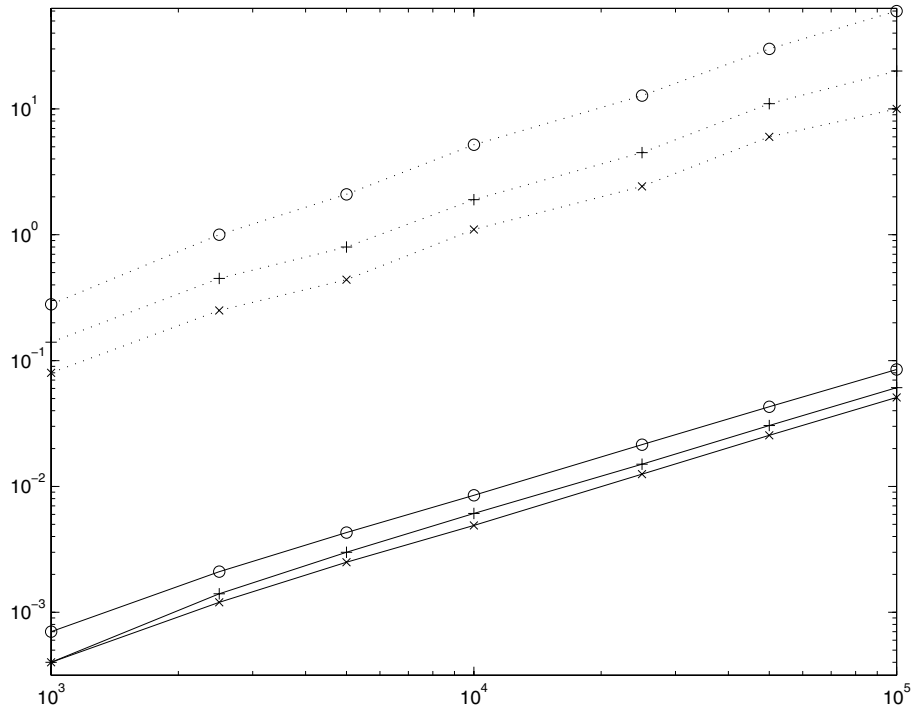

FIG. 3. *The CPU time required for evaluating the sum in* (6.1) *with* $\varepsilon = 10^{-3.5}$, 10^{-7}, *and* 10^{-14}, *using the algorithm of section* 5, *plotted against problem size* N. *The solid lines give the time for a matrix-vector multiply, while the dotted lines give the time required for precomputation.*

of the kernel, it is applicable in many environments in which precomputation-free methods are not available.

One application that seems particularly well suited for the fast summation technique of this paper concerns the rapid computation of the SVD of a matrix. A very fast algorithm for this task based on a divide-and-conquer technique is described in [12]. A core observation of [12] is that the seemingly expensive task of updating a unitary matrix can, surprisingly, be accelerated using the FMM. However, the break-even point of previous versions of the FMM made the algorithm of [12] competitive only for very large matrices. Research into combining the fast summation technique of this paper with the algorithm of [12] is currently under way.

Appendix. Computational results. This appendix contains detailed statistics for the computational experiments summarized in section 6. The numbers upon which Figure 2 is based can be found in Tables 2, 3, and 4. The numbers upon which Figure 3 is based can be found in Table 5. Table 6 provides the CPU times required for an uncompressed matrix-vector multiply and a length-N FFT using FFTPACK and FFTW.

The following numbers are given for each experiment:

N	Problem size.
ε	Requested accuracy.
$E_{\max}$	Maximum error (see Remark 17).
E_{rms}	Root mean square error (see Remark 17).
t_{pre}	CPU time required for precomputation.

t_{eval} CPU time required for an accelerated matrix-vector multiply.
M_{keep} Amount of memory required to store the compressed operator.
M_{pre} Amount of memory required for precomputation.
t_{uncomp} CPU time required for an uncompressed matrix-vector multiply.
t_{matvec} CPU time required for multiplying a stored matrix by a vector.
t_{fft} CPU time required for a length-N (equispaced) FFT using FFTPACK.
t_{fftw} CPU time required for a length-N (equispaced) FFT using FFTW.

All CPU times are given in seconds, and all memory requirements are given in terms of storage for double precision reals. The memory required for applying the operator to a vector is not reported since it is far smaller than M_{keep} (asymptotically, it is a couple of reals per node).

17. We report both the maximum error $E_{\max}$ and the root mean square error E_{rms}. Letting $(u_n)_{n=1}^N$ denote the result of an uncompressed matrix-vector multiply, and letting $(u'_n)_{n=1}^N$ denote the result of an accelerated matrix-vector multiply, we have

$$E_{\max} = \frac{\max_{1\le n\le N} |u_n - u'_n|}{(1/N)\sum_{n=1}^N |u_n|} \quad \text{and} \quad E_{\text{rms}} = \sqrt{\frac{\sum_{n=1}^N (u_n - u'_n)^2}{\sum_{n=1}^N |u_n|^2}}. \tag{A.1}$$

In each of the experiments reported, the charges q_n were drawn from a uniform random distribution on $[-1, 1]$.

NONOSCILLATORY INTERPOLATION METHODS APPLIED TO VLASOV-BASED MODELS*

J. A. CARRILLO† AND F. VECIL†

Abstract. We demonstrate the ability of nonoscillatory interpolation strategies for solving efficiently the transport phase in kinetic systems with applications to charged particle transport in plasmas and semiconductors. Pointwise weighted essentially nonoscillatory (PWENO) interpolation is applied to obtain semi-Lagrangian and flux balance methods that together with splitting techniques form the building blocks of our numerical approach. These methods do not present the restrictive CFL condition typical of finite-difference methods with explicit time-solvers, and, moreover, they provide reliable results controlling parasite oscillations from classical polynomial interpolation while giving highly accurate approximations of smooth parts of the solutions. We perform and compare these methods in different benchmark problems for Vlasov or collisional models for charged particle transport.

1. Introduction.

The Vlasov equation

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f + \frac{F}{m} \cdot \nabla_v f = 0$$

is the basic kinetic model for the description of the motion of charged particles in electronic devices and plasmas under the effect of a force field $F(t,x)$. Here, $f(t,x,v)$ represents the particle number density in phase space (x,v) at time $t > 0$. In order to compute the force field $F = -\nabla_x \Phi$ it is coupled with the Poisson equation

$$\epsilon_0 \Delta_x \Phi = e\,(\rho[f] - C) = e\left(\int f dv - C\right)$$

for the computation of the electric potential $\Phi(t,x)$ due to both the self-consistent electric potential and an external density $C(x)$, like the doping profile in semiconductors or a background ion density in plasmas. Moreover, when collisional effects have to be taken into account, a Boltzmann operator appears as the right-hand side of the Vlasov equation

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f + \frac{F}{m} \cdot \nabla_v f = \mathcal{Q}[f].$$

One of the main problems while simulating Vlasov-like systems is the presence of violent gradients in the distribution function, which, if not properly controlled by the numerical method, may drive to a false physical description of the phenomena due to

a massive formation of spurious oscillations. Several approaches to solving Vlasov-based equations have been proposed in the literature; we refer the reader to [13] for a good review and comparison of different Eulerian solvers. These oscillations appear naturally due to the energy conservation of the system and its Hamiltonian character, the phenomena of the Landau damping being an example of this behavior [30, 13, 14]. When collisions are considered, oscillations are damped, but the control of spurious oscillations continues to be important since high gradients on the moments of the solution (density, mean velocity, and temperature) are typical in the simulations; see [7, 5, 6], for instance, in the semiconductor case.

One of the approaches to attacking the numerical simulation of these models is based on a classical time splitting method, whose theoretical bases were given by Strang [29] and whose application to the Vlasov system goes back to Cheng and Knorr [9]. Time splitting algorithms are used to subdivide a problem into simpler tasks—in our case the transport and the collision steps. In semiconductor devices and plasma simulations, the transport (Vlasov) step in (x, v)- or (x, p)-phase space can be reduced by dimensional splitting to performing advection steps in either dimension. We will elaborate on this later, but let us remark that there are situations in which this dimensional splitting cannot be performed; see [18] for fully relativistic models. Semi-Lagrangian methods were first introduced for meteorology problems [2] and for turbulence study [1]. The application to the Vlasov equation was started by Sonnendrücker et al. in [27]. This method is based on following backward the characteristics, and makes use of some interpolation method: Lagrange polynomials, spline [27], Hermite, or essentially nonoscillatory (ENO) [26]; see [13] for an overview. Flux balance methods were proposed in [14], the third order positive flux conservative method (PFC-3) being a particular case. This method preserves mass and positivity of the solution apart from controlling the total variation of the solution, although it is only third order accurate. This method has been modified in [10] in order to conserve the total energy, too. Several improvements concerning unstructured and adaptive grids and different interpolation techniques have recently been developed in [15, 3].

Another successful approach in the case of collisional semiconductor and plasma models is based on the method of lines with high order nonoscillatory finite-difference reconstructions of the derivatives of the distribution function $f(t, x, v)$ in phase space while performing a total-variation-diminishing (TVD) third order explicit Runge–Kutta method for the time discretization. In this case, spurious oscillations are controlled by ENO [26] or weighted ENO (WENO) [19, 25] reconstructions of the fluxes and thus of the derivatives.

We propose in this paper a semi-Lagrangian (SL) method and a flux balance method (FBM) for Vlasov's systems based on a WENO interpolation for the computation of point values (PWENO); see [24]. We will review this numerical technique for point values reconstruction in section 2.

In section 3, the SL method and the FBM are described. Both methods are based on integrating backward in the characteristics, the second one being mass-conservative and the first one being better as for the control of the total variation. The main advantage with respect to previous semi-Lagrangian methods is the oscillation control while keeping a high order approximation of the solution. Compared to WENO finite-difference methods, our approach avoids the restrictive CFL condition on the time stepping [21] for plasmas and [7, 5, 6] for semiconductors. The proposed numerical method allows the time step Δt to be larger and constant, and the method requires far fewer steps (of an equivalent computational cost) than WENO finite differences. Finally, these numerical techniques could be extended for multidomain or multigrid

computations as done in [24].

In section 4, we show the numerical simulations of five experiments: two pure transport problems and three coupled with collisions. We will elaborate on the advantages and drawbacks of this method in both situations. The exact problems are as follows:

1. A one-dimensional (1D) nonlinear Landau damping [14], where we can observe the filamentation of the phase space during the first phase (strong oscillations in the (x, v)-space) and check whether the method is able to not add noise.
2. A 1D symmetric two stream instability, where we want to observe a vortex appearing after initial time, rotate, and form a typical hole structure.
3. A 1D Vlasov–Boltzmann equation with given confining potential and a linear relaxation operator. Its asymptotic behavior was described in [4, 16].
4. A 1D Vlasov–Fokker–Planck equation with given confining potential. Its asymptotic behavior was described in [11, 17] and it is useful for checking the behavior when variable advection terms appear.
5. A Silicon $n^+ - n - n^+$-structured semiconductor [8, 7], where collisions are modeled through a linear Boltzmann operator: we compare results given by time splitting methods and finite-difference methods with explicit and implicit-explicit time integrators.

The simulation results demonstrate overall the main features of this numerical approach: no CFL condition, good control of numerical oscillations, and high accuracy of the approximations for transport phases.

2. PWENO interpolations. Pointwise weighted essentially nonoscillatory interpolation methods have been developed in order to compute a direct reconstruction which avoids Lagrange spurious oscillations produced where high derivatives appear.

2.1. Description of the method. We have an interval $[x_L, x_R]$ divided into a grid of N points $x_L = x_0 < x_1 < x_2 < \cdots < x_{N-1} = x_R$, and the values of a function f in these points $\{f_i = f(x_i)\}_{i=0,\ldots,N-1}$. We choose a stencil of *ntot* consecutive points from this grid

$$\mathcal{S} = \{x_{first}, \ldots, x_{last}\} = \{x_{first}, \ldots, x_{first+ntot-1}\}$$

and *nlp* substencils

$$\mathcal{S}_r = \{x_{last-lpo+1-r}, \ldots, x_{last-r}\} = \{x_{i-r}, \ldots, x_{last-r}\}$$

for $r = 0, \ldots, nlp - 1$, where $lpo := ntot - nlp + 1$ and $i := last - lpo + 1$. Refer to Figure 2.1 for a summary of all the parameters. Let $p_r(x)$ be the Lagrange polynomials of order *lpo* interpolating f in the stencil $\mathcal{S}_r$:

$$p_r(x) = p_r^{lpo}(x) = \sum_{j=0}^{lpo-1} f_{i-r+j} \prod_{l=0,\, l\neq j}^{lpo-1} \frac{x - x_{i-r+l}}{x_{i-r+j} - x_{i-r+l}} = \sum_{j=0}^{lpo-1} f_{i-r+j} c_{r,j}(x).$$

The reconstructed value at point x will be a convex combination of the reconstructions at point x given by the *nlp* Lagrange polynomials in the substencils $\mathcal{S}_r$:

$$p^W(x) = \sum_{r=0}^{nlp-1} \omega_r(x) p_r(x).$$

The weights $\omega_r(x)$ shall give more or less relevance to the stencils depending on how smooth the $p_r(x)$ are, in a way such that the reconstruction is nonoscillatory.

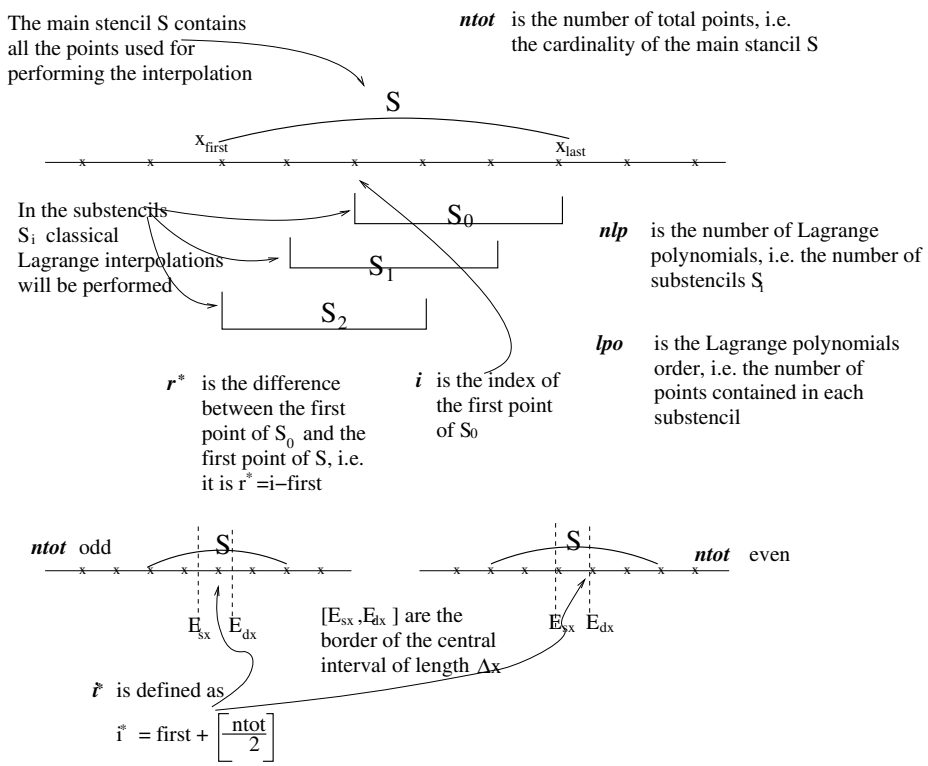

FIG. 2.1. *The notation for all the parameters used in the description of the method.*

2.2. The smoothness indicators β_r. We shall call smoothness of the polynomial $p_r(x)$ a measure of its derivatives in the interval

$$[\mathcal{E}_L, \mathcal{E}_R] = \begin{cases} \left[x_{i^*-\frac{1}{2}}, x_{i^*+\frac{1}{2}}\right] & \text{if } ntot \text{ is odd,} \\ [x_{i^*-1}, x_{i^*}] & \text{if } ntot \text{ is even,} \end{cases}$$

where the dependencies of $\mathcal{E}_L$ and $\mathcal{E}_R$ will be omitted and we have used the notation

$$i^* = first + \left[\frac{ntot}{2}\right],$$

in which $[x]$ means the integer part of x. Figure 2.1 graphically shows the meaning of the last notation. If the derivatives are large, the smoothness indicator should be large, and vice versa. The following measurement is proposed by Jiang and Shu in [19]:

$$\beta_r = \sum_{l=1}^{lpo-1} \Delta x^{2l-1} \left\| \frac{d^l}{dx^l} p_r \right\|^2_{L^2(\mathcal{E}_L, \mathcal{E}_R)}.$$

This a sort of Sobolev norm, where the weights Δx^{2l-1} are needed to make all the terms of the sum independent of Δx, i.e., to make them all be of the same order. Other measurements would be possible, but we shall omit discussing this point.

2.3. The weights $d_r(x)$. In order to achieve a high order reconstruction for regular functions, we define coefficients $d_r(x)$ as

$$p[f](x) = \sum_{r=0}^{nlp-1} d_r(x) p_r(x), \tag{2.1}$$

where $p[f](x)$ is the *ntot* order Lagrange polynomial interpolating the values of f in the whole stencil $\mathcal{S}$

$$p[f](x) = \sum_{j=0}^{ntot-1} f_{first+j} \prod_{l=0,\, l\neq j}^{ntot-1} \frac{x - x_{first+j}}{x_{first+j} - x_{first+l}}.$$

Lagrange interpolation gives an *ntot* order method; by means of these coefficients we want PWENO-*ntot*,*lpo* interpolation to approach an *ntot* order method nonoscillatory for homogeneously regular functions, i.e., whenever all the weights β_r have the same order of magnitude.

PROPOSITION 2.1 (existence and uniqueness of the weights $d_r(x)$). [illegible] $\mathcal{I} = [x_L, x_R] \subset \mathbb{R}$ [illegible] $x_L = x_0 < x_1 < \cdots < x_{N-1} = x_R$ [illegible] $d_r(x)$ [illegible] (2.1) [illegible]. The *ntot* order Lagrange interpolation is exact on $\mathbb{P}^{ntot-1}$, i.e.,

$$f \in \mathbb{P}^{ntot-1} \mapsto p[f](x) = f(x),$$

since $p[f]$ is the Lagrange polynomial which interpolates f in *ntot* points. If $\mathcal{B} = \{b_i\}_{i=0}^{ntot-1}$ is a basis of $\mathbb{P}^{ntot-1}$, $f(x) = \sum_{i=0}^{ntot-1} f^i b_i(x)$ and

$$c_{r,j}(x) = \prod_{l=0,\, l\neq j}^{lpo-1} \frac{x - x_{i-r+l}}{x_{i-r+j} - x_{i-r+l}};$$

$$p\left[f\right](x) = p\left[\sum_i f^i b_i\right](x) = \sum_j \sum_i f^i b_i(x_j) c_{r,j}(x) \tag{2.2}$$

$$= \sum_i f^i \sum_j b_i(x_j) c_{r,j}(x) = \sum_i f^i p\left[b_i\right](x), \tag{2.3}$$

so we need only to impose condition (2.1) on the elements of $\mathcal{B}$. Take as basis

$$\mathcal{B} = \{b_0, b_1, \ldots, b_{ntot-1}\} = \left\{1, \prod_{l=0}^{m} (x - x_{first+l}),\, m \in \{0, \ldots, ntot-2\}\right\}.$$

For $deg \leq lpo - 1$, condition (2.1) gives $b_{deg}(x) = \sum_{r=0}^{nlp-1} d_r(x) b_{deg}(x)$, which means

$$\sum_{r=0}^{nlp-1} d_r(x) = 1.$$

For $lpo \leq deg \leq ntot - 1$, condition (2.1) gives

$$b_{deg}(x) = \sum_{r=0}^{nlp-1} d_r(x) p_{r,deg}(x),$$

where $p_{r,deg}(x)$ is the Lagrange polynomial interpolating polynomial $b_{deg}(x)$ at points $\{x_{i-r},\dots,x_{i-r+lpo-1}\}$, i.e.,

$$p_{r,deg}(x)=\sum_{j=0}^{lpo-1} b_{deg}(x_{i-r+j})c_{r,j}(x).$$

We get the following linear system:

$$L=\left(\begin{array}{cccc|c} 1 & 1 & \dots & 1 & 1\\ p_{0,lpo}(x) & p_{1,lpo}(x) & \dots & p_{nlp-1,lpo}(x) & b_{lpo}(x)\\ p_{0,lpo+1}(x) & p_{1,lpo+1}(x) & \dots & p_{nlp-1,lpo+1}(x) & b_{lpo+1}(x)\\ \vdots & \vdots & \vdots & \vdots & \vdots\\ p_{0,ntot-1}(x) & p_{1,ntot-1}(x) & \dots & p_{nlp-1,ntot-1}(x) & b_{ntot-1}(x) \end{array}\right).$$

Note that $b_{deg}(x_{i-r+j})=0$ for $i-r+j\le deg-1$, which implies that the matrix has the following appearance:

$$L=\left(\begin{array}{ccccc|c} 1 & 1 & 1 & \dots & 1 & 1\\ p_{0,lpo}(x) & p_{1,lpo}(x) & \dots & p_{nlp-2,lpo}(x) & 0 & b_{lpo}(x)\\ p_{0,lpo+1}(x) & p_{1,lpo+1}(x) & \dots & 0 & 0 & b_{lpo+1}(x)\\ \vdots & \vdots & \vdots & \vdots & \vdots & \\ p_{0,ntot-1}(x) & 0 & 0 & \dots & 0 & b_{ntot-1}(x) \end{array}\right). \tag{2.4}$$

Call $L=(L_1|L_2)$. The computation of the determinant of L_1 is straightforward:

$$\det(L_1)=-\prod_{s=0}^{nlp-2} p_{s,(ntot-1)-s}(x)\neq 0,$$

which is not zero because none of the terms can be zero. Since

$$p_{s,(ntot-1)-s}(x)=\sum_{j=0}^{lpo-1} b_{(ntot-1)-s}(x_{i-s+j})c_{s,j}(x)$$

and $b_{(ntot-1)-s}(x_{i-s+j})=0$ for $j=0,\dots,lpo-2$, then

$$p_{s,(ntot-1)-s}(x)=b_{(ntot-1)-s}(x_{i-s+lpo-1})c_{s,lpo-1}(x)\neq 0$$

because $b_{(ntot-1)-s}(x_{i-s+lpo-1})\neq 0$; if not, we should get a contradiction: a nonzero polynomial of degree $(ntot-1)-s$ would have $ntot-1$ zeros. $c_{s,lpo-1}(x)\neq 0$ because x does not belong to the points of the grid. In this way, the existence and uniqueness of the $d_r(x)$ have been proven. □

The proof of this proposition, which is quite straightforward, has been reported in full detail since the general code computing any PWENO interpolation, i.e., with any *ntot* and *lpo*, uses the linear system (2.4) to compute the weights $d_r(x)$.

2.3.1. Uniqueness of the weights $d_r(x)$ as polynomials. We are able to get an explicit formula for the polynomials $d_r(x)$ by an iterative method. Assume the interpolation points are $\{x_0,x_1,\dots,x_n\}$. Suppose we have two polynomials: $p(x)$ interpolates a function f at the points $x_0,x_1,\dots,x_{n-1}$, and $q(x)$ interpolates at the points $x_1,x_2,\dots,x_n$. A simple exactness argument (Aitken–Neville method) allows

us to check that the polynomial interpolating f at the points $x_0, x_1, \ldots, x_n$ is given by

$$r(x) = \frac{p(x)(x - x_n) - q(x)(x - x_0)}{x_0 - x_n}.$$

An explicit recursion procedure based on the previous formula gives us the explicit value of $\tilde{d}_r(x)$. In the case of three points ($n = 2$) we get

$$\begin{cases} \tilde{d}_0(x) = \frac{(x-x_{i-1})(x-x_{i-2})}{(x_{i-1}-x_{i+2})(x_{i-2}-x_{i+2})}, \\ \tilde{d}_1(x) = -\left[\frac{(x-x_{i+2})(x-x_{i-2})}{(x_{i-1}-x_{i+2})(x_{i-2}-x_{i+2})} + \frac{(x-x_{i-2})(x-x_{i+2})}{(x_{i-2}-x_{i+1})(x_{i-2}-x_{i+2})}\right], \\ \tilde{d}_2(x) = \frac{(x-x_{i+1})(x-x_{i+2})}{(x_{i-2}-x_{i+1})(x_{i-2}-x_{i+2})}. \end{cases}$$

PROPOSITION 2.2 (uniqueness of the weights $d_r(x)$). [illegible] $\mathcal{I} = [x_L, x_R] \subset \mathbb{R}$ [illegible] $x_L = x_0 < x_1 < \cdots < x_{N-1} = x_R$ [illegible] $d_r(x)$ [illegible] $\mathbb{P}^{ntot-lpo}$ [illegible]. Polynomials $\tilde{d}_r(x)$ are explicitly constructed by a standard recursive method based on finite differences, so they exist (no denominator can be zero because $i \neq j \Rightarrow x_i \neq x_j$) and their degree is $(ntot - 1) - (lpo - 1) = ntot - lpo$. Moreover,

$$\forall x \in \mathbb{R} \setminus \{x_i\}_{i=0,\ldots,N-1}, \qquad \tilde{d}_r(x) = d_r(x)$$

by construction and Proposition 2.1; then the weights $d_r(x)$ are unique as polynomials in $\mathbb{P}^{ntot-lpo}$. □

2.4. The coefficients $\omega_r(x)$. Once we have computed the smoothness indicators, we define

$$\tilde{\omega}_r(x) = \frac{d_r(x)}{(\epsilon + \beta_r)^2}, \tag{2.5}$$

where ϵ is just a constant which keeps the denominator from being zero (in the code $\epsilon = 10^{-6}$ is used). To get the weights $\omega_r(x)$ we just have to normalize the $\tilde{\omega}_r(x)$ given by (2.5):

$$\omega_r(x) = \frac{\tilde{\omega}_r(x)}{\sum_{j=0}^{nlp-1} \tilde{\omega}_j(x)}.$$

On one hand, if the function is smooth enough in the stencil $\mathcal{S}$ (all the smoothness indicators are of the same order), then the main role in the coefficients $\omega_r(x)$ is played by the weights $d_r(x)$ making the PWENO reconstruction approach a Lagrange reconstruction, which achieves the best interpolation order for smooth functions. For instance, if all the β_r were equal, then PWENO interpolation would coincide with Lagrange interpolation. On the other hand, if the function has some "irregularity" in the stencil $\mathcal{S}$ (the smoothness indicators are not all of the same order), then the main role in the coefficients $\omega_r(x)$ is played by the smoothness indicators β_r giving more or less weight to the substencils $\mathcal{S}_r$ following the regularity of $p_r(x)$.

2.5. The order of the method. First we recall a standard result about the error committed by Lagrange interpolation (see, for instance, [28]).

PROPOSITION 2.3 (order of Lagrange reconstruction). $\mathcal{I} = [x_L, x_R] \subset \mathbb{R}$ $f \in \mathcal{C}^{n+1}[x_L, x_R]$ $p \in \mathbb{P}^n$ f $n+1$ $\{x_0, x_1, \dots, x_n\}$ $[x_L, x_R]$ $\forall x \in [x_L, x_R]$ $\xi_x \in]x_L, x_R[$

$$f(x) - p(x) = \frac{1}{(n+1)!} f^{(n+1)}(\xi_x) \prod_{i=0}^{n} (x - x_i).$$

In the case of a regular grid this means that

$$p(x) = f(x) + O(\Delta x^{n+1}).$$

LEMMA 2.4.

$$\beta_r = A(1 + O(\Delta x^n)), \tag{2.6}$$

A r

$$\omega_r(x) - d_r(x) = O(\Delta x^n). \tag{2.7}$$

. Straightforward calculations using Taylor's theorem imply that

$$\frac{1}{(\epsilon + \beta_r)^2} = \frac{1}{(\epsilon + A)^2} + O(\Delta x^n)$$

and

$$\tilde{\omega}_r = \frac{d_r}{(\epsilon + \beta_r)^2} = d_r \left[\frac{1}{(\epsilon + A)^2} + O(\Delta x^n) \right] = \frac{1}{(\epsilon + A)^2} d_r + O(\Delta x^n)$$

with

$$\sum_{j=0}^{nlp-1} \tilde{\omega}_j(x) = \frac{1}{(\epsilon + A)^2} d_r + O(\Delta x^n).$$

Finally, putting together previous estimates, we get

$$\omega_r = \frac{\tilde{\omega}_r}{\sum_{j=0}^{nlp-1} \tilde{\omega}_j(x)} = \frac{\frac{1}{(\epsilon+A)^2} d_r + O(\Delta x^n)}{\frac{1}{(\epsilon+A)^2} + O(\Delta x^n)} = d_r + O(\Delta x^n),$$

giving the desired accuracy result. □

The general error for PWENO interpolation is obtained now.

PROPOSITION 2.5 (order of PWENO reconstruction). $d_r(x)$

$$\sum_{r=0}^{nlp-1} d_r(x) = 1 \tag{2.8}$$

$\beta_r = A(1 + O(\Delta x^n))$ A r
$ntot,lpo$ $(lpo + n)$

. First, by Lemma 2.4 we know that (2.7) holds. Since

$$\begin{aligned} p^W(x) - f(x) &= p^W(x) - p(x) + p(x) - f(x) \\ &= \sum_{r=0}^{nlp-1} \omega_r(x) p_r(x) - \sum_{r=0}^{nlp-1} d_r(x) p_r(x) + \sum_{r=0}^{nlp-1} d_r(x) p_r(x) - f(x) \\ &= \sum_{r=0}^{nlp-1} \omega_r(x) p_r(x) - \sum_{r=0}^{nlp-1} d_r(x) p_r(x) + O(\Delta x^{ntot}), \end{aligned}$$

we already know that the method cannot be more than *ntot* order, and we need to calculate

$$\mathcal{I} = \sum_{r=0}^{nlp-1} \omega_r(x) p_r(x) - \sum_{r=0}^{nlp-1} d_r(x) p_r(x)$$

to check which is the order. By simple manipulations,

$$\begin{aligned} \mathcal{I} &= \sum_{r=0}^{nlp-1} \omega_r(x) p_r(x) - \sum_{r=0}^{nlp-1} d_r(x) p_r(x) = \sum_{r=0}^{nlp-1} \left[\omega_r(x) - d_r(x)\right] p_r(x) \\ &= \sum_{r=0}^{nlp-1} \left[\omega_r(x) - d_r(x)\right] \left[p_r(x) - f(x)\right], \end{aligned}$$

due to (2.8).

$$\mathcal{I} = \sum_{r=0}^{nlp-1} \left[\omega_r(x) - d_r(x)\right] \left[p_r(x) - f(x)\right] = \sum_{r=0}^{nlp-1} \left[\omega_r(x) - d_r(x)\right] O(\Delta x^{lpo})$$

because of Proposition 2.3. We finally deduce

$$\mathcal{I} = \sum_{r=0}^{nlp-1} \left[\omega_r(x) - d_r(x)\right] O(\Delta x^{lpo}) = \sum_{r=0}^{nlp-1} O(\Delta x^n) O(\Delta x^{lpo}),$$

due to (2.7). □

Our problem is now translated to the Taylor expansion of the smoothness indicators β_r. Once we have been able to compute n in (2.6), then the method will be order $lpo + n$. By simple manipulations, the smoothness indicators can be expressed as

$$\begin{aligned} \beta_r &= \sum_{l=1}^{lpo-1} \int_{\mathcal{E}} \Delta x^{2l-1} \left[D^l p_r(x)\right]^2 dx \\ &= \sum_{j,k} f_{i-r+j} f_{i-r+k} K^r_{j,k}, \end{aligned}$$

where K^r is the symmetric matrix

$$K^r_{j,k} = \sum_{l=1}^{lpo-1} \int_{\mathcal{E}} \Delta x^{2l-1} D^l c_{r,j} D^l c_{r,k} dx.$$

We can now expand $f(x)$ around the point x_i:

$$f(x) = \sum_n \frac{1}{n!} f^{(n)}(x_i)(x - x_i)^n$$

so that

$$f_{i-r+j} = \sum_n \frac{1}{n!} f^{(n)}(x_i)(\Delta x(i - r + j - i))^n = \sum_n \frac{1}{n!} f^{(n)}(x_i)(j - r)^n \Delta x^n.$$

Therefore,

$$\beta_r = \sum_{n,m} \Delta x^{n+m} f^{(n)} f^{(m)} \mathcal{D}^r_{n,m},$$

where $\mathcal{D}^r$ is the symmetric matrix

$$\mathcal{D}^r_{n,m} = \frac{1}{n!m!} \sum_{j,k=0}^{lpo-1} K^r_{j,k}(j - r)^n (k - r)^m.$$

Computation of these coefficients leads directly to the general order of PWENO methods; for instance, we have the following:

- Numerical computation of $\mathcal{D}^r$ for method WENO-6,4 shows that

  $$0 \le r \le 2, \qquad \mathcal{D}^r_{1,1} = 1,\ \mathcal{D}^r_{2,2} = \frac{4}{3},$$

  and therefore, if $f' \neq 0$, then

  $$\beta_r = (f'(x_i)\Delta x)^2(1 + O(\Delta x))$$

  (where $A = (f'(x_i)\Delta x)^2$, $n = 1$ in (2.6)), and if $f'(x_i) = 0$, then

  $$\beta_r = \frac{4}{3}(f''(x_i)\Delta x^2)^2(1 + O(\Delta x))$$

  ($A = \frac{4}{3}(f''(x_i)\Delta x^2)^2$, $n = 1$ in (2.6)), i.e., that the method is fifth order.
- Computations for WENO-5,3 imply that if $f'(x_i) \neq 0$, then

  $$\beta_r = (f'(x_i)\Delta x)^2(1 + O(\Delta x^2))$$

  (where $A = (f'(x_i)\Delta x)^2$, $n = 2$ in (2.6)). This implies that WENO-5,3 has order 5.

3. Time splittings and linear advection. For integrating both the Vlasov–Boltzmann coupling

$$\frac{\partial f}{\partial t} + \underbrace{v \cdot \nabla_x f + F \cdot \nabla_v f}_{\text{Vlasov}} = \underbrace{\mathcal{Q}[f]}_{\text{Boltzmann}}$$

and the Vlasov equation

$$\frac{\partial f}{\partial t} + \underbrace{v \cdot \nabla_x f}_{\text{adv. in } x} + \underbrace{F \cdot \nabla_v f}_{\text{adv. in } v} = 0$$

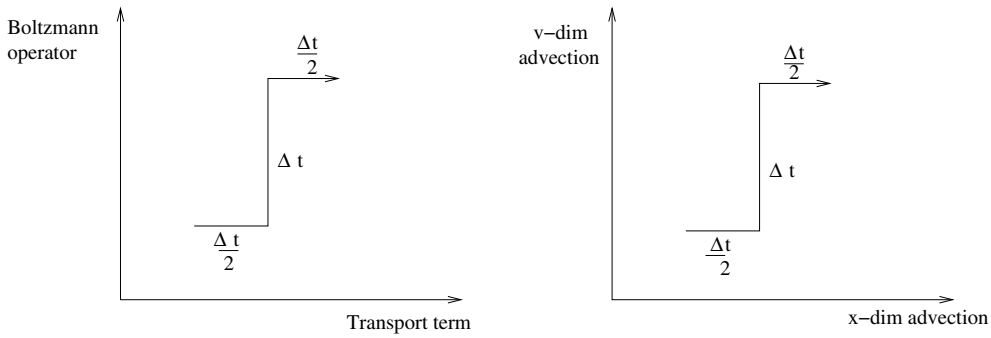

FIG. 3.1. *Time splitting schemes.*

we use Strang [29] and Cheng–Knorr [9] splitting schemes shown in Figure 3.1. In our simulations all reduce to solving the 1D linear advection equation

$$\begin{cases} \dfrac{\partial f}{\partial t} + v\dfrac{\partial f}{\partial x} = 0, \\ f(t=0,x) = f_0(x), \end{cases}$$

whose solution is the translation with velocity v of the initial function

$$f(t,x) = f_0(x - vt)$$

and is obviously mass-conservative.

Two methods are proposed: the semi-Lagrangian (SL) method and the flux balance method (FBM), the second one being mass-conservative and the first one being better as for controlling oscillations.

3.1. Semi-Lagrangian method. This method is based in directly following backward the characteristics of the system; i.e., knowing

$$f_i^n = f(t^n, x_i),$$

we perform the step in time this way:

$$f_i^{n+1} = f(t^{n+1}, x_i) = f(t^n, x_i - v\Delta t) \simeq p^n(x_i - v\Delta t),$$

where p^n is any chosen interpolation from point values of $f(t^n, \cdot)$. Here, we will choose PWENO as the interpolation method. This method is not mass-conservative.

3.2. Flux balance method. The flux balance method (FBM) is used in [14] to construct a conservative method. We already know that

$$f(t + \Delta t, x) = f(t, x - v\Delta t).$$

Now, let us integrate over an interval $[b_1, b_2]$ to get

$$\begin{aligned} \int_{b_1}^{b_2} f(t+\Delta t,\xi)d\xi &= \int_{b_1}^{b_2} f(t,\xi - v\Delta t)d\xi = \int_{b_1 - v\Delta t}^{b_2 - v\Delta t} f(t,\xi)d\xi \\ &= \int_{b_1 - v\Delta t}^{b_1} f(t,\xi)d\xi + \int_{b_1}^{b_2} f(t,\xi)d\xi - \int_{b_2 - v\Delta t}^{b_2} f(t,\xi)d\xi. \end{aligned}$$

If we use as notation

$$\Psi(t,x) = \int_{x-v\Delta t}^{x} f(t,\xi)d\xi,$$

we get

$$\int_{b_1}^{b_2} f(t+\Delta t,\xi)d\xi = \int_{b_1}^{b_2} f(t,\xi)d\xi + \Psi(t,b_1) - \Psi(t,b_2),$$

and dividing by $\Delta = b_2 - b_1$,

$$\frac{\int_{b_1}^{b_2} f(t+\Delta t,\xi)d\xi}{\Delta} = \frac{\int_{b_1}^{b_2} f(t,\xi)d\xi}{\Delta} + \frac{\Psi(t,b_1)-\Psi(t,b_2)}{\Delta},$$

which means

$$\bar{f}_{(b_1,b_2)}(t+\Delta t) = \bar{f}_{(b_1,b_2)}(t) + \frac{\Psi(t,b_1)-\Psi(t,b_2)}{\Delta},$$

i.e., the local description of mass-conservation. By denoting by $F(t,\cdot)$ the primitive of $f(t,\cdot)$, the numerical method we get applying the previous argument on the interval $[x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}}]$ is

$$f_i^{n+1} = f_i^n + \frac{\Psi^n(x_{i-\frac{1}{2}}) - \Psi^n(x_{i+\frac{1}{2}})}{\Delta x},$$

where we have approximated the mean value of the function over the interval by its value at the center and

$$\Psi^n(x_{i-\frac{1}{2}}) = \int_{x_{i-\frac{1}{2}}-v\Delta t}^{x_{i-\frac{1}{2}}} f(t^n,\xi)d\xi = F(x_{i-\frac{1}{2}}) - F(x_{i-\frac{1}{2}} - v\Delta t).$$

Finally, $F(x_{i-\frac{1}{2}} - v\Delta t)$ will be approximated by a chosen interpolation from the known point values of F at $x_{i+\frac{1}{2}}$. Here, we will choose PWENO as the interpolation method. A method belonging to this family is the positive flux conservative method (PFC-3) introduced in [14].

3.3. Total variation control. The discrete total variation (DTV) is defined as

$$\sum_{i=0}^{N-2} \|f_i^n - f_{i+1}^n\|.$$

The exact solution of the linear advection equation obviously conserves the total variation. If the numerical method is able to respect this property, then it is not adding spurious oscillations due to the interpolation to the shape of the function. Take as initial datum

$$f^{step}(x) = \begin{cases} 0 & \text{if } x < 0, \\ 1 & \text{if } x \geq 0 \end{cases}$$

for the linear advection equation with periodic boundary conditions on $x \in [-1,1]$. As we see in Figure 3.2, Lagrange interpolation has the worst behavior both in the SL method and in the FBM, while PWENO interpolation has a very good conservation of the DTV in the SL method. In the FBM PWENO behaves a little bit worse, but in exchange this second method conserves the mass.

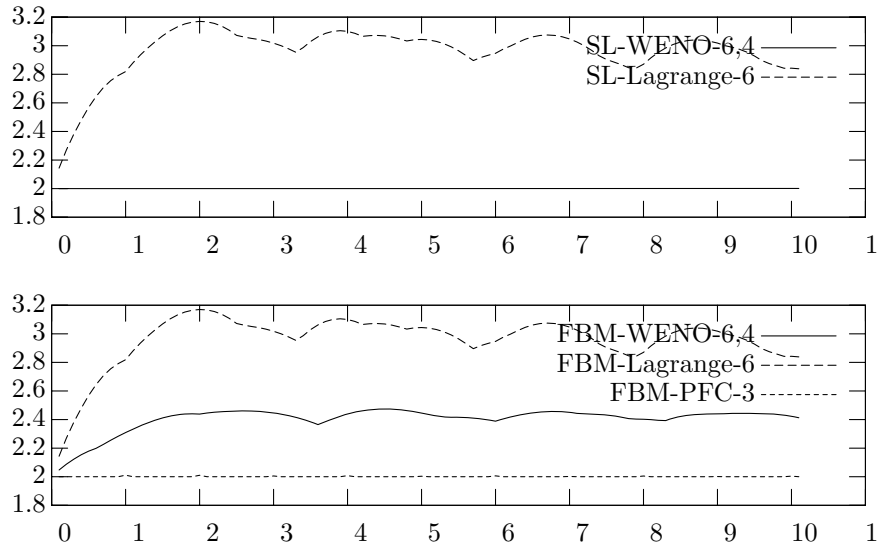

FIG. 3.2. *The evolution of DTV against time for the step as initial function.*

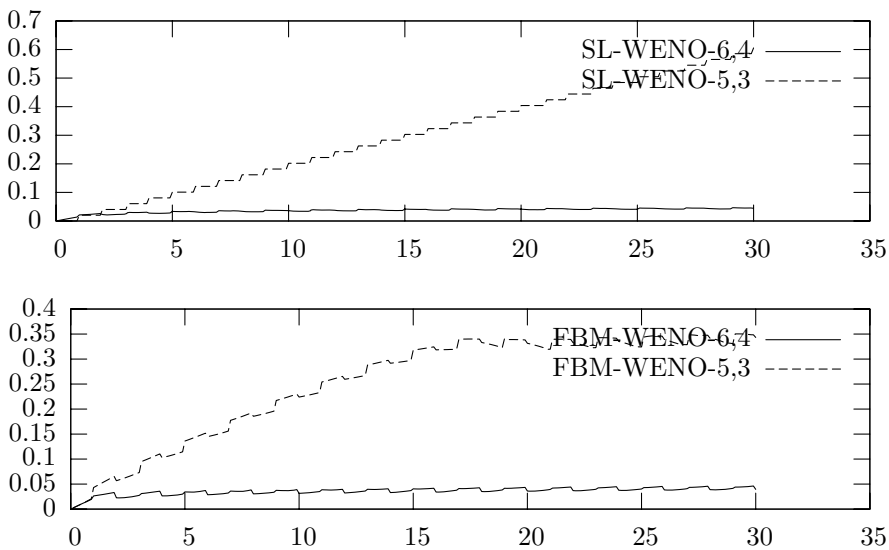

FIG. 3.3. *The evolution of L^1-norm error against the time for $N = 100$, $x \in [-\pi, \pi]$, $\Delta t = 0.1$, $t_{max} = 30$, $f_0(x) = f^{step}(x)$.*

3.4. Disphasement errors. Now we want to focus our attention on how important the choices of the substencils, and thus, of the parameters *ntot* and *lpo* in the PWENO-*ntot*,*lpo* interpolation, are. In Figure 3.3, we see that WENO-6,4 is more accurate than WENO-5,3 both in the semi-Lagrangian method and in the flux balance methods. This difference is due to the fact that in WENO-5,3 not all the substencils "feel" that there is a jump point. Suppose we are interpolating close to x_i, and suppose the jump point is situated between x_i and x_{i+1}. If there is a substencil

which does not contain the irregularity, the WENO method will give weights 0 to all of them but this one. This means that the jump runs with the wrong speed $\frac{\Delta x}{\Delta t}$ with an error after time T with respect to the real speed of $\frac{\Delta x}{\Delta t}\,[\alpha - 1] \times T$ with $\alpha = v\frac{\Delta t}{\Delta x}$. Then, it is essential to use a WENO method such that every substencil contains any discontinuity which may appear, like WENO-6,4. In general, it must be

$$lpo \geq \left[\frac{ntot+1}{2}\right] + 1.$$

3.5. Variable advection equation. Previous methods were written for constant advection equations since most of the time they are the ones appearing in Vlasov-like models. However, both the semi-Lagrangian method and the FBM can be applied for transport equations of the type

$$\begin{cases} \dfrac{\partial f}{\partial t} + \dfrac{\partial}{\partial x}[a(t,x)f] = 0, \\ f(t=0,x) = f_0(x), \end{cases}$$

whose solution can be written in terms of the characteristics given by the solution $r(s;t,x)$ of $r'(s) = a(s, r(s)))$ with $r(t) = x$ as

$$f(t,x) = f_0(r(0;t,x))\frac{\partial r}{\partial x}(0;t,x);$$

see also [13]. The semi-Lagrangian approximation is obtained as

$$f_i^{n+1} = f(t^{n+1}, x_i) = f(t^n, r(t^n; t^{n+1}, x_i))\,\frac{\partial r}{\partial x}(t^n; t^{n+1}, x_i),$$

where $f(t^n, \cdot)$ is approximated by interpolation if the Jacobian of the flow map is explicitly known. The flux balance method can also be applied in this case without any change since the solution to our transport equation satisfies

$$\int_{b_1}^{b_2} f(t+\Delta t, \xi)\, d\xi = \int_{r(t;t+\Delta t,b_1)}^{r(t;t+\Delta t,b_2)} f(t,\xi)\, d\xi$$

for any interval $[b_1, b_2]$ from which the same procedure as in subsection 3.2 applies to obtain the FBM; see also [13].

3.6. Splitting and collisions. Semi-Lagrangian and flux balance methods do not have any CFL limitation as already stressed in the introduction. This is a clear advantage especially when dealing with kinetic equations that possess very large velocities. However, there is an important drawback of using SL methods or FBMs. Due to their "characteristic nature" it is hard to couple them efficiently with a collisional/relaxation right-hand side when this relaxation part is stiff with respect to transport terms. This situation happens in diffusive scalings of kinetic equations, for instance [20]. This is due to the fact that the choice of time integrators is limited to splitting strategies which have a limited accuracy of second order in time away from stiff regions of the right-hand side. The reader should be aware of this potential loss of accuracy induced by the coupling with collisions through splitting.

Finally, let us remark that dimensional splitting for the computation of the transport phases for collisionless Vlasov equations is not always a good choice. Actually, for the Vlasov–Maxwell system for laser-plasma interaction, the instability of a particular

dimensional splitting scheme has been reported in [18]. This system has the feature of having variable advection in both position and momentum and it has to be written in divergence form in phase space leading to a two-dimensional (2D) numerical scheme; we refer the reader to [18] for full details.

4. Numerical simulations. We expose and compare results concerning the simulation of five models:

- A noncollisional coupled Vlasov–Poisson system, by which we study the nonlinear Landau damping.
- A noncollisional coupled Vlasov–Poisson system, by which we study the symmetric two stream instability problem.
- A 1D Vlasov system with a linear Boltzmann operator and a given confining potential.
- A 1D Vlasov system with a linear Fokker–Planck operator and a given confining potential.
- A collisional Vlasov–Poisson system, by which a silicon n^+-n-n^+-structured semiconductor is simulated.

4.1. 1D nonlinear Landau damping. The (normalized) model is

$$\begin{cases} \dfrac{\partial f}{\partial t} + v\dfrac{\partial f}{\partial x} - \dfrac{\partial \Phi}{\partial x}\dfrac{\partial f}{\partial v} = 0, \\ \dfrac{\partial^2 \Phi}{\partial x^2} = 1 - \displaystyle\int_{\mathbb{R}} f\,dv, \\ f_0(x,v) = f_0(x,v) = \dfrac{1}{\sqrt{2\pi}} e^{-\frac{v^2}{2}} \left[1 + 0.5\cos\left(\dfrac{x}{2}\right)\right]. \end{cases}$$

Landau theory has been developed in order to study the propagation of small amplitude waves in a uniform plasma (with no magnetic field and no collisions). It conjectures an interchange of energy between the electric field (potential energy) and resonant particles (kinetic energy) driven by the wave, which produces an oscillating evolution of the electric energy

$$\int_0^L |E(t,x)|^2 dx.$$

Its decay is expected to be exponential in the first phase of the evolution, then it should start oscillating around some equilibrium value.

The numerical method must properly take into account two aspects: the filamentation of the phase space and the conservation properties.

The best results are given by FBM-PWENO-5,3: this method is able to describe the filamentation of the phase space; it controls the strong oscillations (part of the physical phenomenon), which, after some time, should start to disappear. It has a good conservation of the total energy (oscillations about 0.03%, 0.015% for Lagrange and 0.05% for PFC-3, as we see in Figure 4.1).

As for FBM-Lagrange-5 and FBM-PFC-3, both give physically unreliable results, the first one because of the spurious growth of the oscillations, and the second one because of the almost total repression of them, as we can see in Figure 4.2. From Figure 4.3 we can see that the reconstruction given by PFC-3 is, in effect, less definite than the other ones, due to the low order. Lagrange reconstruction is more irregular, due to the parasite oscillations.

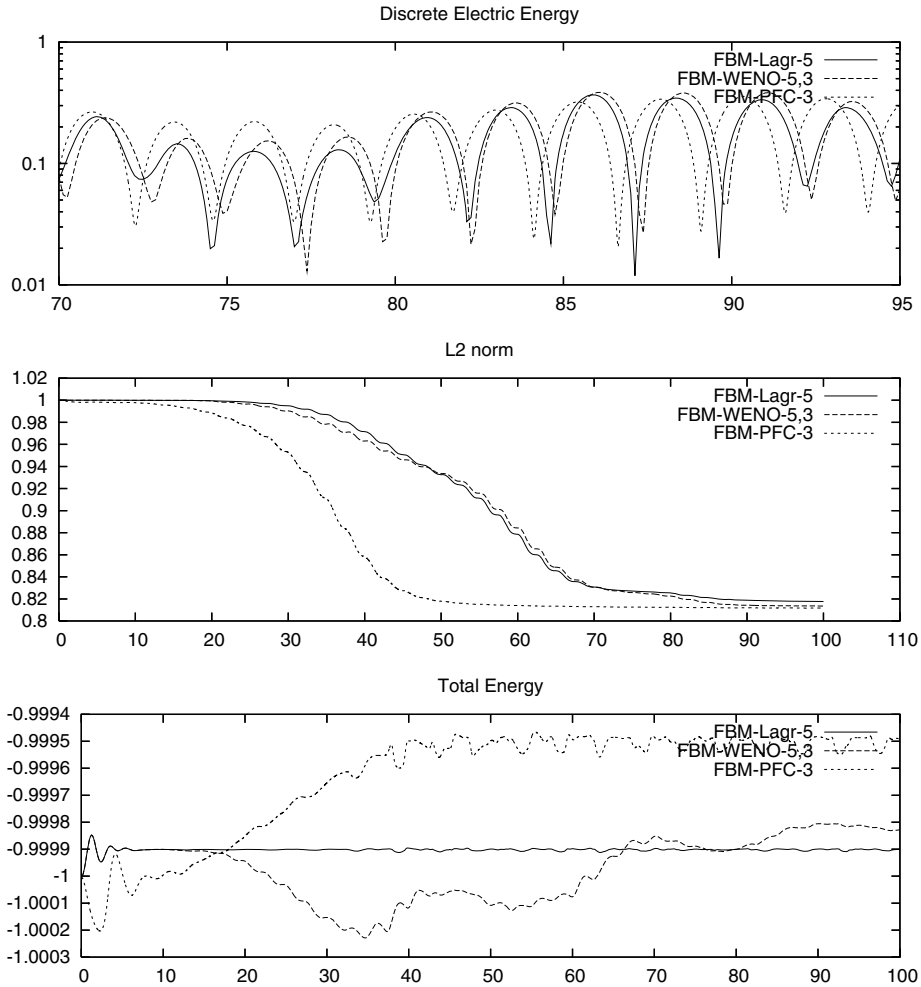

FIG. 4.1. 1D *nonlinear Landau damping. Evolution of the discrete electric energy, the* L^2*-norm, and the total energy. Test performed with* 256×256 *points,* $\Delta t = 0.125$ *for WENO,* $\Delta t = 0.01$ *for PFC-3,* $x \in [0, 4\pi]$, $v \in [-6, 6]$.

4.2. Two stream instability. The (normalized) model is

$$\begin{cases} \dfrac{\partial f}{\partial t} + v\dfrac{\partial f}{\partial x} - \dfrac{\partial \Phi}{\partial x}\dfrac{\partial f}{\partial v} = 0, \\ \dfrac{\partial^2 \Phi}{\partial x^2} = 1 - \displaystyle\int_{\mathbb{R}} f dv, \\ f_0(x,v) = Z\dfrac{2}{7\sqrt{2\pi}}\left(1+5v^2\right)\left[1+\alpha\left(\dfrac{\cos(2kx)+\cos(3kx)}{1.2}+\cos(kx)\right)\right]e^{-\frac{v^2}{2}} \end{cases}$$

with $\alpha = 0.01$, $k = 0.5$, and Z a normalizing factor to impose periodicity boundary conditions on the electric field. This test has been studied in [13]; there, Filbet and Sonnendrücker compare several methods for a coarse points grid and observe which ones have good conservation properties and which ones are able to follow thin details

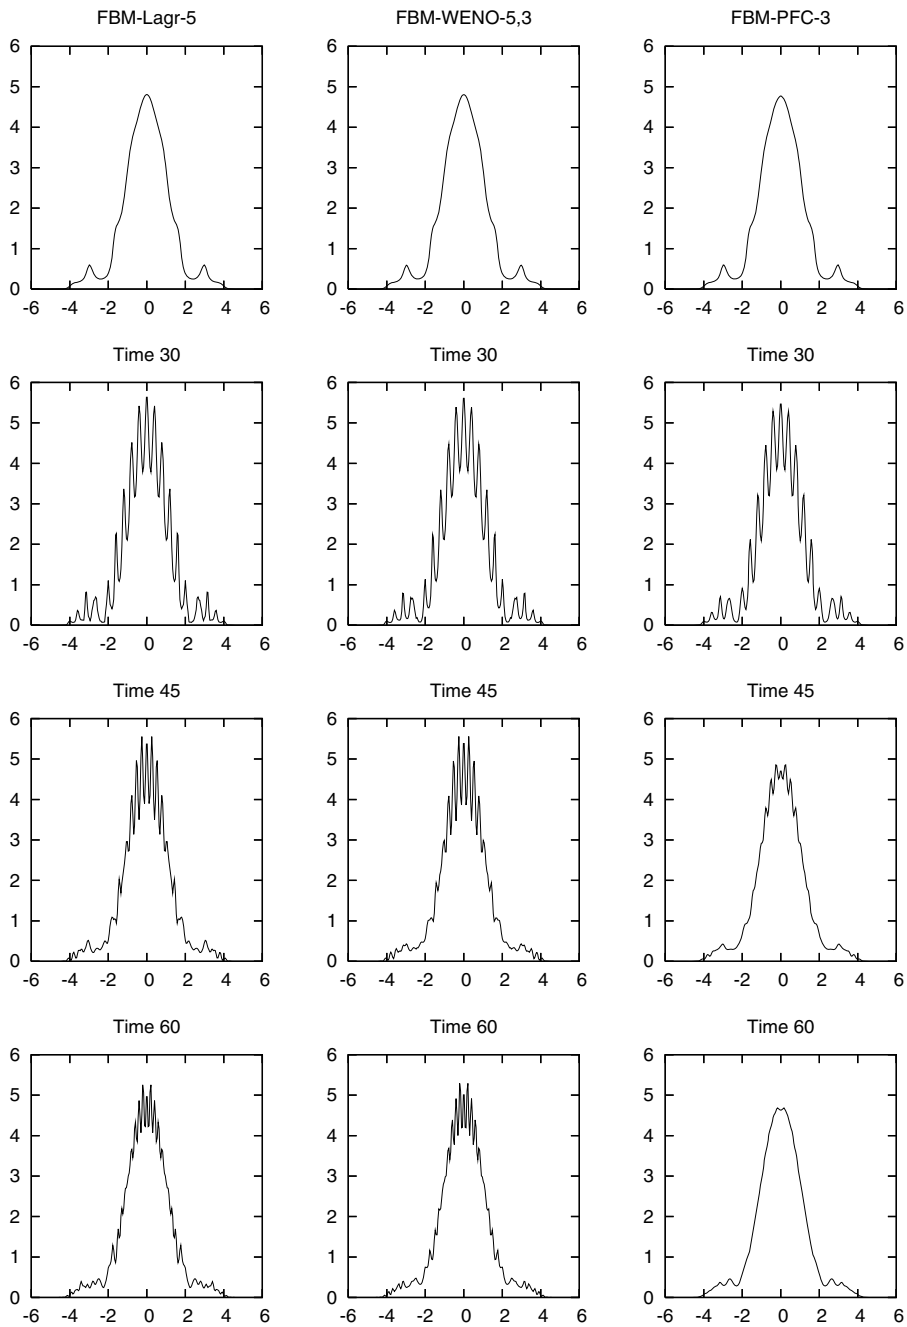

FIG. 4.2. 1D *nonlinear Landau damping. Evolution of the x-integrated distribution function for several methods. Test performed with* 256×256 *points,* $\Delta t = 0.125$ *for WENO,* $\Delta t = 0.01$ *for PFC-*3, $x \in [0, 4\pi]$, $v \in [-6, 6]$.

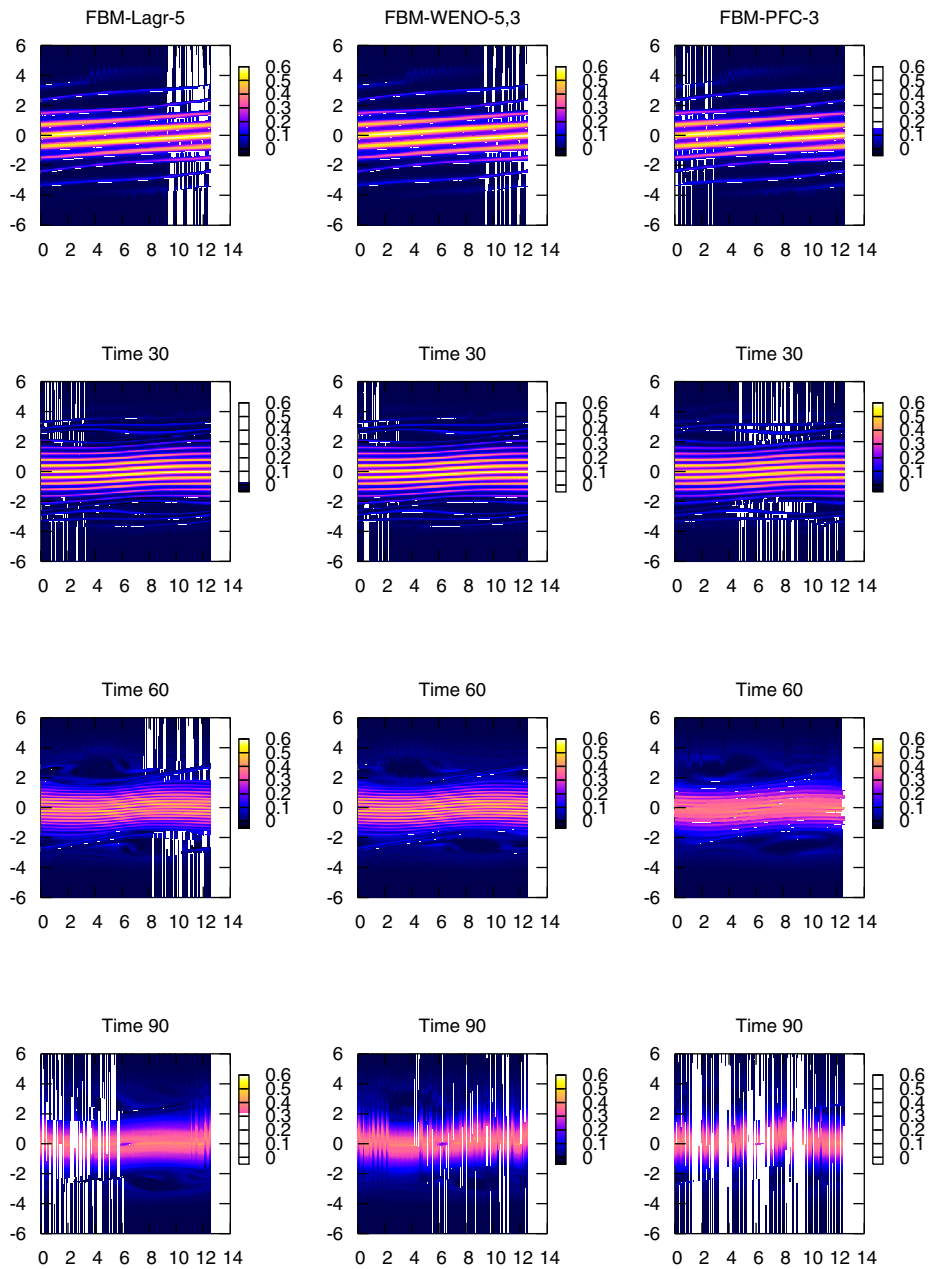

FIG. 4.3. 1D *nonlinear Landau damping. Evolution of the level curves of the distribution function for several methods. Test performed with* 256×256 *points,* $\Delta t = 0.125$ *for WENO,* $\Delta t = 0.01$ *for PFC-3,* $x \in [0, 4\pi]$, $v \in [-6, 6]$.

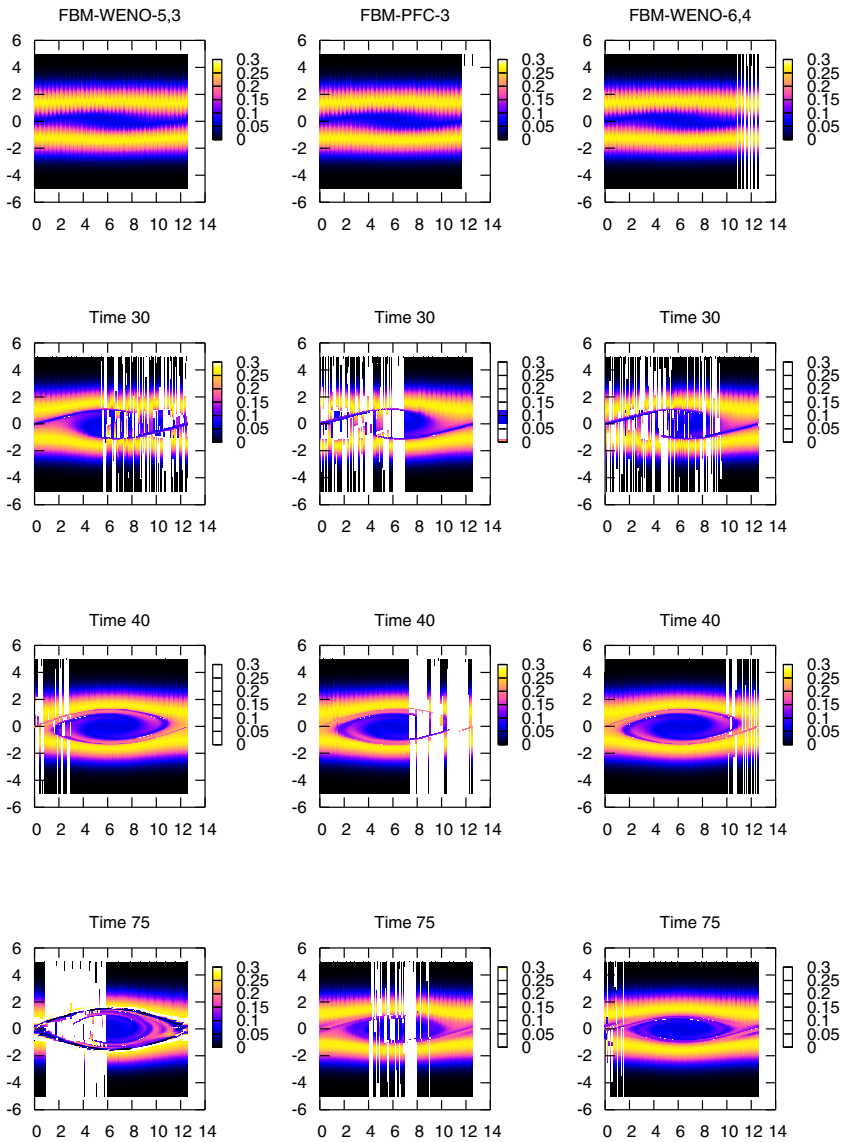

FIG. 4.4. *Two stream instability. Evolution of the level curves. Simulation performed with* 256×256 *points,* $\Delta t = 0.125$ *for WENO methods,* $\Delta t = 0.01$ *for PFC-3,* $x \in [0, 4\pi]$, $v \in [-5, 5]$.

of the distribution function: among their cases, a semi-Lagrangian method with a cubic spline interpolation has given the most reliable results.

Our simulations show that even if both FBM-WENO-5,3 and FBM-WENO-6,4 are fifth order, there may be a substantial difference in their reconstructions, due to the problem the first method has in following shock-like situations, which is the case of this test. Dispersion errors become too important, and in the phase space violent oscillations are produced (look at the level curves in Figure 4.4) which desta-

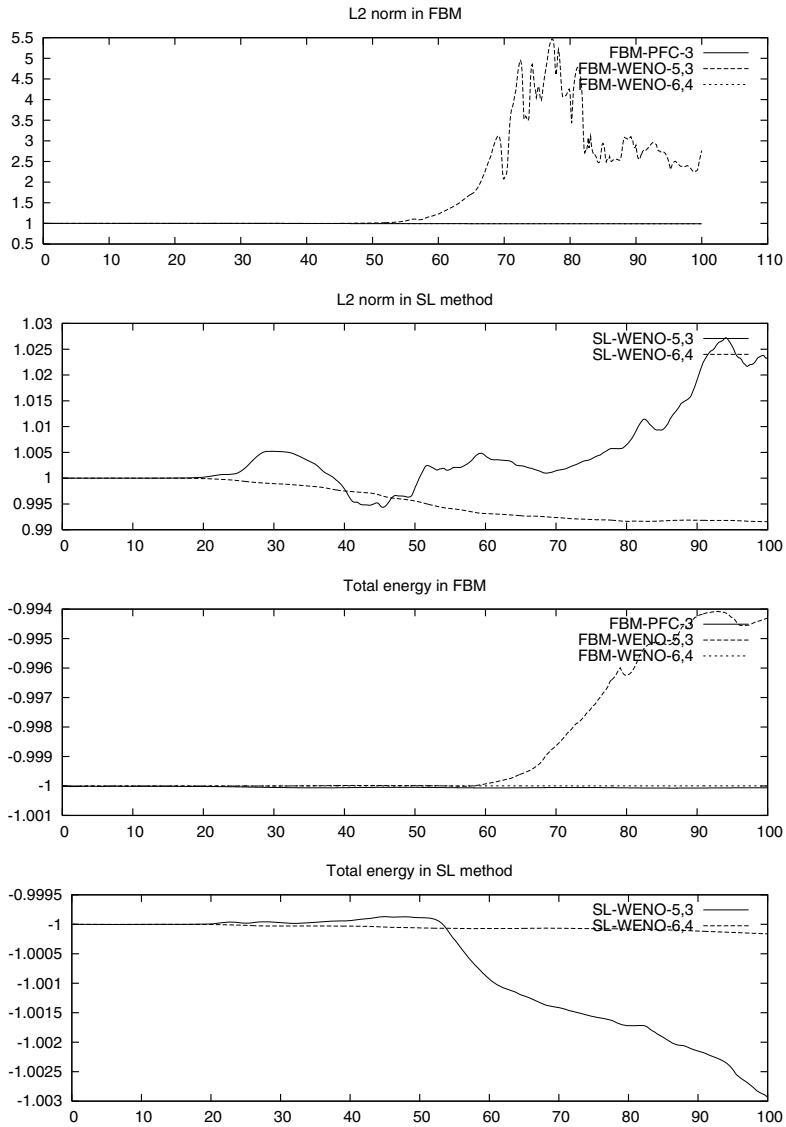

FIG. 4.5. *Two stream instability. Evolution of the L^2-norm and the total energy. Simulation performed with 256×256 points, $\Delta t = 0.125$ for WENO methods, $\Delta t = 0.01$ for PFC-3, $x \in [0, 4\pi]$, $v \in [-5, 5]$.*

bilize the simulation (the variation of the L^2-norm is about 400%, as we can remark from Figure 4.5). As for the PFC-3 method, it has good conservation properties (Figure 4.5), but, compared with FBM-WENO-6,4, observing the level curves in Figure 4.4, it is evident that it is lower order and the reconstruction is less detailed.

Let us finally remark that the semi-Lagrangian schemes behave similarly: SL-WENO-5,3 is unstable, too, even if it behaves better than FBM-WENO-5,3; SL-WENO-6,4 as well as FBM-WENO-6,4 gives a fairly detailed reconstruction almost indistinguishable; and the L^2-norm and the total energy are worse-conserved in the SL method.

4.3. Vlasov–Boltzmann with confining potential. We solve the 1D Vlasov–Boltzmann equation with a confining potential $\Phi_0(x)$ and the simplest linear collision operator:

$$\begin{cases} \dfrac{\partial f}{\partial t} + v\dfrac{\partial f}{\partial x} - \dfrac{\partial \Phi_0}{\partial x}\dfrac{\partial f}{\partial v} = \dfrac{1}{\tau}\left[\rho M_1 - f\right], \\ f(0,x) = f_0(x). \end{cases}$$

From [4] we know that the solution tends to a global equilibrium given by

$$f_s = M\left(\int_{\mathbb{R}} \exp\left(-\Phi_0(x)\right) dx\right)^{-1} \exp\left(-\Phi_0(x)\right) M_1(v)$$

in the L^1-norm, whenever the external potential verifies the confinement conditions

$$\begin{cases} \bullet\ \Phi_0 \geq 0,\ \Phi_0 \in C^\infty(\mathbb{R}), \\ \bullet\ \exp(-\Phi_0(x)) \in L^1(\mathbb{R}), \\ \bullet\ \Phi_0 \text{ is a bounded perturbation of a uniformly convex potential on } \mathbb{R}: \\ \Phi_0 = \Phi_0^{uc} + \Phi_0^{bp} \text{ such that} \\ \qquad \text{there exists } \lambda_1 > 0 \text{ such that } \frac{\partial^2}{\partial^2 x}\Phi_0^{uc}(x) \geq \lambda_1\ \forall x \in \mathbb{R}, \\ \text{and} \\ \qquad \text{there exist } a \text{ and } b \text{ such that } 0 < a \leq \Phi_0^{bp}(x) \leq b < \infty\ \forall x \in \mathbb{R}. \end{cases}$$

The decay rate was proved to be "almost exponential" [4], i.e.,

$$\|f - f_s\|_{L^1}^2 \leq H[f; f_s] \leq C(\epsilon, f_0) t^{-\frac{1}{\epsilon}} \tag{4.1}$$

$\forall \epsilon > 0$. Global and local relative entropies are measures of how far f is from the global equilibrium f_s and the local equilibrium $\rho(t,x)M_1$:

$$\begin{cases} H[f; f_s] = \displaystyle\int_{\mathbb{R}}\int_{\mathbb{R}} \frac{|f - f_s|^2}{f_s}\, dvdx, \\ \tilde{H}[f; \rho M_1] = \displaystyle\int_{\mathbb{R}}\int_{\mathbb{R}} \frac{|f - \rho M_1|^2}{f_s}\, dvdx. \end{cases} \tag{4.2}$$

Global and local relative entropies satisfy the ODE inequalities system [4]

$$\begin{cases} -\dfrac{d}{dt} H[f; f_s] \geq K\tilde{H}[f; \rho M_{\theta_0}], \\ \dfrac{d^2}{dt^2}\tilde{H}[f; \rho M_{\theta_0}] \geq K' H[f; f_s] - C(f, \epsilon)\tilde{H}[f; \rho M_{\theta_0}]. \end{cases} \tag{4.3}$$

We show numerical results in the particular case of $\Phi_0(x) = \frac{x^2}{2}$. In this case, the Vlasov part gives a rotation of the initial function $f_0(x,v)$ while the collision part thermalizes the velocity distribution toward $M_1(v)$. Moreover, an analysis of the spectrum of operator

$$f \longmapsto -v\frac{\partial f}{\partial x} + x\frac{\partial f}{\partial v} + \frac{1}{\tau}\left[\rho M_1 - f\right]$$

has recently been done in [16] showing the existence of a spectral gap in a suitable L^2-weighted space and, thus, of the exponential convergence in that space and as a consequence in L^1 toward f_s.

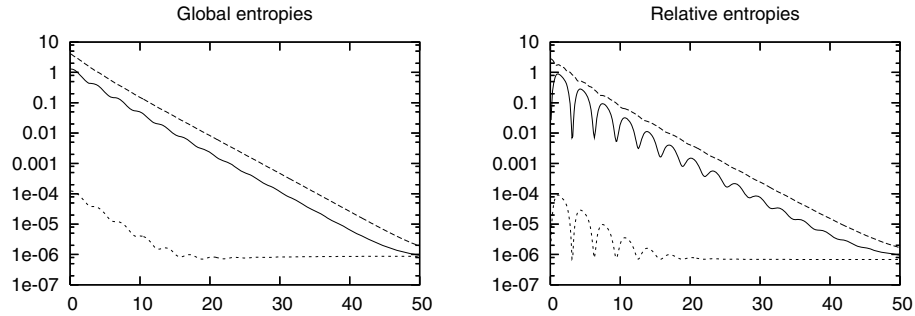

FIG. 4.6. 1D *Vlasov–Boltzmann with confining potential. Tests performed with* 400×400 *points,* $\Delta t = 0.1$*, SL method with PWENO-6,4,* $\tau = 3.5$*. Left figure: H-entropy; right figure:* $\tilde{H}$*-entropy. For the three cases: solid line* ($f_0^{(1)}$)*, dashed line* ($f_0^{(2)}$)*, and small dashed line* ($f_0^{(3)}$)*.*

The system of ODE inequalities (4.3) suggests the appearance of oscillations in the trend of solutions toward global equilibrium. The ODE inequalities (4.3) show that the trend of convergence toward local equilibria is compensated by the transport term that should push the solution out of the local equilibria manifold whenever the solution approaches a local equilibrium which is not the global one. This fact may induce an oscillation both in the local and global relative entropies, and thus, on the trend of convergence toward equilibrium.

In Figure 4.6, we compare the decay of global and relative entropies for three different initial functions, two of them far from equilibrium,

$$f_0^{(1)}(x) = Z_1 \sin^2\left(\frac{x^2}{2}\right) e^{-\frac{x^2+v^2}{2}},$$

$$f_0^{(2)}(x) = Z_2 \sin^2\left(\frac{x^2}{2}\right) \sin^2\left(\frac{v^2}{2}\right) e^{-\frac{x^2+v^2}{2}},$$

and a close-to-equilibrium initial data

$$f_0^{(3)}(x) = Z_3 \left[1 + 0.05 \sin^2\left(\frac{x^2}{2}\right)\right] e^{-\frac{x^2+v^2}{2}}$$

with suitable normalizing factors Z_i, $i = 1, \ldots, 3$.

From these log-plot results, we first observe the exponential L^1-convergence of f toward f_s, as shown in [16], led by the exponential decay of $H[f; f_s]$ due to the first inequality in (4.1). Oscillations of both the global and the local entropies appear. Even if the amplitude of the oscillation is different, stronger for local entropies, it seems evident that the oscillation rate and the decay slope coincide. These oscillations are damped gradually in time; this behavior is observed for the two initial data far from equilibrium, by computing for longer times, while for the close-to-equilibrium initial data this is observed quickly before achieving a steady value due to the accuracy. In [12] oscillations have been reported in the case of the nonlinear Boltzmann equation for rarefied gases in a box with periodic boundary conditions.

4.4. 1D Vlasov–Fokker–Planck with confining potential. We solve the 1D Vlasov equation with a confining potential $\Phi_0(x) = \frac{x^2}{2}$ and a Fokker–Planck operator

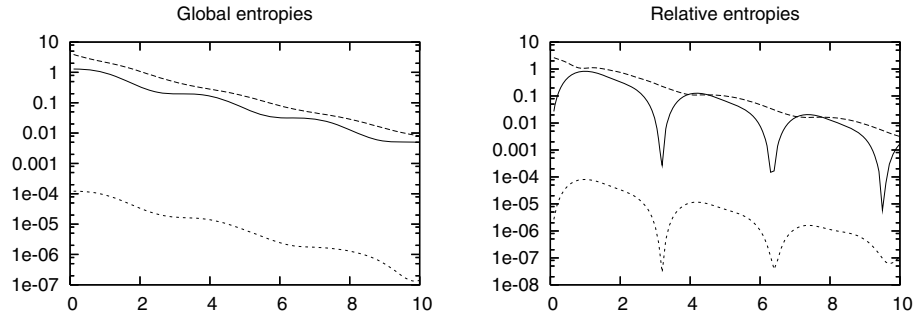

FIG. 4.7. 1D *Vlasov–Fokker–Planck. Test performed with* 400×400 *points,* $\Delta t = 0.01$, *SL method with PWENO-6,4,* $\tau = 3.5$, $\Theta = 1$. *Left figure: H-entropy; right figure:* $\tilde{H}$*-entropy. For the three cases: solid line* ($f_0^{(1)}$), *dashed line* ($f_0^{(2)}$), *and small dashed line* ($f_0^{(3)}$).

as collision operator:

$$\begin{cases} \dfrac{\partial f}{\partial t} + v\dfrac{\partial f}{\partial x} - x\dfrac{\partial f}{\partial v} = \dfrac{1}{\tau}\dfrac{\partial}{\partial v}\left[vf + \Theta\dfrac{\partial f}{\partial v}\right], \\ f(0,x) = f_0(x). \end{cases} \tag{4.4}$$

As for the Vlasov–Boltzmann equation, the solution of the above equation tends exponentially fast to a global equilibrium given by

$$f_s = M\left(\int_{\mathbb{R}} \exp\left(-\frac{x^2}{2}\right) dx\right)^{-1} \exp\left(-\frac{x^2}{2}\right) M_\Theta(v)$$

in the L^1-norm. Actually, an almost exponential rate of convergence was obtained in [11] based on a different system of global and local relative logarithmic entropies. In [17] the exponential convergence was shown by spectral theory. In Figure 4.7 we show how far f is from the global equilibrium f_s and the local equilibrium ρM_Θ by means of the global and local entropies, respectively, as in the previous test.

Equation (4.4) becomes, after an obvious manipulation,

$$\frac{\partial f}{\partial t} + v\frac{\partial f}{\partial x} - \frac{\partial f}{\partial v}\left[-\left(x + \frac{v}{\tau}\right) f\right] = \frac{\Theta}{\tau}\frac{\partial^2 f}{\partial v^2}.$$

In this case the v-advection velocity is not constant: the term $\left[-\left(x + \frac{v}{\tau}\right) f\right]$ depends on v. Therefore, in order to follow backward the characteristics, we need to solve the ODE $\frac{dv}{dt} = -\frac{v}{\tau} - x$. Applying the procedure of subsection 3.5, the v-advection step with a Δt time step is

$$f(t + \Delta t, x, v) = f\left[t, x, v\, e^{\Delta t/\tau} - \tau x\left(e^{\Delta t/\tau} - 1\right)\right] e^{\Delta t/\tau}.$$

As for the collision step,

$$\frac{\partial f}{\partial t} = \frac{\Theta}{\tau}\frac{\partial^2 f}{\partial v^2}$$

is solved through an explicit Euler step, the second derivative being approximated by centered second order finite difference keeping the standard parabolic CFL condition inside the collision step.

4.5. Simple model of transport in semiconductors. The model is

$$\begin{cases} \dfrac{\partial f}{\partial t} + v\dfrac{\partial f}{\partial x} - \dfrac{e}{m}E\dfrac{\partial f}{\partial v} = \dfrac{1}{\tau}\left[M_{\Theta_0}\rho[f] - f\right], \\ \epsilon_{Si}\dfrac{\partial^2 \Phi}{\partial x^2} = -e\left[\rho[f] - C\right], \qquad E = -\dfrac{\partial \Phi}{\partial x}, \\ f_0(x,v) = M_{\Theta_0}(v)C(x), \\ \tau(t,x) = \dfrac{m}{e}\dfrac{2\mu_0}{1+\sqrt{1+4((\mu_0/v_0)E(t,x))^2}}, \end{cases}$$

which describes the electron transport in an $n^+ - n - n^+$ diode where the interaction with the semiconductor crystal is taken into account by an effective relaxation time operator. The lattice temperature is set $T_0 = 300K$ and is related to the thermal energy of the lattice by $\Theta_0 = \frac{k_B}{m}T_0$. The relaxation time depends nonlinearly on the electric field producing a saturation on the drift speed; see [7, 8] for more details. We consider a diode of channel length $L = 0.4\mu m$ and doping profile

$$C(x) = \begin{cases} 5\times 10^5 \frac{1}{\mu m^3}, & 0 \le x \le 0.1, \\ 2\times 10^3 \frac{1}{\mu m^3}, & 0.1 < x < 0.5, \\ 5\times 10^5 \frac{1}{\mu m^3}, & 0.5 \le x \le 0.6. \end{cases}$$

We apply a potential drop at the drain, $\Phi(t,0) = 0$ V, and $\Phi(t,L) = V_{bias}$ V. Concerning boundary conditions at $x = 0$ and $x = L$, we use inflow boundary conditions fixed by Maxwellians with the lattice temperature for the ghost points outside the physical grid needed for computing PWENO interpolation.

In Figure 4.8, density, mean velocity, electric field, potential, energy, and the distribution function in v at a point near the end of the channel at the stationary state are plotted. We are comparing the results of our time splitting method based on FBM-WENO-6,4 with time step $\Delta t = 0.01$, finite-difference WENO5 coupled with an explicit adaptive in time third order Runge–Kutta (RK3) scheme for time discretization [7, 8] and finite-difference WENO5 coupled with an implicit (collisions)-explicit (transport) Runge–Kutta (IMEX-RK) LRR$(3,2,2)$ scheme for time discretization [22, 23] with time step $\Delta t = 0.001$. Results of three simulations are almost indistinguishable; the time step of the explicit RK3 is $\Delta t \simeq 0.0005$ chosen by the CFL due to the explicit discretization of the transport terms.

In Figure 4.9, we compare the results given by the explicit RK3 finite-difference WENO5 method and by FBM-WENO-6,4 for several time steps. One of the main advantages of SL or FBM-WENO schemes is that they do not have an a priori restriction on the time step as the CFL condition for finite-difference WENO5. Therefore, our scheme is much less costly from the computational point of view. Actually, 200 time steps corresponding to $\Delta t = 0.05$ of FBM-WENO-6,4 are enough to give results with less than 4% L^∞-difference in density to 9000 time steps corresponding to $\Delta t \simeq 0.00075$ of the WENO5 method with explicit RK3 time integrator with comparable computational cost for each time step between the methods. On the other hand, WENO5 with IMEX-RK time integrator with $\Delta t \simeq 0.003$, 2250 time steps, gives comparable results, less than 4% L^∞-difference in density, while the cost is higher since at each time step one linear system of the order of the velocity grid per position grid point has to be solved.

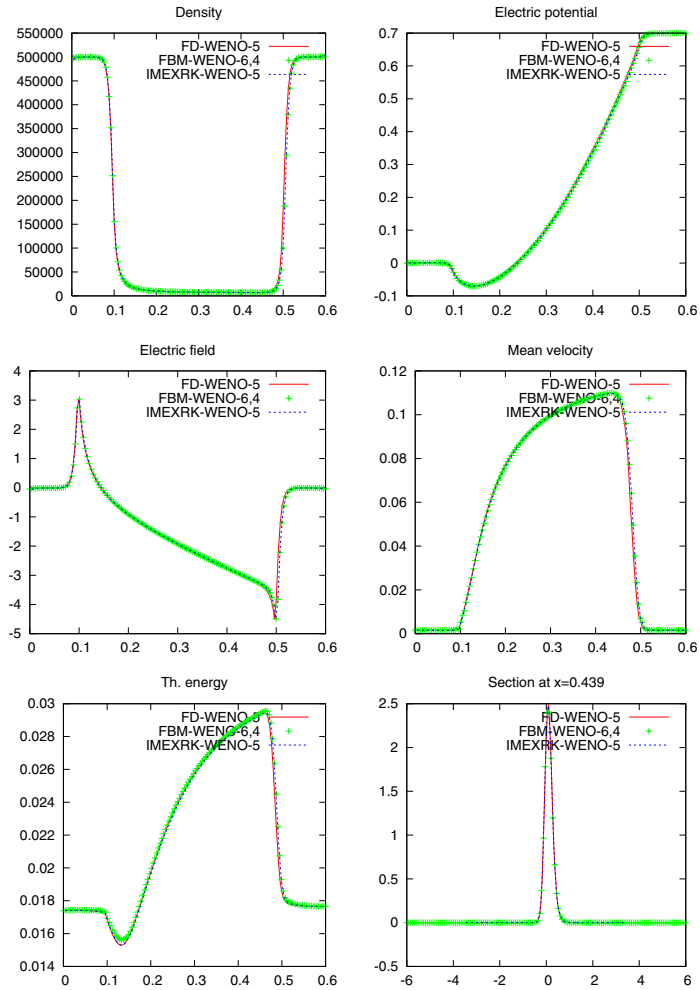

FIG. 4.8. 1D $n^+ - n - n^+$ *Silicon semiconductor. Evolution of several macroscopic magnitudes, for explicit Runge–Kutta-3 WENO-5 finite-difference method (CFL is set to* 0.3*), WENO-6,4 flux balance method with* $\Delta t = 0.01$*, and an IMEX-LRR*$(3, 2, 2)$ *WENO-5 finite-difference method with* $\Delta t = 0.001$*. Grids are set* 150×150 *points.*

Finally, we show in the next table the maximal time step needed to get such 4% L^∞-relative difference between density for different values of the temperature:

Temperature	Maximal Δt for densities
300	0.05
273	0.05
177	0.04
77	0.01

This table together with the behavior of the L^1-relative difference for different temperatures observed on the right in Figure 4.9 shows the problem gets stiffer as the temperature goes down and the mesh has to be taken finer. We summarize the phys-

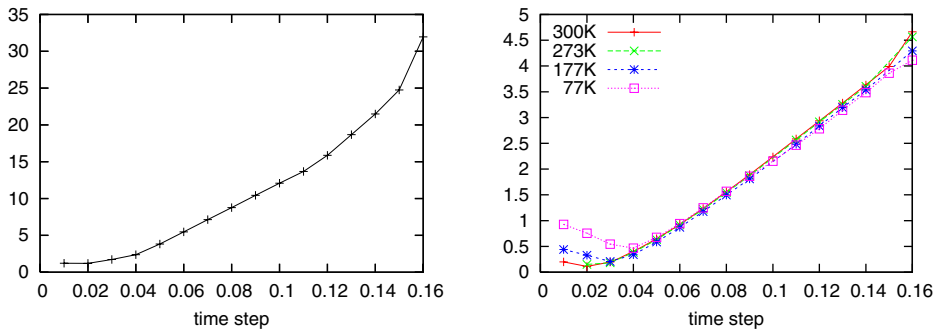

FIG. 4.9. *Left: L^∞-relative difference in % between densities given by the explicit RK*3 *finite-difference WENO*5 *method and by the FBM-WENO*-6,4 *for several time steps. ical constants used for the simulation:

Constant	Physical meaning	Magnitude
m	effective electron mass	$0.26 \times 0.9109(10^{-30}Kg)$
e	elementary electric charge	$0.1602(10^{-18}C)$
k_b	Boltzmann's constant	$0.138046 \times 10^{-4}(10^{-18}\frac{J}{K})$
ϵ_{Si}	Silicon dielectric permittivity	$11.7 \times 8.85418(10^{-18}\frac{F}{\mu m})$
μ_0	bulk mobility	0.1323
v_0	saturation velocity	0.13.

5. Conclusions. We have proposed a general family of methods based on essentially nonoscillatory interpolations (PWENO) for solving transport phases of Vlasov-like systems. Dimensional splitting has been used to reduce transport phases to 1D advection. The 1D advection is solved by semi-Lagrangian or flux balance methods coupled with the PWENO interpolation. Interpolation methods that feel all candidate stencils perform better in shock-like situations, and due to mass conservation, we take FBM-WENO-6,4 as the preferred method for transport phases. The performances of these methods have been shown in the detailed list of numerical experiments both for collisionless systems and nonstiff collisional systems where coupling has been done through time-splitting. Since the coupling of collisions and transport is reduced to splitting techniques of low order in time due to the characteristic nature of the transport schemes, the reader should be aware of the potential loss of accuracy when coupling this kind of method with stiff collisional terms.

Acknowledgments. We thank Simon Labrunie for fruitful comments and discussions and José M. Mantas for his help with the IMEX-RK method and general purpose codes applied to the last test.

NUMERICAL QUADRATURES FOR SINGULAR AND HYPERSINGULAR INTEGRALS IN BOUNDARY ELEMENT METHODS*

MICHAEL CARLEY†

Abstract. A method is developed for the computation of the weights and nodes of a numerical quadrature which integrates functions containing singularities up to order $1/x^2$, without the requirement to know the coefficients of the singularities exactly. The work is motivated by the need to evaluate such integrals on boundary elements in potential problems and is a simplification of a previously published method, but with the advantage of handling singularities at the endpoints of the integral. The numerical performance of the method is demonstrated by application to an integral containing logarithmic, first, and second order singularities, characteristic of the problems encountered in integrating a Green's function in boundary element problems. It is found that the quadrature is accurate to 11–12 decimal places when computed in double precision.

Key words. numerical quadrature, hypersingular integrals, Hilbert transform, integral equations, boundary element methods, Legendre polynomials

DOI. 10.1137/060666093

1. Introduction.

Boundary integral methods employing hypersingular integrals have become increasingly popular over recent decades with applications in potential problems such as acoustics [6] and fracture mechanics [13]. Hypersingular integrals arise naturally when it is required to compute the field quantities in such problems, for example, the potential and its gradients, and when specialized techniques for the avoidance of "interior resonance" are used, such as that of Burton and Miller [5]. When such integrals arise, they require special numerical treatment and cannot be evaluated using the standard tools of Gaussian quadrature. Instead, approaches tailored to the problem must be used, which can add considerable complexity to the code. This paper introduces a method for the design of numerical quadrature rules which evaluate hypersingular integrals without requiring a detailed analysis of the integrand. The method is based on that of Kolm and Rokhlin [12], who developed a procedure for the design of such rules, but is considerably simplified by the use of Brandão's approach to finite part integrals [4] and is extended to the case of integrals with endpoint singularities—essential if such a scheme is to be used with boundary elements.

To fix ideas, we assume that we are dealing with a two-dimensional potential problem, such as the Laplace or Helmholtz equation:

$$\nabla^2\phi = 0,$$
$$\nabla^2\phi + k^2\phi = 0.$$

In the case of the Helmholtz equation, the singular behavior of the Green's function will be related to the Green's function of the corresponding Laplace equation [8, for example]. The Green's functions for the Laplace equation will have a logarithmic

singularity in the planar and axisymmetric case (where the Green's function is proportional to an elliptic integral) and also in the case of an asymmetric problem in an axisymmetric domain [3, 6]. In each case, discretization of the boundary of the domain and use of a collocation method give rise to integrals of the form

$$I(x) = \int_{-1}^{1} (\log|x-t| + f(x,t))L(t)\,\mathrm{d}t, \tag{1.1}$$

where t, $-1 \le t \le 1$, is the local coordinate on an element and x is the local coordinate of the collocation point, which may be on the element, or on some adjacent element. The shape function $L(t)$ is typically a polynomial of order up to three.

Obviously, numerical integration of the $\log|x-t|$ term will require that the singular behavior be handled correctly, but since the logarithmic singularity is integrable, this does not present great difficulties; indeed, quadratures for such a problem exist [18]. If, however, it is required to evaluate first, or higher, derivatives of I, the integral is improper and more advanced approaches are required. Such integrals arise in the calculation of acoustic scattering by thin bodies [16], due to the "thin-shape breakdown" of the Helmholtz equation, when the Burton and Miller approach is used to avoid spurious resonances [5] and when gradients of the potential are required as, for example, in computing velocities in potential problems in fluid dynamics. It should be noted that in many problems, such as those in axisymmetric domains, $f(x,t)$ will contain logarithmic terms of the form $(x-t)\log|x-t|$ which are exposed by differentiation so that the integrand will contain singularities of more than one order.

The resulting integrals are of the form

$$\frac{\mathrm{d}I}{\mathrm{d}x} = \int_{-1}^{1} \frac{L(t)}{(x-t)} + L(t)g(x,t)\,\mathrm{d}t \tag{1.2}$$

and

$$\frac{\mathrm{d}^2 I}{\mathrm{d}x^2} = \int_{-1}^{1} \frac{L(t)}{(x-t)^2} + L(t)h(x,t)\,\mathrm{d}t \tag{1.3}$$

and must be interpreted as a Cauchy principal value [14, p. 37] and as a Hadamard finite part, respectively [14, p. 31], denoted by $\fint$ and $\fint\!\!\!\fint$, when $-1 \le x \le 1$. Even when the collocation point x is not on the element but is close to an endpoint, numerical problems arise due to the "offstage singularity" [1], meaning that the integrand is not well approximated by a polynomial.

A number of approaches have been used to handle the strong singularities in the singular and hypersingular integrals. The most obvious is to analyze the integral kernel to extract the singular parts explicitly so that the finite part integral can be evaluated directly [9]. This has the advantage of reliability as the integrand is broken into a singular part or parts and a regular part. The regular part is integrated using Gaussian quadrature and the integrals of the singular part(s) can be interpreted as principal value or finite part integrals using published results [11, for example]. Such an approach is limited, however, in that it requires an analysis of the integrand, i.e., of the kernel of the integral equation, which may be a complicated function not amenable to detailed study.

An alternative approach is to use a quadrature rule which evaluates the integral directly without requiring that it be broken into its singular part(s) and a regular remainder. Such quadratures have been reviewed and developed by Monegato [17]

among others and allow the integration of functions with singularities of order one or two. While this is useful in some applications, it is preferable to be able to integrate functions containing singularities of all orders up to and including two without having to extract them explicitly. An algorithm for the design of such quadrature rules has been presented by Kolm and Rokhklin [12] and allows finite part integrals to be evaluated using only the value of the integrand at each node and without having to analyze the function. This flexibility, however, comes at the price of losing the property of Gaussian quadratures that they integrate exactly all polynomials up to order $2N-1$, where N is the number of points in the quadrature rule. In practice, this is not a serious drawback as accuracy indistinguishable from machine precision is rapidly attained. In the case of offstage singularities, they use the algorithm of Ma, Rokhlin, and Wandzura [15] to derive a generalized Gaussian quadrature which can be used to integrate singular functions exactly. The design of such quadratures requires the use of Newton's method to solve a nonlinear system of equations. The effectiveness and accuracy of the method were demonstrated by application to integrals containing singularities of various orders up to and including two over a range of x, $-2.002 \leq x \leq 2.002$, $x \neq \pm 1$.

The method presented in this paper is similar to that of Kolm and Rokhlin [12] but is simpler to implement and includes the important case of a singularity at an endpoint, a case not considered by Kolm and Rokhlin. The simplification comes about through the use of Brandão's approach to finite part integrals [4]. In the original method, the finite part integrals are computed using special quadratures which must be found as part of the calculation; in this paper, standard Gauss–Legendre quadratures are used, simplifying implementation. It should also be noted that the use of the simpler approach to finite part integrals allows the extension of the method to higher order singularities with no modification to the theory—it is not clear how the special quadratures in the Kolm and Rokhlin approach can be generalized to include singularities of order three and higher or, indeed, singularities of noninteger order.

The extension to include endpoint singularities, easily implemented via the alternative approach to finite part integrals, is important because in boundary element calculations there will always be a need to evaluate integrals at the endpoints of elements and the Kolm and Rokhlin method as published is not applicable to these cases.

2. Quadratures. This section introduces a method for the calculation of the weights of quadrature rules which integrate functions with singularities up to second order, evaluating the integrals in the finite part or principal value sense. The technique is based on that of Kolm and Rokhlin [12], who base their rules on the nodes of an N-point Gauss–Legendre quadrature and compute the weights by solving a system of equations for the integrals of Legendre polynomials weighted by each of the singularities which must be handled (equation (2.7) in this paper). The integrals of the weighted polynomials are found numerically, using specially computed quadratures, whose weights must be found as part of the algorithm. In this paper, the procedure is simplified by using Brandão's approach to finite part integrals [4], outlined in section 2.1, which allows the finite part integrals to be computed using standard quadratures. This also allows the method to handle functions with endpoint singularities; this is important when boundary elements with collocation points at their ends are used.

2.1. Finite part integrals. The most convenient approach to the evaluation of finite part integrals seems to be that of Brandão [4], who gives a simple method for computing a finite part integral by breaking the integrand into a singular part and a

regular part which can be integrated exactly using standard Gaussian quadratures:

$$\text{(2.1a)}\qquad \fint_{-1}^{1} \frac{f(t)}{x-t}\,\mathrm{d}t = \int_{-1}^{1} \frac{f(t)-f(x)}{x-t}\,\mathrm{d}t + f(x)\fint_{-1}^{1} \frac{1}{x-t}\,\mathrm{d}t,$$

$$\fint_{-1}^{1} \frac{f(t)}{(x-t)^2}\,\mathrm{d}t = \int_{-1}^{1} \frac{f(t)-f(x)+f'(x)(x-t)}{(x-t)^2}\,\mathrm{d}t$$

$$\text{(2.1b)}\qquad + f(x)\fint_{-1}^{1} \frac{1}{(x-t)^2}\,\mathrm{d}t - f'(x)\fint_{-1}^{1} \frac{1}{x-t}\,\mathrm{d}t.$$

The finite part integrals are (see also Monegato [17])

$$\text{(2.2a)}\qquad \fint_{-1}^{1} \frac{1}{x-t}\,\mathrm{d}t = \begin{cases} \log|(x+1)/(1-x)|, & |x|\neq 1,\\ \pm\log 2, & x=\pm 1,\end{cases}$$

$$\text{(2.2b)}\qquad \fint_{-1}^{1} \frac{1}{(x-t)^2}\,\mathrm{d}t = \begin{cases} 2/(x^2-1), & |x|\neq 1,\\ -1/2, & x=\pm 1.\end{cases}$$

The formulae given are also valid for x outside the range of integration so that the same approach can also be used for "near-singular" integrals.

2.2. Integrals of Legendre polynomials. A basic tool in the calculation of the quadrature weights in section 2.3 is the evaluation of finite part and principal value integrals of Legendre polynomials, which are the polynomials orthogonal on the range $-1 \le t \le 1$ with a unit weight function. The required integrals are listed below. In most cases, these can be found in standard tables [10] or have been published elsewhere [11]. For $x = \pm 1$, the values are derived in the appendix.

$$\text{(2.3a)}\qquad \int_{-1}^{1} P_n(t)\,\mathrm{d}t = \begin{cases} 2, & n=0,\\ 0, & n\neq 0,\end{cases}$$

$$\text{(2.3b)}\qquad \int_{-1}^{1} P_n(t)\log|x-t|\,\mathrm{d}t = 2(Q_{n+1}(x)-Q_{n-1}(x))/(2n+1), \quad |x|\neq 1,$$

$$\text{(2.3c)}\qquad \int_{-1}^{1} P_{2m}(t)\log|\pm 1-t|\,\mathrm{d}t = \frac{2}{4^m}\sum_{k=0}^{m} \frac{(-1)^k(4m-2k)!}{k!(2m-k)!(2m-2k+1)!} \times \left(\log 2 - \sum_{q=0}^{m-k} \frac{1}{2q+1}\right),$$

$$\text{(2.3d)}\qquad \int_{-1}^{1} P_{2m+1}(t)\log|\pm 1-t|\,\mathrm{d}t = \pm\frac{1}{4^m}\sum_{k=0}^{m} \frac{(-1)^k(4m-2k+2)!}{k!(2m-k+1)!(2m-2k+2)!} \times \sum_{q=0}^{m-k} \frac{1}{2q+1},$$

$$\text{(2.3e)}\qquad \fint_{-1}^{1} \frac{P_n(t)}{x-t}\,\mathrm{d}t = P_n(x)\fint_{-1}^{1} \frac{1}{x-t}\,\mathrm{d}t + \sum_{j=0}^{M-1} w_j \frac{P_n(t_j)-P_n(x)}{x-t_j},$$

$$\text{(2.3f)}\qquad \fint_{-1}^{1} \frac{P_n(t)}{(x-t)^2}\,\mathrm{d}t = P_n(x)\fint_{-1}^{1} \frac{1}{(x-t)^2}\,\mathrm{d}t - P_n'(x)\fint_{-1}^{1} \frac{1}{x-t}\,\mathrm{d}t + \sum_{j=0}^{M-1} w_j \frac{P_n(t_j)-P_n(x)+P_n'(x)(x-t_j)}{x-t_j},$$

where $Q_n(x)$ is the Legendre function of the second kind, and (2.3e) and (2.3f) are Brandão's method for finite part integrals using an M-point Gauss–Legendre quadrature rule (t_j, w_j).

The derivatives of the Legendre polynomials, required in evaluating the finite part integral, (2.3f), can be found in standard tables [10] for $x \neq 1$ and are derived in the appendix for $x = \pm 1$:

$$P_n'(x) = \begin{cases} n(xP_n(x) - P_{n-1}(x))/(x^2-1), & |x| \neq 1, \\ n(n+1)/2, & x = 1, \\ -(-1)^n n(n+1)/2, & x = -1. \end{cases} \tag{2.4}$$

2.3. Quadrature rules. The paper of Kolm and Rokhlin [12] presents an algorithm for the design of quadrature rules for integrals of the form

$$f(x,t) = A(x,t) + B(t)\log|x-t| + \frac{C(t)}{x-t} + \frac{D(t)}{(x-t)^2}. \tag{2.5}$$

The N-point rule approximates the integral of f,

$$⨍_{-1}^{1} f(x,t)\,\mathrm{d}t \approx \sum_{j=0}^{N-1} w_j f(x,t_j), \tag{2.6}$$

with the weights w_i being functions of x. The advantage of such a quadrature is that the functions A, B, C, and D of (2.5) need not be known explicitly; it is assumed only that they are polynomials of order up to $M-1$. Then they can be represented as sums of Legendre polynomials P_n, and the requirement for the quadrature rule is that it integrate exactly $P_i(t)$, $P_i(t)\log|x-t|$, $P_i(t)/(x-t)$, and $P_i(t)/(x-t)^2$ for $i = 0, 1, \ldots, M-1$.

The nodes of the rule are chosen to be the nodes of an N-point Gauss–Legendre quadrature which can be computed using the method of Davis and Rabinowitz [7, p. 369]. Then the weights are the solution of the system of equations

$$[\psi_i(x,t_j)]\,[w_j] = [m_i], \tag{2.7}$$

where

$$\psi_i(x,t) = \begin{cases} P_i(t), & i = 0, \ldots, M-1, \\ P_i(t)\log|x-t|, & i = M, \ldots, 2M-1, \\ P_i(t)/(x-t), & i = 2M, \ldots, 3M-1, \\ P_i(t)/(x-t)^2, & i = 3M, \ldots, 4M-1, \end{cases} \tag{2.8}$$

and

$$m_i(x) = ⨍_{-1}^{1} \psi_i(x,t)\,\mathrm{d}t. \tag{2.9}$$

This is essentially the method of Kolm and Rokhlin [12] simplified by the use of Brandão's approach to finite part integrals. Equations (2.3) allow m_i to be calculated using Gauss–Legendre quadrature instead of special quadratures for different orders of singularity [12, equations 71–73]. Using this approach to finite part integrals also opens the way to handling higher order singularities, so-called "supersingular" integrals, and to incorporating singularities of noninteger order. Brandão also gives formulae for finite part integrals with endpoint singularities, a case not considered by Kolm and Rokhlin, and these formulae make the inclusion of endpoint singularities no more difficult than the handling of internal or external singularities.

2.4. Algorithm. Combining the results of sections 2.1–2.3, an algorithm for the computation of an N-point quadrature rule for functions containing singularities up to and including second order and polynomials up to order $M-1$ is made up of the following steps:

1. Find the nodes of the N-point Gauss–Legendre quadrature, using, for example, the algorithm of Davis and Rabinowitz [7].
2. At each node, compute the functions $\psi_i(x,t_j)$ (see (2.8)).
3. Compute the moments m_i (see (2.9)), using (2.3) and an M-point Gauss–Legendre quadrature.
4. Solve (2.7) for the weights w_j.

The $N\times 4M$ system of equations (2.7) may be well-posed or under- or overdetermined. It is solved in the least-squares sense when overdetermined and in the minimum norm sense when underdetermined, using the appropriate LAPACK solver [2].

3. Numerical performance. As a check on the accuracy of the method, a reference integral

$$I_n(x) = \int_{-1}^{1} t^n \log|x-t|\,\mathrm{d}t, \tag{3.1}$$

$$I_{2m}(x) = \frac{1}{2m+1}\left[(1-x^{n+1})\log|1-x| + ((-1)^n + x^{n+1})\log|1+x|\right] - \frac{2}{2m+1}\sum_{k=0}^{m}\frac{x^{2k}}{2m-2k+1}, \tag{3.2}$$

$$I_{2m+1}(x) = \frac{1}{2m+2}\left[(1-x^{n+1})\log|1-x| + ((-1)^n + x^{n+1})\log|1+x|\right] - \frac{2}{2m+2}\sum_{k=0}^{m}\frac{x^{2k+1}}{2m-2k+1} \tag{3.3}$$

was computed, using quadrature rules of the type derived above. This integral was chosen because it has an integrand of the type which is common in boundary element calculations and because it has an analytical solution which can be compared to the numerical results. The analytical solution can also be differentiated to check the quadrature rule when used on higher order singularities. In each case, the quadrature rule was computed in double precision arithmetic. Kolm and Rokhlin [12] note that constructing the quadratures in double precision gives "11 or 12 correct digits" which is sufficient accuracy for most applications.

Figure 3.1 shows the relative error ϵ for $M=4$ and $n=0,3,5$ as a function of the number of quadrature points N, with

$$\epsilon = \frac{\left(\sum_i |K_n(x_i) - J_n(x_i)|^2\right)^{1/2}}{\left(\sum_i K_n^2(x_i)\right)^{1/2}}, \tag{3.4}$$

where $K_n(x)$ is the exact value of the integral,

$$K_n(x) = I_n(x) + \frac{\mathrm{d}I_n}{\mathrm{d}x} + \frac{\mathrm{d}^2 I_n}{\mathrm{d}x^2}, \tag{3.5}$$

and $J_n(x)$ is the value computed using the quadrature rule. The integrals were evaluated for $x_i = -2 + 0.0125i$, $i=0,1,\ldots,320$, which includes $x_i=\pm 1$. The values of

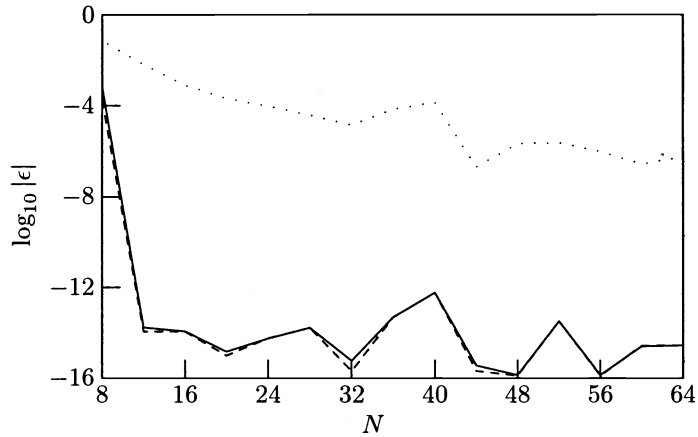

FIG. 3.1. *Relative error* ϵ *for* $M = 4$, $N = 12, 16, \ldots, 64$, *and* $n = 0$, 3, *and* 5 *(solid, dashed, and dotted, respectively).*

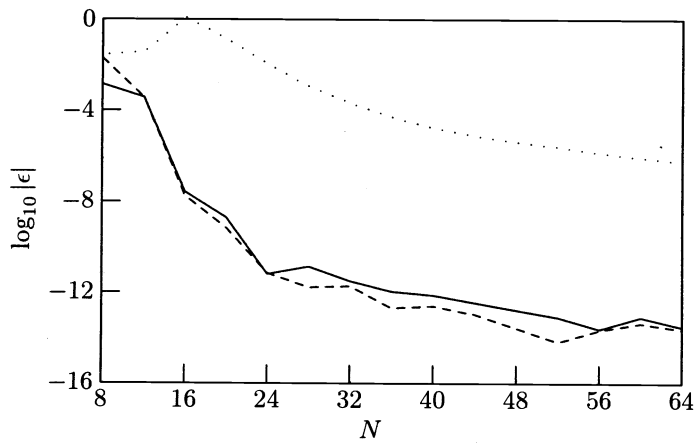

FIG. 3.2. *Relative error* ϵ *for* $M = 8$, $N = 12, 16, \ldots, 64$, *and* $n = 0$, 7, *and* 11 *(solid, dashed, and dotted, respectively).*

n were selected as a check on the performance of the quadrature rule for values of n within the selected range of order, i.e., $n \leq M - 1$, and to examine the performance of the algorithm for n outside that range. As can be seen, for $n = 0, 3$ the relative error is quite large (10^{-4}) for the eight point quadrature but quickly drops to, and remains, less than 10^{-12} for $N \geq 12$. The "out of range" function with $n = 5$ is never accurately integrated, as would be expected from the definition of the quadrature, showing that care would have to be taken in applications where the Green's function contains terms of higher order such as, for example, in the case of the elliptic integral in axisymmetric potential problems. On the other hand, it is useful to know that the full accuracy of the quadrature is attained at about $N = 16$ so that the computational burden of using it is not too great.

Figure 3.2 plots similar data for $M = 8$ and $n = 0, 7, 11$. The behavior is similar to that in the $M = 4$ case, but an error of $\epsilon \leq 10^{-12}$ is not attained until about $N = 24$. Likewise, the error in the $n > M$ case is quite large ($\epsilon \approx 1$) and does not

drop below about 10^{-4}. The most obvious conclusion to be drawn is that the best accuracy of the rule is achieved at about $N = 3M$ and that there is little be gained by increasing N further, unless M is also increased. The results also confirm the conclusion of Kolm and Rokhlin that 11–12 places of accuracy can be achieved when the quadrature weights are computed in double precision.

4. Conclusions. A method has been developed for the derivation of quadrature rules suitable for use in boundary element methods where the integrand has strong singularities up to order two. The technique is a simplification and extension of that of Kolm and Rokhlin [12], allowing for singularities inside and outside the range of integration and at the endpoints, which is an important feature for boundary element methods. The approach has been tested on a reference integral of the type used in boundary element calculations and has been found to be accurate and robust, being accurate to 11–12 places when the quadrature weights are computed in double precision. The approach which has been used is quite general and can be extended to singularities of order higher than two. This will also make the method useful in developing quadratures for three-dimensional boundary element methods.

Appendix. Formulae.

Most of the formulae used in developing the quadrature technique can be found in standard references [10], but some need to be derived, in particular for the behavior of the Legendre functions at $x = \pm 1$.

The derivative of $P_n(x)$ at $x = \pm 1$ can be most readily evaluated from the definition [10, 8.910.2],

$$P_n(x) = \frac{1}{2^n n!} \frac{\mathrm{d}^n}{\mathrm{d}x^n}(x^2 - 1)^n, \tag{A.1}$$

and the derivative is

$$P_n'(x) = \frac{1}{2^n n!} \frac{\mathrm{d}^{n+1}}{\mathrm{d}x^{n+1}}(x^2 - 1)^n. \tag{A.2}$$

Application of Leibnitz's rule [10, 0.42] yields

$$P_n'(x) = \frac{1}{2^n n!} \sum_{q=0}^{n+1} \binom{n+1}{q} \frac{\mathrm{d}^{n+1-q}}{\mathrm{d}x^{n+1-q}}(x+1)^n \frac{\mathrm{d}^q}{\mathrm{d}x^q}(x-1)^n, \tag{A.3}$$

and, since only the term with $q = 1$ survives when $x = -1$,

$$P_n'(-1) = -(-1)^n \frac{n(n+1)}{2}. \tag{A.4}$$

Similarly

$$P_n'(1) = \frac{n(n+1)}{2}. \tag{A.5}$$

The second formula required is the integral

$$\int_{-1}^{1} P_n(t) \log |x - t| \, \mathrm{d}t \tag{A.6}$$

for $x = \pm 1$. Standard tables [10] give

$$\int_{-1}^{1} t^{2m} \log|\pm 1 - t| \, \mathrm{d}t = \frac{2}{2m+1} \left(\log 2 - \sum_{q=0}^{m} \frac{1}{2q+1} \right), \tag{A.7a}$$

$$\int_{-1}^{1} t^{2m+1} \log|\pm 1 - t| \, \mathrm{d}t = \frac{\pm 1}{m+1} \sum_{q=0}^{m} \frac{1}{2q+1}, \tag{A.7b}$$

which, upon insertion into the expansion for the Legendre polynomials [10, 8.911.1], yields

$$\int_{-1}^{1} P_{2m}(t) \log|\pm 1 - t| \, \mathrm{d}t = \frac{2}{4^m} \sum_{k=0}^{m} \frac{(-1)^k (4m-2k)!}{k!(2m-k)!(2m-2k+1)!} \times \left(\log 2 - \sum_{q=0}^{m-k} \frac{1}{2q+1} \right), \tag{A.8a}$$

$$\int_{-1}^{1} P_{2m+1}(t) \log|\pm 1 - t| \, \mathrm{d}t = \frac{\pm 1}{4^m} \sum_{k=0}^{m} \frac{(-1)^k (4m-2k+2)!}{k!(2m-k+1)!(2m-2k+2)!} \times \sum_{q=0}^{m-k} \frac{1}{2q+1}. \tag{A.8b}$$

A HYBRID HIGH-ORDER ALGORITHM FOR RADAR CROSS SECTION COMPUTATIONS*

M. GANESH† AND S. C. HAWKINS‡

Abstract. We describe a high-order method for computing the monostatic and bistatic radar cross section (RCS) of a class of three-dimensional targets. Our method is based on an electric field surface integral equation reformulation of the Maxwell equations. The hybrid nature of the scheme is due to approximations based on a combination of tangential and nontangential basis functions on a parametric reference spherical surface. A principal feature of the high-order algorithm is that it requires solutions of linear systems with substantially fewer unknowns than existing methods. We demonstrate that very accurate RCS values for medium (electromagnetic-) sized scatterers can be computed using a few tens of thousands of unknowns. Thus linear systems arising in the high-order method for low to medium frequency scattering can be solved using direct solves. This is extremely advantageous in monostatic RCS computations, for which transmitters and receivers are co-located and hence the discretized electromagnetic linear system must be solved for hundreds of right-hand sides corresponding to receiver locations. We demonstrate the high-order convergence of our method for several three-dimensional targets. We prove the high-order spectral accuracy of our approximations to the RCS for a class of perfect conductors described globally in spherical coordinates.

1. Introduction.

Computer simulations of the radar cross section (RCS) of three-dimensional model targets through electromagnetic scattering are a cost effective tool for designing stealth objects. The RCS values (measured using simulated transmitters and receivers) reflect the stealth property of an obstacle [20]. Hence a prerequisite for manufacturing vehicles such as stealth aircraft is to simulate the monostatic and bistatic RCS of various geometries [30] at several frequencies to high-order accuracy. Such simulations are also useful in biological applications. For example, it is common to use light scattering measurements in laboratories to count erythrocytes (red bloods cells). Of recent interest [19, 31] is the simulation of the RCS of a celebrated model of an erythrocyte, which is biconcave, for an incident plane wave whose wavelength is about one tenth the diameter of the erythrocyte. Computational electromagnetic scattering algorithms with high-order accuracy facilitate efficient simulations of the RCS values.

In this work we develop, implement, and analyze a high-order algorithm to compute the monostatic and bistatic RCS of a perfectly conducting obstacle $D \subseteq \mathbb{R}^3$, with surface ∂D, situated in a homogeneous medium with vanishing conductivity, the free space permittivity $\epsilon_0 = 10^7/(4\pi c^2)\mathrm{F/m}$, and permeability $\mu_0 = 4\pi \times 10^{-7}\mathrm{H/m}$,

where $c = 299\ 792\ 458$m/s is the speed of light. Our simulation geometries include benchmark radar targets [30] and erythrocytes [19, 31].

The RCS of the obstacle, induced by a transmitter located in the direction $-\widehat{\boldsymbol{d}}_0$ and measured in decibels by a receiver located in the direction

$$\widehat{\boldsymbol{x}} = \boldsymbol{p}(\theta,\phi) = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)^T, \qquad \theta,\phi \in \mathbb{R}, \tag{1.1}$$

is a functional on the unit sphere (denoted by ∂B) and is defined as

$$\sigma^{\mathrm{dB}}(\widehat{\boldsymbol{x}};\widehat{\boldsymbol{d}}_0) = 10\log_{10}\left(4\pi\left|\boldsymbol{E}_\infty(\widehat{\boldsymbol{x}})\right|^2/k^2\right), \qquad \widehat{\boldsymbol{x}},\widehat{\boldsymbol{d}}_0 \in \partial B, \tag{1.2}$$

where

$$\boldsymbol{E}_\infty(\widehat{\boldsymbol{x}}) = \lim_{|\boldsymbol{x}|\to\infty} \boldsymbol{E}^{\mathrm{s}}(\boldsymbol{x}) e^{-ik|\boldsymbol{x}|}|\boldsymbol{x}|, \qquad \widehat{\boldsymbol{x}} = \boldsymbol{x}/|\boldsymbol{x}| \in \partial B, \tag{1.3}$$

is the far field pattern of the scattered field, which has frequency ω and wavenumber $k = 2\pi\omega/c$. The scattered electric field $\boldsymbol{E}^{\mathrm{s}}$ and magnetic field $\boldsymbol{H}^{\mathrm{s}}$ satisfy the time harmonic Maxwell equations

$$\mathbf{curl}\,\boldsymbol{E}(\boldsymbol{x}) - ik\boldsymbol{H}(\boldsymbol{x}) = \boldsymbol{0}, \qquad \mathbf{curl}\,\boldsymbol{H}(\boldsymbol{x}) + ik\boldsymbol{E}(\boldsymbol{x}) = \boldsymbol{0}, \quad \boldsymbol{x} \in \mathbb{R}^3 \setminus \overline{D}, \tag{1.4}$$

and the Silver–Müller radiation condition

$$\lim_{|\boldsymbol{x}|\to\infty} [\boldsymbol{H}^{\mathrm{s}}(\boldsymbol{x}) \times \boldsymbol{x} - |\boldsymbol{x}|\boldsymbol{E}^{\mathrm{s}}(\boldsymbol{x})] = \boldsymbol{0},$$

subject to the perfect conductor boundary condition

$$\boldsymbol{n}(\boldsymbol{x}) \times \boldsymbol{E}^{\mathrm{s}}(\boldsymbol{x}) = -\boldsymbol{n}(\boldsymbol{x}) \times \boldsymbol{E}^{\mathrm{i}}(\boldsymbol{x}) =: \boldsymbol{f}(\boldsymbol{x}), \quad \boldsymbol{x} \in \partial D, \tag{1.5}$$

where $\boldsymbol{n}(\boldsymbol{x})$ denotes the unit outward normal at $\boldsymbol{x} \in \partial D$. The boundary condition in (1.5) (and hence the RCS in (1.2)) is induced by the incident plane wave $\left[\boldsymbol{E}^{\mathrm{i}}, \boldsymbol{H}^{\mathrm{i}}\right]$, with direction $\widehat{\boldsymbol{d}}_0$ and polarization $\widehat{\boldsymbol{p}}_0$ (perpendicular to $\widehat{\boldsymbol{d}}_0$), which originates from the transmitter and is defined as

$$\boldsymbol{E}^{\mathrm{i}}(\widehat{\boldsymbol{x}}) = ik\widehat{\boldsymbol{p}}_0 e^{ik\boldsymbol{x}\cdot\widehat{\boldsymbol{d}}_0}, \quad \boldsymbol{H}^{\mathrm{i}}(\widehat{\boldsymbol{x}}) = ik(\widehat{\boldsymbol{d}}_0 \times \widehat{\boldsymbol{p}}_0) e^{ik\boldsymbol{x}\cdot\widehat{\boldsymbol{d}}_0}. \tag{1.6}$$

When the transmitter and receiver are co-located, $\widehat{\boldsymbol{d}}_0 = -\widehat{\boldsymbol{x}}$, and σ^{dB} in (1.2) is called the monostatic RCS. When the transmitter and receiver are not co-located and $\widehat{\boldsymbol{d}}_0$ is fixed, σ^{dB} in (1.2) is called the bistatic RCS. The RCS with receiver polarization $\widehat{\boldsymbol{p}}_1$ is defined by

$$\sigma^{\mathrm{dB}}(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{p}}_1;\widehat{\boldsymbol{d}}_0) = 10\log_{10}\left(4\pi\left|\boldsymbol{E}_\infty(\widehat{\boldsymbol{x}})\cdot\widehat{\boldsymbol{p}}_1\right|^2/k^2\right), \qquad \widehat{\boldsymbol{x}},\widehat{\boldsymbol{p}}_1,\widehat{\boldsymbol{d}}_0 \in \partial B. \tag{1.7}$$

The industrial standard tool for simulation of electromagnetic scattering from a perfect conductor is the Fast Illinois Solver Code (FISC); see [25, 6] and references therein for related boundary integral algorithms. FISC is based on a surface integral reformulation of the Maxwell equations and is solved using the method of moments. For medium frequency scattering problems, implementation of FISC requires solution of a dense complex linear system with hundreds of thousands of unknowns to achieve a couple of digits of accuracy. (For example, in a FISC simulation exterior to a sphere of diameter 12 times the incident wavelength, 602 112 unknowns are required

to compute the RCS with just one decimal place of accuracy [25].) Solution of large dense linear systems in FISC calculations is made possible only by using an iterative solver with matrix vector products implemented using the fast multipole method (FMM), and recently by using modified FMM algorithms based on efficient spherical harmonic expansions. A high-order algorithm for acoustic scattering was given in [4] and applied to electromagnetic scattering in [3, p. 56]. We refer the reader to [2, 3, 6, 9, 10, 19, 21, 23, 31] and references therein for the current state of the art in computational electromagnetics. The existing three-dimensional electromagnetic scattering algorithms with demonstrated numerical experiments do not achieve spectral accuracy. Spectral boundary integral methods for three-dimensional model problems in acoustic, elasticity, and potential theory were considered in [12, 13, 14, 17, 29].

In [15] we considered an electromagnetic counterpart of [12] using vectorial basis functions that are tangential on the reference surface. Such vector spherical harmonics are widely used in many applications involving vector valued quantities on the sphere [11, 26, 28]. However, the approach in [15] does not yield spectrally accurate approximations [16, Remark 2]. In [16] we used a componentwise basis that is not tangential, for which we proved and demonstrated spectral accuracy. However, tangential basis functions are a natural choice for the surface integral formulation of the Maxwell equations. Further, for spherical scatterers, approximation of surface currents using tangential spherical harmonics can give almost a one third reduction in the number of unknowns required in [16]. This work is motivated by the desire to obtain this reduction by using tangential harmonics and yet obtain a spectrally accurate algorithm. We achieve the reduction and spectral accuracy in this paper with hybrid approximations, combining ideas from [15] and [16] and involving a combination of tangential and nontangential harmonics.

A clearly described parametrization of the two-dimensional manifold ∂D (based on a reference domain or surface) is essential for computer implementation of any surface integral equation algorithm. We assume throughout the paper that each coordinate (x, y, z) on the bounded target surface ∂D can be parametrized as

$$(1.8) \qquad (x, y, z)^T = (q_1(\theta, \phi), q_2(\theta, \phi), q_3(\theta, \phi))^T, \qquad (x, y, z)^T \in \partial D, \quad \theta, \phi \in \mathbb{R},$$

for some nonlinear functionals $q_j : \mathbb{R}^2 \to \mathbb{R}$ for $j = 1, 2, 3$ that yield, via $\boldsymbol{p}$ in (1.1), a bijective parametrization map $\boldsymbol{q} : \partial B \to \partial D$. In fact, it is sufficient to know a suitable approximation to the parametrization map $\boldsymbol{q}$, for example, based on the Fourier coefficients of q_j for $j = 1, 2, 3$. Our algorithm has spectral accuracy only when $\boldsymbol{q}$ is smooth.

Such a specific description of the target is required in our mathematical analysis to prove the spectral accuracy of the method. Many benchmark radar targets, such as those described in [30], satisfy the specific description (1.8) after converting the material construction (cylindrical) coordinates [30] to spherical coordinates [12], and biologically interesting models such as the erythrocyte [19, 31] can be written in the parametric form (1.8). Simulation geometries considered in this work and those in [12, 16] demonstrate the wealth of obstacles satisfying (1.8). Application of the algorithm in this paper to complicated geometries is restricted by the difficulty of finding globally smooth parametrizations. Application to such geometries would require partition of the conductor surface into several charts, with appropriate use of local mappings. This approach was used in combination with a partition of unity to evaluate weakly singular integrals to spectral accuracy in [4]. Such an extension to our algorithm is nontrivial and not considered in this paper.

In many cases the obstacle restriction imposed in this paper is not a disadvantage. For example, in forward scattering by complex structures the surface integral equation often arises through introduction of a smooth artificial interface surrounding the scatterer [1, 2, 21]. A partial differential equation form of the Maxwell equations—formulated in the interior of the artificial interface and coupled with the surface integral equation on the interface—is solved by finite elements. In inverse scattering, obtaining general qualitative information about the scatterer is more important than resolving fine details such as corners and edges.

We test our algorithm on a range of perfectly conducting scatterers. We include scatterers with concave surface features, and nonsmooth scatterers. We show that just a few tens of thousands of unknowns are sufficient in our algorithm to obtain satisfactory solutions for medium electromagnetic-sized scatterers. Such relatively small linear systems allow us to use direct solves as well as iterative solves. In the case of smooth scatterers our solutions are very accurate, with several decimal places of accuracy. In the case of nonsmooth scatterers with singularity points in their surface, our algorithm yields visually accurate solutions but does not yield the rapid convergence demonstrated for smooth scatterers. In general, only a few decimal places of accuracy are possible for nonsmooth scatterers.

The possibility of using direct solves is a great advantage in monostatic RCS computations. For the monostatic case, since the transmitter and receiver are co-located and because hundreds of receiver measurements are required for the RCS analysis, the exterior Maxwell equations are to be solved with hundreds of boundary conditions induced by various receiver directions. This leads to the requirement of solving hundreds of linear systems with one electromagnetic discretization matrix and hundreds of different right-hand sides. A direct LU factorization of the electromagnetic matrix is very cost effective in this case. Such factorizations are not possible using surface discretization based algorithms such as FISC, because they lead to dense complex linear systems with hundreds of thousands of unknowns. We demonstrate that we can compute the monostatic RCS of medium (electromagnetic-) sized scatterers at over one thousand points in a few hours of CPU time.

The structure of the paper follows that in [16], and we recall various derivations from [16] that are essential for this paper. We follow [16] in section 2 to describe the electric field surface integral equation reformulation of (1.4)–(1.5) using a standard ansatz for electromagnetic fields exterior to the conductor surface ∂D, and we use (1.8) to appropriately transplant the equation onto the surface ∂B, the set of all unit directional vectors. In section 3 we give the details of our method based on tangential and nontangential bases for computing a spectrally accurate approximation to the surface current on ∂D that solves the surface integral equation. In section 4 we describe an efficient way to use the surface current to compute the RCS of the scatterer. In section 5 we present numerical results showing the high-order convergence of our method.

Throughout the paper we denote by $\underline{C}(\partial D)$ and $\underline{C}^{0,\alpha}(\partial D)$, respectively, the spaces of all continuous and uniformly Hölder continuous vector fields on ∂D, where α is the Hölder exponent. We denote by $\underline{\mathcal{T}}(\partial D)$ and $\underline{\mathcal{T}}^{0,\alpha}(\partial D)$, respectively, the spaces of all continuous and uniformly Hölder continuous tangential vector fields on ∂D.

2. Reformulation of the exterior Maxwell equations. Standard boundary integral formulations for the time harmonic Maxwell equations restrict the domain of the magnetic dipole operator to $\underline{\mathcal{T}}(\partial D)$ [8, p. 167]. The restriction is useful because it reduces the order of the singularity of the operator. In fact, it is sufficient to

project the density in the integral operator to $\underline{T}(\partial D)$ (rather than restricting the domain) to achieve the reduction in the order of the singularity. Any vector field in $\underline{C}(\partial D)$ can be projected onto $\underline{T}(\partial D)$ by applying the 3×3 matrix projection operator $\mathcal{P}(\boldsymbol{y}) = I - \boldsymbol{n}(\boldsymbol{y})\boldsymbol{n}(\boldsymbol{y})^T$ for $\boldsymbol{y} \in \partial D$. For $\boldsymbol{a} \in \underline{T}(\partial D)$, since $\mathcal{P}\boldsymbol{a} = \boldsymbol{a}$, the generalized magnetic dipole operator

$$(\mathcal{M}\boldsymbol{a})(\boldsymbol{x}) = 2\int_{\partial D} \boldsymbol{n}(\boldsymbol{x}) \times \mathbf{curl}_{\boldsymbol{x}} \{\Phi(\boldsymbol{x},\boldsymbol{y})\mathcal{P}(\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y})\}\, ds(\boldsymbol{y}), \quad \boldsymbol{x} \in \partial D, \tag{2.1}$$

is the same as the standard magnetic dipole operator [8, p. 167]. In (2.1),

$$\Phi(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{4\pi}\frac{e^{ik|\boldsymbol{x}-\boldsymbol{y}|}}{|\boldsymbol{x}-\boldsymbol{y}|} \tag{2.2}$$

is the fundamental solution of the Helmholtz equation. Application of [8, Theorem 6.13] shows that the linear operator $\mathcal{M}$ is bounded from $\underline{C}(\partial D)$ into $\underline{T}^{0,\alpha}(\partial D)$ for $0 < \alpha < 1$.

Using (1.5), the boundary data $\boldsymbol{f} \in \underline{T}^{0,\alpha}(\partial D)$, and so if $\boldsymbol{w} \in \underline{C}(\partial D)$ is a solution of the surface integral equation

$$\boldsymbol{w}(\boldsymbol{x}) + (\mathcal{M}\boldsymbol{w})(\boldsymbol{x}) = 2\boldsymbol{f}(\boldsymbol{x}), \qquad \boldsymbol{x} \in \partial D, \tag{2.3}$$

then $\boldsymbol{w} \in \underline{T}^{0,\alpha}(\partial D)$. If the wavenumber k is not an interior Maxwell eigenvalue, then (2.3) has a unique solution [7, Theorem 4.23]. [illegible]
k [illegible]

Using the unique tangential solution $\boldsymbol{w}$ of (2.3), we define

$$\boldsymbol{E}(\boldsymbol{x}) = \mathbf{curl} \int_{\partial D} \Phi(\boldsymbol{x},\boldsymbol{y})\boldsymbol{w}(\boldsymbol{y})\, ds(\boldsymbol{y}), \quad \boldsymbol{H}(\boldsymbol{x}) = \frac{1}{ik}\mathbf{curl}\, \boldsymbol{E}(\boldsymbol{x}), \quad \boldsymbol{x} \in \mathbb{R}^3 \setminus \overline{D}. \tag{2.4}$$

Then $\boldsymbol{E}, \boldsymbol{H}$ comprise a unique radiating solution of the harmonic Maxwell equations that satisfies the boundary condition $\boldsymbol{n}(\boldsymbol{x}) \times \boldsymbol{E}(\boldsymbol{x}) = \boldsymbol{f}(\boldsymbol{x})$, $\boldsymbol{x} \in \partial D$ [7, Theorem 4.19]. A representation of the far field pattern required for RCS calculations can be obtained from the following asymptotics of the fundamental solution in (2.2): For $\boldsymbol{a} \in \underline{C}(\partial D)$ and as $|\boldsymbol{x}| \to \infty$ uniformly for all $\boldsymbol{y} \in \partial D$ [8, p. 164],

$$\mathbf{curl}_{\boldsymbol{x}} \{\boldsymbol{a}(\boldsymbol{y})\Phi(\boldsymbol{x},\boldsymbol{y})\} = \frac{ik}{4\pi}\frac{e^{ik|\boldsymbol{x}|}}{|\boldsymbol{x}|}\left\{e^{-ik\widehat{\boldsymbol{x}}\cdot\boldsymbol{y}}\widehat{\boldsymbol{x}} \times \boldsymbol{a}(\boldsymbol{y}) + O\left(\frac{|\boldsymbol{a}(\boldsymbol{y})|}{|\boldsymbol{x}|}\right)\right\}, \tag{2.5}$$

where $\widehat{\boldsymbol{x}} = \boldsymbol{x}/|\boldsymbol{x}| \in \partial B$. Using (2.4) and (2.5) in (1.3), the electric far field pattern of the scattered electric field $\boldsymbol{E}$ in (2.4) can be represented as

$$\boldsymbol{E}_\infty(\widehat{\boldsymbol{x}}) = \frac{ik}{4\pi}\int_{\partial D} e^{-ik\widehat{\boldsymbol{x}}\cdot\boldsymbol{y}}\widehat{\boldsymbol{x}} \times \boldsymbol{w}(\boldsymbol{y})\, ds(\boldsymbol{y}), \quad \widehat{\boldsymbol{x}} \in \partial B. \tag{2.6}$$

Thus high-order approximate solutions of (2.3) facilitate accurate simulation of the electromagnetic waves and measurement of the RCS using (2.6) and (1.2)–(1.7).

Using the following identity for a tangential field $\boldsymbol{b}$ [8, p. 166],

$$\begin{aligned}\boldsymbol{n}(\boldsymbol{x}) \times\ \mathbf{curl}_{\boldsymbol{x}} \{\Phi(\boldsymbol{x},\boldsymbol{y})\boldsymbol{b}(\boldsymbol{y})\} &= \mathbf{grad}_{\boldsymbol{x}}\Phi(\boldsymbol{x},\boldsymbol{y})\,[\boldsymbol{n}(\boldsymbol{x}) - \boldsymbol{n}(\boldsymbol{y})]^T\,\boldsymbol{b}(\boldsymbol{y}) \\ &\quad -\boldsymbol{b}(\boldsymbol{y})\boldsymbol{n}(\boldsymbol{x})^T\mathbf{grad}_{\boldsymbol{x}}\Phi(\boldsymbol{x},\boldsymbol{y}),\end{aligned} \tag{2.7}$$

and (2.1), (2.7), and (2.2), the generalized magnetic dipole operator can be written as

$$\mathcal{M}\boldsymbol{a}(\boldsymbol{x}) = \int_{\partial D} \left[\frac{1}{|\boldsymbol{x}-\boldsymbol{y}|} m_1(\boldsymbol{x},\boldsymbol{y}) + m_2(\boldsymbol{x},\boldsymbol{y})\right] \mathcal{P}(\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y})\, ds(\boldsymbol{y}), \quad \boldsymbol{x} \in \partial D, \tag{2.8}$$

where for $i = 1, 2$,

$$\begin{aligned} m_i(\boldsymbol{x},\boldsymbol{y}) &= m_{i,1}(\boldsymbol{x},\boldsymbol{y}) \frac{1}{|\boldsymbol{x}-\boldsymbol{y}|^2} (\boldsymbol{x}-\boldsymbol{y}) \left[\boldsymbol{n}(\boldsymbol{x}) - \boldsymbol{n}(\boldsymbol{y})\right]^T \\ &\quad + m_{i,2}(\boldsymbol{x},\boldsymbol{y}) \frac{1}{|\boldsymbol{x}-\boldsymbol{y}|^2} \boldsymbol{n}(\boldsymbol{x})^T (\boldsymbol{x}-\boldsymbol{y}) I + m_{i,3}(\boldsymbol{x},\boldsymbol{y}), \end{aligned} \tag{2.9}$$

with I being the 3×3 identity matrix, $m_{2,3} = 0$ the 3×3 zero matrix, and

$$\begin{aligned} &m_{1,1}(\boldsymbol{x},\boldsymbol{y}) = -\frac{1}{2\pi} t(\boldsymbol{x},\boldsymbol{y}), \qquad m_{1,2}(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{2\pi} t(\boldsymbol{x},\boldsymbol{y}), \\ &m_{1,3}(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{2\pi} ks(\boldsymbol{x},\boldsymbol{y}) \left[\boldsymbol{n}(\boldsymbol{x})^T (\boldsymbol{x}-\boldsymbol{y}) I - (\boldsymbol{x}-\boldsymbol{y}) \left(\boldsymbol{n}(\boldsymbol{x}) - \boldsymbol{n}(\boldsymbol{y})\right)^T\right], \\ &m_{2,1}(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{2\pi} \left[ikt(\boldsymbol{x},\boldsymbol{y}) - is(\boldsymbol{x},\boldsymbol{y})\right], \qquad m_{2,2}(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{2\pi} \left[is(\boldsymbol{x},\boldsymbol{y}) - ikt(\boldsymbol{x},\boldsymbol{y})\right], \\ &s(\boldsymbol{x},\boldsymbol{y}) = \begin{cases} \sin(k|\boldsymbol{x}-\boldsymbol{y}|)/|\boldsymbol{x}-\boldsymbol{y}| & \text{if } \boldsymbol{x} \neq \boldsymbol{y}, \\ k & \text{if } \boldsymbol{x} = \boldsymbol{y}, \end{cases} \qquad t(\boldsymbol{x},\boldsymbol{y}) = \cos(k|\boldsymbol{x}-\boldsymbol{y}|). \end{aligned} \tag{2.10}$$

Each $m_{i,j}$ $(i = 1, 2,\ j = 1, 2, 3)$ is infinitely differentiable on $\mathbb{R}^3 \times \mathbb{R}^3$. It is important for our spectrally accurate method to separate the kernel of $\mathcal{M}$ in (2.1) into its weakly singular and smooth parts in this way. Next we use the bijective parametrization $\boldsymbol{q} : \partial B \to \partial D$ to transplant (2.8) onto the reference spherical surface, which facilitates exact treatment of the weakly singular part using a singularity division technique.

For a given density field $\boldsymbol{A} \in \underline{C}(\partial B)$, using the change of variables, we derive the equivalent form of (2.8),

$$\mathcal{M}\boldsymbol{A}(\widehat{\boldsymbol{x}}) = \mathcal{M}_1\boldsymbol{A}(\widehat{\boldsymbol{x}}) + \mathcal{M}_2\boldsymbol{A}(\widehat{\boldsymbol{x}}), \qquad \widehat{\boldsymbol{x}} \in \partial B, \tag{2.11}$$

with

$$\mathcal{M}_1\boldsymbol{A}(\widehat{\boldsymbol{x}}) = \int_{\partial B} \frac{1}{|\widehat{\boldsymbol{x}}-\widehat{\boldsymbol{y}}|} M_1(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{y}})\boldsymbol{A}(\widehat{\boldsymbol{y}})\, ds(\widehat{\boldsymbol{y}}), \tag{2.12}$$

$$\mathcal{M}_2\boldsymbol{A}(\widehat{\boldsymbol{x}}) = \int_{\partial B} M_2(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{y}})\boldsymbol{A}(\widehat{\boldsymbol{y}})\, ds(\widehat{\boldsymbol{y}}), \tag{2.13}$$

where for each $\widehat{\boldsymbol{x}}, \widehat{\boldsymbol{y}} \in \partial B$, $M_1(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{y}})$ and $M_2(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{y}})$ are 3×3 matrices defined by

$$M_1(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{y}}) = R(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{y}}) J(\widehat{\boldsymbol{y}})\, m_1(\boldsymbol{q}(\widehat{\boldsymbol{x}}),\boldsymbol{q}(\widehat{\boldsymbol{y}}))\mathcal{P}(\boldsymbol{q}(\widehat{\boldsymbol{y}})), \tag{2.14}$$

$$M_2(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{y}}) = J(\widehat{\boldsymbol{y}})\, m_2(\boldsymbol{q}(\widehat{\boldsymbol{x}}),\boldsymbol{q}(\widehat{\boldsymbol{y}}))\mathcal{P}(\boldsymbol{q}(\widehat{\boldsymbol{y}})), \tag{2.15}$$

J is the Jacobian of $\boldsymbol{q}$, and

$$R(\widehat{\boldsymbol{x}},\widehat{\boldsymbol{y}}) := \frac{|\widehat{\boldsymbol{x}}-\widehat{\boldsymbol{y}}|}{|\boldsymbol{q}(\widehat{\boldsymbol{x}}) - \boldsymbol{q}(\widehat{\boldsymbol{y}})|}. \tag{2.16}$$

The integral operator $\mathcal{M}_2$ has a smooth kernel that can be approximated to spectral accuracy using spherical polynomials. Spectrally accurate approximation of

the weakly singular operator $\mathcal{M}_1$ can be achieved by introducing a rotated coordinate system on ∂B, under which the weak singularity in the transformed operator occurs only at the north pole. To this end, we first define the 3×3 rotation matrices corresponding to positive rotations by ψ about the z-axis and y-axis:

$$\mathcal{R}_z(\psi) := \begin{pmatrix} \cos\psi & -\sin\psi & 0 \\ \sin\psi & \cos\psi & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \mathcal{R}_y(\psi) := \begin{pmatrix} \cos\psi & 0 & \sin\psi \\ 0 & 1 & 0 \\ -\sin\psi & 0 & \cos\psi \end{pmatrix}. \tag{2.17}$$

For each $\widehat{\boldsymbol{x}} = \boldsymbol{p}(\theta, \phi)$, the orthogonal matrix

$$T_{\widehat{\boldsymbol{x}}} := \mathcal{R}_z(\phi)\mathcal{R}_y(-\theta)\mathcal{R}_z(-\phi) \tag{2.18}$$

maps $\widehat{\boldsymbol{x}}$ to the north pole $\widehat{\boldsymbol{n}} = (0, 0, 1)^T$. The matrix $T_{\widehat{\boldsymbol{x}}}$ induces a linear transformation

$$\mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\widehat{\boldsymbol{z}}) := \boldsymbol{A}(T_{\widehat{\boldsymbol{x}}}^{-1}\widehat{\boldsymbol{z}}), \qquad \widehat{\boldsymbol{z}} \in \partial B, \qquad \boldsymbol{A} \in \underline{C}(\partial B), \tag{2.19}$$

and its bivariate analogue

$$\mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\widehat{\boldsymbol{z}}_1, \widehat{\boldsymbol{z}}_2) := \boldsymbol{A}(T_{\widehat{\boldsymbol{x}}}^{-1}\widehat{\boldsymbol{z}}_1, T_{\widehat{\boldsymbol{x}}}^{-1}\widehat{\boldsymbol{z}}_2), \qquad \widehat{\boldsymbol{z}}_1, \widehat{\boldsymbol{z}}_2 \in \partial B, \qquad \boldsymbol{A} \in \underline{C}(\partial B \times \partial B). \tag{2.20}$$

Using the orthogonality of $T_{\widehat{\boldsymbol{x}}}$, we have, for $\widehat{\boldsymbol{x}}, \widehat{\boldsymbol{z}} \in \partial B$ and $\widehat{\boldsymbol{y}} = T_{\widehat{\boldsymbol{x}}}^{-1}\widehat{\boldsymbol{z}}$,

$$|\widehat{\boldsymbol{x}} - \widehat{\boldsymbol{y}}| = |T_{\widehat{\boldsymbol{x}}}^{-1}(\widehat{\boldsymbol{n}} - \widehat{\boldsymbol{z}})| = |\widehat{\boldsymbol{n}} - \widehat{\boldsymbol{z}}|. \tag{2.21}$$

Using (2.12) and the fact that the surface measure on ∂B is invariant,

$$\mathcal{M}_1\boldsymbol{A}(\widehat{\boldsymbol{x}}) = \int_{\partial B} \frac{1}{|\widehat{\boldsymbol{n}} - \widehat{\boldsymbol{z}}|} \mathcal{T}_{\widehat{\boldsymbol{x}}} M_1(\widehat{\boldsymbol{n}}, \widehat{\boldsymbol{z}})\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\widehat{\boldsymbol{z}})\ ds(\widehat{\boldsymbol{z}}), \quad \boldsymbol{A} \in \underline{C}(\partial B). \tag{2.22}$$

The transformed coordinate system has two crucial benefits. First, in spherical polar coordinates, with $\widehat{\boldsymbol{z}} = \boldsymbol{p}(\theta', \phi')$, the denominator $|\widehat{\boldsymbol{n}} - \widehat{\boldsymbol{z}}| = 2\sin\theta'/2$ in (2.22) is canceled out by the surface element $\sin\theta'\ d\theta'\ d\phi'$. Second, the operator $(\theta', \phi') \mapsto \mathcal{T}_{\widehat{\boldsymbol{x}}} M_1(\widehat{\boldsymbol{n}}, \boldsymbol{p}(\theta', \phi'))$ is infinitely continuously differentiable, with all derivatives 2π-periodic in each variable, and each partial derivative is uniformly bounded with respect to $\widehat{\boldsymbol{x}} \in \partial B$ (see the proof of [16, Theorem 1]).

Finally, we write $\boldsymbol{W}(\widehat{\boldsymbol{x}}) = \boldsymbol{w}(\boldsymbol{q}(\widehat{\boldsymbol{x}}))$ and $\boldsymbol{F}(\widehat{\boldsymbol{x}}) = \boldsymbol{f}(\boldsymbol{q}(\widehat{\boldsymbol{x}}))$, and we use (2.22) and (2.13) to derive the transplant of (2.3) onto ∂B,

$$\boldsymbol{W}(\widehat{\boldsymbol{x}}) + \mathcal{M}\boldsymbol{W}(\widehat{\boldsymbol{x}}) = 2\boldsymbol{F}(\widehat{\boldsymbol{x}}), \qquad \widehat{\boldsymbol{x}} \in \partial B, \quad \boldsymbol{W} = \boldsymbol{w} \circ \boldsymbol{q}, \qquad \boldsymbol{F} = \boldsymbol{f} \circ \boldsymbol{q}. \tag{2.23}$$

In (2.23) we have an ideal reformulation of (2.3) to obtain high-order approximation of the surface current $\boldsymbol{w}$ through a spectrally accurate evaluation of (2.11), where we approximate both the smooth kernels and the transplanted surface current in a hybrid way from the space of vector spherical polynomials.

3. A computer implementable spectral algorithm. In this section, we describe a high-order fully discrete algorithm that requires no further approximations (such as approximations of Galerkin integrals) to compute spectrally accurate approximate solutions of (2.23). Details required for computer implementation of our algorithm are in section 3.3.

In the special case where the scatterer ∂D is spherical, we seek a spectrally accurate tangential approximation to the solution of (2.23) in the tangential harmonics

$$\underline{\mathbb{T}}_n = \text{span}\left\{ \boldsymbol{Y}_{l,j}^{(\widetilde{k})} \ : \ 1 \le l \le n, \ |j| \le l, \ \widetilde{k} = 1, 2 \right\},$$

where

$$\boldsymbol{Y}_{l,j}^{(1)}(\widehat{\boldsymbol{x}}) = \frac{1}{\sqrt{l(l+1)}} \mathbf{Grad}\, Y_{l,j}(\widehat{\boldsymbol{x}}), \qquad \boldsymbol{Y}_{l,j}^{(2)}(\widehat{\boldsymbol{x}}) = \widehat{\boldsymbol{x}} \times \boldsymbol{Y}_{l,j}^{(1)}(\widehat{\boldsymbol{x}}), \qquad \widehat{\boldsymbol{x}} \in \partial B, \tag{3.1}$$

where **Grad** is the surface gradient [8, p. 167] and using (1.1),

$$Y_{l,j}(\widehat{\boldsymbol{x}}) = (-1)^{(j+|j|)/2} \sqrt{\frac{2l+1}{4\pi} \frac{(l-|j|)!}{(l+|j|)!}} P_l^{|j|}(\cos\theta) e^{ij\phi}, \quad 0 \le l \le n, \ |j| \le l, \tag{3.2}$$

with $P_l^{|j|}$ being the associated Legendre functions. The vector spherical harmonics $\boldsymbol{Y}_{l,j}^{(1)}$ and $\boldsymbol{Y}_{l,j}^{(2)}$ are tangential on ∂B.

In the case of a nonspherical scatterer, since the solution of the transplanted equation (2.23) need not be tangential on ∂B, we seek a spectrally accurate approximation in the augmented space

$$\underline{\mathbb{Q}}_n = \underline{\mathbb{T}}_n \oplus \text{span}\left\{ \boldsymbol{Y}_{l,j}^{(3)} \ : \ 0 \le l \le n, \ |j| \le l \right\}, \tag{3.3}$$

where

$$\boldsymbol{Y}_{l,j}^{(3)}(\widehat{\boldsymbol{x}}) = \widehat{\boldsymbol{x}} Y_{l,j}(\widehat{\boldsymbol{x}}), \quad \widehat{\boldsymbol{x}} \in \partial B. \tag{3.4}$$

Using (1.1), (3.2), (3.1), and (3.4), for $\widetilde{k} = 1, 2, 3$, we have the convenient representation

$$\boldsymbol{Y}_{l,j}^{(\widetilde{k})}(\widehat{\boldsymbol{x}}) = \sum_{t=1}^{3} \alpha_{l,j}^{(\widetilde{k},t)}(\theta) e^{ij\phi} \boldsymbol{v}^{(t)}(\theta, \phi), \qquad \widehat{\boldsymbol{x}} \in \partial B, \tag{3.5}$$

where, denoting the normalizing coefficient in (3.2) by c_l^j,

$$\begin{aligned}
&\boldsymbol{v}^{(1)}(\theta,\phi) = (\cos\theta\cos\phi, \cos\theta\sin\phi, -\sin\theta)^T, \ \boldsymbol{v}^{(2)}(\theta,\phi) = (-\sin\phi, \cos\phi, 0)^T, \\
&\boldsymbol{v}^{(3)}(\theta,\phi) = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)^T, \\
&\alpha_{l,j}^{(1,1)}(\theta) = \alpha_{l,j}^{(2,2)}(\theta) = c_l^j P_l^{|j|\prime}(\cos\theta)/\sqrt{l(l+1)}, \\
&\alpha_{l,j}^{(1,2)}(\theta) = -\alpha_{l,j}^{(2,1)}(\theta) = c_l^j (ij/\sin\theta) P_l^{|j|}(\cos\theta)/\sqrt{l(l+1)}, \\
&\alpha_{l,j}^{(3,3)}(\theta) = c_l^j P_l^{|j|}(\cos\theta), \\
&\alpha_{l,j}^{(1,3)}(\theta) = \alpha_{l,j}^{(2,3)}(\theta) = \alpha_{l,j}^{(3,1)}(\theta) = \alpha_{l,j}^{(3,2)}(\theta) = 0.
\end{aligned}$$

The standard Galerkin scheme for (2.23) requires evaluation of the L_2 inner product integrals

$$(\boldsymbol{G}, \boldsymbol{H}) = \mathcal{I}(\overline{\boldsymbol{H}}^T \boldsymbol{G}) = \int_{\partial B} \overline{\boldsymbol{H}(\widehat{\boldsymbol{x}})}^T \boldsymbol{G}(\widehat{\boldsymbol{x}}) \, ds(\widehat{\boldsymbol{x}}), \qquad \boldsymbol{G}, \boldsymbol{H} \in \underline{C}(\partial B). \tag{3.6}$$

In practice, a quadrature rule on ∂B is required to evaluate the integrals in (3.6). We approximate the inner product integrals using the Gauss-rectangle quadrature rule

$$\int_{\partial B} G(\widehat{\boldsymbol{x}})\, ds(\widehat{\boldsymbol{x}}) \approx Q_N(G) = \sum_{r=0}^{2N+1} \sum_{s=1}^{N+1} \mu_r^N \nu_s^N G(\widehat{\boldsymbol{z}}_{rs}^N), \quad G \in C(\partial B), \tag{3.7}$$

where, using (1.1), $\widehat{\boldsymbol{z}}_{rs}^N = \boldsymbol{p}(\theta_s^N, \phi_r^N)$, $\theta_s^N = \cos^{-1} z_s$, z_s are the zeros of the Legendre polynomial of degree $N+1$, ν_s^N are the corresponding Gauss–Legendre weights ($s = 1, \ldots, N+1$), and

$$\mu_r^N = \frac{\pi}{N+1}, \qquad \phi_r^N = \frac{r\pi}{N+1}, \qquad r = 0, \ldots, 2N+1. \tag{3.8}$$

Since the quadrature (3.7) is exact for spherical polynomials of degree at most $2N$, it induces the discrete inner product

$$(\boldsymbol{G}, \boldsymbol{H})_N = Q_N(\overline{\boldsymbol{H}}^T \boldsymbol{G}) = \sum_{r=0}^{2N+1} \sum_{s=1}^{N+1} \mu_r^N \nu_s^N \overline{\boldsymbol{H}(\widehat{\boldsymbol{z}}_{rs}^N)}^T \boldsymbol{G}(\widehat{\boldsymbol{z}}_{rs}^N), \quad \boldsymbol{G}, \boldsymbol{H} \in \underline{C}(\partial B), \tag{3.9}$$

on $\underline{\mathbb{P}}_N$, the space of vector spherical polynomials whose Euclidean components are spherical polynomials of degree not greater than N. That is, $(\boldsymbol{G}, \boldsymbol{H}) = (\boldsymbol{G}, \boldsymbol{H})_N$ for $\boldsymbol{G}, \boldsymbol{H} \in \underline{\mathbb{P}}_N$. Since $\boldsymbol{Y}_{n,j}^{(\widetilde{k})}$ for $\widetilde{k} = 1, 2, 3$ in (3.1)–(3.4) is a vector spherical polynomial of degree $n+1$, we have $\underline{\mathbb{Q}}_n \subseteq \underline{\mathbb{P}}_{n+1}$, and hence the vector spherical harmonics in (3.1) and (3.4) are orthonormal with respect to the discrete inner product (3.9) with $N = n+1$.

We approximate the transplanted surface current in (2.23) by a computable projection onto the finite dimensional space $\underline{\mathbb{Q}}_n$. In particular, we approximate the theoretical solution $\boldsymbol{W}$ of (2.23) using a computable representation $\underline{\mathcal{O}}_n \boldsymbol{W}$, where $\underline{\mathcal{O}}_n$ is a fully discrete projection operator defined as

$$\underline{\mathcal{O}}_n \boldsymbol{A} = \sum_{l=0}^{n} \sum_{|j| \le l} \sum_{\widetilde{k}=1}^{3} (\boldsymbol{A}, \boldsymbol{Y}_{l,j}^{(\widetilde{k})})_{n+1} \boldsymbol{Y}_{l,j}^{(\widetilde{k})}, \qquad \boldsymbol{A} \in \underline{C}(\partial B), \tag{3.10}$$

where, for convenience, throughout the paper, we use the notation $\boldsymbol{Y}_{00}^{(1)} = \boldsymbol{Y}_{00}^{(2)} = \boldsymbol{0}$. Using the orthonormality of the vector harmonics with respect to the discrete inner product in (3.10), we get $\underline{\mathcal{O}}_n \boldsymbol{Y}_{l,j}^{(\widetilde{k})} = \boldsymbol{Y}_{l,j}^{(\widetilde{k})}$ for $0 \le l \le n$, $|j| \le l$, $1 \le \widetilde{k} \le 3$. Throughout the paper, when ∂D is a sphere, we replace $\sum_{\widetilde{k}=1}^{3}$ in (3.10) by $\sum_{\widetilde{k}=1}^{2}$, and $\underline{\mathbb{Q}}_n$ by $\underline{\mathbb{T}}_n$.

3.1. Fully discrete approximations of magnetic dipole integrals. For evaluation of inner integrals in the Galerkin scheme, for example, $\mathcal{M}_1 \boldsymbol{A}(\widehat{\boldsymbol{x}})$, we need to approximate the integrand $\mathcal{T}_{\widehat{\boldsymbol{x}}} M_1(\widehat{\boldsymbol{n}}, \cdot)\, \mathcal{T}_{\widehat{\boldsymbol{x}}} \boldsymbol{A}(\cdot)$ in (2.22) for $\boldsymbol{A} \in \underline{C}(\partial B)$, $\widehat{\boldsymbol{x}} \in \partial B$. One approach is to project this integrand using the fully discrete operator $\underline{\mathcal{O}}_n$ in (3.10), as in [15]. However, as described in [16, Remark 2], using a technical analysis, such an approximation, leads to stagnated convergence instead of the spectral accuracy we seek in this work. In this hybrid scheme, to approximate the inner integral, we use the componentwise nontangential harmonics defined using (3.2) as

$$\boldsymbol{Y}_{l,j,\widetilde{k}} = Y_{l,j} \boldsymbol{e}_{\widetilde{k}}, \qquad 0 \le l \le n', \ |j| \le l, \ 1 \le \widetilde{k} \le 3, \tag{3.11}$$

where $\boldsymbol{e}_{\widetilde{k}}$ denotes the $\widetilde{k}$th Euclidean vector. To this end, analogous to (3.10), using the discrete inner product (3.9), we define a fully discrete orthogonal projection operator

$$\underline{\mathcal{L}}_{n'}\boldsymbol{A} = \sum_{l=0}^{n'}\sum_{|j|\le l}\sum_{\widetilde{k}=1}^{3}(\boldsymbol{A},\boldsymbol{Y}_{l,j,\widetilde{k}})_{n'}\boldsymbol{Y}_{l,j,\widetilde{k}}, \qquad \boldsymbol{A}\in\underline{C}(\partial B). \tag{3.12}$$

Clearly $\underline{\mathcal{L}}_{n'}\boldsymbol{Y}_{l,j,\widetilde{k}} = \boldsymbol{Y}_{l,j,\widetilde{k}}$ for $0\le l\le n',\ |j|\le l,\ 1\le\widetilde{k}\le 3$. Here, n' depends on n and will be specified later in this section. We approximate $\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\cdot)\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\cdot)$ in (2.22) by $\underline{\mathcal{L}}_{n'}\{\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\cdot)\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\cdot)\}$ and follow the details in [16].

More precisely, for $\boldsymbol{A}\in\underline{C}(\partial B)$ and $\widehat{\boldsymbol{x}}\in\partial B$, using (2.22) and (3.12), the approximation to $\mathcal{M}_1\boldsymbol{A}(\widehat{\boldsymbol{x}})$ is

$$\begin{aligned}
\mathcal{M}_{1,n'}\boldsymbol{A}(\widehat{\boldsymbol{x}}) &= \int_{\partial B}\frac{1}{|\widehat{\boldsymbol{n}}-\widehat{\boldsymbol{z}}|}\underline{\mathcal{L}}_{n'}\left\{\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\cdot)\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\cdot)\right\}(\widehat{\boldsymbol{z}})\ ds(\widehat{\boldsymbol{z}})\\
&= \int_{\partial B}\frac{1}{|\widehat{\boldsymbol{n}}-\widehat{\boldsymbol{z}}|}\sum_{l=0}^{n'}\sum_{|j|\le l}\sum_{\widetilde{k}=1}^{3}\left(\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\cdot)\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\cdot),\boldsymbol{Y}_{l,j,\widetilde{k}}(\cdot)\right)_{n'}\boldsymbol{Y}_{l,j,\widetilde{k}}(\widehat{\boldsymbol{z}})\ ds(\widehat{\boldsymbol{z}})\\
&= \sum_{l=0}^{n'}\sum_{|j|\le l}\sum_{\widetilde{k}=1}^{3}\left(\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\cdot)\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\cdot),\boldsymbol{Y}_{l,j,\widetilde{k}}(\cdot)\right)_{n'}\int_{\partial B}\frac{1}{|\widehat{\boldsymbol{n}}-\widehat{\boldsymbol{z}}|}\boldsymbol{Y}_{l,j,\widetilde{k}}(\widehat{\boldsymbol{z}})\ ds(\widehat{\boldsymbol{z}})\\
&= \sum_{l=0}^{n'}\sum_{|j|\le l}\sum_{\widetilde{k}=1}^{3}\left(\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\cdot)\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\cdot),\boldsymbol{Y}_{l,j,\widetilde{k}}(\cdot)\right)_{n'}\frac{4\pi}{2l+1}\boldsymbol{Y}_{l,j,\widetilde{k}}(\widehat{\boldsymbol{n}}).
\end{aligned} \tag{3.13}$$

In the last step we have used the standard eigenfunction property of the spherical harmonics [11]. Using (3.9), we expand the discrete inner product and obtain

$$\begin{aligned}
&\mathcal{M}_{1,n'}\boldsymbol{A}(\widehat{\boldsymbol{x}})\\
&= \sum_{l=0}^{n'}\sum_{|j|\le l}\sum_{\widetilde{k}=1}^{3}\sum_{s'=1}^{n'+1}\sum_{r'=0}^{2n'+1}\mu_{r'}^{n'}\nu_{s'}^{n'}\frac{4\pi}{2l+1}\overline{\boldsymbol{Y}_{l,j,\widetilde{k}}(\widehat{\boldsymbol{z}}_{r's'}^{n'})}^{T}\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\widehat{\boldsymbol{z}}_{r's'}^{n'})\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\widehat{\boldsymbol{z}}_{r's'}^{n'})\boldsymbol{Y}_{l,j,\widetilde{k}}(\widehat{\boldsymbol{n}})\\
&= \sum_{l=0}^{n'}\sum_{\widetilde{k}=1}^{3}\sum_{s'=1}^{n'+1}\sum_{r'=0}^{2n'+1}\mu_{r'}^{n'}\nu_{s'}^{n'}\frac{4\pi}{2l+1}\boldsymbol{e}_{\widetilde{k}}\boldsymbol{e}_{\widetilde{k}}^{T}\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\widehat{\boldsymbol{z}}_{r's'}^{n'})\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\widehat{\boldsymbol{z}}_{r's'}^{n'})\sum_{|j|\le l}\overline{Y_{l,j}(\widehat{\boldsymbol{z}}_{r's'}^{n'})}Y_{l,j}(\widehat{\boldsymbol{n}}).
\end{aligned}$$

Using the addition theorem for the spherical harmonics [8, Theorem 2.8], this simplifies to

$$\begin{aligned}
\mathcal{M}_{1,n'}\boldsymbol{A}(\widehat{\boldsymbol{x}}) &= \sum_{l=0}^{n'}\sum_{\widetilde{k}=1}^{3}\sum_{s'=1}^{n'+1}\sum_{r'=0}^{2n'+1}\mu_{r'}^{n'}\nu_{s'}^{n'}\boldsymbol{e}_{\widetilde{k}}\boldsymbol{e}_{\widetilde{k}}^{T}\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\widehat{\boldsymbol{z}}_{r's'}^{n'})\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\widehat{\boldsymbol{z}}_{r's'}^{n'})P_l(\widehat{\boldsymbol{n}}\cdot\widehat{\boldsymbol{z}}_{r's'}^{n'})\\
&= \sum_{s'=1}^{n'+1}\sum_{r'=0}^{2n'+1}\mu_{r'}^{n'}\nu_{s'}^{n'}\alpha_{s'}^{n'}\mathcal{T}_{\widehat{\boldsymbol{x}}}M_1(\widehat{\boldsymbol{n}},\widehat{\boldsymbol{z}}_{r's'}^{n'})\ \mathcal{T}_{\widehat{\boldsymbol{x}}}\boldsymbol{A}(\widehat{\boldsymbol{z}}_{r's'}^{n'}),
\end{aligned} \tag{3.14}$$

where $\alpha_{s'}^{n'}=\sum_{l=0}^{n'}P_l(\cos\theta_{s'}^{n'})$, and we have used $\widehat{\boldsymbol{n}}\cdot\widehat{\boldsymbol{z}}_{r's'}^{n'}=\cos\theta_{s'}^{n'}$. Thus $\mathcal{M}_{1,n'}\boldsymbol{A}$ is a fully discrete computable approximation to the transplanted weakly singular part of the generalized magnetic dipole operator in (2.8).

We use a similar approximation for the smooth part of the operator. We write (2.13) in the rotated coordinate system as

$$\mathcal{M}_2\boldsymbol{A}(\widehat{\boldsymbol{x}}) = \int_{\partial B} \mathcal{T}_{\widehat{\boldsymbol{x}}} M_2(\widehat{\boldsymbol{n}}, \widehat{\boldsymbol{z}})\, \mathcal{T}_{\widehat{\boldsymbol{x}}} \boldsymbol{A}(\widehat{\boldsymbol{z}})\, ds(\widehat{\boldsymbol{z}}). \tag{3.15}$$

Our approximation to $\mathcal{M}_2\boldsymbol{A}$ is then

$$\begin{aligned}
\mathcal{M}_{2,n'}\boldsymbol{A}(\widehat{\boldsymbol{x}}) &= \int_{\partial B} \underline{\mathcal{L}}_{n'} \left\{ \mathcal{T}_{\widehat{\boldsymbol{x}}} M_2(\widehat{\boldsymbol{n}}, \cdot)\, \mathcal{T}_{\widehat{\boldsymbol{x}}} \boldsymbol{A}(\cdot) \right\} (\widehat{\boldsymbol{z}})\, ds(\widehat{\boldsymbol{z}}) \\
&= \int_{\partial B} \sum_{l=0}^{n'} \sum_{|j|\le l} \sum_{\widetilde{k}=1}^{3} \left(\mathcal{T}_{\widehat{\boldsymbol{x}}} M_2(\widehat{\boldsymbol{n}}, \cdot)\, \mathcal{T}_{\widehat{\boldsymbol{x}}} \boldsymbol{A}(\cdot), \boldsymbol{Y}_{l,j,\widetilde{k}}(\cdot) \right)_{n'} \boldsymbol{Y}_{l,j,\widetilde{k}}(\widehat{\boldsymbol{z}})\, ds(\widehat{\boldsymbol{z}}) \\
&= \sum_{l=0}^{n'} \sum_{|j|\le l} \sum_{\widetilde{k}=1}^{3} \left(\mathcal{T}_{\widehat{\boldsymbol{x}}} M_2(\widehat{\boldsymbol{n}}, \cdot)\, \mathcal{T}_{\widehat{\boldsymbol{x}}} \boldsymbol{A}(\cdot), \boldsymbol{Y}_{l,j,\widetilde{k}}(\cdot) \right)_{n'} \int_{\partial B} \boldsymbol{Y}_{l,j,\widetilde{k}}(\widehat{\boldsymbol{z}})\, ds(\widehat{\boldsymbol{z}}).
\end{aligned} \tag{3.16}$$

Noting that $\boldsymbol{Y}_{0,0,\widetilde{k}} = \boldsymbol{e}_{\widetilde{k}}/\sqrt{4\pi}$, the orthogonality of the $\boldsymbol{Y}_{l,j,\widetilde{k}}$ gives

$$\mathcal{M}_{2,n'}\boldsymbol{A}(\widehat{\boldsymbol{x}}) = \sum_{\widetilde{k}=1}^{3} \left(\mathcal{T}_{\widehat{\boldsymbol{x}}} M_2(\widehat{\boldsymbol{n}}, \cdot)\, \mathcal{T}_{\widehat{\boldsymbol{x}}} \boldsymbol{A}(\cdot), \boldsymbol{e}_{\widetilde{k}} \right)_{n'} \boldsymbol{e}_{\widetilde{k}}.$$

Expanding the discrete inner product using (3.9),

$$\begin{aligned}
\mathcal{M}_{2,n'}\boldsymbol{A}(\widehat{\boldsymbol{x}}) &= \sum_{\widetilde{k}=1}^{3} \sum_{s'=1}^{n'+1} \sum_{r'=0}^{2n'+1} \mu_{r'}^{n'} \nu_{s'}^{n'} \boldsymbol{e}_{\widetilde{k}} \boldsymbol{e}_{\widetilde{k}}^{T} \mathcal{T}_{\widehat{\boldsymbol{x}}} M_2(\widehat{\boldsymbol{n}}, \widehat{\boldsymbol{z}}_{r's'}^{n'})\, \mathcal{T}_{\widehat{\boldsymbol{x}}} \boldsymbol{A}(\widehat{\boldsymbol{z}}_{r's'}^{n'}) \\
&= \sum_{s'=1}^{n'+1} \sum_{r'=0}^{2n'+1} \mu_{r'}^{n'} \nu_{s'}^{n'} \mathcal{T}_{\widehat{\boldsymbol{x}}} M_2(\widehat{\boldsymbol{n}}, \widehat{\boldsymbol{z}}_{r's'}^{n'})\, \mathcal{T}_{\widehat{\boldsymbol{x}}} \boldsymbol{A}(\widehat{\boldsymbol{z}}_{r's'}^{n'}).
\end{aligned} \tag{3.17}$$

Combining (3.14) and (3.17), we approximate the reformulated and projected magnetic dipole operator (2.11) by the computable representation

$$\mathcal{M}_{n'}\boldsymbol{A}(\widehat{\boldsymbol{x}}) = \mathcal{M}_{1,n'}\boldsymbol{A}(\widehat{\boldsymbol{x}}) + \mathcal{M}_{2,n'}\boldsymbol{A}(\widehat{\boldsymbol{x}}). \tag{3.18}$$

Finally, we must choose n' to ensure that $\mathcal{M}_{n'}\boldsymbol{A}$ converges to $\mathcal{M}\boldsymbol{A}$ with spectral accuracy. Following the proof of [16, Theorem 1] it can be shown that if $n' = an + 1$ for some fixed constant $a > 1$, and $n' - n \ge 3$, then for , $s \in \mathbb{N}$, there exists $c_s > 0$, independent of n and n', such that

$$\|(\mathcal{M} - \mathcal{M}_{n'})\boldsymbol{P}_n\|_{\infty,\partial B} \le c_s \frac{1}{n^s} \|\boldsymbol{P}_n\|_{\infty,\partial B} \quad \text{for all } \boldsymbol{P}_n \in \underline{\mathbb{P}}_{n+1}. \tag{3.19}$$

As in [16, Theorem 1], if the conductor surface is smooth then (3.19) holds for , number s. We remark that in our computational algorithm, the density function of the fully discrete magnetic dipole operator is a spherical polynomial of degree at most $n + 1$. For computations in section 5 we set $n' = 2n + 1$.

3.2. Complete algorithm. We are now ready to describe the complete algorithm to solve (2.23), using the various spectrally accurate approximations described

above. Our fully discrete scheme for (2.23) is as follows: compute $\boldsymbol{W}_n \in \underline{\mathbb{Q}}_n$ such that

$$\boldsymbol{W}_n + \underline{\mathcal{O}}_n \mathcal{M}_{n'} \boldsymbol{W}_n = 2\underline{\mathcal{O}}_n \boldsymbol{f}. \tag{3.20}$$

Since $\boldsymbol{W}_n \in \underline{\mathbb{Q}}_n$ can be written as

$$\boldsymbol{W}_n(\widehat{\boldsymbol{x}}) = \mathrm{w}_{003}\boldsymbol{Y}_{00}^{(3)}(\widehat{\boldsymbol{x}}) + \sum_{l=1}^{n}\sum_{|j|\le l}\sum_{\widetilde{k}=1}^{3} \mathrm{w}_{lj\widetilde{k}}\boldsymbol{Y}_{l,j}^{(\widetilde{k})}(\widehat{\boldsymbol{x}}), \quad \widehat{\boldsymbol{x}} \in \partial B, \tag{3.21}$$

the operator equation (3.20) is equivalent to the requirement that the coefficients $\mathrm{w}_{lj\widetilde{k}}$ solve the fully discrete Galerkin system

$$(\boldsymbol{W}_n, \boldsymbol{Y}_{l',j'}^{(k')})_{n+1} + (\mathcal{M}_{n'}\boldsymbol{W}_n, \boldsymbol{Y}_{l',j'}^{(k')})_{n+1} = 2(\boldsymbol{F}, \boldsymbol{Y}_{l',j'}^{(k')})_{n+1}, \quad (l', j', k') \in \mathcal{I}, \tag{3.22}$$

where $\mathcal{I} = \{(0,0,3)\} \cup \{(\widehat{l}, \widehat{j}, \widehat{k}) \ : \ 1 \le \widehat{l} \le n,\ |\widehat{j}| \le \widehat{l},\ \widehat{k} = 1,2,3\}$. In matrix form, $\mathrm{w} = (\mathrm{w}_{lj\widetilde{k}})$ satisfies

$$(\mathrm{I} + \mathrm{M})\mathrm{w} = 2\mathrm{f},$$

and for $(l, j, \widetilde{k}), (l', j', k') \in \mathcal{I}$,

$$\begin{aligned} \mathrm{M}_{l'j'k',lj\widetilde{k}} &= (\mathcal{M}_{n'}\boldsymbol{Y}_{l,j}^{(\widetilde{k})}, \boldsymbol{Y}_{l',j'}^{(k')})_{n+1}, \quad \mathrm{I}_{l'j'k',lj\widetilde{k}} = \delta_{ll'}\delta_{jj'}\delta_{\widetilde{k}k'}, \\ \mathrm{f}_{l'j'k'} &= (\boldsymbol{F}, \boldsymbol{Y}_{l',j'}^{(k')})_{n+1}. \end{aligned} \tag{3.23}$$

Our corresponding approximation to the solution $\boldsymbol{w}$ of (2.3) is then

$$\boldsymbol{w}_n(\boldsymbol{x}) = \boldsymbol{W}_n(\boldsymbol{q}^{-1}(\boldsymbol{x})), \quad \boldsymbol{x} \in \partial D. \tag{3.24}$$

Using (3.19) and following the proof of [16, Theorem 3] (with $\underline{\mathcal{L}}_n$ replaced by $\underline{\mathcal{O}}_n$), it can be shown that for smooth conductors, $\boldsymbol{w}_n$ (and $\boldsymbol{W}_n$) are spectrally accurate approximations to the unique solutions $\boldsymbol{w}$ (and $\boldsymbol{W}$) in the maximum norm: $\|\boldsymbol{w} - \boldsymbol{w}_n\|_{\infty,\partial D} = O(n^{-q})$ (and $\|\boldsymbol{W} - \boldsymbol{W}_n\|_{\infty,\partial B} = O(n^{-q})$) for any positive integer q, provided that the Lebesgue constant of $\underline{\mathcal{O}}_n$ is $O(n^{\alpha})$ for some $\alpha < 1$. The proof of [16, Theorem 3] is based on the known result that the Lebesgue constant of $\underline{\mathcal{L}}_n$ is $O(\sqrt{n})$ [16, 22, 24]. In this work, we conjecture that the Lebesgue constant of $\underline{\mathcal{O}}_n$ is the same as that of $\underline{\mathcal{L}}_n$; a complete proof of this result similar to the theoretical analyses in [22, 24] is beyond the scope of this paper.

3.3. Computer implementation details. As a prerequisite for implementation, special care must be taken to avoid overflow in the evaluation of the basis functions—in particular the associated Legendre values in (3.5) when l is large. We compute directly the normalized associated Legendre values

$$\widehat{P}_l^j(x) = \sqrt{\frac{l-j}{l+j}}P_l^j(x), \qquad 0 \le l \le n,\ 0 \le j \le l,$$

using the relation

$$\widehat{P}_l^j(x) = \sigma_l^j Q_l^j(x)$$

and the recurrences

$$(l-j)Q_l^j(x) = (2l-1)xQ_{l-1}^j(x) - (l+j-1)Q_{l-2}^j(x), \qquad l > j+1,$$
$$\sigma_l^j = \sqrt{\frac{l-j}{l+j}}\sigma_{l-1}^j, \qquad l > j+1,$$

with the seeds

$$\sigma_j^j = 1, \quad \sigma_{j+1}^j = \sqrt{\frac{1}{2j+1}},$$
$$Q_j^j(x) = \eta(j)(1-x^2)^{j/2}, \quad Q_{j+1}^j(x) = x(2l+1)Q_j^j(x), \quad \eta(j) = (2j-1)!!/\sqrt{(2j)!}.$$

Overflow in computing $\eta(j)$ is avoided using the stable expression

$$\eta(j) = \prod_{\tilde{j}=1}^{j} \sqrt{\frac{2\tilde{j}-1}{2\tilde{j}}}.$$

As in [16], we describe an efficient way to set up the $N \times N$ electromagnetic scattering matrix M in only $O(N^{2.5})$ operations, where $N = 3(n+1)^2 - 2$. This complexity can be reduced further by utilizing fast transforms. We also describe a parallel implementation.

Using (3.23), (3.18), (3.17), (3.14), and (3.9), we write

$$\mathrm{M}_{l'j'k',lj\tilde{k}} = \sum_{r=0}^{2n+3}\sum_{s=1}^{n+2} \mu_r^{n+1}\nu_s^{n+1} \sum_{r'=0}^{2n'+1}\sum_{s'=1}^{n'+1} \mu_{r'}^{n'}\nu_{s'}^{n'} \overline{\boldsymbol{Y}_{l',j'}^{(k')}(\widehat{\boldsymbol{x}}_{rs})}^T \Big[\alpha_{s'}^{n'} \mathcal{T}_{\widehat{\boldsymbol{x}}_{rs}} M_1(\widehat{\boldsymbol{n}}, \widehat{\boldsymbol{z}}_{r's'})$$
$$+ \mathcal{T}_{\widehat{\boldsymbol{x}}_{rs}} M_2(\widehat{\boldsymbol{n}}, \widehat{\boldsymbol{z}}_{r's'})\Big] \mathcal{T}_{\widehat{\boldsymbol{x}}_{rs}} \boldsymbol{Y}_{l,j}^{(\tilde{k})}(\widehat{\boldsymbol{z}}_{r's'}), \tag{3.25}$$

where $\widehat{\boldsymbol{x}}_{rs} = \boldsymbol{p}(\theta_s^{n+1}, \phi_r^{n+1})$ and $\widehat{\boldsymbol{z}}_{r's'} = \boldsymbol{p}(\theta_{s'}^{n'}, \phi_{r'}^{n'})$.

Direct computation of M using (3.25) has complexity $O(N^4)$ because M has $O(N^2)$ entries, and each entry requires $O(N^2)$ function evaluations to approximate a double integral over ∂B. The efficient assembly algorithm presented below reduces this complexity to $O(N^{2.5})$. Optimal complexity for the matrix would be $O(N^2)$, but the spectrally accurate nature of the algorithm compensates for the slightly higher complexity.

We write $\boldsymbol{y}_{rs}^{r's'} = T_{\widehat{\boldsymbol{x}}_{rs}}^{-1}\widehat{\boldsymbol{z}}_{r's'}$ so that

$$\mathrm{M}_{l'j'k',lj\tilde{k}} = \sum_{r=0}^{2n+3}\sum_{s=1}^{n+2} \mu_r^{n+1}\nu_s^{n+1} \sum_{r'=0}^{2n'+1}\sum_{s'=1}^{n'+1} \mu_{r'}^{n'}\nu_{s'}^{n'} \overline{\boldsymbol{Y}_{l',j'}^{(k')}(\widehat{\boldsymbol{x}}_{rs})}^T \Big[\alpha_{s'}^{n'} M_1(\widehat{\boldsymbol{x}}_{rs}, \widehat{\boldsymbol{y}}_{rs}^{r's'})$$
$$+ M_2(\widehat{\boldsymbol{x}}_{rs}, \widehat{\boldsymbol{y}}_{rs}^{r's'})\Big] \mathcal{T}_{\widehat{\boldsymbol{x}}_{rs}} \boldsymbol{Y}_{l,j}^{(\tilde{k})}(\widehat{\boldsymbol{z}}_{r's'}).$$

From [11, (12.7.4), p. 341] the rotated vector spherical harmonic $\mathcal{T}_{\widehat{\boldsymbol{x}}_{rs}} \boldsymbol{Y}_{l,j}^{(\tilde{k})}$ can be written as a linear combination of vector spherical harmonics of the same degree. As in [12], the complexity of computing M can be reduced by taking advantage of this property. A stable and efficient representation based on [11, (12.7.4), p. 341] using [12,

p. 224] is

$$\mathcal{T}_{\widehat{\boldsymbol{x}}_{rs}} \boldsymbol{Y}^{(k)}_{l,j} = T^{-1}_{\widehat{\boldsymbol{x}}_{rs}} \sum_{|\widetilde{j}|\le l} F_{sl\widetilde{j}j} e^{i(j-\widetilde{j})\phi_r^{n+1}} \boldsymbol{Y}^{(k)}_{l,\widetilde{j}}, \tag{3.26}$$

$$F_{sl\widetilde{j}j} = e^{i(j-\widetilde{j})\pi/2} \sum_{|\widetilde{m}|\le l} d^{(l)}_{\widetilde{j}\widetilde{m}}(\pi/2) d^{(l)}_{j\widetilde{m}}(\pi/2) e^{i\widetilde{m}\theta_s^{n+1}},$$

where

$$d^{(l)}_{\widetilde{j}j}(\pi/2) = 2^{\widetilde{j}} \left[\frac{(l+\widetilde{j})!(l-\widetilde{j})!}{(l+j)!(l-j)!} \right]^{1/2} P^{(j-\widetilde{j},-j-\widetilde{j})}_{l+\widetilde{j}}(0).$$

For given nonnegative integers a, b and $s \ge 0$, $P^{(a,b)}_s(0)$ is the normalized Jacobi polynomial evaluated at zero,

$$P^{(a,b)}_s(0) = 2^{-s} \sum_{t=0}^{s} (-1)^t \begin{pmatrix} s+a \\ s-t \end{pmatrix} \begin{pmatrix} s+b \\ t \end{pmatrix}.$$

When a or b is negative, $d^{(l)}_{\widetilde{j}j}$ can be computed using the symmetry relations

$$d^{(l)}_{\widetilde{j}j}(\alpha) = (-1)^{\widetilde{j}-j} d^{(l)}_{j\widetilde{j}}(\alpha) = d^{(l)}_{-j-\widetilde{j}}(\alpha) = d^{(l)}_{j\widetilde{j}}(-\alpha).$$

Using (3.26), (3.2), and (3.5), we get

$$\begin{aligned}
&\mathrm{M}_{l'j'k',lj\widetilde{k}} \\
&= \sum_{r=0}^{2n+3} \sum_{s=1}^{n+2} \mu_r^{n+1} \nu_s^{n+1} \sum_{r'=0}^{2n'+1} \sum_{s'=1}^{n'+1} \mu_{r'}^{n'} \nu_{s'}^{n'} \sum_{t'=1}^{3} \alpha^{(k',t')}_{l',j'}(\theta_s^{n+1}) e^{-ij'\phi_r^{n+1}} \boldsymbol{v}^{(t')}(\theta_s^{n+1}, \phi_r^{n+1})^T \\
&\quad \left[\alpha^{n'}_{s'} M_1(\widehat{\boldsymbol{x}}_{rs}, \widehat{\boldsymbol{y}}^{r's'}_{rs}) + M_2(\widehat{\boldsymbol{x}}_{rs}, \widehat{\boldsymbol{y}}^{r's'}_{rs}) \right] \sum_{|\widetilde{j}|\le l} F_{sl\widetilde{j}j} e^{i(j-\widetilde{j})\phi_r^{n+1}} \\
&\quad \sum_{t=1}^{3} \alpha^{(\widetilde{k},t)}_{l,\widetilde{j}}(\theta^{n'}_{s'}) e^{i\widetilde{j}\phi^{n'}_{r'}} T^{-1}_{\widehat{\boldsymbol{x}}_{rs}} \boldsymbol{v}^{(t)}(\theta^{n'}_{s'}, \phi^{n'}_{r'}).
\end{aligned}$$

The matrix M, which has $O(N^2) = O(n^4)$ entries, can be computed by successively computing the following arrays. Each array is a sum with $O(n)$ terms and depends on four labels (ignoring $\widetilde{k}$ and k'). Thus M can be computed in $O(n^5) = O(N^{2.5})$ operations.

$$\mathrm{E}_{srs'\widetilde{j}t} = \sum_{r'=0}^{2n'+1} \mu^{n'}_{r'} e^{i\widetilde{j}\phi^{n'}_{r'}} \left[\alpha^{n'}_{s'} M_1(\widehat{\boldsymbol{x}}_{rs}, \widehat{\boldsymbol{y}}^{r's'}_{rs}) + M_2(\widehat{\boldsymbol{x}}_{rs}, \widehat{\boldsymbol{y}}^{r's'}_{rs}) \right] T^{-1}_{\widehat{\boldsymbol{x}}_{rs}} \boldsymbol{v}^{(t)}(\theta^{n'}_{s'}, \phi^{n'}_{r'}),$$

$$\mathrm{D}_{srl\widetilde{j}\widetilde{k}} = \sum_{s'=1}^{n'+1} \sum_{t=1}^{3} \nu^{n'}_{s'} \alpha^{(\widetilde{k},t)}_{l,\widetilde{j}}(\theta^{n'}_{s'}) \mathrm{E}_{srs'\widetilde{j}t}, \quad \mathrm{C}_{srlj\widetilde{k}} = \sum_{|\widetilde{j}|\le l} F_{sl\widetilde{j}j} e^{i(j-\widetilde{j})\phi_r^{n+1}} \mathrm{D}_{srl\widetilde{j}\widetilde{k}},$$

$$\mathrm{B}_{sj't'lj\widetilde{k}} = \sum_{r=0}^{2n+3} \mu_r^{n+1} e^{-ij'\phi_r^{n+1}} \boldsymbol{v}^{(t')}(\theta_s^{n+1}, \phi_s^{n+1})^T \mathrm{C}_{srlj\widetilde{k}},$$

$$\mathrm{M}_{l'j'k',lj\widetilde{k}} = \sum_{s=1}^{n+2} \sum_{t'=1}^{3} \nu_s^{n+1} \alpha^{(k',t')}_{l',j'}(\theta_s^{n+1}) \mathrm{B}_{sj't'lj\widetilde{k}}.$$

Once E has been used to compute D, it is discarded. Similarly, D is discarded after it has been used to compute C, and so on. The fast Fourier transform (FFT) can be used to speed up the computation of the arrays above, and for calculating f and F in (3.23) and (3.26), respectively. As we shall demonstrate in the numerical experiments section, $5 \le n \le 125$ is sufficient for low to medium frequency problems because of the high-order spectral accuracy of our algorithm. Hence we can use direct or iterative solves in a single or multiprocessor environment.

For a cluster computing-type environment (with multiple processors and limited RAM for each processor), we consider a parallel implementation of the above algorithm. For a cluster computer implementation with $n_{\rm proc}$ free CPUs, we partition the s index set $\{1, \ldots, n+2\}$ into $n_{\rm proc}$ disjoint sets S_p for $p = 1, \ldots, n_{\rm proc}$. The array $\mathrm{B}_{sj't'lj\widetilde{k}}$ for $s \in S_p$ is computed and stored on processing node p.

4. High-order RCS and exterior field approximations. In this section, we follow a variant of the approach in [16] to describe a fully discrete high-order approximation to the monostatic and bistatic RCS of the perfect conductor D, and the exterior electromagnetic fields. We use the spectrally accurate numerical solution $\boldsymbol{W}_n$ of (3.21)–(3.23) for this purpose.

4.1. Spectrally accurate RCS computations. The monostatic and bistatic RCS measurements in (1.2) and (1.7) require high-order approximations of the electric far field. Using (2.6), the electric far field corresponding to the unique solution $\boldsymbol{w} = \mathcal{P}\boldsymbol{w}$ of (2.3) can be written as

$$\begin{aligned} \boldsymbol{E}_\infty(\widehat{\boldsymbol{x}}) &= \frac{ik}{4\pi} \int_{\partial D} e^{-ik\widehat{\boldsymbol{x}}\cdot\boldsymbol{y}} \widehat{\boldsymbol{x}} \times \mathcal{P}(\boldsymbol{y}) \boldsymbol{w}(\boldsymbol{y})\, ds(\boldsymbol{y}) \\ &= \int_{\partial B} \widehat{M}_{\widehat{\boldsymbol{x}}}(\widehat{\boldsymbol{y}}) \boldsymbol{W}(\widehat{\boldsymbol{y}})\, ds(\widehat{\boldsymbol{y}}), \quad \widehat{\boldsymbol{x}} \in \partial B, \end{aligned} \tag{4.1}$$

where for each fixed $\widehat{\boldsymbol{x}} \in \partial B$, the smooth function $\widehat{M}_{\widehat{\boldsymbol{x}}}$ is defined by

$$\widehat{M}_{\widehat{\boldsymbol{x}}}(\widehat{\boldsymbol{y}}) \boldsymbol{W}(\widehat{\boldsymbol{y}}) = \frac{ik}{4\pi} J(\widehat{\boldsymbol{y}}) e^{-ik\widehat{\boldsymbol{x}}\cdot\boldsymbol{q}(\widehat{\boldsymbol{y}})} \widehat{\boldsymbol{x}} \times \mathcal{P}(\boldsymbol{q}(\widehat{\boldsymbol{y}})) \boldsymbol{W}(\widehat{\boldsymbol{y}}), \qquad \widehat{\boldsymbol{y}} \in \partial B, \tag{4.2}$$

and $\boldsymbol{W}$ is the solution of (2.23).

Using the approximation $\boldsymbol{W}_n$ to $\boldsymbol{W}$ given by (3.21)–(3.23), our fully discrete approximation $\boldsymbol{E}_{n,\infty}(\widehat{\boldsymbol{x}})$ to $\boldsymbol{E}_\infty(\widehat{\boldsymbol{x}})$ for $\widehat{\boldsymbol{x}} \in \partial B$ is given by

$$\boldsymbol{E}_{n,\infty}(\widehat{\boldsymbol{x}}) = \int_{\partial B} \underline{\mathcal{O}}_n \left\{ \widehat{M}_{\widehat{\boldsymbol{x}}}(\cdot) \boldsymbol{W}_n(\cdot) \right\} (\widehat{\boldsymbol{y}})\, ds(\widehat{\boldsymbol{y}}) \tag{4.3}$$

$$= \sum_{l=0}^{n} \sum_{|j|\le l} \sum_{\widetilde{k}=1}^{3} \mathrm{w}_{lj\widetilde{k}} \int_{\partial B} \underline{\mathcal{O}}_n \left\{ \widehat{M}_{\widehat{\boldsymbol{x}}}(\cdot) \boldsymbol{Y}_{l,j}^{(\widetilde{k})}(\cdot) \right\} (\widehat{\boldsymbol{y}})\, ds(\widehat{\boldsymbol{y}}), \tag{4.4}$$

where, for convenience, we set $\mathrm{w}_{001} = \mathrm{w}_{002} = 0$. Using (3.10) and (3.7),

$$\boldsymbol{E}_{n,\infty}(\widehat{\boldsymbol{x}}) = \sum_{l=0}^{n} \sum_{|j|\le l} \sum_{\widetilde{k}=1}^{3} \mathrm{w}_{lj\widetilde{k}} \sum_{r=0}^{2n+3} \sum_{s=1}^{n+2} \mu_r^{n+1} \nu_s^{n+1} A_{rs} \widehat{M}_{\widehat{\boldsymbol{x}}}(\widehat{\boldsymbol{z}}_{rs}^{n+1}) \boldsymbol{Y}_{l,j}^{(\widetilde{k})}(\widehat{\boldsymbol{z}}_{rs}^{n+1}),$$

where

$$A_{rs} = \sum_{l'=0}^{n} \sum_{|j'|\le l} \sum_{k'=1}^{3} \left(\int_{\partial B} \boldsymbol{Y}_{l',j'}^{(k')}(\widehat{\boldsymbol{y}})\, ds(\widehat{\boldsymbol{y}}) \right) \overline{\boldsymbol{Y}_{l',j'}^{(k')}(\widehat{\boldsymbol{z}}_{rs}^{n+1})}^{T}.$$

Only the integrals $(l', j', k') \in \{(0,0,3), (1,\pm 1,1), (1,\pm 1,2)\}$ are nonzero, and they can be easily computed analytically. Proceeding as in [16], we have

$$\boldsymbol{E}_{n,\infty}(\widehat{\boldsymbol{x}}) = \sum_{l=0}^{n} \sum_{|j|\le l} \sum_{\tilde{k}=1}^{3} \mathrm{w}_{lj\tilde{k}} \widehat{\boldsymbol{M}}_{lj\tilde{k}}^{n+1}(\widehat{\boldsymbol{x}}),$$

$$\widehat{\boldsymbol{M}}_{lj\tilde{k}}^{n+1}(\widehat{\boldsymbol{x}}) = \sum_{r=0}^{2n+3} \sum_{s=1}^{n+2} \mu_r^{n+1} \nu_s^{n+1} A_{rs} \widehat{M}_{\widehat{\boldsymbol{x}}}(\widehat{\boldsymbol{z}}_{rs}^{n+1}) \boldsymbol{Y}_{l,j}^{(\tilde{k})}(\widehat{\boldsymbol{z}}_{rs}^{n+1}).$$

The quantities $\widehat{\boldsymbol{M}}_{lj\tilde{k}}^{n+1}$ do not depend on $\boldsymbol{W}_n$ and can be precomputed independently. As in [16, Theorem 3], assuming the conjecture of section 3.2, we can prove that $\boldsymbol{E}_{n,\infty}$ is a spectrally accurate approximation to $\boldsymbol{E}_\infty$.

The approximation σ_n^{dB} to the RCS σ^{dB} is obtained by replacing $\boldsymbol{E}_\infty$ by $\boldsymbol{E}_{n,\infty}$ in (1.2) and (1.7). That is, we compute the spectrally accurate approximation to the RCS of the perfect conductor $D \subseteq \mathbb{R}^3$ using the fully discrete formulas

$$\sigma_n^{\mathrm{dB}}(\widehat{\boldsymbol{x}}; \widehat{\boldsymbol{d}}_0) = 10 \log_{10} \left(4\pi \left| \boldsymbol{E}_{n,\infty}(\widehat{\boldsymbol{x}}) \right|^2 / k^2 \right),$$

$$\sigma_n^{\mathrm{dB}}(\widehat{\boldsymbol{x}}, \widehat{\boldsymbol{p}}_1; \widehat{\boldsymbol{d}}_0) = 10 \log_{10} \left(4\pi \left| \boldsymbol{E}_{n,\infty}(\widehat{\boldsymbol{x}}) \cdot \widehat{\boldsymbol{p}}_1 \right|^2 / k^2 \right), \quad \widehat{\boldsymbol{x}} \in \partial B. \tag{4.5}$$

For each $\widehat{\boldsymbol{x}} \in \partial B$, direct computation of $\boldsymbol{E}_{n,\infty}(\widehat{\boldsymbol{x}})$ has complexity $O(n^4)$ because $\widehat{\boldsymbol{M}}^{n+1}$ has $O(n^2)$ entries, and each entry requires $O(n^2)$ function evaluations to approximate an integral over ∂B. However, $\boldsymbol{E}_{n,\infty}(\widehat{\boldsymbol{x}})$ can be computed in $O(n^3)$ operations by successively computing the quantities below to obtain $\widehat{\boldsymbol{M}}^{n+1}$:

$$\widehat{\boldsymbol{B}}_{sjt}^{n+1}(\widehat{\boldsymbol{x}}) = \sum_{r=0}^{2n+3} \mu_r^{n+1} A_{rs} \widehat{M}_{\widehat{\boldsymbol{x}}}(\widehat{\boldsymbol{z}}_{rs}^{n+1}) e^{ij\phi_r^{n+1}} \boldsymbol{v}^t(\theta_s^{n+1}, \phi_r^{n+1}),$$

$$\widehat{\boldsymbol{M}}_{lj\tilde{k}}^{n+1}(\widehat{\boldsymbol{x}}) = \sum_{s=1}^{n+2} \sum_{t=1}^{3} \nu_s^{n+1} \alpha_{l,j}^{(\tilde{k},t)}(\theta_s^{n+1}) \widehat{\boldsymbol{B}}_{sjt}^{n+1}(\widehat{\boldsymbol{x}}).$$

The computation of $\widehat{\boldsymbol{B}}^{n+1}$ can be accelerated using the FFT. Once $\widehat{\boldsymbol{M}}^{n+1}(\widehat{\boldsymbol{x}})$ has been evaluated, it can be used for computation of the far field induced by many incident directions in the monostatic RCS approximations.

4.2. Spectrally accurate exterior field computations. We compute a fully discrete approximation to the electric field $\boldsymbol{E}(\boldsymbol{x})$ in the exterior region, given by (2.4), using the approach similar to the far field computation in section 4.1, but we replace $\widehat{M}_{\widehat{\boldsymbol{x}}}$ by $\widetilde{M}_{\boldsymbol{x}}$, where

$$\widetilde{M}_{\boldsymbol{x}}(\widehat{\boldsymbol{y}}) \boldsymbol{W}(\widehat{\boldsymbol{y}}) = J(\widehat{\boldsymbol{y}}) \, \mathbf{grad}_{\boldsymbol{x}} \Phi(\boldsymbol{x}, \boldsymbol{q}(\widehat{\boldsymbol{y}})) \times \mathcal{P}(\boldsymbol{q}(\widehat{\boldsymbol{y}})) \boldsymbol{W}(\widehat{\boldsymbol{y}}), \qquad \widehat{\boldsymbol{y}} \in \partial B. \tag{4.6}$$

We have used (2.4) and the identity $\mathbf{curl}\ \{\phi \boldsymbol{v}\} = \phi\ \mathbf{curl}\ \boldsymbol{v} + \mathbf{grad}\, \phi \times \boldsymbol{v}$, to derive $\widetilde{M}_{\boldsymbol{x}}$. The fully discrete approximation $\boldsymbol{E}_n(\boldsymbol{x})$ to $\boldsymbol{E}(\boldsymbol{x})$ for $\boldsymbol{x} \in \mathbb{R}^3 \setminus \overline{D}$ is then

$$\boldsymbol{E}_n(\boldsymbol{x}) = \sum_{l=0}^{n} \sum_{|j|\le l} \sum_{\tilde{k}=1}^{3} \mathrm{w}_{lj\tilde{k}} \widetilde{\boldsymbol{M}}_{lj\tilde{k}}^{n+1}(\boldsymbol{x}),$$

$$\widetilde{\boldsymbol{M}}_{lj\tilde{k}}^{n+1}(\boldsymbol{x}) = \sum_{r=0}^{2n+3} \sum_{s=1}^{n+2} \mu_r^{n+1} \nu_s^{n+1} A_{rs} \widetilde{M}_{\boldsymbol{x}}(\widehat{\boldsymbol{z}}_{rs}^{n+1}) \boldsymbol{Y}_{l,j}^{(\tilde{k})}(\widehat{\boldsymbol{z}}_{rs}^{n+1}).$$

These computations can be accelerated as in section 4.1.

5. Simulated RCS and exterior electromagnetic fields. We consider the RCS simulation problem (1.1)–(1.7) for various test obstacles including the benchmark radar target cone-sphere [30] and a biologically interesting erythrocyte in standard oblate and in oval of Cassini prolate form [19, 31]. For an incident wave with incident polar and azimuthal angles θ and ϕ, the direction of the plane wave is given by $\widehat{\boldsymbol{d}}_0 = -(\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)^T$. The incident wave is then [illegible] when $\widehat{\boldsymbol{p}}_0 = (\cos\theta\cos\phi, \cos\theta\sin\phi, -\sin\theta)^T$ and [illegible] when $\widehat{\boldsymbol{p}}_0 = (-\sin\phi, \cos\phi, 0)^T$ [27, pp. 8–9]. Throughout this section we denote the RCS $\sigma_n^{\mathrm{dB}}(\boldsymbol{p}(\theta,\phi); \widehat{\boldsymbol{d}}_0)$ in (4.5) by $\sigma_n^{\mathrm{dB}}(\theta,\phi)$.

Given the spatial component of an electric field, denoted by $\boldsymbol{E}$, in $\mathbb{R}^3 \setminus \overline{D}$, the corresponding time harmonic electric field is given by

$$\boldsymbol{\mathcal{E}}(\boldsymbol{x}, t) = \frac{1}{\sqrt{\epsilon_0}} \mathrm{Re}\left\{\boldsymbol{E}(\boldsymbol{x}) e^{-2\pi i \omega t}\right\}, \quad \boldsymbol{x} \in \mathbb{R}^3 \setminus \overline{D}.$$

In our numerical experiments we simulate the monostatic and bistatic RCS and exterior electromagnetic fields induced by smooth convex and nonconvex obstacles, and by the cone-sphere, a benchmark radar target that has conical singularities. The smooth obstacles are a sphere, **sph**([illegible]); a beehive shape, **hive**([illegible]); a Cassini shape in prolate form, **cas**([illegible]); an erythrocyte, **eryth**([illegible]); and a submarine shape, **sub**([illegible]). The nonsmooth benchmark radar target is the perfectly conducting cone-sphere, **cone_sphere**([illegible]). Here [illegible] is the diameter of the obstacle. These obstacles are shown in Figures 1–3. The erythrocyte is constructed according to [31, equation (3)]. As described in [19, 31], the biconcave cross section of the erythrocyte has the shape of the Cassini obstacle in two-dimensional form. The cone-sphere is constructed according to [30]. The hull of the submarine is constructed, as in [18], from an ellipsoid with aspect ratio 10:1:1. The cone-sphere and submarine have higher aspect ratios than the other obstacles considered.

For a fixed positive integer n, the linear system we need to solve to achieve the reported accuracy has $3(n+1)^2 - 2$ unknowns in general. For spherical scattering the linear system has $2(n+1)^2 - 2$ unknowns. The maximum n we used in all the experiments is only 125. Thus we are able to present results obtained with both direct and iterative linear system solvers. In the case of iterative solvers, we use GMRES preconditioned with the inverse of the diagonal part of our matrix. For our experiments, we used a cluster with 2GHz Dual-core Opteron (DcOp) processors. DcOp CPU time mentioned in this paper is for the combined set up, GMRES solve, and error calculation phases of the algorithm.

In the case of plane wave scattering by a sphere, an analytical representation of the scattered field is given by the Mie series. For the sphere case our choice of frequency for the incident wave (and hence of the electromagnetic scattering problem) is motivated by those considered in established electromagnetic scattering algorithms Fastscat [5] and FISC [25]. To compare the efficiency of our algorithm with [5, 25], in the tabulated results we use the RMS error (denoted by ϵ_{dB}) in the bistatic RCS, measured in decibels per square meter. The RMS error is defined as

$$\epsilon_{\mathrm{dB}} = \left\{ \frac{1}{4\pi} \int_{\partial B} \left[\sigma^{\mathrm{dB}}(\widehat{\boldsymbol{x}}) - \sigma_n^{\mathrm{dB}}(\widehat{\boldsymbol{x}})\right]^2 ds(\widehat{\boldsymbol{x}}) \right\}^{1/2},$$

where σ^{dB} and σ_n^{dB} are, respectively, defined by (1.2)–(1.7) and (4.5). We numerically approximate the integral in ϵ_{dB} using over 1300 quadrature points on ∂B.

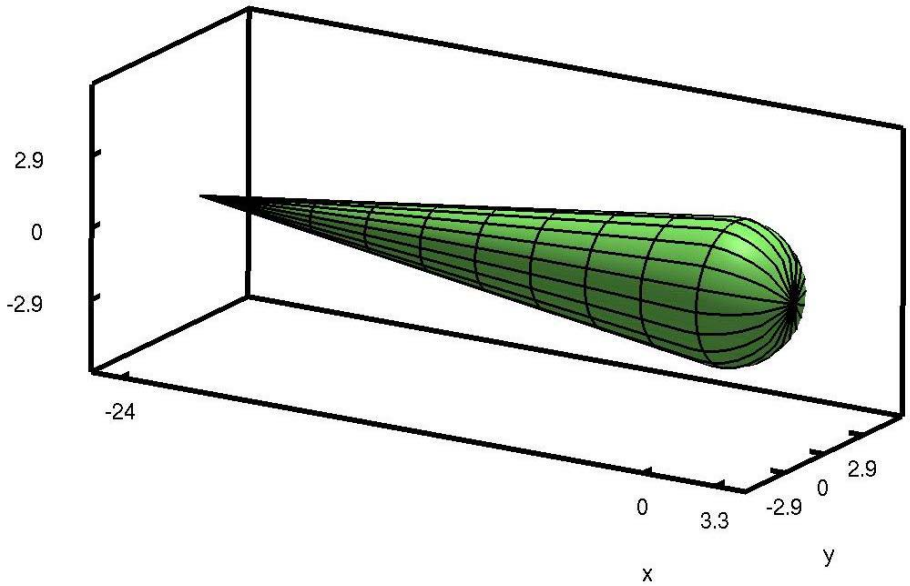

FIG. 1. *Cone-sphere.*

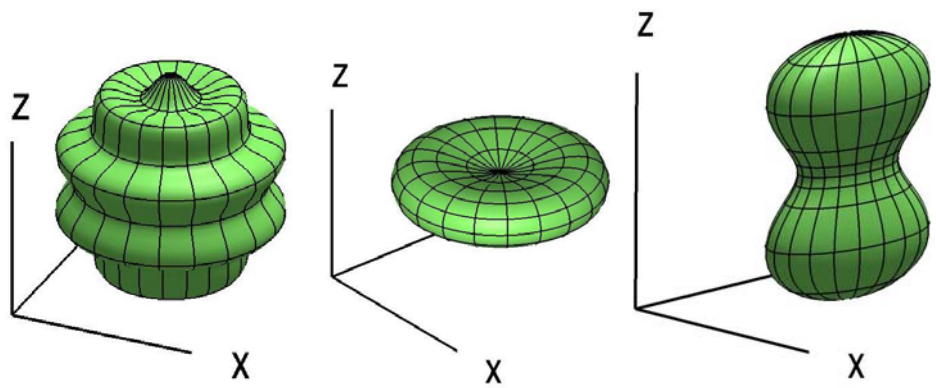

FIG. 2. *Hive, Erythrocyte, and Cassini.*

To demonstrate the spectral convergence of our method for plane wave scattering by nonspherical perfect conductors, we tabulate the monostatic or bistatic RCS at various receiver direction angles. Similar convergence studies for acoustic scattering in two and three dimensions are, respectively, in [8, p. 72] and [12, p. 234].

For the erythrocyte an incident wave with wavelength 632.8 nm (or one tenth the diameter of the erythrocyte) is of considerable recent interest [19, 31]. Hence, for RCS computations of a fixed target, we choose two incident waves: one with wavelength equal to the diameter of the target, and the other with wavelength one tenth the diameter of the target. We observed similar performance for various other targets considered in [16].

The results in Tables 1–15 demonstrate the spectral accuracy of our algorithm.

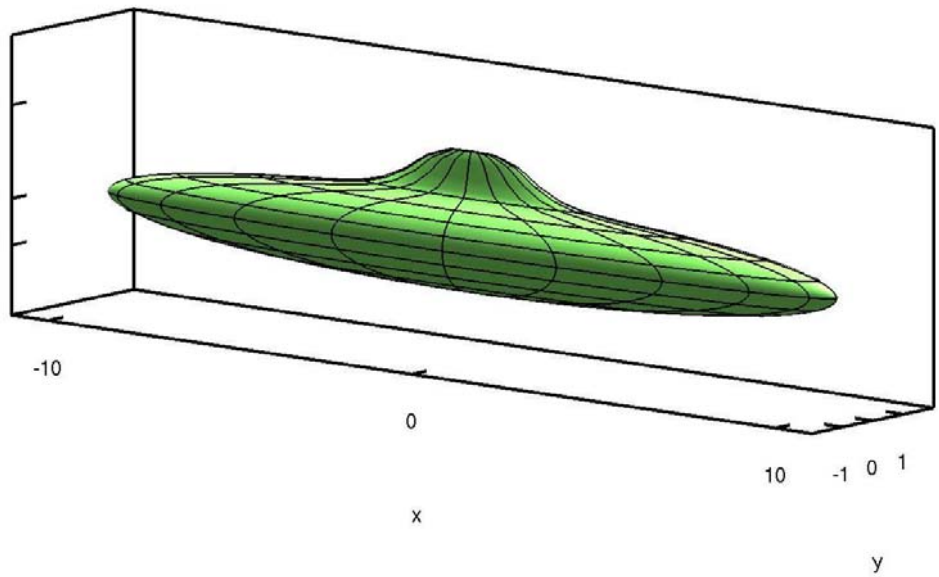

FIG. 3. *Submarine.*

As would be expected, the spherical perfect conductor requires fewer unknowns than the high aspect-ratio and nonconvex obstacles. In general, the number of unknowns depends on the shape and electromagnetic size $\quad /\lambda$ of the conductors, where $\lambda = 2\pi/k = c/\omega$ is the wavelength. The cone-sphere possesses a conical singularity. This nonsmoothness in the object surface precludes spectral accuracy, but our efficient algorithm is able to produce visually accurate results using only a few tens of thousands of unknowns.

We conclude this work by presenting visualizations of RCS values and exterior fields of all the described obstacles simulated using the medium frequency electromagnetic scattering model described in the introduction (see Figures 4–9). The left colorbar values in the figures correspond to the intensity of the surface current. The RCS plots (for all geometries considered in this paper) are given in polar form. For comparison of the experimental and simulated RCS for the cone-sphere benchmark target in [30], we also give the cone-sphere RCS plot in Cartesian form. (All figures in this paper are also at http://www.mines.edu/∼mganesh/ GH_pap2_figures/ GH_RCS_figures.html, to facilitate the viewing of larger pictures.)

A FICTITIOUS DOMAIN METHOD WITH MIXED FINITE ELEMENTS FOR ELASTODYNAMICS*

E. BÉCACHE†, J. RODRÍGUEZ‡, AND C. TSOGKA§

Abstract. We consider in this paper the wave scattering problem by an object with Neumann boundary conditions in an anisotropic elastic body. To obtain an efficient numerical method (permitting the use of regular grids) we follow a fictitious domain approach coupled with a first order velocity stress formulation for elastodynamics. We first observe that the method does not always converge when the $Q_1^{\rm div} - Q_0$ finite element is used. In particular, the method converges for some scattering object geometries but not for others. Note that the convergence of the $Q_1^{\rm div} - Q_0$ finite element method was shown in [E. Bécache, P. Joly, and C. Tsogka, *SIAM J. Numer. Anal.*, 39 (2002), pp. 2109–2132] for the elastodynamic problem in the absence of a scattering object (i.e., without the coupling of the mixed finite elements with the fictitious domain method). Therefore we propose here a modification of the $Q_1^{\rm div} - Q_0$ element following the approach in [E. Bécache, J. Rodríguez, and C. Tsogka, *On the convergence of the fictitious domain method for wave equation problems*, Technical report 5802, INRIA, 2006], where the simpler acoustic case was considered. To study the numerical properties of the new element we carry out a dispersion analysis. Several numerical simulations as well as a numerical convergence analysis show that the proposed method provides a good approximate solution.

Key words. mixed finite elements, fictitious domain method, elastic waves, convergence

1. Introduction.

We consider here the scattering of elastic waves by objects or cracks with a homogeneous Neumann boundary condition. This is of interest in several applications such as ultrasonic nondestructive testing, seismic wave propagation, etc. To develop an efficient numerical method we intend to use a fictitious domain approach. Following this approach, we extend artificially the solution to a fictitious domain with a simple shape, typically a rectangle in 2D. Then the boundary condition on the complex geometry is enforced by introducing an auxiliary unknown that leaves only at the boundary of the object. The key point of the method is that the mesh for the unknowns leaving on the enlarged domain can be chosen independently of the geometry of the object. In particular, one can use regular grids or structured meshes which allows for simple and efficient computations.

The fictitious domain method was initially introduced for stationary problems [3, 30, 24, 18, 20, 27], and it was then successfully generalized to time-dependent problems. In particular, it was used for modeling unsteady incompressible viscous flow with fixed or moving boundaries [25, 21, 22, 23] and in several applications of wave propagation, such as acoustic scattering problems [15, 10, 12], electromagnetic scattering problems [17], and musical acoustics [33, 29, 4]. For both stationary and time-dependent problems the fictitious domain improves the performance of the nu-

merical method in terms of computational time and memory. However, the accuracy of the method is limited by construction due to the lack of regularity of the solution in the extended domain [18].

A main feature of the fictitious domain method is that it can be applied only to essential boundary conditions (i.e., that can be considered as an equality constraint in the functional space). In the case we are interested in, the boundary condition is of the Neumann type for the displacement. To apply the fictitious domain method we have to choose a formulation for which the stress tensor $\boldsymbol{\sigma}$ is included in the unknowns and is sought in a subspace of $(H(\mathrm{div}))^2$: the first order velocity-stress system or the second order stress formulation. In this way the boundary condition becomes of the essential type for $\boldsymbol{\sigma}$. We chose the first order formulation because it can be combined with the perfectly matched absorbing layer model, which is an efficient way of simulating wave propagation in infinite domains [11, 16].

For efficiency reasons we would like to discretize the velocity-stress system with mixed finite elements that are compatible with mass lumping. This will permit us to obtain an explicit in time discretization scheme. To our knowledge this is not so obvious; the main difficulty appearing in this problem is finding a way to take into account the symmetry of the stress tensor. The approach which is usually followed is the relaxed symmetry approach: The symmetry is imposed in a weak sense via the introduction of a Lagrange multiplier [1, 2, 34, 35, 31]. Another approach using spaces of symmetric stress tensors, based on composite elements, was introduced in [28]. None of these, however, are adapted to mass lumping. An answer to this difficulty was proposed in [9], where the $Q_{k+1}^{\mathrm{div}} - Q_k$ finite element has been introduced.

A nonstandard convergence analysis of the $Q_{k+1}^{\mathrm{div}} - Q_k$ elements has been carried out in [7] for their scalar version and in [9] for their elastodynamic vectorial version. However, the convergence analysis presented there deals only with the mixed problem without the scattering object (i.e., without the coupling of the mixed finite elements with the fictitious domain method). Recently, in [10] the authors considered the scalar case and showed through some numerical experiments that this finite element approximation does not always converge when it is coupled with the fictitious domain method. Motivated by this negative result, a new finite element based on the enrichment of the approximation space for the primal unknown (which is the pressure in this case) was introduced. Moreover, in [10] the convergence of this finite element coupled with the fictitious domain method was theoretically proven.

In the present paper we treat the elastodynamic case where the convergence issues are similar to those in the scalar case. Namely, we show through some numerical experiments that the $Q_1^{\mathrm{div}} - Q_0$ element does not always converge when it is coupled with the fictitious domain method (the method converges for some scattering object geometries, while it does not converge for others). Following the same ideas presented in [10] we introduce a modified finite element for the vectorial case, the so-called $Q_1^{\mathrm{div}} - P_1^{disc}$ where we enrich the approximation space for the velocity from Q_0 to P_1 discontinuous functions. This amounts to adding four additional degrees of freedom per element for the velocity and results in introducing spurious modes to the solution. To get rid of this nonphysical part of the solution we propose to attenuate the spurious modes by introducing a damping term in the equations. We study (numerically) the error between the discrete and continuous solutions in terms of the damping parameter (β) and propose a way to determine β in order to minimize this error.

The theoretical convergence of the method is not a straightforward generalization of the one presented in [10] for the scalar case. The main difficulty is due to the lack of regularity of the solution in the extended fictitious domain. However, several

numerical simulations indicate that the method converges, and we conjecture that this is true. The numerical order of convergence obtained for a particular object is in agreement with the conjectured theoretical one.

The outline of the paper is as follows. In section 2 we present the elastodynamic equations and the fictitious domain formulation that we will use in what follows. In section 3.2 we illustrate with numerical experiments that the $Q_1^{\rm div} - Q_0$ element does not always converge. The modified $Q_1^{\rm div} - P_1^{disc}$ element is introduced in section 4 and its dispersion analysis in section 4.3. The proposed method for attenuating the nonphysical part of the solution is then presented in section 4.4, and the difficulties of the theoretical convergence analysis are explained in section 4.2. Numerical results that indicate the convergence of the method are shown in section 4.5. Finally in section 5 we consider a numerical convergence analysis for a particular object.

2. The fictitious domain formulation of the diffraction problem.

2.1. The continuous problem. We consider the diffraction of an elastic wave by a two-dimensional object with a free surface boundary condition (Neumann boundary condition on the velocity field $\mathbf{v}$) on its boundary Γ. The object can be either an obstacle with a closed boundary or a crack with an open boundary (see Figure 2.1), but for the sake of clarity we will consider here only this second configuration. The domain of propagation is denoted by Ω with an exterior boundary Σ (see Figure 2.1), and we assume that $C = \Omega \cup \Gamma$ is a domain of "simple" geometry, typically a rectangle. Under the assumptions of small deformations, wave propagation can be modeled by the velocity-stress formulation of the linear elastodynamic equations (e.g., [9] or [13] for the static case)

$$
\left\{
\begin{array}{rcrcll}
\rho \dfrac{\partial \mathbf{v}}{\partial t} & - & \operatorname{div} \boldsymbol{\sigma} & = & \mathbf{f} & \text{in } \Omega, \quad \text{(a)} \\
\mathbf{A} \dfrac{\partial \boldsymbol{\sigma}}{\partial t} & - & \boldsymbol{\varepsilon}(\mathbf{v}) & = & 0 & \text{in } \Omega, \quad \text{(b)} \\
\boldsymbol{\sigma}\mathbf{n} & & & = & 0 & \text{on } \Gamma, \quad \text{(c)} \\
\mathbf{v} & & & = & 0 & \text{on } \Sigma, \quad \text{(d)}
\end{array}
\right. \tag{2.1}
$$

together with the initial conditions

$$
\mathbf{v}(t=0) = \mathbf{v}_0, \qquad \boldsymbol{\sigma}(t=0) = \boldsymbol{\sigma}_0. \tag{2.2}
$$

In (2.1), the unknowns are the vector $\mathbf{v} \in \mathbb{R}^2$ and the second order symmetric tensor $\boldsymbol{\sigma} \in \mathbb{R}^{2\times 2}$ (i.e., $\boldsymbol{\sigma} = \boldsymbol{\sigma}^t$). These two quantities represent, respectively, the velocity

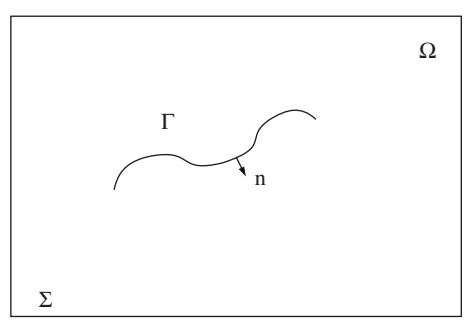

FIG. 2.1. *Geometry of the problem.*

field and the stress tensor. The scalar function ρ and the tensor $\mathbf{A}$ characterize the medium, and the vector field $\mathbf{f}$ represents the external forces. Moreover, we assume that ρ satisfies

$$0 < \rho^- \leq \rho(x) \leq \rho^+ < +\infty,$$

and $\mathbf{A}$ is a fourth order symmetric positive tensor such that

$$0 < \kappa|\boldsymbol{\tau}|^2 \leq \mathbf{A}(x)\boldsymbol{\tau} : \boldsymbol{\tau} \leq \nu|\boldsymbol{\tau}|^2 \quad \forall\ \boldsymbol{\tau} \text{ symmetric}, \quad \boldsymbol{\tau} \neq 0.$$

This formulation is preferred to the classical displacement formulation, because the boundary condition on the crack is natural (of Neumann type) for the displacement while it becomes essential on $\boldsymbol{\sigma}$, and the fictitious domain approach can then be followed.

We also assume that the support of the initial data $(\mathbf{v}_0, \boldsymbol{\sigma}_0)$ and the support of the source $\mathbf{f}$ do not intersect Γ, which means that

$$\text{supp}(\mathbf{v}_0) \cup \text{supp}(\boldsymbol{\sigma}_0) \subset C \setminus \Gamma, \quad \bigcup_{t \leq T} \text{supp}(\mathbf{f}(t)) \subset C \setminus \Gamma. \tag{2.3}$$

The classical variational formulation of (2.1) would be set in some functional spaces that depend on the shape of the obstacle (i.e., depend on Ω). More precisely, the classical formulation is

$$\left\{ \begin{array}{l} \text{Find } (\mathbf{v}(t), \boldsymbol{\sigma}(t)) \in \underline{\underline{X}}_0^{sym} \times \underline{M} \text{ satisfying} \\ \dfrac{\mathrm{d}}{\mathrm{d}t}\displaystyle\int_\Omega \mathbf{A}\boldsymbol{\sigma} : \boldsymbol{\tau}\mathrm{d}x + \int_\Omega \mathrm{div}\boldsymbol{\tau} \cdot \mathbf{v}\mathrm{d}x = 0 \qquad \forall\ \boldsymbol{\tau} \in \underline{\underline{X}}_0^{sym}, \\ \dfrac{\mathrm{d}}{\mathrm{d}t}\displaystyle\int_\Omega \rho\ \mathbf{v} \cdot \mathbf{w}\mathrm{d}x - \int_\Omega \mathrm{div}\boldsymbol{\sigma} \cdot \mathbf{w}\mathrm{d}x = \int_\Omega \mathbf{f} \cdot \mathbf{w}\mathrm{d}x \quad \forall\ \mathbf{w} \in \underline{M}, \\ (\boldsymbol{\sigma}, \mathbf{v})_{t=0} = (\boldsymbol{\sigma}_0, \mathbf{v}_0), \end{array} \right. \tag{2.4}$$

where the functional spaces are defined as

$$\begin{array}{l} \underline{X} = H(\mathrm{div}; \Omega), \quad \underline{\underline{X}} = \underline{X} \times \underline{X}, \quad \underline{\underline{X}}^{sym} = \left\{ \boldsymbol{\tau} \in \underline{\underline{X}} : \boldsymbol{\tau} \text{ is symmetric} \right\}, \\ \underline{\underline{X}}_0^{sym} = \left\{ \boldsymbol{\tau} \in \underline{\underline{X}}^{sym} : \boldsymbol{\tau}\ \mathbf{n} = 0 \text{ on } \Gamma \right\}, \quad M = L^2(\Omega), \quad \underline{M} = M \times M. \end{array} \tag{2.5}$$

The well-posedness of the problem (2.4) results from the classical theory on hyperbolic PDEs.

THEOREM 2.1. [illegible] $\mathbf{f} \in C^0([0,T], \underline{M})$ $\boldsymbol{\sigma}_0 \in \underline{\underline{X}}_0^{sym}(\Omega)$ $\mathbf{v}_0 \in \underline{M}$ [illegible] (2.3) [illegible] (2.4) [illegible] $(\boldsymbol{\sigma}, \mathbf{v}) \in (C^1([0,T], (L^2(\Omega))^{2\times 2}) \cap C^0([0,T], \underline{\underline{X}}_0^{sym}(\Omega))) \times C^1([0,T], \underline{M})$

The fictitious domain formulation of this problem consists in taking into account the boundary condition on Γ in a weak way, by introducing a Lagrange multiplier $\boldsymbol{\lambda}$ defined on Γ. This allows for working in functional spaces (for the volume unknowns) which do not depend any more on the shape of the obstacle. The fictitious domain formulation is then the following (to simplify the notations, we will denote by

$(\boldsymbol{\sigma}(t), \mathbf{v}(t))$ the new unknowns defined now in C):

$$
\text{(2.6)}\quad \begin{cases} \text{Find } (\boldsymbol{\sigma}(t), \mathbf{v}(t), \boldsymbol{\lambda}(t)) \in \underline{\underline{X}}^{sym} \times \underline{M} \times \underline{\mathcal{G}} \text{ satisfying} \\ \dfrac{\mathrm{d}}{\mathrm{d}t} a(\boldsymbol{\sigma}, \boldsymbol{\tau}) + b(\boldsymbol{\tau}, \mathbf{v}) - \langle \boldsymbol{\tau}\ \mathbf{n}, \boldsymbol{\lambda} \rangle_\Gamma = 0 \quad \forall\ \boldsymbol{\tau} \in \underline{\underline{X}}^{sym}, \\ \dfrac{\mathrm{d}}{\mathrm{d}t} (\mathbf{v}, \mathbf{w})_\rho - b(\boldsymbol{\sigma}, \mathbf{w}) = (\mathbf{f}, \mathbf{w}) \quad \forall\ \mathbf{w} \in \underline{M}, \\ \langle \boldsymbol{\sigma}\ \mathbf{n}, \boldsymbol{\mu} \rangle_\Gamma = 0 \quad \forall\ \boldsymbol{\mu} \in \underline{\mathcal{G}}, \\ (\boldsymbol{\sigma}, \mathbf{v})_{t=0} = (\boldsymbol{\sigma}_0, \mathbf{v}_0), \end{cases}
$$

where the functional spaces are now defined as

$$
\text{(2.7)}\quad \begin{aligned} &\underline{X} = H(\mathrm{div}; C), \quad \underline{\underline{X}} = \underline{X} \times \underline{X}, \quad \underline{\underline{X}}^{sym} = \left\{ \boldsymbol{\tau} \in \underline{\underline{X}} : \boldsymbol{\tau} \text{ is symmetric} \right\}, \\ &M = L^2(C), \quad \underline{M} = M \times M, \quad \mathcal{G} = H_{00}^{1/2}(\Gamma), \quad \underline{\mathcal{G}} = \mathcal{G} \times \mathcal{G}, \end{aligned}
$$

the bilinear forms as

$$
\text{(2.8)}\quad \begin{cases} a(\boldsymbol{\sigma}, \boldsymbol{\tau}) = \displaystyle\int_C \mathbf{A}\boldsymbol{\sigma} : \boldsymbol{\tau} \mathrm{d}x & \forall (\boldsymbol{\sigma}, \boldsymbol{\tau}) \in \underline{\underline{X}} \times \underline{\underline{X}}, \\ (\mathbf{v}, \mathbf{w})_\eta = \displaystyle\int_C \eta\ \mathbf{v} \cdot \mathbf{w} \mathrm{d}x & \forall (\mathbf{v}, \mathbf{w}) \in \underline{M} \times \underline{M}, \\ b(\boldsymbol{\tau}, \mathbf{w}) = \displaystyle\int_C \mathrm{div}(\boldsymbol{\tau}) \cdot \mathbf{w} \mathrm{d}x & \forall \underline{\underline{X}} \times \underline{M}, \end{cases}
$$

and the bracket $\langle \boldsymbol{\sigma}\ \mathbf{n}, \boldsymbol{\mu} \rangle_\Gamma$ is the duality product between $\underline{\mathcal{G}}$ and $\underline{\mathcal{G}}'$. Note that, due to assumption (2.3), the data also belong to

$$
\mathbf{f} \in C^0([0,T], \underline{M}), \quad \boldsymbol{\sigma}_0 \in \underline{\underline{X}}(C), \quad \mathbf{v}_0 \in \underline{M}.
$$

In the following we will denote by $(\cdot,\cdot) := (\cdot,\cdot)_1$ the usual $L^2(C)$ scalar product.

. . . . 1 (on the regularity of the solution). For regular data, one can expect more regularity on the solution. However, in general, the space regularity of the solution is at most

$$
\boldsymbol{\sigma}(t) \in (H^{\frac{1}{2}-\varepsilon}(\mathrm{div}, C))^2, \quad \mathbf{v}(t) \in (H^{\frac{1}{2}-\varepsilon}(C))^2, \qquad \varepsilon > 0,
$$

and this is obtained for regular enough data and a regular geometry of the crack. This is due to the fact that the unknowns are defined on the whole domain C without considering the geometry of the obstacle, so that $\mathbf{v}$ has now a jump in C.

The regularity in Ω (i.e., outside the obstacle) is, in general, higher and depends on the geometry of the obstacle. In particular, for data $(\boldsymbol{\sigma}_0, \mathbf{v}_0, \mathbf{f})$ satisfying (2.3), we have

- for a closed boundary

$$
\mathbf{v}_{/\Omega}(t) \in (H^2(\Omega))^2, \quad \boldsymbol{\lambda}(t) \in (H^{3/2}(\Gamma))^2;
$$

- for an open boundary, due to the singular behavior near the tip of the crack [26] (the solution behaves as $\sqrt{r}$, r being here the distance to the tip), we have

$$
\mathbf{v}_{|\Omega}(t) \in (H^{3/2-\varepsilon}(\Omega))^2, \quad \boldsymbol{\lambda}(t) \in (H^{1-\varepsilon}(\Gamma))^2, \qquad \varepsilon > 0.
$$

2.2. The semidiscrete approximation. For the approximation in space of this problem, we introduce finite dimensional spaces $\underline{\underline{X_h}}^{sym} \subset \underline{\underline{X}}^{sym}$, $\underline{M}_h \subset \underline{M}$, and $\underline{\mathcal{G}}_H \subset \underline{\mathcal{G}}$ satisfying the approximation properties

$$\left|\begin{array}{lcll} \lim\limits_{h\to 0} \inf\limits_{\boldsymbol{\tau}_h \in \underline{\underline{X_h}}} \|\boldsymbol{\sigma} - \boldsymbol{\tau}_h\|_{\underline{\underline{X}}} & = & 0 & \forall \boldsymbol{\sigma} \in \underline{\underline{X}}, \\ \lim\limits_{h\to 0} \inf\limits_{\mathbf{w}_h \in \underline{M}_h} \|\mathbf{v} - \mathbf{w}_h\|_{\underline{M}} & = & 0 & \forall \mathbf{v} \in \underline{M}, \\ \lim\limits_{H\to 0} \inf\limits_{\boldsymbol{\mu}_H \in \underline{\mathcal{G}}_H} \|\boldsymbol{\lambda} - \boldsymbol{\mu}_H\|_{\underline{\mathcal{G}}} & = & 0 & \forall \boldsymbol{\lambda} \in \underline{\mathcal{G}}. \end{array}\right. \tag{2.9}$$

The semidiscrete problem is then

(2.10)

$$\left\{\begin{array}{l} \text{Find } (\boldsymbol{\sigma}_h(t), \mathbf{v}_h(t), \boldsymbol{\lambda}_H(t)) \in \underline{\underline{X}}_h^{sym} \times \underline{M}_h \times \underline{\mathcal{G}}_H \text{ satisfying} \\ \dfrac{\mathrm{d}}{\mathrm{d}t} a(\boldsymbol{\sigma}_h, \boldsymbol{\tau}_h) + b(\boldsymbol{\tau}_h, \mathbf{v}_h) - \langle \boldsymbol{\tau}_h\, \mathbf{n}, \boldsymbol{\lambda}_H \rangle_\Gamma = 0 \quad \forall\, \boldsymbol{\tau}_h \in \underline{\underline{X}}_h^{sym}, \\ \dfrac{\mathrm{d}}{\mathrm{d}t} (\mathbf{v}_h, \mathbf{w}_h)_\rho - b(\boldsymbol{\sigma}_h, \mathbf{w}_h) = (\mathbf{f}, \mathbf{w}_h) \quad \forall\, \mathbf{w}_h \in \underline{M}_h, \\ \langle \boldsymbol{\sigma}_h\, \mathbf{n}, \boldsymbol{\mu}_H \rangle_\Gamma = 0 \quad \forall\, \boldsymbol{\mu}_h \in \underline{\mathcal{G}}_H, \\ (\boldsymbol{\sigma}_h, \mathbf{v}_h)_{t=0} = (\boldsymbol{\sigma}_{h,0}, \mathbf{v}_{h,0}), \end{array}\right.$$

where $(\boldsymbol{\sigma}_{h,0}, \mathbf{v}_{h,0}) \in \underline{\underline{X}}_h \times \underline{M}_h$ is an approximation of the exact initial condition.

Now the question is how we can choose the approximate spaces in order to ensure the convergence of $(\boldsymbol{\sigma}_h, \mathbf{v}_h, \boldsymbol{\lambda}_H)$ to $(\boldsymbol{\sigma}, \mathbf{v}, \boldsymbol{\lambda})$.

3. The fictitious domain method using the $\mathcal{Q}_1^{\mathrm{div}} - \mathcal{Q}_0$ element.

3.1. Position of the problem. For the volume unknowns, we introduce a regular mesh $\mathcal{T}_h$ of the rectangular domain C composed of square elements of length h. In [5], the authors introduced for the problem without obstacle new mixed finite elements, the so-called $\mathcal{Q}_{k+1}^{\mathrm{div}} - \mathcal{Q}_k$ elements, inspired by Nédélec's second family [32]. These elements, which are a generalization to elastodynamics of those presented in [6] for the scalar case, are compatible with mass lumping and therefore allow for constructing explicit schemes in time. A nonstandard convergence analysis of these $\mathcal{Q}_{k+1}^{\mathrm{div}} - \mathcal{Q}_k$ elements has been carried out, showing the convergence without the fictitious domain method. Our first choice for the approximation spaces of the problem with an obstacle was naturally the lowest order element $\mathcal{Q}_1^{\mathrm{div}} - \mathcal{Q}_0$ for the stress tensor and the velocity field

$$\left\{\begin{array}{l} \underline{\underline{X}}_h^{sym} = \left\{ \boldsymbol{\tau}_h \in \underline{\underline{X}}^{sym} \;/\; \forall\, K \in \mathcal{T}_h, \tau_{h|K} \in (\mathcal{Q}_1 \times \mathcal{Q}_1)^2 \right\}, \\ \underline{M}_h = \underline{M}_h^0 = \left\{ \mathbf{w}_h \in \underline{M} \;/\; \mathbf{w}_{h\,K} \in (Q_0)^2 \right\}. \end{array}\right. \tag{3.1}$$

We point out that due to the symmetry of the stress tensor, another characterization of $\underline{\underline{X}}_h^{sym}$ is

$$\left\{\begin{array}{l} \underline{\underline{X}}_h^{sym} = \Big\{ \boldsymbol{\tau}_{1,2} \in H^1(C) \;/\; \boldsymbol{\tau}_{1,2|K} \in Q_1 \;\forall\, K \in \mathcal{T}_h \text{ and} \\ \qquad\qquad (\boldsymbol{\tau}_{1,1}, \boldsymbol{\tau}_{2,2}) \in H(\mathrm{div}, C) / (\boldsymbol{\tau}_{1,1}, \boldsymbol{\tau}_{2,2})_{|K} \in (Q_1)^2 \;\forall\, K \in \mathcal{T}_h \Big\}. \end{array}\right. \tag{3.2}$$

The degrees of freedom of the lowest order element are illustrated in Figure 3.1. We recall here the approximation properties for the space $\underline{\underline{X_h}}^{sym}$. Let $\tau \in \underline{\underline{X}}^{sym}$ with

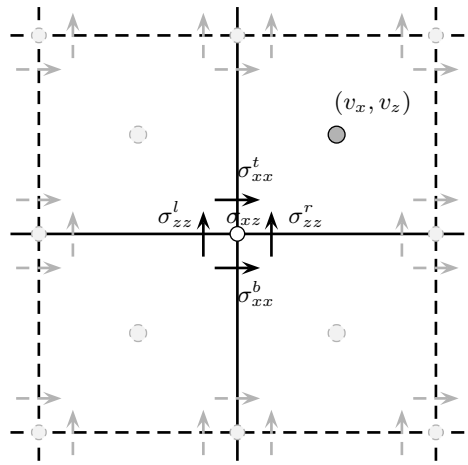

FIG. 3.1. *Degrees of freedom for the mixed finite element defined by* (3.1).

$(\tau_{11}, \tau_{22}) \in H^{1,0} \times H^{0,1}$ (see [9] for the definition of these spaces) and $\tau_{12} = \tau_{21} \in H^1$; then

$$\lim_{h \to 0} \inf_{\boldsymbol{\tau}_h \in \underline{\underline{X_h}}^{sym}} \|\boldsymbol{\tau} - \boldsymbol{\tau}_h\|_{\underline{\underline{X}}} = 0.$$

Moreover, if $(\tau_{11}, \tau_{22}) \in H^{2,1} \times H^{1,2}$ and $\tau_{12} \in H^2$, then

$$\inf_{\boldsymbol{\tau}_h \in \underline{\underline{X_h}}^{sym}} \|\boldsymbol{\tau} - \boldsymbol{\tau}_h\|_{\underline{\underline{X}}} \leq Ch(|\tau_{11}|_{H^{2,1}} + |\tau_{22}|_{H^{1,2}} + |\tau_{12}|_{H^2}). \tag{3.3}$$

For the approximation of the Lagrange multiplier, we introduce a mesh of Γ composed by N curvilinear segments S_j of length H_j, and we set $H = \sup_j H_j$. We assume that this mesh is uniformly regular

$$\exists\, \nu, 0 < \nu \leq 1 \text{ such that: } \forall\ j, 1 \leq j \leq N,\ H_j \geq \nu H. \tag{3.4}$$

We then choose the space of continuous linear piecewise functions:

$$\underline{\mathcal{G}}_H = \left\{ \nu_h \in \underline{\mathcal{G}} \ / \ \forall S_j, j = 1, \ldots, N \ ; \ \nu_{H|S_j} \in (P_1)^2 \right\}. \tag{3.5}$$

The spaces $(\underline{\underline{X}}_h, \underline{M}^0_h, \underline{\mathcal{G}}_H)$ clearly satisfy the approximation properties (2.9).

This choice which seemed to us natural, since the convergence was proven without obstacle, is the one that was used in [8]. However, we have not been able to prove the convergence of the fictitious domain method with these spaces.

The convergence analysis of the fictitious domain method applied to other problems [3, 18, 29] shows that convergence holds if a compatibility condition between the step sizes of the two meshes is satisfied,

$$H \geq \alpha h. \tag{3.6}$$

We will show in what follows some numerical illustrations which seem to indicate that for some special configurations of obstacles, the method does not converge.

Before showing these numerical results, let us briefly recall the main difficulty of the convergence analysis in the case without an object. Introducing the linear

operators

$$\begin{array}{lccccccc} B: & \underline{\underline{X}} & \longrightarrow & \underline{M}' & & & & \\ & \boldsymbol{\sigma} & \mapsto & B(\boldsymbol{\sigma}): & \underline{M} & \longrightarrow & \mathbb{R} \\ & & & & \mathbf{w} & \mapsto & \langle B(\boldsymbol{\sigma}), \mathbf{w}\rangle = b(\boldsymbol{\sigma}, \mathbf{w}), \\ B_h: & \underline{\underline{X}}_h & \longrightarrow & \underline{M}_h' & & & & \\ & \boldsymbol{\sigma}_h & \mapsto & B_h(\boldsymbol{\sigma}_h): & \underline{M}_h & \longrightarrow & \mathbb{R} \\ & & & & \mathbf{w}_h & \mapsto & \langle B_h(\boldsymbol{\sigma}_h), \mathbf{w}_h\rangle = b(\boldsymbol{\sigma}_h, \mathbf{w}_h), \end{array}$$

it is easy to verify that the inclusion

$$\mathrm{Ker}(B_h) \subset \mathrm{Ker}(B) \tag{3.7}$$

is not satisfied and that furthermore the bilinear form $a(.,.)$ is not coercive on $\mathrm{Ker}(B_h)$ (even if it is on $\mathrm{Ker}(B)$), so that our problem does not fit the classical mixed finite element theory (cf. [13, 19]). It was, however, possible to overcome this difficulty when dealing with the problem without the fictitious domain method. When coupled with the fictitious domain method, the same technique cannot be applied.

3.2. Numerical illustrations. We present in what follows some numerical results that illustrate the difficulties related to the convergence of the method that we discussed in the previous section.

The computational domain is the square $[0, 10] \times [0, 10]$ mm^2 composed by a homogeneous isotropic material with density and Lamé coefficients given by

$$\rho = 1000 \text{ Kgr/m}^3, \quad \lambda = 3.45 \times 10^9 \text{ Pa}, \quad \mu = 2.04 \times 10^9 \text{ Pa}. \tag{3.8}$$

We introduce an initial condition on the velocity field centered on $(x_c, z_c) = (5, 5)$ mm,

$$\mathbf{v}((x, z), t = 0) = 0.1 \; F\left(\frac{r}{r_0}\right) \frac{\mathbf{r}}{r},$$

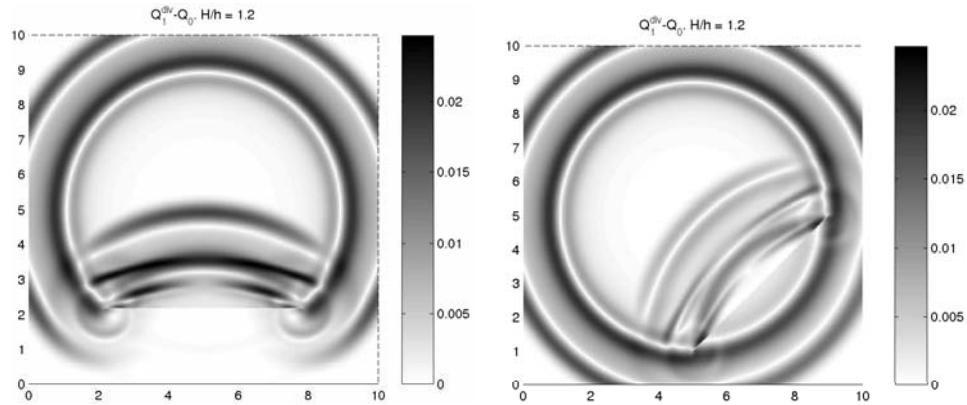
where $F(r)$ is supported in $[0, 1]$ and given by (for $r \in [0, 1]$)

$$F(r) = A_0 - A_1 \cos(2\pi r) + A_2 \cos(3\pi r) - A_3 \cos(6\pi r),$$

with $\mathbf{r} = (x - x_c, z - z_c)^t$, $r = \|\mathbf{r}\|$, $r_0 = 1.5$ mm, and

$$A_0 = 0.35875, \quad A_1 = 0.48829, \quad A_2 = 0.14128, \quad A_3 = 0.01168.$$

We consider a uniform mesh of squares using a discretization step $h = 0.025$ mm. The time discretization is done using a leapfrog scheme with the time step Δt chosen in such a way that the ratio $\Delta t/h$ is equal to the maximal value that ensures the stability. Perfectly matched layers [11, 16] are used to simulate a nonbounded domain in all of the boundaries.



(a) $t = 1.7310\ \mu$s (b) $t = 1.7310\ \mu$s

FIG. 3.2. $Q_1^{\rm div} - Q_0$. *Isotropic medium. Modulus of the velocity field.* $H/h = 1.2$.

In the first experiment we consider a plane horizontal crack

$$(x, z) = (5 + 2\sqrt{2}(2t - 1), 5 - 2\sqrt{2}) \text{ mm}, \qquad t \in [0, 1], \tag{3.9}$$

that we discretize using a uniform mesh of step $H = Rh$. The method converges, and we obtain good results for reasonable values for the parameter R (in the interval $[0.75, 3]$). In Figure 3.2(a) we show a snapshot of the modulus of the velocity field for $R = 1.2$. We can see the incident pressure wave that has reached the boundary of the computational domain, the reflected waves, and the scattered waves created by the two tips of the crack.

In the second experiment we treat a plane diagonal defect given by

$$(x, z) = (5 + 4t, 1 + 4t) \text{ mm}, \qquad t \in [0, 1], \tag{3.10}$$

that is, the same obstacle considered in the previous paragraph rotated by $\pi/4$ radians with respect to (x_c, z_c), the center of the initial condition. We point out that the initial condition satisfies

$$v((x, z), t = 0) \;=\; Q\; v((\tilde{x}, \tilde{z}), t = 0),$$

with

$$(\tilde{x}, \tilde{z})^t \;=\; Q^t\; (x, z)^t \;+\; (x_c, z_c)^t, \qquad Q \;=\; \begin{pmatrix} \cos(\frac{\pi}{4}) & \sin(\frac{\pi}{4}) \\ -\sin(\frac{\pi}{4}) & \cos(\frac{\pi}{4}) \end{pmatrix}.$$

As the domain is isotropic, the velocity field obtained with the diagonal crack, denoted by $\mathbf{v}_{diag}$, and the one obtained with the horizontal one, denoted by $\mathbf{v}_{hor}$, satisfy

$$\mathbf{v}_{hor}(x, z) \;=\; Q\; \mathbf{v}_{diag}(\tilde{x}, \tilde{z}) \quad \text{and} \quad |\mathbf{v}_{hor}|(x, z) \;=\; |\mathbf{v}_{diag}|(\tilde{x}, \tilde{z}).$$

In the same way as in the horizontal case, we discretize the Lagrange multiplier using a uniform grid of step $H = Rh$, with several values for the parameter R. However, this time, the approximated solution does not seem to converge towards the physical solution (see, for instance, Figure 3.2(b) for $R = 1.2$). The incident wave is not completely reflected but also transmitted through the interface. The scattered waves created by the tips of the crack are also poorly approximated.

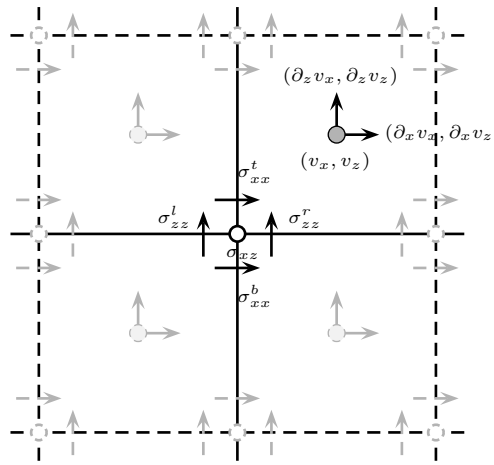


FIG. 4.1. *Degrees of freedom of the modified mixed finite element* $Q_1^{\mathrm{div}} \times P_1^{disc}$.

4. The modified element $Q_1^{\mathrm{div}} - P_1^{disc}$.

4.1. Presentation of the modified element. As explained in section 3.1, one of the difficulties of the convergence analysis of the $Q_1^{\mathrm{div}} \times P_1^{disc}$, even in the absence of an obstacle, was the fact that inclusion (3.7) is not satisfied. In order to avoid this problem, and following the same ideas the authors introduced in [10], we propose to modify the space M_h in such a way that

$$\mathrm{div}\left(\underline{\underline{X}}_h^{sym}\right) \subset \underline{M}_h, \tag{4.1}$$

which easily implies (3.7) and could get rid of the lack of convergence observed in section 3.2 and simplify the analysis. That is why we have chosen to discretize the pressure in the space

$$\underline{M}_h = \underline{M}_h^1 \quad \text{with} \quad \underline{M}_h^1 = \left\{ \mathbf{w}_h \in \underline{M} \ / \ \forall\ K \in \mathcal{T}_h,\ \mathbf{w}_{h|K} \in (P_1(K))^2 \right\}.$$

With this enrichment of the approximation space, we will have six degrees of freedom per element on the unknown $\mathbf{v}_h$ as shown in Figure 4.1. Since $\underline{M}_h^0 \subset \underline{M}_h^1$ we have obviously

$$\inf_{\mathbf{w}_h \in \underline{M}_h} \|\mathbf{v} - \mathbf{w}_h\|_\rho \ \leq \ \inf_{\mathbf{w}_h^0 \in \underline{M}_h^0} \|\mathbf{v} - \mathbf{w}_h^0\|_\rho,$$

and, in consequence, the approximation properties (2.9) are still satisfied.

REMARK 2. Assuming (4.1) and that the density is constant on each element, we have that

$$\boldsymbol{\tau}_h \in \underline{\underline{X}}_h \Longrightarrow \mathbf{w}_h := \frac{1}{\rho}\mathrm{div}(\boldsymbol{\tau}_h) \in \underline{M}_h.$$

Introducing this particular test function in the second equation of (2.10), we obtain

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_C \mathbf{v}_h \cdot \mathrm{div}(\boldsymbol{\tau}_h) - \int_C \frac{1}{\rho}\mathrm{div}(\boldsymbol{\sigma}_h) \cdot \mathrm{div}(\boldsymbol{\tau}_h) = \int_C \frac{1}{\rho}\ \mathbf{f}\ \cdot \mathrm{div}(\boldsymbol{\tau}_h).$$

Deriving with respect to time the first and third equations of (2.10) and using the last expression, we deduce that our variational formulation implies the following second order formulation:

$$\begin{cases} \text{Find } (\boldsymbol{\sigma}_h(t), \tilde{\boldsymbol{\lambda}}_H(t)) \in \underline{\underline{X}}_h \times \underline{\mathcal{G}}_H \text{ such that } \ \forall \ \ (\boldsymbol{\tau}_h, \boldsymbol{\mu}_H) \in \underline{\underline{X}}_h \times \underline{\mathcal{G}}_H, \\ \dfrac{\mathrm{d}^2}{\mathrm{d}t^2} \displaystyle\int_C \mathbf{A}\boldsymbol{\sigma}_h : \boldsymbol{\tau}_h + \int_C \frac{1}{\rho}\mathrm{div}(\boldsymbol{\tau}_h) \cdot \mathrm{div}(\boldsymbol{\sigma}_h) - \int_\Gamma \boldsymbol{\tau}_h \mathbf{n} \ \cdot \tilde{\boldsymbol{\lambda}}_H = \int_C -\frac{1}{\rho} f \cdot \mathrm{div}(\boldsymbol{\tau}_h), \\ \displaystyle\int_\Gamma \boldsymbol{\sigma}_h \mathbf{n} \ \cdot \boldsymbol{\mu}_H = 0, \\ \boldsymbol{\sigma}_h(t=0) = \boldsymbol{\sigma}_{h,0}, \qquad \dfrac{\partial \boldsymbol{\sigma}_h}{\partial t}(t=0) = \mathbf{C}\ \varepsilon(\mathbf{v}_{h,0}), \end{cases}$$

where $\tilde{\boldsymbol{\lambda}}_H = \dfrac{\partial \boldsymbol{\lambda}_H}{\partial t}$. The nature of this problem is close to the ones analyzed in [18, 29].

4.2. Some comments about the convergence of the modified element. From the numerical point of view we observe that the method converges under a compatibility condition of the form (3.6) between the two meshes. In section 4.5, repeating the numerical experiment of section 3.2 using the $Q_1^{\mathrm{div}} \times P_1^{disc}$ element, we observe that the results are similar regardless of the orientation of the crack, concluding that the method converges. In section 5 we compute numerically the order of convergence of the new method for a particular case.

From the theoretical point of view the convergence proof in this case is not a straightforward generalization of the result obtained in [10] for the scalar case. The main difficulty comes from the nonstandard regularity required to obtain the approximation properties for $\underline{\underline{X}}_h^{sym}$ (see (3.3)). Indeed, the maximal regularity (in space) of the stress tensor in the case of a domain with a crack is $\boldsymbol{\sigma} \in (H^{\frac{1}{2}-\varepsilon}(\mathrm{div}, C))^2$, and $\boldsymbol{\sigma}$ is symmetric. This regularity is not sufficient to obtain (3.3), and thus we cannot conclude (see [10] for more details on the differences with the scalar case). However, guided by the results obtained for the scalar case, we conjecture the following result.

CONJECTURE 4.1. [illegible] $\mathbf{f} \in C^0([0,T], \underline{M})$ $\boldsymbol{\sigma}_0 \in \underline{\underline{X}}^{sym}$ $\mathbf{v}_0 \in \underline{M}$ [illegible] (2.3) $(\boldsymbol{\sigma}, \mathbf{v}, \boldsymbol{\lambda})$ [illegible] (2.6). [illegible] $(\boldsymbol{\sigma}_h, \mathbf{v}_h, \boldsymbol{\lambda}_H)$ [illegible] (2.10) [illegible] $(\boldsymbol{\sigma}_{h,0}, \mathbf{v}_{h,0})$ [illegible] $(\boldsymbol{\sigma}_0, \mathbf{v}_0)$ [illegible] (3.6). [illegible] $(\boldsymbol{\sigma}, \mathbf{v}, \boldsymbol{\lambda}) \in C^2\big([0,T], (H^{\frac{1}{2}-\varepsilon}(\mathrm{div}, C))^2 \times (H^{\frac{1}{2}-\varepsilon}(C))^2 \times (H^{1-\varepsilon}(\Gamma))^2\big)$

$$\begin{aligned} &\|\boldsymbol{\sigma}_h - \boldsymbol{\sigma}\|_{C^0([0,T];\underline{\underline{X}}^{sym})} \ + \ \|\mathbf{v}_h - \mathbf{v}\|_{C^0([0,T];\underline{M})} \ + \ \|\boldsymbol{\lambda}_H - \boldsymbol{\lambda}\|_{C^0([0,T];\underline{\mathcal{G}})} \ \leq \\ &\mathcal{C}\left(h^{\frac{1}{2}-\varepsilon} + H^{\frac{1}{2}-\varepsilon}\right)(1+T)\left(\|\boldsymbol{\sigma}\|_{C^2([0,T];(H^{\frac{1}{2}-\varepsilon}(\mathrm{div},C))^2)} \ + \right. \\ &\left. \|\mathbf{v}\|_{C^2([0,T];(H^{\frac{1}{2}-\varepsilon}(C))^2)} \ + \ \|\boldsymbol{\lambda}\|_{C^2([0,T];(H^{1-\varepsilon}(\Gamma))^2)}\right). \end{aligned} \tag{4.2}$$

The numerical results obtained in section 5 confirm this result.

4.3. Dispersion analysis of the modified element. It is useful and classical to perform a dispersion analysis in order to specify the properties of a discrete scheme (in the absence of an obstacle) (e.g., [36, 14]). This consists in studying the behavior of discrete plane waves propagated with the scheme. We will show that four spurious modes that contaminate the discrete solution appear, for the modified element, because four new degrees of freedom per element were added to the velocity field.

Assume that our computational domain $\Omega = \mathbb{R}^2$ is homogeneous and that we use a uniform mesh composed by squares of edge h. In this way, the degrees of freedom of the stress tensor are placed at the vertices of the squares, that is, at the points $(x_i, z_j) = (ih, jh)$. We thus have

$$(\sigma^t_{x,x})_{i,j}, \qquad (\sigma^b_{x,x})_{i,j}, \qquad (\sigma^r_{z,z})_{i,j}, \qquad (\sigma^l_{z,z})_{i,j}, \qquad (\sigma_{x,z})_{i,j}, \qquad (i,j) \in \mathbb{Z} \times \mathbb{Z}.$$

The degrees of freedom for the velocity field are defined at the center of each element, that is, at the points $(x_{i+\frac{1}{2}}, z_{j+\frac{1}{2}}) = ((i+1/2)h, (j+1/2)h)$. The corresponding unknowns are denoted by

$$\begin{array}{llll} (v_x)_{i+\frac{1}{2},j+\frac{1}{2}}, & (\partial_x v_x)_{i+\frac{1}{2},j+\frac{1}{2}}, & (\partial_z v_x)_{i+\frac{1}{2},j+\frac{1}{2}}, & (i,j) \in \mathbb{Z} \times \mathbb{Z}, \\ (v_z)_{i+\frac{1}{2},j+\frac{1}{2}}, & (\partial_x v_z)_{i+\frac{1}{2},j+\frac{1}{2}}, & (\partial_z v_z)_{i+\frac{1}{2},j+\frac{1}{2}}, & (i,j) \in \mathbb{Z} \times \mathbb{Z}. \end{array}$$

The numerical scheme is thus given by

$$\left| \begin{array}{rcl} \dfrac{\mathrm{d}}{\mathrm{d}t}(v_x)_{i+\frac{1}{2},j+\frac{1}{2}} & = & \dfrac{1}{2\rho h}\left\{(\sigma^t_{xx})_{i+1,j} - (\sigma^t_{xx})_{i,j} + (\sigma^b_{xx})_{i+1,j+1} - (\sigma^b_{xx})_{i,j+1}\right. \\ & & \qquad \left. + (\sigma_{xz})_{i+1,j+1} - (\sigma_{xz})_{i+1,j} + (\sigma_{xz})_{i,j+1} - (\sigma_{xz})_{i,j}\right\}, \\ \dfrac{\mathrm{d}}{\mathrm{d}t}(\partial_x v_x)_{i+\frac{1}{2},j+\frac{1}{2}} & = & \dfrac{1}{\sqrt{12}\rho h}\left\{(\sigma_{xz})_{i+1,j+1} + (\sigma_{xz})_{i,j} - (\sigma_{xz})_{i+1,j} - (\sigma_{xz})_{i,j+1}\right\}, \\ \dfrac{\mathrm{d}}{\mathrm{d}t}(\partial_z v_x)_{i+\frac{1}{2},j+\frac{1}{2}} & = & \dfrac{1}{\sqrt{12}\rho h}\left\{(\sigma^b_{xx})_{i+1,j+1} + (\sigma^t_{xx})_{i,j} - (\sigma^t_{xx})_{i+1,j} - (\sigma^b_{xx})_{i,j+1}\right\}, \end{array} \right.$$

$$\left| \begin{array}{rcl} \dfrac{\mathrm{d}}{\mathrm{d}t}(v_z)_{i+\frac{1}{2},j+\frac{1}{2}} & = & \dfrac{1}{2\rho h}\left\{(\sigma_{xz})_{i+1,j} - (\sigma_{xz})_{i,j} + (\sigma_{xz})_{i+1,j+1} - (\sigma_{xz})_{i,j+1}\right. \\ & & \qquad \left. + (\sigma^r_{zz})_{i,j+1} - (\sigma^r_{zz})_{i,j} + (\sigma^l_{zz})_{i+1,j+1} - (\sigma^l_{zz})_{i+1,j}\right\}, \\ \dfrac{\mathrm{d}}{\mathrm{d}t}(\partial_x v_z)_{i+\frac{1}{2},j+\frac{1}{2}} & = & \dfrac{1}{\sqrt{12}\rho h}\left\{(\sigma^l_{zz})_{i+1,j+1} + (\sigma^r_{zz})_{i,j} - (\sigma^l_{zz})_{i+1,j} - (\sigma^r_{zz})_{i,j+1}\right\}, \\ \dfrac{\mathrm{d}}{\mathrm{d}t}(\partial_z v_z)_{i+\frac{1}{2},j+\frac{1}{2}} & = & \dfrac{1}{\sqrt{12}\rho h}\left\{(\sigma_{xz})_{i+1,j+1} + (\sigma_{xz})_{i,j} - (\sigma_{xz})_{i+1,j} - (\sigma_{xz})_{i,j+1}\right\}. \end{array} \right.$$

$$\begin{bmatrix} \frac{A_{1,1}}{2} & 0 & \frac{A_{1,2}}{4} & \frac{A_{1,2}}{4} & \frac{A_{1,3}}{2} \\ 0 & \frac{A_{1,1}}{2} & \frac{A_{1,2}}{4} & \frac{A_{1,2}}{4} & \frac{A_{1,3}}{2} \\ \frac{A_{1,2}}{4} & \frac{A_{1,2}}{4} & \frac{A_{2,2}}{2} & 0 & \frac{A_{2,3}}{2} \\ \frac{A_{1,2}}{4} & \frac{A_{1,2}}{4} & 0 & \frac{A_{2,2}}{2} & \frac{A_{2,3}}{2} \\ \frac{A_{1,3}}{2} & \frac{A_{1,3}}{2} & \frac{A_{2,3}}{2} & \frac{A_{2,3}}{2} & A_{3,3} \end{bmatrix} \begin{bmatrix} \frac{\mathrm{d}}{\mathrm{d}t}(\sigma^t_{xx})_{i,j} \\ \frac{\mathrm{d}}{\mathrm{d}t}(\sigma^b_{xx})_{i,j} \\ \frac{\mathrm{d}}{\mathrm{d}t}(\sigma^r_{zz})_{i,j} \\ \frac{\mathrm{d}}{\mathrm{d}t}(\sigma^l_{zz})_{i,j} \\ \frac{\mathrm{d}}{\mathrm{d}t}(\sigma_{xz})_{i,j} \end{bmatrix} = \begin{bmatrix} (B_1)_{i,j} \\ (B_2)_{i,j} \\ (B_3)_{i,j} \\ (B_4)_{i,j} \\ (B_5)_{i,j} \end{bmatrix},$$

with

$$
\begin{aligned}
(B_1)_{i,j} &= \frac{1}{2h}\left((v_x)_{i+\frac12,j+\frac12}-(v_x)_{i-\frac12,j+\frac12}-\frac{1}{\sqrt{3}}((\partial_z v_x)_{i+\frac12,j+\frac12}-(\partial_z v_x)_{i-\frac12,j+\frac12})\right),\\
(B_2)_{i,j} &= \frac{1}{2h}\left((v_x)_{i+\frac12,j-\frac12}-(v_x)_{i-\frac12,j-\frac12}+\frac{1}{\sqrt{3}}((\partial_z v_x)_{i+\frac12,j-\frac12}-(\partial_z v_x)_{i-\frac12,j-\frac12})\right),\\
(B_3)_{i,j} &= \frac{1}{2h}\left((v_z)_{i+\frac12,j+\frac12}-(v_z)_{i+\frac12,j-\frac12}-\frac{1}{\sqrt{3}}((\partial_x v_z)_{i+\frac12,j+\frac12}-(\partial_x v_z)_{i+\frac12,j-\frac12})\right),\\
(B_4)_{i,j} &= \frac{1}{2h}\left((v_z)_{i-\frac12,j+\frac12}-(v_z)_{i-\frac12,j-\frac12}+\frac{1}{\sqrt{3}}((\partial_x v_z)_{i-\frac12,j+\frac12}-(\partial_x v_z)_{i-\frac12,j-\frac12})\right),\\
(B_5)_{i,j} &= \frac{1}{2h}\left((v_x)_{i+\frac12,j+\frac12}-(v_x)_{i+\frac12,j-\frac12}+(v_x)_{i-\frac12,j+\frac12}-(v_x)_{i-\frac12,j-\frac12}\right)\\
&\quad+\frac{1}{2h}\left((v_z)_{i+\frac12,j+\frac12}-(v_z)_{i-\frac12,j+\frac12}+(v_z)_{i+\frac12,j-\frac12}-(v_z)_{i-\frac12,j-\frac12}\right)\\
&\quad+\frac{1}{\sqrt{12}h}\left((\partial_x v_x)_{i+\frac12,j-\frac12}-(\partial_x v_x)_{i+\frac12,j+\frac12}+(\partial_x v_x)_{i-\frac12,j+\frac12}-(\partial_x v_x)_{i-\frac12,j-\frac12}\right)\\
&\quad+\frac{1}{\sqrt{12}h}\left((\partial_z v_z)_{i-\frac12,j+\frac12}-(\partial_z v_z)_{i+\frac12,j+\frac12}+(\partial_z v_z)_{i+\frac12,j-\frac12}-(\partial_z v_z)_{i-\frac12,j-\frac12}\right).
\end{aligned}
$$

For the sake of simplicity we treat the isotropic case; that is, we assume that

$$
\begin{pmatrix} A_{1,1} & A_{1,2} & A_{1,3}\\ A_{1,2} & A_{2,2} & A_{2,3}\\ A_{1,3} & A_{2,3} & A_{3,3}\end{pmatrix}
=\begin{pmatrix} \frac{2\mu+\lambda}{4\mu(\lambda+\mu)} & -\frac{\lambda}{4\mu(\lambda+\mu)} & 0\\ -\frac{\lambda}{4\mu(\lambda+\mu)} & \frac{2\mu+\lambda}{4\mu(\lambda+\mu)} & 0\\ 0 & 0 & \frac{1}{\mu}\end{pmatrix}, \tag{4.3}
$$

where λ and μ are the Lamé coefficients of the material. The next step is to eliminate the unknowns associated to the stress tensor and to consider a plane wave with frequency ω and wave vector $\boldsymbol{k}=(k_x,k_z)=k(\cos\ \theta,\sin\ \theta)$:

$$
\begin{aligned}
\begin{pmatrix}(v_x)_{i+\frac12,j+\frac12}\\(v_z)_{i+\frac12,j+\frac12}\\(\partial_x v_x)_{i+\frac12,j+\frac12}\\(\partial_z v_z)_{i+\frac12,j+\frac12}\\(\partial_x v_z)_{i+\frac12,j+\frac12}\\(\partial_z v_x)_{i+\frac12,j+\frac12}\end{pmatrix} &= \mathbf{V}\exp\left[i\left(ct-(\cos(\theta)x_{i+\frac12}+\sin(\theta)z_{j+\frac12})\right)\right],\\
\mathbf{V} &= [\ \mathbf{v_x}\ ,\ \mathbf{v_z}\ ,\ \partial_{\mathbf{x}}\mathbf{v_x}\ ,\ \partial_{\mathbf{z}}\mathbf{v_z}\ ,\ \partial_{\mathbf{x}}\mathbf{v_z}\ ,\ \partial_{\mathbf{z}}\mathbf{v_x}\ ]^t,
\end{aligned} \tag{4.4}
$$

where $c=\omega/k$ is the phase velocity and $\mathbf{V}$ is the amplitude vector. Plugging this expression into the numerical scheme, we observe that the couple $(\omega^2,\boldsymbol{V})$ has to satisfy the following eigenvalue problem:

$$
\mathcal{K}_h\boldsymbol{V} = \frac{\omega^2}{k^2}\boldsymbol{V},\quad \text{with } k=|\boldsymbol{k}|, \tag{4.5}
$$

where the nonzero elements of the matrix $\mathcal{K}_h$ are given in Appendix A.

The matrix $\mathcal{K}_h$ is Hermitian; thus, there are six real eigenvalues with six orthogonal eigenvectors. Performing a Taylor expansion we obtain the following results. For the two first couples denoted by $(\omega_T^2, \boldsymbol{V}_T),\ T \in \{P, S\}$, we have

$$\left|\begin{array}{rcl} c_P = \dfrac{\omega_P}{k} & = & \sqrt{\dfrac{\lambda+2\mu}{\rho}} + \mathcal{O}(kh)^2, \\ \mathbf{V_P} & = & [\ \cos\theta\ ,\ \sin\theta\ ,\ 0\ ,\ 0\ ,\ 0\ ,\ 0\ ]^t + \mathcal{O}(kh), \end{array}\right. \tag{4.6}$$

$$\left|\begin{array}{rcl} c_S = \dfrac{\omega_S}{k} & = & \sqrt{\dfrac{\mu}{\rho}} + \mathcal{O}(kh)^2, \\ \mathbf{V_S} & = & [\ -\sin\theta\ ,\ \cos\theta\ ,\ 0\ ,\ 0\ ,\ 0\ ,\ 0\ ]^t + \mathcal{O}(kh). \end{array}\right. \tag{4.7}$$

The phase velocity of the these two waves is a second order approximation of the phase velocity of the continuous waves. The other four solutions of the eigenvalue problem are spurious modes produced by the introduction of the additional degrees of freedom and are given by

$$\left|\begin{array}{rcl} c_{spur1} = \dfrac{\omega_{spur1}}{k} & = & \mathcal{O}(kh), \\ \mathbf{V_{spur1}} & = & [\ 0\ ,\ 0\ ,\ 1\ ,\ 0\ ,\ 0\ ,\ 0\ ]^t + \mathcal{O}(kh), \end{array}\right. \tag{4.8}$$

$$\left|\begin{array}{rcl} c_{spur2} = \dfrac{\omega_{spur2}}{k} & = & \mathcal{O}(kh), \\ \mathbf{V_{spur2}} & = & [\ 0\ ,\ 0\ ,\ 0\ ,\ 1\ ,\ 0\ ,\ 0\ ]^t + \mathcal{O}(kh), \end{array}\right. \tag{4.9}$$

$$\left|\begin{array}{rcl} c_{spur3} = \dfrac{\omega_{spur3}}{k} & = & \sqrt{\dfrac{4\sin^2(\theta)(\lambda+\mu)\mu}{3\rho(\lambda+2\mu)}} + \mathcal{O}(kh)^2, \\ \mathbf{V_{spur3}} & = & [\ 0\ ,\ 0\ ,\ 0\ ,\ 0\ ,\ 1\ ,\ 0\ ]^t + \mathcal{O}(kh), \end{array}\right. \tag{4.10}$$

$$\left|\begin{array}{rcl} c_{spur4} = \dfrac{\omega_{spur4}}{k} & = & \sqrt{\dfrac{4\cos^2(\theta)(\lambda+\mu)\mu}{3\rho(\lambda+2\mu)}} + \mathcal{O}(kh)^2, \\ \mathbf{V_{spur4}} & = & [\ 0\ ,\ 0\ ,\ 0\ ,\ 0\ ,\ 0\ ,\ 1\ ]^t + \mathcal{O}(kh). \end{array}\right. \tag{4.11}$$

We remark that the first two spurious modes propagate with a phase velocity that goes to zero, and thus they are not really visible in the numerical simulations. The phase velocity of the other two modes is nonzero and always smaller than the shear wave velocity. Therefore, these spurious waves will propagate and pollute the physical solution.

4.4. Damping of the spurious modes. As we have seen in the previous section, the modified element gives rise to some spurious modes. In this section we propose a way to damp the amplitude of these modes (without damping the "physical" part of the solution), so that they do not pollute too much the approximate solution.

The approximate space $\underline{M}_h$ can be decomposed as

$$\underline{M}_h = \underline{M}_h^0 \oplus \underline{M}_h^r,$$

where $\underline{M}_h^0$ is the space of piecewise constants on each component and $\underline{M}_h^r$ is its orthogonal complement (for the L^2 scalar product). The space $\underline{M}_h^r$ is composed of P^1 discontinuous functions with a vanishing mean value per element and per component.

From the dispersion analysis, we observe that the main components of the spurious modes (the $\mathcal{O}(1)$ part) belong to $\underline{M}_h^r$. In order to damp this main part, we introduce the L^2 orthogonal projection on $\underline{M}_h^r$, which we denote by $P_{\underline{M}_h^r}$, defined for any $\mathbf{v}_h \in \underline{M}_h$ as

$$P_{\underline{M}_h^r}(\mathbf{v}_h) \in \underline{M}_h^r \quad \text{and} \quad (P_{\underline{M}_h^r}(\mathbf{v}_h), \mathbf{w}_h) = (\mathbf{v}_h, \mathbf{w}_h) \quad \forall\, \mathbf{w}_h \in \underline{M}_h^r.$$

The approximate problem with damping consists in finding $(\boldsymbol{\sigma}_h, \mathbf{v}_h, \boldsymbol{\lambda}_H) \in \underline{\underline{X}}_h^{sym} \times \underline{M}_h \times \underline{\mathcal{G}}_H$ such that

(4.12)
$$\begin{cases} \text{Find } (\boldsymbol{\sigma}_h(t), \mathbf{v}_h(t), \boldsymbol{\lambda}_H(t)) \in \underline{\underline{X}}_h^{sym} \times \underline{M}_h \times \underline{\mathcal{G}}_h \text{ satisfying} \\ \dfrac{\mathrm{d}}{\mathrm{d}t} a(\boldsymbol{\sigma}_h, \boldsymbol{\tau}_h) + b(\boldsymbol{\tau}_h, \mathbf{v}_h) - \langle \boldsymbol{\tau}_h\, \mathbf{n}, \boldsymbol{\lambda}_H \rangle_\Gamma = 0 \qquad \forall\, \boldsymbol{\tau}_h \in \underline{\underline{X}}_h^{sym}, \\ \dfrac{\mathrm{d}}{\mathrm{d}t} (\mathbf{v}_h, \mathbf{w}_h)_\rho + (P_{\underline{M}_h^r}(\mathbf{v}_h), \mathbf{w}_h)_\beta - b(\boldsymbol{\sigma}_h, \mathbf{w}_h) = (\mathbf{f}, \mathbf{w}_h) \qquad \forall\, \mathbf{w}_h \in \underline{M}_h, \\ \langle \boldsymbol{\sigma}_h\, \mathbf{n}, \boldsymbol{\mu}_H \rangle_\Gamma = 0 \qquad \forall\, \boldsymbol{\mu}_h \in \underline{\mathcal{G}}_H. \end{cases}$$

In this system β represents a damping parameter, which is chosen as a positive constant in the applications. The case $\beta = 0$ gives back the nondamped problem, while a strictly positive β corresponds to a dissipative problem. In section 5 we will explain how to choose the value for this parameter.

4.5. Numerical illustrations using the modified element. Let us now show some numerical illustrations of the behavior of the fictitious domain method with the new finite element space. The numerical experiments that we have considered are the same as in section 3.2 and will allow us to compare both finite elements.

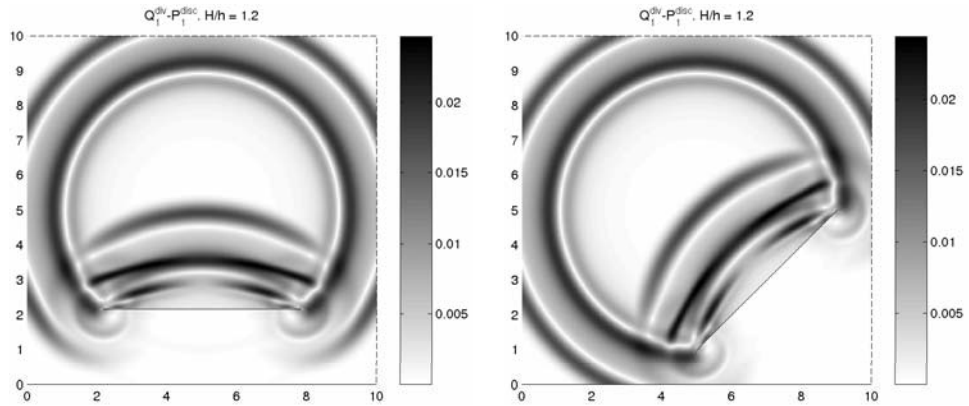
Once again we discretize the horizontal crack defined by (3.9) using a uniform mesh of step $H = Rh$. The results obtained with the new mixed finite element $Q_1^{\mathrm{div}} - P_1^{disc}$ are similar to those given by the $Q_1^{\mathrm{div}} - Q_0$ element. The method converges for reasonable values of the parameter R (in the interval $[0.75, 3]$). In Figure 4.2(a) we can see the results for $R = 1.2$.

We now consider the diagonal crack defined by the expression (3.10). We recall that the continuous problem is a rotation of $\pi/4$ radians with respect to the point $(x_c, z_c) = (5, 5)$.

The Lagrange multiplier is again discretized using an uniform mesh of step $H = Rh$. Contrary to the results obtained with the element $Q_1^{\mathrm{div}} - Q_0$, the ones given by the modified element $Q_1^{\mathrm{div}} - P_1^{disc}$ converge towards the physical solution when choosing reasonable values for the ratio H/h. In Figure 4.2(b), this time the incident wave is almost completely reflected by the obstacle. The scattered waves created by the tips of the crack are well approximated.

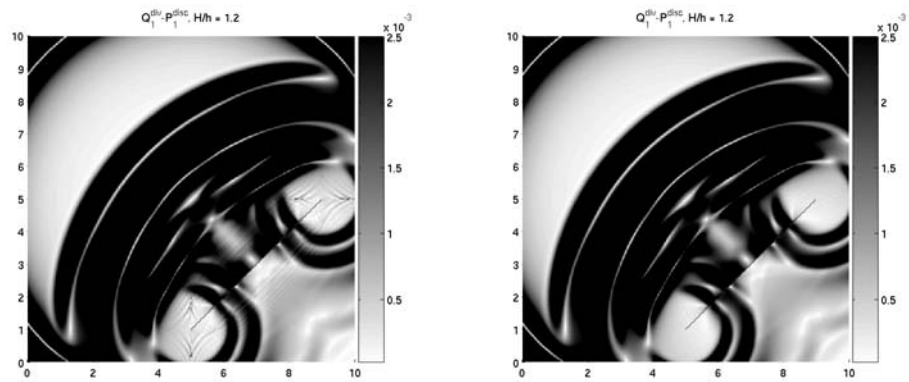
As explained before, the enrichment of the $\underline{M}_h$ approximation space introduces spurious modes in the solution. Although the amplitude of these nonphysical waves goes to zero with the size of the discretization step, it is still significant for a usual choice of the discretization parameters, typically corresponding to 20 points per wavelength. These spurious modes are, for example, visible in the results presented in Figure 4.3(a) where we have changed the scale to amplify the spurious phenomena.

In order to study in more detail these phenomena we represent in Figure 4.4 the evolution in time of the modulus of the velocity field at three points: $\mathbf{x_1} = (x_1, z_1) = (6.5, 3.5)$ mm, $\mathbf{x_2} = (x_2, z_2) = (7.5, 2.5)$ mm, and $\mathbf{x_3} = (x_3, z_3) = (5, 0.5)$ mm. The first two points are centered with respect to the crack, one behind and the other in



(a) $t = 1.7310\ \mu$s (b) $t = 1.7310\ \mu$s

FIG. 4.2. $Q_1^{\text{div}} - P_1^{disc}$. *Isotropic medium. Modulus of the velocity field.* $H/h = 1.2$.



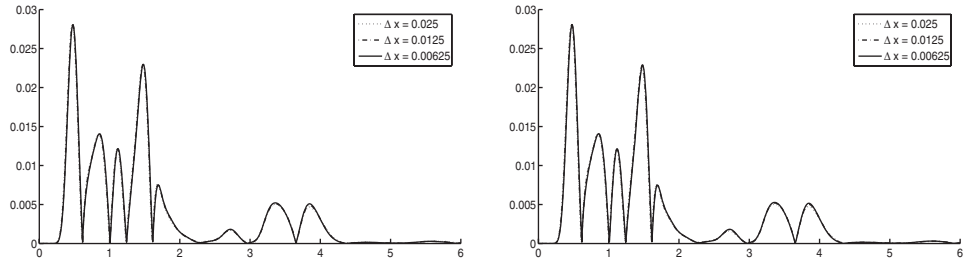
(a) $Q_1^{\text{div}} - P_1^{disc}$. $\beta = 0$ (b) $Q_1^{\text{div}} - P_1^{disc}$. $\beta = 5\rho 10^6$

FIG. 4.3. *Modulus of the velocity field at* $t = 2.5965\ \mu$s.

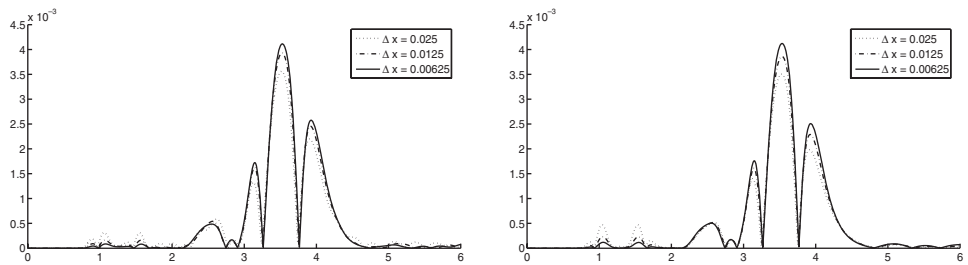
front of it. The third point is located near the lower tip of the crack, where the spurious waves seem stronger. To determine the speed of convergence of the method, we use three different meshes with a space discretization step of $h = 0.025, 0.0125$, and 0.00625 mm, respectively.

The results obtained at the first point (in front of the crack) are already good with the coarse mesh (see Figure 4.4, top left). The amplitude of the spurious waves is very small with respect to the amplitude of the incident ($t \in [0.25, 1]\ \mu$s), reflected ($t \in [0.75, 2]\ \mu$s), and (first) scattered waves ($t \in [2.75, 4.25]\ \mu$s).

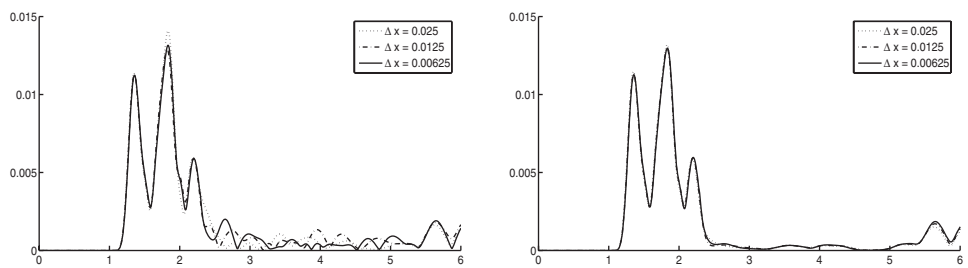
The second point is in the "shadow region," where the amplitude of the physical waves is about 15% smaller than the amplitude of the incident wave (see Figure 4.4, middle left). Consequently the error is more visible. In the time interval $t \in [0, 2]\ \mu$s we can see the part of the incident wave that has been transmitted across the obstacle. The amplitude of those waves goes to zero when we refine the mesh. From $t = 2$ to



(a) $|v|((6.5, 3.5)\ \text{mm}, t)$, $\beta = 0$ (b) $|v|((6.5, 3.5)\ \text{mm}, t)$, $\beta = 5\varrho 10^6$



(c) $|v|((7.5, 2.5)\ \text{mm}, t)$, $\beta = 0$ (d) $|v|((7.5, 2.5)\ \text{mm}, t)$, $\beta = 5\varrho 10^6$

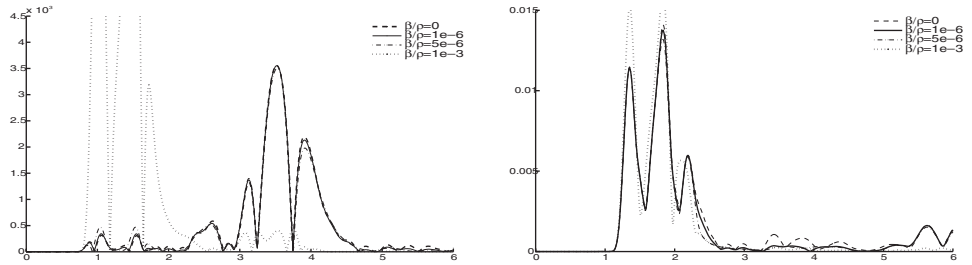


(e) $|v|((5.0, 0.5), t)$, $\beta = 0$ (f) $|v|((5.0, 0.5), t)$, $\beta = 5\varrho 10^6$

FIG. 4.4. *The modulus of the velocity* $|\mathbf{v}|(\mathbf{x_i}, t)$, $t \in [0, 6]$, $i \in \{1, 2, 3\}$, *computed using the* $Q_1^{\text{div}} \times P_1^{disc}$ *element with* $\beta = 0$ *on the left column and* $\beta = 5\varrho 10^6$ *on the right one.*

$t = 4.5$ μs we can see the first group of scattered waves. At the beginning and at the end of this time interval we can see some oscillations that come from the spurious modes introduced by the enrichment of the velocity field discretization space. The error on those amplitudes is about 2% of the amplitude of the incident wave.

At the third point, the spurious phenomena are much stronger (see Figure 4.4, bottom left). Here the amplitude of the incident and scattered waves is about 40% of the amplitude of the actual incident wave. As we can observe, comparing the solutions obtained with the different meshes, the method converges very slowly (see the time interval $t \in [2, 5.5]$ μs). This is due to the spurious modes created by the singularity on the tips of the crack (see also Figure 4.3(a)).



(a) $|v|((7.5, 2.5)\text{ mm}, t)$ (b) $|v|((5.0, 0.5)\text{ mm}, t)$

FIG. 4.5. *The modulus of the velocity* $|\mathbf{v}|(\mathbf{x_i}, t)$, $t \in [0,6]$ μs, $i \in \{2,3\}$, *computed using the* $Q_1^{\text{div}} \times P_1^{disc}$ *element with* $h = 0.025$ mm *and different values of the damping parameter* β.

These spurious phenomena can be reduced using a positive value of β, the damping coefficient. We will explain how to chose β in section 5.1. Let us analyze here the results obtained with $\beta = 5\varrho 10^6$. As we can see in Figure 4.3(b) the results seem to be better than those obtained with $\beta = 0$ (see Figure 4.3(a)). The signal obtained at the first point $\mathbf{x_1}$ is very similar for both choices (see Figure 4.4, top right). The results for the second point are also comparable. We remark that some oscillations on the time intervals $t \in [2,3]$ and $t \in [4.5,6]$ are removed with the damping. It is in the signal recorded on the third point where the effect of the damping of the spurious modes is more efficient (see Figure 4.4, bottom right). The oscillations observed with $\beta = 0$ are completely removed, and the method gives a good solution even with the coarsest mesh.

To illustrate the effect of the damping parameter β on the solution, we present in Figure 4.5 results obtained on the coarsest grid for different values of β. We have made the following observations: When we do not use any damping, the solution is polluted by spurious modes. On the other hand, the amplitude of the transmitted (nonphysical) waves through the crack increases as the value of the damping β increases. This is expected, because the limit case $\beta \to +\infty$ corresponds to seeking the velocity in Q_0, and we know that in this case the method does not converge. There is thus an optimal value for the damping parameter β to be determined so, as the spurious modes are damped, while the transmitted nonphysical wave remains small. In the next section we determine numerically the rate of convergence of the method for a particular geometry, and we discuss a procedure to choose the value of β.

5. Numerical error estimates. In this section we estimate numerically the order of convergence of the method. To do so, we consider solving the elastodynamic system on a disk $\Omega \subset \mathbb{R}^2$ with homogeneous Neumann boundary conditions on its boundary $\Gamma = \delta\Omega$. The geometry of the problem is presented in Figure 5.1.

To compute the solution we extend the unknowns in the domain of simple geometry C (see Figure 5.1) and use the fictitious domain formulation (2.10) with zero force term $\mathbf{f} = 0$ and an initial condition on the velocity field, given by

$$\mathbf{v}((x,z), t=0) = 0.1\ F\left(\frac{r}{r_0}\right)\frac{\mathbf{r} + \mathbf{r}^{\perp}}{r},$$

where $F(\cdot)$, $\mathbf{r}$, and r have been defined in section 3.2 and $r_0 = 1.5$ mm. The domain

of propagation is an isotropic medium with the density and Lamé coefficients given by (3.8). The extended domain C is truncated using perfectly matched layers [11, 16]. We consider the final time equal to $T = 5$ μs when both the pressure and shear waves have reached the boundary.

The fact of having a problem that is rotationally invariant allows us to compute a reference solution solving a one-dimensional problem. More precisely, rewriting (2.1) in polar coordinates

$$
\left|\begin{array}{rcll}
\rho\dfrac{\partial v_r}{\partial t} & = & \dfrac{\partial \sigma_{rr}}{\partial r} + \dfrac{1}{r}\dfrac{\partial \sigma_{r\theta}}{\partial \theta} + \dfrac{1}{r}(\sigma_{rr}-\sigma_{\theta\theta}) & \text{in } [0,R]\times[0,2\pi],\\
\rho\dfrac{\partial v_\theta}{\partial t} & = & \dfrac{\partial \sigma_{r\theta}}{\partial r} + \dfrac{1}{r}\dfrac{\partial \sigma_{\theta\theta}}{\partial \theta} + \dfrac{2}{r}\sigma_{r\theta} & \text{in } [0,R]\times[0,2\pi],\\
\dfrac{\partial \sigma_{rr}}{\partial t} & = & (2\mu+\lambda)\dfrac{\partial v_r}{\partial r} + \lambda\dfrac{v_r}{r} + \lambda\dfrac{1}{r}\dfrac{\partial v_\theta}{\partial \theta} & \text{in } [0,R]\times[0,2\pi],\\
\dfrac{\partial \sigma_{\theta\theta}}{\partial t} & = & (2\mu+\lambda)\left(\dfrac{1}{r}\dfrac{\partial v_\theta}{\partial \theta}+\dfrac{v_r}{r}\right) + \lambda\dfrac{\partial v_r}{\partial r} & \text{in } [0,R]\times[0,2\pi],\\
\dfrac{\partial \sigma_{r\theta}}{\partial t} & = & \mu\left(\dfrac{1}{r}\dfrac{\partial v_r}{\partial \theta} + \dfrac{\partial v_\theta}{\partial r} - \dfrac{v_\theta}{r}\right) & \text{in } [0,R]\times[0,2\pi],\\
\sigma_{rr}=0 \quad \sigma_{r\theta}=0 & & & \text{in } R\times[0,2\pi],
\end{array}\right. \tag{5.1}
$$

with the initial conditions

$$
v_s((r,\theta),t=0) = 0.1F\left(\frac{r}{r_0}\right), \quad s\in\{r,\theta\}, \tag{5.2}
$$

we remark that the solution depends only on r, and the former equations are equivalent to the two following decoupled one-dimensional problems:

$$
\left|\begin{array}{rcll}
\rho\dfrac{\partial v_r}{\partial t} & = & \dfrac{\partial \sigma_{rr}}{\partial r} + \dfrac{1}{r}(\sigma_{rr}-\sigma_{\theta\theta}) & \text{in } [0,R],\\
\dfrac{\partial \sigma_{rr}}{\partial t} & = & (2\mu+\lambda)\dfrac{\partial v_r}{\partial r} + \lambda\dfrac{v_r}{r} & \text{in } [0,R],\\
\dfrac{\partial \sigma_{\theta\theta}}{\partial t} & = & (2\mu+\lambda)\dfrac{v_r}{r} + \lambda\dfrac{\partial v_r}{\partial r} & \text{in } [0,R],\\
\sigma_{rr}=0 & & & \text{in } R,
\end{array}\right. \tag{5.3}
$$

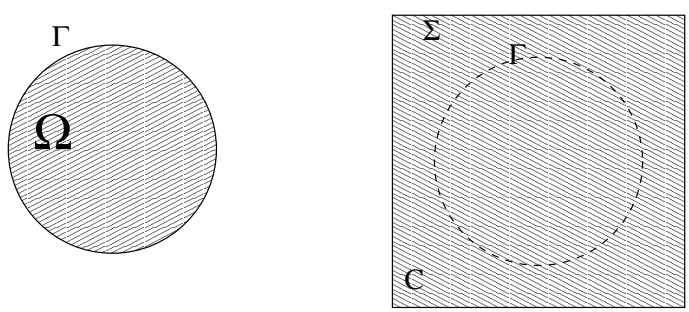


FIG. 5.1. *The geometry of the problem. On the left is the initial domain of propagation* Ω*, and on the right is the extended domain* C *introduced by the fictitious domain formulation of the problem.*

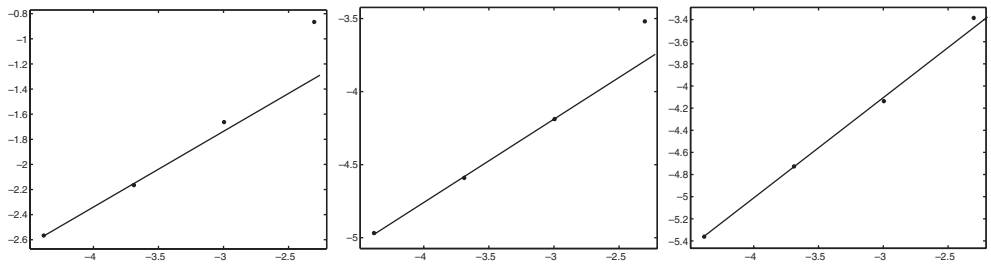


(a) $\sup_{t\leq T} \|\boldsymbol{\sigma} - \boldsymbol{\sigma}_h\|_{\underline{\underline{X}}}$, $s = 0.59$ (b) $\sup_{t\leq T} \|\mathbf{v} - \mathbf{v}_h\|_{\underline{M}}$, $s = 0.55$ (c) $\sup_{t\leq T} \|\boldsymbol{\lambda} - \boldsymbol{\lambda}_h\|_{\underline{L^2}}$, $s = 0.92$

FIG. 5.2. *Numerical error on* $\boldsymbol{\sigma}$, $\mathbf{v}$, *and* $\boldsymbol{\lambda}$ *versus the discretization step.*

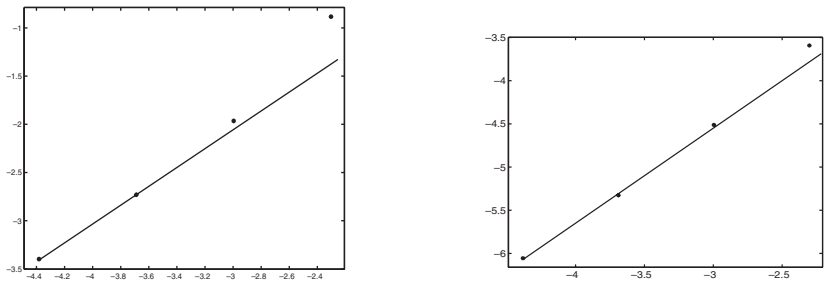
$$
\left|\begin{array}{lcll}
\rho\dfrac{\partial v_\theta}{\partial t} & = & \dfrac{\partial \sigma_{r\theta}}{\partial r} + \dfrac{2}{r}\sigma_{r\theta} & \text{in } [0,R]\times[0,2\pi], \\
\dfrac{\partial \sigma_{r\theta}}{\partial t} & = & \mu\left(\dfrac{\partial v_\theta}{\partial r} - \dfrac{v_\theta}{r}\right) & \text{in } [0,R]\times[0,2\pi], \\
\sigma_{r\theta} y = 0 & & & \text{in } R\times[0,2\pi].
\end{array}\right. \tag{5.4}
$$

We solve numerically those systems using piecewise constant functions for the discretization of the velocity field and continuous linear functions for the stress tensor. For the time discretization we use a leapfrog scheme. The reference solution is obtained using a very fine mesh ($h_{1d} \approx 1/800$). The two-dimensional problem is solved using four different meshes with $h_z = h_z = 1/10, 1/20, 1/40$, and $1/80$. We use the larger time step Δt authorized by the CFL condition. The mesh for the object is uniform and with a discretization step H such that $H/h \approx 4$ for each mesh. In all cases the damping parameter β is equal to zero. For each numerical experiment we compute the difference between the approximated solution and the reference solution. In Figure 5.2 we display the logarithm of the error on the stress tensor, the velocity field, and the Lagrange multiplier versus the logarithm of the discretization step. The rate of convergence is thus given by the slope of the lines. We observe that the order of convergence for $\boldsymbol{\sigma}$ in $L^\infty([0,T],(H(\mathrm{div},C))^2)$ norm and for $\mathbf{v}$ in $L^\infty([0,T],(L^2(C))^2)$ norm are near the values we could expect (i.e., $1/2$). The convergence rate obtained for the Lagrange multiplier $\boldsymbol{\lambda}$ (close to 1) is computed in $L^\infty([0,T];(L^2(\Gamma))^2)$ norm, which means that we recover the conjectured convergence rate $(1/2)$ in $L^\infty([0,T];(H^{\frac{1}{2}}(\Gamma))^2)$ norm.

In Figure 5.3 we display the same results but with the norm of the error now computed in $\widetilde{C} = C/B_b(\Gamma)$, i.e., the domain C restricted from $B_b(\Gamma)$, defined by

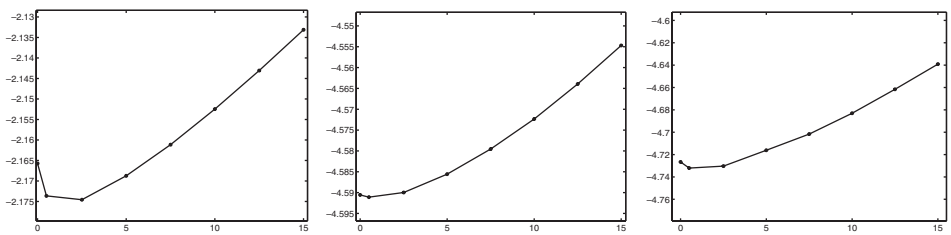
$$
B_b(\Gamma) = \left\{ \mathbf{x} \in C \text{ subject to } \min_{\mathbf{y}\in\Gamma} |\mathbf{x}-\mathbf{y}| \leq b \right\}. \tag{5.5}
$$

In this case, we observe that the convergence rate of the method is higher. This agrees with our intuition in the sense that the elements that we need to remove are the ones in which the solution has less regularity (see Remark 1), i.e., the elements that have nonzero intersection with the boundary Γ.



(a) $\sup_{t\leq T} \|\boldsymbol{\sigma} - \boldsymbol{\sigma}_h\|_{\underline{\underline{H_{\mathrm{div}}}}(\tilde{C})}$. $s = 0.96$. (b) $\sup_{t\leq T} \|\mathbf{v} - \mathbf{v}_h\|_{\underline{L^2}(\tilde{C})}$. $s = 1.05$.

FIG. 5.3. *Numerical error* $\boldsymbol{\sigma}$, $\mathbf{v}$ *versus the discretization step. Here we compute the norm of the error in* $\widetilde{C}$.



(a) $\sup_{t\leq T} \|\boldsymbol{\sigma} - \boldsymbol{\sigma}_h\|_{\underline{\underline{X}}}$. (b) $\sup_{t\leq T} \|\mathbf{v} - \mathbf{v}_h\|_{\underline{M}}$. (c) $\sup_{t\leq T} \|\boldsymbol{\lambda} - \boldsymbol{\lambda}_h\|_{\underline{\mathcal{G}}}$.

FIG. 5.4. *Numerical error on* $\boldsymbol{\sigma}$, $\mathbf{v}$, *and* $\boldsymbol{\lambda}$ *versus the damping parameter* β/ρ.

5.1. Determination of $\boldsymbol{\beta}$. Finally we discuss the influence of the damping parameter β on the convergence results. In order to do so we repeat the experiment described above using the mesh with $h = 1/40$ mm for $\beta/\rho 10^{-6} = 0, 0.5, 2.5, 5, 7.5, 10$, 12.5, and 15. We display in Figure 5.4 the logarithm of the error on $\boldsymbol{\sigma}$, $\mathbf{v}$, and $\boldsymbol{\lambda}$ as a function of the value of $\beta/\rho 10^{-6}$. As we can see, better results are obtained for values of $\beta/\rho 10^{-6}$ between 2.5 and 5. We also observe that the error increases when we choose β too large. The same experiments done for different materials show that the optimal range for β/ρ is independent of the material. It depends only on the number of points per wavelength in the discretization. It should be proportional to $1/\Delta t$:

$$\frac{\beta}{\rho} = \frac{\zeta}{\Delta t},$$

where ζ, an adimensional constant, determined by the previous experiment, should be chosen in the interval $[0.03, 0.06]$.

Conclusions. In this paper we proposed a numerical method for solving the elastodynamic problem in anisotropic media with cracks (or more general objects) of complex geometry. Our approach leads to an efficient numerical method that uses regular grids for the space discretization (due to the fictitious domain formulation) and is explicit in time. The last point is achieved using a mixed finite element that is

compatible with mass lumping for the discretization of the velocity-stress system. Although the theoretical convergence analysis is still an open problem, several numerical experiments suggest that the method provides a good approximate solution.

Appendix. The matrix $\mathcal{K}_h$. We give here the expressions of the nonzero elements of the Hermitian matrix $\mathcal{K}_h$ that appears in the dispersion relation (4.5):

$$(\mathcal{K}_h)_{1,1} = \frac{2}{\rho(kh)^2}\left(\mathcal{A}\sin^2\left(\frac{k_x h}{2}\right) + \mathcal{B}\cos(k_z h)\sin^2\left(\frac{k_x h}{2}\right) + 2\mathcal{D}\cos^2\left(\frac{k_x h}{2}\right)\sin^2\left(\frac{k_z h}{2}\right)\right),$$

$$(\mathcal{K}_h)_{1,2} = \frac{-2\ \mathbf{i}\ \mathcal{D}}{\sqrt{3}\rho(kh)^2}\sin(k_x h)\sin^2\left(\frac{k_z h}{2}\right), (\mathcal{K}_h)_{1,3} = \frac{-2\ \mathbf{i}\ \mathcal{B}}{\sqrt{3}\rho(kh)^2}\sin(k_z h)\sin^2\left(\frac{k_x h}{2}\right),$$

$$(\mathcal{K}_h)_{1,4} = \frac{\mathcal{C}+\mathcal{D}}{\rho(kh)^2}\sin(k_x h)\sin(k_z h), (\mathcal{K}_h)_{1,5} = \frac{-2\ \mathbf{i}\ \mathcal{C}}{\sqrt{3}\rho(kh)^2}\sin(k_z h)\sin^2\left(\frac{k_x h}{2}\right),$$

$$(\mathcal{K}_h)_{1,6} = \frac{-2\ \mathbf{i}\ \mathcal{D}}{\sqrt{3}\rho(kh)^2}\sin(k_x h)\sin^2\left(\frac{k_z h}{2}\right), (\mathcal{K}_h)_{2,2} = \frac{4\mathcal{D}}{3\rho(kh)^2}\sin^2\left(\frac{k_x h}{2}\right)\sin^2\left(\frac{k_z h}{2}\right),$$

$$(\mathcal{K}_h)_{2,4} = \frac{2\ \mathbf{i}\ \mathcal{D}}{\sqrt{3}\rho(kh)^2}\sin(k_z h)\sin^2\left(\frac{k_x h}{2}\right), (\mathcal{K}_h)_{2,6} = \frac{4\mathcal{D}}{3\rho(kh)^2}\sin^2\left(\frac{k_x h}{2}\right)\sin^2\left(\frac{k_z h}{2}\right),$$

$$(\mathcal{K}_h)_{3,3} = \frac{2}{3\rho(kh)^2}\left(\mathcal{A}\sin^2\left(\frac{k_x h}{2}\right) - \mathcal{B}\cos(k_z h)\sin^2\left(\frac{k_x h}{2}\right)\right),$$

$$(\mathcal{K}_h)_{3,4} = \frac{2\ \mathbf{i}\ \mathcal{C}}{\sqrt{3}\rho(kh)^2}\sin(k_x h)\sin^2\left(\frac{k_z h}{2}\right), (\mathcal{K}_h)_{3,5} = \frac{-4\mathcal{C}}{3\rho(kh)^2}\sin^2\left(\frac{k_x h}{2}\right)\sin^2\left(\frac{k_z h}{2}\right),$$

$$(\mathcal{K}_h)_{4,4} = \tfrac{2}{\rho(kh)^2}\left(\mathcal{A}\sin^2\left(\tfrac{k_z h}{2}\right) + \mathcal{B}\cos(k_x h)\sin^2\left(\tfrac{k_z h}{2}\right) + 2\mathcal{D}\cos^2\left(\frac{k_z h}{2}\right)\sin^2\left(\frac{k_x h}{2}\right)\right),$$

$$(\mathcal{K}_h)_{4,5} = \frac{-2\ \mathbf{i}\ \mathcal{B}}{\sqrt{3}\rho(kh)^2}\sin(k_x h)\sin^2\left(\frac{k_z h}{2}\right), (\mathcal{K}_h)_{4,6} = \frac{-2\ \mathbf{i}\ \mathcal{D}}{\sqrt{3}\rho(kh)^2}\sin(k_z h)\sin^2\left(\frac{k_x h}{2}\right),$$

$$(\mathcal{K}_h)_{5,5} = \frac{2}{3\rho(kh)^2}\left(\mathcal{A}\sin^2\left(\frac{k_z h}{2}\right) - \mathcal{B}\cos(k_x h)\sin^2\left(\frac{k_z h}{2}\right)\right),$$

$$(\mathcal{K}_h)_{6,6} = \frac{4\mathcal{D}}{3\rho(kh)^2}\sin^2\left(\frac{k_x h}{2}\right)\sin^2\left(\frac{k_z h}{2}\right),$$

and the coefficients $\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$, and $\mathcal{D}$ are given by

$$\mathcal{A} = \frac{8\mu^2 + 8\lambda\mu + \lambda^2}{2\mu+\lambda}, \quad \mathcal{B} = \frac{\lambda^2}{2\mu+\lambda}, \quad \mathcal{C} = \lambda, \quad \mathcal{D} = \mu.$$

A NEW ITERATIVE METHOD FOR SOLVING LARGE-SCALE LYAPUNOV MATRIX EQUATIONS*

V. SIMONCINI†

Abstract. In this paper we propose a new projection method to solve large-scale continuous-time Lyapunov matrix equations. The new approach projects the problem onto a much smaller approximation space, generated as a combination of Krylov subspaces in A and A^{-1}. The reduced problem is then solved by means of a direct Lyapunov scheme based on matrix factorizations. The reported numerical results show the competitiveness of the new method, compared to a state-of-the-art approach based on the factorized alternating direction implicit iteration.

Key words. matrix equations, Krylov subspace, model order reduction, iterative methods, large-scale equations

1. Introduction.

Given the time-invariant linear system

$$\mathbf{x}'(t) = A\mathbf{x}(t) + B\mathbf{u}(t), \qquad \mathbf{x}(0) = x_0, \tag{1.1}$$

with $A \in \mathbb{R}^{n\times n}$ and $B \in \mathbb{R}^{n\times s}$, with $s \le n$, the solution of the associated continuous-time Lyapunov equation

$$AX + XA^T + BB^T = 0 \tag{1.2}$$

has a fundamental role in many application areas such as signal processing and system and control theory. We assume that $s \ll n$ and that A is dissipative; that is, $x^T(A + A^T)x < 0$ for all real vectors x. The symmetric solution X, called the reachability Gramian, carries important information on the stability and energy of the linear system (1.1) and on the feasibility of order reduction techniques [1], [4], [9].

The numerical solution of the Lyapunov matrix equation has been addressed in a large body of literature, and well-established methods exist for small dimensional problems [2], [20]. Research has recently focused mostly on schemes for medium- to large-scale Lyapunov equations, for which methods based on matrix factorizations become too demanding, in terms of both computational costs and memory requirements. For dense problems, efforts have been devoted to the development of matrix iterative methods based on the sign function, possibly exploiting the problem structure; see, e.g., [3], [6], and references therein.

In the case of sparse matrix A, projection-type methods based on Krylov subspaces, using either polynomials or rational functions of A, have been employed; see, e.g., [23], [24], [25], [26], [28], [32], and the general treatment in [1]. In particular, since the work by Ellner and Wachspress in [12], the alternating direction implicit (ADI) iteration has found great applicability in the solution of (1.2), and software implementing an efficient variant is now available; see, e.g., [30]. A common feature of all of these projection methods is that the approximate solution $\widehat{X}$ is given in factored form, $\widehat{X} = ZZ^T$, with Z of low column rank. The possibility of obtaining a

†Dipartimento di Matematica, Università di Bologna, Piazza di Porta S. Donato 5, I-40127 Bologna, Italy and CIRSA, Ravenna, Italy (valeria@dm.unibo.it).

good low rank approximate solution is supported by recent theoretical results showing that a rapid decay of the eigenvalues of the symmetric and positive semidefinite exact solution may be observed under certain conditions on A; see [16], [29], [37]. This property can be fully exploited when dealing with large problems, since storing the whole, in general, full matrix $\widehat{X}$ would require a significant amount of memory space. Other methods have been investigated, such as that in [22], which, however, do not build a low rank approximation.

In spite of these recent efforts, projection methods that are directly based on Krylov subspace approaches (cf. [32], [23]) may be slow, requiring the generation of a very large approximation space to obtain a sufficiently accurate solution; see the experiments reported in [28]. On the other hand, ADI-type methods need the a priori evaluation of some parameters which may be hard to tune. In addition, memory and CPU time requirements remain an issue, for these methods perform various large matrix factorizations.

In this paper we propose a new projection-type method for large-scale problems that is, in general, faster than approaches based on the ADI iteration and does not require estimation of parameters. The new method projects the problem onto a small approximation space, generated as a combination of Krylov subspaces in A and A^{-1}. The reduced problem is then solved by means of a standard scheme for small Lyapunov equations. The method is equipped with a natural stopping criterion, which can be computed inexpensively. The performance of the new method is compared on benchmark problems to that of the cyclic implementation of the factorized ADI method available in [30].

The paper is organized as follows. Section 2 describes the general subspace projection framework, which characterizes the new approach and several other reduction methods. Section 3 and its subsections describe the new method and its algorithmic aspects. Section 4 reviews the ADI iteration and its efficient variant to prepare the notation for the numerical experiments reported in section 5. Finally, in section 6 we provide some conclusive remarks.

The following notation is used throughout. The square identity and zero matrices are denoted by I and O, respectively; rectangular portions will be identified by using subscripts. The only exceptions are the (block) columns of the identity, denoted by e_i, the ith column (resp., E_i, the ith block of $2s$ columns of the identity matrix). Matlab notation is used whenever possible [27]. $\|\cdot\|$ indicates the 2-norm for vectors and the induced norm for matrices, while $\|\cdot\|_F$ denotes the Frobenius norm; that is, $\|A\|_F^2 = \sum_{i=1}^{n}\sum_{j=1}^{m} a_{i,j}^2$ for $A \in \mathbb{R}^{n\times m}$. Range$(V)$ indicates the space spanned by the columns of V. Finally, exact arithmetic is assumed throughout.

2. Projection methods for the Lyapunov equation. In this section we review a general framework associated with projection methods for the Lyapunov equation. This will allow us to simplify the presentation of the new approach in section 3.

Consider a subspace K of $\mathbb{R}^n$, and let V be a matrix whose orthonormal columns span K, with $B = VE$ for some matrix E, so that the columns of B belong to K. We project the Lyapunov equation onto this subspace K: We set $H = V^TAV$ and seek an approximate solution in K in the form $\widehat{X} = VYV^T$. The projected problem may be obtained by imposing that the residual $R = A\widehat{X} + \widehat{X}A^T + BB^T$ be orthogonal to the approximation space K, the so-called Galerkin condition. In matrix terms, this can be written as[1] $V^TRV = O$. Since V has orthonormal columns, imposing $V^TRV = 0$

[1]This condition can be derived by first defining the matrix inner product $\langle X, Y\rangle = \mathrm{tr}(XY^T)$ and then imposing $\langle R, P\rangle = 0$ for any $P = VGV^T$ [32].

gives the following projected Lyapunov equation:

$$V^T AVY + YV^T A^T V + EE^T = 0, \tag{2.1}$$

whose solution Y defines $\widehat{X}$. Since we assume that A is dissipative, $V^T AV$ is stable, and the equation (2.1) admits a unique solution. The projection is effective if a good approximation is attained for a small dimensional subspace, so that (2.1) can be cheaply solved by means of procedures based on matrix factorizations; cf. [2], [20]. In turn, this effectiveness is more likely to take place whenever the exact solution can be accurately approximated by low rank matrices. An additional theoretical motivation for using such a technique is given by the exponential form of the analytical solution:

$$X = \int_0^\infty e^{tA} BB^T e^{tA^T} dt. \tag{2.2}$$

Note that the use of this formulation has led to different approximation procedures such as that in [17]. The quantity $W = e^{tA}B$ can be approximated in K as $\widehat{W} = Ve^{tH}E$. Therefore, an approximation to X can be obtained as

$$\widehat{X} = \int_0^\infty \widehat{W}\widehat{W}^T \, dt = V \left(\int_0^\infty e^{tH} EE^T e^{tH^T} \, dt \right) V^T =: VYV^T.$$

Using the fact that $H = V^T AV$ is stable, the following result can be readily established; see, e.g., [9].

PROPOSITION 2.1. [illegible] $Y = \int_0^\infty e^{tH} EE^T e^{tH^T} dt$ [illegible] (2.1).

Although the procedure above holds independently of the specific approximation space K, its [illegible] crucially depends on K. The presentation outlined above was first introduced in [32] for $B \in \mathbb{R}^n$ and K corresponding to the Krylov subspace $\mathcal{K}_k(A, B) = \text{span}\{B, AB, \ldots, A^{k-1}B\}$. Further developments of Krylov subspace methods for $B \in \mathbb{R}^{n \times s}$ and using conditions on the residual different from the Galerkin one were discussed in [23]. Reasons for expecting good accuracy in the approximation for a sufficiently large dimension of the Krylov subspace comes from the approximation properties of the exponential. Let V_k be such that $\text{Range}(V_k) = \mathcal{K}_k(A, B)$, and $H_k = V_k^T AV_k$. If $\widehat{W}_k = V_k e^{tH} E$ is a good approximation to $W = e^{tA}B$, we expect the corresponding integral to approximate X. In particular, assuming for the sake of the presentation $t = 1$, if the numerical range of A is contained in the complex disk $|z + \rho| \le \rho$ for some $\rho > 0$, then a bound of the form $\| \exp(A)v - V_k \exp(H_k)e_1 \| = O((\frac{e\rho}{k})^k)$ holds for $k \ge 2\rho$; see [21]. More accurate bounds can be obtained in the symmetric case [21], [40], [10].

Assume now that a sequence of approximation subspaces K_k of dimension k is given, with $K_k \subset K_{k+1}$, and satisfies $AK_k \subset K_{k+1}$. Note that these conditions on K_k are reasonably general.

Let the columns of V_k span K_k, $\underline{H}_k = V_{k+1}^T AV_k$, and let $X_k = V_k Y_k V_k^T$ be the approximate solution to (1.2) in K_k, obtained by imposing the Galerkin condition. The associated residual $R_k = AX_k + X_k A^T + BB^T$ satisfies (see, e.g., [32])

$$R_k = V_{k+1} \underline{H}_k Y_k V_k^T + V_k Y_k \underline{H}_k^T V_{k+1}^T + V_k EE^T V_k^T =: V_{k+1} \widehat{R} V_{k+1}^T. \tag{2.3}$$

The selection $K_k = \mathcal{K}_k(A, B)$ fulfills all conditions above, and in addition it can be shown that $\|R_k\| = \|E_{k+1}^T \underline{H}_k Y_k\|$, so that the quality of the approximation X_k can be measured by computing the residual norm, without explicitly evaluating the residual matrix. This setting has been heavily exploited to devise competitive approaches and to derive theoretical properties; see, e.g., [24], [23], [31].

3. The new iterative procedure. The general description of the previous section suggests that the approximation space K could be enriched to contain more information than that of the regular Krylov subspace $\mathcal{K}_k(A, B)$. To this end, starting with the pair $\{B, A^{-1}B\}$, we propose to generate a sequence of approximation spaces that contain information on both A and A^{-1}, by adding two vectors at a time, one multiplied by A and one by A^{-1}; that is,

$$\text{span}\{B, A^{-1}B, AB, A^{-2}B, A^2B, A^{-3}B, \dots\},$$

where the span is intended blockwise; see, e.g., [33]. As discussed in section 2, once the approximation space is generated, the original problem is projected onto this space, and the resulting small dimensional problem is solved. Our approach is inspired by a related acceleration procedure for the approximation of matrix functions developed in [11]; see the discussion at the end of section 3.2.

An outline of the algorithm is given next. Implementation details of the approach are provided in section 3.1.

Given B, A, set $V_1 = \texttt{gram_sh}([B, A^{-1}B])$, $\mathcal{V}_0 = \emptyset$.

For $m = 1, 2, \dots,$

1. $\mathcal{V}_m = [\mathcal{V}_{m-1}, V_m]$.
2. Set $\mathcal{T}_m = \mathcal{V}_m^T A \mathcal{V}_m$ and $E = \mathcal{V}_m^T B$.
3. Solve $\mathcal{T}_m Y + Y \mathcal{T}_m^T + EE^T = 0$ and set $Y_m = Y$.
4. If converged, then $X_m = \mathcal{V}_m Y_m \mathcal{V}_m^T$ and stop.
5. Set $V_m^{(1)}$: first s columns of V_m; $V_m^{(2)}$: second s columns of V_m.
6. $V'_{m+1} = [AV_m^{(1)}, A^{-1}V_m^{(2)}]$.
7. $\widehat{V}_{m+1} \leftarrow$ orthogonalize V'_{m+1} w.r.t. $\mathcal{V}_m$.
8. $V_{m+1} = \texttt{gram_sh}(\widehat{V}_{m+1})$.

At each iteration of this process, two new blocks of s vectors are added to the space, so that the space dimension increases by $2s$. Unless breakdown occurs, at the mth iteration the method has constructed an orthonormal basis of dimension $2sm$, given by the columns of the matrix $\mathcal{V}_m = [V_1, V_2, \dots, V_m]$, $V_i \in \mathbb{R}^{n \times 2s}$, and $\mathbf{K}_m := \text{Range}(\mathcal{V}_m)$. The orthogonalization is performed first with respect to the previous basis vectors and then within the new block of $2s$ vectors (function `gram_sh`; see section 3.1). At each iteration (cf. step 3), a small dimensional Lyapunov equation with matrices of size $2sm \times 2sm$ is solved. Only at convergence (step 4), the approximate solution to X is constructed as

$$X_m = \mathcal{V}_m Y_m \mathcal{V}_m^T, \tag{3.1}$$

with Y_m symmetric. This step can be omitted if X_m is not required explicitly. The following important properties are a consequence of the subspace definition.

PROPOSITION 3.1. [illegible] $m \geq 1$ [illegible] $\mathbf{K}_m$ [illegible] $\mathbf{K}_m = \mathcal{K}_{2m}(A, A^{-m}B)$ [illegible] $\mathcal{K}_{2m}$ [illegible]

$$A\mathbf{K}_m \subseteq \mathbf{K}_{m+1}. \tag{3.2}$$

We observe that the results of Proposition 3.1 ensure that $\mathcal{T}_m$ is block upper Hessenberg, since $V_k^T A V_j = O$ for $k > j + 1$, $j = 1, 2, \dots$. In particular, property (3.2) allows us to employ the framework of section 2. Moreover, since A is dissipative, $\mathcal{T}_m$ is stable, so that Y_m is positive (semi)definite.

To simplify the presentation, we limit the following discussion to the case $s = 1$; however, the stated relations formally hold unchanged for $s \geq 1$, by replacing scalar

quantities with $s \times s$ matrices. We derive some recursive relations that can be used to significantly reduce the computational cost of the basic algorithm. Let

$$\underline{\mathcal{H}}_m = \begin{bmatrix} \mathcal{H}_m \\ \chi_m E_m^T \end{bmatrix} \in \mathbb{R}^{2(m+1)\times 2m}$$

collect all orthonormalization coefficients; that is,

$$\widehat{V}_{m+1} = [AV_m^{(1)}, A^{-1}V_m^{(2)}] - \mathcal{V}_m \mathcal{H}_m [e_{2m-1}, e_{2m}], \tag{3.3}$$

$$V_{m+1}\chi_m = \widehat{V}_{m+1}. \tag{3.4}$$

Here χ_m is an upper 2×2 triangular matrix such that V_{m+1} has orthonormal columns; note that $\mathcal{H}_m$ is block upper Hessenberg with 2×2 blocks. Let also $\underline{\mathcal{T}}_m := \mathcal{V}_{m+1}^T A \mathcal{V}_m$. The computation of $\mathcal{T}_m$ seems to require additional matrix-vector products with A and extra inner products of long vectors. We next derive a recursion for $\underline{\mathcal{T}}_m$ that completely avoids this expensive step.

PROPOSITION 3.2. [illegible] $\ell^{(k)} = (\ell_{ij})$ [illegible] 2×2 [illegible] $V_k = \hat{V}_k \ell^{(k)}$ [illegible]
(3.3) $k = 1, \dots, m$ [illegible]

$$\underline{\mathcal{T}}_m = (t_{i,j})_{i=1,\dots,2m+2, j=1,\dots,2m} \qquad \mathcal{H}_m = (h_{i,j})_{i=1,\dots,2m, j=1,\dots,2m}.$$

[illegible]

$$t_{:,2k-1} = h_{:,2k-1}, \quad k = 1, \dots, m,$$

[illegible]

$$\begin{aligned}
(k=1) \quad & t_{:,2} = h_{:,1}(\ell_{11}^{(1)})^{-1}\ell_{12}^{(1)} + e_1(\ell_{11}^{(1)})^{-1}\ell_{22}^{(1)}, \qquad t_{:,4} = (e_2 - \underline{\mathcal{T}}_1 h_{1:2,2})\ell_{22}^{(2)}, \\
& \rho^{(2)} = (\ell_{11}^{(2)})^{-1}\ell_{12}^{(2)}, \\
(1 < k \le m) \quad & t_{:,2k} = t_{:,2k} + t_{:,2k-1}\rho^{(k)}, \\
& t_{:,2k+2} = (e_{2k} - \underline{\mathcal{T}}_k h_{1:2k,2k})\ell_{22}^{(k+1)}, \qquad \rho^{(k+1)} = (\ell_{11}^{(k+1)})^{-1}\ell_{12}^{(k+1)}.
\end{aligned}$$

[illegible]. For $k \ge 1$, we write $V_k = [V_k^{(1)}, V_k^{(2)}] \in \mathbb{R}^{n\times 2}$. Using (3.3), we immediately have $AV_k^{(1)} = V_{k+1}\chi_k e_1 + \mathcal{V}_k \mathcal{H}_k e_{2k-1} = \mathcal{V}_{k+1}\underline{\mathcal{H}}_k e_{2k-1}$, so that the odd columns of $\mathcal{T}_m$ satisfy

$$\mathcal{V}_m^T A \mathcal{V}_m e_{2k-1} = \mathcal{V}_m^T A V_k^{(1)} = \begin{bmatrix} I_{2k+1} \\ O \end{bmatrix} \underline{\mathcal{H}}_k e_{2k-1} = \mathcal{H}_k e_{2k-1}.$$

The even columns need to take into account that the recurrence comes from multiplications by A^{-1}, and thus the term $AV_k^{(2)}$ is not explicitly available. However, from (3.3) we obtain

$$V_k^{(2)} = A\widehat{V}_{k+1}^{(2)} + A\mathcal{V}_k \mathcal{H}_k e_{2k},$$

which gives a recurrence for the $(2k+2)$th column $A\widehat{V}_{k+1}^{(2)}$. Hence,

$$\mathcal{V}_{m+1}^T A \widehat{V}_{k+1}^{(2)} = \mathcal{V}_{m+1}^T V_k^{(2)} - \mathcal{V}_{m+1}^T A \mathcal{V}_k \mathcal{H}_k e_{2k} = e_{2k} - \begin{pmatrix} \underline{\mathcal{T}}_k \\ O_{m-k,2k} \end{pmatrix} \mathcal{H}_k e_{2k}.$$

To complete the derivation, we recall that $V_{k+1} = \widehat{V}_{k+1}\ell^{(k+1)}$, with $\ell^{(k+1)} = (\ell_{ij})$ upper triangular, so that $V_{k+1}^{(2)} = \widehat{V}_{k+1}^{(1)}\ell_{12} + \widehat{V}_{k+1}^{(2)}\ell_{22}$, from which $AV_{k+1}^{(2)} = A\widehat{V}_{k+1}^{(1)}\ell_{12} + A\widehat{V}_{k+1}^{(2)}\ell_{22} = AV_{k+1}^{(1)}\ell_{11}^{-1}\ell_{12} + A\widehat{V}_{k+1}^{(2)}\ell_{22}$. Therefore,

$$\mathcal{V}_{m+1}^T A V_{k+1}^{(2)} = \mathcal{V}_{m+1}^T \mathcal{V}_{k+2} \underline{\mathcal{H}}_{k+1} e_{2k+1}\ell_{11}^{-1}\ell_{12} + \left(e_{2k} - \begin{pmatrix} \underline{\mathcal{T}}_k \\ O_{m-k,2k} \end{pmatrix} \mathcal{H}_k e_{2k} \right) \ell_{22}.$$

The recursion thus follows. ∎

The recurrence for $\underline{\mathcal{T}}_m$ shows that the lower diagonal 2×2 block has a zero second row. This fact can be used to simplify the computation of the residual norm.

PROPOSITION 3.3. [illegible] $m \geq 1$ [illegible] $\mathbf{K}_m = \mathrm{Range}(\mathcal{V}_m)$ [illegible] X_m [illegible] (3.1) [illegible] $R_m = AX_m + X_m A^T + BB^T$ [illegible] $\mathrm{Range}(R_m) = \mathrm{Range}(\mathcal{V}_{m+1})$ [illegible] $\|R_m\| = \|e_{2m+1}^T \underline{\mathcal{T}}_m Y_m\|$ [illegible]. Since $A\mathcal{V}_m = \mathcal{V}_{m+1}L$, for some matrix L, the first result follows from (2.3). Therefore, $R_m = \mathcal{V}_{m+1}\widehat{R}_m\mathcal{V}_{m+1}^T$, with

$$\widehat{R}_m = \mathcal{V}_{m+1}^T R_m \mathcal{V}_{m+1} = \begin{pmatrix} 0 & \mathcal{V}_m^T R_m V_{m+1} \\ V_{m+1}^T R_m \mathcal{V}_m & 0 \end{pmatrix}.$$

Using $V_{m+1}^T R_m \mathcal{V}_m = E_{m+1}^T \underline{\mathcal{T}}_m Y_m$, it follows that $\|R_m\| = \|\widehat{R}_m\| = \|V_{m+1}^T R_m \mathcal{V}_m\| = \|E_{m+1}^T \underline{\mathcal{T}}_m Y_m\| = \|e_{2m+1}^T \underline{\mathcal{T}}_m Y_m\|$. ∎

The matrix Y_m in the solution $X_m = \mathcal{V}_m Y_m \mathcal{V}_m^T$ is often numerically positive semidefinite [29], [16], [37]. If this is so, it is possible to generate a lower rank X_m as $X_m = Z_m Z_m^T$, with Z_m of rank lower than $2m$, the dimension of Y_m. More precisely, let $Y_m = WDW^T$ be the eigendecomposition of the $2m \times 2m$ matrix Y_m, with D diagonal having diagonal entries sorted in decreasing order, and let $W_k D_k W_k^T$ be the approximate decomposition obtained by truncating to the first k columns of W, with $k \ll 2m$. Then $Y_m \approx W_k D_k W_k^T$, and the approximation is determined by using $Z_m = V_m W_k D_k^{\frac{1}{2}}$. The number k of columns to retain may be determined by inspecting the diagonal elements of D. In our implementation, we discarded the columns of W corresponding to diagonal elements of D less than 10^{-12}; a more conservative tolerance could also be employed.

Due to the form of the approximate solution, it is also possible to monitor at low cost the amount by which the approximate solution varies as the iterations proceed. Indeed, letting

$$Y_m = \begin{bmatrix} \widehat{Y}_m & y_m \\ y_m^T & \eta_m \end{bmatrix},$$

with $\widehat{Y}_m$ of size $(2m-2)\times(2m-2)$, we have

$$X_m - X_{m-1} = [\mathcal{V}_{m-1}, V_m] \begin{bmatrix} \widehat{Y}_m - Y_{m-1} & y_m \\ y_m^T & \eta_m \end{bmatrix} [\mathcal{V}_{m-1}, V_m]^T =: \mathcal{V}_m G_m \mathcal{V}_m^T,$$

so that

$$\frac{\|X_m - X_{m-1}\|_F}{\|X_{m-1}\|_F} = \frac{\|G_m\|_F}{\|Y_{m-1}\|_F}, \tag{3.5}$$

where both G_m and Y_{m-1} have small dimension. We do not advocate using this quantity as a stopping criterion; however, we shall sometimes refer to it in our experiments for comparison purposes.

3.1. Implementation details. An implementation of the algorithm associated with the procedure outlined above is given by the function Krylov-plus-inverted-Krylov (hereafter K-PIK). For the sake of simplicity, we report here the case $s = 1$. The general case $s \geq 1$ is depicted in the appendix. The two codes differ only in the matrix indexing. Both codes are available from the author upon request.

```
function Z=K_PIK(A,rhs,m_max,k_max,tol)

nrmb=norm(rhs,'fro')^2;
nrma=norm(A,'fro');

[LA,UA]= lu(A);               % For sym matrices use UA=chol(-A); LA=-UA';
[ibeta,U(:,1:2)] = gram_sh([rhs, UA\ (LA\ rhs)]);

for j=1:m_max,

  % Expand the approximation space
  jms=(j-1)*2+1;j1s=(j+1)*2;js=j*2;js1=js+1;
  Up(:,1) = A*U(:,jms);     Up(:,2) = UA\ (LA\ U(:,js));

  %New Basis Block
  for il=1:2           % Reorthogonalization
      k_min=max(1,j-k_max);
      for kk=k_min:j
         k1=(kk-1)*2+1; k2=kk*2;
         coef= U(1:n,k1:k2)'*Up;
         H(k1:k2,jms:js) = H(k1:k2,jms:js)+ coef;
         Up = Up - U(:,k1:k2)*coef;
      end
  end
  if (j<=m_max)
      [hinv,U(1:n,js1:j1s)]=gram_sh(Up);    H(js1:j1s,jms:js)=inv(hinv);
  end
  I = speye(js+2);

  % Update the T recurrence

Y0 = uY(:,1:is)*diag(sqrt(sY(1:is)));
Z = U(:,1:js)*Y0;
```

A few comments are in order. The LU factorization of A is employed for medium-size matrices, and the Cholesky factorization of $-A$ should be used for A symmetric. For large matrices, a preconditioned iterative method could be employed to solve systems with A at each iteration, where the preconditioner could be generated once for all; see section 5.3 for some experiments.

Function `gram_sh` performs the modified Gram–Schmidt orthogonalization of the new block [14]. The same process is used for the orthogonalization with respect to older vectors in the basis. Note that this reduces to a procedure similar to the block Lanczos algorithm (see [15]) when the problem is symmetric, by setting `k_max = 2`, so that only orthogonalization with respect to the previous two blocks is enforced. In particular, for A symmetric, the whole matrix $\mathcal{V}_m$ is needed only at convergence to recover the solution factor. Therefore, one can either store the columns that are not needed in the orthogonalization process or use a "two-pass" procedure, in which the basis vectors are first discarded. At convergence, the short-term iteration is performed once again to recover the basis vectors and update the final solution. Although this procedure is expensive, essentially doubling the computational cost of the generation of the approximation space, the memory requirements become extremely limited, allowing one to tackle very large problems, in the symmetric case. It is well known that if orthogonality is not enforced explicitly, as is the case when using short-term recurrences for A symmetric, loss of orthogonality of the columns of $\mathcal{V}_m$ may affect the computation of the matrix $\mathcal{H}_m$ and of the residual norm in Proposition 3.3. If one is willing to keep the whole basis in fast memory, orthogonalization of all basis vectors can be explicitly performed. Problems increase for $s > 1$. We refer to [19] for a recent presentation of these issues and for safeguard strategies that can be implemented to mitigate the problem in the block setting.

The function `lyap` computes the numerical solution of the small dimensional Lyapunov equation by means of a Schur decomposition-type method; in our experiments, we used the algorithm proposed by Sorensen and Zhou [38], which implements the Bartels–Stewart method with only real arithmetic; other alternatives may be considered as, e.g., in the SLICOT package ([5], [36], [41]). Since the matrix $\mathcal{T}_m$ is stable, other procedures such as the Hammarling method could also be employed [20]. Note also that the fact that $\mathcal{T}_m$ is block upper Hessenberg significantly reduces the computational work of the method. We should remark, however, that as the approximation subspace increases, this step becomes the most computationally demanding task of the algorithm.

The stopping criterion is

$$\frac{\|AX_m + X_m A^T + BB^T\|}{2\|A\|_F\|Y_m\|_F + \|B\|_F^2} \leq \texttt{tol}, \tag{3.6}$$

where `tol` is a chosen fixed threshold. The numerator is obtained by using the computationally inexpensive relation of Proposition 3.3. We observe that the output matrix is the memory-conserving factor Z_m of $X_m = Z_m Z_m^T$.

3.2. Finite termination and convergence. For the sake of simplicity, in this section we mostly limit our discussion to the case $s = 1$. In exact arithmetic, the procedure just described has finite termination, since for m such that $2m \geq n$ the generated vectors span the whole space. However, since two vectors at a time are added to the current basis, loss of rank may occur during the orthogonalization with respect to the older basis vectors, so that the next basis pair using V_{m+1} cannot be built. We next show that this implies convergence, as expected by the result of Proposition 3.1.

PROPOSITION 3.4. [illegible] $m-1$ [illegible] $B \in \mathbb{R}^n$ [illegible] m [illegible] $\widehat{V}_{m+1}$ [illegible] (3.3) [illegible] $\mathcal{V}_m \cup \{\widehat{V}_{m+1}\}$ [illegible] A [illegible] B [illegible] $\mathrm{Range}(\mathcal{V}_m \cup \{\widehat{V}_{m+1}\})$ [illegible]. We recall that $\mathrm{Range}(\mathcal{V}_m) = \mathcal{K}_{2m}(A, A^{-m}B)$. Therefore, the given assumption requires that there exist $\alpha_i \in \mathbb{R}$, $i = -m-1, \ldots, m$, not all zero such that

$$\alpha_{-m}A^{-m}B + \cdots + \alpha_{-1}A^{-1}B + \alpha_0 B + \alpha_1 AB + \cdots + \alpha_{m-1}A^{m-1}B + \alpha_m A^m B + \alpha_{-m-1}A^{-m-1}B = 0.$$

Assume first $\alpha_{-m-1} = 0$ and $\alpha_m \neq 0$. Then $A(A^{m-1}B) = \sum_{j=0}^{2m-1} \beta_j A^j A^{-m} B$, which shows that $A\mathcal{V}_m = \mathcal{V}_m \mathcal{T}_m$, and thus $\mathcal{V}_m$ is invariant for A. Using $X_m = \mathcal{V}_m Y_m \mathcal{V}_m^T$, we obtain

$$AX_m + X_m A^T + BB^T = \mathcal{V}_m(\mathcal{T}_m Y_m + Y_m \mathcal{T}_m + EE^T)\mathcal{V}_m^T = O.$$

Next, assume that $\alpha_{-m-1} \neq 0$ and $\alpha_m \neq 0$. Then

$$A^{-1}A^{-m}B = \sum_{j=0}^{2m-1} \beta_j A^j A^{-m} B + \beta_{2m} A^m B,$$

or, equivalently, $A^{-m}B - \sum_{j=1}^{2m} \beta_j A^j A^{-m} B = \beta_{2m} A(A^m B)$, so that $A[\mathcal{V}_m, V_m^{(1)}] = [\mathcal{V}_m, V_m^{(1)}]\widehat{\mathcal{T}}_m$, where $\widehat{\mathcal{T}}_m$ is the restriction of $\mathcal{T}_{m+1}$ to the first $(2m+1)$ columns and rows. Therefore, $[\mathcal{V}_m, V_m^{(1)}]$ is invariant for A. As in the previous case, writing $X'_m = [\mathcal{V}_m, V_m^{(1)}] Y'_m [\mathcal{V}_m, V_m^{(1)}]^T$, where Y'_m is the solution to the Lyapunov equation with coefficient matrix $\widehat{\mathcal{T}}_m$, we obtain $AX'_m + X'_m A^T + BB^T = [\mathcal{V}_m, V_m^{(1)}](\widehat{\mathcal{T}}_m Y'_m + Y'_m \widehat{\mathcal{T}}_m + EE^T)[\mathcal{V}_m, V_m^{(1)}]^T = O$, and the proof is completed. ∎

If B is not a vector, then loss of rank while generating the basis may occur without convergence taking place. In this case, deflation strategies should be employed, as in standard block Krylov subspace methods [19].

In section 2 we discussed the relation between the approximation to the exponential and the projected Lyapunov equation. The new approach implicitly approximates $W = \exp(A)B$, with $\widehat{W} = \mathcal{V}_m \exp(\mathcal{T}_m)E$ in $\mathbf{K}_m = \mathcal{K}_{2m}(A, A^{-m}B)$, and results in this context can be used to theoretically motivate our approach. For A symmetric and B a vector, it is shown by Druskin and Knizhnerman in [11] that the choice $\mathcal{K}_{2m}(A, A^{-m}B)$ yields an improved approximation to the exponential, over the standard Krylov subspace $\mathcal{K}_{2m}(A, B)$. More precisely, they show that the quality of the approximation to the exponential (and in fact to a whole class of functions) in $\mathcal{K}_{2m}(A, B)$ corresponds to that in $\mathcal{K}_{\sqrt{2m}}(A, A^{-m}B)$. Therefore, using $\mathcal{K}_{\sqrt{2m}}(A, A^{-m}B)$ allows one to achieve the same approximation quality as a regular Krylov space with a much lower subspace dimension.

We explicitly observe that the method proposed in [11] aims at approximating [illegible]. In addition, the authors suggest to fix a priori the number k of matrix-vector products with A^{-1}, so as to implicitly build the approximation space $\mathrm{span}\{A^{-k}v, A^{-k+1}v, \ldots, Av, \ldots, A^{m-1}v, \ldots\}$, where m (but not k) is allowed to increase. Here we propose to increase the subspace dimension in "both directions" until convergence. This can be easily done thanks to the recurrence in Proposition 3.2 for the matrix $\mathcal{T}_m$.

4. The Cholesky-factorized ADI iteration. The Lyapunov equation was shown to be a "model problem" for the classical ADI iteration; see [12], [42], [13], [26]. More recently, a Cholesky-factorized (CF) version has made the method more appealing for large-scale computation, for the approximate solution can be written as the product of two low rank matrices [25], [28], [30]. We next review various implementation details of this method to clarify its use in our numerical comparisons in section 5. Finally, we should mention that for the CF-ADI method to be derived, A is required only to be stable; that is, its eigenvalues should lie in the left-half plane, whereas projection-type methods need dissipativity, to ensure that the matrix V^TAV in (2.1) is stable.

Given a set of parameters $p_1, p_2, \ldots, p_\ell$, the basic ADI iteration determines an approximate solution as (cf., e.g., [25])

$$X_0 = 0,\ X_j = -2p_j(A+p_jI)^{-1}BB^T(A+p_jI)^{-T} + (A+p_jI)^{-1}(A-p_jI)X_{j-1}(A-p_jI)^T(A+p_jI)^{-T}, \quad j=1,\ldots,\ell.$$

It can be shown that X_j is symmetric and positive (semi)definite, so that it can be represented as $X_j = Z_jZ_j^T$, and is iteratively built one set of s columns at a time. The actual implementation, hereafter CF-ADI, requires s solutions with $A+p_jI$ per iteration; see, e.g., [25, Algorithm 2]. A cyclic procedure is obtained by continuing the iteration above and cyclically using the parameters, and this is also referred to as the cyclic low rank Smith(ℓ) method [28]. The recurrence can be stopped as soon as the residual matrix $AZ_jZ_j^T + Z_jZ_j^TA^T + BB^T$ is sufficiently small in some norm. It was shown in [28] that

$$\|AZ_jZ_j^T + Z_jZ_j^TA^T + BB^T\|_F = \|[AZ_j, Z_j, B][Z, AZ_j, B]^T\|_F = \|r\mathcal{I}r^T\|_F, \tag{4.1}$$

where r is the triangular square matrix of the "economy-size" QR factorization of the matrix $[AZ_j, Z_j, B]$, and $\mathcal{I}$ is a permutation matrix. Due to memory limitations, the previous quantities cannot be computed explicitly for large problems; therefore, a criterion based on the current iterate is commonly employed. More precisely, if $Z_j = [Z_{j-1}, z_j]$, then using $\|Z_jZ_j^T - Z_{j-1}Z_{j-1}^T\|_F = \|z_j\|^2$, the iteration is stopped if $\|z_j\|$ (absolute) or $\|z_j\|/\|Z_{j-1}\|_F$ (relative) is sufficiently small, which implies that the recurrence stagnates. Note that neither of these last two stopping criteria ensures that convergence has taken place.

The ADI parameters represent the key ingredient for the real success of the method. Optimal parameters are known analytically when A has a real spectrum; see, e.g., the discussion in [13]. The situation is significantly more complicated for a complex spectrum. In both cases, however, quite accurate information on the spectral region is required. The computation of quasi-optimal parameters has raised considerable attention; see, e.g., [39], [13], [34], and references therein. In particular, an economical procedure was proposed by Penzl in [28]. In our experiments, we used the function[2] `lp_para` in the LYAPACK package [30] to compute these suboptimal ADI parameters.

Another important implementation aspect is related to the solutions with $A+p_jI$, $j=1,\ldots,\ell$. Each matrix $A+p_jI$ can be factorized once for all and the Cholesky factor stored and used cyclically when p_j is employed; cf., e.g., [30]. For the sake of comparison, we use this strategy in Example 5.1, where factorizing the matrix requires limited

[2]The Arnoldi procedures in `lp_para` were modified to include reorthogonalization, so as to limit the occurrence of unstable shifts.

memory resources. Since this procedure is clearly too memory-consuming in large-scale applications, we opted for solving systems with $A+p_jI$ repeatedly at occurrence.

An additional difficulty is given by the use of complex arithmetic when A is non-symmetric and the ADI parameters are complex conjugate. In the original CF-ADI iteration, conjugate parameters can be coupled [25]. In the cyclic version, coupling does not seem to be doable, and the whole computation is carried out in complex arithmetic to get a complex Z_j. Note that it is possible to recover a real factor Z_j at the cost of additional computation [30]; alternatively, Gugercin, Sorensen, and Antoulas suggest only dealing with real parameters, even when the matrix has a complex spectrum [18]. To fully explore the properties of the method, in our experiments with the cyclic CF-ADI method we decided to use complex parameters and thus allowed complex arithmetic throughout the iteration. Further considerations regarding the typical behavior of this method are reported in the next section.

5. Numerical experiments. In this section we report on our numerical experience with the new method described in section 3. Comparisons with the cyclic CF-ADI method are also considered. All reported experiments were obtained using Matlab 7.1 (R3) [27], on a PC with a 2 GHz processor, and 2 GBytes of RAM.

Both CPU time (in seconds) and number of iterations (as defined next) are used to measure the cost of the approaches. For the CF-ADI method, the number of iterations (counted as s times the number of cycles times the number of parameters) coincides with the number of shifted systems to be solved and also with the number of long vectors that need to be stored. For the K-PIK method, each (block) iteration involves s system solutions with A and $2s$ new vectors entering the basis. Therefore, for the Krylov approach the final memory requirements for the approximation space are given by at most $2s$ times the number of iterations.

In all tests with the new method, we also report the rank of the final approximate solution as discussed in section 3. The cost of this computation is included in the overall cost of the method. For the CF-ADI iteration, we did not attempt to compute the factor rank to limit the computational costs. Nonetheless, we remark that a procedure has been proposed in [18] to more cheaply determine a lower rank factor that is updated at each iteration. For the sake of generality, we do not reproduce this implementation, as it requires further conditions and additional computation per iteration, although it may provide significant memory savings when the ADI solution space is large. In general, this procedure does not improve the convergence rate of the method; more details can be found in [18]; see also [34] for a recent thorough analysis of the method.

Unless explicitly stated, the CF-ADI complex parameters were determined with search parameters $(\ell, k, m) = (10, 40, 20)$, where ℓ is the number of ADI parameters,[3] k is the number of Arnoldi iterations, and m is the number of inverted-Arnoldi iterations in the procedure `lp_para`; these are the parameters suggested in [28] for similar problems. We stress that the cost of generating the ADI parameters was taken into account in the performance evaluation. Indeed, unless some tuning on (ℓ, k, m) is needed (cf., for instance, Example 5.2), this preprocessing employs only a low percentage of the whole cost of the algorithm. Our numerical experience showed that the computation of the parameters was also sensitive to the choice of the starting vector that was used for generating spectral information. ADI parameters determined with the same values (ℓ, k, m) but with a different starting vector for the two Krylov subspaces were significantly different, affecting the performance of the ADI iteration.

[3] This number may need to be adjusted to accommodate complex conjugates.

. As already mentioned, a comparison between the new method and the cyclic CF-ADI method faces the problem of the different stopping criteria used in the two cases, namely, (3.6) and the one discussed in section 4. Indeed, the fact that the two stopping criteria are satisfied in the two cases does not ensure that the quality of the approximate solution is comparable. For this reason we decided to take the "user point of view"; that is, we measure what the user can really handle during the run of the algorithm. To this end, we fix a certain tolerance and evaluate the performance of the two methods by monitoring the associated "standard" stopping criterion. More precisely,

$$\text{K-PIK:} \qquad \frac{\|AX_m + X_m A^T + BB^T\|}{2\|A\|_F\|Y_m\|_F + \|B\|_F^2} \le \texttt{tol}, \tag{5.1}$$

$$\text{Cyclic CF-ADI:} \qquad \frac{\|z_j\|}{\|Z_{j-1}\|_F} \le \sqrt{\texttt{tol}}. \tag{5.2}$$

We recall that (5.2) corresponds to $\|X_j - X_{j-1}\|_F / \|X_{j-1}\|_F \le \texttt{tol}$. In all examples considered, we used $\texttt{tol} = 10^{-10}$. In some cases, the final residual norm (4.1) of the CF-ADI iteration was also computed, but this cost was not included in the total computational requirements of the method, because in most cases it was overwhelming. We found the CF-ADI residual norm often to be above the requested residual tolerance.

5.1. The case $s = 1$. In this section we focus on the case where B is a vector, that is, $s = 1$, to emphasize some implementation issues.

5.1. This example is taken from [28, Example 6.3] and describes a model of heat flow with convection in the given domain. The associated parabolic equation is given by

$$\mathbf{x}' = \mathbf{x}_{xx} + \mathbf{x}_{yy} - 10x\mathbf{x}_x - 1000y\mathbf{x}_y + \mathbf{b}(x,y)\mathbf{u}(t)$$

on the unit square, with Dirichlet boundary conditions. The 4900×4900 matrix A resulting from the centered finite difference discretization of the differential terms is nonsymmetric with complex eigenvalues and has 24220 nonzero entries. Vector b was taken to be the vector of all ones. This choice allows one to completely replicate the reported experiments. The results in the following table show the performance of the new method, compared to the cyclic CF-ADI iteration. For the sake of completeness, in this example we also report the performance of the CF-ADI method when all matrix factorizations are carried out at the beginning of the computation and thus stored, so that at each ADI iteration only triangular solutions are performed (CF-ADI_m column).

	K-PIK	CF-ADI	CF-ADI_m
CPU time (s)	1.1	14	9
# iterations	19	80	80
Dim. approx. space	38	80	80
Solution rank	35	80	80

The reported values show the competitiveness of the new method on this medium-size problem, with low CPU time and memory requirements. A posteriori, we computed the residual norm of the CF-ADI solution and found that it was above 10^{-5}. Following (3.5), we also computed the relative norm of the variation in the solution of the new method, which for this example was $5.7 \cdot 10^{-8}$. All of these numbers show

that the quality of the approximate solutions significantly differs, depending on the employed measure. In this particular case, we observed in a separate experiment that letting the K-PIK solution difference (3.5) go below the threshold 10^{-10} took only less than one additional second of CPU time.

EXAMPLE 5.2. This example is a three-dimensional variant of the previous problem, and the differential equation is given by

$$\mathbf{x}' = \mathbf{x}_{xx} + \mathbf{x}_{yy} + \mathbf{x}_{zz} - 10x\mathbf{x}_x - 1000y\mathbf{x}_y - 10\mathbf{x}_z + \mathbf{b}(x, y)\mathbf{u}(t)$$

on the unit cube, with Dirichlet boundary conditions. The nonsymmetric matrix resulting from centered finite difference discretization with 18 nodes in each direction is of size 5832×5832 and has 38880 nonzero entries. Once again, b was taken to be the vector of all ones. The results are shown in the first part of the following table.

n		K-PIK	CF-ADI (10,40,20)	CF-ADI (16,60,40)
5832	CPU time (s)	15	149	112
	# iterations	56	110	85
	Dim. approx. space	112	110	85
	Solution rank	47	110	85
		K-PIK	CF-ADI (16,60,40)	CF-ADI (30,60,60)
10648	CPU time (s)	43	336	236
	# iterations	45	85	65
	Dim. approx. space	90	85	65
	Solution rank	45	85	65

The reported numbers are consistent with those of the previous experiments. It is worth noticing that at completion, for the new method the difference $\|X_m - X_{m-1}\|/\|X_{m-1}\|$ was equal to about $2 \cdot 10^{-8}$ in both problems (cf. (3.5)).

The behavior for different CF-ADI parameters is also reported. The computed parameters for the two choices are also depicted in Figure 5.1, where the symbol "×"

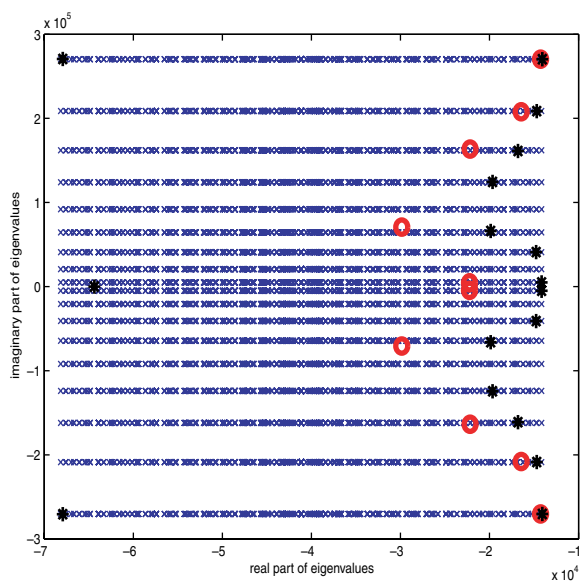

FIG. 5.1. *Example* 5.2. *Spectrum of matrix A (×), ADI parameters for* $(\ell, k, m) = (10, 40, 20)$ *(symbol o) and for* $(\ell, k, m) = (16, 60, 40)$ *(symbol *).*

denotes the eigenvalues of A, "o" the ADI parameters for $(\ell, k, m) = (10, 40, 20)$, and "*" the case $(\ell, k, m) = (16, 60, 40)$. The last choice is clearly more successful in capturing the relevant spectral boundary, suggesting better performance.

In the table above we also report the results for a run of the same problem with a slightly finer discretization, leading to a 10648×10648 nonsymmetric matrix A with 71632 nonzero entries. The results are consistent with those for the coarser mesh, confirming the difficulty of the CF-ADI preprocessing in finding effective ADI parameters even for different discretizations of the same problem. For $\ell = 30$, the CF-ADI stopping criterion was monitored at every iteration.

EXAMPLE 5.3. With this example we start our tests on symmetric problems. Here we consider the parabolic equation

$$\mathbf{x}' = \mathbf{x}_{xx} + \mathbf{x}_{yy} + \mathbf{x}_{zz} + \mathbf{b}(x, y)\mathbf{u}(t)$$

with homogeneous boundary conditions and discretize the 3D Laplace operator with centered finite differences in the unit cube. The resulting symmetric matrix for the given discretization mesh has size $n = 27000$. The vector b is the vector of all ones. Note that both methods can take great advantage of the symmetry of A. In particular, the CF-ADI is all performed in real arithmetic, with $\ell = 10$ real parameters. The results are reported below.

	K-PIK	CF-ADI
CPU time (s)	132	202
# iterations	8	20
Dim. approx. space	16	20
Solution rank	14	20

The numbers confirm the competitiveness of the new method, which does not require any preprocessing to gain spectral information.

EXAMPLE 5.4. We next consider a benchmark problem stemming from a semidiscretized heat transfer problem for optimal cooling of steel profiles [7]. The associated linear time-invariant system is given by

$$\begin{aligned} M\mathbf{x}'(t) &= N\mathbf{x}(t) + B_0\mathbf{u}(t), \quad \text{with} \quad t > 0, \\ \mathbf{x}(0) &= \mathbf{x}_0, \\ \mathbf{y}(t) &= C_0\mathbf{x}(t), \end{aligned}$$

with M symmetric positive definite, N symmetric negative definite, and B_0 of small column rank. We considered two tests available in the data set in [8], corresponding to different mesh resolutions, with dimensions $n = 1357$ (file `rail_1357_c60`) and $n = 5177$ (`rail_5177_c60`). In our experiments, we used the first column of B_0 for each data set.

The numerical treatment of this problem requires the discussion of some additional details. For M nonsingular, the problem can be recast as in (1.1). Using $M = LL^T$, we have $A = L^{-1}NL^{-T}$, $B = L^{-1}B_0$, and $C = C_0L^{-1}$. Clearly, none of these matrices is computed explicitly; rather, the following operations are performed:

$$Av = L^{-1}(N(L^{-T}v)), \qquad A^{-1}v = L^T(N^{-1}(Lv)).$$

Thus, matrix-vector products with A require the sequential solution of two triangular systems. To limit the computational cost, the stopping criterion (5.1) was used with $\|A\|_F \approx \|N\|_F$. In the case of the ADI iteration, the system solution is given as $(A + pI)^{-1}v = L^T(N + pM)^{-1}Lv$, therefore requiring the solution of $\ell = 10$ systems with coefficient matrix $N + pM$ at each ADI cycle.

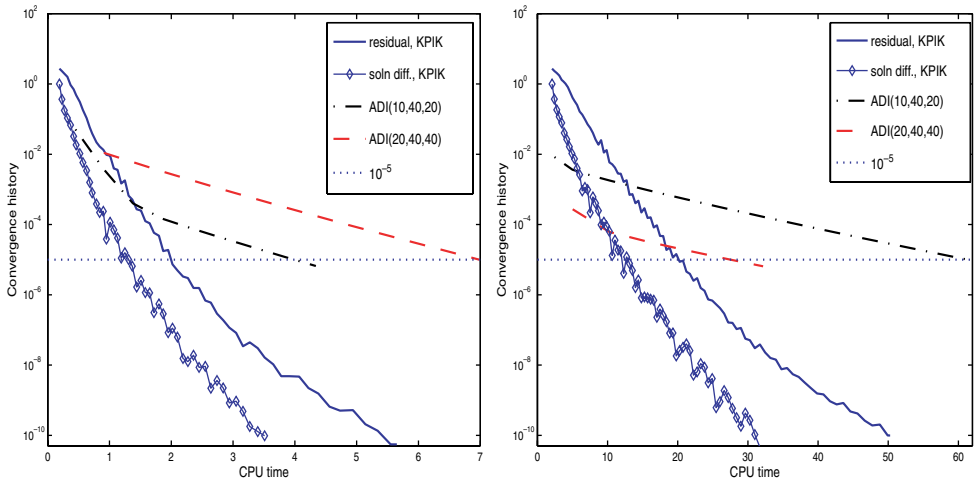

FIG. 5.2. *Example* 5.4. *Convergence history of the two methods. Left:* $n = 1357$. *Right:* $n = 5177$.

The results for both problems are summarized in the following table.

n		K-PIK	CF-ADI (10,40,20)	CF-ADI (20,40,40)
1357	CPU time (s)	5.67	4.36	6.96
	# iterations	59	90	140
	Dim. approx. space	118	90	140
	Solution rank	12	90	140
	Final residual F-norm	$< 10^{-10}$(†)	$2.8 \cdot 10^{-5}$	$2.8 \cdot 10^{-5}$
5177	CPU time (s)	50	62	32
	# iterations	86	220	120
	Dim. approx. space	172	220	120
	Solution rank	13	220	120
	Final residual F-norm	$< 10^{-10}$(†)	$9.9 \cdot 10^{-5}$	$9.9 \cdot 10^{-5}$

†: Before rank truncation

We observe that the first problem is quite small, and the K-PIK method is penalized, since its auxiliary costs (reorthogonalizations and the solution of a small Lyapunov equation) may be significant.

In this set of experiments, $\|B\| \approx 10^{-7}$ and $\|A\|_F \approx 10^{-3}$, so that $\|X\| \approx 10^{-3}$. These figures make the two stopping criteria behave very differently and seem to show that the CF-ADI method performs better than Krylov, when the parameters are properly chosen (note, however, that the performance of the parameters is dimension-dependent). We investigate further this example by reporting the convergence curves in Figure 5.2. There, we show the behavior of the relative difference $\|X_m - X_{m-1}\|/\|X_{m-1}\|$ for both methods and also the residual norm for the Krylov approach. Clearly, had the K-PIK convergence been measured in terms of the solution difference, the iteration would have been stopped much earlier, with significant savings in both memory and CPU time requirements. In the table above we also report the final relative residual norm (cf. (5.1)) of the CF-ADI iteration. According to this measure, the accuracy of the CF-ADI solution is not satisfactory, for a tolerance `tol`$=10^{-10}$.

5.2. The case $s \geq 1$. The algorithm for the general case $s \geq 1$ is reported in the appendix. In Table 5.1 we display the performance of the K-PIK and CF-ADI

TABLE 5.1
Experiments when B has multiple columns ($s \geq 1$).

	s	K-PIK			CF-ADI		
		CPU time	# its	dim. space	CPU time	# its	dim. space
Example 5.4	1	5.95	12	24	31.66	6	120
`tol`=10^{-5}	2	8.08	10	40	30.83	5	200
	4	11.11	7	56	40.20	5	400
	7	18.12	6	84	54.22	5	700
Example 5.2	1	38.95	34	68	588.68	5	150
`tol`=10^{-8}	2	50.50	33	132	633.41	5	300
	4	90.69	33	264	722.92	5	600
	7	204.91	32	448	857.57	5	1050

methods for $s = 1, 2, 4, 7$ on the largest matrices of two of the test problems. To make the comparison easier to interpret, and in light of the discussion related to Example 5.4, the relative change in the iterative solution is used as the stopping criterion for both methods. The original data in Example 5.4 included up to 7 columns of B, and these are all considered in the experiment. For Example 5.2 we picked up the first $s \leq 7$ columns of the matrix $B \in \mathbb{R}^{n\times 10}$ with random normal entries (random number generator initialized as `randn(''state'',0)`).

The K-PIK method clearly outperforms the CF-ADI procedure by keeping both CPU time and memory allocation limited. We recall that for the CF-ADI method, memory requirements may be reduced at some additional cost per iteration [18]. As s increases, the dimension of the "small" Lyapunov equation to be solved in K-PIK may become significant. To save computational time, the numerical solution of this equation may be thus performed periodically. Note that the number of iterations decreases as s increases; this is typical of "block" Krylov subspace methods.

5.3. The solution of the linear system with A. The K-PIK method requires solving s systems with A at each iteration, and this was performed by a direct method in the previous examples. For the sake of generality, in our experiments we have used natural orderings for the entries of A; however, it is well known that reordering techniques can dramatically improve the performance and memory requirements of a sparse direct solver. In practice, an appropriate reordering technique may allow the LU factorization to generate much sparser factors, which in turn implies faster solution with the triangular factors at each iteration. A typical such case is depicted in the following table, where K-PIK is used for the largest matrices in Examples 5.2 and 5.3, with $s = 1$ and with or without reordering of the matrix entries before the computation starts. The stopping tolerance for the Lyapunov solver is fixed at 10^{-10}, and the stopping criterion is (5.1). The functions `symamd` and `symrcm` are the Matlab implementation of "symmetric minimum degree" and of "reverse Cuthill–McKee" permutations, respectively. The former is particularly well suited for symmetric problems.

Example 5.3	Natural ordering	132 secs (8 iterations)
(sym. pb)	`symamd` ordering	31 secs (8 iterations)
Example 5.2	Natural ordering	43 secs (45 iterations)
(nonsym. pb)	`symrcm` ordering	22 secs (45 iterations)

If direct system solvers become prohibitively expensive, the K-PIK method can be implemented so that preconditioned iterative methods are used to solve the linear systems with A. In Table 5.2 we report the CPU time of K-PIK and $s = 1$, when the systems with A are solved by the bcgstab method with incomplete LU-type preconditioning (Matlab functions `luinc` and `cholinc`). The threshold used in the in-

TABLE 5.2
K-PIK on two test problems, with $s = 1$ and iterative solution of systems with A. Cholesky or LU preconditioners with fill-in threshold (Matlab functions `cholinc` *and* `luinc`*).*

	Inner tolerance	CPU time	# its	Avg. # inner its	Comments
Example 5.3	10^{-8}	26.19	8	17	Fill-in threshold 10^{-2}
(sym. pb)	10^{-5}	19.39	9	10	Fill-in threshold 10^{-2}
	10^{-3}	14.64	10	6	Fill-in threshold 10^{-2}
	10^{-3}	12.19	10	6	`symamd` permut., thr. 10^{-2}
Example 5.2	10^{-8}	22.92	45	4.5	Fill-in threshold 10^{-2}
(nonsym. pb)	10^{-5}	17.75	45	3	Fill-in threshold 10^{-2}
	10^{-3}	15.06	45	2	Fill-in threshold 10^{-2}
	10^{-3}	10.81	45	2	`symrcm` permut., thr. 10^{-2}
	10^{-3}	17.87	45	6	`symrcm` permut., thr. 10^{-1}

complete factorization allowed us to decrease the memory requirements for the factor by at least one order of magnitude. The stopping tolerance for the Lyapunov solver is again 10^{-10}, whereas various tolerances are tested for the iterative solution with A. All of these results significantly improve the performance of the corresponding direct method.

The first lines in Table 5.2 display results with a symmetric matrix. Due to the iterative solution of the system with A, so-called inexact solutions, this symmetry is lost. Nonetheless, the computation of the Lyapunov solver is still carried out by means of a short-term recurrence as if the operator were symmetric. This fact should explain the slight change in the total number of iterations as the inner system is solved less accurately, although the significant improvement in computational time more than compensates the higher number of iterations. We refer to [35] for pointers to similar so-called inner-outer methods in the linear system setting. The second set of experiments is with a nonsymmetric solver, for which full orthogonalization is performed. Note that the method does not seem to be particularly sensitive to a quite inaccurate solution of systems with A, showing that a rough approximation of the action of A^{-1} is sufficient to maintain fast convergence.

6. Conclusions. In this paper we have presented a new projection method for determining low rank approximate solutions to large-scale Lyapunov algebraic equations with a dissipative coefficient matrix. Our experiments show that the new algorithm is extremely competitive with the state-of-the-art solver cyclic CF-ADI, and it does not require parameter estimation. The new approach provides a natural, cheaply computable a posteriori stopping criterion. Note that such a measure is missing in the cyclic CF-ADI iteration. Moreover, the new method provides an economical procedure to further decrease the rank of the final approximate factor. The approach effectively reduces the original problem to one of much smaller dimension in a way that information on the problem augments as the dimension of the approximation space increases. This viewpoint is completely different from the CF-ADI type of iteration, where spectral information on the problem is gathered beforehand and then used repeatedly. This difference is reminiscent of the differences between semi-iterative and fully nonstationary methods in the solution of systems of linear equations [14]. We have tested the new approach on medium-size problems, while even greater benefits can be obtained when solving larger problems. In this case, the advantages observed in section 5.3 in using preconditioned iterative system solvers may be even more significant. We also mention that if the dimension of the approximation space becomes

large, then the costly step of solving the projected Lyapunov equation can be done periodically and not at every iteration. This small variant may significantly reduce the overall cost of the method.

The general framework described in section 2 suggests that further acceleration techniques could be derived by constructing new approximation spaces that satisfy the given constraints. Moreover, several computational issues deserve deeper investigation, such as the possibility of implementing truncation, restarting, or some other memory-conserving strategy. Finally, a complete round-off error analysis of the procedure would help fully understand the behavior of the method in finite precision arithmetic.

Appendix. In this appendix we describe the Matlab implementation of the K-PIK method when B is a tall $n \times s$ matrix. A direct method is used to solve systems with A.

```
function X=K_PIK(A,rhs,m,tol,k_max,period)

t=cputime;
[n,sh]=size(rhs);
nrmb=norm(rhs,'fro')^2;  nrma=norm(A,'fro');

PARALLEL SYMBOLIC FACTORIZATION FOR SPARSE LU WITH STATIC PIVOTING*

LAURA GRIGORI†, JAMES W. DEMMEL‡, AND XIAOYE S. LI§

Abstract. This paper presents the design and implementation of a memory scalable parallel symbolic factorization algorithm for general sparse unsymmetric matrices. Our parallel algorithm uses a graph partitioning approach, applied to the graph of $|A|+|A|^T$, to partition the matrix in such a way that is good for sparsity preservation as well as for parallel factorization. The partitioning yields a so-called separator tree which represents the dependencies among the computations. We use the separator tree to distribute the input matrix over the processors using a block cyclic approach and a subtree to subprocessor mapping. The parallel algorithm performs a bottom-up traversal of the separator tree. With a combination of right-looking and left-looking partial factorizations, the algorithm obtains one column structure of L and one row structure of U at each step. The algorithm is implemented in C and MPI. From a performance study on large matrices, we show that the parallel algorithm significantly reduces the memory requirement of the symbolic factorization step, as well as the overall memory requirement of the parallel solver. It also often reduces the runtime of the sequential algorithm, which is already relatively small. In general, the parallel algorithm prevents the symbolic factorization step from being a time or memory bottleneck of the parallel solver.

Key words. sparse LU factorization, parallel symbolic factorization, memory scalability

1. Introduction.

We consider solving a sparse unsymmetric system of linear equations $Ax = b$ using a direct method, which first factorizes the matrix A into the product of a unit lower triangular matrix L and an upper triangular matrix U, and then solves $LUx = b$ via two triangular solutions. One distinct property of sparse LU factorization is the notion of fill-in. That is, a zero element in the original matrix A can become nonzero in L and U. The purpose of [illegible] is to compute the nonzero structure of the factors L and U, which contains the original nonzero elements in A as well as the filled elements. When there is no need to pivot during numerical factorization, the nonzero structure of L and U can be computed without referring to the numerical values of the matrix. This allows us to allocate sufficient memory and to organize computations before numerical factorization. Computationally, symbolic factorization is usually much faster than numerical factorization, and hence there has not been much motivation to parallelize this step. However, as numerical factorization has been made more and more scalable, symbolic factorization

can become a serious bottleneck. In particular, a sequential algorithm requires the nonzero structure of the matrix A to be assembled onto one processor, which leads to a serious bottleneck in memory (if not timewise). We have therefore designed and implemented a memory scalable symbolic factorization algorithm for distributed memory machines. The parallel algorithm and the software are suitable for sparse LU factorization with static pivoting [19].

We developed this parallel algorithm in the context of the SuperLU_DIST [19] solver, which is a widely used sparse direct solver for distributed memory parallel computers. SuperLU_DIST contains several distinct steps in the solution process:

1. Choose a permutation matrix P_1 and diagonal matrices D_1 and D_2 so that the diagonal entries of $P_1 D_1 A D_2$ are ± 1 and the magnitudes of the off-diagonal entries are bounded by 1. The above equilibration and permutation help ensure accuracy of the computed solution. Currently, this is achieved using the HSL routine MC64 [5]. The purpose of the large-diagonal permutation is to decrease the probability of encountering small pivots during factorization.
2. Reorder the equations and variables by using a heuristic that chooses a permutation matrix P_2 so that the number of fill-in elements in the factors L and U of $P_2 P_1 D_1 A D_2 P_2^T$ is reduced.
3. Perform the symbolic factorization to identify the locations of the nonzero entries of L and U.
4. Compute the numerical values of L and U.
5. Perform triangular solutions.
6. Perform a few steps of an iterative method like iterative refinement if the solution is not accurate enough.

In the current version of SuperLU_DIST, the numerical factorization and triangular solutions are performed in parallel, but the first three steps are done sequentially. Our new parallel symbolic factorization algorithm uses ParMetis [17] (parallel Metis) to find a sparsity-preserving ordering (second step) and performs the subsequent structural analysis in parallel using a distributed input matrix (third step). Therefore, once we have integrated this algorithm in the solver, the only remaining sequential bottleneck will be in the first step, for which parallelization work is underway [20].

There are few results published in the literature on the parallelization of the symbolic factorization. Most of them consider the Cholesky factorization of symmetric positive definite (SPD) matrices. For these matrices, the symbolic factorization can be expressed by a tree structure, called the elimination tree, that represents the transitive reduction of the graph of the Cholesky factor L. The approach used in [22, 23] consists of computing in parallel first the structure of the elimination tree and then the symbolic factorization. While the latter step can be easily parallelized, the parallelization of the former is a difficult task and leads to modest speedup. A parallel symbolic factorization algorithm is also presented in [15] and is part of the PSPASES direct solver for SPD matrices. The algorithm is driven by the two-dimensional (2D) distribution of the data (designed for the numerical factorization step) and the elimination tree of A. The authors report that the parallel symbolic factorization takes relatively little time compared to the other steps of the solver.

In the case of unsymmetric matrices, the transitive reduction of the graphs of L and U leads to general directed acyclic graphs. The parallelization of the symbolic factorization of unsymmetric matrices is even more difficult than that of symmetric matrices, since it does not get the benefit of using a tree structure. A parallel algorithm for the factorization of unsymmetric matrices is presented in [2]. It is based on a

sequential algorithm that exhibits ideal parallelism but has two main drawbacks. It needs the input matrix to be replicated on every processor's local memory and hence is not scalable in memory. The sequential algorithm on which the parallel formulation is based is much slower in practice than more recent and improved sequential symbolic factorization algorithms.

The difficulty in formulating a scalable parallel algorithm lies in the small computation-to-communication ratio and in the sequential data dependency. Our primary goal in this research is to develop a parallel algorithm that provides memory scalability. At the same time, even if the serial runtime of the symbolic factorization is already relatively small, we still want to achieve reasonable speedup; otherwise it will dominate runtime with a larger number of processors. Our purpose is to obtain enough speedup to prevent this step from being a computational bottleneck. For this, our algorithm exploits two types of parallelism. The first type of parallelism relies on a graph partitioning approach, to reduce the fill-in and to permute the matrix to a suitable form for parallel execution. The graph partitioning is applied on the symmetrized matrix $|A| + |A|^T$, where $|A|$ denotes the matrix of absolute values of the entries of matrix A. The second type of parallelism is based on a block cyclic distribution of the matrix, which is a standard technique used in parallel matrix computations. To further decrease the runtime, we exploit the fact that as the elimination proceeds, the remaining submatrices in L and U have more and more nonzero elements, and at some point we can treat the remaining submatrix as a full matrix.

The choice of using a graph partitioning approach is in accordance with the state-of-the-art in parallelizing the ordering algorithms. The algorithms based on a local greedy strategy, such as the minimum-degree ordering algorithm, have proved to be difficult to parallelize. For example, the parallelization of one of the minimum-degree ordering algorithm's variants was discussed by Chen, Gilbert, and Toledo [1]. The parallel algorithm was designed for shared memory machines, and only limited speedups were obtained. The main sources of inefficiency come from insufficient parallelism and load imbalance. Nested dissection, on the other hand, is an algorithm that uses a top-down divide-and-conquer paradigm. It first computes a vertex separator of the entire graph that divides the matrix into two disconnected parts. The matrix is reordered such that the variables corresponding to the separator are ordered after those in the disconnected parts. This splitting-reordering process is then recursively applied to the two disconnected parts, respectively. The main advantage is that the reordered form of the matrix is suitable for parallel computation. The state-of-the-art nested dissection algorithms use multilevel partitioning [12, 13, 16]. A widely used, highly parallel code is ParMetis [17], which we will use as our ordering front-end preceding the symbolic factorization.

The rest of the paper is organized as follows. Section 2 briefly reviews several sequential symbolic factorization algorithms. Section 3 discusses the parallel symbolic factorization algorithm. Section 4 describes several techniques to identify dense submatrices in the factors L and U and thus reduce the runtime of the symbolic factorization. Section 5 presents the experimental results obtained when applying the algorithm on real world matrices, and section 6 concludes the paper.

2. Unsymmetric symbolic factorization. In this section we present briefly the various sequential algorithms described in the literature [6, 9, 10, 21], with an emphasis on the algorithm used in our parallel approach. The differences between the existing algorithms lie mostly in three aspects: (1) whether the algorithm uses the structure of A alone or also uses the partly computed structure of L and U; (2) dif-

ferent ways to improve the runtime of the algorithm; and (3) whether the algorithm computes the nonzero structure of the factors by rows, by columns, or by both rows and columns. As noted in [9], the algorithms' complexities are comparable. In practice, the number of operations performed is greater than $nnz(L+U)$, but is much smaller than the number of floating-point operations required for numerical factorization. However, the experiments performed on small sized matrices [9] and discussion of aspect (1) showed that the algorithms that use the structure of A alone are slower than the algorithms that use the structure of A and the partly computed structure of L and U. The other results addressing aspect (2) showed that improvements based on approaches like, for example, supernodes and symmetric pruning (we will describe these approaches later in this section) significantly reduced the symbolic factorization time.

Let A be a sparse unsymmetric $n \times n$ matrix and let $nnz(A)$ denote the number of its nonzero elements. In what follows, $Str(A)$ refers to the nonzero structure of the matrix A. a_{ij} represents the element of row i and column j of matrix A, while $A(k\colon r, i\colon j)$ represents the submatrix consisting of elements in rows k through r and columns i through j of A. When $k = 1$ and $r = n$, we use the notation $A(:, i\colon j)$, which represents columns i through j of A. $G(A)$ denotes the directed graph associated with matrix A. This graph has n vertices and an edge (i, j) for each nonzero element a_{ij}.

Our parallel algorithm is based on a variant that computes progressively the nonzero structure of L by columns and that of U by rows, using at each step the partial structure previously computed. That is, the structure of the ith column of L is formed by the union of $Str(A(i\colon n, i))$ with a subset of the previous columns of L. This subset of columns is determined from $Str(U(:, i))$. And the structure of the ith row of U is given in a similar way by the union of $Str(A(i, i\colon n))$ with a subset of the previous rows of U. The following theorem states how the structure of L can be determined by those of A and U.

THEOREM 2.1 (Rose and Tarjan [21]).

$$Str(L(:,i)) = Str(A(i\colon n, i) \cup \bigcup \{Str(L(i\colon n, j)) \mid (j,i) \in G(U(1\colon i-1,:))\}.$$

To decrease the runtime of the algorithm, we use two different improvements. The first improvement, called symmetric reduction or symmetric pruning, was proposed by Eisenstat and Liu [6]. It is based on the observation from Theorem 2.1 that only the structures of a subset of the columns $L(:, j)$ need to be considered in computing $Str(L(:, i))$. This subset is determined by the symmetric elements of the factors, which are used to remove some (but not all) redundant edges in the graphs of L and U. For example, if both l_{kj} and u_{jk} are nonzero and $k < i$, we must have $Str(L(k\colon n, j) \subseteq Str(L(:, k))$. Then, when computing $Str(L(:, i))$, to avoid redundant work, it is sufficient to consider only $Str(L(:, k))$. The symmetric reduction of the structure of $U(j, :)$ (structure of $L(:, j)$) is obtained by removing all nonzeros u_{jt} (nonzeros l_{tj}) for which l_{kj} and u_{jk} are nonzeros and $t > k$.

The second improvement is based on the notion of supernode, used in one of the more recent algorithms [4] and also in SuperLU_DIST [19]. In SuperLU_DIST, the symbolic factorization computes the structure of L and U by columns. A supernode groups together successive columns of L with the same nonzero structure, such that they can be treated as a dense submatrix. At the end of each step, the symbolic factorization algorithm decides whether the new column i of L belongs to the same

supernode as column $i-1$ of L. If it does, then it is not necessary to store the structure of column i in memory. That is, for each supernode, only the structure of its first column is stored. This leads to an important reduction in the memory needs of the symbolic factorization. Furthermore, supernodes also help reduce the runtime of the symbolic factorization. This is because to compute $Str(L(:,i))$, the previous supernodes are used instead of the columns $1,\ldots,i-1$.

In our variant, a supernode groups together successive columns of L having the same structure and successive rows of U having the same structure. This definition is appropriate for our algorithm that computes the structure of L by columns and that of U by rows. The symmetric pruning for each supernode consists of finding the first symmetric nonzero that does not belong to the diagonal block of the supernode. This is equal to the first symmetric nonzero of the last column of L and the last row of U of the supernode.

From a memory point of view, the usage of supernodes leads to a decrease in the memory needs of the symbolic factorization algorithm. From a computation point of view, the supernodes used in our variant do not lead to removing more redundant work in Theorem 2.1 than symmetric pruning alone does. For example, consider the computation of the structure of L and a supernode formed by indices $s, s+1,\ldots,t$. Denote by i the first symmetric nonzero of this supernode, where $i > t$. When supernodes are used, the structure of the first column of the supernode $L(:,s)$ is used in the computation of the structure of all the columns $L(:,j)$, with $t < j \leq i$ and $u_{sj} \neq 0$. Consider now that only symmetric pruning is used. For every index k such that $s \leq k < t$, the first symmetric nonzero corresponds to index $k+1$; that is, $l_{k+1,k}$ and $u_{k,k+1}$ are nonzero. Hence, all the entries after $k+1$ will be pruned. And the symmetric pruning information corresponding to column t of L and row t of U is the same as the symmetric pruning information corresponding to the supernode. For all the indices j with $t < j \leq i$ and $u_{tj} \neq 0$, the structure of column $L(:,t)$ is included in the structure of all the columns $L(:,j)$. But the structure of column t of L is the same as the structure of column s of L, and the structure of row t of U is the same as the structure of row s of U. Hence, computing the structure of $L(:,j)$ involves the same number of operations when symmetric pruning is used or when supernodes and symmetric pruning are used. However, since the symmetric pruning information corresponding only to the first column of L and row of U of a supernode is stored, the usage of supernodes helps decrease the time and the memory necessary for storing the symmetric pruning information.

Algorithm 1 presents this variant in a so-called left-looking approach. When it arrives at the ith step of computation, $Str(L(:,1{:}i-1))$ and $Str(U(1{:}i-1,:))$ are known. $Str(L(:,i))$ is formed using column i of the pruned structure of $U(1{:}i-1,:)$ (denoted as $prU(1{:}i-1,:)$). $Str(U(i,:))$ is formed using row i of the pruned structure of $L(:,1{:}i-1)$ (denoted as $prL(:,1{:}i-1)$). Then the first symmetric nonzero in $Str(L(:,i))$ and $Str(U(i,:))$ is determined. The pruned column i of L is added to prL, and the pruned row i of U is added to prU. For the sake of clarity, this algorithm does not use supernodes. In Section 3 we will also use a right-looking approach, in which, for example, for the structure of L, at the ith step of computation, the structure of column i is computed and then is used to update the partially computed structure of columns $i+1$ to n that need it.

The time spent in step 1 of Algorithm 1 is bounded by the number of operations needed to multiply the matrix $L(:,1{:}i-1)$ by the vector $prU(:,i)$ at each step i, which is written as $ops(L \cdot prU)$ [9]. Similarly, the time spent in step 2 is bounded by $ops(prL \cdot U)$. The complexity of the entire algorithm is dominated by these two steps.

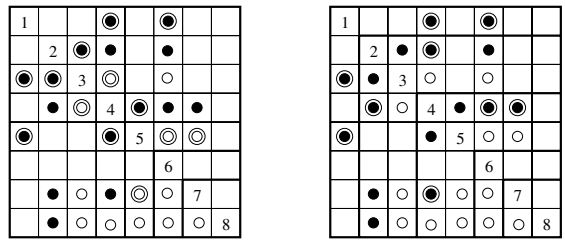

FIG. 2.1. *Example matrix A that illustrates Algorithm* 1 *using only symmetric pruning (left) and using symmetric pruning and supernodes (right).*

Algorithm 1. Left-Looking Symbolic Factorization.

  $Str(A(i{:}\,n,i)) \cup \bigcup \{Str(L(i{:}\,n,j)) \mid (j,i)$ is an edge of $G(prU(1{:}\,i-1,:))\}$
  Compute $Str(U(i,:)) =$
  $Str(A(i,i{:}\,n)) \cup \bigcup \{Str(U(j,i{:}\,n)) \mid (i,j)$ is an edge of $G(prL(:,1{:}\,i-1))\}$
  $k := n$
  determine $k := \min(j)$ such that l_{ji} and u_{ij} are nonzeros
  add $Str(L(i{:}\,k,i))$ to prL and $Str(U(i,i{:}\,k))$ to prU
end for

We illustrate Algorithm 1 in Figure 2.1 on an example matrix A with nonzero diagonal and of order 8. The matrix at the left shows the results obtained when only symmetric pruning is used, while the matrix at the right shows how Algorithm 1 performs when supernodes are used in addition to symmetric pruning. We suppose that the first 5 columns of L and the first 5 rows of U have been computed and that the algorithm arrives at the computation of the 6th column of L. The dark circles represent nonzero elements of the original matrix A, and the empty circles represent fill-in elements of the factors. The elements belonging to prL and prU are doubly circled.

Consider first that only symmetric pruning is used (left-hand side of Figure 2.1). For example, l_{32} and u_{23} are nonzeros; then for the index 2, only these two elements belong to prL and prU. The structure of $prU(:,6)$ is formed by the elements u_{16} and u_{56}. Hence, to compute the structure of $L(:,6)$, the algorithm forms the union of structures of $A(6{:}\,8,6)$, $L(6{:}\,8,1)$, and $L(6{:}\,8,5)$.

Consider now that supernodes are used in addition to symmetric pruning (right-hand side of Figure 2.1). Nodes 2 and 3 form a supernode, because columns 2 and 3 of L have the same structure and rows 2 and 3 of U have the same structure. Similarly, nodes 4 and 5 form another supernode. Symmetric pruning information corresponding only to the first column of L and row of U of a supernode is added to prL and prU. For example, l_{42} and u_{24} are nonzeros; then only elements l_{42} and u_{24} belong to prL and, respectively, prU (we store only the off-diagonal block indices). The symmetric nonzeros considered for pruning are l_{42} and u_{24}, because 4 is the first node not in the supernode formed by 2 and 3.

To compute the structure of $L(:,6)$, the algorithm forms the union of structures of $A(6{:}\,8,6)$, $L(6{:}\,8,1)$, and $L(6{:}\,8,4)$. Since indices 4 and 5 belong to the same supernode, the structure of $L(6{:}\,8,4)$ is the same as the structure of $L(6{:}\,8,5)$. Hence,

from a computation point of view, forming the structure of column 6 of L using supernodes and symmetric pruning is equivalent to the previous approach that uses only symmetric pruning. But the usage of supernodes decreases the memory needs. Only the columns of L and rows of U corresponding to indices $1, 2$, and 4 are stored.

3. Parallel unsymmetric symbolic factorization. We now describe our parallel unsymmetric symbolic factorization algorithm. Our algorithm uses the partly computed $Str(L)$ and $Str(U)$ as the algorithm progresses and exploits two types of parallelism. The first type comes from the graph partitioning approach, which is used as a fill-reducing ordering step. This approach partitions the matrix in a suitable way for parallel factorization and also provides a tree structure representing the dependencies among the computations. The second type of parallelism depends on a block cyclic distribution of the data.

The partitioning approach uses the graph of the symmetrized matrix $|A| + |A|^T$ to identify a vertex separator that splits the graph into two disconnected subgraphs. If the vertices of the separator are ordered after the vertices in the disconnected subgraphs, a blocked matrix suitable for parallel computation is obtained. The partitioning defines a binary tree structure, called the [illegible]. Each node of this tree corresponds to a separator. The root of the tree corresponds to the separator from the first level partitioning. Then each branch corresponds to one of the disconnected subgraphs. The partitioning can then be applied recursively on each subgraph. Figure 3.1 illustrates a matrix partitioned in two levels with four disconnected subgraphs. Its corresponding separator tree is depicted in Figure 3.2, where we number the levels of the binary tree starting with 0 at the bottom. This numbering does not reflect the top-down graph partitioning approach. Instead, it reflects the bottom-up traversal of the tree during our symbolic factorization algorithm. In Figure 3.1, the patterned blocks illustrate portions of the matrix that can contain nonzero elements. The meaning of the different patterns used will be described later in this section.

The separator tree plays an important role in sparse factorizations because it shows the parallelism from the partition of the matrix and identifies dependencies among the computations. If $Str(L(:, j))$ is needed in computing $Str(L(:, i))$, then the node owning index j belongs to the subtree rooted at the node owning index i.

In order to perform the symbolic factorization in parallel, the nodes of the separator tree are assigned to processors using the standard subtree-to-subcube algorithm [8, 11]. This algorithm considers that the separator tree is well balanced. That is, each partitioning leads to two disconnected graphs of roughly the same size. In practice, unbalanced trees can be obtained, and a better mapping of nodes to processors can be used. We plan to address this problem in our future work.

The subtree-to-subcube algorithm maps nodes to processors during a top-down traversal of the separator tree. It starts by assigning all the p processors to the root. Then it assigns $p/2$ processors to each of the two subtrees of the root. This process is continued until only one processor is assigned to a subtree. The advantage of this algorithm is that the communication in a subtree is restricted to only the processors assigned to this subtree, thus hopefully ensuring a low communication cost. Each node of the tree is associated with a range of indices. All the processors assigned to a node will cooperate to compute the structure of the columns of L and of the rows of U whose indices are associated with the node. The indices are distributed among those processors using a one-dimensional (1D) block cyclic distribution along the diagonal, in a block arrow shape.

Consider again Figures 3.1 and 3.2. Suppose that we have 4 processors. The

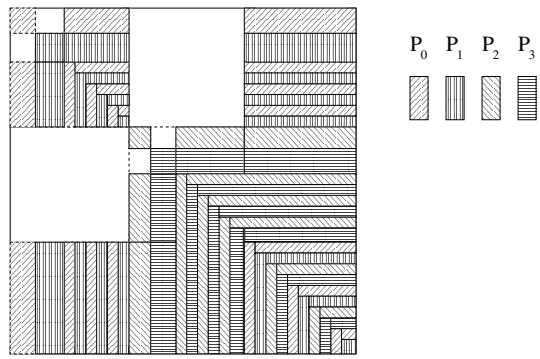

FIG. 3.1. *Example matrix and data distribution for the parallel symbolic factorization algorithm executed on* 4 *processors.*

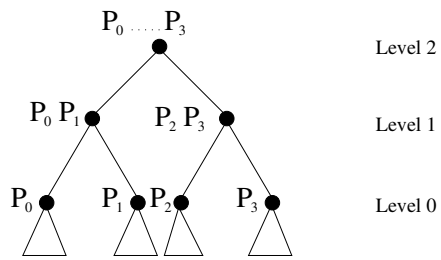

FIG. 3.2. *Separator tree corresponding to the example matrix in Figure* 3.1.

subtree-to-subcube mapping is illustrated in Figure 3.2 in which we label the processors assigned to each node of the separator tree. The 1D block cyclic data distribution is illustrated in Figure 3.1, where we use different patterns for different processors.

Algorithm 2 describes the main steps of the parallel symbolic factorization algorithm. Each processor performs a bottom-up traversal of the separator tree to participate in factorizing the nodes it owns. It starts with an independent symbolic factorization phase for the indices associated with its leaf node, using a left-looking algorithm similar to Algorithm 1. Then at each higher level of the tree, each processor is involved in computing one node D that it owns at this level. The computation of each D consists of two phases. In the first phase, named factorization, the columns of L and rows of U corresponding to the indices associated with D are updated in a right-looking manner by the columns of L and rows of U belonging to the predecessors of D in the separator tree. In the second phase, named factorization, all the processors participate in completing the symbolic factorization of node D, using a combination of right-looking and left-looking partial symbolic factorization methods.

We now use Figure 3.3 to illustrate the execution of Algorithm 2 step by step. Consider Level 1 of the tree. The computation of the right node D (doubly circled in the figure) is assigned to processors P_2, P_3. We use the following notation to distinguish the indices and their corresponding columns of L and rows of U associated with each node. The indices corresponding to the right node of Level 1 are marked in patterned white, and the indices to be used to update this node and that correspond to the leaf nodes assigned to P_2 and P_3 are in dark gray. All the other indices, not involved in the computation considered here, are displayed in light gray.

Algorithm 2. Parallel Symbolic Factorization.

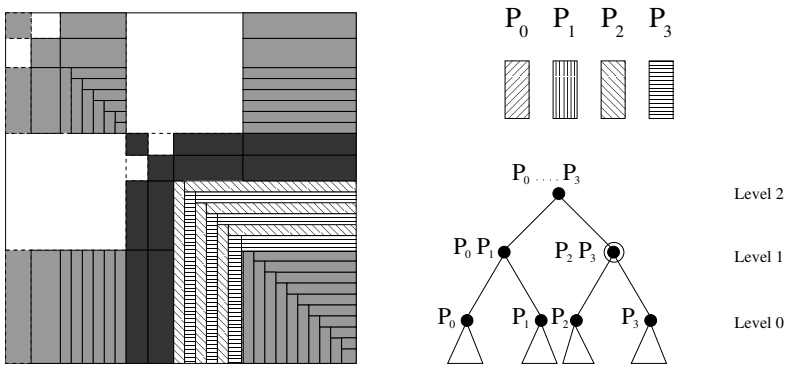

FIG. 3.3. *Example illustrating the parallel symbolic factorization (Algorithm 2) on the example matrix in Figure 3.1 for the doubly circled node assigned to processors P_2, P_3. Its associated indices are marked in patterned white, and the indices to be used to update this node and that correspond to the leaf nodes assigned to P_2 and P_3 are in dark gray. All the other indices are displayed in light gray.*

At this stage, processor P_2 has already computed the structures of L and U of the indices associated with the left leaf node, and processor P_3 has done so with the right leaf node. During inter-level factorization, processors P_2 and P_3 will determine which columns of L and which rows of U from the leaf nodes are needed for updating node D. This data is first exchanged between P_2 and P_3, and node D is then updated in a right-looking fashion. During intra-level factorization, the factorization of node D is completed using a block cyclic algorithm, where the factorization of each block is performed in a left-looking fashion, and then the block is used to update the subsequent blocks in a right-looking fashion.

Algorithm 3 details the inter-level factorization. Consider the computation of node D at level l, which is assigned to processors $P_r, \ldots, P_q$. This phase performs all the updates that the indices of node D must receive from the indices below node D. Only the indices associated with the nodes in the subtree rooted at D can contribute to these updates. Each processor determines the source of the updating data (columns of L and rows of U) that it owns and that belongs to nodes of the subtree rooted at D. Then the data is copied in a send buffer. Because of sparsity, it is very likely that this processor needs to send data to only a small subset of the processors that own node D. Several implementations of this collective communication are possible. In our current implementation, we use a simple scheme that assumes that the receive

buffer of each processor is large enough to store all the incoming messages. We have tested this scheme on the matrices in our test set and we have observed that the size of the receive buffer represents a small fraction of the total memory needs. Thus, we expect that this scheme will not affect the memory scalability of our algorithm.

Each processor can determine the destination processors to send the data. After a global exchange among the processors owning node D, each processor also knows from whom the data needs to be received. Afterwards, each processor sends its data to destination processors in a nonblocking manner, and then posts all the necessary receives. Since we need to release the send/receive buffers, the received data has to be consumed right away. This is achieved by using a right-looking approach, as described in Algorithm 5, to update the indices associated with node D. In our example, the indices that contribute to this update are shown in dark gray. Processors P_1 and P_2 exchange necessary parts of columns of L and rows of U corresponding to these indices.

Algorithm 3. Inter-level Symbolic Factorization.

Input: $myPE$: my processor number, l : level in the separator tree
let D be the node at level l owned by processor $myPE$
let $P_r, \ldots, P_q$ be the processors assigned to node D
let μ and ν be the first and last indices of node D
copy data (columns of L, rows of U) to be sent to $P_r, \ldots, P_q$ in $sendBuf$
determine the processors that $myPE$ needs to exchange data with
for each processor P in $P_r, \ldots, P_q$ to which data needs to be sent **do**
  nonblocking Send $sendBuf$ to P
end for
for each processor P in $P_r, \ldots, P_q$ from which data needs to be received **do**
  Recv data (columns of L, rows of U) in $recvBuf$
  Right-Looking update of $U(\mu{:}\,\nu, :)$ and $L(:, \mu{:}\,\nu)$ using $recvBuf$
end for
Wait for all nonblocking Sends to complete

Algorithm 4 details the intra-level factorization. The goal is to complete the factorization of node D by performing all the necessary updates between the indices associated with node D. The algorithm is a block variant of right-looking factorization. It provides a general framework to perform asynchronously a right-looking factorization of a sparse matrix. The algorithm proceeds as follows. Each processor $myPE$ iterates over the blocks of node D that it owns. Let $P_r, \ldots, P_q$ be the $q-r+1$ processors that are assigned to node D in 1D block cyclic fashion. Assume processor $myPE$ arrives at the computation of block K.

First, processor $myPE$ has to receive a number of messages from the processors that computed blocks $K-q+r, \ldots, K-1$ to update its blocks in a right-looking fashion. To determine the number of messages that have to be received, we use an auxiliary array, $noMsgsToRcv$, that is initialized to 0. This array keeps global information on the number of messages that every processor needs to receive. Locally, each processor stores the number of messages that were already received in the variable $myMsgs$.

Processor $myPE$ will receive the array $noMsgsToRcv$ from the owner of block $K-1$, and $noMsgsToRcv[myPE]$ gives the number of messages $myPE$ has to receive at this step of computation. This is implemented as follows. Processor $myPE$ posts a nonblocking receive from the owner of block $K-1$, anticipating the array $noMsgsToRcv$. The condition variable $rcvdArray$ is set when this nonblocking re-

ceive is completed. While waiting for this message, $myPE$ iterates over a loop, in which a nonblocking receive for data is posted at each iteration. When a message is received, if it corresponds to data, the later blocks of node D owned by $myPE$ are updated in a right-looking fashion. The variable $myMsgs$ is incremented by one. If the message received corresponds to the array $noMsgsToRcv$, then $myPE$ knows how many messages must be received. If all the messages were received, the last posted data receive is canceled. If not, $myPE$ continues with receiving all the necessary data messages.

Second, processor $myPE$ has to complete the factorization of block K itself. This is performed using a left-looking approach, similar to Algorithm 1. The difference is that the algorithm iterates from the first index of block K (μ_K) to the last index of block K (ν_K), instead of iterating from 1 to n as in Algorithm 1, where n is the order of the matrix A.

Third, processor $myPE$ needs to identify all the processors to which block K should be sent. For each such processor P, the value of $noMsgsToRcv[P]$ is incremented. And if K is not the last block of node D, $myPE$ sends the array $noMsgsToRcv$ to the owner of block $K+1$. Since the matrix is sparse, the data needs to be sent to only a small subset of processors. Empirically, we have observed that this number is usually 2 or 3. In particular, in symmetric cases, the data needs to be sent to only the processor owning the next block.

The block cyclic distribution of columns of L and rows of U helps maintain load balance. Note that we need the rows of U to determine what columns of L need to be sent to which processors. Similarly, we need the columns of L to determine to which processors we need to send the rows of U. It is easy to determine this communication pattern because of the arrow shape layout.

4. Exploiting density in the separators. In this section, we describe one optimization technique that can easily improve the runtime of symbolic factorization. It is well known that toward the end of the elimination, the factored matrices have more and more nonzero elements. In addition, we also observed that the submatrices associated with the separators have more and more nonzero elements. A symbolic factorization algorithm that computes $Str(L)$ by columns and $Str(U)$ by rows can easily identify the density in the factors. Moreover, since our parallel algorithm uses a 1D distribution of the data along the diagonal, this detection can be implemented without any communication.

4.1. Separator with dense diagonal block. Consider Algorithm 2 when it arrives at the intra-level computation of node D consisting of indices $\mu, \ldots, \nu$. Let B be the diagonal block submatrix associated with the separator, that is, $B = L(\mu{:}\,\nu, \mu{:}\,\nu) + U(\mu{:}\,\nu, \mu{:}\,\nu)$. Once the structures of column μ of L and row μ of U have been computed, the sizes $r = nnz(L(\mu{:}\,\nu, \mu))$ and $q = nnz(U(\mu, \mu{:}\,\nu))$ are known. The product rq gives a lower bound on the fill in B. If the product rq is $(\nu-\mu)^2$, B would be completely full. Then, there is no need to compute the subsequent rows of L and columns of U corresponding to the indices $\mu+1$ to ν. Note that even if B is not entirely full, we can use the ratio $rq/(\nu-\mu)^2$ as a parameter to control [illegible], that is, padding zeros in B to increase the size of supernodes.

The following theorems show that, given a full B on the diagonal, the off-diagonal block structures for L and U can also be easily determined. In fact, the L part is formed by the dense subrows that end at column ν, and the U part is formed by the dense subcolumns that end at row ν, as depicted in Figure 4.1. These structures are often referred to as [illegible] structures.

Algorithm 4. Intra-level Symbolic Factorization.

Input: $myPE$: my processor number, l : level in the separator tree
let D be node of level l owned by processor $myPE$
let $P_r, \ldots, P_q$ be the processors assigned to node D
let μ and ν be the first and last indices of node D
let N_l be number of blocks node D is divided into
initialize array $noMsgsToRcv[]$ to 0
initialize variable $myMsgs$ to 0
for each block K from 1 to N_l that $myPE$ owns **do**
  let μ_K and ν_K be the first and last indices of block K
  if K is not the first block **then**
    $rcvdArray = FALSE$
    post nonblocking Recv for array $noMsgsToRcv$ from owner of block $K-1$
    post nonblocking Recv for data in $recvBuf$
    while $myMsgs \neq noMsgsToRcv[myPE]$ *and* $rcvdArray \neq TRUE$ **do**
      Wait for a receive to complete
      if message received corresponds to data **then**
        increment variable $myMsgs$ by one
        Right-Looking update of $L(:, \mu_K{:}\nu)$ and $U(\mu_K{:}\nu, :)$ using $recvBuf$
      else
        /* message received corresponds to $noMsgsToRcv[]$*/
        Cancel nonblocking receive of data if $myMsgs = noMsgsToRcv[myPE]$
        $rcvdArray = TRUE$
      end if
    end while
  end if
  Left-Looking symbolic factorization to compute $L(:, \mu_K{:}\nu_K)$ and $U(\mu_K{:}\nu_K, :)$
  if K is not the last block **then**
    for each processor P in $P_r, \ldots, P_q$ to which $myPE$ needs to send data **do**
      increment $noMsgsToRcv[P]$ by one
      Send $L(:, \mu_K{:}\nu_K)$ and $U(\mu_K{:}\nu_K, :)$ to P
    end for
    Send $noMsgsToRcv[]$ to owner of block $K+1$
  end if
end for

Algorithm 5. Right-Looking Update of $L(:, \mu{:}\nu)$, $U(\mu{:}\nu, :)$.

Input: $recvBuf$, $L(:, \mu{:}\nu)$, $U(\mu{:}\nu, :)$, $myPE$
Output: Updated $L(:, \mu{:}\nu)$, $U(\mu{:}\nu, :)$
initialize prL, prU to empty
for each index j of $recvBuf$ **do**
  let k be such that l_{jk} and u_{kj} are nonzeros
  if there is an i such that $l_{ij} \neq 0$, $i \leq k$, $\mu \leq i \leq \nu$, $myPE$ owns index i **then**
    add pruned column j of L to prL
  end if
  if there is an i such that $u_{ji} \neq 0$, $i \leq k$, $\mu \leq i \leq \nu$, $myPE$ owns index i **then**
    add pruned row j of U to prU
  end if
end for
for $i := \mu$ to ν such that $myPE$ owns index i **do**
  Add to $Str(L(:, i))$ the union $\cup \{Str(L(i{:}n, j)) \mid (j, i)$ is an edge of $G(prU)\}$
  Add to $Str(U(i, :))$ the union $\cup \{Str(U(j, i{:}n)) \mid (i, j)$ is an edge of $G(prL)\}$
end for

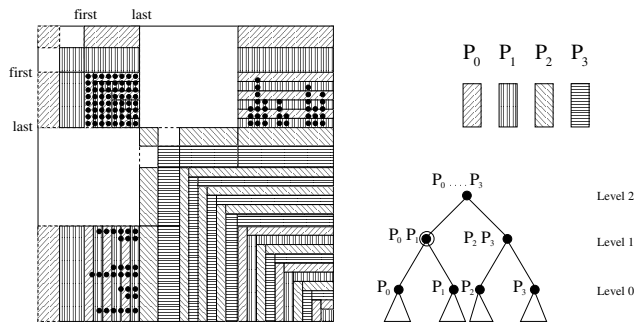

FIG. 4.1. *Example of the skyline structures of L and U when the separator has a dense diagonal block. The left node of level* 1 *(doubly circled) has the dense diagonal block from* μ *to* ν.

THEOREM 4.1. [illegible] $A = LU$ [illegible] $u_{i,i+1}$ [illegible] $i = \mu, \ldots, \nu - 1$ [illegible] a_{jk} [illegible] j [illegible] $\mu \leq k \leq \nu$ [illegible] $j > \nu$ [illegible] l_{jt} [illegible] t [illegible] $k < t \leq \nu$

[illegible]. First, l_{jk} is nonzero because a_{jk} is nonzero (here as elsewhere, we do not consider cancellation). Since $u_{i,i+1}$ is nonzero for all i, $\mu \leq i \leq \nu - 1$, then by Theorem 2.1, $Str(L(:,i)) \subseteq Str(L(:,i+1))$ for all i, $\mu \leq i \leq \nu - 1$. Hence l_{jt} is nonzero for all t from k to ν. □

THEOREM 4.2. [illegible] $A = LU$ [illegible] $l_{i+1,i}$ [illegible] $i = \mu, \ldots, \nu - 1$ [illegible] a_{jk} [illegible] j [illegible] $\mu \leq j \leq \nu$ [illegible] $k > \nu$ [illegible] u_{tk} [illegible] t [illegible] $j < t \leq \nu$

[illegible]. The proof is similar to the proof of Theorem 4.1. □

We explain now how the nonzero structure of a range of indices of L corresponding to node D is computed, using the fact that the diagonal B is full. The computation of the nonzero structure of U is similar. The key is to compute for each column i ($\mu \leq i \leq \nu$) a set $FNZ(i)$ that contains the row indices of the rows of A that have the first nonzero in column i. More formally, FNZ is defined as

$$FNZ(i) = \{j \mid a_{ji} \neq 0 \text{ and } a_{jt} = 0 \text{ for all } t \in (\mu{:}\, i-1)\}.$$

The computation of FNZ is achieved as follows. Let processors $P_r, \ldots, P_q$ be assigned to node D. First, every processor determines locally the column index i of the first nonzero in row j of A owned by this processor. Then a parallel reduction operation is applied among all the processors $P_r, \ldots, P_q$ to determine the first nonzero column index for each entire row j. This information is used to compute the structure FNZ. Then the structure of column i of L is simply the union of $FNZ(k)$ for $\mu \leq k \leq i$.

Note that the sets $FNZ(\mu), \ldots, FNZ(\nu)$ are disjoint. If data is well balanced among processors, the total computational cost is dominated by $O(nnz(L)/P)$ plus the cost of a call to *MPI_Allreduce*. In intra-level symbolic factorization, Algorithm 4 tries to identify dense diagonals after computing the structure of each index. When a dense column and row are found, this computation is performed for the rest of the separator.

4.2. Separators with dense structures belonging to a path of the separator tree. One further optimization is to identify the dense separators on a path of the separator tree. Consider again Algorithm 2 when it arrives at the intra-level

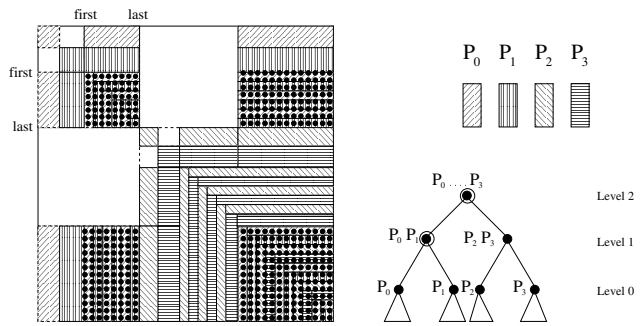

FIG. 4.2. *Example of the dense structures of L and U when there are dense separators on a path to the root. The nodes of the tree corresponding to the dense separators are doubly circled.*

computation of node D consisting of variables $\mu, \ldots, \nu$. Let B be the submatrix containing the variables associated with all the nodes on the path from node D to the root. Define $r = nnz(L(:, \mu))$ and $q = nnz(U(\mu, :))$. The product rq represents a lower bound on the number of fill in the submatrix B. If r and q are the same and equal the order of B, then we know B is full. That is, all the submatrices associated with the nodes on the path from D to the root are dense. This is illustrated in Figure 4.2. The processor that detects this μ column sends messages to all the other processors involved in the nodes on the path from D to the root. The rest of the algorithm is simply to generate the indices of these dense submatrices.

5. Experimental results. In this section, we present experimental results for our parallel symbolic factorization algorithm applied to real world matrices. We tested the algorithm on an IBM SP RS/6000 distributed memory machine at NERSC (National Energy Research Scientific Computing Center). The system contains 2944 compute processors distributed among 184 compute nodes. Each processor is clocked at 375 Mhz and has a peak performance of 1.5 GFlops. Each node of 16 processors has 16 to 64 Gbytes of shared memory.

We use several medium to large size matrices that are representative of a variety of application domains. The matrices and their characteristics are summarized in Table 5.1, which includes the matrix order, the number of nonzeros, the structural symmetry, and the application domain. We show the average number of nonzeros per column of original matrix A, as a measure of sparsity. The matrices are available from University of Florida Sparse Matrix collection [3] (BBMAT, STOMACH, PRE2, TORSO1, TWOTONE, MARK3JAC140SC, G7JAC200SC, LHR71C) and the accelerator design project at the Stanford Linear Accelerator Center [18] (DDS.QUAD.K-SM, DDS15.K-SM). To analyze the memory scalability of our algorithm, we also use matrices obtained from the 11-point discretization of the Laplacian operator on three-dimensional (3D) grids (REG3D).

The goal of the experiments is twofold. First, we want to study the performance of the new parallel symbolic factorization algorithm itself. Second, we want to examine the performance improvement of the entire solution process of SuperLU_DIST gained by parallelizing the symbolic factorization step. Our performance criteria include both runtime and memory usage. As stated in the introduction, our goal is to prevent the symbolic factorization step from being a bottleneck (especially in terms of memory) in the entire solution process. We show here that this goal is indeed achieved.

For the second study, we present detailed performance results for the first six

matrices in our test set. We compare the performance of two configurations of SuperLU_DIST: one is referred to as SLU_SFseq in which the serial symbolic factorization algorithm is used as before, and the other is referred to as SLU_SFpar in which the new parallel symbolic factorization algorithm is used. We keep the other phases the same as much as possible, including the scaling and the prepivoting using the sequential routine MC64 [5] from the HSL collection [14], the fill-reducing ordering using PARMETIS applied to the structure of $|A| + |A|^T$, the numerical LU factorization, and the triangular solutions.

Because of the different data structures used in symbolic factorization, the redistribution of the matrix from the storage format used in symbolic factorization to the storage format used in numeric factorization is different. We will report separately the timings for symbolic factorization ("SFseq" for SLU_SFseq and "SFpar" for SLU_SFpar) and the timings for redistribution ("RDseq" for SLU_SFseq and "RDpar" for SLU_SFpar). Another difference between the two configurations lies in the supernode definitions. SLU_SFseq groups in a supernode the columns of L with the same structure, whereas SLU_SFpar groups in a supernode the indices corresponding to the columns of L with the same structure and to the rows of U with the same structure. Thus, the definition in SLU_SFpar is more restrictive, and tends to give more supernodes of smaller sizes. This difference may lead to different runtimes of numerical factorization and triangular solutions, but empirically we observed that the differences are very small, and thus we report the average time obtained by these steps in the two solvers.

The matrix A is distributed among processors in a block row format, which is consistent with the input format required by PARMETIS. In SLU_SFseq, the distributed matrix is gathered such that every processor has a copy of it. Then MC64 is called on one processor to determine a row permutation, which in turn is broadcast to every other processor. The structure of $|A| + |A|^T$ is computed in parallel using the distributed input matrix, and then PARMETIS is called. The symbolic factorization step is performed redundantly on each processor. The distributed structure of L and U is then set up among the processors with a 2D block-cyclic distribution over a 2D processor grid, which will be used in numerical factorization.

In SLU_SFpar, the matrix is gathered on one processor only to perform the first step (calling MC64) sequentially. All the other steps involve the distributed input matrix. (Although this means that the solver as tested is not yet memory scalable,

the work in progress that parallelizes the first step [20] should solve this problem.) The structure of $|A| + |A|^T$ is computed in parallel, and then ParMetis is called. The data is then distributed in the arrow shaped format among the processors, and parallel symbolic factorization is performed. Afterwards, the data is redistributed from this arrow shaped format to the 2D block-cyclic distribution over a 2D processor grid, which will be used in numerical factorization.

Notice that SuperLU_DIST can be used on any number of processors. But the partitioning performed by ParMetis is only applicable to a number of processors that is a power of two. Therefore, in our code, we have another data redistribution phase when the number of processors to be used is not a power of two. That is, we choose the largest power of two that is at most the total number of processors and distribute the data to this subset of processors for parallel ordering and symbolic factorization. After that, we repopulate the matrix to the full set of processors.

To perform the same numeric factorization in both configurations, we turned off supernode relaxation in SuperLU_DIST. This is because the relaxation is determined using the elimination tree that we do not have in SLU_SFpar when the input matrix is distributed. Ideally, each processor can locally compute a partial elimination tree associated with each leaf node of the separator tree, and perform relaxation locally. But we have not implemented this scheme. In [4] it was shown that supernode relaxation leads to improvements of 5% to 15% in the running time of sequential SuperLU. We expect that similar improvements can be obtained in the running time of the distributed numeric factorization.

The experimental results for the first six matrices in our test set are presented in the runtime plots of Figure 5.1 and in the memory usage plots of Figure 5.2.

For the runtime performance, we display in each plot of Figure 5.1 the total time of the solver when using sequential or parallel symbolic factorization (SLU_SFseq and SLU_SFpar), the runtime of numerical factorization (Factor), parallel reordering (ParMetis), sequential and parallel symbolic factorization (SFseq and SFpar), and redistribution (RDseq and RDpar).

For memory usage evaluation, we report in the plots in Figure 5.2 the maximum memory requirement per processor throughout the entire solution process (except MC64; see below). The peak is likely to occur in the redistribution routine from the symbolic factorization data structure to the numeric factorization data structure, or in the numeric factorization routine. The redistribution routine needs as input the nonzero structures of L and U. Memory is allocated to store these structures along with the space for the numerical values of L and U. Several auxiliary arrays are used in this routine when placing the numerical values of A into their corresponding positions of the factors L and U. Those arrays and the input nonzero structures of L and U are deallocated on return. The memory need in the numerical factorization routine is given by the 2D storage of structural and numerical information of the factors plus several supplementary arrays needed for communication.

We ignore for the moment the memory needs of MC64, which is dominated by the size of the matrix A, because in the future this step will be replaced by a parallel algorithm [20]. We report only the memory needs of the symbolic factorization step and of the numeric factorization step. The memory needs of the other steps of the algorithm are dominated by the size of the distributed matrix A, the size of the distributed factor L, or the size of the distributed factor U, which are not the bottlenecks in the solver. Therefore, we do not report memory statistics for any of the other steps.

Our parallel symbolic factorization algorithm uses two kinds of data, replicated data and distributed data. The replicated data consists of two arrays of size n, where

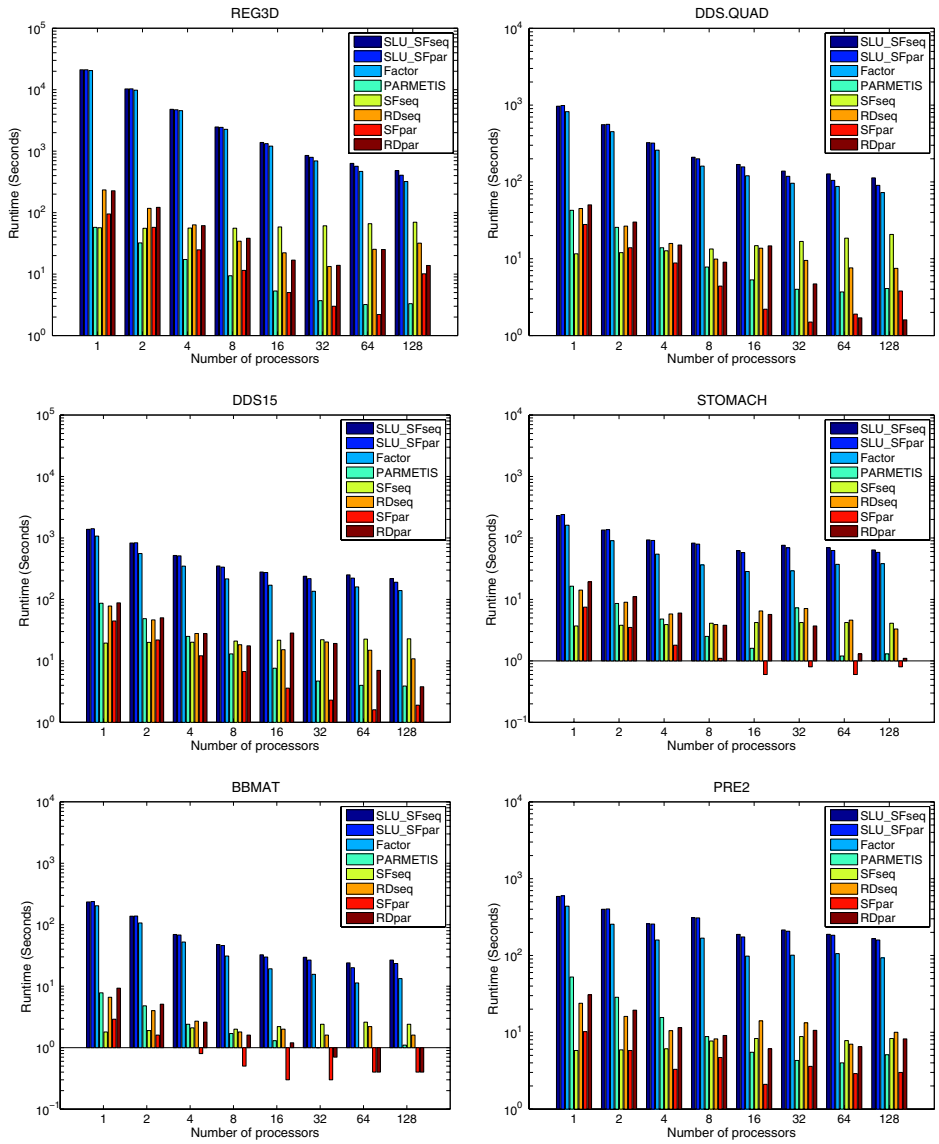

FIG. 5.1. *Runtimes (in logarithmic scale) for parallel reordering (*PARMETIS*), sequential and parallel symbolic factorization and redistribution (SFseq and SFpar, RDseq and RDpar), numeric factorization (Factor), and the entire solvers (SLU_SFseq and SLU_SFpar) for matrices in our test set.*

n is the order of the matrix. The first replicated array is used as a marker during the computation of $Str(L)$ and $Str(U)$. The second replicated array is a mapping array that shows for each variable its owner and its local index. That is, every variable has a global index which is known by all the processors and a local index which is known and used only by its owner. To set up the communication in the algorithms, each processor needs to determine the owners of certain variables. This local-global index translation is achieved by this mapping array. The distributed data are those whose size per processor is expected to decrease when increasing the number of processors.

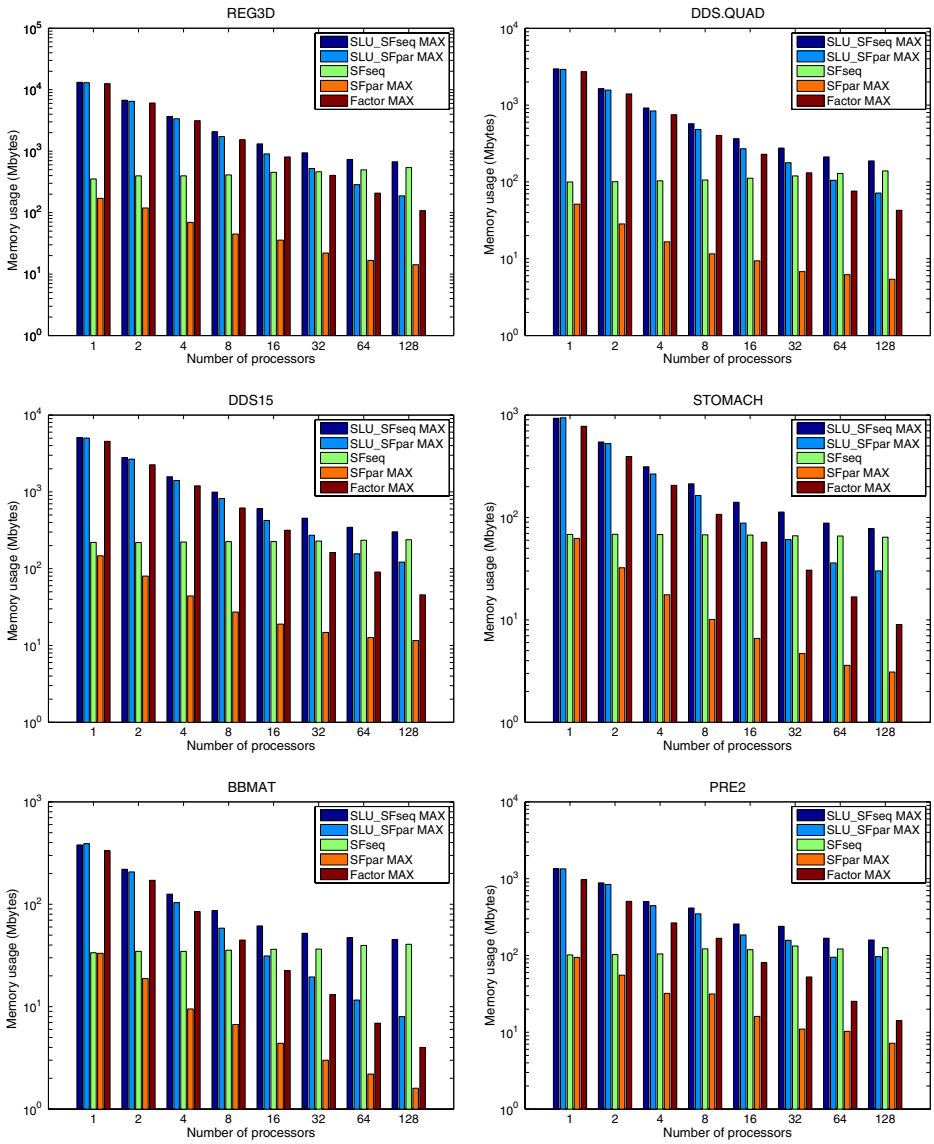

FIG. 5.2. *Memory usage (in logarithmic scale) for sequential and parallel symbolic factorization (SFseq and SFpar MAX), numeric factorization (Factor), and the entire solvers (SLU_SFseq and SLU_SFpar) for matrices in our test set.*

These are the arrays used to store the $Str(L)$ and $Str(U)$, the arrays used to store the pruned structures of L and U, and the buffers needed for communication.

In summary, the data reported is as follows: maximum memory used by the solver using sequential and parallel symbolic factorization (SLU_SFseq MAX and SLU_SFpar MAX), memory used during sequential and parallel symbolic factorization (SFseq and SFpar MAX), and maximum memory used during numerical factorization (Factor MAX).

Notice that the ordering results of PARMETIS differ using different number of processors. (They are usually worse with increasing number of processors.) Conse-

quently, the runtime and the memory usage corresponding to the sequential symbolic factorization change with different numbers of processors.

Since the algorithm behaviors are very different for the matrices that are structurally symmetric compared to those that are very unsymmetric, we first report the results separately for these two classes of problems.

5.1. Performance with structurally symmetric matrices. In this section we discuss the results with the structurally symmetric matrices. In fact, our symmetric test matrices are also positive definite, so there is no need to call MC64 (that can destroy the symmetry of the input matrix). The code was compiled using 64-bit addressing mode so that each process can use more than 2 GBytes of memory. In the parallel symbolic factorization algorithm, the block size used in the 1D block cyclic layout is 50.

In our parallel algorithm, the symmetrically pruned graph determines the communication pattern. For symmetric matrices, we obtain the benefit of symmetric reduction to the maximum extent. That is, the pruned graph contains only the first off-diagonal nonzero element in the first off-diagonal block, and is in fact the same as the supernodal elimination tree. Then, every variable is used in the computation of at most one other variable. The communication volume is therefore bounded by the number of nonzeros in $Str(L)$ and $Str(U)$. Thus the algorithm needs a low communication volume in both inter-level and intra-level factorizations. On the other hand, this also implies that the algorithm has a limited parallelism in the intra-level factorization, where a right-looking block cyclic approach is used.

We first examine the results for the model problem REG3D. We use a cubic grid of size $NX = NY = NZ = 90$ with an 11-point discretization. We see in the plot REG3D of Figure 5.1 that the runtime of SFpar continues to decrease with increasing number of processors up to 64, achieving very good speedup—30.0 on 64 processors. The redistribution routine implemented in SLU_SFpar is usually a little faster than that in SLU_SFseq, with differences larger on more processors. Overall, the entire SLU_SFpar solver is about 16% faster than SLU_SFseq on 128 processors.

The plot REG3D in Figure 5.2 reports the memory usage. On 32 processors, the memory need of SFseq becomes larger than that of the per-processor need in numeric factorization. On 128 processors, the memory need of SFseq is 5 times more than that of the per-processor need in numeric factorization. Thus, sequential symbolic factorization is indeed the bottleneck for memory scalability of SuperLU_DIST. Our parallel symbolic factorization algorithm achieves a good memory scalability. For example, on 128 processors, the memory need of SFpar is 38-fold smaller than that of SFseq. The reduction in the symbolic factorization phase also leads to significant reduction in the overall memory usage. On 128 processors, the maximum per-processor memory need of SLU_SFpar is only about 28% of that required by SLU_SFseq. Therefore, SLU_SFpar can solve a much larger problem.

We notice that on 8 and 16 processors, the entire memory needs of SLU_SFseq are larger than 16 GBytes, which is the available memory on most of the compute nodes of IBM SP RS/6000 at NERSC. In order to fit the problem in memory, we had to use more compute nodes than necessary. For example, SLU_SFseq on 16 processors was run on two compute nodes, with only 8 processors per node used. In addition, the runtime can slow down severely when the memory used per node is too large (causing disk swapping). In our experiments, this happened when SLU_SFseq was run on 32 processors and when SLU_SFpar was run on 16 processors. Hence, to obtain the best runtimes, we have used for these two runs two times more nodes than necessary.

We now examine the results for the irregular problems from the accelerator design. The plots DDS.QUAD.K-SM and DDS15.K-SM in Figure 5.1 show the runtimes of SLU_SFpar and SLU_SFseq for the two matrices. Again, SFpar exhibits good performance, with a maximum speedup of 14.1 on 64 processors for the matrix DDS15.K-SM. The time of SFpar is always smaller than the time spent in PARMETIS. On a small number of processors, the times spent in redistribution are comparable for RDseq and RDpar. But with increasing number of processors, the time spent in RDpar can be up to four times smaller than the time spent in RDseq. Overall, the entire SLU_SFpar solver is about 20% faster than SLU_SFseq on 128 processors for DDS.QUAD.K-SM.

The plots DDS.QUAD.K-SM and DDS15.K-SM in Figure 5.1 compare the memory usage of SLU_SFpar and SLU_SFseq and various steps in the solvers. We see again that with increasing number of processors, SFseq becomes the memory bottleneck of the SLU_SFseq solver. The parallel algorithm reduces the memory usage by more than 20-fold in symbolic factorization. Overall, the maximum per-processor memory need by the entire SLU_SFpar solver is only about 38–40% of that needed by SLU_SFseq.

5.2. Performance of structurally unsymmetric matrices. The plots BBMAT, STOMACH, and PRE2 in Figures 5.1 and 5.2 show the results with the unsymmetric matrices. Since these matrices are smaller than the symmetric ones, each processor needs no more than 2 GBytes of memory, and the code could succeed when compiled with 32-bit addressing mode. In the parallel symbolic factorization algorithm, the block size used in the 1D block cyclic layout is 50.

When comparing the runtimes of the two solvers SLU_SFpar and SLU_SFseq, we see that the time spent in numeric factorization dominates the time spent in any other step, which is true even on 128 processors. The runtime of SFseq is modest for all the matrices. This is probably because the sizes of those unsymmetric matrices are still quite moderate. The parallel algorithm further reduces this time. In particular, the time of SFpar is always smaller than the time spent in PARMETIS. The times spent for redistribution (RDseq and RDpar) are comparable on smaller numbers of processors (less than 16). But on larger numbers of processors, RDpar can be much faster than RDseq (up to 5-fold for BBMAT).

When comparing the memory usage of the sequential symbolic factorization of SLU_SFseq and the parallel symbolic factorization of SLU_SFpar, we observe that the memory usage is significantly reduced for all the matrices. It continues to decrease when increasing the number of processors up to 128. The parallel algorithm reduces the memory usage by up to 25-fold in symbolic factorization. Overall, the maximum per-processor memory usage of the entire SLU_SFpar ranges between 18% (BBMAT) and 60% (PRE2) of that of the SLU_SFseq solver.

5.3. Summary. Figure 5.3 summarizes the runtime and the memory usage of our parallel symbolic factorization algorithm for the first six matrices in our test set. In addition, the performance of our algorithm applied to matrices with higher asymmetry is shown in Figure 5.4.

For runtime scaling, we show the speedup obtained by our parallel symbolic factorization algorithm with respect to the sequential symbolic factorization algorithm. We see that for symmetric matrices, the runtime continues to decrease with increasing number of processors up to 32 for DDS.QUAD.K-SM, and up to 64 for REG3D and DDS15.K-SM. A maximum speedup of 30.0 on 64 processors is obtained for REG3D. We found that the technique for identifying dense separators plays an important role for symmetric matrices, significantly reducing the number of operations in symbolic factorization. The matrix REG3D represents the best case in terms of exploiting the

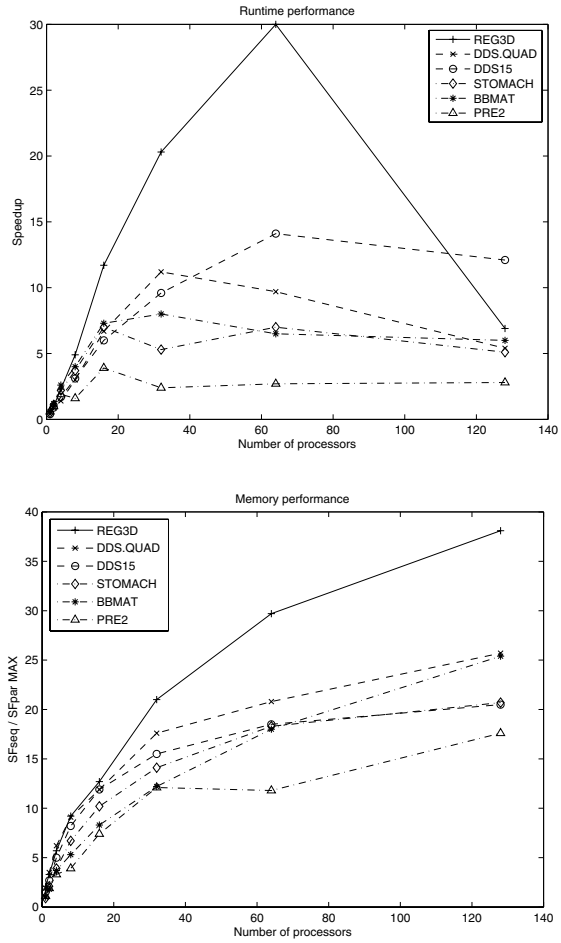

FIG. 5.3. *Speedup and memory saving of the parallel symbolic factorization algorithm for the first six matrices in our test set.*

dense separators, but we observe a big performance drop on 128 processors. After further investigation, we found that the technique of identifying dense separators was much less effective on 128 processors.

For five of our unsymmetric matrices, the time of the parallel symbolic factorization decreases when increasing the number of processors up to 16. The best speedups for SFpar are for matrices BBMAT (8-fold on 32 processors) and LHR71C (9-fold on 32 processors). These three matrices are relatively denser than the other matrices, and the technique of exploiting dense separators is more effective. For matrix PRE2, which is more unsymmetric and has very little dense structure, the algorithm achieves a speedup of almost 4 on 16 processors. For the other three matrices in our test set (TORSO1, TWOTONE, and G7JAC200SC), SFpar achieves only a speedup of two, even with increasing number of processors. However, for these matrices the time of SFpar is generally smaller than the time of PARMETIS. For TORSO1, the time spent in the graph partitioning phase can be 10 times larger than the time spent in SFpar.

For memory scaling, we display in Figures 5.3 and 5.4 the decrease in the mem-

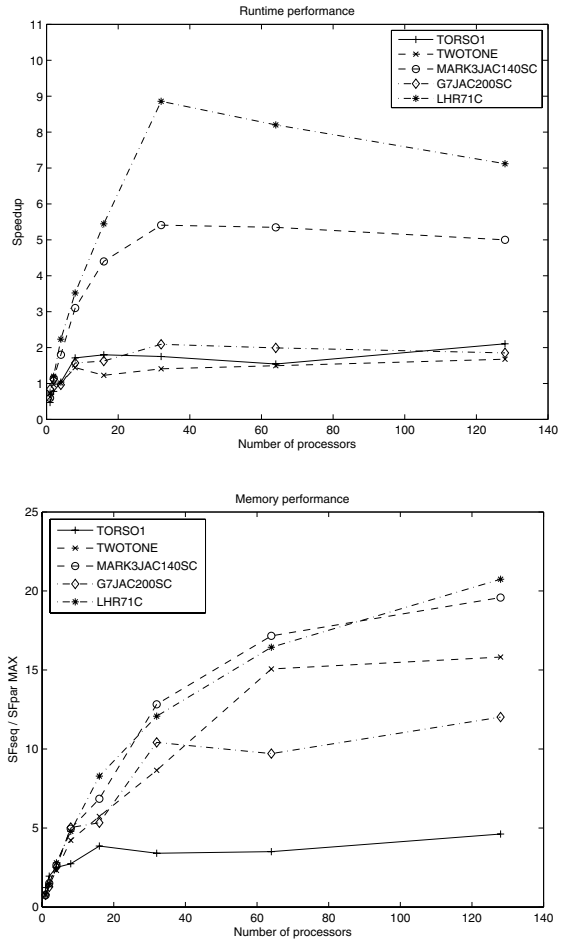

FIG. 5.4. *Speedup and memory saving of the parallel symbolic factorization algorithm for the last five matrices in our test set.*

ory usage of the parallel symbolic factorization algorithm SFpar with respect to the memory needs of the sequential symbolic factorization algorithm SFseq. The memory usage is significantly reduced for all the matrices, with the exception of TORSO1. In the former case, the reduction of memory is observed all the way up to 128 processors. The largest reduction is obtained with REG3D for which on 128 processors, the memory need of SFpar is 38-fold smaller than that of SFseq. For the unsymmetric matrices, the largest reductions occur with matrices BBMAT (up to 25-fold) and LHR71C (up to 21-fold). Note that on a large number of processors, for the unsymmetric matrices, the memory used to store the replicated data may become more than what is needed to store the distributed data. For example, for STOMACH the replicated data represents 77% of the memory needs on 128 processors. Still, these matrices help show that the parallel algorithm exhibits good memory scalability.

For TORSO1, the parallel symbolic factorization uses only 4.6 times less memory than the sequential symbolic factorization. However, in this case PARMETIS leads to very unbalanced partitioning, as quantified by differences in the sizes of the separators

(in terms of the number of their indices and the number of their nonzero elements of the input matrix) at each level of the separator tree. For example, we have found that on 64 processors, the largest ratio of the maximum number of indices per separator relative to the level's average number of indices per separator is obtained at the second level of the separator tree, where it is 9.6. On 128 processors this ratio is 9.9, and it is also obtained at the second level of the separator tree. At the lower level of the separator tree, the ratio of the maximum number of nonzero elements in a partition relative to the average number of nonzero elements at this level is equal to 24.9 on 64 processors and 43.3 on 128 processors. As we mentioned already earlier, our data distribution algorithm is not the best choice for unbalanced separator trees and can lead to disparity in the per-processor memory usage in such cases and to low overall memory reduction rates. Indeed, in the case of TORSO1, we find that the maximum per-processor memory usage is 7.6 times larger than the average memory usage on 64 processors and is 8.5 times larger on 128 processors, consistent with the above hypothesis. We plan to address this problem in our future work.

5.4. Scalability analysis. Recall that our main goal of this research is to develop a parallel symbolic factorization algorithm that is memory scalable. We now quantify the memory scalability of SFpar using the matrices arising from the 11-point discretization of the Laplacian operator on 3D cubic grids. The notion of isoefficiency is useful when studying the scalability of a parallel algorithm. A parallel algorithm is considered highly scalable if it keeps a constant efficiency as the number of processors increases while the problem size per processor is kept constant, where the problem size could be the size of the dataset or the amount of work. For a memory scalability study, the suitable quantity would be the dataset size, which is the size of the L and U factors in this case. The memory efficiency on P processors is computed as the ratio of the memory usage of the sequential algorithm (SFseq) over the product of the maximum per-processor memory usage of the parallel algorithm (SFpar) and P. That is, Mem. eff. $= \frac{mem(SFseq)}{max.mem(SFpar)\times P}$. Therefore, we choose the dimensions of the cubic grids in such a way that the nonzeros of L and U are maintained roughly constant per processor while increasing the number of processors. Theoretically, when nested dissection ordering is used, for each matrix of order n, the number of nonzeros is on the order of $O(n^{4/3})$ while the amount of work is on the order of $O(n^2)$ [7].

Note that since SFseq and SFpar use very different data organizations (SFseq is column oriented, whereas SFpar is both column and row oriented), the total memory requirements are very different. In fact, when run on one processor, SFpar usually uses less memory than SFseq. Therefore, for ease of understanding, we will use a simulated single processor run of SFpar as the sequential code baseline. Since the PARMETIS ordering gives different numbers of fill-ins using different numbers of processors, we do not use the actual run of SFpar on one processor. Instead, we compute a lower bound of the memory need of Algorithm 1 based on the amount of fill in L and U after PARMETIS ordering using P processors. This algorithm stores the structure of L by columns and the structure of U by rows. It also assumes that the input matrix A is stored by columns below the diagonal and by rows above the diagonal. The memory needs are as follows. Two arrays of size n and two arrays of size equal to the supernodal structure of L and U store the structure of the factors. Two arrays of size n and two arrays, each of size twice the number of supernodes, store the pruned graphs of L and U. Two arrays, each of size n, are used to identify supernodes. One array, of size n, is used as a marker during the computation of the structure of L and U. Two arrays of size n and two arrays of size equal to the number of nonzeros of the

TABLE 5.2
Time and memory usage of the parallel symbolic factorization algorithm when the average number of nonzeros of L and U per processor is kept constant.

P	Grid size	Flops/P (10^9)	$nnz(L+U)$/P (10^6)	Time	Mem. SFpar MAX	Mem. SFpar AVG	Mem. SFseq	Mem. eff. (%)
1	29	5.5	9.5	.8	5.3	5.3	5.2	98
2	34	8.6	10.2	.9	5.0	4.9	9.4	94
4	39	12.2	10.0	.8	5.3	4.8	17.6	83
8	46	16.2	9.9	.8	6.0	4.8	34.9	73
16	53	21.2	9.7	.7	5.9	5.0	63.0	67
32	62	29.6	9.8	.8	6.8	5.5	111.1	51
64	74	46.0	10.7	1.1	8.8	7.2	220.2	39
128	85	55.8	10.0	9.8	12.1	9.2	390.2	25

original matrix A are used to store the structure of the input matrix.

Table 5.2 reports the size of the grids used, the number of operations and the size of the factors per process, the time of SFpar, and the memory used in the algorithm. The last two columns give the computed memory lower bound of a sequential symbolic factorization and the memory efficiency. We see that the algorithm achieves very respectable efficiencies ranging from 89% on 2 processors to 25% on 128 processors. The decrease in efficiency with increasing number of processors is mainly due to the two duplicated arrays of size n, which increase with increasing problem size. For example, the size of the two arrays on 64 processors is 3.2 MBytes, and on 128 processors is 4.9 MBytes. This represents almost half of the per-processor memory need. But since now the memory demand in the symbolic factorization phase is not a bottleneck anymore, there is no point in reducing this memory usage at the expense of the extra runtime.

The parallel runtime is almost constant up to 64 processors. But we observe a significant increase on 128 processors. With further study, we found that this is due to the same reasons as were previously observed with matrix REG3D. That is, the technique of identifying dense separators was less effective on 128 processors than on a smaller number of processors.

6. Conclusions. We have presented a parallel symbolic factorization algorithm for sparse Gaussian elimination with static pivoting. The algorithm is suitable when the equations and variables are preordered by a nested dissection algorithm, from which a binary separator tree is available, and our symbolic factorization algorithm exploits parallelism exposed by this separator tree.

The performance of the parallel algorithm depends on the partitioning and reordering (e.g., by PARMETIS), the structural symmetry, and the density of the matrix. The more symmetric the matrix is, the smaller the symmetrically pruned graph is, which leads to a smaller amount of communication. The denser the matrix, the denser the separators, which the parallel algorithm exploits for faster structural analysis. For the symmetric test cases, the parallel symbolic factorization algorithm SFpar has achieved a 14.1-fold speedup on 64 processors when compared with the sequential symbolic factorization algorithm SFseq (DDS15.K-SM; see Figure 5.3), and the entire solver SLU_SFpar is up to 20% faster than the solver SLU_SFseq (DDS.QUAD.K-SM; see Figure 5.1). For the unsymmetric cases, the parallel algorithm SFpar has achieved a 9-fold speedup on 32 processors (LHR71C; see Figure 5.4), and the entire solver SLU_SFpar is up to 16.7% faster than the solver SLU_SFseq on 64 processors (BBMAT; see Figure 5.1).

On one processor, SFpar can be slower than SFseq. But on a larger number of processors, SFpar can be much faster than SFseq.

In the redistribution step, both versions achieve good speedup. During this step, the communication patterns for numerical factorization and triangular solutions are determined. In SLU_SFseq, since every processor has a copy of the reduced structures of L and U, there is no communication when computing the communication pattern. In SLU_SFpar, with the distributed reduced structures of L and U, there are fewer accesses to the data on each processor, but there are more all-to-all communications to determine the communication pattern. This explains why on smaller numbers of processors, RDseq is faster, while on large number of processors, RDpar is faster (up to four times faster for several matrices).

The SFpar algorithm exhibits very good memory scalability. For many matrices, on one processor the memory usage of SFpar is less than that of SFseq. For all the matrices, with the exception of one (TORSO1), the maximum per-processor memory usage of SFpar continues to decrease with increasing number of processors up to 128. For the unsymmetric test cases, on 128 processors, the SFpar maximum per-processor memory reduction is up to 25-fold compared with SFseq, and the entire SLU_SFpar solver has up to a 5-fold reduction in maximum per-processor memory need compared with the entire SLU_SFseq solver (BBMAT; see Figure 5.2).

For matrix TORSO1, PARMETIS leads to an unbalanced partitioning and a corresponding unbalanced separator tree. Our data distribution algorithm is not well suited for unbalanced separator trees, and SFpar leads to a modest reduction of the memory requirement of the symbolic factorization. The imbalance in the partitioning can be related to the fact that the graph partitioning is applied on the symmetrized input matrix $|A|+|A|^T$. Two possible solutions can be envisaged, which could remedy this problem. First, one could try to use a partitioning algorithm that accounts for the asymmetry of the input matrix. Second, one could use a better mapping of the data to processors that takes into account that the separator tree is unbalanced. We will leave these options to be addressed in the future.

Notwithstanding that, the experimental results show that SFpar greatly increases the problem size the parallel SuperLU solver can handle, and the symbolic factorization effectively removes a memory bottleneck in many, if not most, common cases.

Acknowledgment. The authors thank the anonymous reviewers for their careful reading and the suggestions for improving the paper.

COMPATIBLE COARSE NODAL AND EDGE ELEMENTS THROUGH ENERGY FUNCTIONALS*

F. MUSY†, L. NICOLAS‡, AND R. PERRUSSEL†‡

Abstract. We propose new algorithms for the setup phase of algebraic multigrid (AMG) solvers for linear systems coming from edge element discretization. The construction of coarse levels is performed by solving an optimization problem with a Lagrange multiplier method: we minimize the energy of coarse bases under a constraint linking coarse nodal and edge element bases. On structured meshes, the resulting AMG method and the geometric multigrid method behave similarly as preconditioners. On unstructured meshes, the convergence rate of our method compares favorably with the AMG method of Reitzinger and Schöberl.

Key words. multigrid, constrained optimization, edge finite elements

1. Introduction.

Edge element discretization plays a key role in computational electromagnetism; it can be implemented for evaluating the electric or magnetic field using the vector wave equation or for evaluating the magnetic potential using the eddy current formulation. As this finite element discretization leads to sparse but generally large linear systems, efficient methods are required for the solution. Multilevel techniques have been introduced by Hiptmair [5] and Arnold, Falk, and Winther [1]; they are shown to be optimal on a hierarchy of nested grids. However, the inherent need of hierarchical finite element meshes in geometric multigrid methods is very restricting for industrial applications. It is more convenient to make use of a grey-box multilevel algorithm which needs a single grid but takes into account additional information on the initial problem.

For this purpose, algebraic multilevel methods have already been developed. Beyond the use of specific smoothers as proposed in [1, 5], Reitzinger and Schöberl [14] have highlighted an essential geometric compatibility relation which means that the gradient of a coarse nodal element function must belong to the coarse edge element space. Based on this relation, Reitzinger and Schöberl achieved an efficient method, which is now widespread in the computational electromagnetism community [7, 9, 10, 18, 17]. However, the combinatorial approach used there does not lead to an optimal convergence rate. Some improvements have been proposed by Bochev and coworkers [2, 6] based on smoothed aggregation techniques [15] and a compatibility with a larger class of nodal prolongation operators.

Here, we propose a somewhat different approach. Following ideas from [16] and [19], we construct coupled nodal and edge coarse bases by energy minimization, and we enforce the compatibility relation as a constraint. A connection can be made with

the smoothed aggregation method [8], which also involves energy minimization. In order to simplify the notation, we present our construction in a two-level framework.

In section 2, the problem and the properties of the considered finite element space are reviewed, especially the essential geometric relation. The constrained minimization problem is presented in section 3. Then we introduce the resulting linear system, with Lagrange multipliers and the edge prolongation matrix as unknowns. Section 4 describes in detail the conditions for obtaining a well-posed minimization problem. First, we clarify the construction of the edge function supports from a given graph and the coarse nodal function supports, and we point out the satisfied constraints. Then, we prove that the coarse graph has to satisfy a connectivity condition if the implicit constraints are not enforced, and we propose a construction of the coarse nodal function supports together with a suitable definition of the coarse graph. Finally, in section 5, we evaluate the efficacy of various versions of the algorithm corresponding to different choices of energy norm. We give numerical results for 2D and 3D problems on structured and unstructured meshes. On a hierarchy of nested meshes, the edge bases being computed from the geometric nodal bases at each level, the resulting AMG method, and the geometric multigrid method behave similarly as preconditioners. On unstructured meshes, the convergence rate of our method is better than the method of Reitzinger and Schöberl [14]. However, because of the solution of the constrained minimization problem, we pay for this improvement with a large increase in the computing cost for the edge bases.

2. Definition of the continuous problem and its discretization.

2.1. Formulation. The following problem has to be solved on a domain $\Omega \subset \mathbb{R}^d$, $d = 2, 3$:

$$\begin{cases} \text{Find } \mathbf{E} \in V \text{ such that } a(\mathbf{E}, \mathbf{E}') = F(\mathbf{E}') \ \forall \mathbf{E}' \in V_0, \\ \text{with } a(\mathbf{E}, \mathbf{E}') = \displaystyle\int_\Omega \delta \operatorname{curl} \mathbf{E} \cdot \operatorname{curl} \mathbf{E}' + \int_\Omega \gamma \mathbf{E} \cdot \mathbf{E}'. \end{cases} \tag{2.1}$$

V is an affine subspace of $\mathbf{H}(\operatorname{curl}, \Omega)$ [11], taking into account essential boundary conditions; V_0 is the vector subspace parallel to V; F is a linear form on V_0, which describes the source term; δ and γ are strictly positive functions, so that a is coercive; F, δ, and γ depend on the applications under consideration.

This formulation includes many static and transient electromagnetic models: potential vector formulation for magnetostatic or eddy currents and electric or magnetic field formulation in the transient case. For instance, for an eddy current formulation in the transient case discretized by an implicit Euler scheme with time parameter $\triangle t$, $\mathbf{E}$ is the electric field, δ is equal to $\triangle t/\mu$ with μ the magnetic permeability, and γ is the electric conductivity.

2.2. Finite element space and properties. Problem (2.1) is discretized by using the lowest order edge elements introduced by Nédélec [13], which are conforming in $\mathbf{H}(\operatorname{curl}, \Omega)$. We consider triangular and tetrahedral meshes. For a tetrahedron K, the local polynomial space V_K is defined by

$$V_K = \{x \mapsto \mathbf{p} \times \mathbf{x} + \mathbf{q}, \ \mathbf{x} \in K, \text{ and } \mathbf{p}, \mathbf{q} \in \mathbb{R}^3\}. \tag{2.2}$$

The symbol $\times$ denotes the cross-product.

The local degrees of freedom which permit us to ensure the conformity in $\mathbf{H}(\mathrm{curl}, \Omega)$ are given by path integrals along the edges of the element:

$$\mathbf{E}_h \mapsto \int_e \mathbf{E}_h \cdot \mathbf{t} \, \mathrm{ds}, \tag{2.3}$$

where e is an edge of K, $\mathbf{t}$ is a tangential vector to e, and $\mathbf{E}_h$ belongs to V_K. Based on this local description, an edge finite element space can be defined on a mesh of the domain. V_h will denote the edge finite element space, defined on a mesh T_h of the domain Ω, and taking into account essential boundary conditions.

Therefore using this finite element space, we are led to solve a linear system:

$$Ax = f. \tag{2.4}$$

A fundamental property links the edge elements to the nodal P_1-Lagrange elements: the gradient of a nodal function belongs to the space of edge functions. If we denote the finite element bases as follows,

(i) $(\phi_p^h)_{p=1,\ldots,N^h}$ is the nodal basis,

(ii) $(\lambda_i^h)_{i=1,\ldots,E^h}$ is the edge basis,

this property can be recast as

$$\mathrm{grad}\, \phi_p^h = \sum_{i=1}^{E^h} G_{ip}^h \lambda_i^h \qquad \forall p \in \{1, \ldots, N^h\}, \tag{2.5}$$

where G^h is known and is the edge-node incidence matrix of the mesh T_h; in what follows, the superscript h for the fine level will be opposed to H used for the coarse level. G^h is a discrete analogue of the gradient operator on this mesh. Moreover, if the domain is contractible, the subspace spanned by the $\mathrm{grad}\, \phi_p^h$'s coincides exactly with the kernel of the curl operator in the edge element space [4].

Our aim, as highlighted in [14], is to preserve the analogous compatibility relation for coarse bases, which is natural with a hierarchy of nested grids. Thus, a coherent representation of the kernel of the curl operator is preserved, which permits the efficient use of the smoothers proposed by Hiptmair [5] and by Arnold, Falk, and Winther [1]. Therefore the gradient of a coarse nodal function must be a combination of coarse edge functions.

Let us introduce the following notation:

(i) $(\phi_n^H)_{n=1,\ldots,N^H}$ is the coarse nodal basis,

(ii) $(\lambda_e^H)_{e=1,\ldots,E^H}$ is the coarse edge basis.

Then the compatibility condition is written algebraically as

$$\mathrm{grad}\, \phi_n^H = \sum_{e=1}^{E^H} G_{en}^H \lambda_e^H \qquad \forall n \in \{1, \ldots, N^H\}, \tag{2.6}$$

where G^H is the discrete analogue of the gradient operator and is the edge-node incidence matrix of a coarse graph. This operator G^H or equivalently the associated coarse graph has to be constructed before the computation of the coarse edge basis. The way to obtain the coarse graph from the fine graph is postponed to section 4.

These coarse bases are constructed so as to satisfy the inclusion of finite element spaces, the "coarse" being included in the "fine," which is expressed by the following

algebraic relations:

$$\phi_n^H = \sum_{p=1}^{N^h} \alpha_{pn} \phi_p^h \qquad \forall n \in \{1, \dots, N^H\}, \tag{2.7a}$$

$$\lambda_e^H = \sum_{i=1}^{E^h} \beta_{ie} \lambda_i^h \qquad \forall e \in \{1, \dots, E^H\}. \tag{2.7b}$$

According to relations (2.5), (2.6), and (2.7), the components α_{pn} and β_{ie} of the coarse bases must satisfy

$$\sum_{e=1}^{E^H} \sum_{i=1}^{E^h} \beta_{ie} G_{en}^H \lambda_i^h = \sum_{p=1}^{N^h} \sum_{i=1}^{E^h} G_{ip}^h \alpha_{pn} \lambda_i^h \qquad \forall n \in \{1, \dots, N^H\}, \tag{2.8a}$$

or equivalently

$$\sum_{e=1}^{E^H} \beta_{ie} G_{en}^H = \sum_{p=1}^{N^h} G_{ip}^h \alpha_{pn} \qquad \forall i \in \{1, \dots, E^h\},\ \forall n \in \{1, \dots, N^H\}. \tag{2.8b}$$

Finally, if α denotes the matrix of components α_{in} and β the matrix of components β_{ie}, the compatibility relation (2.6) can be written, also under assumptions (2.5) and (2.7), as

$$\beta G^H = G^h \alpha. \tag{2.9}$$

3. Overview of the coarse bases construction.

3.1. Energy minimization problems. The domain Ω is decomposed into overlapping subdomains Ω_n^H, for n in $\{1, \dots, N^H\}$; this decomposition enables us to restrict the support of the coarse nodal basis functions.

In the same way, Ω is decomposed into overlapping subdomains $\mathcal{U}_e$, for e in $\{1, \dots, E^H\}$ in order to localize the supports of the coarse edge basis functions. The subdomain $\mathcal{U}_e$ will be the intersection of two subdomains Ω_l^H and Ω_m^H.

Given the subdomains Ω_n^H, the choice of the matrix G^H determines the definition of the subdomains $\mathcal{U}_e$; we will clarify this point in subsection 4.1.

Two minimization problems under constraints are solved successively. In analogy with the nodal element case [16], we first solve

$$\begin{cases} \text{Find } (\phi_n^H)_{n=1,\dots,N^H} \text{ minimizing } \displaystyle\sum_{n=1}^{N^H} c(\phi_n^H, \phi_n^H) \text{ under the constraints:} \\ \displaystyle\sum_{n=1}^{N^H} \phi_n^H(x) = 1 \quad \forall x \in \overline{\Omega} \quad \text{and} \quad \operatorname{supp}(\phi_n^H) \subset \overline{\Omega_n^H} \quad \forall n \in \{1, \dots, N^H\}. \end{cases} \tag{3.1}$$

The bilinear form c can be, for instance, $c(\phi, \psi) = \int_\Omega \gamma \operatorname{grad} \phi \cdot \operatorname{grad} \psi$ or more simply the bilinear form associated with the Laplacian of the graph, i.e., $(G^h)^t G^h$. Here the superscript t denotes transposition.

Next, from the coarse nodal basis $(\phi_n^H)_{n=1,\dots,N^H}$ we compute the coarse edge basis $(\lambda_e^H)_{e=1,\dots,E^H}$ by solving the problem

$$\text{(3.2)}\qquad \begin{cases} \text{Find } (\lambda_e^H)_{e=1,\dots,E^H} \text{ minimizing } \displaystyle\sum_{e=1}^{E^H} b(\lambda_e^H, \lambda_e^H) \text{ under the constraints:} \\ \operatorname{grad} \phi_n^H = \displaystyle\sum_{e=1}^{E^H} \lambda_e^H G_{en}^H \quad \forall n \in \{1,\dots,N^H\}, \\ \operatorname{supp}(\lambda_e^H) \subset \overline{U_e} \quad \forall e \in \{1,\dots,E^H\}. \end{cases}$$

The letter b denotes a scalar product on V_h, which can be the bilinear form $a(\cdot,\cdot)$ from (2.1) or variants, which will be introduced in subsection 5.2 and implemented in numerical examples in section 5.

Problem (3.1) can be solved by using the method described in [16]. This is the reason why we mainly concentrate our attention on problem (3.2).

We introduce algebraic notation which encodes the support constraints. First for all e in $\{1,\dots,E^H\}$, I_e is a subset of the set of indices of the fine edge basis functions whose support is included in $\overline{U_e}$. We assume that, for all e, I_e is nonempty, and we define

$$\text{(3.3)}\qquad \widetilde{M} = \sum_{e=1}^{E^h} |I_e|.$$

The term $|Z|$ denotes the number of elements in a finite set Z. Then for e in $\{1,\dots,E^H\}$ with $I_e = \{i_1,\dots,i_{|I_e|}\}$, we introduce the projection operator which keeps only the components indexed by I_e:

$$\text{(3.4)}\qquad \begin{aligned} &Q_e : \mathbb{R}^{E^h} \to \mathbb{R}^{|I_e|}, \\ &(Q_e x)_k = x_{i_k} \quad \forall x \in \mathbb{R}^{E^h},\ \forall k \in \{1,\dots,|I_e|\}. \end{aligned}$$

The term x_{i_k} denotes the i_kth component of x. It is straightforward that the transposed operation Q_e^t is defined by

$$\text{(3.5)}\qquad \begin{aligned} &Q_e^t : \mathbb{R}^{|I_e|} \to \mathbb{R}^{E^h}, \\ &(Q_e^t y)_i = \begin{cases} 0 \text{ if } i \notin I_e, \\ y_k \text{ if } i = i_k \in I_e, \end{cases} \qquad \forall y \in \mathbb{R}^{|I_e|}. \end{aligned}$$

Secondly, in order to restrict the number of constraints in problem (3.2), we introduce sets J_n for all n in $\{1,\dots,N^H\}$. The sets J_n, like the sets I_e, are subsets of indices of the fine edge basis functions.

The sets J_n will be carefully defined with the help of support conditions, so as to decrease as much as possible the number of constraints coming from (2.8b) and to obtain a well-posed problem; the construction of the J_n's is described in subsection 4.2. We introduce an integer for denoting the number of constraints :

$$\text{(3.6)}\qquad M = \sum_{n=1}^{N^H} |J_n|.$$

Since some J_n's can be empty, we introduce the set

$$F = \{n \in \{1, \dots, N^H\} \mid J_n \neq \emptyset\}. \tag{3.7}$$

Similarly to the operator Q_e from set I_e, we introduce a canonical projection operator associated with J_n for n in F:

$$R_n : \mathbb{R}^{E^h} \to \mathbb{R}^{|J_n|}. \tag{3.8}$$

Let K be the matrix whose coefficients are $b(\lambda_j^h, \lambda_i^h)$. In order to obtain a matrix form of the minimization problem, we define matrices which are restrictions to the subdomains under consideration of the matrix K:

$$K_e = Q_e K Q_e^t. \tag{3.9}$$

We also define

$$\xi_n = R_n G^h \alpha_{\bullet n} \quad \forall n \in F \quad \text{and} \quad \beta_e = Q_e \beta_{\bullet e} \quad \forall e \in \{1, \dots, E^H\}, \tag{3.10}$$

where $\alpha_{\bullet n}$ denotes the nth column of α, and $\beta_{\bullet e}$ the eth column of β.

After solving problem (3.1), which gives the matrix α, we compute the β_e's by solving the problem

$$\begin{cases} \text{Minimize } \displaystyle\sum_{e=1}^{E^H} \beta_e^t K_e \beta_e \text{ under the constraints:} \\ R_n \left(\displaystyle\sum_{e=1}^{E^H} G_{en}^H Q_e^t \beta_e \right) = \xi_n \qquad \forall n \in F. \end{cases} \tag{3.11}$$

3.2. Solution of problem (3.11). The constrained problem (3.11) can be solved by a Lagrange multiplier method. Let us introduce column vectors ξ and ρ of $\mathbb{R}^M$ and matrices D and T.

The components of the vector ρ are Lagrange multipliers relative to the constraints in (3.11), and ξ is the vector defined by (3.10). If we suppose that $F = \{i_1, \dots, i_{|F|}\}$, ξ and ρ are defined blockwise as

$$\xi = \begin{pmatrix} \xi_{i_1} \\ \vdots \\ \xi_{i_{|F|}} \end{pmatrix}, \quad \rho = \begin{pmatrix} \rho_{i_1} \\ \vdots \\ \rho_{i_{|F|}} \end{pmatrix} \quad \text{with } \xi_{i_n}, \rho_{i_n} \in \mathbb{R}^{|J_n|}. \tag{3.12}$$

The matrix D of dimension $(\widetilde{M}, \widetilde{M})$ is the block-diagonal matrix whose diagonal blocks are the matrices K_e, $e \in \{1, \dots, E^H\}$. Finally, the matrix T maps a vector from $\mathbb{R}^M$ to $\mathbb{R}^{\widetilde{M}}$ in the following way:

$$T : \rho \mapsto \begin{pmatrix} Q_1 \left(\displaystyle\sum_{n \in F} G_{1n}^H R_n^t \rho_n \right) \\ \vdots \\ Q_{E^H} \left(\displaystyle\sum_{n \in F} G_{E^H n}^H R_n^t \rho_n \right) \end{pmatrix}. \tag{3.13}$$

The minimization problem (3.11) can now be written

$$\text{Find } \bar{\beta}_c \in \mathbb{R}^{\widetilde{M}} \text{ minimizing } \bar{\beta}^t D \bar{\beta} \text{ in } \mathbb{R}^{\widetilde{M}} \text{ under the constraint } T^t \bar{\beta} = \xi, \tag{3.14}$$

or by introducing Lagrange multipliers:

$$\begin{cases} \text{Find a critical point } (\bar{\beta}_c, \rho_c) \in \mathbb{R}^{\widetilde{M}} \times \mathbb{R}^M \text{ of the Lagrangian } \mathcal{L} \text{ defined by} \\ \mathcal{L}(\bar{q}\beta, \rho) = \dfrac{1}{2} \bar{\beta}^t D \bar{\beta} + \rho^t (\xi - T^t \bar{\beta}). \end{cases} \tag{3.15}$$

This critical point must satisfy the system of equations

$$\begin{pmatrix} D & -T \\ T^t & 0 \end{pmatrix} \begin{pmatrix} \bar{\beta} \\ \rho \end{pmatrix} = \begin{pmatrix} 0 \\ \xi \end{pmatrix}. \tag{3.16}$$

This linear system can be solved in the following way:

— First, the vector ρ_c of Lagrange multipliers is determined by applying an iterative method to the system

$$T^t D^{-1} T \rho = \xi. \tag{3.17}$$

As we will see in subsection 4.2, the matrix $T^t D^{-1} T$ in (3.17) is symmetric positive definite; the construction of the R_n's will precisely ensure this property.

— Second, we return to the computation of $\bar{\beta}_c$ by solving

$$D \bar{\beta} = T \rho_c. \tag{3.18}$$

The matrix $T^t D^{-1} T$ will not be assembled, and its multiplication by a vector can be made efficiently; details will be given in subsection 5.1.

4. Elements required by the construction.

4.1. Algebraic decomposition into subdomains. Associated with the fine nodal basis $(\phi_p^h)_{p=1,\dots,N^h}$, we give an oriented simple connected graph by its set of vertices indexed by $\{1, \dots, N^h\}$ and its set of edges $\mathcal{S}^h \subset \{1, \dots, N^h\}^2$. The orientations of the edges are arbitrary; there are no loops, i.e., no elements (p, p) in $\mathcal{S}^h$, and if (p, q) belongs to $\mathcal{S}^h$, (q, p) does not belong to $\mathcal{S}^h$. By convention, p is the origin and q is the end of the edge (p, q). The edges could be the geometric edges of the mesh, but we do not restrict ourselves to this situation: starting from the second finest grid, we will have no more geometric edges.

The edges are numbered by $i \in \{1, \dots, E^h\}$, where $E^h = |\mathcal{S}^h|$; the ith edge is denoted by $(p(i), q(i))$ and conversely if $p = p(i)$ and $q = q(i)$, we will write $i = \overline{pq}^h$.

Let us now give the precise definition of the edge-node incidence matrix G^h of size $E^h \times N^h$:

$$G_{il}^h = \begin{cases} -1 & \text{if } l = p(i), \\ +1 & \text{if } l = q(i), \\ 0 & \text{otherwise.} \end{cases} \tag{4.1}$$

Two assumptions on the fine bases are supposed to be satisfied at the beginning. We suppose that the fine nodal basis $(\phi_p^h)_{p=1,\dots,N^h}$ satisfies the property

$$\sum_{p=1}^{N^h} \phi_p^h(x) = 1 \qquad \forall x \in \overline{\Omega}. \tag{4.2}$$

We assume that there exists a set of subdomains $(\Omega_p^h)_{p=1,\dots,N^h}$ of Ω such that

$$\Omega = \bigcup_{p=1}^{N^h} \Omega_p^h \quad \text{and} \quad \left(\bigcup_{q \neq p} \Omega_q^h \right)^c \neq \emptyset \qquad \forall p \in \{1, \dots, N^h\}, \tag{4.3}$$

where the superscript c is the standard set-complement, and satisfying

$$\begin{aligned} &\operatorname{supp}(\phi_p^h) \subset \overline{\Omega_p^h} \qquad \forall p \in \{1, \dots, N^h\}, \\ \text{and } &\operatorname{supp}(\lambda_i^h) \subset \overline{\Omega_p^h \cap \Omega_q^h} \qquad \text{if } i = \overline{pq}^h. \end{aligned} \tag{4.4}$$

Assumptions (4.3) and (4.4) on the subdomains $(\Omega_p^h)_{p=1,\dots,N^h}$ enable us to control the supports of the nodal (edge) functions and to avoid the linear dependence of these functions.

4.1.1. Notations and principle of the construction for the coarse nodal basis. Several steps have to be considered:

1. In order to localize the supports of the coarse nodal functions $(\phi_n^H)_{n=1,\dots,N^H}$, we introduce sets $(L_n)_{n=1,\dots,N^H}$ of indices in $\{1, \dots, N^h\}$ such that

$$\bigcup_{n=1}^{N^H} L_n = \{1, \dots, N^h\}, \tag{4.5}$$

and we will write

$$\Omega_n^H = \bigcup_{p \in L_n} \Omega_p^h. \tag{4.6}$$

Then it is equivalent to state $\operatorname{supp}(\phi_n^H) \subset \overline{\Omega_n^H}$ and to require the unknowns (α_{pn}) in (2.7a) to satisfy

$$\alpha_{pn} = 0 \qquad \forall n \in \{1, \dots, N^H\},\ \forall p \in \{1, \dots, N^h\} \setminus L_n. \tag{4.7}$$

We introduce a reciprocal set-valued function $\widetilde{L}$ defined by

$$\widetilde{L}_p = \left\{ n \in \{1, \dots, N^H\} \mid p \in L_n \right\} \qquad \forall p \in \{1, \dots, N^h\}. \tag{4.8}$$

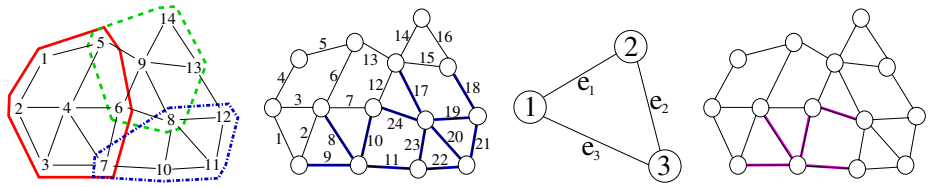
Because of (4.5), $\widetilde{L}_p$ is nonempty. Observe that (4.7) can be rewritten as

$$\alpha_{pn} = 0 \qquad \forall p \in \{1, \dots, N^h\},\ \forall n \in \{1, \dots, N^H\} \setminus \widetilde{L}_p. \tag{4.9}$$

An illustration of these definitions is given in Figure 4.1. For the fine graph in Figure 4.1(a), we set $L_1 = \{1, 2, 3, 4, 5, 6, 7\}$, $L_2 = \{5, 6, 8, 9, 13, 14\}$, and $L_3 = \{7, 8, 10, 11, 12\}$. One obtains, for instance, the sets $\widetilde{L}_7 = \{1, 3\}$ and $\widetilde{L}_4 = \{1\}$.

2. The constant preservation constraint of (3.1) is obtained by enforcing

$$\sum_{n=1}^{N^H} \alpha_{pn} = 1 \qquad \forall p \in \{1, \dots, N^h\}. \tag{4.10}$$



(a) Fine graph with node indices. Sets $(L_n)_{n=1,\dots,3}$ are surrounded.

(b) Fine graph with edge indices. Set C_3 is represented by bold edges.

(c) Coarse graph.

(d) Set I_{e_3} is represented by bold edges.

FIG. 4.1. *Representation of the fine and coarse graphs, sets* $(L_n)_{n=1,\dots,3}$, C_3, *and* I_{e_3}.

Indeed, we substitute (2.7a) into the constant preservation constraint and we use (4.2):

$$\sum_{n=1}^{N^H} \phi_n^H(x) = \sum_{n=1}^{N^H} \left(\sum_{p=1}^{N^h} \alpha_{pn} \phi_p^h(x) \right)$$
$$= \sum_{p=1}^{N^h} \phi_p^h(x) \left(\sum_{n=1}^{N^H} \alpha_{pn} \right) = \sum_{p=1}^{N^h} \phi_p^h(x) = 1.$$

3. We compute the prolongation matrix α with the encoded support constraint (4.7) by minimizing the energy functional from (3.1) under the constant preservation constraint (4.10). A method is given in [16].

4.1.2. More notation and definitions: How to relate coarse and fine, edge and nodal elements. For all n in $\{1,\dots,N^H\}$, we let C_n be a set of fine edge indices; these fine edges start or end in a node whose index is in L_n:

$$C_n = \left\{ i \in \{1,\dots,E^h\} \mid i = \overline{pq}^h \text{ with } p \text{ or } q \in L_n \right\}. \tag{4.11}$$

By (4.4) and (4.6), for i in C_n, the support of the fine edge basis function λ_i^h is included in the nth coarse nodal domain:

$$i \in C_n \implies \operatorname{supp}(\lambda_i^h) \in \overline{\Omega_n^H}. \tag{4.12}$$

We say that the fine edge function λ_i^h contributes to the gradient of the coarse nodal function ϕ_n^H if i belongs to C_n. Indeed, from (2.5) and (2.7a), we get

$$\operatorname{grad} \phi_n^H = \sum_{p=1}^{N^h} \alpha_{pn} \left(\sum_{i=1}^{E^h} G_{ip}^h \lambda_i^h \right) = \sum_{i=1}^{E^h} (G^h \alpha_{\bullet n})_i \lambda_i^h,$$

and from (4.1), (4.7), and (4.11),

$$(G^h \alpha_{\bullet n})_i = 0 \qquad \forall n \in \{1,\dots,N^H\},\ \forall i \in \{1,\dots,E^h\} \setminus C_n. \tag{4.13}$$

We introduce the reciprocal set-valued function $\widetilde{C}$:

$$\widetilde{C}_i = \left\{ n \in \{1,\dots,N^H\} \mid i \in C_n \right\} \qquad \forall i \in \{1,\dots,E_h\}. \tag{4.14}$$

In Figure 4.1(b), the fine edges are numbered, set C_3 is highlighted, and we can draw out, for instance, the set $\widetilde{C}_8 = \{1, 3\}$.

According to (4.8), (4.11), and (4.14) we infer

$$\widetilde{C}_i = \widetilde{L}_p \cup \widetilde{L}_q \quad \text{if } i = \overline{pq}^h. \tag{4.15}$$

As a consequence, $\widetilde{C}_i$ cannot be empty, and the constant preservation constraint (4.10) with (4.9) becomes

$$\sum_{n \in \widetilde{C}_i} \alpha_{pn} = \sum_{n \in \widetilde{C}_i} \alpha_{qn} = 1 \quad \text{if } i = \overline{pq}^h. \tag{4.16}$$

By analogy with the beginning of subsection 4.1, we let $\mathcal{S}^H$ be the set of edges of a simple oriented connected graph whose vertices are indexed by $\{1, \dots, N^H\}$; the elements of $\mathcal{S}^H$ are indexed by $e \in \{1, \dots, E^H\}$, and the inverse of the bijection $e \mapsto (n(e), m(e))$ is $(n, m) \mapsto \overline{nm}^H$. Similarly to the matrix G^h, we introduce the coarse edge-node incidence matrix G^H of dimension $E^H \times N^H$ with $E^H = |\mathcal{S}^H|$.

The set $\mathcal{S}^H$ has to satisfy a compatibility relation with the sets C_n

$$C_n \cap C_m \neq \emptyset \qquad \forall (n, m) \in \mathcal{S}^H. \tag{4.17}$$

For e in $\{1, \dots, E^H\}$, we define the nonempty index set I_e of the coarse edge corresponding to $e = \overline{nm}^H$:

$$I_e = C_n \cap C_m \quad \text{if } e = \overline{nm}^H. \tag{4.18}$$

Then from (4.12), if i belongs to I_e, the fine edge function λ_i^h has its support included in $\overline{\mathcal{U}_e}$:

$$i \in I_e \implies \operatorname{supp}(\lambda_i^h) \subset \overline{\mathcal{U}_e} \quad \text{with } \mathcal{U}_e = \Omega_n^H \cap \Omega_m^H.$$

The coarse graph in Figure 4.1(c) is related to the fine graph in Figure 4.1(a). Set I_{e_3} is represented in Figure 4.1(d).

In order to satisfy the support constraint $\operatorname{supp}(\lambda_e^H) \subset \overline{\mathcal{U}_e}$, we impose on the unknowns (β_{ie}) in (2.7b) the constraints

$$\beta_{ie} = 0 \qquad \forall e \in \{1, \dots, E^H\},\ \forall i \in \{1, \dots, E^h\} \setminus I_e. \tag{4.19}$$

By introducing the reciprocal set-valued function $\widetilde{I}$ defined by

$$\widetilde{I}_i = \big\{ e \in \{1, \dots, E^H\} \mid i \in I_e \big\} \qquad \forall i \in \{1, \dots, E^h\}, \tag{4.20}$$

the relation (4.19) can be rewritten as

$$\beta_{ie} = 0 \qquad \forall i \in \{1, \dots, E^h\},\ \forall e \in \{1, \dots, E^H\} \setminus \widetilde{I}_i. \tag{4.21}$$

The set $\widetilde{I}_i$ might be empty for some $i \in \{1, \dots, E^h\}$; i.e., some fine edge function might not contribute to any coarse edge function, but, as the sets I_e are never empty, we get

$$\bigcup_{i=1}^{E^h} \widetilde{I}_i = \{1, \dots, E^H\}.$$

4.1.3. Graph- and set-theoretical properties of $\widetilde{I}$ and $\widetilde{C}$. We will show that it is not necessary to enforce the constraints (2.8b) for all (i,n). We need the following lemma, which is a direct consequence of (4.14), (4.18), and (4.20).

LEMMA 4.1. $\widetilde{I}_i$

$$\overline{mn}^H \in \widetilde{I}_i \Leftrightarrow (m,n) \in \mathcal{S}^H \qquad \{m,n\} \subset \widetilde{C}_i.$$

Thus the edges indexed by $\widetilde{I}_i$ are the edges of $\mathcal{S}^H$ whose extremity nodes are indexed by $\widetilde{C}_i$. From this result, we will first deduce that the relations in (2.8b) are always fulfilled in the case $n \notin \widetilde{C}_i$.

PROPOSITION 4.2. i $\{1,\dots,E^h\}$ n $\{1,\dots,N^H\} \setminus \widetilde{C}_i$ (2.8b) (i,n) . According to (4.13), the (i,n) coefficient of the right-hand side of (2.8b) vanishes.

Conversely, according to (4.21) the left-hand side of (2.8b) is given by

$$\sum_{e \in \widetilde{I}_i} \beta_{ie} G^H_{en}.$$

It vanishes if $\widetilde{I}_i$ is empty. If $e = \overline{lm}^H$ belongs to $\widetilde{I}_i$, Lemma 4.1 implies that l and m belong to $\widetilde{C}_i$. However, for G^H_{en} not to vanish, m and l must be equal to n, and this contradicts the assumption $n \notin \widetilde{C}_i$. ∎

Secondly, the following proposition points out that some relations in (2.8b) are linearly dependent.

PROPOSITION 4.3. i $\{1,\dots,E^h\}$ m $\widetilde{C}_i$ (2.8b) (i,n) n $\widetilde{C}_i \setminus \{m\}$ (i,m) .

. It is sufficient to prove the equality

$$\sum_{n \in \widetilde{C}_i} \left(\sum_{e=1}^{E^H} \beta_{ie} G^H_{en} \right) = \sum_{n \in \widetilde{C}_i} \left(\sum_{r=1}^{N^h} G^h_{ir} \alpha_{rn} \right).$$

For $i = \overline{pq}^h$, according to (4.1) and (4.16), the right-hand side vanishes since

$$\sum_{n \in \widetilde{C}_i} \left(\sum_{r=1}^{N^h} G^h_{ir} \alpha_{rn} \right) = \sum_{n \in \widetilde{C}_i} \alpha_{qn} - \sum_{n \in \widetilde{C}_i} \alpha_{pn}.$$

For the left-hand side, according to (4.21), we have

$$\sum_{n \in \widetilde{C}_i} \left(\sum_{e=1}^{E^H} \beta_{ie} G^H_{en} \right) = \sum_{e \in \widetilde{I}_i} \beta_{ie} \left(\sum_{n \in \widetilde{C}_i} G^H_{en} \right).$$

It vanishes if $\widetilde{I}_i = \emptyset$ and also if $\widetilde{I}_i \neq \emptyset$ since for all e in $\widetilde{I}_i$, by Lemma 4.1 and the definition of G^H,

$$\sum_{n \in \widetilde{C}_i} G^H_{en} = \sum_{n=1}^{N^H} G^H_{en} = 0. \qquad ∎$$

4.2. How to choose the R_n's in order to simplify the computational process and to have a unique coarse edge basis. The choice of the index set J_n and therefore the projections R_n can now be explicitly defined.

All the matrices $(K_e)_{e=1,\dots,E^H}$ are assumed to be symmetric positive definite; from the definition of the matrix D (subsection 3.2), it is clear that D^{-1} is symmetric positive definite. Therefore, in order to obtain a unique solution of (3.17), the matrix T must have full column rank, which has to be enforced by a proper choice of the R_n's. If T does not satisfy this property, the set of β satisfying (2.9) can be empty, and the existence of a solution to (3.17) is not ensured.

We define the reciprocal set-valued function $\widetilde{J}$:

$$\widetilde{J}_i = \big\{n \in \{1,\dots,N^H\} \mid i \in J_n\big\} \qquad \forall i \in \{1,\dots,E^h\}. \tag{4.22}$$

Since the sets $\widetilde{I}_i$ and $\widetilde{J}_i$ may be empty, we introduce the set $\widetilde{F}$:

$$\widetilde{F} = \big\{i \in \{1,\dots,E^h\} \mid \widetilde{I}_i \neq \emptyset \text{ and } \widetilde{J}_i \neq \emptyset\big\}. \tag{4.23}$$

Then, for i in $\widetilde{F}$, we can define $\widetilde{G}^{H,i}$ the matrix of dimensions $|\widetilde{I}_i|\times|\widetilde{J}_i|$ extracted from the matrix G^H by keeping only the rows $e \in \widetilde{I}_i$ and the columns $n \in \widetilde{J}_i$.

PROPOSITION 4.4. [illegible] T [illegible]

$$\ker(\widetilde{G}^{H,i}) = \{0\} \qquad \forall i \in \widetilde{F}, \tag{4.24a}$$

$$\forall i \in \{1,\dots,E^h\}, \qquad \widetilde{I}_i = \emptyset \Rightarrow \widetilde{J}_i = \emptyset. \tag{4.24b}$$

[illegible]. Let ρ be in $\mathbb{R}^M$. For n in F defined in (3.7), we observe that

$$R_n^t \rho_n = \sum_{i \in J_n} \rho_{n,i} u_i, \tag{4.25}$$

where u_i is the ith vector of the canonical basis of $\mathbb{R}^{E^h}$. We let T operate on ρ, and for that purpose we look at the blockwise result. Let e be in $\{1,\dots,E^H\}$, by the definition of T in (3.13):

$$(T\rho)_e = Q_e\left(\sum_{n\in F} G^H_{en}\left(\sum_{i\in J_n}\rho_{n,i}u_i\right)\right) \tag{4.26a}$$

$$= \sum_{n=1}^{N^H}\sum_{i\in J_n} G^H_{en}\rho_{n,i}Q_e(u_i). \tag{4.26b}$$

From (4.22), the components of ρ indexed by the set of pairs (n,i) with n in $\{1,\dots,N^H\}$ and i in J_n can equivalently be indexed by i in $\{1,\dots,E^h\}$ and n in $\widetilde{J}_i$. Thus $(T\rho)_e$ can be rewritten as

$$(T\rho)_e = \sum_{i=1}^{E^h}\left(\sum_{n\in\widetilde{J}_i} G^H_{en}\rho_{n,i}\right)Q_e(u_i), \tag{4.26c}$$

but $Q_e(u_i)$ is equal to 0 if i is not in I_e. Then

$$(T\rho)_e = \sum_{i\in I_e} \left(\sum_{n\in \widetilde{J}_i} G^H_{e,n}\rho_{n,i} \right) Q_e(u_i). \tag{4.26d}$$

Since the vectors $(Q_e(u_i))_{i\in I_e}$ are linearly independent in $\mathbb{R}^{|I_e|}$, we infer from relation (4.26d)

$$T\rho = 0 \Leftrightarrow \sum_{n\in \widetilde{J}_i} G^H_{e,n}\rho_{n,i} = 0 \qquad \forall e \in \{1,\dots,E^H\},\ \forall i \in I_e, \tag{4.27a}$$

Remarking that $i \in I_e$ corresponds to $e \in \widetilde{I}_i$, (4.27a) becomes

$$T\rho = 0 \Leftrightarrow \sum_{n\in \widetilde{J}_i} G^H_{e,n}\rho_{n,i} = 0 \qquad \forall i \in \widetilde{F},\ \forall e \in \widetilde{I}_i, \tag{4.27b}$$

which can be written, according to the definition of $\widetilde{G}^{H,i}$, as

$$T\rho = 0 \Leftrightarrow \widetilde{G}^{H,i}\rho^i = 0 \qquad \forall i \in \widetilde{F}, \tag{4.27c}$$

where $\rho^i \in \mathbb{R}^{|\widetilde{J}_i|}$ is of components $\rho_{n,i}$ for n in $\widetilde{J}_i$. Finally, one obtains

$$T\rho = 0 \Leftrightarrow \rho^i \in \ker(\widetilde{G}^{H,i}) \qquad \forall i \in \widetilde{F}. \tag{4.28}$$

We can now prove the sufficiency of (4.24). If we assume that condition (4.24b) is satisfied, then

$$\widetilde{F} = \left\{ i \in \{1,\dots,E^h\} \mid \widetilde{J}_i \neq \emptyset \right\},$$

and ρ, vector of $\mathbb{R}^M$, is defined by the knowledge of its blocks ρ^i for all i in $\widetilde{F}$. Condition (4.24a) associated with relation (4.28) enables us to conclude

$$T\rho = 0 \Rightarrow \rho = 0.$$

Then, conditions (4.24) are sufficient for T to be one-to-one.

Conversely, assume that

$$\exists i_0 \in \widetilde{F}, \qquad \ker(\widetilde{G}^H_{i_0}) \neq \{0\},$$

Let ρ be in $\mathbb{R}^M \setminus \{0\}$ such that

$$\rho^j = \{0\} \quad \forall j \neq i_0 \quad \text{and} \quad \rho^{i_0} \in \ker(\widetilde{G}^H_{i_0}) \setminus \{0\}.$$

By relation (4.28), ρ is in $\ker(T)$. Hence, condition (4.24a) is necessary for T to be one-to-one.

In the same way, assume that

$$\exists i_0 \in \{1,\dots,E^h\}, \qquad \widetilde{I}_{i_0} = \emptyset \quad \text{and} \quad \widetilde{J}_{i_0} \neq \emptyset,$$

Let ρ in $\mathbb{R}^M \setminus \{0\}$ be such that

$$\rho^j = \{0\} \qquad \forall j \neq i_0.$$

Since i_0 is not in $\widetilde{F}$, ρ is in $\ker(T)$ from (4.28). Condition (4.24b) is necessary for T to be one-to-one. ∎

In order to reduce the number of enforced constraints, from Propositions 4.2 and 4.3, a suitable choice of sets $\widetilde{J}_i$ is

$$\widetilde{J}_i = \widetilde{C}_i \setminus \{m\}, \text{ with } m \in \widetilde{C}_i, \ \forall i \in \{1, \dots, E^h\}.$$

For such a choice, the condition of Proposition 4.4 can be given in terms of connectivity of induced subgraphs of the graph of edges in $\mathcal{S}^H$. More precisely, for any fine edge i of $\mathcal{S}^h$, let $\mathcal{S}^{H,i}$ be the induced subgraph of the graph of edges in $\mathcal{S}^H$, whose vertices are indexed by $\widetilde{C}_i$ and edges by $\widetilde{I}_i$.

COROLLARY 4.5. [illegible] $\widetilde{J}_i = \widetilde{C}_i \setminus \{m\}$ $i = 1, \dots, E^h$ [illegible] i [illegible] $\{1, \dots, E^h\}$ [illegible] $\mathcal{S}^{H,i}$ [illegible]. Observe first that $\widetilde{J}_i$ is empty iff the subgraph $\mathcal{S}^{H,i}$ reduces to one vertex, which happens by Lemma 4.1 if $\widetilde{I}_i$ is empty.

Assume now $\widetilde{I}_i$ is nonempty. By Lemma 4.1 the edge-node incidence matrix of the subgraph is deduced from G^H by keeping only the rows $e \in \widetilde{I}_i$ and the columns $n \in \widetilde{C}_i$. By deleting one column of index $m \in \widetilde{C}_i$, the obtained matrix $\widetilde{G}^{H,i}$ satisfies the condition (4.24a) of Proposition 4.4 iff the subgraph $\mathcal{S}^{H,i}$ is connected. ∎

The following subsection is devoted to the construction of index sets L_n and an incidence matrix G^H which satisfy the connectivity condition on the induced subgraph $\mathcal{S}^{H,i}$.

4.3. Construction of the index sets L_n. We start from an $N^h \times N^h$ nodal symmetric matrix B^h. When passing from a fine level to a coarser level, we just require

$$B^h_{pp} \neq 0 \qquad \forall p \in \{1, \dots, N^h\} \tag{4.29}$$

and a compatibility condition with the set $\mathcal{S}^h$:

$$(p, q) \in \mathcal{S}^h \implies B^h_{pq} \neq 0. \tag{4.30}$$

This condition means that B^h_{pq} must not vanish on the pairs (p, q) corresponding to the edges belonging to $\mathcal{S}^h$, but it might also be different from zero on other pairs. In other words, there may be more edges (p, q) determined by the condition $B^h_{pq} \neq 0$ than elements (p, q) or (q, p) in $\mathcal{S}^h$.

As Reitzinger and Schöberl do in [14], we define a map:

$$\begin{aligned} \text{ind} : \ & \mathbb{R}^{N^h} \to \mathbb{R}^{N^H} \\ & p \mapsto \text{ind}(p). \end{aligned} \tag{4.31}$$

The inverse images of n by the mapping ind make up a partition of $\{1, \dots, N^h\}$ into sets. The set H_n is the aggregate of fine indices indexed by n:

$$H_n = \big\{p \in \{1, \dots, N^h\} \mid \text{ind}(p) = n\big\}. \tag{4.32}$$

An example of a fine graph with the partition of the nodes is given in Figure 4.2(a). The H_n's make up an arbitrary partition of $\{1, \dots, N^h\}$, but there are algorithms for choosing good partitions, for instance the aggregation algorithm proposed in [15, section 5].

For every fine index p in $\{1,\dots,N^h\}$, we define

$$\mathcal{N}_p = \{q \in \{1,\dots,N^h\} \mid B^h_{pq} \neq 0\}. \tag{4.33}$$

This is the set of all the B^h-neighbors of the nodal variable p and the variable itself. From the compatibility relation (4.30), we remark that

$$(p,q) \in \mathcal{S}^h \implies q \in \mathcal{N}_p. \tag{4.34}$$

For all n in $\{1,\dots,N^H\}$, we will write

$$L_n = \bigcup_{p \in H_n} \mathcal{N}_p. \tag{4.35}$$

Observe that the set $\widetilde{L}_p$ defined in (4.8) is related to $\mathcal{N}_p$ as follows:

$$\widetilde{L}_p = \mathrm{ind}(\mathcal{N}_p). \tag{4.36}$$

We also infer from (4.33) and the symmetry of B^h

$$p \in \mathcal{N}_q \Leftrightarrow q \in \mathcal{N}_p.$$

Some sets L_n corresponding to the partition of Figure 4.2(a) are represented in Figure 4.2(b).

REMARK 4.6. B [7] (4.29) (4.30) $B^h = (G^h)^t G^h$ $\alpha^t B^h \alpha$

4.4. Definition of a compatible coarse edge incidence matrix G^H. By analogy with Reitzinger and Schöberl in [14], we choose $\mathcal{S}^H$ such that (n,m) or (m,n) is an edge if there exists $p \in H_n$ and $q \in H_m$ defined in (4.32) such that p and q are B^h-neighbors, i.e.,

$$\begin{aligned}\mathcal{S}^H = \{(n,m) \in \{1,\dots,N^H\}^2 \mid n \neq m,\ \exists p,q \in \{1,\dots,N^h\} \\ \text{with } \mathrm{ind}(p) = n,\ \mathrm{ind}(q) = m,\ p < q \text{ and } B^h_{pq} \neq 0\}.\end{aligned} \tag{4.37}$$

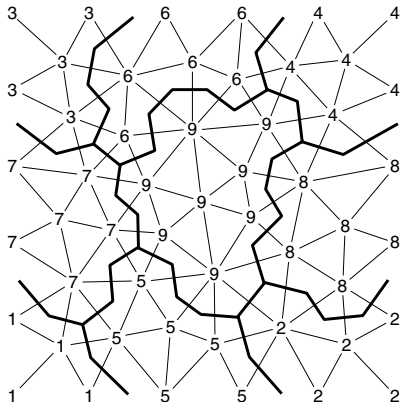
From this definition, we easily verify that the connectivity property of the fine graph $\mathcal{S}^h$ remains for the coarse graph $\mathcal{S}^H$. Observe also that $B^h_{pq} \neq 0$ implies that p is in $L_{\mathrm{ind}(p)} \cap L_{\mathrm{ind}(q)}$. Then $C_{\mathrm{ind}(p)} \cap C_{\mathrm{ind}(q)}$ is nonempty, and $\mathcal{S}^H$ satisfies condition (4.17).

The coarse graph coming from the graph partition of Figure 4.2(a) is represented in Figure 4.2(c). Some sets $\widetilde{L}_p$ are also represented in Figure 4.2(d).

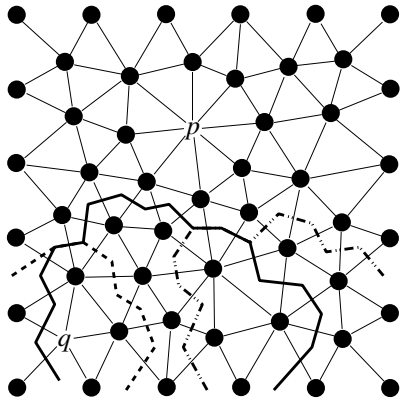
For proving the connectivity of the induced graph $\mathcal{S}^{H,i}$, we need an intermediate result.

LEMMA 4.7. $p \in \{1,\dots,N^h\}$ $\widetilde{L}_p$ $\mathrm{ind}(p)$ $\widetilde{L}_p$ $\mathcal{S}^H$. Let n be in $\widetilde{L}_p \setminus \{\mathrm{ind}(p)\}$. By (4.36), there exists p_n in $\mathcal{N}_p$ such that $n = \mathrm{ind}(p_n)$; then

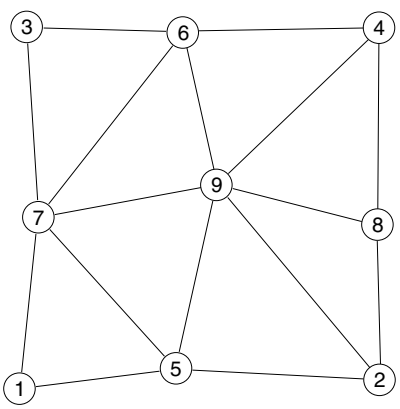
$$B^h_{pp_n} \neq 0 \quad \text{and} \quad \mathrm{ind}(p) \neq \mathrm{ind}(p_n).$$



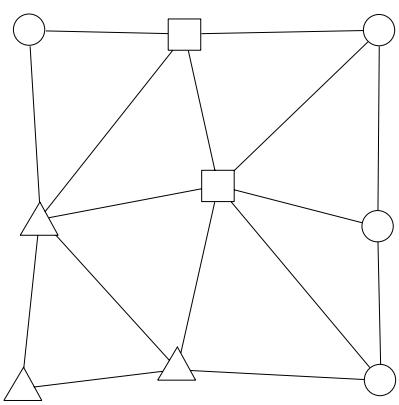
(a) Initial graph and partition.



(b) Representation of L_1, L_5, and L_2.



(c) Coarse graph for partition in (a).



(d) Representation of $\widetilde{L}_q$ (△) and $\widetilde{L}_p$ ( ). Nodes p and q are shown in (b).

FIG. 4.2. (a) *Initial graph and partition of nodes in sets* H_n*;* (b) *some sets* L_n*;* (c) *construction of the coarse graph corresponding to the partition in* (a)*, and* (d) *representation of the sets* $\widetilde{L}_q$ *and* $\widetilde{L}_p$*, referring to* (b).

From definition (4.37) of S^H, we conclude that $(n, \mathrm{ind}(p))$ or $(\mathrm{ind}(p), n)$ is in $\mathcal{S}^H$. ∎

PROPOSITION 4.8. [illegible] $\{1, \dots, E^h\}$ [illegible] $\mathcal{S}^{H,i}$ [illegible] Let $i = \overline{pq}^h$; then from (4.15), $\widetilde{C}_i = \widetilde{L}_p \cup \widetilde{L}_q$. From (4.34) and (4.36), we infer

$$\{\mathrm{ind}(p), \mathrm{ind}(q)\} \subset \widetilde{L}_p \cap \widetilde{L}_q.$$

Assume first that $\mathrm{ind}(p) \neq \mathrm{ind}(q)$. Lemma 4.7 implies that $\mathrm{ind}(p)$ and $\mathrm{ind}(q)$ are connected and, for all n in $\widetilde{C}_i \setminus \{\mathrm{ind}(r)\}$ with $r \in \{p, q\}$, n and $\mathrm{ind}(r)$ are connected.

Assume now $\mathrm{ind}(p) = \mathrm{ind}(q) = n$ with $|\widetilde{C}_i| > 1$. From Lemma 4.7, we infer

$$\forall m \in \widetilde{C}_i \setminus \{n\}, \quad n \text{ and } m \text{ are connected.} \qquad \square$$

5. Numerical experiments.

5.1. Matrix multiplication algorithm. In order to solve the linear system (3.17), a nonpreconditioned conjugate gradient algorithm is used. Thus only the multiplication of $T^t D^{-1} T$ by a vector of $\mathbb{R}^M$ is required. We can compute $T^t D^{-1} T \rho = \widetilde{\rho}$ in three steps:

- Step 1: For $e = 1, \ldots, E^H$, compute

$$b_e = Q_e \left(\sum_{n \in F} G^H_{en} R^t_n \rho_n \right) = Q_e (R^t_m \rho_m - R^t_n \rho_n) \quad \text{for } e = \overline{nm}^H. \tag{5.1}$$

- Step 2: For $e = 1, \ldots, E^H$, solve

$$K_e x_e = b_e. \tag{5.2}$$

- Step 3: For $n = 1, \ldots, N^H$, compute

$$\widetilde{\rho}_n = R_n \left(\sum_{e=1}^{E^H} G^H_{en} Q^t_e x_e \right). \tag{5.3}$$

Step 1 requires $\widetilde{M}$ additions, and the number of arithmetical operations in Step 3 is bounded by $\max_n (\sum_{e=1}^{E^H} |G^H_{en}|) M$. The most expensive part is the solution of all the local problems: $K_e x_e = b_e$ for all e in $\{1, \ldots, E^H\}$.

Observe that such solutions of local problems are also required for the computation of the prolongation matrix $\bar{\beta}_c$ from the Lagrange multiplier vector ρ_c by using (3.18). For an exact solution of local problems, a factorization of each matrix K_e must be done.

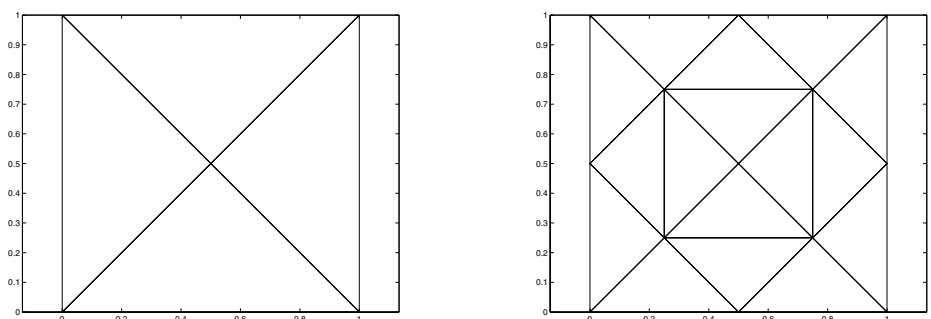
5.2. Choice of the bilinear form *b*. In the following tables, different bilinear forms b are used for the minimization. For convenience, we define a few abbreviations:

- A refers to the bilinear form a of the problem. With this choice, spatial variations of γ and δ together with mesh heterogeneity are completely taken into account for the construction of the finite element basis.
- $A + G^h M_\phi^{-1} (G^h)^t$ refers to the bilinear form defined from this matrix, M_ϕ being the mass matrix on nodal elements, with mass lumping; hence M_ϕ is diagonal. This choice enables us to improve the conditioning of local matrices K_e, as will be noted for two-dimensional (2D) simulations.

- $S + \mathrm{reg}(\eta)$ refers to the bilinear form $\int_\Omega \mathrm{curl}\, E \cdot \mathrm{curl}\, E'$ added to a local regularization depending on the parameter η; more precisely, the matrix of the local problem is $S_e + \eta \max(\mathrm{diag}(S_e))\,\mathrm{Id}$, where the matrix Id, is the identity matrix and S_e is the local matrix computed from $\int_\Omega \mathrm{curl}\, E \cdot \mathrm{curl}\, E'$. The focus is to improve the conditioning of the local matrices, the essential part of the original bilinear form a being kept.
- Id refers to the use of the identity matrix for the local problems. Then no factorization is needed, but the original problem is no longer taken into account in the definition of b.

The annotation GSsym means that one symmetric Gauss–Seidel iteration is performed in the local systems instead of an exact solution in order to significantly reduce the complexity.

5.3. Structured meshes and constant coefficients. In order to validate the proposed choices of bilinear form b, we begin the numerical experiments with structured meshes and constant coefficients in the problem. The coefficients δ and γ are set equal to 1. A sequence of nested meshes $(\tau_k^h)_{k=0,\dots,4}$ is constructed by a regular refinement starting from a simple triangular or tetrahedral mesh on the unit square and the unit cube (see Figures 5.1 and 5.2). The source term is given by nonhomogeneous boundary conditions. For each level, the edge prolongation matrix β is computed by solving system (3.16) with the right-hand-side member ξ defined from the standard nodal prolongation operator [3, Chapter 6]. The sets L_n together with the edge-node incidence matrices are defined from the meshes as described in Remark 4.10.



(a) (b)

FIG. 5.1. (a) *Initial mesh* τ_0^h *and* (b) *first refinement* τ_1^h.

5.3.1. Dimensions. For the finest level, the number of Lagrange multipliers M given by the vector ρ is reported in Table 5.1 for the 2D case and Table 5.2 for the 3D case. The number of unknowns E^h for each problem is also recalled. Observe that the number of multipliers is less than twice the number of unknowns in the 2D case. The ratio is slightly larger in three dimensions except for problems with few unknowns.

5.3.2. Computation of Lagrange multipliers. The multipliers are initialized to zero. The number of iterations required to divide the Euclidean norm of the residual by 10^3 during the iterative process is reported in Table 5.3 for the 2D case and Table

5.4 for the 3D case. These numbers are given for several choices of bilinear forms b. We also give the number of iterations for each level: finest level $+ \cdots +$ coarsest level.

In the 2D case, the behavior of the algorithm with the original matrix A is not good since the number of iterations increases with the fineness of the initial mesh. The surprising thing is that the number of iterations becomes constant when a Gauss–Seidel iteration is used instead of an exact solution. For the other cases, the behavior is relatively homogeneous, and the number of iterations is almost constant. In three

dimensions, we notice a slow increase in the number of iterations, and the behavior for the original matrix A is not as bad as in the 2D case. The behavior for the matrix Id is the best in both cases.

5.3.3. Solution of system (2.4)**.** System (2.4) is solved by a preconditioned conjugate gradient algorithm. The preconditioner is a multilevel method which uses one pre- and one post-smoothing step by Arnold's smoother [1]; on the coarse grid, a direct solver is used. The conjugate gradient method stops when the Euclidean norm of the residual has been divided by 10^{10}. Table 5.5 gives the results for the 2D case and Table 5.6 for the 3D case. The term "geometric" corresponds to the classical geometric multigrid.

Once the multipliers are computed, and for all choices of bilinear forms b, the efficacy of the geometric and algebraic multigrid methods are comparable.

5.4. Unstructured meshes and varying coefficients. We consider a 2D problem whose structure is pictured in Figure 5.3; γ is set equal to 1 and δ takes

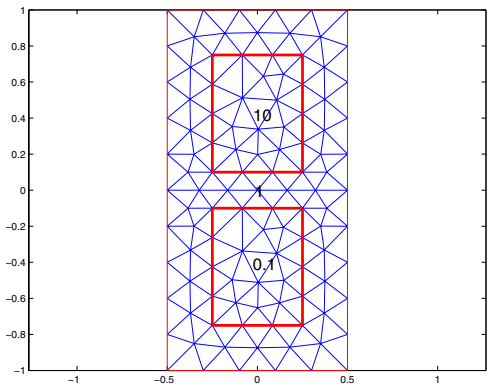

FIG. 5.3. *Geometry of the problem with the values of δ.*

the values displayed in this figure.

A mesh generator gives an initial unstructured mesh. We control only the maximal diameter $h_{\max}$ of elements, and the generator takes the interfaces into account.

The matrix B^h for the initial level is given by $(G^h)^t G^h$, the simplest choice underlined in Remark 4.6. The nodal prolongation matrix α is obtained from the solution of (3.1) with the bilinear form $c(\cdot,\cdot)$ associated with $(G^h)^t G^h$. The sets L_n and the matrix G^H are defined as in (4.35) and (4.37) with the map ind constructed from the aggregation algorithm given in [15].

5.4.1. Number of unknowns. In Table 5.7, the number of unknowns on each level is given for several choices of $h_{\max}$. The notation "new" denotes our algorithm, and RS denotes the algorithm of Reitzinger and Schöberl given in [14].

5.4.2. Computation of the Lagrange multipliers.

The number of multipliers for every mesh and every level is given in Table 5.8. This number is roughly twice the number of unknowns for every level.

The Euclidean norm of the residual is divided by 10^3. The number of iterations required to compute the Lagrange multipliers with different norms are gathered in Table 5.9. Compared to the results of Table 5.3, we can observe a significant increase for all methods, but the results are similarly ordered.

R. S.	14	20	33	56

5.4.3. Solution of system (2.4)**.** The multilevel method is used as a preconditioner; the results for the different norms are gathered in Table 5.10.

The choices Id and $A+G^h M_\phi^{-1} (G^h)^t$ (GSsym) are the most efficient because they provide us with a performing preconditioner and the lowest computational cost for the setup phase.

The prolongation matrix β built by our method provides us with a more efficient preconditioner than the method proposed by Reitzinger and Schöberl in [14]. Thus in this simple example, the number of iterations approximately grows like $h_{\max}^{-0.75}$ for the method of Reitzinger and Schöberl and like $h_{\max}^{-0.5}$ for the choice Id. This validates the theoretical interest of our algebraic method.

However, the construction of the matrix β remains really more expensive than in the Reitzinger and Schöberl algebraic multigrid method, and the solution of the initial problem with our method is finally more time-consuming. In order to improve the efficacy for the solution of problem (3.11), an algorithm that avoids the Lagrange multiplier computation can be employed [12].

Acknowledgment. We thank Michelle Schatzman for many fertile discussions.

BIVARIATE SPLINES OF VARIOUS DEGREES FOR NUMERICAL SOLUTION OF PARTIAL DIFFERENTIAL EQUATIONS*

XIAN-LIANG HU†, DAN-FU HAN†, AND MING-JUN LAI‡

Abstract. Bivariate splines with various degrees are considered in this paper. A matrix form of the extended smoothness conditions for these splines is presented. Upon this form, the multivariate spline method for numerical solution of partial differential equations (PDEs) proposed by Awanou, Lai, and Wenston in [*The multivariate spline method for scattered data fitting and numerical solutions of partial differential equations*, in Wavelets and Splines, G. Chen and M. J. Lai, eds., Nashboro Press, Brentwood, TN, 2006, pp. 24–76] is generalized to obtain a new spline method. It is observed that, combined with prelocal refinement of triangulation and automatic degree raising over triangles of interest, the new spline method of bivariate splines of various degrees is able to solve linear PDEs very effectively and efficiently.

Key words. bivariate splines, smoothness condition, splines of various degrees, numerical solution of Poisson and biharmonic equations

1. Introduction.

Let $\Omega \subset \mathbf{R}^2$ be a polygonal domain and $\triangle$ be a given triangulation of Ω. A standard spline space $S_d^r(\triangle)$ is the space of all smooth piecewise polynomial functions of degree d and smoothness r over $\triangle$ with $r < d$. That is,

$$S_d^r(\triangle) = \{s \in C^r(\Omega),\, s|_t \in \mathbf{P}_d, \quad t \in \triangle\},$$

where $\mathbf{P}_d$ denotes the space of polynomials of degree d, t denotes a triangle, and $\Omega = \bigcup\{t,\ t \in \triangle\}$. Such a spline space has been studied for a long time in the literature and in practice. (See [6] and references therein.)

In this paper we would like to consider bivariate splines of various degrees d_t, $t \in \triangle$, where d_t is a positive integer for each t. That is, for a given triangulation $\triangle$ and a degree vector $\mathbf{d} = \{d_t,\, t \in \triangle\}$, we let

$$\mathcal{S}_{\mathbf{d}}^r(\triangle) = \{s \in C^r(\Omega),\, s|_t \in \mathbf{P}_{d_t}, \quad t \in \triangle\}.$$

Our study of such a spline space $\mathcal{S}_{\mathbf{d}}^r(\triangle)$ is motivated by our interest in numerically solving partial differential equations (PDEs) more effectively and efficiently. For a PDE with a singularity at the boundary of the domain Ω, a finite element method requires a much finer mesh at the singularity. Otherwise, one has to increase the degrees of finite elements. Instead of increasing degrees globally, we would like to increase the degrees locally and combine this with local triangulation refinement near the singularity to efficiently solve the PDE. For continuous finite elements, there are several constructions of finite elements of various degrees available in the literature, e.g., [15] and [16]. More recently, optimal meshes of p- and hp-finite element methods

for PDEs with singularity are discussed in [13], and a constructive scheme for p-finite elements is explained in [14]. However, the implementation of such p-finite elements is very complicated. Recently, in [1], Awanou, Lai, and Wenston introduced a multivariate spline method for numerical solution of PDEs which overcomes the difficulty of the implementation. The researchers in [1] streamlined the process by skipping the construction of smooth finite elements. Instead, they simply used discontinuous piecewise polynomial functions over a triangulation and treated any desired smoothness conditions across edges of triangles as side constraints. Together with the side constraints of boundary conditions, they applied a Lagrange multiplier method to solve the system associated with the PDE of interest. Another key ingredient was to use a special iterative algorithm to solve the associated linear system. (See [1] for more details.) Smooth spline spaces with various degrees were also considered in [1], where a degree reduction condition is introduced and incorporated with standard smoothness conditions acting as constraints. In other words, let $d = \max\{d_t,\, t \in \triangle\}$, $\mathcal{S}^r_{\mathbf{d}}(\triangle) \subset S^r_d(\triangle)$. As the largest degree d among d_t, $t \in \triangle$, becomes large, the size of the linear system arising from the spline space $S^r_d(\triangle)$ grows rapidly. This will not lead to an efficient algorithm. Hence in this paper we propose a different approach. To keep the given degrees over various triangles, we need a new smoothness condition for polynomial pieces over two adjacent triangles with different degrees. Then we use the new smoothness conditions in the place of the original smoothness conditions in the multivariate spline method for numerical solution of PDEs proposed by Awanou, Lai, and Wenston in [1]. For simplicity, we shall refer to the original multivariate spline method for PDEs as the ALW spline method. To solve a PDE with singularity on the boundary of the domain Ω, we do not know in advance which degrees we should use to achieve the given accuracy of the solution. We adopt a strategy of combining local refinement and local degree raising to effectively solve PDEs with singularity on the boundary.

The present paper is organized as follows: A matrix form of the new smoothness conditions for splines of various degrees is considered in section 2. In section 3, we shall explain how to use bivariate splines of various degrees for numerical solution of PDEs. Numerical examples are shown in section 4 to illustrate that our new spline method is more efficient and effective. Finally we make some remarks about our spline method in section 5.

2. A matrix form of the new smoothness condition. Let T be a fixed triangle in $\triangle$. It is known that any polynomials of degree d can be expressed as the following so-called B-form:

$$p(x,y) = \sum_{i+j+k=d} c_{i,j,k} B^d_{i,j,k}(x,y), \tag{2.1}$$

where $c_{i,j,k}$ are Bézier coefficients of p and $B^d_{i,j,k}(x,y)$ are Bernstein polynomials of degree d, which are both sorted in lexicographical order with respect to their Bézier ordinate (i,j,k). That is, the order of indices (i,j,k) is actually arranged by the following ordering function:

$$q(i,j,k) = \binom{j+k+1}{2} + k + 1. \tag{2.2}$$

For example, when $d = 3$, the linear order of Bézier coefficients is as follows:

$$c_{3,0,0}, c_{2,1,0}, c_{2,0,1}, c_{1,2,0}, c_{1,1,1}, c_{1,0,2}, c_{0,3,0}, c_{0,2,1}, c_{0,1,2}, c_{0,0,3}.$$

Note that all the Bézier coefficients are sorted by this ordering function in the remainder of this paper.

The smoothness condition of polynomial patches over two adjacent triangular domains is an important and useful tool in the study of multivariate splines. It can be found in the literature, e.g., [3] in the bivariate setting and [2] in the multivariate setting. A geometric interpretation of bivariate C^r smoothness conditions for general $r \geq 0$ is given in [4]. For convenience, we include the smoothness conditions in this paper.

LEMMA 2.1. $T := \langle v_1, v_2, v_3 \rangle$ $\tilde{T} := \langle v_4, v_2, v_3 \rangle$ $e := \langle v_2, v_3 \rangle$

$$p_d(v) := \sum_{i+j+k=d} c_{ijk} B^d_{ijk}(v) \qquad \widetilde{p}_d(v) := \sum_{i+j+k=d} \tilde{c}_{ijk} \tilde{B}^d_{ijk}(v),$$

$B^d_{ijk}(v)$ $\tilde{B}^d_{ijk}(v)$ T $\tilde{T}$ D^n_u u

$$D^n_u p_d(v) = D^n_u \widetilde{p}_d(v) \qquad \forall v \in \langle v_2, v_3 \rangle$$

$n = 0, \ldots, r$

$$\widetilde{c}_{n,j,k} = \sum_{\mu+\nu+\kappa=n} c_{\mu,j+\nu,k+\kappa} B^n_{\mu\nu\kappa}(\lambda), \qquad j+k = d-n, \qquad n = 0, \ldots, r, \tag{2.3}$$

λ v_4 T

In practice, when applying the spline space $S^r_d(\triangle)$ for numerical solution of PDEs as in [1] and [7], the smoothness conditions (2.3) are assembled into matrix form for all interior edges of $\triangle$:

$$H\mathbf{c} = 0, \tag{2.4}$$

where $\mathbf{c}$ is a vector of Bézier coefficients of a polynomial of degree d over triangle T for all $T \in \triangle$. To extend the smoothness conditions to the case of different degrees on adjacent patches, we first need the following matrix form of the de Casteljau algorithm.

LEMMA 2.2. $\lambda = (\lambda_1, \lambda_2, \lambda_3)$ (x, y) T (2.1)

$$P_d(\lambda) = \sum_{i+j+k=d-r} c^{(r)}_{i,j,k}(\lambda) B^{d-r}_{i,j,k}(\lambda) \quad \forall r = 0, 1, \ldots, d, \tag{2.5}$$

$c^{(0)}_{i,j,k} = c_{i,j,k}$

$$c^{(r+1)}_{i,j,k}(\lambda) = \lambda_1 c^{(r)}_{i+1,j,k}(\lambda) + \lambda_2 c^{(r)}_{i,j+1,k}(\lambda) + \lambda_3 c^{(r)}_{i,j,k+1}(\lambda), \tag{2.6}$$

$$\mathbf{c}^{(r+1)}(\lambda) = \mathcal{D}_{\lambda,d-r} \mathbf{c}^{(r)}(\lambda) \tag{2.7}$$

$\mathbf{c}^{(r)}(\lambda) = \{c^{(r)}_{i,j,k}(\lambda)\}_{i+j+k=d-r}$ $r = 1, \ldots, d$ q (2.2) $D_{\lambda,d}$ $d(d+1)/2 \times (d+1)(d+2)/2$

$$
\begin{array}{ccccccccccccccc}

$$

FIG. 2.1. *The hierarchical structure of matrix* $\mathcal{D}_{\lambda,d}$.

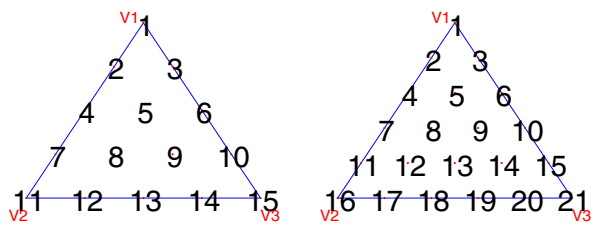

FIG. 2.2. *The hierarchical structure of Bézier ordinates.*

. The first part of this lemma is the standard de Casteljau algorithm of triangular B-form, and (2.7) is easy to verify by writing (2.6) in its matrix form. □

Let us point out an interesting property of the matrix $\mathcal{D}_{\lambda,d}$. First we present the matrix $\mathcal{D}_{\lambda,d}$ with degrees d from 1 to 4 as shown in Figure 2.1. The top-left 1×3 submatrix represents $\mathcal{D}_{\lambda,1}$, the top-left 3×6 matrix represents $\mathcal{D}_{\lambda,2}$, etc. Observe that the matrix has a nice pattern. This is because of the definition of the ordering function q; i.e., the Bézier ordinates are sorted line by line incrementally. In Figure 2.2, the ordinate ordering for Bézier ordinates of $d = 4$ indexed by 1–15 is a part of the ordinate ordering for $d = 5$ indexed by 1–21. Then it is easy to see that $\mathcal{D}_{\lambda,d}$ is a block of $\mathcal{D}_{\lambda,d+1}$ when (2.6) is written into (2.7). This property is referred to as a hierarchical property.

On the other hand, if the Bézier ordinate indices are ordered in another form as shown in Figure 2.3 for $d = 4$ and $d = 5$, we find that this new ordering does not share the hierarchical property as in Figure 2.2.

Based on the above matrix form of the de Casteljau algorithm, we can express the standard smoothness conditions in the following matrix form version.

LEMMA 2.3. $\tilde{\mathbf{c}}$ $\mathbf{c}$ $\{\tilde{c}_{ijk}\}_{i+j+k=d}$ $\{c_{ijk}\}_{i+j+k=d}$

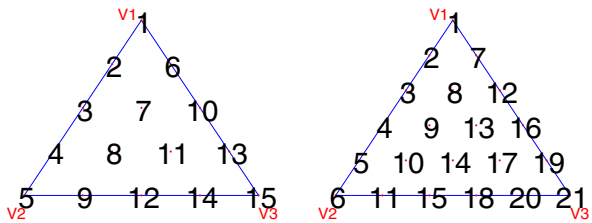

FIG. 2.3. *A new ordering of Bézier ordinates.*

$$D_u^n p_d(v) = D_u^n \widetilde{p}_d(v) \quad \forall v \quad \langle v_2, v_3 \rangle$$

$$P_{n,d}\tilde{\mathbf{c}} = P_{0,d-n}\left\{\prod_{l=1}^{n} \mathcal{D}_{\lambda,d+1-l}\right\}\mathbf{c} \qquad \forall n = 0,\dots,r, \tag{2.8}$$

$P_{n,d}$ $(d-n+1)\times(d+1)(d+2)/2$

$$P_{n,d}(i,j) = \begin{cases} 1, & j = q(n,i-1,d+1-n-i), \quad i = 1,\dots,d+1-n, \\ 0 & \end{cases}$$

$n = 0,\dots,r$

. We need to prove that (2.8) is equivalent to (2.3). By the definition of $P_{n,d}$, it has only one nonzero entry in each row. So we name it the picking matrix, whose geometric meaning is to pick out the Bézier coefficients on the nth line parallel to common edge e from all the Bézier coefficients of degree d. Then we have

$$\{\tilde{c}_{n,j,k}\}_{j+k=d-n} = P_{n,d}\tilde{\mathbf{c}} \qquad \forall n = 0,\dots,r. \tag{2.9}$$

By (2.5), for all $n = 0,\dots,r$, it is true that

$$\sum_{\mu+\nu+\kappa=n} c_{\mu,j+\nu,k+\kappa} B^n_{\mu\nu\kappa}(\lambda) = \sum_{\mu+\nu+\kappa=n} c^{(0)}_{\mu,j+\nu,k+\kappa} B^n_{\mu\nu\kappa}(\lambda) = c^{(n)}_{0,j,k}(\lambda), \quad j+k = d-n.$$

It can also be written in vector form. That is, applying (2.7) for n times, we get

$$\begin{aligned} \{c^{(n)}_{0,j,k}(\lambda)\}_{j+k=d-n} &= P_{0,d-n}\mathbf{c^{(n)}} \\ &= P_{0,d-n}\mathcal{D}_{\lambda,d+1-n}\mathbf{c^{(n-1)}} \\ &= \cdots \\ &= P_{0,d-n}\left\{\prod_{l=1}^{n} \mathcal{D}_{\lambda,d+1-l}\right\}\mathbf{c}. \end{aligned} \tag{2.10}$$

Combining (2.3), (2.9), and (2.10), we have (2.8). □

Next we express the well-known degree raising algorithm for the B-form in matrix form as in Lemma 2.2.

LEMMA 2.4. [illegible] p [illegible] d [illegible] T [illegible] (2.1) [illegible] $c_{ijk}^{[d]}$ c_{ijk} [illegible]

$$p = \sum_{i+j+k=d+1} c_{ijk}^{[d+1]} B_{ijk}^{d+1},$$

[illegible]

$$c_{ijk}^{[d+1]} = (ic_{i-1,j,k}^{[d]} + jc_{i,j-1,k}^{[d]} + kc_{i,j,k-1}^{[d]})/(d+1) \tag{2.11}$$

[illegible] $i+j+k = d+1$ [illegible] $\mathbf{c}^{[d+1]} = \{c_{ijk}^{[d+1]}\}_{i+j+k=d+1}$ [illegible] $\mathbf{c}^{[d]} = \{c_{ijk}^{[d]}\}_{i+j+k=d}$ [illegible] (2.2) [illegible]

$$\mathbf{c}^{[d+1]} = \frac{1}{d+1} A_d \mathbf{c}^{[d]}, \tag{2.12}$$

[illegible] A_d [illegible] $(d+2)(d+3)/2 \times (d+1)(d+2)/2$ [illegible]

[illegible]. It is easy to see that the degree raising algorithm (2.11) can be expressed in a matrix form (2.12). It is trivial to prove that the pattern of A_d is hierarchical. □

We now extend (2.8) to the case of different degrees on the neighboring triangles and get the desired explicit smoothness condition.

THEOREM 2.5. [illegible] $d_1 \geq d_2$ [illegible]

$$p_{d_1}(v) := \sum_{i+j+k=d_1} c_{ijk} B_{ijk}^{d_1}(v) \qquad \widetilde{p}_{d_2}(v) := \sum_{i+j+k=d_2} \widetilde{c}_{ijk} \tilde{B}_{ijk}^{d_2}(v).$$

[illegible] $\mathbf{c}$ [illegible] $\tilde{\mathbf{c}}$ [illegible] $\{c_{ijk}\}_{i+j+k=d_1}$ [illegible] $\{\widetilde{c}_{ijk}\}_{i+j+k=d_2}$ [illegible] q [illegible]

$$D_u^n p_{d_1}(v) = D_u^n \widetilde{p}_{d_2}(v) \qquad \forall v \in \langle v_2, v_3 \rangle$$

[illegible]

$$P_{n,d_1} \left\{ \frac{d_2!}{d_1!} \prod_{d=d_2}^{d_1-1} A_d \right\} \tilde{\mathbf{c}} = P_{0,d_1-n} \left\{ \prod_{l=1}^{n} \mathcal{D}_{\lambda,d_1+1-l} \right\} \mathbf{c} \qquad \forall n = 0, \ldots, r. \tag{2.13}$$

[illegible]. We separate the proof into two cases: $d_1 = d_2$ and $d_1 > d_2$. For the first case, it is easy to see that (2.13) is reduced to (2.8).

For the second case, we raise the degree d_2 of polynomial to d_1 by applying (2.11) for $d_1 - d_2$ times to get

$$\tilde{\mathbf{c}}^{[d_1]} = \frac{d_2!}{d_1!} \left\{ \prod_{d=d_2}^{d_1-1} A_d \right\} \tilde{\mathbf{c}}.$$

Note that Bézier coefficients $\tilde{\mathbf{c}}^{[d_1]}$ have the same degree as d_1. Then we can apply the usual smoothness conditions, i.e., (2.8). Thus the smoothness conditions for various degrees follow. □

They are the new smoothness conditions which will be used in the rest of the paper.

3. A new spline method for numerical solution of PDEs. In [1], Awanou, Lai, and Wenston proposed a multivariate spline method (i.e., the ALW method) for numerical solution of Poisson and biharmonic equations. The most striking advantage of the ALW method is that one can directly use piecewise polynomial functions for solving Poisson and biharmonic equations without constructing finite elements, macroelements, and locally supported basis functions. The ALW spline method can be explained briefly as follows: It uses piecewise polynomials over a triangulation and treats smoothness conditions as side constraints together with boundary conditions to minimize the Euler–Lagrange functionals associated with Poisson or biharmonic equations. An iterative method is introduced to solve the special linear systems arising from the discretization using bivariate spline functions. The method is shown to be very convenient for numerical solution of Poisson and biharmonic equations. In this section, our main purpose is to improve the ALW spline method by using bivariate splines of various degrees through adaptive procedure.

3.1. A unified model for Poisson and biharmonic equations. First let us introduce some necessary notation. Let L_k be a symmetric partial differential operator of order $2k$ with $k \geq 1$. In the bivariate setting, let

$$D^\alpha = \left(\frac{\partial}{\partial x}\right)^{\alpha_1} \left(\frac{\partial}{\partial y}\right)^{\alpha_2} \quad \forall \alpha = (\alpha_1, \alpha_2)$$

and let $|\alpha| = \alpha_1 + \alpha_2$. We intend to find approximate solutions of the following boundary value problem:

$$\left\{ \begin{array}{lcll} L_k u & = & f & \text{in } \Omega, \\ D^\alpha u & = & D^\alpha g & \text{on } \partial\Omega, \ |\alpha| \leq k-1, \end{array} \right. \tag{3.1}$$

where Ω is a polygonal domain in $\mathbf{R}^2$ and $f \in L^2(\Omega)$, $g \in C^{k-1}(\Omega)$. Note that model problem (3.1) includes the Poisson equation in the case $L_1 = -\Delta$ and the biharmonic equation in the case $L_2 = \Delta^2$.

The weak formulation for model problem (3.1) reads as follows: Find $u \in H^k(\Omega)$ which satisfies its boundary condition such that

$$a(u, v) = \langle f, v \rangle \quad \forall v \in H_0^r(\Omega), \tag{3.2}$$

where $a(u, v)$ is the bilinear form defined by

$$a(u, v) = \left\{ \begin{array}{ll} \displaystyle\int_\Omega \nabla u \cdot \nabla v dx dy, & k = 1, \\ \displaystyle\int_\Omega \triangle u \triangle v dx dy, & k = 2, \end{array} \right.$$

and $\langle f, v \rangle = \int_\Omega f(x, y) v(x, y) dx dy$ is the L_2 inner product of f and v. Here $H^k(\Omega)$ and $H_0^k(\Omega)$ are standard Sobolev spaces.

It is known (cf. [8]) that model problem (3.2) has a unique solution u in $H^k(\Omega)$. The proof can be adapted to show that there is a unique solution s_u in spline space $S_{\mathbf{d}}^r(\triangle) \subset H^k(\Omega)$, where $r = k - 1$ and s_u satisfies

$$a(S_u, v) = \langle f, v \rangle \quad \forall v \in S_{\mathbf{d}}^r(\triangle) \tag{3.3}$$

and the boundary conditions.

Based on the standard calculus of variations, model problem (3.1) is the Euler–Lagrange equation of the following energy functional:

$$E_r(s) = \frac{1}{2}a(s,s) - \langle f, s\rangle.$$

It is known that the weak solution of the model problem is the minimizer of the energy functional $E(s)$ in the following spline space (cf. [8, section 8.2.3]):

$$V = \{s \in S^r_{\mathbf{d}}(\triangle),\, D^\alpha s = D^\alpha g_h \quad \text{on } \partial\Omega,\, |\alpha| \le k-1\},$$

where $g_h \in S^r_{\mathbf{d}}(\triangle)$ is a spline such that $g_h|_{\partial\Omega}$ is a good approximation of the Dirichlet boundary condition g. For simplicity let us assume that g is a function of piecewise polynomial of degree $\le d$. Then the weak solution u satisfies

$$E_r(u) = \min_{s\in V} E_r(s). \tag{3.4}$$

Also any minimizer satisfying (3.4) is the weak solution.

3.2. Spline solution for (3.4). Next we discuss how to approximate weak solutions using spline spaces $S^r_{\mathbf{d}}(\triangle)$, which is also denoted as $S^r_{\mathbf{d}}$ if no confusion arises. We shall compute the approximation $s_u \in S^r_{\mathbf{d}}$ satisfying

$$E_r(s_u) = \min_{s\in S^r_{\mathbf{d}}\cap V} E_r(s).$$

Let us write a spline function $s \in S^r_{\mathbf{d}}$ in the following piecewise polynomial format:

$$s(x,y)|_t = \sum_{i+j+k=d_t} c^t_{i,j,k} B^t_{i,j,k}(x,y), \quad (x,y) \in t \in \triangle.$$

Let $\mathbf{c} = (c^t_{i,j,k},\, i+j+k = d_t,\, t \in \triangle)$ be the B-coefficient vector associated with s. The above energy functional can be written as

$$\tilde{E}_r(\mathbf{c}) = \frac{1}{2}\mathbf{c}^T K_r \mathbf{c} - \mathbf{c}^T M \mathbf{f}$$

with respect to B-coefficient vector $\mathbf{c}$, subject to the smoothness conditions $H\mathbf{c} = 0$ according to (2.13) and boundary condition $B\mathbf{c} = G$, as treated in [1]. Here, $\mathbf{K}_r = \mathrm{diag}(K^t_r,\, t \in \triangle)$ is the stiffness matrix with blocks

$$K^t_1 = \left[\int_t \nabla B^t_{ijk} \nabla B^t_{lmn} dxdy\right]^{l+m+n=d_t}_{i+j+k=d_t} \qquad \forall t \in \triangle$$

when $r = 1$, while K_r is the bending matrix in case $r = 2$, with

$$K^t_2 = \left[\int_t \Delta B^t_{ijk} \Delta B^t_{lmn} dxdy\right]^{l+m+n=d_t}_{i+j+k=d_t} \qquad \forall t \in \triangle$$

as its blocks. Similarly, let $\mathbf{M} = \mathrm{diag}(M_t,\, t \in \triangle)$ be the mass matrix with blocks

$$M_t = \left[\int_t B^t_{ijk} B^t_{lmn} dxdy\right]^{l+m+n=d_t}_{i+j+k=d_t} \qquad \forall t \in \triangle$$

and let $\mathbf{f}$ be the B-coefficient vector of the spline S_f interpolating f at the domain points of t of degree d_t for $t \in \triangle$. By using a Lagrange multiplier method, we let

$$\tilde{L}_r(\mathbf{c}, \alpha, \beta) = \frac{1}{2}\mathbf{c}^T\mathbf{K}_r\mathbf{c} - \mathbf{c}^T\mathbf{M}\mathbf{f} + \alpha H\mathbf{c} + \beta(B\mathbf{c} - G)$$

and compute local minimizers. It is easy to see that we need to solve the following system:

$$\begin{bmatrix} B^T & H^T & \mathbf{K}_r \\ 0 & 0 & B \\ 0 & 0 & H \end{bmatrix} \begin{bmatrix} \lambda_1 \\ \lambda_2 \\ \mathbf{c} \end{bmatrix} = \begin{bmatrix} \mathbf{M}\mathbf{f} \\ G \\ 0 \end{bmatrix}. \tag{3.5}$$

Note that the existence and uniqueness of s_u imply that there exists a unique $\mathbf{c}$ satisfying the above linear system. Thus the iterative method in [1] can be applied and is effective in solving this linear system. If we denote $L^T = [B^T H^T]$, $\lambda = [\lambda_1^T \lambda_2^T]^T$, $\mathbf{F} = \mathbf{M}\mathbf{f}$ and the vector G absorbs the zero vector, then system (3.5) becomes

$$\begin{bmatrix} L^T & \mathbf{K}_r \\ 0 & L \end{bmatrix} \begin{bmatrix} \lambda \\ \mathbf{c} \end{bmatrix} = \begin{bmatrix} \mathbf{F} \\ G \end{bmatrix}.$$

For any fixed $\epsilon > 0$, given an initial guess $\lambda^{(0)}$, e.g., $\lambda^{(0)} = 0$, we first compute

$$c^{(1)} = \left(\mathbf{K_r} + \frac{1}{\epsilon}L^T L\right)^{-1} \left(F + \frac{1}{\epsilon}L^T b - L^T\lambda^{(0)}\right),$$

and for $k = 1, 2, \ldots,$ we iteratively compute

$$c^{(k+1)} = \left(\mathbf{K_r} + \frac{1}{\epsilon}L^T L\right)^{-1} \left(\mathbf{K_r}c^{(k)} + \frac{1}{\epsilon}L^T b\right). \tag{3.6}$$

The matrix $(\mathbf{K_r} + \frac{1}{\epsilon}L^T L)$ can be proved to be invertible, and the iterative algorithm (3.6) is convergent (cf. [1] for more details). For large-scale problems, the conjugate gradient method for the above iteration is preferred.

3.3. Adaptive algorithms. For the case $r = 0$ or $r = 1$, it is known that when $d_t = d$ for all $t \in \triangle$ with $d \geq 3r + 2$, the spline space S_d^r possesses the optimal approximation order (cf. [5]). So we require $\min_{t\in\triangle} d_t \geq 3r + 2$. What we need to do now is decide the degree vector $\mathbf{d}$ triangle by triangle. It depends on an error indicator and an adaptive procedure. For most problems, an a posteriori error estimate combined with a robust adaptive strategy is necessary as in adaptive finite element methods. So robust adaptive procedures are introduced here, and we leave the a posteriori error estimate to the numerical examples. For a better understanding of the performance of spline spaces with various degrees, we pay attention only to the performances of the local mesh refinement and the local degree raising. Let us present these two adaptive procedures in the following pseudocodes.

ALGORITHM 3.1 (hVersion).

```
mesh = initialize the Mesh;
TOL = 1e-5;
STEP = 1;
MAXSTEP = 30;
refine_percent = 0.8;
```

```
while STEP <MAXSTEP
    x = solve PDE with fixed degree method on mesh;
    error = posteriori_estimate(mesh,x);
    if sum(error) < TOL
        STEP = MAXSTEP + 1;
        break;
    end
    tris = indicate_by_fraction(error,refine_percent);
    mesh = refine_mesh(mesh,tris);
    STEP = STEP + 1;
end
```

In the above algorithm, the PDE is solved by any fixed degree algorithms such as the finite element method in Example 4.1 and the ALW spline method in Example 4.2. We use the fixed fraction strategy for mesh refinement, in which some fraction of elements with highest error are marked for refinement. It appears to be the most robust and convenient strategy among error equidistribution, fixed threshold, error density equidistribution, and fixed fraction strategies (cf. [11]), and has been proved to be convergent in energy norm for the Poisson equation in [12]. The marked elements are refined by Rivara's algorithm, which bisects the prescribed triangle. It was originally developed in [10] to produce a conforming triangulation. Rivara's algorithm is given as follows:

```
find the midpoint P of the longest side in T;
Bisect T with P;
while P is a nonconforming point for T' different to T
    find the midpoint Q of the longest side in T';
    bisect T' with Q;
    if P != Q
        join P and Q;
        P = Q
    end
end,
```

which can be illustrated as in Figure 3.1.

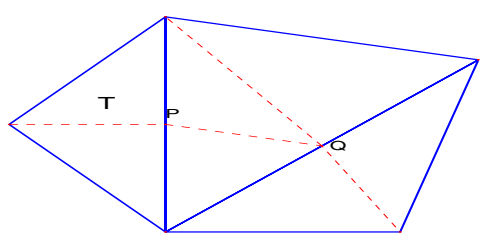

FIG. 3.1. *Conforming refinement using Rivara's algorithm.*

ALGORITHM 3.2 (pVersion).

```
mesh = initMesh;
TOL = 1e-5;
STEP = 1;
MAXSTEP = 50;
refine_percent = 0.8;
```

```
while STEP < MAXSTEP
    x = solve (3.5) with extended smoothness condition (2.13) on mesh;
    error = posteriori_estimate(mesh,x);
    error = smooth_error(mesh,error);
    if max(error) < TOL
        STEP = MAXSTEP + 1;
        break;
    end
    tris = refine_by_fraction(error,refine_percent);
    degree(tris) = degree(tris) + 1;
    STEP = STEP + 1;
end
```

In the above algorithms, we have adopted an error smoothing scheme which is as follows:

```
step 1: compute the mean error on each node according to its
        adjacent elements.
step 2: recompute the mean error on each element
        according to its adjacent nodes.
```

It is important for the convergence of our p-version algorithm to have such an error smoothing scheme because it is not desired that the degree vary too rapidly for adjacent triangles.

We shall use these two adaptive procedures in the next section where numerical results are presented.

4. Numerical examples. We first present our numerical experiments for the Poisson equation.

4.1. Consider the Poisson equation on an L-shaped domain:

$$\begin{cases} -\triangle u &= f & \text{in } \Omega, \\ u &= g & \text{on } \partial\Omega, \end{cases}$$

where $\Omega = \{(x,y),\ (x,y) \in (-1,1)\times(-1,1)\backslash(-1,0)\times(-1,0)\}$. Note that our spline method does not require the information of an analytic solution. For a clear comparison, let

$$u(x,y) = r^{\frac{2}{3}} \sin\left(\frac{2\theta+\pi}{3}\right)$$

be an analytic function, where $r(x,y) = \sqrt{(x^2+y^2)}$ and θ is the angle between vector (x,y) and the position direction of axis x with $\tan(\theta) = y/x$. We use the standard finite element method and our spline method to approximate $u(x,y)$ by solving the Poisson equation with $f = -\Delta u$ inside Ω and $g = u$ on the boundary.

Since we do not use any information about the analytic solution during the adaptive procedure, it is standard to introduce an a posteriori error estimator. We prefer the explicit residual a posteriori error esitmator given in [9] for the Poisson equation. That is, for any triangle T, its L_2 error indicator is

$$\eta_T := \left\{ |T|^4 ||f + \triangle u_h||^2_{0,2;T} + \frac{1}{2}\sum_{e\in\partial T} |e|^3 ||R_e||^2_{0,2;e} \right\}^{\frac{1}{2}}, \tag{4.1}$$

where $|T|$ is the minimal diameter of circles that contain triangle T, $|e|$ is the length of edge e, and R_e stands for the jump of $\frac{\partial u_h}{\partial n}$ on the internal edges or the jump of $\frac{\partial u_h}{\partial n} - g$ on the boundary edges.

The properties of solution for this problem have been discussed theoretically in [15], and its p/hp finite element solution is presented in [14]. For both methods we begin with a special triangulation as shown in Figure 4.1.

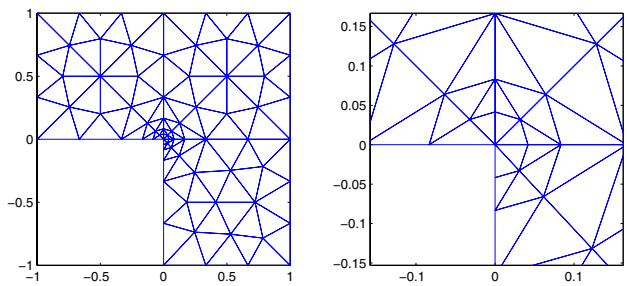

FIG. 4.1. *At the left is an original triangulation, which is amplified at the right.*

We use such a specially designed mesh, which is generated by hand, to capture the corner singularity. The full automatic hp adaptive procedure proposed in [14] required a more accurate reference solution and hence is too expensive to use. Since we pay attention only to the performance of our p-version spline method, a prebuilt mesh is enough.

In Table 4.1 we list the performance of a continuous fixed degree finite element method based on Algorithm 3.1 (hVersion) as well as the performance of our spline method with local degree raising (Algorithm 3.2) starting with continuous bivariate splines of degree 3, referred to as $S_3^0(\triangle)$. We show the number of triangles and the number of unknown coefficients of the finite element solutions and spline solutions which achieve a given tolerance $5e-3$, $5e-4$, or $5e-5$, respectively. We use cubic, quartic, and quintic finite element methods according to different tolerances because the low order finite element method yields too many elements, which is beyond the ability of our machine when the tolerance is small. In addition, we show the total CPU time for computing the finite element solution and spline solution for each of the tolerances. Our machine is equipped with Intel Celeron 2.0GHz and 512M memory.

TABLE 4.1
The performance of fixed order finite element methods and our spline method.

	$5e-3$		$5e-4$		$5e-5$	
	Cubic	Spline	Quartic	Spline	Quintic	Spline
Number of elements	872	116	953	180	1078	216
Number of unknowns	8720	2942	14295	4361	22638	6681
CPU time	29.21s	9.83s	45.98s	16.71s	72.89s	32.46s

From Table 4.1, it is clear to see that our spline method with local degree raising yields higher efficiency due to the smaller size of its system matrix. We also plot in Figure 4.2 the approximated solutions of both approaches whose tolerance is $5e-3$ and in Figure 4.3 the differences of both solutions against the exact analytic solution.

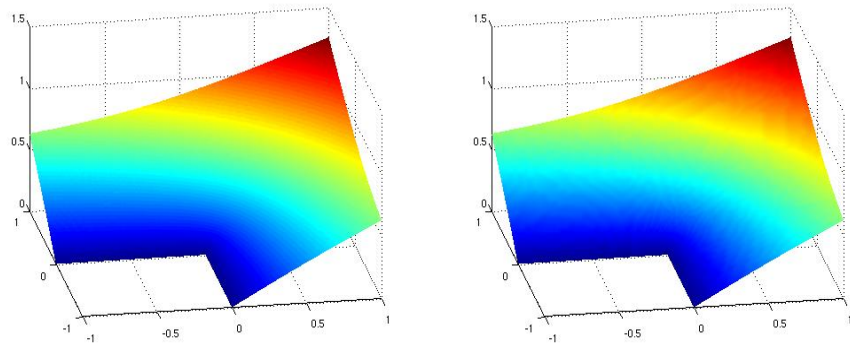

FIG. 4.2. *The approximate solution of the cubic finite element (left) and our spline method (right) under tolerance* $5e-3$.

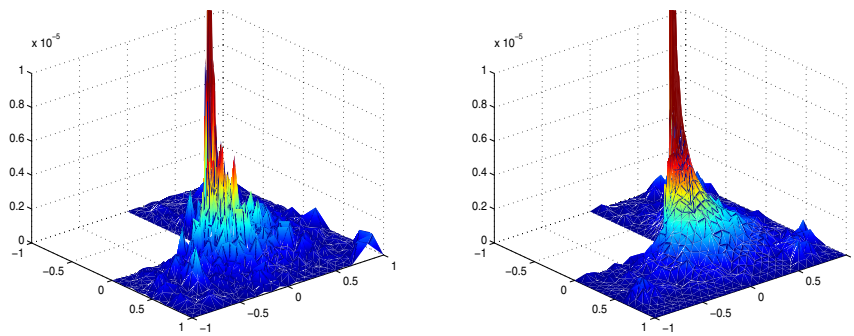

FIG. 4.3. *The error of approximate solution of the cubic finite element (left) and our spline method (right) under tolerance* $5e-3$.

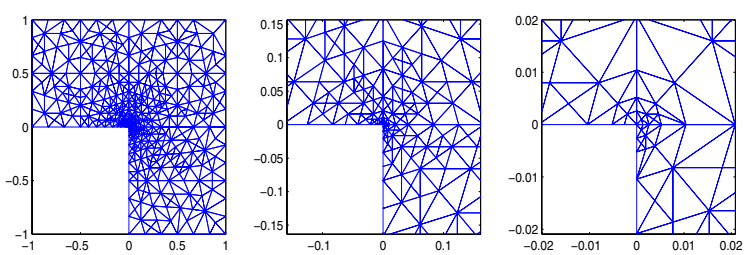

FIG. 4.4. *The resulting triangulation (left) for finite element solution and corner amplification (middle and right).*

From the figures in Figure 4.3, we can see that the error plot of our spline solution is less bumpy than that of the finite element solution and hence, that the surface of our spline solution is closer to the surface of the exact solution that of the finite element solution.

In addition, we present in Figure 4.4 the triangulation of the finite element solution

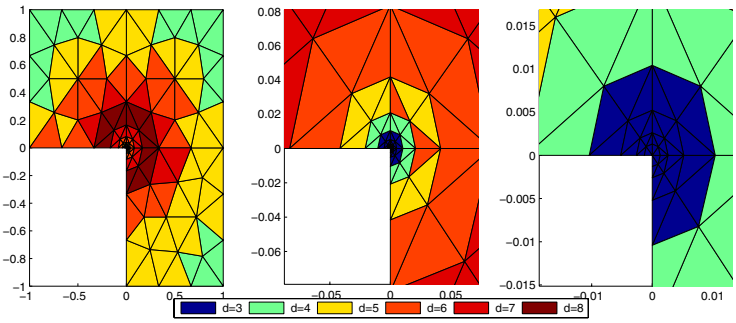

FIG. 4.5. *The triangulation and degrees for our spline solution and two corner amplifications.*

when the given tolerance is $5e-3$, and in Figure 4.5 the degrees as well as the triangulation of the spline solution when the given tolerance is $5e-3$, where we can see that the highest degree in our spline solution is 8, which happens in a few triangles around the singularity.

Next we present our numerical results for biharmonic equations.

EXAMPLE 4.2. We consider a biharmonic problem on an L-shaped domain:

$$\begin{cases} \Delta^2 u &= f & \text{in } \Omega, \\ u &= g & \text{on } \partial\Omega, \\ \frac{\partial}{\partial \mathbf{n}} u &= h & \text{on } \partial\Omega, \end{cases}$$

where Ω is the same L-shaped domain as in the previous example. We test the analytic solution

$$u(x,y) = r^{\frac{5}{2}} \sin\left(\frac{5\theta}{2}\right),$$

where $r(x,y) = \sqrt{(x^2+y^2)}$ and θ is the angle between vector (x,y) and the position direction of axis x with $\tan(\theta) = y/x$. Then f, g, h can be computed directly from u.

If we denote $[\cdot]_e$ as the jump of a function from inside T to outside through edge e, then the L_2 error indicator for any triangle T is the following explicit residual a posteriori estimator, as proposed in [9]:

(4.2)
$$\eta_T := \left\{ |T|^4 ||\triangle^2 u_h - f||^2_{0,2;T} + \sum_{e\in\partial T} [|e|\,||[\triangle u_h]_e||^2_{2;e} + |e|^3 ||[n_e \cdot \nabla \triangle u_h]_e||^2_{2;e}] \right\}^{\frac{1}{2}},$$

where the means of $|T|$ and $|e|$ are the same as above and n_e is the unit outward normal to edge $e \in \partial T$. The behavior of the true solution is very similar to the one in Example 4.1. We first use $S^1_5(\triangle)$ based on the special triangulation as in Figure 4.1 to solve this biharmonic problem by using the ALW spline method in [1] together with Algorithm 3.1. Then we start with $S^1_5(\triangle)$ using Algorithm 3.2 to solve this problem again. For each tolerance $1e-3$, $1e-4$, $1e-5$, we show in Table 4.2 the number of triangles, the number of unknown coefficients, and the total computational times of two spline solutions.

TABLE 4.2
The performance of the ALW spline method and our spline method.

	$1e-3$		$1e-4$		$1e-5$	
	ALW	New	ALW	New	ALW	New
Number of elements	210	116	370	122	716	128
Number of unknowns	4410	3766	7770	4484	15036	5192
Total CPU time	13.45s	15.93s	31.52s	27.61s	75.73s	39.10s

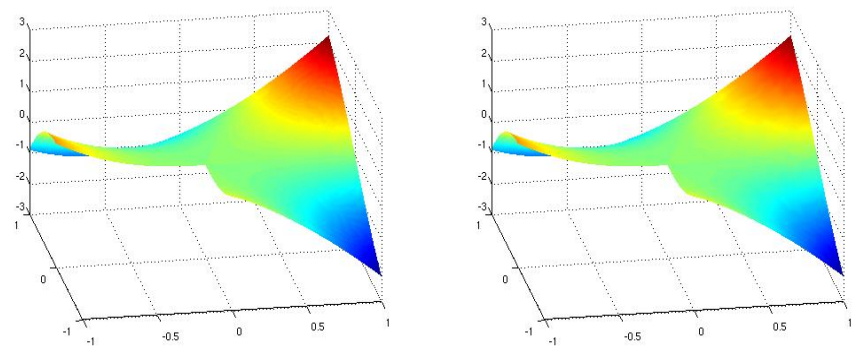

FIG. 4.6. *The approximate solution of the ALW spline method (left) and our spline method (right) under tolerance* $1e-5$.

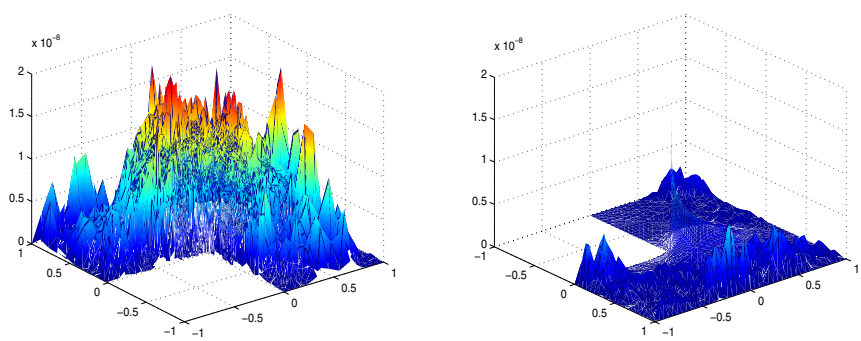

FIG. 4.7. *The error of approximate solution of the ALW spline method (left) and our spline method (right) under tolerance* $1e-5$.

Table 4.2 clearly shows that our spline method is much more efficient than the ALW spline method using h-adaptivity when the tolerance is small. We also plot in Figure 4.6 the approximated solutions of both approaches whose tolerance is $1e-5$ and in Figure 4.7 the differences of both solutions against the exact analytic solution. Comparing the figures in Figure 4.7, we can see that our spline solution is closer to the exact solution than the ALW solution.

In addition, we present in Figure 4.8 the triangulation of the ALW spline solution when the given tolerance is $1e-5$ and in Figure 4.9 the degrees as well as the triangulation of the spline solution with the same tolerance, where we can see that the highest degree in our spline solution is 12, which happens in a few triangles close to the singularity.

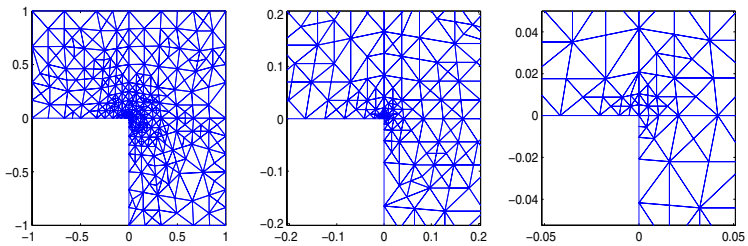

FIG. 4.8. *The resulting triangulation (left) for the ALW spline method and corner amplifications (middle and right).*

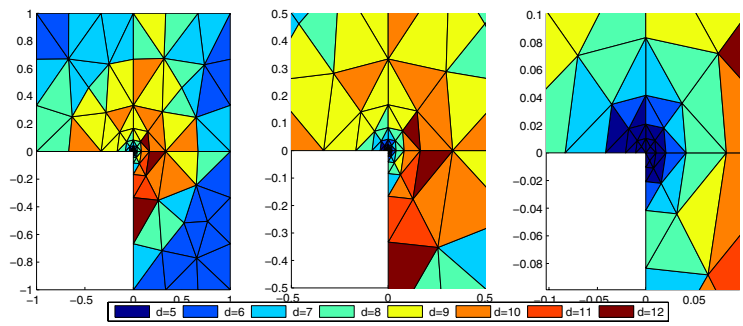

FIG. 4.9. *The triangulation and degrees for our spline solution and two corner amplifications.*

In general, we do not have an analytic solution available to guide our adaptive procedures. Our adaptive algorithms work for these cases. On the other hand, more accurate a posteriori error estimators are preferred for deciding whether to raise degrees or refine the triangle. In fact, a full automatic strategy that combines Algorithms 3.1 and 3.2 is favorable. It is left for future research.

5. Conclusion and remarks. In this paper, we give a new smoothness condition for polynomials with difference degrees over two adjacent triangular patches. Based on the new smoothness conditions we implement bivariate splines of various degrees for numerical solution of PDEs. The p-version adaptive strategy enables us to efficiently solve Poisson and biharmonic equations with singularity on the boundary.

We offer the following remarks:

REMARK 5.1. It is easy to see that the new smoothness conditions can be generalized to deal with polynomials over adjacent simplices in $\mathbf{R}^s$, $s \geq 3$.

REMARK 5.2. It is also easy to see that our spline method can be generalized to numerically solve trivariate partial differential equations, e.g., three-dimensional Poisson equations and three-dimensional biharmonic equations.

REMARK 5.3. It is possible to use our spline method together with local adaptive procedures (h-version) to solve nonlinear PDEs such as two-dimensional Navier–Stokes equations. It will be useful to capture the details for eddies of fluid flows. We are currently working on this research problem.

NUMERICAL METHODS FOR COMPUTING NONLINEAR EIGENPAIRS: PART I. ISO-HOMOGENEOUS CASES*

XUDONG YAO† AND JIANXIN ZHOU‡

Abstract. With a Rayleigh quotient formulation, a local minimax method is developed to solve a class of (iso-homogeneous) nonlinear eigenpair problems for multiple solutions in Banach spaces following their instability order. The algorithm is implemented to compute (weighted) eigenpairs of the p-Laplacian. Numerical eigenfunctions are illustrated by their graphics. Several interesting phenomena have been observed and are open for further investigation. Mathematical analysis related to convergence and instability order of computed eigenfunctions, etc., is also presented.

Key words. nonlinear eigenpairs, multiple critical points, local minimax method

1. Introduction and some preliminaries.

The semilinear Schrödinger equation

$$iw_t + \Delta w + \kappa f(|w|)w = 0, \tag{1.1}$$

where κ is a physical parameter, is one of the canonical nonlinear equations in physics, arising in various fields, such as nonlinear optics, plasma fluids, quantum physics, Bose–Einstein condensates, and surface waves. For example, the Gross–Pitaevskii equation [10, 27]

$$\begin{aligned} i\psi_t &= -\frac{1}{2}\Delta\psi + V(x)\psi + \beta|\psi|^2\psi, \quad t > 0, x \in \Omega \subseteq \mathbb{R}^d, \\ \psi(x,t) &= 0, \quad x \in \Gamma = \partial\Omega, t \geq 0, \end{aligned} \tag{1.2}$$

on a bounded open domain $\Omega \in \mathbb{R}^d$, is extensively used to model the single particle of the Bose–Einstein condensate after the first experimental realization of the Bose–Einstein condensate in dilute weakly interacting gases shows great agreement. To study stability/instability, pattern, and other solution properties, people are interested in finding the standing (solitary) wave solutions of the form $w(x,t) = u(x)e^{-i\lambda t}$, where λ is a normalized potential and u is a real function of x, and also the steady-state solutions $w(x,t) = u(x)$. Then (1.1) leads to two semilinear elliptic PDEs

$$\lambda u(x) + \Delta u(x) + \kappa f(|u|)u(x) = 0, \tag{1.3}$$

$$-\Delta u(x) = \kappa f(|u|)u(x). \tag{1.4}$$

Several different types of quasi-linear Schrodinger equations are also proposed to model "Schrodinger flows" in various fields; see [16, 14, 22] for general study and

physical applications of this topic. When non-Darcian or non-Newtonian fluids are considered, Darcy's law is replaced by other relations between the specific discharge (shear stress) $\vec{q}$ and the flow head w. One of them is the Izbash formula [15, 4]: $\vec{q} = -M|\nabla w|^{p-2}\nabla w$ for some constant $M > 0$ and the (rheological) characteristic $p > 1$ of the fluid. Then after replacing the Laplacian Δu by the p-Laplacian $\Delta_p u(x) = \nabla \cdot (|\nabla u(x)|^{p-2}\nabla u(x))$, (1.3) and (1.4) are generalized to

$$\lambda u(x) + \Delta_p u(x) + \kappa f(|u(x)|)u(x) = 0, \tag{1.5}$$

$$-\Delta_p u(x) = \kappa f(|u(x)|)u(x), \tag{1.6}$$

two quasi-linear elliptic PDEs. When $p = 2, p < 2, p > 2$, the fluid is called, respectively, (Darcian) Newtonian, pseudoplastic, dilatant. The p-Laplacian Δ_p is also used to model phenomena in reaction-diffusion in porous media ($p = \frac{3}{2}$), nonlinear elasticity ($p > 2$), and glaciology ($p \in (1, \frac{4}{3})$); see [4, 24] and references there. When $p = 2$, (1.5) and (1.6) reduce to (1.3) and (1.4). When the nonlinear term $f(|u(x)|)u(x)$ is primitive, i.e., $f(|t|)t = \frac{d}{dt}F(t)$ for some function F, the problems are variational and (1.5) and (1.6) are, respectively, the Euler–Lagrange equations ($J'(\cdot) = 0$) of the (energy) functionals

$$J(u, \lambda) = \int_\Omega \left[\frac{1}{p}|\nabla u(x)|^p - \kappa F(u(x)) - \frac{\lambda}{2}(|u(x)|^2 - \alpha)\right] dx, \tag{1.7}$$

$$J(u) = \int_\Omega \left[\frac{1}{p}|\nabla u(x)|^p - \kappa F(u(x))\right] dx. \tag{1.8}$$

People are interested in knowing the values of λ and κ for which (1.5) and (1.6) have nontrivial, positive, or nodal solutions. It turns out that those values are either directly determined by or closely related to the eigenvalues of Δ_p as defined in (1.9) [23]. So we leave more general problems (1.5) and (1.6) to a subsequent paper [38] and consider, in this paper, computing eigenpairs $(\lambda, u) \in \mathbb{R} \times (B \setminus \{0\})$ of the (weighted) p-Laplacian

$$-\Delta_p u(x) = \lambda w(x)|u(x)|^{p-2}u(x) \quad \forall x \in \Omega, \quad u \in B = W_0^{1,p}(\Omega), \tag{1.9}$$

where $\Omega \subset \mathbb{R}^n$ is open and bounded, $w : \Omega \to \mathbb{R}$ is a weight function, and $|\nabla u|^2 = \sum_{i=1}^n (\frac{\partial u}{\partial x_i})^2$. Equation (1.9) is also closely related to the resonance phenomenon, spectral theory of nonlinear operators, Sobolev embedding and inequality, etc.; see, e.g., [7, 24]. When $p = 2$, (1.9) reduces to an eigenproblem of the Laplacian Δ and is well known for its importance in many applications and theoretical studies. Thus (1.9) provides a new way to study the eigenproblem of Δ by embedding it into a one-parameter family of operators Δ_p. Hence new and better understanding can be obtained; see Figure 15 and its remarks. For the existence of multiple solutions to (1.9), we refer to [18, 3].

Equation (1.9) leads us to study the following nonlinear eigenpair problem (NEP). Let B be a Banach space, B' its dual, $\langle , \rangle$ the dual relation, and $\|\cdot\|$ the norm in B. Let F' and G' be the Fréchet derivatives of functionals F and G in $C^1(B, \mathbb{R})$. For given $\alpha > 0$, find eigenpairs $(\lambda, u) \in \mathbb{R} \times (B \setminus \{0\})$ such that (s.t.)

$$F'(u) = \lambda G'(u) \text{ in } B' \qquad \text{subject to } G(u) = \alpha, \tag{1.10}$$

where λ is called an [illegible] and u is called an [illegible] associated with λ. Under certain conditions, existence of countable eigenpairs of (1.10) can be established (see Proposition 44.26 in [39]).

Recall that for $J \in C^1(B, \mathbb{R})$, a point $u^* \in B$ is a critical point of J if u^* solves its Euler–Lagrange equation $J'(u) = 0$, where $J'(u)$ is its Fréchet derivative at u. $c = J(u^*)$ is called the critical level of J at u^*. A critical point u^* is nondegenerate if $J''(u^*)$ exists and has a bounded inverse. Otherwise u^* is degenerate. The first candidates for critical points are the local extrema of J. Critical points that are not local extrema are called [illegible]. In a physical system, saddle points appear as unstable equilibria or excited states.

Eigenpairs (λ, u) of (1.9) correspond to critical points of its Lagrange functional

$$\mathcal{L}(u, \lambda) = F(u) - \lambda(G(u) - \alpha). \tag{1.11}$$

People used to be interested only in the stable solutions (ground states) to a physical system, which correspond to the local minima of its energy functional. Thus traditional existence analysis and numerical methods were focused on such solutions. Other solutions are unstable equilibria or excited states and correspond to saddle critical points of its energy functional. They are much harder for theoretical analysis and more elusive for numerical approximation. However, multiply/highly excited states have been observed in various physical systems to have a variety of configurations, instability/maneuverability. With new advanced laser (synchrotronic) technologies, scientists are able to induce and reach those excited unstable solutions and search for new applications [1, 25, 29, 28, 31]. Such advanced study and applications have changed people's view about unstable (excited) solutions. Thus a huge literature [12, 13] is available in modern critical point theory on the existence of multiple unstable solutions to various nonlinear equations including (1.3)–(1.6) and (1.10). For related numerical computations, a large literature exists in computational physics/chemistry. However most of these results are just for lowly (simply/doubly) excited states (see, e.g., a survey paper [11]). The methods are usually based upon physical intuition of a problem and are not mathematically justified. Although this type of problem did not gain enough attention in the computational mathematics community, we have witnessed the momentum building up in recent years; see [2, 5, 26], and a series of publications, e.g., [8, 9], by Garcia-Ripoll and Perez-Garcia and their associates. Even numerical results for computing highly excited states have appeared more often recently [1, 6, 17, 26, 34]. However, most of them are based on a Newton-type method. They depend heavily on a good initial guess; i.e., an initial guess must be chosen close to the unknown solution to be found, they cannot handle degenerate cases and do not assume or use the variational structure of a problem, and thus are blind to instability order of multiple solutions. However, instability of excited states is an important issue in applications. So far, the only mathematically justified numerical method for computing multiple saddle points of a functional following their instability order is the local minimax (LMM) developed in [20, 21, 40, 41, 32, 33, 35, 36]. But it does not quite fit to NEP (1.10) due to the constraint.

For NEP (1.10), the simplest case is where both F' and G' are linear, e.g., $F'(u) = Au$ and $G'(u) = u$, where A is a linear self-adjoint operator from a Hilbert space B to B. Then (1.10) is a well-studied linear eigenpair problem whose wide applications are well known with various numerical packages available. When either F' or G' is nonlinear, (1.10) is a nonlinear eigenpair problem. For example, in (1.4), F' is linear but G' is nonlinear; in (1.3), G' is linear but F' is nonlinear; and in (1.6), both F' and G' are nonlinear.

So far, people's understanding of (1.10) is still quite limited, and its exact solutions are too hard to obtain. Due to the space setting, the nonlinearity, and the

multiplicity of solutions, (1.10) is very difficult to solve numerically. The first problem one has to overcome is how to numerically search for a *new* solution, not those known solutions. A saddle-type unstable solution may be easily perturbed to decay to a solution in a lower critical level. Whether or not a proposed numerical algorithm can find eigenfunctions following their instability order becomes an important issue. First, with an order, one can avoid a search going to those known solutions, and one can discuss whether or not some eigenfunctions have been missing in a computation. Second, since all eigenfunctions are unstable solutions, except those corresponding to local minima of the energy functional, their instability index is important information in an application. Since all eigenvalues in (1.10) are real, a natural order of eigenfunctions is the order of their eigenvalues. Then two questions must be answered: (a) Can a numerical algorithm find eigenfunctions in this order? If the answer to (a) is yes, then (b) is there a relation between this natural order and the instability order of their eigenfunctions? When (1.10) is linear and in a Hilbert space (Example 1.1)), due to the orthogonality between two different eigenfunctions, the Rayleigh–Ritz method (see [39] and Theorem 2.2) uses the orthogonal complement space of the known solutions to find eigenfunctions following the order of their eigenvalues. The eigenvalues are also the critical values of the Rayleigh quotient at their eigenfunctions. Thus this order coincides with the order of critical (energy) level of the eigenfunctions. Can one do it the same way when (1.10) is nonlinear in a Banach space, and the orthogonality between two different eigenfunctions is broken? Such a numerical method is not available so far in the literature.

LMM can be modified to find critical points of (1.11) following the order of their local minimax index (LMI) (an instability index) [41]. What is the relation between LMI of critical points of (1.11) and the order of eigenvalues of (1.10)? The literature does not provide any information. It turns out that in general this is a very tough question. Can we classify eigenpair problems that may provide us with such information? In a sequence of papers we will try to answer these questions. In this paper, we assume that the eigenpair problem (1.10) satisfies the iso-homogeneous condition; i.e., there are $k = l > 0$ s.t.

$$F'(tu) = t^k F'(u) \quad \text{and} \quad G'(tu) = t^l G'(u) \qquad \forall t > 0, u \in B. \tag{1.12}$$

1.1. A linear eigenpair problem. Find $(\lambda, u) \in \mathbb{R} \times (B \setminus \{0\})$ s.t. $Fu = \lambda Gu$ where F and G are self-adjoint linear operators on a Hilbert space B and G is also positive definite, bounded. Then the iso-homogeneous condition (1.12) is satisfied with $k = l = 1$

Equation (1.9) satisfies the iso-homogeneous condition (1.12) with $k = l = p - 1$. Let $U = \{u \in B | G(u) = 0\}$. For most iso-homogeneous NEP including (1.9), $U = \{0\}$; thus, to simplify our discussion, we assume $U = \{0\}$. Define the Rayleigh quotient

$$J(u) = \frac{F(u)}{G(u)} \quad \forall u \in B \setminus U. \tag{1.13}$$

Then $J \in C^1(B \setminus U, \mathbb{R})$. Even without the iso-homogeneous condition, critical points and their critical values of J are always eigenfunctions and their eigenvalues of (1.10). The converse is not true in general. With the iso-homogeneous condition, it is proved in section 2 that the converse is also true. Thus we can focus on finding critical points of J. However, this problem has its own characters: due to the iso-homogeneous condition, α in (1.10) can be replaced by any nonzero number; i.e., if u^* is an eigenfunction, then so is tu^* for any $t > 0$; i.e., no eigenfunction is isolated, and also

$J(tu) \equiv J(u)\ \forall t > 0$ and $u \in B \setminus U$. Thus $\langle J'(u), u\rangle = 0$ and $J''(u)$ is not invertible everywhere, a severe degenerate case. We limit J on the unit sphere, and then the problem becomes constrained (still degenerate). We need to modify the LMM to solve for multiple critical points of J restricted to a unit sphere following the order of their LMI. To do so, section 2 is used to develop a corresponding LMM characterization of critical points. Its relations with other characterizations such as Rayleigh–Ritz, Courant–Fischer, and Ljusternik–Schnirelman are also presented there. Based upon this LMM characterization, a modified LMM is devised in section 3. Then in section 4, we implement the algorithm to solve our model problem (1.9). Except for the first eigenpair, which has been numerically computed in the literature [19], this is the first time that all of these eigenpairs have been numerically captured. Thus observations of those eigenfunctions on certain interesting phenomena are reported. In section 5, we present mathematical analysis related to convergence of the algorithm, an instability order of eigenfunctions, etc. In a subsequent paper [38], we solve (1.10) for nonhomogeneous cases, e.g., (1.3).

2. Characterization of eigenpairs.

2.1. Equivalence between critical points and eigenpairs.

LEMMA 2.1. (λ, u) (1.10) u J $\lambda = J(u)$

The "if" part is always true. To see the "only if" part, let $u \in B \setminus U$. Then we have

$$\int_0^1 \langle F'(tu), u\rangle dt = \int_0^1 \frac{d}{dt} F(tu) dt = F(u).$$

Similarly, $\int_0^1 \langle G'(tu), u\rangle dt = G(u)$. Thus, if (λ, u) is an eigenpair of (1.10), i.e., $F'(u) = \lambda G'(u)$, then the iso-homogeneous condition implies $F'(tu) = \lambda G'(tu)\ \forall t > 0$. This leads to $F(u) = \int_0^1 \langle F'(tu), u\rangle dt = \int_0^1 \lambda \langle G'(tu), u\rangle dt = \lambda G(u)$. Thus

$$\lambda = \frac{F'(u)}{G'(u)} = \frac{F(u)}{G(u)} \equiv J(u) \quad \text{and} \quad J'(u) = \frac{F'(u)G(u) - F(u)G'(u)}{G^2(u)} = 0. \qquad \square$$

2.1. We can focus on finding critical points of J. An important consequence of Lemma 2.1 is that if critical points are found in such a way that their critical values are in a monotone (increasing) order, then eigenvalues are obtained in the same order. Thus it is easy for us to discuss whether or not we miss any eigenfunctions.

2.2. A modified local minimax characterization. To modify the original LMM, let us introduce the following related notions. Define $L = [u_1, u_2, \ldots, u_{n-1}]$ as the space spanned by linearly independent normalized $u_1, u_2, \ldots, u_{n-1} \in B$ and $B = L \oplus L'$, where L' is the complement of L. Let $\mathcal{P} : B \to L'$ be the corresponding linear projection operator and $S_{L'}$ be the unit sphere in L'. For each $u \in S_{L'}$ denote $[L, u]_S = \{w = \sum_{k=1}^{n-1} t_k u_k + t_0 u | \sum_{k=1}^{n-1} t_k^2 + t_0^2 = 1\}$.

DEFINITION 2.2. $P : S_{L'} \to 2^B$ J *w.r.t.* L $u \in S_{L'}$ $P(u)$ J $[L, u]_S$ $w \in [L, u]_S$ $P(u)$ $\mathcal{N}(w)$ w $J(v) \le J(w)\ \forall v \in [L, u]_S \cap \mathcal{N}(w)$ $p : S_{L'} \to B$ J L $p(u) \in P(u)\ \forall u \in S_{L'}$ $u \in S_{L'}$ p local J u p u

Since J is a function continuous on the nonempty compact set $[L,u]_S$ for each $u \in S_{L'}$, $P(u)$ is always nonempty. Such a defined peak selection has some interesting properties that will be frequently used.

LEMMA 2.3. [illegible] $u_0 \in S_{L'}$ [illegible] p [illegible] J [illegible] u_0 [illegible] $\langle J'(p(u_0)), u_i\rangle = 0 \quad i = 0, 1, \ldots, n-1$

[illegible]. By the assumption, let $w = p(u_0) = \sum_{i=0}^{n-1} t_i u_i \in [L, u_0]_S$, where $\sum_{i=0}^{n-1} t_i^2 = 1$. For $0 \le i \le n-1$, if $\langle J'(w), u_i\rangle \ne 0$, let $w(s) = \frac{w+su_i}{c(s)} \in [L, u_0]_S$, where $c(s) = [(t_i+s)^2 + \sum_{k=0,k\ne i}^{n-1} t_k^2]^{\frac{1}{2}}$. Since $w(s) \to w$ as $s \to 0$, there exists $s_0 > 0$ s.t. when $0 < |s| < s_0$, we have

$$J(w(s)) - J(w) = \left\langle J'(w), \frac{s}{c(s)} u_i \right\rangle + o(\|w(s) - w\|),$$

where we have used the fact that $\langle J'(w), w\rangle = 0$. Thus when $|s|$ is small, the term $\frac{s}{c(s)}\langle J'(w), u_i\rangle$ dominates the difference of $J(w(s)) - J(w)$. Since this term can be made either positive or negative as we wish by properly selecting $s \ne 0$, it contradicts the assumption that w is a local maximum of J on $[L, u_0]_S$. Thus $\langle J'(w), u_i\rangle = 0$. ∎

Since $J'(u) \in B'$ not B, to find a descent direction, the role of the gradient in a Hilbert space is replaced by that of a pseudogradient in a Banach space.

DEFINITION 2.4. [illegible] $\bar{B} = \{u \in B : J'(u) \ne 0\}$ [illegible] $\theta \in (0, 1]$ [illegible] $u \in \bar{B}$ [illegible] $\mathcal{G}(u) \in B$ [illegible] pseudogradient [illegible] J [illegible] u [illegible] θ

$$\|\mathcal{G}(u)\| \le 1 \quad \textit{and} \quad \langle J'(u), \mathcal{G}(u)\rangle \ge \theta \|J'(u)\|.$$

[illegible] $\mathcal{G}$ [illegible] $\mathcal{G}$ [illegible] pseudogradient flow

The following lemma leads to a new LMM characterization of critical points of J and also a stepsize rule in our modified LMM method; see Step 4 of the flow chart in section 3.

LEMMA 2.5. [illegible] p [illegible] J [illegible] $\bar{u} \in S_{L'}$ [illegible] $J'(p(\bar{u})) \ne 0$ [illegible] $p(\bar{u}) \notin L$ [illegible] $s > 0$ [illegible] $\bar{u}(s) = \frac{\bar{u}+sw(\bar{u})}{\|\bar{u}+sw(\bar{u})\|} \in S_{L'}$ [illegible]

$$J(p(\bar{u}(s))) < J(p(\bar{u})) - \frac{1}{4} s\theta |t_n| \|J'(p(\bar{u}))\|, \quad \text{[illegible]} \quad p(\bar{u}) = \sum_{i=1}^{n-1} t_i u_i + t_n \bar{u} \in [L, \bar{u}]_S,$$

[illegible] $\sum_{k=1}^{n} t_k^2 = 1$ $w(\bar{u}) = -\mathrm{sign}(t_n)\mathcal{P}(\mathcal{G}(p(\bar{u})))$ [illegible] $\mathcal{P}(\mathcal{G}(p(\bar{u})))$ [illegible] [illegible] J [illegible] $p(\bar{u})$ [illegible] $\theta \in (0, 1]$

[illegible] Since $\langle J'(w), w\rangle = 0 \ \forall w \in B \setminus U$, p is continuous at $\bar{u}$, and $p(\bar{u}) \in [L, \bar{u}]_S$ when $s > 0$ is small, we have

$$\begin{aligned} J(p(\bar{u}(s))) &= J(p(\bar{u})) + \langle J'(p(\bar{u})), p(\bar{u}(s)) - p(\bar{u})\rangle + o(\|p(\bar{u}(s) - p(\bar{u}))\|) \\ &= J(p(\bar{u})) + \langle J'(p(\bar{u})), p(\bar{u}(s))\rangle + o(\|p(\bar{u}(s) - p(\bar{u}))\|). \end{aligned}$$

Since $p(\bar{u}) \notin L$ implies $t_n > 0$ and, by Lemma 2.3, as $s > 0$ is small, we have $t_n(s) > 0$ and

$$\langle J'(p(\bar{u})), p(\bar{u}(s))\rangle = -\frac{\mathrm{sign}(t_n) t_n(s) s}{\|\bar{u} + sw(\bar{u})\|} \langle J'(p(\bar{u})), \mathcal{P}(\mathcal{G}(p(\bar{u})))\rangle < -\frac{1}{2} s\theta |t_n| \|J'(p(\bar{u}))\|,$$

where $p(\bar{u}(s)) \equiv p(\frac{\bar{u}+sw(\bar{u})}{\|\bar{u}+sw(\bar{u})\|}) = t_1(s)u_1 + \cdots + t_{n-1}(s)u_{n-1} + t_n(s)\frac{\bar{u}+sw(\bar{u})}{\|\bar{u}+sw(\bar{u})\|} \in [L, \bar{u}(s)]_S$. Hence, when $s > 0$ is small,

$$J(p(\bar{u}(s))) < J(p(\bar{u})) - \frac{1}{4} s\theta |t_n| \|J'(p(\bar{u}))\|. \quad \blacksquare$$

2.2. From the last two lemmas, it is clear that the notion of a peak selection $p(\bar{u})$ can be generalized to satisfy $\langle J'(p(\bar{u})), \bar{u}\rangle = \langle J'(p(\bar{u})), u_i\rangle = 0$, $i = 1, \ldots, n-1$. As a direct consequence of Lemma 2.5, we have the following LMM characterization.

THEOREM 2.6. [illegible] p [illegible] J [illegible] $\bar{u} \in S_{L'}$ [illegible] $\bar{u} = \arg\min_{u \in S_{L'}} J(p(u))$ [illegible] $(p(\bar{u}), L) > 0$ [illegible] $p(\bar{u})$ [illegible] J. [illegible] $p(\bar{u})$ [illegible] (1.10) [illegible] $\lambda = J(p(\bar{u}))$ [illegible]

2.3. Comparison to other characterizations. Denote the generalized solution set $\mathcal{M} = \{p(u) | u \in S_{L'}\}$. Theorem 2.6 states that the nth eigenfunction u_n can be obtained through finding a local minimum of J on $\mathcal{M}$ or solving

$$\min_{u \in S_{L'}} \max_{v \in [u_1, \ldots, u_{n-1}, u]_S} J(v). \tag{2.1}$$

Next we discuss the relation between (2.1) and other well-known minimax principles.

THEOREM 2.7. [illegible] 1.1 [illegible] B [illegible] (2.1) [illegible] [39]; [illegible] $\langle u, v\rangle_G = \langle Gu, v\rangle$ [illegible] $\|u\|_G = (\langle u, u\rangle_G)^{\frac{1}{2}}$ [illegible] B $L' = L^{\perp} = \{u \in B | \langle u, u_i\rangle_G = 0, i = 1, \ldots, n-1\}$ [illegible] $S_{L^{\perp}} = \{u \in L^{\perp} : \|u\|_G = 1\}$ [illegible]

$$u_n = \arg \min_{u \in S_{L^{\perp}}} \max_{v \in [u_1, \ldots, u_{n-1}, u]_S} J(v) = \arg \min_{u \in S_{L^{\perp}}} J(u).$$

[illegible] It is known that $\langle u_i, u_j\rangle_G = 0, 1 \le i < j \le n$. Thus we only have to find $v = p(u) \in L^{\perp}$. Then (2.1) reduces to the Rayleigh–Ritz orthogonal method
