$$\min_{u \in S_{L^{\perp}}} \max_{v \in [u]_S} J(v) = \min_{u \in S_{L^{\perp}}} J(u). \tag{2.2}$$

Conversely, if $u_n = \arg\min_{u \in S_{L^{\perp}}} J(u) = \arg\min_{u \in S_{L^{\perp}}} \langle Fu, u\rangle$, i.e., u_n is found by the Rayleigh–Ritz method, then there is a neighborhood $\mathcal{N}(u_n)$ of u_n s.t. $\forall u \in \mathcal{N}(u_n) \cap S_{L^{\perp}}$,

$$\max_{v \in [u_1, \ldots, u_{n-1}, u]_S} \langle Fv, v\rangle \ge \langle Fu, u\rangle \ge \langle Fu_n, u_n\rangle.$$

In addition, $\forall u \in [u_1, \ldots, u_{n-1}, u_n]_S$, we have $u = \sum_{i=1}^{n} c_i u_i$ with $\sum_{i=1}^{n} c_i^2 = 1$. Then

$$\begin{aligned} J(u) &= \langle Fu, u\rangle \\ &= \sum_{i=1}^{n}\sum_{j=1}^{n} c_i c_j \langle Fu_i, u_j\rangle = \sum_{i=1}^{n}\sum_{j=1}^{n} c_i c_j \lambda_i \langle Gu_i, u_j\rangle = \sum_{i=1}^{n} c_i^2 \lambda_i \le \lambda_n = J(u_n), \end{aligned}$$

where λ_i is the eigenvalue corresponding to u_i. Therefore

$$\begin{aligned} J(u_n) = \langle Fu_n, u_n\rangle &= \min_{u \in S_{L^{\perp}}} \max_{v \in [u_1, \ldots, u_{n-1}, u_n]_S} \langle Fv, v\rangle \\ &= \min_{u \in S_{L^{\perp}}} \max_{v \in [u_1, \ldots, u_{n-1}, u_n]_S} J(v). \qquad \square \end{aligned}$$

As for the NEP, since the orthogonality between two different eigenfunctions is broken, the Courant–Fischer minimax principle [39] states that u_n can be found by solving

$$\min_{W_n} \max_{v \in W_n \cap S} J(v), \tag{2.3}$$

where min is taken over all the subspaces W_n of dimension n in B, and max is global on $W_n \cap S$. The Courant–Fischer minimax principle is originally designed for linear eigenpair problems. People then found that it was also valid for nonlinear eigenpair problems where the iso-homogeneous condition is satisfied. The Ljusternik–Schnirelman minimax principle [39], which is commonly regarded as a generalization of the Courant–Fischer minimax principle, is used to characterize saddle points of a nonlinear functional J through solving

$$\inf_{K\in\mathcal{K}_n} \sup_{u\in K} J(u), \tag{2.4}$$

where $\mathcal{K}_n$ is the class of all compact subsets K of B with $\mathrm{ind}(K) \geq n$, sup is global on K, and inf is global over $\mathcal{K}_n$. When the iso-homogeneous condition is satisfied and J is the Rayleigh quotient, (2.4) coincides with (2.3). However, they are all two-level global minimax characterizations and do not help much in algorithm implementation. In contrast, our LMM method (2.1) can be implemented as the following numerical algorithm.

3. A modified LMM algorithm. Let $u_1, \ldots, u_{n-1}$ be $n-1$ previously found normalized critical points of J, $L = [u_1, \ldots, u_{n-1}]$, $B = L \oplus L'$, and $\mathcal{P} : B \to L'$ be the corresponding linear continuous projection operator.

1. Given $\theta \in (0,1)$ and $\lambda > 0$. Set $k = 1$. Choose $v_n^1 \in S_{L'}$, and solve for

$$u_n^1 \equiv p(v_n^1) \equiv \sum_{i=1}^{n-1} t_i^1 u_i + t_n^1 v_n^1 \equiv \arg\max \left\{ J(v) | v = \sum_{i=1}^{n-1} t_i u_i + t_n v_n^1, \sum_{i=1}^{n} t_i^2 = 1 \right\}.$$

2. Compute a descent direction $w_n^k = -\mathrm{sign}(t_n^k)\mathcal{P}(\mathcal{G}_n^k)$, where $\mathcal{G}_n^k$ is a pseudo-gradient of J at u_n^k with constant θ.
3. If $\|J'(p(v_n^k))\| \leq \epsilon$, then output $u_n^k = p(v_n^k)$ and stop. Otherwise, do Step 4.
4. Define $v_n^k(s) = \frac{v_n^k + s w_n^k}{\|v_n^k + s w_n^k\|}$ and

$$u_n^k(s) \equiv p(v_n^k(s)) \equiv \arg\max \left\{ J(v) | v = \sum_{i=1}^{n-1} t_i u_i + t_n v_n^k(s), \sum_{i=1}^{n} t_i^2 = 1 \right\},$$

where $(t_1^k, \ldots, t_n^k)$ is used as an initial point. Determine the stepsize

$$s_n^k = \max_{m\in N} \left\{ \frac{\lambda}{2^m} | 2^m \geq \|w_n^k\|, J\left(p\left(v_n^k\left(\frac{\lambda}{2^m}\right)\right)\right) - J(u_n^k) \ \leq -\frac{s\theta|t_n^k|}{4}\|J'(u_n^k)\| \right\}.$$

5. Set $v_n^{k+1} = v_n^k(s_n^k), u_n^{k+1} = u_n^k(s_n^k) \equiv p(v_n^{k+1}) \equiv \sum_{i=1}^{n-1} t_i^{k+1} u_i + t_n^{k+1} v_n^k(s_n^k)$. $k = k+1$ and go to Step 2.

3.1. (a) In Step 1, since L is finite-dimensional, we may either use a decomposition and normalization to choose $v_n^1 \in S_{L'}$ or use observation, among all functions "orthogonal" to L, to choose a normalized v_n^1 with the simplest nodal line structure. Our choice does not have to be exact. For example, when $L = \{0\}$, v_1^1 can be any nonzero function, but a positive one has the simplest nodal line structure. When $L = [u_1]$, where u_1 is positive, among all functions orthogonal to L we choose v_2^1 to be sign-changing and normalized with one nodal line, etc.

(b) In Step 2, theoretically we can either follow a pseudogradient flow or just find a pseudogradient. The projection is important to avoid a decay to the trivial/known

solutions, i.e., to satisfy $u^* = p(v^*) \notin L$. For a practical technique to compute the projection of a pseudogradient to a complement subspace of L in case of $B = W^{1,p}(\Omega)$, see section 4.1.

(c) In Step 4, it is important to use the initial guess $(t_1^k, \ldots, t_n^k)$ in order to consistently trace a peak selection and keep it continuous.

(d) It is easy to check that $\frac{1}{2}s^k \le s_n^k \le s^k$, where s^k is the exact stepsize defined by

$$s^k = \max\left\{ s | J(p(v_n^k(s))) - J(u_n^k) \le -\frac{1}{4} s\theta |t_n^k| \|J'(u_n^k)\|, \lambda \ge s\|w_n^k\| \ge 0 \right\} \tag{3.1}$$

and is actually used in our convergence analysis [36].

(e) The algorithm is stable in the sense $J(u_n^{k+1}) < J(u_n^k)$.

4. Some numerical results for eigenpairs of the p-Laplacian. In this section we implement the modified LMM to numerically solve our model problem (1.9) for multiple eigenpairs. The Rayleigh quotient is of the form

$$J(u) = \frac{\int_\Omega |\nabla u(x)|^p dx}{\int_\Omega w(x)|u(x)|^p dx}, \quad u \in B = W_0^{1,p}(\Omega),\ u \ne 0. \tag{4.1}$$

4.1. A practical technique for computing a pseudogradient. We develop a practical technique for computing the projection of a pseudogradient to a complement subspace of L based on the gradient of J and successfully apply it to all our numerical computations. The idea is described below.

The gradient $J'(u)$ of J at $u \in B$ is in the dual space $B' = W^{-1,q}(\Omega), (\frac{1}{p} + \frac{1}{q} = 1)$, where the smoothness is poor, and thus not qualified as a candidate for a pseudogradient in B. To increase its smoothness, we use ∇J instead of J', where $d = \nabla J(u)$ is in $W_0^{1,q}(\Omega)$ and defined by $\langle d, v\rangle_{W_0^{1,q}\times W_0^{1,p}} = \langle J'(u), v\rangle_{W^{-1,q}\times W_0^{1,p}}\ \forall v \in W_0^{1,p}(\Omega)$, or

$$\int_\Omega \nabla d(x)\cdot\nabla v(x)\,dx = -\int_\Omega \Delta d(x) v(x)\,dx = \int_\Omega J'(u)(x)v(x)\,dx \quad \forall v \in W_0^{1,p}(\Omega),$$

where $J'(u)(x) = \frac{p}{b^2}(b\Delta_p u(x) + aw(x)|u(x)|^{p-2}u(x))$ when J is given by (4.1). This leads us to solve

$$-\Delta d(x) = J'(u)(x) = \frac{p}{b^2}(b\Delta_p u(x) + aw(x)|u(x)|^{p-2}u(x)),\ x \in \Omega, \quad \text{and} \quad d|_{\partial\Omega} = 0,$$

where $a = \int_\Omega |\nabla u(x)|^p dx$ and $b = \int_\Omega w(x)|u(x)|^p dx$. Since in a numerical computation "nice" functions are usually used to approximate a solution, we check the ratio

$$\gamma = \frac{\|d\|_2^2}{\|d\|_p \cdot \|d\|_q}, \tag{4.2}$$

where $\|\cdot\|_r$ is the norm in $W_0^{1,r}(\Omega)$. By the Holder inequality, $\gamma \le 1$. If $\gamma > \alpha > 0$ at all points generated by the algorithm, then $\mathcal{G}(u) = \frac{d}{\|d\|_p} \in W_0^{1,p}(\Omega) \cap W_0^{1,q}(\Omega)$ is a pseudogradient of J at u w.r.t. α, since $\|J'(u)\| \le \|d\|_q$ [36]. All our numerical results show that $\gamma \gg 0$, although it has not been mathematically proved. As for the projection of $\mathcal{G}(p(u)) = \frac{d}{\|d\|_p}$, where $d = \nabla J(p(u))$, to a complement subspace of L, by the definition of p, we note that

$$0 = \langle J'(p(u)), v\rangle_{W^{-1,q}\times W_0^{1,p}} = \langle d, v\rangle_{W_0^{1,q}\times W_0^{1,p}} \quad \forall v \in L;$$

i.e., d is "orthogonal" to L in some sense. Thus no projection is needed. For such a pseudogradient, to get related convergence of the algorithm [36], in the flow chart, the expression of w_n^k in Step 2 should be $w_n^k = -\text{sign}(t_n^k)\nabla J(u_n^k)$, and the inequality to decide s_n^k in Step 4 and (3.1) should be $J(p(v_n^k(\frac{\lambda}{2^m}))) - J(u_n^k) \le -\frac{|t_n^k|}{4}\|\nabla J(u_n^k)\|_2^2$. Then the expression of $w(\bar{u})$ in Lemma 2.5 should be $w(\bar{u}) = -\text{sign}(t_n)\nabla J(\bar{u})$, and under the assumption $\|\nabla J(p(\bar{u}))\|_2 < +\infty$, the inequality should be $J(p(\bar{u}(s))) < J(p(\bar{u})) - \frac{1}{4}s|t_n|\|\nabla J(p(\bar{u}))\|_2^2$.

4.2. Some numerical results and observations. We select $\Omega = [0,2]\times[0,2]$, $p = 1.75, 2.5, 3.0$ for $w(x) \equiv 1$ and $p = 1.75, 2.5$, $r = 0.5, 6.0$ for $w(x) = |x - \bar{1}|^r$, where $\bar{1} = (1,\dots,1) \in \mathbb{R}^n$ and $|\cdot|$ is the Euclidean norm in $\mathbb{R}^n$. Either 800×800 or 1000×1000 linear square elements are used in the computation, and $\|\nabla J(p(v_n^k))\| \le \varepsilon = 10^{-3}$ is used to terminate the iteration. In Figures 1–14, for each case, we display the profiles of the first few numerical eigenfunctions following the order of their LMI. If two eigenfunctions have the same LMI, we list the one with a smaller eigenvalue first.

In the remaining part of this section, let us shorten the notation: (right) by (r), (middle) by (m), and (left) by (l). In Figures 1(l), 3(m), 5(r), 8(l), 9(r), 11(m), and 13(l) are the ground states (LMI = 1) computed with $L = \{0\}$. For other solutions, due to higher LMI, for computational efficiency, we utilized their symmetries. For example, for Figures 3(l), 5(l), 7(m), 9(m), 11(l), 12(r), and 14(r), we used their symmetries with $L = [u_1]$, where u_1 is their ground state, and other solutions are computed by using their symmetries with $L = \{0\}$. See [32] for details. Several interesting phenomena related to the (weighted) eigenpairs of Δ_p on the square domains have been observed from our numerical results.

(a) By comparing Figure 8(l) to Figure 9(r) and Figure 11(m) to Figure 13(l), we see that a peak-breaking phenomenon takes place for the first weighted eigenfunctions of Δ_p as r increases.

(b) By comparing eigenfunctions in each of the following groups: Figures 1(l), 3(m), and 5(l); Figures 1(m), 4(l), and 6(m); Figures 1(r), 3(r), and 6(l); Figures 2(l), 4(m), and 6(r); Figures 2(m), 5(m), and 7(r); Figures 2(r), 4(r), and 7(l); Figures 3(l), 5(l), and 7(m), we observe that for different values of p, they have the same number of peaks, similar peak locations, and peaks that become sharper when p gets larger.

(c) Keeping the order of eigenvalues in mind and grouping them by their patterns, Figures 1(m), 4(l), and 6(m) (side-to-side peak); Figures 1(r), 3(r), and 6(l) (corner-to-corner peak); Figures 2(m), 5(m), and 7(r) (3-peak); Figures 2(r), 4(r), and 7(l) (4-side-peak); Figures 3(l), 5(l), and 7(m) (5-peak), we find a very interesting pattern order switching phenomenon when p crosses 2, worth further investigation. Those phenomena also imply that when $p = 2$, the eigenvalues of the eigenfunctions with the same LMI should be the same. To see this phenomenon more clearly, we plot the first three eigenvalues of Δ_p for $1.6 \le p \le 2.4$ in Figure 15.

It is clear that the second and the third eigenfunctions of Δ_p switch their pattern order when p crosses 2. That is why the second eigenvalue of Δ is double. To our surprise, from the plot, the first eigenvalue of Δ_p seems to have a linear relation in p. This is the first time such relations have been numerically captured. They are certainly interesting and worthy of further theoretical analysis.

(d) If we pay attention to the peak locations and compare Figure 8(l) to Figure 9(r), Figure 8(m) to Figure 10(l), Figure 9(m) to Figure 11(l), Figure 11(m) to Figure 13(l), Figure 12(l) to Figure 13(r), and Figure 12(r) to Figure 14(r), we can see that the peaks prefer the corners when r increases and crosses some numbers.

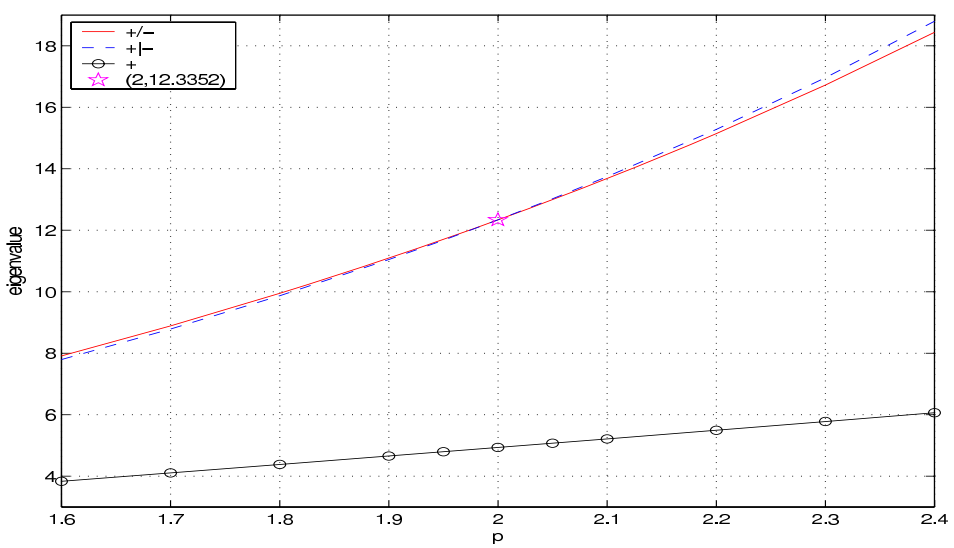

FIG. 15. *The first three eigenvalues of* Δ_p *for* $1.6 \le p \le 2.4$.

(e) To the weighted eigenpair problem of Δ_p, there is a corresponding p-Henon equation

$$-\Delta_p u + |x - \vec{1}|^r |u|^q u = 0,\ x \in \Omega, \quad u|_{\partial\Omega} = 0.$$

Usually, $q > p-2$. By the numerical results in [35], the symmetry of the ground state will be broken when r becomes large. This interesting case is called a symmetry-breaking phenomenon. But by our numerical results in this paper, it seems that for the weighted eigenpair problems, such a phenomenon never occurs. This observation motivates us to do further numerical investigations. Our findings will be reported in [37].

5. Some theoretical issues. The original LMM method was designed for finding multiple unconstrained saddle points. In contrast, our model problem in this paper is constrained and the critical points of the Rayleigh quotient J are always degenerate, which causes some theoretical issues related to the modified LMM. In this section, we present some mathematical analysis on those issues.

5.1. On convergence of the algorithm. To establish some convergence results, as suggested in Remark 2.2, we need to generalize the notion of a peak selection as follows.

DEFINITION 5.1. $P : S_{L'} \to 2^B$ $L \perp$ J $\forall v \in S_{L'}, P(v) = \{u = \sum_{i=1}^{n-1} t_i u_i + t_n v | \sum_{i=1}^{n} t_i^2 = 1, \langle \nabla J(u), u_i \rangle = 0, i = 1, \ldots, n-1\}$ $p : S_{L'} \to B$ $L \perp$ J $p(v) \in P(v)$ $\forall v \in S_{L'}$ $v \in S_{L'}$ J $L \perp$ v $\mathcal{N}(v)$ v $p : \mathcal{N}(v) \cap S_{L'} \to B$ $p(u) \in P(u)$ $\forall u \in \mathcal{N}(v) \cap S_{L'}$

The iso-homogeneous condition implies $\langle \nabla J(p(v)), p(v) \rangle = 0$ and $\langle \nabla J(p(v)), v \rangle = 0$ if $p(v) \notin L$. Then, a min-orthogonal algorithm can be designed through replacing a peak selection in the LMM approach by an L-$\perp$ selection $p(v) = t_1 u_1 + \cdots + t_{n-1} u_{n-1} + t_n v$, which is solved from

$$\langle \nabla J(t_1 u_1 + \cdots + t_{n-1} u_{n-1} + t_n v), u_i \rangle = 0, \qquad i = 1, .., n-1, \ \sum_{i=1}^{n} t_i^2 = 1. \tag{5.1}$$

We need the following condition.

DEFINITION 5.2. $u_i \in B$ $\|u_i\| = 1$ $i = 1, \ldots, n-1$ $J \in C^1(B, \mathbb{R})$ $\{w_i\} \subset B$ $w_i = \sum_{j=1}^{n-1} t_j^i u_j + t_n^i v_i$ $\{v_i\} \subset B, \|v_i\| = 1$ $\sum_{j=1}^{n} (t_j^i)^2 = 1$ $J(w_i)$ $\nabla J(w_i) \to 0$

Then with some modifications along the lines of the proofs, similar convergence results as in [36] can be established. Since the proofs are similar and very long, we omit them here.

5.2. On smoothness of L-$\perp$ selection. Since the selection of an L-$\perp$ is implicitly defined and its continuity or smoothness is important for our algorithm-design/convergence-analysis, the following implicit function theorem (IFT) approach is used to check whether p is smooth. This is one of the theoretical reasons why a peak selection has to be generalized to an L-$\perp$ selection. According to the definition of an L-$\perp$ selection, when $L = [u_1, u_2, \ldots, u_{n-1}]$, $p(v) = \sum_{i=1}^{n-1} t_i u_i + t_n v$, where $\sum_{i=1}^{n} t_i^2 = 1$ and $v \in S_{L'}$, is solved from (5.1). To apply the IFT to (5.1), we need to resolve the problem caused by the normalization $\sum_{i=1}^{n} t_i^2 = 1$, which represents the constraint of the problem and prevents us from taking derivative w.r.t. t_i. Since the system in (5.1) is iso-homogeneous, the normalization $\sum_{i=1}^{n} t_i^2 = 1$ can always be satisfied afterward through dividing each t_i by $(\sum_{j=1}^{n} t_j^2)^{\frac{1}{2}}$. Thus the normalization

condition can be released. Then for given $v \in S_{L'}$, the system (5.1) contains n unknowns $t_1, \ldots, t_n$ but $n-1$ equations. To obtain a square Hessian matrix of (5.1) and keep in mind the nondegeneracy condition $\operatorname{dis}(p(v), L) > 0$ in our local minimax characterization, Theorem 2.6, let us solve

$$\langle \nabla J(t_1 u_1 + \cdots + t_{n-1} u_{n-1} + v), u_i \rangle = 0, \quad i = 1, \ldots, n-1. \tag{5.2}$$

That is, we force $t_n = 1$ in (5.1). The IFT states that if $u = p(v) = t_1 u_1 + \cdots + t_{n-1} u_{n-1} + v$ satisfies (5.2), the $(n-1) \times (n-1)$ matrix

$$Q = \begin{bmatrix} \langle J''(u)u_1, u_1 \rangle & \cdots & \langle J''(u)u_{n-1}, u_{n-1} \rangle \\ \cdots & \cdots & \\ \langle J''(u)u_1, u_{n-1} \rangle & \cdots & \langle J''(u)u_{n-1}, u_{n-1} \rangle \end{bmatrix}$$

is invertible; i.e., $|Q| \neq 0$; then $(t_1(w), \ldots, t_{n-1}(w))$ can be solved from (5.2) around v; i.e., $p(w) = \sum_{i=1}^{n-1} t_i(w) u_i + w$ satisfies (5.2) and $(t_1(w), \ldots, t_{n-1}(w))$ is continuously differentiable around v. Thus the L-$\perp$ selection p is well defined and continuously differentiable near $v \in S_{L'}$. Then we can normalize $p(w)$ through a differentiable operation, i.e., multiplying $p(w)$ by $t_n(w) = 1/(\sum_{i=1}^{n-1} t_i(w)^2 + 1)^{\frac{1}{2}}$ to get the new $p(w) \in [L, w]_S \ \forall w$ near v in $S_{L'}$. Then (5.1) is satisfied, and the condition $|Q| \neq 0$ can be easily numerically checked.

5.3. On an instability order of eigenfunctions. In this subsection, we establish an instability order for eigenpairs of (1.10) computed by the modified LMM. Note that the role played by the iso-homogeneous condition (1.12) to define this order is double-edged, it enables the eigenvalues of (1.10) to coincide with the critical values of the Rayleigh quotient J (see Lemma 2.1), and it also makes J degenerate.

Let B be a Hilbert space and $J \in C^2(B, \mathbb{R})$. If $u^* \in B$ is a nondegenerate critical point of J, then $B = B^- \oplus B^+$, where B^- and B^+ are, respectively, the maximum negative and positive definite subspaces of $J''(u^*)$. The integer $\mathrm{MI}(u^*) = \dim(B^-)$ is called the Morse index (MI) of u^*. MI is commonly used to define an instability order for nondegenerate and unconstrained saddle points in a Hilbert space [30, 41]. But MI cannot handle degenerate cases and is not defined in a Banach space. Thus another approach allowing a Banach space setting, constrained, and degenerate cases has to be developed.

In computational chemistry and physics, the following notion of saddle order is of interest.

DEFINITION 5.3. $J \in C^1(B, \mathbb{R})$ $u^* \in B$ J $B = B^I \oplus B^D$ B^I, B^D B $u_1 \in B^I$ $u_2 \in B^D$ $\|u_1\| = 1$ $\|u_2\| = 1$ $r_1 > 0$ $r_2 > 0$

$$J(u^* + t u_1) \geq J(u^*) \qquad \forall\, 0 < |t| \leq r_1, \tag{5.3}$$

$$J(u^* + t u_2) < J(u^*) \qquad \forall\, 0 < |t| \leq r_2. \tag{5.4}$$

$\dim(B^D)$ J u^* saddle order u^*

Since (5.3) and (5.4) lack characterization and robustness, it is difficult for us to apply, in particular, in a Banach space. Thus in the definition, we replace (5.4) by

$$J(u^* + t u_2 + o(t)) < J(u^*) \qquad \forall\, 0 < |t| \leq r_2, \tag{5.5}$$

where $o(t)$ represents a higher order term. The integer $\dim(B^D)$ is then called the local saddle index (LSI) and will be used to define an instability order for critical points of J.

If u^* is a nondegenerate saddle point of J on a Hilbert space $B = B^- \oplus B^+$, then

$$J(u^* + tu_1 + o(t)) - J(u^*) = \frac{t^2}{2}\langle J''(u^*)u_1, u_1\rangle + o(t^2) > 0,$$
$$J(u^* + tu_2 + o(t)) - J(u^*) = \frac{t^2}{2}\langle J''(u^*)u_2, u_2\rangle + o(t^2) < 0$$

for any $u_1 \in B^+$, $u_2 \in B^-$ and $|t|$ small; i.e., $\mathrm{LSI}(u^*) = \mathrm{MI}(u^*)$. Since the definition of LSI by (5.3) and (5.5) does not concern the degeneracy of u^*, LSI is more general than MI. Next we assume that (5.3) and (5.5) are satisfied and prove that for a saddle point $u^* = p(v^*)$ found by our modified LMM, $\mathrm{LSI} = \dim(L) = k$, where $L = [u_1, \ldots, u_k]$ and $u_1, \ldots, u_k$ are linear independent and normalized. Due to the iso-homogeneous condition, the definition of the Rayleigh quotient J, and the condition $u^* \notin L$, as pointed out in section 5.2, our LMM characterization

$$v^* = \arg\min_{v \in S_{L'}} \max_{u \in [u_1, \ldots, u_k, v]_S} J(u), \tag{5.6}$$

i.e., $p(v) = \sum_{i=1}^{n-1} t_i u_i + t_n v, \sum_{i=1}^{n} t_i = 1$, is equivalent to solving

$$\bar{v} = \arg\min_{v \in S_{L'}} \max_{(t_1, \ldots, t_k) \in \mathbb{R}^k} J(t_1 u_1 + \cdots + t_k u_k + v), \tag{5.7}$$

i.e., $p(v) = t_1 u_1 + \cdots + t_k u_k + v$. However, (5.7) has an advantage that the local maximization at the second level is taken on a finite-dimensional space, not just on a manifold as in (5.6).

THEOREM 5.4. [illegible] B [illegible] $\|\cdot\|'$ [illegible] $B \setminus \{0\}$ [illegible] $v^* \in S_{L'}$ [illegible] J [illegible] p [illegible] L [illegible] v^* [illegible] p [illegible] v^* $u^* \equiv p(v^*) \notin L$ [illegible] $v^* = \arg\min_{v \in S_{L'}} J(p(v))$ [illegible] (5.7) [illegible] u^* [illegible] $k = \dim(L)$ [illegible]. Let B^D and B^I be defined as in (5.3) and (5.5). If $k = 0$, there is no local maximization in (5.7), or, $v^* = p(v^*)$ is a local minimum point of J. It is clear that $k = 0 = \dim(B^D)$. Now we assume that $k > 0$. Since $k > \dim(B^D)$ implies $L \cap B^I \neq \emptyset$, it contradicts our assumption that the local maximum in (5.7) is strict. Thus we have $k \leq \dim(B^D)$. To prove $k = \dim(B^D)$, recall $B = L \oplus L', v^* \in S_{L'}$. For each $v \in L'$ with $v \neq 0$, we define $E(v) = \frac{v}{\|v\|}$. We have $E'(v)w = \frac{w}{\|v\|} - \frac{v}{\|v\|}\langle \|\frac{v}{\|v\|}\|', w\rangle$. Let $L_{v^*}^{\perp} = \{w \in L' : \langle \|v^*\|', w\rangle = 0\}$. For each $w \in L'$, we can write $w = cv^* + (w - cv^*)$, where $c = \frac{d}{d\alpha}|_{\alpha=0}\|v^* + \alpha w\| = \langle \|v^*\|', w\rangle$ and $\langle \|v^*\|', v^*\rangle = \|v^*\| = 1$. Thus $w - cv^* \in L_{v^*}^{\perp}$. Since $[v^*] \cap L_{v^*}^{\perp} = \{0\}$, we have $L_{v^*}^{\perp} \oplus [v^*] = L'$. For each $w \neq 0$ in $L_{v^*}^{\perp}$, $E'(v^*)w = w$. Let $\alpha(s) \equiv \mathcal{P}(p(E(v^* + sw))) = E(v^* + sw)$, where $\mathcal{P}$ is the linear projection operator onto L'. We have $\alpha'(0) = \mathcal{P}(p'(E(v^*))E'(v^*)w) = E'(v^*)w = w$, i.e., $\mathcal{P}(p'(v^*)w) = w$. It follows that $w \in \{p'(v^*)(w), L\}$. Since $w \in L_{v^*}^{\perp} \subset L'$, we have $p'(v^*)w \notin L$. This leads to

$$p'(v^*)(L_{v^*}^{\perp}) \oplus [v^*] \oplus L = B. \tag{5.8}$$

Now we suppose $k < \dim(B^D)$. Then (5.8) implies $(p'(v^*)(L_{v^*}^{\perp}) \oplus [v^*]) \cap B^D \neq \{0\}$. Since $J(v) \equiv J(tv)\ \forall t \neq 0$ and $\forall v \neq 0$, we must have $p'(v^*)(L_{v^*}^{\perp}) \cap B^D \neq \{0\}$. Let

$w \in L_{v^*}^{\perp}$ s.t. $p'(v^*)(w) \in (B^D \setminus \{0\})$. Then $E(v^* + sw) \in \mathcal{N}(v^*) \cap S_{L'}$ for $|s|$ small. It follows that

$$\begin{aligned} p(E(v^* + sw)) &= p(E(v^*)) + sp'(E(v^*))E'(v^*)(w) + o(s) \\ &= p(v^*) + sp'(v^*)(w) + o(s) = u^* + sp'(v^*)(w) + o(s). \end{aligned}$$

Since $p'(v^*)(w) \in (B^D \setminus \{0\})$, we have, for $|s|$ small,

$$J(p(v^*(s))) = J(u^* + sp'(v^*)(w) + o(s)) < J(u^*) = J(p(v^*)).$$

On the other hand, by our assumption on v^* and (5.7), we should have

$$J(p(v^*(s))) = \max_{(t_1,\ldots,t_k)\in\mathbb{R}^k} J(t_1u_1 + \cdots + t_ku_k + v^*(s)) \geq J(p(v^*)).$$

This leads to a contradiction. We conclude that $k = \dim(B^D)$. □

The integer $k = \dim(L)$ is called the [illegible] of the constrained saddle point $u^* = p(v^*)$ of J. Theorem 5.4 states that LSI = LMI. Following our modified LMM, we start with $k = 0$ or $L = \{0\}$, to find a local minimum point u^1 of J. The LMI of u_1 is $k = 0$. Then we go to $k = 1$ or $L = [u_1]$ to find a saddle point u_2 of J of LMI $k = 1, \ldots$. Continuing in this way, we use $L = [u_1, \ldots, u_k]$ to find a saddle point u_{k+1} of J of LMI $= k$. Therefore for each $k = 0, 1, \ldots$, at least one saddle point u_{k+1} with LMI $= k$ will be found. The dimension of the maximum subspace of decreasing directions of J (energy function) at u_{k+1} is LSI = LMI $= k$. Thus the order of LMI coincides with the instability order of saddle points. In contrast, the order of the LMI can be easily followed by our modified LMM method. It is clear that $J(u_j) < J(u_k)$ for $j = 0, 1, \ldots, k-1$. Since Theorem 2.6 states $J(u_k) = \lambda_k$, we also have $\lambda_j < \lambda_k$ for $j = 0, 1, \ldots, k-1$. Since the modified LMM is local, this order may be partial and contains multiple branches. If the order contains only one branch, then no eigenfunction will be missed and the order of eigenfunctions coincides with the natural order of their eigenvalues. However, when the order contains multiple branches, i.e., more than one eigenfunction has the same LMI or a bifurcation takes place, each branch contains a sequence of eigenfunctions according to their LMI whose order coincides with the natural order of their eigenvalues. For linear eigenpair problems as in Example 1.1, all eigenfunctions with the same LMI have the same eigenvalues. For a nonlinear eigenpair problem, as we found in our numerical results, a significant difference is that eigenfunctions with the same LMI may have different eigenvalues. Eigenvalues of two eigenfunctions from two different branches cannot be compared, whether they have the same or different LMI.

REGULARITY THEORY AND SUPERALGEBRAIC SOLVERS FOR WIRE ANTENNA PROBLEMS*

OSCAR P. BRUNO† AND MICHAEL C. HASLAM†

Abstract. We consider the problem of evaluating the current distribution $J(z)$ that is induced on a straight wire antenna by a time-harmonic incident electromagnetic field. The scope of this paper is twofold. One of its main contributions is a regularity proof for a straight wire occupying the interval $[-1, 1]$. In particular, for a smooth time-harmonic incident field this theorem implies that $J(z) = I(z)/\sqrt{1-z^2}$, where $I(z)$ is an *infinitely differentiable* function—the previous state of the art in this regard placed I in the Sobolev space $W^{1,p}$, $p > 1$. The second focus of this work is on numerics: we present three *superalgebraically convergent* algorithms for the solution of wire problems, two based on Hallén's integral equation and one based on the Pocklington integrodifferential equation. Both our proof and our algorithms are based on two main elements: (1) a new decomposition of the kernel of the form $G(z) = F_1(z)\ln|z| + F_2(z)$, where $F_1(z)$ and $F_2(z)$ are analytic functions on the real line; and (2) removal of the end-point square root singularities by means of a coordinate transformation. The Hallén- and Pocklington-based algorithms we propose converge superalgebraically: faster than $\mathcal{O}(N^{-m})$ and $\mathcal{O}(M^{-m})$ for any positive integer m, where N and M are the numbers of unknowns and the number of integration points required for construction of the discretized operator, respectively. In previous studies, at most the leading-order contribution to the logarithmic singular term was extracted from the kernel and treated analytically, the higher-order singular derivatives were left untreated, and the resulting integration methods for the kernel exhibit $\mathcal{O}(M^{-3})$ convergence at best. A rather comprehensive set of tests we consider shows that, in many cases, to achieve a given accuracy, the numbers N of unknowns required by our codes are up to a factor of five times smaller than those required by the best solvers previously available; the required number M of integration points, in turn, can be several orders of magnitude smaller than those required in previous methods. In particular, four-digit solutions were found in computational times of the order of four seconds and, in most cases, of the order of a fraction of a second on a contemporary personal computer; much higher accuracies result in very small additional computing times.

1. Introduction.

The problem of evaluating the current distribution that is induced on a thin straight wire antenna by a given time-harmonic incident electromagnetic field was first described by Pocklington [10] more than a century ago; its computation remains an important and difficult engineering problem to this day. Once such currents have been calculated, the fields scattered by the wire can easily be produced by integration. The current $J(z)$ induced on a thin wire of radius a by an incident electromagnetic field with wave number k and axial component $e(z)$ can be obtained as a solution of the Pocklington equation

$$\left(\frac{\partial^2}{\partial z^2} + k^2\right) \int_{-1}^{1} G(z-t)\, J(t)\, dt = -4\pi i k e(z) \tag{1.1}$$

subject to the end-point conditions

$$J(-1) = J(1) = 0. \tag{1.2}$$

An alternative (and, in exact arithmetic, equivalent) formulation for this problem is given by the Hallén equation, which results from (1.1) by inverting the Helmholtz operator. The Hallén equation thus reads

$$\int_{-1}^{1} G(z-t)\, J(t)\, dt = \alpha_1 \cos kz + \alpha_2 \sin kz - 4\pi i \int_{-1}^{z} e(t) \sin[k(z-t)] dt, \tag{1.3}$$

where α_1 and α_2 are constants which are chosen so that the current distribution satisfies the end-point conditions (1.2). The kernel $G(z)$ in these equations, which is given by

$$G(z) = \frac{1}{\pi} \int_0^{\pi} \frac{\mathrm{e}^{ik\sqrt{z^2+4a^2\sin^2\psi}}}{\sqrt{z^2+4a^2\sin^2\psi}}\, d\psi, \tag{1.4}$$

has a logarithmic singularity at $z = 0$; see section 2.

The scope of this paper is twofold. One of its main contributions is a regularity proof: expressing the current in the form $J(z) = I(z)/\sqrt{1-z^2}$ (which has been known since the work by Jones [7] and Rynne [13]), our result relates the regularity of the function $I(z)$ to that of the incident field. In particular, for an infinitely differentiable incident field our theorem implies that the "reduced current" $I(z)$ is infinitely differentiable as well—the previous state of the art in this regard placed I in the Sobolev space $W^{1,p}$, $p > 1$. The second focus of this work is on numerics: we present three superalgebraically convergent algorithms for the solution of wire scattering problems, two based on Hallén's integral equation and one based on the Pocklington integrodifferential equation. To achieve superalgebraic convergence, these algorithms rely on a number of techniques which address specifically the difficulties posed by wire scattering problems.

Some of the concepts we present in this paper are used in both our theoretical and our numerical treatments; others are specifically designed to tackle numerical issues presented by the problem at hand. In particular, to both establish our regularity result and produce algorithms of high-order accuracy for this problem, we do the following:

1. Introduce a new decomposition of the kernel, of the form

   $$G(z) = F_1(z) \ln|z| + F_2(z), \tag{1.5}$$

   where $F_1(z)$ and $F_2(z)$ are analytic functions on the real line. Albeit analytic, the functions F_i exhibit a rather interesting "nearly singular" behavior.
2. Utilize a coordinate transformation of the form $z = \cos(\theta)$. This transformation, which is essential for our theoretical discussion (section 3), is also quite useful from a numerical standpoint, since it simultaneously regularizes the integration problem and leads to a Chebyshev representation of the reduced current I.

To obtain accurate and efficient algorithms we introduce additional numerical strategies. In particular:

3. For very thin wires we use the transformation $z = 2\cos w/(1+\cos^2 w)$ instead of the one mentioned in point 2 above. The $w \to z$ transformation results

in significantly improved performance for very thin wires (see points (a), (b), and (c) in section 5.1): instead of the quadratic z-clustering introduced at $z = \pm 1$ by the $\theta \to z$ transformation, the $w \to z$ change of variables introduces quartic point clustering around the end-points. This additional refinement resolves a near singularity that occurs in the reduced current I for a very close to zero.

4. To produce well-conditioned linear systems we discretize our integral equations by sampling them at z points corresponding to equispaced θ or w grids, depending on whether the $\theta \to z$ or the $w \to z$ transformation is used. A sampling of the integral operators at regular z grids gives rise to highly ill-conditioned linear algebra problems.
5. The integration algorithm itself, on the other hand, utilizes (i) a localized integration scheme based on use of fine and coarse Chebyshev grids for integration of highly peaked integrands that arise from corresponding (smooth) peaks in the functions F_1 and F_2, as well as (ii) a new weighted-quadrature formula for log-Chebyshev integrals (see Appendix B).
6. For efficiency, the kernel evaluations are based on a new asymptotic formula (equation (2.20)) which we use for sufficiently large values of a certain dimensionless version ρ of the spatial variable, together with numerical procedures based on expansions and integral representations for the rapid and accurate evaluation of the newly introduced functions F_1 and F_2.

Having accounted to all orders for all integrand singularities and near-singularities and in view of our regularity result, we find that the Hallén- and Pocklington-based algorithms we propose converge superalgebraically: faster than $\mathcal{O}(N^{-m})$ and $\mathcal{O}(M^{-m})$ for any positive integer m, where N and M are the numbers of unknowns and the number of integration points required for construction of the discretized operator (i.e., the linear system's matrix), respectively. Previous solution techniques for this problem, in contrast, have not taken into account the precise nature of the kernel's singularity—which, to our knowledge, had not been established before the present work. In many contributions, furthermore, the end-point singularities of the current distribution were not fully accounted for. We show, albeit not straightforward, that it is very advantageous to account for all singularities to high order: as we show in a variety of examples in section 5, in many cases, to achieve a given accuracy, the numbers N of unknowns required by our codes are as much as five times smaller than those required by the best solvers previously available. The required number M of integration points, in turn, can be several orders of magnitude smaller than those required by previous methods; see paragraph (d) below.

A few comments are in order with regards to the kernel mentioned above and its relationship to various expressions available in the literature:

(a) The normalization of the kernel (1.4) coincides with that of Jones [7] and Rynne [13]; the normalization employed by Davies, Duncan, and Funken [4], on the other hand, includes an additional multiple of $1/(4\pi)$, which, here, is incorporated on the right-hand side of (1.1) instead.

(b) Another kernel for the equations above, which results from use of approximations additional to those implicit in (1.1), (1.3), and (1.4), is the so-called reduced kernel

$$G_{red}(z) = \frac{\mathrm{e}^{ik\sqrt{z^2+a^2}}}{\sqrt{z^2+a^2}}. \tag{1.6}$$

We will not utilize this kernel: as pointed out in [4] and [5], it is not possible

to obtain reliable results using the reduced kernel $G_{red}(z)$ in place of $G(z)$ in (1.1) or (1.3).

(c) In a concise paper [16], Wang derives the expansion

$$G(z) = \frac{e^{ik\sqrt{z^2+2a^2}}}{\sqrt{z^2+2a^2}} + ik \sum_{m=1}^{\infty} \frac{(ka)^{4m}(2m-1)!!}{(2m)!(2m)!!} \frac{h_{2m}^{(1)}\left(k\sqrt{z^2+2a^2}\right)}{k^{2m}(z^2+2a^2)^m} \tag{1.7}$$

for the exact straight wire kernel, where $h_m^{(1)}(z)$ is a spherical Hankel function of the first kind [1]. This expansion is particularly useful for values of z far away from the origin, for which the series in (1.7) converges rapidly. Unfortunately, this expansion does not seem as useful for values of z close to $z = 0$, since the asymptotic behavior of the kernel in this important region cannot be easily produced from (1.7).

(d) It has been known for some time that the kernel (1.4) has the form

$$G(z) = -\frac{1}{a\pi} \ln|z| + G_1(z), \tag{1.8}$$

where the function $G_1(z)$ is continuous, it has a bounded derivative and an unbounded second derivative; see [7, p. 115], [13], or section 2.2 below. The logarithmic behavior of the function $G(z)$ can be easily grasped by consideration of the expression

$$G(z) = \frac{2}{\pi\sqrt{z^2+4a^2}} K\left(\frac{2a}{\sqrt{z^2+4a^2}}\right) - \frac{1}{\pi} \int_0^{\pi} \frac{1 - e^{ik\sqrt{z^2+4a^2\sin^2\psi}}}{\sqrt{z^2+4a^2\sin^2\psi}} d\psi, \tag{1.9}$$

where K, the complete elliptic integral of the first kind [3], contains the leading-order singularity. Equations (1.8) and (1.9) have been used as the basis for many numerical solvers for Pocklington and Hallén problems [4, 9]. Numerical integration schemes for integrands containing such singularities which, based on polynomial interpolation, do not explicitly account for the singularity of the second derivative of the integrand typically exhibit low-order convergence. Indeed, the leading singular term in $G_1(z)$ is of the form $z^2 \ln|z|$ [9]. The error that results as an nth degree Newton–Cotes scheme (e.g., Simpson's rule for $n = 2$) is used to integrate such a function is of the order of $\mathcal{O}(h^3)$ for $n \geq 2$, where h is the integration mesh size. The decomposition (1.5) we introduce extends the result embodied in (1.8) and allows for superalgebraic evaluation of the kernel and its integrals; see section 2.3 and Appendix B, respectively. In particular, efficient algorithms for the evaluation of the functions F_1 and F_2 can be found in section 2.3.

This paper is organized as follows: After introducing the new decomposition for the exact kernel in section 2, we discuss in section 3 the regularity properties of the current $J(z)$. Our approach to the discretization of the Pocklington and Hallén integral equations is then described in section 4 and Appendix B. A variety of numerical results and conclusions, finally, are presented in section 5.

2. New decomposition for the exact kernel. In this section we present a derivation of the decomposition (1.5) together with explicit expressions and algorithms for fast and accurate evaluation of the analytic functions F_1 and F_2.

2.1. Taylor expansion of the integrand's exponential. Substituting the exponential in (1.4) by its Taylor expansion and interchanging the order of summation and integration, we obtain

$$G(z) = g(\rho)/a, \quad \rho = z/(2a), \tag{2.1}$$

where, defining

$$B_m(\rho) = \int_0^\pi \left(\rho^2 + \sin^2\psi\right)^{m/2} d\psi, \tag{2.2}$$

$$\begin{aligned} g_r(\rho) &= \frac{1}{2\pi}\sum_{n=0}^{\infty} \frac{(-1)^n (2ka)^{2n}}{(2n)!} B_{2n-1}(\rho) \quad \text{and} \\ g_i(\rho) &= \frac{1}{2\pi}\sum_{n=0}^{\infty} \frac{(-1)^n (2ka)^{2n+1}}{(2n+1)!} B_{2n}(\rho), \end{aligned} \tag{2.3}$$

the dimensionless function g is given by

$$g(\rho) = g_r(\rho) + i g_i(\rho). \tag{2.4}$$

For $m = 2n$ (n a nonnegative integer), the integrals in (2.2) define a set of polynomials. In particular, calling

$$R = \sqrt{\rho^2 + 1}, \tag{2.5}$$

we have the expression

$$B_{2n}(\rho) = \pi \sum_{m=0}^{n} \frac{(-1)^m}{2^{2m}} \begin{pmatrix} n \\ m \end{pmatrix} \begin{pmatrix} 2m \\ m \end{pmatrix} R^{2n-2m}, \tag{2.6}$$

which follows from the hypergeometric function representation of the integral in (2.2) [14, eqn. IV(2)] and the series expansion for these functions [1, eqn. 15.4.1]. Using (2.6) and reversing the order of summation in the second equation of (2.3) we obtain an exponentially convergent series for the imaginary part of the kernel: denoting by $j_n(z)$ the spherical Bessel function of the first kind [1], our expansion reads

$$g_i(\rho) = ka \sum_{n=0}^{\infty} \frac{1}{2^{2n} n!} \begin{pmatrix} 2n \\ n \end{pmatrix} \left(\frac{ka}{R}\right)^n j_n(2kaR)\,. \tag{2.7}$$

A corresponding closed-form result can be obtained for the real part of the kernel as well: for the values $m = 2n - 1$ (n a nonnegative integer) relevant in this case, the integrals in (2.2) are related to the associated Legendre functions of the second kind, $Q_\nu^\mu(z)$, of degree ν and order μ. It follows directly from the integral representation for the functions $Q^\mu_{m-1/2}(z)$ [14, eqn. VI(73c)] that

$$B_{2n-1}(\rho) = \frac{2}{\sqrt{\pi}}\,\Gamma(1/2 - n)(|\rho|R)^n Q^n_{-1/2}(2\rho^2 + 1). \tag{2.8}$$

2.2. Decomposition of the real part of the kernel. To make explicit the singular nature of the kernel $g_r(\rho)$, we use (2.3) and (2.8) together with known formulae for the Legendre functions of integer order $Q^n_\nu(z)$. In particular, from [14, eqn. VI(46')] and using the notation (2.5), we obtain

(2.9)
$$Q^n_{-1/2}(2\rho^2+1) = -P^n_{-1/2}(2\rho^2+1)\ln\left(\frac{|\rho|}{R}\right) + \frac{\sqrt{\pi}}{2R}\left(\frac{|\rho|}{R}\right)^n \Gamma(n+1/2)F^n_{-1/2}(2\rho^2+1),$$

where $P^\mu_\nu(z)$ is the Legendre function of the first kind of degree ν and order μ. Using a slightly different notation from that of [14] we have set

(2.10)
$$F^n_{-1/2}(2\rho^2+1) = \frac{2}{\pi}(-1)^n\left[\sum_{m=1}^{n}\frac{1}{2m}\frac{\phi_{n-m}}{\phi_m}\left(\frac{R}{\rho}\right)^{2m} + \frac{1}{2}\sum_{m=0}^{\infty}(\beta_m+\beta_{m+n})\phi_m\phi_{m+n}\left(\frac{\rho}{R}\right)^{2m}\right],$$

where

(2.11)
$$\phi_\ell = \frac{1}{2^{2\ell}}\begin{pmatrix} 2\ell \\ \ell \end{pmatrix} = \frac{1\cdot 3\cdot 5\cdots(2\ell-1)}{2\cdot 4\cdot 6\cdots(2\ell)}, \quad \ell \geq 1$$

(with $\phi_0 = 1$), and where, using the digamma function Ψ [1], $\beta_\ell = \Psi(\ell+1)-\Psi(\ell+1/2)$.

In view of (2.9), the real part of the kernel may be expressed in the form

(2.12)
$$g_r(\rho) = -\frac{1}{\pi}\,g_{r1}(\rho)\ln\left(\frac{|\rho|}{R}\right) + g_{r2}(\rho),$$

where the functions g_{r1} and g_{r2} are given by

(2.13)
$$g_{r1}(\rho) = \frac{1}{\sqrt{\pi}}\sum_{n=0}^{\infty}\frac{(-1)^n(2ka)^{2n}}{(2n)!}\,\Gamma(1/2-n)(|\rho|R)^n P^n_{-1/2}(2\rho^2+1)$$

and

(2.14)
$$g_{r2}(\rho) = \frac{1}{2R}\sum_{n=0}^{\infty}\frac{(2ka\rho)^{2n}}{(2n)!}\,F^n_{-1/2}(2\rho^2+1);$$

as shown in what follows, these functions are analytic for real values $|\rho| < \infty$.

The expression (2.13) for g_{r1} may be simplified considerably. To do this we use the integral representation

(2.15)
$$P^n_{-1/2}(1+2\rho^2) = \frac{1}{\pi^{3/2}}(-1)^n\Gamma(n+1/2)\left(\frac{|\rho|}{R}\right)^n\int_0^\pi \frac{\sin^{2n}\psi\, d\psi}{\sqrt{1+\rho^2\cos^2\psi}},$$

which follows from a corresponding integral representation for the hypergeometric function [14, eqn. IV(2)] together with a known expression [14, eqn. VI(45)] for the Legendre functions in terms of the hypergeometric function. Substituting equation (2.15) in (2.13) and reversing the order of summation and integration yields the simple expression

(2.16)
$$g_{r1}(\rho) = \frac{1}{\pi}\int_0^\pi \frac{\cos(2ka\rho\sin\psi)d\psi}{\sqrt{1+\rho^2\cos^2\psi}}.$$

In addition to showing that $g_{r1}(\rho)$ is, indeed, an analytic function for real values of ρ, this formula gives rise to an efficient method for the evaluation of this function in a neighborhood of the origin.

To show that g_{r2} (equation (2.14)) is analytic, in turn, we establish appropriate upper bounds on the growth with respect to n of each one of the two sums in (2.10). To this end we first note from (2.11) that (i) $0 < \phi_\ell \le 1$ for $\ell = 0, 1, 2, \ldots$, and (ii) $\phi_\ell \ge 1/(2\ell)$ for $\ell = 1, 2, 3, \ldots$. Hence

$$\frac{2}{\pi}\rho^{2n}\sum_{m=1}^{n}\frac{1}{2m}\frac{\phi_{n-m}}{\phi_m}\left(\frac{R}{\rho}\right)^{2m} \le \begin{cases} 2nR^{2n}/\pi, & |\rho| \le 1, \\ 2n\rho^{2n}R^{2n}/\pi, & |\rho| > 1. \end{cases} \tag{2.17}$$

In order to obtain a bound on the infinite series in (2.10), in turn, we recall [1] that the digamma function Ψ is monotonically increasing for real $z > 0$. It follows that $\Psi(z+1) - \Psi(z+1/2) \le \Psi(z+1) - \Psi(z) = 1/z$ [1, eqn. 6.3.5], and thus $0 < \beta_m \le 1/m$ for $m \ge 1$. Since $\phi_{m+n} \le \phi_m$ and $\beta_{m+n} \le \beta_m$ for all nonnegative integers m and n, and since $\phi_0 = 1$ and $\beta_0 = 2\ln 2$ [1, eqns. 6.3.2, 6.3.3], for all real ρ we obtain the inequality

$$\sum_{m=0}^{\infty}(\beta_m + \beta_{m+n})\phi_m\phi_{m+n}\left(\frac{\rho}{R}\right)^{2m} \le 2\sum_{m=0}^{\infty}\beta_m\phi_m \le 4\ln 2 + 2\sum_{m=1}^{\infty}\frac{\phi_m}{m}. \tag{2.18}$$

It is easy to check, further, that $0 < \phi_m < C/m^{1/2}$ for some positive constant C, so that the series on the right-hand side of (2.18) is convergent, and thus the series on the left-hand side of (2.18), which is a positive quantity, is bounded above by a positive constant independent of n. (To check that $0 < \phi_m < C/m^{1/2}$ for some constant C note that $\ln(\phi_m) = \sum_{\ell=1}^{m}\ln(1 - 1/2\ell)$, use the relation $\ln(1-x) = -x + \mathcal{O}(x^2)$, and, using an integral, estimate $\sum_{\ell=1}^{m} 1/\ell \ge \ln(m)$.) The analyticity of $g_{r2}(\rho)$ for all real $|\rho| < \infty$ then follows as a result of the rapid convergence of the series (2.14).

From the dimensional and dimensionless forms considered above for the kernel function, equations (1.5), (2.4), (2.1), and (2.12), we can write $F_1(z) = f_1(\rho)/a$ and $F_2(z) = f_2(\rho)/a$, where the dimensionless functions f_1 and f_2 are given by

$$f_1(\rho) \equiv -\frac{1}{\pi}\,g_{r1}(\rho) \qquad \text{and} \qquad f_2(\rho) \equiv \frac{1}{\pi}\,g_{r1}(\rho)\ln(2aR) + g_{r2}(\rho) + ig_i(\rho). \tag{2.19}$$

In view of the rapid convergence of the series (2.7) it can be easily established that the function g_i is analytic. Thus, the analyticity of f_1 and f_2, and therefore that of F_1 and F_2, follow from the analyticity results given above for g_{r1} and g_{r2}.

2.3. Evaluation of the thin-wire kernel. As mentioned above, our algorithms for the solution of the Hallén and Pocklington problems rely on the new decomposition (1.5) of the integral kernel. More precisely, our algorithms require explicit, fast, and accurate evaluation of the analytic functions $F_1(z)$ and $F_2(z)$ for values of z close to zero (to allow for explicit treatment to arbitrarily high order of the logarithmic singularity) as well as highly accurate evaluation of the full kernel $G(z)$ for values of z away from the origin. These problems involve a degree of subtlety; the algorithms we devised for their solution are based on a number of representations for these functions and consideration of a number of subcases, as discussed in what follows.

Our numerical solvers require values of the kernel $G(z) = g(\rho)/a$ for all $z \in [-2, 2]$ ($\rho \in [-1/a, 1/a]$) and values of the functions $F_1(z)$ and $F_2(z)$ in subintervals of $[-1/a, 1/a]$ near the origin that are symmetric with respect to the origin. It is clear

that, by symmetry, however, it suffices to evaluate the functions $F_1(z)$ and $F_2(z)$ and the kernel $G(z)$ for points $\rho \geq 0$. For accuracy and efficiency we use two different algorithms within this domain: one for $\rho \in [0, \Delta]$, near the kernel's singularity, and a different one for $\rho \in (\Delta, 1/a]$, away from the singularity. The splitting parameter Δ is a suitably chosen $\mathcal{O}(1)$ constant; based on numerical experimentation we have selected the value $\Delta = 5$, which was used in finding all of the numerical results presented in this paper. In some cases we use separate treatments for evaluation of the real and imaginary parts g_r and g_i of the kernel; see (2.4). Once these functions have been obtained, the corresponding dimensional forms in (1.5) may then be produced as indicated at the end of section 2.2.

[illegible] $g_r(\rho)$ [illegible] $g_i(\rho)$ [illegible] $\rho \in (\Delta, 1/a]$. In this region our integral equation solver does not require separate evaluation of the functions $g_{r1}(\rho)$ and $g_{r2}(\rho)$. Both real and imaginary parts of the kernel are computed by means of the expansion

$$g(\rho) = \frac{\mathrm{e}^{ika\tilde{R}}}{\tilde{R}} \left\{ \sum_{n=0}^{M} \frac{(-1)^n \mathcal{A}_n[(ka)^2]}{2^{2n}(n!)^2 \tilde{R}^{2n}} + i(ka) \sum_{n=1}^{M} \frac{(-1)^n n(2n+1)\mathcal{B}_{n-1}[(ka)^2]}{2^{2n}(n!)^2 \tilde{R}^{2n+1}} + \mathcal{O}\left(\frac{1}{\tilde{R}^{2M+2}} \right) \right\} \tag{2.20}$$

($\tilde{R} = \sqrt{4\rho^2 + 2}$), which, as $M \to \infty$, converges to $g(\rho)$ for every real value of ρ. This expansion results as the finite-sum expression [1, eqn. 10.1.16] for the spherical Hankel function is substituted into Wang's expression (1.7) (thus avoiding evaluation of Hankel functions) and, subsequently, like powers of $\tilde{R}$ are collected. The coefficients $\mathcal{A}_n(x)$ and $\mathcal{B}_n(x)$ in (2.20) are polynomials of degree n; in Appendix A we present all of the polynomials necessary to evaluate the expansion (2.20) up to $M = 10$. With $M = 10$ this expansion yields at least double precision accuracy for all $ka \leq 1$ when $\rho \geq 3$—certainly sufficient for our purposes, given our choice $\Delta = 5$ of the splitting parameter.

[illegible] $g_i(\rho)$ [illegible] $\rho \in [0, \Delta]$. In this domain the imaginary part of the kernel $g_i(\rho)$ is computed using the rapidly convergent expansion (2.7).

[illegible] $g_r(\rho)$ [illegible] $\rho \in [0, \Delta]$. In the region $\rho \in [0, \Delta]$ our approach calls for separate evaluation of the analytic functions $g_{r1}(\rho)$ and $g_{r2}(\rho)$ of (2.12)—to allow for explicit treatment to arbitrarily high order of the logarithmic singularity.

(a) [illegible] $g_{r1}(\rho)$ [illegible] $\rho \in [0, \Delta]$. Since the integrand in (2.16) is analytic and periodic on the domain of integration, numerical evaluation of the integral by means of the trapezoidal rule gives rise to an exponentially convergent algorithm for evaluation of g_{r1}. Naturally, for large values of ρ this procedure would produce significant cancellation errors. For the limited set $[0, \Delta]$ of values of ρ considered here, trapezoidal-rule integration with sufficiently many (rather few!) points yields full double precision accuracy. For efficiency, the function $g_{r1}(\rho)$ is not computed by this method at every point where it is needed; instead this approach is used to precompute values of f_1 on a Chebyshev mesh within $[0, \Delta]$. These values are then used to produce a Chebyshev expansion [8, 12] of g_{r1}—which can, in turn, be utilized to produce values of g_{r1} as needed.

(b) [illegible] $g_{r2}(\rho)$ [illegible] $\rho \in [0, \Delta]$. To evaluate the function $g_{r2}(\rho)$ in this region, we introduce two subpartitions, $\rho \in [0, \delta]$ and $\rho \in (\delta, \Delta]$. The parameter δ is a suitably chosen small constant; based on our experiments we have selected the value $\delta = 1/10$, which was used to find all of the numerical

results presented in this paper. In the interval $(\delta, \Delta]$, g_{r2} can be evaluated, quite simply, by means of the expressions

$$g_{r2}(\rho) = g_r(\rho) + \frac{1}{\pi}\, g_{r1}(\rho) \ln\left(\frac{|\rho|}{R}\right) \tag{2.21}$$

and

$$g_r(\rho) = \frac{1}{2\pi} \int_0^\pi \frac{\cos(2ka\sqrt{\rho^2 + \sin^2\psi})d\psi}{\sqrt{\rho^2 + \sin^2\psi}}. \tag{2.22}$$

As in the case of the integral expression used for evaluation of the function g_{r1}, the integrand in (2.22) is analytic (for real $\rho > 0$) and periodic on the domain of integration, so that the trapezoidal rule converges exponentially fast. On the other hand, the computation of $g_{r2}(\rho)$ in the interval $\rho \in [0, \delta]$ near the singular point is accomplished by direct summation of the series (2.14). The efficiency of this process is greatly improved by a simple observation: since both $P_\nu^\mu(z)$ and $Q_\nu^\mu(z)$ satisfy the recurrence relation [14, eqn. VI(25a)], it follows that so does the second term on the right-hand side of (2.9). It thus may be shown that the function $\Xi_n(\rho) = \rho^{2n} F^n_{-1/2}(2\rho^2 + 1)$ satisfies

$$\Xi_{n+1}(\rho) = -\frac{2n}{2n+1}\,(1 + 2\rho^2)\Xi_n(\rho) - \frac{2n-1}{2n+1}\,\rho^2(1+\rho^2)\Xi_{n-1}(\rho). \tag{2.23}$$

The necessary initial values $\Xi_0(\rho)$ and $\Xi_1(\rho)$ are obtained by the direct evaluation of (2.10), whose coefficients can themselves be generated recursively using the relations $\Gamma(z+1) = z\Gamma(z)$ and $\Psi(z+1) = \Psi(z) + 1/z$ [1]. Using (2.23) the sequence of functions $\Xi_n(\rho)$ can be evaluated accurately and efficiently; clearly knowledge of these functions suffices to evaluate any truncation of the series on the right-hand side of (2.14). The function g_{r2} is precomputed on a Chebyshev mesh within $[0, \Delta]$ by the methods described in the present point (b); these values are then used to produce the Chebyshev expansion of g_{r2}, to accompany the analogous expansion for g_{r1}, discussed in point (a) above.

3. Regularity of solutions. It is well known that the solution J of (1.1) and (1.3) [illegible] (1.2) tends to zero like $\sqrt{1-z^2}$ as $z \to \pm 1$ [4, 7, 13]. Jones [7] established that if $e(z)$ has a bounded derivative, then, under the conditions (1.2), equations (1.1) and (1.3) admit unique integrable solutions $J(z)$. Rynne [13] showed that an appropriate representation of the unknown current distribution is

$$J(z) = \frac{I(z)}{\sqrt{1-z^2}}\,, \quad z \in [-1, 1], \tag{3.1}$$

where the function $I(z)$, which we refer to as the reduced current, is in the Sobolev space $W^{1,p}$ (with $p > 1$), provided the right-hand side of the Hallén equation lies in $W^{2,p}$. The end-point conditions for $I(z)$, which result from the corresponding conditions (1.2) for $J(z)$, are given by

$$I(-1) = I(1) = 0. \tag{3.2}$$

Since, as established below, $I \in C^1[-1, 1]$, provided the function e on right-hand side of (1.1) is sufficiently smooth, it follows that the current J vanishes at the end-points like a square root, as mentioned above.

In this section, defining the reduced Hallén operator by

$$\mathcal{H}\{I\}(z) = \int_{-1}^{1} \frac{G(z-t)I(t)}{\sqrt{1-t^2}}\, dt\,, \quad z \in [-1,1], \tag{3.3}$$

we expand on the work of Rynne mentioned above and further relate the smoothness of a solution of the equation

$$\mathcal{H}\{I\} = h \tag{3.4}$$

to the smoothness of the right-hand side h. Our regularity proof is made possible by the kernel decompositions presented in section 2, together with a result concerning regularity of solutions of Symm's integral equation [15]. The actual result we use on Symm's equation, which is related to a theorem that can be found in [17], does not require an assumption made in that paper on the value of the logarithmic capacity of the interval of definition. Therefore, prior to the main discussion of this section on regularity of solutions of (3.4), which concludes with Theorem 3.7, we provide a brief discussion concerning Symm's equation.

Following [17], we call $C_e^k(2\pi)$ (resp., $C_e^\infty(2\pi)$) the set of all functions v defined on the real line that are [illegible], 2π [illegible], and k times continuously differentiable (resp., infinitely differentiable). For a function $v \in C_e^\infty(2\pi)$ and $s \geq 0$, further, we define the norm $\|\cdot\|_s$ by

$$\|v\|_s^2 = |a_0|^2 + 2\sum_{m=1}^{\infty} m^{2s}|a_m|^2,$$

where a_m denotes the mth cosine coefficient of v:

$$v(\theta) = \frac{1}{2}\, a_0 + \sum_{m=1}^{\infty} a_m \cos(m\theta).$$

The Sobolev space $H_e^s(2\pi)$ of even and 2π-periodic functions, finally, is defined as the completion of $C_e^\infty(2\pi)$ with respect to the norm $\|\cdot\|_s$. The ordinary Sobolev spaces $H^s[a,b]$ will also be used in what follows (see, e.g., [2]), as will the spaces $C^k[a,b]$, $k = 0, 1, \ldots$ or $k = \infty$, of k-times continuously differentiable functions on the interval $[a,b]$.

The 2π-periodic even functions mentioned above arise in our context mainly through composition of various functions defined in the interval $[-1,1]$ with the function $\cos(\theta)$; since such compositions will occur frequently in what follows we introduce a special notation for them: for a function $g : [-1,1] \to \mathbb{R}$ we will write

$$\tilde{g}(\theta) = g(\cos(\theta)). \tag{3.5}$$

Similarly, for an operator $\mathcal{K}$ whose codomain is a space of functions defined in the interval $[-1,1]$, we will denote by $\tilde{\mathcal{K}}$ the operator defined by

$$\tilde{\mathcal{K}}\{I\}(\theta) = \mathcal{K}\{I\}(\cos(\theta)). \tag{3.6}$$

Finally, in what follows $[x]$ denotes the integer part of x. With these notations, we have the following lemma.

LEMMA 3.1. $s \geq 0$ h_0 $[-1,1]$ $\tilde{h}_0 \in H_e^{s+1}(2\pi)$ $\tilde{h}_0(\theta) = h_0(\cos(\theta))$ $I \in C^0[-1,1]$

$$h_0(z) = \int_{-1}^{1} \ln|z-t| \, \frac{I(t)}{\sqrt{1-t^2}} \, dt, \quad z \in [-1,1], \tag{3.7}$$

(a) $\tilde{I} \in H_e^s(2\pi)$ $h_0 \in C^\infty[-1,1]$ $\tilde{I} \in C_e^\infty(2\pi)$
(b) k $s > k + 1/2$ $\tilde{I} \in C^k(2\pi)$ $I \in C^{[k/2]}[-1,1]$ $h_0 \in C^\infty[-1,1]$ $I \in C^\infty[-1,1]$

. The changes of variables $t = \cos\theta$, $z = \cos\alpha$ transform (3.7) into

$$\tilde{h}_0(\alpha) = \int_0^\pi \ln|\cos\alpha - \cos\theta| \tilde{I}(\theta) d\theta \, , \quad \alpha \in \mathbb{R}. \tag{3.8}$$

Since $\tilde{I} \in H_e^0(2\pi)$ and $\tilde{h}_0 \in H_e^0(2\pi)$ we have the H_e^0-convergent cosine expansions

$$\tilde{I}(\theta) = \frac{1}{2} b_0 + \sum_{m=1}^{\infty} b_m \cos(m\theta)$$

and

$$\tilde{h}_0(\alpha) = \frac{1}{2} c_0 + \sum_{m=1}^{\infty} c_m \cos(m\alpha)$$

for these functions. As is well known, in view of (3.8) we have

$$b_m = -\frac{1}{\pi} m c_m \quad \text{for } m \geq 1;$$

see, e.g., [11, 17] or [8, p. 211]. Thus, since $\tilde{h}_0 \in H_e^{s+1}(2\pi)$, we see that $\tilde{I} \in H_e^s(2\pi)$ and point (a) follows. The fact that $\tilde{I} \in C^k(2\pi)$ for $s > k + 1/2$, on the other hand, follows directly from point (a) and Sobolev's lemma. Since $\tilde{I}$ is even and 2π-periodic, finally, it is easy to check that $\tilde{I} \in C^k(2\pi)$ implies that $I(t) = \tilde{I}(\cos^{-1}(t))$ is a $[k/2]$-times continuously differentiable function, and the proof of the lemma is thus complete. □

REMARK 3.2. $\tilde{h}_0$ h_0 $h_0(z) = \sqrt{1-z^2}$ $\tilde{h}_0 \in H_e^1(2\pi)$ $h_0 \notin H_e^1(2\pi)$ $\tilde{h}_0$ h_0 3.8

Continuing with the preliminaries for our main proof, we define the operator

$$\mathcal{T}\{I\}(z) = \int_{-1}^{1} \frac{F_1(z-t)I(t)}{\sqrt{1-t^2}} \ln|z-t| dt = \mathcal{H}\{I\}(z) - \int_{-1}^{1} \frac{F_2(z-t)I(t)}{\sqrt{1-t^2}} \, dt, \tag{3.9}$$

where F_1 and F_2 are the analytic functions in (1.5), and where z, as in many analogous situations throughout this section, lies in the interval $[-1,1]$; $z \in [-1,1]$ Since F_2 is analytic (section 2.2) and since $J = I/\sqrt{1-z^2}$ is integrable it

follows that the last integral in (3.9) is infinitely differentiable. Thus, taking into account our conventions (3.5)–(3.6), we note the following.

REMARK 3.3. [illegible] (3.4) [illegible] $\tilde{h} \in H_e^{s+1}(2\pi)$ [illegible] $\tilde{\mathcal{T}}\{I\} \in H_e^{s+1}(2\pi)$

To establish our regularity result for $I(z)$, let

$$F_{1,2m}(z) = \sum_{k=0}^{m} \frac{F_1^{(2k)}(0)}{(2k)!}\, z^{2k} \tag{3.10}$$

denote the truncated Taylor series of F_1 (it is easy to verify from (2.16) and (2.19) that all of the odd derivatives of F_1 vanish at $z = 0$). Further, define the operators

$$\mathcal{S}_{2m}\{I\}(z) = \int_{-1}^{1} \frac{F_{1,2m}(z-t)I(t)}{\sqrt{1-t^2}}\, \ln|z-t|dt \tag{3.11}$$

and

$$\mathcal{R}_{2m}\{I\}(z) = \int_{-1}^{1} \frac{[F_1(z-t) - F_{1,2m}(z-t)]\, I(t)}{\sqrt{1-t^2}}\, \ln|z-t|dt \tag{3.12}$$

so that

$$\mathcal{T}\{I\} = \mathcal{S}_{2m}\{I\} + \mathcal{R}_{2m}\{I\}. \tag{3.13}$$

For all nonnegative integers m, $\mathcal{R}_{2m}\{I\} \in C^{2m+2}[-1,1]$, so that in view of Remark 3.3 we have the following.

REMARK 3.4. [illegible] (3.4) [illegible] $\tilde{h} \in H_e^{s+1}(2\pi)$ [illegible] s $p_m = \min(s+1,\, 2m+2)$ [illegible] m [illegible] $\mathcal{S}_{2m}\{I\} \in H_e^{p_m}(2\pi)$

In view of (3.10) we have

$$\mathcal{S}_{2m}\{I\} = \sum_{k=0}^{m} \frac{F_1^{(2k)}(0)}{(2k)!}\, \mathcal{V}_{2k}\{I\}, \tag{3.14}$$

where

$$\mathcal{V}_\ell\{I\}(z) = \int_{-1}^{1} \frac{(z-t)^\ell I(t)}{\sqrt{1-t^2}}\, \ln|z-t|dt. \tag{3.15}$$

The following lemma follows directly by differentiation of (3.15).

LEMMA 3.5. [illegible] $I \in C^0[-1,1]$ [illegible] $k \geq 0$ $\mathcal{V}_k\{I\} \in C^k[-1,1]$ [illegible]

$$\mathcal{V}_k^{(k)}\{I\} = k!\,(\mathcal{V}_0\{I\} - \mathcal{W}_k\{I\}), \tag{3.16}$$

[illegible] $\mathcal{W}_k\{I\}$ [illegible]

$$\mathcal{W}_k\{I\} = \left[\sum_{m=1}^{k} \binom{k}{m} \frac{(-1)^m}{m}\right] \cdot \int_{-1}^{1} \frac{I(t)}{\sqrt{1-t^2}}\, dt. \tag{3.17}$$

The connection between Symm's integral equation and Hallén's integral equation stems from the (inductive) proof of the following lemma. (Note that $\mathcal{V}_0$ coincides with the Symm's integral operator on the right-hand side of (3.7).)

LEMMA 3.6. $s \geq 0$ (3.4) $\tilde{h} \in H_e^{s+1}(2\pi)$ $\tilde{\mathcal{V}}_0\{I\} \in H_e^{s+1}(2\pi)$

. By induction in $m = 0, 1 \ldots$ we establish that $\tilde{\mathcal{V}}_0\{I\} \in H_e^{p_m}(2\pi)$ for all integers m, where $p_m = \min(s+1, 2m+2)$ (see Remark 3.4). Taking m such that $2m+2 \geq s+1$ then shows that $\tilde{\mathcal{V}}_0\{I\} \in H_e^{s+1}(2\pi)$, as desired.

For $m = 0$, we note from (3.14) that

$$\mathcal{S}_0\{I\} = F_1(0)\mathcal{V}_0\{I\}.$$

Since $F_1(0) \neq 0$ (see (2.1), (2.16), and (2.19)) and since, by Remark 3.4, $\tilde{\mathcal{S}}_0\{I\} \in H_e^{p_0}(2\pi)$, it follows that $\tilde{\mathcal{V}}_0\{I\} \in H_e^{p_0}(2\pi)$, as needed.

Assume now that $\tilde{\mathcal{V}}_0\{I\} \in H_e^{p_m}(2\pi)$. In the case $2m+2 \geq s+1$ we have $p_{m+1} = p_m$ and the inductive step is complete. Let us consider, then, the case $2m+2 < s+1$. We know that $\tilde{\mathcal{V}}_0\{I\} \in H_e^{p_m}(2\pi)$ and thus, from Lemma 3.5, that $\tilde{\mathcal{V}}_{2k}\{I\} \in H_e^{p_m+2k}(2\pi)$. In particular, for all $k \geq 1$, $\tilde{\mathcal{V}}_{2k}\{I\} \in H_e^{p_m+2}(2\pi)$. In view of the relation (3.14) we have

$$\tilde{\mathcal{S}}_{2m+2}\{I\} = \sum_{k=0}^{m+1} \frac{F_1^{(2k)}(0)}{(2k)!}\, \tilde{\mathcal{V}}_{2k}\{I\}.$$

Since as noted above $F_1(0) \neq 0$, and since by Remark 3.4 $\tilde{S}_{2m+2} \in H_e^{p_{m+1}}(2\pi)$, it follows that $\tilde{\mathcal{V}}_0\{I\} \in H_e^r(2\pi)$, where $r = \min\{p_{m+1}, p_m + 2\} = p_{m+1}$, and thus the inductive step and the proof of the lemma are complete. □

In view of Lemmas 3.1, 3.6, and the Sobolev lemma, the main result of this section now follows directly.

THEOREM 3.7. I (3.4) $\tilde{h} \in H_e^{s+1}(2\pi)$ $\tilde{I} \in H_e^s(2\pi)$ $h \in C^k[-1,1]$ $\tilde{I} \in C_e^{k-2}(2\pi)$ $I \in C^{[(k-2)/2)]}[-1,1]$ $h \in C^\infty[-1,1]$ $\tilde{I} \in C^\infty[0,\pi]$ $I \in C^\infty[-1,1]$

4. Numerical treatment of the Hallén and Pocklington equations. In this section we present our solvers for the Hallén and Pocklington problems. The theoretical equivalence of the Hallén and Pocklington equations is well established [7, 13]; a comparison of the performance of our numerical solvers for these equations is provided in section 5. In section 4.1 we introduce our Hallén solver, which we base on a Chebyshev series representation of the reduced current function (equation (3.1)), the use of which allows us to incorporate explicitly the current's end-point singularities within a high-order treatment. Our Pocklington solver, which results as a natural extension of the methods of section 4.1, is then presented in section 4.2. Finally, in section 4.3, we introduce an alternative formulation of the Hallén problem, which is suitable for use in problems involving very thin wires.

4.1. Hallén solver. Since the singular weight function $(1-t^2)^{-1/2}$ in the integrand of (3.3) can be eliminated by means of the Chebyshev change of variables $t = \cos\theta$ [8, eqn. (1.1)], the set of Chebyshev polynomials $T_n(z)$ is a natural choice of basis functions to represent $I(z)$ for $z \in [-1,1]$. We thus use the discretization

$$I(z) \approx \frac{1}{2}\, b_0 + \sum_{n=1}^{N} b_n T_n(z), \tag{4.1}$$

where the Chebyshev coefficients b_n are the unknowns of the problem. The use of such an expansion is highly advantageous: for the case of an incident plane wave, for example, the solution $I \in C^\infty[-1,1]$ (see section 3), and the Chebyshev series (4.1) thus converges faster than $\mathcal{O}(N^{-m})$ for any positive integer m—i.e., it achieves superalgebraic convergence.

From (4.1), the action of the Hallén operator $\mathcal{H}$ in (3.3) can be approximated by

$$\mathcal{H}\{I\}(z) \approx \frac{1}{2}\, b_0 A_0(z) + \sum_{n=1}^{N} b_n A_n(z), \tag{4.2}$$

where $A_n = \mathcal{H}\{T_n\}$. In Appendix B we tackle the difficult and important problem of evaluating the functions A_n accurately and efficiently. The problems of evaluating both the kernel of the operator $\mathcal{H}$ (section 2.3) and the functions A_n, which present similar challenges, constitute two of the main contributions of this paper.

The discrete form (4.2) of the operator $\mathcal{H}$ is the basis of our collocation method to solve the Hallén problem. Each column of the resulting system matrix corresponds to a particular index n of the function A_n, while the rows are generated by testing (4.2) at $N+1$ values of $z \in [-1,1]$.

REMARK 4.1.

$$z_j = \cos\left(\frac{j\pi}{N}\right), \qquad j = 0,1,2,\ldots,N, \tag{4.3}$$

5

Jones [7] has shown that the solution to the Hallén problem may be obtained by linear superposition. We implement Jones's idea in our context by writing the reduced current as the sum

$$I(z) = \alpha_1 I^{(1)}(z) + \alpha_2 I^{(2)}(z) + I^{(3)}(z), \tag{4.4}$$

where $\mathcal{H}\{I^{(1)}\}(z) = \cos kz$, $\mathcal{H}\{I^{(2)}\}(z) = \sin kz$, and

$$\mathcal{H}\{I^{(3)}\}(z) = -4\pi i \int_{-1}^{z} e(t)\sin[k(z-t)]dt; \tag{4.5}$$

the values of the constants α_1 and α_2 follow from the end-point conditions (3.2). Since, as is easy to check, we have $I^{(1)}(1) = I^{(1)}(-1)$ and $I^{(2)}(1) = -I^{(2)}(-1)$, it follows that

$$\alpha_1 = -\frac{1}{2}\left(\frac{I^{(3)}(1) + I^{(3)}(-1)}{I^{(1)}(1)}\right) \quad \text{and} \quad \alpha_2 = -\frac{1}{2}\left(\frac{I^{(3)}(1) - I^{(3)}(-1)}{I^{(2)}(1)}\right). \tag{4.6}$$

To obtain I numerically we use a representation of the form (4.1) for each one of the quantities $I^{(1)}$, $I^{(2)}$, and $I^{(3)}$. The corresponding Chebyshev coefficients $b_n^{(j)}$ of $I^{(j)}(z)$ $(n = 0, 1, \dots)$ are obtained from the equations for the $I^{(j)}$'s (equation (4.5) and immediately above) and repeated use of the LU decomposition of the $(N+1)\times(N+1)$ matrix that discretizes the operator $\mathcal{H}$ (as described earlier in this section), together with back- and forward substitution for $j = 1, 2, 3$. Once these Chebyshev coefficients have been obtained, the constants α_1 and α_2 are calculated by means of (4.6), using the Chebyshev series to produce $I^{(j)}(\pm 1)$. The reduced current I is then found by summation of its Chebyshev series, whose coefficients are given by

$$b_n = \alpha_1 b_n^{(1)} + \alpha_2 b_n^{(2)} + b_n^{(3)}, \qquad n = 0, 1, \dots, N. \tag{4.7}$$

4.2. Pocklington solver. A method for solving the Pocklington problem embodied in (1.1) and (1.2), which uses, again, a representation of the form (4.1) and the coefficients b_n as unknowns, is readily derived from results presented in section 4.1. To obtain such a method we first represent the functions $A_n(z)$ by truncated Chebyshev expansions

$$A_n(z) \approx \frac{1}{2}\, a_0^{(n)} + \sum_{m=1}^{N} a_m^{(n)} T_m(z). \tag{4.8}$$

The coefficients in the series (4.8) can be obtained directly from an (FFT-based) Chebyshev transform of the columns of the matrix for the Hallén problem—which, by construction, contain the point values of the functions A_n at the Chebyshev points (4.3).

Using the coefficients in (4.8) we can then obtain the Chebyshev series coefficients of $(\partial^2/\partial z^2 + k^2)A_n(z)$,

$$c_m^{(n)} = \frac{2}{\pi}\int_{-1}^{1} \frac{T_m(z)}{\sqrt{1-z^2}} \left(\frac{\partial^2}{\partial z^2} + k^2\right) A_n(z)\, dz = k^2 a_m^{(n)} + 4 \sum_{\ell=1}^{\left[\frac{N-m}{2}\right]} \ell(\ell+m)(2\ell+m) a_{2\ell+m}^{(n)}, \tag{4.9}$$

which is valid for $m = 0, 1, 2, \dots$. The second derivative of the Chebyshev polynomial in (4.9) is evaluated by means of the relation [8, p. 38].

The Pocklington system matrix contains the quantity $c_m^{(n)}$ in the mth row and nth column. Since it is necessary to enforce vanishing of the reduced current at the end-points $z = \pm 1$ we only use the first $N-1$ of these equations to allow for the two additional equations enforcing the end-point conditions (3.2):

$$\frac{1}{2}\, b_0 + \sum_{n=1}^{N} b_n = 0 \quad \text{and} \quad \frac{1}{2}\, b_0 + \sum_{n=1}^{N} (-1)^n b_n = 0. \tag{4.10}$$

The right-hand side of the system consists of the first $N-1$ Chebyshev coefficients of $-4\pi ike(z)$ and zeros in the last two positions. The system is solved directly by an LU decomposition.

4.3. Alternative Hallén method for very thin wires. For particular physical cases involving very thin wires ($a \ll$ wire-length, independently of the value of ka), the rate of convergence to the solution may be substantially improved by means of a distribution of discretization points within the wire different from those used

in the previous sections. We speculate that the slower convergence in the absence of such change of variables must be the result of a small-weight singularity in the thin-wire solutions located near the origin on the imaginary axis (associated with a corresponding singularity, the kernel itself has at $(z - z') = 2ai$; see (1.4)). While the methods outlined in sections 4.1 and 4.2 exhibit superalgebraic convergence even for such cases, use of the point-distributions described in what follows, which are more concentrated on the end-points than those considered in previous sections, result in significant additional convergence acceleration. For the sake of brevity, here we restrict attention to the Hallén equation; the development of this method proceeds in analogy to that presented in section 4.1.

In contrast with the Chebyshev (cosine) change of variables used earlier in this text, here we introduce the coordinate transformation

$$z = \frac{2\cos w}{1 + \cos^2 w}, \tag{4.11}$$

which maps $w \in [0, \pi]$ to $z \in [-1, 1]$ and which, like the cosine change of variables used earlier, eliminates the end-point singularities in the integrand of (3.3). The cosine change of variables results in a locally quadratic clustering of points near the ends of the wire; the clustering of points near the ends of the wire induced by the transformation (4.11), on the other hand, is quartic. It is precisely this property which gives rise to the improved convergence rates of the solution for very thin wires. The reduced current is an even, periodic function of the new variables, and thus it may be approximated by the cosine series

$$I\left(\frac{2\cos w}{1 + \cos^2 w}\right) \approx \frac{1}{2} b_0 + \sum_{n=1}^{N} b_n \cos(nw), \tag{4.12}$$

where the coefficients b_n are the unknowns of the problem. For $I(z) \in C^{m+1}[-1, 1]$, the error of the cosine series (4.12) is $\mathcal{O}(N^{-m})$ for all $w \in [-\pi, \pi]$. In particular, for $I(z) \in C^{\infty}[-1, 1]$, the cosine series (4.12) converges superalgebraically to $I(z)$. As discussed in section 5.1, for thin wires, the representation (4.12) converges much more quickly than the expansion (4.1).

In the new variables, the Hallén operator may be approximated by the discrete form

$$\mathcal{H}\{I\}\left(\frac{2\cos w}{1 + \cos^2 w}\right) \approx \frac{1}{2}\, b_0 B_0(w) + \sum_{n=1}^{N} b_n B_n(w). \tag{4.13}$$

The integral functions resulting from the method may be written as

$$B_n(w) = -2 \int_0^{\pi} \frac{\sin u \cos(nu)}{1 + \cos^2 u}\, G\left(\frac{2\cos w}{1 + \cos^2 w} - \frac{2\cos u}{1 + \cos^2 u}\right) du. \tag{4.14}$$

Much in the same way as in section 4.1, the discrete form of the operator (4.13) is the basis for a collocation method to solve the Hallén problem. The collocation points are chosen to be the $N + 1$ uniformly spaced values of $w \in [0, \pi]$, which, as will be demonstrated in section 5, results in a well-conditioned system. The total current is found by our adaptation of Jones's method, as outlined in (4.4) and below.

5. Results and discussion. In addition to several efficient novel algorithms for wire problems, the contribution [4] presents an excellent survey of modern methods in the area; we therefore use the results in that reference to demonstrate the improvements that can be offered by our algorithms. We note that only the Pocklington equation is treated in [4], and, further, that our methods differ substantially from those presented in that contribution. In fact, several methods are discussed in [4], some which exhibit $\mathcal{O}(N^{-1})$ or $\mathcal{O}(N^{-2})$ convergence in the solution, and some methods which exhibit much faster convergence. In particular, the hp-geometric Galerkin scheme introduced in [4] appears to exhibit superalgebraic convergence and is, quite definitely, the most efficient and accurate of the methods available previously. In what follows, we therefore compare our results to hp-geometric Galerkin data in every instance for which such data was made available in [4]; our results compare much more favorably to all others in the literature.

The identification of parameters and unknowns between [4] and the present text is as described in Table 5.1. In that reference, the right-hand side of the Pocklington equation is taken to equal unity in all cases. To account for this prescription, as well as the different kernel normalization and wire-length, we set $\mathcal{H}\{I^{(3)}(z)\} = \pi/k^2$ for the Hallén problem, and $e(z) = i/(4k)$ for the Pocklington problem; with these definitions the current J we consider matches that of [4].

In this section the maximum relative errors e_{max} are defined by

$$e_{max} = \frac{\max_j |J(z_j) - J_{ref}(z_j)|}{\max_j |J_{ref}(z_j)|}. \tag{5.1}$$

The reference data sets $J_{ref}(z_j)$ we used for evaluation of e_{max} were obtained using large numbers $N+1$ of unknowns, to ensure high accuracies. The numerical values of e_{max} displayed in the tables, in turn, were obtained by evaluating J and J_{ref} at sufficiently fine Chebyshev meshes $\{z_j\}$, so that the quantity $|J(z) - J_{ref}(z)|$, which experiences rapid oscillations near the wire end-points, is fully resolved, and thus allows for accurate computation of e_{max}. See the captions of Tables 5.2 to 5.6 for full details on the meshes used for evaluation of J_{ref} and e_{max}. Details concerning the accurate evaluation of the total current $J(z) = I(z)/\sqrt{1-z^2}$ from the reduced current $I(z)$ are presented in Appendix C; here we simply point out that a straightforward division does give rise to significant error increases—unbounded, in fact, as the evaluation points tend toward the end-points. The strategies described in Appendix C completely resolve this difficulty and result in currents J that are as accurate as the corresponding reduced currents I.

In what follows we first examine the convergence rates of our algorithms, with attention to the relative advantages offered by our Hallén, Pocklington, or alternative Hallén approaches. All computations presented here were performed on an AMD 2600+ computer system. Solutions of all linear systems were obtained by means of the LU-based direct solvers provided in the LAPACK linear algebra package

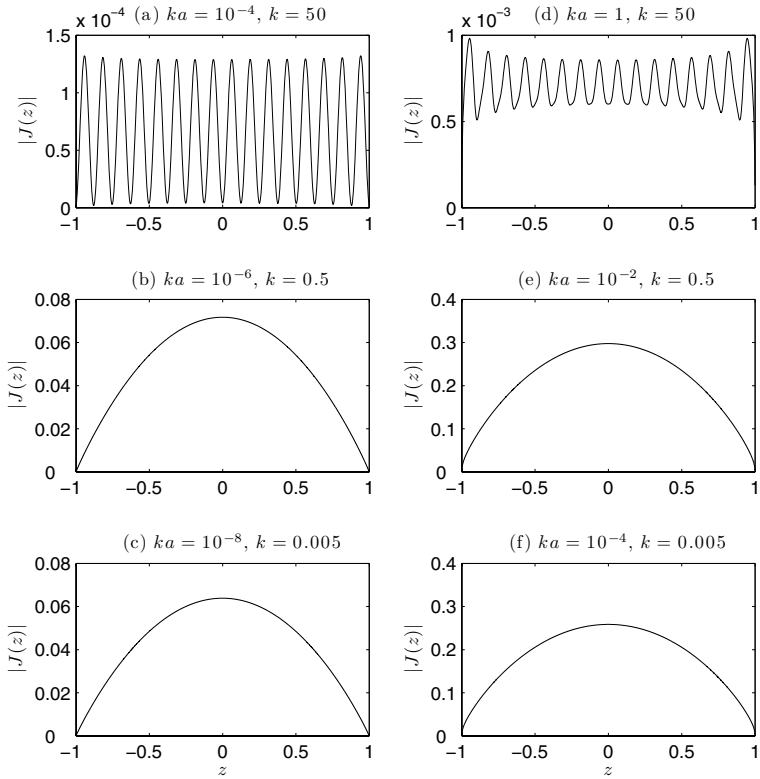

FIG. 5.1. *Profiles of the current function $J(z)$ studied by Davies, Duncan, and Funken* [4].

(www.netlib.org/lapack/). In a rather comprehensive set of tests that we consider, four-digit solutions, for example, were found in a execution time of at most four seconds; in most cases computing time for a four-digit solve was a fraction of a second. As shown below, further, in all cases much higher accuracies result in very small additional computing times: see Tables 5.2 to 5.6 in section 5.1; in all tables the execution time is denoted by T.

5.1. Numerical results. To demonstrate the superalgebraic convergence of our methods we consider a set of six test cases put forward in [4], which span a broad range of physical configurations. The profiles of the total currents J for these cases are displayed in Figure 5.1; note that all cases in the left-hand column of that figure have radii $a = 0.5 \cdot 10^{-6}$, while those in the right-hand column have radii $a = 0.5 \cdot 10^{-2}$. The tables presented in this section display, among other quantities, the computational times required to obtain the Chebyshev series of the reduced current I; in all cases the table captions list the (very small) corresponding additional times required to evaluate the current J on a fine Chebyshev grid (of a size also listed on the table captions); see also Appendix C. Note, however, that in the context of our algorithm, it is possible (and most efficient) to use the reduced current I, not the physical current J, to evaluate the scattered fields in space. Thus, if the quantity of interest is the field scattered by the wire, the calculation of the current J is unnecessary.

TABLE 5.2

Alternative Hallén solver for case (a)*:* $k = 50$ *and* $ka = 10^{-4}$ *(very thin wires). The current profile is shown in Figure* 5.1(a)*. An* $N + 1$*-term cosine series is used, and the algorithm is run with integration parameters* M_1 *and* M_2 *and splitting parameter* $\Delta = 5$ *(see Appendix* C*). The quantity* C_N *is the estimate of the reciprocal condition number provided by the linear algebra package LAPACK. The error oscillations are fully resolved: the maximum relative error* e_{max} *(see* (5.1)*) was obtained by evaluation of* J *and* J_{ref} *on a* $2^{13} + 1$*-point Chebyshev grid; the reference solution* J_{ref} *was obtained with* $N = 240$*,* $M_1 = 2^{12}$*, and* $M_2 = 2^9$*. The evaluation of* J *at the* $2^{13} + 1$*-point Chebyshev grid required approximately* 0.07 *s of computational time in addition to the tabulated computing times. Note from Figure* 5.1(a) *that the maximum value of the solution is of the order of* 10^{-4} *so that the maximum absolute errors decrease up to order of* 10^{-12}*—consistent, for the* 16*-digit accuracy used, with a condition number of the order of* 10^{-4} *listed above.*

130	2^9	2^3	1.50	$2.0 \cdot 10^{-3}$	$4.2 \cdot 10^{-4}$
140	2^{10}	2^3	3.43	$6.1 \cdot 10^{-5}$	$3.8 \cdot 10^{-4}$
150	2^{11}	2^4	8.11	$3.2 \cdot 10^{-6}$	$3.6 \cdot 10^{-4}$
160	2^{11}	2^4	9.18	$7.3 \cdot 10^{-8}$	$3.4 \cdot 10^{-4}$
170	2^{11}	2^4	10.29	$2.0 \cdot 10^{-8}$	$3.2 \cdot 10^{-4}$

(a) $ka = 10^{-4}$, $k = 50$. The current profile is shown in Figure 5.1(a). The relative error and the reciprocal matrix condition number (estimated by LAPACK) are presented in Table 5.2 for increasing values of the index N of truncation of the solution's cosine expansion. For this case, a very thin wire problem, we used the alternative Hallén method described in section 4.3. We see from Table 5.2 that, for example, full single precision accuracy results from this method in an $N = 160$, 9-second computation. (Use of the regular Hallén and Pocklington methods of sections 4.1 and 4.2 requires much larger numbers of unknowns, of the order of $N = 800$, to achieve comparable accuracies.) Note that the condition number remains virtually constant throughout the table. A graphical solution J, consistent with our Figure 5.1(a), was given in [4] (case $a = 1e - 6$, $\omega = 100$ in that work), but errors were not reported there for this case. Through comparison with cases (c) and (d) below we speculate that the hp-geometric Galerkin method of [4] in the present case (a) requires a number of the order of at least $N = 350$ unknowns to achieve errors of the order of 10^{-5}—since, in the present case, the discretization needs to resolve both the extreme end-point singularities arising from the very thin wire (for which hp-geometric Galerkin requires $N = 50$ in case (c)) as well as the higher frequency $k = 50$ (which for hp-geometric Galerkin requires $N = 350$ in case (d)). Taking into account, further, the superalgebraic convergence (in M_1 and M_2) of the integration methods we use versus the third-order or lower convergence inherent in previous methods (see paragraph (b) in the introduction), we expect the approaches in the present paper should prove significantly advantageous over most solvers otherwise available.

(b) $ka = 10^{-6}$, $k = 0.5$. The current profile is shown in Figure 5.1(b). Statistics for this case are virtually identical to those of case (c). A graphical solution J, consistent with our Figure 5.1(b), was given in [4] (case $a = 1e - 6$, $\omega = 1$ in that work). In that reference, errors were reported for slower numerical methods (which require approximately 100 unknowns to produce errors of order 10^{-3}), but not for the hp-geometric Galerkin approach, which is the main subject of our comparison.

(c) $ka = 10^{-8}$, $k = 0.005$. The current profile is shown in Figure 5.1(c). The relative error and the reciprocal matrix condition number are presented

TABLE 5.3

Same as Table 5.2*, with the following exceptions:* $k = 0.005$*,* $ka = 10^{-8}$*; the current profile is shown in Figure* 5.1(c)*; the reference solution* J_{ref} *was obtained with* $N = 140$*,* $M_1 = 2^{12}$*, and* $M_2 = 2^9$*; in this case, in which the maximum value of the solution is of order* 0.08*, the condition number is not consistent with stagnation at the level* 10^{-8} *—which, in fact, does not occur: a certain oscillatory behavior exhibited by the cosine series coefficients, shown in Figure* 5.2*, gives rise to nonmonotone convergence.*

N	M_1	M_2	T (s)	e_{max}	C_N

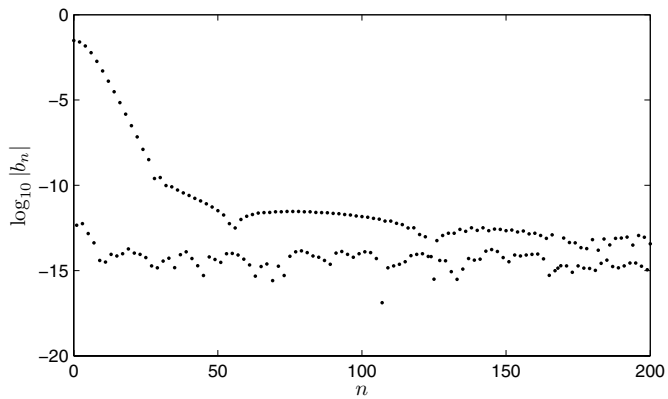

FIG. 5.2. *Cosine series coefficients of the alternative Hallén formulation for case* (c) *with* $k = 0.005$*,* $ka = 10^{-8}$*; a thin wire case (*$a \ll 1$*). Virtually identical behavior is seen for case* (b)*. The coefficients are divided into two sets: the even-index coefficients are clustered in the upper set, and the odd-index coefficients in the lower set. Note that the even set demonstrates extremely rapid convergence for* $0 \leq n \leq 50$*, followed by a regime of slower convergence. We speculate this must be the result of a small-weight singularity in the thin-wire solutions located near the origin on the imaginary axis (associated with a corresponding singularity the kernel itself has at* $(z - z') = 2ai$*), which results in a decrease of the convergence rates for* $n > 50$*; see Table* 5.3*.*

in Table 5.3. For this case, yet again a very thin wire problem, we used the alternative Hallén method described in section 4.3. We see from Table 5.3 that, for example, single precision accuracy results from this method for $N = 40$; use of the regular Hallén and Pocklington methods of sections 4.1 and 4.2 requires much larger numbers of unknowns, of the order of $N = 500$, to achieve comparable accuracies. Note that the condition number remains virtually constant throughout the table. A graphical solution J, consistent with our Figure 5.1(c), was given in [4] (case $a = 1e{-}6$, $\omega = 0.01$ in that work). Errors of the order of 10^{-6} were reported in that reference from use of the hp-geometric Galerkin approach with 50 unknowns; Table 5.3 shows an accuracy of the order of 10^{-6} for $N = 30$ unknowns.

TABLE 5.4

Hallén and Pocklington solvers for case (d)*: $k = 50$, $ka = 1$. The current profile is shown in Figure* 5.1(d). *An $N + 1$-term Chebyshev is used, and the algorithm is run with integration parameters M_1 and M_2 and splitting parameter $\Delta = 5$. The quantity C_N is the estimate of the reciprocal condition number provided by the linear algebra package LAPACK. The error oscillations are fully resolved: the maximum relative error e_{max} was obtained by evaluation of J and J_{ref} on a $2^{10} + 1$-point Chebyshev grid; the reference solution J_{ref} was obtained by means of the Hallén solver with $N = 140$, $M_1 = 2^{12}$, and $M_2 = 2^9$. The evaluation of J at the $2^{10} + 1$-point Chebyshev grid required approximately* 0.004 *s of computational time in addition to the tabulated computing times. Note that in this case, in which the maximum value of the solution is of order 10^{-3}, the solution errors are smaller than what might have been expected for the condition numbers reported in the table.*

(d) $ka = 1$ $k = 50$. The current profile is shown in Figure 5.1(d), and numerical results for the regular Hallén and Pocklington methods of sections 4.1 and 4.2 are presented in Table 5.4. Both methods produce errors of the order of 10^{-7} for $N = 70$, and yield double precision accuracy for $N = 120$. The hp-geometric Galerkin approach of [4] (case $a = 0.01$, $\omega = 100$ in that work) yields results with an accuracy of 10^{-5} using a number of the order $N = 350$ unknowns.

(e) $ka = 10^{-2}$ $k = 0.5$. The current profile is shown in Figure 5.1(e), and numerical results for the regular Hallén and Pocklington methods of sections 4.1 and 4.2 are presented in Table 5.5. Both methods produce virtually identical results in this case, with rapid convergence in N to nearly double precision accuracy. In particular, Table 5.5 shows results with errors of 10^{-5} and 10^{-6} for $N = 30$ and

TABLE 5.6

Same as Table 5.4*, with the following exceptions:* $k = 0.005$*,* $ka = 10^{-4}$*; the current profile is shown in Figure* 5.1(f)*; the reference solution* J_{ref} *was obtained by means of the Pocklington solver with* $N = 140$*,* $M_1 = 2^{12}$*, and* $M_2 = 2^9$*; the maximum value of the solution is of order* 0.3*—the detailed discussion of conditioning and errors is given in the text.*

$N = 40$, respectively. The hp-geometric Galerkin approach of [4] (case $a = 0.01$, $\omega = 1$ in that work) yields results with an accuracy of 10^{-4} using a number of the order $N = 40$ unknowns.

(f) $ka = 10^{-4}$ $k = 0.005$. The current profile is shown in Figure 5.1(f), and numerical results for both methods are presented in Table 5.6. This is the only case in which we have found that the regular Pocklington method is clearly superior to the Hallén method. While both methods exhibit rapid convergence, the Hallén approach appears to break down beyond a relative error $\mathcal{O}(10^{-9})$, while the relative error of the Pocklington method continues to decrease to $\mathcal{O}(10^{-11})$. The reason for this is subtle: the current generated by the Hallén method relies on a superposition of solutions, shown in (4.4). We have noted that, under some circumstances, a subtractive cancellation occurs here that limits the accuracy obtainable using finite precision arithmetic. In view of these considerations, in this table, unlike all others, we use the results provided by the Pocklington method to produce the reference solution J_{ref}. A graphical solution J, consistent with our Figure 5.1(f), was given in [4] (case $a = 0.01$, $\omega = 0.01$ in that work), but errors were not reported in that reference for this case.

5.2. Conclusions. In contrast to published reports, we have found our Hallén and Pocklington approaches numerically equivalent in many situations. For very thin wires, the alternative method developed in section 4.3 (which gives rise to higher mesh-densities at the end-points than those implicit in the Chebyshev method of sections 4.1 and 4.2) results in significant efficiency improvements. The numerical results we presented show that, in many cases, to achieve a given accuracy, the numbers N of unknowns required by our codes are up to five times smaller than those required by the best solvers previously available. The short computing times demonstrated in section 5.1 arise not only from use of small numbers of unknowns but also from the small numbers M_1 and M_2 of integration points required for construction of the discretized operator. Unfortunately, timings have not been reported previously in the literature. In view of the superalgebraic convergence in the numbers M_1 and M_2 (see point (d) in the introduction) and the small numbers N of unknowns required by the present solvers, we suggest that these methods should be significantly faster than others available previously.

Appendix A. Asymptotic expansion of the kernel. We present the exact polynomials required to evaluate the asymptotic form of the thin-wire kernel given in (2.20) to order $M = 10$.

Appendix B. Numerical evaluation of the A_n and B_n functions. In this section we discuss the efficient computation of the quantities A_n and B_n in (4.2) and (4.14), respectively. The numerical evaluation of these functions is complicated not only by the logarithmic singularity of the kernel at $z = t$ (resp., $\rho = 0$) but also by an interesting near-singular behavior of the kernel functions F_1 and F_2 in a neighborhood of the singularity. As the wire radius a decreases, the real part of each of the kernel functions F_1 and F_2 on the domain $[-1/a, 1/a]$ contains increasingly rapid variations, developing a sharp peak in a neighborhood of $z - t = \mathcal{O}(a)$. This behavior, which is closely related to the complex singularities mentioned in section 4.3, is depicted in Figure B.1 for the function $g_{r1}(\rho)$—which is related to the dimensional kernel function $F_1(z - t)$ by (2.19). Qualitatively similar behavior is exhibited by the function F_2. While these functions remain analytic, their resolution with an evenly spaced FFT may require prohibitively large numbers of sampling points. In what follows we outline our procedure for simultaneously treating the unusual combination in the kernel of a logarithmic singularity and the sharp peaks discussed above.

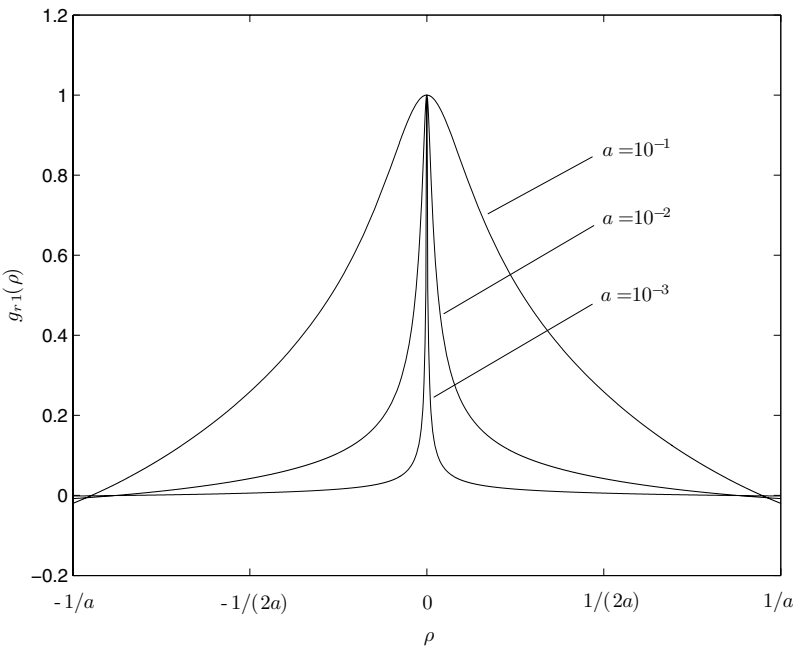

FIG. B.1. *The nondimensional kernel function $g_{r1}(\rho)$ for $k = 1$ and $a = 10^{-1}$, $a = 10^{-2}$ and $a = 10^{-3}$. Both kernel functions $g_{r1}(\rho)$ and $g_{r2}(\rho)$ exhibit a sharp peak in the neighborhood $\rho = \mathcal{O}(1)$.*

B.1. Evaluation of the functions A_n. In what follows we are concerned with the evaluation of the integrals

$$A_n(z) = \mathcal{H}\{T_n\}(z) = \int_{-1}^{1} [F_1(z-t)\ln|z-t| + F_2(z-t)]\,\frac{T_n(t)}{\sqrt{1-t^2}}\,dt. \tag{B.1}$$

Since $G(z)$ is an even function of z, it easy to verify that the functions A_n satisfy

$$A_n(-z) = (-1)^n A_n(z) \tag{B.2}$$

so that, although the values of the A_n's in the full interval $z \in [-1, 1]$ are required by our method, actual integrations to produce these functions numerically need only be performed for $z \in [0, 1]$.

To evaluate the functions A_n on a Chebyshev grid (see Remark 4.1) and to eliminate the end-point singularities in (B.1) we introduce the substitutions $z = \cos\alpha$ and $t = \cos\theta$, which reduce the corresponding integrals to

$$A_n(\cos\alpha) = \int_0^{\pi} G(\cos\alpha - \cos\theta)\cos n\theta d\theta. \tag{B.3}$$

The irregular features in the integrand of (B.3), which arise from corresponding features of F_1 and F_2, can be resolved with a reasonable expense by means of a local integration scheme using a fine grid on the domain $|z-t| \le 2a\Delta$, where Δ is the splitting parameter defined in section 2.3. Outside this domain, integration on a much coarser grid is sufficient to achieve the desired accuracy.

In detail, we partition the integration domain $[0,\pi]$ into two regions, the fine- and coarse-discretization domains, that correspond to regions of fast and slow variations of the integrand in (B.1) and (B.3). To define the fine-discretization region, in most cases it is sufficient to restrict the angular coordinate in (B.3) to the domain $\theta \in [\theta_1, \theta_2]$, with $\theta_1 = \cos^{-1}(z + 2a\Delta)$ and $\theta_2 = \cos^{-1}(z - 2a\Delta)$. One notable exception occurs when $z + 2a\Delta > 1$; this special case is treated by setting $\theta_1 = 0$. The analogous case, when $z - 2a\Delta < 1$, does not occur in our method, since values of (B.3) for $z \in [-1, 0)$ are obtained by the symmetry relation (B.2). Setting $\varepsilon_1 = \alpha - \theta_1$ and $\varepsilon_2 = \theta_2 - \alpha$, the domain of integration is thus partitioned as

$$[0,\pi] \equiv [0, \alpha - \varepsilon_1] \cup [\alpha - \varepsilon_1, \alpha] \cup [\alpha, \alpha + \varepsilon_2] \cup [\alpha + \varepsilon_2, \pi]\,. \tag{B.4}$$

Owing to (B.2), we have the restriction $\alpha \in [0, \pi/2]$. In the fine-discretization region $\theta \in [\alpha - \varepsilon_1, \alpha + \varepsilon_2]$ we develop a special integration method which treats the logarithmic singularity of G. Outside of this region, different methods are applied on a coarse grid. [illegible] $\theta \in [0, \alpha - \varepsilon_1] \cup [\alpha + \varepsilon_2, \pi]$. In this region, which lies away from the $\theta = \alpha$ singularity, the kernel G is smooth and contributions to the A_n functions are computed by means of an FFT-based $M_1 + 1$-point Clenshaw–Curtis integration rule on each of the two relevant subintervals.

[illegible] $\theta \in [\alpha - \varepsilon_1,\ \alpha + \varepsilon_2]$. We illustrate the method of computation of contributions to $A_n(\cos\alpha)$ for the left-hand interval $\theta \in [\alpha - \varepsilon_1, \alpha]$; results for the right-hand interval $\theta \in [\alpha, \alpha + \varepsilon_2]$ are obtained in an analogous fashion. We map $x \in [-1, 1]$ to $\theta \in [\alpha - \varepsilon_1, \alpha]$ with the change of variables $\theta = \varepsilon_1(x - 1)/2 + \alpha$, and for each n, we introduce the approximation

$$F_1(\cos\alpha - \cos\theta)\cos n\theta \approx \frac{1}{2}\, e_0^{(n)}(\alpha) + \sum_{m=1}^{M_2} e_m^{(n)}(\alpha) T_m(x); \quad \theta = \theta(x). \tag{B.5}$$

A similar expansion of length $M_2 + 1$ for $F_2(\cos\alpha - \cos\theta)\cos n\theta$ is introduced. The quantity $M_2 + 1$, which is independent of M_1, is the length of the fast cosine transform used to compute the series coefficients in this region. The integrals involving F_2 are computed using an FFT-based $M_2 + 1$-point Clenshaw–Curtis integration rule. In view of (1.5), the integral involving F_1 possesses a logarithmic singularity at $x = 1$ which, for high-order integration, requires special treatment. The method we use to resolve this singularity integrates the logarithmic terms exactly: For $\alpha \neq 0$ and $\alpha = 0$ we use the identities

$$\ln|\cos\alpha - \cos\theta| = \ln\left|\frac{\cos\alpha - \cos\theta}{x - 1}\right| + \ln|x - 1| \tag{B.6}$$

and

$$\ln|1 - \cos\theta| = \ln\left|\frac{1 - \cos\theta}{(x-1)^2}\right| + 2\ln|x - 1|\,, \tag{B.7}$$

respectively. The Taylor expansion

$$\cos\alpha - \cos\theta = \frac{\varepsilon_1}{2}\,(x-1)\sin\alpha + \frac{\varepsilon_1^2}{8}\,(x-1)^2\cos\alpha + \mathcal{O}\big(\varepsilon_1^3(x-1)^3\big) \tag{B.8}$$

then shows that the first logarithmic term on the right-hand side of each of (B.6) and (B.7) is regular, so that the integrals involving those terms may be computed with

high-order accuracy by means of the $M_2 + 1$-point Clenshaw–Curtis integration rule. The singular terms are integrated using the rule

$$\int_{-1}^{1} F_1(\cos\alpha - \cos\theta)\cos n\theta \ln|x-1|\,dx \approx \frac{1}{2}\,w_0 e_0^{(n)}(\alpha) + \sum_{m=1}^{M_2} w_m e_m^{(n)}(\alpha), \tag{B.9}$$

where w_m are the integration weights

$$w_m = \int_{-1}^{1} T_m(t)\ln|1-t|\,dt. \tag{B.10}$$

A closed-form expression for the weights w_m may be derived by making the substitution $t = \cos 2\psi$ in (B.10), expanding the terms $\cos m\psi$ in powers of $\cos\psi$, and applying the identity [6, 4.387] on a term-by-term basis. This leads to the results $w_0 = 2\ln 2 - 2$, $w_1 = -1$, and, for $m > 1$,

$$\begin{aligned} w_m =& \frac{[1+(-1)^m]\ln 2}{1-m^2} \\ &- 2m\sum_{n=0}^{m} \frac{(-1)^n 2^{2m-2n}}{(m-n+1)(2m-n)} \left(\begin{array}{c} 2m-n \\ n \end{array} \right) [\gamma + \Psi(m-n+2)]\,, \end{aligned} \tag{B.11}$$

where $\gamma = 0.57721566\ldots$ is Euler's constant. In our implementation, the weights (B.11) have been precomputed to machine precision for all values of m up to $m = 2^9$ and saved in a data file which is read into memory every time the code is executed. The logarithmic integrals over the subinterval $\theta \in [\alpha, \alpha + \varepsilon_2]$ are computed in a similar manner, with integration weights that can be obtained from the data set above, namely,

$$\int_{-1}^{1} T_m(t)\ln|1+t|\,dt = (-1)^m w_m. \tag{B.12}$$

B.2. Integration for the alternative Hallén method. We now consider the efficient evaluation of the B_n functions defined in (4.14); these must obey the symmetry relations

$$B_n(w + \pi/2) = (-1)^n B_n(w), \qquad w \in [0, \pi/2]; \tag{B.13}$$

compare with (B.2). Thus, numerical integration of the B_n functions need only be performed for uniformly spaced values of $w \in [0, \pi/2]$. The integration of the B_n functions follows in close analogy to the treatment of the A_n functions, outlined in Appendix B.1.

Appendix C. Computation of the total current. As mentioned in section 5, the accurate evaluation of the total current $J(z) = I(z)/\sqrt{1-z^2}$ from the reduced current $I(z)$ requires special consideration: clearly the error in the current obtained by straightforward division tends to infinity as the evaluation points tend toward the end-points. To resolve this difficulty it is convenient to rewrite $J(z)$ in terms of a trigonometric series, and avoid the explicit division by the quantity $\sqrt{1-z^2}$. In what follows, we derive a representation for the total current which is used to evaluate currents arising from all three methods of solution presented in this paper.

With the substitution $z = \cos\theta$ in (3.1) and (4.1), an approximation for the total current is readily derived by exploiting the orthogonality of the trigonometric functions:

$$J(\cos\theta) \approx \sum_{n=1}^{N+1} c_n \sin(n\theta). \tag{C.1}$$

The coefficients in (C.1) are given in terms of the b_n coefficients in (4.1) by $c_1 = b_0$, $c_2 = 2b_1$, and

$$c_{n+1} = 2b_n + c_{n-1}, \qquad 2 \le n \le N. \tag{C.2}$$

The coefficients c_n for $n \ge 2$ are easily found by forward recursion using (C.2). Accurate values of the total current on a , Chebyshev grid (which is necessary to obtain maximum relative errors owing to fast error oscillations) are obtained by means of a zero-padded fast-sine-evaluation of the series (C.1).

In the context of the very thin wire algorithm, in turn, it is possible to derive a formula analogous to (C.1) for the current J in the w variables to produce this quantity everywhere in the wire. However, the current J in the w variables vanishes quadratically at the end-points, while it only vanishes linearly at those points in the θ variables. The vanishing order at the end-points is related to ill-conditioning in evaluation of the J function: evaluation of quadratically vanishing quantities on the basis of cosine coefficients of order 1 is clearly more ill-conditioned than evaluation of corresponding quantities that only vanish linearly at the end-points. Thus, higher accuracy can be extracted for J if the reduced current function I in w-space is first transformed to θ-space and then a sine series of J in θ is used as earlier in this section. In detail, given the N-term cosine series for the reduced current in (4.12), values of I are computed at the set of N_2 Chebyshev points (see (4.3)) for $N_2 \gg N$—which can be accomplished by an appropriately zero-padded FFT, together with low-order polynomial interpolation. For the results presented in this work, we have used $N_2 = 2^{10} + 1$. Using this data the b_n coefficients of the Chebyshev series (4.1) can be obtained, and can then be used to compute the c_n coefficients of the sine-series representation for the total current in (C.1). This method produces uniformly accurate solutions throughout the wire for the very thin wire problem—including around the wire end-points. Note that the supersampling procedure described here is computationally inexpensive (as supported by data in the relevant table captions), since it can be accomplished by means of an FFT.

STABILITY RESULTS FOR SCATTERED DATA INTERPOLATION BY TRIGONOMETRIC POLYNOMIALS*

STEFAN KUNIS† AND DANIEL POTTS†

Abstract. A fast and reliable algorithm for the optimal interpolation of scattered data on the torus $\mathbb{T}^d$ by multivariate trigonometric polynomials is presented. The algorithm is based on a variant of the conjugate gradient method in combination with the fast Fourier transforms for nonequispaced nodes. The main result is that under mild assumptions the total complexity for solving the interpolation problem at M arbitrary nodes is of order $\mathcal{O}(M \log M)$. This result is obtained by the use of localized trigonometric kernels where the localization is chosen in accordance with the spatial dimension d. Numerical examples show the efficiency of the new algorithm.

Key words. trigonometric approximation, scattered data interpolation, localization, iterative methods, fast Fourier transforms for nonequispaced nodes, FFT

1. Introduction.

We discuss the approximation of scattered data by d-variate periodic functions $f : \mathbb{T}^d \to \mathbb{C}$, where $\mathbb{T} := [-\frac{1}{2}, \frac{1}{2})$ denotes the torus. In practical applications we are often confronted with the situation that experimental data or measured values of a function are known only at a finite sampling set $\mathcal{X} := \{\boldsymbol{x}_j \in \mathbb{T}^d : j = 0, \dots, M-1\}$. Especially, nonuniform sampling sets appear in more and more applications in recent years. Given a notion of the distance of two points by $\operatorname{dist}(\boldsymbol{x}, \boldsymbol{x}_0) := \min_{\boldsymbol{j} \in \mathbb{Z}^d} \|(\boldsymbol{x} + \boldsymbol{j}) - \boldsymbol{x}_0\|_\infty$, we measure the "nonuniformity" of $\mathcal{X}$ by the mesh norm and the separation distance, defined by

$$\delta := 2 \max_{\boldsymbol{x} \in \mathbb{T}^d} \min_{j=0,\dots,M-1} \operatorname{dist}(\boldsymbol{x}_j, \boldsymbol{x}), \qquad q := \min_{j,l=0,\dots,M-1; j \neq l} \operatorname{dist}(\boldsymbol{x}_j, \boldsymbol{x}_l),$$

respectively. Obviously, the relation $q \leq M^{-1/d} \leq \delta$ is fulfilled.

For given samples $(\boldsymbol{x}_j, y_j) \in \mathbb{T}^d \times \mathbb{C}$, $j = 0, \dots, M-1$, a polynomial degree $N \in 2\mathbb{N}$, and the index set $I_N := \left\{-\frac{N}{2}, \dots, \frac{N}{2} - 1\right\}^d$ of frequencies, we construct a d-variate trigonometric polynomial

$$f(\boldsymbol{x}) := \sum_{\boldsymbol{k} \in I_N} \hat{f}_{\boldsymbol{k}} \mathrm{e}^{2\pi \mathrm{i} \boldsymbol{k} \boldsymbol{x}}$$

such that $f(\boldsymbol{x}_j) \approx y_j$, $j = 0, \dots, M-1$. Turning this into matrix vector notation, we aim to solve the system of linear equations

$$\boldsymbol{A} \hat{\boldsymbol{f}} \approx \boldsymbol{y} \tag{1.1}$$

for the unknown vector of Fourier coefficients $\hat{\boldsymbol{f}} := (\hat{f}_{\boldsymbol{k}})_{\boldsymbol{k} \in I_N} \in \mathbb{C}^{N^d}$. Throughout the paper, we denote the vector of the given sample values by $\boldsymbol{y} := (y_j)_{j=0,\dots,M-1} \in \mathbb{C}^M$

and the nonequispaced Fourier matrix by

$$\boldsymbol{A} = \boldsymbol{A}_{\mathcal{X}} := \left(\mathrm{e}^{2\pi \mathrm{i} \boldsymbol{k} \boldsymbol{x}_j}\right)_{j=0,\ldots,M-1;\boldsymbol{k}\in I_N} \in \mathbb{C}^{M\times N^d}.$$

In contrast to the widely used nonequispaced FFT for the fast matrix vector multiplication with $\boldsymbol{A}$ (see [16] and its references), the [illegible] solution of (1.1) is still a challenging goal. Besides recently developed sparse reconstruction techniques (see, e.g., [5, 13] and their references), a standard method to determine $\hat{\boldsymbol{f}}$ is to solve the general linear least squares problem $\|\hat{\boldsymbol{f}}\|_2 \to \min$ subject to $\|\boldsymbol{y} - \boldsymbol{A}\hat{\boldsymbol{f}}\|_2 = \min$ (see, e.g., [3, p. 15]). This can be done by means of the singular value decomposition, which is not practical in the present situation for large problems due to its time and memory requirements. Direct solvers for the univariate case $d = 1$ in [6, 18] obtain a solution in $\mathcal{O}(NM)$ floating point operations.

For $N^d < M$, the linear system (1.1) is overdetermined, so that, in general, the given data $\boldsymbol{y}$ will be approximated only up to a [illegible] $\boldsymbol{r} := \boldsymbol{y} - \boldsymbol{A}\hat{\boldsymbol{f}}$. In order to compensate for clusters in the sampling set $\mathcal{X}$, it is useful to incorporate weights $w_j > 0$ and to consider the weighted approximation problem

$$\|\boldsymbol{y} - \boldsymbol{A}\hat{\boldsymbol{f}}\|_{\boldsymbol{W}}^2 = \sum_{j=0}^{M-1} w_j |y_j - f(\boldsymbol{x}_j)|^2 \xrightarrow{\hat{\boldsymbol{f}}} \min, \tag{1.2}$$

where $\boldsymbol{W} := \operatorname{diag}(w_j)_{j=0,\ldots,M-1}$. In [10] it has been proven that this problem has a unique solution if $N < (\frac{\pi}{\log 2}\, d\, \delta)^{-1}$. Its solution is computed iteratively by means of the conjugate gradient method in [7, 2, 9], where the multilevel Toeplitz structure of $\boldsymbol{A}^{\mathsf{H}}\boldsymbol{W}\boldsymbol{A}$ is used for fast matrix vector multiplications. Slightly more stable with respect to rounding errors is the Conjugate gradient method, Normal equation, Residual minimization (CGNR) method (cf. [3, p. 288]), which iterates the original residual $\boldsymbol{r}_l = \boldsymbol{y} - \boldsymbol{A}\hat{\boldsymbol{f}}_l$ instead of the residual $\boldsymbol{A}^{\mathsf{H}}\boldsymbol{W}\boldsymbol{r}_l$ of the normal equations. Note, furthermore, that it has been suggested in [17] to incorporate some "knowledge on the decay of the Fourier coefficients" $\hat{\boldsymbol{W}} := \operatorname{diag}(\hat{w}_{\boldsymbol{k}})_{\boldsymbol{k}\in I_N}$, $\hat{w}_{\boldsymbol{k}} > 0$. Their approach is based on the weighted least squares problem

$$\|\boldsymbol{A}^{\mathsf{H}}\boldsymbol{W}(\boldsymbol{y} - \boldsymbol{A}\hat{\boldsymbol{f}})\|_{\hat{\boldsymbol{W}}^{-1}} \xrightarrow{\hat{\boldsymbol{f}}} \min.$$

In contrast, we focus on the underdetermined and consistent linear system $\boldsymbol{A}\hat{\boldsymbol{f}} = \boldsymbol{y}$; i.e., we expect to interpolate the given data $y_j \in \mathbb{C}$, $j = 0, \ldots, M-1$, exactly. We show that the nonequispaced Fourier matrix $\boldsymbol{A}$ has full rank M for every polynomial degree $N > 2\, d\, q^{-1}$. In particular, we incorporate [illegible] $\hat{w}_{\boldsymbol{k}} > 0$, $\boldsymbol{k} \in I_N$, and consider the [illegible]

$$\|\hat{\boldsymbol{f}}\|_{\hat{\boldsymbol{W}}^{-1}}^2 = \sum_{\boldsymbol{k}\in I_N} \frac{|\hat{f}_{\boldsymbol{k}}|^2}{\hat{w}_{\boldsymbol{k}}} \xrightarrow{\hat{\boldsymbol{f}}} \min \quad \text{subject to} \quad \boldsymbol{A}\hat{\boldsymbol{f}} = \boldsymbol{y}, \tag{1.3}$$

where $\hat{\boldsymbol{W}} := \operatorname{diag}(\hat{w}_{\boldsymbol{k}})_{\boldsymbol{k}\in I_N}$. We prove that for a large class of "smooth" damping factors $\hat{w}_{\boldsymbol{k}}$ problem (1.3) is well-conditioned, where the "smoothness" has to be chosen with respect to the spatial dimension d. We propose to solve problem (1.3) by a version of the conjugate gradient method in combination with the nonequispaced FFT [19, 16, 12] to efficiently perform each iteration step.

The outline of this paper is as follows: In section 2 we set up the basic notation and relate the optimal interpolation problem (1.3) to a particular trigonometric kernel.

Furthermore, we propose Algorithm 1 for computing the solution of the interpolation problem efficiently. For the sake of analyzing the convergence of this algorithm, we then present our theory on localized trigonometric kernels in section 3. Our first result in Theorem 3.3 is a version of the typical smoothness-decay principle in Fourier analysis and relates the smoothness of the weights in (1.3) to the localization of the corresponding trigonometric kernel. We use this decay in section 4 to prove that well-separated sampling nodes yield a stable interpolation problem (1.3). The eigenvalue estimates are given for the univariate setting in Theorem 4.1 and for the multivariate setting in Theorem 4.6. Subsequently, Corollary 4.7 applies the general result to a particular class of damping factors and concludes with conditions sufficient for the full rank of $\boldsymbol{A}$. As the equidistant case in Theorem 4.10 and Corollary 4.11 reveals, the assumption on the separation distance is of optimal order. We provide numerical examples in section 5 and draw our conclusion in section 6. The software and all numerical examples are available from our NFFT homepage [12].

2. Optimal interpolation and its iterative solution. After setting up our notation in Definition 2.1, we prove in Lemma 2.2 that the optimal interpolation problem (1.3) can be stated as normal equations and that the matrix in these equations obeys special structure. Furthermore, we propose Algorithm 1 for the iterative solution of the interpolation problem and state a basic convergence result for this scheme.

DEFINITION 2.1. $d \in \mathbb{N}$, $N \in 2\mathbb{N}$, $I_N = \{-\frac{N}{2}, \dots, \frac{N}{2}-1\}^d$, $\hat{w}_{\boldsymbol{k}} > 0$, $\boldsymbol{k} \in I_N$, $\sum_{\boldsymbol{k}\in I_N} \hat{w}_{\boldsymbol{k}} = 1$, $\boldsymbol{x} \in \mathbb{T}^d$, kernel

$$K_N(\boldsymbol{x}) := \sum_{\boldsymbol{k}\in I_N} \hat{w}_{\boldsymbol{k}} \mathrm{e}^{2\pi \mathrm{i} \boldsymbol{k}\boldsymbol{x}}.$$

tensor product kernels

$$K_N(\boldsymbol{x}) = \prod_{t=0}^{d-1} \tilde{K}_N(x_t),$$

$\tilde{K}_N$, $\boldsymbol{x} = (x_0, \dots, x_{d-1})^\top$, $\mathcal{X} \subset \mathbb{T}^d$, kernel matrix

$$\boldsymbol{K}_N := (K_N(\boldsymbol{x}_j - \boldsymbol{x}_l))_{j,l=0,\dots,M-1} \in \mathbb{C}^{M\times M}. \tag{2.1}$$

$\Lambda = \Lambda(\boldsymbol{K}_N)$, $\lambda = \lambda(\boldsymbol{K}_N)$, $\boldsymbol{K}_N$, $\operatorname{cond}(\boldsymbol{K}_N) = \frac{\Lambda}{\lambda}$

Note that from the definition immediately follows $K_N(\boldsymbol{0}) = \max_{\boldsymbol{x}\in\mathbb{T}^d} |K_N(\boldsymbol{x})| = 1$ and $(\boldsymbol{K}_N)_{j,j} = 1$, $j = 0, \dots, M-1$. The following theorem collects some basic facts.

LEMMA 2.2. $M \in \mathbb{N}$, $\mathcal{X} \subset \mathbb{T}^d$, $N \in 2\mathbb{N}$, $\hat{w}_{\boldsymbol{k}} > 0$, $\boldsymbol{k} \in I_N$, (1.3), damped normal equations of the second kind

$$\boldsymbol{K}_N \tilde{\boldsymbol{f}} = \boldsymbol{y}, \qquad \hat{\boldsymbol{f}} = \hat{\boldsymbol{W}} \boldsymbol{A}^{\mathsf{H}} \tilde{\boldsymbol{f}}, \tag{2.2}$$

$\boldsymbol{K}_N \in \mathbb{C}^{M\times M}$

$$\boldsymbol{K}_N = \boldsymbol{A} \hat{\boldsymbol{W}} \boldsymbol{A}^{\mathsf{H}} \tag{2.3}$$

. The second assertion follows from $(\boldsymbol{A}\hat{\boldsymbol{W}}\boldsymbol{A}^{\mathrm{H}})_{j,l} = \sum_{\boldsymbol{k}\in I_N} \mathrm{e}^{2\pi\mathrm{i}\boldsymbol{k}\boldsymbol{x}_j}\hat{w}_{\boldsymbol{k}}\mathrm{e}^{-2\pi\mathrm{i}\boldsymbol{k}\boldsymbol{x}_l}$ and Definition 2.1. Furthermore, a solution $\hat{\boldsymbol{f}}$ of $\boldsymbol{A}\hat{\boldsymbol{f}} = \boldsymbol{y}$ has minimal weighted norm if and only if it is perpendicular with respect to the weights to the null-space of $\boldsymbol{A}$, i.e., $\hat{\boldsymbol{W}}^{-1/2}\hat{\boldsymbol{f}} \perp \mathcal{N}(\boldsymbol{A}\hat{\boldsymbol{W}}^{1/2})$. We conclude (2.2) by the fact that the orthogonal complement of the null-space of a matrix is just the range of its adjoint. □

Denoted in Algorithm 1 by Conjugate gradient method, Normal equation, Error minimization (CGNE) (cf. [3, p. 288]), we solve the normal equations (2.2) by the conjugate gradient method, minimizing in each iteration the error.

Algorithm 1. CGNE.

Input: dimension $d \in \mathbb{N}$, number of samples $M \in \mathbb{N}$, polynomial degree $N \in 2\mathbb{N}$; sampling set $\mathcal{X} \subset \mathbb{T}^d$, samples $\boldsymbol{y} \in \mathbb{C}^M$, and initial vector $\hat{\boldsymbol{f}}_0 \in \mathbb{C}^{N^d}$

$\boldsymbol{r}_0 = \boldsymbol{y} - \boldsymbol{A}\hat{\boldsymbol{f}}_0$

$\hat{\boldsymbol{p}}_0 = \boldsymbol{A}^{\mathrm{H}}\boldsymbol{r}_0$

for $l = 0, \ldots$ **do**

$\alpha_l = \boldsymbol{r}_l^{\mathrm{H}}\boldsymbol{r}_l \,/\, \hat{\boldsymbol{p}}_l^{\mathrm{H}}\hat{\boldsymbol{W}}\hat{\boldsymbol{p}}_l$

$\hat{\boldsymbol{f}}_{l+1} = \hat{\boldsymbol{f}}_l + \alpha_l\hat{\boldsymbol{W}}\hat{\boldsymbol{p}}_l$

$\boldsymbol{r}_{l+1} = \boldsymbol{r}_l - \alpha_l\boldsymbol{A}\hat{\boldsymbol{W}}\hat{\boldsymbol{p}}_l$

$\beta_l = \boldsymbol{r}_{l+1}^{\mathrm{H}}\boldsymbol{r}_{l+1} \,/\, \boldsymbol{r}_l^{\mathrm{H}}\boldsymbol{r}_l$

$\hat{\boldsymbol{p}}_{l+1} = \beta_l\hat{\boldsymbol{p}}_l + \boldsymbol{A}^{\mathrm{H}}\boldsymbol{r}_{l+1}$

end for

Output: the lth iterate $\hat{\boldsymbol{f}}_l$

The proposed method finds approximations from a Krylov space closely related to the one of the CGNR method for (1.2) but with minimal error instead of minimal residual. Note that we exploit the factorization in (2.3) to iterate the original vector $\hat{\boldsymbol{f}}$ instead of the vector $\tilde{\boldsymbol{f}}$; cf. (2.2). Hence, we use fast matrix vector multiplications for $\boldsymbol{A}$ and $\boldsymbol{A}^{\mathrm{H}}$ by means of the fast Fourier transforms at nonequispaced nodes (NFFT) having an arithmetical complexity of $\mathcal{O}(N^d\log(N^d) + M|\log\epsilon|^d)$ in each iteration, where ϵ is the prescribed accuracy. Details concerning NFFT algorithms can be found, for example, in [19, 16] and a corresponding software package in [12]. Applying the standard estimate for the convergence of the conjugate gradient method, we obtain the following lemma.

LEMMA 2.3. $\boldsymbol{K}_N$ (2.1) $\hat{\boldsymbol{e}}_l := \hat{\boldsymbol{f}}_l - \hat{\boldsymbol{W}}\boldsymbol{A}^{\mathrm{H}}\boldsymbol{K}_N^{-1}\boldsymbol{y}$ l 1

$$\|\hat{\boldsymbol{e}}_l\|_{\hat{\boldsymbol{W}}^{-1}} \leq 2\left(\frac{\sqrt{\Lambda}-\sqrt{\lambda}}{\sqrt{\Lambda}+\sqrt{\lambda}}\right)^l \|\hat{\boldsymbol{e}}_0\|_{\hat{\boldsymbol{W}}^{-1}}$$

. We note that $\|\hat{\boldsymbol{e}}_l\|_{\hat{\boldsymbol{W}}^{-1}} = \|\tilde{\boldsymbol{f}}_l - \boldsymbol{K}_N^{-1}\boldsymbol{y}\|_{\boldsymbol{K}_N}$, where $\tilde{\boldsymbol{f}}_l$ denotes the lth iterate of the conjugate gradient method applied to the equation $\boldsymbol{K}_N\tilde{\boldsymbol{f}} = \boldsymbol{y}$ (cf. Lemma

2.2), and apply the standard estimate for the conjugate gradient method; see also [3, p. 288]. □

This result includes the special case of $M = N^d$ equispaced nodes and no damping, i.e., $\hat{w}_{\boldsymbol{k}} = 1$, $\boldsymbol{k} \in I_N$, where the first iterate of our algorithm is already the solution to (2.2). We present estimates for the extremal eigenvalues λ and Λ dependent only on the quantities N and q and the damping factors $\hat{w}_{\boldsymbol{k}}$, $\boldsymbol{k} \in I_N$. Analogous results for the stability of the interpolation by radial and zonal functions are obtained in [15, 20]. Section 3 prepares our estimates by constructing localized kernels.

. . . . 2.4. Before that, we would like to comment on the following:

The weighted norm in (1.3) is induced by the inner product $\hat{\boldsymbol{g}}^{\mathsf{H}} \hat{\boldsymbol{W}}^{-1} \hat{\boldsymbol{f}}$. In particular, the definition $\langle f, g \rangle_{\hat{\boldsymbol{W}}^{-1}} := \hat{\boldsymbol{g}}^{\mathsf{H}} \hat{\boldsymbol{W}}^{-1} \hat{\boldsymbol{f}}$ makes the space of trigonometric polynomials $T_N := \operatorname{span} \left\{ \mathrm{e}^{2\pi \mathrm{i} \boldsymbol{k} \cdot} : \boldsymbol{k} \in I_N \right\}$ to a reproducing kernel Hilbert space. Its reproducing kernel is given by K_N; i.e., the point evaluations obey $f(\boldsymbol{x}) = \langle f, K_N(\cdot - \boldsymbol{x}) \rangle_{\hat{\boldsymbol{W}}^{-1}}$.

Moreover, the solution $f(\boldsymbol{x}) = \sum_{\boldsymbol{k} \in I_N} \hat{f}_{\boldsymbol{k}} \mathrm{e}^{2\pi \mathrm{i} \boldsymbol{k} \boldsymbol{x}}$ of the normal equations (2.2) has a comparable norm to the given samples, i.e.,

$$\Lambda^{-1} \|\boldsymbol{y}\|_2^2 \leq \langle f, g \rangle \leq_{\hat{\boldsymbol{W}}^{-1}} \leq \lambda^{-1} \|\boldsymbol{y}\|_2^2 .$$

This norm equivalence is due to the fact that the field of values of the matrix $\boldsymbol{K}_N^{-1}$ is bounded by its extremal eigenvalues and $\boldsymbol{y}^{\mathsf{H}} \boldsymbol{K}_N^{-1} \boldsymbol{y} = \tilde{\boldsymbol{f}}^{\mathsf{H}} \boldsymbol{K}_N \tilde{\boldsymbol{f}} = \hat{\boldsymbol{f}}^{\mathsf{H}} \hat{\boldsymbol{W}}^{-1} \hat{\boldsymbol{f}}$.

3. Localized kernels. Starting from a class of admissible weight functions in Definition 3.1, we construct localized trigonometric kernels in Theorem 3.3, where Lemma 3.2 serves as an intermediate step. Following the smoothness-decay principle in Fourier analysis, we relate the smoothness of the weight function to the decay of the kernel K_N built upon the sampled weights. A related approach is taken in [14, Thm. 2.2] for the detection of singularities. The particular class of B-spline kernels (cf. Definition 3.4) is considered in Corollary 3.5. While we present our results on the connection between smooth weight functions and localized kernels for the univariate case, we give its generalization to the class of tensor product kernels in Corollary 3.7.

Definition 3.1. . . $\beta \in \mathbb{N}$ $\beta \geq 2$ . . . . . $g : \mathbb{R} \to \mathbb{R}$ . . admissible weight function of order β . . . . . $(\beta - 1)$ . . . . . $g^{(\beta-1)}$ . . . . . .

$$|g^{(\beta-1)}|_V := \int_{\mathbb{R}} |\mathrm{d} g^{(\beta-1)}(z)| = \sup \sum_{j=0}^{n-1} |g^{(\beta-1)}(z_{j+1}) - g^{(\beta-1)}(z_j)| < \infty,$$

. . . . . $\{z_j\}_{j \in \mathbb{N}_0}$ . . . . . $\operatorname{supp} g = [-\frac{1}{2}, \frac{1}{2}]$ $g^{(\gamma)}(\pm\frac{1}{2}) = 0$ . . $\gamma = 0, \ldots, \beta - 1$ $g(z) > 0$, $|z| < \frac{1}{2}$ . . . . . $\|g\|_{L^1} = 1$ . . . . . $BV_0^{\beta-1}$ . . . . . β . . . . . zeta function $\zeta(\beta) := \sum_{r=1}^{\infty} r^{-\beta}$ $\beta > 1$ . . . $g \in BV_0^{\beta-1}$ . . norm of the samples

$$\|g\|_{1,N} := \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} g\left(\frac{k}{N}\right) .$$

The following lemma prepares Theorem 3.3.

LEMMA 3.2. [illegible] $\beta \in \mathbb{N}$, $\beta \geq 2$ [illegible] $g \in BV_0^{\beta-1}$ [illegible] $N \in 2\mathbb{N}$ $N \geq 2\beta$ [illegible] $x \in \left[-\frac{1}{2}, \frac{1}{2}\right] \setminus \{0\}$ [illegible]

$$\left| \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} g\left(\frac{k}{N}\right) \mathrm{e}^{2\pi \mathrm{i} k x} \right| \leq \frac{\left(2^{\beta}-1\right) \zeta\left(\beta\right) \left| g^{(\beta-1)} \right|_V}{(2N)^{\beta-1} \left|2\pi x\right|^{\beta}},$$

$$\|g\|_{1,N} \geq N \left(1 - 2\zeta\left(\beta\right) \left(4\pi\beta\right)^{-\beta} |g^{(\beta-1)}|_V\right).$$

[illegible] First, we define for $x, z \in \left[-\frac{1}{2}, \frac{1}{2}\right]$ the function $h_x(z) := g(z) \mathrm{e}^{2\pi \mathrm{i} N x z}$. Thus, the Poisson summation formula yields

$$\frac{1}{N} \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} g\left(\frac{k}{N}\right) \mathrm{e}^{2\pi \mathrm{i} k x} = \frac{1}{N} \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} h_x\left(\frac{k}{N}\right) = \sum_{r \in \mathbb{Z}} \int_{-\frac{1}{2}}^{\frac{1}{2}} h_x(z) \, \mathrm{e}^{-2\pi \mathrm{i} N r z} \mathrm{d}z,$$

and, by applying integration by parts and the fact that $g^{(\gamma)}\left(\pm\frac{1}{2}\right) = 0$ for $\gamma = 0, \ldots, \beta - 2$ further,

$$\begin{aligned}
\left| \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} h_x\left(\frac{k}{N}\right) \right| &= \left| N \sum_{r \in \mathbb{Z}} \left(2\pi \mathrm{i} N (r-x)\right)^{-(\beta-1)} \int_{-\frac{1}{2}}^{\frac{1}{2}} g^{(\beta-1)}(z) \, \mathrm{e}^{2\pi \mathrm{i} N z (x-r)} \mathrm{d}z \right| \\
&= \left| \frac{N}{(2\pi \mathrm{i} N)^{\beta}} \sum_{r \in \mathbb{Z}} (r-x)^{-\beta} \int_{-\frac{1}{2}}^{\frac{1}{2}} g^{(\beta-1)}(z) \left(\frac{\mathrm{d}}{\mathrm{d}z} \mathrm{e}^{2\pi \mathrm{i} N z (x-r)} \right) \mathrm{d}z \right| \\
&\leq \frac{1 + |x|^{\beta} \sum_{r \in \mathbb{Z} \setminus \{0\}} |r-x|^{-\beta}}{(2\pi)^{\beta} N^{\beta-1} |x|^{\beta}} \sup_{r_0 \in \mathbb{Z}} \left| \int_{-\frac{1}{2}}^{\frac{1}{2}} g^{(\beta-1)}(z) \left(\frac{\mathrm{d}}{\mathrm{d}z} \mathrm{e}^{2\pi \mathrm{i} N z (x-r_0)} \right) \mathrm{d}z \right|.
\end{aligned}$$

Using $1 + |x|^{\beta} \sum_{r \in \mathbb{Z} \setminus \{0\}} |r-x|^{-\beta} \leq (2^{\beta}-1) 2^{1-\beta} \zeta(\beta)$ for $|x| \leq \frac{1}{2}$ and

$$\left| \int_{-\frac{1}{2}}^{\frac{1}{2}} g^{(\beta-1)}(z) \left(\frac{\mathrm{d}}{\mathrm{d}z} \mathrm{e}^{2\pi \mathrm{i} N z (x-r_0)} \right) \mathrm{d}z \right| \leq \left| g^{(\beta-1)} \right|_V$$

yields the assertion.

By the Poisson summation formula, we note furthermore that

$$\frac{1}{N} \|g\|_{1,N} \geq 1 - \left| \sum_{r \in \mathbb{Z} \setminus \{0\}} \int_{-\frac{1}{2}}^{\frac{1}{2}} g(z) \, \mathrm{e}^{-2\pi \mathrm{i} N r z} \mathrm{d}z \right|$$

and proceed analogously in order to prove the second assertion, where we use $N \geq 2\beta$ to obtain an estimate independent of N. □

THEOREM 3.3. [illegible] $\beta \in \mathbb{N}$, $\beta \geq 2$ [illegible] $g \in BV_0^{\beta-1}$ [illegible] $N \in 2\mathbb{N}$ $N \geq 2\beta$ [illegible]

$$\hat{w}_k = \frac{g\left(\frac{k}{N}\right) + g\left(\frac{k+1}{N}\right)}{2 \|g\|_{1,N}}, \qquad k = -\frac{N}{2}, \ldots, \frac{N}{2} - 1,$$

[illegible] K_N [illegible] 2.1 [illegible]

$$|K_N(x)| \leq \frac{\left(2^{\beta}-1\right) \zeta\left(\beta\right) \left| g^{(\beta-1)} \right|_V}{2^{\beta-1} \left(2\pi\right)^{\beta} - \zeta\left(\beta\right) \beta^{-\beta} \left| g^{(\beta-1)} \right|_V} \frac{1}{N^{\beta} |x|^{\beta}}$$

[illegible] $x \in \left[-\frac{1}{2}, \frac{1}{2}\right] \setminus \{0\}$

. Note first that

$$K_N(x) = \frac{1 + \mathrm{e}^{-2\pi \mathrm{i} x}}{2 \|g\|_{1,N}} \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} g\left(\frac{k}{N}\right) \mathrm{e}^{2\pi \mathrm{i} k x}.$$

Thus, we obtain $K_N(0) = 1$ and by applying Lemma 3.2 also the decay property. □

We apply Theorem 3.3 in the following to the particular class of B-spline kernels.

DEFINITION 3.4. $\beta \in \mathbb{N}$ normalized B-spline

$$g_\beta(z) := \beta N_\beta\left(\beta z + \frac{\beta}{2}\right),$$

N_β β $N_1(z) = 1$ $z \in (0,1)$ $N_1(z) = 0$ $N_{\beta+1}(z) = \int_{z-1}^{z} N_\beta(\tau)\mathrm{d}\tau$ [4]

$\beta \in \mathbb{N}$ $N \in 2\mathbb{N}$ B-spline kernel

$$B_{\beta,N}(x) := \frac{1 + \mathrm{e}^{-2\pi \mathrm{i} x}}{2 \|g_\beta\|_{1,N}} \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} g_\beta\left(\frac{k}{N}\right) \mathrm{e}^{2\pi \mathrm{i} k x}.$$

COROLLARY 3.5. $\beta \in \mathbb{N}$, $\beta \geq 2$ $N \in 2\mathbb{N}$ $N \geq 2\beta$ $B_{\beta,N}(x)$ 3.4

$$|B_{\beta,N}(x)| \leq \frac{\left(2^\beta - 1\right)\zeta(\beta)\,\beta^\beta}{2^{\beta-1}\pi^\beta - \zeta(\beta)} |Nx|^{-\beta}$$

$x \in \left[-\frac{1}{2}, \frac{1}{2}\right] \setminus \{0\}$ $B_{\beta,N}(0) = 1$

. Note that $g_\beta \in BV_0^{\beta-1}$. Using $N_\beta'(z) = N_{\beta-1}(z) - N_{\beta-1}(z-1)$, we conclude

$$\left|g_\beta^{(\beta-1)}\right|_V = \beta^\beta \left|N_\beta^{(\beta-1)}\right|_V = \beta^\beta \left|\sum_{\tau=0}^{\beta-1} (-1)^\tau \binom{\beta-1}{\tau} N_1(\cdot - \tau)\right|_V = (2\beta)^\beta$$

and apply Theorem 3.3. □

Note that in contrast to [15] the order β of the B-spline and the degree $N \in 2\mathbb{N}$ of the kernel $B_{\beta,N}$ are independent of each other. The special case $\beta = 1$, i.e., the "top-hat function" $g_1(z) = 1$ for $|z| < \frac{1}{2}$ and $g_1(z) = 0$ elsewhere, leads to the well-known $B_{1,N}(x) = \frac{1}{N}\sum_{k \in I_N} \mathrm{e}^{2\pi \mathrm{i} k x}$. Analogously, $\beta = 2$, i.e., the "hat function" $g_2(z) = 2 - 4|z|$ for $|z| \leq \frac{1}{2}$ and $g_2(z) = 0$ elsewhere, leads to the . The increasing localization of the B-spline kernels is illustrated in Figure 3.1.

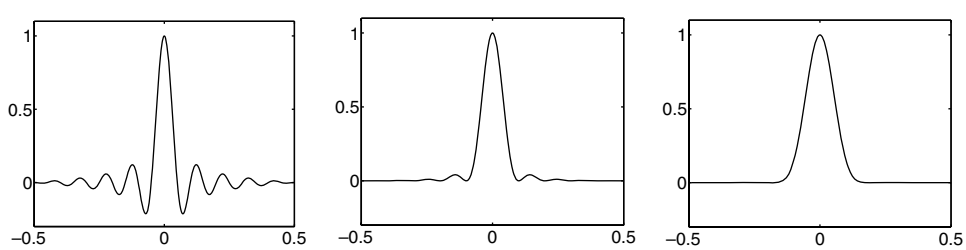

FIGURE 3.1. *From left to right: Real part of the Dirichlet kernel $B_{1,20}$, the Fejér kernel $B_{2,20}$, and the B-spline kernel $B_{4,20}$.*

3.6. If we assume in Corollary 3.5, furthermore, that $N = \beta\sigma$, $\sigma \in \mathbb{N}$, then the stronger estimate $|B_{\beta,N}(x)| \leq 2\zeta(\beta)(1-2^{-\beta})(\frac{\beta}{\pi})^{\beta}|Nx|^{-\beta}$ holds true. This improvement is due to $\|g_\beta\|_{1,N} = N$ in Lemma 3.2 and follows from the partition of unity of the cardinal B-spline N_β and the refinement equation $N_\beta(z) = \sum_{\tau\in\mathbb{Z}} a_\tau^{(\beta,\sigma)} N_\beta(\sigma z - \tau)$ for some finitely supported coefficients $a_\tau^{(\beta,\sigma)} > 0$; see, e.g., [4, p. 8].

In particular, the Fejér kernel fulfills $|B_{2,N}(x)| \leq |Nx|^{-2}$, $N \in 2\mathbb{N}$, which also follows from the estimate $|\sin(\pi x)| \geq 2|x|$ for $|x| \leq 1/2$ and the representation

$$B_{2,N}(x) = \frac{2\left(1+\mathrm{e}^{-2\pi \mathrm{i} x}\right)}{N^2}\left(\frac{\sin\left(\frac{N}{2}\pi x\right)}{\sin(\pi x)}\right)^2.$$

Along the same line follows the localization property $B_{1,N}(x) \leq |Nx|^{-1}$ and $B_{1,N}(0) = 1$ for the Dirichlet kernel.

We complete this section by an extension of our result to the multivariate case $d > 1$. Indeed, tensor products of the kernels constructed in Theorem 3.3 also yield localized multivariate kernels as shown in the following corollary.

COROLLARY 3.7. [illegible] $\tilde{K}_N$ [illegible] 2.1 [illegible] $\beta \in \mathbb{N}$ [illegible] $C_\beta > 1$ [illegible] $x \in \left[-\frac{1}{2},\frac{1}{2}\right] \setminus \{0\}$ [illegible] $|\tilde{K}_N(x)| \leq C_\beta |Nx|^{-\beta}$ [illegible] $K_N(\boldsymbol{x}) = \prod_{t=0}^{d-1} \tilde{K}_N(x_t)$ [illegible] $\boldsymbol{x} \in \left[-\frac{1}{2},\frac{1}{2}\right]^d \setminus \{\boldsymbol{0}\}$ [illegible]

$$|K_N(\boldsymbol{x})| \leq \frac{C_\beta}{N^\beta \|\boldsymbol{x}\|_\infty^\beta}.$$

[illegible] The assertion follows simply from the estimate $|K_N(\boldsymbol{x})| \leq |\tilde{K}_N(\|\boldsymbol{x}\|_\infty)|$. ∎

4. Stability of the interpolation problem. The nonequispaced Fourier matrix $\boldsymbol{A}$ has full rank M for $d = 1$ and $N \geq M$. Unfortunately and due to the famous result of Mairhuber–Curtis (see, e.g., [20, Thm. 2.3]), we cannot expect full rank of the matrix $\boldsymbol{A}$ for $N \geq M^{\frac{1}{d}}$ in the multivariate case $d > 1$.

However, we prove stability results for the trigonometric interpolation problem at q-separated nodes in the univariate case (cf. Theorem 4.1) and the multivariate case (cf. Theorem 4.6). Basically, a localized kernel K_N yields a diagonal-dominated kernel matrix $\boldsymbol{K}_N$ and thus full rank of the nonequispaced Fourier matrix $\boldsymbol{A}$ for q-separated nodes. Furthermore, we prove stability results for a slightly generalized interpolation problem at equispaced nodes and subsets of equispaced nodes in Theorem 4.10. These results are applied to the B-spline kernels from section 3 in Corollaries 4.7 and 4.11.

The univariate setting. The following theorem gives estimates for the extremal eigenvalues of the matrix $\boldsymbol{K}_N$ under reasonable assumptions on the kernel K_N.

THEOREM 4.1. [illegible] $N \in 2\mathbb{N}$ [illegible] K_N [illegible] 2.1 [illegible] $\beta > 1$ [illegible] $x \in \left[-\frac{1}{2},\frac{1}{2}\right] \setminus \{0\}$ [illegible]

$$|K_N(x)| \leq \frac{C_\beta}{N^\beta |x|^\beta}.$$

[illegible] $\mathcal{X}$ [illegible] $q > 0$ [illegible] $\boldsymbol{K}_N$ [illegible]

$$1 - \frac{2\,\zeta(\beta)\,C_\beta}{N^\beta q^\beta} \leq \lambda \leq 1 \leq \Lambda \leq 1 + \frac{2\,\zeta(\beta)\,C_\beta}{N^\beta q^\beta}.$$

. As usual, let M denote the number of nodes in $\mathcal{X}$. Due to $K_N(0) = 1$ (cf. Definition 2.1) we obtain $\operatorname{trace}(\boldsymbol{K}_N) := \sum_{j=0}^{M-1} K_N(0) = M$. Since the trace is invariant under similarity transforms, all eigenvalues sum up to M, and, thus, the inequality $\lambda \le 1 \le \Lambda$ is fulfilled.

Now let $\lambda_\star$ be an arbitrary eigenvalue of $\boldsymbol{K}_N$; then for some index $0 \le j < M$ Gershgorin's circle theorem yields

$$|\lambda_\star - 1| \le \sum_{l=0; l\neq j}^{M-1} |K_N(x_j - x_l)|.$$

By using that the separation distance of the sampling set is q and by the localization of the kernel K_N, we obtain

$$|\lambda_\star - 1| \le \frac{C_\beta}{N^\beta} \sum_{l=0; l\neq j}^{M-1} \frac{1}{|x_j - x_l|^\beta} \le \frac{2\,C_\beta}{N^\beta q^\beta} \sum_{l=1}^{\lfloor M/2 \rfloor} l^{-\beta} < \frac{2\,\zeta(\beta) C_\beta}{N^\beta q^\beta}. \qquad \square$$

Indeed, the kernels constructed in Theorem 3.3 yield well-conditioned matrices $\boldsymbol{K}_N$. We also note that the decay of the Dirichlet kernel allows only for a weaker result.

. 4.2. Let a sampling set $\mathcal{X} \in \mathbb{T}$ with separation distance $q > 0$ be given. Then the application of Theorem 4.1, where the last step of its proof is replaced by the estimate $\sum_{l=1}^{\lfloor M/2 \rfloor} l^{-1} \le 1 + \ln \frac{1}{2q}$, yields: The matrix $(B_{1,N}(x_j - x_l))_{j,l=0,\dots,M-1} = \frac{1}{N} \boldsymbol{A}\boldsymbol{A}^{\mathsf{H}}$ is nonsingular for $N > (1 + |\log(2q)|)\, q^{-1}$. The logarithmic term in this condition is clearly suboptimal.

As an immediate consequence of Theorem 4.1 we state a stability result for an equispaced grid disturbed by jitter.

Corollary 4.3. 4.1 $x_j = -\frac{1}{2} + \frac{j - \varepsilon_j}{M}$, $j = 0, \dots, M-1$, $0 \le \varepsilon_j \le \varepsilon < 1$ $\boldsymbol{K}_N$

$$1 - \frac{2\,\zeta(\beta)\, C_\beta M^\beta}{N^\beta (1-\varepsilon)^\beta} \le \lambda \le 1 \le \Lambda \le 1 + \frac{2\,\zeta(\beta)\, C_\beta M^\beta}{N^\beta (1-\varepsilon)^\beta}.$$

. Since the separation distance is bounded by $q \ge M^{-1}(1-\varepsilon)$, the result follows by Theorem 4.1. $\square$

The multivariate setting. First, we borrow a packing argument on the sphere from [15] and refine it in Lemma 4.5 for the present setting; i.e., we show how many q-separated nodes can be placed in a certain distance to a reference node; see also Figure 4.1.

Definition 4.4. $d \in \mathbb{N}$ q $0 < q \le \frac{1}{2}$

$$R_{q,m} := \left\{ \boldsymbol{x} \in \mathbb{T}^d : mq \le \operatorname{dist}(\boldsymbol{x}, \boldsymbol{0}) < (m+1)\, q \right\}$$

$m = 0, \dots, \lfloor q^{-1}/2 \rfloor - 1$

$$R_{q,\lfloor q^{-1}/2 \rfloor} := \left\{ \boldsymbol{x} \in \mathbb{T}^d : \lfloor q^{-1}/2 \rfloor\, q \le \operatorname{dist}(\boldsymbol{x}, \boldsymbol{0}) \le 1/2 \right\}.$$

$\mathcal{X}$ $R_{\mathcal{X},q,m} := R_{q,m} \cap \mathcal{X}$

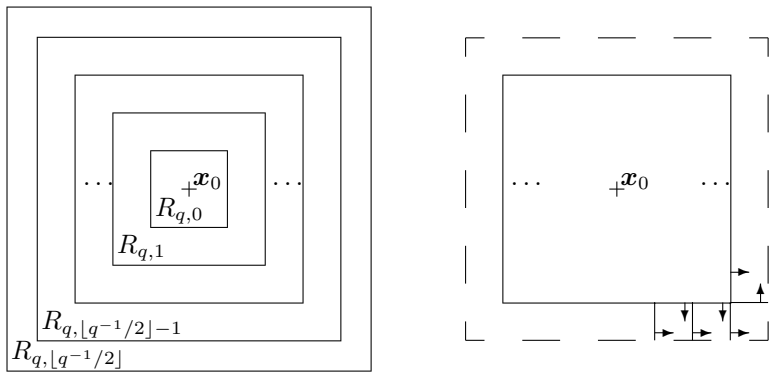

FIGURE 4.1. *Partitioning of the torus $\mathbb{T}^2$ into the rings $R_{q,m}$, $m = 0, \ldots, \lfloor q^{-1}/2 \rfloor$ (left). Further subdivision into shifted and rotated versions of the cube $[0, q)^d$, where arrows indicate the "ownership" of the faces to a particular cube (right).*

LEMMA 4.5. [illegible] $d \in \mathbb{N}$ [illegible] q [illegible] $\mathcal{X}$ [illegible] $0 < q \leq \frac{1}{2}$ [illegible] $R_{\mathcal{X},q,m}$ [illegible]

$$|R_{\mathcal{X},q,m}| \leq 2^d \left(2^d - 1\right) m^{d-1}, \qquad m = 1, \ldots, \left\lfloor q^{-1}/2 \right\rfloor.$$

[illegible]. We use a packing argument for the partition $\{R_{q,m}, m = 0, \ldots, \lfloor q^{-1}/2 \rfloor\}$ of the torus $\mathbb{T}^d$. Each ring $R_{q,m}$ is subdivided into shifted and rotated versions of the cube $[0, q)^d$; cf. Figure 4.1 (right). This is done such that each point in $R_{q,m}$ is contained in at least one of these boxes and the boxes share no interior points with each other. Every box contains at most one node of the sampling set, and, hence, the estimate

$$|R_{\mathcal{X},q,m}| \leq \frac{1}{q^d} \int_{R_{q,m}} \mathrm{d}\boldsymbol{x} \leq 2^d \left((m+1)^d - m^d\right) = 2^d \sum_{t=1}^{d} \binom{d}{t} m^{d-t} \leq 2^d m^{d-1} \sum_{t=1}^{d} \binom{d}{t}.$$

is valid. □

Using localized kernels in conjunction with a separated sampling set and Lemma 4.5, we state the following theorem on the stability of the interpolation problem.

THEOREM 4.6. [illegible] $d \in \mathbb{N}$ $N \in 2\mathbb{N}$ [illegible] K_N [illegible] 2.1 [illegible] $\beta > d$ [illegible] $\boldsymbol{x} \in \left[-\frac{1}{2}, \frac{1}{2}\right]^d \setminus \{\mathbf{0}\}$ [illegible]

$$|K_N(\boldsymbol{x})| \leq \frac{C_\beta}{N^\beta \|\boldsymbol{x}\|_\infty^\beta}.$$

[illegible] $\mathcal{X}$ [illegible] $0 < q \leq \frac{1}{2}$ [illegible] $\boldsymbol{K}_N$ [illegible]

$$1 - \frac{2^d \left(2^d - 1\right) \zeta\left(\beta - d + 1\right) C_\beta}{N^\beta q^\beta} \leq \lambda \leq 1 \leq \Lambda \leq 1 + \frac{2^d \left(2^d - 1\right) \zeta\left(\beta - d + 1\right) C_\beta}{N^\beta q^\beta}.$$

[illegible]. Let $\lambda_\star$ be an arbitrary eigenvalue of $\boldsymbol{K}_N$. Without loss of generality, let the diagonal element of the matrix $\boldsymbol{K}_N$ used in Gershgorin's circle theorem correspond to $\boldsymbol{x}_0 = \mathbf{0}$. Then we conclude by $K_N(\mathbf{0}) = 1$ (cf. Definition 2.1) that

$$|\lambda_\star - 1| \leq \sum_{l=1}^{M-1} |K_N(\mathbf{0} - \boldsymbol{x}_l)|.$$

Using the partition from Definition 4.4, Lemma 4.5, and the localization of the kernel K_N, we get

$$\begin{aligned}|\lambda_\star - 1| &\leq \sum_{m=1}^{\lfloor q^{-1}/2 \rfloor} \sum_{\boldsymbol{x}_l \in R_{\mathcal{X},q,m}} |K_N(-\boldsymbol{x}_l)| \\ &\leq \frac{2^d\left(2^d-1\right) C_\beta}{N^\beta} \sum_{m=1}^{\lfloor q^{-1}/2 \rfloor} m^{d-1} \max_{\boldsymbol{x}\in R_{q,m}} \|\boldsymbol{x}\|_\infty^{-\beta} \\ &\leq \frac{2^d\left(2^d-1\right)\zeta(\beta-d+1)\, C_\beta}{N^\beta q^\beta}. \qquad \square\end{aligned}$$

Particularly, this result includes Theorem 4.1 if we set $d = 1$.

COROLLARY 4.7. [illegible] $d \in \mathbb{N}$ [illegible] $\mathcal{X} \in \mathbb{T}^d$ [illegible] $0 < q \leq \frac{1}{2}$ [illegible] $N \in 2\mathbb{N}$ $N > 2dq^{-1}$ [illegible] $\boldsymbol{A}$ [illegible] $\boldsymbol{K}_N = \boldsymbol{A}\hat{\boldsymbol{W}}\boldsymbol{A}^{\mathsf{H}}$ [illegible] $\beta = d+1$ [illegible]

$$0 < 1 - \left(\frac{2d}{Nq}\right)^{d+1} \leq \lambda \leq 1 \leq \Lambda \leq 1 + \left(\frac{2d}{Nq}\right)^{d+1}.$$

[illegible]. Note first that $N \geq 2\beta$. We apply Theorem 4.6 where we use the estimates for C_β given in Corollary 3.5 and simplify the involved constant. Hence, the full rank of $\boldsymbol{A}$ follows. $\square$

Thus, we have shown that the optimal trigonometric interpolation problem at q-separated nodes in d dimensions obeys a uniformly bounded condition number for a polynomial degree $N > 2dq^{-1}$ and appropriate damping factors. The dependence on q^{-1} is optimal as the subsequent analysis of the equispaced case shows. However, the constant $2d$ is not optimal for high spatial dimensions. As pointed out in [2] for the related approximation problem (1.2), it is an open problem to improve on this.

In summary, Lemma 2.3 and Corollary 4.7 assure in our situation a prescribed reduction of the error $\|\hat{\boldsymbol{e}}_l\|_{\hat{\boldsymbol{W}}^{-1}}$ in a constant number of iterations. Hence, if we assume an additional uniformity condition $q = cM^{-\frac{1}{d}}$ for the sampling set $\mathcal{X}$, the total arithmetical complexity of Algorithm 1 for solving (1.3) up to a prescribed error is bounded by $\mathcal{O}(M \log M)$.

[illegible] 4.8. Other frequently applied kernels also possess specific localization properties and, thus, yield stable interpolation at q-separated nodes by means of Theorem 4.6 as follows:

We define for $\beta \in 2\mathbb{N}$, $\sigma \in \mathbb{N}$, and $N = \beta(\sigma-1)+2$ the Jackson kernel by

$$J_{\beta,N}(x) := \frac{1+\mathrm{e}^{-2\pi \mathrm{i} x}}{2\sigma^\beta}\left(\frac{\sin(\sigma\pi x)}{\sin(\pi x)}\right)^\beta.$$

Being a normalized power of the Fejér kernel $B_{2,2\sigma}$, the coefficients $\hat{w}_k$ of the Jackson kernel can be obtained by an iterated discrete convolution of the coefficients of the Fejér kernel; see [1] for details. In contrast, the B-spline kernel relies on a continuous convolution. The Jackson kernel is localized as $|J_{\beta,N}(x)| \leq (\frac{\beta}{2})^\beta |Nx|^{-\beta}$ for $x \in \left[-\frac{1}{2}, \frac{1}{2}\right] \setminus \{0\}$ and fulfills $J_{\beta,N}(0) = 1$. Hence, the tensor product Jackson kernel of appropriate order yields for $N \in 2\mathbb{N}$, $N > 2.1dq^{-1}$, the nonsingular kernel matrix

$$\left(J_{2\lceil \frac{d+1}{2} \rceil, N}(\boldsymbol{x}_j - \boldsymbol{x}_l)\right)_{j,l=0,\ldots,M-1}.$$

Second, it is well known that the weight $1+(2\pi k)^{2\alpha}$ is associated to the squared Sobolev norm $\|f\|_2^2+\|f^{(\alpha)}\|_2^2$. For $\beta\in\mathbb{N}$ and $\alpha,\gamma>0$, a regularized and slightly generalized weight is given by

$$g_{\alpha,\beta,\gamma}(z):=c_{\alpha,\beta,\gamma}\frac{\left(\frac{1}{4}-z^2\right)^{\beta}}{\gamma+|z|^{2\alpha}}$$

for $|z|\le\frac{1}{2}$ and $g_{\alpha,\beta,\gamma}(z)=0$ elsewhere, where the constant $c_{\alpha,\beta,\gamma}$ is chosen such that $\|g_{\alpha,\beta,\gamma}\|_{L_1}=1$. Here, the denominator generalizes the weight $1+(2\pi k)^{2\alpha}$, and the nominator ensures $g_{\alpha,\beta,\gamma}\in BV_0^{\beta-1}$. We define for $N\in 2\mathbb{N}$ the Sobolev kernel by

$$S_{\alpha,\beta,\gamma,N}(x):=\frac{1+\mathrm{e}^{-2\pi\mathrm{i}x}}{2\,\|g_{\alpha,\beta,\gamma}\|_{1,N}}\sum_{k=-\frac{N}{2}}^{\frac{N}{2}}g_{\alpha,\beta,\gamma}\left(\frac{k}{N}\right)\mathrm{e}^{2\pi\mathrm{i}kx}.$$

The kernel is localized as $|S_{\alpha,\beta,\gamma,N}(x)|\le\tilde{c}_{\alpha,\beta,\gamma}|Nx|^{-\beta}$ for $x\in\left[-\frac{1}{2},\frac{1}{2}\right]\setminus\{0\}$ and some constant $\tilde{c}_{\alpha,\beta,\gamma}>0$ and fulfills $S_{\alpha,\beta,\gamma,N}(0)=1$.

Results for equispaced nodes. In the case of equispaced nodes we employ the fact that the matrix $\boldsymbol{K}_N$ is circulant. We present a slightly generalized result in Theorem 4.10.

DEFINITION 4.9. [illegible] $d,n\in\mathbb{N}$ [illegible] $\hat{w}_{\boldsymbol{k}}\in\mathbb{R}$, $\boldsymbol{k}\in\mathbb{Z}^d$ [illegible] $\sum_{\boldsymbol{k}\in\mathbb{Z}^d}|\hat{w}_{\boldsymbol{k}}|<\infty$ [illegible]

$$K(\boldsymbol{x}):=\sum_{\boldsymbol{k}\in\mathbb{Z}^d}\hat{w}_{\boldsymbol{k}}\mathrm{e}^{2\pi\mathrm{i}\boldsymbol{k}\boldsymbol{x}}$$

[illegible] $\boldsymbol{j}=(j_0,\ldots,j_{d-1})^{\top}\in I_n$ [illegible]

$$\boldsymbol{K}:=\left(K\left(\frac{\boldsymbol{j}-\boldsymbol{l}}{n}\right)\right)_{\boldsymbol{j},\boldsymbol{l}\in I_n}\in\mathbb{C}^{n^d\times n^d}.$$

THEOREM 4.10. [illegible] $\boldsymbol{K}$ [illegible] 4.9 [illegible]

$$\lambda_{\boldsymbol{s}}(\boldsymbol{K})=n^d\sum_{\boldsymbol{r}\in\mathbb{Z}^d}\hat{w}_{\boldsymbol{s}+n\boldsymbol{r}}$$

[illegible] $\boldsymbol{s}\in I_n$ [illegible] $\hat{w}_{\boldsymbol{k}}=\prod_{t=0}^{d-1}\hat{w}_{k_t}$ $\sum_{k\in\mathbb{Z}}|\hat{w}_k|<\infty$ [illegible]

$$\lambda_{\boldsymbol{s}}(\boldsymbol{K})=n^d\prod_{t=0}^{d-1}\sum_{r_t\in\mathbb{Z}}\hat{w}_{s_t+nr_t}$$

[illegible] $\boldsymbol{s}\in I_n$ [illegible]

$$\boldsymbol{K}_{\Gamma}:=\left(K\left(\frac{\boldsymbol{j}-\boldsymbol{l}}{n}\right)\right)_{\boldsymbol{j},\boldsymbol{l}\in\Gamma}$$

[illegible] $\boldsymbol{K}$ [illegible] $\Gamma\subset I_n$

. The matrix $\boldsymbol{K}$ is multilevel circulant and thus diagonalized by the Fourier matrix $\boldsymbol{F}_n = (\mathrm{e}^{2\pi \mathrm{i} \boldsymbol{k}\boldsymbol{j}/n})_{\boldsymbol{j},\boldsymbol{k}\in I_n}$. We calculate

$$\begin{aligned}\left(\boldsymbol{F}_n^{\mathsf{H}} \boldsymbol{K} \boldsymbol{F}_n\right)_{\boldsymbol{s},\boldsymbol{t}} &= \sum_{\boldsymbol{j},\boldsymbol{l}\in I_n} \mathrm{e}^{-2\pi \mathrm{i} \boldsymbol{s}\boldsymbol{j}/n} K\left(\frac{\boldsymbol{j}-\boldsymbol{l}}{n}\right) \mathrm{e}^{2\pi \mathrm{i} \boldsymbol{t}\boldsymbol{l}/n} \\ &= \sum_{\boldsymbol{k}\in\mathbb{Z}^d} \hat{w}_{\boldsymbol{k}} \sum_{\boldsymbol{j}\in I_n} \mathrm{e}^{-2\pi \mathrm{i} \boldsymbol{j}(\boldsymbol{s}-\boldsymbol{k})/n} \sum_{\boldsymbol{l}\in I_n} \mathrm{e}^{2\pi \mathrm{i} \boldsymbol{l}(\boldsymbol{t}-\boldsymbol{k})/n}\end{aligned}$$

for $\boldsymbol{s}, \boldsymbol{t} \in I_n$ and use

$$\sum_{\boldsymbol{j}\in I_n} \mathrm{e}^{2\pi \mathrm{i} \boldsymbol{j}(\boldsymbol{s}-\boldsymbol{k})/n} = \begin{cases} n^d & \text{if } \ \frac{\boldsymbol{s}-\boldsymbol{k}}{n} \in \mathbb{Z}^d, \\ 0 & \text{otherwise.} \end{cases}$$

See also [15, Cor. 3.10, Thm. 3.11] for the univariate case.

The second assertion is due to the Kronecker product structure of the matrix $\boldsymbol{K}$ in the case of tensor product kernels. The last assertion follows from the fact that removing a node is nothing else than removing its corresponding row and column in $\boldsymbol{K}$ and from the interlacing property for eigenvalues; see [11, p. 185]. ∎

Now let $d, n \in \mathbb{N}$, $N \in 2\mathbb{N}$, and the equispaced sampling set $\mathcal{X} = \frac{1}{n} I_n \subset \mathbb{T}^d$ be given. A simple consequence of Theorem 4.10 is the fact that the kernel matrix $\boldsymbol{K}_N = \frac{1}{N} \boldsymbol{A}\boldsymbol{A}^{\mathsf{H}}$ is singular whenever $N < q^{-1} = n$. Hence, the condition $N > 2dq^{-1}$ for the full rank of $\boldsymbol{A}$ is optimal with respect to q. Nevertheless, we also apply Theorem 4.10 to obtain positive results in the equispaced setting for the Dirichlet and the Fejér kernels.

COROLLARY 4.11. $d \in \mathbb{N}$ $\mathcal{X}$ $M \geq 2$ $N \in 2\mathbb{N}$ $N > q^{-1} = M^{\frac{1}{d}}$ $B_{1,N}$ $d > 1$ $\boldsymbol{K}_N$

$$\left(\frac{\lfloor Nq \rfloor}{Nq}\right)^d = \lambda \leq 1 \leq \Lambda = \left(\frac{\lceil Nq \rceil}{Nq}\right)^d.$$

$B_{2,N}$

$$\left(1 - \frac{1}{N^2 q^2}\right)^d \leq \lambda \leq 1 \leq \Lambda \leq \left(1 + \frac{1}{N^2 q^2}\right)^d,$$

$N = (2\sigma+1)\, q^{-1}$, $\sigma \in \mathbb{N}$ K_N

. Throughout this proof, let $n = q^{-1}$ and the damping factors be extended by $\hat{w}_{\boldsymbol{k}} = 0$ for $\boldsymbol{k} \notin I_N$. We apply for $d = 1$ the first statement of Theorem 4.10 to the weights $\hat{w}_k = \frac{1}{N}$, $k \in I_N$, of the Dirichlet kernel for $N \in 2\mathbb{N}$ and to the weights $\hat{w}_k = \frac{2}{N}(1 - \frac{|2k+1|}{N})$, $k \in I_N$, of the Fejér kernel, if $N = (2\sigma+1)\, q^{-1}$, $\sigma \in \mathbb{N}$, respectively.

The assertion is a little more delicate for the univariate Fejér kernel and $N \neq (2\sigma+1)\, q^{-1}$. We use the representation

$$|B_{2,N}(x)| = \frac{4}{N^2} \sum_{r=0}^{\frac{N}{2}-1} \sum_{k=-r}^{r} \mathrm{e}^{2\pi \mathrm{i} k x}.$$

Now let $\lambda_\star$ be an arbitrary eigenvalue of the kernel matrix $\boldsymbol{K}_N$; then Gershgorin's circle theorem yields

$$|\lambda_\star - 1| \le \sum_{l=1}^{n-1} \left| B_{2,N}\left(\frac{l}{n}\right)\right| = \frac{4n}{N^2} \sum_{r=0}^{\frac{N}{2}-1} \left(2\left\lfloor \frac{r}{n}\right\rfloor + 1\right) - 1.$$

Since for $Q := \left\lfloor \frac{N-2}{2n}\right\rfloor$ and $R := \frac{N}{2} - 1 - nQ$ the identity

$$\sum_{r=0}^{\frac{N}{2}-1} \left\lfloor \frac{r}{n}\right\rfloor = \sum_{s=0}^{Q-1} \sum_{r=sn}^{(s+1)n-1} s + \sum_{r=nQ}^{nQ+R} Q = \frac{(N-n)^2 - (2(R+1)-n)^2}{8n}$$

holds, we proceed:

$$\begin{aligned}\frac{4n}{N^2} \sum_{r=0}^{\frac{N}{2}-1} \left(2\left\lfloor \frac{r}{n}\right\rfloor + 1\right) - 1 &= \frac{4n}{N^2}\left(2\frac{(n-N)^2 - (2(R+1)-n)^2}{8n} + \frac{N}{2}\right) - 1 \\ &= \frac{n^2}{N^2} - \left(\frac{2(R+1)-n}{N}\right)^2 \\ &\le \frac{n^2}{N^2}.\end{aligned}$$

The case $d > 1$ is due to the second statement in Theorem 4.10. ∎

5. Numerical results. In this section, we exemplify our findings on the stability of the optimal interpolation problem (1.3) and its iterative solution by Algorithm 1.

The estimates for the condition number of the kernel matrix $\boldsymbol{K}_N$ for equispaced nodes (cf. Corollary 4.11) are shown in Figure 5.1 (left). For $Nq \in \mathbb{N}$ and the Dirichlet kernel $B_{1,N}$ the matrix $\boldsymbol{K}_N$ is just the identity. However, using the better localized Fejér kernel $B_{2,N}$ improves the condition number already for $N > \sqrt{3}q^{-1}$ when $Nq \notin \mathbb{N}$.

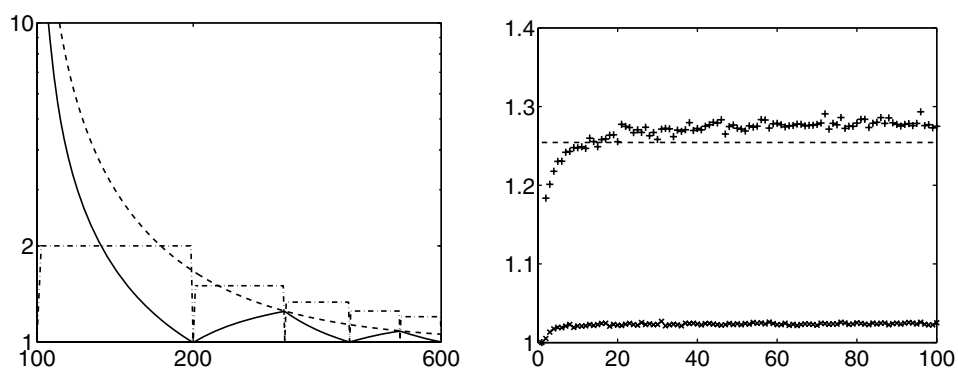

FIGURE 5.1. *Condition number of the kernel matrix $\boldsymbol{K}_N$. Left: Condition number with respect to polynomial degree $N = 100, \dots, 600$, no weights, i.e., Dirichlet kernel (dashed-dotted line); weight function g_2, i.e., Fejér kernel (solid line), and the estimate of Corollary* 4.11 (dashed line)*; here the number of equispaced nodes is $M = 100$. Right: Condition number with respect to the number of nodes $M = 1, \dots, 100$; the nodes are equispaced perturbed by $\varepsilon_{rel.} = 0.1$ jitter error; and the polynomial degree is $N = 6M$; no weights, i.e., Dirichlet kernel ($+$), weight function g_2, i.e., Fejér kernel ($\times$), and its estimate by Corollary* 4.3 *(dashed line).*

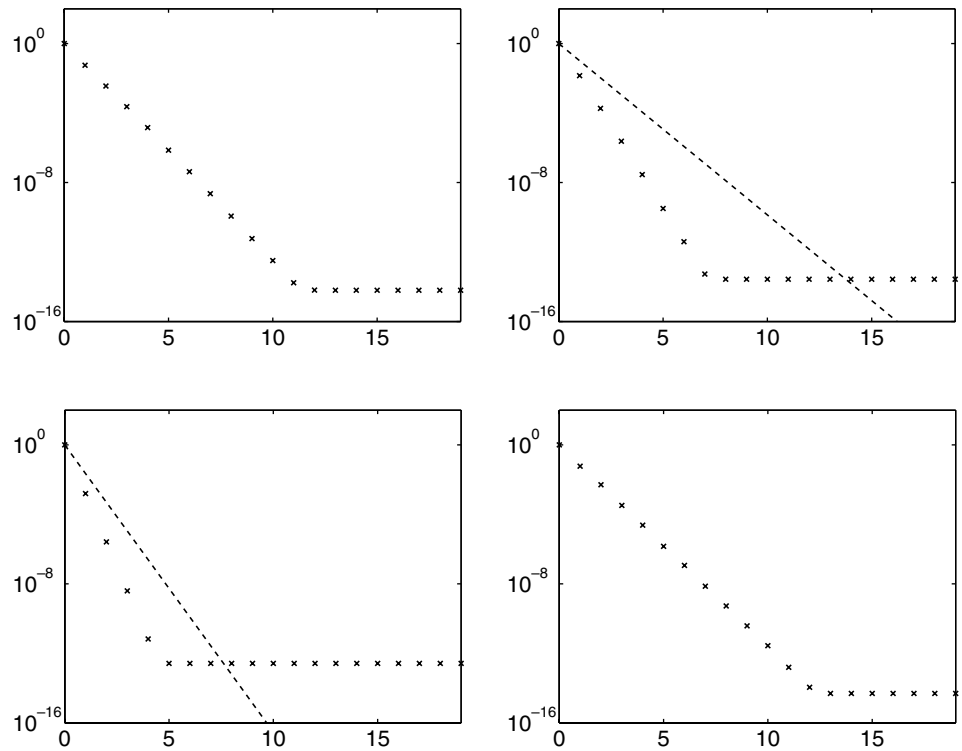

FIGURE 5.2. *Native error* $\|\hat{\boldsymbol{f}}_l - \hat{\boldsymbol{W}}\boldsymbol{A}^{\mathsf{H}}\boldsymbol{K}_N^{-1}\boldsymbol{y}\|_{\hat{W}^{-1}}$ *for the univariate interpolation problem with respect to the current iteration* l*. The number of samples is* $M = 100$*, the number of computed Fourier coefficients is* $N = 1000$*, and the separation distance of the nodes is* $q = 4 \times 10^{-3}$*. Top left: no weights, i.e., Dirichlet kernel. Top right: weight function* g_2*, i.e., Fejér kernel, and the predicted decay rate (dashed line). Bottom left: weight function* g_4*, i.e., B-spline kernel, and the predicted decay rate (dashed line). Bottom right: weight function* $g_{1,2,10^{-2}}$*, i.e., Sobolev kernel.*

We present the effect on the stability of the interpolation problem when the equispaced nodes are perturbed by jitter error (cf. Corollary 4.3) in Figure 5.1 (right). We choose different sampling sets of size $M = 1, \ldots, 100$ with equispaced nodes disturbed by 10% jitter error and evaluate the maximum condition number over 100 reruns for the Dirichlet kernel $B_{1,6M}$ and the Fejér kernel $B_{2,6M}$, respectively. The Fejér kernel produces a lower condition number, which is also validated by the shown upper bound. These results confirm the theoretical results of Corollaries 4.11 and 4.3.

Furthermore, we apply Algorithm 1 using the NFFT software package [12] to reconstruct a univariate signal from randomly scattered data in Figure 5.2 and show in Figure 5.3 the reconstruction of a bivariate signal from a glacier data set [8]. The main tool in our iterative algorithms is the NFFT, i.e., the fast matrix times vector multiplication with $\boldsymbol{A}$ and $\boldsymbol{A}^{\mathsf{H}}$, respectively. Details concerning NFFT algorithms can be found, for example, in [16], and a software package can be found in [12].

The reconstruction of the randomly sampled univariate signal shows the decay rates of our iterative scheme. The sampling set consists of $M = 100$ nodes separated by $q = 4 \times 10^{-3}$, and we reconstruct with a polynomial degree $N = 1000$ and the Dirichlet, Fejér, B-spline, and Sobolev kernels. All schemes converge within 15 iterations where this is justified only for the Fejér and the B-spline kernels.

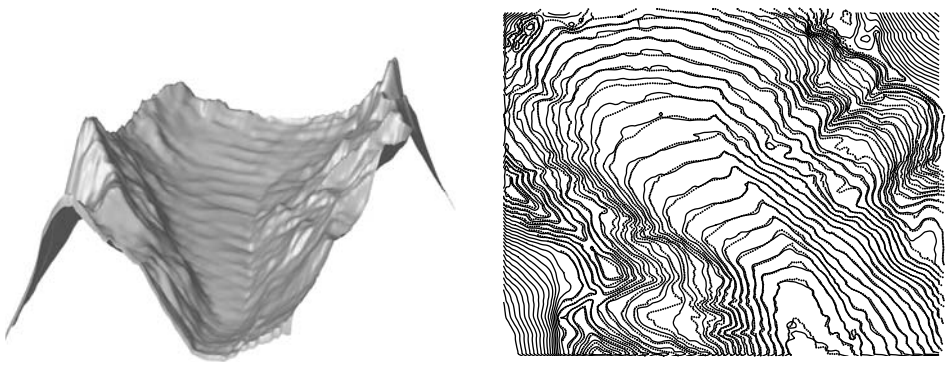

FIGURE 5.3. *Reconstruction of the glacier data set* `vol87.dat` *from* [8], $M = 8345$ *nodes,* $N = 256$, 40 *iterations, tensor product damping factors* $\hat{w}_{\mathrm{k}}$ *to the weight function* $g_{\frac{1}{2},3,10^{-3}}$; *see* `glacier` *in* [12]. *Left: Surface plot. TABLE 5.1

Cross-validation of the reconstructions. The parameters of the CGNE scheme are as before. Moreover, we show the residuals of the CGNR scheme for the least squares problem (1.2) *with* $N = 256$ *(underdetermined) and* $N = 64$ *(overdetermined).*

	CGNE		CGNR ($N = 256$)		CGNR ($N = 64$)	
$\tilde{M}$	r	$\tilde{r}$	r	$\tilde{r}$	r	$\tilde{r}$
200	$6.9e-04$	$1.7e-02$	$5.0e-04$	$1.4e-01$	$8.3e-03$	$1.7e-02$
400	$4.7e-04$	$2.3e-02$	$5.0e-04$	$2.0e-01$	$8.3e-03$	$2.3e-02$
600	$5.7e-04$	$2.9e-02$	$5.1e-04$	$2.5e-01$	$8.1e-03$	$2.9e-02$
800	$4.7e-04$	$3.4e-02$	$5.0e-04$	$2.8e-01$	$8.0e-03$	$3.4e-02$
1000	$4.6e-04$	$3.8e-02$	$4.7e-04$	$3.2e-01$	$8.0e-03$	$3.8e-02$

The last example shows a typical test case known in radial basis function methods. We reconstruct from a data set of $M = 8345$ samples on level curves of a glacier a total number of $2^8 \times 2^8 \approx 8M$ Fourier coefficients. Note, however, that the sampling set is highly nonuniform in the sense that the separation distance is very small compared to the mesh norm. The assumptions of Theorem 4.6 are not fulfilled. Nevertheless, the proposed method yields a very good approximation to the given data after 40 iterations, which is also supported by the cross validation test in Table 5.1. Here we exclude $\tilde{M}$ randomly chosen samples $\tilde{\mathcal{X}} \subset \mathcal{X}$, $\boldsymbol{y}_{\tilde{\mathcal{X}}} \in \mathbb{C}^{\tilde{M}}$ from the reconstruction process and compare our approximations at these left-out nodes. The comparison is done by means of the relative data residual and the relative validation residual after 40 iterations:

$$r := \frac{\|\boldsymbol{y}_{\mathcal{X}\setminus\tilde{\mathcal{X}}} - \boldsymbol{A}_{\mathcal{X}\setminus\tilde{\mathcal{X}}}\hat{\boldsymbol{f}}_{40}\|_2}{\|\boldsymbol{y}\|_2}, \qquad \tilde{r} := \frac{\|\boldsymbol{y}_{\tilde{\mathcal{X}}} - \boldsymbol{A}_{\tilde{\mathcal{X}}}\hat{\boldsymbol{f}}_{40}\|_2}{\|\boldsymbol{y}\|_2}.$$

As can be readily seen, the CGNE scheme achieves both a small data residual r and a small validation residual $\tilde{r}$. The proposed CGNE method combines the good data fit of the CGNR scheme ($N = 256$) with the smooth approximation of the CGNR scheme ($N = 64$).

6. Conclusion. We have shown that the optimal trigonometric interpolation problem at q-separated nodes in d dimensions is well conditioned for a polynomial

degree $N > 2dq^{-1}$. However, in our further extensive numerical examples we observe that for $N \sim M^{1/d}$ one can expect fast convergence of Algorithm 1. If we assume furthermore a uniformity condition $q = cM^{-\frac{1}{d}}$ for the sampling set $\mathcal{X}$ of cardinality M, then the total arithmetical complexity for solving the interpolation problem (1.3) up to a prescribed error is of order $\mathcal{O}(M \log M)$.

We remark that, dependent on the application, one solves the weighted approximation problem (1.2) or the optimal interpolation problem (1.3). Under some further mild conditions on the sampling set, both problems are solved efficiently by means of the conjugate gradient method in conjunction with the nonequispaced FFT.

Acknowledgment. We thank the referees for their valuable suggestions.

A FAST ALGORITHM FOR THE CALCULATION OF THE ROOTS OF SPECIAL FUNCTIONS*

ANDREAS GLASER†, XIANGTAO LIU†, AND VLADIMIR ROKHLIN‡

Abstract. We describe a procedure for the determination of the roots of functions satisfying second-order ordinary differential equations, including the classical special functions. The scheme is based on a combination of the Prüfer transform with the classical Taylor series method for the solution of ordinary differential equations and requires $O(1)$ operations for the determination of each root. When the functions in question are classical orthogonal polynomials (Legendre, Hermite, etc.), the techniques presented here also provide tools for the evaluation of the weights for the associated Gaussian quadratures. The performance of the scheme for several classical special functions (prolate spheroidal wave functions, Bessel functions, and Legendre, Hermite, and Laguerre polynomials) is illustrated with numerical examples.

Key words. roots, special functions, Gaussian quadratures, Sturm–Liouville

DOI. 10.1137/06067016X

1. Introduction.

Zeros of classical special functions play an important role in the mathematical sciences, being related to Gaussian quadratures (both classical and generalized), resonances in mechanical and electrical systems, quantum mechanical calculations, etc. As a result, algorithms for the determination of roots of functions of this type are quite well developed; most of them are based on the existence of three-term recurrence relations for the classical special functions and the associated connection to the eigenvalues of certain tridiagonal matrices (see, for example, [6, 9, 2]). The latter are dealt with via well-understood and reliable techniques, such as the QR iteration.

While such methods are quite efficient for small-scale problems, they require order n^2 operations, where n is the number of roots to be computed. Relatively recently, algorithms for the diagonalization of tridiagonal matrices were introduced with CPU time requirements proportional to $n \cdot \log(n)$ (see [7]); a detailed description of the resulting fast root-finding scheme is given in [13]. Another relatively recent development involves straightforward root-finding algorithms applied to the orthogonal polynomials (see [15, 11]); this leads to more efficient schemes producing nodes and weights to higher precision. However, the cost of the resulting procedures is still of the order n^2, albeit with a smaller constant. The scheme of this paper is a modification of this latter approach using the solution of the underlying ordinary differential equation (ODE) as a tool for the evaluation of the special function whose roots are to be found.

The subject of this paper is the observation that the roots of classical special functions (and of many others) can be found for a cost proportional to n, using the

fact that such functions satisfy ordinary differential equations of the form

$$p(x)\,\frac{d^2u}{dx^2}(x) + q(x)\,\frac{du}{dx}(x) + r(x)\,u(x) = 0, \tag{1}$$

where $p(x)$, $q(x)$, and $r(x)$ are polynomials of degree 2. Using classical tools such as Taylor series and Prüfer transformation, our approach leads to remarkably simple and efficient schemes for the construction of classical Gaussian quadratures, roots of Bessel and prolate spheroidal wave functions, and roots of other functions satisfying a second-order differential equation with polynomial coefficients.

The numerical procedure of this paper uses two steps to find each root (except the first one, which has to be determined by some other means). In the first step, an approximation to the root is found via the (numerical) solution of the Cauchy problem for an auxiliary differential equation; the equation is obtained via the so-called Prüfer transform (see, for example, [3]), and the initial condition is provided by the preceding root. In the second step, the root is found via the Newton method, coupled with a Taylor series-based scheme for the solution of the original equation (1).

It is worth noting that each of the two approaches [illegible] leads to a scheme with an asymptotically optimal CPU time estimate (i.e., requiring order n operations to determine n roots); we have implemented and tested such schemes. However, each of the two schemes has its drawbacks. The Taylor-based solution of the ODE (1) is extremely accurate and efficient but requires a local search (Newton, bisection, etc.) to find the root, and local search algorithms require initial values. Constructing such initial values is not very expensive, and the subject is quite well understood; on the other hand, schemes of this type tend to be problem-dependent or to require highly adaptive search algorithms.

In contrast, the Prüfer-based approach finds the root as a solution of a Cauchy problem for an ODE, obviating the need for a search. However, the Prüfer ODE has to be solved numerically and is not susceptible to high-order Taylor-based techniques. Thus, obtaining a high-accuracy solution tends to be relatively expensive (though the asymptotic cost is $O(n)$). In this paper we combine the two approaches, solving the Prüfer ODE to a low accuracy (2 to 4 digits) via a cheap low-order scheme and using the obtained solution as a starting point for a Taylor-based Newton method. However, in the case of classical Gaussian quadratures we eschew the use of the Prüfer equation, taking advantage of a well-known analytical approximation (see, for example, [15]).

The structure of the paper is as follows. In section 2, we summarize the mathematical and numerical tools to be used in the paper, while section 3 contains a description of the algorithm, and in section 4 we demonstrate numerical results for a number of special functions.

2. Mathematical and numerical preliminaries. In this section we summarize several well-known facts to be used in this paper; all of these can be found in [1, 3, 4, 12, 5]. Throughout this paper, the derivative of a function $f : \mathbb{R} \to \mathbb{R}$ will be denoted by f', and p, q, r will denote the second-order polynomials introduced in (1). All functions are assumed to be sufficiently smooth.

2.1. Taylor series for special functions. As is well known, any function $u : \mathbb{R} \to \mathbb{R}$ that is sufficiently smooth in the neighborhood of the point $x_0 \in \mathbb{R}$ can be approximated by its Taylor series

$$u(x_0 + h) = \sum_{k=0}^{m} \frac{u^{(k)}(x_0)}{k!} h^k + \varepsilon, \tag{2}$$

with

$$|\varepsilon| \leq \sup_{|x-x_0|\leq h} \left\{ \frac{u^{m+1}(x)}{(m+1)!} h^{m+1} \right\}, \tag{3}$$

where $u^{(k)}$ denotes the kth derivative of u; the Taylor series for u' is

$$u'(x_0+h) = \sum_{k=1}^{m} \frac{u^{(k)}(x_0)}{(k-1)!} h^{k-1} + \tilde{\varepsilon}, \tag{4}$$

with

$$|\tilde{\varepsilon}| \leq \sup_{|x-x_0|\leq h} \left\{ \frac{u^{m+1}(x)}{m!} h^{m} \right\}. \tag{5}$$

If u satisfies (1), and p, q, r are polynomials of order 2, then the consecutive derivatives of u can be obtained via a simple recursion. Indeed, differentiating (1) k times and carrying out elementary manipulations, we have

$$\begin{aligned} pu^{(k+2)} = &- (kp' + q)\, u^{(k+1)} - \left(\frac{k(k-1)}{2} p'' + kq' + r \right) u^{(k)} \\ &- \left(\frac{k(k-1)}{2} q'' + kr' \right) u^{(k-1)} - \frac{k(k-1)}{2} r'' u^{(k-2)} \end{aligned} \tag{6}$$

for any $k \geq 0$.

2.2. The Prüfer transform. Given (1) and a differentiable positive function $\gamma : \mathbb{R} \to \mathbb{R}$, we define the function $\theta : \mathbb{R} \to \mathbb{R}$ as the solution of the differential equation

$$\theta' = -\frac{\gamma}{p} \sin^2(\theta) - \frac{r}{\gamma} \cos^2(\theta) - \left(\frac{\gamma'}{\gamma} + \frac{q-p'}{p} \right) \frac{\sin(2\theta)}{2}, \tag{7}$$

where θ, γ, p, q, r are functions of x; integrating both sides of (7) with respect to x and carrying out elementary manipulations, we obtain

$$\theta(x) = \arctan\left(\frac{1}{\gamma(x)} \frac{p(x)u'(x)}{u(x)} \right) + k\,\pi, \tag{8}$$

where u is the function defined by (1), and k is an arbitrary integer; we observe that, for any $\tilde{x}$ such that $u(\tilde{x}) = 0$,

$$\theta(\tilde{x}) = (n + 1/2)\pi, \tag{9}$$

with n an integer. Similarly, for any $\tilde{x}$ such that $u'(\tilde{x})$=0,

$$\theta(\tilde{x}) = n\pi, \tag{10}$$

where again n is some integer.

The choice of the function γ in (8) influences the behavior of the function θ, without changing the solutions of (9) and (10). For example, if $\gamma \equiv 1$ and (1) is self-adjoint (i.e., $q = p'$), then

$$\theta' = -\frac{1}{p} \sin^2(\theta) - r \cos^2(\theta), \tag{11}$$

and the function θ is strictly decreasing if p and r are everywhere positive.

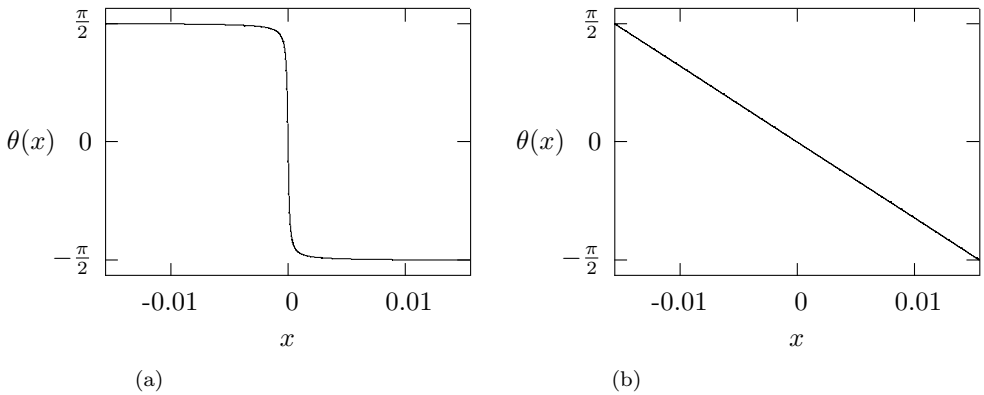

FIG. 1. (a) *shows* θ *as defined in* (7) *and* (8) *for a Legendre polynomial of order* 100 *with* $\gamma \equiv 1$. (b) *shows* θ *for the same polynomial with* $\gamma \equiv \sqrt{rp}$.

However, it often happens that $1/p$ and r are of different orders of magnitude; this causes the value of θ' to vary dramatically on the interval $\theta = [-\pi/2, \pi/2]$, making it inconvenient when used as a numerical tool. Figure 1(a) illustrates the last point. It shows θ for a Legendre polynomial of order $l = 100$, with $p = 1 - x^2$, $q = p'$, and $r = l(l+1)$, in the interval between the polynomial's greatest negative root and its least positive root.

Such steplike behavior complicates many numerical operations involving (7) and can be controlled via an appropriate choice of γ. Indeed, choosing

$$\gamma \equiv \sqrt{rp} \tag{12}$$

converts (8) into

$$\theta(x) = \arctan\left(\frac{1}{\sqrt{r(x)p(x)}}\frac{p(x)u'(x)}{u(x)}\right), \tag{13}$$

and substituting (12) into (7) yields

$$\theta' = -\sqrt{\frac{r}{p}} - \frac{r'p - p'r + 2rq}{2rp} \cdot \frac{\sin(2\theta)}{2}. \tag{14}$$

In this case, the large values of the product rp do not cause excessive variations in the magnitude of θ', which is illustrated by Figure 1(b), which shows θ for the same Legendre polynomial as in Figure 1(a) but with γ defined in (12).

Whenever $\frac{d\theta}{dx} < 0$, the ODE (14) can be rewritten in the form

$$\frac{dx}{d\theta} = -\left(\sqrt{\frac{r}{p}} + \frac{r'p - p'r + 2rq}{2rp} \cdot \frac{\sin(2\theta)}{2}\right)^{-1}, \tag{15}$$

where θ, γ, r, q, p are functions of x, and (15) can be viewed as a differential equation defining x as a function of θ. Clearly, θ' is guaranteed to be negative whenever

$$\left|\frac{r'p - p'r + 2rq}{4rp}\right| < \sqrt{\frac{r}{p}}, \tag{16}$$

and the latter condition is easy to test for and is satisfied by all standard special functions. We also observe that, given a solution x of (15) and an integer n, the function $\bar{x}$ defined by the formula

$$\bar{x}(\theta) = x(\theta + n\,\pi) \tag{17}$$

is also a solution of (15).

Historically, the Prüfer transform has been used as an instrument of analysis for differential equations in the vicinity of the WKB regime. Indeed, whenever

$$\left| \frac{r'p - p'r + 2rq}{2rp} \right| << \sqrt{\frac{r}{p}}, \tag{18}$$

the solution of the differential equation (14) is close to the solution of

$$\theta' = -\sqrt{\frac{r}{p}}, \tag{19}$$

and combining the latter with (13) yields the classical WKB approximation to the solution u of (1); higher-order terms in the WKB expansion of u are obtained via more detailed analysis of (14).

Observation 1. The combination of (9) and (10) with (15) suggests the use of (15) as a tool for finding roots of the function u defined by (1), as well as roots of the derivative u' of u.

Indeed, suppose that x_0 is a root of u. Defining the function x via the ODE (15) with the initial condition

$$x\left(\frac{\pi}{2}\right) = x_0, \tag{20}$$

we observe that, for each root $\tilde{x}$ of u, there exists an integer n such that

$$\tilde{x} = x\left(\frac{\pi}{2} + n\,\pi\right); \tag{21}$$

by the same token, for each root $\tilde{y}$ of u', there exists an integer n such that

$$\tilde{x} = x(n\,\pi). \tag{22}$$

In other words, given a single root x_0 of u, all other roots (and all roots of the derivative) of u can be determined by solving the Cauchy problem (15) with the initial condition (20). A trivial modification of the above procedure permits one to start from a root y_0 of the derivative of u; in this case, one has to solve (15) with the initial condition

$$x(0) = y_0. \tag{23}$$

An interesting characteristic of the above construction is the fact that it finds roots of the differential equation (1) by solving the Cauchy problem for an auxiliary equation, eliminating the need for a "solver" (bisection, Newton, etc.) as such.

Observation 2. Observation 1 is behind the use of the Prüfer transform as an analytical tool for the construction of asymptotic formulas for the roots of special functions (and also of their derivatives, etc.) in the vicinity of the WKB regime. In this paper, we use the Prüfer transform as a numerical tool applicable in a much less

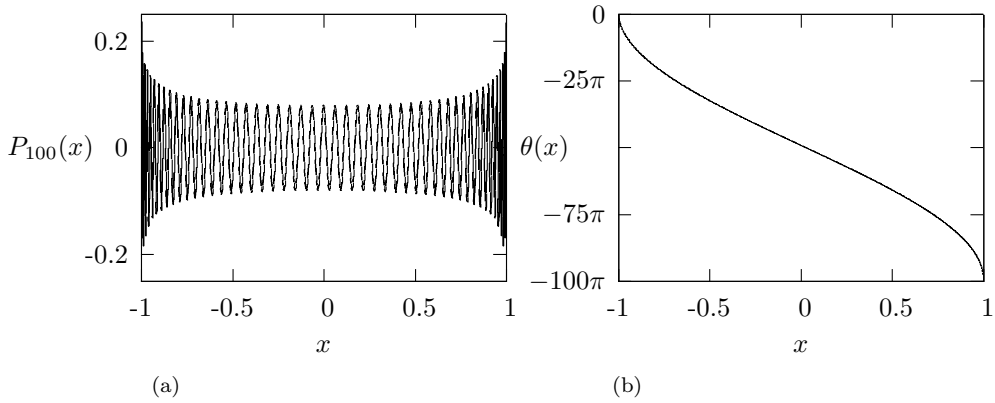

FIG. 2. (a) *shows the Legendre polynomial of order* 100. (b) *shows* θ *as defined in* (7) *and* (8) *for the same polynomial.*

restrictive environment. We solve (15) to low accuracy, and use the result as an initial approximation for the Newton procedure; the latter is based on a high-order Taylor method (see section 2.3.2 below).

In the WKB regime, our numerical solution of (15) is close to the WKB approximation and can be replaced by the latter. However, this involves detailed asymptotic analysis of each particular differential equation and results in only moderate reduction in the CPU time requirements of the method. Thus we use this latter approach only for the case of the Legendre nodes, where it is both trivial and well-known (see section 4.1 below).

. . . . 3. In our codes, we solve ODE (15) via a second-order Runge–Kutta scheme; it takes about 5 steps to march from one root of u to the next while maintaining three-digit accuracy. Replacing a second-order Runge–Kutta scheme with a second-order leapfrog scheme produces essentially identical results; replacing it with the Euler method leads to a minor increase in the CPU time requirements of the method. The Runge–Kutta scheme was chosen because of its simplicity.

We further illustrate the behavior of θ (as opposed to that of u) in Figures 2(a) and 2(b), containing graphs on the interval $[-1, 1]$ of the Legendre polynomial P_{100} of order 100 and of the corresponding θ defined via (7), with γ defined in (12). The difference in the behaviors of the functions θ and u implicit in Figures 2(a) and 2(b) is the reason for the popularity of the Prüfer transform as a tool of analysis; we use it as a numerical tool by converting (7) into (15), solving the latter to low precision on appropriately chosen intervals, and using the results as initial values for the Newton process.

2.3. Numerical tools. In this section we summarize several numerical techniques to be used in the paper. All of them can be found, for example, in [4].

2.3.1. A second-order Runge–Kutta method. The second-order Runge–Kutta method solves the initial-value problem

$$\begin{aligned} y(x_0) &= y_0, \\ y'(x) &= f(x, y) \end{aligned} \tag{24}$$

on the interval $[x_0, x_0 + L]$ by taking a sequence of n steps:

$$\begin{aligned} x_{i+1} &= x_i + h, \\ k_{i+1} &= h\, f(x_i + h, y + k_i), \\ y_{i+1} &= y_i + \frac{1}{2}(k_i + k_{i+1}), \end{aligned} \tag{25}$$

where $h = L/n$ and $k_0 = hf(x_0, y_0)$. The cost of this algorithm is of order n, where in this version of the scheme exactly $n + 1$ evaluations of the function f are required, producing the global truncation error of order h^2.

2.3.2. The Taylor series method for the solution of ODEs. The Taylor series method is a classical numerical scheme for the solution of ODEs. Given (1), the values of $u(x_k)$ and $u'(x_k)$ at the point x_k, and an appropriately chosen integer $m \geq 2$, the Taylor series method calls for repeated differentiation of the differential equation (1), resulting in the values of $u'''(x_k), u^{(4)}(x_k), \ldots, u^{(m-1)}(x_k), u^{(m)}(x_k)$. The latter are used to evaluate approximations to $u(x_{k+1}), u'(x_{k+1})$ via the expansions (2) and (4), with $h = x_{k+1} - x_k$. Obviously, the truncation error of one step of the Taylor series method is of the order h^m, and its cost is determined by the cost of finding the derivatives $u'''(x_k), \ldots, u^{(m-1)}(x_k), u^{(m)}(x_k)$; in the case of (1), the recursion (6) permits $u'''(x_k), \ldots, u^{(m-1)}(x_k), u^{(m)}(x_k)$ to be evaluated in $O(m)$ operations.

By choosing the order m of the expansions (2) and (4), one can control the accuracy of the Taylor series method, and often it makes sense to choose very high orders, obtaining essentially machine precision.

In our experience, choosing $m = 30$ results in slightly better than 16-digit accuracy, and $m = 60$ produces about 34 digits; we use the first choice in our double precision codes and the second choice in extended precision calculations (see section 4 below). Figure 3 depicts stability regions (in the usual λh-plane) in the two cases. Examination of Figure 3 indicates that the 30-term scheme is stable as long as the

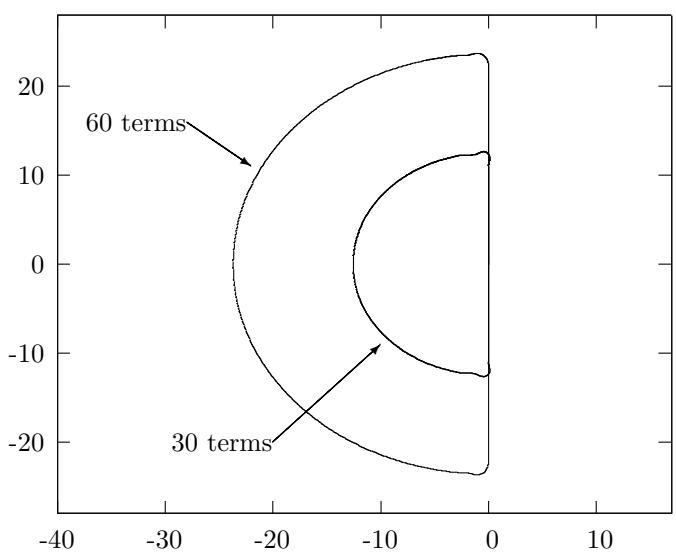

FIG. 3. *Stability domain of the Taylor series method for* 30 *terms and* 60 *terms.*

step is less than roughly 2 wavelengths (1 wavelength being 2π), and the 60-term scheme stays stable for steps that are roughly 4 wavelengths. Our algorithm makes steps from one root of the special function function to the next; if the function in question were $\sin(\lambda x)$ or $\cos(\lambda x)$, this would be exactly 1/2 of a wavelength, keeping us well away from stability problems. This crude analysis indicates that the algorithm should be stable in our environment and is supported by our numerical experience.

2.3.3. Newton's method. Given an initial approximation x_0, Newton's method solves the equation $f(x) = 0$ iteratively, with the nth iteration defined by the formula

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)}. \tag{26}$$

If $\tilde{x}$ is a simple root of f and x_0 has been chosen sufficiently close to $\tilde{x}$, then the convergence is quadratic; i.e., the number of correct digits of the approximation x_n will double after each iteration.

2.4. Orthogonal polynomials, Bessel functions, and prolate spheroidal wave functions. This section summarizes certain well-known properties of several classes of special functions, used in section 4 to test the performance of the algorithm of this paper; all of the facts in this section can be found in [1, 12, 5, 8], where the reader is referred for a more exhaustive discussion.

2.4.1. Orthogonal polynomials. Given a (possibly infinite) interval (a, b) and a positive function w such that the product of w with any polynomial is integrable on (a, b), we say that $p_0, p_1, \ldots, p_n$ is an orthogonal family of polynomials on (a, b) with weight w, if for each $k = 1, 2, 3, \ldots$, the polynomial p_k is of degree k and

$$\int_a^b p_i(x)\, p_j(x)\, w(x)\, dx = \begin{cases} 0, & i \neq j, \\ a_i, & i = j, \end{cases} \tag{27}$$

where $a_i > 0$.

In this subsection we briefly discuss properties of Legendre, Hermite, and Laguerre polynomials (denoted P_n, H_n, and L_n, respectively), which are examples of classical orthogonal families of polynomials. Polynomials within each of these families are orthogonal on an interval $(a, b) \in R^1$ with a certain weight function ω, and each polynomial p_k satisfies a homogeneous second-order ordinary differential equation of the form (1); the interval (a, b), the function ω, and coefficients $p(x), q(x), r(x)$ in (1) are specific for each family and can be found in columns 2–6 in Table 1. Each family satisfies a three-term recurrence relation of the form

$$a_m\, p_{m+1}(x) = (b_m + c_m x)\, p_m(x) - d_m\, p_{m-1}(x), \tag{28}$$

with $c_0, c_1, c_2, c_3, \ldots$, $d_0, d_1, d_2, d_3, \ldots$ real sequences specific to the families of orthogonal polynomials. Thus, given $x \in \mathbb{R}$, an integer $n > 2$, and the values $p_0(x)$ and $p_1(x)$, it follows from (28) that the values $p_2(x), p_3(x)$, $p_4(x), \ldots, p_n(x)$ can be evaluated in $O(n)$ operations.

Differentiating (28), we obtain the recurrence

$$a_m\, p'_{m+1}(x) = (b_m + c_m x)\, p'_m(x) - d_m\, p'_{m-1}(x) + c_m p_m(x), \tag{29}$$

which can be used for the efficient evaluation of the derivatives of $p_2, p_3, \ldots$. For the Legendre, Hermite, and Laguerre polynomials, the coefficients a_m, b_m, c_m, d_m can be found in columns 3–6 in Table 2.

TABLE 1
Intervals of orthogonality, weight functions, and coefficients of the ODEs.

Case	$[a, b]$	ω	p	q	r
P_n	$[-1, 1]$	1	$1 - x^2$	$-2\,x$	$n\,(n+1)$
H_n	$[-\infty, \infty]$	e^{-x^2}	1	$-2x$	$2n$
L_n	$[0, \infty]$	e^{-x}	x	$1 - x$	n

TABLE 2
Quadrature weights and coefficients of three-term recurrences.

Case	w_n^k	a_n	b_n	c_n	d_n
P_n	$2(1 - x_k^2)^{-1}\, P_n'^{-2}(x_k)$	$n + 1$	0	$2n + 1$	n
H_n	$\sqrt{\pi} 2^{n+1} n!\, H_n'^{-2}(x_k)$	1	0	2	$2n$
L_n	$[x_k L_n'^2(x_k)]^{-1}$	$n + 1$	$2n + 1$	-1	n

The Legendre and Hermite polynomials of even degrees are even and have a local extremum at $x = 0$; for odd degrees they are odd and have a root at $x = 0$. We will also make use of the fact that the first (smallest) root x_1^n of the nth Laguerre polynomial satisfies the inequality

$$x_1^n > \frac{2}{4n + 2} \tag{30}$$

(see, for example, formula 22.16.8 in [1]).

Orthogonal polynomials are a classical tool for the design of numerical integration rules known as Gaussian quadratures. Given the roots $x_1, \ldots, x_n$ of the nth degree polynomial p_n of an orthogonal family on the interval (a, b) with weight function w, there exist real numbers $w_1^n, \ldots, w_n^n$ such that the formula

$$\int_a^b f(x)\, w(x)\, dx \approx \sum_{k=1}^{n} w_k^n\, f(x_k) \tag{31}$$

is exact for any f that is a polynomial of degree $2n - 1$ or less.

Given the roots of the appropriate polynomials, the quadrature weights for the classical Gaussian quadratures are available analytically, and the formulas for the Legendre, Hermite, and Laguerre cases can be found in column 2 of Table 2.

4. As is well known, numerical evaluation of the polynomials on the interval $[-1, 1]$ cannot cause overflow problems, since $|P_n(x)| \leq 1$ for all $x \in [-1, 1]$. On the other hand, the polynomials H_n and L_n grow rapidly with x, even for moderate values of x; for all practical purposes, they cannot be evaluated in the standard floating point arithmetic.

This problem is easily avoided by replacing the polynomials H_n and L_n with the so-called normalized Hermite and Laguerre functions, defined by the formulas

$$\widetilde{H}_n(x) = \frac{e^{-x^2/2}}{\pi^{\frac{1}{4}} 2^{n/2} \sqrt{n!}} H_n(x), \tag{32}$$

$$\widetilde{L}_n(x) = e^{-x/2} L_n(x), \tag{33}$$

respectively. Obviously, the functions $\widetilde{H}_n(x)$ and $\widetilde{L}_n(x)$ have the same roots as $H_n(x)$ and $L_n(x)$, and $|\widetilde{H}_n(x)| < 1$, $|\widetilde{L}_n(x)| \leq 1$ for all $x \geq 0$, since

$$|H_n(x)| < \pi^{\frac{1}{4}} 2^{n/2} \sqrt{n!}\, e^{x^2/2}, \tag{34}$$

$$|L_n(x)| \leq e^{x/2} \tag{35}$$

(see, for example, section 22.14 in [1]).

Simple algebraic manipulations show that

$$\widetilde{H}_n''(x) + (2n + 1 - x^2)\widetilde{H}_n(x) = 0, \tag{36}$$

$$x^2 \widetilde{L}_n''(x) + x\, \widetilde{L}_n'(x) - \left(\frac{1}{4}x^2 - \left(n + \frac{1}{2}\right) x\right) \widetilde{L}_n(x) = 0, \tag{37}$$

and

$$\widetilde{H}_{n+1}(x) = \sqrt{\frac{2}{n+1}}\, x\, \widetilde{H}_n(x) - \sqrt{\frac{n}{n+1}}\, \widetilde{H}_{n-1}(x), \tag{38}$$

with $\widetilde{H}_{-1} = 0$, $\widetilde{H}_0 = \pi^{-\frac{1}{4}} e^{-x^2/2}$. Furthermore, if x is a root of H_n, then $\widetilde{H}_n'(x)$ can be evaluated via the recurrence

$$\widetilde{H}_{n+1}'(x) = \sqrt{\frac{2}{n+1}} \left(x\, \widetilde{H}_n'(x) + \widetilde{H}_n(x)\right) - \sqrt{\frac{n}{n+1}}\, \widetilde{H}_{n-1}'(x), \tag{39}$$

with $\widetilde{H}_{-1} = 0$, $\widetilde{H}_0 = 0$. Combining (32) with column 2 in Table 2, we observe that

$$w_k^n = \frac{2\, e^{-x_k^2}}{\widetilde{H}_n'^2(x_k)}. \tag{40}$$

The functions $\widetilde{L}_n$ can be evaluated via the recurrence

$$\widetilde{L}_{n+1}(x) = \frac{2n + 1 - x}{n+1} \widetilde{L}_n(x) - \frac{n}{n+1} \widetilde{L}_{n-1}(x), \tag{41}$$

the same recurrence relation as for L_n, with $\widetilde{L}_{-1}(x) = 0$, $\widetilde{L}_0(x) = e^{-x/2}$. If x is a root of $\widetilde{L}_n$, then $\widetilde{L}_n(x)$ can be evaluated via the recurrence

$$\widetilde{L}_{n+1}'(x) = \frac{2n + 1 - x}{n+1} \widetilde{L}_n'(x) - \frac{1}{n+1} \widetilde{L}_n(x) - \frac{n}{n+1} \widetilde{L}_{n-1}'(x), \tag{42}$$

with $\widetilde{L}_{-1}(x) = 0$, $\widetilde{L}_0(x) = 0$, $\widetilde{L}_{-1}'(x) = 0$, $\widetilde{L}_0'(x) = 0$. Finally, combining (33) with column 2 in Table 2, we obtain

$$w_k^n = \frac{e^{-x_k}}{x_k \widetilde{L}_n'^2(x_k)}. \tag{43}$$

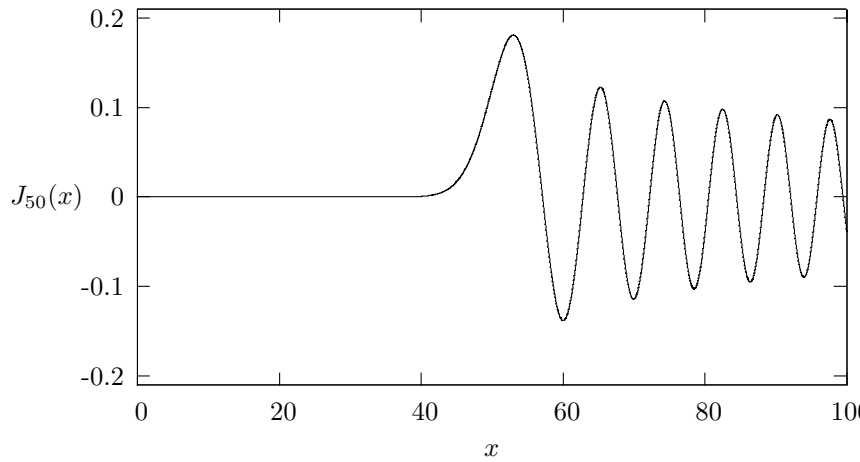

FIG. 4. *Plot of* J_{50}.

2.4.2. Bessel functions. The Bessel function J_n of order n is analytic in the whole plane and satisfies the differential equation

$$x^2 J_n''(x) + x\, J_n'(x) + (x^2 - n^2) J_n(x) = 0. \tag{44}$$

The behavior of J_n on the real axis is illustrated in Figure 4, where the graph of J_{50} is depicted. The Bessel function of order n is small and monotone for $|x| < n + n^{1/3}$ and starts to oscillate after that; for any $n \geq 1$

$$x_1 > n + n^{\frac{1}{3}}, \tag{45}$$

with x_1 the smallest positive root of J_n. For large values of x, the asymptotic behavior of J_n is given by the formula

$$J_n(x) \approx \sqrt{\frac{2}{\pi\, x}} \cos\left(x - \left(n + \frac{1}{2}\right)\frac{\pi}{2}\right) + \quad \left(\frac{1}{x^{1.5}}\right). \tag{46}$$

Numerical evaluation of J_n is a well-studied subject; there exist several classical schemes for the evaluation of $J_n(x)$ and its derivative for a cost proportional to n; several are described in [1].

2.4.3. Prolate spheroidal wave functions. Prolate spheroidal wave functions corresponding to the band limit c are eigenvectors of the integral operator G_c defined via the formula

$$F_c(\psi)(x) = \int_{-1}^{1} e^{icxt} \psi(t)\, dt; \tag{47}$$

they are also the eigenvectors of the differential operator

$$G_c(\psi)(x) = (1 - x^2)\psi''(x) - 2x\, \psi'(x) - c^2 x^2 \psi(x). \tag{48}$$

The nth eigenvalue of the operator (48) is normally denoted by χ_n, so that the nth eigenvector ψ_n of (48) satisfies the ODE

$$(1 - x^2)\psi_n''(x) - 2x\, \psi_n'(x) + (\chi_n - c^2 x^2)\psi_n(x) = 0, \tag{49}$$

which provides standard tools for the evaluation of the functions ψ_n, eigenvalues χ_n, and related quantities.

The function ψ_n has n roots on the interval $[-1, 1]$; for even n the function ψ_n is even and has a local extreme value at $x = 0$; for odd n the function ψ_n is odd and has a root at $x = 0$. We refer the reader to [14, 10] for more detailed information about prolate spheroidal wave functions.

3. Description of the algorithm. In this section we describe an algorithm for computing the roots of a function u satisfying (1). We start with an informal outline in the section below, followed by a more detailed description in section 3.2.

3.1. Informal description. The algorithm of this paper finds all roots of a function u satisfying (1) recursively, in that the values of u and its derivatives at the preceding root are used in finding the next one.

Given a starting value x_s, the algorithm calculates the smallest root x_1 that is larger or equal to x_s in two steps. First, it finds an approximation $\tilde{x_1}$ to the initial root by calculating $\theta_0 = \theta(x_s)$ via (13) and solving the differential equation (15) with the initial condition $x(\theta_0) = x_s$ in the interval $\theta \in (\theta_0, -\pi/2)$ via the Runge–Kutta method (25). Due to (9), the value of x at $-\pi/2$ is a root of u.

5. In our experience, four steps of the Runge–Kutta method are sufficient to yield x_1 with two to three digits of accuracy. Using a higher-order scheme for the solution of the differential equation (15) and increasing the number of nodes in the discretization of the interval $(\pi/2, -\pi/2)$, one could obtain the root x_1 with arbitrarily high precision. While this scheme could be used to find all roots $x_1, x_2, \ldots, x_n$ for a cost proportional to n, its actual cost would be much greater than the cost of the scheme of this paper, where we solve (15) to low precision and refine the solution via the Newton procedure described below.

The second step uses the Newton procedure (26) to obtain the root x_1, starting with the approximation $\tilde{x}_1$. Since the Newton process is quadratically convergent, it takes about three steps per root to obtain 16-digit accuracy, and each of the steps requires the evaluation of u and u' at a point in the vicinity of x_{i+1}.

The evaluation of u and u' is performed by a scheme specific to the function u. If the cost of the evaluation is k operations, then the cost for calculating the first root is $O(k)$. For orthogonal polynomials, u and u' can be evaluated via the recurrence relations (28) and (29) for a cost proportional to the degree of the polynomial.

6. In many cases (such as Legendre and Hermite polynomials, prolate spheroidal wave functions, etc.), the initial root or extreme value are available analytically due to symmetry considerations, since an odd function always has a root at 0, and the derivative of an even function is odd. In such cases, the determination of the initial root is trivial. We discuss some of the specific details in sections 3.2 and 4 below.

Given a root x_i of u, the algorithm finds the next bigger root x_{i+1} of u in two steps. The first step finds an approximation $\tilde{x}_{i+1}$ by solving the differential equation (15) via the Runge–Kutta scheme (25) on the interval $\theta \in (\pi/2, -\pi/2)$ with the initial condition $x(\pi/2) = x_i$. Due to (9), $\tilde{x}_{i+1}$ is an approximation to the root x_{i+1}.

The second step uses the Newton procedure (26) to increase the accuracy of the approximation $\tilde{x}_{i+1}$. The values of u and u' required by the Newton method are evaluated via the expansions (2) and (4), and the derivatives of u are computed via the recurrence (6).

. . . . 7. While inequalities (3) and (5) provide an analytical tool for estimating the required number m of terms in the Taylor expansion (2), we have found it convenient to determine the appropriate values of m numerically. For all examples in this paper, 30 terms are sufficient for double precision (16-digit) accuracy, and 60 terms produce 34 digits.

The cost of evaluating expansion (2) is more or less independent of the coefficients p, q, r of (1) and is reasonably small. Adding up the costs for all n roots, we observe that the total cost of the algorithm is of the order $n\,m + k$ operations, with n the number of roots to be found, m the number of terms in the Taylor series, and k the (problem-specific) cost of a single evaluation of u and u'. The repeated evaluation of u via its Taylor expansion can be seen as a version of the Taylor series method described in section 2.3.2.

. . . . 8. In the algorithm described above, Taylor expansions are used to evaluate u close to its roots. Needless to say, Taylor expansions can also be used to evaluate u between roots, thus providing a scheme for the rapid evaluation of u. Specifically, given a set of M points $\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_M$, where $\tilde{x}_{i-1} \leq \tilde{x}_i$, and n roots $x_1, x_2, \ldots, x_n$ of u, where $x_{i-1} \leq x_i$, the scheme finds the closest root to each point $\tilde{x}_i$ and evaluates u at $\tilde{x}_i$ via a Taylor expansion at that root. Including the cost of computing the n roots of u, the total cost of this scheme is of the order of $(M+n)\,m+k$ operations.

3.2. Detailed description. In this section we describe the numerical scheme of this paper in some detail. Algorithm 1 describes the core procedure. As input, it requires the smallest root of u and the number N of roots to be determined. It returns the roots $x_1 \ldots x_N$ and the derivatives $u'(x_1) \ldots u'(x_N)$ for a cost of $O(N)$ operations. Algorithms 2 and 3 are auxiliary schemes for finding the initial root.

Algorithm 1
Comment[The input parameters are the polynomial coefficients of p, q, and r in (1), an initial root x_1 of u, the number of roots N which are greater than or equal to x_1, and the derivative $u'(x_1)$ at the initial root x_1. Algorithm 1 returns in the array *roots* the N roots $x_1, x_2, \ldots, x_N$ of u such that $x_i \geq x_1$ for all $i = 1, 2, \ldots, N$. Furthermore, it returns in the array *ders* the values $u'(x_i)$ for $i = 1, 2, \ldots, N$.]

Set $roots(1) = x_1$ and $ders(1) = u'(x_1)$.

do $i = 1,\ N - 1$

1. Use the Runge–Kutta method (25) to solve (15) for $\theta = \pi/2$ to $-\pi/2$ with initial conditions $\theta_0 = \pi/2$ and $x(\theta_0) = roots(i)$. The resulting value for $x(-\pi/2)$ is the initial approximation to $roots(i+1)$.
2. Use recurrence relation (6) to calculate the first m derivatives of u at $x = roots(i)$, starting with $u(x) = 0$, $u'(x) = ders(i)$.
3. Improve the precision of $roots(i+1) = x(-\pi/2)$ via Newton's method (26), where u and u' are evaluated via the first m terms of the Taylor expansion around $roots(i)$. Set $ders(i+1) = u'(roots(i+1))$.

end do

If a local extremum instead of a root of u is given, an analogous procedure to steps 1–3 of Algorithm 1 can be used to calculate the next biggest root. This procedure is described in Algorithm 2.

Algorithm 2
Comment [The input parameters are the polynomial coefficients of p, q, and r in (1), an extreme value x_e of u, and $u(x_e)$. Algorithm 2 returns the smallest root x_1 of u such that $x_1 > x_e$; it also returns the derivative $u'(x_1)$ of u at x_1.]

1. Use the Runge–Kutta method (25) to solve (15) for $\theta = 0$ to $-\pi/2$ with initial conditions $\theta_0 = 0$ and $x(\theta_0) = x_e$. The resulting value for $x(-\pi/2)$ is the initial approximation to x_1.
2. Use recurrence relation (6) to calculate the first m derivatives of u at x_e, starting with $u(x_e)$, $u'(x_e) = 0$.
3. Improve the precision of $x_1 = x(-\pi/2)$ via Newton's method (26), where u and u' are evaluated via the first m terms of the Taylor expansion around x_e. Return x_1 and $u'(x_1)$.

If the first roots of u lie in a regime where the Taylor expansion converges poorly, the following algorithm can be used.

Algorithm 3
Comment [Algorithm 3 requires a routine for evaluating u and u'. Its input parameters are such a routine, the polynomial coefficients of p, q, and r in (1), and a starting value x_s such that $x_s < x_1$, with x_1 the smallest root of u. Algorithm 3 returns the smallest root x_1 of u and the derivative $u'(x_1)$ of u at x_1.]

1. Compute $\theta(x_s)$ via (13).
2. Use the Runge–Kutta method (25) to solve (15) for $\theta = \theta(x_s)$ to $-\pi/2$ with initial conditions $\theta_0 = \theta(x_s)$ and $x(\theta_0) = x_s$. The resulting value for $x(-\pi/2)$ is the first approximation to x_1.
3. Improve the precision of $x_1 = x(-\pi/2)$ via Newton iterations, where u and u' are evaluated by the given routine, which is specific to u. Return x_1 and $u'(x_1)$.

9. Once the algorithms described above were implemented and profiled, it turned out that, in most cases, about 30% of the CPU time was spent solving (15) via the Runge–Kutta method, and most of that time was expended evaluating the *sine* function in (15). Observing that the algorithm uses the solution of (15) to compute initial approximations to the roots with approximately 3-digit accuracy, we replaced the standard FORTRAN evaluation of the *sine* function with a table lookup using a table with 1000 entries. This modification reduced the CPU time requirements of the scheme by about 20%.

4. Implementation and numerical results. The algorithm of this paper has been implemented in FORTRAN 77 and tested on several classical families of special functions. We used the Lahey–Fujitsu FORTRAN 95 compiler with the optimization flag set to –o2, run on Intel Pentium 4, 3.6 GHz with 3 GB RAM. The algorithm has been applied to Legendre, Hermite, and Laguerre polynomials, Bessel functions, and prolate spheroidal wave functions.

The results of our tests involving Legendre, Hermite, and Laguerre polynomials are summarized in Tables 3, 4, and 5, respectively; since one of the principal uses of roots of orthogonal polynomials is in numerical integration, we included the evaluation of the weights of the corresponding quadratures via (40), (43), and Table 2. In each case, the roots of the corresponding polynomial and the associated weights were evaluated in double precision with the number of terms m in the expansion (2) set to 30 and in extended precision with $m = 60$; the difference between values of a root (or a weight) obtained via these two calculations was viewed as the error of the double precision calculation.

Throughout this section, given the roots

$$x_1, x_2, \ldots, x_n \tag{50}$$

of a special function, $x_1^{(d)}, x_2^{(d)}, \ldots, x_n^{(d)}$ will denote the approximation to (50) obtained via our double precision calculation, and $x_1^{(q)}, x_2^{(q)}, \ldots, x_n^{(q)}$ will denote the approximation to (50) obtained via our extended precision calculation. Similarly, given the weights

$$w_1, w_2, \ldots, w_n \tag{51}$$

of a quadrature formula, $w_1^{(d)}, w_2^{(d)}, \ldots, w_n^{(d)}$ will denote the approximation to (51) obtained via our double precision calculation, and $w_1^{(q)}, w_2^{(q)}, \ldots, w_n^{(q)}$ will denote the approximation to (51) obtained via our extended precision calculation.

Several measures of error were calculated.

1. The maximum relative error $\varepsilon_{mr}(\{x_i\})$ of the nodes $x_1, x_2, \ldots, x_N$ defined by the formula

$$\varepsilon_{mr}(\{x_i\}) = \max_i \left\{ \frac{\left| x_i^{(d)} - x_i^{(q)} \right|}{|x_i|} \right\} \tag{52}$$

TABLE 6

TABLE 7
Prolate spheroidal wave functions.

Number of nodes	Band limit c	$\varepsilon_{mr}(\{x_i\})$	CPU time (seconds)
2 000	1 000	4.10×10^{-15}	0.002
20 000	10 000	6.28×10^{-15}	0.018
200 000	100 000	2.08×10^{-14}	0.18
2 000 000	1 000 000	4.13×10^{-14}	1.83
2 000 000	1 000 000	Extended (32-digit) precision	386.6

was evaluated in all cases and can be found in column 2 of each of Tables 3, 4, and 5 and in column 3 of Tables 6 and 7.

2. The maximum relative error $\varepsilon_{mr}(\{w_i\})$ of the weights $w_1, w_2, \ldots, w_N$ defined by the formula

$$\varepsilon_{mr}(\{w_i\}) = \max_i \left\{ \frac{\left| w_i^{(d)} - w_i^{(q)} \right|}{|w_i|} \right\} \tag{53}$$

was evaluated for each quadrature (Legendre, Hermite, Laguerre) and can be found in column 3 of each of Tables 3, 4, and 5.

3. The relative maximum error $\varepsilon_{rm}(\{w_i\})$ of the weights $w_1, w_2, \ldots, w_N$ defined by the formula

$$\varepsilon_{mr}(\{w_i\}) = \left\{ \frac{\max_i \left| w_i^{(d)} - w_i^{(q)} \right|}{\max_i |w_i|} \right\} \tag{54}$$

was evaluated for each quadrature and can be found in column 4 of each of Tables 3, 4, and 5.

4. Measuring the accuracy of the quadratures (as opposed to the accuracy of nodes or weights separately) does not involve comparison between results of double precision calculations and those obtained in extended precision. Indeed, the quadrature is expected to evaluate exactly polynomials of orders up to $2N-1$ with the appropriate weight function, and some of these integrals are known analytically, in particular,

$$\int_a^b \omega(x)\, p_j(x)\, p_l(x)\, dx = \sum_{i=1}^{N} w_i\, p_j(x_i)\, p_l(x_i) = \delta_{jl}, \tag{55}$$

for any j, l such that $j, l \leq 2N-1$, and δ_{jl} denoting the Kronecker δ-function.

We use the identity (55) to test the accuracy of our quadratures by choosing at random K indices $i_1, i_2, \ldots, i_K$ between 0 and $N-1$ and viewing the maximum

$$\varepsilon_{quad}(\{(x_i, w_i)\}) = \max_{j,l \in [1,K]} \left| \delta_{jl} - \sum_{k=1}^{n} w_k \, p_{i_j}(x_k) p_{i_l}(x_k) \right| \tag{56}$$

as a measure of the accuracy of the scheme. The polynomials p_{i_j} in (56) are evaluated via the procedure described in Remark 8. In order to avoid additional accuracy loss from this computation, we perform the evaluation of p_{i_j} in extended precision. Furthermore, K in (56) above is chosen to be sufficiently large to provide a reasonable estimate and sufficiently small to keep the calculation feasible. For the calculations in extended precision, we set $K = 20$; the values of $\varepsilon_{quad}(\{(x_i, w_i)\})$ can be found in column 5 in each of Tables 3, 4, and 5.

To conclude the description of Tables 3–7, we note that the last column in each of them contains the CPU time taken by the corresponding calculation in seconds; for the polynomials (Legendre, Hermite, and Laguerre), this includes the time used to calculate the weights of the corresponding quadrature weights. Finally, the last row describes an extended precision calculation involving 1,000,000 roots; in the latter case, we report $\varepsilon_{quad}(\{(x_i, w_i)\})$ for the Gaussian quadratures (when applicable) and the CPU time taken by the calculation.

4.1. Legendre polynomials. Since for every positive root of a Legendre polynomial there exists a negative root of the same absolute value, it is sufficient to compute only the positive roots. If n is even, P_n has an extreme value at $x = 0$, and Algorithm 2 is used to find the first positive root, followed by Algorithm 1 to find the $n/2 - 1$ subsequent roots. If n is odd, P_n has a root at $x = 0$, and Algorithm 1 is used to find the $(n-1)/2$ positive roots. The values for $P_n(0)$ or $P_n'(0)$ which are required as input for Algorithm 2 or 1 are calculated via the recurrence relations (28) and (29). Finally, the Legendre quadrature weights are calculated via the appropriate formula in column 2 of Table 2.

. . . . 10. In this case, we replaced the initial low-accuracy approximation of each root via the numerical solution of the Prüfer equation (step 1 in Algorithm 1) with a well-known asymptotic formula

$$x_k = \left\{ 1 - \frac{(n-1)}{8n^3} - \frac{1}{384n^4} \left(39 - \frac{28}{\sin^2(\theta_k)} \right) \right\} \cos(\theta_k) + O(n^{-5}), \tag{57}$$

with

$$\theta_k = \left(\frac{4(\lceil \frac{n}{2} \rceil - k) - 1}{4n + 2} \right) \pi, \tag{58}$$

and $\lceil \frac{n}{2} \rceil$ denoting the integer part of $\frac{n}{2}$ (see, for example, [15]); this change resulted in a reduction in the CPU time requirements of the scheme of about 25%. While asymptotic formulas of various types are available for roots of all of the special functions considered in this section, in other cases we used the generic step 1 in Algorithm 1, in order to demonstrate the general nature of the approach.

The results of our numerical experiments with Legendre polynomials are summarized in Table 3.

4.2. Hermite polynomials. To avoid numerical overflow, we applied our algorithm to the normalized Hermite functions $\widetilde{H}_n$ instead of the polynomials (see Remark 4).

Since Hermite polynomials have the same symmetry as Legendre polynomials, the computation of the first root and the application of the main algorithm is analogous. The values $\widetilde{H}_n(0)$ and $\widetilde{H}'_n(0)$ are calculated via the recurrence relations (38) and (39). Formula (40) is used to calculate the Hermite weights from the obtained roots and derivatives of the Hermite functions. Instead of weights w_k^n defined in (40), we calculate the "scaled" version $w_k^n e^{x_k^2}$, in order to avoid underflow problems. Results of our experiments with Hermite polynomials are summarized in Table 4.

4.3. Laguerre polynomials. To avoid overrflow problems, we used the differential equation (37) for the normalized Laguerre functions, instead of the standard Laguerre equation (see Remark 4). Inequality (30) motivates the starting value $x_s = \frac{2}{4n+2}$, and recurrence relations (41) and (42) are used for the evaluation of the function and its derivative. The quadrature weights are calculated via formula (43) and returned in the form $w_k^n e^{x_k}$. Results of these experiments are summarized in Table 5.

[illegible] 11. This is the only case discussed in this paper where the procedure of section 3 had to be altered slightly. Indeed, the differential equation (37) has a singularity at $x = 0$, causing the roots to concentrate near that point. Thus, the Taylor series (2) with the origin at x_i does not converge at x_{i+1} for the first several values of i and converges slowly for several more. Without analyzing the problem carefully, we changed the procedure, as follows. We started with the procedure described in section 3 but omitting the Newton step altogether in other words, we used the Prüfer ODE to find all of the roots to low precision. After that, we refined the obtained approximations using the Taylor series exactly as described in section 3 but starting with the node x_n (i.e., the [illegible] node) and marching in the direction of decreasing roots. Since this simple expedient eliminated the problem completely, we did not investigate the matter further.

4.4. Bessel functions. The function J_n satisfies the differential equation (44). The first root is found via Algorithm 3 with the starting value $x_s = n + n^{\frac{1}{3}}$ motivated by (45). The values for $J_n(x_s)$ and $J'_n(x_s)$ are calculated by means of a standard scheme found, for example, in sections 9.12 and 9.1.27 of [1].

In each case, we calculated the first $20\,n$ roots of J_n, and results of these numerical experiments are summarized in Table 6.

4.5. Prolate spheroidal wave functions. The function ψ_n satisfies the ODE (49); the reader is referred to [14, 10] for the procedure we used to to evaluate the eigenvalue χ_n in each case. The determination of the first root is analogous to that for the Legendre polynomials, since the symmetry structures of these two classes of functions are similar. Results of these numerical experiments are summarized in Table 7.

4.6. Observations. Several observations can be made from Tables 3–7 and from our more detailed numerical experiments.

1. The cost of the algorithm increases linearly with n (the number of roots), as expected, and is not very sensitive to the choice of the special function.

2. While the procedure for the determination of the first root to be found depends somewhat on the class of special functions to which the algorithm is applied, the principal part of the calculation ("marching" from one root to the other) is performed by a single "black-box" subroutine. The Laguerre polynomials are the single (fairly minor) exception (see Remark 11).

3. The algorithm determines the roots to (essentially) machine precision, more or less independently of the value of n or the type of special function, with the

exception of the Laguerre polynomials. In the latter case, the [illegible] precision is virtually independent of n, while the [illegible] error is proportional to n, due to the concentration of nodes near 0.

4. The absolute error in the evaluation of the weights is proportional to the number of nodes n, while the relative error is proportional to n in the Hermite and Laguerre cases and $n^{3/2}$ in the Legendre case. This phenomenon is well known, and [15, 11] describe two different procedures for the reduction of the rate of growth of the error to n in the case of classical Gaussian quadrature (Legendre case).

5. The obtained Gaussian quadratures evaluate the appropriate integrals with the precision proportional to n.

6. When actually applied on a modern computer, the algorithm is extremely fast: Finding 1,000,000 roots in double precision takes from 0.5 to 3 seconds on a low-end desk-top PC. So, while extended precision calculations tend to be almost 500 times slower than the double precision ones, it might be attractive to precompute the necessary nodes and weights in extended precision, perhaps in advance. Indeed, even constructing 1,000,000 nodes in extended precision costs only a few minutes of CPU time.

Acknowledgments. We thank Dr. Mark W. Tygert for many useful discussions and suggestions. Furthermore, we thank an anonymous referee for several suggestions that improved the paper significantly.

A NEW APPROACH TO SIMULATING FLOW IN DISCRETE FRACTURE NETWORKS WITH AN OPTIMIZED MESH*

HUSSEIN MUSTAPHA† AND KASSEM MUSTAPHA‡

Abstract. Natural fractured media are highly unpredictable because of existing complex structures at the fracture and at the network levels. Fractures are by themselves heterogeneous objects of broadly distributed sizes, shapes, and orientations that are interconnected in large correlated networks. With little field data and evidence, numerical modeling can provide important information on the underground hydraulic phenomena. However, it must overcome several barriers. First, the complex network structure produces a structure difficult to mesh. Second, the absence of a priori homogenization scale, along with the double fracture and network heterogeneity levels, requires the calculation of large but finely resolved fracture networks resulting in very large simulation domains. To tackle these two related issues, we reduce the highly complex geometry of the fractures by applying a local transformation that suppresses the cumbersome meshing configurations while keeping the networks fundamental, geological, and geometrical characteristics. We show that the flow properties are marginally affected while the problem complexity (i.e., memory capacity and resolution time) can be divided by orders of magnitude. The goal of this article is to propose a method of resolution which takes into account the geometrical complexity met in the networks and which makes it possible to treat a few thousand fractures. The principal aim of this article is to present a tool to slowly modify the structures of the fracture networks to have a good quality mesh with a marginal loss in precision.

Key words. fractured medium, Darcy flow, stochastic discrete fracture network, mixed hybrid finite element method, projection method

1. Introduction.

The underground waste repository projects and exploitation of hot, dry, rock geothermal energy have spurred studies in fracture networks transport properties. Many site-specific studies have flourished around various projects [7], which are generally based on a careful characterization of the structure of the fractured rock mass, with the classical difficulty of deducing three-dimensional information from one- or two-dimensional field data [3]. Then the hydraulic properties are computed by using reconstructed model networks, based on the experimental geometrical characteristics, and various flow models. The flow fluid modeling in underground media requires taking into account the very high geological heterogeneity. The complexity of the geological mediums comes from metamorphic and sedimentary processes, and mechanics which create structures having hydraulic properties varying on several orders of magnitude and correlated on a broad range of scales. A general overview of stochastic generation of fractured media problems is given in [11]. Numerically, the challenge is to integrate this range of heterogeneity in models of great extension and good resolution outcome, with linear systems from 10^6 to 10^8 unknown factors. In the fractured medium with a matrix of very low permeability, the fluid flow is focused in the highly heterogeneous fractures [21]. The objective of numerical modeling consists of simulating hydraulic phenomena in a large number of networks containing a high

number of fractures, e.g., from 10^3 to 10^5. In the second phase we seek an optimum between the quality of the hydraulic simulation approximation on one hand and the costs of calculation (CPU time and memory capacity) on the other.

The major purpose of the present paper is to develop a full solution of the steady flow problem in a general three-dimensional complex network made of two-dimensional ellipse fractures as illustrated in Figure 1. A literature survey shows that, in most cases, the description is two-dimensional [25] or that the three-dimensional network is replaced by a capillary model. The intersection of two fractures is schematized by a channel that joins their centers with an effective hydraulic conductivity that results from simple geometric arguments; this model is improved in [7, 3, 6, 2] by introducing flow channels in the fractures, which results in complex capillary networks. In this model, the authors assume that the flow occurs through bonds joining the center of each fracture to the center of adjacent fractures, provided that the fractures are connected (Figure 2). Nordqvist et al. [22] went one step further by building the network with spatially variable apertures for which flow was solved beforehand. However, again, the final representation is a tube model. These capillary models suffer two main flaws. First, the assignment of the bond conductivities is somewhat arbitrary and the assumption that the fluid flows from center to center is unrealistic. Second, only pair intersections are taken into account. Another method is the boundary element method [3], in which the solution is correctly computed in the planes of the fractures. This method is limited to the homogeneous fractures, and the treated fracture networks contain a very limited number of fractures [10, 16]. Maryška, Severýn, and Vohralík [17] and Vohralík [27] have developed a new method based in the simplification of complex configurations. The authors have showed an extension of the mixed hybrid finite element (MHFE) method to a geometrical domain composed by a network of planar circle disks placed in three-dimensional space. In their works, the MHFE method is validated on a simple geometrical case. But the simplification method of the fracture network complexities is not validated. The authors showed only an example of computed solution in a fracture network without discussion about

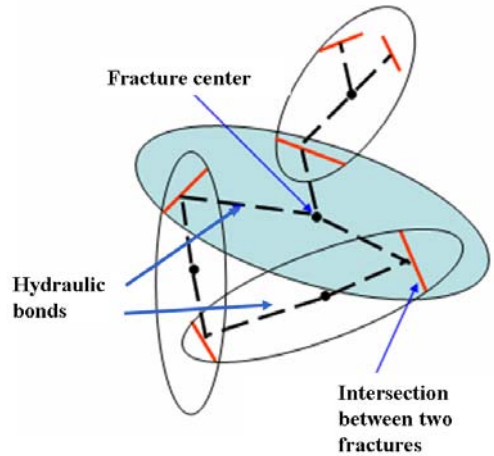

FIG. 2. *Flow fluid simulation in capillary network model* [7].

the error in precision, or a comparison with a solution computed without simplification of geometry. To conclude, the general limits of these methods are obtained from the limited number of fractures and by taking into account only of a part of natural networks complexity.

In Figure 1, we present a very complex discrete fracture network (FN) [5, 4, 9]. This network contains difficult configurations that complicate the generation of the fractures' mesh (to simplify the notation, a mesh of a network means a triangulation). Their number and their difficulty increase with the number of the generated fractures. These configurations are found mainly in the stochastic generation and in the natural environment's fracture networks. It is possible to discretize these configurations provided that we have a sufficient number of elements. However, for very large fracture networks, these configurations are, generally, not essential for the hydraulic properties but very penalizing for the number of elements of the mesh. A mesh of good properties contains a minimum number of triangles for a given precision of resolution.

To realize our object, we have developed and validated a new method of simplification different from the method of Maryška, Severýn, and Vohralík [17] and Vohralík [27]. The principal aim of this article is to present a tool to slowly modify the structures of the fracture networks to have a good quality mesh with a marginal loss in precision. This is the originality and the news of this paper. The developed method is not based on work of other authors; it is original. Then, the goal of this article is to propose a method of resolution which takes into account the geometrical complexity met in the networks and which makes it possible to treat a few thousand fractures. The achievement of this objective is done in two parts: (1) establishment of the mesh and (2) resolution of the flow equation. The principles of the proposed method are based on two essential points: (1) the penalizing configurations are replaced by very close configurations for which we can easily generate a good quality mesh without adaptation; (2) the resolution method of the flow equation is efficient because it is based on a good quality mesh.

The MHFE methods are known to accurately approximate the velocity field and locally conserve the mass on each element. Thus, we have decided to use the lowest

order Raviart–Thomas mixed finite element method in order to find an approximate solution of the local second-order elliptic problem with a discontinuous permeability tensor. We can easily note that an essential property of the fracture networks is the existence of interelement edges (i.e., intersection edges) which belong to three or more triangular elements. We note that the MHFE method is used in this work as a tool to give an idea about the computed solution, and it is not developed by the author.

This paper is organized as follows: First, we present the differential and algebraic equations describing the problem of stationary Darcy flow in a fracture network. Different aspects of the numerical approach and the discretization of Darcy's law by the MHFE method are discussed in detail in section 3. To apply the MHFE method, we need to have a complete mesh of the network. Then, in section 4 we present the difficulties that accompany the generation of the mesh of fractures, and then we explain in detail the proposed approach (i.e., the principal aim of this article) to analyze these difficulties. We present numerical examples in order to validate the developed method and show the originality and efficiency of our approach in section 5. A discussion about the optimality of the mesh is detailed in section 6. Finally, a summary and a preview of future work are presented.

2. Mathematical model. The original three-dimensional fracture network can be approximated by planar elliptic whose frequency, size, assigned aperture, and orientation are statistically derived from field measurements and considers two-dimensional Darcy flow in such a network. However, due to the high computer requirements, it is only possible to solve local problems by using stochastic discrete fracture network models. We refer the reader to [10] for more details. The network is included in a cube of size L; the fractures are modeled by ellipses. The fractures' length is modeled by a random power-law distribution. We define the fracture network R by $R = \bigcup_{i=1,NF} \bar{Fi} \backslash \partial R$. R is the bounded domain with boundary $\partial R = \Gamma^D \cup \Gamma^N$, and Γ^D (resp., Γ^N) corresponds to the Dirichlet (resp., Neumann) boundary conditions. Fi is the fracture i, and NF is the total number of fractures. We seek the fracture flow velocity u (a two-dimensional vector in each Fi), which is the solution of the problem

$$u = -K(p + z) \quad \text{in } R, \tag{2.1}$$

$$\nabla . u = f \quad \text{in } R, \tag{2.2}$$

$$p = p^D \quad \text{in } \Gamma^D, \tag{2.3}$$

$$u.n = u_N \quad \text{in } \Gamma^N, \tag{2.4}$$

where all the variables are expressed in the local coordinates of appropriate Fi and the differentiation is always done with respect to these local coordinates. Equation (2.1) is Darcy's law, (2.2) is the mass balance equation, and (2.3)–(2.4) describe Dirichlet and Neumann boundary conditions. The variable p denotes the piezometric head, $p = \bar{p}/\rho g$, where $\bar{p}$ is the fluid pressure, g is the gravitational acceleration constant, ρ is the fluid density, f represents stationary sources or sinks density, and z is the elevation, i.e., the upward vertical three-dimensional coordinate. The second-rank tensor K of hydraulic conductivity is a function of the original three-dimensional fracture aperture, wall roughness, and filling. We suppose that K is symmetric and uniformly positive definite on each Fi.

3. Numerical method in fracture network. The numerical approach used to solve the system of equations (2.1)–(2.4) is based on the MHFE method. For

more details about the theoretical and validation of the MHFE method in a three-dimensional domain composed by a simple set of rectangles, we refer the reader to [17]. We consider a spatial triangulation of the computational domain R consisting of triangles. Throughout the paper we use the following notation: b is the discretized triangle, E is the edges of the triangle b, NT is the number of triangles in the mesh, and NE is the number of edges in the mesh not belonging to Γ^D.

3.1. Discretization of Darcy's law. The essential idea of the mixed methods is to individually approximate Darcy's law and the flow equation, and we get additionally the Darcy velocity as an unknown function. Thus, the variation formulations of the given PDE systems are chosen in such a way as to have the pressure and its gradient in the basic formulation. The Raviart–Thomas space of lowest order ($RT0$) is used to approximate the velocity [23, 26, 13, 14]. The main idea is to express the velocity over each grid cell with respect to the fluxes across the cell edges. Based on Raviart–Thomas approximation space, the vectors u in (2.1) can be expressed as

$$u = \sum_{b} \sum_{E \in \partial b} q_{b,E} W_{b,E}, \tag{3.1}$$

where $W_{b,E}$ is an $RT0$ basis function and $q_{b,E}$ is the total flux across an edge E. These vectors are determined by their normal fluxes across the cell edges. By inverting K, Darcy's velocity equation becomes

$$K^{-1}u = -(\nabla p + \nabla z). \tag{3.2}$$

We denote by E' (resp., b' or b'_i) an edge (resp., a triangle) of the triangulation mesh. Multiplying (3.2) by the test function and integrating by parts, the total flux is suppressed through each edge E as a function of the cell-pressure average p_b and the edge-pressure averages $tp_{b,E}$ for each triangle b, i.e.,

$$q_{b,E} = \alpha_{b,E} p_b - \sum_{E' \in \partial b} (B_b^{-1})_{E,E'} tp_{b,E'}, \quad E \in \partial b, \tag{3.3}$$

where B_b is a $3 * 3$ symmetric positive definite matrix whose elements are

$$B_b = \int_b W_{b,E}^T K^{-1} W_{b,E'} \quad \text{and} \quad \alpha_{b,E} = \sum_{E' \in \partial b} (B_b^{-1})_{E,E'}.$$

The continuity of the fluxes across the interelement boundaries provides

$$q_{b,E} = \left\{ \begin{array}{ll} \sum\limits_{E', E' \in \partial b'} q_{b',E} & \text{if } E \notin \Gamma^N,\ E \in \bigcap\limits_{i=1,nbE} b'_i, \\ q^{N,E} & \text{if } E \notin \Gamma^N \end{array} \right| , \tag{3.4}$$

where nbE is the number of triangles which contain the edge E. We note that $nbE > 2$ if E is an intersection edge between fractures. Equations (3.3) and (3.4) lead to the following algebraic linear system with main unknowns the pressure-cell averages in P and the pressure-edge averages in Tp:

$$S^T P - MTp - V = 0, \tag{3.5}$$

where S is a sparse matrix of dimension $NT * NE$ with nonzero elements given by $S_{b,E} = \alpha_{b,E}$, $E \in \partial b$, M is an $NE * NE$ sparse matrix with nonzero entries defined as $M_{E,E'} = \sum_{b,E,E' \in \partial b} (B_b^{-1})_{E,E'}$ for $E \notin \Gamma^D$, and V is an NE-dimensional vector corresponding to the Dirichlet and Neumann boundary conditions. For more details, we refer the reader to [13, 19, 20].

3.2. Discretization of the mass conservation equation. By integrating the mass conservation equation where the test functions are successively replaced by the basis functions of M^0 (M^0 is the space of discrete functions constant by triangles), we get

$$\sum_{E\in\partial b} q_{b,E} = f^b, \tag{3.6}$$

where f^b is the approximation of the sink/source term over b.

Therefore, using (3.3) to replace the sum of fluxes in (3.6), we obtain an ordinary differential system given in its matrix form

$$DP - STp = F, \tag{3.7}$$

where D is an $NT * NT$ diagonal matrix whose coefficients are $(D_{b,b}) = \alpha_b = \sum_{E\in\partial b} \alpha_{b,E}$ and F is a vector of dimension NT; it corresponds to the source/sink function as well as to the imposed pressure given by the Dirichlet boundary conditions.

3.3. The derived algebraic systems. The spatial discretization of the governing equations obtained by applying the mixed hybrid formulation leads to two systems. The first one, given in (3.5), is an algebraic system of unknowns P and Tp, and the second is an algebraic equation (3.7). They can be written in a matrix form given by

$$\begin{bmatrix} D & -S \\ S^T & M \end{bmatrix} * \begin{bmatrix} P \\ Tp \end{bmatrix} = \begin{bmatrix} F \\ V \end{bmatrix}. \tag{3.8}$$

4. Fracture network triangular meshes. The discretization of fracture networks into triangular meshes has presented a crucial problem. First, each fracture has to be discretized into a triangular mesh respecting the intersections with other fractures. In order to decrease the number of elements and to avoid ill-conditioned matrices resulting from the cases where there exist elements with very small angles, the algorithm should in addition simplify the geometrical situation.

The fracture F illustrated in Figure 3 contains complex configurations like the small distance between the points. To have a mesh of good quality, we must use an adaptation method to be able to remove the flattened triangles. In Figure 4, we present the distribution of the values of network mesh triangles angles. The results obtained show that 28% of the angles are less than 40°, and 9% of the angles are more than 100°. In conclusion, the resulting mesh is not of good quality. To solve this problem, we use an adaptation method to improve the quality of the mesh. Such an approach requires a high capacity memory cost because of the large number of elements (triangles) obtained. Moreover, the resulting linear system is of large size and leads to a significant CPU time. Because our aim is to simulate a very large fracture network, the refinement of the mesh is an ineffective solution. A more powerful solution is required. The principle of the suggested solution consists in very slightly modifying the positions of the intersections to transform the complex configurations to very close configurations. This facilitates the mesh generation. In other words, the geometry is modified slightly to contribute to the generation of a good quality mesh. The suggested method consists in discretizing the boundaries of the fractures and the intersections between the fractures on a three-dimensional regular grid ($3DRG$).

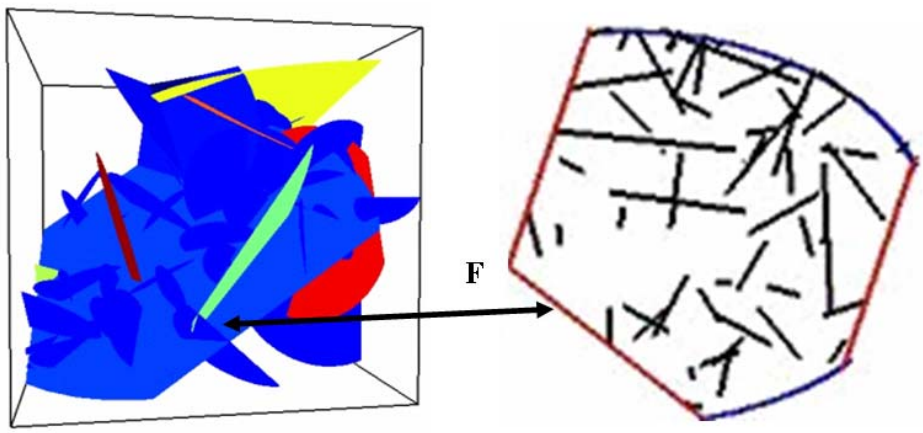

FIG. 3. *Left: The fracture F of radius $6 * lmin$ is extracted from FN. Only the 56 fractures intersecting the fracture F are represented in the figure. Right: Plane representation of the fracture F.*

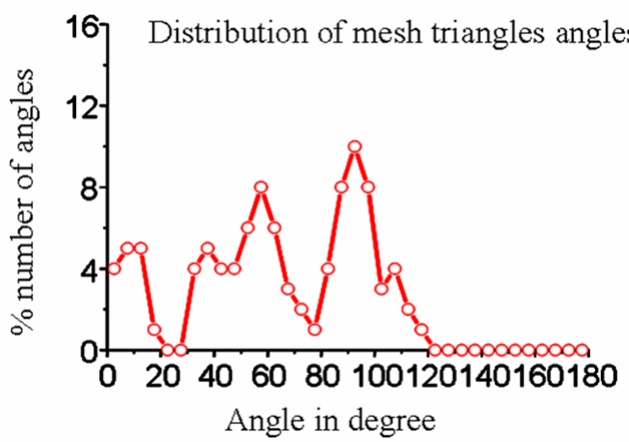

FIG. 4. *Distribution of mesh triangles angles of FN. The angles are grouped in packages of 5°.*

4.1. Discretization of fractures on a 3*DRG*. To have a complete conforming mesh of the fracture networks, the intersections between fractures must be treated in the same manner. During the considered modification, the following constraints must be respected: (1) connectivity between the fractures must be preserved; (2) the discretization of an intersection in three dimensions is the same in all the fractures that belong to it. The suggested approach respects the constraints mentioned above and consists in projecting the intersections between the fractures of the network and the boundaries of fractures, on the cubes of a regular grid of step equal to the uniform step of the mesh (h). The principal characteristics of this method are that (1) each intersection of fracture or limit of fracture is approached by the whole of the crossed cubes; (2) two intersections of fractures are intersected if and only if they have a joint cube. These characteristics make it possible to respect the connectivity of the

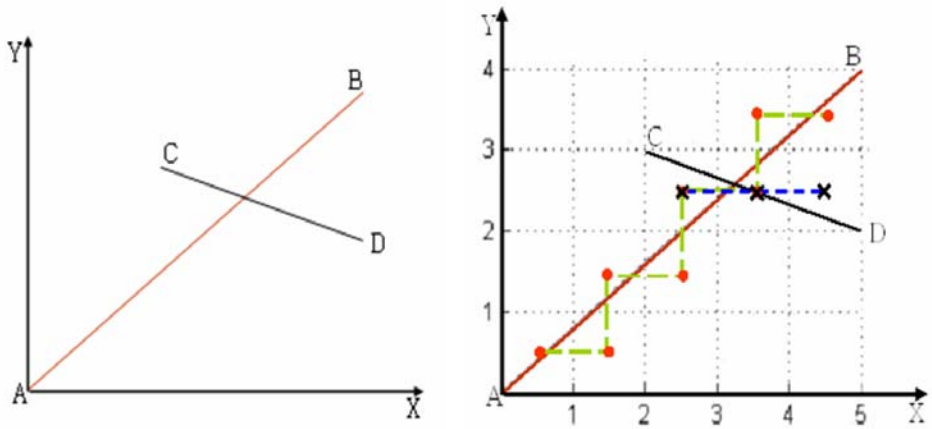

FIG. 5. *Left: Two segments AB and CD to be discretized. Right: Projected AB and CD on a 2DRG. Each segment is approached by the whole of the centers of the squares crossed by the segment.*

network and to ensure a minimal distance and angles of 90° or 180° between two successive cubes belonging to the discretized object. To simplify the ideas, we explain the principle in two dimensions and then generalize the results in three dimensions. Let us consider the two segments of straight lines AB and CB, which represent the intersections of a given fracture (Figure 5, left). The segments AB and CD are approached by the set of squares centers crossed by these segments (Figure 5, right). The segment AB is approached by the set of points ($\bullet$) and CD is replaced by the crosses ($\times$). The angle between the approximation of AB and CD is equal to 90° and outdistances it between the projected points is equal to the regular grid step (h). To generalize this method in three dimensions, the boundaries of the fractures and the intersections between the fractures of the network are approached by the centers of the cubes crossed by these segments (Figure 6, right).

4.2. Fractures' mesh. After discretizing the boundaries and the intersections of the fractures in a $3DRG$, we need to make a passage of the three-dimensional reference mark toward the plane of the fractures. This phase is obligatory in order to be able to generate the mesh of the fractures. At the time of the discretization in the $3DRG$, each intersection or boundary is represented by a succession of cubes which are very close to the fracture. The centers of these cubes are projected in the plane of the fractures and are connected to each other to form a succession of edges corresponding to the intersection of the projection (Figure 7). The regularization of the complexity of fractures is illustrated in Figure 8. The geometry of the fracture F contains penalizing configurations. Using the suggested method, we have obtained a rather regular geometry which does not present any problem of mesh, and where the stresses on the geometry are relieved. In conclusion, the developed method offers a regular base to generate a mesh of good quality (Figures 9 and 10). The mesh quality is measured with respect to the number of angles equal to 60°. Therefore, we do not need to adapt the mesh to improve the quality anymore. We can generate the mesh for all the fracture networks presenting complex configurations. As an example, we illustrate in Figure 11 (left) the mesh of the network FN.

The grid mesh of each fracture is stored in three vectors. The first vector is of

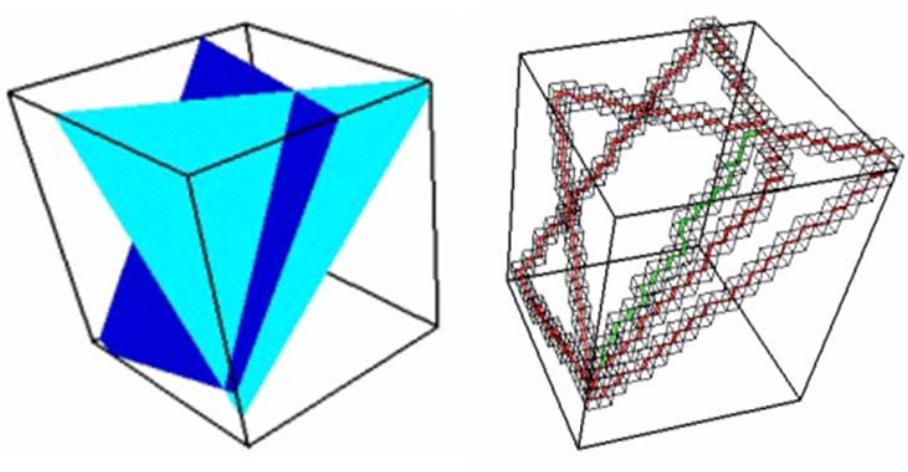

FIG. 6. *Discretization of the intersection and the edges of the two fractures represented in the left. Right: The projection of the boundaries of the fractures and their intersections on the centers of the cubes of a 3DRG.*

type [illegible] to store the coordinates of the vertices, and it is of size Nv (i.e., the number of mesh vertices). The two other vectors are of type [illegible], and of sizes NE and NT, respectively. For each vertex of the mesh, there are two coordinates to store. For each edge (resp., triangle), we have seven (resp., six) values to store. We suppose that the number of triangles or the number of vertices is equal to half of the number of edges; see [12] for more details. Therefore, we must store $2 * Nv$ [illegible] $+ 7 * NE$ [illegible] $+ 6 * NT$ [illegible], or in total the memory mesh $MemMesh = 6 * NE$ [illegible]. We note that $NE = SL$.

We note by $nz(A)$ the number of nonzero elements of the linear system matrix A. On each line of A we have five nonzero elements, except for the lines corresponding

to the edges' intersections which have more than five elements. Therefore, $nz(A)$ is equal to about $5 * SL$.

5. Validation tests and results. In this section, we develop three types of tests. In the first test, we validate the projection method by comparison to a reference solution computed in finest mesh. We give an idea about the error in precision in the second test. To look further into the study of the error in precision, we present a Monte Carlo simulation in the third test. In the following, we present the details of each one of tests. We note that all the fracture networks used are generated stochastically. The definition of fractures' principal characteristics is based on observations and experiments. The treated examples represent real tests of natural fracture networks.

A. [illegible] 1: [illegible]. Projection on a $3DRG$ of the intersections and the boundaries of fractures is an intermediate step to generate the mesh and to solve the flow equations. To validate such an approach, we have compared

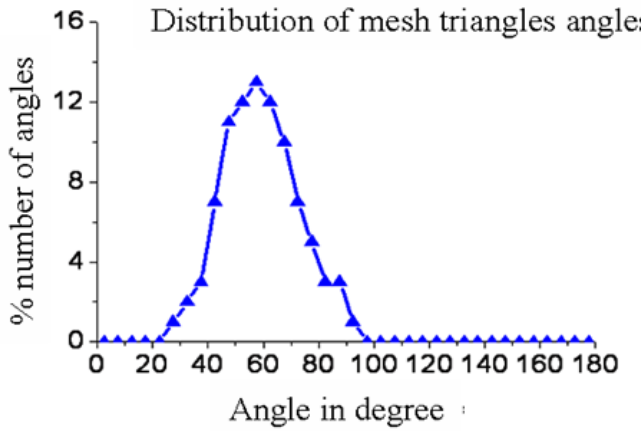

FIG. 10. *Distribution of the mesh triangles angles of FN. All the angles that are not between* $20°$ *and* $100°$ *have disappeared.*

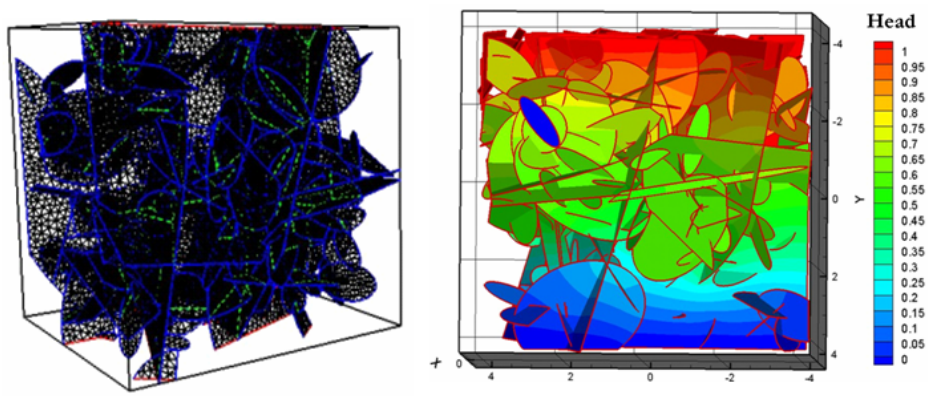

FIG. 11. *Example of mesh and flow computation in the network FN (left picture: mesh and right picture: flow computation).*

the approximate solution with a reference solution obtained from a very fine mesh (e.g., using a very small step of mesh h) without using the projection method. We chose the fracture network (FN) because the mesh of this network is possible without and with projection. We note that the developed method is validated with more examples. To compare the mesh in terms of quantity and quality, we compared the number of triangles and the size of the linear system corresponding to each mesh and we measured the quality of the mesh compared to the values of the angles of the triangles (Table 1 and Figure 12). An exhaustive study of other more localized measurements consists in calculating the differences between the two methods: the flows crossed by the fractures and the flows crossed by the intersections (Table 2). The projection method makes it possible to obtain a solution close to the solution obtained without projection. The error made while projecting on the grid is small. In general, it is about 10^{-5}.

In this test, we showed that by working with a finest mesh, the proposed approach

EF	$1.8 * 10^{-5}$
EI	$2 * 10^{-5}$

gives a very precise solution. Then, this very interesting result helps us to study the very complex fracture networks. In fact, because of complex configurations of the fracture network, the triangulation of this network is in most cases impossible. To conclude, the projected method can give a reference solution (working in a finest mesh) for all complex fracture networks. Finally, Figure 11 (right) shows the distribution of the piezometric head in the whole simulated fracture network FN. To fix the idea, in the following we consider the approximate solution obtained using the projection method in finest regular grid as a reference solution.

B. [illegible] 2: [illegible] FN [illegible]. In this section, we measure the precision error by varying h. First, we evaluate the errors

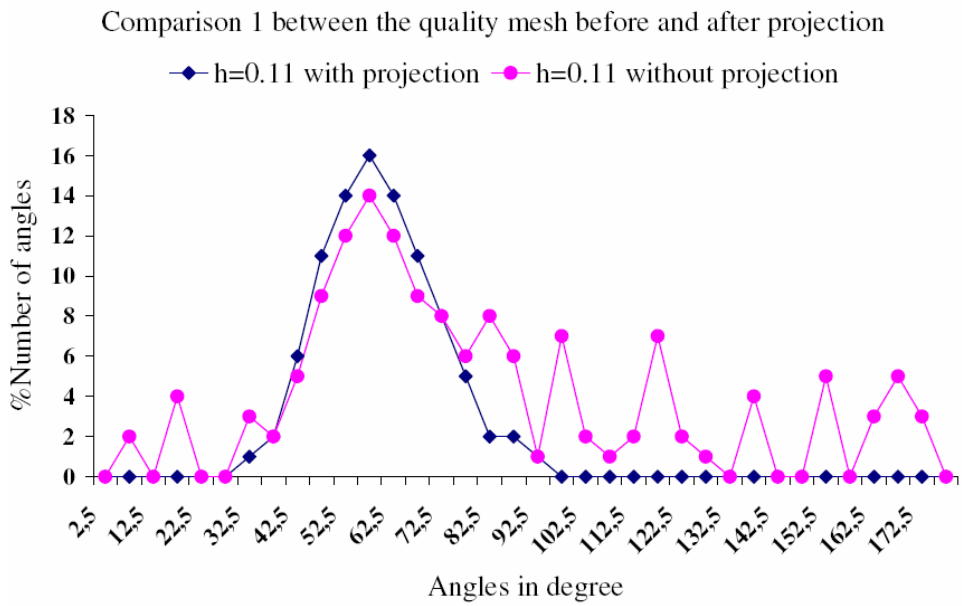

FIG. 13. *Comparison* 1 *between the quality mesh before and after projection.* $h = 0.11$.

in global equivalent permeability, the flow across each fracture and each intersection. Then we observe the mesh quality obtained; we compute the linear system size and the memory capacity for each step h. In this test, we simulate the flow in the fracture network FN. For this network we compute some solutions for different values of h. The aim is to observe the evolution of precision error, the mesh quality, and the improvement in CPU time and memory capacity with respect to h.

1. [illegible]. In Figures 13, 14, and 15, we present the curves that represent the mesh quality of the network (FN) for each mesh step using the projection method and without it. These figures show that the majority of mesh triangle angles is close to 60° for the projection method and the quality is bad without projection. Then, we deduce that the mesh quality remains very good by varying the mesh step for the projection method. This result is interesting because it is necessary to have a good quality mesh to correctly compute all solutions by reducing the problem size at the same time.

2. [illegible]. For each step h, we calculate the differences between the approximate solution and the reference solution calculated on a finest grid (Figure 16). The difference between the approximate solution and the reference solution always remains weak when we use the projection method. The errors increase quickly if we do not project. For example, for the mesh step $h = 0.21$ we have a loss in precision equal to 33% for the classical method and 2 to 4% for the projection method. We can conclude that the projection solution calculated by increasing the step mesh remains precise. We carry out a linear regression to consider the error corresponding to the equivalent permeability. According to what precedes, the straight regression lines represent more than 98% of the distribution of the points and the data are well estimated using the projection method. This result is coherent with the numerical estimate error of the MHFE method which is $O(h)$ (method of order 1). We checked in the two preceding parts that the approximate solution obtained with the projection

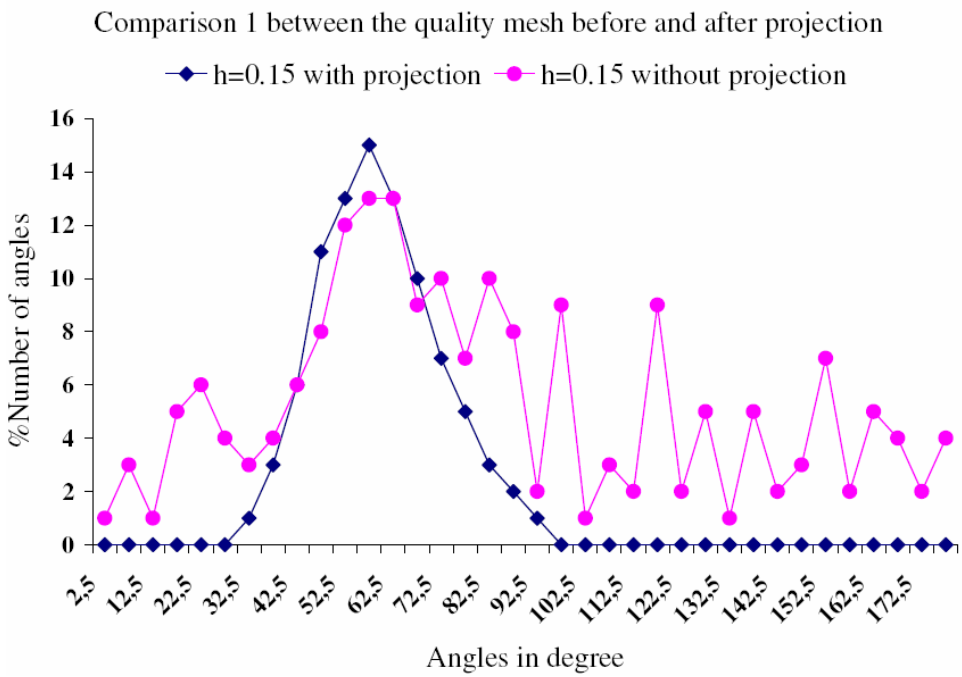

FIG. 14. *Comparison* 1 *between the quality mesh before and after projection.* $h = 0.15$.

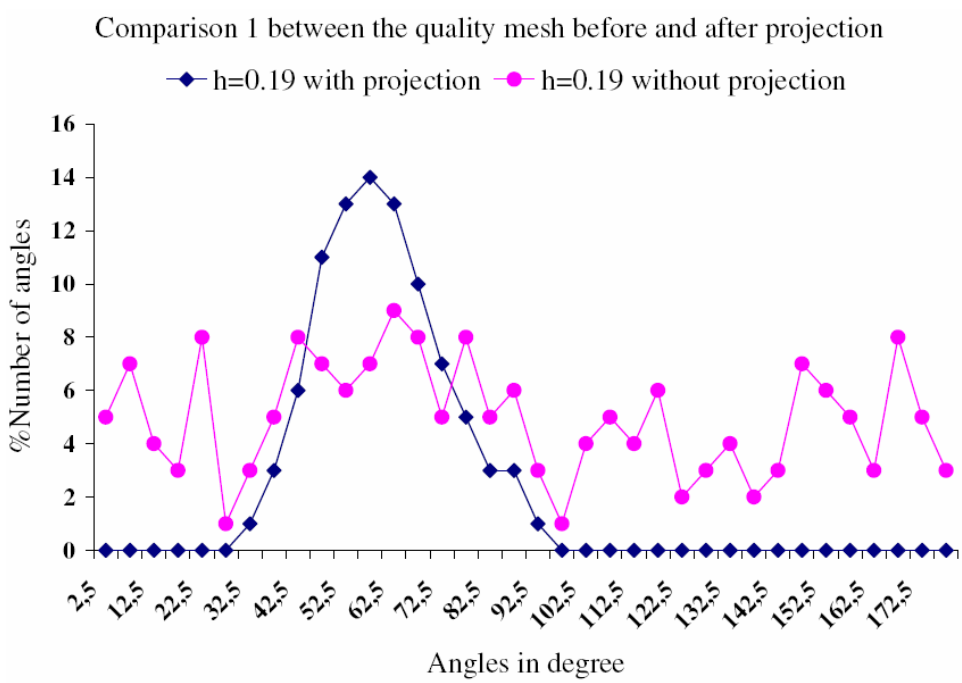

FIG. 15. *Comparison* 1 *between the quality mesh before and after projection.* $h = 0.19$.

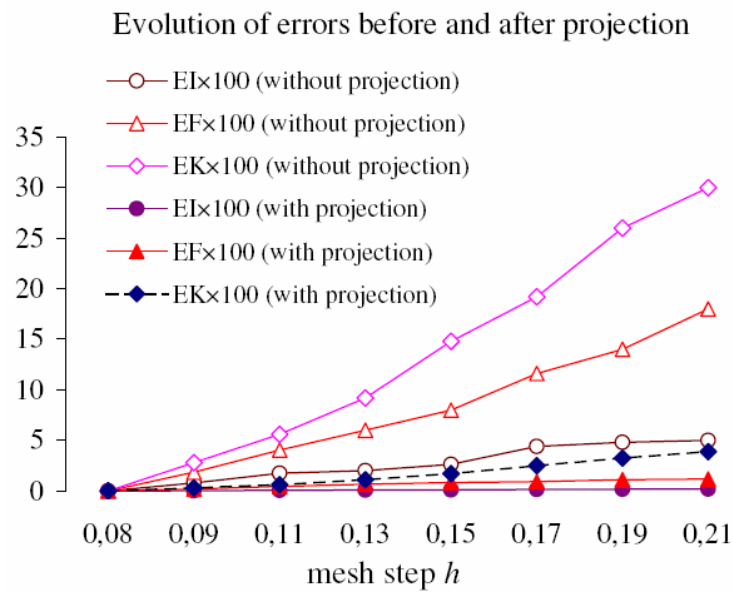

FIG. 16. *Evolution of the difference expressed as a percentage between the approximate solutions obtained with projection and without projection.*

TABLE 3
Linear system size, memory capacity, and CPU time for various mesh steps.

h	SL	$MemMesh$	$nz(A)$	$Time$
0.08	313776	1882656	$1.58 * 10^6$	27.65
0.21	50588	303528	$0.26 * 10^6$	2.36

method makes it possible to consider rather large steps of mesh.

3. [illegible]. The projection method provides an improvement in CPU time and memory capacity by decreasing the size of the problem. The larger the step of the mesh is, the better the improvements of CPU time and memory capacity are (Table 3). For one variation of h between 0.08 and 0.21 the linear system size (resp., the memory mesh and the nonzero elements of A) decreases from 313776 to 50588 (resp., from 1882656 to 303528 and from $1.58{*}10^6$ to $0.26 * 10^6$ real values to storage). To conclude, the decrease of memory capacity needed is of 85%. However, the decrease of the linear system size reduces the time of the linear system resolution. The obtained result (Table 3) shows that the CPU time decreases from 28 seconds to 2.5 seconds, using the direct linear solver [illegible] [8].

To conclude, the improvement in CPU time is equal to 92%. In this part, we show that the improvement in CPU time can be realized because the loss in precision is small with respect to the mesh step. We do not need to speak about the improvement in CPU when we do not use the projection method because the loss in precision becomes significant. To conclude, in these tests we want to realize a compromise between the precision of the solution and the CPU time.

C. [illegible] 3: [illegible]. The characteristics of fractures are generated stochastically. The orientation, the length, the position, and the eccentricity of the fractures are generated according to statistical laws. To generate a network of fractures, we fix the type of distributions and the seeds. For the same parameter dis-

tributions, we can generate a high number of networks by changing the seeds. In this part, we choose a set of parameter distributions (SD) (Table 4). We generate 700 networks for SD by changing the seeds and fixing the exponent of the power law, the cube size, the minimal length of a fracture, and the density of the fracture (a threshold density). To begin, we note by GN the set of NN (NN: number of networks) networks generated with the distributions SD. Afterward, we compute the reference solutions represented by the average equivalent permeability reference ($Kref$) (e.g., average of the permeability computed, on a finest mesh, in the set of networks GN) and the standard deviation ($\sigma kref$) of this solution. We also seek the average size ($SLmref$) of the linear systems associated to the packages of networks, the average time ($Tmref$) of resolution of these linear systems, and finally, the variations of these values ($\sigma SLref$ and $\sigma Tref$). The results are summed up in Table 5. After computing the reference solution, we vary the mesh step h. The average numerical error for a given value of h is defined as the difference between the average permeability obtained for this step on one hand and the weakest step on the other hand. In this test, we vary h between 0.02 and 0.2 to observe the variations of the parameters $SLmref$, $Tmref$, and $Kref$ and of their variations ($\sigma kref$, $\sigma SLref$, $\sigma Tref$) in the sets of networks GN. We note by Tm (resp., Tm and $\langle K \rangle$) the average time (resp., the average size and the average of equivalent permeability) obtained for each step of mesh and by σTm, σSLm, and σk the standard deviations. The results (Table 6) show that the error in equivalent permeability, by varying h from 0.02 to 0.2, is about 7% on one hand and the improvement in CPU time of calculation and in memory capacity are,

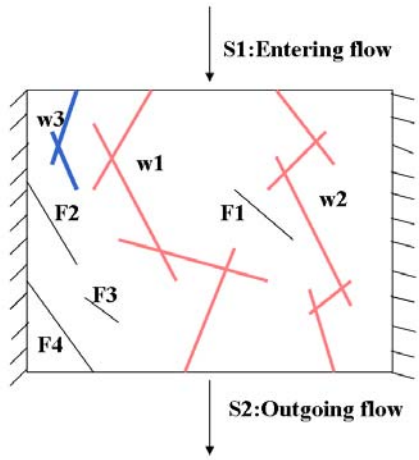

FIG. 17. *Two-dimensional fracture network. The fractures are modeled by lines. $w1$ and $w2$ cross the domain from $S1$ to $S2$. The other fractures are isolated and do not have an effect on the flow.*

respectively, about 96% and 92% on the other hand. These results are dependent on the value of the parameters and probably on deterministic information (e.g., position of the greatest fractures) available on the site. It is foreseeable that the more the quantity of data is significant, the better the quality of numerical simulation should be.

6. Discussion about the optimized mesh. The fractures of the network are linked by lines in three-dimensional space and by points in two dimensions (Figure 17). In Figure 17, the fractures are modeled by lines. The intersections between fractures are points. Suppose that the flow in the domain is from the side $S1$ to the side $S2$ and the other boundaries of the domain are impervious. We will study different cases that can be presented as follows:

A. [illegible]. The generation mesh of complex fracture networks using automatic generators is a challenge. Each generator mesh has a control parameter ε. This parameter can be the small distance or angle between two neighbor points or the small size acceptable of an edge mesh. If one of these cases is available, the generator cannot work. For example; in Figure 18 (left), we present a two-dimensional fracture network. The distances and angles between certain fractures are shown by the zoom (Figure 18, right) on Figure 18 (left). In general, the structures of the fracture network depend on the distribution of fractures. Because the fractures are distributed randomly, it is possible to have a distance or angle between tow fractures small than ε. The same conclusion can be obtained regarding the length of the fracture F (Figure 18, left) which can be smaller than ε. In this case, we can say that the generation mesh is impossible using an automatic generator.

Now, suppose that we do not have these cases. Then the small fracture's length or the small distance or angle between the fractures is greater than or equal to ε. In this case we have two possibilities: (1) The generation mesh is possible but perhaps the quality of the mesh is bad regarding the angle distribution (Figure 4). The quality of this case depends on the geometrical structure of the fracture networks. For example, if the number of fractures is small we can have a simple geometry without complexities, and then the generation of a good quality mesh is possible. In [24, 1], the authors simulate multiphase flow in fractured porous media. The studied fracture

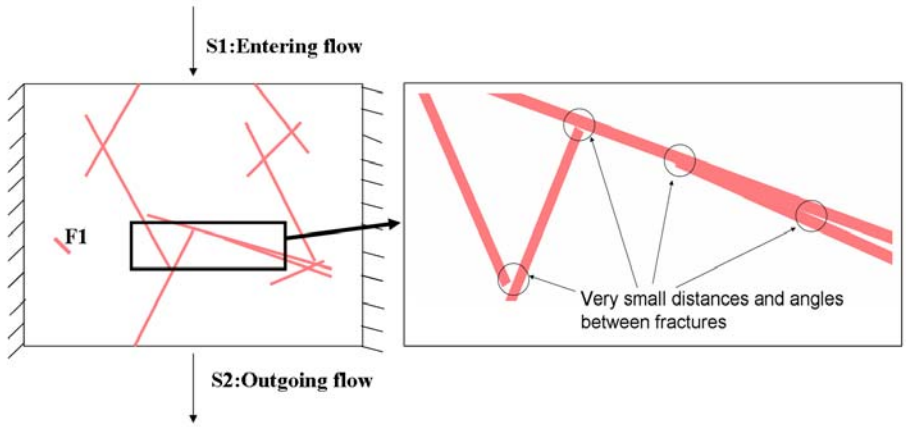

FIG. 18. *Two-dimensional fracture network. Left: Example of a distribution of fractures. Right: Zoom of the left figure to show the small distances and angles between fractures.*

media contain a small number of fractures, and then the geometrical configurations can be simple to generate the mesh. We note that, in this paper, we are interested in the highly heterogeneous fractured media. (2) The improvement in the quality of the mesh can be done by refinement, and then the size of the problem becomes very large. In this case, we will be interested in the precision of the solution. This idea is not effective because of the geological inaccuracy and the large size of the studied fracture networks.

B. . To cure the above difficulties, the projection method is developed. This method can work with the existence of a small distance or angle between fractures because the fractures are projected on a regular grid (Figure 5).

Now, to make a prediction about the mesh step that can be used to project the fractures, we perform the following steps. First, we determine all the ways that fractures cross the domain from $S1$ to $S2$ (Figure 17). We find $w1$ and $w2$. In the second step, the other fractures $F1$, $F2$, $F3$, and $F4$ and way $w3$ are identified. We note that the size of a fracture is equal to the length of the line. In our method we are interested in the treatment of the fractures that form the ways $w1$ and $w2$. The mesh step h needs to be greater than the smallest size of these fractures. This condition makes it possible to guarantee the connection of the essential ways of the flows. We note that this problem is the same in the case of resolution without projection.

C. . The mesh step h can be a function of the small fracture size, of the density of fractures, or of other characteristics of the fracture networks. When h increases, the error in precision increases for two reasons. The first is the numerical approximation of the solution. The second reason is that some of the essential ways can disappear. A way is removed from the network if h is bigger than one of the fractures that form this way, and then the quantity of outgoing flux decreases.

Because the geometry is very complex, we do not have an idea about the form of the generated structures. This is because of the random generation and stochastic properties of the fractures. The determination of the fracture networks is based on observations and experiences. Then, we have a geological inaccuracy.

In the fractured medium with a matrix of very low permeability, the fluid flow is focused in the highly heterogeneous fractures [21]. In our study, we are interested in these fractures. For each fracture network, we define the ways of flow as explained

above. For us, these ways are the base of the fluid flow. The rest of the fractures do not have an effect on the flow. Because the number of found ways depends on the mesh step h, we cannot exactly define the error in precision. This is because the quantity of outgoing flux depends on the number of effective ways. In the case of very dense fracture networks [15], the variation of the mesh step is more relevant and the quantity of capture flow remains important with respect to h.

The results evolve according to the mesh and converge toward the exact solution, but how do we determine an optimal mesh density? We note that an analytical solution does not exist, and then the convergence is shown with respect to the mesh step. The optimality of the mesh depends on the application and then can have different definitions according to the phenomenon in question. The precision of a solution calculated in a fracture network cannot compensate for the problem of geological inaccuracy of the synthetic fractured media. Now, a good quality mesh helps to have a well-approximated solution. This idea is clearly checked in several examples above. In Figures 13, 14, and 15, we show that the quality of the mesh obtained without projection is bad when h increases and the error in precision increases significantly, too (Figure 16). Then to have a better precision a refinement of the mesh must be used. But we remark that the quality of the mesh using the projection method remains good with the increase of h, and then the errors in precision are small (Figure 16). We have shown that for all mesh steps, the quality of the mesh is better when using the projection method. For each mesh step, the best compromise between the quality of the mesh, the precision of the approximated solution, the memory capacity, and the CPU time is obtained using the projection method. Here, we say that the obtained mesh using the projection method is optimal because it realizes this compromise as detailed above.

7. Conclusion. In this paper, we have proposed a simplified method of the complex geometries of fracture networks. The goal of this method is to remove the singularities in the geometry using a method of projection on a $3DRG$. For more details, see [18, 19, 20]. These singularities are represented by the small distances between the points and the small angles between the intersections of fractures. The obtained geometry is very regular and does not have penalizing configurations. The small angles are completely removed, and the obtained mesh is of good quality. Therefore, the main goal is to carry out a better compromise between the size of the problem and the quality of the mesh on one hand, and the precision of the approximate solution on the other hand. In this context, the regularization of the geometry should not induce a significant error in the approximate solution. Because the principal goal of our study is to search the laws of scaling, it is very interesting to study a very large number of fracture networks that contain varying numbers of fractures. The proposed method in this article aims to facilitate the simulation in heterogeneous fracture networks that have complex geometries.

We note that it is very difficult (section 4.2) to generate the mesh of most of these networks using an automatic generator mesh. The proposed method offers regular and similar geometries of the complex networks for which we can easily generate a good quality mesh. The validation of the method is carried out in several steps. We initially checked the precision of the approximate solution. In the first part, we showed the good quality of the mesh obtained using the projection method. We checked the precision of the solution by comparing it with a reference solution calculated on a finest mesh without projection in the second part. Afterward, we varied the step of mesh. We showed that the good quality of the mesh is preserved. This property

is a significant advantage compared to the mesh obtained without projection. We measured the error in precision made during this change of h and observed that the algorithm remains of order 1. Finally, we measured the improvement in CPU time and memory capacity and we found that results are significant and show the efficiency of the numerical approach developed. To conclude, in this paper we showed that the relative error is lower than 7% when h varies from 0.08 to 0.21, and the linear system becomes six to ten times smaller. This reduction in the linear system size induced a reduction of the needed memory and a significant decrease in CPU times. For example, with a loss of precision lower than 5%, the CPU time and the memory capacity are divided by 10.

The refinement of the mesh to improve the quality is not a good solution in networks containing large numbers of fractures. The definition of the error in precision is a problem to solve. We need to do further tests on various types of networks that contain various numbers of fractures. In forthcoming work, we will focus in detail on the three following essential tasks: (1) perform stochastic tests on various types of networks to precisely determine the error; (2) study other hydraulic phenomena: transient, transport, etc.; (3) take into account the matrix (for oil studies).

Nomenclature.

FN: Fracture network of Figure 1.
ref: Reference.
app: Approached.
NF: Number of fractures.
Ni: Number of intersections.
$Kref, Kapp$: Global equivalent permeability.
$Iiref, Iiapp$: Flow through the intersection number i.
$Firef, Fiapp$: Flow across the fracture i.
$Iref, Iapp$: $(Iiref), (Iiapp)$, $i = 1, Ni$.
$Fref, Fapp$: $(Firef), (Fiapp)$, $i = 1, NF$.
EK: $(Kref - Kapp)/Kref$.
EF: $norm1(Fref - Fapp)/norm1(Fref)$.
EI: $norm1(Iref - Iapp)/norm1(Iref)$.
h: Mesh step.
NT: Number of mesh triangles.
SL: Linear system size.
, : Time of generation mesh in seconds.
$2DRG$ and $3DRG$: Two- and three-dimensional regular grid.

ON GLOBAL ERROR ESTIMATION AND CONTROL FOR INITIAL VALUE PROBLEMS*

J. LANG† AND J. G. VERWER‡

Abstract. This paper addresses global error estimation and control for initial value problems for ordinary differential equations. The focus lies on a comparison between a novel approach based on the adjoint method combined with a small sample statistical initialization and the classical approach based on the first variational equation. Control is achieved through tolerance proportionality. Both approaches are found to work well and to enable estimation and control in a reliable manner.

Key words. numerical integration for ODEs, global error estimation, global error control, defects and local errors, tolerance proportionality, adjoint method, small sample statistical initialization

1. Introduction.

Suppose one is given in $\mathbb{R}^m$ the initial value problem for the system of ODEs

$$w' = F(t, w)\,, \quad w(0) = w_0\,, \qquad 0 < t \le T\,, \tag{1.1}$$

and a sequence of approximations w_n to its exact solution values $w(t_n)$ computed by a numerical integration method at a certain time grid

$$0 = t_0 < t_1 < \cdots < t_n < \cdots < t_{N-1} < t_N = T\,. \tag{1.2}$$

Hereby the major research concerns are efficiency—how to get the w_n at minimal CPU costs (if $m \gg 1$)—and reliability—how large are the global errors

$$\varepsilon_n = w(t_n) - w_n\,, \qquad n = 0\,, \ldots\,, N\,. \tag{1.3}$$

In the past, numerical ODE research has focused on the efficiency question. The reliability question has received much less attention in spite of the by now twenty years old survey paper [23]. Existing popular codes focus on efficiency by adaptively optimizing time grids (1.2) in accordance with local error control. Such a control makes sense if solutions exhibit sharp changes at local intervals much smaller than the total interval $[0, T]$ and are smooth elsewhere. However, local errors (errors made within a single integration step) may substantially differ from the global ones (1.3). This largely depends on the conditioning (stability) of the system (1.1) at hand (sensitivity to growth in time of perturbations of w_0 and $F(t, w)$). If a system is well-conditioned, a well-designed local error control [20, 21] will work out reliably. But if the conditioning is bad, even the best-designed local error control should not be trusted.

For global error control it is necessary to take into account the conditioning of system (1.1), similar to the matrix condition number in numerical linear algebra.

Herewith it is desirable to avoid strict a priori error bounds as these can be overly pessimistic, e.g., when fortunate cancellation effects occur. Taking into account the conditioning of system (1.1) is best done during actual computation. This requires at least two full integrations over $[0,T]$, in both the classical (forward-forward) and the adjoint (forward-backward) approaches. In recent years the adjoint approach has gained popularity for a posteriori error estimation purposes [2, 6, 13, 17], in particular for PDEs where it is used for goal-oriented adaptive control, that is, control of relevant physical quantities [1, 5, 7].

Our interest in this paper lies in estimation and control of the global errors (1.3), i.e., for the ODE initial value problem (1.1). Specifically, regarding estimation we will compare a novel approach based on the adjoint method combined with a small sample statistical initialization proposed by Cao and Petzold [2] to the classical approach based on the first variational equation. For both, global control is achieved by exploiting the property of tolerance proportionality derived from local control [20]. As a typical integration method we will use the existing Runge–Kutta–Rosenbrock method ROS3P [16]. Both approaches are found to work well and to enable estimation and control in a reliable manner.

2. The classical (forward-forward) approach.

2.1. The perturbed system. In the spirit of backward error analysis and following an approach proposed in [26] (see also [23, 24]), let us suppose that there exists a nearby solution $v(t) \approx w(t)$, that is the exact solution of a perturbed system

$$v' = F(t,v) + r(t)\,, \quad v(0) = v_0\,, \qquad 0 < t \le T\,, \tag{2.1}$$

with perturbation $v_0 - w_0$ at $t = 0$ and perturbation $r(t)$ for $0 < t \le T$. Assuming F to be continuously differentiable, so that the mean-value theorem for vector functions is applicable, the error function

$$e(t) = v(t) - w(t)\,, \qquad 0 \le t \le T\,, \tag{2.2}$$

then satisfies

$$e' = A(t)e + r(t)\,, \quad e(0) = v_0 - w_0\,, \qquad 0 < t \le T\,, \tag{2.3}$$

where

$$A(t) = \int_0^1 F'\big(t, v(t) + (s-1)e(t)\big)ds = \int_0^1 F'\big(t, w(t) + se(t)\big)ds\,. \tag{2.4}$$

Here F' denotes the Jacobian matrix with respect to the dependent variable. As we speak of perturbations we tacitly assume that $e(0)$ is significantly smaller than w_0 and likewise that $r(t)$ is significantly smaller than $F(t, v(t))$. The error function $e(t)$ can be expressed as

$$e(t) = \Phi^{-1}(t)\Phi(0)\, e(0) + \Phi^{-1}(t) \int_0^t \Phi(s) r(s)\, ds\,, \tag{2.5}$$

where the $m \times m$ fundamental matrix solution $\Phi(t)$ solves $\Phi'(t) = -\Phi(t)A(t)$. Note that $\Phi(t) = \Phi(0)\exp(-At)$ for constant A, where $\Phi(0)$ is an arbitrary nonsingular matrix. Apparently, the product $\Phi^{-1}(t)\Phi(s), 0 \le s \le t$, governs growth or decay of $e(t)$ in time and thus determines the conditioning of (1.1).

2.1. For practical purposes the fundamental matrix solution concept is clearly of little use. An a priori bound which sometimes can be used in practice is based on the logarithmic matrix norm. Let $\mu(A(t))$ denote the logarithmic matrix norm of $A(t)$, and suppose $\mu(A(t)) \leq \omega$, with ω a constant valid for all $t \in [0,T]$. Then, with $\|\cdot\|$ denoting the associated vector norm in $\mathbb{R}^m$, there holds [3, 12]

$$\|e(t)\| \leq e^{\omega t}\|e(0)\| + \int_0^t e^{\omega(t-s)}\|r(s)\|ds\,, \qquad 0 \leq t \leq T\,. \tag{2.6}$$

This a priori bound is useful for strictly negative ω. Let for simplicity $e(0) = 0$, and suppose that $\|r(t)\|$ is uniformly bounded by a small number δ_r. Then

$$\|e(t)\| \leq \frac{1}{\omega}\left(e^{\omega t} - 1\right)\delta_r\,, \tag{2.7}$$

uniformly bounding $e(t)$ in norm by $\delta_r/|\omega|$ for infinite time if $\omega < 0$. Due to the negative logarithmic norm this is an instance of a well-conditioned ODE system (1.1). On the other hand, with a positive logarithmic norm the bound predicts exponential growth in time. Then we speak of an ill-conditioned ODE system, provided the bound is realistic or even sharp. However, any result of this sort depends on the chosen vector norm since $\mu(A(t))$ depends on the norm. More precisely, it can happen that $\mu(A(t)) \gg 0$, even if in a global sense the problem is well-conditioned; see, e.g., [3] and Example I.2.5 in [12]. Also, for hard problems from practice, finding estimates of ω may be very cumbersome.

For properly using the perturbed system in the classical (forward-forward) approach for pth order consistent one-step integration methods, it is helpful to associate (2.3) with the well-known first variational equation for the global error ε_n of such a one-step method. For this purpose we adopt for the one-step method the general Henrici notation [9]

$$w_{n+1} = w_n + \tau_n\Psi(t_n, w_n; \tau_n)\,, \qquad \tau_n = t_{n+1} - t_n\,, \tag{2.8}$$

and introduce its local error

$$\delta_n = w(t_{n+1}) - w(t_n) - \tau_n\Psi(t_n, w(t_n); \tau_n)\,. \tag{2.9}$$

Assuming now a constant step size τ (for simplicity only), pth order consistency, and a sufficiently smooth solution, the local error defined at $(t, w(t))$

$$\delta(t) = w(t+\tau) - w(t) - \tau\Psi(t, w(t); \tau) \tag{2.10}$$

possesses an expansion of the form $\delta(t) = \tau\rho(t) + \mathcal{O}(\tau^{p+2})$. Hence in this notation the principal error function $\rho(t) = \mathcal{O}(\tau^p)$. Next, let $G(t) = F'(t, w(t))$. With this local expansion at hand the global error ε_n is then known to possess an expansion $\varepsilon_n = \eta(t_n) + \mathcal{O}(\tau^{p+1})$, where $\eta(t)$ is the solution of the first variational equation

$$\eta' = G(t)\eta + \rho(t)\,, \quad \eta(0) = 0\,, \qquad 0 < t \leq T\,. \tag{2.11}$$

We refer to [9, section 3.3] and [8, section II.8] for further details. One can now connect (2.3) to (2.11). To that end put $e(0) = 0$ (this bears no restriction) and approximate $A(t) = G(t) + \mathcal{O}(e(t))$ by $G(t)$, so that (2.3) is replaced by

$$e' = G(t)e + r(t)\,, \quad e(0) = 0\,, \qquad 0 < t \leq T\,. \tag{2.12}$$

Apparently, by implementing a proper choice of the defect $r(t)$, solving (2.3) or likewise (2.12) will in leading order amount to solving the first variational equation (2.11) for the true global error. We will illustrate this next.

Remark 2.2. In spite of the fact that the asymptotic theory behind (2.11) is classical in the sense that F is assumed Lipschitz without taking into account stiffness ($\tau\|F'(w)\| \gg 1$), we will use it successfully for stiff problems in section 4. For success it is important that the stiffness does not enter the defect computation. We prevent this by filtering; see (2.23). Equally important is validity of the asymptotics, that is, the local error is well approximated by its leading term. For smooth, sufficiently differentiable solutions this always holds for linear multistep methods. For Runge–Kutta-type methods applied to semidiscrete PDEs, this generally holds with periodic boundary conditions. With prescribed boundary conditions, such as Dirichlet conditions, it also holds for Runge–Kutta methods, except that temporal error coefficients can get large on fine grids due to order reduction. In such cases smaller step sizes are needed to catch the leading local error term with sufficient accuracy. As is well known, this may also be needed with stiff problems not originating from PDEs.

2.2. Interpolation and defect computation. We define the nearby solution $v(t)$ by piecewise cubic Hermite interpolation of the given approximation sequence. Hence at every subinterval $[t_n, t_{n+1}]$, $n = 0, 1, \ldots, N-1$, we form

$$P(t) = w_n + (t-t_n)\,\mathcal{A}_n + (t-t_n)^2\,\mathcal{B}_n + (t-t_n)^3\,\mathcal{C}_n\,, \qquad t_n \le t \le t_{n+1}\,, \tag{2.13}$$

and choose the coefficients such that $P(t_n) = w_n, P(t_{n+1}) = w_{n+1}$ and $P'(t_n) = F_n$, $P'(t_{n+1}) = F_{n+1}$, where $F_n = F(t_n, w_n)$ and $F_{n+1} = F(t_{n+1}, w_{n+1})$. This gives

$$\begin{aligned} \mathcal{A}_n &= F_n\,,\\ \mathcal{B}_n &= \big(3w_{n+1} - 3w_n - \tau F_{n+1} - 2\tau F_n\big)/\tau^2\,,\\ \mathcal{C}_n &= \big(2w_n - 2w_{n+1} + \tau F_n + \tau F_{n+1}\big)/\tau^3\,. \end{aligned} \tag{2.14}$$

Were one to interpolate (smooth) exact solution values $w(t), w'(t)$ at $t = t_n$ and $t = t_{n+1}$, then

$$\mathcal{A} = w^{(1)}\,, \quad \mathcal{B} = \tfrac{1}{2}w^{(2)} - \tfrac{1}{24}\tau^2 w^{(4)} + \mathcal{O}(\tau^3)\,, \quad \mathcal{C} = \tfrac{1}{6}w^{(3)} + \tfrac{1}{12}\tau w^{(4)} + \mathcal{O}(\tau^2)\,, \tag{2.15}$$

where the expressions are evaluated at $t = t_n$. Writing $t = t_n + s\tau$, $0 \le s \le 1$, yields

$$\begin{aligned} P(t) &= w(t) + \tfrac{1}{24}\big(2s^3 - s^2 - s^4\big)\tau^4 w^{(4)}(t_n) + \mathcal{O}(\tau^5)\,,\\ P'(t) &= w'(t) + \tfrac{1}{24}\big(6s^2 - 2s - 4s^3\big)\tau^3 w^{(4)}(t_n) + \mathcal{O}(\tau^4)\,, \end{aligned} \tag{2.16}$$

so that at every subinterval $[t_n, t_{n+1}]$ the defect function $d(t) = P'(t) - F(t, P(t))$ satisfies

$$d(t) = P'(t) - w'(t) + F\big(t, w(t)\big) - F\big(t, P(t)\big) = \begin{cases} \mathcal{O}(\tau^3)\,, & s \ne \frac{1}{2}\,,\\ \mathcal{O}(\tau^4)\,, & s = \frac{1}{2}\,. \end{cases} \tag{2.17}$$

Here we have assumed that F is Lipschitz and have used that $6s^2 - 2s - 4s^3 = 0$ for $s = \frac{1}{2}$.

In actual application the interpolation is based on numerical approximations of order p. By assuming exact local solution values at $t = t_n$ and corresponding local Taylor expansions of w_{n+1}, F_{n+1}, it then follows in the same way as above that $d(t) =$

$\mathcal{O}(\tau^q)$, where $q = \min(p, 3)$, and with the special value $s = \frac{1}{2}$ we have $q = \min(p, 4)$. Hence the cubic Hermite polynomial can be used up to consistency order $p = 3$, and when using only $s = \frac{1}{2}$ even up to order $p = 4$. In the remainder we will employ the defect $d(t)$ halfway to the step intervals, that is,

(2.18)
$$d(t_{n+1/2}) = \frac{3w_{n+1} - 3w_n}{2\tau} - \frac{F_n + F_{n+1}}{4} - F\Big(t_{n+1/2}, \frac{w_n + w_{n+1}}{2} + \frac{\tau}{8}\left(F_n - F_{n+1}\right)\Big)\,.$$

Now let $w_n = w(t_n)$, and consider local expansions

$$w_{n+1} = w + \tau w' + \sum_{k=2}^{p} \frac{\tau^k}{k!} w^{(k)} + \frac{\tau^{p+1}}{(p+1)!} C_{p+1} + \mathcal{O}(\tau^{p+2})\,, \tag{2.19}$$

with the right-hand side evaluated at $w = w(t_n)$ and an empty sum for $p = 1$. Hence the ρ-term in the local error expansion at $t = t_n$ then reads

$$\rho_n = \frac{\tau^p}{(p+1)!}\Big(w^{(p+1)}(t_n) - C_{p+1}\Big)\,, \tag{2.20}$$

and inserting the expansion for w_{n+1} into $d(t_{n+1/2})$ will reveal

$$d(t_{n+1/2}) = -\tfrac{3}{2}\,\rho_n + \mathcal{O}(\tau^{p+1})\,, \qquad 1 \le p \le 3\,. \tag{2.21}$$

The cubic Hermite defect halfway to the step interval thus can be used to retrieve in leading order the local error of any one-step method of order $1 \le p \le 3$.

Finally we connect (2.12) and (2.11) by putting $r(t_{n+1/2}) = \frac{2}{3}\,d(t_{n+1/2})$ in the stepwise frozen version of (2.12), i.e.,

$$e' = F'(t_n, w_n)e + r(t_{n+1/2})\,, \quad t_n < t \le t_{n+1}\,, \qquad n = 0, \ldots, N-1\,, \tag{2.22}$$

which will be integrated for the global error estimation. In this manner we actually work in leading order with the stepwise frozen version of the first variational equation (2.11) for the true global error (both $G(t)$ and $\rho(t)$ are frozen at $t = t_n$) multiplied by -1, i.e., $e = -\eta$ in first-order approximation. Within the more general setting of continuous Runge–Kutta methods, this use of defects and relations like (2.21) was discussed earlier; see, e.g., [4, 10, 11, 21, 22]. Trivially, multiplying $r(t_{n+1/2})$ by a certain constant multiplies the solution by the same constant (if $e(0) = 0$). This simple property forms the basis for tolerance proportionality, which we shall use for attempting control over the global errors (in both the classical and the novel approaches).

2.3. The example integration formulas. As the example integrator for the comparison between the adjoint and the classical approaches, we have used an A-stable scheme, viz., the third-order Runge–Kutta–Rosenbrock scheme ROS3P [16]. To save space we refer to [15, 16] for details.

The implemented step size strategy by which the time grid (1.2) is generated with ROS3P is standard, except that, different from [16], the defect $r(t_{n+1/2})$ is used. So for local control we work with

$$Est = (I - \gamma\tau_n A)^{-1} r(t_{n+1/2})\,, \qquad A = F'(t_n, w_n)\,, \tag{2.23}$$

where γ is a ROS3P coefficient. The common filter $(I - \gamma\tau_n A)^{-1}$ serves to damp spurious stiff components which would otherwise be amplified through the F-evaluations

within $r(t_{n+1/2})$.[1] Note that, while the local error is $\mathcal{O}(\tau_n^4)$, this estimate is $\mathcal{O}(\tau_n^3)$ by which we asymptotically have tolerance proportionality [20].

Let $D_n = \|Est\|$, with $\|\cdot\|$ the L_2-norm.[2] The step is accepted if $D_n \le Tol_n$, where $Tol_n = Tol_A + Tol_R\,\|w_n\|$, with Tol_A and Tol_R given tolerances. Otherwise the step is rejected and redone. In both cases the new step size is determined by the standard rule $\tau_{new} = \min(1.5, \max(2/3, 0.9\,r))\tau_n$, where $r = (Tol_n/D_n)^{1/3}$. After each step size change we adjust τ_{new} to $\tau_{n+1} = (T - t_n)/\lfloor(1 + (T - t_n)/\tau_{new})\rfloor$ so as to guarantee to reach the end point T with a step of averaged normal length. The initial step size τ_0 is prescribed and is adjusted similarly.

Simultaneously, (2.22) is integrated by means of the implicit midpoint rule

$$e_{n+1} = e_n + \tau_n A\Big(\frac{e_{n+1} + e_n}{2}\Big) + \tau_n r(t_{n+1/2})\,, \qquad A = F'(t_n, w_n)\,, \tag{2.24}$$

implemented in the equivalent form

$$\begin{aligned} \tilde{e}_{n+1} &= 2e_n + \tfrac{1}{2}\tau_n A\tilde{e}_{n+1} + \tau_n r(t_{n+1/2})\,,\\ e_{n+1} &= \tilde{e}_{n+1} - e_n\,. \end{aligned} \tag{2.25}$$

The main additional costs for (2.25) come from an extra decomposition since $\gamma \neq \frac{1}{2}$ (assuming a direct solve). Due to freezing $G(t)$ and $\rho(t)$ at $t = t_n$ as discussed above, the second-order midpoint rule (2.24) is a first-order method when interpreted for solving the first variational equation (2.11). As a result, the associated local error takes the form $C(t_n)\tau_n^2 + \text{h.o.t.}$, where the leading error constant $C(t_n) = \mathcal{O}(\tau_{max}^3)$ as it is proportional to $\eta(t)$, which itself is $\mathcal{O}(\tau_{max}^3)$. Consequently, the global error approximations e_n satisfy $e_n = -\epsilon_n + \mathcal{O}(\tau_{max}^4)$.

2.4. The control rule. Suppose ROS3P and (2.25) have delivered a numerical solution w_N and a global error estimate e_N at time $t_N = T$. We then verify whether

$$\|e_N\| \le C_{control}\,Tol_N\,, \qquad Tol_N = Tol_A + Tol_R\,\|w_N\|\,, \tag{2.26}$$

where $C_{control} \approx 1$, typically > 1. If (2.26) holds, the true global error is considered small enough relative to the chosen tolerance, and w_N is accepted. Otherwise, the computation with ROS3P and (2.25) is redone over $[0, T]$ with the same (small) τ_0 and the adjusted tolerances

$$Tol_A = Tol_A \times fac\,, \quad Tol_R = Tol_R \times fac\,, \qquad fac = Tol_N/\|e_N\|\,. \tag{2.27}$$

The primary aim of global error estimation is to provide an additional check on accuracy. Especially when the problem at hand is ill-conditioned (unstable), this is useful since local control will not detect instability so that ε_N might be substantially larger than the imposed tolerance. The second (control) computation with ROS3P (and (2.25) for an additional check) serves to reduce ε_N to the imposed tolerance level. If all is going well, with (2.26) we thus count on the quality of the global error estimation and with (2.27) on tolerance proportionality, thus expecting that reducing the local error estimates with the factor fac will reduce ε_N by fac [20].

[1] The defect contains a new F-evaluation, which in turn contains $F(t_n, w_n)$ and $F(t_{n+1}, w_{n+1})$, indicating that two filter steps would be needed. Our practical experience is that one filter step is sufficient, although we know of at least one hypothetical problem (the Kaps problem given at page 215 of [3]) for which two filter steps are appropriate.

[2] By L_2-norm we mean the weighted inner product norm, i.e., $\|v\|^2 = v^T v/m$, $v \in \mathbb{R}^m$. This norm will also be used for the adjoint approach.

2.3. It is possible to avoid (2.27) by storing the whole step size sequence (1.2) from the first run over $[0,T]$ and to carry out the second computation on a new step size sequence obtained by dividing all intervals $[t_n, t_{n+1}]$ into $\lceil 1/fac^{1/3} \rceil$ equal subintervals. We then count only on the quality of (2.26) and even would have the possibility to also use global Richardson extrapolation for global error estimation for an additional check. However, we then also give up local control. This renders no problem if all is going well, but it might result in numerical instability which otherwise would have been detected by local control.

3. The adjoint (forward-backward) approach. Like for the classical approach the analysis of the adjoint approach starts from the perturbed system derived in section 2.1.

3.1. Error representation for scalar-derived functions. The error representation formula (2.5) reveals that an approximation of $\Phi^{-1}(t)\,\Phi(s), \quad 0 \le s \le t$, would be desirable to estimate the sensitivity of (1.1) with respect to perturbations $v_0 - w_0$ and $r(t)$. Instead of computing these matrix products, which is in general far too expensive or even unattainable, we first derive error estimates for a scalar-derived function. The analysis is based on the adjoint method, which has been used successfully to obtain goal-oriented a posteriori error estimation for an adaptive error control for PDEs (see [1, 5, 7]) and ODEs (see [2, 6, 13, 17]).

Let $M(w(t))$ be the scalar quantity of interest. Then one has for the error in M

$$\triangle M(t) := M\big(v(t)\big) - M\big(w(t)\big) = \overline{M}(t)\, e(t), \tag{3.1}$$

with row vector

$$\overline{M}(t) = \int_0^1 M'\big(v(t) + (s-1)e(t)\big)\, ds = \int_0^1 M'\big(w(t) + se(t)\big)\, ds\,. \tag{3.2}$$

Hence, using (2.5),

$$\triangle M(t) = \overline{M}(t)\Phi^{-1}(t)\Phi(0)e(0) + \overline{M}(t)\Phi^{-1}(t) \int_0^t \Phi(s)r(s)\, ds\,. \tag{3.3}$$

Solving backward in time the adjoint equation

$$\phi'(s) = -A^T(s)\phi(s), \quad \phi(t) = \overline{M}^T(t), \quad 0 \le s < t, \tag{3.4}$$

and taking into account that $\Phi^{-T}(s)$ is the fundamental matrix of this equation if (and only if) $\Phi(t)$ is the fundamental matrix of (2.3) defined in (2.5), one gets

$$\phi^T(s) = \overline{M}(t)\Phi^{-1}(t)\Phi(s)\,. \tag{3.5}$$

Thus

$$\triangle M(t) = \phi^T(0)e(0) + \int_0^t \phi^T(s)r(s)\, ds, \quad 0 \le t \le T. \tag{3.6}$$

Formula (3.6) serves as the fundamental relation to derive a strategy for global error estimation. The adjoint solution value $\phi^T(0)$ measures sensitivity of $M(w(t))$ with respect to $e(0)$. Likewise, the integral term measures sensitivity with respect to the defects.

. . . . 3.1. In principle one may consider quantities $M(w(t)) = \xi_i^T w(t)$, $i = 1, \ldots, m$, where ξ_i is the ith unit vector in $\mathbb{R}^m$. Then $\triangle M(t) = \xi_i^T e(t) = e^{(i)}(t)$, the ith component of the error vector $e(t)$. Thus $\overline{M}^T(t) = \xi_i$. Denoting by ψ_i the solution of (3.4) with ξ_i as the initial value, one gets from (3.6)

$$\xi_i^T e(t) = e^{(i)}(t) = \psi_i^T(0)e(0) + \int_0^t \psi_i^T(s)r(s)\,ds\,. \tag{3.7}$$

In this way all components of the error vector $e(t)$ could be computed at the price of solving the adjoint equation m times. However, if $m \gg 1$, one would have to solve a tremendous number of adjoint systems, making this method impractical. The best choice would be $M(w(t)) = e^T(t)w(t)/(m\|e(t)\|)$ [2]. Then $\triangle M(t) = \|e(t)\|$ directly from (3.1), but one does not have $e(t)$. The choice of appropriate initial conditions for the adjoint system is the main challenge for the adjoint approach [2, 7].

. . . . 3.2. To set up the adjoint equation (3.4) we have to replace $A^T(s)$ by a suitable approximation in the neighborhood of $v(s)$. Thus the adjoint equation depends on the solution of the original ODE. A first possibility is to store the forward solution for every time step to determine the adjoint equation. Alternatively, the solution is stored at only a few selected times $0 = T_0 < T_1 < \cdots < T_K = T$. As the adjoint equation solver marches backwards in time from T_k to T_{k-1}, one recomputes the solution over that time interval using the previously stored solution T_{k-1} as the initial value. This approach reduces the storage requirements at the price of a second forward solution. The need to make the forward equation available to the adjoint equation is a drawback of the adjoint approach. Solution storage is of course not needed for linear systems (1.1) of type $w' = A(t)w + g(t)$. On the other hand, in all cases all defects must be stored. Another drawback of the adjoint approach is that it is defined for single output times t at which estimation is wanted. In other words, if estimation is wanted at multiple times t, the adjoint solution must be computed separately for each value of t.

3.2. Global error estimation. We have implemented global error estimation applying ROS3P to solve (1.1) as described in section 2.3 and using (3.6) and the small sample statistical method proposed by Cao and Petzold for backward differentiation formua (BDF) methods [2] (see also [14] for more details). The main idea is to replace the vectors ξ_i in (3.7) by a small number of orthonormal vectors $z_1, z_2, \ldots, z_k$, which are selected uniformly and randomly from the unit sphere S_{m-1} in m dimensions. Instead of computing accurate error estimates of global errors, we try to approximate them with a high probability.

Let $\eta_i(t) = |z_i^T e(t)|$. Then an estimate for $\|e(t)\|$ is given by

$$\|e(t)\| \approx g_k(t) = \frac{E_k}{E_m}\sqrt{\frac{1}{m}\Big(\eta_1^2(t) + \eta_2^2(t) + \cdots + \eta_k^2(t)\Big)}\,, \tag{3.8}$$

where $E_1 = 1$, $E_2 = 2/\pi$, and for $n > 2$

$$E_n = \begin{cases} \dfrac{1\cdot 3\cdot 5\cdots(n-2)}{2\cdot 4\cdot 6\cdots(n-1)} & \text{for } n \text{ odd,} \\[2ex] \dfrac{2}{\pi}\cdot\dfrac{2\cdot 4\cdot 6\cdots(n-2)}{1\cdot 3\cdot 5\cdots(n-1)} & \text{for } n \text{ even.} \end{cases} \tag{3.9}$$

E_n can be estimated by $\sqrt{2/(\pi(n-1/2))}$. The "$\approx$" in (3.8) has to be understood in the sense of probability. More precisely, the expected value of the random variable

$g_k(t)$ is given by $E(g_k(t)) = \|e(t)\|$ (see [14], Theorem 3.1). For $k = m$ the vectors $z_1, \ldots, z_k$ form an orthonormal basis in $\mathbb{R}^m$, and hence from the definition in (3.8) we get for $k = m$ directly the identity $g_m(t) = \|e(t)\|$.

The important question now is, what is the probability that the estimator $g_k(t)$ provides upper and lower bounds for $\|e(t)\|$? Let $c > 1$ be a given factor. Then one has for two and three random vectors [14]

$$P\left(\frac{g_2(t)}{c} \le \|e(t)\| \le c\, g_2(t)\right) \approx 1 - \frac{\pi}{4c^2}\,, \tag{3.10}$$

$$P\left(\frac{g_3(t)}{c} \le \|e(t)\| \le c\, g_3(t)\right) \approx 1 - \frac{32}{3\pi^2\, c^3}\,. \tag{3.11}$$

To achieve 99% probability of accuracy, for example, one can use $k = 2$ for $c = 10$ and $k = 3$ for $c = 5$. In [2] it is pointed out that in practice usually at most two or three random vectors are sufficient, although without giving numerical evidence because in their numerical experiments $k = m$. Hence the small sample statistical method was not tested in [2].

3.3. To generate vectors uniformly and randomly on S_{m-1} one can use the following procedure: Let $\lambda^{(1)}, \ldots, \lambda^{(m)}$ be normally distributed independent random variables with mean zero and variance one. Then the vector $\lambda/\|\lambda\|$ is uniformly and randomly distributed over S_{m-1} where $\lambda = (\lambda^{(1)}, \ldots, \lambda^{(m)})^T$ [25].

The small sample statistical method described above thus will be used to estimate $\|e(T)\|$. We first select random vectors $\hat{z}_1, \ldots, \hat{z}_k$ from S_{m-1} and construct an orthonormal basis $z_1, \ldots, z_k$ for their span by using a Gram–Schmidt procedure or a QR decomposition. Then we solve the corresponding adjoint equations

$$\phi_i'(s) = -A^T(s)\,\phi_i(s)\,, \quad \phi_i(T) = z_i\,, \tag{3.12}$$

for $\phi_i, i = 1, \ldots, k$. From (3.1) and (3.6) with $\triangle M(T) = z_i^T e(T)$ we have for each ϕ_i the identity

$$z_i^T\, e(T) = \phi_i^T(0) e(0) + \int_0^T \phi_i^T(s) r(s)\, ds. \tag{3.13}$$

In the following we assume $e(0) = 0$. Using (3.8) and recalling $\eta_i(T) = |z_i^T\, e(T)|$ we get

$$g_k(T) = \frac{E_k}{E_m}\left(\frac{1}{m}\sum_{i=1}^{k}\left(\int_0^T \phi_i^T(s) r(s)\, ds\right)^2\right)^{1/2}. \tag{3.14}$$

The integral terms must be approximated (recall that with $k = m$ and an exact computation of these integrals we have $\|e(T)\| = g_m(T)$). We integrate (3.12) using the second-order implicit midpoint rule on the same grid as selected to solve (1.1) by means of ROS3P, but now backward in time starting from z_i,

$$\begin{aligned} &\tilde{\phi}_{i,n} = 2\,\phi_{i,n+1} + \frac{\tau_n}{2}\, A^T\, \tilde{\phi}_{i,n}\,, \quad A^T = \left(F'\left(t_{n+1/2}, \frac{w_n + w_{n+1}}{2}\right)\right)^T, \\ &\phi_{i,n} = \tilde{\phi}_{i,n} - \phi_{i,n+1}\,, \quad n = N-1, \ldots, 0. \end{aligned} \tag{3.15}$$

Note that for larger problems one cannot store all Jacobians A from the forward integration, so one has to recompute them. The practical need for recomputing Jacobians

is another drawback of the adjoint approach. Further note that, like in the forward approach, A^T is an accurate approximation to the integrated Jacobian $A(t)$ defined in (2.4) as long as the global error $e(t)$ is sufficiently small. The adjoint problems are not coupled and hence can be solved in parallel. Also recomputing Jacobians for use in the backward in time midpoint rule is needed only once, that is, once for all adjoint problems.

To approximate the integrals in (3.14) we use the 1-point, second-order Gaussian formula for each integration interval to obtain

$$g_k(T) \approx \frac{E_k}{E_m} \left(\frac{1}{m} \sum_{i=1}^{k} \left(\sum_{n=0}^{N-1} \tau_n \, \frac{\phi_{i,n}^T + \phi_{i,n+1}^T}{2} \, r(t_{n+1/2}) \right)^2 \right)^{1/2}, \tag{3.16}$$

where the residual $r(t_{n+1/2})$ is computed in exactly the same way as within the classical approach described in sections 2.2 and 2.3; i.e., we take $r(t_{n+1/2}) = \frac{2}{3} d(t_{n+1/2})$.

3.3. The control rule. The possible need for a second forward computation with ROS3P is decided on the same control rule as in the classical approach, which we described in section 2.4. Hence also for the adjoint approach we rely on tolerance proportionality for the global error control. If a second forward computation is decided, then for an additional error check we apply (3.15) once again for the already chosen random vectors z_i taken as initial values, similar to the additional error check in the classical approach.

. . . . 3.4. The conditioning of system (1.1) with respect to small perturbations $r(t)$ can be estimated using (3.14). There holds

$$\|e(T)\| \approx |g_k(T)| \le K_T \cdot \max_{0 \le s \le T} \|r(s)\|, \tag{3.17}$$

with the condition number

$$K_T = K_T(\phi_1, \ldots, \phi_k) = \frac{E_k \sqrt{m}}{E_m} \left(\sum_{i=1}^{k} \left(\int_0^T \|\phi_i(s)\| \, ds \right)^2 \right)^{1/2}. \tag{3.18}$$

If K_T is small, a well-designed defect-based local error control will work out well. But if K_T is large, one could end up with a global error much larger than the imposed local tolerance. As proposed in [5] for parabolic problems, and discussed in [2] for BDF methods, one could tighten the local tolerance for the second ROS3P run within (2.27) through $fac = 1/K_T$. However, when taking norms in (3.17), favorable effects of error cancellation and nearly zero defect values are completely ignored, and therefore the new local tolerance can be extremely pessimistic. Indeed, this is observed for the example system of section 4.4. Its condition number computed from (3.18) with $k = 2$, while using the 1-point, second-order Gaussian formula, is huge, being about 10^{20}. On the other hand, the integral terms in (3.14) are of moderate size due to cancellation and many zero entries in the defect function $r(s)$. So for the example system of section 4.4, the use of the condition number K_T for global error control is impossible. In fact, K_T is of the same size as the a priori condition number $K_{\mu_2} = (e^{\omega T} - 1)/\omega$, based on the logarithmic matrix norm μ_2, given in (2.7). Inserting the accurate bound $\omega = 100$, which in this case is just the largest eigenvalue of the Jacobian matrix due to symmetry [12], yields $K_{\mu_2} \approx 5.2 \times 10^{19}$.

4. Numerical illustrations. Numerical results are given for (i) a 2-dimensional unstable nonstiff example problem from [2], (ii) the 3-dimensional stable stiff Robertson chemical kinetics problem [8], (iii) a 100-dimensional unstable semidiscrete diffusion-reaction problem (an often used test problem from combustion theory [12]), and (iv) a 400-dimensional unstable semidiscrete diffusion-reaction problem (from pattern formation and often called the bistable Allen–Cahn problem). For the semidiscrete problems spatial errors are left out of consideration; i.e., we compare to a highly accurate ODE reference solution.

All four problems are solved with $Tol_A = Tol_R = Tol$ for the four tolerance values $Tol = 10^{-l}, l = 3, 4, 5, 6$, using one and the same initial step size $\tau_0 = 10^{-5}$. If after the first attempt (2.26) is violated with $C_{control} = 1$, a second attempt is carried out with the same τ_0 and the automatically adjusted new value for Tol through (2.27). Needless to say, $C_{control} = 1$ is too stringent. We use it here only for the sake of illustrating the good performance of the global control rule (2.27). It will be clear from the tables of results whether a second attempt was necessary.

The tables of results contain the following quantities $Tol_N = Tol\,(1+\|w_N\|)$ from (2.26): for the classical approach the ratio $\|\varepsilon_N\|/\|e_N\|$ of the true global error and the estimated global error, for the adjoint approach the ratio $\|\varepsilon_N\|/g_k(T)$ of the true global error and the estimated global error defined by (3.16), and for both approaches the ratio $\|\varepsilon_N\|/Tol_N$. The first and second ratios serve to illustrate the quality of the estimation, while the third does this for the control. In addition, the numbers of accepted and rejected ROS3P steps are given.

Finally, for the small sample statistical initialization used in the adjoint method, $k = m$ orthonormal random vectors were used for the two small-sized problems, whereas for the other two much larger problems we used only two random vectors. So only for the two larger problems was the small sample statistical initialization tested, and for the two small-sized problems the classical and adjoint approach should give identical results, except for minor implementation differences. Also observe that the randomness of the initialization will lead to differences in the results when computations are repeated, although minor ones.

4.1. A low-dimensional nonstiff ODE system. The first test problem is the 2-dimensional unstable linear system [2]

$$w' = \begin{pmatrix} \frac{1}{2(1+t)} & -2t \\ 2t & \frac{1}{2(1+t)} \end{pmatrix} w, \quad w(0) = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \qquad 0 < t \le T = 10\,, \tag{4.1}$$

with increasing oscillatory solution $w_1(t) = \cos(t^2)\sqrt{1+t}$, $w_2(t) = \sin(t^2)\sqrt{1+t}$. Table 4.1 shows the results for the classical approach. Since $k = m = 2$, the adjoint approach results are identical except for negligible implementation differences. The quality of the global error estimates is very high, and the second runs based on tolerance proportionality yield perfect control for all tolerances.

4.2. A low-dimensional stiff ODE system. Our second test problem is the well-known Robertson problem from the stiff ODE field [8]

(4.2)

$$\begin{aligned} w_1' &= -4.0 \times 10^{-2}\, w_1 + 10^4\, w_2 w_3\,, & w_1(0) &= 1\,, \\ w_2' &= 4.0 \times 10^{-2}\, w_1 - 10^4\, w_2 w_3 - 3.0 \times 10^7\, w_2^2\,, & w_2(0) &= 0\,, \\ w_3' &= 3.0 \times 10^7\, w_2^2\,, & w_3(0) &= 0\,, \quad 0 < t \le T = 1\,. \end{aligned}$$

Tol	Tol_N	$\|\epsilon_N\|/Tol_N$	$\|\epsilon_N\|/g_3(T)$	Accept	Reject
10^{-3}	1.56×10^{-3}	7.39×10^{-5}	1.05	29	0
10^{-4}	1.56×10^{-4}	1.05×10^{-3}	0.94	31	0
10^{-5}	1.56×10^{-5}	8.68×10^{-3}	1.01	40	1
10^{-6}	1.56×10^{-6}	7.64×10^{-2}	1.02	62	2

This stiff problem is highly stable, resulting in global errors much smaller than imposed local tolerances (the effect of the small initial $\tau_0 = 10^{-5}$ is less strong). So global error control is redundant here, and no control runs were carried out. The global error estimation appears to work very well for this stiff problem. Table 4.2 shows results of the adjoint approach. Since $k = m = 3$, the results of the classical approach again are identical, except for negligible implementation differences. These exist only for the column for the values of $\|\epsilon_N\|/g_3(T)$. The corresponding values $\|\epsilon_N\|/\|e_N\|$ for the classical approach are $(1.07, 1.02, 1.03, 1.04)^T$.

4.3. High-dimensional stiff ODE system I. Our third ODE test system is derived from spatially discretizing the well-known 1D combustion example problem (see, e.g., [12, p. 434] for the 2D version)

$$u_t = u_{xx} + \tfrac{1}{4}(2-u)\, e^{20(1-1/u)}\,, \quad 0 < x < 1\,, \qquad 0 < t \le T = 0.28\,, \tag{4.3}$$

subjected to the initial condition $u(x,0) = 1$, the zero Neumann boundary condition $u_x = 0$ at $x = 0$, and the Dirichlet boundary condition $u = 1$ at $x = 1$. The spatial discretization is done by second-order central differencing on a uniform hybrid grid (because of the Neumann condition) with mesh width $1/100.5$, resulting in a 100-dimensional ODE system $w' = F(w)$. We have chosen this system because it requires variable step sizes and it is unstable. The instability emanates from the reaction term whose derivative ranges between approximately $+1000$ and -5500; see [12] for details. Furthermore, the 100-dimensional ODE system poses a challenging test for the small sample statistical method using $k = 2$ only.

For the classical approach Table 4.3 reveals an excellent estimation of the global error and likewise a high quality of the control for all tolerances. Observe that for $Tol = 10^{-6}$ the second control run is redundant. Regarding the adjoint approach we emphasize the high quality of the small sample statistical method. From inequality (3.10) one would expect the ratios $\|\varepsilon_N\|/g_2(T)$ to lie asymptotically between 0.1 and 10.0 with 99% probability. Table 4.4, however, shows ratio values ranging between

3.66×10^{-6}	2.84×10^{-5}	0.57	0.76	3695	4
10^{-6}	2.84×10^{-6}	0.91	0.72	5736	3
7.93×10^{-7}	2.84×10^{-6}	0.65	0.72	6204	3

0.72 and 1.38. Taking k larger with this large dimension m is no option. For example, doubling k to 4 does not lead to a notable improvement yet increases the costs for the global error estimation. Noting the small deviations from 1.0 of all listed ratios, especially after the control run, both approaches perform excellently with respect to estimation and control.

4.4. High-dimensional stiff ODE system II. Similar to the third, the fourth test problem was chosen because it is unstable, again challenging global error control. It is derived from spatially discretizing the following version of the bistable Allen–Cahn equation:

$$u_t = 10^{-2}\, u_{xx} + 100u\,(1-u^2)\,, \quad 0 < x < 2.5\,, \qquad 0 < t \le T = 0.5\,, \tag{4.4}$$

with the initial function and Dirichlet boundary values taken from the exact wave front solution $u(x,t) = (1 + e^{\lambda\,(x-\alpha\,t)})^{-1}$, $\lambda = 50\sqrt{2}$, $\alpha = 1.5\sqrt{2}$. Uniform second-order central discretization in space yields our ODE test system, now with $m = 400$ components. The instability emanates from the unstable stationary state $u = 0$. Further, since $m = 400$ and $k = 2$, this problem also poses an even more challenging test for the small sample statistical method.

Table 4.5 reveals again a high quality of the global error estimation for the classical approach and the control process also works very well. The ratios for $\|\epsilon_N\|/Tol_N$ lie between 0.71 and 0.93 after the control run. Observe that for $Tol = 10^{-5},\ 10^{-6}$ the control runs are redundant. In actual practice, taking the control parameter $C_{control} > 1$ in (2.26), this would also hold for the other tolerances. For the adjoint approach, the ratios $\|\epsilon_N\|/g_2(T)$ given in Table 4.6 range from 0.53 to 2.56, which is by a factor of 4 better than one would expect from inequality (3.10). The adjoint approach does not require a second run for $Tol = 10^{-4},\ 10^{-6}$, and for the other cases

10^{-6}	1.65×10^{-6}	0.76	2.56	3998	0

the control is also very efficient (only a factor 0.45 to 0.78 off the imposed tolerance after the control run).

5. Summary and main conclusions. Inspired by [2] and related earlier literature, e.g., [1, 5, 6, 7, 13], we have discussed and compared classical global error estimation based on the first variational equation to a recent more novel approach based on the adjoint equation. The common starting point for both approaches is the perturbed equation with the residual or defect function defined by piecewise, cubic Hermite interpolation. As a base integrator for the comparison we have chosen the third-order, A-stable Runge–Kutta–Rosenbrock method ROS3P. We have also implemented global error control, for which we have used the property of tolerance proportionality for both the classical and the adjoint approaches.

On the basis of the four example problems, ranging from nonstiff to stiff, the computational effort of each of the two approaches, and the insight from the analysis, we have come to three main conclusions. (i) The classical approach is remarkably reliable, with respect to both estimation and control. Although well known in the numerical ODE literature, it seems that the virtue of this approach has been insufficiently brought forward, since as yet this form of global error estimation and control is far less popular than the commonly used local techniques. (ii) Most notable for the adjoint approach is the excellent performance of the small sample statistical method which forms the heart of the method. We have applied it successfully using only $k = 2$ random vectors for dimensions $m = 100, 400$ (in [2] it was not tested since there $k = m \leq 2$). With $k = 2$ the computational costs are only marginally higher than those of the classical approach. Were we to omit the second control run, then our Matlab runs in the adjoint case would be on average only about 15% more costly in CPU time. Omitting the second control run can make a difference, because in the adjoint case the second control run can be significantly more expensive than in the classical case due to the need of reevaluating many Jacobian matrices. (iii) The main

disadvantage of the adjoint approach is the need either to store the whole approximation sequence $(w_n; 0 \leq 1 \leq N)$ or to store part of it and to carry out a second forward computation. When using Jacobians, as is the case for ROS3P, storage becomes truly a handicap with large problems calling for Jacobian reevaluations and hence additional CPU costs.

Something we haven't discussed in this paper is that the adjoint approach can give precious sensitivity information which can be used to advantage for a different step size adaptation (see, e.g., [17]). Such information is not available within the classical approach. Our step size adaptation is standard and based on local error control. Other approaches based on a posteriori information and the adjoint approach do exist and are claimed to give better results for global error control; see [17, 18, 19].

INCOMPLETE LU PRECONDITIONING WITH THE MULTILEVEL FAST MULTIPOLE ALGORITHM FOR ELECTROMAGNETIC SCATTERING*

TAHİR MALAS† AND LEVENT GÜREL†‡

Abstract. Iterative solution of large-scale scattering problems in computational electromagnetics with the multilevel fast multipole algorithm (MLFMA) requires strong preconditioners, especially for the electric-field integral equation (EFIE) formulation. Incomplete LU (ILU) preconditioners are widely used and available in several solver packages. However, they lack robustness due to potential instability problems. In this study, we consider various ILU-class preconditioners and investigate the parameters that render them safely applicable to common surface integral formulations without increasing the $\mathcal{O}(n \log n)$ complexity of MLFMA. We conclude that the no-fill ILU(0) preconditioner is an optimal choice for the combined-field integral equation (CFIE). For EFIE, we establish the need to resort to methods depending on drop tolerance and apply pivoting for problems with high condition estimate. We propose a strategy for the selection of the parameters so that the preconditioner can be used as a black-box method. Robustness and efficiency of the employed preconditioners are demonstrated over several test problems.

Key words. preconditioning, incomplete LU preconditioners, multilevel fast multipole algorithm, electromagnetic scattering

1. Introduction.

A popular approach in studying wave scattering phenomena in computational electromagnetics (CEM) is to solve discretized surface integral equations, which give rise to large, dense, complex systems in the form of $\overline{\mathbf{A}} \cdot \mathbf{x} = \mathbf{b}$. Two kinds of surface integral equations are commonly used. The electric-field integral equation (EFIE) can be used for both open and closed geometries, but it results in poorly conditioned systems, especially when the geometry is large in terms of the wavelength. On the other hand, the combined-field integral equation (CFIE) produces well-conditioned systems, but it is applicable to closed geometries only [21].

For the solution of such dense systems, direct methods based on Gaussian elimination are still widely used due to their robustness [34]. However, the large problem sizes confronted in computational electromagnetics prohibit the use of these methods which have $\mathcal{O}(n^2)$ memory and $\mathcal{O}(n^3)$ computational complexity for n unknowns. On the other hand, by making use of the multilevel fast multipole algorithm (MLFMA) [12], the dense matrix-vector products required at least once in each step of the iterative solvers can be performed in $\mathcal{O}(n \log n)$ time and by storing only the sparse near-field matrix elements, rendering these solvers very attractive for large problems.

However, the iterative solver may not converge, or convergence may require too many iterations. We need to have a suitable preconditioner to reach convergence in

a reasonable number of iterations and retain the $\mathcal{O}(n \log n)$ complexity of MLFMA. We can use the sparse near-field matrix $\overline{\mathbf{N}}$ to construct a preconditioner. Since this matrix is the best available approximation to the coefficient matrix $\overline{\mathbf{A}}$, it makes sense to use the near-field matrix as a preconditioner and solve (for example) the left-preconditioned system

$$\overline{\mathbf{N}}^{-1} \cdot \overline{\mathbf{A}} \cdot \mathbf{x} = \overline{\mathbf{N}}^{-1} \cdot \mathbf{b}. \tag{1.1}$$

The inversion of the near-field matrix $\overline{\mathbf{N}}$ can be accomplished using direct methods which decompose the matrix into a product of a unit lower-triangular matrix $\overline{\mathbf{L}}$ and an upper-triangular matrix $\overline{\mathbf{U}}$. However, during the factorization of sparse matrices, in general, fill-in occurs and the resulting factors lose their sparsity [28]. This may make it difficult to preserve the $\mathcal{O}(n \log n)$ complexity of MLFMA. Nevertheless, we can discard part of the fill-in and partially incorporate the robustness of the LU factorization into the iterative method by using the incomplete factors of $\overline{\mathbf{N}}$ as a preconditioner. This is the general idea behind the incomplete LU (ILU) preconditioners.

In a general setting, depending on the dropping strategy, we can talk about two kinds of ILU-class preconditioners. The first one depends on the matrix structure and the entries are dropped by their position. A "levels of fill-in" concept is introduced and stronger preconditioners can be constructed by increasing the level of fill-in [31]. Since this technique does not consider numerical values, it becomes ineffective in predicting the locations of the largest entries, particularly for matrices that are far from being diagonally dominant and indefinite [13]. This is the case for the matrices arising from the EFIE formulation. Alternatively, one can drop the matrix elements depending on their magnitudes, and the zero pattern is generated dynamically during the factorization. Among such methods, ILUT(τ, p) proposed by Saad has been successful for many general systems [3]. During the factorization, ILUT drops matrix elements that are smaller than τ times the 2-norm of the current row; and of all the remaining entries no more than the p largest ones are kept. ILUT is known to yield more accurate factorizations than the level-of-fill methods with the same amount of fill-in [13].

Although ILUT is more robust than its counterparts depending on the level of fill-in, it may occasionally encounter problems of instability for real-life problems. Even when factorization terminates normally, the resulting incomplete factors may sometimes be unstable. The common reasons of instability are in general excessive dropping and small pivots [13]. If the problem is related to the small pivots, one can significantly increase the quality of the ILUT preconditioner by using partial pivoting as in the complete factorization case. The resulting preconditioner is called ILUTP [31].

In order to understand the quality of the preconditioner, or to understand the reason for failure when it occurs, we can use $\|(\overline{\mathbf{L}} \cdot \overline{\mathbf{U}})^{-1} \cdot \mathbf{e}\|_\infty$, where $\mathbf{e}$ is the vector of ones. This statistic is called *condest* (for condition estimate) and it provides an upper bound for $\|(\overline{\mathbf{L}} \cdot \overline{\mathbf{U}})^{-1}\|_\infty$ [13]. If the *condest* value is not very high, but the preconditioner still does not work, one can deduce that fill-in should be increased to achieve a successful preconditioner. On the other hand, if the *condest* value is high, one can first try pivoting to remedy the situation instead of including more elements in the incomplete factors.

Considering the remarkable success of ILU-class preconditioners for general non-symmetric and indefinite systems [13] and the wide availability of ILU-class preconditioners in various packages [2, 24, 6], the present study aims to develop a strategy for

both selecting the most appropriate ILU-class preconditioner and determining their parameters to use them as black-box preconditioners for CFIE and EFIE formulations. We perform tests on canonical, quasi-canonical, and real-life problems with increasing number of unknowns and show that when these preconditioners fail for the reasons stated earlier, the failure can be circumvented using pivoting strategies without increasing the memory cost. We also show that the *condest* value is very useful for determining the quality of the resulting factorization before starting the iterative solution.

ILU-class preconditioners have been tested for electromagnetic problems in [8, 32, 26]. In [8], ILU(0) was tried on systems resulting from EFIE formulation with discouraging results in all test problems. Sertel and Volakis [32] tried ILU(0) on two model problems. For the very small problem of 480 unknowns, ILU(0) was successful with the EFIE and CFIE formulations, but clearly such a small problem is not representative of large-scale CEM simulations. They presented only CFIE results for the 50,000-unknown problem; in this case, ILU(0) was quite successful in reducing the number of iterations. Probably the most impressive results are those of Lee, Zhang, and Lu [26], who tried the ILUT preconditioner on hybrid surface-volume integral equations and showed it to be successful on many test problems. However, they neither tried commonly used EFIE or CFIE formulations nor applied pivoting or any other techniques to increase the effectiveness of the preconditioner.

The rest of the paper is organized as follows. In the next section, we outline the surface integral equations of CEM, their discretizations, resulting matrix equations, and MLFMA. Spectral properties of such matrices are analyzed in section 3. Then, in section 4, we comment on the preconditioning of the systems arising from integral-equation formulations. In section 5, we present experimental results for the CFIE and EFIE formulations. In the last section, we make some suggestions for the effective and safe usage of ILU-class preconditioners with EFIE and CFIE.

2. Surface integral equations and fast solvers. EFIE and CFIE are surface integral equations that are formed from the application of physical boundary conditions; they are formulated to solve the radiation and scattering problems of arbitrarily shaped geometries. This leads to the reduction of a three-dimensional problem into a two-dimensional problem, but the resulting matrix equation becomes fully populated.

The boundary condition stating that the total tangential electric field should vanish on a conducting surface can be mathematically expressed to obtain EFIE as

$$\hat{\boldsymbol{t}} \cdot \int_{S'} \mathrm{d}\mathbf{r}' \overline{\mathbf{G}}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') = \frac{i}{k\eta} \hat{\boldsymbol{t}} \cdot \mathbf{E}^{inc}(\mathbf{r}), \tag{2.1}$$

where $\mathbf{E}^{inc}$ represents the incident electric field, S' is the surface of the object, $\hat{\boldsymbol{t}}$ is any tangential unit vector on S', $\mathbf{J}(\mathbf{r}')$ is the unknown induced current residing on the surface,

$$\overline{\mathbf{G}}(\mathbf{r}, \mathbf{r}') = \left[\bar{\mathbf{I}} + \frac{\nabla\nabla}{k^2} \right] g(\mathbf{r}, \mathbf{r}') \tag{2.2}$$

is the dyadic Green's function, and

$$g(\mathbf{r}, \mathbf{r}') = \frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \tag{2.3}$$

is the scalar Green's function for the three-dimensional scalar Helmholtz equation. Green's function represents the response at $\mathbf{r}$ due to a point source located at $\mathbf{r}'$.

Similarly, the boundary condition for the tangential magnetic field on a conducting surface is used to derive the magnetic-field integral equation (MFIE) [22, 14] as

$$\mathbf{J}(\mathbf{r}) - \hat{\boldsymbol{n}} \times \int_{S'} \mathrm{d}\mathbf{r}' \mathbf{J}(\mathbf{r}') \times \nabla' g(\mathbf{r}, \mathbf{r}') = \hat{\boldsymbol{n}} \times \mathbf{H}^{inc}(\mathbf{r}), \tag{2.4}$$

where $\hat{\boldsymbol{n}}$ is any unit normal on S' and $\mathbf{H}^{inc}(\mathbf{r})$ is the incident magnetic field. It should be noted that EFIE is valid for both open and closed geometries, whereas MFIE is valid only for closed surfaces [18, 16].

Combining EFIE and MFIE, we obtain CFIE, i.e.,

$$\mathrm{CFIE} = \alpha \mathrm{EFIE} + (1 - \alpha)\mathrm{MFIE}, \tag{2.5}$$

where α is a parameter between 0 and 1. CFIE is free from the internal resonance problems of both EFIE and MFIE and leads to well-conditioned systems [19]. On the other hand, CFIE is not applicable to open geometries since it contains MFIE. Therefore, CFIE is preferred over MFIE for closed geometries, but EFIE is the only choice for open geometries. CFIE can also be extended for geometries containing both closed and open surfaces [23].

Surface integral equations can be converted to linear systems of equations using the method of moments (MOM). In fact, MOM can be used to reduce any linear-operator equation to a matrix equation. Using a linear operator L, we can represent EFIE and CFIE as

$$L\{\mathbf{f}\} = \mathbf{g}, \tag{2.6}$$

where $\mathbf{f}$ is the unknown vector function, and $\mathbf{g}$ is the excitation. To discretize this equation, $\mathbf{f}$ is first approximated by a set of vector basis functions via the expansion

$$\mathbf{f} \approx \sum_{j=1}^{n} x_j \mathbf{f}_j, \tag{2.7}$$

where x_j is the unknown coefficient of the jth basis function. Then this discretized equation is tested at n points and a linear system is obtained, i.e.,

$$\sum_{j=1}^{n} x_j \langle \mathbf{t}_i, L\{\mathbf{f}_j\} \rangle = \langle \mathbf{t}_i, \mathbf{g} \rangle, \qquad i = 1, \ldots, n. \tag{2.8}$$

In (2.8), $\mathbf{t}_i$ is the vector testing function and the inner product is defined as

$$\langle \mathbf{t}, \mathbf{f} \rangle = \int_S \mathrm{d}\mathbf{r}\, \mathbf{t}(\mathbf{r}) \cdot \mathbf{f}(\mathbf{r}). \tag{2.9}$$

By defining the elements of the coefficient matrix (or the so-called impedance matrix) as

$$A_{ij} = \langle \mathbf{t}_i, L\{\mathbf{f}_j\} \rangle \tag{2.10}$$

and the elements of the right-hand-side vector (or the excitation vector) as

$$b_i = \langle \mathbf{t}_i, \mathbf{g} \rangle, \tag{2.11}$$

the linear system of equations can be expressed as

$$\overline{\mathbf{A}} \cdot \mathbf{x} = \mathbf{b}. \tag{2.12}$$

In order to implement a Galerkin approach for discretization, we use Rao–Wilton–Glisson (RWG) functions [29] for both basis and testing functions. RWG functions are linearly varying vector functions defined on planar triangular domains. They are widely used in MOM applications to discretize surface current distributions.

Surfaces of geometries are meshed with planar triangles in accordance with the RWG functions. Each basis function is associated with an edge; hence the number of unknowns n is equal to the total number of edges in a triangulation. For high accuracy, triangle sizes have to be small, but this leads to problems with large numbers of unknowns. As a rule of thumb, we choose the average size of the mesh about one-tenth of the wavelength.

Since the integrodifferential operator L for both EFIE and CFIE involves long-distance interactions, the resulting coefficient matrix is dense, which is expensive to store and to solve. However, when we use iterative solvers, direct solution is replaced with a series of matrix-vector multiplications, and we have the opportunity to perform the matrix-vector product with $\mathcal{O}(n \log n)$ complexity using MLFMA.

MLFMA can be described as the multilevel application of the fast multipole method (FMM). An important concept, on which FMM relies, is the diagonalized factorization of the Green's function, i.e.,

$$g(\mathbf{r}, \mathbf{r}') = \frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} = \frac{e^{ik|\mathbf{D}+\mathbf{d}|}}{4\pi|\mathbf{D}+\mathbf{d}|} \approx \frac{1}{4\pi} \int d^2\hat{\boldsymbol{k}} e^{i\hat{\boldsymbol{k}}\cdot\mathbf{d}} T_L(k, D, \psi), \tag{2.13}$$

where $D = |\mathbf{D}| < d = |\mathbf{d}|$, the integration is on the unit sphere, $\hat{\boldsymbol{k}}$ is the unit vector normal to the unit sphere, and T_L is the truncated sum

$$T_L(k, D, \psi) = \frac{ik}{4\pi} \sum_{l=0}^{L} i^l (2l+1) h_l^{(1)}(kD) P_l \cos(\psi), \tag{2.14}$$

which is called the translation function [17]. In (2.14), $h_l^{(1)}(x)$ is the spherical Hankel function of the first kind, P_l is the Legendre polynomial, and ψ is the angle between unit vectors $\hat{\boldsymbol{k}}$ and $\hat{\boldsymbol{D}}$. The truncation number L is determined by the formula given in [12],

$$L \approx kd + 1.8 d_0^{2/3} (kd)^{1/3}, \tag{2.15}$$

where d_0 is the number of accurate digits required in the matrix-vector multiplication.

In a physical setting, we can think of a matrix-vector multiplication as a set of electromagnetic interactions between the basis and testing functions. When the basis and testing functions are clustered according to the proximity of their locations in space, the same translation function can be used for all interactions between pairs of functions in any two clusters, instead of calculating the interactions separately. For this purpose, radiation patterns of the basis functions $\mathbf{f}_j$ weighted with the corresponding coefficients x_j are evaluated on the unit sphere at K directions. Next, in each basis group, the radiation patterns are added at each direction, a process called aggregation. For each pair of basis and testing groups, a translation function is defined. The overall radiation pattern of each basis group is multiplied by a translation function and thereby translated to the center of a testing cluster. Following

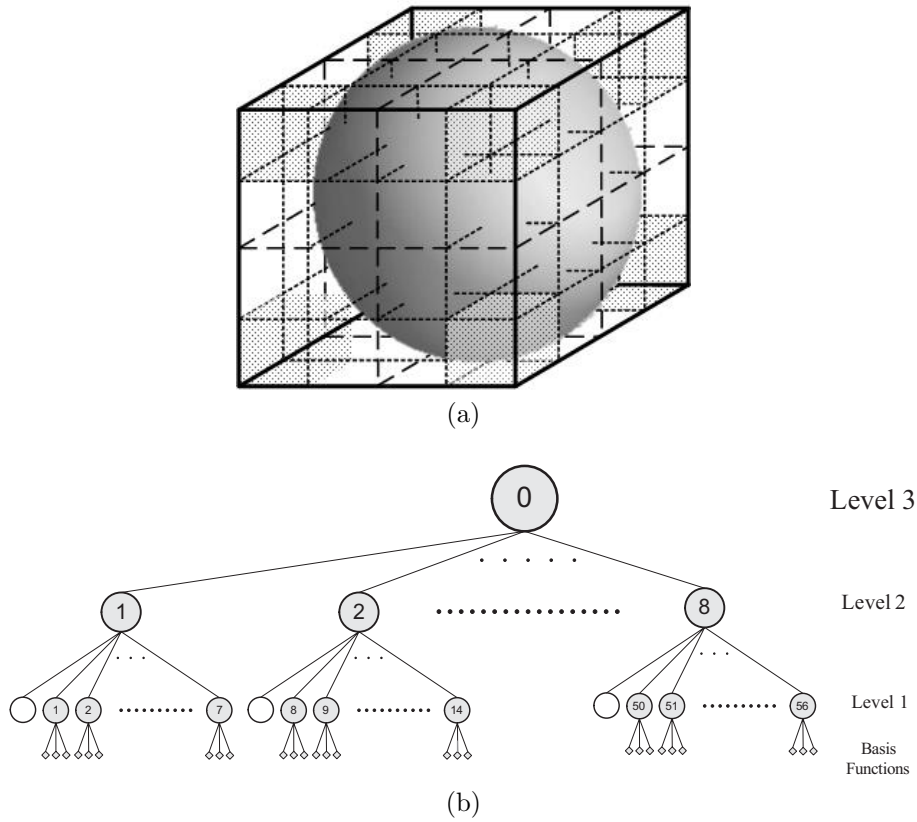

FIG. 2.1. (a) *Multilevel partitioning of the scatterer for the case of a sphere with diameter* 1λ. *The shaded boxes are empty.* (b) *Tree structure of MLFMA for the sphere. Unfilled nodes correspond to empty boxes.*

the translations, radiation patterns of the basis groups are added at the center point of each testing group. Finally, the total radiation from all basis functions at each testing cluster is disaggregated onto individual testing functions in order to complete the testing process. Since the factorization of the Green's function is not valid for basis and testing functions that are close to each other, the near-field interactions are calculated directly. In a multilevel scheme, MLFMA requires interpolations and anterpolations to pass from one level to another [15].

In MLFMA, to perform a multilevel application of FMM, the whole geometry is placed in a cube and then this cube is recursively divided into smaller ones until the smallest cube contains only a few basis or testing functions. However, during the partitioning, if any cube becomes empty, recursion stops there. This partitioning defines the levels of MLFMA and corresponds to a tree structure. An example of a sphere with a diameter of one wavelength (1λ) is shown in Figure 2.1.

With the partitioning scheme described, we can easily determine the near-field and far-field clusters. On any level, pairs of same-size cubes touching at any point are in the near-field zone of each other and the others are in the far-field zone. In the MLFMA tree, we refer to the filled cubes as clusters. A cluster contains either some basis functions (in the lowest level) or low-level clusters. In MLFMA, the replacement of the element-to-element interactions with cluster-to-cluster interactions is made in

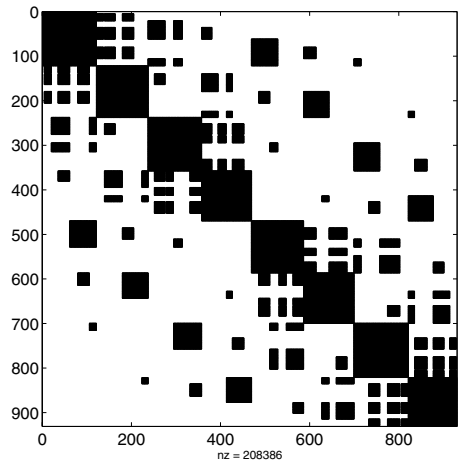

FIG. 2.2. *Near-field pattern of the* 930*-unknown sphere problem.*

a multilevel scheme.

In the lowest level, interactions between the near-field clusters are computed exactly and stored in the sparse near-field matrix. When the ordering of the unknowns is in accordance with the clustering, the near-field matrix is composed of small blocks, but the distribution of the blocks does not exhibit any structured pattern. For the sphere geometry shown in Figure 2.1, the nonzero pattern of the near-field matrix is presented in Figure 2.2. Self-interactions of the second-level clusters can easily be observed in the diagonal blocks of the nonzero pattern.

Interactions among the far-field clusters are computed approximately (but with controllable accuracy) and efficiently. For each level excluding the highest two, radiated fields of each cluster are aggregated at the centers of the clusters. Then, for each pair of far-field clusters whose parents are in the near-field zone of each other, cluster-to-cluster interaction is computed via a single translation. If the parents of the pair of clusters are not in the near-field of each other, the cluster-to-cluster interaction is included in a higher-level translation. Finally, after the translations, the summed values at the centers of the testing clusters are disaggregated towards the testing functions, completing the matrix-vector multiplication.

3. Spectral analysis. For electromagnetic scattering problems, iterative methods with MLFMA provide new opportunities to solve large-scale problems that were previously unsolvable. However, EFIE, MFIE, and CFIE formulations produce indefinite systems for which convergence becomes an issue. Moreover, since we consider the solution of very large problems with millions of unknowns, the condition of the matrix deteriorates (especially for EFIE) as the problem sizes grow. Hence, effective preconditioning is indispensable for attaining convergence in a reasonable time.

Though they are indefinite and nonhermitian, CFIE produces well-conditioned systems that are close to being diagonally dominant. As a consequence, the number of iterations required for convergence has been limited with a simple block-Jacobi preconditioner even for large-scale problems [19]. Nonetheless, for some geometries, the number of iterations is still large. Considering the dominant cost of matrix-vector product for large problems, better preconditioners for CFIE are still desirable.

Systems resulting from EFIE are much more difficult to solve. In addition to being

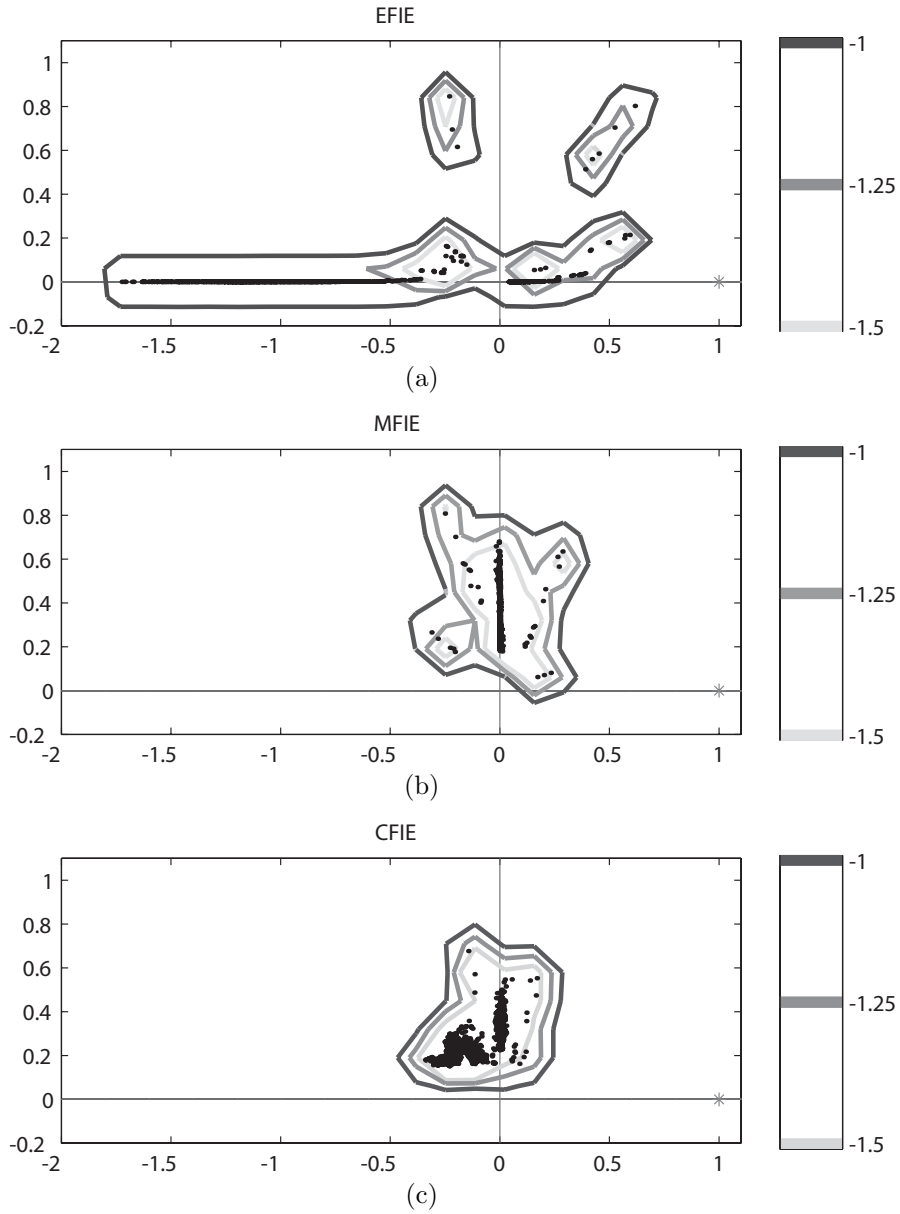

FIG. 3.1. *Pseudospectra of the EFIE, MFIE, and CFIE formulations for three ϵ values, i.e., 10^{-1}, $10^{-1.25}$, and $10^{-1.5}$. The black dots denote the exact eigenvalues of the unperturbed matrices.*

indefinite and nonhermitian, EFIE matrices may have large elements away from the diagonal, and some of the nonstored far-field interactions may be stronger than the near-field interactions.

For a better understanding of the properties of the systems resulting from surface integral equations, we show in Figure 3.1 both the eigenvalues and the pseudospectra of the EFIE, MFIE, and CFIE matrices for the 930-unknown sphere problem. For nonnormal matrices, information obtained from eigenvalues may be misleading, since

they may become highly unstable [33]. More reliable and telling information can be obtained using the ϵ-pseudospectrum, $\wedge_\epsilon(\overline{\mathbf{A}})$, which can be defined as

$$\wedge_\epsilon(\overline{\mathbf{A}}) = \left\{ z \mid z \in \mathbb{C}^n,\ \|(z\overline{\mathbf{I}} - \overline{\mathbf{A}})^{-1}\|_2 \geq \frac{1}{\epsilon} \right\}. \tag{3.1}$$

Denoting the spectrum of $\overline{\mathbf{A}}$ with $\wedge(\overline{\mathbf{A}})$, if an eigenvalue $\lambda \in \wedge(\overline{\mathbf{A}})$, then $\|(z\overline{\mathbf{I}} - \overline{\mathbf{A}})^{-1}\|_2 = \infty$, so $\wedge(\overline{\mathbf{A}}) \subset \wedge_\epsilon(\overline{\mathbf{A}})$ for any $\epsilon > 0$. The pseudospectrum represents the topology of the eigenvalues of the perturbed matrices associated with the exact matrix $\overline{\mathbf{A}}$, and thus gives an idea about the nonnormality.

The ultimate aim in preconditioning is to move all eigenvalues towards the point (1,0). However, if the matrix is close to normal, a spectrum clustered away from the origin also implies rapid convergence for Krylov subspace methods [3, 25]. Comparison of the EFIE and CFIE pseudospectra in Figure 3.1 indicates that combining EFIE with MFIE (to obtain CFIE) has the effect of clustering the distributed eigenvalues and moving them towards the right half-plane. In contrast, most of the eigenvalues of EFIE are scattered in the left half-plane. Moreover, the 0.1-pseudospectrum of the EFIE matrix contains the origin, signaling the near-singularity of the matrix. Hence, effective preconditioning for EFIE becomes more difficult, and also more crucial.

4. ILU-class preconditioners. Various preconditioners have been used for the solution of CEM problems. For CFIE, a block-Jacobi preconditioner is frequently used. In an MLFMA setting, a block-Jacobi preconditioner can be constructed from the self-interactions of the lowest-level clusters. Since there are $\mathcal{O}(n)$ such blocks and each block is composed of a fixed number of unknowns, both the construction and the application of the preconditioner scale with $\mathcal{O}(n)$. Because of its optimal complexity and success with many problems, this simple preconditioner is a common choice for CFIE. However, probably due to the weaker diagonal dominance and indefiniteness of EFIE, the block-Jacobi preconditioner performs even worse than the no-preconditioner case. Sparse approximate inverse (SAI) preconditioners depending on a fixed a priori pattern have been thoroughly studied in some recent works [9, 10, 11, 27, 1]. The electromagnetics community has started to use SAI preconditioners more frequently because of ease of parallelization. However, the construction cost of SAI can become prohibitively large unless one chooses the prefiltering and postfiltering threshold parameters carefully [27]. Hence, it is not suitable for use as a black-box preconditioner; there is still the need for a more easily attainable preconditioner, particularly for sequential implementations.

As an alternative, the ILU-class preconditioners have been widely used and included in several solver packages. They were historically developed for positive-definite and structured matrices arising from the discretization of partial differential equations. For general systems, the failure rate of ILU-class preconditioners is still high. Nonetheless, there have been many improvements to increase their robustness [13, 4, 5].

For iterative solvers utilizing MLFMA, the near-field matrix $\overline{\mathbf{N}}$ is the natural candidate to generate the incomplete factors. Consider an incomplete factorization of the near-field matrix, $\overline{\mathbf{N}} \approx \overline{\mathbf{L}} \cdot \overline{\mathbf{U}}$. If we let the sparsity patterns of $\overline{\mathbf{N}}$ and $\overline{\mathbf{L}} + \overline{\mathbf{U}}$ be the same, that is, if we retain nonzero values of $\overline{\mathbf{L}}$ and $\overline{\mathbf{U}}$ only at the nonzero positions of $\overline{\mathbf{N}}$, we end up with the no-fill LU method, or ILU(0). This simple idea works successfully for well-conditioned matrices [31]. Denser and potentially more effective preconditioners can be obtained by increasing the level of fill-in, but this strategy is unsuccessful in determining the largest entries, particularly for matrices

that are indefinite and far from being diagonally dominant. A more robust strategy is to drop the nonzero elements by comparing the magnitudes during the factorization. Such a strategy discards elements that are small with respect to a suitably chosen drop tolerance τ.

One of the disadvantages of the dropping strategy, which depends on the size of matrix entries, is the difficulty in predicting storage. For this purpose, a dual threshold strategy can be used [30]. The resulting preconditioner, called ILUT(τ, p), retains no more than p elements in the incomplete factors after dropping all the elements that are smaller than τ times the 2-norm of the current row. The threshold parameter τ determines the CPU time and p determines the storage requirement of the preconditioner. This preconditioner is known to be quite powerful and robust.

Despite ILUT's good reputation, there are two important drawbacks preventing its use as a black-box and general library software. The first problem is determining the appropriate parameters. For our specific applications and in the context of MLFMA, we propose to select a small drop tolerance and then set the parameter p so that the preconditioner will have approximately the same number of nonzero elements as the near-field matrix $\overline{\mathbf{N}}$. Once the near-field matrix is generated, this value can easily be found. With this strategy, we aim to obtain a powerful preconditioner with modest storage and low complexity.

Probably the more problematic aspect of threshold-based ILU-class preconditioners is their potential inaccuracy and/or instability. Accuracy refers to how close the incomplete factors are to $\overline{\mathbf{A}}$; this is measured by the norm of the error matrix, i.e., $accuracy = \|\overline{\mathbf{E}}\| = \|\overline{\mathbf{A}} - \overline{\mathbf{L}} \cdot \overline{\mathbf{U}}\|$. Stability refers to how close the preconditioned matrix is to the identity matrix and is measured by the norm of the preconditioned error, i.e., $stability = \|(\overline{\mathbf{L}} \cdot \overline{\mathbf{U}})^{-1} \cdot \overline{\mathbf{E}}\|$. If $\|\overline{\mathbf{L}}^{-1}\|$ or $\|\overline{\mathbf{U}}^{-1}\|$ are extremely large, a factorization may turn out to be accurate but unstable; in that case, the preconditioner may not work even if fill-in is increased [13]. Thus, for general matrices, stability is a more informative measure of the preconditioning quality.

Although we cannot compute these metrics with MLFMA, a rough estimate of $\|(\overline{\mathbf{L}} \cdot \overline{\mathbf{U}})^{-1}\|$, called *condest*, gives a clue about the instability of the triangular factors [13]. This condition estimate is defined as

$$\|(\overline{\mathbf{L}} \cdot \overline{\mathbf{U}})^{-1} \cdot \mathbf{e}\|_\infty, \qquad \mathbf{e} = [1, \ldots, 1]^T. \tag{4.1}$$

One can easily compute *condest* before the iterations, by using a forward substitution followed by a backward substitution, and it provides a strong indicator of the quality of the ILU preconditioner.

When the incomplete factors turn out to be unstable, there are some remedies that can be utilized depending on the cause. Preprocessing steps such as diagonal perturbation, reordering, and scaling can be applied on the coefficient matrix to stabilize the preconditioner. To increase the stability, diagonal perturbations can be used to make the LU factors more diagonally dominant, but quite large perturbations may be required for indefinite systems, and such large perturbations may introduce too much inaccuracy into the preconditioner. Diagonal shifts have already been tried on EFIE systems to increase the robustness of ILU, but the effect of the shift is undetermined, and furthermore it is difficult to select suitable shift parameters [7]. Reorderings aimed at improving the condition of the incomplete factors are widely studied. Indeed, some reordering schemes significantly improve the convergence of the Krylov methods [4]. However, the effect of ordering becomes significant when the incomplete factors are allowed to be denser than the original matrix [3]. We usually

prefer to keep the memory required by the preconditioner bounded by the storage needed for the near-field matrix. Hence, this remedy is not a good candidate because of the storage considerations. Finally, for threshold-based ILU-class preconditioners, it is recommended to scale the matrix so that each column has unit 2-norm, and then scale it again so that each row has unit 2-norm. This suggestion is not applicable in the context of MLFMA, since the preconditioner is constructed from a sparse portion of the coefficient matrix and the coefficient matrix is not explicitly available.

On the other hand, if the instability is caused by the small pivots, partial pivoting is helpful. This is a well-known and much simpler method. Column pivoting can be applied in a rowwise factorization with negligible cost. The resulting preconditioner is known as ILUTP [31]. In some cases, it may be useful to include a permutation tolerance , ., ., and perform the permutation for the ith row when $permtol \times |a_{ij}| > |a_{ii}|$. It is best not to select a very small value for *permtol*; 0.5 is accepted as a good choice [31].

5. Results. In this section, we show the effectiveness of ILU-class preconditioners for electromagnetic scattering problems. We first identify the most appropriate ILU-class preconditioner for the problem type (i.e., open geometries vs. closed geometries, EFIE vs. CFIE), then compare the selected ILU preconditioner with other commonly used preconditioners. For this purpose, we implement an SAI preconditioner, whose sparsity pattern is chosen to be the same as the near-field matrix. In this way, it has the same storage cost as that of ILU(0).

Instead of giving several results with varying parameters for ILUT, we adopt the following strategy for the selection of the parameters. We set the drop tolerance τ to a low value such as 10^{-6} and set p, the maximum number of nonzero elements per row, such that the memory cost of factorization does not exceed that of the no-fill ILU preconditioner. We accomplish this by simply letting p be the average number of nonzero elements in a row of the near-field matrix. In this way, we obtain robust preconditioners with modest computational requirements.

For the specific implementation of the MLFMA considered here, we set the size of the smallest clusters to 0.25λ, the number of accurate digits d_0 to 3, and the α parameter of CFIE to 0.2. The CPU times reported in this section were obtained on a 64-bit server with 1.8 GHz AMD Opteron 244 processors and 4 GB of memory. In addition to performing numerical experiments involving ILU-class preconditioners, we also obtain the exact solution of the near-field matrix to use it as a benchmark preconditioner. This solution, which is denoted by LU, is performed on another 64-bit server with 24 GB of memory. Due to its excessive computational requirements, this LU preconditioner is presented merely for comparison purposes.

For the iterative solver, starting with the zero initial guess, we try to reduce the initial residual norm by 10^{-6} and set the maximum number of iterations at 1,500. We use the generalized minimal residual method (GMRES) with no-restart and apply right-preconditioning in order to minimize the true residual norm. For CFIE solution of closed geometries, the performance of other Krylov subspace methods, such as conjugate gradient squared (CGS), biconjugate gradient (Bi-CG) or biconjugate gradient stabilized (Bi-CGSTAB), approximates GMRES in terms of the number of matrix-vector products. However, for EFIE, other solvers are less robust and do not always converge with preconditioning. Even when they converge, they require more matrix-vector multiplications than GMRES. Though GMRES with no-restart brings extra CPU and memory costs with increasing number of iterations, reduction in the number of matrix-vector products significantly decreases the overall solution time due

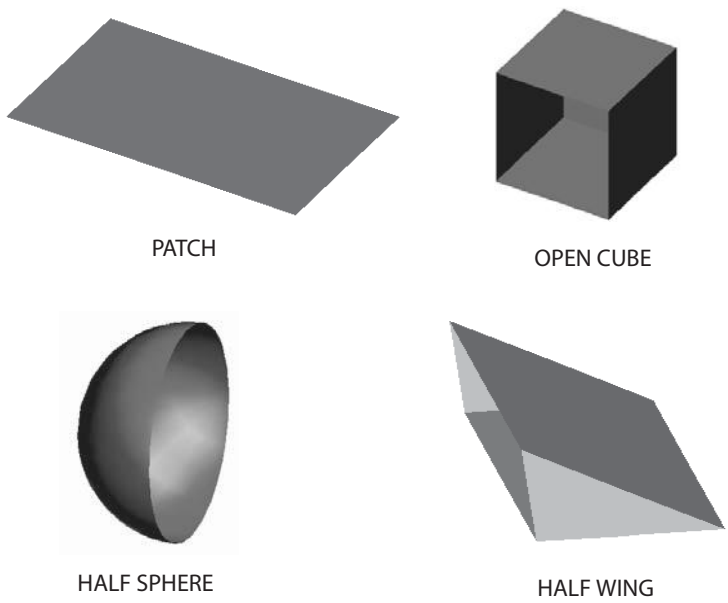

FIG. 5.1. *Open geometries.*

to the high cost of matrix-vector multiplications, particularly for large problems.

5.1. Open geometries. Figure 5.1 displays the open geometries used in the numerical experiments, i.e., a patch (P), a half sphere (HS), an open prism (OP), and an open cube (OC). These geometries are solved at various frequencies, requiring different meshes and numbers of unknowns as shown in Table 5.1. In Table 5.1 the "Size" column stands for the diameter for the spheres, and the maximum side length for others. The subsection sizes of different meshes are consistently selected as one-tenth of the wavelength. As mentioned in section 2, EFIE is the only choice for these geometries.

We compare the ILU-class preconditioners in Table 5.2. The summary of our observations are as follows:

(i) It is easily noticed that as the number of unknowns increases, ILU(0) produces highly unstable and hence useless factorizations. ILU(0) works well for small problems due to the fact that the near-field matrices used to generate the preconditioner and consequently the incomplete factors are nearly dense for such problems.

(ii) ILUT produces stable factors for all geometries except HS3. When we use 0.5 pivoting tolerance (ILUTP5) or 1.0 pivoting tolerance (ILUTP), we overcome the problem. However, for HS3, ILUTP yields a larger *condest* value and requires more iterations compared to ILUTP5. A similar situation is also encountered in some other experiments and the high value of *condest* for full pivoting is related to a poor pivoting sequence [13].

(iii) From the results, we also see a strong relationship between *condest* and the usefulness of the preconditioner. When the *condest* value is very high (i.e., higher than 10^5), the iterative method either requires too many iterations or does not converge at all.

Since ILUTP5 is robust for all our geometries, in Table 5.3 we compare it with other commonly used preconditioners. Block-Jacobi preconditioning performs poorer

than the no-preconditioner case, so the Jacobi preconditioner is used instead. We emphasize the following observations:

(i) Although we use a robust solver, for a simple preconditioner such as Jacobi, either the number of iterations turns out to be very high or convergence is not attained in 1,500 iterations. This is in good agreement with the conclusions derived in section 4.

(ii) ILUTP5 reduces iteration numbers by an order of magnitude compared to the Jacobi preconditioner. Moreover, the iteration numbers of ILUTP5 are not extremely higher than those of LU, indicating that the ILUTP5 preconditioners provide good approximations to the near-field matrices.

(iii) We see that the setup cost of SAI is prohibitively large, proving its inappropriateness for sequential implementations. Moreover, except for OC3, ILUTP5 yields fewer number of iterations compared to SAI.

(iv) Furthermore, the iteration counts reveal that the algebraic scalability of

ILUTP5 is favorable for open geometries. For two orders of increase in the number of unknowns, the iteration numbers increase approximately four times for patch and half sphere, and 10 times for the open cube and open prism.

5.2. Closed geometries. As mentioned in section 2, both EFIE and CFIE can be used for closed geometries. However, CFIE yields better-conditioned systems, so it is usually preferred over EFIE. Nonetheless, we will present some of the results obtained from EFIE for comparison purposes.

Figure 5.2 shows the model problems that we consider for the numerical experiments. These include two canonical geometries, i.e., a sphere (S) and a cube (C); two quasi-canonical geometries, i.e., a thin box (TB) and a wing (W); and two real-life problems, i.e., a helicopter (H) and Flamme (F), which is a stealth target [20]. Table 5.4 presents the operating frequency and the size of the geometries in terms of the wavelength. For Flamme and the helicopter, "Size" denotes the length of the objects in longitudinal direction.

Due to the well-conditioning of CFIE, ILU(0) is expected to be free from instability problems. In Table 5.5, we compare ILU(0) and ILUT by presenting the *condest* values and corresponding number of iterations for the systems obtained with CFIE. Pivoting does not change the iteration counts, and hence is not included in this case.

We note that ILU(0) and ILUT produce very similar preconditioners for CFIE. This is also observed for regular problems arising from the discretization of partial differential equations [35]. Since ILU(0) has a lower computational cost and is easier to implement compared to ILUT, we conclude that ILU(0) is the most appropriate choice among ILU-class preconditioners for CFIE.

When we use EFIE with closed geometries, it becomes even more difficult to solve the linear systems. Table 5.6 shows the [illegible] values and iteration numbers for ILU-class preconditioners. W3 does not converge in 1,500 iterations, and for H2 memory limitation is exceeded during the iterations. All other problems converge with ILUTP5, but with higher iteration counts compared to open geometries.

In Table 5.7, for CFIE, ILU(0) is compared to the block-Jacobi preconditioner (where only the self-interactions of the smallest MLFMA clusters are used in the

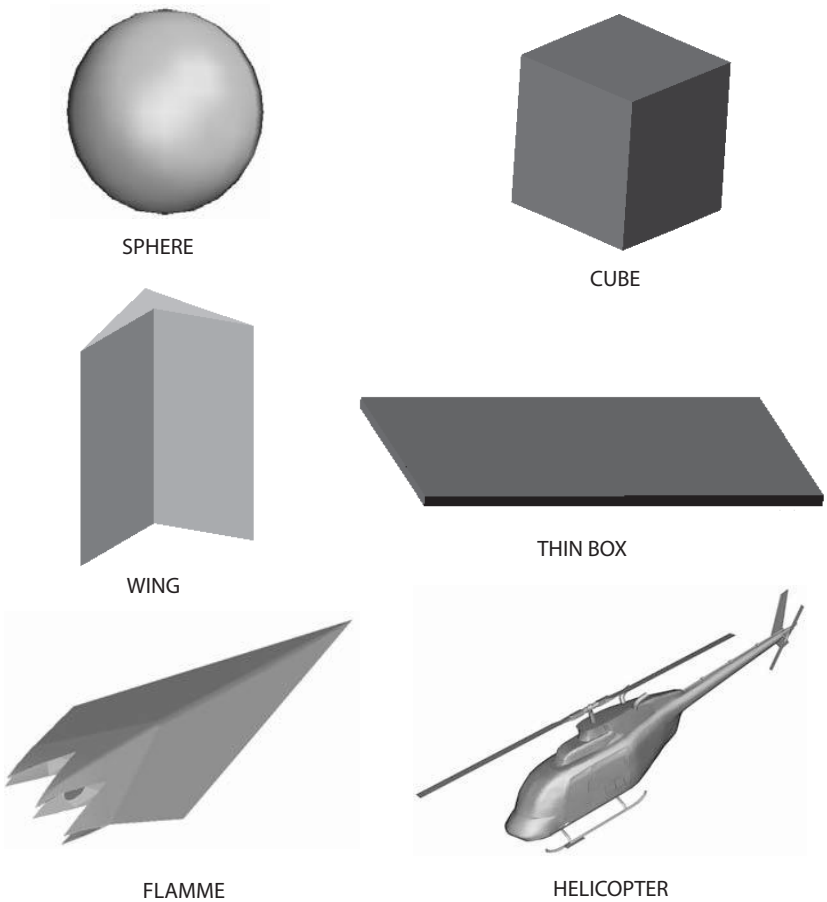

FIG. 5.2. *Closed geometries.*

near-field matrices) and the SAI preconditioner. We summarize the results as follows:

(i) For canonical geometries, compared to the block-Jacobi preconditioner, ILU(0) decreases the iteration numbers slightly. However, due to the larger setup time of ILU(0), total solution times become comparable. For multiple right-hand-side solutions, ILU(0) may be still preferable.

(ii) For quasi-canonical geometries and real-life problems, ILU(0) performs remarkably better compared to the block-Jacobi preconditioner. The number of iterations are halved for the largest problems, and more than halved for smaller sizes. Also, total solution times are significantly smaller.

(iii) Even though SAI has iteration numbers similar to ILU(0), the setup time of SAI is too large.

(iv) ILU(0) iteration numbers are very close to those of LU. Hence, among sequential-algebraic preconditioners for CFIE, ILU(0) emerges as the optimal choice for preconditioning MLFMA in the context of this study.

(v) Finally, even though the near-field matrix becomes sparser as the number of unknowns gets larger, we observe that the algebraic scalability of ILU(0) is surprisingly favorable. For the canonical geometries, as n increases two orders of magnitude, the iteration numbers only double. For quasi-canonical geometries, the iteration numbers

increase by a factor of only 3 or 4. For Flamme, as the number of unknowns increases 15 times, the iteration number only triples. For the helicopter, the increase in the iteration number is 1.4 compared to 5.5 times increase in the number of unknowns.

6. Conclusion. For iterative solvers, ILU-class preconditioners have been intensively studied and widely used. However, potential instability is still a shortcoming that reduces their reliability. We show that this drawback can be eliminated when it occurs, and ILU-class preconditioners can be safely applied to CEM problems employing MLFMA.

For open geometries, EFIE is the only choice of formulation. For the resulting systems, ILUT works remarkably well (about 10 times faster than Jacobi and with disproportionately lower setup time compared to SAI), but sometimes incomplete factors turn out to be unstable. We show that this situation can be handled by pivoting without incurring significant CPU costs; 0.5 pivoting tolerance gives the best results. We also show that the *condest* value is a strong indicator of the resulting preconditioner. Hence, considering the extra cost of pivoting (though not very significant), we propose the following strategy for the solution of problems involving open geometries. Before the iterations begin, compute *condest* for ILUT. If the condition estimate is not high (such as less than 10^4), use ILUT as the preconditioner. Otherwise, switch to ILUTP5. With this strategy, we have obtained robust and effective preconditioners for all our test problems.

CFIE can be used for closed geometries and yields linear systems that are well-conditioned. ILU(0) and ILUT produce very similar factorizations, and therefore cheaper ILU(0) should be preferred. With ILU(0), overall solution times have been decreased by at least one-half compared to the commonly used block-Jacobi preconditioner for real-life problems. Iteration numbers obtained with ILU(0) are very close to those of the exact solution of the near-field matrix, showing that ILU(0) is the optimum preconditioner in the context of this study. Though EFIE can also be used with closed geometries, it becomes harder to obtain fast convergence even with the exact solution of the near-field matrix.

GENERAL TOOTH BOUNDARY CONDITIONS FOR EQUATION FREE MODELING*

A. J. ROBERTS† AND I. G. KEVREKIDIS‡

Abstract. We are developing a framework for multiscale computation which enables models at a "microscopic" level of description, for example, lattice Boltzmann, Monte Carlo, or molecular dynamics simulators, to perform modeling tasks at "macroscopic" length scales of interest. The plan is to use the microscopic rules restricted to small "patches" of the domain, the "teeth," using interpolation to bridge the "gaps." Here we explore general boundary conditions coupling the widely separated "teeth" of the microscopic simulation that achieve high order accuracy over the macroscale. We present the simplest case when the microscopic simulator is the quintessential example of a PDE. We argue that classic high order interpolation of the macroscopic field provides the correct forcing in whatever boundary condition is required by the microsimulator. Such interpolation leads to tooth boundary conditions, which achieve arbitrarily high order consistency. The high order consistency is demonstrated on a class of linear PDEs in two ways: first through the eigenvalues of the scheme for selected numerical problems, and second using the dynamical systems approach of holistic discretization on a general class of linear PDEs. Analytic modeling shows that, for a wide class of microscopic systems, the subgrid fields and the effective macroscopic model are largely independent of the tooth size and the particular tooth boundary conditions. When applied to patches of microscopic simulations these tooth boundary conditions promise efficient macroscale simulation. We expect the same approach will also accurately couple patch simulations in higher spatial dimensions.

Key words. multiscale computation, gap-tooth scheme, coupling boundary conditions, high order consistency

1. Introduction.

The components of physical systems often operate on vastly different space and time scales [5]. We must somehow simulate such systems on the scale of interest and operation. But systems that depend on physical processes at multiple scales pose notorious difficulties. These multiscale difficulties are major obstacles to progress in fields as diverse as environmental and geosciences, climate, materials, combustion, high energy density physics, fusion, bioscience, chemistry, power grids, and information networks [5].

Here we further develop the equation free approach to multiscale modeling [10]. Given a numerical simulator for physical components at much smaller scales than the scale of primary interest, the aim of the methodology is to bridge the space and time scales to simulations resolving the macroscale of interest. Here we focus on bridging [illegible] by improving the accuracy of the gap-tooth methodology for microsimulators [7, 20, 21]. Crucially, our gap-tooth methods must adapt to whatever microsimulator code is provided; one key application of this work is to microsimulators that are tried and tested legacy codes that we do not want to modify.

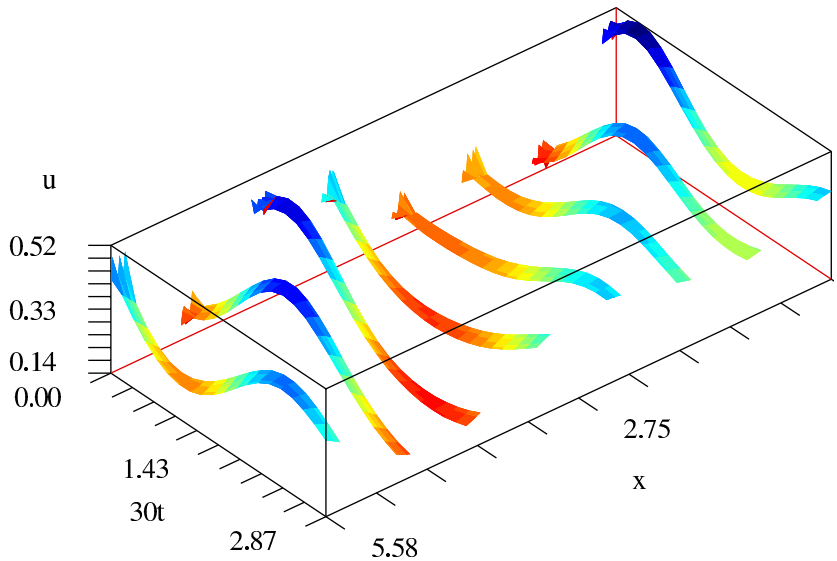

FIG. 1. *Simulation of the Burgers equation using Dirichlet boundary conditions on the teeth (specified u on the edges).*

The equation free approach provides [illegible] closure methods which constitute critical components of, for example, mathematical homogenization (e.g., [21, 8, 1]), renormalization group techniques (e.g., [6, 13, 4]), and multiscale finite elements (e.g., [9, 3]). These closure methods not only need to be computationally efficient but also need to be capable of reproducing the physical dynamics with high fidelity. Our approach avoids inefficiencies in the oversampling methods through using correct coupling conditions, to some order of accuracy, between the macroscale separated teeth. That is, we seek a methodology that can be systematically refined.

Using microscopic simulators of the one dimensional Burgers equation, Roberts and Kevrekidis [19] demonstrated the possibility of achieving high order accuracy in the gap-tooth scheme for macroscale dynamics. The particular microsimulator we use is a fine scale discretization of the PDE which we execute only in the interior of the teeth (see Figure 1). At each time step during execution, the microsimulator within each tooth requires boundary values which must be continuously updated. If the microsimulator was to be executed over the entire macrodomain, these boundary values would naturally come from the immediately neighboring fine grid; this grid is missing in gap-tooth simulation. That pilot study considered only microsimulators which had boundary conditions of specified [illegible] at the edges of their simulation teeth. Here we generalize the analysis to consider microsimulators with

- Dirichlet boundary conditions of specified field u at the tooth edges (section 2),
- mixed boundary conditions of specified $av_j \pm b\partial_x v_j$ at the tooth edges (section 3), or
- nonlocal two-point boundary conditions such as those arising in a microscale discretization of a PDE (section 4).

Consider the gap-tooth scheme (e.g., [7, 20]) illustrated in Figure 1. Let $v_j(x,t)$ be the fine scale, microscopic field in the jth tooth and U_j the jth coarse grid value, that is, the value at the center of each tooth. Let the tooth width be h. Then the edge of

a tooth lies at a distance $h/2$ from its coarse grid point, a fraction $r = h/(2H)$ to the next coarse grid point. The amount of computation performed by microsimulators is proportional to the width of the (microscale) teeth. Hence we aim for the fraction r to be as small as possible so that the teeth are a relatively small part of the physical domain and the computational cost is minimized; we call r the length scale ratio as a small r corresponds to a large disparity in the microscopic and macroscopic length scales. The coupling rule developed in sections 2, 3, and 4 is that you [illegible] macroscopic [illegible]. As a nonlinear example of the coupling we develop, Figure 1 shows a gap-tooth simulation of the nonlinear dynamics of the Burgers equation in one spatial dimension.

This coupling rule promotes a strong connection between classic finite difference discretizations of PDEs, classic finite elements, and the methodology of the gap-tooth scheme. First, the PDE, or a very fine discretization, acts as the quintessential example of a microsimulator in that it informs us of the dynamics in an "infinitesimal patch." The only difference between the gap-tooth scheme and the spatial discretization of PDEs is that the microsimulators in the gap-tooth scheme encode the dynamics on [illegible], whereas the PDE encodes the dynamics on [illegible] patches. Consequently, classic interpolation serves the same role in both: namely, the interpolation appropriately transfers information from the macroscale of interest to the microscale simulators. One result is that our approach reproduces classic finite difference models when applied to the limit of a microsimulator becoming an algebraic PDE. Second, the theoretical support for the gap-tooth scheme is based upon a subgrid scale structure, as is the classic finite element method. Also, the algebraic solvability condition in the construction of the theoretical gap-tooth model is similar to the Galerkin projection of finite elements. But whereas finite elements [illegible] a class of subgrid fields, both the theoretical approach here and the gap-tooth scheme use actual subgrid scale dynamics, obtained from the microsimulator or the PDE, to [illegible] appropriate subgrid scale fields on demand. Thus this approach systematically implements model closures for macroscale discretizations.

In section 5 we prove that classic interpolation accurately connects the teeth across the gaps for the general [illegible] fourth order PDE. The technique of holistic discretization (e.g., [17]) resolves subgrid scale structures to reproduce with high fidelity the dynamics of specified PDEs [18]. The techniques were adapted by Roberts and Kevrekidis [19] to the gap-tooth scheme in the case where the microsimulator requires Neumann boundary conditions of specified slope/flux (see section 3). Using the same techniques, section 5 analyzes the use of classic interpolation of macroscale grid values in the microscale simulators and shows the following desirable properties:

- the approach generates macroscopic discretizations which are consistent with the microscopic dynamics to high order in the macroscopic tooth separation H;
- the macroscopic model and the microscopic solution field are essentially independent of the size of the teeth, measured by r; and
- the macroscopic model and the microscopic solution field are essentially independent of the details of the tooth boundary conditions (TBCs) that couple the teeth together.

Thus our proposed rule generates gap-tooth schemes that may be systematically refined to high order accuracy and gives rise to macroscale simulations that are largely independent of physically irrelevant microscale parameters. Using such high order ac-

curate schemes will reduce errors on the macroscale. Since the microscale boundary forcing is determined from the macroscale coupling, reducing errors on the macroscale will consequently reduce the errors on the microscale.

Our analysis here is only for patches in one spatial dimension. MacKenzie [12] shows that similar coupling of PDEs generates holistic discretizations in two space dimensions. We expect that the coupling here can be straightforwardly generalized to spatial problems in higher dimensions.

2. Dirichlet teeth (specified u). In this section we consider the case of microsimulators that require at each time step the field values on the edge of each spatial patch to be specified. We model this case by PDEs with Dirichlet conditions coupling the dynamics in the teeth. The values for these Dirichlet conditions are obtained by interpolation across the gaps between the teeth using finite difference operators and the exact relationships between the operators. When applied to simple diffusion, the resulting scheme has high order accuracy.

Discrete operators are essential in the analysis. Define the shift operator $Eu(x) = u(x+H)$ and equivalently $EU_j = U_{j+1}$ as appropriate for steps on the coarse grid size H. Then we use the following identities for discrete operators (e.g., [14, p. 65]):

$$\text{mean} \quad \mu = \tfrac{1}{2}(E^{1/2} + E^{-1/2})\,, \tag{1}$$

$$\text{difference} \quad \delta = E^{1/2} - E^{-1/2}\,, \tag{2}$$

$$\text{shift} \quad E = 1 + \mu\delta + \tfrac{1}{2}\delta^2\,, \tag{3}$$

$$\text{derivative} \quad H\partial_x = 2\sinh^{-1}\tfrac{1}{2}\delta = \delta - \tfrac{1}{6}\delta^3 + \mathcal{O}\big(\delta^5\big)\,, \tag{4}$$

$$\mu^2 = 1 + \tfrac{1}{4}\delta^2\,. \tag{5}$$

Formulae involving these operators become more accurate as the differences δ become small. Such small differences arise either as the macroscopic grid size $H \to 0$ or equivalently as the gradients of the physical field u become small.

For example, Roberts and Kevrekidis [19] showed arbitrary order consistent macroscopic dynamics from a gap-tooth scheme as the grid size $H \to 0$. The key to that analysis is the following transformation of the operator for evaluating spatial derivatives $H\partial_x$ at the two patch boundaries $E^{\pm r}$:

$$E^{\pm r}H\partial_x = (1 + \mu\delta + \tfrac{1}{2}\delta^2)^{\pm r} 2\sinh^{-1}\tfrac{1}{2}\delta\,.$$

But this right-hand side, when expanded in a Taylor series in small differences δ, is composed of terms which have an odd number of centered operators δ and μ. Consequently the right-hand side above would require field values halfway between the grid values. These are unknown. Instead, from (5), multiply the right-hand side

by the identity $\mu/\sqrt{1+\delta^2/4}$, and then expand in small differences δ:

$$\begin{aligned}
E^{\pm r}H\partial_x &= (1+\mu\delta+\tfrac{1}{2}\delta^2)^{\pm r}2\sinh^{-1}\tfrac{1}{2}\delta \\
&= \frac{\mu}{\sqrt{1+\frac{1}{4}\delta^2}}(1+\mu\delta+\tfrac{1}{2}\delta^2)^{\pm r}2\sinh^{-1}\tfrac{1}{2}\delta \\
&= \mu\delta \pm r\delta^2 - (\tfrac{1}{6}-\tfrac{1}{2}r^2)\mu\delta^3 \mp r(\tfrac{1}{12}-\tfrac{1}{6}r^2)\delta^4 \\
&\quad + (\tfrac{1}{30}-\tfrac{1}{8}r^2+\tfrac{1}{24}r^4)\mu\delta^5 \pm r(\tfrac{1}{90}-\tfrac{1}{36}r^2+\tfrac{1}{120}r^4)\delta^6 \\
&\quad - (\tfrac{1}{140}-\tfrac{7}{240}r^2+\tfrac{1}{72}r^4-\tfrac{1}{720}r^6)\mu\delta^7 \\
&\quad \mp r(\tfrac{1}{560}-\tfrac{7}{1440}r^2+\tfrac{1}{480}r^4-\tfrac{1}{5040}r^6)\delta^8 + \mathcal{O}\big(\delta^9\big). \qquad (6)
\end{aligned}$$

For microsimulators with Dirichlet boundary conditions, we adapt the earlier analysis of Roberts and Kevrekidis [19]. But instead of determining the slopes at the tooth boundaries as above, the following interpolation of the macroscopic field determines the field values u on the edges of the teeth:

$$\begin{aligned}
E^{\pm r} &= (1+\mu\delta+\tfrac{1}{2}\delta^2)^{\pm r} \\
&= 1 \pm r\mu\delta + \tfrac{1}{2}r^2\delta^2 \pm \tfrac{1}{3!}r(r^2-1)\mu\delta^3 + \tfrac{1}{4!}r^2(r^2-1)\delta^4 \\
&\quad \pm \tfrac{1}{5!}r(r^2-1)(r^2-4)\mu\delta^5 + \tfrac{1}{6!}r^2(r^2-1)(r^2-4)\delta^6 \\
&\quad \pm \tfrac{1}{7!}r(r^2-1)(r^2-4)(r^2-9)\mu\delta^7 \\
&\quad + \tfrac{1}{8!}r^2(r^2-1)(r^2-4)(r^2-9)\delta^8 + \mathcal{O}\big(\delta^9\big). \qquad (7)
\end{aligned}$$

The pattern in the above interpolation formula is clear. Now we explore the numerical performance of a gap-tooth scheme using this formula to determine teeth boundary conditions.

Consider gap-tooth simulations of the simple diffusion equation

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} \quad \text{and } 2\pi\text{-periodic in } x. \qquad (8)$$

Imagine we have access to the dynamics only through a microscopic simulator of the diffusion (8), here coded by a fine discretization on n grid points, spaced a distance $\eta = h/(n-1)$ apart, across a tooth of microscopic width $h = 2rH$. The time integration is an explicit scheme with a microscopic time step, typically $\Delta t = 10^{-6}$–10^{-4}. Figure 2 shows an example of the initially rapid microscopic evolution within one tooth; the microsimulator, coupled to its neighbors, rapidly evolves to a smooth state. Figure 3 similarly shows the initial evolution in two neighboring teeth and how the smooth subgrid field arises through the coupling to the neighboring teeth. Similar dynamics take place during the initial instants of the Burgers evolution shown in Figure 1.

First, we implement the following TBC. On the edge of the jth tooth, at $x = X_j \pm rH$, the boundary condition of the fine discretization is that the field

$$v_j = \big[1 \pm r\mu\delta + \tfrac{1}{2}r^2\delta^2 \pm \tfrac{1}{6}r(r^2-1)\mu\delta^3 + \tfrac{1}{24}r^2(r^2-1)\delta^4\big]\,U_j\,. \qquad (9)$$

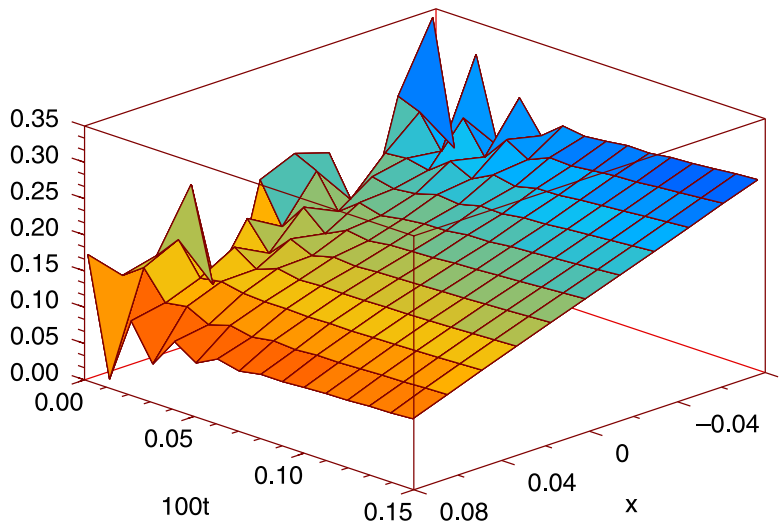

FIG. 2. *View of the initial microscopic evolution within a tooth with dynamics described by the diffusion PDE* (8) *and coupled to its neighbors.*

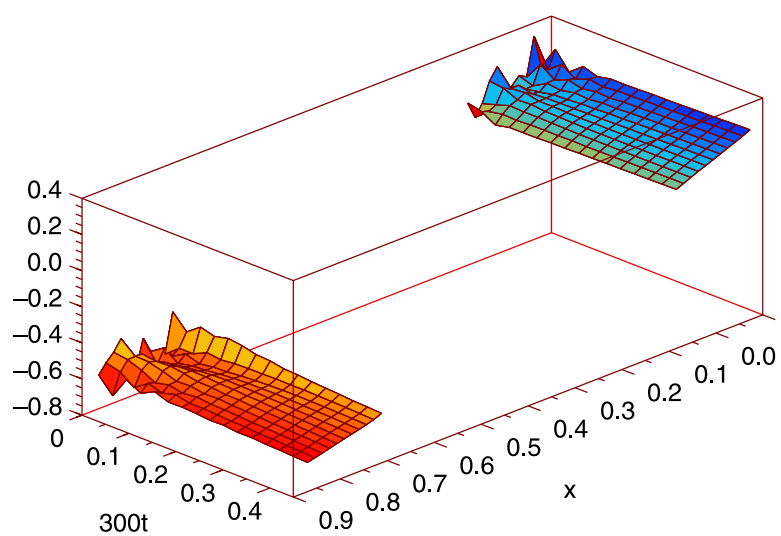

FIG. 3. *View of the initial microscopic evolution within a pair of neighboring teeth with dynamics described by the diffusion PDE* (8) *and also coupled to their neighbors.*

TABLE 1

Growth rates λ of perturbations from steady state $u = 0$: For diffusion (8) *with m teeth, $H = 2\pi/m$; with length scale ratio $r = 0.1$; $n = 11$ points in the microscale grid; and with the fourth order TBC* (9).

The first few terms of (7) provide this patch boundary condition by interpolation from the surrounding coarse grid values. For the jth tooth this TBC involves macroscopic grid values $U_{j-2},\ldots,U_{j+2}$ only, and thus we should be able to achieve $\mathcal{O}(H^4)$ consistency with the microsimulator. We numerically linearize the map over one microscopic time step by systematically perturbing each and every microscopic value from zero (there are mn such microscopic values, one for each of n fine grid points in each of m teeth). We then transform the eigenvalues μ of this map to growth rates $\lambda = \log(\mu)/\Delta t$. The mn growth rates fall into n groups of m modes. Each group corresponds to a microscopic [illegible] of the dynamics; the mode is essentially the same in each tooth. Large negative growth rates correspond to rapidly decaying internal modes with significant microscopic structure within each tooth. The group of m modes with [illegible] growth rates corresponds to the relatively slowly evolving [illegible] modes of interest that arise through the coupling of the microscopic dynamics across the teeth. Table 1 shows the leading seven growth rates, and the magnitude of the leading internal growth rate, for various numbers of teeth, $m = 4, 8, 16, 32$. The exact growth rates of the diffusion PDE (8) are $\lambda = -k^2$ for integer k. The table shows that as the number of teeth doubles, the accuracy of the growth rates of the macroscopic modes improves by a factor of about 16. This is consistent with an $\mathcal{O}(H^4)$ method, as predicted for diffusion with TBC (9).

Table 2 shows the even higher order accuracy from implementing sixth order TBCs from (7)—growth rates slightly larger than the ideal seem to be due to the relatively small number of microscopic grid points within the teeth. These sixth order TBCs are used in the simulations of the nonlinear Burgers equation shown in Figure 1. This simulation suggests that gap-tooth schemes employing such TBCs even for nonlinear systems are effective.

3. Mixed boundary conditions for the teeth. Let us explore mixed boundary conditions at the edges of the teeth: suppose the microsimulator requires $av_j \pm b\partial_x v_j$ specified on the edge of the teeth $x = x_j \pm rH$ for some constants a and b. The case $a = 1$ and $b = 0$ constitutes Dirichlet TBCs discussed in the previous section. The case $a = 0$ and $b = 1$ constitutes Neumann TBCs as discussed by Roberts and Kevrekidis [19]: there we used the interpolation formula (6) to specify slopes/fluxes on the edge of each tooth; we obtained spectra of accuracy similar to those in Tables 1 and 2.

For mixed TBCs we propose to simply combine (6) and (7) to give, for example, the fourth order in macroscopic grid size $H = 2\pi/m$ boundary condition

$$\begin{aligned} &av_j \pm b\partial_x v_j \\ &= a\left[1 \pm r\mu\delta + \tfrac{1}{2}r^2\delta^2 \pm \tfrac{1}{6}r(r^2-1)\mu\delta^3 + \tfrac{1}{24}r^2(r^2-1)\delta^4\right]U_j \\ &\pm \frac{b}{H}\left[\mu\delta \pm r\delta^2 - (\tfrac{1}{6}-\tfrac{1}{2}r^2)\mu\delta^3 \mp r(\tfrac{1}{12}-\tfrac{1}{6}r^2)\delta^4\right]U_j \\ &\text{on } x = x_j \pm rH\,. \end{aligned} \tag{10}$$

TABLE 3
Growth rates λ of perturbations from steady state $u = 0$: For diffusion (8) with m teeth, $H = 2\pi/m$; with length scale ratio $r = 0.1$; $n = 11$ points in the microscale grid; and with the mixed TBC (10) with $a = 0.95$ and $b = 0.05$.

m	1	2,3	4,5	6,7	$m+1:2m$
4	$9\cdot10^{-12}$	-0.939448	-2.151772	n/a	-240.7
8	$-2\cdot10^{-11}$	-0.990854	-3.766007	-7.089004	-756.9
16	$7\cdot10^{-11}$	-0.996405	-3.971027	-8.803476	$-2417.$
32	$6\cdot10^{-10}$	-0.998047	-3.991243	-8.971213	$-8153.$

TABLE 4
Growth rates λ of perturbations from steady state $u = 0$: For diffusion (8) with $m = 8$ teeth; with length scale ratio $r = 0.1$; n points in the microscale grid to show variation with microscale resolution; and with the mixed TBC (10) with $a = 0.95$ and $b = 0.05$.

n	1	2,3	4,5	6,7
11	$-2\cdot10^{-11}$	-0.990854	-3.766007	-7.089004
21	$1\cdot10^{-10}$	-0.994896	-3.781289	-7.117588
41	$-3\cdot10^{-10}$	-0.995792	-3.784677	-7.123924

We use $a = 0.95$ and $b = 0.05$ in the mixed TBC: this gives a mixed boundary condition where the effects of the function value v_j and its gradient $\partial_x v_j$ are roughly comparable in the TBC (if the parameter b is significantly larger, then the gradient term dominates the TBC). The numerical eigenvalues given in Table 3 for the diffusion equation (8) with these TBCs again show convergence to the correct eigenvalues as the number of teeth increases, that is, as the macroscopic grid size $H \to 0$. However, the convergence is not as rapid as for Dirichlet TBCs. The poorer convergence as $H \to 0$ seems to be due to the microscopic grid resolution: successive doubling of the number of interior points (see Table 4) demonstrates that there are significant errors of $\mathcal{O}(\eta^2)$ in the microscale grid size η. Thus the total error in this implementation of the mixed TBCs seems to be $\mathcal{O}(H^4, \eta^2)$. This example illustrates that generally there are two types of errors: the error in the microscale simulator, here $\mathcal{O}(\eta^2)$, and the error due to the multiscale coupling, here $\mathcal{O}(H^4)$. But, recall that we adopt the policy that we cannot change the microscale simulator as it is a legacy code handed to us from past development. Thus the errors our methodology seeks to control are those due to the multiscale coupling.

Here the microscale simulation is that of a fine discretization of a PDE. Thus the derivatives in the mixed TBC (10) are subject to the significant errors of numerical differentiation when computed on the microscale. As Table 4 shows, the approximation of derivatives does incur errors; we would be better off without such errors. Higher order formulae for microscale interpolation would reduce the microscale errors in the boundary derivatives, perhaps from $\mathcal{O}(\eta^2)$ to $\mathcal{O}(\eta^4)$, but would ruin the small bandwidth of the microscale simulator. Again, recall that we adopt the policy that we cannot change the microscale simulator. We cannot (do not want to) change the nature nor accuracy of its boundary conditions. Consequently we proceed to address the problem of supplying boundary conditions at the edge of the teeth, [illegible] of the legacy microscale simulator.

4. Teeth with two-point boundary conditions. A microscale simulator may have implemented boundary conditions that do not fit into the classic PDE form of Dirichlet, Neumann, nor mixed Dirichlet–Neumann. Here the microscale simulator

TABLE 5

Growth rates λ of perturbations from steady state $u = 0$: For diffusion (8) with $m = 8$ teeth; with length scale ratio $r = 0.1$; n points in the microscale grid to show variation with microscale resolution $\eta \propto 1/n$; and with the fourth order general TBC (12) with $\beta = 1$.

n	1	2,3	4,5	6,7
11	$1 \cdot 10^{-10}$	-0.999741	-3.984137	-8.831209
21	$-3 \cdot 10^{-10}$	-0.999742	-3.984159	-8.831368
41	$1 \cdot 10^{-9}$	-0.999742	-3.984169	-8.831453

implements a discretization of three-point stencil width. Consequently the simulator has been written so that the supplied boundary conditions depend only upon each of the two extreme pairs of points in each tooth. We thus investigate TBCs that specify a combination of these two point values of the field at the edge of each tooth. This specific case is just one example of the wide range of possible nonlocal TBCs that specific microsimulators may require.

Suppose the microsimulator, here a fine spatial discretization of the diffusion PDE (8), implements a TBC of the (linear) form

$$v_{j,1} + \beta v_{j,2} \quad \text{and} \quad \beta v_{j,n-1} + v_{j,n} \quad \text{are specified,} \tag{11}$$

where $v_{j,i}$ denotes the microscale field value at the ith microscale grid point in the jth tooth. For example, the case $\beta = 1$ approximates Dirichlet boundary conditions at the microscale grid midpoints $x_{j,3/2}$ and $x_{j,n-1/2}$ near the edges of each tooth, which is exactly the case $a = 0$ and $b = 1$ implemented in section 3. Different values of β would [illegible] different mixed boundary conditions of the previous section.

The procedure is straightforward: we interpolate the macroscale grid values to find the specific values required by the boundary conditions (11). Recall that (9) gives a fourth order interpolation from the macroscale grid to points at the tooth boundaries $x = X_j \pm rH$; this gives appropriate values for $v_{j,1}$ and $v_{j,n}$. Get appropriate values for $v_{j,2}$ and $v_{j,n-1}$ through simply replacing in the formula the length scale ratio $r = h/(2H)$ by the ratio required to reach the penultimate microgrid point, namely, $r' = (h/2 - \eta)/H$, where $\eta = h/(n-1)$ is the microgrid size. Thus the fourth order version of the boundary condition (11) is that at $x = X_j \pm rH$

$$\begin{aligned} &(1 + \beta E^{\mp \eta/H}) v_j \\ &= \left[1 \pm r\mu\delta + \tfrac{1}{2} r^2 \delta^2 \pm \tfrac{1}{6} r(r^2 - 1)\mu\delta^3 + \tfrac{1}{24} r^2 (r^2 - 1)\delta^4\right] U_j \\ &\quad + \beta \left[1 \pm r'\mu\delta + \tfrac{1}{2} r'^2 \delta^2 \pm \tfrac{1}{6} r'(r'^2 - 1)\mu\delta^3 + \tfrac{1}{24} r'^2 (r'^2 - 1)\delta^4\right] U_j \,. \end{aligned} \tag{12}$$

Implementing the TBC (12) for the diffusion equation (8) gives a numerical approximation scheme with eigenvalues shown in Table 5 for varying microgrid resolution. See that there is only an extremely weak dependence upon the microgrid size η. [illegible]

Last, Table 6 shows the eigenvalues of the gap-tooth scheme for varying numbers m of teeth in the domain. Note that the eigenvalues converge to their correct values like $\mathcal{O}(H^4)$ as expected by the construction.

Higher order TBCs, in the macroscopic grid size H, would similarly be based upon the expansion (7). We then expect even more rapid convergence as the macroscale grid size $H \to 0$.

TABLE 6

Growth rates λ of perturbations from steady state $u = 0$: For diffusion (8) with m teeth, $H = 2\pi/m$; with length scale ratio $r = 0.1$; $n = 11$ points in the microscale grid; and with the fourth order general TBC (12) with $\beta = 1$.

m	1	2,3	4,5	6,7	$m+1:2m$
4	$-8\cdot10^{-12}$	-0.946069	-2.165068	n/a	-489.5

5. The model is independent of the TBCs. Here we use analytic methods of holistic discretization (e.g., [17]) to explore the gap-tooth scheme on a general class of PDEs with general mixed boundary conditions. The analysis establishes three important properties:

- the approach generates macroscopic models which are consistent with the microscopic dynamics to high orders in grid spacing H;
- the macroscopic model and the microscopic solution field are essentially independent of the size of the teeth, as parametrized by r; and
- the macroscopic model and the microscopic solution field are essentially independent of the details of the TBCs.

5.1. Theory underpins analysis of a PDE with TBCs. We explore solutions of the class of [illegible] hyper–advection-diffusion PDEs

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} - \epsilon\left(c\frac{\partial u}{\partial x} + b\frac{\partial^3 u}{\partial x^3} + a\frac{\partial^4 u}{\partial x^4}\right), \tag{13}$$

where a, b, and c are arbitrary parameters, and where ϵ is introduced as a convenient mechanism to control truncation of the multivariate power series solutions in the parameters a, b, and c. This PDE is solved with mixed TBCs inspired by (10), namely, that on $x = x_j \pm rH$, and in terms of an artificial parameter γ that we explain shortly,

$$\begin{aligned}
&\pm\alpha v_j + \partial_x v_j \\
&= \pm\alpha\left\{1 + \gamma r\left[\pm\mu\delta + \tfrac{1}{2}r\delta^2\right] + \gamma^2\tfrac{1}{6}r(r^2-1)\left[\pm\mu\delta^3 + \tfrac{1}{4}r\delta^4\right]\right. \\
&\quad \left. + \gamma^3\tfrac{1}{120}r(r^2-1)(r^2-4)\left[\pm\mu\delta^5 + \tfrac{1}{6}r\delta^6\right]\right\}U_j \\
&+ \frac{1}{H}\left\{\gamma\left[\mu\delta \pm r\delta^2\right] + \gamma^2\left[-(\tfrac{1}{6}-\tfrac{1}{2}r^2)\mu\delta^3 \mp r(\tfrac{1}{12}-\tfrac{1}{6}r^2)\delta^4\right]\right. \\
&\quad \left. + \gamma^3\left[(\tfrac{1}{30}-\tfrac{1}{8}r^2+\tfrac{1}{24}r^4)\mu\delta^5 \pm r(\tfrac{1}{90}-\tfrac{1}{36}r^2+\tfrac{1}{120}r^4)\delta^6\right]\right\}U_j \\
&+\mathcal{O}\left(\gamma^4\right).
\end{aligned} \tag{14}$$

Explore the structure of this complicated looking TBC: $\pm\alpha v_j + \partial_x v_j$ represents a general linear combination of the microscopic field at the edge of each tooth that needs to be specified for the microscopic simulator; those terms in the right-hand side multiplied by $\pm\alpha$ form the estimate of the field v_j interpolated from the surrounding macroscopic grid values; those terms in the right-hand side multiplied by $1/H$ form the estimate of the field's gradient $\partial_x v_j$ interpolated from the surrounding macroscopic grid values. However, these two interpolations hold only when the artificial parameter

$\gamma = 1$; the value 1 is the physically interesting case. Why then do we introduce the parameter γ? The reason is that, as in "discretization" [16], based around the special values of the parameters $\gamma = \alpha = \epsilon = 0$, the general PDE (13) with TBC (14) possesses a slow center manifold parametrized by the macroscopic grid values. On this slow manifold the evolution of these macroscopic grid values forms a macroscale model of the PDE. This model has rigorous theoretical support based upon $\gamma = 0$, and it becomes physically relevant when evaluated at $\gamma = 1$.

We briefly explain how center manifold theory underpins the macroscale model. Initially set $\gamma = \alpha = \epsilon = 0$; then the PDE + TBC become the diffusion equation with [illegible] boundaries at the edges of the teeth, $x = x_j \pm rH$. Thus, exponentially quickly, all structure within each tooth diffuses away to become constant—but a different constant for each tooth depending upon the initial conditions. See a similar evolution in Figures 2 and 3; but there the teeth are coupled so that the rapid evolution is to a smooth variation in each tooth, whereas here the insulated evolution, $\gamma = \alpha = \epsilon = 0$, is to a constant in each tooth. But we are interested in only fully coupled teeth for which $\gamma = 1$, and in nonzero α and ϵ. Thus from the simple base of piecewise constant fields, we construct a description of the field u and its slow evolution as a power series in the "perturbations" measured by γ, α, and ϵ. The departure of the field u from a constant within each tooth gives the microscopic (subgrid, subtooth) field, as shown, for example, in the smooth fields of Figures 2 and 3 that are quickly established. The slow evolution of the coarse grid values U_j gives the macroscopic model.

The various powers of γ in the TBC (14) are chosen so that truncation of the expressions to errors $\mathcal{O}(\gamma^p)$ will generate a discrete macroscopic model expressing the time derivative $\dot{U}_j$ in terms of only $U_{j-p+1}, \ldots, U_{j+p-1}$ (a spatial stencil of width $2p-1$). Center manifold theory (e.g., [2, 11]) asserts that

- such a model exists,
- through its exponential attractiveness, the model is relevant in some finite neighborhood of $\gamma = \alpha = \epsilon = 0$, and
- we may systematically construct the power series approximation to the model.

Because truncation to errors $\mathcal{O}(\gamma^p)$ results in a model with stencil width $2p-1$, [illegible] $2p-1$ [illegible] $U_{j-p+1}, \ldots, U_{j+p-1}$

Computer algebra[1] performs all the tedious details of constructing the model [15]. We seek a model where the subtooth/subgrid field

$$u(x,t) = v_j(x, \boldsymbol{U}; \alpha, \gamma, \epsilon)\,. \tag{15}$$

That is, the subtooth field has some spatial structure, such as that in Figures 2 and 3, which depends upon the neighboring grid values $U_{j-p+1}, \ldots, U_{j+p-1}$; may depend upon the specific TBC through its parameter α; depends upon the specific PDE though its parameter ϵ; and depends upon the coupling parameter γ. Center manifold theory ensures that the evolution of the system is governed by the evolution of the grid values:

$$\dot{U}_j = g_j(\boldsymbol{U}; \alpha, \gamma, \epsilon); \tag{16}$$

this formula is the macroscopic (closed) discretization. We solve by iteration the PDE (13) with TBC (14) to find the center manifold (15) and its associated coarse

[1] http://www.sci.usq.edu.au/staff/aroberts/CA/burgermixed.red is the source script which was available at the time of writing.

discretization (16). The results are expressions for the microscopic fields v_j and the macroscopic evolution, $\dot{U}_j = g_j$, that are accurate to some specified order in the small parameters α, γ, and ϵ.

5.2. Modeling $\mathcal{O}(\epsilon)$ changes to the PDE. The subgrid fields in each tooth will in general depend upon the coefficients a, b, and c that determine the PDE. For example, there are nontrivial dependencies upon the advection speed that ensure that the macroscale model naturally transforms to an upwind discretization for large advection speeds c [18]—such influences show up in the $\mathcal{O}(\epsilon^2)$ terms that we explore in the next subsection. Here we first explore the models linear in a, b, and c, that is, linear in the general changes to the PDE (13) with the TBC (14).

For example, to errors $\mathcal{O}(\alpha^3, \gamma^4, \epsilon^2)$, computer algebra generates the macroscopic evolution

$$\begin{aligned}\dot{U}_j = {} & \frac{1}{H^2}\left[\gamma\delta^2 - \tfrac{1}{12}\gamma^2\delta^4 + \tfrac{1}{90}\gamma^3\delta^6\right] U_j \\ & - \frac{\epsilon c}{H}\left[\gamma\mu\delta - \tfrac{1}{6}\gamma^2\mu\delta^3 + \tfrac{1}{30}\gamma^3\mu\delta^5\right] U_j \\ & - \frac{\epsilon b}{H^3}\left[\gamma^2\mu\delta^3 - \tfrac{1}{4}\gamma^3\mu\delta^5\right] U_j \\ & - \frac{\epsilon a}{H^4}\left[\gamma^2\delta^4 - \tfrac{1}{6}\gamma^3\delta^6\right] U_j + \mathcal{O}(\alpha^3, \gamma^4, \epsilon^2)\,. \end{aligned} \tag{17}$$

When evaluated at the physically relevant parameter $\gamma = 1$, these are the classical finite difference operators for the PDE (13), truncated to $\mathcal{O}(\delta^7)$. Consequently the terms in the macroscopic model (17) are [illegible] with the PDE (13) to various orders in the macroscopic grid size H. The order of consistency depends upon the order of truncation in the artificial coupling parameter γ and the order of the derivatives in each term. [illegible] independent [illegible] r [illegible] independent [illegible] α [illegible] (14)

Now we explore the microscopic field within the teeth. To low order in the coupling parameter γ and in terms of the microscopic tooth space variable $\xi = (x - X_j)/H$, we find

$$\begin{aligned} v_j = {} & U_j + \gamma\left\{\left[\xi\mu\delta + \tfrac{1}{2}\xi^2\delta^2\right]\right. \\ & \left. + \epsilon c H\left[(\tfrac{1}{6}\xi^3 - \tfrac{1}{2}r^2\xi) + \tfrac{1}{3}H\alpha r^3\xi - \tfrac{1}{3}H^2\alpha^2 r^4\xi\right]\delta^2\right\} U_j \\ & + \mathcal{O}(\alpha^3, \gamma^2, \epsilon^2)\,. \end{aligned} \tag{18}$$

The first line gives the classic quadratic interpolation through the grid values U_j and $U_{j\pm1}$. The second line shows microscopic field structure in the advection speed c. But it exhibits undesirable dependence upon the tooth width r and nature α of the TBC.

However, inspect the next order terms in coupling parameter γ:

$$
\begin{aligned}
v_j = \cdots + \gamma^2 \Bigg\{ & \left[\tfrac{1}{6}(-\xi+\xi^3)\mu\delta^3 + \tfrac{1}{24}(-\xi^2+\xi^4)\delta^4\right] \\
& + \epsilon c H \left[-(\tfrac{1}{6}\xi^3 - \tfrac{1}{2}r^2\xi) - \tfrac{1}{3}H\alpha r^3\xi + \tfrac{1}{3}H^2\alpha^2 r^4\xi\right]\delta^2 \\
& + (-\tfrac{1}{18}\xi^3 + \tfrac{1}{60}\xi^5 + \tfrac{1}{6}r^2\xi - \tfrac{1}{12}r^2\xi^3\tfrac{1}{6}r^4\xi)\delta^4 \\
& + \alpha H(-\tfrac{1}{9}r^3\xi + \tfrac{1}{18}r^3\xi^3 - \tfrac{4}{15}r^5\xi)\delta^4 \\
& + \alpha^2 H^2(\tfrac{1}{9}r^4\xi - \tfrac{1}{18}r^4\xi^3 + \tfrac{17}{45}r^6\xi)\delta^4 \\
& + \frac{\epsilon b}{H}\left[-(\tfrac{1}{6}\xi^3 - \tfrac{1}{2}r^2\xi) - \tfrac{1}{3}H\alpha r^3\xi + \tfrac{1}{3}H^2\alpha^2 r^4\xi\right]\delta^4 \Bigg\} U_j \\
& + \mathcal{O}\big(\alpha^3, \gamma^3, \epsilon^2\big). \qquad (19)
\end{aligned}
$$

The dots denote the terms given in the right-hand side of (18). The first line in the above higher order terms reassuringly contains the classic quartic interpolation formulae. The second line, when we set $\gamma = 1$, cancels all the undesirable α and r dependence in the lower order (18). The third and later lines above describe higher order microscopic structure; some of this undesirably depends upon the TBC through α and the size of the teeth through r, but as far as we have explored, any α and r dependence introduced at any order in γ is canceled by terms at higher orders in γ. Thus any finite truncation of the power series expansion for the model may have undesirable dependence upon α and r, but as the order in the artificial parameter γ is increased, this dependence is removed. In this sense, the microscopic field is "essentially" independent of the details of the TBC and independent of the tooth width r.

5.3. Modeling $\mathcal{O}(\epsilon^2)$ effects in the PDE. In our analysis we find that even order operators in the microscale PDE, such as the diffusion u_{xx} and the hyperdiffusion au_{xxxx}, are represented simply in the macroscale discretization. However, odd order operators in the microscale PDE, such as advection cu_x and the dispersion bu_{xxx}, create nontrivial effects; these first show up in terms quadratic in their amplitude, and hence they first appear in terms of $\mathcal{O}(\epsilon^2)$. We now show that the effects of $\mathcal{O}(\epsilon^2)$ terms typically act to stabilize the $\mathcal{O}(\epsilon)$ discrete model. The implication for the gap-tooth method is that the resolution of the subgrid structures by the microscale simulator will also typically maintain stability of the discrete macroscale model. That is, the microscale simulator will provide successful closure for the macroscale discretization when coupled with the proposed TBCs.

To illustrate this, we constructed the approximate model of the PDE (13) with TBC (14) to errors $\mathcal{O}(\alpha^2, \gamma^4, \epsilon^3)$; that is, we include quadratic effects in the coefficients a, b, and c. The details of the model are too long to record here. However, we find that the equivalent PDE to the macroscale discrete model (17) with its $\mathcal{O}(\epsilon^2)$ modifications

is

$$\begin{aligned}
\frac{\partial u}{\partial t} &= \gamma\frac{\partial^2 u}{\partial x^2} - \epsilon\left[\gamma c\frac{\partial u}{\partial x} + \gamma^2 b\frac{\partial^3 u}{\partial x^3} + \gamma^2 a\frac{\partial^4 u}{\partial x^4}\right] \\
&+ \epsilon^2\left[-(\gamma-\gamma^2)bc\frac{\partial^2 u}{\partial x^2} - (\gamma^2-\gamma^3)b^2\frac{\partial^4 u}{\partial x^4}\right] \\
&+ H^2\left\{\tfrac{1}{12}(\gamma-\gamma^2)\frac{\partial^4 u}{\partial x^4}\right. \\
&\quad + \epsilon\left[-\tfrac{1}{6}(\gamma-\gamma^2)c\frac{\partial^3 u}{\partial x^3} - \tfrac{1}{4}(\gamma^2-\gamma^3)b\frac{\partial^5 u}{\partial x^5} - \tfrac{1}{6}(\gamma^2-\gamma^3)a\frac{\partial^6 u}{\partial x^6}\right] \\
&\quad + \epsilon^2\left[+\tfrac{1}{3}(\gamma-\gamma^2)c^2r^2\frac{\partial^2 u}{\partial x^2} - \tfrac{1}{12}(\gamma-5\gamma^2+4\gamma^3)bc\frac{\partial^4 u}{\partial x^4}\right. \\
&\qquad \left.\left. + \tfrac{2}{3}(\gamma^2-\gamma^3)bcr^2\frac{\partial^4 u}{\partial x^4} - \tfrac{1}{6}(\gamma^2-7\gamma^3+4\gamma^3r^2)b^2\frac{\partial^6 u}{\partial x^6}\right]\right\} \\
&+ \mathcal{O}\big(H^3,\alpha^2,\gamma^4,\epsilon^3\big)\,. \qquad (20)
\end{aligned}$$

Observe that to this level of accuracy there is no dependence upon the TBC parameter α; thus our comments apply for all the TBCs. Now consider the components of (20) in turn. The first line of (20) is the original general linear PDE (13) when evaluated at the physically meaningful $\gamma = 1$. The second line shows some error terms, quadratic in ϵ, that disappear for $\gamma = 1$. The bcu_{xx} error disappears when $\mathcal{O}(\gamma^2)$ terms are retained, which is as soon as the discretization stencil is wide enough to model the third order dispersion term bu_{xxx}. The b^2u_{xxxx} dispersion-induced term shows that the method initially incorporates its effects as enhanced dissipation, as the coefficient of γ^2 is negative; then, when higher order accuracy is requested by retaining $\mathcal{O}(\gamma^3)$ terms, the method proceeds to remove the incurred error via the γ^3 term.

Consider applying these TBCs to a microscale simulator; for slow enough spatial variations, the microsimulator is equivalent to some "infinite order" PDE. For example, the [illegible] discretization $\dot{u}_i = (1/\eta^2)\delta^2 u_i$ is, by (4), equivalent to the PDE $u_t = (4/\eta^2)\sinh^2(\eta\partial_x/2)u$. We expect the behavior of errors in the gap-tooth scheme seen here, induced by the u_{xxx} and u_{xxxx} terms, to be representative of the behavior of errors in the "high order" equivalent terms of any given microscopic simulator.

The remaining terms in (20) are $\mathcal{O}(H^2)$ and hence vanish as the macroscopic grid size $H \to 0$. Nonetheless look at the H^2 terms in the third to sixth lines as they apply to simulations with finite H. The third and fourth lines show that the initial discretization errors of the linear terms are eliminated, for the physical $\gamma = 1$, via the next higher order in coupling parameter γ. The particular focus of this subsection is on the ϵ^2 terms on the next two lines. The c^2u_{xx} terms show that at low order truncations in γ the method treats advection in a manner that increases dissipation, as the coefficient is positive, and thus helps to maintain the stability of the macroscale discretization to high advection speeds c [16, 18]. The interaction between advection cu_x and dispersion bu_{xxx} can maintain stability or be destabilizing depending upon the sign of bc: whether we truncate at γ when $-bcu_{xx}$ dominates (second line) or we truncate at γ^2 when bcu_{xxxx} dominates (fifth and sixth lines), the

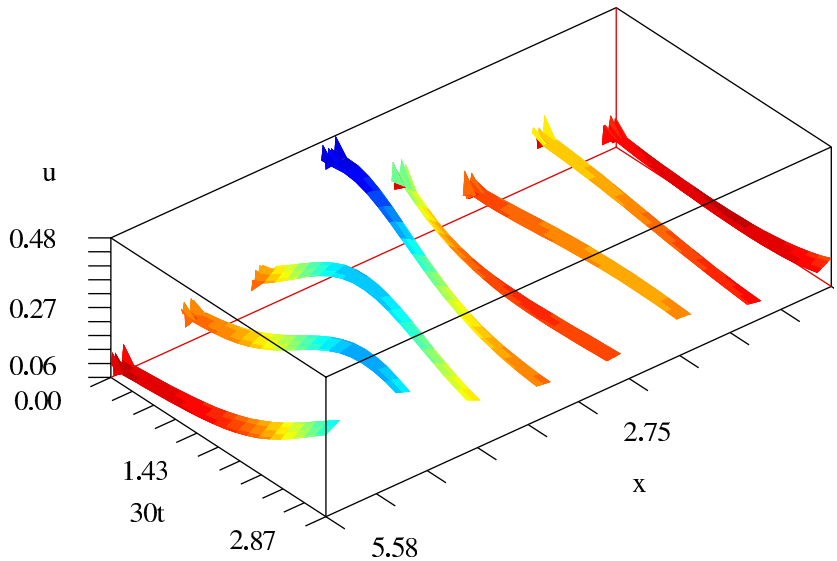

FIG. 4. *Simulation of the Burgers equation using the general* 2*-point boundary condition on the teeth of the fourth order* (12) *with* $\beta = 1$ *demonstrates that the method is stable even for nonlinear PDEs.*

combination is stabilizing whenever $bc < 0$, that is, when the phase velocity of wave-like effects does not change direction as a function of wavenumber. The last term on the sixth line will be dominated by the dissipative $b^2 u_{xxxx}$ term on the second line, and we presume will vanish at higher orders in the coupling parameter γ. Thus, from the equivalent PDE (20) of the macroscale model, we deduce that the subgrid scale interactions between processes in the PDE, and hence for microscale simulators in general, are accounted for in this approach to generate a macroscale model that is typically stable.

Indeed this equivalent PDE (20) confirms support by center manifold theory for the gap-tooth scheme with TBC. Theory asserts that the original system, here the PDE (20), and the slow manifold model, here the macroscale discretization (16), have the same stability. Thus when the microscale system is stable, so will be the macroscale discretization. The caveat is that we can only construct the center manifold approximately; we control the errors to some order in the parameters α, γ, and ϵ, but there will be some error, albeit of high order in the parameters.

6. Conclusion. We use macroscale interpolation based upon the expansions (6) and (7) to determine TBCs for the boundary conditions at the edge of the teeth in the gap-tooth scheme. The interpolation was used to implement whatever boundary conditions are needed by the microscale legacy code during execution. Figure 4 shows a simulation of the nonlinear Burgers equation with two-point boundary conditions at the boundaries of each tooth as an illustrative example. We found that the macroscopic models resulting from the microsimulator and the constructed TBC were consistent, to high order, with the microscopic dynamics and that the macroscopic models and the microscopic (subgrid, subtooth) fields were essentially independent of the tooth size and the detailed nature of the TBC. We expect the same type of TBC to be effective for microsimulations in more than one spatial dimension. Interesting future research would seek TBCs that do not require commu-

nication across the gaps between the teeth at each and every microscale time step and would explore the interplay of TBCs with implicit integration schemes.

Further exciting research would explore issues of existence and performance of TBCs for stochastic microsimulators.

DUAL FUNCTIONS FOR A PARALLEL ADAPTIVE METHOD*

RANDOLPH E. BANK† AND JEFFREY S. OVALL‡

Abstract. In this paper, we investigate the effects of pollution error on the performance of the parallel adaptive finite element technique proposed by Bank and Holst in 2000 [R. E. Bank and M. Holst, *SIAM J. Sci. Comput.*, 22 (2000), pp. 1411–1443]. In particular, we consider whether the performance of the algorithm as it was originally proposed can be improved through the use of certain dual functions which give an indication of the global influences on subdomain errors.

Key words. dual functions, Bank–Holst algorithm, parallel adaptive grid generation

AMS subject classifications. 65N50, 65N30, 65Y05

DOI. 10.1137/060668304

1. Introduction.

One of the most difficult aspects of adaptive computations in a parallel environment is the issue of load balancing. If an initial mesh is distributed fairly among a number of processors, a good error estimator coupled with adaptive refinement may quickly produce a very bad load imbalance among the processors. A number of static and dynamic load balancing approaches for unstructured meshes have been proposed in the literature [23, 17, 19, 20, 13, 27, 29]. Such approaches tend to be communication intensive, since they must first assess the current state of imbalance among the processors and then perform a redistribution step to equalize the load.

The Bank–Holst adaptive meshing paradigm [9, 10, 8] presented a new way of addressing the issue of load balancing. Their scheme has the additional benefits of keeping communication costs low and using existing sequential adaptive software such as PLTMG without the need for extensive investment in recoding for use in a parallel environment. The paradigm consists of three major steps.

Step 1: Load balancing. We solve a small problem on a coarse mesh and use a posteriori error estimates to partition the mesh into p subdomains—one for each processor. Each subregion has approximately the same error, although subregions may vary considerably in terms of numbers of elements or grid points.

Step 2: Adaptive meshing. Each processor is provided the complete coarse mesh and instructed to sequentially solve the [illegible] problem, with the stipulation that its adaptive refinement should be limited largely to its assigned subdomain. The target number of elements and grid points for each problem is the same. At the end of this step, the global mesh should be regularized so that the global mesh described in Step 3 will be conforming.

Step 3: Global solution. A final mesh is computed using the union of the refined subdomains provided by each processor. A final solution is computed

using a standard domain decomposition solver or parallel multigrid technique. For the experiments done in this paper, the final global iterative solve is performed by use of the domain decomposition solver described in [6].

Here the load balancing problem is reduced to the numerical solution of a small elliptic problem on a single processor, using a sequential adaptive solver, without requiring any modifications to the sequential solver. The small elliptic problem is used to produce a posteriori error estimates to predict future element densities in the mesh, which are then used to partition the mesh according to equal error. The underlying assumption here is that roughly equal element densities imply roughly equal workload. We note that, although this assumption is seemingly fragile, the procedure does generally produce good workload balance in practice. It is important to emphasize that the adaptive mesh generation in Step 2 is done asynchronously and without communication. The only communication needed prior to the final global solve in Step 3 is the initial fan-out of the coarse mesh at the end of Step 1 and the mesh regularization at the the end of Step 2. (The fan-out could be avoided by having every processor solve the same course problem and compute the same load balance in Step 1.) By providing each processor with the entire problem, information about the global behavior of the solution, which normally would require some communication between processors, is generated independently and without communication on each processor, albeit on a coarse mesh. In effect, extra coarse grid computations are substituted for the interprocessor communication that would otherwise be required. This is likely to be an advantageous trade-off in situations where communication costs are high relative to computation costs, which is a situation typical of small Beowulf clusters.

In early investigations of the algorithm, the issue of restricting refinement on a given processor largely to its own subdomain was addressed by multiplying a posteriori error estimates for elements outside the subdomain by 10^{-6}. This small change allowed sequential adaptive codes (like the PLTMG package used here) to work in parallel without additional changes. This scheme tricks the adaptive refinement routine into thinking errors outside the given subdomain are much smaller than they actually are and hence not good candidates for refinement. Some refinement outside the given processor's subdomain is still required for other reasons, e.g., the shape-regular grading of the mesh from the small elements inside the refined region to the larger elements in the coarse regions.

While initially derived as a simple way to implement and test the concept, the 10^{-6} trick proved to be surprisingly effective for a wide variety of elliptic PDEs. However, because of the important role the course grid plays in the paradigm, it is important to consider heuristics based on more solid mathematical foundations than the 10^{-6} trick to help determine an appropriate refinement of the coarse grid outside the subregion assigned to the processor. It is this point that is the main focus of the present work.

For example, the coarse grid provides information about the effect of singularities outside the given subdomain on the solution inside (so-called pollution effects). See [1, 16, 28] for some discussion of such pollution errors. If convection is present, good information about the solution along the upstream boundaries of the subregion is needed to form an accurate impression of the convective behavior within the subregion. Because of the continuous dependence of the solution of elliptic problems on data throughout the domain, the approximation quality in any given subdomain depends on the approximation quality in the rest of the domain.

Dual functions and goal related adaptivity have a long history in the context of adaptive meshing algorithms [4, 3, 2, 5, 21, 18, 14, 15, 22]. Usually the functional is some quantity of physical interest for a particular application (lift, drag, stress intensity factor, etc.). Our idea here is to adapt this goal oriented adaptive meshing technology to the present situation. In Step 2 of the paradigm, we view each processor as having the "goal" of producing a good mesh in its subregion. Thus the goal related functional in this case is not provided externally by the user but rather is developed internally and independently by the software running on each processor. The dual functions developed on each processor may be quite different from one another, since the subregions assigned to each processor for refinement may require quite different refinement patterns for their respective coarse meshes in order to produce good fine meshes for their assigned subregions. In particular, for this heuristic, we develop functionals intended to express the influence of the solution outside a given processor's subdomain on the solution within. The dual solution, generated by solving a problem with the adjoint operator and given functional as data, should then reflect the influence of the coarse parts of the domain on the processor's own region. The adjoint problem is solved using the same mesh as the primal problem, i.e., fine in its own region and coarse elsewhere. Then values (or local norms) of the dual function are used in place of 10^{-6} to weight the a posteriori error estimates in the coarse subregions, which in turn are used in the adaptive refinement procedure on that processor.

We emphasize that the primary objective of Step 2 in the algorithm is for each processor to generate a well-adapted mesh in its subdomain as part of the global fine mesh. However, a secondary objective is for each processor to contribute to a reasonable initial guess in its subdomain of the solution of the global fine problem in Step 3—this speeds up the convergence of the parallel solver. Clearly these two goals are related, but it is not always necessary to have a good approximate solution in order to generate a well-adapted mesh from the associated error estimates. Indeed, the ability to generate good meshes from relatively inaccurate solutions explains the success of many adaptive methods. However, if the solution quality in a given subdomain is relatively poor and is not improved by further refinement in that subdomain, then the quality of the initial guess for Step 3 will be diminished. This is another motivation for investigating the use of dual weighted error estimates, the topic of section 3, which might better indicate global influences on subdomain error.

The rest of this manuscript is organized as follows. In section 2, we establish notation and assumptions for this study. In section 3, we develop the functionals and corresponding dual solutions suitable for our parallel adaptive meshing algorithm. Finally, in section 4, we present some numerical examples.

2. Notation and assumptions. Let $\Omega \subset \mathbb{R}^2$ be a bounded domain with Lipschitz boundary $\partial\Omega = \partial\Omega_D \cup \partial\Omega_N$, and define

$$\mathcal{H} \equiv \left\{ v \in H^1(\Omega) : v|_{\partial\Omega_D} = 0 \text{ in the trace sense} \right\}. \tag{2.1}$$

For simplicity, we will assume that $\partial\Omega$ is a polygon. The usual spaces $W_p^k(\Omega)$ and $H^k(\Omega) \equiv W_2^k(\Omega)$ are equipped with norms $\|\cdot\|_{k,p,\Omega}$ and $\|\cdot\|_{k,\Omega} \equiv \|\cdot\|_{k,2,\Omega}$, respectively. Let data functions $a : \bar{\Omega} \to \mathbb{R}^{2\times 2}$, $\mathbf{b} : \bar{\Omega} \to \mathbb{R}^2$, $c, f : \bar{\Omega} \to \mathbb{R}$, and $g : \partial\Omega_N \to \mathbb{R}$ be

given. The primal problem is to find $u \in \mathcal{H}$ such that

$$B(u,v) = F(v) \text{ for all } v \in \mathcal{H}, \tag{2.2}$$

$$B(u,v) \equiv \int_\Omega a\nabla u \cdot \nabla v + (\mathbf{b}\cdot\nabla u + cu)v\,dx, \tag{2.3}$$

$$F(v) \equiv \int_\Omega fv\,dx + \int_{\partial\Omega_N} gv\,dS. \tag{2.4}$$

We assume that the data functions are smooth and that the matrix a is positive-definite, with the smallest eigenvalue bounded below on Ω by some constant $\gamma > 0$. We make the following standard boundedness and coercivity assumptions for the bilinear form B and linear functional F: There exist constants $\alpha, \nu, \mu > 0$ such that, for all $v, w \in \mathcal{H}$,

$$|F(v)| \le \alpha\|v\|_{1,\Omega},$$

$$|B(v,w)| \le \nu\|v\|_{1,\Omega}\|w\|_{1,\Omega},$$

$$B(v,v) \ge \mu\|v\|^2_{1,\Omega}.$$

Let $\mathcal{T}_h$ denote a shape-regular triangulation of Ω with mesh size $h \in (0,1)$. Let $V_h \subset \mathcal{H}$ denote the space of continuous, piecewise-linear polynomials defined on $\mathcal{T}_h$, and let $\bar{V}_h \subset \mathcal{H}$ denote the continuous, piecewise-quadratic polynomials. Let $u_\ell \in V_h$ and $u_q \in \bar{V}_h$ denote piecewise-linear and -quadratic interpolants of u on $\mathcal{T}_h$. We make the following standard assumptions about their asymptotic approximation quality:

$$\|u - u_\ell\|_{k,\Omega} \lesssim h^{2-k}\|u\|_{2,\Omega}, \tag{2.5}$$

$$\|u - u_q\|_{k,\Omega} \lesssim h^{3-k}\|u\|_{3,\Omega} \tag{2.6}$$

for $0 \le k \le 1$.

In this work we assume the existence of a gradient recovery operator $\mathcal{R}\nabla u_h \in V_h \times V_h$ possessing certain superconvergence properties. Let $u \in H^3(\Omega) \cap W^{2,\infty}(\Omega)$, and let $u_h \in V_h$ be any approximation of u satisfying

$$\|u - u_h\|_{k,\Omega} \lesssim h^{2-k}|u|_{2,\Omega}, \quad k = 0, 1, \tag{2.7}$$

$$\|u - u_h\|_{0,\infty,\Omega} \lesssim h^2|\log h||u|_{2,\infty,\Omega}. \tag{2.8}$$

Then we assume

$$\|\nabla u - \mathcal{R}\nabla u_h\|_{0,\Omega} \lesssim h\delta\left(\|u\|_{3,\Omega} + |u|_{2,\infty,\Omega}\right), \tag{2.9}$$

where $\delta \to 0$ as $h \to 0$.

Some recovery procedures that satisfy bounds like (2.9) are described in [11, 12]. It is important to note that u_h needs only to satisfy the required approximation properties in order for (2.9) or Lemma 2.1 to apply; in particular, there is no requirement that u_h be an approximate solution to (2.2)–(2.4). That stated, for the rest of this work we will use $u_h \in V_h$ to denote the finite element solution of the variational problem

$$B(u_h, v) = F(v) \text{ for all } v \in V_h. \tag{2.10}$$

For tables and figures, we will use the abbreviation $e_h = u - u_h$ to denote the error in the finite element approximation.

Although the details of $\mathcal{R}$ are not needed in the analysis here, for completeness we briefly summarize the scheme analyzed in [12]. In this case

$$\mathcal{R}\nabla u_h = S^m Q_h \nabla u_h,$$

where Q_h is the operator corresponding to the L^2 projection onto V_h, and $S : V_h \to V_h$ is a smoothing operator. In other words, the discontinuous, piecewise constant gradient ∇u_h is projected into the space of continuous piecewise-linear polynomials and then smoothed with a multigrid-like smoothing operator. Typically $m = 1$ or $m = 2$ smoothing steps are used.

Given a superconvergent gradient approximation, one can form $\mathcal{R}\nabla u_h - \nabla u_h$ to approximate the error $\nabla u - \nabla u_h$. In many cases we can expect such an estimate to be asymptotically exact.

LEMMA 2.1. [illegible] $u \in H^3(\Omega) \cap W^{2,\infty}(\Omega)$ [illegible] $u_h \in V_h$ [illegible] (2.7)–(2.8), [illegible]

$$\|\nabla u - \nabla u_h\|_{0,\Omega} \geq c_0 h$$

[illegible] $c_0 > 0$ [illegible]

$$\lim_{h \to 0} \frac{\|(\mathcal{R} - I)\nabla u_h\|_{0,\Omega}}{\|\nabla u - \nabla u_h\|_{0,\Omega}} = 1.$$

[illegible]. It holds that

$$\left| \frac{\|(\mathcal{R} - I)\nabla u_h\|_{0,\Omega}}{\|\nabla u - \nabla u_h\|_{0,\Omega}} - 1 \right| \leq \frac{\|\mathcal{R}\nabla u_h - \nabla u\|_{0,\Omega}}{\|\nabla u - \nabla u_h\|_{0,\Omega}} \lesssim \delta \,,$$

and $\delta \to 0$ as $h \to 0$. □

The local error indicators $\|(\mathcal{R} - I)\nabla u_h\|_{0,\tau}$ form the basis of the standard adaptive refinement algorithm for PLTMG [7], the PDE software used for the experiments in this work.

3. Duality and global influence on local error. In many applications, it is not the PDE solution u which is of primary interest, but rather some functional $G(u)$, where $G \in \mathcal{H}^*$. The examples often given in the literature are related to physical quantities of interest which can be computed from u, such as the lift or drag on a wing of an airplane during cruising conditions (see, for example, [25]). The use of appropriate dual (adjoint) problems for the accurate approximation of functional quantities and for driving adaptive algorithms (goal oriented adaptive refinement) has been an active area of research for some time [21, 22, 25, 26, 24]. The sort of functionals that are of interest to us in the context of the Bank–Holst paradigm are those where we can use the dual solution to extract information concerning outside influences on the solution u within a given subdomain. We include some of the basic theory below for completeness before presenting the dual error estimator used in this work.

Given a functional G, we define the related dual problem

$$B^*(\omega, v) = G(v) \text{ for all } v \in \mathcal{H}, \tag{3.1}$$

where $B^*(w,v) \equiv B(v,w)$. The key relation between the solutions of the primal and dual problems is that

$$G(u-u_h) = B^*(\omega, u-u_h) \tag{3.2}$$

$$= B(u-u_h, \omega) \tag{3.3}$$

$$= F(\omega) - B(u_h, \omega). \tag{3.4}$$

In this context, ω provides a weighting of the global error (3.2), (3.3) or of the global residual (3.4) that indicates the influence of global approximation errors on the subdomain error $G(u-u_h)$.

Because we cannot generally compute ω, we must approximate $G(u-u_h)$ using one of the expressions (3.2), (3.3), (3.4). For the computations in this paper, we use the dual error estimate weighting technique (DEW) introduced in [24]. In order to make this paper more self-contained, we briefly present the pertinent details below.

Let $\omega_h \in V_h$ be the piecewise-linear finite element solution of the dual problem

$$B^*(\omega_h, v) = G(v) \text{ for all } v \in V_h. \tag{3.5}$$

Noting that

$$B(u-u_h,\omega) = B(u-u_h, \omega-\omega_h) = \int_\Omega a\nabla(u-u_h)\cdot\nabla(\omega-\omega_h)\,dx + \mathcal{O}(h^3),$$

we define the approximator $\mathcal{G}_h \approx G(u-u_h)$ by

$$\mathcal{G}_h = \int_\Omega a(\mathcal{R}-I)\nabla u_h \cdot (\mathcal{R}-I)\nabla\omega_h\,dx. \tag{3.6}$$

We bound the approximation error, $|G(u-u_h)-\mathcal{G}_h|$, in the following theorem.

THEOREM 3.1. [illegible] $u, \omega \in H^3(\Omega)\cap W^{2,\infty}(\Omega)$ [illegible] $u_h, \omega_h \in V_h$ [illegible] (2.7))–((2.8), [illegible]

$$|G(u-u_h)-\mathcal{G}_h| \lesssim h^2\delta\left(\|u\|_{3,\Omega} + |u|_{2,\infty,\Omega}\right)\left(\|\omega\|_{3,\Omega} + |\omega|_{2,\infty,\Omega}\right), \tag{3.7}$$

[illegible] $\delta \to 0$ [illegible] $h \to 0$ [illegible]. We have, by the triangle and Cauchy–Schwarz inequalities,

$$\begin{aligned}|G(u-u_h)-\mathcal{G}_h| \lesssim{}& \|\nabla u - \mathcal{R}\nabla u_h\|_{0,\Omega}\|\nabla(\omega-\omega_h)\|_{0,\Omega} \\ &+ \|(\mathcal{R}-I)\nabla u_h\|_{0,\Omega}\|\nabla\omega - \mathcal{R}\nabla\omega_h\|_{0,\Omega} + \mathcal{O}(h^3).\end{aligned}$$

We have the bounds

$$\|\nabla u - \mathcal{R}\nabla u_h\|_{0,\Omega} \lesssim h\delta\left(\|u\|_{3,\Omega} + |u|_{2,\infty,\Omega}\right),$$

$$\|(\mathcal{R}-I)\nabla u_h\|_{0,\Omega} \lesssim h\left(\|u\|_{3,\Omega} + |u|_{2,\infty,\Omega}\right),$$

$$\|\nabla\omega - \mathcal{R}\nabla\omega_h\|_{0,\Omega} \lesssim h\delta\left(\|\omega\|_{3,\Omega} + |\omega|_{2,\infty,\Omega}\right),$$

$$\|\nabla(\omega-\omega_h)\|_{0,\Omega} \lesssim h\|\omega\|_{2,\Omega}.$$

Combining these four estimates completes the proof. ∎

We have the following immediate corollary.

COROLLARY 3.2. [illegible] 3.1, [illegible] $c_0 > 0$ [illegible] $|G(u-u_h)| \geq c_0 h^2$ [illegible] $\mathcal{G}_h$ [illegible] $G(u-u_h)$

$$\frac{\mathcal{G}_h}{G(u-u_h)} \to 1.$$

[illegible]. It holds that

$$\left|1 - \frac{\mathcal{G}_h}{G(u-u_h)}\right| = \left|\frac{G(u-u_h) - \mathcal{G}_h}{G(u-u_h)}\right| \lesssim \delta \left(\|u\|_{3,\Omega} + |u|_{2,\infty,\Omega}\right)\left(\|\omega\|_{3,\Omega} + |\omega|_{2,\infty,\Omega}\right),$$

which implies the conclusion. □

We motivate our local error indicators for duality-based adaptive refinement, where the objective is to reduce $|G(u-u_h)|$, by observing that

$$\begin{aligned}|\mathcal{G}_h| &= \left|\sum_{\tau\in\mathcal{T}} \int_\tau a(\mathcal{R}-I)\nabla u_h \cdot (\mathcal{R}-I)\nabla\omega_h \, dx\right| \\ &\leq \sum_{\tau\in\mathcal{T}} \left|\int_\tau a(\mathcal{R}-I)\nabla u_h \cdot (\mathcal{R}-I)\nabla\omega_h \, dx\right| \\ &\leq \sum_{\tau\in\mathcal{T}} \|a(\mathcal{R}-I)\nabla\omega_h\|_{0,\tau}\|(\mathcal{R}-I)\nabla u_h\|_{0,\tau}.\end{aligned}$$

So we use the local indicators

$$\|a(\mathcal{R}-I)\nabla\omega_h\|_{0,\tau}\|(\mathcal{R}-I)\nabla u_h\|_{0,\tau} \tag{3.8}$$

for adaptive refinement in this context. The local error estimates $\|(\mathcal{R}-I)\nabla u_h\|_{0,\tau}$ for the primal problem are the basis for the standard adaptive refinement procedure in PLTMG, so the quantities $\|a(\mathcal{R}-I)\nabla\omega_h\|_{0,\tau}$ can be thought of as dual weights which indicate global influences on the functional error.

We describe below the choice of functional which we will later use in our parallel experiments. Suppose that we are given a subdomain $\Omega_s \subset \Omega$. For purposes of practical implementation, we assume that Ω_s has a polygonal boundary and that all triangulations of Ω line up with $\partial\Omega_s$ perfectly. We have in mind subdomains Ω_s of the sort generated during the load balancing phase of the Bank–Holst algorithm. We define our dual functional by

$$G(v) = \int_{\Omega_s} fv - a\nabla u_h \cdot \nabla v - (\mathbf{b}\cdot\nabla u_h + cu_h)v \, dx + \int_{\partial\Omega_s} a\nabla u_h \cdot \mathbf{n} v \, ds. \tag{3.9}$$

If the function u is a classical solution of the PDE in question, then we have

$$\begin{aligned}G(u-u_h) &= \int_{\Omega_s} a\nabla(u-u_h)\cdot\nabla(u-u_h) + (\mathbf{b}\cdot\nabla(u-u_h) \\ &\qquad + c(u-u_h))(u-u_h)\, dx - \int_{\partial\Omega_s} a\nabla(u-u_h)\cdot\mathbf{n}(u-u_h)\, ds \\ &= \int_{\Omega_s} a\nabla(u-u_h)\cdot\nabla(u-u_h)\, dx + \mathcal{O}(h^3|\log h|).\end{aligned}$$

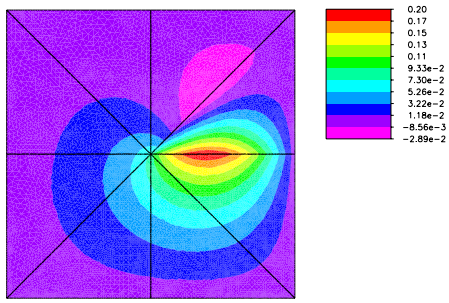

FIG. 1. *A contour plot of the approximate dual solution on a mesh with* 16036 *vertices.*

TABLE 1
The subdomain error $|e_h|^2_{1,\Omega_s}$*, the dual approximation* $\mathcal{G}_h$*, and its effectivity.*

N	$\lvert e_h\rvert^2_{1,\Omega_s}$	$\mathcal{G}_h$	EFF
244	1.97e-3	1.93e-3	0.98
996	3.36e-4	2.18e-4	0.65
4004	7.35e-5	5.78e-5	0.79
16036	1.41e-5	1.18e-5	0.84

We point out that the definition of G depends on the approximate solution u_h.

It is difficult to give a priori predictions of the smoothness of the dual solution ω. Therefore, we do not know that the assumptions of Theorem 3.1 generally apply. In other words, it is difficult to assess the effectivity of the approximation

$$\mathcal{G}_h \approx \int_{\Omega_s} a\nabla(u-u_h)\cdot\nabla(u-u_h)\,dx \tag{3.10}$$

apart from experimentation. We provide empirical evidence of the effectivity of the dual approximator in the following example. The example, henceforth called the ˛imple Problem, has primal problem

$$\begin{aligned} -\Delta u &= \sin(2\pi y)(2+4\pi^2 x(1-x)) \quad && \text{in } \Omega, \\ u &= 0 && \text{on } \partial\Omega, \end{aligned}$$

where Ω is the unit square $(0,1)\times(0,1)$. The primal solution is $u = x(1-x)\sin(2\pi y)$. For the dual problem, we choose the subdomain Ω_s with $x > y$ and $x > 0$. The approximate dual solution is pictured in Figure 1 on a mesh with approximately 16,000 vertices.

In Table 1 we see the results of several stages of the dual weighted functional error estimation for the Simple Problem. We use N for the number of unknowns, e_h for the finite element error $u-u_h$, $\mathcal{G}_h$ as our dual approximator, and EFF as the effectivity in approximation. The final row of data corresponds to the dual function pictured in Figure 1. We see that the initial effectivity is exceptionally good, decreases after the first refinement, and then begins to improve again upon successive refinements—all the while remaining in a useful range.

4. Parallel experiments. During Step 2 of the Bank–Holst algorithm as presented in [9, 10], the adaptive refinement done on processor k is driven by the weighted

error estimates

$$\eta_\tau = w_\tau \|(\mathcal{R} - I)\nabla u_h\|_{0,\tau} \text{ with } w_\tau = \begin{cases} 1 & \text{if } \tau \in \mathcal{T}_k, \\ 10^{-6} & \text{otherwise,} \end{cases}$$

where $\mathcal{T}_k$ is the portion of the triangulation coinciding with the subdomain Ω_k assigned to processor k. In this section we compare that weighting scheme with dual weighting,

$$\eta_\tau = w_\tau \|(\mathcal{R} - I)\nabla u_h\|_{0,\tau} \text{ with } w_\tau = \begin{cases} 1 & \text{if } \tau \in \mathcal{T}_k, \\ \|a(\mathcal{R} - I)\nabla \omega_h^k\|_{0,\tau} & \text{otherwise,} \end{cases}$$

where ω_h^k is the solution of the dual problem presented in the previous section associated with the subdomain Ω_k assigned to processor k.

This choice of weighting scheme deserves further explanation. In particular, why not use the dual weights in $\mathcal{T}_k$ as well? We recall that the goal of Step 2 of the algorithm is to produce a well-adapted, globally fine mesh and initial guess for use in the final global iterative solve. In other words, Step 2 should provide a good set-up for Step 3. Evidence that the dual weighting scheme has provided a better set-up than the original approach would include reduced solve times and better load balance during Step 3. Implicit in the original, 10^{-6}, version of Step 2 is the assumption that only coarse information outside Ω_k is needed for processor k to make a good contribution to the final global problem; so any defects due to essentially ignoring finer-scale pollution errors will be adequately addressed in Step 3, with negligible negative effects on its performance. In contrast, refinement on processor k which uses the dual weights both inside and outside $\mathcal{T}_k$ is acting as though there will be no Step 3 at all—as if the ultimate quality of the solution within its assigned subdomain is completely dependent upon what can be accomplished in Step 2. What one could reasonably expect at the end of Step 2 in this case is a mesh which is not significantly finer in its "fine" region than in its "coarse" region, with the effect that many degrees of freedom are discarded when the final global problem is constructed from the fine portions on each processor. The weighting scheme used for our experiments is one of many potential compromises between these two extremes, which aims to use duality to better address finer-scale pollution effects while still recognizing that the independent adaptive refinement phase is not the final phase of the algorithm.

We ran a series of experiments on two problems using PLTMG on a cluster of Dual AMD Opteron 250s with 2.4 GHz CPU clockrate, 4GB RAM, and a 2x Gigabit Ethernet Interconnect. The first problem is the Simple Problem introduced in the previous section. The second problem, which we call the -C-R Problem (diffusion-convection-reaction), is given by

$$-2(u_{xx} + u_{ux} + u_{yy}) + u_x + u_y + 3u = 2e^x(5\sin 2y - \cos 2y)$$

in $(0,1) \times (0,1)$, with Dirichlet conditions on the top and bottom of the square and Neumann conditions on the left and right chosen to match the solution $u = e^x \sin 2y$.

For Step 1 of the algorithm a coarse problem of size N_C is solved, and error estimates are used to partition the domain into p subdomains—one for each processor. During Step 2 of the algorithm, error estimates weighted by either the 10^{-6} or the dual schemes mentioned above are used for adaptive refinement, until a problem having the target size N_T is reached on each processor. We expect that most of the refinement done in Step 2 will be in the interior of the assigned subdomains on each processor; so the final global problem size N should be close to, though smaller than,

$p(N_T - N_C) + N_C$. We use the domain decomposition algorithm of Bank and Lu [6] for the final global solve in Step 3.

We take $N_C = 1000$ for Step 1 and refine until we reach a target problem size of $N_T = 50\,000,\ 100\,000,\ 150\,000,\ 200\,000,\ 250\,000$. This is done on $p = 4,\ 8,\ 16$ processors. The data for these experiments is collected in Tables 2 and 3, and is organized into blocks of six pieces of information in the following form:

$$\boxed{\begin{array}{ccc} N & |e_h|_{1,\Omega} & \|e_h\|_{0,\Omega} \\ T_{fin} & T_{tot} & T_{dif} \end{array}}, \tag{4.1}$$

where N is the final global problem size, $e_h = u - u_h$ is the error in the finite element solution, and T_{fin}, T_{tot}, and T_{dif} are the average processor time to perform the domain decomposition solve, the average processor time for the entire algorithm, and the difference between the slowest and fastest processor times for the entire algorithm respectively. For greater ease in reading the numerical results, we also include the legend (4.1) at the bottom of Tables 2 and 3.

The initial guess for the global domain decomposition solve is constructed from the fine portion of the solution on each of the processors. It is, therefore, multivalued (hence discontinuous) along the interfaces between subdomains. One of the objectives of the domain decomposition algorithm, which is based on a mortar finite element formulation, is to move toward continuity at these interfaces upon convergence. The errors are computed as

$$|e_h|^2_{1,\Omega} = \sum_{k=1}^{p} |e_h|^2_{1,\Omega_k} \quad \text{and} \quad \|e_h\|^2_{0,\Omega} = \sum_{k=1}^{p} \|e_h\|^2_{0,\Omega_k}.$$

This is a slight abuse of notation for $|e_h|_{1,\Omega}$ because e_h may remain discontinuous at the interfaces upon convergence, so $|e_h|_{1,\Omega}$ is actually infinite. We include $\|e_h\|_{0,\Omega}$ in the data primarily because, if the measure $|e_h|_{1,\Omega}$ is nearly the same for both weighting schemes then a smaller measure $\|e_h\|_{0,\Omega}$ for one of the schemes probably indicates smaller jump-discontinuities at the interfaces.

4.1. The Simple Problem in parallel. Looking at Table 2, we first point out that the global fine problem size N is approximately the same for both weighting schemes in each run of the program. The problem size is slightly smaller for the dual method than it is for the 10^{-6} method, which is expected because the dual weighting on a given processor is likely to cause more refinement outside of the region assigned to that processor. We also note that the values $|e_h|_{1,\Omega}$ are essentially identical in each case, but the values for $\|e_h\|_{0,\Omega}$ tend to be better for the dual method—sometimes dramatically better. As mentioned above, this is an indication that the final computed solution is more nearly continuous for the dual method than for the 10^{-6} method.

We see the greatest difference between the two methods in terms of the execution times for the algorithm. The dual method generally tends to lead to better times T_{fin}, T_{tot} for the final solve and the algorithm in total, as well as in the measure of load balance/imbalance T_{dif}. The most dramatic case is $p = 4$, $N_T = 250\,000$, where T_{fin} for the dual method is less than half of its counterpart! Because the problem sizes are roughly equivalent for both methods, the better values for T_{fin} indicate that using the dual method during Step 2 of the algorithm provides a better set-up for Step 3. In fact, comparing the difference $T_{tot} - T_{fin}$ for both methods shows that the time to reach Step 3 is essentially the same, so the only real difference is how well each method sets up this final global solve in Step 2.

N	$\lvert e_h\rvert_{1,\Omega}$	$\lVert e_h\rVert_{0,\Omega}$
T_{fin}	T_{tot}	T_{dif}

We make one final point before moving to the next problem. As the number of processors increased, the difference between the solve times for the two methods decreased. However, we also point out that the tendency is for the difference in execution times to increase in favor of the dual method. The only real violation of this tendency is the case $p = 16$, $N_T = 200\,000$, where the dual method is unusually fast.

4.2. The D-C-R Problem in parallel. We first note in Table 3 that, in contrast to the behavior for the Simple Problem, here we see a noticeable difference in the final problem size generated by the two methods, with the dual method producing smaller problems for the global parallel solve. This is due to the fact that the dual weighting on each processor causes more refinement to be done outside of its assigned subdomain than the 10^{-6} weighting during Step 2, so the "fine" subdomains on each processor tend to be less fine for the dual method. In Figure 2 we see a contour plot of the dual solution and a plot of the element sizes during a stage of Step 2, correspond-

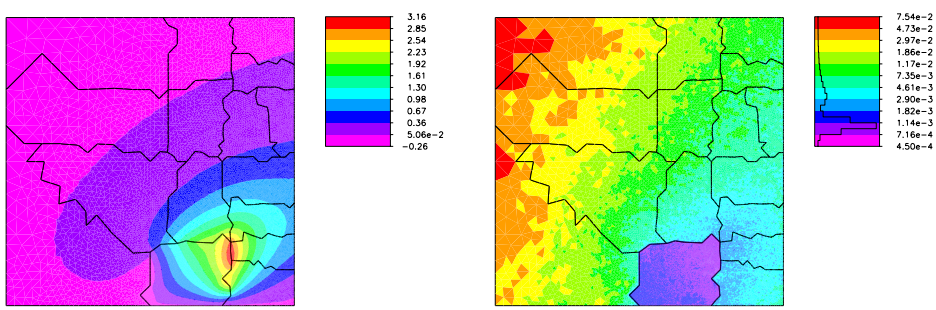

FIG. 2. *A contour plot of the approximate dual solution (left) and a plot of the element sizes.*

ing to $p = 16$, $N_T = 100\,000$. We see that the dual solution is more pronounced in the direction of the convection and that the refinement is also heavier in this direction.

Because the final global problem sizes for the two methods are noticeably different, it is not surprising that the final errors are also different. In this case $|e_h|_{1,\Omega}$ tends to be slightly smaller for the 10^{-6} method, but $\|e_h\|_{0,\Omega}$ tends to be smaller for the dual method—often by an order of magnitude! To compare the gradient errors on more equal footing we consider the ratios $|e_h|_{1,\Omega}/\sqrt{N}$, because it is expected that $|e_h|_{1,\Omega} \sim h$ and $N \sim h^2$. The ratios $|e_h|_{1,\Omega}/\sqrt{N}$ are similar in each case for both methods, with the 10^{-6} method having slightly smaller values but the dual method catching up as N_T and/or p is increased. We emphasize that the smaller values of the function error $\|e_h\|_{0,\Omega}$ for the dual method indicate a final solution which is more nearly continuous—as it should be.

Concerning the timing comparisons, the situation is similar to that for the Simple Problem. We see that the dual method is uniformly better in terms of time for the domain decomposition solve T_{fin} and total time for the algorithm T_{tot}, and tends to be better in terms of load balance T_{dif} as well. The differences between T_{fin} can be dramatic in some cases, with the value for $p = 4$, $N_T = 250\,000$ for the dual method being less than half of its counterpart!

BOUNDARY PRESERVING SEMIANALYTIC NUMERICAL ALGORITHMS FOR STOCHASTIC DIFFERENTIAL EQUATIONS*

ESTEBAN MORO† AND HENRI SCHURZ‡

Abstract. Construction of splitting-step methods and properties of related nonnegativity and boundary preserving semianalytic numerical algorithms for solving stochastic differential equations (SDEs) of Itô type are discussed. As the crucial assumption, we oppose conditions such that one can decompose the original system of SDEs into subsystems for which one knows either the exact solution or its conditional transition probability. We present convergence proofs for a newly designed splitting-step algorithm and simulation studies for numerous well-known numerical examples ranging from stochastic dynamics occurring in asset pricing in mathematical finance (Cox–Ingersoll–Ross (CIR) and constant elasticity of variance (CEV) models) to measure-valued diffusion and super-Brownian motion (stochastic PDEs (SPDEs)) as met in biology and physics.

Key words. stochastic differential equations, absorbing boundary, numerical methods, super-Brownian motion, splitting-step algorithm, convergence, nonnegativity, simulation

1. Introduction and examples.

Stochastic differential equations (SDEs) are fundamental to describe and understand random phenomena in different areas of physics, engineering, economics, etc. Particularly, they serve as models for price fluctuations as in the famous Black–Scholes option pricing model, description of erratic movements of particles as in the Langevin equation, or spatial processes like the super-Brownian motion (sBm). In most cases, explicit solutions of SDEs are very difficult to obtain and numerical approximations need to be exploited. In fact a wealth of methods for numerically integrating SDEs are known and tested [27, 28, 31, 40, 41, 42, 43, 46].

In some practical applications autonomous Itô-type SDEs of the form

$$dX(t) = f(X(t))\,dt + \sigma(X(t))\,dW(t), \quad X(0) = X_0 \in \mathcal{D} \tag{1.1}$$

are well defined only with certain boundary conditions at the boundaries of the domain $\mathcal{D}$ in which $X(t)$ lives for all t (almost surely). These boundary conditions could be additionally imposed or naturally inherent in (1.1). For example, if $X(t)$ is the price of a stock and (1.1) gives its time-evolution, then $\mathcal{D} = [0, \infty)$, where $X(t) = 0$ implies an absorbing or reflecting state. Or, if $X(t)$ models the number of certain species in a noisy environment, then $\mathcal{D} = [0, K]$, where K is an attracting carrying capacity of the environment. When the boundaries are unattainable in finite time, conditions at the boundary are not needed to define the problem (1.1). This is the case of [illegible], according to Feller's classification [14, 15, 16, 17].

The aim of this paper is to present an alternative strategy, based on [illegible] to numerically integrate SDEs (1.1) subject to natural boundary conditions,

that guarantees both that the numerical solutions live in the domain $\mathcal{D}$ and that the character of the boundary is preserved. Our analysis focuses mainly on the case of naturally inherent boundaries in the exact solution and its numerical approximation. It is important to stress that, although our method relies heavily on the knowledge of the exact solution of related stochastic processes and thus its validity is not strictly general, a wide variety of paramount problems known in the literature ranging from finance to physics or biology can be treated efficiently. Moreover, the consistency of this new method shall be mathematically justified by two convergence theorems, namely, one for sufficiently smooth Lipschitzian coefficients of involved SDEs (Theorem 3.1 in the main text) and another one (Theorem C.1 in the appendix) based on the variation-of-parameters formula (VOP). By those theorems we are going to establish the convergence rates which are equal to or higher than standard methods (e.g., 1.0 for global L^2-convergence in contrast to the rate 0.5 of Euler-type methods). Finally, the computational method is complemented with a very fast algorithm to sample an important class of conditional transition probabilities found in important problems.

The standard (unrestricted) Brownian motion on $\mathbb{R}$ is the most obvious example of natural boundaries at infinity. Reasonable population models in ecology, interest rates, or asset prices in finance possess the natural boundary at 0 (i.e., nonnegativity). The situation is different when the solution of (1.1) attains the boundaries in finite time. In this case, boundary conditions can be naturally inherent or imposed such as [illegible] —for example, the Brownian motion on $\mathbb{R}^+$ for which a boundary condition at $x = 0$ needs to be specified to completely define its solution.

The problem of how to handle boundary conditions also appears in the numerical approximations of (1.1). Naturally inherent boundary conditions do need to be incorporated in the construction of its numerical approximations too. In fact, standard numerical methods such as Euler methods may fail to meet these boundary conditions; see [39]. This is also true for higher order converging Taylor-type methods [27, 28, 41]. Numerical time-discretizations face two kinds of different (though related) problems when a boundary condition is specified. The first one is to restrict the values of the numerical approximations to live within the domain $\mathcal{D}$; second, they also have to preserve the character of the boundary (natural, reflecting, absorbing, etc.).

There are several methods of numerically approximating the solutions of (1.1) when boundary conditions are imposed at the boundaries of $\mathcal{D}$. In the case of natural boundaries (related to Neumann boundary conditions in approximations of parabolic PDEs), methods involving projection techniques [29], penalty methods [26, 38], or symmetrized schemes [1] have been proved successful. For absorbing boundary conditions (related to Dirichlet boundary conditions in PDEs), the strategies involving direct Euler schemes [13, 19, 20] or exploiting the well-known Feynman–Kac representation formula [3] are applied. Finally, in the case of natural boundaries, i.e., when the diffusion does not reach the boundary, balanced implicit methods (see [32, 40, 41]), balanced Milstein methods [25], or composition methods based on Lie algebra techniques [33] are efficient methods of incorporating boundary restrictions. In other specific cases, numerical approximations of (1.1) in $\mathcal{D}$ are obtained by using standard methods and modifying the equation whenever the approximation lies outside $\mathcal{D}$ (e.g., [21, 8]).

In contrast to all forementioned citations, we shall follow a rather different, semi-analytic numerical approach to systems of SDEs (1.1). Our approach heavily relies on the exploitation of the specific structure of the original system (1.1) which al-

lows a natural splitting into explicitly known parts of the underlying dynamics with well-known boundary behavior and the remaining parts to be treated numerically with naturally incorporated boundary behavior (or even without restrictions). The method is especially efficient at approximating solutions of SDEs (1.1) where boundary conditions are naturally inherent. To exemplify the class of problems and its numerical approximations, consider the well-known square-root diffusion of Cox, Ingersoll, and Ross [5],

$$dX(t) = [a + bX(t)]\,dt + \sigma\sqrt{X(t)}\,dW(t), \quad X(0) = x_0 \geq 0 \tag{1.2}$$

with real parameters $a \geq 0$, $b \in \mathbb{R}$, and $\sigma > 0$, which is widely used for interest rate modeling or as an alternative to geometric Brownian motion occurring in the Black–Scholes model of dynamic asset pricing in mathematical finance. It is well known that the (strong) solution of (1.2) is unique, preserves the nonnegativity of the initial data, and has different boundary behavior at $X(t) = 0$ depending on the values of a and σ (see section 5.1). For the real-valued numerical implementation of the $\sqrt{X(t)}$-term, the nonnegativity of numerical approximations of (1.2) is of special importance. In fact, the nonnegativity (and hence the exclusive real-valued numerical evaluation) can be easily achieved in numerical approximations by means of balanced implicit methods (see [32, 40, 41]), balanced Milstein methods [25], and composition methods based on Lie algebra techniques [33]. However, the latter-mentioned or other methods may fail to incorporate the right boundary properties in the numerical paths. Other methods, while converging in the limit $\Delta t \to 0$, do not even conserve the nonnegativity of the solution like that of the straightforward fixing by taking $\sqrt{|X(t)|}$ instead of the diffusion term $\sqrt{X(t)}$ in (1.2) (as done in [21] or [8]). Recall that convergence as $\Delta t \to 0$ is an asymptotic property, but nonnegativity or boundary preserving property is more of qualitative nature and important from the point of view of adequate modeling interpretation (while using nonzero step sizes as in computational practice).

The following sections are structured as follows. We introduce and discuss the general splitting-step algorithm in section 2. Section 3 reports on a general convergence theorem and its mathematical proof. Several numerical experiments in sections 4–6 strongly support the suggested algorithm and results from previous sections by ordinary SDEs. In section 4 we present some simple models and related experiments. Section 5 is devoted to the simulation of processes as often met in dynamic asset pricing in mathematical finance. In section 6 we mention some applications to measure-valued diffusions and reaction-diffusion equations demonstrating the potential range of the splitting-step algorithm for numerical treatment of random PDEs. Section 7 concludes with some supplemental remarks. Eventually, there are three small appendices on aspects of random number generation and strong path approximations and on a convergence theorem based on the VOP with an illustrative example.

2. Splitting-step algorithm. The general structure of a splitting-step algorithm, which is based on the idea in [37] (see also [34, 10]), is as follows. Suppose that the more general equation which is to be integrated is of the form

$$dX(t) = [\alpha(X(t), t) + \beta(X(t), t)]\,dt + \sigma(X(t), t)\,dW(t). \tag{2.1}$$

We then decompose the above equation into the two equations

$$dX_1(t) = \beta(X_1(t), t)\,dt + \sigma(X_1(t), t)\,dW(t), \tag{2.2}$$

$$dX_2(t) = \alpha(X_2(t), t)\,dt, \tag{2.3}$$

where the splitting is done assuming that we know the exact strong solution for $X_1(t)$ or the conditional probability $\mathcal{P}[X_1(t)|X_1(0)]$. Thus, we can approximate the solution of (2.1) by a stochastic process Y_t along time intervals $[t, t+\Delta t]$ using the following two-step algorithm for each Δt, which we call the [illegible]:

Step 1. Knowing the value of Y_t we obtain an intermediate value $\tilde{Y}_t$ which is obtained through the exact integration of (2.2) and $\tilde{Y}_t = X_1(t+\Delta t)$ and with initial condition $X_1(t) = Y_t$.

Step 2. Then $\tilde{Y}_t$ is used as the initial condition for (2.3) which is now integrated using any converging deterministic numerical algorithm to get $\tilde{X}_2$ (at least of deterministic order 1). Then $Y_{t+\Delta t} = \tilde{X}_2(t+\Delta t)$.

As said before, we [illegible] that either the analytic expression of the exact strong solution of X_1 governed by (2.2) or its conditional transition probabilities $\mathcal{P}[X_1(t)|X_1(0)]$ are explicitly known. Thus, the advantage of this splitting-step technique for SDEs subject to boundary conditions is that if (2.2) is simple enough and we know the solution X_1 of (2.1), then the stochastic part of the problem can be handled correctly. For example, for the case $\beta(X_1, t) = 0$ and $\sigma(X_1, t) = \sqrt{X_1}$, it is known that the conditional probability distribution is given by

$$\mathcal{P}[X_1(t)|X_1(0)] = \frac{2}{t}\left(\frac{X_1(0)}{X_1(t)}\right)^{1/2} I_1\left(\frac{4}{t}\sqrt{X_1(t)X_1(0)}\right) e^{-\frac{2}{t}[X_1(t)+X_1(0)]} + e^{-\frac{4}{t}X_1(0)}\delta(X_1(t)), \tag{2.4}$$

where I_1 is the modified Bessel function and $\delta(x)$ is the Dirac delta function.

This cdf can be sampled using the rejection or inverse methods but this is computationally expensive. However, we introduce here a very simple method [34] (see also [2]) for obtaining $X_1(t)$ by noting that the variable $Z(t) = \frac{4}{t}X_1(t)$ has a probability distribution given by the noncentral χ^2-distribution, that is,

$$\mathcal{P}[Z|Z_0] = \sum_{j=1}^{\infty} \frac{(\lambda/2)^j e^{-\lambda/2}}{j!} \mathcal{P}_{\chi^2_{2j}}(Z) + e^{-\lambda/2}\delta(Z), \tag{2.5}$$

where $\lambda = \frac{4}{t}Z_0$ and $\mathcal{P}_{\chi^2_{2j}}(X)$ is the χ^2-pdf with $2j$ degrees of freedom. Equation (2.5) reveals that the probability distribution for Z is a linear combination of χ^2-pdfs with Poisson weights. This fact can be exploited to generate $X_1(t)$ efficiently. If we choose K from a Poisson distribution with mean $\lambda/2$, then

$$X_1(t) = \frac{1}{2k}\begin{cases} 0 & \text{if } K = 0, \\ \sum_{i=1}^{2K} z_i^2 & \text{if } K \neq 0, \end{cases} \tag{2.6}$$

where z_i are independent Gaussian random numbers with zero mean and unit variance. Computationally, it is faster to sample the random number $\sum_{i=1}^{2K} z_i^2$ using standard algorithms for random number generation of the χ^2 distribution. Other examples of this sampling can be found in section 4 and the appendix.

The obvious advantage of the splitting algorithm is that we exploit the structure of the original equation more efficiently. For example, in the above example, we get numbers from (2.6) which are nonnegative and thus, if $\alpha(X, t)$ has nice properties, the approximated values for $X(t)$ are nonnegative, too. Such a splitting algorithm is not known from the literature to the best of our current knowledge, although the idea of

splitting is not new for dynamical systems and their numerical integration. A different kind of splitting technique has been suggested in [22]. However, their algorithm, called the split-step Euler method, is related to another subclass of splitting of SDEs and their resulting split-step algorithm is of lower order 0.5 of mean square convergence, which is restricted by their use of the (drift-implicit) backward Euler method. Their method indirectly refers to the splitting

$$dX_1(t) = [\alpha(X_1(t),t) + \beta(X_1(t),t)]\,dt,$$
$$dX_2(t) = \sigma(X_2(t),t)\,dW(t),$$

of the original system (1.1) in our set-up, where both equations for X_1 and X_2 are numerically integrated in a separated fashion. In contrast to them, by a more efficient choice of splitting, we even suggest removing stochastic integrals from numerical integration by appropriate splitting of (1.1) in order to achieve a higher order of convergence, and our technique is not restricted only to techniques of direct pathwise simulation. It may be noted that the explicit removal of stochastic integrals from numerical integration by splitting techniques is always possible and leads to converging numerical approximations with higher order under some appropriate assumptions on the diffusion coefficient σ (for example, $\sigma\sigma\prime$ has sufficiently many bounded derivatives) in $\mathbb{R}^1$. Another form of splitting has been suggested in [6]. They present an algorithm which also takes advantage of techniques of numerical integration of ODEs. However, neither [6] nor [22] discusses the issue of pathwise preservation of nonnegativity, monotonicity, and boundedness by their numerical approximation techniques.

3. A convergence theorem of splitting algorithm for nonautonomous equations. Let $C^{i,j}(\mathbb{R}^d \times [0,T])$ denote the vector space of continuous functions $f = f(x,t)$ which are i times continuously differentiable with respect to the space-coordinate $x_k \in \mathbb{R}$ $(k = 1,2,\ldots,d)$ and j times continuously differentiable with respect to time-coordinate $t \in [0,T]$. Recall that the original equation is

$$dX(t) = [\alpha(X(t),t) + \beta(X(t),t)]\,dt + \sigma(X(t),t)\,dW(t). \tag{3.1}$$

For the proof of splitting techniques below, we refer the reader to the splitting

$$dX_1(t) = \beta(X_1(t),t)\,dt + \sigma(X_1(t),t)\,dW(t), \tag{3.2}$$
$$dX_2(t) = \alpha(X_2(t),t)\,dt. \tag{3.3}$$

THEOREM 3.1. [illegible] $\alpha, \beta \in C^{2,1}(\mathbb{R}^d \times [0,T])$ $\sigma \in C^{3,2}(\mathbb{R}^d \times [0,T])$ [illegible]

$$\sup_{0\le t\le T} \mathbb{E}\left[|X(t)|^2 + |\alpha(X(t),t)|^2 + |\beta(X(t),t)|^2 + |\sigma(X(t),t)|^2\right] < +\infty$$

[illegible] $T > 0$ [illegible] 1 2 [illegible] 1.0 [illegible] $[0,T]$ [illegible]. For simplicity, suppose that $d = 1$. Let

$$0 = t_0 < t_1 < \cdots < t_n < t_{n+1} < \cdots < t_N = T$$

be any nonrandom partition of the given time-interval $[0,T]$ with sufficiently small maximum step size $\Delta = \max_{i=1,2,\ldots,N} |t_i - t_{i-1}| \le 1$. Define the local pathwise error

by $\varepsilon_{n+1}^{loc} = X(t_n + \Delta_n t) - \tilde{X}(t_n + \Delta_n t)$ assuming that both exact solution X and its approximation $\tilde{X}$ have started at the same value $X(t_n)$ at time t_n. To investigate this error, apply the stochastic Taylor formula to the processes X, X_1, and X_2—an idea which originates from the Wagner–Platen expansion [47] and was popularized by [27] (more precisely speaking, this exploits the idea of an iterative application of the Itô formula). For the sake of abbreviation, we shall write z_n or z_u for all occurring coefficients or processes (not referring to partial derivatives here); hence $X_n = X(t_n)$, $\alpha_n = \alpha(X(t_n), t_n)$, $\beta_n = \beta(X(t_n), t_n)$, and $\sigma_n = \sigma(X(t_n), t_n)$, and similarly, $\alpha_u = \alpha(X(u), u)$, $\beta_u = \beta(X(u), u)$, $\sigma_u = \sigma(X(u), u)$, and so on, unless it is stated differently wherever convenient. Define the partial differential operators

$$
\begin{aligned}
L_0^0 f(x,t) &= \frac{\partial f(x,t)}{\partial t} + [\alpha(x,t) + \beta(x,t)] \frac{\partial f(x,t)}{\partial x} + \frac{1}{2}[\sigma(x,t)]^2 \frac{\partial^2 f(x,t)}{\partial x^2}, \\
L_0^1 f(x,t) &= \sigma(x,t) \frac{\partial f(x,t)}{\partial x}, \quad L_1^1 f(x,t) = L_0^1 f(x,t), \\
L_1^0 f(x,t) &= \frac{\partial f(x,t)}{\partial t} + \beta(x,t) \frac{\partial f(x,t)}{\partial x} + \frac{1}{2}[\sigma(x,t)]^2 \frac{\partial^2 f(x,t)}{\partial x^2}, \\
L_2^0 f(x,t) &= \frac{\partial f(x,t)}{\partial t} + \alpha(x,t) \frac{\partial f(x,t)}{\partial x},
\end{aligned}
$$

where L_i^0 is mapping from $C^{2,1}(\mathbb{R}^d \times [0,T])$ to $C^{0,0}(\mathbb{R}^d \times [0,T])$ and L_i^1 from $C^{1,0}(\mathbb{R}^d \times [0,T])$ to $C^{0,0}(\mathbb{R}^d \times [0,T])$ for $i = 1, 2$, and L_2^0 from $C^{1,1}(\mathbb{R}^d \times [0,T])$ to $C^{0,0}(\mathbb{R}^d \times [0,T])$. First, apply Taylor-type approximations to the solutions of (3.1) to obtain

$$
\begin{aligned}
X_{n+1} &= X_n + \int_{t_n}^{t_{n+1}} [\alpha(X(s), s) + \beta(X(s), s)]\, ds + \int_{t_n}^{t_{n+1}} \sigma(X(s), s)\, dW(s) \\
&= X_n + [\alpha_n + \beta_n]\Delta_n t + \sigma_n \Delta_n W \\
&\quad + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^0(\alpha_u + \beta_u)\, du\, ds + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^1(\alpha_u + \beta_u)\, dW(u)\, ds \\
&\quad + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^0 \sigma_u\, du\, dW(s) + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^1 \sigma_u\, dW(u)\, dW(s) \\
&= X_n + [\alpha_n + \beta_n]\Delta_n t + \sigma_n \Delta_n W + \frac{1}{2} L_0^1 \sigma_n [(\Delta_n W)^2 - \Delta_n t] + R_{0,n} \qquad (3.4)
\end{aligned}
$$

with the remainder term

$$
\begin{aligned}
R_{0,n} &= \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^0(\alpha_u + \beta_u)\, du\, ds + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^1(\alpha_u + \beta_u)\, dW(u)\, ds \\
&\quad + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^0 \sigma_u\, du\, dW(s) + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \int_{t_n}^{u} L_0^0 L_0^1 \sigma_v\, dv\, dW(u)\, dW(s) \\
&\quad + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \int_{t_n}^{u} L_0^1 L_0^1 \sigma_v\, dW(v)\, dW(u)\, dW(s).
\end{aligned}
$$

Now, we compare (3.4) with what we get from the expansion of the splitting method. In the latter case, by application of the Wagner–Platen expansion [47] again, we arrive at

$$
X_{1,n+1} = X_n + \int_{t_n}^{t_{n+1}} \beta(X_1(s), s)\, ds + \int_{t_n}^{t_{n+1}} \sigma(X_1(s), s)\, dW(s)
$$

$$
\begin{aligned}
&= X_n + \beta_n \Delta_n t + \sigma_n \Delta_n W \\
&\quad + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^0 \beta_u \, du \, ds + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^1 \beta_u \, dW(u) \, ds \\
&\quad + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^0 \sigma_u \, du \, dW(s) + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^1 \sigma_u \, dW(u) \, dW(s) \\
&= X_n + \beta_n \Delta_n t + \sigma_n \Delta_n W + \frac{1}{2} L_1^1 \sigma_n [(\Delta_n W)^2 - \Delta_n t] + R_{1,n} \qquad (3.5)
\end{aligned}
$$

with the remainder term

$$
\begin{aligned}
R_{1,n} = &\int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^0 \beta_u \, du \, ds + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^1 \beta_u \, dW(u) \, ds \\
&+ \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^0 \sigma_u \, du \, dW(s) + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \int_{t_n}^{u} L_1^0 L_1^1 \sigma_v \, dv \, dW(u) \, dW(s) \\
&+ \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \int_{t_n}^{u} L_1^1 L_1^1 \sigma_v \, dv \, dW(u) \, dW(s).
\end{aligned}
$$

Here, the coefficients β and σ involved in the above integrals are evaluated at the arguments $(X_1(u), u)$ and $(X_1(v), v)$, respectively. Similarly, by deterministic Taylor expansion for the local approximation of (3.3) in the framework of the splitting method, one gets

$$
X_{2,n+1} = X_{1,n+1} + \int_{t_n}^{t_{n+1}} \alpha(X_2(s), s) \, ds = X_{1,n+1} + \alpha(X_{1,n+1}, t_n) \Delta_n t + R_{2,n} \qquad (3.6)
$$

with the remainder term

$$
\begin{aligned}
R_{2,n} &= \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_2^0 \alpha_u \, du \, ds \\
&= \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \left[\frac{\partial \alpha(X_2(u), u)}{\partial u} + \alpha(X_2(u), u) \frac{\partial \alpha(X_2(u), u)}{\partial x} \right] du \, ds.
\end{aligned}
$$

Here, the coefficients α involved in the above integrals are evaluated at the arguments $(X_2(u), u)$. An expansion of $\alpha(X_{1,n+1}, t_n)$ with respect to space-variable x gives

$$
\alpha(X_{1,n+1}, t_n) = \alpha_n + \int_{t_n}^{t_{n+1}} L_1^0 \alpha(X_1(s), s) \, ds + \int_{t_n}^{t_{n+1}} L_1^1 \alpha(X_1(s), s) \, dW(s). \qquad (3.7)
$$

Now, plug expansions (3.7) and (3.5) into (3.6) in order to obtain

$$
X_{2,n+1} = X_n + [\alpha_n + \beta_n] \Delta_n t + \sigma_n \Delta_n W + \frac{1}{2} L_1^1 \sigma_n [(\Delta_n W)^2 - \Delta_n t] + R_{3,n} \qquad (3.8)
$$

with the remainder term

$$
R_{3,n} = R_{1,n} + R_{2,n} + \left[\int_{t_n}^{t_{n+1}} L_1^0 \alpha_s \, ds + \int_{t_n}^{t_{n+1}} L_1^1 \alpha_s \, dW(s) \right] \Delta_n t.
$$

Consequently, the local pathwise error $\varepsilon_{n+1}^{loc} = X_{n+1} - X_{2,n+1}$ can be represented by

$$\begin{aligned}
\varepsilon_{n+1}^{loc} &= X_{n+1} - X_{2,n+1} = R_{0,n} - R_{3,n} \\
&= \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^0(\alpha_u + \beta_u)\, du\, ds + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^1(\alpha_u + \beta_u)\, dW(u)\, ds \\
&\quad + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_0^0 \sigma_u\, du\, dW(s) + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \int_{t_n}^{u} L_0^0 L_0^1 \sigma_v\, dv\, dW(u)\, dW(s) \\
&\quad + \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \int_{t_n}^{u} L_0^1 L_0^1 \sigma_v\, dW(v)\, dW(u)\, dW(s) \\
&\quad - \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^0 \beta_u\, du\, ds - \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^1 \beta_u\, dW(u)\, ds \\
&\quad - \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_1^0 \sigma_u\, du\, dW(s) - \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \int_{t_n}^{u} L_1^0 L_1^1 \sigma_v\, dv\, dW(u)\, dW(s) \\
&\quad - \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} \int_{t_n}^{u} L_1^1 L_1^1 \sigma_v\, dv\, dW(u)\, dW(s) - \int_{t_n}^{t_{n+1}} \int_{t_n}^{s} L_2^0 \alpha_u\, du\, ds \\
&\quad - \left[\int_{t_n}^{t_{n+1}} L_1^0 \alpha_s\, ds + \int_{t_n}^{t_{n+1}} L_1^1 \alpha_s\, dW(s) \right] \Delta_n t. \qquad (3.9)
\end{aligned}$$

Now recall that α, β, σ have exclusively uniformly bounded derivatives and their second moments along the solution of (3.1) are bounded on $[0, T]$. Therefore, all operators L_i^j applied to coefficients α, β, and σ have images with uniformly bounded second moments. This implies that $\mathbb{E}\,\varepsilon_n^{loc} = \mathcal{O}([\Delta_n t]^2)$ and $\mathbb{E}\,(\varepsilon_n^{loc} - \mathbb{E}\,\varepsilon_n^{loc})^2 = \mathcal{O}([\Delta_n t]^3)$. For mean square convergence, it remains to apply fairly general convergence theorems as known from [31, 42, 43] with local rates $r_1 = 2$ and $r_2 = 1.5$ in order to conclude the global strong (i.e., in the L^2-sense) convergence order $r = 1.0$. More precisely, we have

$$\max_{n=0,1,\ldots,N} \Big(\mathbb{E}\,|X(t_n) - \tilde{X}(t_n)|^2 \Big)^{1/2} = \mathcal{O}(\Delta)$$

provided that the initial errors $\mathbb{E}\,|X(0) - \tilde{X}(0)|^2 = \mathcal{O}(\Delta^2)$ started at L^2-integrable initial values which are independent of the σ-algebra generated by the underlying Wiener process W. Eventually, the global order $r_w = 1.0$ of weak convergence with respect to smooth, polynomially bounded test functions is rather obvious from the fact that the local weak rate $r_w = 2.0$ (exploiting standard techniques known from [17] and [31] on weak convergence analysis). Consequently, the splitting-step algorithm has the claimed convergence orders, and the proof is complete. □

4. First illustrative numerical experiments. In this section we give several illustrative and important examples of applying our new stochastic numerical schemes to SDEs and test the rate of convergence obtained in section 3.

4.1. Using the transition probability. Consider the splitting-step method applied to the SDE

$$dX(t) = (1 + X(t))\, dt + 2\sqrt{X(t)}\, dW(t) \qquad (4.1)$$

with $\alpha(X,t) = 1 + X$, $\beta(X,t) = 0$, and $\sigma(X,t) = 2\sqrt{X}$. The conditional transition probability for the stochastic part of the splitting algorithm is sampled using (2.6).

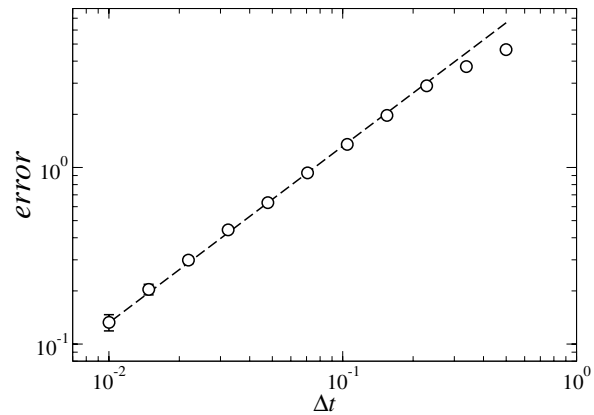

FIG. 4.1. *Absolute value of the error* (4.3) *as a function of* Δt *for* $t = 1.0$ *and* $X(0) = 1$ *obtained using the splitting-step algorithm. The dashed line is proportional to* Δt.

The conditional mean value is given by

$$\mathbb{E}\,(X(t)|X(0) = x_0) = (x_0 + 1)e^t - 1 \tag{4.2}$$

for any nonrandom value $x_0 \geq 0$. In Figure 4.1 the error

$$\varepsilon_1 = |\mathbb{E}\,\tilde{X}(t) - [(x_{0-1})e^t - 1]| \tag{4.3}$$

versus the decreasing uniform step size Δt is depicted, where $\tilde{X}(t)$ is the solution obtained through the numerical approximation. Figure 4.1 shows statistical numerical evidence that the method has weak order 1.0 while using constant step sizes Δt.

4.2. Using the exact solution. Consider the splitting-step algorithm applied to

$$dX(t) = (X(t) - [X(t)]^3)\,dt + X(t)\,dW(t), \tag{4.4}$$

which is called the stochastic planar Ginzburg–Landau equation. In this case we take advantage of the known exact solution for the linear part of this equation which is

$$dX_1(t) = X_1(t)\,dt + X_1(t)\,dW(t) \Rightarrow X_1(t) = X_1(s)\exp\Big((t-s)/2 + W(t) - W(s)\Big). \tag{4.5}$$

To integrate the second part of the split system

$$dX_2(t) = -[X_2(t)]^3\,dt \tag{4.6}$$

we use a partial-implicit nonstandard technique which is a nonnegativity preserving one[1] given by

$$X_2(t + \Delta t) = X_2(t) - \frac{\Delta t}{2}X_2^2(t)[X_2(t) + X_2(t + \Delta t)]. \tag{4.7}$$

[1]This is true if current step size $\Delta_n t$ is chosen such that $[X_2(t_n)]^2\Delta_n t < 2$.

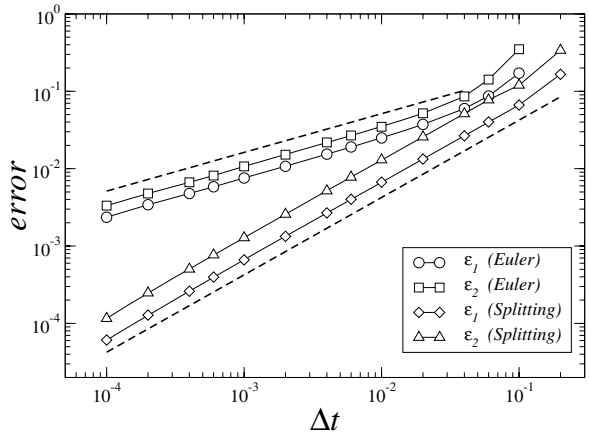

FIG. 4.2. *Value of the error* (4.8) *as a function of* Δt *for* $t = 5.0$ *and* $X(0) = 1.0$ *using the splitting-step and Euler algorithms. Dashed lines are the power laws* Δt *and* $\sqrt{\Delta t}$.

Our results for the strong error

$$\varepsilon_k(t) = (\mathbb{E}\,|X(t) - \tilde{X}(t)|^k)^{1/k} \tag{4.8}$$

are shown in Figure 4.2 for $k = 1, 2$ and compared to the Euler algorithm for the same equation. Obviously, our results indicate that our proposed splitting method indeed is of strong order 1.0 while using constant step sizes Δt.

5. Stochastic models in finance. In this section we apply the splitting-step method to some fundamental models in mathematical finance. This application will also serve to introduce other algorithmically simple samplings of conditional probability transitions as for the $\sqrt{X_1(t)}$ case shown in the introduction.

5.1. Interest rate model of Cox, Ingersoll, and Ross. An interesting example in which the splitting-step scheme is particularly efficient is the Cox–Ingersoll–Ross (CIR) model [5] for stochastic interest rates

$$dX(t) = [a + bX(t)]\,dt + \sigma\sqrt{X(t)}\,dW(t), \quad X(0) = x_0 \geq 0 \tag{5.1}$$

with real parameters $a \geq 0$, $b \in \mathbb{R}$, and $\sigma > 0$. As stated in the introduction, strong solutions of (5.1) are nonnegative. However, depending on the specific values of parameters a, b, and σ, distinct behavior at the boundary is possible.

- If $a \geq \sigma^2/2$, then the solution is always positive. $X(t) > 0$ if $x_0 > 0$, because the boundary $X_(t) = 0$ becomes unattainable.
- If $a < \sigma^2/2$, there are infinite many values of $t > 0$ for which $X(t) = 0$. The boundary becomes attainable, but it is (instantaneously) reflecting. That is, when a sample path reaches 0, then it returns immediately to the interior of the state space in a reflecting manner.

The exact transition density for the CIR process is known, but its sampling can be difficult depending on the parameters a, b, and σ. Here we may exploit the simplest splitting which appropriately reflects the boundary behavior of the CIR process by SDEs

$$dX_1(t) = a\,dt + \sigma\sqrt{X_1(t)}\,dW(t), \tag{5.2}$$

$$dX_2(t) = bX_2(t)\,dt, \tag{5.3}$$

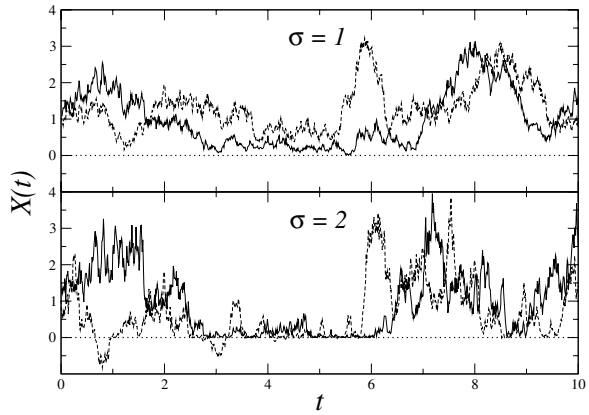

FIG. 5.1. *Numerical approximation of the CIR process* (5.1) *using the splitting-step method* (5.2) *(solid line) and the method proposed in* [21] *(dashed line) with* $a = b = 1$, $\Delta t = 10^{-2}$, $X(0) = 1$, *and different values of* σ*: The upper panel shows the case* $a \geq \sigma^2/2$ *where the boundary at zero becomes unattainable, while the lower panel is for* $a < \sigma^2/2$. *The splitting-step numerical approximation reproduces the attainability of the boundary condition while preserving the nonnegativity of the solution of* (5.1), *whereas the method in* [21] *has trajectories which take negative values for* $X(t)$.

which can be easily inferred by noting that the boundary behavior does not depend on the parameter b. To integrate the first step in the splitting-step system (5.2)–(5.3) we note that the process defined by (5.2) represents an a-dimensional Bessel process [17]. Its transition density $\mathcal{P}[X_1(t+\Delta t)|X_1(t)]$ can be written in terms of a noncentral χ^2 distribution and, in particular, we have

$$X_1(t+\Delta t) = \frac{\sigma^2 \Delta t}{4} \chi'^2_d(\lambda), \tag{5.4}$$

where

$$\lambda = \frac{4X_1(t)}{\sigma^2 \Delta t}, \qquad d = \frac{4a}{\sigma^2}, \tag{5.5}$$

and $\chi'^2_d(\lambda)$ random numbers can be sampled using the algorithms in the appendix. The last part of the splitting-step scheme (5.3) can be integrated exactly or using numerical approximations. In our case we use deterministic Euler approximations where nonnegativity is preserved if Δt is small enough. Our simulations for the CIR process are shown in Figure 5.1. The boundary behavior for different values of a and σ is reproduced and, at the same time, nonnegativity is conserved. Note that other usual integration strategies such as that of [21] eventually produce negative values for $X(t)$ (for finite Δt) which lack any possible interpretation in the context of finance and could induce severe errors in option valuation.

5.2. Constant elasticity volatility models. Another important stochastic process in finance is the constant elasticity of variance (CEV) diffusion to model asset prices. This process, first introduced to finance by Cox [4], is capable of reproducing the volatility smile observed in the empirical data unlike other standard price models such as the Black–Scholes–Merton geometric Brownian motion. The process is defined as

$$dX(t) = \mu X(t)\, dt + \sigma X(t)^\gamma\, dW(t), \quad X(0) = x_0. \tag{5.6}$$

The CEV model includes the geometric Brownian model of Black, Scholes, and Merton ($\gamma = 1$) and the square-root model of Cox and Ross ($\gamma = 1/2$). Contrary to the Black–Scholes–Merton model, the CEV model incorporates a variance adjustment that causes the absolute level of the variance to decline as the stock price rises and to rise as the stock price declines, as seen empirically in most equity and interest rate volatilities.

For our purposes, the CEV model encompasses most of the boundary conditions we can implement at $X(0) = 0$. Depending on γ, the boundary $X(0) = 0$ is the following:

- a [illegible] for $\gamma \geq 1$, which means that boundary is unattainable in finite time;
- an [illegible] for $1/2 \leq \gamma < 1$; i.e., $X(t)$ reaches zero with finite probability in finite time and gets absorbed at it;
- a [illegible] for $\gamma < 1/2$. Now the boundary can be reached in finite time, and we need to specify a boundary condition at $X(0) = 0$. Typical choices are reflecting or absorbing ones.

The transition density for the CEV process is known for general values of γ and μ (see [4]). However, due to the fact that the boundary behavior of $X(t)$ does not depend on μ, we propose here the following splitting-step system:

$$dX_1 = \sigma X_1^{\gamma}\, dW(t), \tag{5.7}$$

$$dX_2 = \mu X_2\, dt. \tag{5.8}$$

The classification of the boundary $X_1(t) = 0$ for (5.7) is the same as for (5.6). We discuss now the sampling of the transition density for each value of γ.[2]

5.2.1. $\gamma > 1$, natural boundary. In this case $X_1(t) = 0$ is unattainable and its probability transition density is given by

$$\mathcal{P}[x_t|x_0] = \frac{x_t^{1/2-2\gamma} x_0^{1/2}}{\sigma^2(\gamma-1)} \exp\left[-\frac{x_0^{2(1-\gamma)} + x_t^{2(1-\gamma)}}{2\sigma^2(1-\gamma)^2 t}\right] I_{\frac{1}{2(\gamma-1)}}\left[\frac{x_0^{1-\gamma} x_t^{1-\gamma}}{\sigma^2(1-\gamma)^2 t}\right]. \tag{5.9}$$

To sample this distribution, we can consider the relationship between the CEV and the CIR processes. Since $X_1(t) = 0$ is not accessible, we can make the change of variables $Y_1 = X_1^{2(1-\gamma)}/[4(\gamma-1)^2\sigma^2]$ to find that $dY_1 = \lambda\, dt + \sqrt{Y_1}\, dW(t)$ where $\lambda = (1-2\gamma)/[4(1-\gamma)]$. Thus Y_1 is a Bessel process which can be sampled using the noncentral χ^2 distribution. At the end we have that

$$X_1(t+\Delta t) = \left[(\gamma-1)^2\sigma^2 \Delta t\, \chi'^2_d\left(\frac{X_1(t)^{2(1-\gamma)}}{\sigma^2(\gamma-1)^2\Delta t}\right)\right]^{\frac{1}{2(1-\gamma)}}, \tag{5.10}$$

where $d = (1-2\gamma)/(1-\gamma) \geq 1/2$. A typical path of the CEV process for $\gamma > 1$ is shown in Figure 5.2.

5.2.2. $1/2 \leq \gamma < 1$, absorbing boundary. In this case $X_1(t) = 0$ is an absorbing boundary. The transition probability density was found by Cox [4] and is given by

$$\mathcal{P}[x_t|x_0] = \frac{x_t^{1/2-2\gamma} x_0^{1/2}}{\sigma^2(1-\gamma)} \exp\left[-\frac{x_0^{2(1-\gamma)} + x_t^{2(1-\gamma)}}{2\sigma^2(1-\gamma)^2 t}\right] I_{\frac{1}{2(1-\gamma)}}\left[\frac{x_0^{1-\gamma} x_t^{1-\gamma}}{\sigma^2(1-\gamma)^2 t}\right]. \tag{5.11}$$

[2]We do not consider the case $\gamma = 1$, since this can be integrated using the strong solution (4.5).

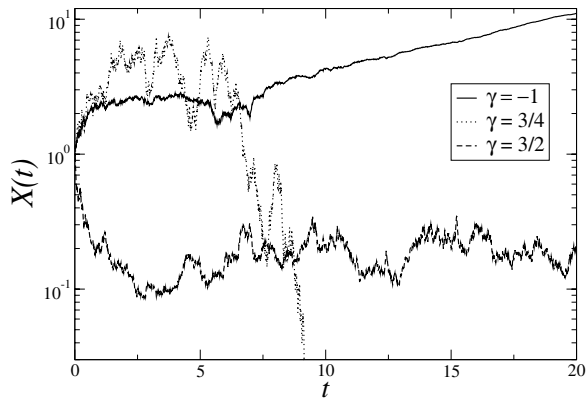

FIG. 5.2. *Numerical approximation of the CEV process* (5.6) *using the splitting-step method* (5.7)–(5.8) *for different values of* γ. *The case* $\gamma = -1$ *is the solution of* (5.6) *with reflecting boundary conditions, while the case* $\gamma = 3/4$ *gets absorbed at zero at finite time (not shown in the logarithmic scale). Parameters are* $\mu = 0.1$, $\Delta t = 10^{-2}$.

This transition probability does not integrate to one because there is a finite probability that the trajectory gets absorbed at zero given by [4]:

$$\mathcal{P}[0|X_1(t)] = G\left(\frac{1}{2(1-\gamma)}, \frac{x_1(t)^{-2(1-\gamma)}}{2\sigma^2(1-\gamma)^2\Delta t}\right), \tag{5.12}$$

where $G(\nu, x)$ is the complementary Gamma function. For this equation, we know that trajectories of (5.7) get absorbed at zero with probability one while taking the limit $\Delta t \to \infty$. Actually, this is also the case for the solutions of (5.6) for $1/2 \le \gamma < 1$. This is counterintuitive since the mean $\mathbb{E}[X_1(t)]$ is constant for (5.7) or grows exponentially like $x_0 e^{\mu t}$ for (5.6). This intriguing feature of (5.6) hampers the numerical simulations of this process, and in fact only exact sampling of the probability transition density (5.11) and (5.12) correctly accounts for it at finite Δt.

While similar to (5.9), the transition probability density (5.11) cannot be sampled using the relationship to the CIR process, since the solution of $dX_1 = X_1^\gamma dW(t)$ has a finite probability to be absorbed at $X_1(t) = 0$. However, using the relationship $I_n(x) = I_{-n}(x)$, $n \in \mathbb{N}$, for the modified Bessel function, we have that if $1/[2(1-\gamma)] = n$, X_1 can be sampled from a noncentral χ^2 distribution with negative (integer) number of degrees of freedom (see the appendix):

$$X_1(t+\Delta t) = \left[(\gamma-1)^2\sigma^2\Delta t\, \chi'^2_d\left(\frac{X_1(t)^{2(1-\gamma)}}{\sigma^2(\gamma-1)^2\Delta t}\right)\right]^{\frac{1}{2(1-\gamma)}}, \tag{5.13}$$

where $d = 2 - 2n = 0, -2, -4, \ldots$, and then $\gamma = 1 - 1/2n = 1/2, 3/4, 5/6, \ldots$. In Figure 5.2 we show a typical path for the CEV process for $\gamma = 3/4$ ($d = -2$) in which we see that it gets absorbed at zero for finite time.

5.2.3. $\gamma < 1/2$, regular boundary. Now the boundary is attainable and, contrary to the previous case, a boundary condition should be provided. If we consider the simplest cases, namely, an absorbing or reflecting boundary condition, then the transition probability density is given by

$$\mathcal{P}_\pm[x_t|x_0] = \frac{x_t^{1/2-2\gamma}x_0^{1/2}}{\sigma^2|1-\gamma|}\exp\left[-\frac{x_0^{2(1-\gamma)}+x_t^{2(1-\gamma)}}{2\sigma^2(1-\gamma)^2 t}\right] I_{\pm\frac{1}{2|1-\gamma|}}\left[\frac{x_0^{1-\gamma}x_t^{1-\gamma}}{\sigma^2(1-\gamma)^2 t}\right], \tag{5.14}$$

where $\mathcal{P}_+$ corresponds to the absorbing case and $\mathcal{P}_-$ to the reflecting one. In the latter case, the relationship of the CEV and CIR processes can be exploited to sample the probability distribution (5.14), with the same result as in (5.10). Simulation of the CEV process in this case is shown in Figure 5.2. However, in the absorbing case, $\mathcal{P}_-$ cannot be sampled either by using the corresponding CIR process or by using [illegible] as in the previous case, since for $\gamma < 1/2$ we have that $1 < 1/[2(\gamma-1)] \leq 0$. Thus $\mathcal{P}_-$ should be sampled using rejection or transformation methods.

6. Measure valued diffusions / reaction-diffusion problems. During the last decade much attention has been devoted to stochastic spatial models of interacting and branching particles like the contact model, the voter model, and the normal and oriented percolation [45, 23, 7]. Despite its simplicity these models display interesting critical properties at high spatial dimensions and serve as universality classes for more complicated situations. While much analytical progress has been made in the study of these models, some of their properties must be understood by using numerical methods. In this respect, several efficient particle stochastic simulations have been proposed and studied. An alternative approach is to study the convergence of the particle process to a continuum measure value diffusion in which the system is described by the (stochastic) concentration of particles $u(x,t)$ at a given spatial location x. This accelerates the numerical simulations and also could help to identify the relevant dynamics at the coarse-grained dynamics. Useful representations of these measure-valued diffusions are the ones interpreted as solutions of a martingale problem in terms of stochastic PDEs (SPDEs). Despite its clear interpretation, this representation is not usually considered in numerical simulations. The reason for that is the inability of usual numerical methods to handle correctly the nonnegativity character and the Poissonian fluctuations of the concentration of particles close to $u = 0$ [34, 18]. In this respect, we will see that the splitting scheme provides a very efficient and accurate method to study these models.

6.1. Super-Brownian motion. The most simple and studied measured-valued diffusion is the super-Brownian motion (sBm). The sBm arises as the scaling limit in various critical branching systems when the interaction between them is weak, i.e., when the system is above some [illegible] [45]. Above this critical dimension we expect a Gaussian limit and indeed the sBm is the Gaussian limit of a number of models: the voter model above two dimensions, the contact process above four dimensions, oriented percolation above four dimensions, and percolation over six dimensions.

sBm can be studied analytically by using the log-Laplace transform that maps its dynamics into a nonlinear PDE, a result due to Dynkin [12]. More general situations or particular properties of the sBm can be reached only through numerical simulations. To our knowledge there is no numerical simulation of the martingale problem of the sBm so far. In one dimension, the martingale problem of the sBm is described by the SPDE

$$du(x,t) = \Delta u(x,t)\,dt + \sqrt{\sigma u(x,t)}\,dW(x,t), \tag{6.1}$$

where $W(x,t)$ is a Wiener sheet. It is well known that the solutions of the sBm die in finite time almost surely. Another interesting property is that the support of the solution, i.e., the set for which $u(x,t) > 0$, is compact, provided that the initial condition has a compact support. This compact support property is related to the absorbing nature of $u(x,t) = 0$. Thus it can only be recovered in the numerical

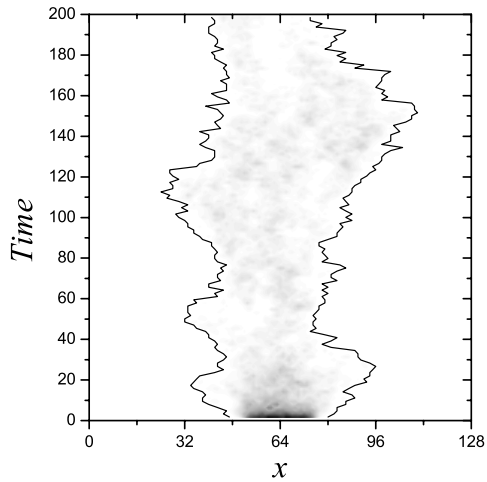

FIG. 6.1. *Realization of the sBm in one dimension. The figure shows density plots for $u(x,t)$ as a function of time with initial condition $u(x,0) = 0.1$. The solid line depicts the extremes of the support at each time. Parameters are $\Delta x = 1$, $\Delta t = 0.1$, and $\sigma = 1.0$ in an $L = 128$ lattice.*

approximations if the behavior of the boundary is incorporated. For example, the method of Gaines [18], while implementing the nonnegativity of the solutions, fails to reproduce the compact support property for the solutions of (6.1).

We use the splitting-step method for approximating the strong path solutions of (6.1). To this end we approximate the sBm by the superrandom walk on $\mathbb{Z}^d$ (see [7])

$$du_i(t) = \Delta_i u_i(t)\, dt + \sqrt{\frac{\sigma u_i(t)}{(\Delta x)^d}}\, dW_i(t), \tag{6.2}$$

where Δ_i is the discrete Laplacian operator

$$\Delta_i u = \frac{u_{i+1} - 2u_i + u_{i-1}}{(\Delta x)^2}$$

in $\mathbb{Z}^d$, Δx is the lattice spacing, and $W_i(t)$ are independent Wiener processes in time t. Equation (6.2) represents a model of interacting Feller diffusions. The splitting-step algorithm in this case is based on

$$du_i^{(1)}(t) = \sqrt{\frac{\sigma u_i^{(1)}(t)}{(\Delta x)^d}}\, dW_i(t), \quad du_i^{(2)}(t) = \Delta_i u_i^{(2)}, \tag{6.3}$$

where the first step is integrated using the transition probability (2.5) and its sampling (2.6). The second equation can be integrated using standard schemes. In Figure 6.1 we observe a simulation of the sBm in one dimension. Our method not only provides an accurate description in both the strong and weak sense of the sBm; it also incorporates one of its main properties, namely, the compact support property.

In two dimensions (6.1) is not well defined, but still we can study (6.2) in the lattice $\mathbb{Z}^2$. As our simulations show (see Figure 6.2), the compact support properties of sBm in two dimensions are preserved, and we also see the clusters' formation and their disappearance at large times.

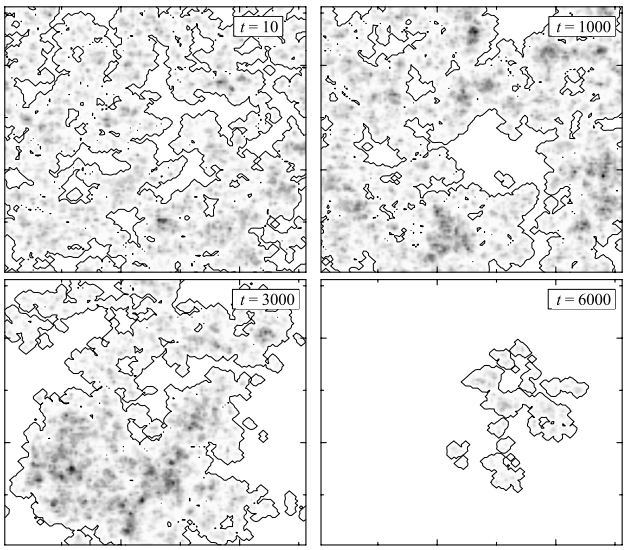

FIG. 6.2. *Strong path approximation of the sBm in two dimensions. The figures show density plots of $u(x,t)$ surrounded by the border of the support (solid line) at different times. The initial condition is $u(\vec{r},0) = 0.1$. Parameters are $\Delta x = 1$, $\Delta t = 0.1$ in a 256×256 lattice.*

6.2. Contact process. The contact process is a model of the spreading of infection in a lattice in which a site can be infected via contact with an infected site in its neighborhood [45]. Infection and recovery happen at different rates and there is a critical value of them for which an infection started from a single infected individual will die out in finite time. The contact process with a finite range of infection has a critical dimension $d_c = 4$. At higher dimensions the critical contact process converges to the sBm, but not below d_c. At lower dimensions, it is not known what the scaling limits should be.

However, long-range interaction with suitable scalings shows that the contact process converges to the sBm for $d \geq 2$; see [11]. In one dimension, Mueller and Tribe [35, 36] showed that the rescaled density of particles for the long-range contact process weakly converges to the solution of the SPDE

$$du(x,t) = [\Delta u(x,t) + \theta u(x,t) - u(x,t)^2]\, dt + \sqrt{u}\, dW(x,t), \tag{6.4}$$

where $W(x,t)$ denotes a space-time Wiener process. Moreover, they showed that the above equation undergoes a phase transition at a critical value of θ_c for which

$$\mathcal{P}(u(x,t) \text{ survives}) \begin{cases} = 0 & \text{if } \theta < \theta_c, \\ > 0 & \text{if } \theta > \theta_c. \end{cases} \tag{6.5}$$

The nontrivial behavior of the solution of (6.4) is believed to represent the well-known universality class for contact processes (also named the directed percolation universality class [23, 34]).

As before, numerical simulations of (6.4) can be now addressed using the splitting scheme and the efficient random number generators for the conditional probability [34]. In particular, we discretize the spatial operators in a lattice $\mathbb{Z}$ (as in (6.2)) and split the dynamics as follows:

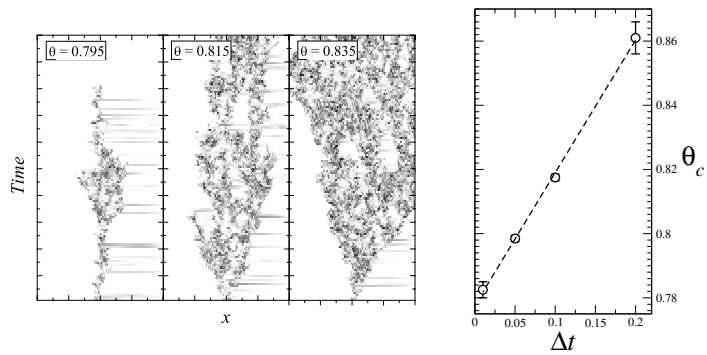

FIG. 6.3. *(Left) Strong path approximation of* (6.4) *for* $\Delta x = 1$ *and* $L = 2^{14}$ *and different values of* θ *below and above the phase transition. (Right) Critical value of* θ_c *as defined in* (6.5) *as a function of* Δt*. The straight line is a linear fit to the data. Parameters are* $\Delta x = 1$*,* $L = 2^{14}$*.*

$$du_i^{(1)} = \sqrt{u_i^{(1)}}\, dW(t), \quad du_i^{(2)} = [\Delta_i u_i^{(2)} + \theta u_i^{(2)} - (u_i^{(2)})^2]\, dt, \tag{6.6}$$

where the last equation is numerically integrated using Euler approximations with sufficiently small step sizes. Results for strong approximations of $u_i(t)$ are shown in Figure 6.3, where we can see a typical realization for the subcritical (infection dies out), critical, and supercritical (infection spreads) for different values of θ.

We can calculate the critical value of θ_c in one dimension using our algorithm. To this end, we identify the critical point θ_c using (6.5) and finite scaling techniques of statistical mechanics. In particular, we found that $\theta_c = 0.777 \pm 0.001$ for $\Delta x = 1$, and the convergence to this value is of order one.

7. Conclusion. The general idea of this paper is to propose a splitting of SDE (1.1) into two new SDEs for which one can keep nonnegativity during integration of both subsystems. This is achieved by either solving one subsystem exactly in the pathwise sense or using its transition probabilities, and solving the other (here nonrandom) subsystem by nonnegativity preserving numerical methods. In this way one is able to preserve nonnegativity and a maximum of convergence order 1.0 in both weak and strong sense. For the efficiency of our splitting algorithm, it is crucial to find a splitting into appropriate subsystems. For this purpose, one also tries to incorporate more complicated boundary conditions of the original SDE (1.1) into an explicitly solvable subsystem such that a fairly easier numerical integration of the remaining subsystem remains to be implemented. For example, for SDEs

$$dX(t) = [\alpha(X(t), t) + \lambda X(t)]\, dt + \sigma X(t)\, dW(t),$$

one makes use of the splitting into

$$dX_1(t) = \lambda X_1(t)\, dt + \sigma X_1(t)\, dW(t), \quad dX_2(t) = \alpha(X_2(t), t)\, dt,$$

where the explicit solution of the first component X_1 is given by

$$X_1(t) = X_1(0) \exp\left(\left(\lambda - \frac{1}{2}\sigma^2\right) t + \sigma W(t)\right),$$

which possesses the monotone property of leaving the positive axes $[0, +\infty)$ invariant by this type of random mapping (almost surely). This idea can be easily extended to

nonlinear systems of SDEs with its splitting into linear and nonlinear subsystems in several dimensions. Another type of splitting is found for nonlinear systems

$$dX(t) = f(X(t),t)\,dt + \sigma(X(t),t)\,dW(t) \tag{7.1}$$

with continuously differentiable coefficients σ as follows. Rewrite this equation as

$$dX(t) = \left[f(X(t),t) - \frac{1}{2}\sigma(X(t),t)\frac{\partial\sigma(X(t),t)}{\partial x} + \frac{1}{2}\sigma(X(t),t)\frac{\partial\sigma(X(t),t)}{\partial x}\right]dt + \sigma(X(t),t)\,dW(t)$$

and set

$$\alpha(x,t) = f(x,t) - \frac{1}{2}\sigma(x,t)\frac{\partial\sigma(x,t)}{\partial x}, \quad \beta(x,t) = \frac{1}{2}\sigma(x,t)\frac{\partial\sigma(x,t)}{\partial x}.$$

Then the splitting-step algorithm is applied to system (X_1, X_2) satisfying (2.2) and (2.3) with coefficients α and β as defined above. This works at least efficiently if $\sigma(x,t) = \sigma(x)$ does not depend on t and the invertible integral $H(z) = \int^z [b(z)]^{-1}\,dz$ exists on the domain of definition of the original equation (7.1) for X. In this case one finds $X_1(t) = H^{-1}(W(t) + H(X_1(0)))$.

Once an appropriate splitting is found then it is relatively easy to implement the related numerical algorithm. The proposed splitting-step method efficiently works since its implementation essentially relies on the well-known variation-of-parameters formula for perturbed dynamical systems which extends to SDEs. Recall that, by this formula, if the equation

$$dX(t) = \beta(X(t),t)\,dt + \sigma(X(t),t)\,dW(t)$$

has known fundamental solution $\Phi = \Phi(t, X_0)$ then the exact solution of the original equation (2.1) possesses the pathwise representation

$$\begin{aligned} X(t+\Delta t) &= \Phi(t+\Delta t, X(t)) + \Phi(t+\Delta t, X(t)) \int_t^{t+\Delta t} [\Phi(s, X(t))]^{-1}\alpha(X(s),s)\,ds \\ &\approx \Phi(t+\Delta t, X(t)) + \alpha(X(t),t)\Delta t \end{aligned}$$

on each subinterval $[t, t+\Delta t] \subset [0,T]$. Thus, the motivation of our splitting-step technique is apparent by finding Φ and numerical integration of $\int \alpha(X(s),s)\,ds$.

Final remark on applicability of our splitting algorithm. The applicability of our splitting algorithm heavily relies on the knowledge on the exact solution of SDEs. An extensive list of analytically known solutions is found in textbooks such as [27]. Of course, in one dimension one knows more about explicitly solvable SDEs. However, our technique is also applicable to multidimensional problems. For example, when noise terms are linear, decoupled, commutative, or diagonal, one can apply it successfully, too. In particular, the knowledge of explicitly solvable linear multidimensional stochastic subsystems from appropriately split systems can be exploited (see also Appendix C). So we are not exclusively restricted to one-dimensional problems (although we must admit that the range of highly efficient applicability may shrink with the increase of dimensions). A more detailed discussion on multidimensional extensions of splitting techniques is left to research in the future. We have deliberately chosen some well-known examples from the literature such that the interested

reader may easily compare the performance of his preferred numerical technique to our semianalytic numerical splitting technique.

Appendix A. Noncentral chi-square distribution random number generation. The splitting-step method proposed in this paper relies on the exact numerical sampling of transition probability density for some processes. In particular, efficient generation of random numbers $\chi'^2_d(\lambda)$ with a noncentral chi-square distribution with d degrees of freedom whose probability density function is found by

$$\mathcal{P}[\chi'^2_d(\lambda) = x] = p(x; d, \lambda) = \frac{e^{-(\lambda+x)/2}}{2} \left(\frac{x}{\lambda}\right)^{(d-2)/4} I_{(\nu-2)/2}(\sqrt{\lambda x}), \quad x > 0, \tag{A.1}$$

in [24]. This distribution is properly defined for any positive d and was extended to the case $d = 0$ by Siegel [44]. Here we shall extend it to the case $d = -2, -4, \ldots$ and show how to sample this distribution.

To this end, we use the fact that the distribution (A.1) can be expressed also as a mixture of central χ^2 variables with Poisson weights

$$p(x; d, \lambda) = \sum_{j=0}^{\infty} \frac{(\lambda/2)^j e^{-\lambda/2}}{j!}\, p_0(x; d + 2j), \quad d > 0, \tag{A.2}$$

where $p_0(x; d)$ is the distribution of a chi-square random variable χ^2_d with d degrees of freedom. This expression suggests a simple and efficient procedure to obtain $\chi'^2_d(\lambda)$ random variables:

1. Choose K from a Poisson distribution with mean $\lambda/2$ so that $\mathcal{P}[K = k] = e^{-k/2}(\lambda/2)^k/k!$ $(k = 0, 1, \ldots)$.
2. Then take $\chi'^2_d(\lambda) = \chi^2_{d+2K}$, which can be done using the any standard random number generator of the χ^2_d distribution.

In the $d = 0$ case, the $\chi'^2_d(\lambda)$ distribution has a discrete component at zero with mass $e^{\lambda/2}$ (which represents the probability to get absorbed at zero in our stochastic processes); see [44]. We have

$$p(x; 0, \lambda) = \sum_{j=1}^{\infty} \frac{(\lambda/2)^j e^{-\lambda/2}}{j!}\, p_0(x; 2j) + e^{-\lambda/2}\delta(x), \quad d = 0. \tag{A.3}$$

The procedure above can be modified to account for this discrete component by taking the convention that the central χ^2_d distribution is identically zero when $d = 0$. This convention can be extended to even negative dimensions to get

$$p(x; d, \lambda) = \sum_{j=|d|/2+1}^{\infty} \frac{(\lambda/2)^j e^{-\lambda/2}}{j!}\, p_0(x; d + 2j) + \delta(x) \sum_{j=0}^{|d|/2} \frac{(\lambda/2)^j e^{-\lambda/2}}{j!} \tag{A.4}$$

for $d = 0, -2, -4, \ldots$.

Summarizing, if K is a Poisson random number with mean $\lambda/2$ we have

$$\chi'^2_d(\lambda) = \chi^2_{d+2K}, \qquad d > 0, \tag{A.5}$$

and

$$\chi'^2_d(\lambda) = \begin{cases} 0 & \text{if } d + 2K \le 0, \\ \chi^2_{d+2K} & \text{if } d + 2K > 0, \end{cases} \qquad d = 0, -2, -4, \ldots. \tag{A.6}$$

This sampling of the probability distribution function is exact and should be used especially when λ is small. However, when λ is large, the $\chi'^2_d(\lambda)$ distribution asymptotically converges to the Gaussian distribution and other approximations (like the ones in [24]) might be considered to improve the speed of our algorithm.

Appendix B. Numerical generation of strong path solutions for some processes. The success of the splitting-step method requires the exact numerical integration of step 1 which can be problematic in some situations. That is why we have applied in previous numerical examples such equations which allow us to represent the solution from step 1 in terms of pure functions of the Wiener process and initial values such as $X(t) = F(X(0), W(t))$ or simple deterministic integrals as seen with the example of Bessel-type diffusions $X(t) = (\sqrt{X(0)} + W(t))^2$ or the geometric Brownian motion $X(t) = X(0)\exp((\alpha - \sigma^2/2)t + \sigma W(t))$. Also, for the Ornstein–Uhlenbeck processes or logistic equations, one may use the well-known integration-by-parts formula and / or the information on the exact distribution of involved stochastic integrals with deterministic differentials which can be pathwisely treated by deterministic quadrature methods. As another alternative, one could exploit the Doss representation (see [9]) to develop a semianalytic approach or an ODE-PDE approach to decompose the original problem into a random ODE and a deterministic PDE in order to figure out which numerical implementation is more efficient in conjunction with our splitting technique. However, in general one produces additional discretization errors which might influence the accuracy of the computations using the splitting algorithm as well. Then it is a must to consider its stability properties too. Such a fairly complex and very problem-dependent work is left to the future.

Appendix C. A general theorem on L^2-convergence based on the VOP. To exploit the specific knowledge on solvability of bilinear stochastic systems, once may also make use of the well-known variation-of-constants formula (VOP) (this formula is also sometimes called the variation-of-parameters formula). This possibility is justified through this section. For this purpose, suppose that the original equation is

$$dX(t) = [\alpha(X(t), t) + \beta(t)X(t)]\,dt + \sigma_2(X(t), t)\,dW_2(t) + \sigma_1(t)X(t)\,dW_1(t), \tag{C.1}$$

where W_1 and W_2 are independent Wiener processes. Consider the splitting

$$dX_1(t) = \beta(t)X_1(t)\,dt + \sigma_1(t)X_1(t)\,dW_1(t), \tag{C.2}$$

$$dX_2(t) = \alpha(X_2(t), t)\,dt + \sigma_2(X_2(t), t)\,dW_2(t) \tag{C.3}$$

with Borel-measurable real-valued matrices $\beta(t), \sigma_1(t) \in \mathbb{R}^{d\times d}$. Let $C^0_{locLip}(S)$ denote the vector space of local Lipschitz continuous functions on the open set S.

THEOREM C.1. [illegible] $\alpha, \sigma_2 \in C^0_{locLip}(\mathbb{D} \times [0,T])$ $\beta, \sigma_1 \in \mathbb{R}^{d\times d}$ [illegible] X [illegible] (C.1) $\bar{\mathbb{D}}$

$$\sup_{0\le t\le T} \mathbb{E}\left[|X(t)|^2\right] + \sup_{0\le t<T} \sup_{t\le s\le T} \mathbb{E}\left[|\Phi(s, X(t))|^2\right] < +\infty,$$

$$\sup_{0\le t\le T} \mathbb{E}\left[\int_t^T |[\Phi(s, X(t))]^{-1}\alpha(X(s), s)|^2\,ds + \int_t^T |[\Phi(s, X(t))]^{-1}\sigma_2(X(s), s)|^2\,ds\right] < +\infty$$

[illegible] $T > 0$ [illegible] Φ [illegible] (C.2) [illegible] $r_H \ge 0.5$ [illegible]

1 2 $r_1 \geq 1.0$ $r_2 \geq 0.5$ $\min(r_1, r_H + 1.0) \geq \min(r_2, r_H + 1.0) + 0.5$ 1 2

$$r_g \geq \min(1.0, \min(r_2, r_H + 1.0) - 0.5)$$

L^2 $[0,T]$. The VOP is needed for the proof. This formula for the perturbation of Itô-interpreted fundamental systems

$$dX(t) = A(t)X(t)\,dt + \sum_{j=1}^{m} B_j(t)X(t)\,dW_j(t) \tag{C.4}$$

with real-valued matrices $A(t)$ and $B(t) \in \mathbb{R}^{d\times d}$ by

$$dX(t) = [A(t)X(t) + f(t)]\,dt + \sum_{j=1}^{m}[B_j(t)X(t) + g_j(t)]\,dW_j(t) \tag{C.5}$$

with vector-valued random functions f and g_j can be found as Theorem 3.1 from Mao [30, pp. 96–97]. It says that systems (C.5) have the representation

$$\begin{aligned} X(s) = \Phi(s)\Bigg(X(t) + \int_t^s [\Phi(u)]^{-1}\left[f(u) - \sum_{j=1}^{m} B_j(u)g_j(u)\right]du \\ + \sum_{j=1}^{m}\int_t^s [\Phi(u)]^{-1} g_j(u)\,dW_j(u)\Bigg) \end{aligned} \tag{C.6}$$

in terms of the fundamental solution Φ related to linear system (C.4), where $s \geq t$. Thus, it heavily relies on the specific knowledge of properties of the flow Φ of underlying linear fundamental systems (C.4). Note that autonomous systems (C.4) with $m = 1$, constant matrices A, B, and commutativity condition $[A, B] = AB - BA = 0$ possess the explicit representation in terms of matrix exponentials (for $s \geq t$)

$$\Phi(s, X(t)) = \exp\left(\left(A - \frac{1}{2}B^2\right)(s-t) + B(W(s) - W(t))\right)X(t).$$

. Suppose that (C.2) has known fundamental solution $\Phi = \Phi(t, X_0)$ with a.s. Hölder exponent r_H. Then, following the VOP (C.6) (see the above remark), the exact solution of the original equation (C.1) possesses the pathwise representation

$$X(t+\Delta t) = \begin{cases} \Phi(t+\Delta t, X(t)) \\ + \Phi(t+\Delta t, X(t)) \displaystyle\int_t^{t+\Delta t} [\Phi(s, X(t))]^{-1}\alpha(X(s), s)\,ds \\ + \Phi(t+\Delta t, X(t)) \displaystyle\int_t^{t+\Delta t} [\Phi(s, X(t))]^{-1}\sigma_2(X(s), s)\,dW_2(s) \end{cases}$$

on each subinterval $[t, t+\Delta t] \subset [0, T]$. Note that formula (C.6) is applied with

$$\begin{gathered} A(s) = \beta(s), \quad B_1(s) = \sigma_1(s), \quad B_2(s) = 0, \\ f(s) = \alpha(X(s), s), \quad g_1(s) = 0, \quad g_2(s) = \sigma(X(s), s). \end{gathered}$$

Now, let $Y(t)$ denote the value of right-continuous numerical approximation of splitting step algorithm (which we always can construct using step functions in a standard way). The main idea is to apply the fairly general L^2-convergence theory known from [31, 41, 42, 43]. For this purpose, we need to study the local conditional accuracy of our algorithm. Locally, we may suppose that $X(t) = Y(t) = x$ is deterministic ($\mathcal{F}_t$-adapted). First, consider the local conditional mean accuracy. We find that

$$\begin{aligned}
&\left|\mathbb{E}\left[X(t+\Delta t) - Y(t+\Delta t)\middle|\mathcal{F}_t\right]\right| \\
&= \left|\mathbb{E}\left[\Phi(t+\Delta t,x)\int_t^{t+\Delta t}[\Phi(s,x)]^{-1}\alpha(X(s),s)\,ds\right.\right. \\
&\qquad \left.\left. + \Phi(t+\Delta t,x)\int_t^{t+\Delta t}[\Phi(s,x)]^{-1}\sigma_2(X(s),s)\,dW_2(s) - (Y(t+\Delta t)-x)\middle|\mathcal{F}_t\right]\right| \\
&\le \left|\mathbb{E}\left[\int_t^{t+\Delta t}\Big(\Phi(t+\Delta t,x)-\Phi(s,x)\Big)\,[\Phi(s,x)]^{-1}\alpha(X(s),s)\,ds\middle|\mathcal{F}_t\right]\right| \\
&\quad + \left|\mathbb{E}\left[\int_t^{t+\Delta t}\Big(\Phi(t+\Delta t,x)-\Phi(s,x)\Big)\,[\Phi(s,x)]^{-1}\sigma_2(X(s),s)\,dW_2(s)\middle|\mathcal{F}_t\right]\right| \\
&\quad + \left|\mathbb{E}\left[\int_t^{t+\Delta t}\alpha(X(s),s)\,ds + \int_t^{t+\Delta t}\sigma_2(X(s),s)\,dW_2(s) - (Y(t+\Delta t)-x)\middle|\mathcal{F}_t\right]\right| \\
&\le K_1[\Delta t]^{\min(r_1,(2r_H+1)/2+0.5)},
\end{aligned}$$

where K_1 is a real constant; hence the local conditional mean accuracy rate

$$\min(r_1,(2r_H+1)/2+0.5) = \min(r_1, r_H+1.0)$$

of the splitting algorithm can be verified. Second, consider the local conditional mean square accuracy of the splitting algorithm:

$$\begin{aligned}
&\Big(\mathbb{E}\left[|X(t+\Delta t) - Y(t+\Delta t)|^2\middle|\mathcal{F}_t\right]\Big)^{1/2} \\
&= \left(\mathbb{E}\left[\left|\Phi(t+\Delta t,x)\int_t^{t+\Delta t}[\Phi(s,x)]^{-1}\alpha(X(s),s)\,ds\right.\right.\right. \\
&\qquad \left.\left.\left. + \Phi(t+\Delta t,x)\int_t^{t+\Delta t}[\Phi(s,x)]^{-1}\sigma_2(X(s),s)\,dW_2(s) - (Y(t+\Delta t)-x)\right|^2\middle|\mathcal{F}_t\right]\right)^{1/2} \\
&\le \left(\mathbb{E}\left[\left|\int_t^{t+\Delta t}\Big(\Phi(t+\Delta t,x)-\Phi(s,x)\Big)\,[\Phi(s,x)]^{-1}\alpha(X(s),s)\,ds\right|^2\middle|\mathcal{F}_t\right]\right)^{1/2} \\
&\quad + \left(\mathbb{E}\left[\left|\int_t^{t+\Delta t}\Big(\Phi(t+\Delta t,x)-\Phi(s,x)\Big)\,[\Phi(s,x)]^{-1}\sigma_2(X(s),s)\,dW_2(s)\right|^2\middle|\mathcal{F}_t\right]\right)^{1/2} \\
&\quad + \left(\mathbb{E}\left[\left|\int_t^{t+\Delta t}\alpha(X(s),s)\,ds + \int_t^{t+\Delta t}\sigma_2(X(s),s)\,dW_2(s) - (Y(t+\Delta t)-x)\right|^2\middle|\mathcal{F}_t\right]\right)^{1/2} \\
&\le K_2[\Delta t]^{\min(r_2,(2r_H+1)/2+0.5)},
\end{aligned}$$

where K_2 is a real constant; hence the local conditional mean square accuracy rate

$$\min(r_2, (2r_H + 1)/2 + 0.5) = \min(r_2, r_H + 1.0)$$

of the splitting algorithm can be derived. Now, apply the general convergence theory from [31, 41, 42, 43] to conclude the worst case estimate of global mean square convergence rate r_g as stated in Theorem C.1 along nonrandom partitions of $[0, T]$. □

. Consider the Itô-interpreted example

$$dX(t) = (1 + X(t))\,dt + \sqrt{2}X(t)\,dW_1(t) + 2\sqrt{X(t)}\,dW_2(t). \tag{C.7}$$

Clearly, SDE (C.7) is of the form (C.1) with $\alpha(X,t) = 1$, $\beta(t) = 1$, $\sigma_2(X,t) = 2\sqrt{X(t)}$, and $\sigma_1(t) = \sqrt{2}$. Moreover, this example satisfies the assumptions of Theorem C.1 with $r_H = 0.5$. To see this fact, use the splitting into the subsystems

$$dX_1(t) = X_1(t)\,dt + \sqrt{2}X_1(t)\,dW_1(t), \tag{C.8}$$

$$dX_2(t) = dt + 2\sqrt{X_2(t)}\,dW_2(t). \tag{C.9}$$

The stochastic flows Φ_i related to linear (C.8) and nonlinear subsystems (C.9) are

$$\Phi_1(s,x) = \exp(\sqrt{2}W_1(s))x, \quad \Phi_2(s,x) = (\sqrt{x} + W_2(s))^2$$

as direct applications of Itô's formula. Besides, both flows have uniformly bounded moments of all orders for nonrandom initial data and they are mean square Hölder-continuous with exponent $r_H = 0.5$. For example, for the second subsystem (C.9), we have $\Phi_2(t, X(0)) - \Phi_2(s, X(0)) = 2\sqrt{X(0)}(W_2(t) - W_2(s))$ and

$$\mathbb{E}\,|\Phi_2(t, X(0)) - \Phi_2(s, X(0))|^2 = 2\,\mathbb{E}\,[X(0)]\,\mathbb{E}\,|W_2(t) - W_2(s)|^2 = 2\,\mathbb{E}\,[X(0)]\,|t - s|$$

provided that $X(0) \geq 0$ (a.s.) is independent of the processes W_2. Therefore, the related splitting-step algorithm can be applied and achieve a global L^2-convergence order $r_g = 1.0$ since the splitting-step integration has trivially at least local accuracy rates $r_1 = 2.0$ and $r_2 = 1.0$ thanks to the exact knowledge on the analytic expression of both subflows and the formula for r_g given by Theorem C.1. Moreover, the positivity-preserving character of such a splitting technique is obvious from the explicit formulas of subflows Φ_i. Similarly, we can proceed for other equations with $\sqrt{(.)}$- or other Hölder-continuous terms with Hölder exponent ≥ 0.5.

Acknowledgments. We are grateful to C. Doering and P. Smereka for comments and discussions. The authors would also like to thank the anonymous referees for numerous helpful comments.

A VARIATIONAL APPROACH TO VIDEO SEGMENTATION FOR BOTANICAL DATA*

AARON LUTTMAN† AND JOHN BARDSLEY‡

Abstract. In order to engage in photosynthesis, plant leaves absorb CO_2 via the opening of pores in their surfaces called *stomata*. Water evaporates through open stomata, however, which is a detriment to plant function. Thus a plant will seek a stomatal aperture that balances its need for CO_2 with its aversion to H_2O loss. In order to visualize a particular leaf's stomatal aperture, an experimentalist injects the leaf with dye so that it fluoresces. Regions with a higher relative intensity that do not correspond to veins in the leaf then correspond to areas in which the stomata are closed and the darker nonvein regions to areas in which the stomata are open. A camera is used to collect the emitted light, and a fluorescence pattern is measured. Images are continually recorded as these patterns change with time, resulting in a video sequence. The goal of this paper is to segment one such video sequence into fluorescing and nonfluorescing regions. After preprocessing the video, we take a variational approach to the segmentation problem and solve the associated three-dimensional evolution equation using a semi-implicit numerical scheme. A fixed-point formulation of the method is presented as are results of the segmentation for actual leaf data.

Key words. image segmentation, shape reconstruction, variational methods

1. Introduction. A plant's leaves have pores on their surfaces called [illegible] that occur at densities of tens to hundreds per mm^2 [28]. Carbon dioxide (CO_2), which is used in photosynthetic energy storage, is absorbed when the stomata are open, and, in general, the more open the pores are, the more CO_2 is absorbed. When the stomata are opened, however, water is lost through evaporation, which is detrimental to plant function. Thus, in response to external conditions, the stomatal apertures in a leaf must be regulated in such a way that the plant's need to absorb CO_2 is balanced with its aversion to losing H_2O. Peak, et al. [28] make the following statement regarding this process: "A central paradigm of plant biology is that, in the face of spatially heterogeneous and temporally varying environmental conditions, a plant continually adjusts its stomatal aperture so that, over time, it maximizes CO_2 uptake for a fixed amount of water loss." Moreover, it is thought that this optimization occurs over the entire leaf rather than for each stoma individually. It is not yet understood how plants solve this global optimization problem, but it has been hypothesized (cf. [28]) that the stomatal aperture depends on external environmental conditions as well as on interactions between neighboring stomata. The latter claim is somewhat controversial among plant biologists, and its primary motivation is the observation—made in over 200 plant species—that, even under spatially varying environmental conditions, stomatal apertures are often synchronized into spatially extended patches. This behavior is observed even though patchiness often results in less than optimal

local CO_2 uptake for fixed water loss. At this point it is not known how, or even if, neighboring stomata communicate, but it is believed that a study of stomatal patch dynamics in particular leaves may provide insight into this phenomena.

In order to study stomatal patch dynamics, this phenomenon must be observed in a particular leaf. The data analyzed in this paper was collected by the [illegible] research lab at Utah State University [28]. A cocklebur ([illegible]) leaf is placed in a light-penetrating chamber so that the temperature is controlled and gasses can be independently regulated and measured both on the top and bottom surfaces of the leaf. A dye is injected into the leaf that fluoresces when the stomata close, and stomatal dynamics are initiated by decreasing the concentration of H_2O on the upper surface of the leaf. This causes the stomata to close, since a decrease in environmental humidity causes an increase in H_2O loss through evaporation. This results in increased fluorescence, which is measured by a charge-coupled device (CCD) camera. Each image captured by the camera consists of a 512×512 array of pixels. Regions of high relative intensity correspond to areas in which the stomata are closed, whereas regions of low relative intensity correspond to areas in which the stomata are open. The images in the sequence were collected every 40 seconds over a period of several hours. (For more details on the data collection procedure and chlorophyll fluorescence, see [14, 25, 28].) Four sample images from the video sequence analyzed in this paper are shown in Figure 1.1.

In frames 150, 275, and 400, the light (closed stomata) and dark (open stomata) patches are evident. Our task in this paper is to provide a binary segmentation of the video into these light and dark regions. From such a segmentation, a study of patch dynamics can then be performed.

The first step in processing the data is denoising each of the images in the video sequence. For this we use the PDE-based denoising method of Rudin–Osher–Fatemi [30], with L^1-fidelity as proposed by Chan and Esedoglu in [8]. We choose this method because it is effective at denoising an image without degrading its inherent structure. It is necessary to use such a method so that resolution is not lost in the images, particularly at the boundaries of the stomatal patches and veins, which correspond to the darkest regions in the images of Figure 1.1. Additional noise enters the problem in the form of global lighting changes that occur during the data collection experiment, so the data must also be scaled and normalized against such effects.

Having preprocessed the video data, our final task is to extract the stomatal patches from the video sequence by segmenting the video into the fluorescing and nonfluorescing regions. To do this, we take a variational approach inspired by the methods found in [10, 11, 18, 19]. In contrast to these methods, our segmentation is computed in three dimensions (over the entire video sequence) and segments based on contrast to an [illegible] background model generated from the experiment. We perform the segmentation in three dimensions, because the algorithm is then able to globally compare the changes between the video sequence and the background model. When each frame is considered individually, no such comparison is possible, and, as a result, differences between the images and the background model tend to be overemphasized in frames with little or no dynamics. Such frames occur in the early stages of the video analyzed here. Other standard segmentation approaches include threshold-based methods [31], edge-based methods [3, 4, 17], region-based methods [16, 27], and hybrid techniques [35, 39] that combine several approaches. The reason that such approaches fail for our problem is that vein and nonvein regions fluoresce differently. In particular, the standard methods tend to either ignore the veins, by incorporating them in a background model which is subtracted off, or overemphasize the veins

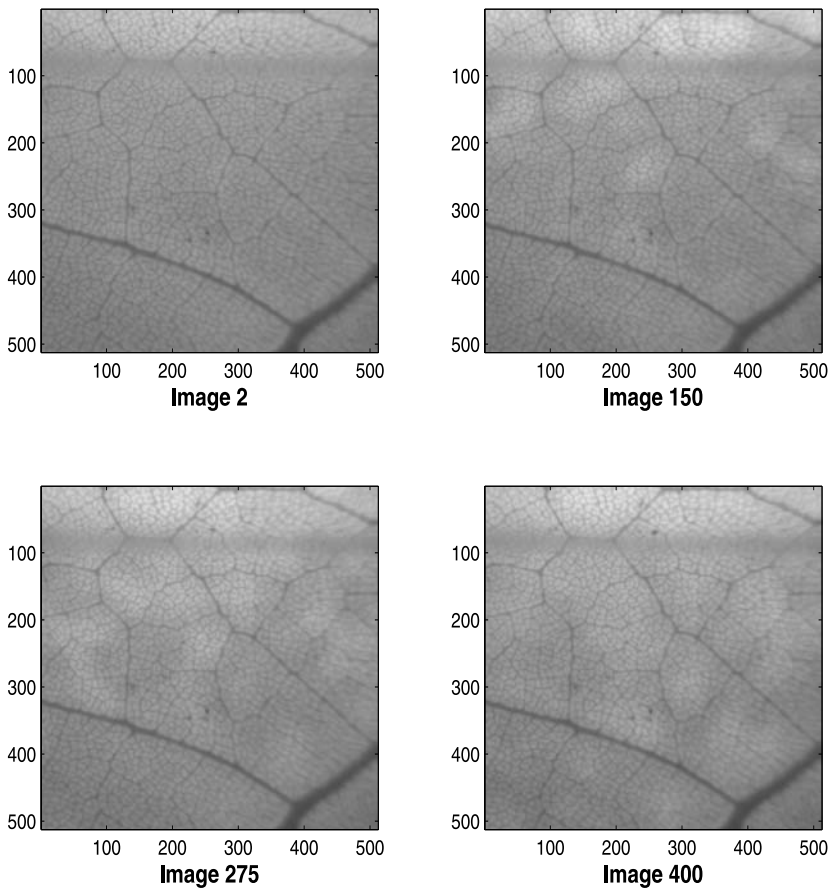

FIG. 1.1. *Four* 512×512 *images from the video sequence of* 436 *frames.*

by applying the same segmentation standard to the vein pixels as the nonvein pixels. The algorithm used here incorporates both the measured data and a static background model into the segmentation, so that the veins are neither ignored nor overemphasized.

The video preprocessing is discussed in section 2. In section 3, we present the variational segmentation method. The numerical implementation of the method is detailed, we present our results in section 4, and conclusions are given in section 5.

2. Data preprocessing. Before segmentation, it is necessary to remove noise from each frame of the video, and two such types of noise will be accounted for. The first is the noise incurred during image formation due to the CCD camera instrumentation. This noise is high frequency and will be removed using the method discussed in section 2.1. In section 2.2 we discuss removal of lower frequency noise due to global lighting changes that occurred during the data collection experiment.

2.1. Denoising. The images in the video sequence of interest are formed via the counting of photons by a mechanism in each pixel of the camera's CCD array.

The imprecision of this counting process together with stochastic instrumental errors results in collected images that are noisy. (For more details on CCD camera noise statistics, see [33].) Instrumentation noise is high frequency and can be removed using a wide array of denoising methods. Due to the fact that the images in the video have edges at the vein boundaries, the method chosen must preserve edges. Several methods of this type have recently been developed [6,12,29], and one of the most popular choices is that of Rudin, Osher, and Fatemi (ROF) [30], which seeks to minimize the sum of the total variation of the digital signal and an L^2 data-fidelity term. The popularity of ROF is due to the fact that the approach is effective, and computationally efficient algorithms exist for its solution [7, 9, 36]. It has been noticed, however, that if an L^1-fidelity is used instead, as is done in [8], less degradation occurs in the structure of the denoised images (see [2] and the references therein). Moreover, the L^1 denoising technique is completely contrast invariant. Since our images are highly structured at multiple contrast scales, we take this approach, minimizing the total variation regularized L^1-fidelity functional using the gradient descent method of [8]. Although we are able to obtain satisfactory results in a computationally feasible manner using this algorithm, it was pointed out to us by the referees that the numerical approach of [8] is typically very slow to converge and that a faster method is presented [2].

Let $I_0(\vec{x})$, where $\vec{x} = (x, y)$, be the input image corresponding to a single frame of the video sequence. Then the denoising corresponds to computing a minimum of the energy functional

$$E(I) = \int_\Omega |\nabla I| \, d\vec{x} + \lambda \int_\Omega |I_0 - I| \, d\vec{x}, \tag{2.1}$$

where $\lambda > 0$ is the regularization parameter and $\Omega \subset \mathbb{R}^2$ is the image domain. The first term on the right-hand side of (2.1) is the [illegible] of I which acts as a local smoothing operator, and the second term is the fidelity term which ensures that the resulting I approximates the input image I_0 in L^1. The minimization cannot be performed directly due to numerical instability, so a differentiable approximation of the functional, given by

$$E(I) = \int_\Omega \sqrt{(\nabla I)^2 + \delta} \, d\vec{x} + \lambda \int_\Omega \sqrt{(I_0 - I)^2 + \epsilon} \, d\vec{x}, \tag{2.2}$$

with parameters δ and ϵ small and positive, is minimized instead (see [11]). The minimization procedure is performed using the gradient descent method for (2.2), which involves evolving the image $I(\vec{x}; t)$ according to

$$I_t = \operatorname{div}\left(\frac{\nabla I}{|\nabla I| + \delta}\right) + \lambda \frac{I_0 - I}{\left((I_0 - I)^2 + \epsilon\right)^{1/2}}, \qquad I_0(\vec{x}) = I(\vec{x}, 0), \tag{2.3}$$

where t is an artificial time parameter. This is done for each frame in the video sequence.

Total-variation regularization is used for image denoising when it is assumed that the image has jump discontinuities. The total-variation penalization strengthens jump discontinuities, which, for our data, means that the veins are enhanced. Enhancing the veins is good, because that will improve our background model for vein pixels and also make the edges along the vein boundaries sharper. Jump discontinuities in our data along the time dimension are experimental artifacts caused by global lighting

changes between frames (recall that the frames are generated every 40 seconds). These artifacts must be removed, so applying the denoising algorithm to the data in 3D would not be appropriate, as this would enhance these experimental artifacts. This is the motivation behind denoising each image in the video sequence individually. Our method for removing these global lighting artifacts is discussed in the next section.

2.2. Median-change normalization. After denoising, the video data must be normalized against global lighting effects. The leaf experiments run over several hours, and there are large-scale, global lighting changes that must be accounted for. We make the following assumption, which is reasonable for our data: the number of pixels that have increasing intensity due to fluorescence dynamics at any given time is less than half of the total number of pixels, and likewise less than half of all pixels demonstrate a decrease in intensity due to dynamics. Given that this assumption is correct, the median intensity changes from one frame to the next are primarily due to global effects. Thus we normalize each frame in the video sequence by subtracting off the median intensity change. If $I(\vec{x}, n)$ represents the nth image in the video sequence, then we replace $I(\vec{x}, n)$ by $I^*(\vec{x}, n)$, where

$$I^*(\vec{x}, n) = I(\vec{x}, n) - \underset{\vec{x}}{\text{median}} \left(I(\vec{x}, n) - I^*(\vec{x}, n-1) \right),$$

with $I^*(\vec{x}, 1) = I(\vec{x}, 1)$. Note that this is not equivalent to simply normalizing each image to have the same median value. Lastly, the video sequence is linearly scaled so that the intensity values in the sequence take up the full range $[0, 255]$.

The preprocessed images corresponding to the original images in Figure 1.1 are given in Figure 2.1. In these images, the fluorescing stomatal patches are much clearer. Furthermore, it is evident that the patches on the leaf change in time, as a large portion of the image in frame 400 is quite bright whereas essentially all of frame 2 is much darker. The goal is to extract the bright regions from each frame in order to determine the evolution of the fluorescence patterns over time. Our method for this segmentation step is presented in the next section.

3. Variational segmentation of the leaf data. Let $\vec{x} = (x, y, z)$ be the coordinates of the video sequence, with x and y denoting pixel coordinates within each frame and z corresponding to frame number. We define $I(\vec{x})$ to be the preprocessed video sequence, and let $D(\vec{x}) = |I(\vec{x}) - B(x, y)|$, where B is a static background model generated using a sequence of frames from the beginning of the video. The value of $B(x, y)$ at pixel (x, y) is taken to be the mean intensity of $I(x, y, z)$ for values of z corresponding to these early frames (the first 40 frames are used for the data analyzed here). The early frames in this video sequence contain no noticeable dynamics, so the background model contains no bright regions. Thus any bright regions that occur in later frames are in contrast to the background model, except at the veins, which do not fluoresce and remain dark even when they are within a bright region.

We define $\Omega \subset \mathbb{R}^3$ to be the (open) domain of D and characterize all possible segmentations of the video sequence by piecewise-constant functions u on Ω that take on two distinct values, c_1 and c_2, such that the sets $\Omega_1 = \{\vec{x} \in \Omega \mid u(\vec{x}) = c_1\}$ and $\Omega_2 = \{\vec{x} \in \Omega \mid u(\vec{x}) = c_2\}$ have piecewise-smooth boundaries of finite surface area. From any such u, a natural segmentation of the video results; namely, Ω_1 corresponds to the bright regions and Ω_2 to the dark regions of the image, or vice versa.

3.1. The segmentation functional. We assume that the optimal segmentation of the video is given by the function u, together with values c_1 and c_2, that minimize

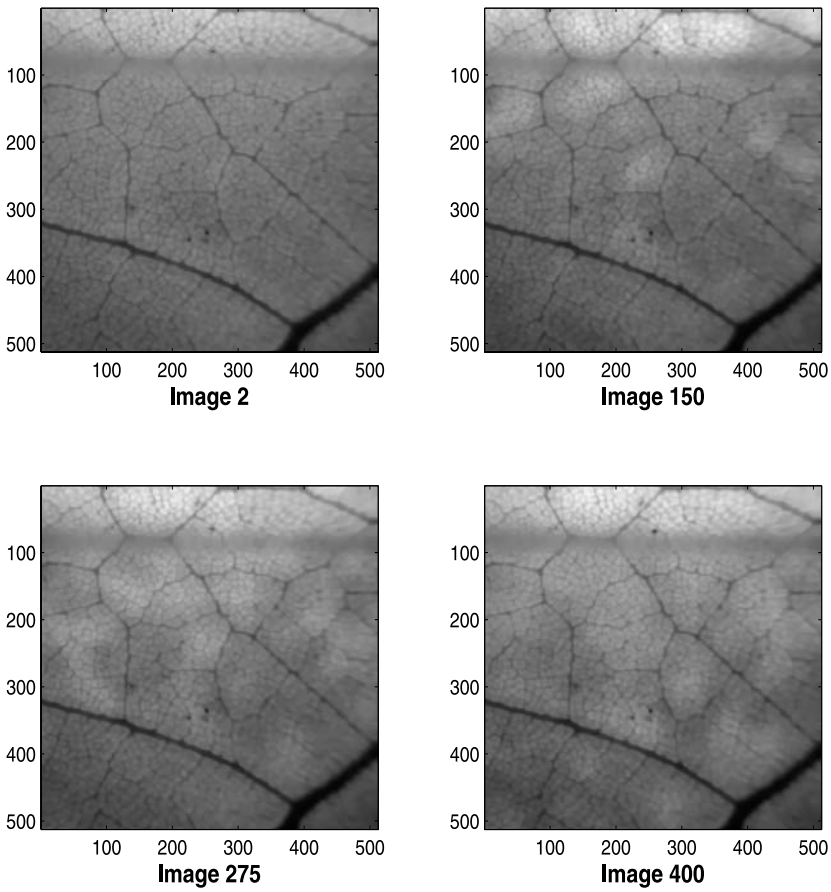

FIG. 2.1. *Images* 2, 150, 275, *and* 400 *after preprocessing.*

the squared L^2 norm of the difference between D and u, i.e.,

$$E(u, c_1, c_2) = \|D(\vec{x}) - u(\vec{x})\|^2_{L^2(\Omega)} = \int_{\Omega_1} (D(\vec{x}) - c_1)^2 \, d\vec{x} + \int_{\Omega_2} (D(\vec{x}) - c_2)^2 \, d\vec{x}. \tag{3.1}$$

Following Kimmel in [18, 19], we reduce E by computing the optimal values of c_1 and c_2 for fixed Ω_1 and Ω_2. Assuming that u and c_2 are fixed, the minimizer of $E(u, c_1, c_2)$ occurs where its derivative with respect to c_1 is zero. Since

$$\begin{aligned} E(u, c_1, c_2) &= \int_{\Omega_1} (D(\vec{x}) - c_1)^2 \, d\vec{x} + \int_{\Omega_2} (D(\vec{x}) - c_2)^2 \, d\vec{x}, \\ &= \int_{\Omega_1} D(\vec{x}) \, d\vec{x} - 2c_1 \int_{\Omega_1} D(\vec{x}) \, d\vec{x} + c_1^2 \int_{\Omega_1} d\vec{x} + \int_{\Omega_2} (D(\vec{x}) - c_2)^2 \, d\vec{x}, \end{aligned}$$

and u and c_2 are assumed fixed, it is readily seen that the derivative of E with respect to c_1 is zero when

$$c_1 = \int_{\Omega_1} D(\vec{x})\, d\vec{x} \Big/ \int_{\Omega_1} d\vec{x}\,, \tag{3.2}$$

which is the mean value of D on Ω_1. Note that E is bounded below with respect to c_1 but not from above. Thus, since (3.2) corresponds to the only local extremum of E, it must be a global minimum with respect to c_1 for fixed c_2 and u. A similar argument shows that, for fixed c_1 and u, the minimizing value of c_2 is the mean value of D on Ω_2,

$$c_2 = \int_{\Omega_2} D(\vec{x})\, d\vec{x} \Big/ \int_{\Omega_2} d\vec{x}. \tag{3.3}$$

In what follows, we will use c_1 to denote (3.2) and c_2 to denote (3.3). The resulting functional E then depends explicitly only on u.

Computing a minimizer of E analytically on the set of piecewise-constant functions u taking on exactly two values is not possible; hence, a numerical approach must be taken. This can be done efficiently if we recast the minimization problem as an evolution equation.

3.2. Formulating the segmentation problem as an evolution equation. For each function u of the type discussed above, there exists a Lipschitz continuous level set function $\Phi\colon \Omega \to \mathbb{R}$ satisfying

$$\Omega_1 = \{\vec{x} \in \Omega \mid u(\vec{x}) = c_1\} = \{\vec{x} \in \Omega \mid \Phi(\vec{x}) < 0\}, \tag{3.4}$$

$$\Omega_2 = \{\vec{x} \in \Omega \mid u(\vec{x}) = c_2\} = \{\vec{x} \in \Omega \mid \Phi(\vec{x}) > 0\}, \tag{3.5}$$

where set equality is always assumed to be up to a set of Lebesgue measure zero. Such a function Φ is called a level set representation for u, and, though level set representations of u are not unique, each particular Φ yields a unique segmentation of the video sequence via (3.4) and (3.5). Then (3.1) can be rewritten as

$$E(\Phi) = \int_{\Omega} |D - c_1|^2 \,(1 - H(\Phi)) + |D - c_2|^2 H(\Phi)\, d\vec{x}, \tag{3.6}$$

where H is the Heaviside function, i.e., $H(\Phi)$ is 1 for $\Phi > 0$ and is 0 for $\Phi \leq 0$. This is the model proposed in [11], and it is based on the variational segmentation algorithm first developed by Mumford and Shah [26].

In order to obtain efficient numerical methods for minimizing (3.6), we seek to recast this problem as an evolution equation of the form

$$\frac{\partial \Phi}{\partial t} = F(\Phi), \tag{3.7}$$

with initial condition $\Phi(\vec{x}; 0) = \Phi_0(\vec{x})$. The function F dictates the deformation of Φ in time and is chosen so that the steady-state solution of (3.7) corresponds to a solution of the Euler–Lagrange equation

$$\frac{\delta E}{\delta \Phi} = 0, \tag{3.8}$$

where $\delta/\delta\Phi$ denotes the variational derivative. Recalling that the distributional derivative of $H(\Phi)$ is the Dirac delta distribution $\delta(\Phi)$, a straightforward calculation yields

$$\frac{\delta E(\Phi)}{\delta \Phi} = -2\left((c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right)\right)\delta(\Phi). \tag{3.9}$$

The standard approach taken in the literature is to approximately solve (3.8) by numerically solving the gradient descent evolution equation

$$\frac{\partial \Phi}{\partial t} = (c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right)\delta(\Phi). \tag{3.10}$$

However, we note that (3.8)–(3.9) is satisfied if

$$(c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right) = 0, \tag{3.11}$$

which leads, instead, to the simplified evolution equation

$$\frac{\partial \Phi}{\partial t} = (c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right). \tag{3.12}$$

To see that (3.12) is a minimization scheme for (3.6), we note that $E(\Phi(\vec{x};t))$ is a nonincreasing function in t provided the variational derivative of E with respect to t, given by

$$\frac{\delta E(\Phi(\vec{x};t))}{\delta t} = \frac{\delta E(\Phi(\vec{x};t))}{\delta \Phi}\frac{\partial \Phi(\vec{x};t)}{\partial t},$$

is nonpositive. A straightforward calculation shows that this is satisfied by both (3.10) and (3.12).

We note that in [11] and related works, approximate solutions of (3.10) are sought, requiring an approximation of the $\delta(\Phi)$ term. In [40], for example, a computationally feasible problem is obtained by replacing $\delta(\Phi)$ with $|\nabla\Phi|$; whereas in [1, 11, 20], $\delta(\Phi)$ is approximated by a piecewise smooth function. Our own numerical experiments suggest, however, that although these approaches can be effective, adequate segmentations and dramatically less computationally intensive algorithms result if (3.12) is used instead. We also note the fact that with the "approximation" $\delta(\Phi) = 1$, (3.10) becomes (3.12).

3.3. Regularizing the segmentation algorithm. There is no guarantee that a solution Φ of (3.12) will yield a segmentation (3.4)–(3.5) in which the boundary of Ω_1 is piecewise-smooth and of finite surface area. To ensure that our solutions have this property, a regularization functional is added to the segmentation functional (3.6). Following Kimmel [18], we begin with the geodesic active contour [5] functional given by

$$E_{\text{reg}}(\Phi) = \oint_{\partial\Omega_1} g \, dS,$$

where $\partial\Omega_1$ denotes the boundary of Ω_1 and g is an edge-indicator function for each image in the video sequence. This corresponds to the regularization used in [11] if $g \equiv 1$. We use, instead, the standard edge indicator function,

$$g(x,y) = \frac{1}{1 + |\nabla I(x,y)|^2}, \tag{3.13}$$

evaluated in each image individually. Note that edges are two-dimensional features, a fact that requires g be evaluated in two dimensions rather than in three dimensions. Moreover, this particular regularization allows us to incorporate edge information directly into the segmentation functional. Using $g = 1$, as is done in [11], does not allow edges of different strengths to be weighted differently. All edges are either enhanced or flattened according to the value of the regularization parameter. Using the edge-indicator function in (3.13), however, allows the segmentation functional to treat edges of different strengths differently, according to the weighting factor determined by g. Thus some edges will be enhanced greatly, some a little bit, some not at all, and some will be flattened. Since determining the impact of the leaf veins on stomatal dynamics is of particular interest, and edges in the data correspond to vein boundaries, this yields a measurement, based on vein size, of the effect of the veins on the segmentation. Moreover, note that the fidelity functional acts on the background-subtracted data, but that g acts on the preprocessed data directly. Thus the regularization allows us to include this vein information directly into the segmentation algorithm, where other segmentation methods that act on background-subtracted data do not.

In order to incorporate the regularization functional into the level set PDE (3.12), it is necessary to compute its variational derivative with respect to Φ, which is (see [5])

$$\frac{\delta E_{\text{reg}}(\Phi)}{\delta \Phi} = -\text{div}\left(g\frac{\nabla\Phi}{|\nabla\Phi|}\right)|\nabla\Phi|. \tag{3.14}$$

In order to optimize computational efficiency (recall that we must numerically solve the evolution equation in three dimensions), we seek an approximation of (3.14) that does not require an evaluation of $|\nabla\Phi|$. Such an approximation can be obtained by appealing to the equality

$$\text{div}\left(g\frac{\nabla\Phi}{|\nabla\Phi|}\right)|\nabla\Phi| = \text{div}(g\nabla\Phi) - \frac{g}{|\nabla\Phi|}\nabla(|\nabla\Phi|).$$

In particular, rather than using the full geodesic active contour model for regularization, we use only the the diffusion term $\text{div}(g\nabla\Phi)$. This then yields the regularized analogue to (3.11), given by the nonlinear equation

$$\alpha\text{div}(g\nabla\Phi) + \beta(c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right) = 0 \tag{3.15}$$

and corresponding gradient descent evolution equation

$$\frac{\partial\Phi}{\partial t} = \alpha\text{div}(g\nabla\Phi) + \beta(c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right), \tag{3.16}$$

where α and β are weighting factors. Note that (3.16) has the form of (3.7), as desired.

4. Numerical methods and results. The most direct method of solving (3.16) is to use an explicit time discretization. This is not a practical approach for our problem, however, since the corresponding stability criterion is computationally prohibitive. Thus, rather than discretizing (3.16) explicitly, we follow Weickert, et al. [37, 38] and use the [illegible] time discretization

$$\Phi^{n+1} - \alpha\Delta t\text{div}\left(g\nabla\Phi^{n+1}\right) = \Phi^n + \Delta t\beta(c_2^n - c_1^n)\left(D - \frac{1}{2}(c_1^n + c_2^n)\right), \tag{4.1}$$

where c_1^n and c_2^n represent the values of c_1 and c_2 at the nth time step. Recall that c_1 and c_2 depend on Φ. This numerical scheme is called semi-implicit, or linear-implicit, because the regularization term is evaluated at the $n+1$ time step, whereas the fidelity term is evaluated at the nth time step. Scheme (4.1) can be rewritten as

$$(\mathcal{I} - \alpha\Delta t\,(A_x + A_y + A_z))\,\Phi^{n+1} = \Phi^n + \Delta t\beta(c_2^n - c_1^n)\left(D - \frac{1}{2}(c_1^n + c_2^n)\right), \tag{4.2}$$

where $A_s = \frac{\partial}{\partial s} g \frac{\partial}{\partial s}$ for $s \in \{x, y, z\}$ and $\mathcal{I}$ is the identity operator. It is shown in [38] that this discretization leads to a convergent, unconditionally stable numerical scheme.

The unconditional stability of (4.2) results in a relaxed restriction on the size of the time step, which is good for computational efficiency. The drawback is that a large linear system must be solved at every iteration. There are various methods for solving large linear systems of this type efficiently such as multigrid, multiplicative operator splitting (e.g., ADI or a locally one dimensional scheme such as in [18,19]), and Additive Operator Splitting (AOS) [37,38]. We use AOS, where the linear system (4.2) is approximately solved at each iteration using

$$\begin{aligned}&(\mathcal{I} - \alpha\Delta t(A_x + A_y + A_z))^{-1}\\ &\qquad \approx \frac{1}{3}\left(\mathcal{I} - 3\alpha\Delta t A_x\right)^{-1} + \frac{1}{3}\left(\mathcal{I} - 3\alpha\Delta t A_y\right)^{-1} + \frac{1}{3}\left(\mathcal{I} - 3\alpha\Delta t A_z\right)^{-1}.\end{aligned} \tag{4.3}$$

This operator splitting yields an $\mathcal{O}(\Delta t^2)$ approximation to the semi-implicit scheme as can be seen from the Taylor series expansions

$$\left(\mathcal{I} - \alpha\Delta t(A_x + A_y + A_z)\right)^{-1} v = v + \alpha\Delta t(A_x + A_y + A_z)v + \mathcal{O}(\Delta t^2),$$

and

$$\begin{aligned}&\frac{1}{3}(\mathcal{I} - 3\alpha\Delta t A_x)^{-1}v + \frac{1}{3}\left(\mathcal{I} - 3\alpha\Delta t A_y\right)^{-1} v + \frac{1}{3}\left(\mathcal{I} - 3\alpha\Delta t A_z\right)^{-1} v\\ &\qquad = \frac{1}{3}\left(v + 3\alpha\Delta t A_x v\right) + \frac{1}{3}\left(v + 3\alpha\Delta t A_y v\right) + \frac{1}{3}\left(v + 3\alpha\Delta t A_z v\right) + \mathcal{O}(\Delta t^2)\\ &\qquad = v + \alpha\Delta t(A_x + A_y + A_z)v + \mathcal{O}(\Delta t^2).\end{aligned}$$

Thus, since (4.2) is already an $\mathcal{O}(\Delta t^2)$ scheme, the global error does not change when AOS is used in its place.

Applying the AOS approximation to (4.2) yields

$$\Phi^{n+1} = \frac{1}{3}\sum_{s\in\{x,y,z\}} \left(\mathcal{I} - 3\alpha\Delta t A_s\right)^{-1}\left(\Phi^n + \Delta t\beta(c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right)\right). \tag{4.4}$$

Convergence and unconditional stability results for this scheme follow directly from the results found in [21, 22], which are obtained using operator semigroup theory. A straightforward proof of these facts is presented in [23] using only the Lax–Equivalence Theorem together with the fact that the eigenvalues of $(\mathcal{I} - 3\alpha\Delta t A_s)^{-1}$ are between 0 and 1 for $s \in \{x, y, z\}$.

In order to use (4.4), we discretize the A_s operators using a standard finite difference approximation (cf. [24, Chapter 6]) with spatial grid size $h = 1$ (the natural

pixel-frame discretization). The A_x approximation is given by

$$(A_x)_{i,j} = \begin{cases} (g_{k,j,l} + g_{k,i,l})/\,2, & j \in \{i+1, i-1\}, \\ -\sum\limits_{n \in \{i-1, i+1\}} (g_{k,n,l} + g_{k,i,l})\,/\,2, & j = i, \\ 0, & \text{otherwise}, \end{cases}$$

where k and l denote the row and frame number, respectively.

Similarly, the A_y approximation has the form

$$(A_y)_{i,j} = \begin{cases} (g_{j,k,l} + g_{i,k,l})/\,2, & j \in \{i+1, i-1\}, \\ -\sum\limits_{n \in \{i-1, i+1\}} (g_{n,k,l} + g_{i,k,l})\,/\,2, & j = i, \\ 0, & \text{otherwise}, \end{cases}$$

where k and l denote the column and frame number, respectively.

Finally, the A_z approximation is given by

$$(A_z)_{i,j} = \begin{cases} (g_{k,l,j} + g_{k,l,i})/\,2, & j \in \{i+1, i-1\}, \\ -\sum\limits_{n \in \{i-1, i+1\}} (g_{k,l,n} + g_{k,l,i})\,/\,2, & j = i, \\ 0, & \text{otherwise}, \end{cases}$$

where k and l denote the row and column number, respectively.

The A_x matrices are generated for every row in each frame; the A_y matrices are generated for every column in each frame; and the A_z matrices are generated for each pixel time series. The associated linear systems are small since each row and column has only 512 pixels, and the time series of each pixel has length 436. Each of these linear systems can be solved independently, and therefore in parallel, using appropriate boundary conditions. We use antireflective boundary conditions [32], which guarantee a C^1 extension of the signal at the boundary. Furthermore, since A_x, A_y, and A_z are tridiagonal and strictly diagonally dominant, the linear systems involving each can be solved efficiently using the well known Thomas algorithm—a special form of Gaussian elimination for tridiagonal systems. Thus, each step of (4.4) can be computed in a computationally efficient manner.

Finally, to further increase computational efficiency, the numerical scheme is implemented at multiple scales. We use a power-of-two pyramid scheme for computing the solution. In this approach, a solution is computed using a subset of the data that is downsampled by a power of 2 in each dimension. This solution is then upsampled to a larger subset of the data and used as an initial condition for the initial-value problem at that scale. The initial condition for the initial-value problem using the full data set is therefore a linearly interpolated version of the computed solution one scale down. In this way, an initial condition $\Phi(\vec{x}, 0)$ that well approximates the steady-state solution of (3.16) is obtained in a computationally efficient manner.

4.1. A fixed-point formulation of the segmentation algorithm. We now make note of the fact that iteration (4.2) can also be formulated as a fixed-point iteration for solving the nonlinear equation (3.15). Specifically, by multiplying (3.15) by Δt and then adding Φ to both sides of the equation, we see that (3.15) is equivalent to

$$(\mathcal{I} - \Delta t\alpha\,(\mathrm{div}(g\nabla)))\,\Phi = \Phi + \Delta t\beta(c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right).$$

If we evaluate the right-hand side of this equation at Φ^n and solve for Φ to obtain Φ^{n+1}, the resulting fixed-point iteration is given by (4.2).

The fixed-point iteration (4.2) can also be expressed in quasi-Newton form. To see this, we note that if we define

$$F(\Phi) = \Delta t\alpha \mathrm{div}(g\nabla\Phi) + \Delta t\beta(c_2 - c_1)\left(D - \frac{1}{2}(c_1 + c_2)\right), \tag{4.5}$$

(4.2) can be written

$$\Phi^{n+1} = \Phi^n - MF(\Phi^n), \tag{4.6}$$

where $M = (\Delta t\alpha\,(\mathrm{div}(g\nabla)) - \mathcal{I})^{-1}$. In our numerical implementation, however, (4.4) is used, which is equivalent to (4.6) with

$$M = \frac{1}{3}\sum_{s\in\{x,y,z\}} (\mathcal{I} - 3\alpha\Delta t A_s^n)^{-1} - \mathcal{I}. \tag{4.7}$$

Equation (4.6) can be viewed as a quasi-Newton method in which the operator M in (4.7) serves as an approximation of the inverse of the Jacobian of F at Φ in (4.5).

Formulation (4.6)–(4.7) of (4.2) allows us to make some observations regarding the convergence properties of this algorithm. First, we recall from above that (4.4) is convergent and unconditionally stable. Time-step size restrictions are therefore greatly relaxed when compared to the corresponding fully explicit formulation, which is given by (4.6) with $M = \mathcal{I}$. This fact, together with the quasi-Newton formulation (4.6)–(4.7), suggests that we can expect (4.4) to converge more rapidly than the fully explicit method. Our numerical experiments support this observation, though a more thorough convergence analysis is saved for a future work.

Before continuing, we make mention of a few other fast methods for minimizing the Chan–Vese segmentation functional: these include the hybrid k-means level set algorithm of [15], which reduces the segmentation problem to the solution of an ODE in order to speed up convergence; the fast algorithm of [34], which does not require the evaluation of the gradient of the segmentation functional (3.6); and the two-stage algorithm of [13], which requires the solution of a related PDE that allows for fast solutions.

4.2. Results. As was noted above, the algorithm is implemented in three dimensions. Because of this both computational and memory issues arise. In particular, although the data I and background model B can be stored as images using relatively small amounts of memory, and D can be computed directly from I and B, the level set function must be stored using floating point values at each node in the data array. For a video sequence of 436 images of 512×512 pixels, this requires almost a gigabyte of memory when floating point values are 64-bit. In addition, the computation is

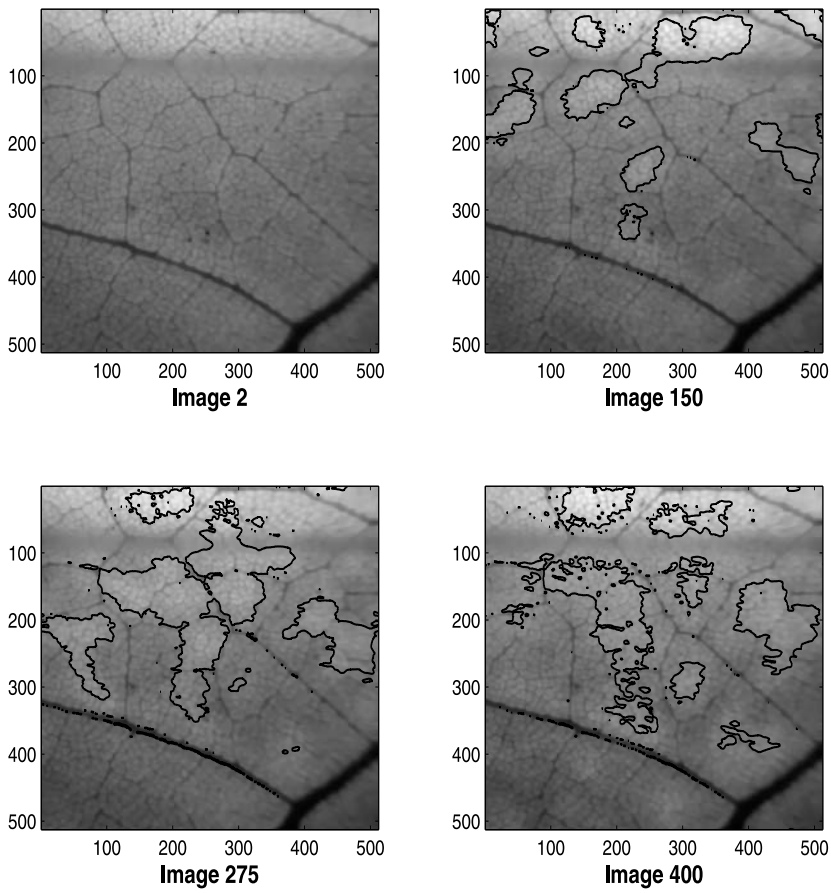

FIG. 4.1. *Segmented images* $2, 150, 275,$ *and* 400.

intensive due, primarily, to the large number of linear system backsolves required at each time iteration (708608 for this particular video sequence at the highest scale).

Our algorithm is implemented on an SGI Origin 2000 with 32 processors and 32 GB of shared memory and is fully parallelized using OpenMP. Though none of the individual processors on this machine is fast by current standards (300 Mhz), the large memory capacity and parallel capabilities make the machine suitable for this application. Though each iteration at the highest scale is quite slow, few iterations are required at the highest scale, since the approximate solution computed at the lower scales is already quite good.

Since the numerical scheme is unconditionally stable with respect to Δt, it is possible to choose Δt to be quite large. For the experiments shown in this work, $\Delta t = 0.5$, though it is also possible to start the algorithm with a larger value of Δt, decreasing it incrementally as the solution stabilizes. The ratio of the weighting factors α and β in (3.16) determines the amount of regularization used in the numerical

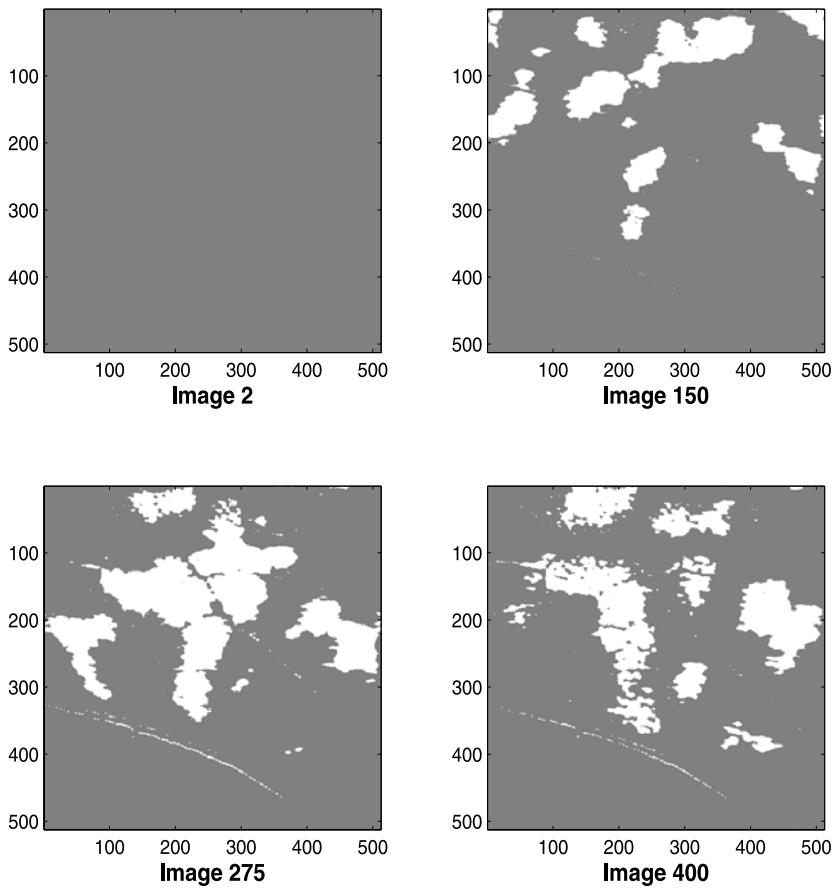

FIG. 4.2. *Binary segmentation for images* $2, 150, 275,$ *and* 400.

implementation, and for the examples shown here, $\alpha = 1$ and $\beta = 2$.

The last important detail of the numerical implementation is the initial surface from which we evolve our solution. For the examples shown here, the initial surface is a sphere contained completely inside the computational domain, and the initial level set representation of the surface, $\Phi(\vec{x}; 0)$, is defined to be the signed distance between $\vec{x}$ and the sphere boundary. The distance is taken to be negative inside the sphere and positive outside the sphere.

The segmented images can be seen in Figure 4.1[1]. Note that there is no segmentation in image 2. This is due to the fact that there are no dynamics in the early images of the video, and it is correctly captured because the algorithm is working on the full three-dimensional video sequence. When a two-dimensional version of the segmentation algorithm is applied to each individual frame, meaningless segmenta-

[1]The full videos of the original, preprocessed, and segmented data can be seen at http://hans.blc.edu/ luttman/.

tion artifacts are obtained in the early frames. This difference is due to the fact that in three-dimensions the algorithm is able to globally compare the changes between the video sequence and the background model, whereas, when each frame is considered individually, no such comparison is possible, resulting in differences between the images and the background model being overemphasized in frames with little-to-no dynamics.

The main goal in this project is to provide a binary segmentation of the video into light and dark regions, since, from such a segmentation, a study of two-dimensional patch dynamics can more easily be done. This is easily obtained from the results given in Figure 4.1 and can be seen in Figure 4.2. The regions of fluorescence are in white and the nonfluorescent regions are in gray.

5. Conclusions. The formation and dynamics of stomatal patches in plant leaves is a phenomenon that is not fully understood. In order to study this process, plant biologists collect video in which dynamically changing light and dark stomatal patches are evident. An in-depth study of the dynamics of these patches is desirable and requires a segmentation of such video into fluorescing (light) and nonfluorescing (dark) regions.

In this paper, we have presented an algorithm that provides such a segmentation for a video sequence with example frames given in Figure 1.1. The algorithm consists of several stages. First, due to experimental inconsistencies, the video in our example requires preprocessing. This is accomplished by first using a denoising algorithm for the removal of high frequency (instrumental) noise. The video is then normalized against global lighting changes, which removes low frequency (experiment specific) noise. Images from the preprocessed video are given in Figure 2.1.

The three-dimensional video segmentation is formulated as a variational inverse problem. Since the problem is ill-posed, a regularization term is added so that solutions of the corresponding minimization problem provide a sufficiently smooth segmentation of the video. The desired minimizer of the segmentation functional is computed via a time-continuous gradient descent method in the form of a three-dimensional evolution equation that is solved efficiently using a semi-implicit time discretization with additive operator splitting. A fixed-point formulation of the numerical scheme is also presented. Frames 2, 150, 275, and 400 of the segmented video are given in Figures 4.1 and 4.2.

Acknowledgments. The authors would like to thank Professor Emily Stone of the University of Montana for introducing us to this problem and for many helpful discussions regarding the leaf data and also Professors David Peak and Keith Mott of Utah State University for providing the leaf data and for helpful discussions regarding the current theories of stomatal patchiness. The authors would also like to thank the referees for their helpful comments and suggestions.

ERRATUM: A VARIATIONAL APPROACH TO VIDEO SEGMENTATION FOR BOTANICAL DATA*

AARON LUTTMAN† AND JOHN BARDSLEY‡

Abstract. In this erratum, we correct the previous explanation of the data-collection procedure as outlined in [*SIAM J. Sci. Comput.*, 29 (2007), pp. 1550–1566].

DOI. 10.1137/070700036

In [1], the authors incorrectly described the data-collection procedure for capturing the botanical fluorescence data.

- In the abstract, the sentence
  "In order to visualize a particular leaf's stomatal aperture, an experimentalist injects the leaf with a dye so that it fluoresces."

  should be reworded as

  "In order to visualize a particular leaf's stomatal aperture, fluorescence is induced corresponding to changes in average stomatal aperture size, and the data are collected at regular intervals."

- On page 2, in the first full paragraph, the sentence
  "A dye is injected into the leaf that fluoresces when the stomata close, and stomatal dynamics are initiated by decreasing the concentration of H_2O on the upper surface of the leaf."

  should be replaced with

  "Chlorophyll molecules in an intact leaf that are excited by visible light, upon deexcitation, dissipate part of the excitation energy as infrared fluorescence. Stomatal dynamics are then initiated by decreasing the concentration of H_2O on the upper surface of the leaf."

These changes reflect that the data-collection procedure used for the data in this work was updated, and the data actually shown in this work are derived from the updated procedure.

BOUNDARY CONDITIONS IN THE SCHUR COMPLEMENT PRECONDITIONING OF DISSIPATIVE ACOUSTIC EQUATIONS*

MIKA MALINEN†

Abstract. This paper is concerned with the development of robust and efficient iterative techniques for solving the coupled systems of linear equations which arise from a mixed finite element discretization of dissipative acoustic equations. The system of linearized, time-harmonic acoustic equations we consider is based on the Navier–Stokes, continuity, and energy equations accompanied by suitable equations of state. In this paper, we focus on the design of preconditioners that can be used in combination with the Krylov subspace methods. Our starting point is the Schur complement formulation of the mixed problem. One of the difficulties encountered with the approach we consider is generally associated with the issue of defining boundary conditions for the associated Schur complement problem. To derive suitable boundary conditions for this problem, we first consider an iterative solution method which is based on the direct use of the Schur complement formulation. This development naturally leads us to address the key question of what boundary conditions should be adjoined to the Schur complement preconditioner. We give numerical examples which demonstrate the effectiveness and robustness of the proposed preconditioner. The examples include both two- and three-dimensional problems with boundary conditions of various types.

1. Introduction.

In this paper we consider the development of robust and efficient iterative techniques for solving the coupled systems of linear equations which arise from a mixed finite element discretization of dissipative acoustic equations. The system of linearized acoustic equations we consider characterizes the flow of a viscous and thermally conducting fluid. This coupled model can be derived by starting from the Navier–Stokes, continuity, and energy equations accompanied by suitable equations of state. Here we limit our consideration to the time-harmonic analysis.

The full system of acoustic equations we consider has not customarily been used as a starting point for the development of numerical methods. The fact that for fluids of low viscosity and conductivity (for example, air) the dissipative effects of viscosity and heat conduction are pronounced only in a thin boundary layer adjacent to a solid boundary has motivated the use of simplified equations. These simplified models approximate the full system of equations for the region either next to the boundaries or outside the boundary layers (for an overview of simplified models see, for example, [1]). Our use of the full model has been motivated by a need for modeling the propagation of sound in small cavities, which nevertheless are so large that the boundary layer equations cannot be used to obtain a proper approximation throughout the entire cavity. Problems posed on regions of such size arise, for example, in the advanced design of mobile phones.

We note that in principle the use of the full model could be circumvented by incorporating the dissipative effects of viscosity and heat conduction into the boundary conditions on the solution mode which dominates in the region outside the boundary

layers [2]. Except for simple problems, such approximate boundary conditions are not directly available, but they should be found iteratively. One possible segregated solution strategy is outlined in [2]. We have found nevertheless that to find appropriate boundary conditions by using such a method is not straightforward, in particular for the range of frequencies near resonance. The avoidance of these difficulties has also motivated our direct start from the full system of acoustic field equations.

The wider range of applicability of the full model with the easiness of specifying suitable boundary conditions comes with the cost of the solution of a larger linear system that arises from the discretization. For most cases of practical interest the system of linear equations is so large that direct solution methods cannot be applied. Instead, iterative methods such as the Krylov subspace methods [3] have to be used. In this paper, we focus on the development of robust and efficient preconditioners that are required to obtain or improve the convergence of iterative methods.

One possible preconditioning strategy leading to preconditioners that are straightforward to implement would be to use the incomplete LU factorizations [4]. The drawback of the basic preconditioners based on this approach is that, when they are applied to the problem we consider, the use of a low level of fill may lead to slow convergence, while the memory usage grows rapidly as more fill is allowed. Often they also perform less advantageously when the discretization is refined. Experience gained from the solution of the systems of linear equations which arise from the approximation of related problems such as the Stokes and incompressible Navier–Stokes equations (see, for example, [5, 6]) indicates that more efficient preconditioning is possible by exploiting the structure of the systems. A preconditioning strategy we explore in this paper is based on the Schur complement approach leading us to considering preconditioners that have block-triangular structure [7].

In general, one of the key components for the design of Schur complement preconditioners is the development of an accurate and inexpensive way to approximate the action of the inverse of an associated Schur complement operator. Another central issue associated with the preconditioner design is the question of defining suitable boundary conditions for the approximation of the Schur complement operator [7, 6]. It seems that this question has not been fully explored. A more special feature of the problem considered is that the associated linear systems are complex-valued. The preconditioning of complex linear systems has been less investigated than the case of real linear systems.

Developing suitable boundary conditions for the Schur complement preconditioner will be the main subject of this paper. General mixed boundary conditions with the surface force prescribed on a part of the boundary are considered, as such boundary conditions are often met in acoustic analyses in the form of impedance boundary conditions. We note that the key principles we use here appear to be generally applicable, although the type of flow problem (such as incompressibility) can have an effect on the details of derivation in a particular case. The demonstration of these observations will be the subject of a further study.

The paper is structured as follows. In section 2 we introduce the system of acoustic equations we consider. It is noted that here we do not make the common assumption of a perfect gas but allow the consideration of more general fluids. Suitable equations of state are obtained by linearized versions of relations that characterize the fluctuations of the pressure and entropy about an equilibrium state. We then transform the system of field equations into a dimensionless form. This development is useful, not only

because it gives insight into the relative importance of various terms in the equations, but because it provides guidelines for constructing reliable finite element methods for the approximation of the system.

The construction of reliable finite element methods for the system of dissipative acoustic equations has already been considered in our previous work [8]. The mixed formulation which is used as a starting point for the finite element approximation is presented in section 3. In this paper, we do not discuss the discretization of the mixed problem in detail. It should be noted that the preconditioner we propose is flexible in the sense that it can be adapted to handle various discretizations which utilize different finite element spaces for the approximation of the velocity, temperature, and an auxiliary unknown introduced in connection with the mixed formulation.

The main development of this paper is contained in section 4, where the derivation of preconditioners is considered. By splitting the velocity solution to the flow problem into a rotational and an irrotational part, we first derive an alternative formulation for the mixed system of field equations. This formulation may be used to separate the solution of the temperature and auxiliary unknown from that of the velocity. By arranging the variables, the system may thus be written in the form of a block-triangular system with the matrix differential operator acting on the temperature and auxiliary unknown now being the exact Schur complement. In principle, this Schur complement formulation opens up a possibility for solving the acoustic problem. However, this approach involves a practical difficulty as the correct boundary conditions for the Schur complement are not generally available. Although the triangular system cannot be employed to directly obtain the solution, we show that this system supplemented by suitable boundary conditions can be used to develop preconditioners. The resulting preconditioner can be employed in combination with iteration methods that are applied directly to the linear system which result from the discretization of the boundary-value problem.

The results of numerical experiments are presented in section 5. The examples include both two- and three-dimensional problems with boundary conditions of various types. The results show that efficient preconditioning is possible, in particular when the proposed preconditioner is applied in combination with nested versions of iterative methods based on the minimal residual approach. The results indicate also that convergence rates are independent of the discretization mesh size. Finally, in section 6 we give a brief summary of the main conclusions and mention some open issues.

2. The mathematical model. In the following we consider a three-dimensional body Ω occupied by a fluid. We denote the outward unit normal vector to its boundary $\partial\Omega$ by $\mathbf{e}_n$ and let $\mathbf{e}_s$ and $\mathbf{e}_t$ be mutually orthogonal unit vectors tangential to the boundary. In addition, the velocity, density, pressure, and temperature fields associated with the fluid flow are denoted by $\mathbf{V}(\mathbf{x},t)$, $\rho(\mathbf{x},t)$, $p(\mathbf{x},t)$, and $T(\mathbf{x},t)$, respectively, with $\mathbf{x}$ and t being place and time. Notations ρ_0, p_0, and T_0 will be used for the values of the density, pressure, and temperature, respectively, at an equilibrium state.

2.1. The boundary-value problem. We consider the acoustic equations based on the linearized equation of motion, the constitutive equation relating the stress to the motion, the kinematic relation, the linearized continuity equation, and the

linearized energy equation:

$$
\begin{aligned}
\rho_0 \frac{\partial \mathbf{V}}{\partial t} &= \operatorname{div} \mathbf{T} + \rho_0 \mathbf{b}, \\
\mathbf{T} &= -p\mathbf{I} + \lambda(\operatorname{div} \mathbf{V})\mathbf{I} + 2\mu \mathbf{D}(\mathbf{V}), \\
\mathbf{D}(\mathbf{V}) &= \frac{1}{2}(\operatorname{grad} \mathbf{V} + \operatorname{grad} \mathbf{V}^T), \\
\frac{\partial \rho}{\partial t} &= -\rho_0 \operatorname{div} \mathbf{V}, \\
\rho_0 \frac{du}{dt} &= \kappa \operatorname{div} \operatorname{grad} T - p_0 \operatorname{div} \mathbf{V} + \rho_0 h.
\end{aligned} \tag{1}
$$

Here $\mathbf{T}$ and $\mathbf{I}$ are the stress and identity tensor, respectively, $\mathbf{b}$ is the body force (per unit mass), λ and μ are parameters characterizing the viscosity of the fluid, u is the specific internal energy, κ is the heat conductivity, and h is the internal supply of heat.

To supplement the system (1) by suitable equations of state, we assume that the properties of the medium are expressible as functions of two state variables, say, the temperature and density. We denote the specific entropy (entropy per unit mass) and its equilibrium value by s and s_0, respectively, and assume that the relation

$$
du = T_0 ds + (p_0/\rho_0^2) d\rho \tag{2}
$$

is valid. In addition, we approximate the equations which give the changes of pressure and specific entropy in terms of the changes of the state variables by (cf. [2, equation (6.4.21)])

$$
p - p_0 = \frac{(\gamma - 1)\rho_0 C_V}{T_0 \beta}(T - T_0) + \frac{(\gamma - 1)C_V}{T_0 \beta^2}(\rho - \rho_0) \tag{3}
$$

and

$$
s - s_0 = \frac{C_V}{T_0}(T - T_0) - \frac{C_V(\gamma - 1)}{T_0 \rho_0 \beta}(\rho - \rho_0), \tag{4}
$$

where C_V is the specific heat at constant volume (per unit mass), γ is the ratio of the specific heats at constant pressure and constant volume, and β is the coefficient of thermal expansion:

$$
\beta = -\frac{1}{\rho}\Big(\frac{\partial \rho}{\partial T}\Big)_p. \tag{5}
$$

We approximate the value of β by evaluating (5) for the equilibrium values of ρ and p.

We confine our consideration to the time-harmonic case, so that the solutions of the primary unknowns are assumed to be of the form

$$
\begin{aligned}
\mathbf{V}(\mathbf{x}, t) &= \mathbf{V}(\mathbf{x}) \exp(i\omega t), \\
\rho(\mathbf{x}, t) &= \rho_0 + \rho(\mathbf{x}) \exp(i\omega t), \\
T(\mathbf{x}, t) &= T_0 + T(\mathbf{x}) \exp(i\omega t),
\end{aligned} \tag{6}
$$

where i is the imaginary unit and ω is the angular frequency. By the substitution of (6), the system of field equations based on (1)–(4) may be reduced to a system where

the only unknown fields are the amplitudes $\mathbf{V}(\mathbf{x})$ and $T(\mathbf{x})$ of the disturbances of the velocity and temperature fields. The reduced system may be written as

$$
\begin{aligned}
i\omega\rho_0\mathbf{V} + \frac{(\gamma-1)C_V\rho_0}{\beta T_0}\operatorname{grad} T - \left(\lambda+\mu - \frac{i(\gamma-1)C_V\rho_0}{\omega T_0\beta^2}\right)\operatorname{grad}\operatorname{div}\mathbf{V} \\
- \mu\operatorname{div}\operatorname{grad}\mathbf{V} = \rho_0\mathbf{b}, \\
-\kappa\operatorname{div}\operatorname{grad} T + i\omega\rho_0 C_V T + \frac{(\gamma-1)C_V\rho_0}{\beta}\operatorname{div}\mathbf{V} = \rho_0 h.
\end{aligned} \tag{7}
$$

It is noted that after the solution of the velocity and temperature the amplitudes $p(\mathbf{x})$ and $\rho(\mathbf{x})$ of the disturbances of the pressure and density fields can readily be obtained from the relations

$$
\begin{aligned}
p &= \frac{(\gamma-1)C_V\rho_0}{\beta T_0}\left(T + \frac{i}{\omega\beta}\operatorname{div}\mathbf{V}\right), \\
\rho &= \frac{i\rho_0}{\omega}\operatorname{div}\mathbf{V}.
\end{aligned} \tag{8}
$$

To solve the system (7), suitable boundary conditions have to be adjoined to it. The most straightforward boundary conditions suitable for fluid flow in a region completely enclosed by rigid walls consist of the requirement that

$$\mathbf{V} = \widehat{\mathbf{V}} \quad \text{and} \quad T = 0 \tag{9}$$

on the boundary, with $\widehat{\mathbf{V}}$ a prescribed function on the boundary. The solution methods considered here admit the consideration of general mixed boundary conditions, so that at each point of the boundary one may prescribe

$$\mathbf{V}\cdot\mathbf{e}_n \quad \text{or} \quad \mathbf{T}\mathbf{e}_n\cdot\mathbf{e}_n \text{ but not both,} \tag{10}$$

$$\mathbf{V}\cdot\mathbf{e}_s \quad \text{or} \quad \mathbf{T}\mathbf{e}_n\cdot\mathbf{e}_s \text{ but not both, and} \tag{11}$$

$$\mathbf{V}\cdot\mathbf{e}_t \quad \text{or} \quad \mathbf{T}\mathbf{e}_n\cdot\mathbf{e}_t \text{ but not both,} \tag{12}$$

where $\mathbf{T}\mathbf{e}_n$ is the surface force vector. Similarly, mixed thermal boundary conditions may also be specified so that at each point of the boundary one prescribes

$$T \quad \text{or} \quad \frac{\partial T}{\partial n} \quad \text{but not both,} \tag{13}$$

where $\partial/\partial n$ denotes the directional derivative in the direction of $\mathbf{e}_n$.

We note that in acoustic simulations the normal surface force is often prescribed by using the impedance boundary condition

$$\mathbf{T}\mathbf{e}_n\cdot\mathbf{e}_n = Z_V(\mathbf{V}\cdot\mathbf{e}_n), \tag{14}$$

where Z_V is a complex quantity which we will refer to as the specific acoustic impedance. We express a similar thermal boundary condition as

$$\frac{\partial T}{\partial n} = Z_T T, \tag{15}$$

with the complex quantity Z_T referred to as the specific thermal impedance.

For simplicity of presentation we consider in the following the model problem where the Dirichlet boundary conditions (9) are imposed on the part Γ_D of the

boundary. On the remainder $\Gamma_I = \partial\Omega \setminus \Gamma_D$ the boundary conditions are given by (14) and (15) together with the tangential conditions

$$\mathbf{T}\mathbf{e}_n \cdot \mathbf{e}_s = \mathbf{T}\mathbf{e}_n \cdot \mathbf{e}_t = 0. \tag{16}$$

Other combinations of boundary conditions could be treated without difficulty.

2.2. Dimensionless field equations. It will be convenient to transform the system (7) into a dimensionless form. To this end, we introduce the dimensionless quantities

$$\theta = kL, \qquad \epsilon = \left(\frac{\mu}{\rho_0 \omega L^2}\right)^{1/2}, \qquad \delta = \left(\frac{C_V \mu}{\kappa}\right)^{1/2}, \qquad \eta = \lambda/\mu, \tag{17}$$

where $L = \operatorname{diam}(\Omega)$ and $k = \omega/c$, with c the adiabatic sound speed defined by the relation

$$T_0 \beta^2 c^2 = \gamma(\gamma - 1) C_V. \tag{18}$$

We also introduce dimensionless unknowns by setting

$$\mathbf{v} = (1/c)\mathbf{V}, \qquad \tau = \frac{\beta T_0}{\gamma\theta}\left(\frac{T}{T_0}\right) \tag{19}$$

and define scaled coordinates x_i' by $x_i' = L^{-1} x_i$.

When the dimensionless variables are introduced, the field equations (7) take the form

$$\begin{aligned} &\mathbf{v} - i\nabla\tau + \frac{1}{\gamma\theta^2}\nabla(\nabla\cdot\mathbf{v}) + i\epsilon^2(\eta+1)\nabla(\nabla\cdot\mathbf{v}) + i\epsilon^2\Delta\mathbf{v} = -\left(\frac{i}{\omega c}\right)\mathbf{b}, \\ &-\frac{i\gamma\epsilon^2\theta^2}{(\gamma-1)\delta^2}\Delta\tau - \frac{\gamma\theta^2}{\gamma-1}\tau + i\nabla\cdot\mathbf{v} = \left(\frac{i\gamma\theta^2}{cL\beta T_0\omega^2}\right) h. \end{aligned} \tag{20}$$

Here ∇ denotes the gradient with respect to the dimensionless coordinates and $\Delta = \nabla \cdot \nabla$.

We close this section by noting that the dimensionless parameter θ characterizes the ratio of the characteristic length L to the acoustic wavelength, while ϵ characterizes the ratio of the thickness of the viscous boundary layer to L. Similarly, the parameter δ characterizes the ratio of the thickness of the viscous boundary layer to that of the thermal boundary layer.

3. Mixed formulation. Our exploration of numerical solution methods for (7) or, equivalently, (20) is motivated by the modeling of the propagation of sound in small cavities. The largest dimension of the cavity typically is at most of the same order of magnitude as the minimum wavelength of the sound over the frequency range considered. When low frequencies are considered, the dimensionless parameter θ thus tends to take small values in comparison to unity. Usually we also have $\epsilon \ll 1$ and $\delta \sim 1$, so that the boundary layers are thin as compared with the characteristic length L.

In [8] we demonstrated that, when $\theta \ll 1$, the straightforward finite element discretization of (20) based on the use of low-degree polynomials does not lead to a reliable approximation method for the solution mode which dominates in the region outside the boundary layers. This was shown to be due to the fact that nearly

incompressible velocity fields need to be approximated. These observations led us to formulate the problem as a mixed problem for which reliable finite element methods were shown to be available.

We write here the mixed formulation of (20) as

$$\begin{aligned} \mathbf{v} - i\nabla\tau - i\nabla\phi + i\epsilon^2\nabla(\nabla\cdot\mathbf{v}) + i\epsilon^2\Delta\mathbf{v} &= i\mathbf{f}, \\ -\frac{i\epsilon^2}{(\gamma-1)\delta^2}\Delta\tau - \frac{1}{\gamma-1}\tau + \frac{1}{1+i\gamma\theta^2\epsilon^2\eta}\phi &= g, \\ i\nabla\cdot\mathbf{v} - \frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\phi &= 0, \end{aligned} \tag{21}$$

where we have set

$$\mathbf{f} = -\left(\frac{1}{\omega c}\right)\mathbf{b} \quad \text{and} \quad g = \left(\frac{i}{cL\beta T_0\omega^2}\right)h. \tag{22}$$

Setting $\hat{\mathbf{v}} = (1/c)\widehat{\mathbf{V}}$, the Dirichlet boundary conditions corresponding to our model problem are then

$$\mathbf{v} = \hat{\mathbf{v}} \quad \text{and} \quad \tau = 0 \tag{23}$$

on Γ_D. On the complementary part Γ_I the boundary conditions are given by

$$\begin{aligned} -i\tau - i\phi + 2i\epsilon^2\mathbf{d}(\mathbf{v})\mathbf{e}_n\cdot\mathbf{e}_n &= z_v(\mathbf{v}\cdot\mathbf{e}_n), \\ 2i\epsilon^2\mathbf{d}(\mathbf{v})\mathbf{e}_n\cdot\mathbf{e}_s &= 0, \\ 2i\epsilon^2\mathbf{d}(\mathbf{v})\mathbf{e}_n\cdot\mathbf{e}_t &= 0, \end{aligned} \tag{24}$$

and

$$\frac{i\epsilon^2}{(\gamma-1)\delta^2}\frac{\partial\tau}{\partial n} = z_\tau\tau, \tag{25}$$

where $\mathbf{d}(\mathbf{v}) = 1/2(\nabla\mathbf{v} + \nabla\mathbf{v}^T)$ is the dimensionless stretching tensor and

$$z_v = \frac{iZ_V}{\rho_0\omega L}, \qquad z_\tau = \frac{i\epsilon^2 LZ_T}{(\gamma-1)\delta^2}. \tag{26}$$

It is also noted that the pressure, which often is of practical interest, may now be obtained readily in terms of τ and the auxiliary unknown ϕ from

$$p = \theta\rho_0 c^2\left(\tau + \frac{1}{1+i\gamma\theta^2\epsilon^2\eta}\phi\right). \tag{27}$$

4. Iterative solution methods. We start this section by deriving an alternative formulation for the mixed system of field equations. We then show how this alternative formulation can be used to develop preconditioners for the iterative solution of discrete systems which result from the finite element approximation of the mixed problem.

4.1. The Schur complement formulation of the mixed problem. It will be convenient to split the velocity solution $\mathbf{v}$ to (21) into components $\mathbf{w} \in W$ and $\mathbf{u} \in U$, with W and U defined by

$$W = \{\mathbf{w} \mid \nabla \times \mathbf{w} = \mathbf{0}\}$$

and

$$U = \{\mathbf{u} \mid \nabla \cdot \mathbf{u} = 0\}.$$

In addition, to introduce the similar representation for the body force, we denote the body-force potential, the gradient of which gives the conservative part of the scaled body force $\mathbf{f}$, by φ. Then $\mathbf{f}$ may be written as

$$\mathbf{f} = \nabla\varphi + (\mathbf{f} - \nabla\varphi). \tag{28}$$

It is noted that these representations for the velocity and body force are unique.

By substituting $\mathbf{v} = \mathbf{w} + \mathbf{u}$ and (28) into (21) and using the identity

$$\Delta\mathbf{v} = \nabla(\nabla \cdot \mathbf{v}) - \nabla \times \nabla \times \mathbf{v},$$

it is found that $\mathbf{w}$, τ, and ϕ satisfy the field equations

$$\begin{aligned} \mathbf{w} - i\nabla\tau - i\nabla\phi + 2i\epsilon^2\,\nabla(\nabla \cdot \mathbf{w}) &= i\nabla\varphi, \\ -\frac{i\epsilon^2}{(\gamma-1)\delta^2}\Delta\tau - \frac{1}{\gamma-1}\tau + \frac{1}{1+i\gamma\theta^2\epsilon^2\eta}\phi &= g, \\ i\nabla \cdot \mathbf{w} - \frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\phi &= 0. \end{aligned} \tag{29}$$

As we now have

$$\mathbf{w} = \nabla(i\tau) + \frac{1+i\gamma\theta^2\epsilon^2(2+\eta)}{1+i\gamma\theta^2\epsilon^2\eta}\nabla(i\phi) + \nabla(i\varphi), \tag{30}$$

we may reduce (29) into a system involving only τ and ϕ:

$$\begin{aligned} -\frac{i\epsilon^2}{(\gamma-1)\delta^2}\Delta\tau - \frac{1}{\gamma-1}\tau + \frac{1}{1+i\gamma\theta^2\epsilon^2\eta}\phi &= g, \\ -\Delta\tau - \frac{1+i\gamma\theta^2\epsilon^2(2+\eta)}{1+i\gamma\theta^2\epsilon^2\eta}\Delta\phi - \frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\phi &= \Delta\varphi. \end{aligned} \tag{31}$$

We may thus separate the solution of τ and ϕ from that of $\mathbf{v}$, so that the system (21) may be rewritten as

$$\begin{aligned} A(\mathbf{v}) + B^*(\tau) + B^*(\phi) &= i\mathbf{f}, \\ C(\tau) + D(\phi) &= g, \\ E(\tau) + G(\phi) &= \Delta\varphi, \end{aligned} \tag{32}$$

where

$$\begin{aligned} &A = I + i\epsilon^2\,\nabla(\nabla\cdot\,) + i\epsilon^2\Delta, \quad B^* = -i\nabla, \\ &C = -\frac{i\epsilon^2}{(\gamma-1)\delta^2}\Delta - \frac{1}{\gamma-1}, \quad D = \frac{1}{1+i\gamma\theta^2\epsilon^2\eta}I, \\ &E = -\Delta, \quad G = -\frac{1+i\gamma\theta^2\epsilon^2(2+\eta)}{1+i\gamma\theta^2\epsilon^2\eta}\Delta - (\gamma\theta^2)D. \end{aligned} \tag{33}$$

We note that the matrix differential operator

$$S = \begin{pmatrix} C & D \\ E & G \end{pmatrix}, \tag{34}$$

which appears in the block-triangular system (32), is the Schur complement for the system of acoustic equations.

In principle, the Schur complement formulation (32) opens up a possibility for solving (21). However, this approach involves a practical difficulty as the correct boundary condition for the last equation of (32) depends on the normal component of the unknown part $\mathbf{w}$. This can also be seen from the variational formulation corresponding to this equation. If we take the inner product of the equation with $q \in H^1(\Omega)$ (the space $H^1(\Omega)$ is defined in the usual way [9]) and integrate by parts, we see that the solution of the acoustic problem satisfies

$$\begin{aligned} &-\frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \phi q\,d\Omega + \int_\Omega \nabla\tau\cdot\nabla q\,d\Omega \\ &+\frac{1+i\gamma\theta^2\epsilon^2(2+\eta)}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \nabla\phi\cdot\nabla q\,d\Omega + \int_\Omega \nabla\varphi\cdot\nabla q\,d\Omega + i\int_{\partial\Omega}\mathbf{w}\cdot\mathbf{n}q\,dS = 0. \end{aligned} \tag{35}$$

By substituting $\mathbf{w} = \mathbf{v} - \mathbf{u}$ we see that we have also

$$\begin{aligned} &-\frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \phi q\,d\Omega + \int_\Omega \nabla\tau\cdot\nabla q\,d\Omega + \frac{1+i\gamma\theta^2\epsilon^2(2+\eta)}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \nabla\phi\cdot\nabla q\,d\Omega \\ &+\int_\Omega \nabla\varphi\cdot\nabla q\,d\Omega - i\int_\Omega \mathbf{u}\cdot\nabla q\,d\Omega + i\int_{\partial\Omega}\mathbf{v}\cdot\mathbf{n}q\,dS = 0 \end{aligned} \tag{36}$$

for any function $q \in H^1(\Omega)$.

Although the system (32) cannot be employed to directly obtain the solution, it can be used to develop iteration methods for the solution of the original system (21). The next section shows that the variational principle (36) plays a key role in the derivation of iterative algorithms.

4.2. The iterative solution using consistent splitting approach. We now turn to the iterative solution of the system (21). The Schur complement formulation (32) is a natural starting point for the derivation of decoupled solution strategies where the solution of the temperature and auxiliary unknown is separated from that of the velocity. Our experiences with iteration methods that directly rely on the Schur complement formulation have nevertheless been discouraging. We have found that the convergence of such methods can be problematic, in particular for the range of frequencies near resonance. These difficulties have turned our interest to developing solution methods where decoupled solution techniques are used only as preconditioners in connection with other iteration methods. Such a possibility arises naturally when the Krylov subspace methods are applied directly to the linear systems which arise from the discretization of the mixed problem.

Although our primary interest here is the preconditioner design, we start our discussion by considering an iteration method which is based on the direct use of the Schur complement formulation (32). This will not be the method we are focusing on, but this introductory consideration gives insight into the key question of developing

suitable boundary conditions for the associated Schur complement operator. It should be noted that the method we consider in the following is closely related to the so-called consistent splitting algorithm [10], originally designed for solving the time-discretized incompressible Navier–Stokes equations.

Now let us assume that the solution of the system (21) is attempted by an iterative process where the new velocity $\mathbf{v}^{(k+1)}$ is computed using the previous approximation of (τ, ϕ) from

$$\mathbf{v}^{(k+1)} - i\nabla\tau^{(k)} - i\nabla\phi^{(k)} + i\epsilon^2\nabla(\nabla\cdot\mathbf{v}^{(k+1)}) + i\epsilon^2\Delta\mathbf{v}^{(k+1)} = i\mathbf{f}, \tag{37}$$

together with the boundary conditions

$$\mathbf{v}^{(k+1)} = \hat{\mathbf{v}} \quad \text{on } \Gamma_D \tag{38}$$

and

$$\begin{aligned} -i\tau^{(k)} - i\phi^{(k)} + 2i\epsilon^2\mathbf{d}(\mathbf{v}^{(k+1)})\mathbf{e}_n\cdot\mathbf{e}_n &= z_v(\mathbf{v}^{(k+1)}\cdot\mathbf{e}_n),\\ 2i\epsilon^2\mathbf{d}(\mathbf{v}^{(k+1)})\mathbf{e}_n\cdot\mathbf{e}_s &= 0,\\ 2i\epsilon^2\mathbf{d}(\mathbf{v}^{(k+1)})\mathbf{e}_n\cdot\mathbf{e}_t &= 0 \end{aligned} \tag{39}$$

on Γ_I. The new pair $(\tau^{(k+1)}, \phi^{(k+1)})$ is then constructed such that, in analogy with (36), we have

$$\begin{aligned} &-\frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \phi^{(k+1)} q\,d\Omega + \int_\Omega \nabla\tau^{(k+1)}\cdot\nabla q\,d\Omega\\ &+\frac{1+i\gamma\theta^2\epsilon^2(2+\eta)}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \nabla\phi^{(k+1)}\cdot\nabla q\,d\Omega + \int_\Omega \nabla\varphi\cdot\nabla q\,d\Omega\\ &-i\int_\Omega \mathbf{u}^{(k+1)}\cdot\nabla q\,d\Omega + i\int_{\partial\Omega}\mathbf{v}^{(k+1)}\cdot\mathbf{n}q\,dS = 0 \end{aligned} \tag{40}$$

for any function $q \in H^1(\Omega)$. Here $\mathbf{u}^{(k+1)}$ is the rotational velocity corresponding to $\mathbf{v}^{(k+1)}$.

It should be noted that the boundary condition resulting from the principle (40) is consistent. If the current velocity iterate is the solution of the problem, then the new pair $(\tau^{(k+1)}, \phi^{(k+1)})$ resulting from the principle (40) together with the second equation of (32) solves the acoustic problem.

Here the key issue is how to compute in (40) the term depending on $\mathbf{u}^{(k+1)}$. Surprisingly, this can be done without explicitly forming $\mathbf{u}^{(k+1)}$. To show this, note that from (37) we get the equation

$$i\mathbf{v}^{(k+1)} + \nabla\tau^{(k)} + \nabla\phi^{(k)} - 2\epsilon^2\nabla(\nabla\cdot\mathbf{v}^{(k+1)}) + \epsilon^2\nabla\times\nabla\times\mathbf{v}^{(k+1)} = -\mathbf{f}, \tag{41}$$

which may also be written as

$$i\mathbf{v}^{(k+1)} + \nabla\tau^{(k)} + \nabla\phi^{(k)} - 2\epsilon^2\nabla(\nabla\cdot\mathbf{v}^{(k+1)}) - i\mathbf{u}^{(k+1)} = -\nabla\varphi. \tag{42}$$

Following the idea presented in [10], we now take the inner product of (42) with ∇q, where $q \in H^1(\Omega)$. In view of the Helmholtz–Hodge decomposition, the resulting

equation simply expresses the requirement that the projection of $i\mathbf{u}^{(k+1)} - i\mathbf{v}^{(k+1)}$ on the set irrotational fields coincides with the field

$$\nabla\tau^{(k)} + \nabla\phi^{(k)} - 2\epsilon^2\nabla(\nabla\cdot\mathbf{v}^{(k+1)}) + \nabla\varphi.$$

Taking the inner product and subtracting the result from (40), we then obtain

$$\begin{aligned}
&-\frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \phi^{(k+1)} q\,d\Omega + \int_\Omega \nabla\tau^{(k+1)}\cdot\nabla q\,d\Omega \\
&+\frac{1+i\gamma\theta^2\epsilon^2(2+\eta)}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \nabla\phi^{(k+1)}\cdot\nabla q\,d\Omega - i\int_\Omega \mathbf{v}^{(k+1)}\cdot\nabla q\,d\Omega \\
&-\int_\Omega \nabla\tau^{(k)}\cdot\nabla q\,d\Omega - \int_\Omega \nabla\phi^{(k)}\cdot\nabla q\,d\Omega + 2\epsilon^2\int_\Omega \nabla(\nabla\cdot\mathbf{v}^{(k+1)})\cdot\nabla q\,d\Omega \\
&+ i\int_{\partial\Omega}\mathbf{v}^{(k+1)}\cdot\mathbf{n} q\,dS = 0.
\end{aligned} \tag{43}$$

Integrating by parts and rearranging the terms, we finally get

$$\begin{aligned}
&-\frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega (\phi^{(k+1)}-\phi^{(k)}) q\,d\Omega + \int_\Omega \nabla(\tau^{(k+1)}-\tau^{(k)})\cdot\nabla q\,d\Omega \\
&+\frac{1+i\gamma\theta^2\epsilon^2(2+\eta)}{1+i\gamma\theta^2\epsilon^2\eta}\int_\Omega \nabla(\phi^{(k+1)}-\phi^{(k)})\cdot\nabla q\,d\Omega \\
&=\int_\Omega\left(\frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\phi^{(k)} - i\nabla\cdot\mathbf{v}^{(k+1)}\right) q\,d\Omega \\
&-2i\epsilon^2\int_\Omega \nabla\left(\frac{\gamma\theta^2}{1+i\gamma\theta^2\epsilon^2\eta}\phi^{(k)} - i\nabla\cdot\mathbf{v}^{(k+1)}\right)\cdot\nabla q\,d\Omega.
\end{aligned} \tag{44}$$

It is noted that the last term of (44) depends on the gradient field of the residual corresponding to the last equation of the system (21). It can be difficult to approximate this term directly in connection with the finite element method. This difficulty can be circumvented by approximating the residual by a continuous function ψ. We thus come to the following iterative method for solving (21) associated with the boundary conditions (23)–(25): Set $\tau^{(0)} = \phi^{(0)} = 0$ and $k = 0$. Then perform the following iteration steps:

1. Find $\mathbf{v}^{(k+1)} \in V$ such that

$$\begin{aligned}
&\int_\Omega \mathbf{v}^{(k+1)}\cdot\mathbf{z}\,d\Omega + i\int_\Omega \tau^{(k)}\nabla\cdot\mathbf{z}\,d\Omega + i\int_\Omega \phi^{(k)}\nabla\cdot\mathbf{z}\,d\Omega \\
&-2i\epsilon^2\int_\Omega \mathbf{d}(\mathbf{v}^{(k+1)})\cdot\mathbf{d}(\mathbf{z})\,d\Omega + i\int_{\Gamma_I} z_v(\mathbf{v}^{(k+1)}\cdot\mathbf{e}_n)(\mathbf{z}\cdot\mathbf{e}_n)\,dS = i\int_\Omega \mathbf{f}\cdot\mathbf{z}\,d\Omega
\end{aligned} \tag{45}$$

for all $\mathbf{z} \in Z$. Here we have

$$V = \{\ \mathbf{v} \mid \mathbf{v} \in [H^1(\Omega)]^3 \text{ and } \mathbf{v} = \hat{\mathbf{v}} \text{ on } \Gamma_D\}$$

and $Z = [H_D^1(\Omega)]^3$, with

$$H_D^1(\Omega) = \{\ z \mid z \in H^1(\Omega) \text{ and } z = 0 \text{ on } \Gamma_D\}.$$

2. Find $(\tau^{(k+1)}, \phi^{(k+1)}, \psi) \in H_D^1(\Omega) \times H^1(\Omega) \times H^1(\Omega)$ such that

$$\begin{aligned}
&\frac{i\epsilon^2}{(\gamma-1)\delta^2}\int_\Omega \nabla(\tau^{(k+1)} - \tau^{(k)}) \cdot \nabla r \, d\Omega - \frac{1}{\gamma-1}\int_\Omega (\tau^{(k+1)} - \tau^{(k)}) r \, d\Omega \\
&+ \frac{1}{1 + i\gamma\theta^2\epsilon^2\eta}\int_\Omega (\phi^{(k+1)} - \phi^{(k)}) r \, d\Omega - \int_{\Gamma_I} z_\tau (\tau^{(k+1)} - \tau^{(k)}) r \, dS \\
&= \int_\Omega g r \, d\Omega - \frac{i\epsilon^2}{(\gamma-1)\delta^2}\int_\Omega \nabla\tau^{(k)} \cdot \nabla r \, d\Omega + \frac{1}{\gamma-1}\int_\Omega \tau^{(k)} r \, d\Omega \\
&- \frac{1}{1 + i\gamma\theta^2\epsilon^2\eta}\int_\Omega \phi^{(k)} r \, d\Omega + \int_{\Gamma_I} z_\tau \tau^{(k)} r \, dS, \qquad (46)
\end{aligned}$$

$$\begin{aligned}
&- \frac{\gamma\theta^2}{1 + i\gamma\theta^2\epsilon^2\eta}\int_\Omega (\phi^{(k+1)} - \phi^{(k)}) q \, d\Omega + \int_\Omega \nabla(\tau^{(k+1)} - \tau^{(k)}) \cdot \nabla q \, d\Omega \\
&+ \frac{1 + i\gamma\theta^2\epsilon^2(2+\eta)}{1 + i\gamma\theta^2\epsilon^2\eta}\int_\Omega \nabla(\phi^{(k+1)} - \phi^{(k)}) \cdot \nabla q \, d\Omega \\
&+ 2i\epsilon^2 \int_\Omega \nabla\psi \cdot \nabla q \, d\Omega = \int_\Omega \Big(\frac{\gamma\theta^2}{1 + i\gamma\theta^2\epsilon^2\eta}\phi^{(k)} - i\nabla \cdot \mathbf{v}^{(k+1)}\Big) q \, d\Omega, \qquad (47)
\end{aligned}$$

and

$$\int_\Omega \psi s \, d\Omega = \int_\Omega \left(\frac{\gamma\theta^2}{1 + i\gamma\theta^2\epsilon^2\eta}\phi^{(k)} - i\nabla \cdot \mathbf{v}^{(k+1)}\right) s \, d\Omega \qquad (48)$$

for all $(r, q, s) \in H_D^1(\Omega) \times H^1(\Omega) \times H^1(\Omega)$. If residuals are small enough, stop the iteration. Otherwise, set $k = k + 1$ and go to Step 1.

Obviously, the first step of the algorithm could also be written in the form of residual correction. It is also noted that the iteration method could be discretized easily by choosing suitable finite element spaces for approximation. In practice, the auxiliary unknown ψ may be solved independently from (48), and the new solution pair $(\tau^{(k+1)}, \phi^{(k+1)})$ can thus be obtained from the coupled system of (46) and (47).

We have seen that the use of the principle (40) leads us to add an additional forcing term to the residual-correction system. We conclude this discussion by demonstrating what velocity boundary conditions underlie this modification. To this end, we split the new velocity solution into three components so that $\mathbf{v}^{(k+1)} = \mathbf{u}^{(k+1)} + \mathbf{w}^{(k)} + \boldsymbol{\delta}\mathbf{w}^{(k+1)}$, where $\mathbf{w}^{(k)}$ is the irrotational velocity corresponding to the pair $(\tau^{(k)}, \phi^{(k)})$. The component $\boldsymbol{\delta}\mathbf{w}^{(k+1)}$ is thus the consistency error giving the difference between the irrotational component of $\mathbf{v}^{(k+1)}$ and $\mathbf{w}^{(k)}$. It follows then that, when the new pair $(\tau^{(k+1)}, \phi^{(k+1)})$ satisfying (40) is solved, the normal component of the velocity is adjusted so that

$$(\mathbf{w}^{(k+1)} - \mathbf{w}^{(k)}) \cdot \mathbf{e}_n = \boldsymbol{\delta}\mathbf{w}^{(k+1)} \cdot \mathbf{e}_n. \qquad (49)$$

4.3. Preconditioned iteration methods for discrete systems. The ideas presented in the preceding section can easily be adapted to develop Schur complement preconditioners for the iterative solution of the discrete system

$$\mathbf{KU} = \mathbf{F} \tag{50}$$

which result from the finite element discretization of the system (21). In the following we consider the use of Krylov subspace methods in combination with right-oriented preconditioning.

The development of the preceding section implies that an approximation to the current error may be solved from the preconditioning system of the form

$$\begin{bmatrix} \mathbf{A} & \mathbf{B}^* & \mathbf{B}^* & \mathbf{0} \\ \mathbf{0} & \mathbf{C} & \mathbf{D} & \mathbf{0} \\ \mathbf{0} & \mathbf{E} & \mathbf{G} & \mathbf{H} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{M} \end{bmatrix} \begin{bmatrix} \mathbf{s}_v \\ \mathbf{s}_\tau \\ \mathbf{s}_\phi \\ \boldsymbol{\psi} \end{bmatrix} = \begin{bmatrix} \mathbf{r}_v \\ \mathbf{r}_\tau \\ \mathbf{r}_\phi \\ \mathbf{r}_\phi \end{bmatrix}. \tag{51}$$

Here the vector $\boldsymbol{\psi}$ contains the unknowns corresponding to the field ψ, and $\mathbf{r}_v$, $\mathbf{r}_\tau$, and $\mathbf{r}_\phi$ are the discrete residuals corresponding to the block structure of (50). In addition, the matrices $\mathbf{M}$ and $\mathbf{H}$ result from the finite element approximation of the identity and Laplace operators, and $\mathbf{A}$, $\mathbf{B}^*, \ldots$ result from the finite element approximation of the operators A, B^*, etc. The boundary conditions adjoined to these operators are as defined in (45)–(48).

By eliminating $\boldsymbol{\psi}$ from (51), we see that the corrections to the primary unknowns are obtained from the system

$$\mathbf{Ps} = \mathbf{r},$$

which has the block structure

$$\begin{bmatrix} \mathbf{A} & \mathbf{B}^* & \mathbf{B}^* \\ \mathbf{0} & \mathbf{C} & \mathbf{D} \\ \mathbf{0} & \mathbf{E} & \mathbf{G} \end{bmatrix} \begin{bmatrix} \mathbf{s}_v \\ \mathbf{s}_\tau \\ \mathbf{s}_\phi \end{bmatrix} = \begin{bmatrix} \mathbf{r}_v \\ \mathbf{r}_\tau \\ \hat{\mathbf{r}}_\phi \end{bmatrix},$$

with $\hat{\mathbf{r}}_\phi = \mathbf{r}_\phi - \mathbf{HM}^{-1}\mathbf{r}_\phi$. In practice the inverse is not constructed as it suffices to solve iteratively the system

$$\mathbf{M}\boldsymbol{\psi} = \mathbf{r}_\phi. \tag{52}$$

This is a cheap operation even when a stringent stopping criterion is used, the principal cost being the allocation of the matrix $\mathbf{M}$. It should also be noted that in practice the explicit construction of the preconditioner in the form (51) is not needed, since a part of the preconditioner matrix is already available.

To make the application of the preconditioner efficient, an inexpensive method for approximating the action of the inverse of $\mathbf{P}$ is required. In practice, in addition to solving (52), we need effective solvers for the linear systems of the type

$$\begin{bmatrix} \mathbf{C} & \mathbf{D} \\ \mathbf{E} & \mathbf{G} \end{bmatrix} \begin{bmatrix} \mathbf{s}_\tau \\ \mathbf{s}_\phi \end{bmatrix} = \begin{bmatrix} \mathbf{r}_\tau \\ \hat{\mathbf{r}}_\phi \end{bmatrix} \tag{53}$$

and

$$\mathbf{As}_v = \hat{\mathbf{r}}_v. \tag{54}$$

In our numerical experiments we will consider the solution of these subproblems by using another Krylov method.

The solution of the subproblems involving $\mathbf{A}$ being relatively inexpensive, the overall cost of the preconditioner depends to a large extent on the cost of the assembly and solution of the Schur complement systems. The development of optimal solution methods for this problem is an open issue. Nevertheless, due to the fact that the size of the Schur complement matrix is significantly smaller than that of $\mathbf{K}$, reasonably efficient solvers can be obtained by using iterative methods where the preconditioning is based on incomplete factorizations of the coefficient matrix. A similar strategy may also be applied to the solution of the subproblems involving $\mathbf{A}$, but it may be possible to solve these systems even without any extra storage by using the Jacobi preconditioning.

We note that ideally it should be possible to make use of rather inaccurate iterative solutions of the preconditioning systems. Otherwise, the computational cost of the preconditioning can be large. We have observed that, although methods based on the exact preconditioning may perform equally well, there can be drastic differences in the performances of their inexact versions. We have found that, when BICGSTAB or BICGSTAB(l) is used as the outer iterative method, accurate solutions of preconditioning systems are needed in order to maintain convergence. This is a serious drawback limiting the usefulness of these methods in this connection.

We have found that iterative methods which perform robustly with respect to inaccuracies in the preconditioning step with reduced storage requirements can be developed by employing nested GCR iterations. The numerical examples of the next section were solved using the following nested GCR algorithm which utilizes the Schur complement preconditioning in inner GCR iterations: Given an initial guess $\mathbf{U}^{(0)}$ and a convergence tolerance ϵ_{outer}, perform the iteration

$\mathbf{r}^{(0)} = \mathbf{F} - \mathbf{K}\mathbf{U}^{(0)}$
$k = 0$
`while` $\|\mathbf{r}^{(k)}\|_\infty < \epsilon_{\text{outer}}(\|\mathbf{K}\|_\infty \|\mathbf{U}^{(k)}\|_\infty + \|\mathbf{F}\|_\infty)$
  $\mathbf{s}^{(k+1)} = GCR(\mathbf{K}, \mathbf{P}, \mathbf{r}^{(k)}, m, \delta_{\text{inner}}, \epsilon_{\text{inner}})$
  $\mathbf{v}^{(k+1)} = \mathbf{K}\mathbf{s}^{(k+1)}$
  `do` $j = 1, k$
    $\mathbf{v}^{(k+1)} = \mathbf{v}^{(k+1)} - \langle \mathbf{v}^{(j)}, \mathbf{v}^{(k+1)} \rangle \mathbf{v}^{(j)}$
    $\mathbf{s}^{(k+1)} = \mathbf{s}^{(k+1)} - \langle \mathbf{v}^{(j)}, \mathbf{v}^{(k+1)} \rangle \mathbf{s}^{(j)}$
  `end do`
  $\mathbf{v}^{(k+1)} = \mathbf{v}^{(k+1)} / \|\mathbf{v}^{(k+1)}\|$
  $\mathbf{s}^{(k+1)} = \mathbf{s}^{(k+1)} / \|\mathbf{v}^{(k+1)}\|$
  $\mathbf{U}^{(k+1)} = \mathbf{U}^{(k)} + \langle \mathbf{v}^{(k+1)}, \mathbf{r}^{(k)} \rangle \mathbf{s}^{(k+1)}$
  $\mathbf{r}^{(k+1)} = \mathbf{r}^{(k)} - \langle \mathbf{v}^{(k+1)}, \mathbf{r}^{(k)} \rangle \mathbf{v}^{(k+1)}$
  $k = k + 1$
`end while.`

Here we have $\langle \mathbf{v}, \mathbf{r} \rangle = \overline{\mathbf{v}} \cdot \mathbf{r}$, and the vector and matrix norms are defined in the usual manner. The function $GCR(\mathbf{K}, \mathbf{P}, \mathbf{r}^{(k)}, m, \delta_{\text{inner}}, \epsilon_{\text{inner}})$ returns the approximate solution of the residual equation

$$\mathbf{K}\mathbf{s}^{(k+1)} = \mathbf{r}^{(k)} \tag{55}$$

obtained by allowing at most m steps of the preconditioned GCR algorithm with the preconditioner $\mathbf{P}$ and the stopping criterion

$$\|\mathbf{r}^{(k)} - \mathbf{K}\mathbf{s}^{(k+1)}\| < \delta_{\text{inner}} \|\mathbf{r}^{(k)}\|. \tag{56}$$

The parameter ϵ_{inner} defines the error tolerance used in connection with the Schur complement preconditioning. In the case of the subproblem (54) the stopping criterion is given by

$$\|\hat{\mathbf{r}}_v - \mathbf{A}\mathbf{s}_v\| < \epsilon_{\text{inner}}\|\hat{\mathbf{r}}_v\|.$$

The stopping criterion for the subproblem (53) is analogous.

While the stopping criterion for the solution of (53) and (54) can be chosen to be mild, it can be advantageous to use a stringent stopping criterion for the solution of (52). As there is no principal cost associated with the solution of the subproblem (52), in the following we always solve these subproblems accurately so that we have

$$\|\mathbf{r}_\phi - \mathbf{M}\boldsymbol{\psi}\| < 10^{-7}\|\mathbf{r}_\phi\|.$$

We close this section by noting that the nested GCR algorithm we consider is similar to the GMRESR algorithm [11], provided the inner iteration of GMRESR is based on a version of GMRES that allows variable preconditioning.

5. Numerical examples. The proposed preconditioner has been implemented in Elmer [12], which is finite element software for the modeling of multiphysical problems. In the following we give the results of numerical experiments which demonstrate the performance of the proposed preconditioner in the case of both two- and three-dimensional problems. Boundary conditions of various types are considered. It is noted that some of the problems were solved using a version capable of handling axially symmetric problems.

The mixed problem is discretized using an enhanced MINI finite element of the type considered already in [8]. This method uses continuous, equal-order approximations for all of the unknown fields with the velocity approximation enriched by elementwise-defined bubble functions. The local bubble basis we use here is analogous to that of the MINI element [9], so that the velocity approximation is augmented by a single bubble degree of freedom.

To facilitate the computation of incomplete LU factorizations, the matrix $\mathbf{A}$ in the preconditioner (51) was constructed explicitly with the contribution resulting from the bubble functions neglected. It is emphasized that the double allocation of the $\mathbf{A}$-block could be avoided easily, so that the only additional assembly required by the preconditioner would be related to the discretization of the Schur complement operator and the construction of the matrices $\mathbf{H}$ and $\mathbf{M}$. In the computations, a row equilibration strategy was also used to reduce the condition numbers of the system matrix $\mathbf{K}$ and the coefficient matrices that arise in the preconditioning. The preconditioning systems were solved using the BICGSTAB(l) method.

5.1. Two-dimensional examples. We consider here a small system consisting of two cavities and a narrow duct which all have circular cross sections. We use axial symmetry to reduce the problem to two dimensions. The computational domain is given by $\Omega = \{\mathbf{x} = (x_1, x_2) \mid \mathbf{x} \in (0, R_1)\times(0, L_1)\cup(0, R_2)\times[L_1, L_2]\cup(0, R_3)\times(L_2, L_3)\}$, where x_1 and x_2 refer to the radial and axial coordinates, respectively, and $R_1 = 9.25 \cdot 10^{-3}$, $L_1 = 2.5 \cdot 10^{-2}$, $R_2 = 7.5 \cdot 10^{-4}$, $L_2 = 2.9 \cdot 10^{-2}$, $R_3 = 5.0 \cdot 10^{-3}$, and $L_3 = 4.4 \cdot 10^{-2}$. We assume that the medium is air at standard conditions and take $T_0 = 293$, $\beta = 1/T_0$, $\rho_0 = 1.21$, $\mu = 1.82 \cdot 10^{-5}$, $\lambda = -2/3\mu$, $\kappa = 2.6 \cdot 10^{-2}$, $C_V = 717.17$, and $\gamma = 1.4$. Here all values are expressed in SI units.

The wave source is defined by prescribing a nonvanishing velocity amplitude on the edge $x_2 = L_3$. We take $V_1(x_1) = 0$ and $V_2(x_1) = J_0(\alpha x_1)$, where J_0 is the Bessel

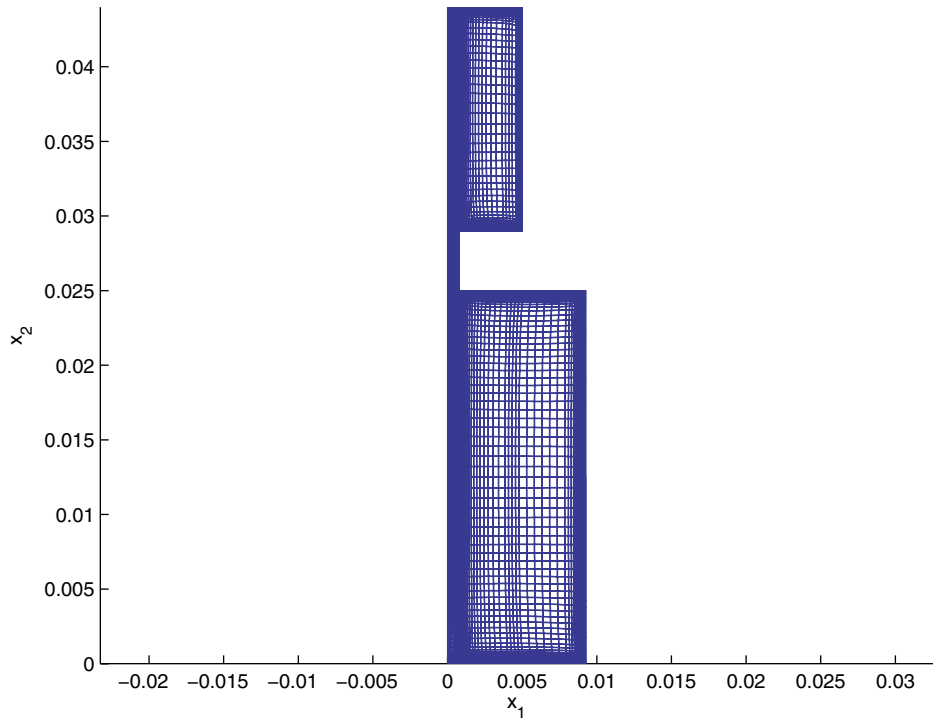

FIG. 5.1. *The finite element mesh.*

function with the maximum value scaled to the value $1.0 \cdot 10^{-3}$. In addition, the scaling factor α is defined so that $x_1 = \alpha R_3$ is the first root of $J_0(x_1)$. We assume that the fluctuation of the temperature vanishes on this edge. On the edge $x_1 = 0$, the symmetry boundary conditions are used (they correspond to the case of $Z_V \longrightarrow \infty$ and $Z_T = 0$). On the remaining part of the boundary, the conventional wall boundary conditions are imposed; i.e., all of the components of the velocity vector as well as the disturbance of the temperature are prescribed to vanish on this part.

We consider frequencies ranging from $f = 2.0 \cdot 10^2$ to $f = 10^4$, where $f = \omega/(2\pi)$. It is noted that the frequency $f = 1000$ is an approximate resonance frequency of the system. The same finite element mesh shown in Figure 5.1 was used to solve the problem for various frequencies. The mesh consists of bilinear quadrilaterals, and the total number of nodes is $N = 8848$ (leading to 70784 real unknowns).

We first demonstrate that the performance of the preconditioner depends drastically on the boundary conditions of the preconditioner. In addition to the proposed preconditioner, we also consider a variant where the terms depending on the auxiliary field ψ are omitted (in this case we have $\mathbf{H} = \mathbf{0}$). It is noted that this version corresponds to using the boundary condition

$$(\mathbf{w}^{(k+1)} - \mathbf{w}^{(k)}) \cdot \mathbf{e}_n = 0$$

instead of (49). We consider the example linear system which results from taking $f = 200$. In Figure 5.2 we illustrate the performances of the two versions by plotting

$$\frac{\|\mathbf{D}_K(\mathbf{F} - \mathbf{K}\mathbf{U}^{(k)})\|}{\|\mathbf{D}_K(\mathbf{F} - \mathbf{K}\mathbf{U}^{(0)})\|}, \tag{57}$$

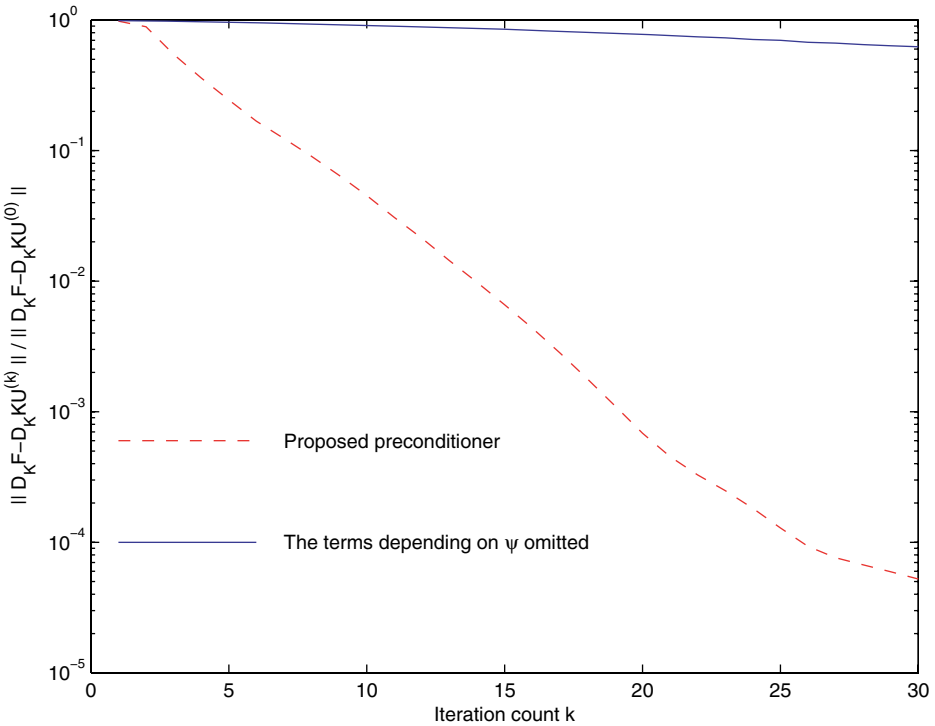

FIG. 5.2. *Convergence histories of the preconditioned GCR method. Two preconditioning strategies were used. The first one was based on omitting all of the terms which depend on ψ, while the second one was based on the proposed preconditioner.*

where $\mathbf{D}_K$ is the diagonal scaling matrix and $\mathbf{U}^{(k)}$, $k > 0$, are generated by the preconditioned GCR algorithm with $\epsilon_{\text{inner}} = 10^{-7}$. It is observed that the terms depending on ψ play a key role, as the omission of these terms essentially prohibits the convergence of residual-minimizing algorithms.

The key feature of the GCR method in connection with the Schur complement preconditioning is that the preconditioning systems can be solved inaccurately without essentially affecting the rate of convergence. Therefore the performance of our nested GCR algorithm depends only mildly on the value of ϵ_{inner}. This makes efficient preconditioning possible. It also follows that the outer iteration count required for convergence can effectively be controlled using the solver parameters m and δ_{inner}. We have found that often an efficient algorithm results when one takes, for example, $m = 5$ or $m = 10$ and $\delta_{\text{inner}} = 10^{-1}$ or $\delta_{\text{inner}} = 10^{-2}$.

To demonstrate the robustness of the nested GCR method with respect to inaccuracies in the preconditioning step, we consider the solution of the example linear system ($f = 200$) when $m = 10$, $\delta_{\text{inner}} = 10^{-2}$, and ϵ_{inner} is varied. Figure 5.3 shows the residual after each inner GCR iteration when $\epsilon_{\text{inner}} = 10^{-5}, \ldots, 10^{-2}$. Figure 5.4 shows the same residual vs. CPU time. It is seen from Figure 5.3 that increasing the value of ϵ_{inner} from 10^{-5} to 10^{-3} does not have a significant effect on the reduction of the residual obtained by the inner GCR iteration. Taking $\epsilon_{\text{inner}} = 10^{-2}$ has a clear effect on the residual reduction. In view of computing time the most efficient algorithm results when $\epsilon_{\text{inner}} = 10^{-3}$.

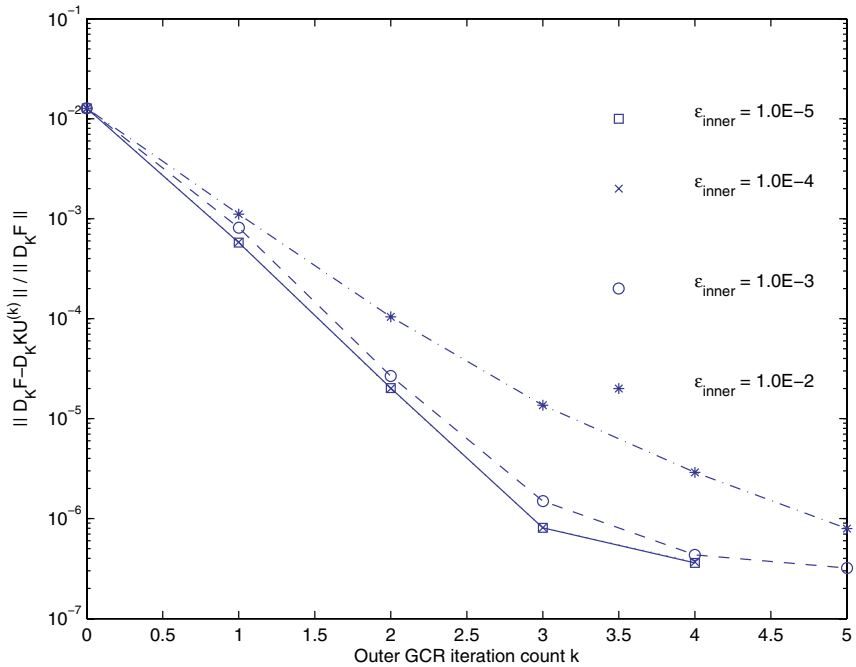

FIG. 5.3. *The residual after each inner GCR iteration when* ϵ_{inner} *is varied in the case of* $f = 200$.

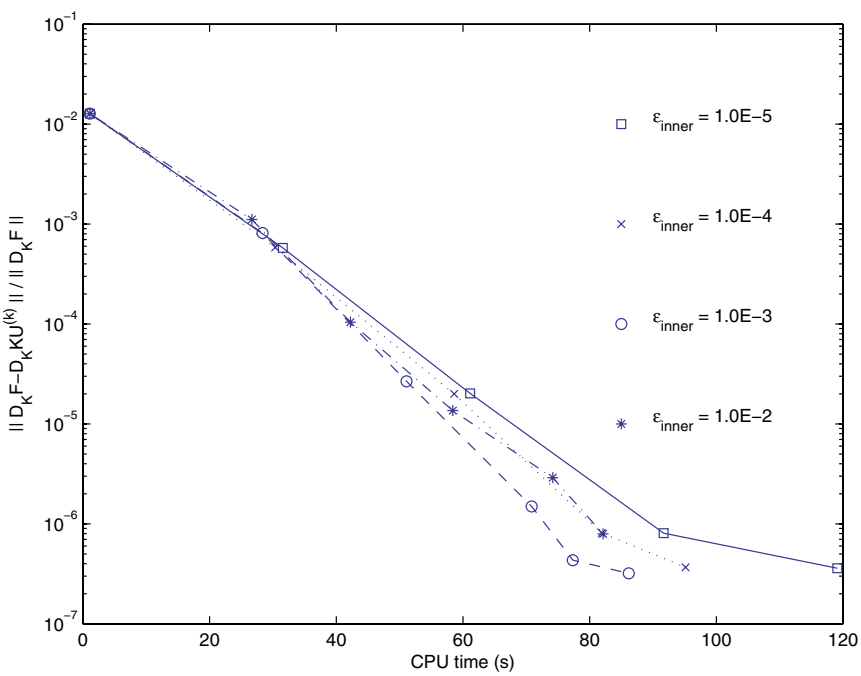

FIG. 5.4. *The residual after each inner GCR iteration vs. CPU time when* ϵ_{inner} *is varied in the case of* $f = 200$.

To demonstrate that the preconditioner is suitable for a wide range of frequencies, we also solved the linear systems which result from the sample frequencies $f = 10^3$ and $f = 10^4$. Figures 5.5–5.8 illustrate the convergence in the case of different values of ϵ_{inner}. It is noted that the results for the frequency $f = 10^4$ are comparable with those for the frequency $f = 200$. A different behavior is seen in the case of the resonance frequency $f = 10^3$, as the preconditioning systems have to be solved more accurately in this case. This can be explained by the greater sensitivity of the Schur complement matrix at the condition of resonance. It is not a surprise that, when the preconditioner is more sensitive, a more stringent stopping criterion is needed to produce a certain level of relative accuracy in the preconditioning.

We finally show how the nested GCR algorithm performs as compared with the BICGSTAB(l) method, which is applied directly to $\mathbf{KU} = \mathbf{F}$ with the preconditioner based on an incomplete LU factorization (ILU) of $\mathbf{K}$. We consider the cases of $l = 2$ and $l = 4$. In Table 5.1 we show the solution time when the fill level n of the incomplete factorization ILU(n) is varied. The iteration was stopped when

$$\|\mathbf{D}_K(\mathbf{F} - \mathbf{K}\mathbf{U}^{(k)})\| < 10^{-6}\|\mathbf{D}_K\mathbf{F}\|.$$

The maximum number of iterations allowed was taken to be 500. The results of Table 5.1 indicate that the incomplete factorization preconditioners perform less advantageously when the frequency and hence θ take smaller values (we have $\theta = 0.16$ when $f = 200$). When $f = 200$, the convergence was attained only in the case of ILU(0). It should be noted that a similar degradation of performance was not observed in the case of the Schur complement preconditioner. By comparing the CPU times, we see that, when incomplete factorization preconditioners with higher levels of fill work,

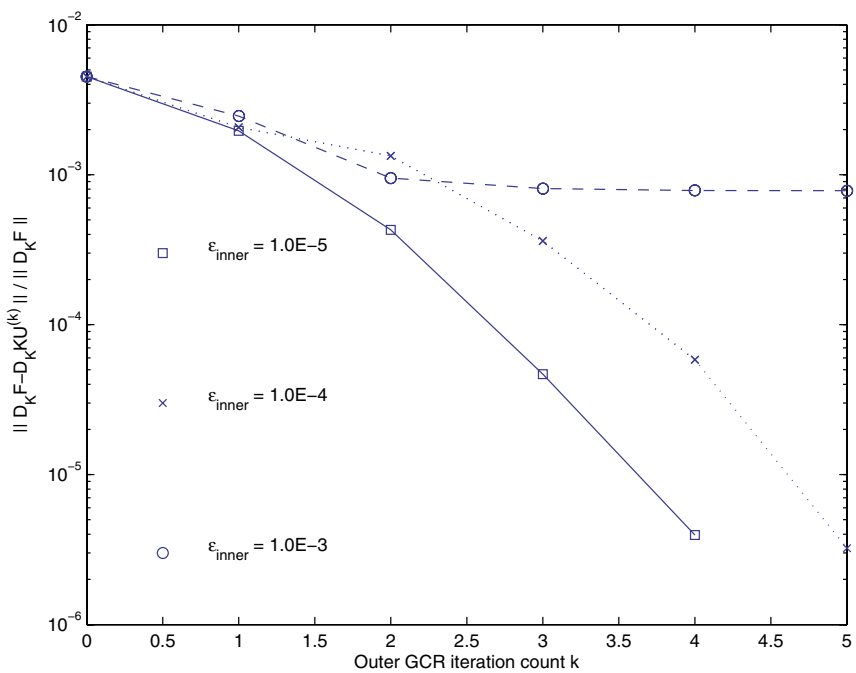

FIG. 5.5. *The residual after each inner GCR iteration when* ϵ_{inner} *is varied in the case of* $f = 10^3$.

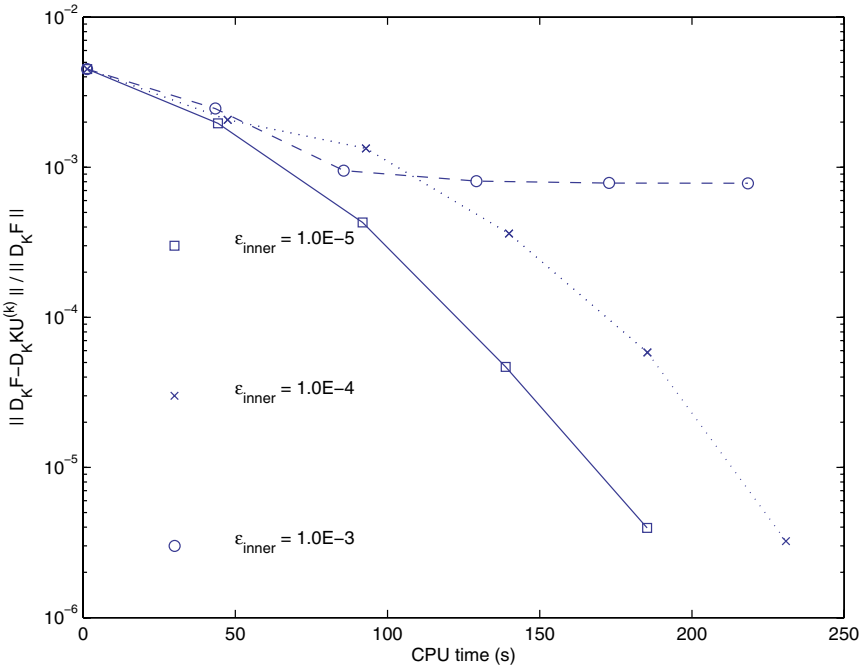

FIG. 5.6. *The residual after each inner GCR iteration vs. CPU time when* ϵ_{inner} *is varied in the case of* $f = 10^3$.

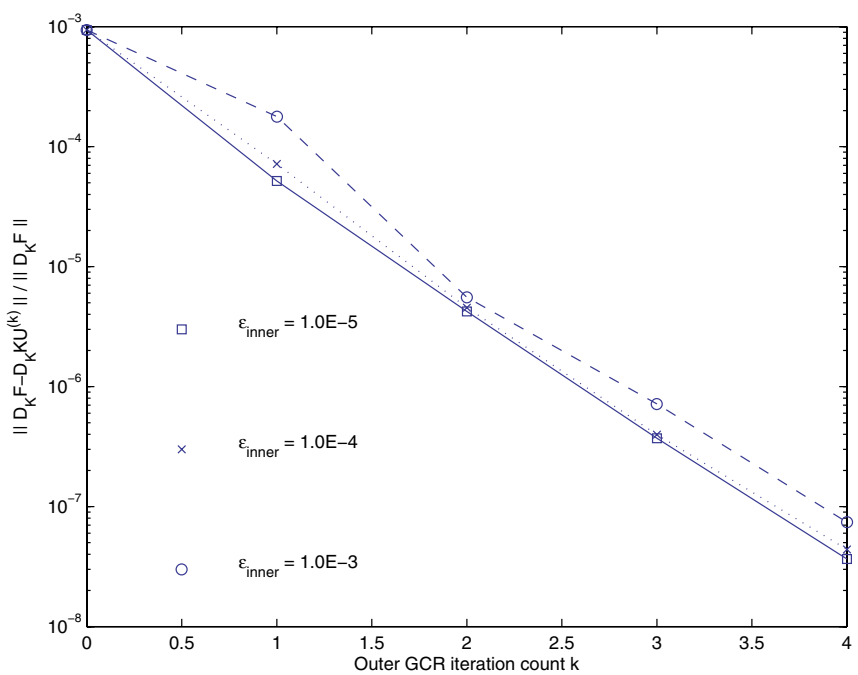

FIG. 5.7. *The residual after each inner GCR iteration when* ϵ_{inner} *is varied in the case of* $f = 10^4$.

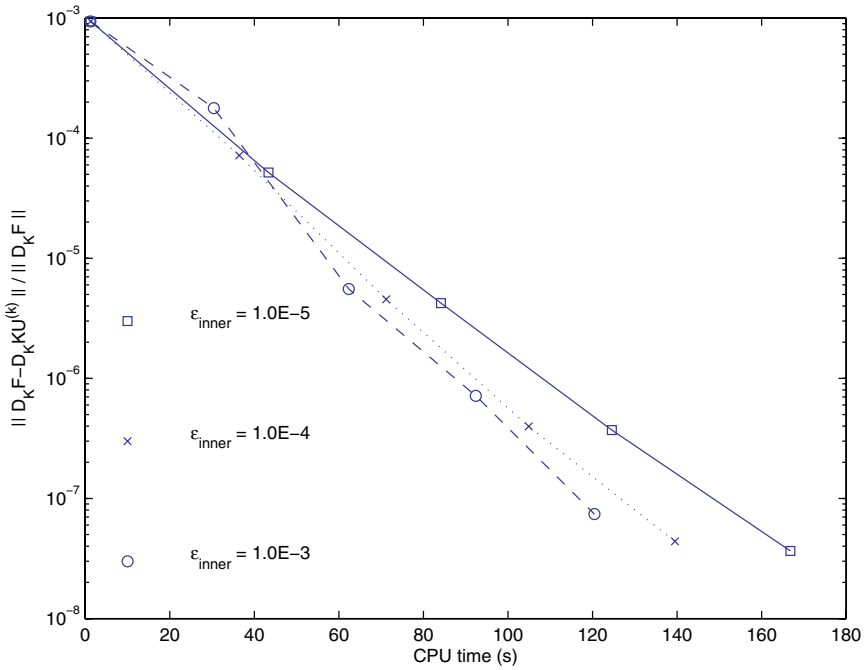

FIG. 5.8. *The residual after each inner GCR iteration vs. CPU time when* ϵ_{inner} *is varied in the case of* $f = 10^4$.

TABLE 5.1
The CPU time (s) to solve the linear system in the case of the BICGSTAB(l*) method.*

	$f = 200$		$f = 10^3$		$f = 10^4$	
	$l = 2$	$l = 4$	$l = 2$	$l = 4$	$l = 2$	$l = 4$
ILU(0)	138.2	109.0	130.6	122.9	82.3	47.9
ILU(1)	—	—	—	—	68.4	61.3
ILU(2)	—	—	60.4	52.8	22.1	20.2
ILU(3)	—	—	44.4	40.6	18.3	15.8

they can be more efficient than the current implementation of the Schur complement preconditioner. To improve the efficiency of the Schur complement preconditioner, a more efficient solver for the linear systems of the type (53) is required.

5.2. Three-dimensional examples. To demonstrate the ability of the preconditioner to handle three-dimensional problems, we now consider a curved tube which makes an angle of $\pi/2$ and has a circular cross section of radius $R = 1.0 \cdot 10^{-3}$. The tube is symmetric with respect to the coordinate plane $x_2 = 0$, so it suffices to consider half of the tube. The other dimensions of the tube are visualized in Figure 5.9, which shows the intersection of the three-dimensional tube with the plane $x_2 = 0$, along with the finite element mesh on that surface.

We assume that the medium is air at standard conditions and consider the case of the frequency $f = 10^4$. At the end $x_3 = 0$, we impose the velocity boundary conditions $V_1 = V_2 = 0$ and $V_3(r) = J_0(\alpha r)$, where $r^2 = x_1^2 + x_2^2$. The maximum value of the Bessel function is scaled to the value $1.0 \cdot 10^{-3}$, and the scaling factor α is defined so that $r = \alpha R$ is the first root of $J_0(r)$. In addition, we assume that the fluctuation of the temperature vanishes on this edge. At the other end of the tube,

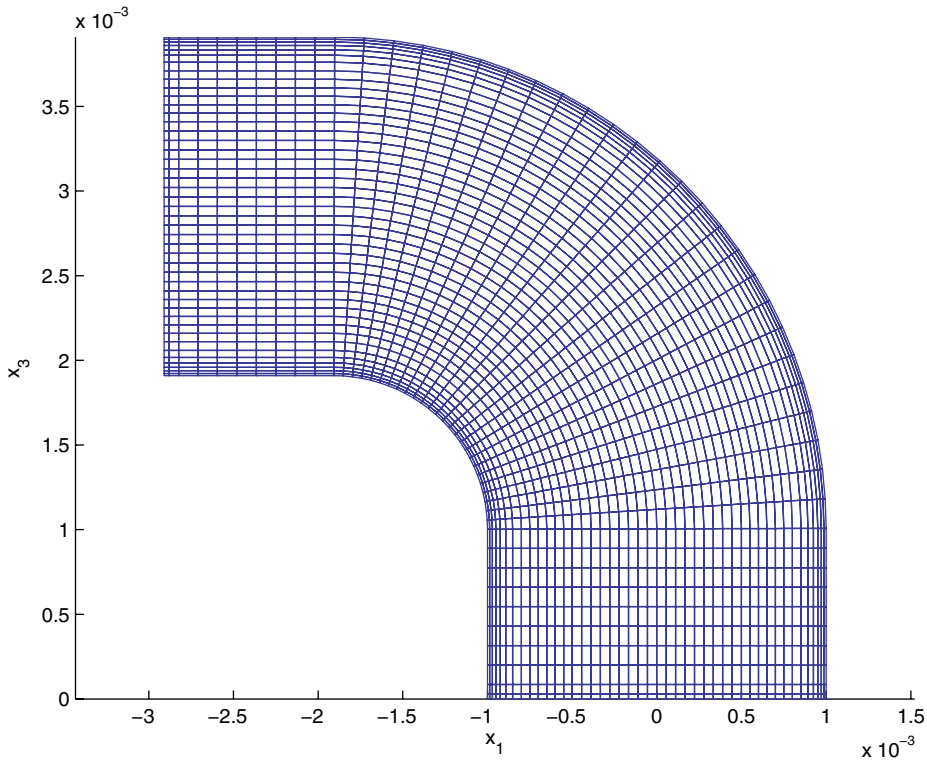

FIG. 5.9. *The intersection of the three-dimensional tube with the plane $x_2 = 0$. The finite element mesh on the surface is also displayed.*

we impose the impedance boundary conditions with the specific acoustic and thermal impedances given by

$$Z_V = -\rho_0 c$$

and

$$Z_T = -i\omega/c.$$

These boundary conditions are supplemented by the tangential velocity boundary conditions $V_2 = 0$ and $V_3 = 0$. On the surface $x_2 = 0$, the boundary conditions are obtained on the basis of symmetry, while on the remaining part of the boundary all of the components of the velocity vector as well as the disturbance of the temperature are prescribed to vanish.

The finite element mesh consists of trilinear elements and is visualized in Figures 5.9 and 5.10, where the intersections of the three-dimensional mesh with the planes $x_2 = 0$ and $x_3 = 0$ are shown. The total number of nodes is $N = 31537$ (leading to 315370 real unknowns). We solved the linear system using the nested GCR algorithm with $m = 10$, $\delta_{\text{inner}} = 10^{-2}$, and $\epsilon_{\text{inner}} = 10^{-2}$. The residual after each inner GCR iteration is again recorded in Table 5.2. We note that the convergence is comparable with that seen in two-dimensional examples.

The axially symmetric problem of section 5.1 was also solved in three dimensions. A quarter of the three-dimensional tube was discretized into tetrahedral elements

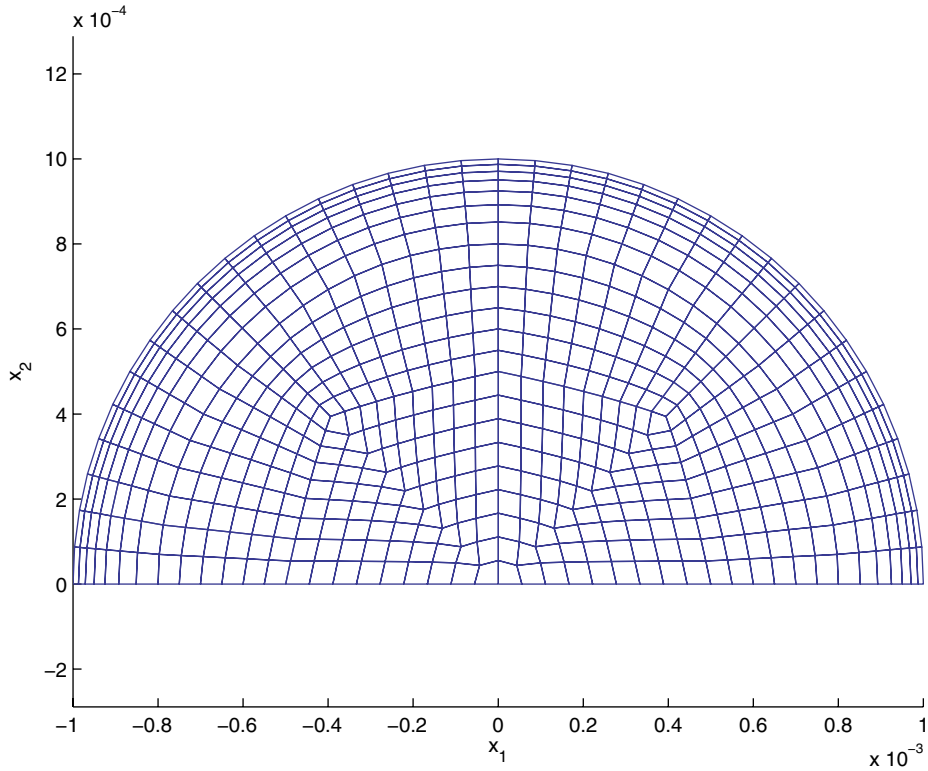

FIG. 5.10. *The intersection of the three-dimensional mesh with the plane* $x_3 = 0$.

TABLE 5.2
The convergence of the nested GCR method in the case of the three-dimensional example.

k	$\|\mathbf{D}_K(\mathbf{F} - \mathbf{K}\mathbf{U}^{(k)})\|/\|\mathbf{D}_K\mathbf{F}\|$
0	$4.259 \cdot 10^{-2}$
1	$3.370 \cdot 10^{-3}$
2	$2.313 \cdot 10^{-4}$
3	$1.710 \cdot 10^{-5}$
4	$1.349 \cdot 10^{-6}$
5	$4.395 \cdot 10^{-7}$

TABLE 5.3
The convergence of the nested GCR method when the axially symmetric problem was solved in three dimensions.

k	$\|\mathbf{D}_K(\mathbf{F} - \mathbf{K}\mathbf{U}^{(k)})\|/\|\mathbf{D}_K\mathbf{F}\|$
0	$1.840 \cdot 10^{-2}$
1	$1.624 \cdot 10^{-4}$
2	$1.219 \cdot 10^{-6}$
3	$1.896 \cdot 10^{-8}$

with the total number of nodes $N = 106802$ (leading to 1068020 real unknowns). The linear system corresponding to the frequency $f = 200$ was solved using $m = 10$, $\delta_{\text{inner}} = 10^{-2}$, and $\epsilon_{\text{inner}} = 10^{-3}$. The results recorded in Table 5.3 show that the outer GCR iteration converges rapidly also in this case.

5.3. Mesh sensitivity. We finally demonstrate an experimental observation that our preconditioner leads to solution algorithms with convergence independent of mesh size. We now consider a straight circular tube having the radius $R = 1.0 \cdot 10^{-3}$ and the length $L = 5.0 \cdot 10^{-3}$. We again exploit axial symmetry, so that the computational domain can be taken to be $\Omega = \{\mathbf{x} = (x_1, x_2) \mid \mathbf{x} \in (0, R) \times (0, L)\}$. In addition, we assume that the medium is air at standard conditions and consider the case of the frequency $f = 10^4$.

The boundary conditions for this example are similar to those used in our first example. On the edge $x_2 = 0$, we prescribe the velocity boundary conditions $V_1 = 0$ and $V_2(x_1) = J_0(\alpha x_1)$, where the maximum value of the Bessel function is scaled to the value $1.0 \cdot 10^{-3}$ and the scaling factor α is defined so that $x_1 = \alpha R$ is the first root of $J_0(x_1)$. In addition, we assume that the fluctuation of the temperature vanishes on this edge. On the edge $x_1 = 0$, the boundary conditions are deduced on the basis of symmetry, while on the remaining part of the boundary all of the components of the velocity vector as well as the disturbance of the temperature are prescribed to vanish.

We solved this problem using four different finite element meshes, for which the numbers of nodes were $N = 1078,\ 2108,\ 4171$, and 8280. The coarsest discretization of the tube into bilinear elements is shown in Figure 5.11. The other three meshes were made so that the fraction of the nodes which are located in the boundary layer to the total number of nodes is approximately the same for all of the meshes. We solved the linear systems using the nested GCR algorithm with the fixed parameters $m = 10$, $\delta_{\text{inner}} = 10^{-2}$, and $\epsilon_{\text{inner}} = 10^{-2}$. The residual after each inner GCR

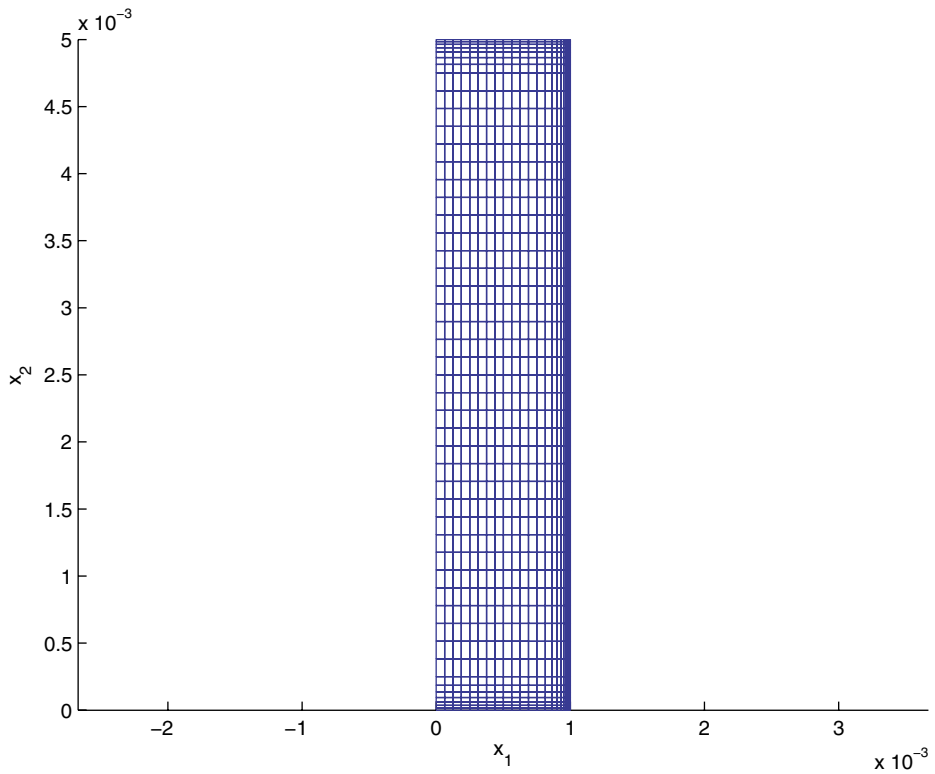

FIG. 5.11. *The coarsest discretization for the mesh sensitivity experiment.*

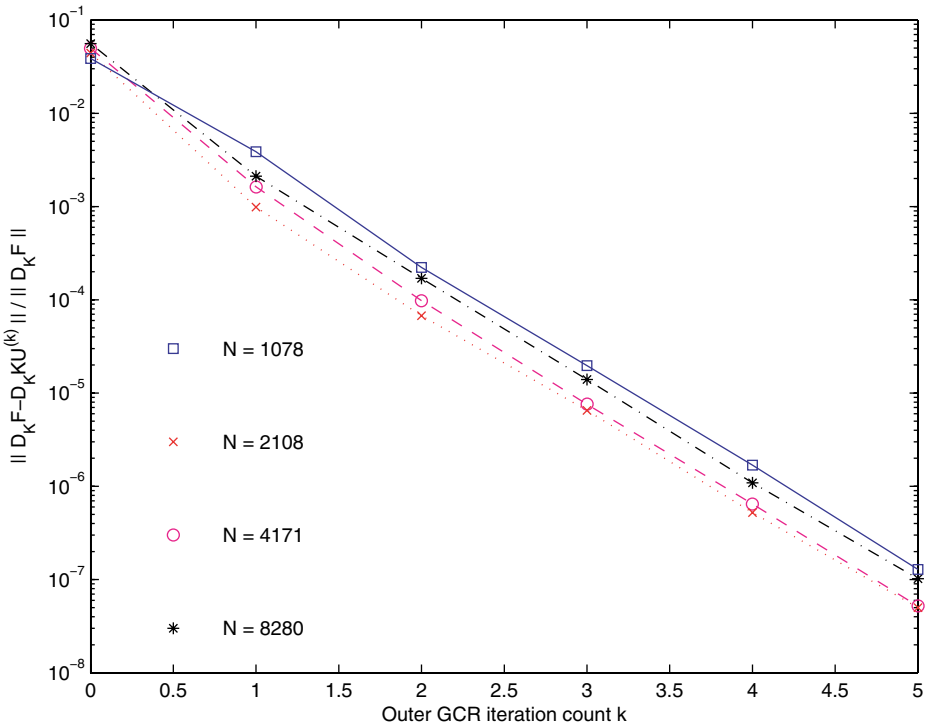

FIG. 5.12. *The residual after each inner GCR iteration when the discretization is refined.*

iteration is displayed in Figure 5.12. It is seen that the performance of the outer GCR iteration does not depend on the discretization; the same outer iteration counts producing residuals of approximately same sizes in all cases. Taking full advantage of this behavior would nevertheless require that this same optimality property would be shared by inner iterative methods. Such inner iteration methods are still to be found.

6. Concluding remarks. The results of this paper show that the performance of Schur complement preconditioners can depend drastically on the boundary conditions of the preconditioner. Here we have derived suitable boundary conditions by relying on a few key principles. The most important of these are the variational characterization of how the unknowns associated with the Schur complement depend on the boundary values of the velocity and the Helmholtz–Hodge decomposition of the velocity solution.

The results of the numerical experiments indicate that the application of the preconditioner we propose leads to robust solution algorithms with convergence independent of discretization mesh size. The construction of an optimal solution method for the dissipative acoustic equations has thus been shown to reduce to developing fast solvers for the subproblems of the preconditioning system. The central issue is the fast solution of the associated Schur complement problem characterized by the coupled system of the heat equation and a wavelike equation. While optimal solvers for this subproblem are still to be found, we have shown that a useful solution algorithm can be obtained when this problem is solved by applying a Krylov method in combination with the incomplete factorization preconditioners.

Acknowledgments. The author thanks Dr. Peter Råback for providing some of the finite element meshes used in the numerical experiments. The author thanks the anonymous referees for their useful comments.

ADDITIVE AND MULTIPLICATIVE TWO-LEVEL SPECTRAL PRECONDITIONING FOR GENERAL LINEAR SYSTEMS*

B. CARPENTIERI†, L. GIRAUD‡, AND S. GRATTON§

Abstract. In this paper we introduce new preconditioning techniques for the solution of general symmetric and unsymmetric linear systems $Ax = b$. These approaches borrow some ideas of the multigrid philosophy designed for the solution of linear systems arising from the discretization of elliptic partial differential equations. We attempt to improve the convergence rate of a prescribed preconditioner M_1. In a two-grid framework, this preconditioner is viewed as a smoother and the coarse space is spanned by the eigenvectors associated with the smallest eigenvalues of M_1A. We derive both additive and multiplicative variants of the resulting iterated two-level preconditioners for unsymmetric linear systems that can also be adapted for Hermitian positive definite problems. We show that these two-level preconditioners shift the smallest eigenvalues to one and tend to better cluster around one those eigenvalues that M_1 already succeeded in moving into the neighborhood of one. We illustrate the behavior of our method through extensive numerical experiments on a set of general linear systems. Finally, we show the effectiveness of these approaches on two challenging real applications; the first comes from a nonoverlapping domain decomposition method in semiconductor device modeling, the second from industrial electromagnetism applications.

1. Introduction.

The large linear systems involved in many intensive numerical simulations are solved using preconditioned Krylov solvers. It is well known that the convergence of these linear solvers often depends to a large extent on the eigenvalue distribution of the preconditioned matrix. In many cases, it is observed that "removing" the extreme eigenvalues can greatly improve the convergence. Several techniques have been proposed in the past few years that attempt to tackle this problem. The proposed approaches can be split into two main families, depending on whether the scheme enlarges the generated Krylov space (see, for instance, [22, 25, 30, 33]) or adaptively updates the preconditioner [1, 6, 11, 20, 27, 29]. Many of these preconditioning techniques based on approximate eigenpairs have been proposed in the past few years. The underlying driving idea behind these approaches is to capture in a low-dimensional space the modes that do not quickly converge with a first-level preconditioner. In order to be efficient and keep the dimension of the low-dimensional space reasonably small, these techniques are generally used in combination with a first-level preconditioner that does a good job of clustering most eigenvalues close to one with relatively few outliers near the origin [10, 26, 36]. These spectral preconditioners can also be split into two main families, depending on their effect on the spectrum. They are referred to as deflation preconditioners [12, 14, 28] if they at-

tempt to move a subset of eigenvalues to a positive quantity σ; they are referred to as coarse grid preconditioners [6, 14] if they only attempt to shift the subset close to σ. The name of those latter techniques comes from domain decomposition and was first introduced in [5]. For this reason $\sigma = 1$ is often considered in practice.

On the other hand, for the solution of a linear system $Ax = b$ arising from the discretization of partial differential equations (PDE), the multigrid methods are among the fastest techniques. The core of the multigrid algorithms is a two-grid procedure that is applied recursively. A classical two-grid cycle can be briefly described as follows. On the fine grid a few iterations of a smoother are applied that attempt to reduce the high frequencies of the error (i.e., the components of the error in the space spanned by the vectors associated with the largest eigenvalues of A). The residual is then projected on the coarse grid where the low frequencies (i.e., the components associated with the smallest eigenvalues) can be captured and the coarse error equation is solved. The error on the coarse space is prolongated back to the fine grid to update the approximation computed by the presmoothing phase and a few more steps of the smoother are applied. Finally, if the new iterate is not accurate enough, the two-grid cycle is applied iteratively. In classical multigrid, the coarse space is not defined explicitly through the knowledge of the eigencomponents but by the selection of a space that is expected to capture them. The scheme presented above is a multiplicative algorithm [19], but additive variants [2, 13, 34] also exist.

In this work, we apply some underlying ideas from the multigrid approach to design preconditioners for the solution of general symmetric and unsymmetric linear systems (not necessarily coming from PDE applications). We attempt to improve a prescribed preconditioner M_1, which is used to define the smoother involved in the two-grid scheme. In many situations such a preconditioner (that is application-dependent) is able to cluster most of the eigenvalues close to one but still leaves a few close to the origin; this is a fairly common situation for a wide range of problems and preconditioners. In that framework we define the coarse space by the span of the eigenvectors associated with the smallest eigenvalues of M_1A that are computed explicitly (i.e., the components of the error that are not efficiently damped by the smoother). We denote by V the matrix having the eigenvectors of M_1A as its columns. In that context, the prolongation operator is $P = V$, the restriction operator is denoted by R, and the matrix involved in the coarse grid error problem is defined by a Petrov–Galerkin formula $A_c = RAP$. The new approaches handle similar ingredients to those exploited in [6] but use them in a completely different way following another philosophy. This results in particular in a different spectral transformation for the preconditioned matrices. We mention that our multiplicative approach is a generalization of the generalized global basis (GGB) method [36]. For a particular choice of M_1, that is, an algebraic multigrid V-cycle, and a particular choice of V, the eigenvectors associated with the largest eigenvalues in modulus, our multiplicative method coincides with GGB if only one iteration of the smoother is performed. In section 2, we describe the proposed preconditioners and establish their effect on the spectrum of the preconditioned matrices. In section 3, we illustrate the numerical effects related to each parameter defining the new preconditioners on a set of unsymmetric and symmetric positive definite (SPD) linear systems from the Matrix Market [4]. We demonstrate their computational efficiency on very challenging linear systems that arise in two-dimensional unstructured mixed finite element calculation for semiconductor device modeling as well as for the solution of dense linear systems arising from boundary element methods in industrial electromagnetic applications.

2. Two-level spectral preconditioning. We consider the solution of the linear system

$$Ax = b, \tag{1}$$

where A is an $n \times n$ nonsingular matrix, and x and b are vectors of size n. The linear system is solved using a preconditioned Krylov solver, and we denote by M_1 the left preconditioner, meaning that we solve

$$M_1 Ax = M_1 b. \tag{2}$$

Let $\{\lambda_1, \ldots, \lambda_n\}$ be the set of eigenvalues of $M_1 A$ in any order where the multiple eigenvalues are repeated. Let the columns of V_k be the basis of a right invariant subspace of $M_1 A$ of dimension k. Suppose without loss of generality that $M_1 A V_k = V_k J_k$, where the eigenvalues of J_k are $\{\lambda_1, \ldots, \lambda_k\}$. In this section we describe two procedures that attempt to improve the eigenvalue distribution of the preconditioned matrix. We formulate the algorithms in the framework of algebraic multilevel methods; the terminology and the design principles are inherited from classical two-grid algorithms. In the next two sections we present these two variants of the algorithm that are either multiplicative or additive.

2.1. Multiplicative two-grid spectral preconditioning. A generic two-level multigrid cycle is illustrated in Algorithm 1, where M_1 is used to define a weighted stationary method that implements the smoother. The algorithm takes as input a vector r that is the residual vector we want to precondition and returns as output the preconditioned residual vector z. After μ_1 smoothing steps we project, using the restriction $R = W^H$, the residual into the coarse subspace and solve the coarse space error equation involving $A_c = W^H A V_k$. Finally, we prolongate back the error using V_k in the original space and smooth again the new approximation. The preconditioner constructed using this scheme depends on A, M_1, μ_1, μ_2, ε, and $\omega > 0$ and could be denoted by $M_{Mul}(A, M_1, k, \omega, \mu_1, \mu_2)$. For the sake of simplicity of exposure, when no confusion is possible we will simply denote it by M_{Mul} or $M_{Mul}(A, M_1)$.

PROPOSITION 1. [illegible] $A_c = W^H A V_k$ [illegible] $z = M_{Mul}\, r$ [illegible] $iter = 1$ [illegible] M_{Mul} [illegible]

$$M_{Mul} = A^{-1} - (I - \omega M_1 A)^{\mu_2} (I - M_c A)(I - \omega M_1 A)^{\mu_1} A^{-1}, \tag{3}$$

[illegible] $M_c = V_k (W^H A V_k)^{-1} W^H$

This is a fairly standard result; for its proof we refer, for instance, to [8]. □

The following proposition describes the eigenvalue distribution of the preconditioned matrix $M_{Mul} A$. Similarly to multigrid, if we choose V_k to be the invariant space associated with the smallest eigenvalues (i.e., the closest to the origin), this result shows that the smallest eigenvalues are shifted to one and that those that were already close to one are clustered closer to this point. On the assumption that the initial preconditioner M_1 has done a good job of clustering most eigenvalues close to one with relatively few outliers near the origin, the effect of M_{Mul} is expected to be very beneficial.

ALGORITHM 1.

set $z^1 = 0$
for $\ell = 1, iter$ **do**
  %
  $s_1^0 = z^\ell$
  for $j = 1, \mu_1$ **do**
    $s_1^j = s_1^{j-1} + \omega M_1 (r - A s_1^{j-1})$
  end for
  %
  $z_2^\ell = z_1^\ell + V_k A_c^{-1} W^H (r - A z_1^\ell)$
  %
  $s_2^0 = z_2^\ell$
  for $j = 1, \mu_2$ **do**
    $s_2^j = s_2^{j-1} + \omega M_1 (r - A s_2^{j-1})$
  end for
end for
$z = z^{iter}$

PROPOSITION 2. M_{Mul} 1 $M_{Mul}A$

$$\begin{cases} \eta_i = 1 & i < k, \\ \eta_i = 1 - (1 - \omega\lambda_i)^{\mu_1+\mu_2} & i \geq k. \end{cases}$$

We will show that the preconditioned matrix is similar to a matrix whose eigenvalues are those indicated. Let $V_k^\perp$ be an orthogonal complement of V_k. We have

$$M_1 A \left[V_k V_k^\perp\right] = \left[V_k V_k^\perp\right] \begin{pmatrix} J_k & E \\ 0 & F \end{pmatrix},$$

where the eigenvalues of J_k are $\{\lambda_1, \ldots, \lambda_k\}$ and those of F are $\{\lambda_{k+1}, \ldots, \lambda_n\}$.

Thus $M_1 A V_k = V_k J_k$ and $M_c A V_k = V_k$. In addition, it is easy to show by induction on j that $(I - \omega M_1 A)^j V_k = V_k (I - \omega J_k)^j$ and $(I - \omega M_1 A)^j V_k^\perp = V_k^\perp (I - \omega F)^j + V_k P_j$, where $P_j \in \mathbb{R}^{k \times (n-k)}$. We also have $(I - M_c A) V_k^\perp = V_k^\perp - V_k P_c$ with $P_c \in \mathbb{R}^{k \times (n-k)}$. Then the following relations hold:

$$M_{Mul} A \left[V_k V_k^\perp\right] = \left[V_k V_k^\perp\right] \begin{pmatrix} I & * \\ 0 & I - (I - \omega F)^{\mu_1+\mu_2} \end{pmatrix}, \tag{4}$$

where the asterisk denotes a nonzero block whose actual expression is unimportant. The equality (4) concludes the proof. □

1. It should be noted that the spectrum of the preconditioned matrix does not depend on the selection of W^H, which would play the role of the restriction operator in the multiplicative two-grid method.

2.2. Additive two-grid spectral preconditioning. In the additive algorithm, the coarse grid correction and the smoothing operation are decoupled. Each process generates an approximation of the preconditioned residual vector in complementary subspaces. The coarse grid correction computes only components in the space spanned by the eigenvectors associated with the few selected small eigenvalues, while at the end of the smoothing step the preconditioned residual is filtered so that only

components in the complementary subspace are retained. These two contributions are summed together for the solution update. A simple additive two-level multigrid cycle is illustrated in Algorithm 2. In this algorithm we follow [13] and select the procedure advocated in [34]: we define the filtering operators using the grid transfer operators as $(I - V_k W^H)$. This operator is supposed to remove all the components in the V_k directions. A natural choice is to select W^H so that $(I - V_k W^H)V_k = 0$ (i.e., $W^H V_k = I$).

ALGORITHM 2.

1: set $z^1 = 0$
2: **for** $\ell = 1, iter$ **do**
3: %
4: $s^\ell = r - Az^\ell$
5: %
6: % 1-
%
7: $e_1^{\ell,0} = 0$
8: **for** $j = 1, \mu_1 + \mu_2$ **do**
9: $e_1^{\ell,j} = e_1^{\ell,j-1} + \omega M_1(s^\ell - Ae_1^{\ell,j-1})$
10: **end for**
11: %
12: $c_1^\ell = (I - V_k W^H)e_1^{\ell,\mu_1+\mu_2}$
13: % 2-
%
14: $c_2^\ell = V_k A_c^{-1} W^H s^\ell$
15: %
%
16: $z^{\ell+1} = z^\ell + c_1^\ell + c_2^\ell$
17: **end for**
18: $z = z^{iter}$

PROPOSITION 3. W $A_c = W^H A V_k$ $(I - V_k W^H)V_k = 0$ 2 $z = M_{Add}\, r$ $iter = 1$ M_{Add}

$$M_{Add} = V_k A_c^{-1} W^H + (I - V_k W^H)(I - (I - \omega M_1 A)^{\mu_1+\mu_2})A^{-1}. \tag{5}$$

The proof follows arguments similar to those for the proof of Proposition 1. ∎

PROPOSITION 4. M_{Add} 3 $M_{Add}A$

$$\begin{cases} \eta_i = 1 & i \le k, \\ \eta_i = 1 - (1 - \omega\lambda_i)^{\mu_1+\mu_2} & i > k. \end{cases}$$

Using arguments similar to those for the proof of Proposition 2, it can be shown that

$$M_{Add}A\left[V_k V_k^\perp\right] = \left[V_k V_k^\perp\right]\begin{pmatrix} I & * \\ 0 & I - (I - \omega F)^{\mu_1+\mu_2} \end{pmatrix}, \tag{6}$$

where the asterisk denotes a nonzero block whose actual expression is unimportant. The equality (6) concludes the proof. ∎

2.3. The Hermitian positive definite linear systems. For Hermitian positive definite (HPD) linear systems a desirable property for M_1 is to be Hermitian positive definite; we denote by $M_1 = L_1 L_1^H$ its Cholesky decomposition. We note that in many situations the preconditioner M_1 is given in this factorized form as in the incomplete factorization [24], approximate inverse (AINV) [3], or factorized sparse approximate inverse (FSAI) [21]. In the rest of this section we review situations where M_{Mul} and M_{Add} are HPD.

PROPOSITION 5. [illegible] M_{Mul} [illegible] $W = V_k$ [illegible] $\mu_1 + \mu_2$ [illegible]

[illegible] We do not give the details of the calculation, but using simple matrix manipulations it can be shown that

$$M_{Mul}(A, M_1) = L_1 M_{Mul}(L_1^H A L_1, I) L_1^H. \tag{7}$$

We first show that $M_{Mul}(L_1^H A L_1, I)$ is Hermitian. Because $L_1^H A L_1$ is HPD we have $L_1^H A L_1 = \tilde{V} D \tilde{V}^H$, where $D = \mathrm{diag}\,(\lambda_1, \ldots, \lambda_n)$ and $\tilde{V} = [\tilde{V}_k \tilde{V}_k^{\perp}]$. If we denote $D_k = \mathrm{diag}\,(\lambda_1, \ldots, \lambda_k)$ and $D_{\bar{k}} = \mathrm{diag}\,(\lambda_{k+1}, \ldots, \lambda_n)$, we have

$$M_{Mul}(L_1^H A L_1, I) = \tilde{V} \begin{pmatrix} D_k^{-1} & 0 \\ 0 & D_{\bar{k}}^{-1}(I - (I - \omega D_{\bar{k}})^{\mu_1+\mu_2}) \end{pmatrix} \tilde{V}^H = \tilde{V} \hat{D} \tilde{V}^H. \tag{8}$$

Because $\mu_1 + \mu_2$ is odd, all diagonal entries of $\hat{D}$ are positive (the function $f(x) = 1 - (1 - \omega x)^k$ is positive $\forall x \in (0, \infty)$ for k odd; see also Figure 1(b)). Furthermore, (7) leads to $M_{Mul} = (L_1 \tilde{V}) \hat{D} (L_1 \tilde{V})^H$. The Sylvester law of inertia implies that all the eigenvalues of M_{Mul} are positive. ∎

PROPOSITION 6. [illegible] $\mu_1 + \mu_2$ [illegible] M_{Mul} [illegible] $W = V_k$ [illegible] $\omega < 2\lambda_{max}^{-1}(M_1 A)$

[illegible] The proof is similar to that of Proposition 5. ∎

In the HPD situation we have the following properties.

PROPOSITION 7. [illegible] $M_1 = L_1 L_1^H$ [illegible] (1) [illegible] $M_{Mul}(A, M_1)$ [illegible] $L_1^H A L_1 y = L_1^H b$ [illegible] $M_{Mul}(L_1^H A L_1, I)$ [illegible] $x = L_1 y$ [illegible] x_k [illegible] y_k [illegible] M_{Mul} [illegible] 5 [illegible] 6 [illegible] $x_0 = L_1 y_0$ [illegible] k $x_k = L_1 y_k$

[illegible] Because the preconditioners are HPD we consider their Cholesky decompositions, which are $M_{Mul}(A, M_1) = L_M L_M^H$ and $M_{Mul}(L_1^H A L_1, I) = \tilde{L}_M \tilde{L}_M^H$. From (7), we have $L_M L_M^T = L_1 \tilde{L}_M \tilde{L}_M^H L_1^H$, which shows that $L_M = L_1 \tilde{L}_M$ (uniqueness of the Cholesky decomposition). We now use the result on CG iterates from [17, 32] that states that solving $By = g$ with CG preconditioned by LL^T generates iterates y_k that can also be generated by unpreconditioned CG on $L^T B L \tilde{y} = L^T g$, provided that the initial guesses are such that $y_0 = L\tilde{y}_0$. We apply this result in the following sequence: CG on A preconditioned by $L_M L_M^T$ generates the same iterates as unpreconditioned CG on $L_M^T A L_M = \tilde{L}_M^H L_1^H A L_1 \tilde{L}_M$; these iterates are the same as those generated by CG on $L_1^H A L_1$ preconditioned by $\tilde{L}_M \tilde{L}_M^H$. ∎

PROPOSITION 8. [illegible] $M_1 = I$ [illegible] $W = V_k$ [illegible] V_k [illegible] $M_{Mul} = M_{Add}$

[illegible] Because A is HPD, A is diagonalizable in an orthonormal basis of eigenvectors. We then have that the vectors $W = V_k$ comply with the assumption $W^H V_k = I$ of Proposition 3.

With the assumptions that V_k is a set of eigenvectors, we have $M_{Mul}AV_k = V_k = M_{Add}AV_k$ and $M_{Mul}AV_k^{\perp} = M_{Add}AV_k^{\perp}$. □

REMARK 2. A situation where the assumptions of Proposition 8 hold is, for instance, when either $M_{Mul}(L_1^H AL_1, I)$ or $M_{Add}(L_1^H AL_1, I)$ is considered (i.e., the two-grid preconditioners are applied to $L_1^H AL_1 y = L_1^H b$). The additive preconditioner is in general not HPD even when A and M_1 are. One way to still use this preconditioner for an M_1 given in a symmetric factorized form $M_1 = L_1 L_1^H$ is to consider $M_{Add}(L_1^H AL_1, I)$ applied to $L_1^H AL_1 y = L_1^H b$. In that case we have $W = V_k$ and Proposition 8 shows that this preconditioner is the same as $M_{Mul}(L_1^H AL_1, I)$. Furthermore, Proposition 7 shows that CG then generates the same approximation with M_{Add} and M_{Mul}. This shows that for HPD linear systems all of these preconditioners are pretty much the same, and the choice of which to use can be made using floating-point arithmetic complexity as described below.

2.4. Some computational considerations. The spectral properties of M_{Mul} and M_{Add} have been derived from Algorithms 1 and 2, where only one outer iteration is considered. With calculations similar to those used so far, it can be shown that implementing "*iter*" outer steps leads to a spectral transformation for the two preconditioners that is defined by the following proposition.

PROPOSITION 9. [illegible] M_{Mul} [illegible] 1 [illegible] $iter \geq 1$ [illegible] $M_{Mul}A$ [illegible]

$$\begin{cases} \eta_i = 1 & \text{[illegible]} \quad i \leq k, \\ \eta_i = 1 - (1 - \omega\lambda_i)^{iter \times (\mu_1 + \mu_2)} & \text{[illegible]} \quad i > k. \end{cases}$$

Similar proposition holds with M_{Add} defined by Algorithm 2.

From a computational point of view, applying M_{Mul} or M_{Add} does not require the same computational effort. In terms of application of M_1 both need $iter \times (\mu_1 + \mu_2)$ matrix-vector products. The number of matrix-vector products involving A is one less for M_{Add} than for M_{Mul} per cycle. For M_{Add} the number of products by A is

$$(\mu_1 + \mu_2 - 1) + (iter - 1) \times (\mu_1 + \mu_2). \tag{9}$$

Under the assumption that the convergence of the Krylov solver is mainly governed by the eigenvalue distributions (i.e., $iter \times (\mu_1 + \mu_2)$ given), Proposition 9 and the number of matrix-vector products given by (9) indicate that for M_{Mul} it is computationally more efficient to use only one two-grid cycle with $(iter \times (\mu_1 + \mu_2))$ smoothing steps rather than *iter* two-grid cycles with $(\mu_1 + \mu_2)$ smoothing steps per cycle. For M_{Add}, the two variants have the same computational cost.

REMARK 3. In [6], the initial linear system is never considered and the idea is to perform an appropriate low rank correction of the preconditioned matrix to shift part of its spectrum. Here, similarly to the two-grid schemes for PDE solution, we solve exactly the error equation of the unpreconditioned system in the invariant subspace associated with the smallest eigenvalues in modulus. In that respect, even though these approaches exploit the same ingredients, the underlying philosophies are different.

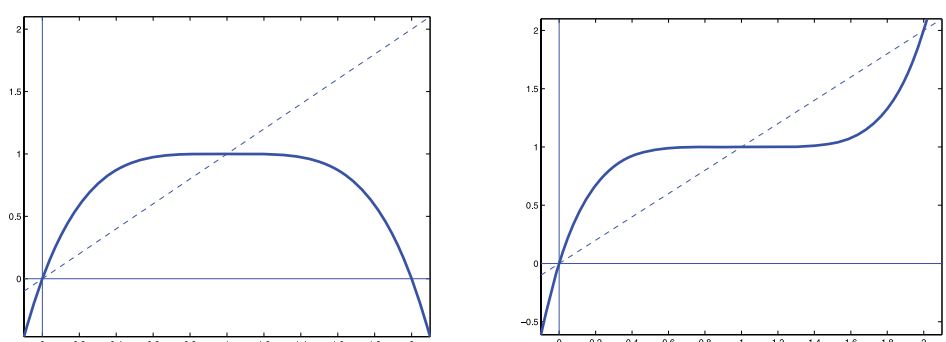
3. Numerical experiments. In this section we illustrate the numerical behavior of the two variants of the spectral algorithm described in the earlier section. In section 3.1 we investigate only the numerical behavior of the proposed schemes and do not address their computational relevance. Their computational efficiency strongly

depends on the relative costs of the smoother, the matrix-vector, and eigenmode calculation, which are application-dependent. Furthermore, the extra cost associated with the setup to compute the eigenvectors might be significant and might not be amortized by the savings in time for the linear system solution. Consequently these computational aspects are investigated on two challenging applications where the preconditioners have been implemented in the real simulation codes and run on front-end computers.

3.1. General test problems. We consider both unsymmetric and SPD systems. The numerical experiments are performed with MATLAB version 7.0. For the sake of simplicity we consider the $ILU(t)$ preconditioner [31] from MATLAB for M_1 in the unsymmetric case and the incomplete Cholesky factorization $IC(t)$ for SPD systems [24]. We report on results using the GMRES and the Bi-CGStab [35] solvers for unsymmetric problems, and the CG method for SPD systems. The experiments are carried out using left preconditioning for the unsymmetric problems. The initial guess for the solution is the zero vector. Because we compare different preconditioners, we choose as a stopping criterion the reduction of the normalized unpreconditioned residual by 10^{-6}, so that the stopping criterion is independent of the preconditioner. We explicitly compute the true unpreconditioned residual at each iteration. For the experiments with M_{Add} we use $W = QR^{-1}$, where $V_k = QR$ to ensure that $W^H V_k = I$. For the experiments with M_{Mul} we consider $W = V_k$. We mention that with these choices of W we have never encountered rank deficiency for A_c. However, it is reasonable to check the nonsingularity of A_c in practice to ensure that the preconditioners are defined; notice that in the HPD situation A_c cannot be singular. The eigenvectors V_k are computed in a preprocessing phase using the MATLAB function `eigs`.

In a first stage we consider both SPD and unsymmetric test matrices from the Matrix Market. In this section, we only report a few results representative of the general trends. For a complete description of the numerical experiments we refer the reader to the appendix of [8], where results on intensive experiments are reported.

For SPD matrices, we display the eigenvalue transformation operated by the preconditioners. These are the curves $f(x) = 1 - (1 - \omega x)^k \ \forall x > 0$ as the eigenvalues of $M_1 A$ are real positive. Figure 1 illustrates that the preconditioned matrices remain SPD for $(\mu_1 + \mu_2)$ odd, while ω should be set such that $\omega < 2\lambda_{max}^{-1}(M_1 A)$ for $(\mu_1 + \mu_2)$ even.



(a) $(\mu_1 + \mu_2)$ even (=4) (b) $(\mu_1 + \mu_2)$ odd (=5)

FIG. 1. *Shape of the polynomial that governs the real eigenvalues distribution of the two-grid spectral preconditioner for* $\omega = 1$.

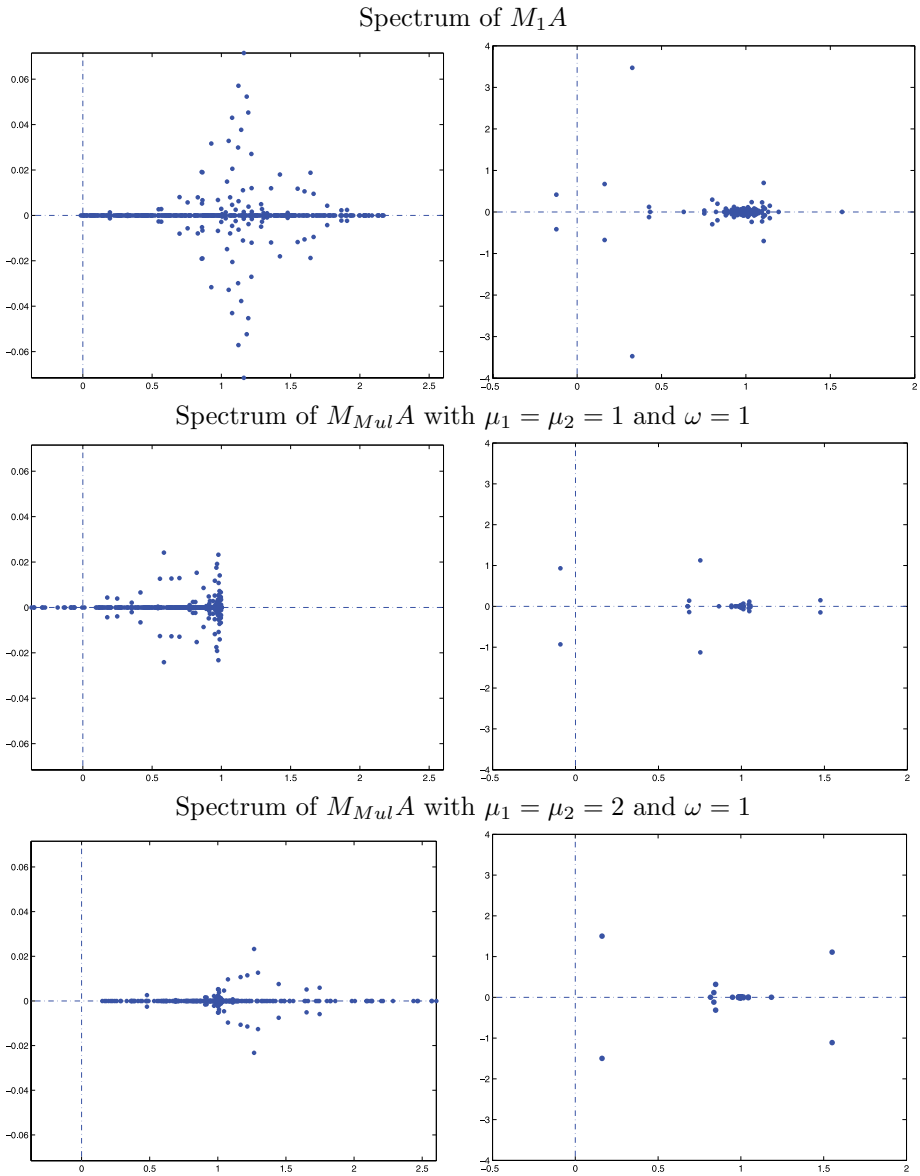


FIG. 2. *Spectrum of the preconditioned matrices (BFW*398*A, left; GRE*1107*, right).*

In Figure 2 we depict the spectrum of preconditioned matrices using only the first-level preconditioner and the two-grid preconditioner with different choices for μ_1 and μ_2. In this figure, it can be seen that the spectral preconditioners do a good job in clustering close to one most of the eigenvalues. More precisely for $\mu_1 + \mu_2 > 1$ all the eigenvalues lying in the open disk of radius one centered in $(1, 0)$ are contracted toward $(1, 0)$; the ones out of this disk are moved away from $(1, 0)$. When $\mu_1 + \mu_2$ is odd, those that are real and larger than 2 become negative, whereas for $\mu_1 + \mu_2$ even they remain positive. This is illustrated by the example of the matrix BFW398A.

In the following subsections we consider the numerical behavior of the proposed

TABLE 1

preconditioners. The efficiency in terms of computational cost is very problem-dependent and is addressed in section 3.2, where two real-world applications are presented.

3.1.1. Numerical behavior of M_{Mul} versus M_{add}. The two preconditioners M_{Add} and M_{Mul} give rise to preconditioned systems that have the same eigenvalue distribution but possibly different eigenspaces. In Table 1 we report on the number of iterations of the Krylov solvers for different matrices and different values of μ_1 and μ_2 when the size of the coarse space is varied. The symbol "M_1" for the dimension of the coarse space means that no coarse space correction is needed and only one smoothing is applied; in that case the preconditioner reduces to the standard incomplete factorization. The symbol "†" indicates that the convergence was not observed in less than 1000 iterations. On all the numerical experiments we have performed, M_{Add} and M_{Mul} exhibit a very similar numerical behavior, as illustrated in Table 1. Small differences appear with Bi-CGStab, diminish with restarted GMRES, and vanish with full GMRES. However, from a numerical point of view none of the two preconditioners appears superior to the other. When the size of the coarse space is increased it can be seen that the two-level preconditioners monotonically improve the convergence of full GMRES. This is no longer strictly true for restarted GMRES and Bi-CGStab, but the trend is still to observe fewer iterations when the size of the coarse space is increased. Generally the larger the coarse space, the faster the convergence. One can see on the SAYLR1 matrix that even without coarse space correction few steps of smoothers can significantly improve the convergence of the Krylov solvers. On this latter example, the combination of the smoothing steps and the coarse grid correction is the only way to ensure the convergence of GMRES(50).

Because M_{Add} and M_{Mul} have a similar behavior and because M_{Mul} is naturally defined for SPD problems, we consider only M_{Mul} for the numerical experiments reported in the next three sections.

3.1.2. Effect of the number of smoothing steps. In Table 2 we display the number of iterations when the number of smoothing steps is varied from 1 to 3. It can

	$\mu_1 + \mu_2 = 2$	†	34	31	28	25	24	22	21	19	18	17	16
	$\mu_1 + \mu_2 = 3$	†	28	26	24	23	21	20	20	18	18	16	14

be seen that increasing the number of smoother iterations improves the convergence for all the test examples but the matrix FS5414. For this latter matrix, the convergence using M_{Mul} is worse than using simply M_1. This poor numerical behavior is probably due to the fact that the preconditioned system $M_1 A$ has eigenvalues close to 2. The even number of smoothing iterations moves those eigenvalues near zero, which dramatically affects the numerical behavior of restarted GMRES. Full GMRES succeeds to converge but still using 2 steps of smoothing gives a larger number of iterations than just 1 step. When we move to 3 steps we reduce the number of iterations compared to 2 but also compared to 1 step of smoothing.

Even though no numerical experiments are reported to illustrate this phenomenon, we observed that only the sum $\mu_1 + \mu_2$ plays a role for the convergence of M_{Mul} wherever these smoothing steps are used only as presmoother, postsmoother, or split between the pre- and postsmoothing steps. Furthermore, we observe that the relative improvement of using more smoothing steps tends to be larger for a small dimension of the coarse space.

3.1.3. Effect of the relaxation parameter ω. In Table 3 we display the number of iterations required by CG, and by restarted and full GMRES on a set of matrices when the relaxation parameter ω is varied. For SPD matrices, when $\mu_1 + \mu_2$ is odd, no damping is required for the smoother to ensure that the preconditioner is SPD, as illustrated for the matrices 1138BUS and BCSSTK27. It can be seen that $\omega = 1.0$ leads to worse iteration counts than the incomplete factorization alone, i.e., the two space cycles slow down the convergence of CG. This might be due to the fact

TABLE 3
Number of iterations with M_{Add} when the relaxation parameter is varied.

that when the number of smoothing steps is increased, they tend to spread the right part of the spectrum if the largest eigenvalues are bigger than two. For this reason, using a damping parameter ensures that the smoother is a contraction that better clusters the right part of the spectrum around one. Nevertheless this contraction may not have a positive effect. For instance, if there were a cluster beyond two, it would be spread by the smoothing iterations, which would possibly penalize the convergence of CG. On the other hand an isolated large eigenvalue would not affect CG, but a scaling to move it below two might shrink the complete spectrum and create clusters near the origin, which might have a negative affect on CG convergence.

For unsymmetric problems, the numerical experiments reveal that the damping also plays a role. Often using a damping parameter improves the convergence of GMRES, especially when the number of smoothing steps is odd. However, no general trends on the suitable choice of this parameter have been revealed by the experiments. Its role is clear in the framework of the stationary iterative method, but a better understanding of the convergence of unsymmetric Krylov solver would be necessary to better understand the influence of this parameter.

3.1.4. Sensitivity to the accuracy of the eigencomputation. As mentioned in the previous section, the eigenvalue calculation is performed in a preprocessing phase. In order to investigate the sensitivity of our algorithm to the eigencomputation accuracy we compute the eigenpairs of a slightly perturbed matrix, $(M_1A + E)$, where E is a random matrix that is scaled so that $\frac{||E||}{||M_1A||} = \eta$. We use these computed eigenvectors to build our preconditioners and compute the backward error of these vectors as if they were eigenvectors of M_1A. By varying η, we can monitor the level of the backward error that becomes comparable for each eigenvector. In Table 4, we give the number of iterations of the Krylov solvers when the backward error of the computed eigenvectors is varied. As there is one backward error per eigenvector, we give the average of them in the table. It can be seen that, in many cases, there is no need for very high accuracy in the computation of the eigenvectors. On the 685BUS matrix $\eta = 10^{-4}$ ($\eta = 10^{-3}$ for HOR131) gives similar results to $\eta = 10^{-14}$. The numerical behavior of the preconditioner slightly deteriorates when η grows on the GRE1107 matrix, which is probably due to some ill-conditioning of the eigenvectors. Furthermore, it seems that when the number of smoothing steps is increased the accuracy of the eigencalculation has a smaller impact on the numerical efficiency of the preconditioner.

Finally we mention that a sensitivity analysis of some spectral preconditioners is performed in [15] in the SPD cases. For the studied preconditioners, it is shown that their quality depends in particular on the magnitude and the clustering of the eigenvalues that are involved in their definition (i.e., the part of the spectrum they attempt to move). Similarly for the preconditioners studied here, it can be expected that if small or clustered eigenvalues are targeted, a good accuracy should be requested when computing them.

3.2. Implementation in applications. In the previous sections we have illustrated the possible numerical benefit of using a few smoothing iterations to improve the convergence of the preconditioned Krylov solver. In some situations it is the only way to get convergence and the benefit is clear. In other cases it improves the convergence but we might have some questions:

1. Is there a final benefit in terms of computational time because of the extra cost introduced by the calculation of the residual at each iteration of the smoother?
2. Is there a way to alleviate this residual calculation cost?

The answer to the first question is very problem- and machine-dependent. On parallel distributed computers, the dot product calculation in CG and the orthogonalization process in GMRES are the main bottlenecks for performance; reducing the number of iterations is an obvious way to alleviate this cost. When the preconditioner enables a significant reduction of iterations of the Krylov solvers, the extra cost of the matrix-vector products (that usually involves only neighbor-to-neighbor communication) can eventually be compensated for by the decrease of the cost of the dot products (that involves global communications).

One way to reduce this extra cost is to implement a cheaper but approximated matrix-vector product. Such a possibility exists, for instance, when the fast multipole techniques are implemented to compute the matrix-vector product in electromagnetics application. Another example arises in nonoverlapping domain decomposition and is further investigated in the next section.

TABLE 4
Sensitivity of M_{Mul} efficiency versus the accuracy of the eigencomputation.

3.2.1. A case study in semiconductor device simulation. The numerical simulation of two-dimensional semiconductor devices is extremely demanding in terms of computational time because it involves complex embedded numerical schemes. At the kernel of these schemes is the solution of very ill-conditioned large linear systems. Such problems are challenging because they are large, very ill-conditioned, and extremely badly scaled. In that respect, robust and efficient linear solvers should be selected in order to reduce the elapsed time required to successfully perform a complete simulation. In this section we present some numerical experiments obtained by

TABLE 5

using the spectral two-level preconditioners for the solution of the Schur complement systems resulting from a nonoverlapping domain decomposition approach. For that example the smoother is defined by an additive Schwarz preconditioner for the Schur complement system; we refer the reader to [16] for more details on this application.

In this implementation of the iterative substructuring approach the Schur complement matrix that is sparse with dense blocks is computed explicitly. In order to reduce the computational cost of the residual calculation involved in each step of the smoother, we consider a sparsified Schur complement to perform this operation. This sparse approximation of the Schur complement is obtained by dropping all the entries that are smaller than a prescribed threshold. Even though we have not considered other variants to get a cheap approximation, we mention that other possibilities exist. For instance, if the Schur complement were not explicitly formed, we might have considered some approximations computed using incomplete factorizations for the local subproblems or using a probing technique [9].

In Table 5 we report numerical experiments observed on one of the SPD linear systems that has to be solved in our semiconductor device simulation. It corresponds to a partitioning of the domain into eight subdomains, as shown in Figure 3. The complete domain is discretized by 155,000 degrees of freedom (dof), and the size of the interface between the subdomains (i.e., the size of the associated Schur complement matrix) is 1607. In this table, we vary the sparsity of $\tilde{S}$, the sparse approximation of the Schur complement matrix, and report the number of CG iterations required to obtain a reduction of the normalized unpreconditioned residual by 10^{-11}. This very small threshold for the stopping criterion of the linear solver was required to ensure the convergence of the nonlinear scheme. It can be seen that when the size of the coarse space is varied, more than half of the entries of S can be dropped for the implementation of the smoother without affecting the numerical behavior of M_{Mul}. This enables us to save a significant amount of floating-point operations involved in the smoother and consequently to reduce its cost substantially. Dropping 70% of the entries doubles the number of iterations while it divides by three the cost of applying the preconditioner. Depending on the target computer this latter situation might possibly lead to saving time.

3.2.2. A case study in electromagnetism applications. Electromagnetic scattering problems give rise to linear systems that are challenging to solve by iterative methods. For three-dimensional problems the boundary integral formulation of Maxwell's equations is often selected because of its nice approximation properties. This approach gives rise to dense complex systems. In recent years, the introduction of fast methods with reduced computational complexity and storage requirement has

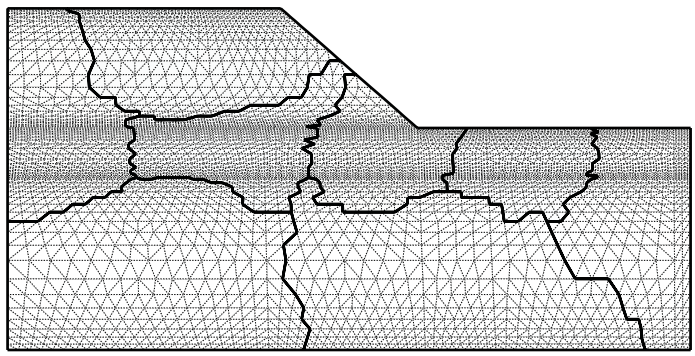

FIG. 3. *Mesh partitioning of the semiconductor discretization.*

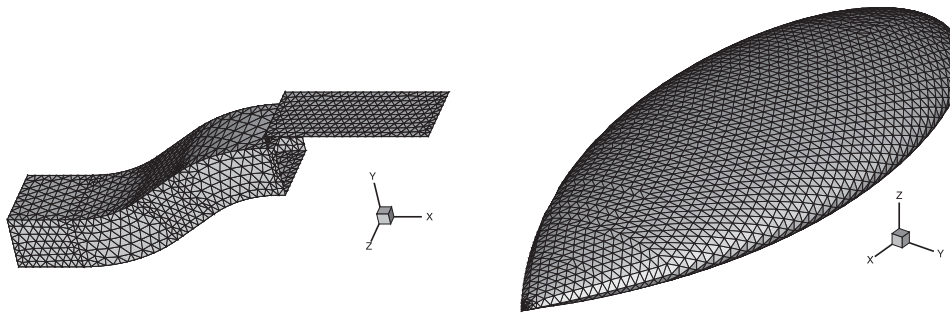
attracted an increasing interest in the use of preconditioned Krylov methods for the simulation of real-life electromagnetic problems. In this section, we consider the surface integral formulation of Maxwell's equations modeled via the electric-field integral equation (EFIE), which is the most general but the most difficult formulation to solve for iterative solvers. Thus preconditioning is crucial and approximate inverse methods based on Frobenius-norm minimization have proved to be among the most effective preconditioners for solving these systems efficiently. We refer the reader to [7] and the references therein for a more detailed presentation of this preconditioning technique on this class of problems.

The Frobenius-norm minimization preconditioner M_{FROB} is very effective in clustering most of the eigenvalues near one, but tends to leave a few isolated eigenvalues close to zero. The presence of these very small eigenvalues can slow down the convergence of iterative solvers especially on large problems, where the memory constraints prevent the use of large restarts in GMRES, which is the best-suited solver for those problems. In this section, we apply the two-space spectral preconditioner on top of the Frobenius-norm minimization method. The preconditioner M_{FROB} is actually used to define a stationary iterative scheme implemented as a smoother. In the numerical experiments, the initial guess is the zero vector, we consider a right preconditioned GMRES method, and the threshold for the stopping criterion is set to 10^{-3} on the normwise backward error $\frac{||r||}{||b||}$, where r denotes the residual and b the right-hand side of the linear system. This tolerance is accurate for engineering purposes, as it enables the correct reconstruction of the radar cross-section of the objects. The parallel runs have been performed in single precision complex arithmetic on sixteen processors of an HP-Compaq Alpha server, a cluster of symmetric multiprocessors. We report results on two industrial problems, namely, a cobra (Figure 4(a)) discretized with 60,695 dof and an almond (Figure 4(b)) discretized with 104,793 dof. We are in the suited situation, where the first-level preconditioner M_{FROB} does a good job in clustering most of the eigenvalues near one and leaves only a few outliers close to the origin. Consequently, the eigenvectors are computed in forward mode by ARPACK in a preprocessing phase.

For the matrix-vector products, we use the fast multipole method (FMM) [18], which performs fast matrix-vector products in $O(n\log n)$ arithmetic operations. More precisely, a highly accurate FMM is used for the standard matrix-vector product operation within GMRES, and a less accurate FMM is used for the extra matrix-vector products involved in the smoother of the preconditioning operation. The price



(a) Cobra (b) Almond

FIG. 4. *Mesh associated with test examples.*

to pay for the accuracy is mainly computational time; high accuracy also means more computational time.

In Table 6 we report on the number of iterations and the elapsed time for different sizes of the coarse space and an increasing number of smoothing steps. For the two test examples we show results with restarted and full GMRES. For these experiments we set up $\omega^{-1} = \frac{2}{3}\lambda_{max}(M_{FROB}A)$, which seems to be an overall good choice. On these problems M_{Add} and M_{Mul} give the same number of iterations. For this reason we report only on the M_{Add} preconditioner, which is about 33% faster than M_{Mul} as it requires fewer matrix-vector operations, as indicated in section 2.4. For instance, on the almond test problem using 3 smoothing steps and 50 eigenvectors, both converge in 87 iterations with GMRES(10), M_{Mul} takes 10 minutes, and M_{Add} only 6 minutes.

In this table we also display the number of iterations and the elapsed time of GMRES with only M_{FROB}. It can be seen that the use of M_{Add} is always beneficial both from a number iterations viewpoint and from a computational time viewpoint. The gain in time varies from 14 to infinity with GMRES(10) and between 2 and 3 with GMRES(∞).

From a numerical point of view we observe in these examples the same behavior as before. That is, the larger the coarse space, the better the preconditioner; the number of GMRES iterations decreases when the number of smoothing steps is increased. Furthermore, the gain is larger if restarted GMRES is considered than if full GMRES is used as solver. In particular on the almond with GMRES(10) and less than 50 eigenvectors, the only way to get convergence is to perform a few steps of smoothing; with 50 eigenvectors the gain introduced by the smoothing iterations is still tremendous (i.e., larger than 21). On the Cobra problem, using 15 eigenvectors the gain is far larger than 2 with GMRES(10), and close to 2 for full GMRES.

Not only is the number of iterations significantly reduced, but the solution time is as well. On the almond problem, using 50 eigenvectors and GMRES(10) we gain a factor of 12 in elapsed time when we increase the number of smoothing steps from 1 to 3. We mention that on large electromagnetic problems (of size larger than 0.5 million unknowns) the use of small restarts is recommended in order to save the heavy cost of reorthogonalization and reduce the final solution cost. The choice of a small restart is also dictated by memory constraints [7]. With full GMRES, the number of iterations is significantly decreased but the total solution cost is likely to only slightly decrease

TABLE 6
Experiments with M_{Add} on the electromagnetics problems.

when the number of smoothing steps is large as the preconditioner is expensive to apply. The optimal selection of the size of the coarse space and of the number of smoothing steps remains an open question, and the choice mainly depends on the clustering properties of the initial preconditioner. In terms of computational cost the coarse grid correction and the smoothing mechanism are complementary components that have to be suitably combined. On the cobra problem, for instance, using 3 smoothing steps and 5 eigenvectors we obtain a better convergence rate but similar computational time than when using 1 smoothing step but 15 eigenvectors; on the almond problem, the solution cost of GMRES(10) with 3 smoothing steps and 30 eigenvectors is similar to the time with 2 smoothing steps but 50 eigenvectors. Enabling a reduction in the number of eigenvectors by using more smoothing steps is a desirable feature in contexts where computing many eigenvalues can become very expensive, which is, for instance, the case in this application for very large problems.

To illustrate the cost related to the eigenvector calculation, we mention that the computation of 30 eigenvectors in the almond problem requires 1100 matrix-vector products, that is, about 2 hours. In the cobra example, 500 matrix-vector products

are needed to calculate 15 eigenvectors, which corresponds to 1 hour. The extra cost associated with this preprocessing is quickly amortized as many right-hand sides have usually to be solved to compute the so-called radar cross-section. In the cobra example, the eigencalculation is amortized if more than 2 right-hand sides are solved using GMRES(10) or more than 5 if full GMRES can be afforded. For the almond, the gain is unbounded if GMRES(10) is used and 15 right-hand sides should be solved to amortize the eigencalculation if full GMRES can be afforded. To conclude, we mention that numerical experiments are reported in [10] on the same test problems with the preconditioner presented in [6]. The observed behavior is similar to those reported here when $\mu_1 + \mu_2 = 1$, which again illustrates the benefits of the new approach when only a few eigenpairs are available.

4. Concluding remarks. In this work, we exploit some ideas implemented in the multigrid techniques for the solution of PDEs to derive new additive and multiplicative spectral two-level preconditioners for the solution of general linear systems. We propose a scheme that enables us to improve a given preconditioner that leaves only few eigenvalues close to zero. We study the spectrum of the new preconditioned matrix associated with these schemes. The effectiveness and robustness of these preconditioners is mainly due to their ability to shift to one a selected set of eigenvalues and to cluster near one most of the others. We illustrate some features of these techniques in small examples from the Matrix Market and illustrate their attractive numerical behavior on two challenging real-world applications. On electromagnetism industrial problems, we show that the preconditioner enables us to save a significant amount of time for the solution of large problems on parallel platforms.

Acknowledgments. The authors would like to thank Ray Tuminaro for the stimulating discussions he had with the second author when he visited him at Sandia. The authors are grateful to Emeric Martin for his assistance in implementing the preconditioner in the electromagnetism code. Finally, we would like to thank the anonymous referees for their valuable remarks, questions, and comments that enabled us to improve this paper.

MULTIGRID FOR HIGH-DIMENSIONAL ELLIPTIC PARTIAL DIFFERENTIAL EQUATIONS ON NON-EQUIDISTANT GRIDS*

H. BIN ZUBAIR†, C. W. OOSTERLEE‡, AND R. WIENANDS§

Abstract. This work presents techniques, theory, and numbers for multigrid in a general d-dimensional setting. The main focus of this paper is the multigrid convergence for high-dimensional partial differential equations on non-equidistant grids such as may be encountered in a sparse-grid solution. As a model problem we have chosen the anisotropic stationary diffusion equation on a rectangular hypercube. We present some techniques for building the general d-dimensional adaptations of the multigrid components and propose grid-coarsening strategies to handle anisotropies that are induced due to discretization on a non-equidistant grid. Apart from the practical formulas and techniques, we present—in detail—the smoothing analysis of the point ω-red-black Jacobi method for a general multidimensional case. We show how relaxation parameters may be evaluated efficiently and used for better convergence. This analysis incorporates *full* and *partial doubling* and *quadrupling* coarsening strategies as well as the second- and the fourth-order finite difference operators. Finally we present some results derived from numerical experiments based on the test problem.

Key words. multigrid, high-dimensional PDEs, anisotropic diffusion equation, coarsening strategies, point-smoothing methods, relaxation parameters, Fourier-smoothing analysis

1. Introduction.

Multidimensional partial differential equations have diverse applications in various fields of applied sciences, including financial engineering [8], molecular biology [3], and quantum dynamics [1, 21]. There are quite a few fast and efficient solution techniques for partial differential equations (henceforth PDEs) of which multigrid ranks among the best. Multigrid is a well-known iterative procedure for the solution of large and sparse linear systems that arise from various kinds of PDE discretizations. The existing literature on the multigrid treatment of various problems, however, rarely explores issues that arise out of growth in the dimensionality of the problem. The implications of dimensionality growth include deterioration of the multigrid convergence rate, impractical storage requirements, and huge amounts of CPU time for single grid solution methods. Our main emphasis in this paper lies on the first challenge. We abbreviate [illegible] d [illegible] as [illegible]. In this paper d represents both [illegible] and [illegible]. So, e.g., $3d$ is to be interpreted as 3-dimensional.

The major hinderance in the numerical solution of multidimensional PDEs is the so-called [illegible], which implies that with the growth in dimensions we have an exponential growth in the number of grid points. This increases the

computational cost of many good algorithms. Although we do not address this issue in particular, we would like to stress that a way to handle dimensionality is the sparse-grid method [9, 21]. One of the characteristics of these [illegible] is that these grids are essentially non-equidistant, and therefore efficient solution methods for this type of grid are quite important.

A multigrid treatment of high-dimensional PDEs based on hyperplane relaxation has been proposed by Reisinger and Wittum in [8]. We present a multigrid treatment based on point relaxation and partial coarsening schemes. We demonstrate how the multigrid convergence factor can be brought down for higher d by the suggested grid-coarsening strategies and a proper choice of the relaxation parameters in the smoothing process.

The strategy that we suggest in this paper for good multigrid convergence is that, keeping the point-smoothing method, we coarsen the grid simultaneously along all of the dimensions where the errors are strongly coupled. We call this strategy [illegible]. This way we relax the anisotropy at each successive grid level, until the problem is isotropic to the point where full coarsening is feasible. Full coarsening from this stage onwards brings the grid to the coarsest possible level, where we solve exactly. These strategies therefore consist of two main phases: the [illegible] and the [illegible]. We show that multigrid based on [illegible] ($h \to 4h$) transfers during the partial coarsening phase of the scheme gives a multigrid speed boost if optimal relaxation parameters are used in the point-smoothing process. We would like to point out that partial coarsening schemes have also been put forward by Larsson, Lien, and Yee identifying the conditions for partial coarsening through local Fourier-smoothing analysis (LFA) [7]. Moreover, the utility of adaptive grid-coarsening in multigrid has also been demonstrated by Elias, Stubley, and Raithby and Horton and Vandewalle in [4] and [5], respectively.

Foremost (in section 2) we point out that the Black–Scholes pricing problem PDE can be reduced to a standard -dimensional heat equation, indicating the need for fast solution methods for high-dimensional PDEs of Poisson type. The discretization and subsequent implementation of a d-dimensional PDE is somewhat involved, and in section 3 we show how this can be done with Kronecker products. Section 4 deals with d-multigrid, point-smoothing, coarsening strategies and concludes with a computational complexity analysis. Next we provide the LFA for the ω-RB Jacobi method and show how it can be extended to d dimensions. This is section 5. We also point out here how we incorporate partial doubling and quadrupling in this analysis. This section concludes with a tabular presentation (up to $6d$) of some optimal relaxation parameters. Finally in the last section we present quite a few versatile numerical experiments and demonstrate the excellent multigrid convergence that we get.

2. Multi-*d* equations in finance. The application on which we focus in this section is the pricing of multiasset options through a Black–Scholes model which is a high-dimensional parabolic PDE, reducible to the heat equation.

A generalized d-asset Black–Scholes equation reads

$$\frac{\partial V}{\partial t} + \frac{1}{2}\sum_{i=1}^{d}\sum_{j=1}^{d}\rho_{ij}\sigma_i\sigma_j S_i S_j \frac{\partial^2 V}{\partial S_i \partial S_j} + r\sum_{i=1}^{d} S_i \frac{\partial V}{\partial S_i} - rV = 0, \tag{2.1}$$
$$(0 < S_1, \ldots, S_d < \infty, \quad 0 \leqslant t < T).$$

V stands for the option price; S_i are the d underlying asset prices; t is the current time; ρ_{ij} are the correlation coefficients between the Wiener processes modeling the

movement of the price of the ith and the jth assets; σ_i is the volatility of the ith asset price; r is the risk-free interest rate. For pricing options on a basket of d assets, it has been shown [6, 20] that (2.1) under the following transform of the asset price S_i:

$$y_i = \frac{1}{\sigma_i}\left(r - \frac{{\sigma_i}^2}{2}\right)\tau + \frac{1}{\sigma_i}\ln S_i, \quad i = 1, 2, \ldots, d, \tag{2.2}$$
$$\tau = T - t$$

(T is a constant and represents the maturity time of the option) yields the equation

$$\frac{\partial V}{\partial \tau} = \frac{1}{2}\sum_{i=1}^{d}\frac{\partial^2 V}{\partial {x_i}^2}, \qquad -\infty < x_i < \infty, \quad 0 < \tau \leqslant T, \tag{2.3}$$

which we identify as the heat-conduction equation in d dimensions. When discretized by the implicit Crank–Nicolson scheme, we get a discrete s.p.d. operator. It is worthwhile to mention that the time discretization adds to the [illegible] of the main diagonal of the discrete operator, and so the stationary diffusion equation serves well as a limiting [illegible] case, in the study of convergence behavior.

3. The discretization. We first recall that discrete operators can be implemented in two different ways. One is the stencil method, and the other is the matrix method. The stencil method saves storage but is inherently difficult to implement due to the visual constraints—imposed by high dimensionality—on the problem. Therefore, to circumvent the complicated implementation issues we use matrices (in sparse storage formats), and here we present some matrix generation formulas based on Kronecker tensor products.

3.1. The continuous problem and its discretization scheme. For analysis and experimentation we choose the -dimensional stationary diffusion equation, with Dirichlet boundary conditions, to serve as our model problem. In what follows $\mathbf{x}$ is a -tuple $\mathbf{x} = (x_1, x_2, \ldots, x_d)$, and $\{a_i, b_i, \varepsilon_i\} \in \mathbb{R}$, with $\varepsilon_i > 0$. The continuous problem reads:

$$-Lu(\mathbf{x}) = -\sum_{i=1}^{d}\varepsilon_i\frac{\partial}{\partial x_i}u(\mathbf{x}) = f^{\Omega}(\mathbf{x}), \quad \mathbf{x} \in \Omega = \prod_{i=1}^{d}(a_i, b_i) \subset \mathbb{R}^d, \tag{3.1}$$
$$u(\mathbf{x}) = f^{\Gamma}(\mathbf{x}), \qquad \mathbf{x} \in \Gamma = \partial\Omega \quad (x_i \in \{a_i, b_i\}).$$

Subsequently, the discrete counterpart reads

$$-L_h u_h(\mathbf{x}) = f_h^{\Omega}(\mathbf{x}), \quad \mathbf{x} \in \Omega_h = \prod_{i=1}^{d}(a_i, b_i) \subset \mathbb{R}^d, \tag{3.2}$$
$$u_h(\mathbf{x}) = f_h^{\Gamma}(\mathbf{x}), \quad \mathbf{x} \in \Gamma_h = \partial\Omega_h \quad (x_i \in \{a_i, b_i\}).$$

The discretization of the Laplacian L_h is chosen to be either $O(h^2)$ accurate, giving a $(2d+1)$-point stencil, or else $O(h^4)$ accurate, with a $(4d+1)$-point long stencil for all [illegible] points. The number of cells in the discretization grid along the ith dimension—represented by N_i—[illegible] be equal to the number of cells along (say)

the jth dimension. So with $h_i = (b_i - a_i)/N_i$—the mesh size along the ith dimension—the 1 variants of these multidimensional stencils are

$$\left(\frac{\partial^2}{\partial x_i^2}\right)_h \triangleq \frac{1}{h_i^2}[1 \quad -\underline{2} \quad 1] + O(h^2), \tag{3.3}$$

$$\left(\frac{\partial^2}{\partial x_i^2}\right)_h \triangleq \frac{1}{12h_i^2}[-1 \quad 16 \quad -\underline{30} \quad 16 \quad -1] + O(h^4). \tag{3.4}$$

It has to be noted that the $O(h^4)$ long stencil uses the so-called [illegible] (points outside the discretization grid) when applied to points [illegible] the boundary. To alleviate this problem we have the option of employing a different stencil, having shorter connections at the boundary. Thus we can either employ the simple $O(h^2)$ operator at the boundaries or else use a different scheme with one-sided differencing. In this work, we use the second-order stencil, for points near the boundaries. The discretization given by (3.2) leads to the following matrix equation:

$$\mathbf{A}_h \mathbf{u}_h = \mathbf{b}_h. \tag{3.5}$$

3.2. The discretization matrix $\mathbf{A_h}$ and implementation in arbitrary dimensions. As we have Dirichlet boundary conditions, we eliminate boundary points from the matrix $\mathbf{A}_h$. This scheme results in a total of M unknowns—$(M \times M)$ being the order of the discretization matrix $\mathbf{A_h}$—with

$$M = \prod_{i=1}^{d} (N_i - 1).$$

We represent the discretization grid $\mathbf{G}$ by

$$\mathbf{G} = [N_1, N_2, \ldots, N_d]. \tag{3.6}$$

The discrete matrix $\mathbf{A}_h$ in (3.5) can be built by the following tensor product formula:

$$\mathbf{A}_h = \sum_{i=1}^{d} \left\{ \bigotimes_{j=i}^{d-1} \mathbf{I}_{(d+i-j)} \otimes \mathbf{L}_i \otimes \bigotimes_{j=1}^{i-1} \mathbf{I}_{(i-j)} \right\}. \tag{3.7}$$

$\otimes$ is the Kronecker tensor product of matrices. Likewise $\bigotimes$ is the cumulative Kronecker tensor product. For example,

$$\bigotimes_{i=1}^{3} \mathbf{P}_i = \mathbf{P}_1 \otimes \mathbf{P}_2 \otimes \mathbf{P}_3.$$

Kronecker tensor products are noncommutative and associative operations (see [10]). The order is determined by the subscripts here, and the associative hierarchy does not matter.

In (3.7), $\mathbf{I}_k$ ($k \in \{1, 2, \ldots, d\}$) is the identity matrix of order $(N_k - 1)$, and $\mathbf{L}_i$ is the one-dimensional discrete-Laplacian matrix, constructed through (3.3) and (3.4) as illustrated by the following example. Suppose that $\mathbf{G} = [8, 6]$ (see (3.6)) is the grid that we have for a certain $2d$ problem; then we construct $\mathbf{L}_i$ by writing down the discrete stencil in (3.4) for each point, including the boundaries. Then we isolate the left and the right boundary vectors (as shown below) and incorporate them in the

right-hand side $\mathbf{b}_h$. For example, $\mathbf{L}_1$ is the following matrix (without the left and the right boundary vectors) according to the choice $O(h^4)$ of the computational accuracy:

$$\frac{\varepsilon_1}{12h_1^2}\begin{bmatrix} & & & & & & & & \\ 12 & -24 & 12 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 16 & -30 & 16 & -1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 16 & -30 & 16 & -1 & 0 & 0 & 0 \\ 0 & 0 & -1 & 16 & -30 & 16 & -1 & 0 & 0 \\ 0 & 0 & 0 & -1 & 16 & -30 & 16 & -1 & 0 \\ 0 & 0 & 0 & 0 & -1 & 16 & -30 & 16 & -1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 12 & -24 & 12 \\ & \multicolumn{7}{c}{\underbrace{\qquad\qquad\qquad\qquad\qquad\qquad\qquad}_{\mathbf{L}_1}} & \end{bmatrix}.$$

$1d$ discrete Laplacian matrices constructed in this way for each grid dimension are to be substituted in (3.7) for building up the discrete d-dimensional operator matrix $\mathbf{A}_h$. (The $O(h^2)$ discretization is handled similarly.)

3.3. The right-hand side $\mathbf{b}_h$. The right-hand side $\mathbf{b}_h$ of (3.5) consists of the source function f_h^Ω and the boundary function f_h^Γ.

It is important to define a consistent [illegible] in high dimensions. In our enumeration scheme we represent the entire set of indices by an [illegible] $\mathcal{I}$, where each row (a d-tuple) represents the index of a grid point and counts in descending order, i.e., from right to left, for the ascending order of the dimensions. This formulation of the index set is the natural extension of the so-called [illegible] order in $2d$. As an illustration of this lexicographic order, we have grid coordinates as a pair (i_2, i_1) in $2d$ and as a triple (i_3, i_2, i_1) in $3d$, and thus, generally in d-dimensions, we have the index of a grid point as $(i_d, i_{(d-1)}, \ldots, i_1)$; piling them up in lexicographic order, we get the entire set as

$$\mathcal{I} = [\iota_d \quad \iota_{(d-1)} \ldots \iota_i \ldots \iota_2 \quad \iota_1], \tag{3.8}$$

where each ι_k is a column vector of length M. Also consider the following definitions, which we require to build the index set for the interior and the boundary points:

$$\begin{aligned} &\eta_i; \quad \ni \quad \eta_i = [1, 2, \ldots, (N_i - 1)]^T \quad (i = 1, 2, \ldots, d) \quad \text{(see (3.6))}, \\ &\mathbf{1}_i; \quad \ni \quad \mathbf{1}_i = \underbrace{[1, 1, \ldots, 1]}_{\text{Total } N_i}{}^T. \end{aligned} \tag{3.9}$$

We now formulate the columns of $\mathcal{I}$ as follows:

$$\iota_i = \bigotimes_{j=i}^{d-1} \mathbf{1}_{(d+i-j)} \otimes \eta_i \otimes \bigotimes_{j=1}^{i-1} \mathbf{1}_{(i-j)}. \tag{3.10}$$

At this stage the vector of source function values can be computed as the development of the index set $\mathcal{I}$ is complete. Thus, computing the source function for each row of $\mathcal{I}$ and denoting it by $\mathcal{S}$, we have $\mathcal{S} = f_{\mathcal{I}}^\Omega$.

Now for computing the contribution of boundaries in $\mathbf{b}_h$, recall that we isolated two column vectors, namely, the left and the right boundary-coefficient vectors from the $1d$ Laplacian operators in each dimension. Considering the case of the ith dimension, if we denote these by l_i and r_i, respectively, then we can define the ith

d-dimensional left and right boundary-coefficient vectors, viz., $\mathcal{L}_i$ and $\mathcal{R}_i$ as follows:

$$\mathcal{L}_i = \bigotimes_{j=i}^{d-1} \mathbf{1}_{(d+i-j)} \otimes l_i \otimes \bigotimes_{j=1}^{i-1} \mathbf{1}_{(i-j)}, \tag{3.11}$$
$$\mathcal{R}_i = \bigotimes_{j=i}^{d-1} \mathbf{1}_{(d+i-j)} \otimes r_i \otimes \bigotimes_{j=1}^{i-1} \mathbf{1}_{(i-j)}.$$

The contribution of the boundary values in $\mathbf{b}_h$ has two parts, i.e., values from the left boundary and values from the right boundary. We denote the two by $\mathcal{B}_L$ and $\mathcal{B}_R$, respectively. $\mathcal{B}_L$ is the cumulative sum of the d left boundaries and likewise for the right. At this point a word about the [illegible] is in order. If in (3.8) any ι_i is replaced by a vector of [illegible], we get a left boundary index set, and if we replace it by a vector of [illegible], we get a right boundary index set. If

$$\mathcal{I}_{L_i} = [\iota_d \quad \iota_{(d-1)} \dots \iota_(i-1) \quad \overline{a_i} \quad \iota_(i+1) \dots \iota_2 \quad \iota_1],$$
$$\mathcal{I}_{R_i} = [\iota_d \quad \iota_{(d-1)} \dots \iota_(i-1) \quad \overline{b_i} \quad \iota_(i+1) \dots \iota_2 \quad \iota_1],$$

then

$$\mathcal{B}_L = \sum_{i=1}^{d} (\mathcal{L}_i \diamond f^{\Gamma}_{\mathcal{I}_{L_i}}), \tag{3.12}$$
$$\mathcal{B}_R = \sum_{i=1}^{d} (\mathcal{R}_i \diamond f^{\Gamma}_{\mathcal{I}_{R_i}}).$$

$\diamond$ represents componentwise multiplication of the operand column vectors.

Thus we have from the right-hand side of (3.5)

$$\mathbf{b}_h = \mathcal{S} + \mathcal{B}_L + \mathcal{B}_R, \tag{3.13}$$

and the discretization is complete.

4. d-multigrid based on point smoothing. The core of this work is the coarsening strategies proposed here, which are based on a mixture of doubling ($h \to 2h$) and quadrupling ($h \to 4h$) grid transfers and which—coupled with point-based relaxation—yield very efficient multigrid methods for problems on non-equidistant grids. The aim is to close upon a robust method that applies for general grid-aligned anisotropies in d dimensions.

Like basic multigrid for two- and three-dimensional problems, -multigrid also consists of the essential components, the smoothing method and the coarse grid correction. The well-known algorithm of multigrid as presented in [14] does not change for the higher-dimensional case; however, the components have to be generalized to match this new situation. General multigrid algorithms are presented in the literature [11, 12, 13, 14, 15, 17].

For anisotropic problems it is a choice to keep the point-smoothing method and to coarsen only along a subset of the dimensions, precisely, along those that are strongly coupled. This ensures that coarsening takes place only where the errors are smooth. For [illegible] isotropic problems the best strategy is to combine the point-smoothing method with doubling-based full coarsening and to use the optimal relaxation parameters obtained for d dimensions.

4.1. The relaxation method. Of the many available point-smoothing-based relaxation methods, we choose the ω-red-black Jacobi method due to its excellent smoothing effect for problems of the Poisson type. The red-black Jacobi method is equivalent to the Gauss–Seidel red-black method for the $O(h^2)$ $(2d+1)$-point discretization stencil and in that it is commonly abbreviated as GS-RB in the literature. In this section we assume familiarity with standard GS-RB for $2d$ problems; see [11, 14]. ω-RB Jacobi consists of two partial steps, each an ω-Jacobi sweep; the first one [illegible] only the [illegible] (odd) points and the second one applying to and updating only the [illegible] (even) points in the grid.

From an implementational point of view, this red-black smoothing procedure which is based on partial steps depends upon a partitioning process by which the grid $\boldsymbol{G}$ can be dissected into the [illegible] part ($\boldsymbol{G}_R$) and the [illegible] part ($\boldsymbol{G}_B$). The grid-point enumeration that we employ in our implementation scheme is such that the points are arranged linearly (in a column vector) and counted out in lexicographical order for a d-dimensional grid. The unequal number of cells along different dimensions of the grid makes this partitioning process somewhat nontrivial. In Appendix A we present a way to bring about this segregation of odd and even points from a purely implementational aspect.

We also employ optimal relaxation parameters ω_{opt} in the relaxation process. It is well known that $\omega = 1$ serves as a good choice for the $2d$ isotropic case. In the case of anisotropy and higher dimensions the error-smoothing effect of the relaxation method can be enhanced by the use of optimal relaxation parameters [19]. This implies that a search for ω_{opt} pays off. We employ a d-dimensional LFA for this purpose; see section 5.

4.2. Coarsening strategies to handle anisotropies. We present two [illegible] coarsening procedures as our test cases, both of which have shown excellent convergence results. We call them [illegible] and [illegible]. Both of the strategies are similar in the sense that they consist of two distinct coarsening phases: the partial coarsening phase and the full coarsening phase. The difference is in the partial coarsening phase, where the [illegible] in strategy 1 is doubling (h $\rightarrow$ 2h) and in strategy 2 is quadrupling (h $\rightarrow$ 4h). In the full coarsening phase both of the strategies are identical and consist of doubling transfers only.

In strategy 1 we first identify the dimension(s) having the strongest coupling. This is indicated by the magnitude of the [illegible] $\tilde{c}_i$ defined as

$$\tilde{c}_i = \varepsilon_i \times \left(\frac{N_i}{b_i - a_i} \right)^2;$$

see (3.1) and (3.6). The larger the coupling factor $\tilde{c}_i$, the stronger the coupling. Fourier analysis suggests that all dimensions having a coupling factor $\tilde{c}_i$ within a range of 1.3 times the largest coupling factor identified can be doubled simultaneously. This decision is made (at each successive grid level) and identifies all of those dimensions along which doubling will take place. Employing this strategy recursively makes the discrete problem isotropic inasmuch as all coupling factors are within this range; onwards from here full doubling takes over. Once the coarsest possible grid is reached, an exact solution takes place. In the last section we evaluate this strategy for the $O(h^2)$ $(2d+1)$-point stencil and for the $O(h^4)$ $(4d+1)$-point long stencil.

In strategy 2 the threshold value is 1.0, which means that we quadruple only along the dimension(s) which are identified as having the strongest coupling (having the largest $\tilde{c}_i$). This ensures that quadrupling (in comparison with doubling) takes

place along fewer dimensions. This strategy gives good convergence when employed in conjunction with optimal relaxation parameters and is cheaper than strategy 1 because of quadrupling in the partial phase. Moreover, we suggest that a strategy based on quadrupling in the full coarsening phase should not be employed in a general multidimensional case, as full quadrupling always loses against full doubling and hence is quite apt to hamper multigrid convergence. See, for an example, section 6, Figure 3.

We take the grid size along each dimension always as a power of 2. When the anisotropy stems only from discretization on non-equidistant grids, as encountered in the sparse-grid solution, the sequence of coarse grids generated by the two strategies are as follows.

[illegible] 1. Suppose that a particular discretization grid for a certain $5d$ problem is $\mathbf{G} = [\,32\ \ 8\ \ 8\ \ 128\ \ 32\,]$. $\varepsilon_i = 1\ \forall\ i$ and $\Omega = (0,1)^5$. Then the sequence of grids that we get is the following:

(4.1)

[illegible] 1							[illegible] 2						
Ω_6	= [	32	8	8	128	32	]						
Ω_5	= [	32	8	8	64	32	]	Ω_4	= [	32	8	8	128	32	]
Ω_4	= [	32	8	8	32	32	]	Ω_3	= [	32	8	8	32	32	]
Ω_3	= [	16	8	8	16	16	]	Ω_2	= [	8	8	8	8	8	]
Ω_2	= [	8	8	8	8	8	]	Ω_1	= [	4	4	4	4	4	]
Ω_1	= [	4	4	4	4	4	]	Ω_0	= [	2	2	2	2	2	]
Ω_0	= [	2	2	2	2	2	]								

Results for this particular experiment are available in section 6, Figure 4.

4.3. Coarse-grid discretization. An important component in the coarse-grid correction process is the choice of the coarse-grid operator L_H. In this paper we use the coarse-grid analog of the discrete operator on the fine grid. Once the next coarser grid is decided, we discretize the Laplacian using the same discrete stencils as presented in section 3.

A particularly good choice of the coarse-grid operator for the $O(h^4)$ accuracy is to employ the $O(h^4)$ long stencil only along the noncoarsened dimensions of the grid and to discretize with the $O(h^2)$ stencil on the coarse grids along the dimensions where partial coarsening takes place. This has the marked advantage of saving CPU time as now the coarse-grid operator has increased sparsity. Moreover, on very coarse grids this is advantageous, because at grid points adjacent to boundary points the long stencil cannot be applied since it has entries which lie outside the discrete domain, whereas the $O(h^2)$ discretization can be applied throughout the domain. The overall accuracy remains fourth-order as we have the fourth-order accuracy on the finest grid. This coarse-grid discretization scheme fits very nicely with the numerical experiments, and 2 [illegible] 3 [illegible] (not shown here) confirm this.

We do not use the Galerkin operator because of its disadvantage of being usually more dense than the simple coarse-grid analog of the fine-grid operator (unless special transfer operators are employed to generate the coarse-grid operators). In high-d dimensions this disadvantage becomes more serious and impractical.

4.4. The transfer operators. We employ the d-dimensional analogs of the full-weighting (FW) restriction operator and of the bilinear interpolation operator in two dimensions for the intergrid transfers of the grid functions. In this section we present a tensor formulation to generate the restriction and prolongation operator matrices.

For completeness we first mention [14] that a $2d$ FW restriction operator

$$I_h^{2h} \triangleq \frac{1}{16}\begin{bmatrix} 1 & 2 & 1 \\ 2 & 4 & 2 \\ 1 & 2 & 1 \end{bmatrix}_h^{2h}$$

is the Kronecker tensor product of the following x_1 and x_2 directional 1-dimensional FW operators:

$$(I_h^{2h})_{x_1} \triangleq \frac{1}{4}\begin{bmatrix} 1 & 2 & 1 \end{bmatrix}, \quad (I_h^{2h})_{x_2} \triangleq \frac{1}{4}\begin{bmatrix} 1 \\ 2 \\ 1 \end{bmatrix}.$$

A formula based on Kronecker tensor products for building up a FW restriction operator matrix $\mathbf{R}$ reads

$$\mathbf{R} = \prod_{i=1}^{d} (\mathbf{R}_i)^{k_i}, \tag{4.2}$$

$$(\mathbf{R}_i)^{k_i} = \prod_{l=0}^{k_i-1} \left[\bigotimes_{j=i}^{d-1} \mathbf{I}_{N_{(d+i-j)}} \otimes \mathbf{O}_{\left[N_i/2^{(k_i-l-1)}\right]} \otimes \bigotimes_{j=1}^{i-1} \mathbf{I}_{\left[N_{(i-j)}/2^{k_{(i-j)}}\right]} \right].$$

We now define the quantities involved in (4.2) for the dummy subscript a.

$\mathbf{I}_a$ is the identity matrix of order $(a-1)\times(a-1)$.

$\mathbf{O}_a$ is the $1d$ FW restriction operator matrix, order $= \left(\frac{a}{2}-1\right)\times(a-1)$.

$\mathbf{G} = [N_1, N_2, \ldots, N_d]$, as in (3.6).

$\mathbf{T} = [k_1, k_2, \ldots, k_d]$ is the coarsening request; k_i is the count of $(h \to 2h)$ transfers along the ith dimension. We say that [illegible] takes place along the ith dimension if $k_i = 2$. For reasons of space it is not possible to verify (in this manuscript) (4.2) for any realistic example; however, it is trivial to verify the same with a matrix manipulation software package.

Once the FW restriction operator matrix in d dimensions is set, the prolongation (d-linear interpolation) operator matrix can be obtained by the following relation:

$$\mathbf{P} = 2^{(\sum_{i=1}^{d} k_i)}(\mathbf{R}^T). \tag{4.3}$$

A generalized restriction operator (4.2) gives us the freedom to experiment with different types of coarsening strategies depending on the grid. Note that the FW restriction operator given by (4.2) provides the required matrix for any number of coarsenings along any number of dimensions for an abstract d-dimensional problem.

4.5. Computational work for *d*-multigrid. The practical feasibility of a d-multigrid method also has to take into account an estimate of the computational work that it involves. Following the notation from [11, 14], we call this work estimate W_l, assuming that a particular multigrid method is based on a hierarchy of grids $(\Omega_l, \Omega_{l-1}, \ldots, \Omega_1, \Omega_0)$, where Ω_0 is the coarsest grid. The [illegible] W_l per multigrid cycle on Ω_l is modeled by the recursion:

$$W_1 = W_1^0 + W_0, \qquad W_k = W_k^{k-1} + \gamma_{k-1} W_{k-1} \quad (k = 1, 2, \ldots, l). \tag{4.4}$$

W_k^{k-1} is the work estimate for a single 2-grid cycle (h_k, h_{k-1}) excluding the work needed to solve the defect equation on $\Omega_{h_{k-1}}$, and W_0 is the work required to solve

exactly on the coarsest grid. It is reasonable to assume that the multigrid components (relaxation, computation of defect, and the transfer of grid functions) applied to a single unknown require a number of arithmetic operations which—independent of k—is bounded by a small constant C. With M_k the total number of unknowns at grid level k, we have

$$W_k^{k-1} \leqslant CM_k \qquad (k = 1, 2, \ldots, l).$$

For a fixed cycle index γ (the number of times the coarse grids are cycled) and with the work on the coarsest grid neglected, this leads to

$$W_l \leqslant C\left[M_l + \gamma M_{l-1} + \gamma^2 M_{l-2} + \cdots + \gamma^{l-1} M_1\right]. \tag{4.5}$$

Before we proceed further, we consider it important to point out at this stage that the coarsening strategies (algorithms) that we use do not employ the same transfers at all grid levels. Depending on the anisotropy of the system, strategy 1 employs $(h \to 2h)$ transfers (along the strongly coupled dimensions) so that after application of this strategy at each level the grid comes closer to isotropy. When an acceptable isotropy is achieved strategy 1 resorts to standard full coarsening until the grid is brought to the coarsest possible level which the particular discretization allows. Strategy 2 is [illegible] in the sense that it is composed of a mixture of standard and quadrupling transfers; moreover, it is [illegible] just like strategy 1. In strategy 2 we employ full $(h \to 2h)$ transfers when isotropy is achieved, because quadrupling along all dimensions did not prove good even with the use of optimal relaxation parameters. Note that, for the type of grid-induced anisotropy encountered in the sparse-grid solution method, the number of dimensions along which the grid is coarsened increases (or remains constant in the case of an equidistant grid) at each successive level. This gives the following:

$$\begin{aligned} W_l &\leqslant \frac{2^{j\cdot s}}{(2^{j\cdot s} - \gamma)} CM_l, \\ W_l &\leqslant \frac{\tau}{(\tau - \gamma)} CM_l \qquad \text{for} \quad \gamma < \tau = 2^{j\cdot s}. \end{aligned} \tag{4.6}$$

Here j represents the number of dimensions coarsened, $s = 1$ for $(h \to 2h)$ transfers, and $s = 2$ for quadrupling. The worst case would be when the grid is highly stretched along a single dimension, which implies that coarsening takes place only along one dimension, so $j = 1$. With quadrupling, i.e., $s = 2$, this still renders $\tau = 4$, which implies that the complexity of the method is still $O(M_l)$ for $\gamma = 1, 2, 3$. This feature makes quadrupling particularly attractive in higher dimensions for non-equidistant grids. Strategy 1 also gives an $O(M_l)$ algorithm for $\gamma = 1, 2, 3$ as long as $j \geq 2$, whereas for $j = 1$ one has to apply a V-cycle.

If the problem is isotropic with an equidistant grid, we essentially have $s = 1$ and $j = d$, which gives the work estimates that appear in Table 4.1.

The $2d$ and $3d$ results are well known [11], and an estimate for a general d (isotropic problem on an equidistant grid) can be obtained by setting $j = d$ in (4.6).

This leads us now to apply the standard multigrid procedure to our model problem as the multigrid components have been adjusted for a general high-dimensional setting, along with a computational complexity estimate. A LFA of the ω-RB Jacobi method follows, through an implementation of which we derive the relaxation parameters for our experiments.

TABLE 4.1
Multigrid work estimates for the isotropic problem on equidistant grids.

1	$\frac{4}{3}\ CM_l$	$\frac{8}{7}\ CM_l$	$\frac{16}{15}\ CM_l$	$\frac{32}{31}\ CM_l$	$\frac{64}{63}\ CM_l$
2	$2\ CM_l$	$\frac{4}{3}\ CM_l$	$\frac{8}{7}\ CM_l$	$\frac{16}{15}\ CM_l$	$\frac{32}{31}\ CM_l$
4	$O(M_l\ \log_2\ M_l)$	$2\ CM_l$	$\frac{4}{3}\ CM_l$	$\frac{8}{7}\ CM_l$	$\frac{16}{15}\ CM_l$

5. Local Fourier smoothing analysis of the ω-RB Jacobi method. LFA [2] is a tool for analyzing the convergence behavior of multigrid methods. The finer details including the validity of LFA along with related theorems and proofs are presented in [15]. In this section we concentrate on the development of a Fourier representation for the ω-RB Jacobi method applied to the model operator from section 3.1, the definition of the [illegible], the evaluation of relaxation parameters, and extension to a general d-dimensional setting. We assume familiarity with the basics of this tool; see [11, 12, 14, 15, 17] for the same. For the most part in this section we carry on the definitions and notations as present in [14, 17, 18, 19].

Consider the d-dimensional anisotropic diffusion operator

$$-\sum_{i=1}^{d} \varepsilon_i \frac{\partial^2}{\partial x_i^2}, \quad \text{with} \quad \varepsilon_i > 0. \tag{5.1}$$

With respect to the analysis it is more convenient to scale the real positive coefficients ε_i as in [18, 19] and to replace (5.1) by

$$-\sum_{i=1}^{d} c_i \frac{\partial^2}{\partial x_i^2}, \quad \text{with} \quad c_i = \varepsilon_i / \sum_{j=1}^{d} \varepsilon_j \quad \text{and hence} \quad \sum_{i=1}^{d} c_i = 1. \tag{5.2}$$

The partial derivatives are discretized by second- or fourth-order differences (see (3.3), (3.4)) leading to the discrete counterparts of (5.2) denoted by L_h^{2o} and L_h^{4o}, respectively. In contrast to section 3.1 we assume that we are dealing with the same mesh size in each space direction, i.e., $h = h_1 = \cdots = h_d$. Here possible anisotropies caused by different mesh sizes are modeled by varying the coefficients c_i, which is more appropriate for the analysis.

LFA takes into account only the [illegible] nature of the operator. Thus for an effective analysis through this tool one has to have constant coefficients, and one has to neglect the boundary effects. More precisely, all occurring operators are extended to an infinite grid

$$\mathbf{G}_h := \left\{ \boldsymbol{x} = (x_1, \ldots, x_d)^T = \boldsymbol{\kappa} h = h\,(\kappa_1, \ldots, \kappa_d)^T \ :\ \boldsymbol{\kappa} \in \mathbb{Z} \right\}, \tag{5.3}$$

with mesh size h. The discrete eigenfunctions ([illegible]) of the resulting infinite grid operators serve as fundamental quantities in LFA; they are obviously given by

$$\varphi(\boldsymbol{\theta}, \boldsymbol{x}) = e^{i\boldsymbol{\theta}\boldsymbol{x}/h}, \quad \boldsymbol{x} \in \mathbf{G}_h. \tag{5.4}$$

For this analysis we assume that $\boldsymbol{\theta}$ varies continously in $\mathbb{R}^d$. As 2π is the period of φ, we are led to the identity:

$$\varphi(\boldsymbol{\theta}, \boldsymbol{x}) \equiv \varphi(\boldsymbol{\theta}', \boldsymbol{x}) \qquad \text{for } \boldsymbol{x} \in \mathbf{G}_h \quad \text{iff } \boldsymbol{\theta} = \boldsymbol{\theta}' (\text{mod } 2\pi), \tag{5.5}$$

where this difference—of multiples of 2π—is between all of the components of the d-tuples, $(\boldsymbol{\theta} \ \& \ \boldsymbol{\theta}')$; thus it suffices to consider these functions only for $\boldsymbol{\theta} \in \Theta = [-\pi, \pi)^d$.

The corresponding eigenvalues ( ) of L_h^{2o} and L_h^{4o} read

$$\widetilde{L}_h^{2o}(\boldsymbol{\theta}) = \frac{2}{h^2}\left(1 - \sum_{i=1}^{d} c_i \cos(\theta_i)\right) \quad \text{and}$$

$$\widetilde{L}_h^{4o}(\boldsymbol{\theta}) = \frac{1}{6h^2}\left(15 - \sum_{i=1}^{d} c_i \left(16\cos(\theta_i) - \cos(2\theta_i)\right)\right),$$

respectively.

5.1. High and low Fourier frequencies. If full coarsening ($\boldsymbol{H} = 2\boldsymbol{h}$ or $\boldsymbol{H} = 4\boldsymbol{h}$ in the case of quadrupling) is selected, the Fourier components $\varphi_h(\boldsymbol{\theta}, \boldsymbol{x})$, with $|\boldsymbol{\theta}| := \max\{|\theta_1|, \ldots, |\theta_d|\} \le \pi/2$ (or $\le \pi/4$), are also visible on the coarse grid $\mathbf{G}_H$, whereas components with $|\boldsymbol{\theta}| > \pi/2$ ($> \pi/4$) coincide with certain $\varphi_h(\hat{\boldsymbol{\theta}}, \boldsymbol{x})$, where $|\hat{\boldsymbol{\theta}}| \le \pi/2$ ($\le \pi/4$). This observation leads to the distinction between high and low Fourier frequencies.

DEFINITION 1 (high and low frequencies for full coarsening). θ_j $(j \in \{1, \ldots, d\})$ low

$$-\pi/2 \le \theta_j < \pi/2 \quad (\ -\pi/4 \le \theta_j < \pi/4 \ ) \quad \boldsymbol{\theta} \in \Theta.$$

high low Fourier frequency $\boldsymbol{\theta} \in \Theta$ high frequency

The distinction obviously depends on the coarsening as, for different coarsening strategies, different sets of Fourier frequencies are visible on the coarse grid. We define the set of coordinate indices by $\mathcal{J} := \{1, \ldots, d\}$. In the case of partial coarsening (compare with section 4.2), the grid is coarsened only in a subset $\{x_j \mid j \in \mathcal{J}^c \subset \mathcal{J}\}$ of the coordinate directions and remains fixed in the other coordinates x_j, with $j \in \mathcal{J}^f = \mathcal{J} \setminus \mathcal{J}^c$. Especially for two-dimensional problems, this is often called semicoarsening as well. In this case, we have for the coarse grid mesh size $\boldsymbol{H}$ that $H_j = 2h_j$ (or $H_j = 4h_j$ in the case of quadrupling) for $j \in \mathcal{J}^c$ and $H_j = h_j$ for $j \in \mathcal{J}^f$. Then the definition of high and low frequencies has to be adapted accordingly.

DEFINITION 2 (high and low frequencies for partial coarsening). $\boldsymbol{\theta} \in \Theta$ low $\theta_j \in \mathcal{I}^c$ 1 high frequency

5.2. Fourier representation of ω-RB Jacobi. ω-RB Jacobi relaxation consists of two partial steps of ω-Jacobi-type; compare with section 4.1. The iteration matrix of classical damped Jacobi relaxation is given by $\mathbf{S}_h = \mathbf{I}_h - \omega \mathbf{D}_h^{-1} \mathbf{A}_h$, where $\mathbf{I}_h$ denotes the $(M \times M)$-identity matrix and $\mathbf{D}_h$ the diagonal part of $\mathbf{A}_h$. Hence, the Fourier components remain eigenfunctions of ω-Jacobi relaxation. The Fourier symbols of ω-Jacobi relaxation applied to L_h^{2o} and L_h^{4o} read

$$A^{2o}(\boldsymbol{\theta}, \omega) = 1 - \omega \frac{h^2}{2} \widetilde{L}_h(\boldsymbol{\theta}) = 1 - \omega\left(1 - \sum_{i=1}^{d} c_i \cos(\theta_i)\right) \quad \text{and}$$

$$A^{4o}(\boldsymbol{\theta}, \omega) = 1 - \omega \frac{6h^2}{15} \widetilde{L}_h(\boldsymbol{\theta}) = 1 - \omega\left(1 - \frac{1}{15}\sum_{i=1}^{d} c_i \left(16\cos(\theta_i) - \cos(2\theta_i)\right)\right),$$

respectively; see [16, 18, 19].

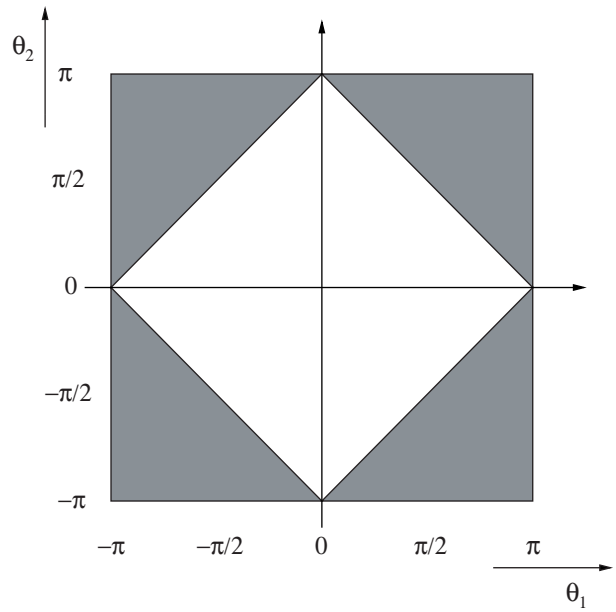

FIG. 1. *Low (white region) and high (shaded region) frequencies for red-black coarsening in two dimensions.*

Note that for pattern relaxations such as ω-RB Jacobi the Fourier components are no longer eigenfunctions. However, the minimal invariant subspaces for ω-RB Jacobi are two-dimensional; see [18]. Each component $\varphi_h(\boldsymbol{\theta}, \boldsymbol{x})$ is coupled only with $\varphi_h(\widehat{\boldsymbol{\theta}}, \boldsymbol{x})$, where

$$\widehat{\theta}_j := \theta_j - \operatorname{sign}(\theta_j)\,\pi, \quad \text{with} \quad j \in \mathcal{J}.$$

Note that ω-RB Jacobi couples those Fourier components that alias on the coarse grid in the case of red-black coarsening. Considering red-black coarsening, the set of low frequencies (compare with Definitions 1 and 2) is given by

$$\Theta_{RB} := \left\{ \boldsymbol{\theta} \in \Theta \,:\, |\boldsymbol{\theta}| := \sum_{i=1}^{d} |\theta_i| \le \frac{d}{2}\pi \right\}. \tag{5.6}$$

For $d = 2$, the set of low frequencies Θ_{RB} is illustrated in Figure 1.

We decompose the set of Fourier frequencies Θ into a direct sum of such two-dimensional subspaces that are coupled by ω-RB Jacobi:

$$\Theta = \bigoplus_{\boldsymbol{\theta} \in \Theta_{RB}} \left\{ \boldsymbol{\theta}, \widehat{\boldsymbol{\theta}} \right\}.$$

The Fourier representations of the half-sweep operators which represent the smoothing steps over the red points (R) and the black points (B) w.r.t. the two-dimensional

minimal invariant subspaces are given in [19]. They read

$$\widetilde{S}_h^R(\boldsymbol{\theta},\omega) = \frac{1}{2}\begin{pmatrix} A(\boldsymbol{\theta},\omega)+1 & A(\widehat{\boldsymbol{\theta}},\omega)-1 \\ A(\boldsymbol{\theta},\omega)-1 & A(\widehat{\boldsymbol{\theta}},\omega)+1 \end{pmatrix}$$

$$\text{and} \qquad \widetilde{S}_h^B(\boldsymbol{\theta},\omega) = \frac{1}{2}\begin{pmatrix} A(\boldsymbol{\theta},\omega)+1 & -A(\widehat{\boldsymbol{\theta}},\omega)+1 \\ -A(\boldsymbol{\theta},\omega)+1 & A(\widehat{\boldsymbol{\theta}},\omega)+1 \end{pmatrix},$$

$$\text{with} \quad A(\boldsymbol{\theta},\omega) = A^{2o}(\boldsymbol{\theta},\omega), A^{4o}(\boldsymbol{\theta},\omega) \quad \text{and} \quad A(\widehat{\boldsymbol{\theta}},\omega) = A^{2o}(\widehat{\boldsymbol{\theta}},\omega), A^{4o}(\widehat{\boldsymbol{\theta}},\omega).$$

The transformation matrix $\widetilde{S}_h(\boldsymbol{\theta},\omega)$ for $(\phi_h(\boldsymbol{\theta},\,.\,), \phi_h(\widehat{\boldsymbol{\theta}},\,.\,))^T$ after one relaxation step is then given by

$$\widetilde{S}_h(\boldsymbol{\theta},\omega) = \widetilde{S}_h^B(\boldsymbol{\theta},\omega)\,\widetilde{S}_h^R(\boldsymbol{\theta},\omega). \tag{5.7}$$

The four components of the (2×2)-matrix $\widetilde{S}_h(\boldsymbol{\theta},\omega) = (s_{ij})_{i,j=1,2}$ read

$$\begin{aligned} s_{11} &= \frac{1}{4}\left[(A(\boldsymbol{\theta},\omega)+1)^2 + (A(\widehat{\boldsymbol{\theta}},\omega)-1)(1-A(\boldsymbol{\theta},\omega))\right], \\ s_{12} &= \frac{1}{4}\left[(A(\boldsymbol{\theta},\omega)+1)(1-A(\widehat{\boldsymbol{\theta}},\omega)) + A(\widehat{\boldsymbol{\theta}},\omega)^2 - 1\right], \\ s_{21} &= \frac{1}{4}\left[(A(\widehat{\boldsymbol{\theta}},\omega)+1)(1-A(\boldsymbol{\theta},\omega)) + A(\boldsymbol{\theta},\omega)^2 - 1\right], \\ s_{22} &= \frac{1}{4}\left[(A(\widehat{\boldsymbol{\theta}},\omega)+1)^2 + (A(\widehat{\boldsymbol{\theta}},\omega)-1)(1-A(\boldsymbol{\theta},\omega))\right]. \end{aligned} \tag{5.8}$$

5.3. Smoothing factor. In order to measure the smoothing properties of pattern relaxation methods, we adopt the general definition of the smoothing factor from [11]. Here the "real" coarse grid correction for a two-grid method is replaced by an "ideal" coarse grid correction operator Q_h^H which annihilates the low-frequency error components and leaves the high-frequency components unchanged. Q_h^H is a projection operator onto the space of high-frequency components. The Fourier representation of the ideal coarse grid correction operator w.r.t. the subspaces $\{\phi_{\boldsymbol{h}}(\boldsymbol{\theta},\,.\,), \phi_{\boldsymbol{h}}(\widehat{\boldsymbol{\theta}},\,.\,)\}$ $(\boldsymbol{\theta}\in\Theta_{RB})$ is then given by

$$\widetilde{Q}_h^H(\boldsymbol{\theta}) = \begin{pmatrix} q(\boldsymbol{\theta}) & 0 \\ 0 & q(\widehat{\boldsymbol{\theta}}) \end{pmatrix}, \tag{5.9}$$

where $q=0$ for a low argument and 1 otherwise; compare with Definitions 1 and 2.

The smoothing factor μ of the ω-RB Jacobi operator is defined as the worst factor by which the high-frequency errors are reduced per iteration step. So with ν denoting the number of relaxation sweeps, and ρ the matrix spectral radius, we have

$$\mu(\omega) := \sup_{\boldsymbol{\theta}\in\Theta_{RB}} \left\{ \sqrt[\nu]{\rho\left(\widetilde{Q}_h^H(\boldsymbol{\theta})\widetilde{S}_h^{\nu}(\boldsymbol{\theta},\omega)\right)} \right\}. \tag{5.10}$$

The smoothing factor can easily be calculated by a computer program which allows for a numerical determination of optimal relaxation parameters for different coarsening

strategies and both types of discretization under consideration. We would like to emphasize that the optimal relaxation parameter depends on the number of relaxation steps ν as can be seen from (5.10).

Note that there are explicit (but very lengthy) analytical formulas for the optimal relaxation parameters ω_{opt} in the case of full coarsening applied to the second-order discretization [16, 19]. Moreover, there is a close to optimal upper bound ω_{ub} [19] for the optimal relaxation parameters which is given by the following handy expression:

$$\omega_{opt} < \omega_{ub} = \frac{2}{1 + \sqrt{1 - \mu(\omega = 1)}}.$$

For partial coarsening and especially for the fourth-order discretization, it seems to be very difficult to derive analytic expressions for ω_{opt}. However, for the second-order discretization it turned out that ω_{ub} is a satisfactory approximation for ω_{opt} even in the case of partial coarsening and quadrupling (but not necessarily an upper bound anymore); see Table 5.1, which presents ω_{opt} (optimized for $\nu = 1$) and ω_{ub} for equidistant and non-equidistant grids. This is a nice generalization of the results from [19]. For the fourth-order discretization this is no longer true, and we have to stay with the numerically derived values.

From the values in Table 5.2 (optimized for $\nu = 2$), we see that the [illegible] of using optimal relaxation parameters is more prominent and pronouced with strategy 2. With strategy 1 this enhancement becomes prominent in the case of [illegible] (with grids that are equidistant along $(d-2)$ or more dimensions). With anisotropic problems where anisotropy is induced by discretization on grids highly elongated along a single dimension (and dealt with strategy 1), the choice $\omega = 1$ is more suitable—first—because the optimal values themselves are very close to 1 and therefore do not bring about a substantial enhancement—and second—the cost of relaxation itself is cut down, which saves CPU time.

6. Numerical experiments. We now present the results of some of our numerical experiments. The emphasis is on grid-induced anisotropies. The PDE is discretized on various equidistant and non-equidistant grids, and the spectral radius ρ of the multigrid iteration operator M_h is presented, which represents the asymptotic convergence factor. During the course of an experiment the only quantity available to estimate this factor is the defect d_h^i after the ith multigrid cycle. The numerical results—presented in Tables 6.1–6.4—depict a close match between the theoretical smoothing factors μ (computed for coarsening based on the finest grid) and an emperical estimate of the multigrid convergence factor $\rho(M_h)$, which we denote by q^m and define as

$$q^m := \frac{\| d_h^m \|}{\| d_h^{m-1} \|},$$

where m represents the number of iterations or multigrid cycles that the discrete problem takes to converge to the numerical solution.

All of the experiments employ one pre- and one postsmoothing, and so the smoothing factor is displayed as a square for a correspondence with q^m; compare with (5.10). The optimal relaxation parameters ω_{opt} that we employ are computed for $\nu = 2$. For each order of accuracy and for each dimension, we have chosen two kinds of grid, one equidistant and one non-equidistant (highly stretched in one dimension). q^m is displayed against the number of multigrid cycles that the experiment took to converge to the tolerance value, which for all of the experiments is 10^{-10}, i.e.,

$$\frac{||\mathbf{b}_h - \mathbf{A}_h \mathbf{u}_h^m||}{||\mathbf{b}_h||} \mid \leq tol.$$

This termination criterion is equivalent to the one based on relative residual reduction because our starting soluton in these experiments is always an all zero vector. Moreover this criterion corresponds to a residual reduction by ≈ 7 orders of magnitude. Through the numerical solution of the model problem we approximate the following test function:

$$u(\mathbf{x}) = \frac{\sum_{i=1}^{d} \sin(d\pi^2 x_i)}{d\pi + \sum_{i=1}^{d} x_i}, \tag{6.1}$$

$\varepsilon_i = 1 \ \forall \ i$, and $\Omega = (0,1)^d$ for all of the problems. The values of this function at the boundary are taken as Dirichlet boundary conditions, and its analytically computed Laplacian forms the source function for these experiments. The experiments include the V- and the W-cycles. In some of the experiments the grids used for the $O(h^2)$ operator are different from the ones for the $O(h^4)$ operator. This serves only the purpose of accumulating results for slightly [illegible] experiments. C_2^2 indicates the use of the second-order stencil along all coarsened and noncoarsened dimensions; likewise for C_4^4. C_2^4 indicates the use of the $O(h^4)$ long stencil along all noncoarsened dimensions and the use of the $O(h^2)$ stencil on the coarse grids along the dimensions where coarsening takes place. This [illegible] coarse grid discretization gives fourth-order accuracy and converges [illegible] than the conventional fourth-order long stencil.

Table 6.1 presents experimental results for equidistant grids. A comparison of the convergence results with and without optimal relaxation parameters indicates the benefits of using them for high-dimensional problems. The cutdown in the multigrid convergence factor as well as in the number of multigrid cycles (required to converge to tol) is quite significant for $d \geq 3$.

Table 6.2 presents experimental results for non-equidistant grids which we have chosen to be highly stretched in only one dimension. Because of this characteristic these experiments are computationally more expensive than any other as coarsening takes place only along the elongated dimension. This is exactly the opposite of the previous case, where coarsening took place along all dimensions, and hence the cutdown in the number of unknowns at each level was optimal. In this table we display the results that we get from strategy 1, which is based purely on $h \rightarrow 2h$ transfers. Optimal relaxation parameters in this case pay off only with V-cycles, with $\omega = 1$ serving as a perfect compromise with W-cycles.

In Table 6.3 we have reworked the experiments of Table 6.2 but with strategy 2 this time. Partial quadrupling (strategy 2) ensures an $O(M_l)$ algorithm even with grids of this type. Note that the computational complexity of the experiments in Table 6.2 is $O(M_l \ \log_2 \ M_l)$, even though the multigrid convergence factor is quite impressive

TABLE 6.1

Results of numerical experiments for $V(1,1)$ and $W(1,1)$ on equidistant grids. The observed convergence rate with the number of iterations, i.e., $(q^m/\#\ it.)$, is presented. For a correspondence comparison the smoothing factors $[\mu(1)]^2$ and $[\mu(\omega_{opt})]^2$ (computed for coarsening based on the finest grid) are also displayed. Results presented include experiments with $\omega = 1$ as well as $\omega = \omega_{opt}$.

there. These results show the important role of optimal relaxation parameters in enhancing convergence of the multigrid with quadrupling transfers.

To make the discussion complete we have included some more experiments on a [illegible]. The results are reported in Figure 2. The convergence report is depicted against the iteration scale as well as against the CPU time scale. A comparison of the results of strategies 1 and 2 suggests that, for these kind of grids, a combination of strategy 2 with V-cycles and optimal relaxation parameters works very nicely.

A graphical presentation of the convergence behavior of an isotropic 4-dimensional multigrid experiment appears in Figure 3. The defect reduction is displayed against the iteration and the CPU time scale. To emphasize the inefficiency of full quadrupling with completely equidistant grids, we have included the results against full doubling. Clearly enough, here standard coarsening is the strategy of choice. This is the main reason why we do not keep quadrupling transfers in strategy 2, once grid equidistance has been achieved, but rather resort to doubling from this stage onwards. Quadrupling along all dimensions at the same time hampers the multigrid convergence rate as well as increasing the overall computation time.

Finally, we have performed two general 5-dimensional anisotropic experiments. For the first experiment the anisotropy comes only from discretization on a non-equidistant grid; and the results appear in Figure 4, the sequence of grids that we get

TABLE 6.2

with both coarsening strategies are displayed in section 4.2, (4.1). It is quite apparent that the use of optimal relaxation parameters pays off significantly well with V-cycles in combination with strategy 1 ($\omega = 1$ serving as a perfect choice for W-cycles) and with both V- and W-cycles with strategy 2. The second experiment is more general in that it has anisotropic coefficients ε_i in the PDE, it is discretized on the same non-equidistant finest grid, and the domain dimensions are not exactly unit. The results are displayed in Table 6.4. Clearly, V-cycles with optimal weighting in the relaxation process coupled with either coarsening strategy give excellent results. We would like to point out that we expect strategy 1 to be more dependable than strategy 2 if the number of dimensions coarsened on the finest grid is greater than $d/2$.

We have used Matlab as our testing platform; the same experiments implemented in C (in more optimized computer programs) are expected to render smaller CPU times than those presented.

. . . . 1. The multigrid convergence factors displayed in the tables are mostly under 0.1, implying that a full multigrid algorithm starting on the coarsest grid is expected to reach an approximate solution up to the discretization accuracy in just one or two cycles.

. . . . 2. It is also important to point out that, for very coarse discretization grids (say, 8 points along all dimensions), the asymptotic convergence of the relaxation

method ω-RB Jacobi is also quite satisfactory. To confirm this, we conducted a 6-dimensional asymptotic convergence experiment without a hierarchy of multiple grids and measured the number of iterations and the time taken to reach the tolerance (10^{-10}). Though the use of multigrid cuts down the number of iterations by around a factor of 2.5, the time taken to meet the tolerance level is the same.

7. Conclusion. The central emphasis of this paper is on multigrid techniques for high-dimensional elliptic PDEs. To alleviate the implementation issues we have

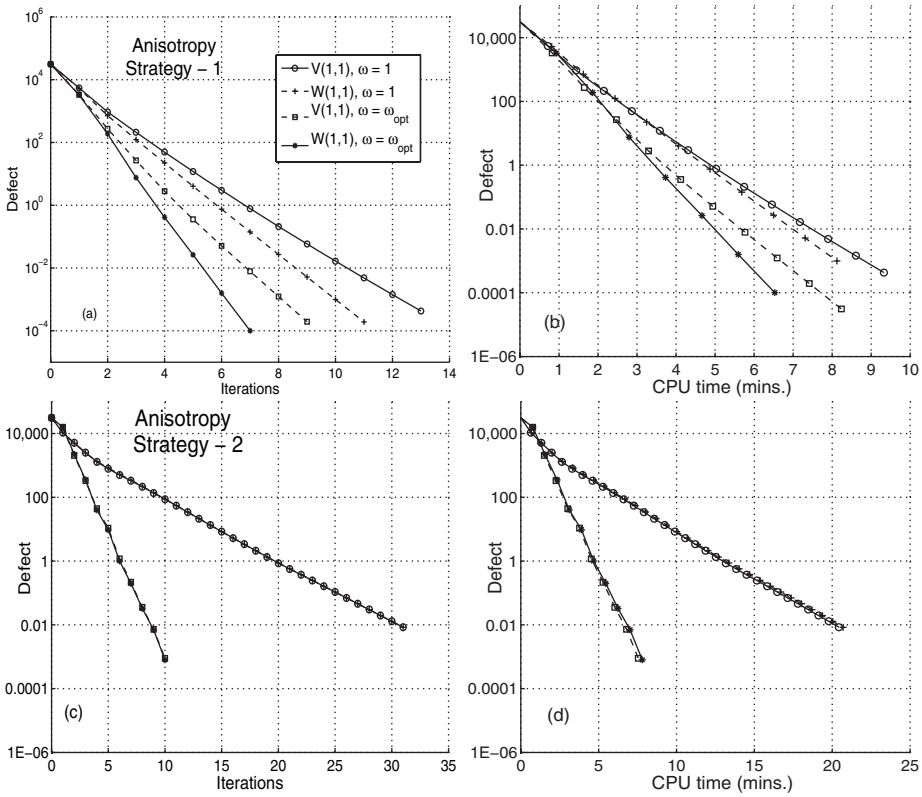

FIG. 2. *Convergence behavior of different multigrid cycles for a* 4*d problem, on a non-equidistant grid* [64 64 64 16] *(anisotropy with* 3,750,705 *unknowns), left side defect vs. iterations, right side defect vs. CPU time.*

shown how difference operator matrices can be put together through tensor methods. This renders testing in abstract higher d dimensions easy. Of course, tailored routines (for specific applications) can be programmed and tuned as per requirement. The main idea has been to demonstrate how the multigrid convergence factor can be reduced efficiently with appropriate coarsening strategies combined with the use of relaxation parameters in the smoothing process. Through numerical results supported by the LFA we have shown that partial quadrupling is a strategy of choice in higher dimensions and ensures a computational complexity of $O(M_l)$ even in the worst case, i.e., coarsening in one dimension only. This we have confirmed through a complexity analysis. Results of the numerical experiments display the excellent multigrid convergence that can be brought about with the presented strategies.

Appendix A. Implementational aspects of ω-RB Jacobi. ω-RB Jacobi can be implemented in several ways depending on the test platform. We have here a method that is suitable for iterations over a solution vector as opposed to explicit updates in a loop. The scheme that we present in this appendix is developed to bring about the odd-even (red-black) partitioning with minimal manipulation of the grid points.

We store three vectors in this scheme (two of which have just half the storage requirement as the first one). The first vector is the unmanipulated vector (henceforth

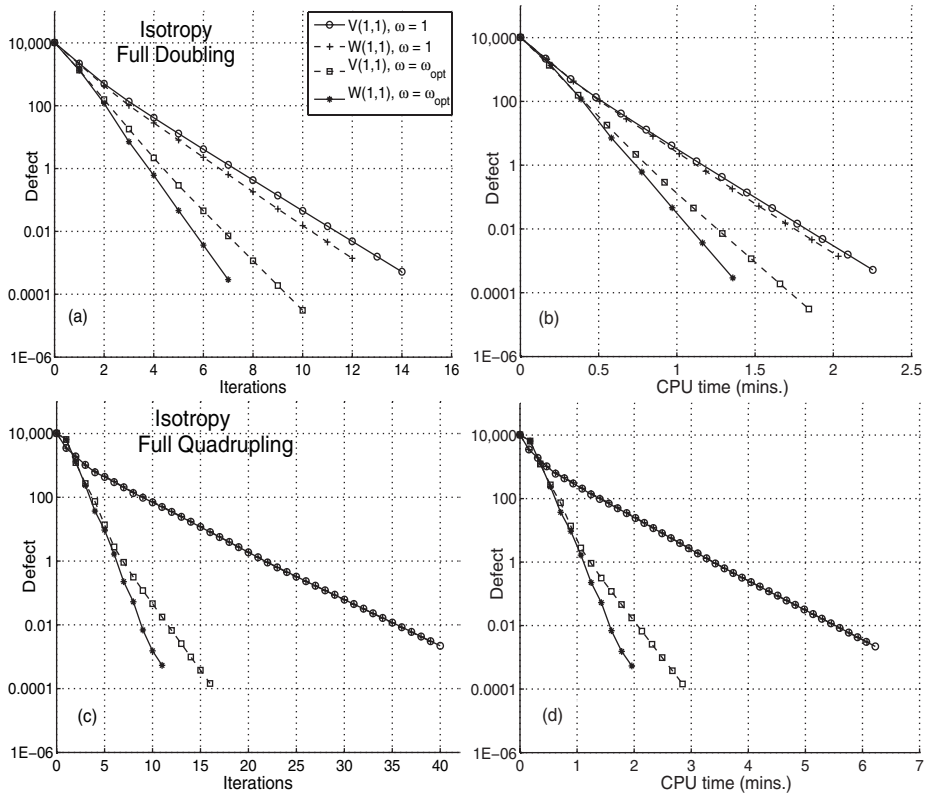

FIG. 3. *Convergence behavior of different multigrid cycles for a 4d problem, on an equidistant grid* 32^4 *(isotropy with* 923,521 *unknowns), left side defect vs. iterations, right side defect vs. CPU time.*

called the , , , ,) containing values for all grid points (red as well as black); the second vector has the values at the black points ejected out and replaced with zeros. Symmetrically, the third has the values at the red positions ejected out and replaced by zeros. This ejection process is actually where our injection operators (henceforth called , , ,) fit in.

First we construct the partition of the main vector storing the red and the black parts; then we carry out the first partial ω-Jacobi sweep by updating only the red part. This new red part along with the previously stored black part represents the main vector after the first partial sweep. Carrying out the second partial sweep in exactly the same manner, now for the black part instead, gives one ω-RB Jacobi iteration.

We present two , , , operators, one for points of each color (even/odd category). We denote these , , , by $\mathcal{E}_R$ and $\mathcal{E}_B$, with

$$\mathcal{E}_R = \left(\bigoplus_{i=1}^{d} \eta_{(d-i+1)} \right) \mod 2,$$

$$\mathcal{E}_B = (\mathcal{E}_R + 1) \mod 2.$$

$\bigoplus$ is the cumulative tensor sum of η_i, which counts the interior points along the ith dimension (see (3.9)); i has the reverse order (from d to 1) to match the lexicographic

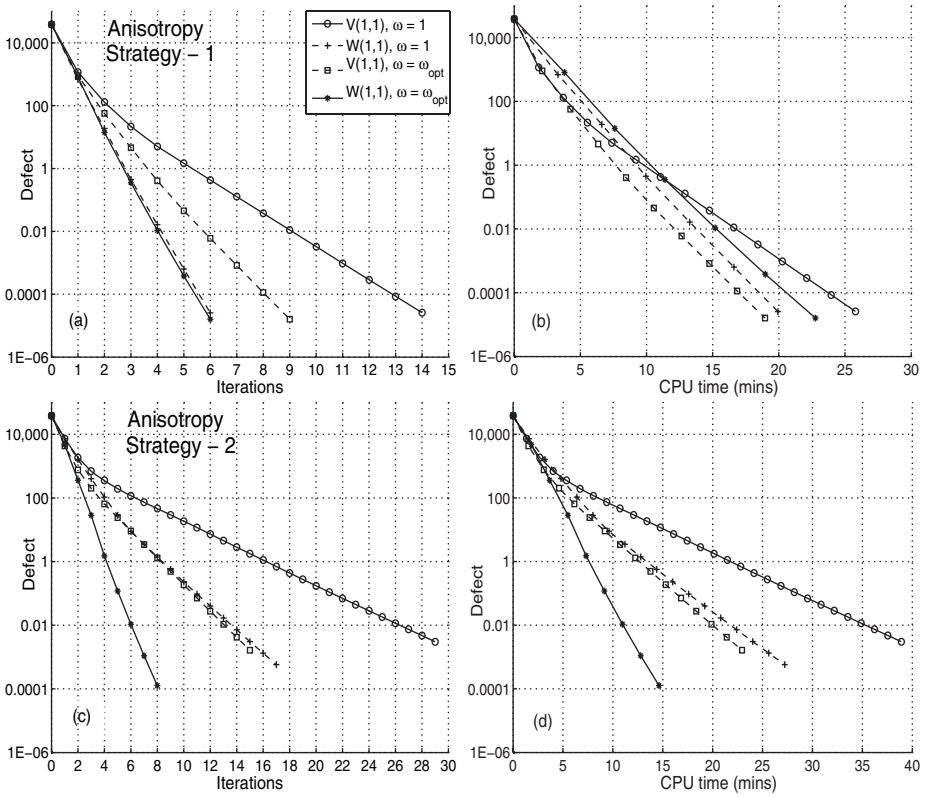

FIG. 4. *Convergence behavior of different multigrid cycles for a* 5*d problem, on a non-equidistant grid* [32 8 8 128 32] *(anisotropy with* 5,980,303 *unknowns), left side defect vs. iterations, right side defect vs. CPU time.*

layout of the grid points. Due to space limitations we can provide only a $2d$ example, although this formulation is true in general for an abstract higher dimension d.

2. Consider a $2d$ grid $\mathbf{G} = [4, 5]$. In all we have 12 interior points, which, when counted in the lexicographic order, appear as follows:

$$\mathbf{u} = [u_{11}\ \ u_{12}\ \ u_{13}\ \ u_{14}\ \ u_{21}\ \ u_{22}\ \ u_{23}\ \ u_{24}\ \ u_{31}\ \ u_{32}\ \ u_{33}\ \ u_{34}]^T.$$

Evidently, $\boldsymbol{G}$, the collection of all of the points, has the following partition:

$$\begin{aligned} \boldsymbol{G}_R &= \{u_{11}, u_{13}, u_{22}, u_{24}, u_{31}, u_{33}\}, \\ \boldsymbol{G}_B &= \{u_{12}, u_{14}, u_{21}, u_{23}, u_{32}, u_{34}\}. \end{aligned}$$

Therefore according to our scheme

$$\begin{aligned} \mathbf{u}_R &= [\ \ u_{11}\ \ \ 0\ \ \ u_{13}\ \ \ 0\ \ \ 0\ \ \ u_{22}\ \ \ 0\ \ \ u_{24}\ \ \ u_{31}\ \ \ 0\ \ \ u_{33}\ \ \ 0\ \ \ ]^T, \\ \mathbf{u}_B &= [\ \ 0\ \ \ u_{12}\ \ \ 0\ \ \ u_{14}\ \ \ u_{21}\ \ \ 0\ \ \ u_{23}\ \ \ 0\ \ \ 0\ \ \ u_{32}\ \ \ 0\ \ \ u_{34}\ \ ]^T, \end{aligned}$$

and η_i in this case would be

$$\eta_1 = [1\ \ 2\ \ 3\ \ 4]^T \quad \text{and} \quad \eta_2 = [1\ \ 2\ \ 3]^T,$$

which leads to

$$\begin{aligned} \mathcal{E}_R &= (\eta_2 \oplus \eta_1) \mod 2 \\ &= [2\ 3\ 4\ 5\ 3\ 4\ 5\ 6\ 4\ 5\ 6\ 7]^T \mod 2 \\ &= [0\ 1\ 0\ 1\ 1\ 0\ 1\ 0\ 0\ 1\ 0\ 1]^T \\ \therefore \quad \mathcal{E}_B &= [1\ 0\ 1\ 0\ 0\ 1\ 0\ 1\ 1\ 0\ 1\ 0]^T. \end{aligned}$$

These red and black point ejectors now can be used to partition the grid as described. Once this partition is obtained, ω-RB Jacobi relaxation sweeps are trivial to perform, in that they are no different than their $2d$ counterparts.

A NEW IMPLEMENTATION OF SYMPLECTIC RUNGE–KUTTA METHODS*

ROBERT I. MCLACHLAN†

Abstract. We propose a "Newton–Taylor" iteration for solving the implicit equations of symplectic Runge–Kutta methods, using the Jacobian of the vector field and matrix-vector multiplications whose extra cost for certain structured problems is negligible. The structure of Hamiltonian ODEs allows this very simple iteration to be effective. The iteration reduces the number of vector field evaluations almost to that of Newton's method, often only one or two per time step, making symplectic Runge–Kutta methods more efficient even at relatively large time steps.

Key words. Runge–Kutta, implicit, symplectic integrators, inexact Newton methods

AMS subject classifications. 65L06, 65P10

DOI. 10.1137/06065338X

1. Introduction. Symplectic integrators based on splitting, such as the leapfrog method for separable Hamiltonian systems, are fast and simple and give very good results for long simulations [8]. They are widely, almost universally, used in applications from accelerator physics to molecular dynamics to celestial mechanics [16]. However, the only symplectic integrators for general Hamiltonian systems are implicit, such as the Gaussian Runge–Kutta methods [11], which has tended to limit their popularity. (The implicit equations must be solved to within round-off error, to preserve symplecticity.) Hairer, Lubich, and Wanner [8] have studied the implementation issues and found the simple ("standard") iteration, (4) below, superior to Newton's method; for very small error tolerances it can even compete with high-order methods based on splitting and composition. However, for the relatively low orders and large time steps often used in long symplectic integrations, the convergence of the standard iteration deteriorates, making the method more expensive, which defeats the purpose of using a large time step.

For other applications of implicit methods, there are methods in which the linear equations defining the Newton step are solved only approximately. In the inexact Newton method an (e.g., Krylov or Chebyshev) iterative method is applied [2, 4, 5]; in the Newton-chord method [18] the Jacobian itself is approximated to simplify the solution step. In the Jacobian-free-Newton–Krylov method [12] the Jacobian-vector multiplications are approximated by finite differences, so the Jacobian itself is never formed.

The application to Hamiltonian systems has a number of special features that lead us to propose a very simple inexact Newton method that, for many structured problems, costs only a constant factor close to 1 times the cost of the standard iteration, yet has a convergence rate very close to Newton's method. For the midpoint rule, for example, the method may require only one or two evaluations of the vector field per time step.

*Received by the editors March 1, 2006; accepted for publication (in revised form) January 9, 2007; published electronically August 1, 2007. This work was supported by the Marsden Fund and the New Zealand Institute of Mathematics and Its Applications.

The method uses the Jacobian of the vector field and performs matrix-vector multiplications. It is efficient when those two operations are cheap compared to the cost of evaluating the vector field itself. Implementations of implicit methods using Newton's method and direct linear solves try to balance the number of Jacobian factorizations against the number of vector field evaluations [19]. In contrast, our goal is to minimize the number of vector field evaluations without performing any operations that cost substantially (e.g., asymptotically, for large systems) more than a vector field evaluation.

First, consider N-body problems with Hamiltonians of the form

$$H = \sum_{i,j=1}^{N} p_i G(\|q_i - q_j\|) p_j + V(\|q_i - q_j\|). \tag{1}$$

The cost of evaluating the vector field directly is $\mathcal{O}(N^2)$. If G, V, and their derivatives are cheap, then the cost is dominated by the cost of computing $\|q_i - q_j\|$, and the Jacobian is available essentially for free. This has been exploited for separable systems ($G = 1$) by designing efficient high-order symplectic integrators using the Jacobian and matrix-vector multiplications [3, 16]. On the other hand, if G and V are special functions, then it often happens that it is relatively cheap to compute their derivatives at the same time. (This happens in the first example below, where G is an exponential or a Bessel function.) The matrix-vector multiplications, on the other hand, are also $\mathcal{O}(N^2)$ and hence carry a constant work overhead compared to the cost of evaluating the vector field.

Second, consider lattice systems with independent variables indexed by a lattice L containing N points and a Hamiltonian of the form

$$H = \sum_{i \in L} F(x_{i+\Delta}), \tag{2}$$

where $\Delta \subset L$ is a fixed template specifying which sites are coupled. The cost of computing the vector field is $\mathcal{O}(N)$. The Jacobian matrix has only $\mathcal{O}(N)$ nonzero entries, and hence matrix-vector multiplications cost $\mathcal{O}(N)$. Again, the cost of forming and multiplying by the Jacobian is negligible for certain functions F.

2. The Newton–Taylor iteration. We describe the algorithm for the implicit midpoint rule. (Its extension to any implicit Runge–Kutta method is straightforward.) For the ODE $\dot{x} = f(x)$ we are required to solve [11]

$$g(z) := z - \frac{1}{2}\Delta t f(x_0 + z) = 0 \tag{3}$$

for z, where Δt is the time step. (The final update is $x_0 \mapsto x_1 := x_0 + 2z$.) The standard fixed-point iteration is

$$z^{k+1} = \frac{1}{2}\Delta t f(x_0 + z^k) = z^k - g(z^k), \tag{4}$$

and Newton's method is

$$z^{k+1} = z^k - g'(z^k)^{-1} g(z^k) = z^k - (I - A_k)^{-1} g(z^k), \tag{5}$$

where $A_k = \frac{1}{2}\Delta t f'(x_0 + z^k)$.

We replace the iteration matrix $(I - A_k)^{-1}$ by its Taylor series $\sum_{i=0}^{M} A_k^i$ of order M to give the following (Newton–Taylor) outer iteration.

Outer iteration:

$$z^{k+1} = h(z^k) := z^k - \left(\sum_{i=0}^{M} A_k^i \right) g(z^k), \tag{6}$$

which can be evaluated using one vector field, Jacobian evaluation at z^k, and M matrix-vector multiplications.

The analysis of the algorithm is standard in the context of inexact Newton methods [6, 7]. However, it is simpler here because of the simple iteration. Let z^* be the desired solution so that $g(z^*) = 0$, and let $e^k = z^k - z^*$ be the error in the current approximation. Then by Taylor's theorem we have for some $\theta \in [0, 1]$,

$$\begin{aligned} e^{k+1} &= h'(z^k)e^k + \frac{1}{2}h''(z^k + \theta(z^{k+1} - z^k))(e^k, e^k) \\ &= \left(I - \left(\sum_{i=0}^{M} A_k^i \right) (I - A_k) \right) e^k + \frac{1}{2}h''(z^k + \theta(z^{k+1} - z^k))(e^k, e^k) \\ &= A_k^{M+1} e^k + P(e^k, e^k) + \mathcal{O}(\|e^k\|^3), \end{aligned} \tag{7}$$

where $P = \frac{1}{2}h''(z^*) = \mathcal{O}((\Delta t)^2)$. The convergence rate of the modified iteration (6) is therefore $\rho(A_k^{M+1}) = \rho(A_k)^{M+1} = \mathcal{O}((\Delta t)^{M+1})$, where $\rho(A_k)$ is the convergence rate of the standard iteration. Not only is the modified iteration higher-order in the time step, but (at the linear level, i.e., for sufficiently small e^k) one step of the modified iteration is [illegible] to $M + 1$ steps of the standard iteration.[1] It is therefore worth increasing M by one precisely when a Jacobian-vector multiplication is cheaper than evaluating the vector field.

We also conclude from (7) that the modified iteration (6) converges for sufficiently small $\|e^0\|$ if and only if the simple iteration converges. We therefore henceforth assume that $\rho(A_k) < 1$.

If M is taken too large, however, then e^{k+1} will be dominated by the quadratic term in (7). Note that as $M \to \infty$, $A_k^{M+1} \to 0$ and $P \to P^\infty$ (say), the iteration tensor for Newton's method. In fact, $P = P^\infty + \mathcal{O}((\Delta t)^{M+1})$, so as $M \to \infty$ the behavior of the modified iteration tends to that of Newton's method. One should therefore adapt M depending on the current iteration, so that $\|A_k^{M+1} e^k\| \approx \|P(e^k, e^k)\|$. This gives the following algorithm, in which (6) is implemented.

Inner iteration:

1. Given z^k, set $w^0 = g(z^k)$;
2. while $\|w^{m+1} - w^m\| > \max(c\|w^0\|^2, \text{[illegible]})$, set $w^{m+1} = w^0 + A_k w^m$;
3. set $z^{k+1} = z^k - w^m$.

Here [illegible] is the tolerance, usually close to machine precision, to which the Runge–Kutta equations are to be solved. The ("forcing") parameter c depends on the problem and is related to the norm of P, i.e., to the second derivatives of the vector field [7]. Note that w^0 is the update to z^k in the standard iteration and hence, as long as $\rho(A_k)$ is bounded away from 1, w^0 can be used as an approximation of e^k.

[1] Often, higher-order methods have large error constants, rendering them useless unless the time step is sufficiently small. This does not happen here.

This algorithm will lead to the number M of inner iterations roughly doubling each outer iteration, just as the error decreases in Newton's method.

It is theoretically possible, as in the automatic detection of stiffness [11] and the traditional convergence tests for implicit methods [19], to maintain running estimates of the slowly varying parameters $\rho(A_k)$ and the norm of P, and hence adapt the choice of M more precisely. However, this seems to be more difficult in the present context than in those just cited, because (i) we do relatively few inner iterations and outer iterations, so there is little data on which to base the estimates; (ii) the last iterations may be polluted by round-off error; (iii) the absolute values of the eigenvalues of the Hamiltonian matrix A_k occur with multiplicity 2 (if the eigenvalue is real or imaginary) or 4 (if the eigenvalue is complex), which means that even in the best case, when A_k is not severely nonnormal, an estimate of the convergence rate of the inner iteration can be obtained only from four consecutive iterations; (iv) if the time step is large, as we hope to achieve, then the parameters vary quite quickly (see the first example below).

A more positive viewpoint is to consider these factors as advantages, as they support the use of a very simple algorithm! Most of the experiments reported below use $c = 1$, $\epsilon_1 = 10^{-15}$, and $\|\cdot\|_\infty$ error norms.

To further reduce the number of evaluations of f we terminate the outer iteration (6) at z^{k+1} when $\|g(z^k)\| < \epsilon_2$, where $\epsilon_2 > \epsilon_1$. Under the model used for terminating the inner iterations, one reasonable choice is to take $\epsilon_2 = \sqrt{\epsilon_1 / c}$, as the final iteration will then take the error down to about $2\epsilon_1$. This saves one evaluation of f and is the termination criterion used in our experiments. If long-term growth of round-off error is a concern, these criteria may need to be tightened.

A good initial guess is essential for the performance of this method, as one wants the underlying Newton's method to stay close to the root where convergence is quickest. For the midpoint rule, we have used polynomial extrapolation from the previous time steps [8]. The order s of extrapolation is adapted based on the decrease of the backward differences, as follows.

Initialization iteration:

1. Set $w^0 = z_n$;
2. while $\|\nabla^{s+1} z_n\| < \|\nabla^s z_n\|$, set $w^{s+1} = w^s + \nabla^{s+1} z_n$;
3. set $z_{n+1}^0 = w^s$.

The modified iteration also works successfully for higher-order Runge–Kutta methods. The tensor product structure of the linear equations means that only s matrix-vector products are needed per inner iteration for an s-stage method. For systems in $\mathbb{R}^N$, $2N^2 s + 2Ns^2$ operations are required per inner iteration, so the overhead does grow with increasing s, but not at leading ($\mathcal{O}(N^2)$) order.

3. Other inexact Newton iterations (see [10, 13, 14]). We are approximating the solution of $(I - B)\delta z = g$ by the Taylor polynomial $\sum_{i=0}^{M} B^i g$, where for a general Runge–Kutta method with coefficients a_{lj} the matrix B is a block matrix whose (l, j) block is given by $\Delta t a_{lj} f'(Z_j)$, where Z_j are the stage values and $f'(z) = JH''(z)$. We have seen that this is a reasonable approximation, but aren't there better approximations? Krylov methods form the best (in some sense) approximation to δz of the form $p(B)g$ over all polynomials p of degree M; Faber methods use the Faber polynomial, which is the best (in some sense) approximation of $(1-t)^{-1}$ on $\Omega \subset \mathbb{C}$, where Ω contains the spectrum of B. These satisfy an (expensive) long-term recurrence; hence one often chooses Ω to be an ellipse, in which case the Faber polynomials are Chebyshev polynomials which satisfy a 2-term recurrence. In this context,

the Taylor polynomials are themselves the special case of the Chebyshev polynomials, obtained when the ellipse is a circle centered on the origin.

In this case the best approximation property is easily seen. Let $a(t)$ be a complex function analytic on a disk of radius r centered (now for convenience only) on the origin. The powers t^n are orthogonal with respect to the L_2-inner product $(a, b) = \int_{|t|\le r} a(t)\overline{b}(t)\,|dt|^2$, and hence, from the general theory of orthogonal functions, the expansion of $a(t)$ in powers of t—the Taylor polynomial—is the best L_2 approximation to $a(t)$ by a polynomial.

The role of two key features of Hamiltonian systems and of symplectic integrators is now apparent. They both stem from the fact that the Jacobian f' is a Hamiltonian matrix whose eigenvalues exhibit "Hamiltonian symmetry"; namely, they occur in λ, $-\lambda$, $\overline{\lambda}$, $-\overline{\lambda}$ quadruplets. For the midpoint rule, $B = \frac{1}{2}\Delta t f'(Z_1)$ is also Hamiltonian.

First, for the implicit equations to have a solution we need to assume $\mathrm{Re}(\lambda(B)) < 1$, which implies $\mathrm{Re}(\lambda(B)) > -1$. We can also assume $|\mathrm{Im}(\lambda(B))| < 1$, for otherwise the fast oscillations are very poorly represented by the integrator and can even destabilize the calculation. (The currently known integrators that are effective when the fast modes are not resolved are quite different; they are explicit and nonsymplectic [8].) Therefore, the assumption $\rho(B) < 1$ that is required for the Taylor series to converge is not overly restrictive. (Applications where Krylov and Chebyshev iterations are effective typically have $\mathrm{Re}(\lambda(B))$ very large and negative [2, 12].)

Second, the eigenvalue symmetry means that a disk centered on 0, enclosing $\lambda(B)$, will tend to be a much better approximation of $\lambda(B)$ than in the general, non-Hamiltonian, case. Further, the Taylor polynomial requires no knowledge of the spectrum and is the best approximation on all disks centered on the origin (i.e., the best regardless of $\rho(B)$).

The eigenvalue symmetry does mean that an ellipse centered on 0 with real and imaginary axes is never a worse approximation to $\lambda(B)$ than the disk. If this ellipse were known, then a Chebyshev polynomial would be a better approximation to $(1-t)^{-1}$, and would lead to faster convergence, than the Taylor polynomial. Two factors suggest that this advantage will be difficult to exploit in our case. First, for Hamiltonian systems the focal interval of the bounding ellipse can be either real or imaginary, typically alternating between the two, making an accurate estimate of it more difficult; see the first example below. (Existing applications of Chebyshev polynomials use far more iterations than we are proposing here, because they are for $\rho(B)$ large, and hence they can afford to do a few secondary iterations to estimate the ellipse that bounds $\lambda(B)$.) Second, when $\rho(B) < 1$ the convergence advantage of Chebyshev over Taylor polynomials is not that great. For small $\rho(B)$ the Chebyshev convergence factor (see, e.g., [13]) is at best $\frac{1}{2}\rho(B)$ and achieves that only when $\lambda(B)$ is entirely real or entirely imaginary. We leave a fuller comparison of the two approaches for the future.

For the midpoint rule—or indeed for any 1-stage Runge–Kutta method—the iteration matrix B is Hamiltonian. This still holds for almost all 2-stage Runge–Kutta methods, as we now show. If $a_{12}a_{21} \neq 0$, then B is a Hamiltonian matrix because it can be written as a product of an antisymmetric and a symmetric matrix:

$$
\begin{aligned}
B &= \Delta t \begin{pmatrix} a_{11}JH''(Z_1) & a_{12}JH''(Z_2) \\ a_{21}JH''(Z_1) & a_{22}JH''(Z_2) \end{pmatrix} \\
&= \Delta t \begin{pmatrix} \frac{a_{11}}{a_{21}}J & J \\ J & \frac{a_{22}}{a_{12}}J \end{pmatrix} \begin{pmatrix} a_{21}H''(Z_1) & 0 \\ 0 & a_{12}H''(Z_2) \end{pmatrix}.
\end{aligned}
$$

(The symplectic structure, given by the first matrix factor, is noncanonical, but this does not affect the eigenvalue symmetry.) On the other hand, if $a_{12} = 0$, say, then B is block lower triangular and not Hamiltonian. However, its eigenvalues are $\Delta t a_{11}\lambda(JH''(Z_1)) \cup \Delta t a_{22}\lambda(JH''(Z_2))$, which do have Hamiltonian symmetry.

For Runge–Kutta methods with ≥ 3 stages the iteration matrix is not in general Hamiltonian, and its eigenvalues need not have Hamiltonian symmetry, numerical examples being easy to construct. In fact, attempting to express the iteration matrix for a 3-stage Runge–Kutta method in the form of an antisymmetric matrix $\alpha_{lj} \otimes J$ times the symmetric matrix $\sum_k \beta_{ljk} H''(Z_k)$ (where $\alpha_{lj} = \alpha_{jl}$, $\beta_{ljk} = \beta_{jlk}$) yields, on eliminating the variables α_{lj}, β_{ljk}, the result that such a factorization exists only if $a_{13}a_{21}a_{32} = a_{12}a_{23}a_{31}$, which does not hold for the 3-stage Gaussian Runge–Kutta. Nevertheless, the iteration matrix will always be [illegible] Hamiltonian, because the matrices $H''(Z_k)$ are all equal to within $\mathcal{O}(\Delta t)$, and in the case of equal matrices such a factorization always exists, namely $a_{lj}JH''(Z) = (a_{lj} \otimes J)(I \otimes H''(Z))$. Therefore the eigenvalues of the iteration matrix will always be close to obeying the same symmetry as those of Hamiltonian matrices.

In other applications, the use of preconditioners is vital [5, 12]. Preconditioning will work here too—decreasing $\rho(B)$, but also destroying, in general, the Hamiltonian structure of B—although not generally as well as in the stiff, dissipative case. We do so few inner iterations anyway that the preconditioner has to be very cheap or extremely effective. An example of a use of a preconditioner, or equivalently a Newton-chord iteration, for a Hamiltonian system is given in [1] for the Korteweg–de Vries equation $u_t = uu_x + u_{xxx}$. The Jacobian is frozen at the stiff term ∂_{xxx}. A second example is given in the solar system study below.

4. Examples. The following example arose in a study of the dynamics of certain curves called momentum sheets in a generalized Camassa–Holm equation that is thought to govern certain classes of solitary waves in shallow water [15]. The curve motion is governed by a PDE which is discretized by placing particles at positions $q_i \in \mathbb{R}^2$ on the curve. Each particle carries momentum $p_i \in \mathbb{R}^2$, and the Hamiltonian is

$$H = \sum_{i=1}^{n} (p_i \cdot p_j) G(\|q_i - q_j\|), \tag{8}$$

which describes geodesics on a Riemannian manifold with metric the inverse of the matrix of G's. The three kernels $G(r)$ of most interest in the application were the Gaussian $\exp(-r^2)$, the modified Bessel functions $K_0(r)$ and $rK_1(r)$ (with the singularity at $r = 0$ appropriately removed). Note that we have, e.g., $K_0'(r) = -K_1(r)$ and $K_0''(r) = K_0(r) + K_1(r)/r$. Since K_0 and K_0' already occur in the vector field, no new Bessel functions have to be computed for the Jacobian.

The motion of the sheet for the Gaussian kernel is shown in Figure 1 for time 50, during which it undergoes a large-scale evolution. There are 50 particles, and the total dimension of the system is 200. To give an idea of the time scale of this problem, both the standard and modified iterations converge at $\Delta t = 6$ but not at $\Delta t = 7$. The final position error is 0.7% at $\Delta t = 1$ and 15.3% at $\Delta t = 5$. The maximum relative energy error during the simulation is 0.2% at $\Delta t = 1$. The spectrum is also shown in Figure 1. The focal interval of the bounding ellipse changes from imaginary to real, to imaginary, and back to real, although the ellipse never becomes very eccentric, and a circle is always a reasonable approximation to the spectrum.

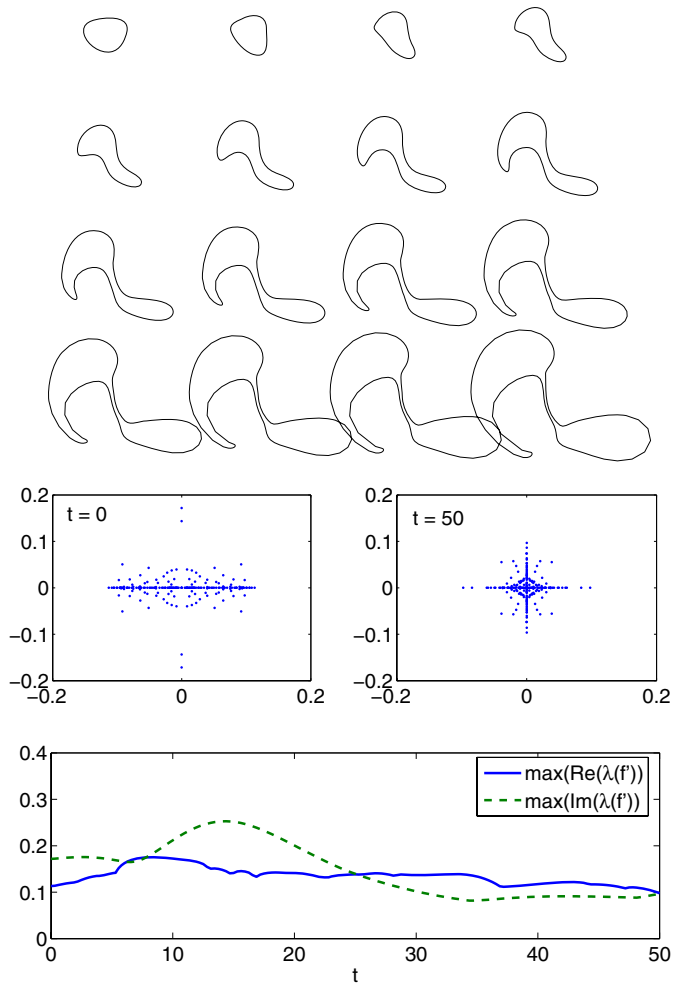

FIG. 1. *Top: Snapshots of the motion of the geodesic curve motion, for* $t \in [0, 50]$. *Middle: Spectrum of the Jacobian at the initial and final times. Bottom: Evolution of the eigenvalues of maximum real and imaginary parts.*

The results are shown in Table 1 and Figure 2. The number of outer iterations (equivalently, number of vector field evaluations) per time step is very close to that used by Newton's method. For the Gaussian kernel with the midpoint rule, one could use $\Delta t = 0.4$ and do about 1 evaluation of f per step (the standard iteration needs 6), achieving a final position error of 0.0011; or one could use $\Delta t = 0.8$ and do about 2 evaluations of f per step (the standard iteration needs 10), achieving a final position error of 0.0045. Clearly, in this problem there is no advantage in the larger time step. But even $\Delta t = 0.4$ is relatively large for this problem and is analogous to the large time steps often used in molecular dynamics problems.

A second observation is that even with the simplest implementation possible, namely using $c = 1$ in the termination criterion for the inner iteration, we have $\overline{N}_{\text{outer}} + \overline{N}_{\text{inner}} \approx \overline{N}_{\text{std}}$ across the whole range of time steps. The algorithm is roughly equivalent to exchanging most iterates of the standard iteration (4) with a matrix-vector multiplication.

TABLE 1

Results for the curve geodesic problem (8) *shown in Figure* 1 *with* 50 *points and dimension* 200. *The integration time is* 50 *and the time step is* $\Delta t = 50/\text{steps}$. $\overline{N}_{\text{outer}}$ *is the mean number of outer iterations (= number of vector field evaluations) per time step used by the modified iteration equation* (6) *(including the initial steps, when the order of the initialization is necessarily lower and more iterations are needed).* $\overline{N}_{\text{inner}}$ *is the mean number of inner iterations (= number of matrix-vector multiplications) per time step.* $\overline{N}_{\text{std}}$ *is the mean number of vector field evaluations per time step used by the standard iteration* (4). *CPU times in seconds are shown for the two methods in a MATLAB implementation. The same extrapolation method is used for initialization for all cases. Its order ranges from* 4 *(for large time steps) to* 14 *(for small time steps).*

$G(r)$	Order	Steps	$\overline{N}_{\text{std}}$	$\overline{N}_{\text{outer}}$	$\overline{N}_{\text{inner}}$	CPU_{std}	CPU

For the Gaussian kernel and fourth-order 2-stage Gaussian Runge–Kutta, the position errors are now only 0.2% at $\Delta t = 5$ and 4×10^{-6} at $\Delta t = 1$, and the maximum relative energy errors 0.3% at $\Delta t = 5$ and 3×10^{-5} at $\Delta t = 1$. The improvements to the fourth-order method are very similar to those enjoyed by the second-order method. The number of outer iterations is reduced slightly, and the number of inner iterations is significantly reduced at large time steps, because the spectral radius of (a_{ij}) is reduced by a factor 0.58. For the same reason, the fourth-order method converges for larger time steps, failing to converge only at $\Delta t = 9$. For this problem, the fourth-order method always gives a smaller error for a given work (see Figure 2). Both methods can be used satisfactorily at large time steps.

The speedup in CPU time is not as great as the reduction in function evaluations. It is generally a factor of about 2 in this MATLAB implementation—more for larger time steps, a bit less if the order is increased to 4.

The following refinement of the algorithm yields further improvement in the CPU times: On outer iterations after the first, update the Jacobian only if the norm of the previous update of z is greater than some chosen tolerance. This use of inexact Jacobians slows the convergence of both the inner and outer iterations, but (depending on the complexity of the Jacobian) can nevertheless lead to an overall speedup. In the first example of Table 1 (Gaussian kernel with the midpoint rule), with tolerance 0.1 the speedup factor was in the range 1.3–1.38 for the critical range of 20–80 time steps ($0.625 \le \Delta t \le 2.5$). Clearly, the choice of the tolerance is crucial and is problem-dependent.

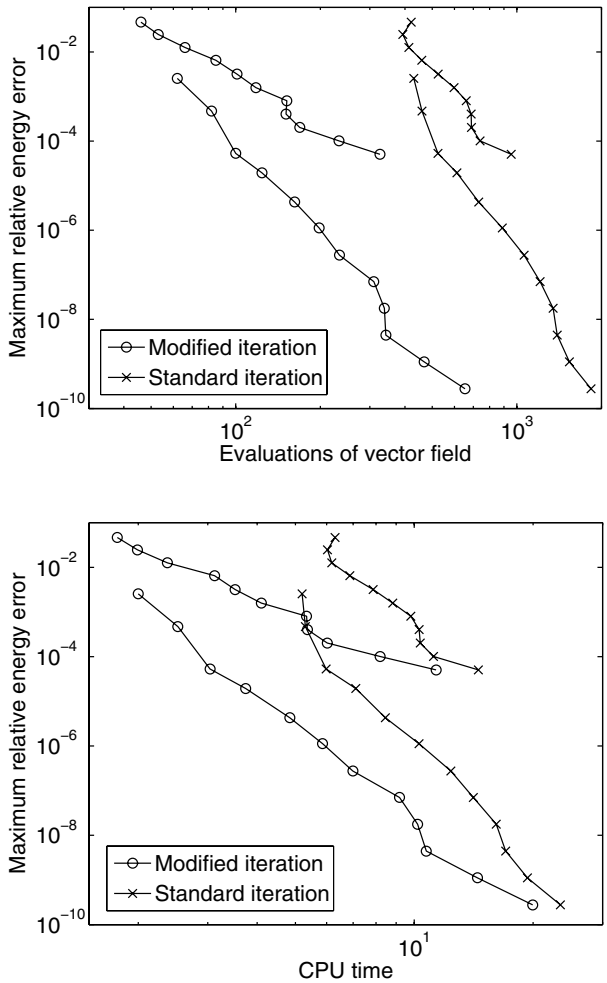

FIG. 2. *Curve geodesics problem. The data from Table* 1 *compared for efficiency* ($G(r) = \mathrm{e}^{-r^2}$, *orders* 2 *and* 4*).*

Sample results are also shown for the more expensive Bessel function kernel $K_0(r)$ with the midpoint rule. $K_0(r)$ can be evaluated in about 78 multiplications, and $K_0(r)$ and $K_1(r)$ together in about 90 multiplications, in MATLAB, which calls a Fortran subroutine. Now the vector field evaluations occupy a larger fraction of the CPU time, and hence the observed speedups are greater.

Two further examples are taken from the results in [8] in a direct comparison with the Fortran code `gnicode`.[2] They are both for separable Hamiltonians of the form $H = \left(\sum_{i=1}^{n} p_i^2/m_i\right) + V(q)$, and in [8] the standard implementation of Gaussian Runge–Kutta methods is compared to explicit composition methods. For these Hamiltonians the momenta at the internal stages can be eliminated, leaving a nonlinear equation for the positions whose Jacobian is now a block matrix with (l, j) block given by $\delta_{lj} I - ((\Delta t A)^2)_{lj} V''(Q_j)$, where A is the matrix of the Butcher tableau and the Q_j are the stage values of the positions. This halves the number of standard iterations,

[2]The results for `gnicode` shown in Table 2 are better than those given in [8], because the code was improved further since the book was published [9].

TABLE 2

Kepler problem. One period of the 2D Kepler problem with period 2π and eccentricity 0.6 is integrated using the standard iteration in the `gnicode` *Fortran implementation and using the modified iteration in an adaptation of the same code. CPU times are reported for the GNU Fortran optimizing compiler 3.4 on a 1GHz G4 Mac. The same initialization is used in each case (extrapolation for order 2, and an order $s+2$ Runge–Kutta-type method for order $2s \geq 4$). N_f is the total number of vector field evaluations including those needed for initialization.*

	$2\pi/50$	951	447	83	3.17	1.16	1.66	591	424
	$2\pi/100$	1255	805	123	2.09	1.01	1.23	829	745
	$2\pi/200$	1923	1605	206	1.60	1.00	1.03	1328	1444
	$2\pi/400$	3367	3205	401	1.40	1.00	1.00	2371	2864

somewhat reduces the number of outer iterations, and halves the number of inner iterations and the size of the matrices involved. We present results for the relative energy errors; results for the global errors are similar.

The first example is the two-dimensional Kepler problem with $H = \frac{1}{2}(p_1^2 + p_2^2) + 1/\sqrt{q_1^2 + q_2^2}$, for which results are given in Table 2. Despite the low dimension, the completely different implementation, and the fact that the vector field evaluations do not dominate the CPU time (the single square root costs only about 7 multiplications) the results are strikingly similar to those for the curve geodesic problem.

The second example is the outer solar system problem. The sun, four outer planets, and Pluto are evolved in standard coordinates for 500,000 days. Again, the problem is not very large, and the $n(n-1)/2 = 15$ square roots actually number less than the $3n = 18$ degrees of freedom. Still, the results are similar to those of the previous two examples. For this problem due to the scaling of the variables it was advantageous to adapt the forcing parameter c that controls the termination of the inner iteration. The results are shown for $c = 100$ in Figure 3. The order 4 implicit and explicit methods now have equal performance for time steps less than about 120 days (indicated by an arrow). The order 8 and 12 methods beat the explicit methods for relative energy errors less than about 10^{-7}.

Because the system is nearly integrable, a good preconditioner is available in the form of the product of the exact inverses of the Jacobians of the sun-planet two-body systems. These can be calculated explicitly in terms of scalar products. The convergence factor $\rho(A)$ is reduced dramatically, so that only one inner iteration per Newton step is required. However, the preconditioning is expensive, and it is not yet clear whether the extra level of complexity is justified. (Besides, explicit methods can also exploit the near integrability.)

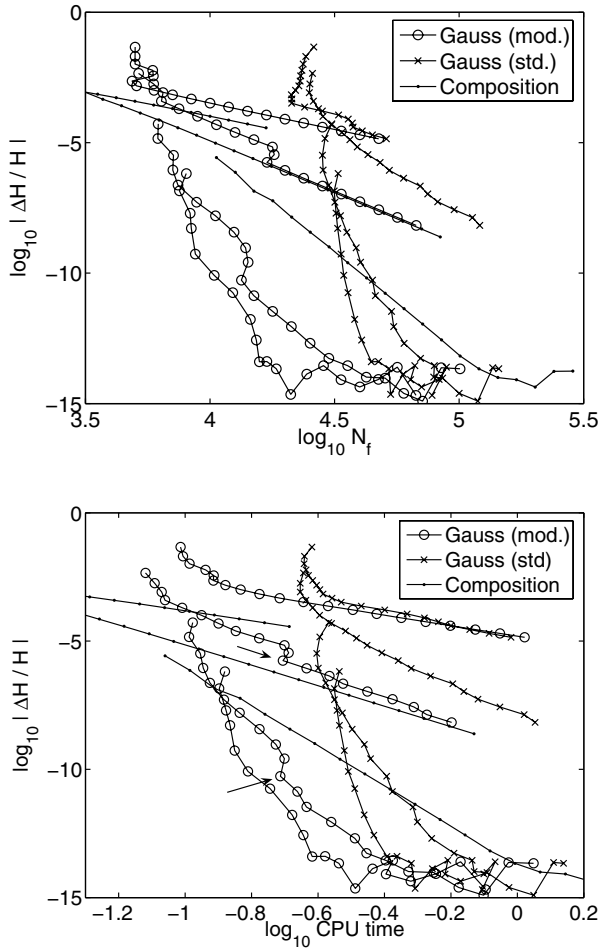

FIG. 3. *Outer solar system problem. Gaussian Runge–Kutta methods of orders* 2, 4, 8, *and* 12 *compared in the standard and modified Fortran implementations. Results for three explicit composition methods are also shown, of orders* 2 *(*1 *stage leapfrog),* 4 *(*5 *stages), and* 8 *(*17 *stages),* `gnicode`*'s methods* 21, 45, *and* 817, *respectively. The performance of the implicit methods is best when the mean number of outer iterations drops to* 1, *which occurs at the points marked by arrows. These correspond to a time step of* 120 *days for order* 4 *and* 240 *days for order* 8. *The order* 12 *results are influenced by round-off for time steps less than* 300 *days.*

5. Conclusions. Even if the vector field has no particular structure, the modified iteration (6) is likely to be an improvement over the standard iteration (4). The only unavoidable requirement is that we need $\rho(A) < 1$; i.e., the problem must not be stiff. However, the case $\rho(A) > 1$ takes us into the entirely different realm of highly oscillatory systems [8]. Therefore the present algorithm is most suited to nonstiff problems in which implicit methods are needed for their geometric properties such as symplecticity.

Many large physical systems have an appropriate structure which reduces the cost of the integration considerably, down to one or two vector field evaluations per time step. Of course, some systems have so much structure that it is possible to exploit it directly in solving the implicit Runge–Kutta equations. For example, for N-body systems one could use a fast multipole method, and for smooth lattice systems such as

those arising as semidiscretizations of PDEs one could use multigrid. However, these approaches are not only vastly more complicated than the present proposal, they are also much more problem-specific.

It is tempting to ask whether the information contained in the Jacobians can be used for purposes other than just speeding up the convergence. Unfortunately, there are no symplectic multiderivative Runge–Kutta methods [8], nor are there any "elementary differential" Runge–Kutta methods using just the Jacobian—the simplest is the midpoint rule applied to the modified Hamiltonian $H + \frac{1}{24}(\Delta t)^2 f^T H'' f$, which requires the second derivative of the vector field f. There are Runge–Kutta-like methods using f' [17], but these are not very developed.

The algorithm presented here is a reasonable one because of the special (Hamiltonian) structure of the problem. It is tempting to consider further specializations of this structure for which the algorithm can be improved further. Directions for future research include automatic selection of the tolerances and exploring cases in which inexact Jacobians, Chebyshev iteration, and/or preconditioners should be used.

Acknowledgements. I would like to thank Stephen Marsland for discussions on the momentum sheet example, and Ander Murua for discussions on the use of Chebyshev iteration.

SENSITIVITIES IN LARGE EDDY SIMULATION AND IMPROVED ESTIMATES OF TURBULENT FLOW FUNCTIONALS*

MIHAI ANITESCU† AND WILLIAM J. LAYTON‡

Abstract. We consider a prototypical problem: simulate velocity and pressure in a turbulent flow using large eddy simulation (LES) and then use the results to estimate the force that the underlying turbulent flow exerts on an immersed body. For eddy viscosity-type LES models we develop the appropriate continuous sensitivity equation and show how it can improve the functional estimate by using the sensitivity with respect to the user-selected length scale to incorporate the effects of the underlying unresolved small-scale fluctuations on the functionals sought.

Key words. large eddy simulations, sensitivity, turbulence

AMS subject classifications. 76D05, 35Q30, 90C31

DOI. 10.1137/050631161

1. Introduction.

For the foreseeable future, computational resources will be insufficient for the direct numerical solution of most turbulent flow problems. On the other hand, important decisions are made and significant designs produced based on estimates of quantities in turbulent flow that are simulated by using various models of turbulence. Even when using the model that current practice considers best for a particular application, often the reliability of the model's predictions for the specific application is not assessed. This situation is particularly troublesome because solutions of turbulence models can display sensitivity to the user-elected model parameters, in addition to sensitivity to the upstream flow, subgrid model, and numerical realization of it (reported by Sagaut and Lê [19]).

For example, calculating the force that a fluid exerts on an immersed body, such as lift or drag, involves first solving the Navier–Stokes equations

$$\begin{aligned} &u_t + \nabla \cdot (u\ u) + \nabla \cdot \sigma(u,p) = f \qquad \text{in } \Omega \times (0,T), \\ &\sigma(u,p) := pI - 2\nu\nabla^s u, \qquad \nabla^s u := \frac{1}{2}(\nabla u + \nabla u^t), \\ &\nabla \cdot u = 0 \text{ in } \Omega \times (0,T), \quad u = 0 \text{ on } \partial\Omega, \quad \text{and} \quad u(x,0) = u_0(x) \text{ in } \Omega. \end{aligned} \tag{1.1}$$

If B denotes the boundary of the immersed body, next the force must be calculated on B:

$$\text{force on } B \;= \int_B \hat{n} \cdot \sigma \, ds = \int_B \hat{n} \cdot [pI - 2\nu \nabla^s u] \; ds, \tag{1.2}$$

$$\hat{n} = \text{outward unit normal to } B.$$

This calculation requires accurate estimation of p and derivatives of u on the flow boundary—a problem harder than accurately predicting the turbulent velocity itself.

The basic approach used for turbulent flows has been to replace the Navier–Stokes equations (1.1) by a turbulence model and then insert the velocity-pressure predicted by the turbulence model into the right-hand side of the functional, such as (1.2). Uncertainties arise immediately, however, because of the typical sensitivity to the model's input parameters. Perhaps more important, turbulence models approximate flow averages. Thus, all the information on fluctuations is lost in them. However, the small-scale fluctuations can have a determining role in functionals such as (1.2). Mathematically, the reason for this is that the derivatives occurring in (1.2) outweigh velocity changes occurring across small distances. One concrete example is drag in the flow over a dimpled versus a smooth golf ball; a related example is riblets. Both change the geometry (and flow) on scales below typical feasible meshes. Indeed, drag reduction strategies of injection of small amounts of microbubbles or polymers near a body are, in part, based on the expectation that a little power input to alter the flow's small scales can have a large effect on the global drag.

This paper considers functional estimation and solution sensitivity for models arising in large eddy simulation (LES). In section 2 we apply the continuous sensitivity idea to a common class of LES models. The sensitivity equation approach has the great advantage of giving computable quantitative estimates of the local sensitivity of the model's predicted flow field to variations in the input parameters. Thus, a sensitivity calculation will show in which regions the predicted velocities are reliable and hence believable and in which regions those predicted velocities are highly sensitive and hence should be viewed with greater suspicion. We focus on the case of sensitivity with respect to the user-selected length scale δ. The reason for this focus is (section 3) that the sensitivity of the flow to variations in δ can be used to improve the estimate of flow functionals, such as lift and drag, which can depend strongly on the unknown and unresolved turbulent fluctuations.

2. The sensitivity equation of eddy viscosity models. The continuous sensitivity equation approach is becoming increasingly important in computational fluid dynamics but is not yet a common tool in LES of turbulence. In this section we apply the sensitivity idea to find the continuous sensitivity equation with respect to variations in the cutoff length scale delta. For a general treatment of sensitivities and applications to other flow problems, see (among many interesting works) [3, 4, 10, 9, 20].

Suppose that a local spatial filter has been selected (denoted by an overbar) associated with the length scale δ. Filtering the Navier–Stokes equations leads to the problem of closure, and one common class of closure models is based on the Boussinesq, or eddy viscosity, hypothesis. The model we consider takes the general form of finding the approximate large-scale velocity $w(x,t)$ and pressure $q(x,t)$ satisfying $\nabla \cdot w = 0$ and

$$w_t + \nabla \cdot (w \; w) - \nu \Delta w + \nabla q - \nabla \cdot (\nu_T(\delta, w) \nabla^s w) = \overline{f}, \tag{2.1}$$

where ν is the kinematic viscosity, $\overline{f}$ is the space filtered body force, and ν_T is the eddy viscosity coefficient that must be specified to select the model. As an example, the Smagorinsky model, while not considered the best, is perhaps the most commonly used model and is given by the eddy viscosity choice

$$\nu_T = \nu_{\text{Smag}}(\delta, w) := (C_s\delta)^2|\nabla^s w|, \quad C_s \sim 0.1. \tag{2.2}$$

For other eddy viscosity models, see the presentation in [18, 13, 2, 16, 12]. Once the Smagorinsky constant, C_s, and the initial and boundary conditions are specified, for a given δ the equations (2.1), (2.2) uniquely determine a solution w, q implicitly as a function of δ.[1]

DEFINITION 2.1. [illegible] w, q [illegible] (2.1). [illegible] w, q [illegible] δ [illegible] w, q [illegible] δ

$$w_\delta := \frac{\partial w}{\partial \delta}, \qquad q_\delta := \frac{\partial q}{\partial \delta}.$$

One can easily derive continuous equations for the sensitivities by implicit differentiation of (2.1) with respect to δ. Doing so gives the equations

$$w_{\delta,t} + \nabla\cdot(ww_\delta + w_\delta w) - \nu\Delta w_\delta + \nabla q_\delta \tag{2.3}$$

$$-\nabla\cdot\left(\left[\frac{\partial}{\partial\delta}\nu_T(\delta,w) + \frac{\partial}{\partial w}\nu_T(\delta,w)\cdot w_\delta\right]\nabla^s w + \nu_T(\delta,w)\nabla^s w_\delta\right) = \frac{\partial}{\partial\delta}(\overline{f}) \quad \text{and}$$

$$\nabla\cdot w_\delta = 0. \tag{2.4}$$

Thus, once the large eddy velocity and pressure, w, q, are calculated, the corresponding sensitivities can be found by solving a linear problem for w_δ, q_δ that is precisely the nonlinear LES model linearized about (w, q). Thus, sensitivities can be quickly and economically calculated by modifying the program used to calculate (w, q). On the other hand, one can simply use an unmodified program to test whether sensitivity information will be useful for a given application before beginning program modifications. This approach involves solving the model for $w(\delta_1)$ and $w(\delta_2)$ for $|\delta_1 - \delta_2|$ small and computing sensitivities by means of the divided difference

$$s = \frac{w(\delta_2) - w(\delta_1)}{\delta_2 - \delta_1}.$$

In our numerical simulations in section 5 we use the latter approach.

For the Smagorinsky model we have $\nu_T = (C_s\delta)^2|\nabla^s w|$. Thus the bracketed term is

$$[\nu_{T,\delta} + \nu_{T,w}\cdot w_\delta] = 2C_s^2\delta|\nabla^s w| + (C_s\delta)^2\left(\frac{\nabla^s w}{|\nabla^s w|}\right) : \nabla^s w_\delta. \tag{2.5}$$

It is interesting to note that the Smagorinsky model enters the fluid flow equation (2.1) only through the term δ^2. It may therefore be useful to use as a natural variable $\gamma = \delta^2$ and to investigate the sensitivity w_γ with respect to γ.

[1] Fundamental theoretical questions arise even at this first step. For example, it is not known whether the solution of the Smagorinsky model is a C^1 function of δ for $\delta > 0$ or whether the branch is continuous down to $\delta = 0$.

In that case the equations for the sensitivity with respect to γ become

$$w_{\gamma,t} + \nabla \cdot (w w_\gamma + w_\gamma w) - \nu \Delta w_\gamma + \nabla q_\gamma \tag{2.6}$$

$$- \nabla \cdot \left(\left[\frac{\partial}{\partial \gamma} \nu_T(\gamma, w) + \frac{\partial}{\partial w} \nu_T(\gamma, w) \cdot w_\gamma \right] \nabla^s w + \nu_T(\gamma, w) \nabla^s w_\gamma \right) = \frac{\partial}{\partial \gamma}(\overline{f}) \text{ and}$$

$$\nabla \cdot w_\gamma = 0, \tag{2.7}$$

where the bracketed term is

$$[\nu_{T,\gamma} + \nu_{T,w} \cdot w_\gamma] = 2C_s^2 |\nabla^s w| + (C_s)^2 \gamma \left(\frac{\nabla^s w}{|\nabla^s w|} \right) : \nabla^s w_\gamma. \tag{2.8}$$

Since from the chain rule we have that $w_\delta = 2\delta w_\gamma$, it follows that all the conclusions that we draw for w_δ extend immediately to w_γ, with one exception outlined in section 5.2.2. Therefore, we will investigate only the sensitivity with respect to δ, the conclusions extending immediately to the sensitivity with respect to γ.

2.1. Calculating $\overline{f}_\delta = \frac{\partial}{\partial \delta} \overline{f}$. If the body forces acting on the flow are smooth enough, $\overline{f}_\delta$ is negligible. Otherwise, in the right-hand side of (2.3), $\overline{f}_\delta$ can play an important role in the sensitivity equation because it incorporates information about body force fluctuations. When f is not smooth, the exact value of $\overline{f}_\delta$ depends on the precise filter specified. When $\overline{f}$ is defined by convolutions, extending f by zero off the flow domain and then defining

$$\overline{f} := \int_{\mathbf{R}^d} \delta^{-d} g\left(\frac{x'}{\delta} \right) f(x - x') dx, \qquad g(x) := \text{ chosen filter kernel,}$$

then $\overline{f}_\delta$ can be calculated explicitly.

When $\overline{f}$ is defined by using differential filters [7, 16, 13, 2], a small modification is needed that depends on the exact differential filter specified. Two interesting differential filters are defined by solving the shifted Poisson problem for $\overline{f}$,

$$-\delta^2 \Delta \overline{f} + \overline{f} = f \text{ in } \Omega, \qquad \overline{f} = 0 \text{ on } \partial\Omega, \tag{2.9}$$

and by solving the shifted Stokes problem for $\overline{f}$,

$$-\delta^2 \Delta \overline{f} + \overline{f} + \nabla \lambda = f \quad \text{and} \quad \nabla \cdot \overline{f} = 0 \text{ in } \Omega, \quad \text{and} \quad \overline{f} = 0 \text{ on } \partial\Omega. \tag{2.10}$$

The second differential filter (2.10) preserves incompressibility and is thus interesting despite costing more than the first.

With the first filter $\overline{f} = (-\delta^2 \Delta + 1)^{-1} f$, we differentiate implicitly with respect to δ to derive an equation for $\overline{f}_\delta$:

$$(-\delta^2 \Delta + 1) \overline{f}_\delta = 2\delta \Delta \overline{f} = (\text{via } (2.9)) = \left(-\frac{2}{\delta} \right) (f - \overline{f}).$$

Thus,

$$\overline{f}_\delta = \left(-\frac{2}{\delta} \right) (\overline{f'}). \tag{2.11}$$

Analogously, we obtain the initial condition for w_δ,

$$w_\delta(x,0) = \overline{u}_{0,\delta}(x) = \left(-\frac{2}{\delta}\right)(\overline{u_0'}). \tag{2.12}$$

Here, we denote by h' the fluctuation of a function $h(x)$, that is, $h' = h - \overline{h}$. Neither (2.11) nor (2.12) introduce singularities as $\delta \to 0$, provided $\nabla f \in L^2(\Omega)$ and $\nabla u_0 \in L^2(\Omega)$. On the other hand, a large value of $\overline{f}_\delta$ or $\overline{u}_{0,\delta}$ for rough data reflects an essential sensitivity of the data.

2.2. Boundary conditions for the sensitivities. Boundary conditions for sensitivities must be specified. The most interesting and important cases are sensitivity with respect to the (modeled) upstream conditions and the (modeled) outflow conditions [19]. At this point, a mathematical formulation of the former is unclear, whereas there exist many options for the latter. Thus we consider here only boundary conditions for the sensitivities at solid walls.

With a differential filter like (2.9) and (2.10), the boundary conditions for the sensitivities are clear because there exist no error and no variability with respect to δ in the conditions for w on the wall: $w_\delta = 0$ on the boundary.

Some slight modifications of the wall models are necessary to compute sensitivities when near-wall models are used. These are usually associated with averaging; see [6] for some mathematical issues involved. Many near-wall models or numerical boundary conditions are possible. For specificity and clarity we treat the simplest ones considered in, for example, [14], in which the large structure's action on the boundary is modeled by no penetration and slip with friction conditions:

$$w \cdot \hat{n} = 0 \quad \text{and} \quad \beta(\delta,\nu) w \cdot \hat{\tau}_j + \hat{n} \cdot (\nu \nabla^s w) \cdot \hat{\tau}_j = 0 \quad \text{on } \partial\Omega,$$

where $\hat{n}$ is the unit normal to the boundary and $\hat{\tau}_1, \hat{\tau}_2$ are a system of tangent vectors on the boundary. This is the original boundary condition of Navier (Navier's slip law). In large eddy simulation it is motivated by the general observation that large structures (e.g., hurricanes) do not stick but rather slip and lose energy as they do. Loosely interpreting an 1869 analysis of Maxwell suggests a scaling for $\beta \sim \frac{\nu L}{\delta}$, explored in [14].

Implicit differentiation with respect to δ gives the boundary conditions for the sensitivities:

$$w_\delta \cdot \hat{n} = 0 \quad \text{and} \quad \beta(\delta,\nu) w_\delta \cdot \hat{\tau}_j + \hat{n} \cdot (2\nu \nabla^s w_\delta) \cdot \hat{\tau}_j = -\beta_\delta(\delta,\nu) w \cdot \hat{\tau}_j \quad \text{on} \quad \partial\Omega.$$

Since $\beta(\delta)$ increases monotonically to infinity as $\delta \to 0$ (see [14]), $\beta_\delta > 0$. Thus, slippage in the flow velocity w acts to decrease the slippage in the sensitivities when they are aligned and increase it when they are opposed.

3. Improving estimates of functionals of turbulent quantities. The usual procedure for estimating a flow functional is to compute the LES velocity w approximating the fluid motion on scales larger than the cutoff length scale and then to approximate the sought solution functional $J(u)$ by $J(w)$. This can be a reasonable approximation when the small scales do not influence the functional and when w is a good approximation to the large scales of u. When the functionals involve derivatives of u, however, those derivatives tend to outweigh the small scales in the functional. We show in this section how the approximation of $J(u)$ can be improved to incorporate some of the unresolved scale effects through sensitivity information. Numerical

tests of the improvement of flow functionals by using sensitivity information (with accompanying mathematical support) have yielded positive results for a different eddy viscosity model in [17].

We suppose that the LES solution w implicitly defines a smooth function of $\delta, w = w(\delta)$, with the property that

$$w(\delta) \to u \quad \text{as} \quad \delta \to 0. \tag{3.1}$$

This is a minimal analytic consistency condition for an LES, which nevertheless has so far been proven to hold for only a few large eddy models; see, for example, [5, 15]. If the functional is C^1, then the composition

$$\delta \mapsto J(w(\delta)) =: J(\delta)$$

defines a smooth map. The value $J(\delta) = J(w(\delta))$ is computable while $J(u) = J(w(0)) = J(0)$ is sought. Since δ is small, the linear approximation to $J(0)$ is justified. This yields the following approximation to $J(u)$:

$$J(u) \doteq J(w(\delta)) - \delta J'(w(\delta)) \cdot w_\delta. \tag{3.2}$$

The increment $\delta J'(w(\delta))$ incorporates effects of unresolved scales on $J(u)$ and is computable once the solution sensitivities w_δ are calculated.

If the functional itself is regularized, $J(u)$ is approximated by a δ-dependent approximation $J(\delta, w(\delta))$. Then (3.2) is modified by

$$J(u) \doteq J(\delta, w(\delta)) - \delta(J_w(\delta, w(\delta)) \cdot w_\delta + J_\delta(\delta, w)). \tag{3.3}$$

3.1. Example: Lift, drag, and other fluid-boundary interactions in turbulent flows. In many applications, forces exerted by the fluid on its boundaries must be estimated. In this case the functional is given by

$$J(u, p) := \oint_B \hat{n} \cdot [pI - 2\nu\nabla^s u] \cdot \hat{a} \, ds, \tag{3.4}$$

where $\hat{a}$ is a unit vector and B is the boundary of the immersed body. If $\hat{a}$ points in the direction of motion, $J(u)$ represents drag, whereas if $\hat{a}$ points in the direction of gravity, $J(u)$ represents lift.

For general surfaces B, the straightforward approximation of $J(u, p)$ by $J(w, q)$ is not so clear because (see, for example, [18]) while $w(\delta) \to u$ as $\delta \to 0$, $q(\delta) \to p + 1/3 \cdot \text{trace}\,(R)$, where R is the large eddy subgrid stress tensor

$$R_{ij} := \overline{u}_i \overline{u}_j - \overline{u_i u_j}.$$

Thus, for a general surface B, $q(\delta)$ is not a direct approximation to p, and its use in (3.4) could skew the estimate of the force on that surface B. For a wall B, the situation is clearer. Indeed, let $k(v) := 1/2|v|^2(x, t)$ denote the kinetic energy distribution of a velocity field v. Then we have

$$q(\delta) = p + (2/3)(k(\overline{u}) - \overline{k(u)}). \tag{3.5}$$

Since w approximates $\overline{u}$, the excess pressure contribution to q from $k(\overline{u})$ is computable and thus correctable by using $k(w)$, but that contributed by $\overline{k(u)}$ is not easily calculable for general surfaces. If B is a solid wall and the averaging operator, such as

(2.9) and (2.10), preserves the no-slip condition, then $k(\overline{u}) = \overline{k(u)} = 0$ on B, and p can be estimated on B by $q(\delta)$.

Since the boundary-force functional $J(w, q)$, given by (3.4), is a linear functional $J' = J$, we obtain the corrected approximation to the force on B:

$$J(u,p) \sim J(w,q) - \delta J(w_\delta, q_\delta) = J(w - \delta w_\delta, q - \delta q_\delta)$$

$$= \oint_B \hat{n} \cdot [(q - \delta q_\delta)I - 2\nu\nabla^s(w - \delta w_\delta)] \cdot \hat{a}\ ds. \tag{3.6}$$

3.2. Example: Flow matching. In flow matching, a desired velocity field u^* is specified, the flow is simulated, a functional such as

$$J(u) := \frac{1}{2}\int_{\Omega\times(0,T)} |u - u^*|^2 dx\ dt$$

is calculated, and the design or control parameters are used to drive $J(\cdot)$ to its minimum value. Thus, one aspect of flow matching involves getting the best estimate of $J(\cdot)$; this is challenging in the case of a turbulence flow.

Abstractly, given the LES velocity w and its sensitivity w_δ, (3.2) provides an estimate of $J(u)$, improving the estimate given by $J(w)$. Since $J(\cdot)$ is quadratic, it is straightforward to calculate

$$J'(w)w_\delta = \int_{\Omega\times(0,T)} (w - w^*) \cdot w_\delta dx\ dt,$$

giving the approximation

$$J(u) \doteq \int_{\Omega\times(0,T)} \frac{1}{2}|w - u^*|^2 - \delta(w - u^*) \cdot w_\delta dx\ dt. \tag{3.7}$$

4. Approximating sensitivities requires a finer mesh. If the selected LES model is accurate, its solution will not vary over scales smaller than $O(\delta)$.[2] On the other hand, if the sensitivity w_δ captures some information in fluctuations through the expansion

$$u \doteq w - \delta w_\delta + O(\delta^2),$$

then w_δ will vary on scales smaller than $O(\delta)$. Formal asymptotics can give some preliminary insight into the width of transition regions of w_δ (and thus into mesh design for the sensitivity equation). The correct beginning point for this is an underresolved laminar flow with a simple Prandtl boundary layer along a flat plate. This is far from the case of turbulence, of course, but it is the case where asymptotic analysis of transition regions is best understood. (We stress that this section is only a beginning point in understanding meshes needed to resolve sensitivity equations.)

The simplest interesting eddy viscosity is a constant $\nu_T = O(\delta^2)$, chosen so that the $O(\nu_T^{\frac{1}{2}})$ boundary layer in w is spread over an $O(\delta)$ transition region. We thus suppose that $\nu \ll \nu_T = O(\delta^2)$, and the flow domain in the upper half plain and the

[2] A general proof of this is open for almost all LES models. Even for homogeneous isotropic turbulence, estimates are not available for the smallest persistent scale in the solution of many LES models.

model velocity approach a fixed value $(v, 0)$. Here v increases from $v = 0$ to $v = O(1)$ rapidly as y increases above the plate.

Consider thus the equilibrium problems for w,

$$w \cdot \nabla w - (\nu + \nu_T)\delta w + \nabla q = 0,$$

and its sensitivity equation for $s = w_\delta$,

$$s \cdot \nabla w + w \cdot \nabla s - (\nu + \nu_T)\delta s - \nu_T'(\delta)\delta w + \nabla q_\delta = 0.$$

We expect the x-sensitivity s_1 to go from 0 to $O(1)$ back to near 0 as y increases from the wall. Supposing that this result occurs over an $O(\alpha)$ transition region (and following the analysis of laminar boundary layers, e.g., [8]), we consider the x-component of the sensitivity equation:

$$w_1 s_{1,x} + w_2 s_{1,y} + s_1 w_{1,x} + s_2 w_{1,y} - \nu_T(s_{1,xx} + s_{1,yy}) - \nu_T'(\delta)(w_{1,xx} + w_{1,yy}) + q_{\delta,x} = 0.$$

The relative orders of magnitude in the transition region of each term in the above equation are

$$O(1)O(1) + O(\delta)O(\alpha^{-1}) + O(1)O(1)$$
$$+O(\alpha)O(\delta^{-1}) + O(\delta^2)(O(1) + O(\alpha^{-2})) + O(\delta)(O(1) + O(\delta^{-2})) = 0.$$

If we keep in mind the expectation that $\alpha < \delta$, the dominant terms are then $\left(\frac{\delta}{\alpha}\right)^2$ and $\frac{1}{\delta}$. Equating this suggests that $\alpha \sim \delta^{\frac{3}{2}} \cong \delta^{\frac{1}{2}}\nu_T^{\frac{1}{2}}$, suggesting that [illegible] w [illegible] $\delta^{\frac{1}{2}}$. This prediction is confirmed in the numerical tests in section 5; see especially Figure 5.5.

5. Numerical simulations. We use the FreeFem package [11] to validate the analytical findings concerning the width of the boundary layer of the sensitivity w_δ and to assess the estimation potential of the sensitivity-based method.

For validation, we used a fine mesh to calculate the "true" Navier–Stokes solution corresponding to $\delta = 0$, which subsequently serves as a starting point for the sensitivity calculations. We will investigate the behavior of the sensitivity calculations by either divided differences, as outlined in section 2, or by numerically integrating (2.6).

When divided differences are used, they are computed on the finer mesh used to calculate the "true" Navier-Stokes solution. In this way we uncouple the important issue of continuous versus discrete sensitivities from evaluating either's potential for improved estimation of flow functionals. The "true" mesh is displayed in Figure 5.1. Of course, normally the LES+sensitivity calculations are performed on a mesh coarser than that required for the Navier–Stokes equation, and numerical errors in the sensitivity calculation must be studied. For first steps in the numerical analysis of sensitivity equations in computational fluid dynamics, see [17]. Moreover, we investigate the dependence on the mesh size of the error in the sensitivity calculations in section 5.2.3.

5.1. Computational setup. For our numerical simulations, we consider the rectangular domain from Figures 5.2 and 5.3. The domain is eight units long and two units wide. A disk of radius 0.15 is placed at $(3, 1)$. We impose no-slip boundary conditions on the horizontal walls and on the boundary of the disk, a do-nothing

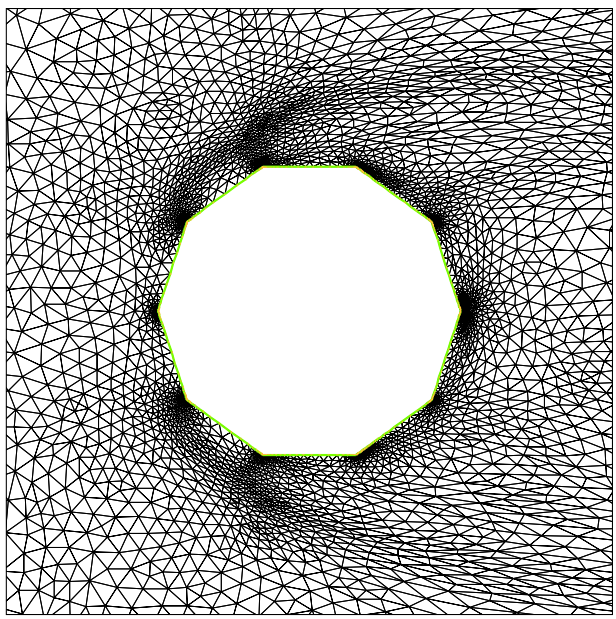

FIG. 5.1. *Final mesh, zoomed around the obstacle.*

condition at the outflow (right) boundary, and a time-independent parabolic profile at the inflow boundary, with the rule $3y(2-y)$. As initial conditions we use the solution of the steady-state Stokes problem with the same boundary conditions.

We use an implicit-explicit time-stepping scheme to approximate the solution of (2.1):

$$\frac{w^{k+1}-w^k}{\Delta t} + \nabla\cdot(w^k\ w^k) - \nu\Delta w^{k+1} + \nabla q^{k+1} - \nabla\cdot(\nu_T(\delta, w^k)\nabla^s w^{k+1}) = 0, \tag{5.1}$$

$$\nabla\cdot w^{k+1} = 0,$$

where we denote the velocity at time step k by w^k. The problem is subsequently discretized in space by a Taylor–Hood finite element from FreeFem [11] and is implemented as a FreeFem script, where, given w^k, we compute w^{k+1}. We choose a time step $\Delta t = 0.015$ and an inverse of the Reynolds number $\nu = \frac{1}{200}$, and we run the computation for 500 steps. The approximation of a circular cylinder by one with a polygonal cross section with 10 faces originates in our need to keep the initial mesh of a reasonable size. The shape of the obstacle is subsequently preserved, even if the mesh is refined. The mesh is initialized to have around 10,000 degrees of freedom on the first pass and is subsequently refined every 50 time steps. The densest portion of the final mesh is presented in Figure 5.1. We use the Smagorinsky model (2.2) with an appropriate choice of δ, specified below.

In Figures 5.2 and 5.3, respectively, we have presented the contour plot of the Euclidean norm of the velocity and the square root of the absolute value of the vorticity at four time steps of the simulation for $\delta = 0$. In the latter case, we chose the square root of the vorticity as a function to plot because it has the same contour plot as the vorticity function but is more sensitive in the range of interest. The results show a time-periodic behavior where vortices are generated behind the disk and shed by the flow which is what was observed in other computational studies. Animations of the

simulations that more clearly support this observation can be found at the website [1]. The result of the Navier–Stokes simulation at 7.5 seconds, which thus represents a realistic velocity distribution, is the starting point for our sensitivity estimations.

5.2. Results and discussions. In this subsection, we validate the various conclusions that we have drawn in sections 2 and 3.

5.2.1. Evaluation of the boundary layer of the sensitivity. We computed the sensitivity at time 7.5 seconds by running the numerical scheme (5.1) for one time step with $\delta = 0.05$, denoting the result by $\hat{w}^k$, and one time step with $\delta = 0$, denoting the result by w^k and approximating the sensitivity as

$$w_\delta^k = \frac{\hat{w}^k - w^k}{\delta}.$$

In Figure 5.4 we plot w^k and $|w^k - \hat{w}^k|$ side-by-side (sensitivity scaled by δ), where the latter is measured in the local 2-norm. The results show that the largest sensitivity occurs roughly at $\pm\frac{3\pi}{4}$, which is also the place where the boundary layer appears to be the thinnest for the velocity w^k.

Subsequently, we computed the w^k and w_δ^k profile on a direction that originates on the center of the disk at the angle -0.79π. In Figure 5.5 we plot the scaled versions of the sensitivity $|w_\delta^k|$, the velocity $|w^k|$, and the sensitivity $|w_\delta^k|$ stretched by $\delta^{-0.5}$, which we denote by $|w_\delta^k(\delta^{-0.5}\cdot)|$. The scaling is done by dividing the data by the largest values of the respective quantities along the specified direction. We see that the position of the maximum of the stretched sensitivity $|w_\delta^k(\delta^{-0.5}\cdot)|$ coincides with the maximum of the velocity $|w^k|$, which validates our theoretical finding that the boundary layer of the sensitivity is $\delta^{0.5}$ thinner than the boundary layer of the velocity.

5.2.2. Improving functional estimation. We now turn to the problem of estimating functionals of the Navier–Stokes flow $\delta = 0$ using computations with $\delta \neq 0$ followed by sensitivity-based correction.

When doing sensitivity-based correction, it is better to use the sensitivity with respect to $\gamma = \delta^2$, for reasons that will become immediately clear. If we denote the

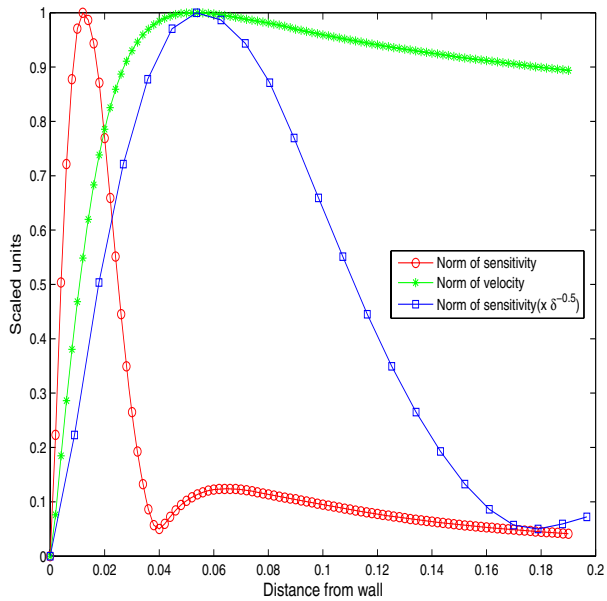

FIG. 5.5. *Comparison of the scaled sensitivity and velocity on a direction at* -0.79π *from the center of the disk.*

dependence of a functional J on γ by $\hat{J}(\gamma)$ and on δ by $J(\gamma)$, the chain rule gives us

$$J'(\delta) = \frac{dJ(\delta)}{d\delta} = 2\delta \frac{d\hat{J}(\gamma)}{d\gamma} = 2\delta \hat{J}'(\gamma).$$

We therefore have that $J'(0) = 0$. Since the correction procedure outlined in (3.6) is tantamount to the use of linear extrapolation at δ to determine $J(0)$, it will perform better if variables are used which reflect the natural ones in the model (δ^2 for the Smagorinsky model) and for which $J'(0) \neq 0$.

We therefore used the sensitivity with respect to $\gamma = \delta^2$ as the vehicle to improve a functional J. As an initial test, we compute the values of $\|w_\delta\|$ and $\|w_\gamma\|$, and we display the results in Figure 5.6. The former is computed by using divided differences between velocity values at two successive δ values, whereas the latter is computed as $\frac{w_\delta}{2\delta}$. The computation is done for one time step of simulation using (5.1) for a range of time steps and parameters δ. We see that $w_\delta \to 0$ and $w_\gamma \to 0$ as $\Delta t \to 0$, as expected (since both sensitivity equations have zero initial conditions). In addition, $w_\delta \to 0$ as $\delta \to 0$, as predicted in the preceding paragraph.

In our functional improvement computations, we consider the computation of the drag functional (3.4) using the correction (3.6), where δ is replaced with γ, and where the sensitivities are either computed by divided differences or simulated using (2.6). Since we use a mesh that is finer than the one needed to resolve the sensitivity w_δ, and since the correction of the functional (3.4) is a linear function of w_δ, determining w_δ by divided differences and then using it in the correction is equivalent to computing the drag functional for $\delta \neq 0$ and then using divided differences for drag estimation at 0.

We computed the drag functional on the disk in the x direction, from the pressure and velocity derivative data, obtained from running the Smagorinsky model for one

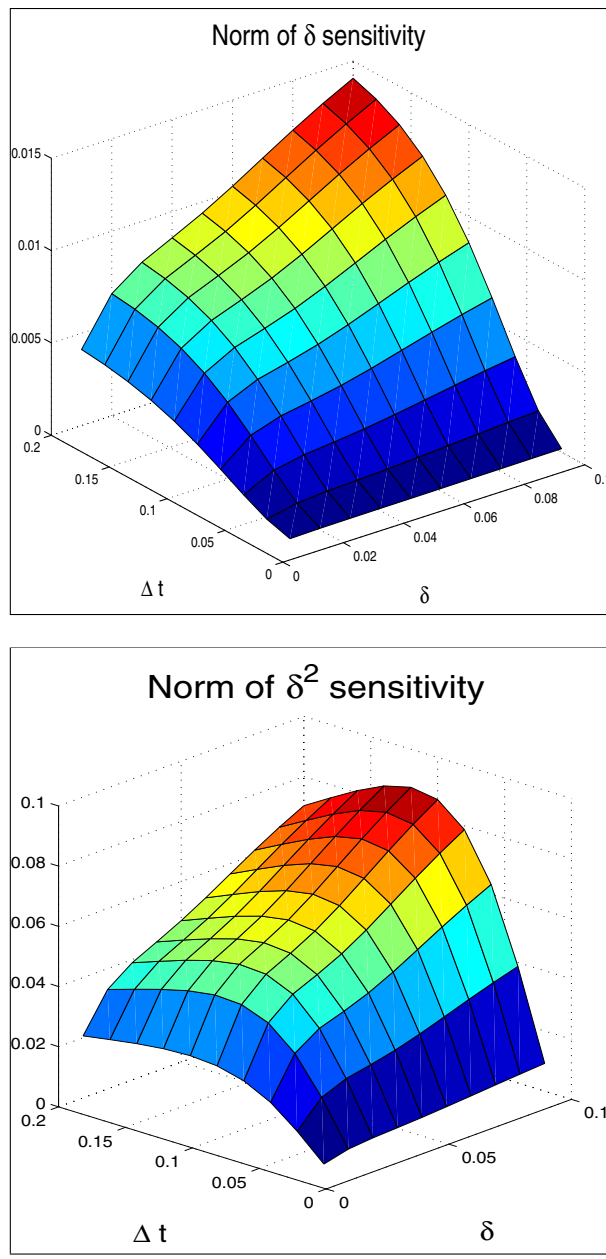

FIG. 5.6. *Sensitivity behavior for two models.*

0.015 second time step for the δ in Table 5.1. The computed values are presented in Table 5.1, with entry "Direct computation" in the "Method" column. We see that the correction using first-order sensitivities computed by numerically integrating the sensitivity equations (2.6) and using (3.6) results in a 77% reduction of the relative error, correction using first-order sensitivities computed by using divided differences using (3.6) results in a 91% reduction of the relative error, whereas correction using second-order sensitivities (quadratic correction) results in a 98% reduction of the

relative error, both compared to the case where the drag is estimated by using only its value at $\delta = 0.2$. We represent these results graphically in Figure 5.7, together with the drag values for δ in the $[0, 0.2]$ range. Both the corrected values and their methods are listed in Table 5.1. The difference in the sensitivities computed by divided differences and the ones computed by numerical integration is reasonably small in size, not surprisingly, since we also incur a time discretization error. The 91% error reduction is asymptotically achievable for increasingly accurate sensitivity computation.

While we did not explicitly describe a higher-order sensitivity development, that extension is straightforward, and we interpret the above results as evidence of the excellent potential of the sensitivity-based estimation method described in this work.

5.2.3. Mesh size-dependence of the sensitivity error. We now numerically investigate our statement about the sensitivity needing to be a result on a finer mesh than the velocity. Since "resolved flow" cannot be easily quantified, we turn our focus to the dependence of the sensitivity error and velocity error on the mesh size.

A comprehensive numerical test for the asymptotic behavior of the error as a function of the mesh size is difficult for the following reason. Since we do not have a

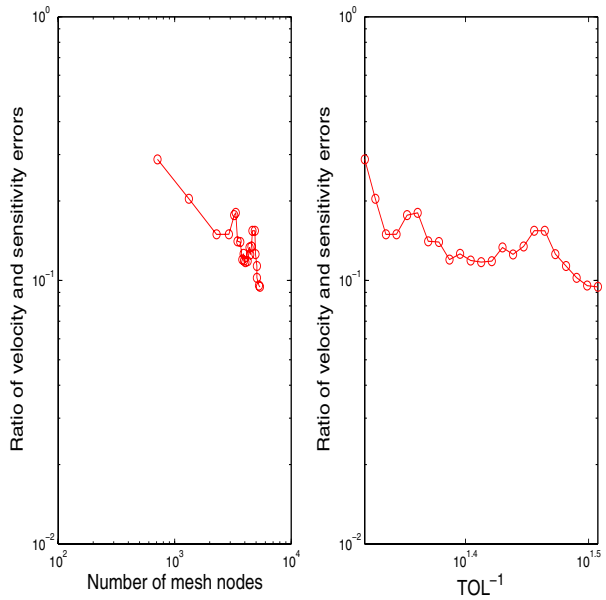

FIG. 5.8. *Mesh-dependency of velocity and velocity sensitivity error on the obstacle, plotted with respect to the number of mesh nodes and with respect to the size of the tolerance parameter that was used in the routine* `adaptmesh` *to generate that mesh.*

rectangular domain (because of the circular inclusion) we cannot use a structured grid of an arbitrary size h. We must use an unstructured mesh, for which an asymptotic analysis requires the regular division with the same factor of all elements of the mesh. If we use a factor of two, after three such divisions, the size of the linear system that is created by one step of the problem (5.1) cannot be solved on our computer. Therefore such an analysis will generate preciously few points.

We will therefore carry out two experiments. The first experiment creates quite a few data points for an increasing number of mesh nodes, though the meshes are not in the same asymptotic family. The second example will generate only three data points, but the meshes are obtained by a regular division procedure by a factor of two and is suitable for proper asymptotic analysis. In both these experiments we integrate numerically the partial differential equation of the sensitivity (2.6) with the same type step but on different meshes.

In the first experiment, the sensitivity is computed at time $t = 1.125$ on a circle of radius 0.151, cocentric with the obstacle, by computing one step of the linear partial differential equation (2.6). The velocity profile at $t = 1.125$ is obtained by using the numerical scheme (5.1) with a time step of Δt and by refining the mesh every three time steps, using the routine `adaptmesh` of FreeFem. When calling this routine, the tolerance parameter is initialized at 0.5 and is decreased every five time steps by a factor of 1.02. This generates 25 meshes, for each of which we compute the velocity v and its sensitivity w_γ for $\delta = 0.2$ (and $\gamma = \delta^2 = 0.04$), for one time step of length 1.5×10^{-4}. We estimate the error (heuristically) by subtracting the values obtained for the sensitivity and the velocity on the finest mesh from all the other sensitivity and velocity values. We plot the ratio of the velocity and sensitivity errors in doubly logarithmic scale in Figure 5.8.

In the second experiment, we use the numerical scheme (5.1) with a time step of

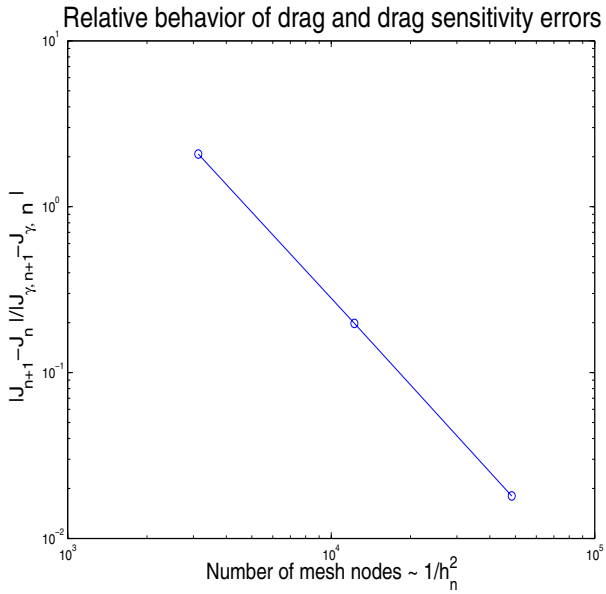

FIG. 5.9. *Mesh-dependency of drag and drag sensitivity error.*

$\Delta = 0.015$ to compute the velocity at the time $t = 7.5$ (as in the numerical experiments of the preceding sections), and the sensitivity w_γ and, respectively, the velocity v are also computed from the time discretization of (2.6) and from the scheme (5.1), both for one time step of length 1.5×10^{-4}, on four nested meshes. Each of these meshes, for which we denote the diameter of the typical element by h_n, $n = 1, 2, 3, 4$, is obtained by uniformly refining the preceding mesh by a factor of two. Therefore $h_{n+1} = \frac{h_n}{2}$, $n = 1, 2, 3$. Once the numerical values for w_γ and v are obtained, the drag J_n and the drag sensitivity $J_{\gamma,n}$, for $n = 1, 2, 3, 4$, are computed on the same circle as in the preceding experiment, using formulas (3.4) and (3.6), where we substitute γ for δ. In Figure 5.9 we plot on a doubly logarithmic scale the factor

$$u_{n+1} = \frac{J_{n+1} - J_n}{J_{\gamma,n+1} - J_{\gamma,n}}, \quad n = 1, 2, 3.$$

We see that both Figures 5.8 and 5.9 are strong evidence for the fact that the error in sensitivity improved more slowly than did the error in the velocity for increasing the finer meshes. This finding supports our statement that, for the same level of error, a finer mesh is needed for sensitivity. In addition, the almost perfect linear behavior (although from only three points) in Figure 5.9 suggests that both the error in drag and drag sensitivity behave like a power of the mesh size h, with smaller exponent for the sensitivity.

6. Conclusions and future prospects. Many fundamental theoretical questions in LES are still open, and many of these are important for the validation of the sensitivity approach to estimating model uncertainty. Nevertheless, we have seen that the continuous sensitivity equation approach in these tests has given a remarkably accurate estimate of the solution change as the length scale parameter varies, [illegible] itself. Formal asymptotics in an oversimplified setting gives preliminary estimates of the mesh-resolution requirements of the continuous sensitivity equation that are, again, remarkably accurate in our test.

The success of the sensitivity equation approach as shown here (and in other tests) suggests its broader usefulness and hints at the possibility of establishing a general analytic foundation for the method in LES.

Acknowledgments. We are grateful to the referees for their helpful comments that have improved the quality of the paper. We are also grateful to Paul Fischer for helpful comments that have improved the quality of the paper.

A CORNER CUTTING ALGORITHM FOR EVALUATING RATIONAL BÉZIER SURFACES AND THE OPTIMAL STABILITY OF THE BASIS*

JORGE DELGADO† AND J. M. PEÑA‡

Abstract. The usual method for evaluating rational Bézier surfaces uses the projection operator and the representation provided by the Bernstein basis. We prove the optimal stability of the basis used in this representation. We also propose an alternative method for evaluating rational surfaces through that representation. We show the stability properties of this last method and prove that it has better properties than other known methods from the point of view of avoiding underflow and overflow.

Key words. rational surfaces, optimal stability, underflow, overflow, error analysis

AMS subject classifications. 65G50, 65D17, 41A20

DOI. 10.1137/060649148

1. Introduction.

Given a matrix of positive weights $(w_{ij})_{0\le i\le m;0\le j\le n}$ and a matrix of control points $(P_{ij})_{0\le i\le m;0\le j\le n}$ in $\mathbf{R}^3$, we define the rational Bézier surface

$$F(x,y)=\sum_{i=0}^{m}\sum_{j=0}^{n}P_{ij}\,\frac{w_{ij}\,b_i^m(x)\,b_j^n(y)}{\sum_{i=0}^{m}\sum_{j=0}^{n}w_{ij}\,b_i^m(x)\,b_j^n(y)},\quad (x,y)\in[0,1]\times[0,1], \tag{1.1}$$

where for any positive integer r and $0\le i\le r$, b_i^r denotes the Bernstein polynomial

$$b_i^r(x)=\binom{r}{i}x^i(1-x)^{r-i},\quad i\in\{0,1,\dots,r\}.$$

The evaluation of rational Bézier surfaces is an important task in the field of geometric modeling (cf. [2], [5], and [12]) as well as in other fields such as finite elements (cf. [1, 16]). The usual method for evaluating rational Bézier surfaces uses the projection operator Π and the representation (1.1) through the Bernstein basis. Evaluation algorithms of nested type and with lower complexity have also been considered (cf. [15]). In the case of evaluating bivariate polynomials defined on triangulations, such an algorithm has been called VS in [14], so that here we also refer to the corresponding algorithm for rational surfaces as the VS algorithm. Finally, the possibility of obtaining corner cutting algorithms for the evaluation of rational surfaces has also been suggested in [2, p. 299]. In this paper we present a corner cutting algorithm for the evaluation of rational Bézier surfaces, we carry out its error analysis, and we show its better behavior with respect to the problem of avoiding underflow and overflow. Thus, the algorithm proposed in this paper is more robust than the other two alternative algorithms. In section 2 we recall the mentioned evaluation algorithms for

rational Bézier surfaces and also present the new evaluation algorithm that also uses the representation (1.1) provided through the Bernstein basis. We call it a corner cutting rational surface algorithm because [illegible] steps are given by convex combinations of previously computed numbers. It is well known that corner cutting algorithms present good stability properties (cf. [7]). In section 3 we perform an error analysis of the new algorithm and show its backward stability.

Let us recall that the bases convenient in computer aided design are bases of nonnegative functions. Bases optimally stable among all bases formed by nonnegative functions have been identified for several spaces of univariate functions (see [3], [9], and [12]) and for some spaces of multivariate functions [6]. In section 4 we prove that the basis used in the representation (1.1) has optimal stability properties.

The numerical examples of section 5 illustrate the nice behavior, in general, of the three algorithms mentioned in the paper even for functions generalizing Wilkinson polynomials (cf. [17], [18], [19]). The ill-conditioning of these polynomials is well known, but the three algorithms considered in this paper present good behavior even for these polynomials. Analogously to the generalization of the Wilkinson polynomials, we have considered another very ill-conditioned function. In this case, the VS algorithm does not present good behavior, in contrast to the other two algorithms. Moreover, we show with very simple examples that the usual rational evaluation algorithm and the VS algorithm can present problems of underflow and overflow, in contrast to the corner cutting rational surface algorithm presented in this paper. In fact, we prove in section 5 that this algorithm avoids overflow and underflow and has optimal growth factor. We finish in the last section by summarizing our main conclusions.

2. Evaluation algorithms. Now, let us consider the following Bernstein tensor product:

$$\widetilde{F}(x,y)=\sum_{i=0}^{m}\sum_{j=0}^{n}\widetilde{P}_{ij}\,b_i^m(x)\,b_j^n(y), \tag{2.1}$$

where $\widetilde{P}_{ij}:=w_{ij}\,(P_{ij},1)^T$. The usual method of evaluating a rational Bézier surface (1.1) at a point $(x,y)\in[0,1]\times[0,1]$ uses the projection operator Π defined by $\Pi(x,y,z,w)=(x/w,y/w,z/w)$, taking into account that, by formulas (1.1) and (2.1),

$$\Pi(\widetilde{F}(x,y))=F(x,y). \tag{2.2}$$

Thus the algorithm can be described as follows: let us denote $f_{ij}^{00}:=w_{ij}\,(P_{ij},1)^T$ for all $i\in\{0,1,\dots,m\}$ and $j\in\{0,1\dots,n\}$; then we obtain the coefficients f_{ij}^{0r} ($i=0,1,\dots,m$, $r=1,\dots,n$, and $j=0,1,\dots,n-r$) performing

$$f_{ij}^{0r}=(1-y)\,f_{ij}^{0,r-1}+y\,f_{i,j+1}^{0,r-1}.$$

Finally we obtain the coefficients f_{i0}^{rn} ($r=1,\dots,m$ and $i=0,1,\dots,m-r$) performing

$$f_{i0}^{rn}=(1-x)\,f_{i0}^{r-1,n}+x\,f_{i+1,0}^{r-1,n}.$$

Then $f_{00}^{mn}=\widetilde{F}(x,y)$ and, by (2.2), $\Pi(f_{00}^{mn})=F(x,y)$. Due to the use of the projection operator, from now on we refer to this algorithm as the [illegible]. We can easily check that the previous algorithm consists of $2(m+1)n(n+1)+2m(m+1)$

sums, $4(m+1)n(n+1)+4m(m+1)+3(m+1)(n+1)$ multiplications, and three quotients.

On the other hand, in [14] Schumaker and Volk introduced a new algorithm for the evaluation of bivariate polynomials on triangulations which was called the VS algorithm. This algorithm presents lower complexity than the de Casteljau algorithm and has a nested nature, like the Horner algorithm. In [10] an error analysis of this polynomial evaluation algorithm was performed. The VS algorithm for bivariate polynomials on triangulations can be adapted for the evaluation of univariate polynomials. Taking into account this adaptation, in [8] a nested VS based algorithm for the evaluation of Bézier tensor products with less computational cost than the usual evaluation algorithm was presented. Analogously, in [15], using the projection operator Π, a nested VS based algorithm for the evaluation of tensor product rational Bézier surfaces with less computational cost than the usual was presented.

Now, let us consider the rational VS surface given by

$$G(x,y)=\sum_{i=0}^{m}\sum_{j=0}^{n}P_{ij}\,\frac{w_{ij}\,z_i^m(x)\,z_j^n(y)}{\sum_{i=0}^{m}\sum_{j=0}^{n}w_{ij}\,z_i^m(x)\,z_j^n(y)},\quad (x,y)\in[0,1]\times[0,1],$$

where $(P_{ij})_{0\le i\le m;0\le j\le n}$ is a matrix of control points, $(w_{ij})_{0\le i\le m;0\le j\le n}$ is a matrix of positive weights, and, for any positive integer r,

$$z_i^r(x)=x^i(1-x)^{r-i},\quad i\in\{0,1,\dots,r\}.$$

Analogously to the Bernstein case, denoting $\widetilde{P}_{ij}:=w_{ij}\,(P_{ij},1)^T$, we can deduce that the tensor product

$$\widetilde{G}(x,y)=\sum_{i=0}^{m}\sum_{j=0}^{n}\widetilde{P}_{ij}\,z_i^m(x)\,z_j^n(y)$$

satisfies $\Pi(\widetilde{G}(x,y))=G(x,y)$. So, analogously to the above projective algorithm, it is straightforward to deduce from the VS algorithm for univariate polynomials another projective algorithm for evaluating $G(x,y)$. From now on we refer to this algorithm as the [illegible].

We can check that the VS algorithm consists of $4(m+1)n+4m$ sums, $8(m+1)n+8m+3(m+1)(n+1)$ multiplications, and five quotients.

The two previous algorithms are not corner cutting algorithms. Now we propose an alternative algorithm for evaluating rational Bézier surfaces as in (1.1), which is a corner cutting algorithm.

Considering a componentwise evaluation of the rational Bézier surface (1.1), in order to perform the error analysis we shall consider from now on rational Bernstein–Bézier surfaces given by

$$F(x,y)=\sum_{i=0}^{m}\sum_{j=0}^{n}f_{ij}\,\frac{w_{ij}\,b_i^m(x)\,b_j^n(y)}{\sum_{i=0}^{m}\sum_{j=0}^{n}w_{ij}\,b_i^m(x)\,b_j^n(y)},\quad (x,y)\in[0,1]\times[0,1],\tag{2.3}$$

where $(f_{ij})_{0\le i\le m;0\le j\le n}$ is a matrix of real numbers and $(w_{ij})_{0\le i\le m;0\le j\le n}$ is a matrix of positive weights.

Observing that formula (2.3) can be written as

$$F(x,y)=\frac{\sum_{i=0}^{m}\left[\left(\sum_{j=0}^{n}\frac{f_{ij}\,w_{ij}\,b_j^n(y)}{\sum_{j=0}^{n}w_{ij}\,b_j^n(y)}\right)\left(\sum_{j=0}^{n}w_{ij}\,b_j^n(y)\right)\,b_i^m(x)\right]}{\sum_{i=0}^{m}\left(\sum_{j=0}^{n}w_{ij}\,b_j^n(y)\right)\,b_i^m(x)}$$

and denoting

$$w_i := \sum_{j=0}^{n} w_{ij}\, b_j^n(y), \tag{2.4}$$

$$f_i := \sum_{j=0}^{n} f_{ij}\, \frac{w_{ij}\, b_j^n(y)}{\sum_{j=0}^{n} w_{ij}\, b_j^n(y)} \tag{2.5}$$

for all $i \in \{0, 1, \ldots, m\}$, we can deduce that

$$F(x, y) = \sum_{i=0}^{m} f_i\, \frac{w_i\, b_i^m(x)}{\sum_{i=0}^{m} w_i\, b_i^m(x)}. \tag{2.6}$$

So, taking into account that in [2] was showed a corner cutting algorithm which evaluates rational Bézier curves (for instance, the rational Bézier curves in formulas (2.5) and (2.6)) and simultaneously provides the evaluation of the denominator of the corresponding rational curve (for instance, the values w_i in formula (2.4) corresponding to the denominators of the rational Bézier curves in (2.5)), we can deduce a corner cutting algorithm to evaluate surfaces $F(x, y)$ as in formula (2.3) at a point $(x, y) \in [0, 1] \times [0, 1]$ through the evaluation of $(m + 2)$ rational Bézier curves (the $(m + 1)$ of degree n in (2.5) and the other one of degree m in (2.6)). Then the algorithm can be described as follows: let us denote $f_{ij}^{00} := f_{ij}$ and $w_{ij}^{00} := w_{ij}$ for all $i \in \{0, 1, \ldots, m\}$ and $j \in \{0, 1 \ldots, n\}$; then we obtain the coefficients f_{ij}^{0r} $(i = 0, 1, \ldots, m,\ r = 1, \ldots, n,$ and $j = 0, 1, \ldots, n - r)$ performing

$$f_{ij}^{0r} = (1 - y)\, \frac{w_{ij}^{0,r-1}}{w_{ij}^{0r}}\, f_{ij}^{0,r-1} + y\, \frac{w_{i,j+1}^{0,r-1}}{w_{ij}^{0r}}\, f_{i,j+1}^{0,r-1} \tag{2.7}$$

with

$$w_{ij}^{0r} = (1 - y)\, w_{ij}^{0,r-1} + y\, w_{i,j+1}^{0,r-1}; \tag{2.8}$$

finally we obtain the coefficients f_{i0}^{rn} $(r = 1, \ldots, m$ and $i = 0, 1, \ldots, m - r)$ performing

$$f_{i0}^{rn} = (1 - x)\, \frac{w_{i0}^{r-1,n}}{w_{i0}^{rn}}\, f_{i0}^{r-1,n} + x\, \frac{w_{i+1,0}^{r-1,n}}{w_{i0}^{rn}}\, f_{i+1,0}^{r-1,n} \tag{2.9}$$

with

$$w_{i0}^{rn} = (1 - x)\, w_{i0}^{r-1,n} + x\, w_{i+1,0}^{r-1,n}; \tag{2.10}$$

so $f_{00}^{mn} = F(x, y)$. This algorithm will be called the [illegible]. Taking into account that the control points of a parametric rational function represented in the Bernstein basis belong to the set $\mathbf{R}^3$, we can easily check that the previous algorithm consists of $3(m + 1)n(n + 1) + 2m(m + 1)$ sums, $6(m + 1)n(n + 1) + 6m(m + 1)$ multiplications, and $3(m + 1)n(n + 1) + 3m(m + 1)$ quotients. Although the other two previous algorithms required only three and five quotients (respectively) and the division operation for floating point numbers has higher complexity than the other elementary operations, let us take into account that m and n are not very great in the context of geometric modeling and that the complexity order of this last algorithm is not higher than that of the projective algorithm

($\mathcal{O}(p^3)$ with $p = \max\{m, n\}$). Moreover, as we show in this paper, this last algorithm is more robust than the other two algorithms presented in this paper: it has good stability properties and even has clear advantages with respect to avoiding overflow and underflow.

3. Error analysis of the corner cutting rational surface algorithm. Let us now introduce some standard notation in error analysis. Given $a \in \mathbf{R}$, the computed element in floating point arithmetic will be denoted by either $fl(a)$ or by $\widehat{a}$. As usual, to investigate the effect of rounding errors we use the model

$$fl(a\ op\ b) = (a\ op\ b)\,(1+\delta), \quad |\delta| \le u, \tag{3.1}$$

with u the unit roundoff and op any of the elementary operations $+, -, \times, /$ (see [4, pp. 44–45] for more details). Given $k \in \mathbf{N}_0$ such that $ku < 1$, let us define

$$\gamma_k := \frac{ku}{1-ku} = ku + \mathcal{O}(u^2). \tag{3.2}$$

In our error analysis we shall deal with quantities satisfying that their absolute value is bounded above by γ_k. Following [4], we denote by θ_k such quantities, and let us take into account that, by Lemmas 3.3 and 3.1 of [4], the following properties hold:

$$(1+\theta_k)\,(1+\theta_j) = 1+\theta_{k+j}, \tag{3.3}$$

$$\frac{1+\theta_k}{1+\theta_j} = \begin{cases} 1+\theta_{k+j}, & j \le k, \\ 1+\theta_{k+2j}, & j > k. \end{cases} \tag{3.4}$$

As in [6], for any $x \in \Omega \subseteq \mathbf{R}^s$, basis $u = (u_0, \dots, u_n)$, and $f = \sum_{i=0}^n c_i u_i$, let us consider the relative condition number for the evaluation of f at x:

$$\operatorname{cond}(u; f, x) := \frac{\sum_{i=0}^n |c_i u_i(x)|}{\|\sum_{i=0}^n c_i u_i\|_\infty}.$$

The numerator $\sum_{i=0}^n |c_i u_i(x)|$ of the previous formula is the absolute condition number for the evaluation of the function f at x. Given $v = (v_0, \dots, v_n)$, let us denote $|v| := (|v_0|, \dots, |v_n|)$. The following result provides a forward error bound for the corner cutting rational surface algorithm.

THEOREM 3.1. [illegible] $F(x,y)$ [illegible] (2.3), [illegible] $(f_{ij})_{0\le i\le m; 0\le j\le n}$ [illegible] $(w_{ij})_{0\le i\le m; 0\le j\le n}$ [illegible] $\widehat{F}(x,y)$ [illegible]

$$|F(x,y) - \widehat{F}(x,y)| \le \gamma_k \sum_{i=0}^m \sum_{j=0}^n |f_{ij}| \frac{w_{ij}\, b_i^m(x)\, b_j^n(y)}{\sum_{i=0}^m \sum_{j=0}^n w_{ij}\, b_i^m(x)\, b_j^n(y)}, \tag{3.5}$$

[illegible] $k = (3m^2+5m) + (3n^2+5n) + 6mn$ [illegible] γ_k [illegible] (3.2).

[illegible]. We deduce from (2.7) that for all $r \in \{1, \dots, n\}$ and $i \in \{0, 1, \dots, m\}$,

$$f_i^{(r)} = V_{i,r}\, f_i^{(r-1)},$$

where $f_i^{(r)} := (f_{i0}^{0r}, \ldots, f_{i,n-r}^{0r})^T$ and $V_{i,r}$ is the $(n-r+1) \times (n-r+2)$ matrix of the form

$$V_{i,r} = \begin{pmatrix} \overline{x}_{i,0}^r & \overline{y}_{i,0}^r & 0 & \cdots & \cdots & 0 \\ 0 & \overline{x}_{i,1}^r & \overline{y}_{i,1}^r & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & \cdots & 0 & \overline{x}_{i,n-r}^r & \overline{y}_{i,n-r}^r \end{pmatrix}$$

with

$$\overline{x}_{i,j}^r := (1-y)\,\frac{w_{ij}^{0,r-1}}{w_{ij}^{0r}}, \quad \overline{y}_{i,j}^r := y\,\frac{w_{i,j+1}^{0,r-1}}{w_{ij}^{0r}}, \quad j = 0, 1, \ldots, n-r.$$

Therefore, for all $k \in \{1, \ldots, n\}$ and $i \in \{0, 1, \ldots, m\}$, we have

$$f_i^{(k)} = V_{i,k} \cdots V_{i,1}\, f_i^{(0)}. \tag{3.6}$$

Analogously, we can also deduce from formula (2.8) that, for all $r \in \{1, \ldots, n\}$ and $i \in \{0, 1, \ldots, m\}$,

$$v_i^{(r)} = U_r\, v_i^{(r-1)},$$

where $v_i^{(r)} := (w_{i0}^{0r}, \ldots, w_{i,n-r}^{0r})^T$ and U_r is the $(n-r+1) \times (n-r+2)$ matrix of the form

$$U_r = \begin{pmatrix} 1-y & y & 0 & \cdots & \cdots & 0 \\ 0 & 1-y & y & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & \cdots & 0 & 1-y & y \end{pmatrix}.$$

Therefore, for all $k \in \{1, \ldots, n\}$ and $i \in \{0, 1, \ldots, m\}$, we can write

$$v_i^{(k)} = U_k \cdots U_1\, v_i^{(0)}. \tag{3.7}$$

From the recursive definition of w_{ij}^{0k} (see (2.8)) and (3.1), we can deduce that, for all $k \in \{1, \ldots, n\}$, $i \in \{0, 1, \ldots, m\}$, and $j \in \{0, 1, \ldots, n-k\}$,

$$\widehat{w}_{ij}^{0k} = ((1-y)\,\widehat{w}_{ij}^{0,k-1}\,(1+\delta_{ij}^{0,k-1}) + y\,\widehat{w}_{i,j+1}^{0,k-1}\,(1+\delta_{i,j+1}^{0,k-1}))\,(1+\overline{\delta}_{ij}^{0k}),$$

where $|\delta_{ij}^{0,k-1}|$, $|\delta_{i,j+1}^{0,k-1}|$, and $|\overline{\delta}_{ij}^{0k}|$ are numbers less than or equal to the roundoff unit. Then, by (3.3), we have

$$\widehat{w}_{ij}^{0k} = (1-y)\,\widehat{w}_{ij}^{0,k-1}\,(1+\theta_2) + y\,\widehat{w}_{i,j+1}^{0,k-1}\,(1+\theta_2)$$

for all $j = 0, 1, \ldots, n-k$. Iterating the previous arguments and using (3.3) and (3.7), we can get

$$\widehat{v}_i^{(k)} = U_k \cdots U_1 \begin{pmatrix} w_{i0}^{00}\,(1+\theta_{2k}) \\ \vdots \\ w_{in}^{00}\,(1+\theta_{2k}) \end{pmatrix} = U_k \cdots U_1 \left(v_i^{(0)} + \begin{pmatrix} w_{i0}^{00}\,\theta_{2k} \\ \vdots \\ w_{in}^{00}\,\theta_{2k} \end{pmatrix} \right)$$

for all $k \in \{1,\dots,n\}$ and $i \in \{0,1,\dots,m\}$. So, again by (3.7), we can write

$$\widehat{v}_i^{(k)} = v_i^{(k)} + U_k \cdots U_1 \begin{pmatrix} w_{i0}^{00}\,\theta_{2k} \\ \vdots \\ w_{in}^{00}\,\theta_{2k} \end{pmatrix}.$$

Hence, taking into account the nonnegativity of the matrices U_j and of the weights, the previous formula, and (3.7), we deduce that

$$|\widehat{v}_i^{(k)} - v_i^{(k)}| \le \gamma_{2k}\,|v_i^{(k)}| = \gamma_{2k}\,v_i^{(k)}$$

for all $k \in \{1,\dots,n\}$ and $i \in \{0,1,\dots,m\}$. Thus we can write

$$\widehat{w}_{ij}^{0k} = w_{ij}^{0k}\,(1+\theta_{2k}) \tag{3.8}$$

for all $i \in \{0,1,\dots,m\}$, $k \in \{1,\dots,n\}$, and $j \in \{0,1,\dots,n-k\}$.

Let us now perform the calculation of the coefficients f_{ij}^{0r} for all $j \in \{0,1,\dots,n-r\}$ and $r \in \{1,\dots,n\}$. From the recursive definition of f_{ij}^{0r} (see formula (2.7)), (3.1), and (3.3), we can deduce that, for all $r \in \{1,\dots,n\}$ and $i \in \{0,1,\dots,m\}$,

$$\widehat{f}_{ij}^{0r} = \left((1-y)\,\frac{\widehat{w}_{ij}^{0,r-1}}{\widehat{w}_{ij}^{0r}}\,\widehat{f}_{ij}^{0,r-1} + y\,\frac{\widehat{w}_{i,j+1}^{0,r-1}}{\widehat{w}_{ij}^{0r}}\,\widehat{f}_{i,j+1}^{0,r-1}\right)(1+\theta_4), \quad j \in \{0,1,\dots,n-r\}.$$

Applying (3.8) in the previous formula, we obtain

$$\widehat{f}_{ij}^{0r} = \left((1-y)\,\frac{w_{ij}^{0,r-1}\,(1+\theta_{2(r-1)})}{w_{ij}^{0r}\,(1+\theta_{2r})}\,\widehat{f}_{ij}^{0,r-1} + y\,\frac{w_{i,j+1}^{0,r-1}\,(1+\theta_{2(r-1)})}{w_{ij}^{0r}\,(1+\theta_{2r})}\,\widehat{f}_{i,j+1}^{0,r-1}\right)(1+\theta_4)$$

for all $j \in \{0,1,\dots,n-r\}$. Then, using (3.4) and (3.3), we derive

$$\begin{aligned}\widehat{f}_{ij}^{0r} &= (1-y)\,\frac{w_{ij}^{0,r-1}}{w_{ij}^{0r}}\,\widehat{f}_{ij}^{0,r-1}\,(1+\theta_{6r+2}) \\ &\quad + y\,\frac{w_{i,j+1}^{0,r-1}}{w_{ij}^{0r}}\,\widehat{f}_{i,j+1}^{0,r-1}\,(1+\theta_{6r+2}), \quad j \in \{0,1,\dots,n-r\}.\end{aligned}$$

Iterating the previous arguments, using (3.3) and (3.6), and taking into account that $\sum_{r=1}^{n}(6r+2) = 3n^2+5n$, analogously as it has been done above for the weights, we can deduce that

$$|\widehat{f}_i^{(n)} - f_i^{(n)}| \le \gamma_{3n^2+5n}\,|f_i^{(n)}|$$

for all $i \in \{0,1,\dots,m\}$. Thus we can write

$$\widehat{f}_i^{(n)} = f_i^{(n)}\,(1+\theta_{3n^2+5n}) \tag{3.9}$$

for all $i \in \{0,1,\dots,m\}$.

In a similar way as has been done above for the points f_{ij}^{0r} and the weights w_{ij}^{0r}, considering now the $(m-r+1)\times(m-r+2)$ matrices of the form

$$M_r := \begin{pmatrix} x_0^r & y_0^r & 0 & \cdots & 0 \\ 0 & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & x_{m-r}^r & y_{m-r}^r \end{pmatrix}, \quad N_r = \begin{pmatrix} 1-x & x & 0 & \cdots & 0 \\ 0 & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & 1-x & x \end{pmatrix}$$

with

$$x_i^r := (1-x)\,\frac{w_{i0}^{r-1,n}}{w_{i0}^{rn}}, \quad y_i^r := x\,\frac{w_{i+1,0}^{r-1,n}}{w_{i0}^{rn}}, \quad i = 0, 1, \ldots, m-r,$$

and the vectors $g^{(r)} := (f_{00}^{rn}, \ldots, f_{m-r,0}^{r,n})^T$ (in particular, $g^{(0)} = (f_0^{(n)}, \ldots, f_m^{(n)})^T$) and $w^{(r)} := (w_{00}^{rn}, \ldots, w_{m-r,0}^{rn})^T$, by formulas (2.9) and (2.10) we have $g^{(r)} = M_r \cdots M_1 g^{(0)}$ and $w^{(r)} = N_r \cdots N_1 w^{(0)}$ for all $r \in \{1, \ldots, m\}$. Taking again into account (3.1), (3.3), and (3.4), the nonnegativity of the weights and of the matrices M_r and N_r, that $\sum_{r=1}^{m}(6(n+r)+2) = 3m^2 + 6mn + 5m$, and, in addition, formulas (3.8) and (3.9), we can deduce

$$\widehat{w}_{i0}^{kn} = w_{i0}^{kn}\,(1 + \theta_{2(n+k)})$$

for all $k \in \{1, \ldots, m\}$ and $i \in \{0, 1, \ldots, m-k\}$, and

$$\widehat{f}_{00}^{mn} = f_{00}^{mn}\,(1 + \theta_{(3m^2+5m)+(3n^2+5n)+6mn}).$$

Hence we can conclude

$$\begin{aligned}|\widehat{f}_{00}^{mn} - f_{00}^{mn}| &\le \gamma_{(3m^2+5m)+(3n^2+5n)+6mn}\,|f_{00}^{mn}| \\ &\le \gamma_{(3m^2+5m)+(3n^2+5n)+6mn} \sum_{i=0}^{m}\sum_{j=0}^{n} |f_{ij}|\,\frac{w_{ij}\,b_i^m(x)\,b_j^n(y)}{\sum_{i=0}^{m}\sum_{j=0}^{n} w_{ij}\,b_i^m(x)\,b_j^n(y)},\end{aligned}$$

and the result follows. □

The previous bound (3.5) for the absolute forward error can be interpreted in the following classical way. The first factor γ_k corresponds to the backward error, and the second factor is the absolute condition number. So Theorem 3.1 guarantees the backward stability of the corner cutting rational surface algorithm. The next section will show that the contribution of the second factor (due to the conditioning of the basis) is as small as possible.

4. Optimal stability of the basis. Consider now the rational Bézier surface (2.3) defined on $\Omega = [0,1]\times[0,1]$. Given the double-index $\alpha = \alpha_1\alpha_2$, with $0 \le \alpha_1 \le m$, $0 \le \alpha_2 \le n$, we can define the corresponding basis function

$$r_\alpha(x,y) := \frac{w_\alpha\,b_{\alpha_1}^m(x)\,b_{\alpha_2}^n(y)}{\sum_{\alpha_1=0}^{m}\sum_{\alpha_2=0}^{n} w_\alpha\,b_{\alpha_1}^m(x)\,b_{\alpha_2}^n(y)}. \tag{4.1}$$

Let

$$U = \left\{\sum_\alpha c_\alpha r_\alpha : c_\alpha \in \mathbf{R}\right\} \tag{4.2}$$

be the corresponding space of rational functions on Ω. We arrange the elements of $r = (r_\alpha)$ in lexicographical order.

The following result proves that the basis given by (4.1) is optimally stable.

THEOREM 4.1. [illegible] $r = (r_\alpha)$ [illegible] (4.1) [illegible] U [illegible] (4.2). [illegible] $u = (u_\alpha)$ [illegible] U [illegible]

$$(u; f, (x,y)) \le \quad (r; f, (x,y)) \tag{4.3}$$

[illegible] $f \in U$ [illegible] $(x,y) \in \Omega$ [illegible] $u = r$ [illegible]
[illegible]. By Lemma 3.1 of [6], there exists a nonnegative matrix A such that

$$r = uA$$

and, by Lemma 3.3 of [6], it is enough to show that the first and last nonzero element in each column of A^{-1} is positive. Fix a column β of A^{-1}, and let (c_α) be the elements of A^{-1} in this column. Then

$$u_\beta(x,y) = \sum_\alpha c_\alpha r_\alpha(x,y). \tag{4.4}$$

Let $\alpha = l_1 l_2$ be the double-index of the first nonzero coefficient c_α in (4.4). The function u_β of (4.4) can be written as

$$u_\beta(x,y) = \sum_{\alpha_1=l_1}^{m} b_{\alpha_1}^m(x) \left(\sum_{\alpha_2=0}^{n} \frac{c_\alpha\, w_\alpha\, b_{\alpha_2}^n(y)}{\sum_{\alpha_1=0}^m \sum_{\alpha_2=0}^n w_\alpha\, b_{\alpha_1}^m(x)\, b_{\alpha_2}^n(y)} \right). \tag{4.5}$$

Using the nonnegativity of u_β and $b_{l_1}^m$ and the fact that

$$0 = \lim_{x\to 0^+} \frac{b_{\alpha_1}^m(x)}{b_{l_1}^m(x)}, \quad \alpha_1 > l_1, \tag{4.6}$$

we deduce that

$$0 \le \lim_{x\to 0^+} \frac{u_\beta(x,y)}{b_{l_1}^m(x)} = g(y), \tag{4.7}$$

where

$$g(y) := \sum_{\alpha_2=l_2}^{n} \frac{c_{l_1\alpha_2}\, w_{l_1\alpha_2}\, b_{\alpha_2}^n(y)}{\sum_{\alpha_2=0}^n w_{0\alpha_2}\, b_{\alpha_2}^n(y)}. \tag{4.8}$$

Taking into account (4.5), (4.7), (4.8), and

$$0 = \lim_{y\to 0^+} \frac{b_{\alpha_2}^n(y)}{b_{l_2}^n(y)}, \quad \alpha_2 > l_2, \tag{4.9}$$

we deduce that

$$0 \le \lim_{y\to 0^+} \frac{g(y)}{b_{l_2}^n(y)} = \frac{w_{l_1 l_2}}{w_{00}}\, c_{l_1 l_2}.$$

Hence, taking into account that $w_{l_1 l_2}$ and w_{00} are positive weights, we conclude that the nonzero coefficient $c_{l_1 l_2}$ is in fact positive.

Let $\alpha = m_1 m_2$ be the double-index of the last nonzero c_α in (4.4). Applying a reasoning analogous to the proof of the positivity of the first nonzero coefficient in (4.4), taking limits as $x, y \to 1^-$, and using

$$0 = \lim_{x\to 1^-} \frac{b_{\alpha_1}^m(x)}{b_{m_1}^m(x)}, \quad \alpha_1 < m_1, \tag{4.10}$$

and

$$0 = \lim_{y \to 1^-} \frac{b_{\alpha_2}^n(y)}{b_{m_2}^n(y)}, \quad \alpha_2 < m_2, \tag{4.11}$$

instead of (4.6) and (4.9) (respectively), we may deduce that the last nonzero coefficient in (4.4) must be also positive, that is, the last nonzero entry of each column of A^{-1} is positive, and the result follows. □

Let us recall that the bases convenient in computer aided design are bases of nonnegative functions. Theorem 4.1 has proved that the basis used by the projective and by the corner cutting algorithms is optimally stable, in the sense that there is not (up to permutation and positive scaling) a better conditioned basis formed by nonnegative functions. Numerical experiments of the next section will confirm these good stability properties as well as the advantages of the corner cutting algorithm.

5. Numerical experiments. In this section we carry out numerical experiments when evaluating rational surfaces through the projective algorithm, the VS algorithm, and the corner cutting rational surface algorithm introduced in this paper. The numerical tests were performed on a Windows XP machine with the C compiler gcc of Mingw. For gcc the difference between 1.0 and the smaller number greater than 1.0 representable by the computer is $1.19209290e-07$ in simple precision and $1.1102230246251568e-16$ in double precision. In addition, gcc uses as a rounding strategy choosing the closest representable number. For more details on the compiler, see http://www.mingw.org.

The polynomials $\prod_{k=1}^{20}(x-\frac{2}{2^k})$ and $\prod_{k=1}^{20}(x-\frac{1}{k})$ with roots $\left\{\left(\frac{2}{2^k}\right) \mid k=1,\dots,20\right\}$ and $\left\{\left(\frac{1}{k}\right) \mid k=1,\dots,20\right\}$, respectively, were originally studied by Wilkinson (see [17], [18], and [19], where he showed the ill-conditioning properties of the roots). So we consider here the following bivariate polynomials:

$$\begin{aligned} I(x,y) &= \textstyle\prod_{i=1}^{12}\left(x-\frac{2}{2^i}\right)\prod_{j=1}^{12}\left(y-\frac{2}{2^j}\right), \\ J(x,y) &= \textstyle\prod_{i=1}^{12}\left(x-\frac{i}{12}\right)\prod_{j=1}^{12}\left(y-\frac{j}{12}\right), \end{aligned} \qquad (x,y)\in[0,1]\times[0,1],$$

which can be seen as a generalization of the univariate polynomials above considered by Wilkinson. Now, taking the strictly positive sequence $(w_{ij})_{0\le i,j\le 12}$ given by $w_{ij} = |i-j|+1$ for all i,j, we can introduce a rational Bézier surface $F(x,y)$ as follows:

$$F(x,y) = \frac{I(x,y)}{\sum_{i=0}^{12}\sum_{j=0}^{12} w_{ij}\, b_i^{12}(x)\, b_j^{12}(y)}, \quad (x,y)\in[0,1]\times[0,1].$$

We evaluated the function $F(x,y)$ at a mesh $(x_i,x_j)_{0\le i,j\le 24}$ such that $x_i = 0.04\,i$ for $i\in\{0,1,\dots,24\}$ using the compiler gcc with double precision arithmetic by the evaluation algorithms considered in this paper, i.e., $\widehat{F}(x_i,x_j)$. Using the algebraic manipulator MATHEMATICA, we computed the exact value of $F(x_i,x_j)$ and the corresponding relative errors $E_{rel}(x_i,x_j) = \frac{|F(x_i,x_j)-\widehat{F}(x_i,x_j)|}{|F(x_i,x_j)|}$ for each evaluation algorithm considered. In the first example we have also measured the time spent by the CPU of the computer (in seconds) for the evaluation of $F(x,y)$ at all points of the mesh $(x_i,x_j)_{0\le i,j\le 24}$ for each of the evaluation algorithms considered for comparing their computational costs. Let us remark that, in contrast to the remaining examples, we have used in the three initial examples double precision due to the well known ill-conditioning properties of these polynomials.

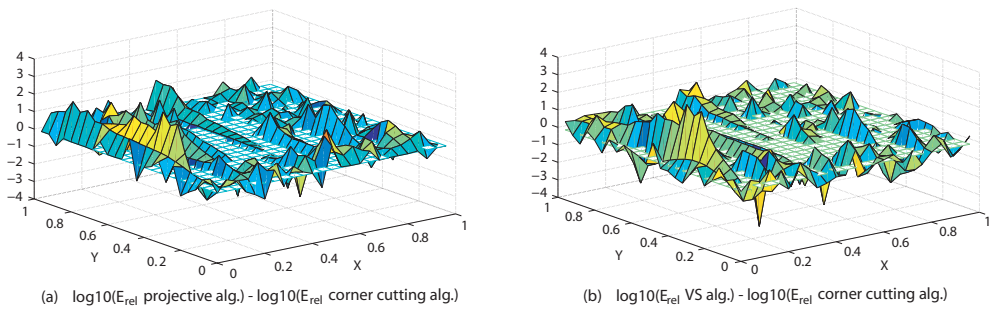

FIG. 5.1. *Comparison of the relative errors in logarithmic scale when evaluating $F(x, y)$.*

We have seen that the three algorithms have very good behavior with respect to the error (in spite of the ill-conditioning of these polynomials) and, in addition, that they produce similar relative errors (see Table 5.1 and Figure 5.1). We can also observe in Table 5.1 that the VS algorithm clocked the fastest time of the three evaluation algorithms, which agrees with section 2. In Figure 5.1(a) is plotted with MATLAB the surface given by the differences between the points of the bilinear surfaces formed by the points $(x_i, x_j, log_{10}(E_{rel}(x_i, x_j)))_{0 \leq i,j \leq 24}$ obtained through the projective and the corner cutting rational surface algorithms. At the points where $z > 0$ the corner cutting rational surface algorithm performs better than the projective algorithm, while at the points where $z < 0$ the projective algorithm performs better. Analogously, in Figure 5.1(b) is plotted the surface given by the differences between the points of the bilinear surfaces formed by the logarithms of the relative errors obtained through the VS and the corner cutting rational surface algorithms. We have also performed the same process for the rational surface $G(x, y)$ given by

$$G(x, y) = \frac{J(x, y)}{\sum_{i=0}^{12} \sum_{j=0}^{12} w_{ij}\, b_i^{12}(x)\, b_j^{12}(y)}, \quad (x, y) \in [0, 1] \times [0, 1],$$

with $w_{ij} = |i - j| + 1$ for all i, j, checking that, in this case, the three algorithms considered also produce very similar and accurate results.

The following example shows that the projective and the corner cutting rational surface algorithms behave better than the VS algorithm with respect to error for some extremely ill-conditioned functions. Let us consider the surface

$$H(x, y) = \left(x - \frac{1}{2}\right)^{12} \left(y - \frac{1}{2}\right)^{12}, \quad (x, y) \in [0, 1] \times [0, 1],$$

which can be expressed as a degenerated rational Bézier surface taking as weights $w_{ij} = 1$ for all $i, j \in \{0, 1, \ldots, 12\}$. Since the polynomial $H(x, y)$ has roots of very

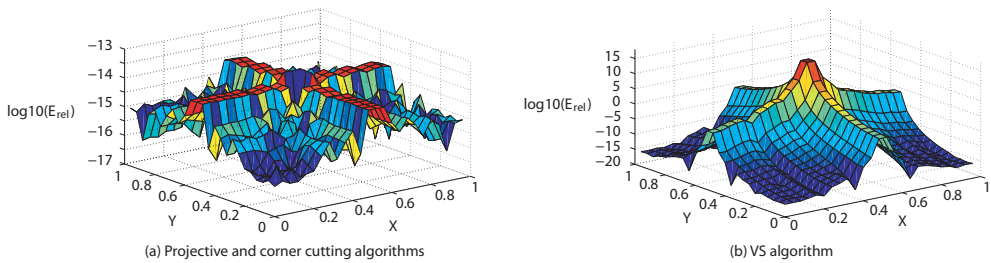

FIG. 5.2. *Relative errors in logarithmic scale.*

high multiplicity on the lines $x = 1/2$ and $y = 1/2$ it is very ill-conditioned. Analogously to the function $F(x, y)$, we evaluated $H(x, y)$ at a mesh $(x_i, x_j)_{0 \le i,j \le 24}$ with $x_i = 0.04\, i$ for $i \in \{0, 1, \ldots, 24\}$ using the compiler gcc with double precision arithmetic by the evaluation algorithms considered in this paper, and with the support of MATHEMATICA we obtained the corresponding relative errors for each evaluation algorithm considered.

On the one hand, we have seen that the projective and the corner cutting rational surface algorithms are very accurate (in spite of the extreme ill-conditioning of polynomial H) and, in addition, both algorithms produce exactly the same relative errors (see Table 5.2 and Figure 5.2(a)) since in this case the algorithms coincide because all the weights are equal to one. On the other hand, the VS algorithm presents catastrophical behavior at some points of the mesh (see Table 5.2 and Figure 5.2(b)), for instance, at every point of the mesh close to either the line $x = 1/3$ or to the line $y = 1/2$.

The following examples illustrate the fact that the corner cutting rational surface algorithm cannot present underflow or overflow, in contrast to the other two algorithms. It is not surprising that the corner cutting rational surface algorithm presents better behavior with respect to avoiding underflow and overflow than the projective and VS algorithms, since all its steps are corner cutting steps. In fact, since the corner cutting rational surface algorithm satisfies, by (2.8) and (2.7), that

$$\min_{0 \le i \le m; 0 \le j \le n} \{w_{ij}\} \le w_{ij}^{0r} \le \max_{0 \le i \le m; 0 \le j \le n} \{w_{ij}\},$$

$$\min_{0 \le i \le m; 0 \le j \le n} \{|f_{ij}|\} \le |f_{ij}^{0r}| \le \max_{0 \le i \le m; 0 \le j \le n} \{|f_{ij}|\},$$

for all $i \in \{0, 1, \ldots, m\}$, $r \in \{1, \ldots, n\}$, and $j \in \{0, 1, \ldots, n - r\}$ and, by (2.10) and (2.9), that

$$\min_{0 \le i \le m; 0 \le j \le n} \{w_{ij}\} \le w_{i0}^{sn} \le \max_{0 \le i \le m; 0 \le j \le n} \{w_{ij}\},$$

$$\min_{0 \le i \le m; 0 \le j \le n} \{|f_{ij}|\} \le |f_{i0}^{sn}| \le \max_{0 \le i \le m; 0 \le j \le n} \{|f_{ij}|\},$$

TABLE 5.3

Maximum relative error	4.11×10^{-5}
Mean relative error	4.21×10^{-7}

for all $s \in \{1, \dots, m\}$ and $i \in \{0, 1, \dots, m-s\}$, underflow and overflow are avoided. In fact, we have proved that this algorithm has optimal growth factor. Let us recall that the growth factor of a numerical algorithm is the quotient between the ∞-norm of the elements calculated during the algorithm and the ∞-norm of the initial data. In general, the control of growth factor avoids overflow and is an indicator of stability.

The following two examples illustrate the good behavior of the corner cutting algorithm with respect to overflow, in contrast to the other two algorithms. We have considered a rational function $K(x, y)$ given by

$$K(x,y) = \sum_{i=0}^{10} \sum_{j=0}^{10} f_{ij} \, \frac{w_{ij} \, b_i^{10}(x) \, b_j^{10}(x)}{\sum_{i=0}^{n} \sum_{j=0}^{n} w_{ij} \, b_i^{10}(x) \, b_j^{10}(x)}, \quad (x,y) \in [0,1] \times [0,1]. \tag{5.1}$$

First we have evaluated the surface $K(x, y)$ given by $f_{ij} = (-1)^{i+j} \, 10^{20+i-j}$ and $w_{ij} = 10^{10+i-j}$ for all $i, j \in \{0, 1, \dots, 10\}$ at a mesh $(x_i, x_j)_{0 \le i,j \le 20}$, where $x_i = 0.05\, i$ for $i \in \{0, 1, \dots, 20\}$, using the C compiler Mingw with simple precision through the three evaluation algorithms considered. On the one hand, for the VS and the projective algorithms the unique result obtained at all points of the mesh $(x_i, x_j)_{0 \le i,j \le 20}$ is $-1.\#IND0 \dots 0$ (out of the range of representation) because some of the products $w_{ij} \, f_{ij}$ in the projective case and some of the products $\binom{10}{i} \binom{10}{j} w_{ij} \, f_{ij}$ in the VS case present overflow. On the other hand, the results obtained with the corner cutting rational surface algorithm were satisfactory and accurate at all points of the mesh, as shown in Table 5.3.

Although the selection of the weights w_{ij} can seem nonstandard, let us take into account that changing weights is a very useful tool for interactive shape design (as remarked in [11, p. 120]). In section 11.3.3 of [11] the effect of modifying a single weight in a rational surface is analyzed. The following example considers a more standard case, where the weights vary no more than three orders of magnitude.

Let $K(x, y)$ be the surface given by $f_{ij} = (-1)^{i+j} \cdot 5 \cdot 10^{26+i-j}$ and $w_{ij} = 10^{(i+j)\%4}$, where $a\%b$ denotes the remainder of dividing a by b. We have evaluated this surface at a mesh $(x_i, x_j)_{0 \le i,j \le 20}$, where $x_i = 0.05\, i$ for $i \in \{0, 1, \dots, 20\}$, using the C compiler Mingw with simple precision through the three evaluation algorithms considered. On the one hand, the unique result obtained for the VS and the projective algorithms at all points of the mesh $(x_i, x_j)_{0 \le i,j \le 20}$ is $-1.\#IND0 \dots 0$ (out of the range of representation) because some of the products $w_{ij} \, f_{ij}$ in the projective case and some of the products $\binom{10}{i} \binom{10}{j} w_{ij} \, f_{ij}$ in the VS case present overflow. On the other hand, the results obtained with the corner cutting rational surface algorithm were satisfactory and accurate at all points of the mesh, as shown in Table 5.4.

Finally we have evaluated the surface $K(x, y)$ in (5.1) given by

$$f_{ij} = (-1)^{i+j} \, 1.2 \, 10^{-33+i-j} \quad \text{and} \quad w_{ij} = \begin{cases} 10^{-10} & \text{if } i+j \text{ is even,} \\ 10^{-7} & \text{if } i+j \text{ is odd,} \end{cases}$$

at a mesh $(x_i, x_j)_{0 \le i,j \le 20}$, where $x_i = 0.05\, i$ for $i \in \{0, 1, \dots, 20\}$, using the C compiler Mingw with simple precision through the three evaluation algorithms considered. On

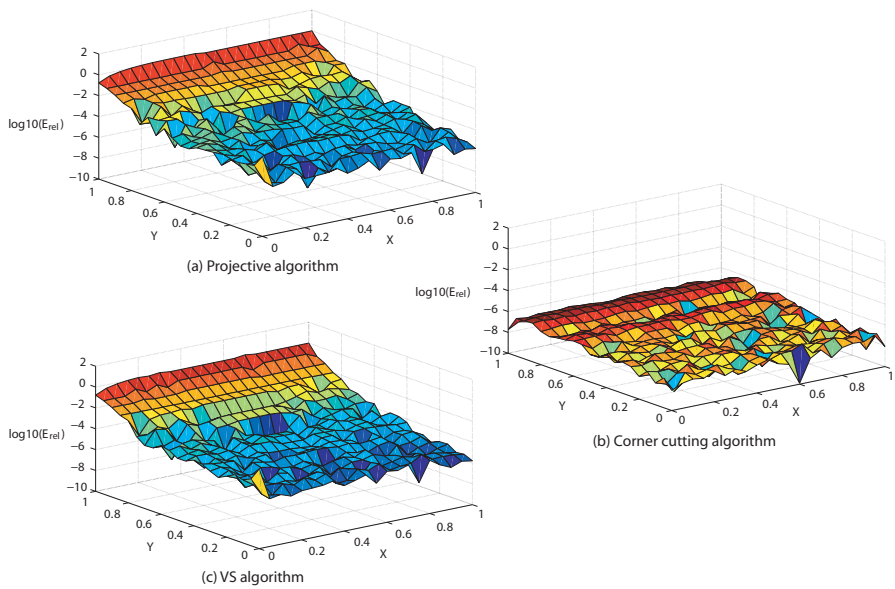

FIG. 5.3. *Relative errors in logarithmic scale.*

the one hand, the results obtained at the points $(1.00, 0.50)$, $(1.00, 0.55)$, $(1.00, 0.60)$, $(1.00, 0.65)$, $(1.00, 0.75)$, $(1.00, 0.80)$, $(1.00, 0.85)$, $(1.00, 0.90)$, and $(1.00, 0.95)$ of the mesh with the VS and the projective algorithms are exactly 0 because some of the products $w_{ij}\, f_{ij}$ in the projective case and some of the products $\binom{10}{i}\binom{10}{j} w_{ij}\, f_{ij}$ in the VS case are taken as 0 due to underflow problems. So these results are completely wrong. But, in addition to this fact, there are more points of the mesh such that the projective and the VS algorithms produce very inaccurate results: for example, both algorithms produce very high relative errors at the points $(1.00, 0.30)$, $(1.00, 0.20)$, $(1.00, 0.10)$, ... For more details on the bad performance of the projective and the VS algorithms, see Table 5.5 and Figure 5.3(a) and (c). On the other hand, the results obtained with the corner cutting rational surface algorithm were satisfactory and accurate at all points of the mesh as the table and Figure 5.3(b) show. The two standard algorithms also suffer from overflow and underflow in double precision.

6. Conclusions. Let us summarize some conclusions on the comparison of the three algorithms considered in this paper. On the one hand, as for the complexity, we have seen in section 2 that the VS algorithm has the lowest computational cost. On the other hand, we have proved in section 4 that the basis (4.1) corresponding to the projective and the corner cutting algorithms is optimally stable. Besides, the stability of the new corner cutting algorithm has been shown in section 3. In section 5, numerical experiments have confirmed the previous results. In spite of the good stability properties of the three algorithms even for ill-conditioned polynomials, we illustrate that the algorithms associated with the basis (4.1) (i.e., the projective and the corner cutting rational surface algorithms) are more stable than the VS algorithm. Moreover, due to the good behavior of the corner cutting rational surface algorithm with respect to avoiding overflow and underflow problems, we can also say that it is more robust than the other algorithms for the evaluation of rational surfaces. In addition, we have proved in section 5 that it has optimal growth factor.

In a future work we will study the possibility of a corner cutting algorithm for evaluating nonuniform rational B-spline (NURBS) surfaces.

Acknowledgment. The authors are thankful to the referees for their valuable comments and suggestions.

PARTITIONING SPARSE MATRICES FOR PARALLEL PRECONDITIONED ITERATIVE METHODS*

BORA UÇAR† AND CEVDET AYKANAT‡

Abstract. This paper addresses the parallelization of the preconditioned iterative methods that use explicit preconditioners such as approximate inverses. Parallelizing a full step of these methods requires the coefficient and preconditioner matrices to be well partitioned. We first show that different methods impose different partitioning requirements for the matrices. Then we develop hypergraph models to meet those requirements. In particular, we develop models that enable us to obtain partitionings on the coefficient and preconditioner matrices simultaneously. Experiments on a set of unsymmetric sparse matrices show that the proposed models yield effective partitioning results. A parallel implementation of the right preconditioned BiCGStab method on a PC cluster verifies that the theoretical gains obtained by the models hold in practice.

1. Introduction.

We consider the parallelization of the preconditioned iterative methods that use explicit preconditioners such as approximate inverses or factored approximate inverses. Our objective is to develop methods for obtaining one-dimensional (1D) partitions on a coefficient matrix and a preconditioner matrix or factors of a preconditioner matrix simultaneously to efficiently parallelize a full step of the preconditioned iterative methods. We assume preconditioner matrices or their sparsity patterns are available beforehand. It has been shown that the rates of convergence of iterative methods depend on the partitioning method when the preconditioners are built from partitioned coefficient matrices [26]. With the above assumption in mind, we neither deteriorate nor improve the effects of the selected preconditioners on the rate of convergence. Our assumption is justified in applications where the preconditioner matrices can be reused; see, for example, [12] and a discussion of it in [10]. The assumption is also justified in the preconditioner constructing methods that require a priori sparsity patterns for the preconditioner matrices [44, 45], where techniques to develop effective sparsity patterns already exist in the literature [23, 24, 39].

Approximate inverse preconditioning techniques explicitly compute and store a sparse matrix $M \approx A^{-1}$ to be used as a preconditioner. Application of such preconditioners requires one or two matrix-vector multiply operations. Two types of approximate inverses exist in the literature. In the first type, an approximate inverse is stored as a single matrix, whereas in the second type it is stored as a product of two matrices. The second type of preconditioners are referred to as factored approximate inverses. Among the most notable approximate inverse preconditioners are AINV and its variants by Benzi et al. [5, 6, 7, 8]; SPAI by Grote and Huckle [33]; FSAI by Kolotilina and Yeremin [44, 45]; and MR by Chow and Saad [25]. See [4, 9, 31] for

a recent survey and the use of the approximate inverse preconditioning techniques. See [48, 52] for a general treatment of the preconditioning techniques.

Hendrickson and Kolda [36] give a thorough survey of the graph partitioning models used for partitioning sparse matrices. In these models, a K-way partition of the vertices of a given graph or hypergraph is computed. The partitioning constraint is to maintain a balance criterion on the number of vertices in each part; if the vertices are weighted, then the constraint is to maintain a balance criterion on the sum of the vertex weights in each part. The partitioning objective is to minimize the cutsize of the partition defined over the edges or hyperedges. The partitioning constraint and objective relate, respectively, to maintaining computational load balance and minimizing the total communication volume. Among those models, the hypergraph models by Aykanat, Pınar, and Çatalyürek [2], Çatalyürek and Aykanat [17, 18], and Pınar et al. [49] and the bipartite graph model by Hendrickson and Kolda [37, 43] are said to have more expressive power than the other models [18, 34, 36, 37]. These models have the flexibility of producing unsymmetric partitions on the input and output vectors of the sparse matrix-vector multiplies. A distinct advantage of the hypergraph models over both the standard graph and the bipartite graph models is that the partitioning objective in the hypergraph models is an exact measure of the total communication volume, whereas the objective in the graph models is an approximation [18, 34, 36, 37]. As noted in the survey [36] and in [34], all these graph and hypergraph models, except the bipartite graph model, are used to optimize a single sparse matrix-vector multiply operation. However, a single sparse matrix-vector multiply operation is only a piece of a larger computation in the preconditioned iterative methods. Therefore, new partitioning models that optimize a full step of these iterative methods are needed—this was also stated by Hendrickson [34].

Optimizing a full step of the preconditioned iterative methods requires partitioning the coefficient and preconditioner matrices. This problem has been formulated in terms of bipartite graph partitioning [37]. In the bipartite graph model, each vertex in one part represents a row of A and a column of M, and each vertex in the other part represents a column of A and a row of M. There is an edge between two vertices if the corresponding entries in A or M are nonzero. Partitioning this bipartite graph produces unsymmetric partitions on A and M, where the row partition of A and the column partition of M are the same, and the column partition of A and the row partition of M are the same. The formulation is based on the cut edges and hence does not capture the total communication volume exactly. The multiphase mesh partitioning method of Walshaw et al. [47, 64] and multiconstraint/multiobjective graph partitioning methods of Karypis et al. [41, 53] address the partitioning problem in scientific computations whose computational structures are similar to that of preconditioned iterative methods. These models can be used to partition a graph corresponding to the sparsity pattern of the matrix $A+M$ to find a single partition for both of the matrices. Partitioning such a graph will produce symmetric partition on the coefficient and preconditioner matrices.

In this work, we propose methods to build composite hypergraph models for preconditioned iterative methods from simple hypergraph models for a single matrix-vector multiply [18]. We show how to use the composite models to obtain 1D partitions on a matrix and its approximate inverse preconditioners for optimizing a full step of the preconditioned iterative methods. The composite hypergraph models encode the total communication volume exactly, can handle unsymmetric dependencies, and can produce unsymmetric partitions. Furthermore, they are more powerful than the

bipartite graph model in the sense that they can produce a variety of partitions on the matrices. For example, given two matrices A and M, it is possible to obtain a symmetric partition on A and a unsymmetric partition on M while optimizing a full step of a preconditioned iterative method.

We review simple hypergraph models which are the building blocks of composite models in section 2. We discuss a procedure to analyze iterative methods in order to determine partitioning requirements for efficient parallelization and illustrate the procedure on a well-known iterative method in section 3. The partitioning requirements of a number of widely used iterative methods are also given in the same section. We propose methods to build composite hypergraph models for meeting the partitioning requirements in the preconditioned iterative methods in section 4. We discuss the applicability of the composite hypergraph models to a few additional scientific applications in section 5. The proposed methods are evaluated in section 6.

2. Preliminaries. The kernel operations in the iterative methods that use approximate inverse preconditioners are matrix-vector multiplies with both coefficient and preconditioner matrices. These multiply operations are performed on vectors that are dependent on each other through linear vector operations. For example, the computations of the form $y \leftarrow AMz$ are performed as $x \leftarrow Mz$ and then $y \leftarrow Ax$. If the partition on the x vector for the first multiply operation is different from that for the second multiply operation, then the x-vector entries should be reordered in between the two multiplies. Since the reordering requires communication, it should be avoided. In order to avoid this reordering operation, there should be only one partition on the intermediate vector x, and the partition should be helpful for both of the parallel multiply operations. We call the problem of finding partitions on two or more matrices in such a way that the common vectors are not reordered in a parallel implementation the simultaneous partitioning problem.

2.1. Parallel multiplies. Given a K-way rowwise partition on a matrix A, a conformable partition on the output vector, and a possibly different K-way partition on the input vector of a matrix-vector multiply operation, the matrix A can be permuted into a block structure:

$$PAQ = A_{BL} = \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1K} \\ A_{21} & A_{22} & \cdots & A_{2K} \\ \vdots & \vdots & \ddots & \vdots \\ A_{K1} & A_{K2} & \cdots & A_{KK} \end{bmatrix}. \tag{2.1}$$

Here, K is the number of processor and P and Q are permutation matrices. The partition on the rows of A is used to define the permutation P by permuting the rows belonging to processor P_k before those belonging to P_ℓ for $k < \ell$. The partition on the input vector is used to define the permutation Q by permuting the columns corresponding to the vector entries belonging to processor P_k before those corresponding to the vector entries belonging to P_ℓ for $k < \ell$. In either of the permutations, the order of the rows or columns associated with a common processor can be arbitrary.

Similarly, given a K-way columnwise partition on A, a conformable partition on the input vector, and a K-way partition on the output vector among K processors, the matrix A again can be permuted into a $K \times K$ block structure $PAQ = A_{BL}$ (2.1). Here, P is defined using the partition on the output vector, and Q is defined using the partition on the matrix columns (and input vector).

Let A be of size $m \times n$. Then the block $A_{k\ell}$ in (2.1) is of size $m_k \times n_\ell$, where

$\sum_k m_k = m$ and $\sum_\ell n_\ell = n$. In a rowwise partitioning, the processor P_k holds the kth row stripe $[A_{k1} \cdots A_{kK}]$ of size $m_k \times n$. In a columnwise partitioning, P_k holds the kth column stripe $[A_{1k}^T \cdots A_{Kk}^T]^T$ of size $m \times n_k$. In the rowwise partitioning, the row stripes should have a nearly equal number of nonzeros for maintaining computational load balance among processors. The same requirement exists for the column stripes in the columnwise partitioning.

2.1.1. Row-parallel multiplies. Consider matrix-vector multiplies of the form $y \leftarrow Ax$, where A is partitioned rowwise. The rowwise partition of matrix A induces a partition on the output vector y, i.e., $y = [y_1^T \cdots y_K^T]^T$, where the processor P_k is set to be responsible for computing the subvector y_k of size m_k. According to the partition on the input vector $x = [x_1^T \cdots x_K^T]^T$, the processor P_k holds the subvector x_k of size n_k. Assume the matrix A has been permuted into the block structure (2.1) using these partitions. Then the [illegible] $y \leftarrow Ax$ executes the following steps at processor P_k [37, 57, 59, 61]:

1. For each nonzero off-diagonal block $A_{\ell k}$, send sparse vector $\hat{x}_k^\ell$ to processor P_ℓ, where $\hat{x}_k^\ell$ contains only those entries of x_k corresponding to the nonzero columns in $A_{\ell k}$.
2. Compute the diagonal block product $y_k^k = A_{kk} \times x_k$, and set $y_k = y_k^k$.
3. For each nonzero off-diagonal block $A_{k\ell}$, receive $\hat{x}_\ell^k$ from processor P_ℓ, then compute $y_k^\ell = A_{k\ell} \times \hat{x}_\ell^k$, and update $y_k = y_k + y_k^\ell$.

In step 1, P_k might be sending the same x_k-vector entry to different processors according to the sparsity pattern of column k of A. This multicast-like operation is referred to here as the [illegible] operation.

2.1.2. Column-parallel multiplies. Consider matrix-vector multiplies of the form $w \leftarrow Az$, where A is partitioned columnwise. The columnwise partition of A induces a partition on the input vector z, i.e., $z = [z_1^T \cdots z_K^T]^T$, where the processor P_k holds the subvector z_k of size n_k. According to the partition on the output vector $w = [w_1^T \cdots w_K^T]^T$, the processor P_k is set to be responsible for computing the subvector w_k of size m_k. Assume the matrix A has been permuted into the block structure (2.1) using these partitions. Then the [illegible] $w \leftarrow Az$ executes the following steps at processor P_k:

1. For each nonzero off-diagonal block $A_{\ell k}$, form sparse vector $\hat{w}_\ell^k$, which contains only those results of $w_\ell^k = A_{\ell k} \times z_k$ corresponding to the nonzero rows in $A_{\ell k}$. Send $\hat{w}_\ell^k$ to processor P_ℓ.
2. Compute the diagonal block product $w_k^k = A_{kk} \times z_k$, and set $w_k = w_k^k$.
3. For each nonzero off-diagonal block $A_{k\ell}$ receive partial-result vector $\hat{w}_k^\ell$ from processor P_ℓ, and update $w_k = w_k + \hat{w}_k^\ell$.

In step 3, the multinode accumulation on the w_k-vector entries is referred to here as the [illegible] operation.

2.2. Hypergraph partitioning. A hypergraph $\mathcal{H} = (\mathcal{V}, \mathcal{N})$ is defined as a set of vertices $\mathcal{V}$ and a set of nets $\mathcal{N}$. Every net is a subset of vertices. The vertices of a net are also called its [illegible]. The size of a net n_i is equal to the number of its pins, i.e., $|n_i|$. The set of nets that contain vertex v_j is denoted by [illegible] (v_j). Weights can be associated with vertices.

Given a hypergraph $\mathcal{H} = (\mathcal{V}, \mathcal{N})$, $\Pi = \{\mathcal{V}_1, \ldots, \mathcal{V}_K\}$ is called a K-way partition of the vertex set $\mathcal{V}$ if each part is nonempty, i.e., $\mathcal{V}_k \neq \emptyset$ for $1 \leq k \leq K$; parts are pairwise disjoint, i.e., $\mathcal{V}_k \cap \mathcal{V}_\ell = \emptyset$ for $1 \leq k < \ell \leq K$; and the union of parts gives $\mathcal{V}$, i.e., $\bigcup_k \mathcal{V}_k = \mathcal{V}$. In Π, a net is said to [illegible] a part if it has at least one pin

in that part. The connectivity set Λ_i of a net n_i is the set of parts connected by n_i. The connectivity $\lambda_i = |\Lambda_i|$ of a net n_i is the number of parts connected by n_i. A net is said to be cut if it connects more than one part and uncut otherwise. The set of cut and uncut nets is also referred to as external and internal nets, respectively. In Π, the weight of a part is the sum of the weights of vertices in that part.

In the hypergraph partitioning problem, the objective is to minimize the cutsize:

$$\text{cutsize}(\Pi) = \sum_{n_i \in \mathcal{N}} (\lambda_i - 1). \tag{2.2}$$

This objective function is widely used in the VLSI community [46] and in the scientific computing community [2, 18, 59], and it is referred to as the connectivity -1 cutsize metric. The partitioning constraint is to satisfy a balancing constraint on part weights:

$$\frac{W_{max} - W_{avg}}{W_{avg}} \leq \epsilon. \tag{2.3}$$

Here W_{max} is the maximum part weight, W_{avg} is the average part weight, and ϵ is a predetermined imbalance ratio. This problem is NP-hard [46].

A recent variant of the above problem is the multiconstraint hypergraph partitioning [16, 20, 42] in which each vertex has a vector of weights associated with it. In this problem, the partitioning objective is the same as in (2.2), and the partitioning constraint is to satisfy a balancing constraint associated with each weight. Another variant is the multiobjective hypergraph partitioning [1, 53, 55], in which there are several objectives to be minimized. Specifically, a given net contributes different costs to different objectives.

2.3. Hypergraph models for row-parallel and column-parallel multiplies. It is inherent in the parallel matrix-vector multiply algorithms given in section 2.1 and existent in the literature [18, 36, 37, 59] that in partitioning a matrix the key is to find permutation matrices P and Q such that most of the nonzeros of the matrix $PAQ = A_{BL}$ (2.1) are in the diagonal blocks. Here, we propose a slight enhancement of the computational hypergraph models [18] to find permutation matrices P and Q. The proposed enhancement is to add a new set of vertices into the column-net and row-net hypergraph models.

In the column-net hypergraph model, an $m \times n$ matrix A is represented as a hypergraph $\mathcal{H} = (\mathcal{V}_\mathcal{R}, \mathcal{N}_\mathcal{C})$ for rowwise partitioning. Vertex and net sets, $\mathcal{V}_\mathcal{R}$ and $\mathcal{N}_\mathcal{C}$, correspond to the rows and columns of A, respectively. There exist one vertex r_i and one net c_j for each row i and column j, respectively. In this model, $r_i \in c_j$ if and only if $a_{ij} \neq 0$. The proposed enhancement is to add n new vertices each representing an input-vector entry of the $y \leftarrow Ax$ multiply. Each new vertex x_j is added to the net c_j, i.e., $c_j = c_j \cup \{x_j\}$ and $\text{vtx}(x_j) = \{c_j\}$. Each vertex r_i corresponds to the task of computing the inner product of the row i with the column vector x. Hence, the computational weight associated with the vertex r_i is equal to the number of nonzeros in row i. Each row vertex r_i also represents the vector entry y_i. Weights can be assigned to the vertices in regard to the vector entries. For example, a unit weight may be assigned to the vertex x_j for the corresponding vector entry, and a unit weight may be assigned to the vertex r_i for the vector entry y_i. These weights can be used in a multiconstraint formulation to balance the linear vector operations.

Figure 2.1 shows a sample matrix and its column-net hypergraph model enhanced with the x vertices. In the figure, the white and black circles represent, respectively,

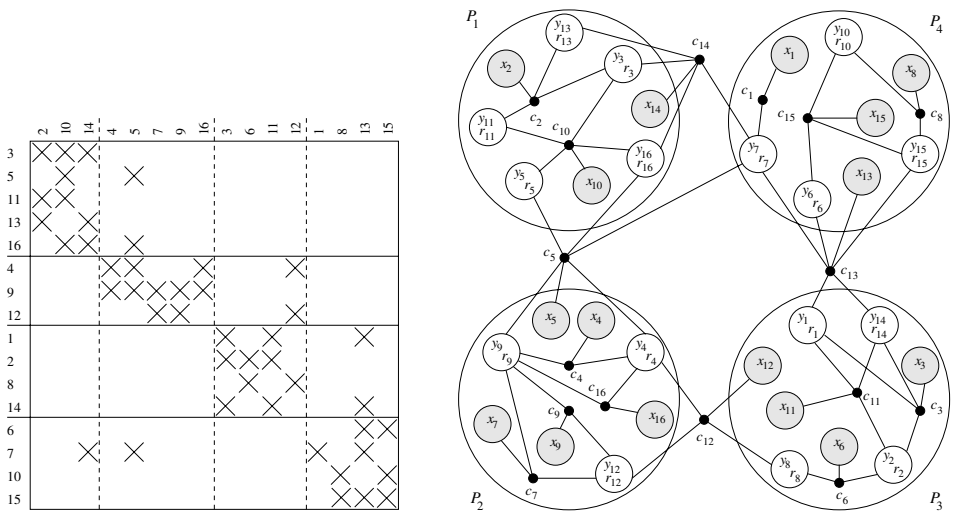

FIG. 2.1. *Matrix A, enhanced column-net hypergraph model for row-parallel $y \leftarrow Ax$, and a four-way rowwise partitioning.*

the vertices and nets of the original column-net hypergraph model [18], and straight lines show pins. The newly added vertices are shown with gray circles. A four-way partition is shown by four big circles encompassing the vertices of the hypergraph.

Given a partition Π on $\mathcal{H}$, the permutations P and Q can be found as follows. The permutation P is partially defined by the partition on the row vertices. The rows corresponding to the row vertices in $\mathcal{V}_k$ are mapped to processor P_k and therefore permuted before the rows corresponding to the row vertices in $\mathcal{V}_\ell$ for $1 \leq k < \ell \leq K$. In Figure 2.1, the permutation of the rows of A is shown by the permuted row indices, where the horizontal solid lines separate row stripes that belong to different processors. The permutation of the rows in the same row stripe can be arbitrary. The permutation Q is partially defined by the partition on the x vertices. The x-vector entries corresponding to the x vertices in $\mathcal{V}_k$ are mapped to processor P_k, and therefore the associated columns are permuted before the columns that are associated with the x vertices in $\mathcal{V}_\ell$ for $1 \leq k < \ell \leq K$. Figure 2.1 shows the permutation on the columns of A, where the vertical dashed lines separate virtual column stripes that are aligned with the x-vector entries belonging to different processors. Again, the permutation of the columns within the same column stripe can be arbitrary. In the figure, the processor P_2 is set to be responsible for computing the inner products of x with the rows in the second row stripe, i.e., the rows 4, 9, and 12. P_2 holds x_4, x_5, x_7, x_9, and x_{16} and thus expands x_5 to the processors P_1 and P_4. Observe that the net c_5 connects the parts P_1, P_2, and P_4. This association between the connectivity of nets and the communication requirements is not accidental, as shown by the following theorem.

THEOREM 2.1. Π A P Q Π Π $y \leftarrow Ax$. Consider an internal net c_i. Since the net is not cut, the row vertices that need x_i should be in the part that contains the vertex x_i. Hence, no communication occurs for the x-vector entries associated with the internal nets. Consider an external

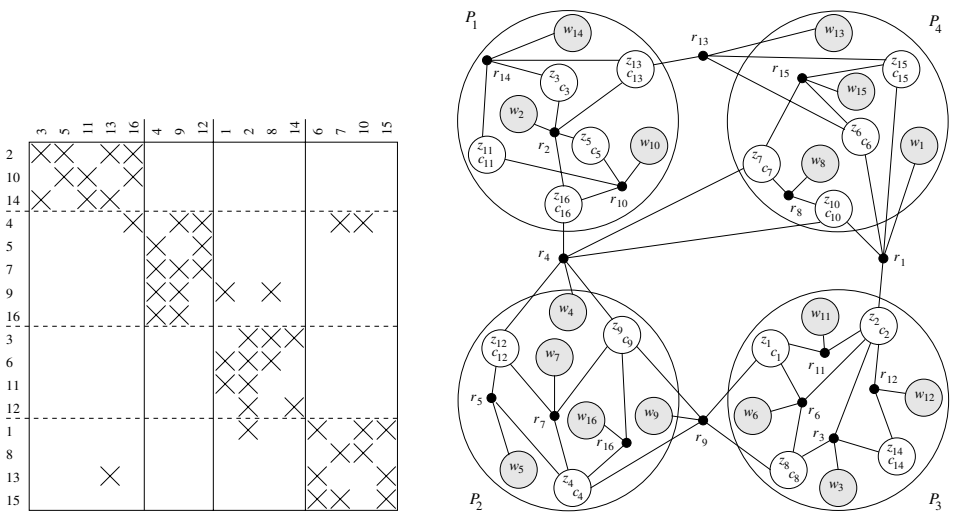

FIG. 2.2. *Matrix A, enhanced row-net hypergraph model for column-parallel $w \leftarrow Az$, and a four-way columnwise partitioning.*

net n_e with the connectivity set Λ_e. The processors corresponding to the parts in the set Λ_e need x_e. One of them owns x_e, since $x_e \in n_e$. The owner should send x_e to the others. That is, for each x_e there are a total of $|\Lambda_e| - 1 = \lambda_e - 1$ messages carrying x_e. The overall sum of these quantities matches the cutsize definition (2.2). □

With similar reasoning, it is concluded in [18] that the hypergraph partitioning objective and constraint correspond, respectively, to minimizing the total communication volume and maintaining the computational load balance. In Figure 2.1, the cutsize and hence the total communication volume is five units, and the part weights and hence the computational loads of the processors are 12, 12, 11, and 11.

The row-net hypergraph model [18] can be enhanced by adding m new vertices, each representing a w-vector entry to find the permutation matrices P and Q for the column-parallel $w \leftarrow Az$ multiplies. Recall that in the row-net model $\mathcal{H} = (\mathcal{V}_\mathcal{C}, \mathcal{N}_\mathcal{R})$, the vertices and nets represent the columns and rows of A, respectively. In this model, $c_i \in r_j$ if and only if $a_{ji} \neq 0$. Each new w_i vertex is added to the net r_i, i.e., $r_i = r_i \cup \{w_i\}$ and $\Lambda_{r_i}(w_i) = \{r_i\}$. Upon partitioning the enhanced row-net hypergraph model, we use the partition on the w vertices and the partition on the column vertices to find the permutation matrices P and Q, respectively, with a procedure similar to that discussed for the column-net model. Figure 2.2 shows a sample matrix and its enhanced row-net hypergraph model. The column stripes determine the computational loads of processors. The virtual row stripes are defined by the partition on the w vertices and therefore designate the processors' responsibilities on folding the w-vector entries. For example, in Figure 2.2, the processor P_2 is set to be responsible for folding the w-vector entries that correspond to the rows in the second virtual row stripe. Therefore, the processors P_1 and P_4 have to send their contributions for w_4 to P_2. Again, there is the same association between the connectivity of the nets and the total communication volume. In the figure, the cutsize and hence the total communication volume is five units.

3. Determining partitioning requirements. In iterative methods, all vectors that participate in a linear vector operation should be partitioned conformally in order

to avoid the communication of the vector entries during the operation. To obtain such conformable partitions, we classify the vectors according to their relations to the inputs and outputs of the matrix-vector multiplies. In particular, we call a vector to be in the [illegible] of a matrix A if it is multiplied by A or it undergoes linear vector operations with other vectors in the input space of A. Accordingly, we call a vector to be in the [illegible] of a matrix A if it is obtained by multiplying A with another vector or it undergoes linear vector operations with other vectors in the output space of A. For example, in the $y \leftarrow Ax$ multiply, the y vector is in the output space of A, whereas x is in the input space of A.

In some iterative methods, e.g., conjugate gradients [30], the input space and output space of the A matrix coincide; i.e., the input-space vectors undergo linear vector operations with the output-space vectors. Such methods require a symmetric partition PAP^T in which all vectors are partitioned conformally with the permutation P. In some other methods, the input space and output space of A differ. Such methods allow unsymmetric partition PAQ in which all output-space vectors are partitioned conformally with P, whereas all input-space vectors are partitioned conformally with Q. If the method involves more than one multiply with different matrices, the output space of one matrix may coincide with the input space of another one. In this case, the output-space permutation for the first one becomes an input-space permutation for the other one.

All vectors in a full step of an iterative algorithm should be analyzed in terms of their relations to the input and output spaces of all matrices to determine the partitioning requirements. We analyze the right preconditioned BiCGStab[1] method [62] given in Figure 3.1 and determine its partitioning requirements as an example. There are ten vectors in the method: r, b, $\tilde{r}$, x, p, v, $\hat{p}$, s, $\hat{s}$, and t. Because of the linear vector operations in lines 1, 2, 4, 7, 10, 14, 15, 19, 20, and 21, the vectors r, b, $\tilde{r}$, p, v, s, t, and x should be partitioned conformally. All these vectors are in the output space of A because of the matrix-vector multiplies in lines 13 and 18. We are left with the vectors $\hat{p}$ and $\hat{s}$. Because of the matrix-vector multiplies in lines 13 and 18, these two are in the input space of A, and thus can have a different partition Q. Since we have completed the classification of vectors, we can determine the partitioning requirements for A and M. The input and output spaces of A differ. Therefore, the partitioning requirement for the A matrix is PAQ. The vectors $\hat{p}$ and $\hat{s}$ are in the output space of M because of the matrix-vector multiplies in lines 12 and 17. Therefore, the output space of M coincides with the input space of A. Similarly, the input space of M coincides with the output space of A because of the vectors p and s. Therefore, the partitioning requirement for the M matrix is $Q^T MP^T$. The overall requirement is thus PAQ and $Q^T MP^T$. We express this requirement as $PAMP^T$ to simplify the notation.

We examined a number of widely used preconditioned iterative methods whose codes are given in the literature. We noticed that different methods have different partitioning requirements, as shown in Table 3.1. Several caveats are necessary for the table to be useful.

1. We analyze the methods in their original form as given in the references; i.e., we do not consider any type of code optimizations for performance gains.

[1]Note that the given code works with preconditioned x vector; i.e., the solution vector x obtained at the termination is a solution to $AMx = b$. That is, in order to get a solution to $Ax = b$ we have to multiply x with the approximate inverse preconditioner M at the termination. However, using $\hat{p}$ and $\hat{s}$ instead of p and s in lines 20 and 16 would yield the solution to $Ax = b$ as given in [3]. In this case, the analysis would yield different classification of vectors.

BiCGStab(A, M, x, b)#Solve $Ax = b$ using the right preconditioner M
begin
(1) $r^{(0)} = b - AMx^{(0)}$ for some initial $x^{(0)} = x$

2. If two matrices are written consecutively in a partitioning requirement, then the two matrix-vector multiplies involving these matrices follow each other without any interleaving synchronization. For example, in the $PAMP^T$ case, the input space of A and the output space of M coincide. In other words, there is an arbitrary permutation matrix and its transpose in between the two matrices which designates a distinct vector partition. Therefore, $PAMP^T$ means unsymmetric partitions PAQ for A and Q^TMP^T for M. We write the number of distinct vector partitions for each method in the rightmost column of Table 3.1.

3. Listing two partitioning requirements separated by "–" means that there is at least one synchronization point between the two matrix-vector multiplies. Therefore, we distinguish the partitioning requirement PAP^T and PMP^T from PAP^T–PMP^T. The first one states only that the output spaces of the matrices coincide with the input spaces of the matrices. The second partitioning requirement further states that the two matrix-vector multiplies are interleaved with synchronizations.

4. Factored approximate inverse M_1M_2 can be used (the table contains such an example for BiCGStab) instead of M by just writing the factors consecutively in place of M to determine their partitioning requirement. For example, the use of a factored approximate inverse in the right preconditioned CGNE necessitates PAQ–$PM_1M_2P^T$, which in turn gives the requirements PAQ, PM_1R, and $R^TM_2P^T$.

5. The given requirements are independent of the dimensions along which the matrices are partitioned. That is, matrices can be partitioned rowwise or columnwise, whichever is preferable.

In choosing a partitioning dimension, three issues should be considered. The first issue is the individual matrix characteristics, i.e., the number of nonzeros per row and column. If, for example, a matrix has dense rows but no dense columns, then it is advisable to partition it along the columns [37]. This choice will more likely lead to reduced communication volume and better computational load balance compared to partitioning along the rows [37].

The second issue in choosing a partitioning dimension is the relation between the partitioning requirement and the set of concurrent tasks to be partitioned. For example, in the $PAMP^T$ case, we have four partitioning choices for the pair of A (of size $m \times n$) and M (of size $n \times m$) matrices: (RR), (RC), (CR), and (CC). In the RR scheme, the partitioning determines the output-space permutation for the two matrices. Since the output spaces of the two matrices differ, there are a total of $m+n$ tasks, each representing computations involving either A or M. In the CC scheme, the partitioning determines the input-space permutation. Since the input spaces differ, there are a total of $n + m$ tasks, each representing computations involving either A or M. In the RC and CR schemes, the partition determines the permutation for the coinciding input and output spaces. Therefore, in the RC and CR schemes, the number of tasks reduces to m and n, respectively, each representing computations involving both A and M. In any reasonable task partitioning for the RC and CR schemes, each processor is guaranteed to take part in both of the multiplies. Therefore, these two schemes may lead to more efficient parallel algorithms.

The third issue is the arrangement of computations and communications. Consider the partitioning requirement of $PAMP^T$ for the multiplies of the form $y \leftarrow AMz$, which are performed as $x \leftarrow Mz$ and then $y \leftarrow Ax$. For each multiply, there exists an expand or a fold communication operation. The partitioning dimension determines whether these communications take place before or after the local com-

putations. In the RC partitioning scheme, the fold and expand operations take place successively in between the two multiplies. There are dependencies between these two communication operations; before expanding a particular x-vector entry it should be folded. Because of these dependencies, the successive fold and expand operations are likely to incur a local synchronization point which separates the two multiplies. Consequently, processor loads should be balanced for the individual matrix-vector multiplies in the RC scheme. The RR and CC schemes have either an expand or a fold in between the two multiply operations. Although such communications do not incur synchronization points under the assumption that each processor has enough local computation which overlaps with the incoming messages, it is advisable to balance processors' loads for the individual matrix-vector multiplies when the matrices have a comparable number of nonzeros. The CR scheme is unique in that the two multiply operations are performed successively without any interleaving communication. Therefore, processor loads may be balanced for the overall computation $y \leftarrow AMz$.

4. Building composite hypergraph models. We combine enhanced hypergraph models of the matrix-vector multiplies with the coefficient matrix A and the preconditioner matrix M or its factors M_1 and M_2 into a composite hypergraph whose partitioning meets the requirements given in section 3. We define two operations to combine the enhanced hypergraph models. These are called vertex amalgamation and vertex weighting. The first operation is used to enforce identical partitions on the vertices of the individual hypergraphs. The second operation is used to enable load balancing. The key point in combining a number of hypergraphs is to preserve the identities of the nets of the individual hypergraphs.

In the following discussion, we assume that A is to be partitioned rowwise and M is assumed to be partitioned columnwise. In the factored case, where $M = M_1M_2$, M_1 is to be partitioned columnwise, and M_2 is to be partitioned rowwise. That is, we have the enhanced column-net hypergraphs for A and M_2 and the enhanced row-net hypergraph for M_1. As discussed in section 2.3, weights can be associated with the vertices in reference to the vector entries. However, we do not use weights for the vector entries and show only the weights corresponding to the matrix rows or columns to simplify the discussion. Figure 4.1 shows portions of the enhanced column-net hypergraph model for $y \leftarrow Ax$ and the enhanced row-net hypergraph model for $w \leftarrow Mz$. These portions will be used while building composite hypergraph models.

Vertex amalgamation. In this operation, the vertices of the individual hypergraphs are combined into a single vertex. The net set of the resulting composite vertex is set to the union of the nets of the constituent vertices. For example, in the $PAMP^T$ case for the operations $w \leftarrow Mz$ and $y \leftarrow Ax$, we amalgamate the row-vertex $r_i(A)$ with the column-vertex $c_i(M)$ into v_i so that $n(v_i) = n(r_i(A)) \cup n(c_i(M))$. Furthermore, we amalgamate the vertex x_i with the vertex w_i to avoid a vector reordering operation. Figure 4.2(a) shows a portion of the resulting composite hypergraph. In a partition of the composite hypergraph, a row or a column vertex v_i being in a part $\mathcal{V}_k$ shows that the processor P_k is responsible for performing multiplications with the ith row or ith column of the matrices. Similarly, a vector-entry vertex x_i being in a part $\mathcal{V}_k$ shows that the processor P_k is responsible for folding or expanding x_i. Figures 4.2(b) to 4.2(d) show portions of the composite hypergraph models built using a vertex amalgamation operation for some other partitioning requirements from Table 3.1.

FIG. 4.2. *Composite hypergraph models for different partitioning requirements. The computations to be carried out are* $y \leftarrow Ax$, $w \leftarrow Mz$, $w \leftarrow M_1z$, *and* $t \leftarrow M_2u$.

Vertex weighting. This operation is used to enable load balancing. Remember that in some of the iterative methods there are synchronization points between different matrix-vector multiplies. That is, computations occur in phases. Therefore, we define multiple weights for vertices—one for each computation phase—and use a multiconstraint formulation to obtain load balance for each computation phase. For a certain phase, the weight of a vertex is set to the weight of the constituent vertex in the hypergraph of the matrix associated with that phase. In case the vertices of the simple hypergraphs bear weights for the vector entries, another weight component should be defined to account for those weights. Consider right preconditioned symmetric-GMRES [21] and its partitioning requirement PAP^T–PMP^T which designates $w \leftarrow Mz$ and $y \leftarrow Ax$, where all vectors are to be partitioned conformally. As seen in Figure 4.2(b), we apply vertex amalgamation to the vertices x_i and w_i. Since symmetric partitions are required for both of the multiplies, we also amalgamate the row-vertex $r_i(A)$ and the column-vertex $c_i(M)$ with the vertex composed of x_i and w_i. The vertex in Figure 4.2(b) has two weights, since the multiplies with A and M occur in different phases. The first weight represents the computational load associated with the ith row of A, i.e., $|r_i(A)|$. The second weight represents the computational load associated with the ith column of M, i.e., $|c_i(M)|$. In some cases, different matrix-vector multiplies occur successively

without any interleaving synchronization. In these cases, the weight of a composite vertex is set to the sum of the weights of its constituent vertices. Consider the TFQMR method using symmetric preconditioning and its partitioning requirement PAP^T–$PM_1M_2P^T$. Since M_1 and M_2 are partitioned columnwise and rowwise, respectively, there is no synchronization between the respective matrix-vector multiplies. Therefore, the weights of $c_i(M_1)$ and $r_i(M_2)$ are added up as seen in Figure 4.2(c).

Note that partitioning a composite hypergraph results in partitioning the coefficient and preconditioner matrices simultaneously, since the vertices of the composite hypergraph cover the rows or columns of each matrix. Given a partition on the composite hypergraph, we obtain a rowwise or columnwise partition and row and column permutations for each matrix by using the partitions on the vertices pertaining to the respective matrix-vector multiply operation. For example, when a matrix A is to be partitioned rowwise, we use the partition on the composite vertices that contain the rows of A to obtain both a rowwise partition on A and a row permutation, and we use the partition on the composite vertices that contain the input vector entries to obtain a column permutation. Having defined the row and column permutations for each matrix, we obtain the following theorem.

THEOREM 4.1. [illegible]. The proof follows easily by using the same arguments stated in the proof of Theorem 2.1 under the following observations. First, the identities of the nets are preserved while building the composite models. Second, each vertex of a net contains at least one vertex of the original enhanced hypergraph model. Third, the connectivity of a net can be calculated by using only the vertices of the respective enhanced hypergraph model. □

Illustration. Consider the right preconditioned BiCGStab method and its partitioning requirement $PAMP^T$ obtained in section 3. Let A and M be the matrices shown in Figures 2.2 and 2.1, respectively. Suppose that A is to be partitioned columnwise and M is to be partitioned rowwise. We generate the enhanced row- and column-net hypergraph models of A and M, respectively, as shown in Figures 2.2 and 2.1. The partitioning requirement imposes identical partitions on the columns of A and rows of M. Hence, we amalgamate the vertices $c_i(A)$ and $r_i(M)$. The method has no synchronization point between the two multiplies, and the separated expand and fold operations do not cause synchronization. Therefore, we add the weights of the vertices $c_i(A)$ and $r_i(M)$. Since the partitioning requirement imposes identical partitions on the output vector y of the first multiply ($y \leftarrow Ax$) and the input vector z of the second multiply ($w \leftarrow Mz$), we apply vertex amalgamation to the vertices y_i and z_i. A 4-way partition of the resulting hypergraph is shown in Figure 4.3(a). In order to distinguish the nets, the source matrix names are written next to them. The pins of the internal nets are not shown for the sake of clarity. The permutations on the matrices induced by the composite hypergraph partitioning are shown in Figure 4.3(b). Note that the resulting partitions and permutations are identical to those shown in Figures 2.2 and 2.1. As seen from Figure 4.3(a), the cutsize is 10, and hence the total volume of communication is 10 units, where each multiply contributes 5.

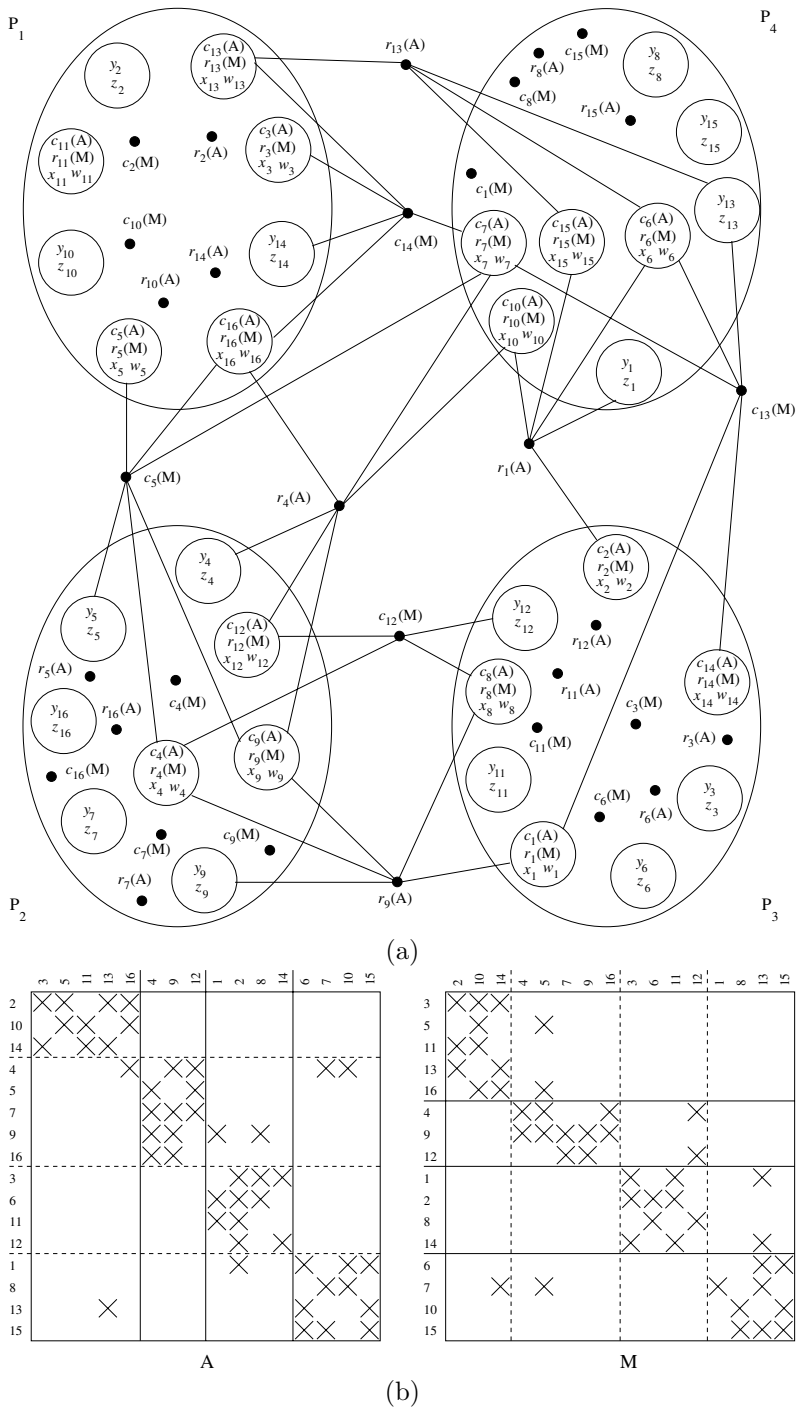

FIG. 4.3. (a) *A composite hypergraph formed by combining the enhanced row-net hypergraph of A and the enhanced column-net hypergraph of M for the computations $y \leftarrow Ax$ and $w \leftarrow Mz$ and a partition which meets the requirement $PAMP^T$. The pins of the internal nets and the weights of the vertices are not shown.* (b) *A columnwise partition of A and a rowwise partition of M induced by the partition on the vertices of the composite hypergraph.*

5. Further notes.

5.1. Investigations on composite models. In the enhanced hypergraph model, the partition on the vertices corresponding to the vector entries are used to obtain permutation matrices. In the previous computational hypergraph models [18], each net is mapped to a part in its connectivity set to obtain permutation matrices. The freedom in mapping a net to one of the parts in its connectivity set has been exploited to minimize communication cost metrics such as the total number of messages and the maximum volume per processor defined in terms of sends [58, 59], and maximum volume per processor [13, 63] defined in terms of both sends and receives. These works achieve their goals by assigning the vector entries to processors upon partitioning the matrix with the computational hypergraph models. In the enhanced hypergraph model and the composite hypergraph model, the vertices that do not contain row or column vertices can be reassigned with the same freedom. For example, the vertex formed by x_i and w_i in Figure 4.2(a) and the vertex x_i in Figure 4.2(d) can be reassigned to optimize the aforementioned communication cost metrics.

5.2. Generalizations. The computational structure of the preconditioned iterative methods is similar to that of a more general class of scientific computations, including multiphase, multiphysics, and multimesh simulations.

In multiphase simulations, there are a number of computational phases separated by global synchronization points. The existence of the global synchronizations necessitates each phase to be load balanced individually. In our model, the multiple weights associated with vertices can be used to achieve this goal as described in [41, 64].

In multiphysics simulations, a variety of materials and processes are analyzed using different physics procedures. In these types of simulations, computational as well as memory requirements are not uniform across the mesh [54]. For scalability issues, processor loads should be balanced in terms of these two components. The multiconstraint partitioning framework also addresses these problems [54].

In multimesh simulations, a number of grids with different discretization schemes and with arbitrary overlaps are used. The existence of overlapping grid points necessitates the simultaneous partitioning of the grids [54]. This simultaneous partitioning should balance the computational loads of the processors and minimize the communication cost due to interactions within a grid as well as interactions among different grids. The vertex amalgamation operation used in our models can be applied to overlapped grid points to build a composite hypergraph. With the use of vertex weighting operations, our models can be used to address the partitioning problem in the multimesh computations. Although simultaneous partitioning seems to be more adequate for these types of problems, independent partitioning is also possible (see, for example, [51] for independent partitionings on a two-grid system).

In some contact/impact problems, there is a priori knowledge about the to-be-contacting surfaces. The implementation in [38] uses this information to decompose the underlying mesh among processors. The implementation uses the graph model and adds edges between the to-be-contacting surface elements. Partitioning such a graph using two constraints balances the loads of processors, both for the finite element analysis and for the contact detection phases. The partitioning algorithm tries to minimize the communication cost by minimizing the edge cut. By modeling the interactions among the to-be-contacting surface elements with hypergraphs, we can build a composite hypergraph to address these problems. However, the implementation in [38] is reported to be suffering from load imbalances and to be limited to a small number of processors; see the comments on it in [50].

In obtaining partitions for two or more computation phases interleaved with synchronization points, our models lead to the minimization of the overall sum of the total volume of communication in all phases. For the preconditioned iterative methods, this approach will likely minimize the communication cost in one full step. However, in more sophisticated simulations, the magnitude of the interactions in one phase may be different from that of the interactions in another one. In such settings, minimizing the total volume of communication in each phase separately may be advantageous [53]. This problem can be formulated as a multiobjective hypergraph partitioning problem [1, 53, 55] on the composite hypergraphs.

As discussed above, our models can be applied to the multiphase, multiphysics, and multimesh computations but with certain limitations. The dependencies must remain the same throughout the computations; our methods cannot be used, for example, in adaptive mesh refinement. The weights assigned to elements, for load balancing issues, should be static and available prior to the partitioning; our methods cannot be used for applications whose computational requirements vary in time [35]. If, however, the computational requirements change gradually in time, then our methods can be used to repartition the load at certain time intervals. Some problems are more suitable to geometric partitioning methods; contact detection without a priori knowledge of the contacting surfaces, for example, should be performed on geometrically close elements [14, 40, 50]. Our methods, in their current forms, will probably be of little help in those problems. To be useful, the models should be enriched with some geometric constructs, as is done in [40].

6. Experiments. We chose the right preconditioned BiCGStab method to evaluate the effectiveness of the proposed composite hypergraph partitioning approach. We used a set of unsymmetric sparse matrices from the University of Florida Sparse Matrix Collection [27]. Approximate inverse preconditioners were obtained using SPAI version 3.0 [32]. Factored approximate inverses were obtained using AINV [11]. These two programs have parameters that affect the quality of the preconditioner matrices. However, we set the parameters in such a way that the number of nonzeros of the approximate inverse or the total number of nonzeros of the factors of the approximate inverse is at most twice and at least half the number of nonzeros of the coefficient matrix. We adjusted the tolerance parameter *eps*, the number of nonzero entries allowed per step *mn*, and the number of steps *ns* in SPAI. In AINV, we adjusted the drop tolerance parameter τ. The properties of the matrices, approximate inverses, and factors of the approximate inverses are given in Table 6.1. In the table, the coefficient matrices are listed with a suffix of A; the approximate inverse matrices are listed with a suffix of M; the factors of the approximate inverse matrices are listed with suffixes of Z and W, where the approximate inverse is equivalent to ZW. The hypergraphs were partitioned using PaToH [19] with default parameters. The imbalance among processor loads is kept below 10% in all partitioning instances. Throughout this section, we use the term "SPAI-matrices" to refer to a pair consisting of a coefficient matrix and its approximate inverse preconditioner. Similarly, we use "AINV-matrices" to refer to a triplet of coefficient matrix and the factors of its approximate inverse preconditioner.

Since the partitioning tool PaToH incorporates randomized algorithms, it was run 20 times starting from different random seeds for partitioning the hypergraphs. Averages of the resulting communication volumes of these runs are displayed in the following tables. PaToH is a fairly stable toolkit; the standard deviation of the total communication volumes of the 20 runs is less than 4% of the mean for all hypergraphs

(except `Zhao1-W` in Table 6.3, which has a negligible total communication volume). Details of the communication patterns can be found in the accompanying report [60].

6.1. Composite versus simple hypergraph partitioning. Here we evaluate two alternative approaches to partitioning composite hypergraphs. These alternative approaches are based on partitioning simple hypergraphs, i.e., partitioning hypergraphs of a single matrix. The first alternative is to obtain independent partitions on the matrices by partitioning the simple hypergraph models of the coefficient and the preconditioner matrices independently. This approach requires vector reordering in between the two matrix-vector multiplies. We discuss this alternative in section 6.1.1. The second alternative is to obtain the same partition for the coefficient and preconditioner matrices. For this purpose, we partition the coefficient matrices symmetrically by rows or columns using hypergraph models and apply the resulting partitions to the preconditioner matrices as well. This alternative avoids the vector reordering op-

eration by partitioning all vectors conformally. Note that since we partition a single matrix, a graph model could also be used. We discuss this alternative in section 6.1.2.

6.1.1. Simple hypergraph partitioning: Independent partitions on the matrices. We have conducted experiments with the CR and RC partitionings of SPAI-matrices where the first partition dimension corresponds to the matrix A and the second to the matrix M. In the independent partitioning approach, we partition the simple hypergraph models of the matrices A and M independently.

Table 6.2 displays the average communication volumes in the sparse matrix-vector multiply (SpMxV) operations resulting from the composite and simple hypergraph partitionings for 64-way partitioning of SPAI-matrices. The table also shows the volume of communication required to reorder the vector entries—in an iteration of the BiCGStab method—when the matrices are partitioned independently. Suppose that symmetric partitions PAP^T and QMQ^T were obtained on the A and M matrices. Then at each iteration we have to reorder $\hat{p}$ and $\hat{s}$ from Q to P after the matrix-vector multiplies at lines 12 and 17 of the BiCGStab method (see Figure 3.1), respectively. We also have to reorder v and t from P to Q before the vector update at line 15 and the inner product at line 19, respectively. The volume of communication in the reordering operation is given as the average of 20 different partitions of SPAI-matrices. In all of the partitioning instances, the volume of communication in the reordering operation

TABLE 6.3

Total communication volume for 64*-way simple hypergraph (C/R/C and R/C/R) and composite hypergraph (CRC and RCR) partitionings for AINV-matrices. In simple hypergraph partitionings, A, Z, and W are partitioned independently, and therefore vector entries are reordered in between the successive multiplies to meet the partitioning requirement.*

itself is higher than that obtained by the simultaneous partitioning method. These high volumes of communication and the associated message start-up overheads prohibit the use of the independent partitioning method. For example, the independent partitioning method incurs higher total communication volume than the proposed simultaneous partitioning method by an average ratio of 8.4 for 32-way CR partitioning (see [60]). The average ratio in 64-way CR partitioning is 6.5. For RC partitioning, the average ratios are 5.6 and 4.2 for 32- and 64-way partitionings, respectively.

Table 6.3 displays the averages of the communication volumes of the 64-way simultaneous and independent partitionings for AINV-matrices. In this table CRC corresponds to the case where the A, Z, and W matrices are partitioned columnwise, rowwise, and columnwise, respectively. Similarly, RCR corresponds to the case where those matrices are partitioned rowwise, columnwise, and rowwise. With AINV preconditioning, the independent partitioning method requires two additional vector-reordering operations (due to the chains of matrix-vector multiplies at lines 12 and 17 of the BiCGStab method). For 64-way partitioning of AINV-matrices, the average ratios of the communication volumes in the independent partitionings (including the reordering cost) to those in the simultaneous partitionings is 7.2 for the CRC case and 6.5 for the RCR case. The average ratios for 32-way partitionings are 10.1 and 9.0 for the CRC and RCR cases, respectively (see [60]). As is clear from these numbers, the independent partitioning approach is not feasible for the AINV-matrices as well.

Consider the difference between the total communication volumes of the composite and simple hypergraph partitionings (without the reordering cost). The increases in the total communication volumes in the composite partitionings remain below 26% of those in the simple partitionings, on average, for the 32-way CR partitioning instances. The minimum and the maximum of these increases are 13% (`Zhao1`) and 61% (`epb3`). The 64-way CR partitionings give better ratios. The average increase is 20% with the minimum and the maximum being 12% and 43%, which are obtained for the same matrices. In fact, for each matrix the increase in the 64-way CR partitioning

TABLE 6.4
Relation between the sparsity patterns of the coefficient matrices and the approximate inverses. We use A and M to represent the set of the positions of the nonzeros in the corresponding matrices.

is smaller than the increase in the 32-way CR partitioning. We investigated the 8- and 16-way CR partitionings as well [60] and observed that for each matrix in our data set the larger the number of parts, the smaller the increases. The same relation holds for most of the RC partitioning cases and for the CRC and RCR partitioning of AINV-matrices [60]. The reason behind this may be the following. The cutsize function almost always increases monotonically with the increasing K. In other words, the flexibility of finding better partitions reduces with the increasing K. At the limit, where $K = |\mathcal{V}|$ and all the nets are in cut, the cutsize of a partition on the composite hypergraph will be equivalent to the sum of the cutsizes of partitions on the simple hypergraphs (i.e., $nnz(A) + nnz(M) - 2m$) that forms it. Therefore, the difference between the total communication volumes should decrease as K increases and has to be zero at the limit.

6.1.2. Simple hypergraph partitioning: The same partition on the matrices. Obtaining a symmetric partition on A and then applying the resulting partition to M results in CC or RR partitionings on the A and M matrices. Recall that in CC and RR partitioning schemes, there is a communication phase in between the two matrix-vector multiplies. Since the A and M matrices have a comparable number of nonzeros (see Table 6.1), processor loads for the two matrix-vector multiplies should be balanced separately, i.e., a two-constraint formulation is necessary.

Observe that the approach evaluated here disregards the sparsity pattern of the preconditioner matrices. However, the sparsity patterns of the approximate inverse preconditioners are usually related to the sparsity patterns of the coefficient matrices [23, 39]. Therefore, the partitions on the coefficient matrices are expected to be effective for the preconditioners. To justify this reasoning, we show the relation between the sparsity patterns of the coefficient matrices and the approximate inverses in Table 6.4. As seen in the table, the relation between the sparsity patterns of the coefficient and preconditioner matrices varies; 63% of the nonzeros of `Zhao1-M` are covered by the nonzeros of `Zhao1-A`, and only 18% of the nonzeros of `mark3jac060-M` are covered by the nonzeros of `mark3jac060-A`. Another reason for using the same partition on the coefficient and preconditioner matrices is the following. Parallel construction of the approximate inverse preconditioners produces preconditioners in such a way that the initial partitions on the coefficient matrices become partitions on the preconditioner matrices. For example, the left approximate inverse preconditioners

can be efficiently constructed rowwise when the coefficient matrix A is partitioned rowwise [24]. The construction yields the same rowwise partition on the approximate inverse M. Equivalently, a right approximate inverse preconditioner can be efficiently constructed columnwise when the coefficient matrix A is partitioned columnwise.

The row-net hypergraph model of A can be used to obtain a CC partition on A and M. In order to obtain load balance for the two multiplies, the vertices of A are assigned two weights which correspond to the number of nonzeros in the respective columns of A and M matrices. That is, v_i has weights $\langle |c_i(A)|, |c_i(M)| \rangle$. Similarly, the column-net hypergraph model of A, with two weights on the vertices, can be used to obtain an RR partition on A and M.

The composite hypergraph model for the CC partitioning scheme is built in three steps as follows. First, the enhanced row-net hypergraph models of $y \leftarrow Ax$ and $w \leftarrow Mz$ are created. Second, vertex amalgamation operations are applied to the vertices y_i and $c_i(M)/z_i$, and also to the vertices $c_i(A)/x_i$ and w_i for each i. Third, vertex weighting operations are applied to the vertices in such a way that the vertex $y_i/c_i(M)/z_i$ has weights $\langle 0, |c_i(M)| \rangle$, and the vertex $w_i/c_i(A)/x_i$ has weights $\langle |c_i(A), 0| \rangle$ for each i. Theoretically, a three-constraint formulation is necessary to balance the vector operations; however, we use a two-constraint formulation in order to ease the job of the hypergraph partitioning tool. The composite hypergraph model for the RR partitioning scheme is built similarly.

Table 6.5 displays the averages of the communication volumes of the 64-way partitioning of the SPAI-matrices with the composite hypergraphs and simple hypergraph models of the coefficient matrices. The "% gain" columns in this table show the

improvements achieved by the composite hypergraph partitioning as the percentage of the total communication volumes found by partitioning the simple hypergraph of A. The minimum improvements are obtained for the `Zhao1` matrices in both CC and RR cases. The maximum improvements are obtained for the `mark3jac060` matrices in both CC and RR cases. As seen in Table 6.4, the `Zhao1-A` and `Zhao1-M` matrix pair have the highest ratio of common nonzeros, and the `mark3jac060-A` and `mark3jac060-M` matrix pair have the lowest ratio of common nonzeros. Although `xenon1-A` covers 61% of `xenon1-M` (second maximum), the improvements achieved for these matrices are quite satisfactory. The average of the improvements is 20% in the 32- and 64-way CC and RR partitioning choices (see also [60]).

We have also experimented with the 32- and 64-way CC and RR partitionings using single constraint formulation. In the single constraint formulation, the weight of a vertex v_i is set to the sum of the number of nonzeros in the ith columns (rows) of A and M for the CC (RR) partitioning. Both the composite hypergraph and the simple hypergraph formulations were able to obtain balance on the total loads of the processors. Since these formulations ignore the fact that there is a local synchronization, both formulations could not obtain balance on the loads of the processors for the individual matrix-vector multiplies. The composite hypergraph partitioning approach obtained (on average 17%) better solutions than the simple hypergraph partitioning [60]. The best and worst improvements are again obtained for the `mark3jac060` and `Zhao1` matrix pairs, respectively.

6.2. Effects of partitioning dimensions on the composite hypergraph partitioning. Comparing the left and right halves of Table 6.2, we see that the CR partitioning yields, on average, 26% better total communication volume than the RC one. This ratio remains the same for 8-, 16-, and 32-way partitionings (see Table 6.6 and [60]). The matrices in our data set do not have dense rows or dense columns. Therefore, the rowwise and columnwise partitionings of the matrices are expected to be comparable in terms of the total communication volume. This theoretical expectation is verified by the communication volume values listed in the SpMxV columns in Table 6.2 for the simple hypergraph partitioning. In light of this observation, we can deduce that the performance difference between the CR and RC partitioning schemes is due to the two-constraint formulation in the RC scheme. This degradation in the multiconstraint formulation is in concordance with the previously reported results [41, 64]. The degradation in our case stems from two facts. First, the additional balance constraints shrink the search space. Second, the heuristics in PaToH are not very well tailored toward handling the multiple vertex weights.

6.3. Parallelization results. It is important to see whether the theoretical improvements obtained by the proposed simultaneous partitioning method hold in practice. For this purpose, we have implemented a parallel program for the BiCGStab method. The program uses the LAM/MPI 6.5.6 [15] message passing library. The tests were carried out on a Beowulf class [56] PC cluster with 24 nodes. Each node has a 400MHz Pentium-II processor and 128 MB memory. The interconnection network comprises a 3COM Superstack II 3900 managed switch connected to Intel Ethernet Pro 100 Fast Ethernet network interface cards at each node. The system runs Linux kernel 2.4.20 and the Debian GNU/Linux 3.0 distribution.

We are not concerned with the numerics of the preconditioners and the BiCGStab method. Therefore, for each matrix, we let the BiCGStab run for 100 iterations and measure the average running time of a single iteration. In order to guarantee 100 iterations, we set ρ and ω of the BiCGStab method (see Figure 3.1) to 1.0 after computing

their actual values. The speedup values corresponding to these running times are given in Table 6.6 under the column *Sp./up*. The given speedup values are the averages of 20 runs corresponding to different partitions. In order to show how the improvements obtained by the proposed method relate to parallel running times, we give the average communication patterns induced by the partitions in the same table as well.

As seen from Table 6.6, CR gives better speedup values than RC for all matrices (the reasons are discussed in section 6.2). On average, CR obtains speedup values of

6.3 and 9.9 for 8- and 16-way partitionings, respectively, where the highest speedups are 7.3 (epb3) and 14.1 (stomach). Meanwhile, RC obtains speedups of 5.8 and 8.4, on average, for 8-way and 16-way partitionings, respectively, where the highest speedups are 7.2 (epb3) and 12.7 (stomach). The lowest speedups for 8-way partitioning are obtained for the cage11 matrix by both of the partitioning schemes. The lowest speedups for 16-way partitioning are obtained for the big and cage11 matrices by the CR and RC schemes, respectively. As seen from Table 6.6, the cage11 matrix pair has a communication pattern inferior to all but the cage12 matrix pair in terms of the total and maximum number of message metrics. Therefore, we were already expecting to have the lowest speedups with the cage matrices. The big matrix has the smallest number of nonzeros. The low granularity of computations may be the reason behind having the lowest speedup with 16-way CR partitioning of the big matrix. The same reasoning may also explain why we obtain better speedups in cage12 than those in cage11.

We have also experimented with the CRC and RCR partitioning schemes for AINV-matrices (see [60]). As expected, the speedup values are not as good as those given in Table 6.6 because of an additional load balancing constraint for the third matrix-vector multiply, and because of an additional communication phase. The highest speedups for 8- and 16-way CRC partitionings are 6.7 and 8.9, respectively. The highest speedups for 8- and 16-way RCR partitionings are 6.4 and 8.9, respectively.

6.4. Partitioning timings. Finally, we comment on the additional partitioning overhead introduced by simultaneous partitioning instead of individual partitionings. Let the sum of the times elapsed in individual partitionings (of the SPAI- and AINV-matrices) be 1.0. Then the average running times of the simultaneous partitioning of the SPAI-matrices with the CR and RC schemes are 1.4 and 1.2, respectively, for all $K = 8$, 16, 32, and 64. The average running times of the simultaneous partitioning of the AINV-matrices with both the CRC and RCR schemes are close to 1.4. These increases are acceptable because the simultaneous partitioning method obtains much smaller total communication volume than the individual partitioning method combined with the reordering cost. See [60] for a list of the partitioning times.

7. Conclusion. We demonstrated that hypergraph models are able to capture the application of multiple matrices. In particular, we developed models that allow simultaneous partitioning of a matrix and its explicit preconditioner or factors of the preconditioner. These points were raised by Hendrickson and Kolda [37].

The computational structure of preconditioned iterative methods abounds in scientific computing applications and data aggregation/reduction applications in large distributed data sets. We discussed the applicability of the proposed work in certain scientific computations. We think that the proposed work is applicable in distributed data-set applications where hypergraph models have already been used [22].

Acknowledgments. We thank Bruce Hendrickson for introducing us to the simultaneous partitioning problem; Michele Benzi, Miroslav Tůma, and Marcus Grote for their research software; Levent Gürel and his computational electromagnetics research group at Bilkent University for granting us access to their computing machinery. We are indebted to anonymous referees for insightful comments.

FAST DIRECTIONAL MULTILEVEL ALGORITHMS FOR OSCILLATORY KERNELS*

BJÖRN ENGQUIST† AND LEXING YING†

Abstract. This paper introduces a new directional multilevel algorithm for solving N-body or N-point problems with highly oscillatory kernels. These systems often result from the boundary integral formulations of scattering problems and are difficult due to the oscillatory nature of the kernel and the non-uniformity of the particle distribution. We address the problem by first proving that the interaction between a ball of radius r and a well-separated region has an approximate low rank representation, as long as the well-separated region belongs to a cone with a spanning angle of $O(1/r)$ and is at a distance which is at least $O(r^2)$ away from from the ball. We then propose an efficient and accurate procedure which utilizes random sampling to generate such a separated, low rank representation. Based on the resulting representations, our new algorithm organizes the high frequency far field computation by a multidirectional and multiscale strategy to achieve maximum efficiency. The algorithm performs well on a large group of highly oscillatory kernels. Our algorithm is proved to have $O(N \log N)$ computational complexity for any given accuracy when the points are sampled from a two dimensional surface. We also provide numerical results to demonstrate these properties.

1. Introduction.

This paper is concerned with the rapid solutions to a class of N-body problems. Let $\{f_i, 1 \le i \le N\}$ be a set of N densities located at points $\{p_i, 1 \le i \le N\}$ in $\mathbb{R}^3$ with $|p_i| \le K/2$, where $|\cdot|$ is the Euclidean norm and K is a fixed constant K. Our goal is to compute the potentials $\{u_i, 1 \le i \le N\}$ defined by

$$u_i = \sum_{j=1}^{N} G(p_i, p_j) \cdot f_j \tag{1}$$

where $G(x, y) = e^{2\pi\imath|x-y|}/|x-y|$ is the Green's function of the Helmholtz equation and is usually called the Helmholtz kernel. Throughout this paper, we use $\imath$ to denote the complex number $\sqrt{-1}$. We have scaled the problem such that the wave length equals one and thus high frequencies correspond to problems with large computational domains.

Such a computation comes mainly from applications in acoustic and electromagnetic scattering, where the usual partial differential equation (PDE) formulations are transformed into boundary integral equation (BIE) formulations. The advantages of the BIE formulations are the convenience of handling the boundary conditions at infinity and the decrease in the dimensionality of the problem. The integral equation formulations are often discretized using appropriate quadrature methods. The resulting linear systems are always dense due to the fact that an integral formulation

†Department of Mathematics, University of Texas at Austin, 1 University Station C1200, Austin, TX 78712 (engquist@math.utexas.edu, lexing@math.utexas.edu).

involves interaction between any two points or elements on the boundary. These dense linear systems are further solved using iterative methods, at each step of which the evaluation in (1) or closely related equations must be carried out.

Two observations are here in order. First, in scattering applications, the complexity of a problem scales with the size of its boundary in terms of the wavelength. For a prescribed accuracy, the complexity of (1) depends on the value of K because the wavelength is equal to one in our setup. In many practical applications, K is usually equal to a few hundred or even thousand. Assuming that the boundary surface in $\mathbb{R}^3$ is discretized with a fixed number of points per wavelength, the number of samples N is of order $O(K^2)$. Second, since the unknown field is supported only on the boundary in a BIE formulation, the points $\{p_i\}$ are samples of a two dimensional manifold. Consequently, the distribution of $\{p_i\}$ is highly nonuniform.

We would like to point out that, though the discussion in this paper mainly focuses on the Helmholtz kernel, our approach is quite general. Since many PDE kernels (e.g. the Green's functions of the time-harmonic Maxwell equations [21] and the linear elasticity equation [36]) are basically derivatives of the Helmholtz kernel, our algorithm can be readily extended to address these cases.

1.1. Previous work. Direct computation of (1) requires $O(N^2)$ operations, which can be intolerably slow for large values of N. During the last few decades, much attention has been devoted to the development of algorithms which evaluate (1) efficiently without compromising accuracy. An early class of algorithms (for example, [7, 8]) use the fast Fourier transform (FFT) by exploiting the fact that the kernel is translation invariant, and hence can be diagonalized through Fourier transform. Though quite efficient for uniformly distributed point sets, they require $O(N^{3/2} \log N)$ complexity in both computation time and storage space for a point set sampled from a two dimensional manifold. This poses a difficulty for large scattering problems. A recent improvement in [12] addresses this issue by using plane densities to reduce the sizes of the required FFTs.

The second class of algorithms (see for example [1, 3, 6, 10, 16]) discretize the boundary integral equations using the Galerkin approximation with either local Fourier bases or wavelet bases as the approximation space. The resulting discrete systems often become approximately sparse in the sense that a majority of the entries are close to zero with these bases. Such approaches have been shown to offer good theoretical estimates. However, constructing the remaining non-negligible entries both efficiently and accurately is non-trivial.

The third, and probably most popular, class of algorithms are the fast multipole methods (FMMs). The original FMM (see for example [17, 32, 34]) was developed for the kernel of the Laplace equation, and it evaluates the N-body problem in $O(N)$ operations for any fixed accuracy. Its success hinges on the observation that the interaction via the kernel between well-separated sets of points is approximately of low rank. Many other related developments, such as the panel clustering method [35], the H-matrix framework [9] and the interpolation techniques [11], are based on the same observation. In the low frequency regime where K is close to 1, this low rank property still holds for the Helmholtz kernel and the FMM for the Laplace equation can be applied to our problem with slight modifications (see [33]). In the high frequency regime where K is much larger than 1, the situation is however drastically different as the low rank assumption is not valid any more. In fact, the approximate rank of the interaction grows linearly with the size of the point sets (in terms of the wavelength). However, Rokhlin [42, 43] observed that the interaction between well-

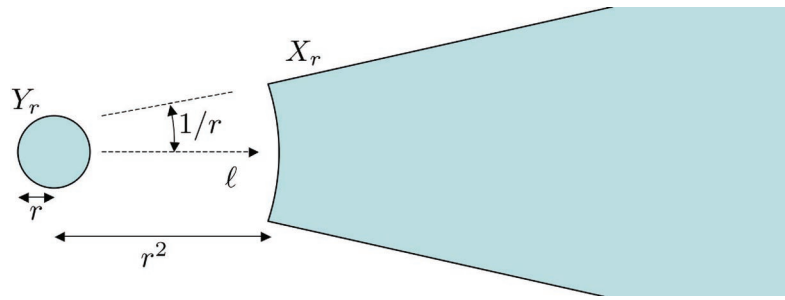

FIG. 1. *Two sets Y_r and X_r which satisfy the directional parabolic separation condition.*

separated point sets, though of large rank, can be applied efficiently by focusing on the far field signature of the potentials. In some sense, this is analogous to the fast Fourier transform. Even if the matrix is dense and of full rank, it can be applied efficiently in almost linear time. The resulting algorithm in the high frequency regime, often named HF-FMM, has $O(N \log N)$ complexity for a given accuracy. Though efficient and accurate, this algorithm is highly technical. It utilizes a large family of tools, such as partial wave expansion, far field signature, exponential expansion, filtering, and interpolation of spherical harmonics (see [37]). Many of these techniques have been developed only recently, and some of them solely for the purpose of the HF-FMM. Good descriptions of the HF-FMM include [18, 27, 41]. Other algorithms using similar techniques are given in [20, 23, 24, 45].

In [40], Michielssen and Boag proposed an interesting development called multilevel matrix decomposition. Their algorithm utilizes the idea of equivalent density, which also serves as the basis of the approaches in [2, 47], and it plays an important role in this paper. Even if their algorithm may not be as efficient as the HF-FMM, its three stage multiplication algorithm is ingenious and reminds one of the FFT.

1.2. Contribution and significance. In this paper, we propose a new directional multilevel algorithm that has $O(N \log N)$ complexity for a given accuracy. The starting point of our approach is a geometric consideration. Suppose Y_r is a ball of radius r centered at a point c, and X_r is the set of all points which are at a distance r^2 or greater from the origin and belong to a cone centered at c with spanning angle $1/r$ (see Figure 1 for an illustration). Whenever two sets Y_r and X_r obey this geometric configuration, we say that Y_r and X_r satisfy the *directional parabolic separation condition*.

At the heart of our algorithm is a *directional low rank property* which states that the interaction between Y_r and X_r via the Helmholtz kernel $G(x, y)$ is approximately of low rank for any fixed accuracy, and more importantly, the rank has an upper bound that is independent of r. To be more precise, the directional low rank property guarantees the following *directional separated representation* which is valid for any $x \in X_r$ and $y \in Y_r$:

$$\left| G(x,y) - \sum_{i=1}^{T(\varepsilon)} \alpha_i(x)\beta_i(y) \right| < \varepsilon$$

where ε is the prescribed accuracy, $T(\varepsilon)$ is a constant which depends only on ε (not on r), and $\{\alpha_i(x)\}$ and $\{\beta_i(y)\}$ are functions of x and y respectively.

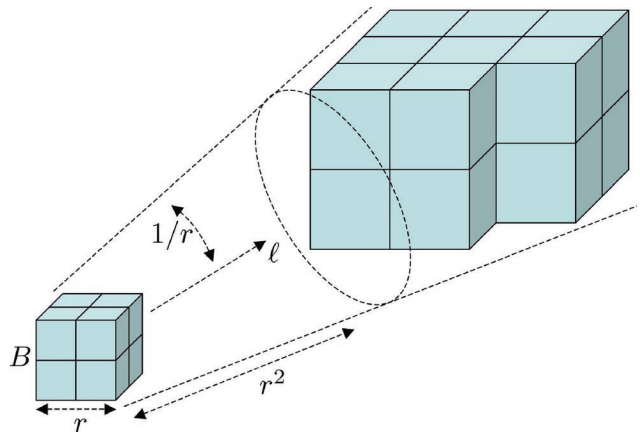

FIG. 2. *For each box B, its far field is partitioned into multiple wedges. Our algorithm constructs one low rank separated representation for each wedge. Each resulting representation can be used to accelerate the interaction computation between B and all the boxes in that wedge.*

The second contribution of this paper is to introduce a randomized procedure for generating the directional separated representation $\{\alpha_i(x)\}$ and $\{\beta_i(x)\}$ for the interaction between X_r and Y_r. This procedure only uses kernel evaluations and stable numerical routines such as the singular value decomposition (SVD) and the QR factorization. The resulting representation allows highly efficient computation of the interaction between sets like X_r and Y_r, and moreover, it can be stored in an economic way.

Our algorithm starts by partitioning the domain recursively using an octree, which is similar to the standard FMM. The top part of the octree that contains the boxes with widths greater than or equal to 1 is called the high frequency regime, while the bottom part that contains the boxes with widths less than 1 is called the low frequency regime. In the low frequency regime, the interactions are computed using the kernel independent FMM [47], which is a variant of the standard FMM. In the high frequency region, the computation is organized in a multidirectional way. For a given box B, all the boxes well separated from it are partitioned into a group of wedges, where each wedge and the box itself follow the directional parabolic separation condition (see Figure 2). The randomized procedure mentioned above is then used repetitively to construct multiple low rank representations about B, one for each wedge. As a result, the calculation of the interactions between B and all the boxes in a specific wedge can be accelerated using the low rank representation associated with this wedge. This framework is repeated recursively at all levels in the high frequency regime to achieve maximum efficiency.

Our directional multilevel algorithm has the following properties. First, it is highly efficient and accurate. A careful complexity analysis shows that, for a finite point set on a two dimensional manifold, our algorithm uses $O(N \log N)$ operations, which is the same as the complexity of the HF-FMM. Second, our algorithm is less technical than the HF-FMM as it uses no analytic expansions and translations. The computational steps of our algorithm only involve kernel evaluation and stable linear algebra routines. Finally, our algorithm works for more general oscillatory kernels as well (see the numerical results in section 5).

This paper is organized as follows. In section 2, we prove the directional low rank property. Following that, we describe the randomized procedure for generating

a directional low rank separated representations in section 3. Our main algorithm is presented in detail in section 4 where also its computational complexity is analyzed. After reporting the numerical results in section 5, we give conclusions and suggestions for future work in section 6.

2. Directional low rank property. In this section, we prove the main theoretical result of this paper: the directional low rank property. Suppose $r \geq \sqrt{3}$ and let

$$Y_r = B(0,r) \quad \text{and} \quad X_r = \{x : \theta(x,\ell) \leq 1/r, |x| \geq r^2\} \tag{2}$$

where ℓ is a given unit vector and $\theta(a,b)$ is the spanning angle between vectors a and b. The geometric relationship between Y_r and X_r is illustrated in Figure 1.

DEFINITION 2.1. *Let $f(x,y)$ be a function for $x \in X$ and $y \in Y$. We say $f(x,y)$ has a T-term ε-expansion for X and Y if there exist functions $\{\alpha_i(x), 1 \leq i \leq T\}$ and $\{\beta_i(y), 1 \leq i \leq T\}$ such that*

$$\left| f(x,y) - \sum_{i=1}^{T} \alpha_i(x)\beta_i(y) \right| \leq \varepsilon$$

for all $x \in X$ and $y \in Y$.

The importance of this definition is that $\{\alpha_i(x)\}$ and $\{\beta_i(y)\}$ depend only on x and y respectively. Expansions of this type are called *separated*. The following theorem is a precise statement of the directional low rank property.

THEOREM 2.2. *For any $\varepsilon > 0$, there exists a number $T(\varepsilon)$ which is independent of r such that $e^{2\pi\imath|x-y|}/|x-y|$ has a $T(\varepsilon)$-term ε-expansion for any X_r and Y_r satisfying* (2).

Results similar to Theorem 2.2 have been discovered before by researchers from applied physics and electric engineering [13, 29, 40]. Their proofs involve special functions such as spherical harmonics and Bessel functions, and give much sharper estimates on the number of terms in the expansion. We believe that our proof in the rest of this section is still of theoretical interest since one can easily adapt it to show similar results for other oscillatory kernels such as $e^{2\pi\imath|x-y|}$. The numerical results in section 5 validate this assertion.

Our proof of Theorem 2.2 is based on the following lemmas.

LEMMA 2.3. *For any $\varepsilon > 0$, there exists a number $T(\varepsilon)$ which is independent of r such that $|x-y|$ has a $T(\varepsilon)$-term ε-expansion for X_r and Y_r.*

Proof. Let us write

$$|x-y| = |x| \cdot f(y/|x|)$$

where $f(p) = |\hat{x}-p|$ and $\hat{x}$ is the unit direction $x/|x|$. Here we suppress the dependence of f on $\hat{x}$. Taylor expansion of f at $p=0$ gives

$$f(p) = \sum_{d=0}^{\infty} \left[\sum_{|\alpha|=d} \frac{f^{(\alpha)}(0)}{\alpha!} p^{\alpha} \right]$$

where α is a multiindex. For any $d \geq 0$, we use $f_d(p)$ to denote the quantity in the square bracket. The series $\sum_{d=0}^{\infty} f_d(p)$ is a convergent series with radius 1. This implies that for any η with $\eta \geq 1$ there exists an integer $D_1(\eta)$ such that $f_d(p) \leq (\eta|p|)^d$ for every $d \geq D_1(\eta)$. We assume, without loss of generality, that $\eta \leq 1.1$.

We argue that there exists a number $D(\varepsilon)$ such that

$$|x| \cdot f_{D(\varepsilon)}(y/|x|) \le \varepsilon.$$

To show this, it is sufficient to find an integer d such that $|x| \cdot (\eta \cdot |y|/|x|)^d \le \varepsilon$. Notice that for $d \ge 2$, $|x| \cdot (\eta \cdot |y|/|x|)^d$ is a decreasing function of $|x|$. Therefore, the function reaches its maximum value when $|x| = r^2$. Since $|y| \le r$,

$$|x| \cdot \left(\eta \cdot \frac{|y|}{|x|}\right)^d \le r^2 \cdot \left(\frac{\eta}{r}\right)^d = \frac{\eta^d}{r^{d-2}} \le \frac{\eta^d}{\sqrt{3}^{d-2}}.$$

Since we have assumed that $\eta \le 1.1$, it is obvious that there exists a $D^2(\eta, \varepsilon)$ such that for any $d \ge D^2(\eta, \varepsilon)$ we have $\eta^d/\sqrt{3}^{d-2} \le \varepsilon$. Therefore, setting $D(\varepsilon) = \max(2, D^1(\eta), D^2(\eta, \varepsilon))$ guarantees that

$$|x| \cdot \left(\eta \cdot \frac{|y|}{|x|}\right)^{D(\varepsilon)} \le \varepsilon.$$

Since the series $\{|x| \cdot (\eta \cdot |y|/|x|)^d : d \ge 0\}$ is geometric and $f_d(y/|x|) \le (\eta \cdot |y|/|x|)^d$, we have the following estimate

$$\sum_{d > D(\varepsilon)} |x| \cdot f_d(y/|x|) \le 4\varepsilon,$$

which is equivalent to

$$\left| |x - y| - \sum_{d=0}^{D(\varepsilon)} |x| \cdot f_d(y/|x|) \right| \le 4\varepsilon. \tag{3}$$

Notice that the number of terms $D(\varepsilon)$ is independent of $|x|$. In fact, it is independent of $\hat{x}$ as well since the kernel is rotation invariant.

Now, each term $f_d(y/|x|)$ can be written as

$$f_d(y/|x|) = \sum_{|\alpha|=d} \frac{f^{(\alpha)}(0)}{\alpha!} \cdot \frac{1}{|x|^{|d|}} \cdot y^\alpha \tag{4}$$

where $f^{(\alpha)}(0)$ depends on $\hat{x}$ implicitly. Since (4) is a separated representation,

$$\sum_{d > D(\varepsilon)} |x| \cdot f_d(y/|x|) \tag{5}$$

has a separated representation as well. Now suppose $T(\varepsilon)$ to be the total number of terms after the expansion of (5). Then (3) states that $|x - y|$ has a $T(\varepsilon)$-term 4ε-expansion. ∎

Similarly, we have the following lemma for the function $1/|x - y|$. In fact, the proof is simpler than the one of Lemma 2.3 because $1/|x - y|$ is bounded for $x \in X_r$ and $y \in Y_r$ for $r \ge \sqrt{3}$.

LEMMA 2.4. *For any $\varepsilon > 0$, there exists a number $T(\varepsilon)$ which is independent of r such that $1/|x - y|$ has a $T(\varepsilon)$-term ε-expansion for X_r and Y_r.*

COROLLARY 2.5. *For any $\varepsilon > 0$, there exists a number $T(\varepsilon)$ which is independent of r such that $|x-y| - \hat{x}\cdot(x-y)$ has a $T(\varepsilon)$-term ε-expansion for X_r and Y_r.*

Proof. Since $\hat{x}\cdot(x-y)$ has a 2-term 0-expansion

$$\hat{x}\cdot(x-y) = |x| - \hat{x}\cdot y,$$

the corollary follows from Lemma 2.3. ∎

The following lemmas show that certain functions are bounded by constants.

LEMMA 2.6. *There exists a constant G such that*

$$|(\hat{x}-\ell)\cdot y| \le G$$

and

$$||x-y| - \hat{x}\cdot(x-y)| \le G$$

for $x \in X_r$ and $y \in Y_r$.

Proof. For the first part, we observe

$$|(\hat{x}-\ell)\cdot y| \le |(\hat{x}-\ell)|\cdot|y| \le \theta(x,\ell)\cdot|y|.$$

From the definitions of X_r and Y_r, we have $|y| \le r$ and $\theta(x,\ell) \le 1/r$. Therefore,

$$|(\hat{x}-\ell)\cdot y| \le r\cdot\frac{1}{r} = 1.$$

For the second part, suppose that θ is the spanning angle between x and $x-y$. From the definitions of X_r and Y_r we have $\theta \le c_1\cdot r/|x-y|$, $|x-y| \ge c_2\cdot r^2$, $1-\cos(\theta) \le c_3\cdot\theta^2$ for constants c_1, c_2 and c_3. Therefore,

$$|x-y| - \hat{x}\cdot(x-y) = |x-y|\cdot(1-\cos(\theta)) \le c_3\cdot|x-y|\cdot\theta^2 \le c_3c_1^2\cdot\frac{r^2}{|x-y|} \le \frac{c_3c_1^2}{c_2}.$$

Setting $G = \max(1, c_3c_1^2/c_2)$ completes the proof. ∎

The next lemma, which is quite elementary, is concerned with the accuracy of the Taylor expansion of the exponential function. We reproduce the proof for completeness (see [14]).

LEMMA 2.7. *For any $Z > 0$ and $\varepsilon > 0$, let $N = \lceil \max(4e\pi Z, \log_2(1/\varepsilon))\rceil$. Then*

$$\left| e^{2\pi\imath x} - \sum_{k=0}^{N-1} \frac{(2\pi\imath x)^k}{k!} \right| \le \varepsilon$$

for any x with $|x| \le Z$.

Proof. Truncated Taylor expansion of $e^{2\pi\imath x}$ at the origin gives

$$e^{2\pi\imath x} = \sum_{k=0}^{N-1} \frac{(2\pi\imath x)^k}{k!} + \frac{(2\pi\imath\tilde{x})^N}{N!}$$

where $\tilde{x}$ lies between 0 and x. Since $|\tilde{x}| \le |x| \le Z$,

$$\left| e^{2\pi\imath x} - \sum_{k=0}^{N-1} \frac{(2\pi\imath x)^k}{k!} \right| \le \frac{(2\pi Z)^N}{N!}.$$

We use the Stirling formula to estimate the last quantity. Since $N! \geq (N/e)^N$,

$$\frac{(2\pi Z)^N}{N!} \leq \left(\frac{2\pi e Z}{N}\right)^N.$$

Now, as $N \geq \max(4e\pi Z, \log_2(1/\varepsilon))$,

$$\left(\frac{2\pi e Z}{N}\right)^N \leq \left(\frac{1}{2}\right)^{\log_2(1/\varepsilon)} = \varepsilon. \qquad \square$$

LEMMA 2.8. *Let $\varepsilon > 0$ and $\eta > 0$. Suppose that a function $f(x,y)$ has a $T^f(\varepsilon)$-term ε-expansion on X_r and Y_r, and $|f(x,y)| \leq B^f$. Suppose also that a function $g(x,y)$ has a $T^g(\eta)$-term η-expansion on X_r and Y_r, and $|g(x,y)| \leq B^g$. Then, $f(x,y) \cdot g(x,y)$ has a $T^f(\varepsilon) \cdot T^g(\eta)$-term $(B^g\varepsilon + B^f\eta + \varepsilon\eta)$-expansion.*

Proof. By assumption, there exist functions $\{\alpha_i^f(x)\}$ and $\{\beta_i^f(x)\}$ for $f(x,y)$ such that

$$\left| f(x,y) - \sum_{i=1}^{T^f(\varepsilon)} \alpha_i^f(x)\beta_i^f(y) \right| \leq \varepsilon.$$

Similarly, there exist functions $\{\alpha_i^g(x)\}$ and $\{\beta_i^g(x)\}$ for $g(x,y)$ such that

$$\left| g(x,y) - \sum_{i=1}^{T^g(\eta)} \alpha_i^g(x)\beta_i^g(y) \right| \leq \eta.$$

Consider two sets of functions $\{\alpha_i^f(x)\alpha_j^g(x) : 1 \leq i \leq T^f(\varepsilon), 1 \leq j \leq T^g(\eta)\}$ and $\{\beta_i^f(y)\beta_j^g(y) : 1 \leq i \leq T^f(\varepsilon), 1 \leq j \leq T^g(\eta)\}$, each containing $T^f(\varepsilon) \cdot T^g(\eta)$ terms.

$$\begin{aligned}
&\left| f(x,y)g(x,y) - \sum_{i,j} (\alpha_i^f(x)\alpha_j^g(x))(\beta_i^f(y)\beta_j^g(y)) \right| \\
&= \left| f(x,y)g(x,y) - \left(\sum_i \alpha_i^f(x)\beta_i^f(y)\right)\left(\sum_j \alpha_j^g(x)\beta_j^g(y)\right) \right| \\
&\leq \left| \left(f(x,y) - \left(\sum_i \alpha_i^f(x)\beta_i^f(y)\right)\right) g(x,y) \right| + \\
&\quad \left| \left(\sum_i \alpha_i^f(x)\beta_i^f(y)\right)\left(g(x,y) - \left(\sum_j \alpha_j^g(x)\beta_j^g(y)\right)\right) \right| \\
&\leq \varepsilon \cdot B^g + (B^f + \varepsilon) \cdot \eta \\
&= (B^g\varepsilon + B^f\eta + \varepsilon\eta). \qquad \square
\end{aligned}$$

We are now ready to prove Theorem 2.2.

Proof of Theorem 2.2. Without loss of generality, we make the assumption that $\varepsilon < 1$.

First, let us construct an expansion for $e^{2\pi\imath(|x-y| - \hat{x}\cdot(x-y))}$. From Corollary 2.5, $|x-y| - \hat{x} \cdot (x-y)$ has a $T^1(\varepsilon)$-term ε-expansion, i.e., there exist functions $\{\alpha_i^1(x)\}$

and $\{\beta_i^1(y)\}$ such that

$$\left|(|x-y| - \hat{x}\cdot(x-y)) - \sum_i \alpha_i^1(x)\beta_i^1(y)\right| \le C^1\varepsilon$$

Lemma 2.6 says that there exists a constant G such that

$$||x-y| - \hat{x}\cdot(x-y)| \le G,$$

which implies

$$\left|\sum_i \alpha_i^1(x)\beta_i^1(y)\right| \le G+\varepsilon.$$

Applying Lemma 2.7 with $Z = G+\varepsilon$ and $N^1(\varepsilon) = \lceil \max(4e\pi(G+\varepsilon), \log_2(1/\varepsilon))\rceil$ gives

$$\left|e^{2\pi\imath\sum_i \alpha_i^1(x)\beta_i^1(y)} - \sum_{k=0}^{N^1(\varepsilon)-1} \frac{(2\pi\imath)^k}{k!}\left(\sum_i \alpha_i^1(x)\beta_i^1(y)\right)^k\right| \le \varepsilon.$$

Expanding the $\left(\sum_i \alpha_i^1(x)\beta_i^1(y)\right)^k$ terms and absorbing the coefficients $\frac{(2\pi\imath)^k}{k!}$, we find that there exists a number $T^2(\varepsilon)$ and two sets of functions $\{\alpha_i^2(x)\}$ and $\{\beta_i^2(y)\}$ such that

$$\left|e^{2\pi\imath\sum_i \alpha_i^1(x)\beta_i^1(y)} - \sum_{i=0}^{T^2(\varepsilon)} \alpha_i^2(x)\beta_i^2(y)\right| \le \varepsilon,$$

or equivalently, that $e^{2\pi\imath\sum_i \alpha_i^1(x)\beta_i^1(y)}$ has a $T^2(\varepsilon)$-term ε-expansion. Since

$$\begin{aligned}\left|e^{2\pi\imath(|x-y|-\hat{x}\cdot(x-y))} - e^{2\pi\imath\sum_i \alpha_i^1(x)\beta_i^1(y)}\right| &\le 2\pi\left|(|x-y| - \hat{x}\cdot(x-y)) - \sum_i \alpha_i^1(x)\beta_i^1(y)\right| \\ &\le 2\pi\varepsilon,\end{aligned}$$

it is obvious that $e^{2\pi\imath(|x-y|-\hat{x}\cdot(x-y))}$ has a $T^2(\varepsilon)$-term $(2\pi+1)\varepsilon$-expansion

$$\left|e^{2\pi\imath(|x-y|-\hat{x}\cdot(x-y))} - \sum_{i=0}^{T^2(\varepsilon)} \alpha_i^2(x)\beta_i^2(y)\right| \le (2\pi+1)\varepsilon. \tag{6}$$

Second, we consider the term $e^{2\pi\imath\hat{x}\cdot(x-y)}$. From Lemma 2.6, we know that there exists a constant G such that $|(\hat{x}-\ell)\cdot y| \le G$. Now applying Lemma 2.7 again with $Z = G$ and $N^3(\varepsilon) = \lceil \max(4e\pi G, \log_2(1/\varepsilon))\rceil$ gives

$$\left|e^{2\pi\imath(\hat{x}-\ell)\cdot y} - \sum_{k=0}^{N^3(\varepsilon)-1} \frac{(2\pi\imath)^k}{k!}((\hat{x}-\ell)\cdot y)^k\right| \le \varepsilon.$$

Expanding the $((\hat{x}-\ell)\cdot y)^k$ terms for all k and absorbing the coefficients $\frac{(2\pi\imath)^k}{k!}$, we have the expansion

$$\left|e^{2\pi\imath(\hat{x}-\ell)\cdot y} - \sum_{i=0}^{T^3(\varepsilon)} \alpha_i^3(x)\beta_i^3(y)\right| \le \varepsilon,$$

where $T^3(\varepsilon)$ is an ε-dependent integer and $\{\alpha_i^3(x)\}$ and $\{\beta_i^3(y)\}$ are two sets of functions. That is to say, $e^{2\pi\imath(\hat{x}-\ell)\cdot y}$ has a $T^3(\varepsilon)$-term ε-expansion. Now exponentiating the identity

$$\hat{x}\cdot(x-y) = |x| - (\hat{x}-\ell)\cdot y - \ell\cdot y$$

gives

$$e^{2\pi\imath\hat{x}\cdot(x-y)} = e^{2\pi\imath|x|}\cdot e^{-2\pi\imath(\hat{x}-\ell)\cdot y}\cdot e^{-2\pi\imath\ell\cdot y}.$$

Then it is obvious that $e^{2\pi\imath\hat{x}\cdot(x-y)}$ has a $T^4(\varepsilon)$-term ε-expansion

$$\left| e^{2\pi\imath\hat{x}\cdot(x-y)} - \sum_{i=0}^{T^4(\varepsilon)} \alpha_i^4(x)\beta_i^4(y) \right| \le \varepsilon, \tag{7}$$

with $T^4(\varepsilon) = T^3(\varepsilon)$ and the functions $\{\alpha_i^4(x)\}$ and $\{\beta_i^4(y)\}$ given by

$$\alpha_i^4(x) = e^{2\pi\imath|x|}\cdot\overline{\alpha_i^3(x)} \quad \text{and} \quad \beta_i^4(y) = e^{-2\pi\imath\ell\cdot y}\cdot\overline{\beta_i^3(y)}.$$

Next, Lemma 2.4 claims that $1/|x-y|$ has $T^5(\varepsilon)$-term ε expansion

$$\left| \frac{1}{|x-y|} - \sum_{i=0}^{T^5(\varepsilon)} \alpha_i^5(x)\beta_i^5(y) \right| \le \varepsilon \tag{8}$$

with functions $\{\alpha_i^5(x)\}$ and $\{\beta_i^5(y)\}$.

Finally, since

$$\frac{e^{2\pi\imath|x-y|}}{|x-y|} = e^{2\pi\imath(|x-y|-\hat{x}\cdot(x-y))}\cdot e^{2\pi\imath\hat{x}\cdot(x-y)}\cdot\frac{1}{|x-y|},$$

applying Lemma 2.8 twice to the product of (6), (7) and (8) shows that $\frac{e^{2\pi\imath|x-y|}}{|x-y|}$ has a $(T^2(\varepsilon)\cdot T^4(\varepsilon)\cdot T^5(\varepsilon))$-term $(12\pi+10)\varepsilon$-expansion. Here we use the facts that

$$\left|e^{2\pi\imath(|x-y|-\hat{x}\cdot(x-y))}\right| < 1, \quad \left|e^{2\pi\imath\hat{x}\cdot(x-y)}\right| < 1 \quad \text{and} \quad \left|\frac{1}{|x-y|}\right| < 2$$

for $x \in X_r$ and $y \in Y_r$ along with the assumption that $\varepsilon < 1$. □

The message of Theorem 2.2 is that, for a fixed ε, the number of terms in an ε-expansion is independent of r, as long as X_r and Y_r satisfy the directional parabolic separation condition, i.e., X_r belongs to a cone with spanning angle $1/r$ and it is an order $O(r^2)$ distance away from Y_r.

The proof given above is not optimal in the sense that $(T^2(\varepsilon)\cdot T^4(\varepsilon)\cdot T^5(\varepsilon))$, the bound of the number of terms in the expansion, can be fairly large. In practice, numerical results show that the actual number of terms grows linearly with $\log(1/\varepsilon)$, see section 5.1.

So far in Theorem 2.2, we have assumed that Y_r is centered at the origin. However, as we have noticed in the proof, what is really important is the relative positions of the sets X_r and Y_r. Since the kernel $e^{2\pi\imath|x-y|}/|x-y|$ is translation invariant, shifting X_r and Y_r together by a constant vector would not change the result of Theorem 2.2. We have also assumed ℓ to be a fixed direction and suppressed the dependence of

X_r on ℓ in our notations. However, all the estimates are independent of the specific choice of ℓ as the kernel $e^{2\pi\imath|x-y|}/|x-y|$ is rotation invariant. Suppose we define $F_r = \{x : |x| \geq r^2\}$. There exists a set of unit vectors $\{\ell\}$ of size $O(r^2)$ such that the union of the cones centered at $\{\ell \in L\}$ with spanning angle $1/r$ cover the whole space. Now let us define

$$X_r^\ell = \{x : \theta(x,\ell) \leq 1/r, |x| \geq r^2\}$$

for each ℓ. Clearly their union is equal to F_r. Applying Theorem 2.2 to each X_r^ℓ results in a different $T(\varepsilon)$-term ε-expansion for Y_r and X_r^ℓ. Even though the expansions are different from one X_r^ℓ to another, the bound $T(\varepsilon)$ on the number of terms is independent of ℓ.

3. Randomized construction of separated representation. The expansion for two sets X_r^ℓ and Y_r introduced in section 2 is a directional separated representation. It is directional since for a given direction ℓ the expansion is valid only for X_r^ℓ that belongs to a directional cone. It is separated since the two sets of functions $\{\alpha_i(x)\}$ and $\{\beta_i(y)\}$ depend only on x and y respectively. The proof of Theorem 2.2 is constructive in the sense that it provides a way to compute the functions $\{\alpha_i(x)\}$ and $\{\beta_i(y)\}$. However, the number of terms in the resulting expansion can be fairly large. In this section, we introduce a procedure which in practice gives expansions with very few terms. This procedure is accurate, efficient and based on random sampling.

In the rest of this section, r and ℓ are not explicitly included in the notation. Our randomized procedure consists of the following steps:

1. Sample Y randomly and densely to obtain a set of samples $\{y_i\}$. By densely, we mean a couple of samples per wavelength. Similarly, sample X to obtain a set of samples $\{x_i\}$. Suppose the numbers of samples in each set are respectively N_y and N_x. Since our problem is confined to a ball of radius $K/2$ where K is the number of wavelengths, there is no reason to sample the part of X that is outside of this ball. As we allow a constant number of samples per wavelength, $N_y = O(vol(Y)) = O(K^{1.5})$. Similarly, $N_x = O(vol(X \cap B(0,K))) = O(K^2)$. Let A be the N_x by N_y matrix defined by

$$A_{ij} = e^{2\pi\imath|x_i-y_j|}/|x_i-y_j|$$

for $1 \leq i \leq N_x$ and $1 \leq j \leq N_y$. In the language of linear algebra, Theorem 2.2 states that A can be factorized, within error $O(\varepsilon)$, into the product of two matrices, the first of size N_x by $T(\varepsilon)$ and the second of size $T(\varepsilon)$ by N_y. In the next few steps, we construct such a factorization.

2. Let A_1 be the submatrix of A containing a set of N_1 randomly selected columns. Here N_1 is set to be a constant multiple of $T(\varepsilon)$. After obtaining the pivoted QR factorization of A_1, we have the decomposition

$$A_1 P_1 = Q_1 R_1$$

where P_1 is a permutation matrix, Q_1 is orthonormal and R_1 is upper triangular. Now, identify the diagonal elements of R_1 which are less than ε and truncate the associated columns of Q_1 and rows of R_1. Denote the resulting matrices by Q_c and R_c. Since A_1, as a submatrix of A, has an approximate factorization of $T(\varepsilon)$, in practice the matrix Q_c has only $O(T(\varepsilon))$ columns after truncation. It is clear from the algorithm of the pivoted QR factorization

that the new matrices Q_c and R_c satisfy the relationship

$$Q_c R_c = A_c$$

where A_c is the submatrix containing the columns of A from which the matrix Q_c is generated. The samples (of Y) associated with these columns are denoted $\{y_i^c\}$. In practice, the columns of Q_c approximately span the column space of A (not just A_1), producing an $O(\varepsilon)$ error with overwhelming probability.

3. Let A_2 be a submatrix of A containing a set of N_2 randomly selected rows. Here N_2 is again set to be a constant multiple of $T(\varepsilon)$. Repeat the previous step on A_2^*. As a result, we have two matrices Q_r and R_r. Q_r is orthonormal and has $O(T(\varepsilon))$ columns again, while R_r is upper triangular. They satisfy the relationship

$$R_r^* Q_r^* = A_r$$

where A_r is a submatrix containing appropriate rows of A. We denote the samples (of X) associated with these rows by $\{x_i^c\}$. Similar to the previous step, the rows of Q_r^* approximately span the row space of A (not just A_2), producing an $O(\varepsilon)$ error with overwhelming probability.

4. Since Q_c and Q_r^* span, respectively, the column and the row spaces of A with error $O(\varepsilon)$, the matrix $M = Q_c^* A Q_r$ satisfies the relationship

$$|A - Q_c M Q_r^*| = O(\varepsilon). \tag{9}$$

Notice that $Q_c M$ and Q_r^* already provide us with a factorization of the matrix A with error $O(\varepsilon)$. However, since A is huge, computing $M = Q_c^* A Q_r$ can be very costly. To this end, we propose the following alternative. We randomly pick a set S of N_s rows and a set T of N_t columns. Set A_3 to be the minor containing the elements from rows in S and columns in T, $Q_{c,S}$ to be the submatrix of Q_c containing the rows in S, and $Q_{r,T}^*$ to be the submatrix of ${Q_r}^*$ containing the columns in T. Now the constraint (9) restricted to S and T becomes

$$\left|A_3 - Q_{c,S} M Q_{r,T}^*\right| = O(\varepsilon).$$

To satisfy this constraint, we choose

$$M = (Q_{c,S})^+ A (Q_{r,T}^*)^+ \tag{10}$$

where $(\ )^+$ stands for pseudo-inverse. In practice, we pick N_s and N_t to be about ten times $T(\varepsilon)$.

5. We claim that

$$|A - Q_c M Q_r^*| = O(\varepsilon).$$

Moreover, since $Q_c R_c = A_c$ and $R_r^* Q_r^* = A_r$, we have

$$\left|A - A_c \cdot (R_c)^+ \cdot M \cdot (R_r^*)^+ \cdot A_r\right| = O(\varepsilon).$$

Let us define D to be the matrix $(R_c)^+ \cdot M \cdot (R_r^*)^+$ sandwiched between A_c and A_r. We then have the approximation

$$\left|A - A_c \cdot D \cdot (R_r^*)^+ \cdot A_r\right| = O(\varepsilon). \tag{11}$$

(11) is often called a pseudoskeleton approximation of A in the literature (see [30, 31]). Notice that the matrix D has only $O(T(\varepsilon))$ rows and columns. Denoting the entries of D by d_{pq}, we can rewrite the previous statement in the form

$$\left| \frac{e^{2\pi\imath|x_i-y_j|}}{|x_i-y_j|} - \sum_{p,q} \frac{e^{2\pi\imath|x_i-y_p^c|}}{|x_i-y_p^c|} \cdot d_{pq} \cdot \frac{e^{2\pi\imath|x_q^c-y_j|}}{|x_q^c-y_j|} \right| = O(\varepsilon)$$

for all x_i and y_j.

6. Finally, since $\{x_i\}$ and $\{y_j\}$ sample the sets X and Y with a constant number of points per wavelength, it is reasonable to expect

$$\left| \frac{e^{2\pi\imath|x-y|}}{|x-y|} - \sum_{p,q} \frac{e^{2\pi\imath|x-y_p^c|}}{|x-y_p^c|} \cdot d_{pq} \cdot \frac{e^{2\pi\imath|x_q^c-y|}}{|x_q^c-y|} \right| = O(\varepsilon) \tag{12}$$

for any $x \in X \cap B(0,K)$ and $y \in Y$.

In (12), both $e^{2\pi\imath|x-y_p^c|}/|x-y_p^c|$ and $e^{2\pi\imath|x_q^c-y|}/|x_q^c-y|$ can be computed directly from the kernel formulae. Therefore, the only quantities that must be stored for (12) are the locations $\{x_q^c\}$ and $\{y_p^c\}$ and the matrix D. This costs only $O(1)$ in storage for a fixed error threshold ε. In fact, for the Helmholtz kernel, one only needs to sample the boundary of the domains X and Y densely in the first step. This improvement, which is due to the uniqueness and existence properties of the Dirichlet boundary value problem of the Helmholtz equation, significantly reduces the computational complexity of our randomized procedure.

The randomized procedure presented here benefits from the existing approaches for constructing low rank separated approximations. Kapur and Long [38] were among the first to use the idea of random sampling to construct low rank representation for electrostatic interaction. The adaptive cross approximation (ACA) by Bebendorf and Rjasanow [4, 5] constructs the approximation in an incremental way. Recently, it has been combined with the H-matrix framework [9] to address several problems in BIE formulations, including the scattering problems in the low frequency regime [22]. The idea of random sampling has been carefully studied in a series of papers by Drineas, Kannan, and Mahoney [25, 26] for general matrices, and our approach shares some similarities with the LinearTimeCUR algorithm [26] proposed by these authors. In [14], a similar algorithm is used to speed up the numerical computation of the Fourier integral operator. Finally, we would like to mention a recent algorithm proposed by Martinsson, Rokhlin, and Tygert [39] which exploits the spectral properties of the Gaussian random matrices and exhibits excellent numerical properties for matrices equipped with fast multiplication algorithms.

Our randomized procedure works well numerically. In section 5, we see that this procedure constructs low rank factorizations in a stable way for ε as small as 10^{-8}. The rank of the resulting factorization, i.e., the minimum of the cardinalities of the sets $\{y_p^c\}$ and $\{x_q^c\}$, is very close to the optimal rank obtained by factorizing A using an SVD.

In most of the cases, we do know the separation rank of A. Since the value of $T(\varepsilon)$ from Theorem 2.2 can be significantly larger than the true separation rank. Setting N_1 and N_2 to be a constant multiple of $T(\varepsilon)$ could be quite wasteful. In our implementation, we adopt the method proposed in [14]. The idea is to start with a relatively small value for N_1. If the columns of Q_c constructed from the second step fail to span the column space of A, we then double N_1 and repeat the second step

until the columns of Q_c span the column space of A within the prescribed error ε. The same strategy is applied to N_2 in the construction of Q_r^*. The time spent on the unsuccessful attempts is bounded by that of the final successful attempt due to the geometric growth rate.

Though we are not able to provide a rigorous proof for the accuracy of this randomized procedure, we argue that its success is based on the following observations:

- For fixed y, the kernel $e^{2\pi\imath|x-y|}/|x-y|$ is a wave-like function of x. The same is true if we fix x and regard $e^{2\pi\imath|x-y|}/|x-y|$ as a function of y. In fact, as verified by numerical computation, the row and column bases of the matrix A contain oscillatory vectors, each of which consists of sufficiently dense samples of an oscillatory function in R^3 with wavelength close to 1. In this regard, one may assume these oscillatory vectors to be the Fourier modes around the frequency 2π. Now, if the row basis contains the Fourier modes, the column vectors of A are incoherent mixtures of the vectors of the column basis. This incoherence property comes from the uncertainty principle between the Fourier and the (canonical) delta bases [15, 44]. As a result, sampling the columns of A with a moderate oversampling factor ensures that the selected vectors contain significant contributions from all of the vectors of the column basis. This is why we are able to construct the column basis of A in a stable way by observing only $N_1 = O(T(\varepsilon))$ of its vectors.
- As the vectors of Q_r are similar to the Fourier basis, the same incoherence property [15, 44] suggests that, as long as the number of rows in S is significantly larger than the number of columns of Q_r, the matrix $Q_{r,S}$ is not too far from an orthogonal matrix and thus has a small condition number. This allows us to invert $Q_{r,S}$ robustly and the same is true for $Q_{r,T}^*$. This allows us to recover M from (10) in a stable way.

In order to prepare for the discussion of our main algorithm in section 4, it is useful to introduce the following definitions. Suppose we have a set of densities $\{f_i\}$ located at points $\{b_i\}$ in Y. Using the representation obtained from the randomized procedure, we have

$$\left| \sum_i \frac{e^{2\pi\imath|x-b_i|}}{|x-b_i|} f_i - \sum_p \frac{e^{2\pi\imath|x-y_p^c|}}{|x-y_p^c|} \sum_q d_{pq} \sum_i \frac{e^{2\pi\imath|x_q^c-b_i|}}{|x_q^c-b_i|} f_i \right| = O(\varepsilon).$$

This states that we can place a set of densities

$$\left\{ \sum_q d_{pq} \sum_i \frac{e^{2\pi\imath|x_q^c-b_i|}}{|x_q^c-b_i|} f_i \right\} \tag{13}$$

at points $\{y_p^c\}$ in order to reproduce the potential generated by the densities $\{f_i\}$ located at points $\{b_i\}$. To this end, the densities in (13) are called the *directional outgoing equivalent densities* of Y in direction ℓ, and the points $\{y_p^c\}$ are called the *directional outgoing equivalent points* of Y in direction ℓ. Here the word outgoing refers to the role of Y in the computation. In addition, we refer to the quantities

$$\left\{ \sum_i \frac{e^{2\pi\imath|x_q^c-b_i|}}{|x_q^c-b_i|} f_i \right\} \tag{14}$$

as the *directional outgoing check potentials* of Y in direction ℓ and the points $\{x_q^c\}$ as the *directional outgoing check points* of Y in direction ℓ.

Notice that in (14) the directional outgoing check potentials can be computed using only kernel evaluation. In addition, as long as one has precomputed the matrix $D = (d_{pq})$, the directional outgoing equivalent densities can be evaluated using a single matrix vector multiplication (i.e., (13)).

Now, let us reverse the situation. Suppose we have a set of densities $\{f_i\}$ located at points $\{a_i\}$ in X so that

$$\left| \sum_i \frac{e^{2\pi\imath|y-a_i|}}{|y-a_i|} f_i - \sum_q \frac{e^{2\pi\imath|y-x_q^c|}}{|y-x_q^c|} \sum_p d_{pq} \sum_i \frac{e^{2\pi\imath|y_p^c-a_i|}}{|y_p^c-a_i|} f_i \right| = O(\varepsilon).$$

This states that we can put a set of densities

$$\left\{ \sum_p d_{pq} \sum_i \frac{e^{2\pi\imath|y_p^c-a_i|}}{|y_p^c-a_i|} f_i \right\} \tag{15}$$

at points $\{x_q^c\}$ and they reproduce the potential generated by the densities $\{f_i\}$ located at points $\{a_i\}$. Therefore, we call the densities in (15) the *directional incoming equivalent densities* of Y in direction ℓ and the locations $\{x_q^c\}$ the *directional incoming equivalent points* of Y in direction ℓ. In analogy to the previous terminology,

$$\left\{ \sum_i \frac{e^{2\pi\imath|y_p^c-a_i|}}{|y_p^c-a_i|} f_i \right\} \tag{16}$$

are called the *directional incoming check potentials* of Y in direction ℓ and the location $\{y_p^c\}$ are called the *directional incoming check points* of Y in direction ℓ.

A couple of remarks are in order here. Let us fix the direction ℓ. Since the kernel $e^{2\pi\imath|x-y|}/|x-y|$ is translation invariant, the equivalent points and check points for a set centered at an arbitrary point can be obtained from those of the set centered at the origin by translation. However, the D matrix remains the same.

The kernel is also rotation invariant. For a fixed radius r, we only need to generate the equivalent points and check points for a fixed direction ℓ. These quantities for any other direction can be obtained by rotation.

4. Algorithm description. Based on the results in the previous section, we are ready to describe our new algorithm for the N-body problem with oscillatory kernels, i.e., the computation of

$$u_i = \sum_{j=1}^{N} G(p_i, p_j) \cdot f_j$$

for all $1 \le i \le N$. Without loss of generality, we assume that $K = 2^{2L}$ for a positive integer L.

4.1. Data structure. Similar to the HF-FMM, our main data structure is an octree. The top level box of width K contains all the points $\{p_i\}$. In the rest of this paper, B denotes a box in the octree and w for its width. We say a box B is in the low frequency regime if $w < 1$ and B is in the high frequency regime if $w \ge 1$.

In the high frequency regime of the octree, no adaptivity is used, i.e., every nonempty box is further partitioned until the width of the box is less than 1. In the low frequency regime, a box B is partitioned as long as the number of points in B is

greater than a fixed constant N_p. In practice, the value of N_p is chosen to optimize the computational complexity.

As we have mentioned already, an FMM algorithm for the Laplace kernel can be easily modified to handle the low frequency case. For a box B in the low frequency regime, its data structure follows the description of the kernel independent FMM in [47]. We modify the notation slightly to accommodate the discussion of the current algorithm.

- The near field N^B is the union of the boxes A that satisfies $dist(A, B) = 0$, where $dist(A, B) = \inf_{x\in A, y\in B} |x - y|$.
- The far field F^B is the complement of N^B.
- The interaction list I^B contains all the boxes in $N^P \backslash N^B$ on B's level, where P is the parent box of B.
- $\{y_k^{B,o}\}$, $\{f_k^{B,o}\}$, $\{x_k^{B,o}\}$ and $\{u_k^{B,o}\}$ are, respectively, the *outgoing* equivalent points, equivalent densities, check points, and check potentials.
- $\{y_k^{B,i}\}$, $\{f_k^{B,i}\}$, $\{x_k^{B,i}\}$ and $\{u_k^{B,i}\}$ are, respectively, the *incoming* equivalent points, equivalent densities, check points, and check potentials.

To simplify the notation, we have omitted the range of the running index k.

Now let us consider a box B in the high frequency regime. The following definitions vary slightly from their low frequency counterparts:

- The near field N^B is the union of all the boxes $\{A\}$ that satisfy $dist(A, B) \leq w^2$.
- The far field F^B is the complement of N^B.
- The interaction list I^B contains all the boxes in $N^P \backslash N^B$ on B's level, where P is B's parent box.

In light of the preceding sections, we need to partition F^B into a group of directional regions, each belonging to a cone with spanning angle $O(1/w)$. To achieve this, we first cut F^B into six pyramids: V_{1+}, V_{1-}, V_{2+}, V_{2-}, V_{3+} and V_{3-}. For example, V_{1+} contains all the points whose first coordinate is positive and greater than the absolute values of the second and third coordinates. The other pyramids are similarly defined. Let us define $C = 4w$. Each part is further partitioned into C^2 wedges. As an example, for each point $p = (p^1, p^2, p^3)$ in V_{1+}, we define

$$\theta(p) = \arctan(p^2/p^1) \quad \text{and} \quad \phi(p) = \arctan(p^3/p^1).$$

Notice $|\theta(p)| \leq \pi/4$ and $|\phi(p)| \leq \pi/4$ for $p \in V_{1+}$. The C^2 wedges of V_{1+} are

$$\left\{p : -\frac{\pi}{4} + \frac{\pi}{2C} i \leq \theta(p) \leq -\frac{\pi}{4} + \frac{\pi}{2C}(i+1), -\frac{\pi}{4} + \frac{\pi}{2C} j \leq \phi(p) \leq -\frac{\pi}{4} + \frac{\pi}{2C}(j+1)\right\}$$

for $0 \leq i < C$ and $0 \leq j < C$. Clearly, the spanning angle for each of these wedges is $O(1/w)$. The wedges for other pyramids are generated in the same way. In total, for a box B of width w, its far field F^B is partitioned into $96 \cdot w^2$ wedges. We index these wedges using their center directions $\{\ell\}$. In Figure 3, we illustrate how these wedges cut the unit sphere into $96 \cdot w^2$ pieces for $w = 1, 2, 4$.

This construction has the advantage of ensuring a hierarchical structure of the wedges across adjacent levels. Suppose $w \geq 2$. For any directional index ℓ of B, one can always find an index ℓ' of the box with width $w/2$ such that the ℓth wedge of B is contained in the ℓ'th wedge of each of B's children. On the other hand, these wedges are not isometric anymore, i.e., one cannot obtain any other wedges by applying a rotation to an existing wedge. This implies that the point sets $\{x_c^q\}$ and $\{y_c^p\}$ and the matrix D can be very different for different wedges, even though the algorithm

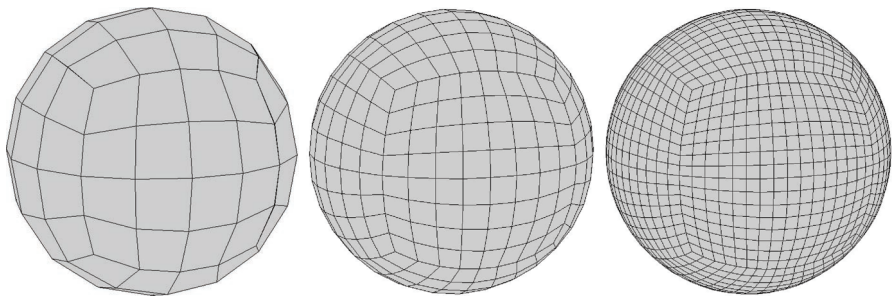

FIG. 3. *The wedges cut the unit sphere into* $96 \cdot w^2$ *pieces. From left to right,* $w = 1, 2, 4$.

used to construct them remains exactly the same. Fortunately, one does not need to construct the point sets $\{x_c^q\}$ and $\{y_c^p\}$ and the matrix D for each of these $96 \cdot w^2$ wedges due to a discrete isometric group acting on them. To be more precise, suppose one has a wedge with center direction $\ell = (\ell^1, \ell^2, \ell^3)$, then it is not difficult to see that we can obtain wedges centered along the following 48 directions through rotations:

$$(\pm\ell^1, \pm\ell^2, \pm\ell^3)(\pm\ell^2, \pm\ell^3, \pm\ell^1)(\pm\ell^3, \pm\ell^1, \pm\ell^2)$$
$$(\pm\ell^3, \pm\ell^2, \pm\ell^1)(\pm\ell^1, \pm\ell^3, \pm\ell^2)(\pm\ell^2, \pm\ell^1, \pm\ell^3).$$

Therefore, one is only required to compute the point sets $\{x_c^q\}$ and $\{y_c^p\}$ and the matrix D for about $2w^2$ wedges.

For each box B and each direction ℓ, we summarize the relevant quantities as follows:

- $\{y_k^{B,o,\ell}\}$, $\{f_k^{B,o,\ell}\}$, $\{x_k^{B,o,\ell}\}$, and $\{u_k^{B,o,\ell}\}$ are the *outgoing directional* equivalent points, equivalent densities, check points and check potentials respectively.
- $\{y_k^{B,i,\ell}\}$, $\{f_k^{B,i,\ell}\}$, $\{x_k^{B,i,\ell}\}$, and $\{u_k^{B,i,\ell}\}$ are the *incoming directional* equivalent points, equivalent densities, check points and check potentials respectively.

4.2. Translation operators. Similar to a standard FMM algorithm, our new algorithm utilizes several translation operators. The translation operators for boxes in the low frequency regime differs from those for boxes in the high frequency regime. Following tradition, we name these operators M2M translation, L2L translation, and L2L translation, though no multipole or local expansions are involved in our algorithm.

Low frequency regime. In the low frequency regime, the M2M, L2L, and M2L translations are exactly the same as the ones introduced in the kernel independent FMM. These operators are non-directional.

M2M operator. For a box B, the M2M operator constructs $\{f_k^{B,o}\}$, the box's outgoing non-directional equivalent densities. We start from a set of source densities, which are either the original densities in B if B is a leaf box or the union of the outgoing non-directional equivalent densities of B's children if B is not. In this procedure, we first calculate B's outgoing non-directional check potentials $\{u_k^{B,o}\}$ using kernel evaluation, and perform a matrix-vector multiplication to obtain $\{f_k^{B,o}\}$.

L2L operator. For a box B, the L2L operator starts with $\{u_k^{B,i}\}$, the box's incoming non-directional check potentials. It first constructs the incoming non-directional equivalent densities $\{f_k^{B,i}\}$ via a matrix-vector multiplication. The second step depends on whether B is a leaf box or not. If B is not a leaf, we evaluate the incoming

non-directional check potentials of B's children. If B is a leaf, then the potentials at the original points inside B are calculated.

M2L operator. The M2L operator works between two boxes A and B on the same level. A and B need to be on each other's interaction lists. The M2L operator transforms the outgoing non-directional equivalent densities of A to the incoming non-directional check potentials of B through kernel evaluation. This operator can be accelerated by the FFT as the kernel is translation invariant.

High frequency regime. The operators in the high frequency regime are more complicated. The main reason is that the computations are now directional.

M2M operator. For a box B in high frequency regime, the M2M operator constructs the outgoing directional equivalent densities of B from the outgoing equivalent densities of B's children. There are two cases to consider. In the first case, $w = 1$. The children boxes only have non-directional equivalent densities. The M2M operator iterates over all the directional indices $\{\ell\}$ of B and the steps for a fixed direction ℓ are:

1. Use $\bigcup_C \{y_k^{C,o}\}$ as source points in B and $\bigcup_C \{f_k^{C,o}\}$ as source densities. Here the union is taken over all the children boxes of B.
2. Compute $\{u_k^{B,o,\ell}\}$ at points $\{x_k^{B,o,\ell}\}$ with kernel evaluation and then obtain $\{f_k^{B,o,\ell}\}$ by multiplying $\{u_k^{B,o,\ell}\}$ with the matrix D associated with B and direction ℓ.

In the second case, $w > 1$. Now the children boxes have directional equivalent densities as well. The M2M operator again iterates over all the directional indices $\{\ell\}$ of B. The steps for a fixed direction ℓ are:

1. Pick ℓ', which is a direction associated with the boxes of width $w/2$, such that the wedge of B indexed by ℓ is contained in the wedge indexed by ℓ' of each of B's children. The existence of ℓ' is ensured by the way we partition F^r.
2. Use $\bigcup_C \{y_k^{C,o,\ell'}\}$ as source points in B and $\bigcup_C \{f_k^{C,o,\ell'}\}$ as source densities. Here the union is taken over all the children boxes of B.
3. Compute $\{u_k^{B,o,\ell}\}$ at $\{x_k^{B,o,\ell}\}$ with kernel evaluation and then obtain $\{f_k^{B,o,\ell}\}$ by multiplying $\{u_k^{B,o,\ell}\}$ with the matrix D associated with B and direction ℓ.

L2L operator. The L2L operator constructs the incoming check potentials of B's children from the incoming directional check potentials of B. Again there are two cases to consider. In the first case $w = 1$. The children boxes only have non-directional check potentials. The L2L operator iterates over all the directional indices $\{\ell\}$ of B and the steps for a fixed direction ℓ are:

1. Compute $\{f_k^{B,i,\ell}\}$ from $\{u_k^{B,i,\ell}\}$ by multiplying it with the appropriate D matrix.
2. For each child C of the box B, add to $\{u_k^{C,i}\}$ the potentials evaluated at $\{x_k^{C,i}\}$ using $\{f_k^{B,i,\ell}\}$ as the source densities at $\{y_k^{B,i,\ell}\}$.

In the second case, $w > 1$. Now the children boxes have directional equivalent densities. The L2L operator iterates over all the directional indices $\{\ell\}$ of B. The steps for a fixed direction ℓ are:

1. Pick ℓ', which is a direction associated with the boxes of width $w/2$, such that the wedge of B indexed by ℓ is contained in the wedge indexed by ℓ' of each of B's children. The existence of ℓ' is ensured by the way we partition F^r.
2. Compute $\{f_k^{B,i,\ell}\}$ from $\{u_k^{B,i,\ell}\}$ by multiplying it with the appropriate D matrix.
3. For each children C of the box B, add to $\{u_k^{C,i,\ell'}\}$ the potentials evaluated at $\{x_k^{C,i,\ell'}\}$ using $\{f_k^{B,i,\ell}\}$ as the source densities at $\{y_k^{B,i,\ell}\}$.

M2L operator. Finally, the M2L operator is applied to pairs of boxes A and B on the same level of the octree. They need to be on each other's interaction lists. Consider ℓ and ℓ' such that B falls into the wedge of A indexed by ℓ while A falls into the wedge of B indexed by ℓ'. The implementation of the M2L operator contains only one step:

1. Add to $\{u_k^{B,i,\ell'}\}$ the potentials evaluated at $\{x_k^{B,i,\ell'}\}$ using the densities $\{f_k^{A,o,\ell}\}$ at points $\{y_k^{A,o,\ell'}\}$.

To summarize the discussion on the transition operators, we would like to emphasize that all these operators involve only kernel evaluation and matrix-vector multiplication with precomputed matrices. Therefore, they are simple to implement and highly efficient.

4.3. Algorithm. Now we are ready to give the overall structure of our new algorithm. It contains the following steps.

1. Construct the octree. In the high frequency regime the boxes are partitioned uniformly. In the low frequency regime, a leaf box contains at most N_p points.
2. Travel up in the octree and visit the boxes in the low frequency regime. These boxes have width less than 1. For each box B, compute its outgoing non-directional equivalent densities $\{f_k^{B,o}\}$. This is done using the low frequency non-directional M2M operator.
3. Travel up in the octree and visit the boxes in the high frequency regime. For every such box B, use the high-frequency directional M2M operator to compute the outgoing directional equivalent densities $\{f_k^{B,o,\ell}\}$ for each outgoing direction ℓ. We skip the boxes with width greater than $\sqrt{K}$ since their interaction lists are empty.
4. Travel down in the octree and visit the boxes in the high frequency regime. For every such box B and for each direction ℓ, perform the following two steps:
   (a) Transform the outgoing directional equivalent densities $\{f_k^{A,o,\ell}\}$ of all the boxes $\{A\}$ in B's interaction list and in direction ℓ via the high-frequency directional M2L operator. Next, add the result to the incoming directional check potentials $\{u_k^{B,i,\ell}\}$.
   (b) Perform the high-frequency directional L2L operator to transform $\{u_k^{B,i,\ell}\}$ to the incoming check potentials for B's children.

   Again, we skip the boxes with width greater than $\sqrt{K}$.
5. Travel down in the octree. For every box B in the low frequency regime, we perform the following two steps:
   (a) Transform the outgoing non-directional equivalent densities $\{f_k^{A,o}\}$ of all the boxes $\{A\}$ in B's interaction list via the low frequency non-directional M2L operator. Next, add the result to the incoming non-directional check potentials $\{u_k^{B,i}\}$.
   (b) Perform the low frequency directional L2L operator. Depending on whether B is a leaf box or not, add the result to the incoming check potentials of B's children or to the potentials at the original points inside B.

An illustration of the various components of the algorithm is given in Figure 4.

In the description of the algorithm, we have assumed that the octree is full. This ensures that the M2L operator itself is sufficient to transform outgoing data to incoming data. When the octree is constructed adaptively, the situation is much more

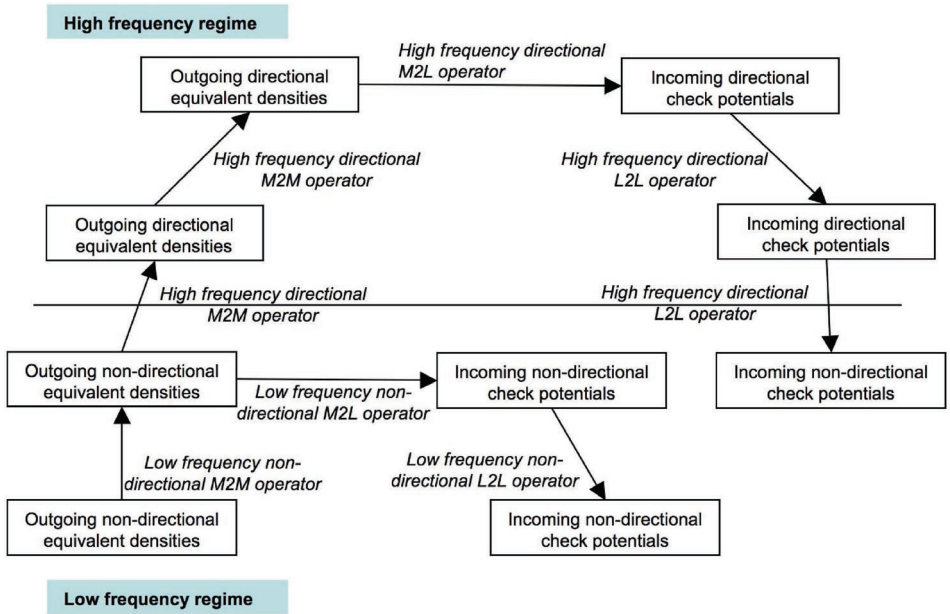

FIG. 4. *A small part of the octree used in the computation. Each rectangular region stands for a box of the octree. The diagram shows how the outgoing non-directional equivalent densities from a leaf box have been transformed into incoming non-directional check potentials at other leaf boxes. Far field interaction involves directional computation in the high frequency regime. The text in each box denotes the quantities involved, while the translation operators are shown in italics.*

complicated as one needs to keep the so-called U, V, W, and X lists for each box B in the low frequency regime. The necessary modifications to include this can be found in [19, 34, 47].

4.4. Complexity. We will now discuss the computational complexity of our algorithm assuming that the N points are sampled from a two dimensinoal surface. This assumption implies that $N = O(K^2)$ and it is generally satisfied for almost all applications which involve boundary integral formulations. In the following analysis, we use K as the main parameter because all the points $\{p_i\}$ satisfy $|p_i| \leq K/2$ by assumption.

THEOREM 4.1. *Let $\mathbb{S}$ be a surface in $B(0, 1/2)$. Suppose that for a fixed K, the points $\{p_i, 1 \leq i \leq N\}$ are samples of $K\mathbb{S}$, where $N = O(K^2)$ and $K\mathbb{S} = \{K \cdot p, p \in \mathbb{S}\}$ (the surface obtained by magnifying $\mathbb{S}$ by a factor of K). Then, for any prescribed accuracy, the proposed algorithm has a computational complexity $O(K^2 \log K) = O(N \log N)$.*

Outline of the proof. We analyze the number of operations for each major step of the algorithm.

- The first step of the algorithm has computational complexity $O(N) = O(K^2)$, due to the efficiency of the octree construction.
- The second step takes $O(N) = O(K^2)$ operations, as there are at most $O(N)$ boxes in the low frequency regime and each one involves a constant number of operations.
- We claim that the third step takes $O(N \log N)$ operations. To verify this, we first look at a single box of a fixed width w $(1 \leq w \leq \sqrt{K})$. Since there are

$O(w^2)$ directions $\{\ell\}$, the M2M operator for this box takes $O(w^2)$ operations. Next count the number of boxes of size w. Noticing that our points are discrete samples from a two dimensional manifold inside $B(0, K/2)$, it is not difficult to see that there are only $O(K^2/w^2)$ of them. This means that the overall complexity of the M2M operator for all the boxes of size w is $O(w^2 \cdot K^2/w^2) = O(K^2)$. Since we have totally $O(\log K)$ levels with $w = 1, 2, 4, \cdots, \sqrt{K}$, the complexity of this step is $O(K^2 \log K) = O(N \log N)$.

- We argue that the fourth step takes $O(N \log N)$ operations. The computation here contains two parts: the M2L operators and the L2L operators. The analysis for the L2L operators is exactly the same as the analysis of the third step, resulting an $O(N \log N)$ operation count. For the M2L operators, we know that, for a box B of width w, the boxes in its high frequency interaction list are approximately located in a ball centered at B with radius $(2w)^2$. Again, the fact that our points are samples from a two dimensional manifold implies that there are at most $O(w^4/w^2) = O(w^2)$ boxes in B's interaction list. Noticing that each M2L operator takes $O(1)$ operations and there are at most $O(K^2/w^2)$ boxes with width w, we conclude that overall complexity of the M2L operators for all the boxes of size w is $O(w^2 \cdot 1 \cdot K^2/w^2) = O(K^2)$. This further implies that the total number of the operations in the M2L operators is $O(K^2 \log K) = O(N \log N)$.
- Similar to the second step, the fifth step takes $O(N) = O(K^2)$ operations by the same argument.

Summing these contributions, we reach the conclusion that the total complexity is $O(N \log N)$, which is the same as the HF-FMM developed by Rokhlin and his collaborators (see, for example, [18]). □

5. Numerical results. In this section, we provide some numerical results to illustrate the properties of our new algorithm. Our implementation is written in C++ and all the computational results below are obtained on a desktop computer with a 3.0 GHz CPU. Due to the memory constraint, we restrict ourselves to problems which are at most 256 wavelengths (i.e., $K \leq 256$). The equivalent points, check points, and the related D matrices are precomputed for boxes with width $w = 1, 2, 4, 8$.

5.1. Separation rank. Let us first study the performance of the randomized procedure presented in section 3. In Table 1, we list the number of terms in the separated representation for two sets X_r and Y_r for different choices of accuracy ε and box width w. Here r is set to be $\sqrt{3}w$ so that the box of width w is contained in Y_r.

We can see from Table 1 that the separation rank is bounded by a constant which is independent of the values of w. This is consistent with our theoretical estimate in Theorem 2.2. In fact, as w grows, it seems that the separation rank decays slightly. The results also show that the separation rank seems to increase linearly with respect to $\log(1/\varepsilon)$. This is compatible with the results mentioned in [40].

TABLE 1

The separation rank of the directional separated representation for different choices of requested accuracy ε and box size w.

	$w = 1$	$w = 2$	$w = 4$	$w = 8$
ε=1e-4	45	45	45	45
ε=1e-6	85	82	81	81
ε=1e-8	121	114	113	111

The actual running time of the high frequency part of our algorithm depends on ε through the separation rank. In fact, the smaller ε, the larger the separation rank, and the longer the running time. As we pointed out already, the low frequency part of our algorithm is almost the same as the one described in [47]. For a prescribed value of ε, we need to choose a value for p, which is the size of the Cartesian grid used for the equivalent and check points. In our implementation, we pick $p = 4$ for ε =1e-4, $p = 6$ for ε=1e-6 and $p = 8$ for ε =1e-8.

5.2. Applications to different geometries. We applied our algorithm, with G being the Helmholtz kernel, to several objects. In our experiments, the surface of each object is represented by a triangular mesh. The point set $\{p_i\}$ is generated by sampling the triangular mesh randomly with 20 points per wavelength on average. This implies that the number of points is roughly 400 times the total surface area. Though these samples are far from optimal for a scattering application, they have the right distribution and are perfectly suitable for studying the performance of our algorithm.

In real applications, the actual sampling density often depends on the geometry of the surface. For example, one often places many more points in regions with large curvature. The result is to shift more computation towards the low frequency regime. Since the computation in the low frequency regime has lower complexity than the one for the high-frequency regime, our algorithm would generally perform better in these cases. Before reporting the results, let us summarize some relevant notations: N is the number of points, K is the size of the problem in terms of the wavelength, and ε is the prescribed error threshold such that the final error of is to be bounded by a constant multiple of ε.

In all experiments, the original densities $\{f_i\}$ are generated from a random distribution with mean 0. Use $\{u_i\}$ to denote the true potentials and $\{u_i^a\}$ to denote the approximations obtained through our algorithm. We estimate the relative error by picking a set S of 200 points from $\{p_i\}$. The true potentials $\{u_i, i \in S\}$ are computed by using direct evaluation. The error is then estimated to be

$$\sqrt{\frac{\sum_{i\in S} |u_i - u_i^a|^2}{\sum_{i\in S} |u_i|^2}}.$$

When reporting the numerical results, we use the following notations:

- T_a: the running time of our algorithm in seconds.
- T_d: the running time of the direct evaluation in seconds. This quantity is estimated by first calculating the time used for evaluating the true potentials at 200 points in S and then multiplying it by $N/200$.
- T_d/T_a: the speedup factor.
- ε_a: the error of our algorithm estimated using the method described above.

The first example is a sphere. The results are summarized in Table 2. The second example is a simplified model of an F16. The results are shown in Table 3. The final example is a submarine model. We summarize the computational results in Table 4.

From these tests, we can make the following observations about the performance of our algorithm:

- The running time scales roughly as $O(N \log N)$ in terms of the number of particles, matching well with the complexity analysis. In our implementation, most of the computation has been spent on computing $\{f_k^{B,o,\ell}\}$ and $\{u_k^{B,i,\ell}\}$ in steps 3 and 4(a) of the proposed algorithm (see section 4.3). The construction of one set of densities $\{f_k^{B,o,\ell}\}$ (or equivalently one set of potentials

TABLE 2

$\{u_k^{B,i,\ell}\}$) requires a couple of matrix multiplications, where the dimensions of the matrices involved are approximately equal to the separation rank. Since the complexity of each matrix multiplication is quadratic in the dimension of the matrix, the overall complexity of our algorithm scales quadratically in terms of the separation rank (see Table 1).

- For a fixed threshold ε, the final error of our directional multilevel algorithm seems to depend linearly on $\log_2 \sqrt{K}$, i.e., the number of levels in the octree. This is easy to understand: every time we compute the equivalent densities in a higher level, we introduce some extra error proportional to ε. Since $\log_2 K$ is a quite small number, for example $K = 256$ gives $\log_2 K = 8$, we still have very good control of the overall error.
- For objects on a fixed scale, our algorithm runs faster if the shape of an object is elongated. For example, the results on the submarine are better than the ones for the plane, which are better than the ones for the sphere. In other words, the algorithm prefers slender objects. The reason is quite simple: for an elongated object, the number of directions $\{\ell\}$ a box needs to address is much smaller than the number of directions for an isotropic object. In fact, the sphere seems to be the most difficult surface to work with.
- A close look at the breakdown of the computation time shows that the algorithm spends most of its time in the high frequency regime. This implies that for real problems where certain parts need sub-wavelength sampling, our algorithm would result a larger speedup factor compared with direct evaluation.

5.3. Generalization. As we have alluded, our algorithm works well for other oscillatory kernels as well. Here we provide some numerical results for the kernel,

$$e^{2\pi\imath|x-y|}.$$

For this kernel, the proof in section 2 remains essentially the same, and the only change is to remove the estimate on the $1/|x-y|$ term. The randomized procedure in section 3 requires no modification as it only relies on the fact that the kernel has a low rank separated representation. Hence, our algorithm remains exactly the same in the high frequency regime. The only modification concerns the low frequency boxes. Our implementation follows the discussion in [46] and we refer to that paper for the details.

In Table 5, we report the results for the sphere with this new kernel. In Table 6, the results of the F16 model are presented.

These results suggest that the overall error of our algorithm for this new kernel with stronger far field oscillations is larger than the error for the Helmholtz kernel. However, the running time still follows the $O(N \log N)$ complexity very closely.

6. Conclusions and future work. In this paper, we introduced a new directional multilevel algorithm for computing the N-body problem with highly oscillatory kernels, and applied it to a boundary integral formulation of the Helmholtz equation. Our algorithm is based on the following three main components:

- The directional low rank property, i.e., the interaction between two sets that follow the directional parabolic separation condition is approximately of low rank.
- A randomized procedure which efficiently and accurately constructs low rank, separated and stable representations.

- A multilevel and multidirectional strategy for organizing the overall computation. The fact that the high frequency part of our algorithm is not only multiscale but also multidirectional differs from the approach in the HF-FMM.

Our algorithm has been proved to have $O(N \log N)$ complexity and the numerical results show that it is also highly accurate. Furthermore, it can be adapted to handle kernels other than the Helmholtz kernel quite easily, which is not true for most other existing algorithms.

In future work, we plan to consider the following:

- It would be valuable to have a rigorous proof for the randomized procedure presented in section 3. The discussion presented here provides a possible outline of a proof.
- Currently, our implementation is capable of handling problems of up to about 256 wavelengths, however, many interesting scattering problems involve thousands of wavelengths. One solution is to design a parallel version of our algorithm. It is well-known that parallelizing standard FMMs is difficult since the top part of the octree is a bottleneck (see [48]). Fortunately, this bottleneck is alleviated by our algorithm, as we never visit the boxes of size greater than $\sqrt{K}$ wavelengths. A trivial implementation of partitioning the work at the level with boxes of size $\sqrt{K}$ would provide an appealing and practical solution.
- An FMM-type algorithm has been developed by Michielssen and his collaborators for time-domain scattering problems (see [20, 28]). It utilizes some of the techniques from the HF-FMM. It would be interesting to see whether our algorithm can be extended to handle time-domain problems.

Acknowledgments. The work presented in this paper is partially supported by startup funds of University of Texas at Austin. The authors thank R. Tsai and M. Tygert for stimulating discussions, L. Greengard, J. Qin, and R. Sharp for helping improve the manuscript, and the reviewers for their comments and suggestions.

A FAST SHADOWING ALGORITHM FOR HIGH-DIMENSIONAL ODE SYSTEMS*

WAYNE B. HAYES† AND KENNETH R. JACKSON‡

Abstract. Numerical solutions to chaotic dynamical systems are suspect because the exponential divergence of nearby trajectories causes numerical errors to be exponentially magnified with time. To bolster confidence in the reliability of such numerical solutions, we turn to the study of *shadowing:* a *shadow* is an exact trajectory of a chaotic dynamical system that stays close to a numerical trajectory for a long time. Finding shadows of numerical trajectories is very computationally intensive, and until recently it has been infeasible to study shadows of higher-dimensional systems. This paper introduces several optimizations to previous algorithms, which collectively achieve an average speedup of almost two orders of magnitude with no measurable loss in effectiveness. We test the algorithm on systems with up to 180 dimensions. Its application to large gravitational N-body integrations has already led to a deeper understanding of the reliability of galaxy and cosmological simulations. The source code (available from the first author) provides to the experienced user a generic interface capable of searching for shadows of any set of ordinary differential equations.

1. Introduction.

1.1. Motivation: Ordinary differential equations, numerical error, and chaos. The subject of [illegible] (IVPs) for autonomous ODEs concerns the solution of

$$\mathbf{y}'(t) = \mathbf{f}(\mathbf{y}(t)), \tag{1}$$

$$\mathbf{y}(t_0) = \mathbf{y}_0, \tag{2}$$

where (1) is called the [illegible] and (2) is the [illegible]. Let $\mathbf{y}(t; t_0, \mathbf{y}_0)$ be the solution of (1), (2), and define the time-h solution operator φ_h to be $\varphi_h(\mathbf{x}) \equiv \mathbf{y}(h; 0, \mathbf{x})$. A [illegible] for solving (1), (2) consists of building an approximation $\tilde{\varphi}_h$ to φ_h for small h, and then computing a sequence of discrete points $\mathbf{y}_{i+1} = \tilde{\varphi}_{h_i}(\mathbf{y}_i)$ representing approximations to $\mathbf{y}(t_{i+1}; t_0, \mathbf{y}_0)$, where $t_{i+1} = t_i + h_i$. We call such a discrete sequence of points a [illegible]. If the pseudotrajectory satisfies a [illegible] of δ such that $\|\mathbf{y}_{i+1} - \varphi_{h_i}(\mathbf{y}_i)\| \le \delta$, then we call it a δ [illegible].

The natural first question to ask about pseudotrajectories is how well they represent exact trajectories. If δ is $O(h^{p+1})$, then $\tilde{\varphi}_h$ is called an [illegible] p method, and the [illegible] $\|\mathbf{y}_i - \mathbf{y}(t_i; 0, \mathbf{y}_0)\|$ is bounded by $O(e^{Lt_i} h^p / |L|)$, where L is a bound on

the [illegible] of the Jacobian of $\mathbf{f}$ [20, subsections 8.1.2, 8.3.6]. If L is negative, then the error is uniformly bounded; otherwise, the forward error is unbounded, and more sophisticated methods of error analysis must be used to gain insight into the value of the numerical solution.

[illegible] relates the pseudotrajectory to the exact solution of a nearby problem. If $\mathbf{x}(t)$ is a continuous approximate solution [24], then the [illegible] is defined as $\delta(t) = \mathbf{x}'(t) - \mathbf{f}(\mathbf{x}(t))$. If for some input tolerance ε we can show that $\|\delta(t)\| \leq \varepsilon$ wherever $\mathbf{x}'(t)$ is defined over the whole of the interpolated solution, then the interpolated solution $\mathbf{x}(t)$ is the exact solution to the defining equation $\mathbf{x}'(t) = \mathbf{f}(\mathbf{x}(t)) + \delta(t)$ [19, 18]. One can sometimes even compute the precise form of $\delta(t)$ analytically [1]. Although defect-based analysis is sometimes appropriate, modifying the defining equation may be undesirable. The present authors are inspired by a desire to understand the meaning of numerical simulations of physical systems in which the physics is well understood and can be well modeled. Since real-world physical systems undergo perturbations, it can be argued that an analysis that allows perturbations of the defining equation is sufficient (see, for example, [18]). However, numerical errors may be biased in qualitatively different ways than other perturbations and may introduce biases into the numerical solution that cause it to behave in an unphysical manner. For example, many physical perturbations would not appreciably change the energy of the system under study, whereas spurious energy dissipation is a major problem in long numerical integrations of systems which should be conservative [7, 41]. Although symplectic integrators [7, 41] and other types of conservative integrators [46] may conserve certain quantities, it is not clear that they do not introduce new biases, such as unphysical energy transport. Physical systems often satisfy properties such as symplecticness, conservation of energy, conservation of phase-space volume, and conservation of various types of momentum. Many of these are well conserved in real systems that experience perturbations, but are not well conserved by many otherwise well-behaved numerical methods. This has been confirmed with several symplectic maps using a fixed-timestep fourth-order Runge–Kutta integrator [7], and by the current authors using the n-body problem and comparing a 7/8-order Runge–Kutta pair [23], two Adams's methods [34, 35], and a Bulirsch–Stöer method [39] to the leapfrog method, which is a second-order symplectic method. In general, for a defect analysis to be fully trustworthy, we want to ensure that changing the field represented by (1) does not affect any quantities of interest [47, 48], but this is difficult to demonstrate.

In contrast, shadowing is a method of backward error analysis in which the defining equation (1) remains fixed, while the initial condition (2) is allowed to change. In other words, a [illegible] is an exact solution to the [illegible] defining equation, which starts close to the pseudotrajectory and remains close to it for a nontrivial duration of time. Shadowing is thus best applied to systems in which the governing equations are well known, and virtually all error is introduced by imprecise knowledge of initial conditions and/or by numerical error in the computation of the solution. It is less applicable to systems in which the mathematics only approximately model the truth, because having an exact solution to an approximate model is of dubious merit.

In addition, "chaotic" systems display [illegible] nearby solutions tend to diverge exponentially away from each other with time. Since numerical methods introduce small errors, it is virtually guaranteed that a pseudotrajectory of a chaotic system will diverge exponentially away from the exact solution with the same initial conditions. Some practitioners (e.g., [25]) have labeled this the "exponential magnification of small errors," leaving open the possibility that numerical trajectories of such simulations are the result of nothing but magnified noise.

Although the presence of exponentially magnified errors is widely recognized, its impact on the qualitative properties of solutions is not well understood.

Nevertheless, numerical solutions can mimic with astounding accuracy the phenomena they purport to simulate. Simulations of galaxies often closely resemble real galaxies [13, 37]. Even galaxy collisions can be modeled in a convincing manner [49, 22]. More generally, exponential divergence of nearby trajectories implies that an initially dense ensemble of points will disperse into a uniform distribution in a relatively short time [47, 48]. This effect is also seen in numerical simulations of chaotic systems [38, 36]. The natural question to ask is whether these simulations are behaving in a fashion similar to real systems, or whether they only superficially mimic real systems but are in fact behaving incorrectly at a more fundamental level. If this were the case, then we could be lulled into a false sense of security while our understanding of these systems becomes compromised.

Since shadowing disallows changes in the defining equation (1), some of these kinds of insidious errors can be ruled out. Furthermore, if the problem (1) arises from a purely mathematical context and not a physical one, we may be earnestly interested in the properties of exact solutions of (1), in which case a recourse to shadowing may be the only option. The only remaining question would then be whether shadows are typical of exact solutions chosen at random.

From the standpoint of physics, the existence of a shadow of a numerical simulation is strong property. In effect, it says that if a shadow exists, then a numerical simulation can be viewed as an [illegible] of an exact trajectory. The distance between the numerical trajectory and the shadow is analogous to experimental error, which is a familiar concept to the physicist. Thus, the study of shadowing is complementary to the study of perturbations of the defining equation.

On the other hand, shadowing algorithms as presented here and elsewhere are extremely expensive. Defect controlled methods are of roughly equal expense compared to more traditional methods of error control, and thus can be used to dynamically control local error at runtime [23]. In contrast, shadowing requires an integration of the variational equation and the inversion of a large matrix, and so costs at least $O(N^3)$, where N is the number of equations. Thus, shadowing is not practical as a method of runtime error control in a numerical integration. Nor is the intent to increase the accuracy of inaccurate trajectories; for this one can simply use a tighter local error tolerance in the original numerical integration. Rather, the intent of shadowing is to perform an a posteriori test of the global accuracy of locally inaccurate integrations, in an effort to discover under what conditions such integrations tend to produce physically meaningful trajectories. These results can then be used to guide error criteria for more efficient (and typically less accurate) integrations. This is precisely the use to which the current algorithm has fruitfully been put elsewhere [31, 30]. More systems can and should be tested for shadowing properties, which is why an efficient and robust algorithm, easily adaptable to new problems, is needed.

To our knowledge, the shadowing algorithm described herein is the first implementation which is demonstrably efficient and effective at shadowing systems with a large number of dimensions. Although shadowing algorithms have previously been described [8, 9, 10, 12, 42, 44, 50], they have been applied exclusively to small test problems with at most a few dimensions. Although all shadowing algorithms, including the one presented here, formally require at least $O(N^3)$ computations, the aim of the current work is to demonstrate that, by the careful analysis of shadowing accuracy requirements and the use of various heuristics, at least two orders of magnitude in runtime can be gained, at no observable cost in efficacy or robustness. We should also

mention that the algorithm here is not rigorous: [illegible] does not prove the existence of a nearby exact trajectory, but only demonstrates the existence of accurate trajectories (i.e., ones with local error close to the machine precision) that remain close to inaccurate ones. Rigorous algorithms do exist [15, 16, 17, 32], but since they require validated integration methods, they are several orders of magnitude more expensive than the ones described here. Our own experiments (as yet unpublished) have also shown that rigorous algorithms tend to be less robust, since the theorems describing the sufficient conditions for shadow existence tend to be more restrictive than is necessary in practice. In other words, the nonrigorous algorithms are able to suggest the existence of shadows under much less restrictive conditions than the rigorous algorithms can cope with.

In this paper we introduce several improvements to the nonrigorous refinement algorithm of [40], resulting in an average speedup of about two orders of magnitude over their implementation. This optimized algorithm has been tested on a smooth, almost hyperbolic Hamiltonian system with 180 dimensions, whose physical size was scaled to be of order unity. To give an idea of the efficacy of the algorithm, recall that nearby solutions of chaotic systems diverge exponentially from each other with time t. If the average distance between the two increases as $e^{\lambda t}$, then λ is called the [illegible] [illegible]. The [illegible] is $1/\lambda$ and defines the average time it takes for the two solutions to diverge by a factor of $\exp(1) \approx 2.718$. Given a numerical trajectory having local error of about 10^{-4}, the algorithm described herein found shadows staying within a distance of about 10^{-3}, for a duration of more than 50 Lyapunov times. Considering that a numerical error of size 10^{-4} is magnified to be comparable to unity after only 9 Lyapunov times (since $e^9 \approx 10^4$), the shadow stays close to the numerical solution for a duration much longer than two solutions would typically remain close together. Thus, the algorithm is capable of finding long, high-dimensional shadows. The algorithm has also been successfully applied to the more realistic problem of gravitational N-body systems with over 200 phase-space dimensions, leading to a deeper understanding of the reliability of galaxy and cosmological simulations [31, 30]. The purpose of this paper is to describe the as-yet unpublished algorithm that was used to produce the above results.

1.2. Background and definitions. We use the terms [illegible], [illegible], and [illegible] interchangeably. For numerical discussions, we assume a machine precision of approximately 16 decimal digits and a well-scaled problem where all macroscopic quantities of interest are of order unity. Like others in the shadowing literature, we abuse the term "noise" to mean "numerical error"; no stochasticity is implied. Throughout this paper, $|\cdot|$ denotes the Euclidean norm, and $\|\cdot\|$ denotes the max norm, although we do not expect the choice of norm to qualitatively affect our results.

An [illegible] $\{\mathbf{x}_i\}_{i=a}^{b}$ of φ satisfies $\mathbf{x}_{i+1} = \varphi(\mathbf{x}_i)$ for $a \le i < b$ (a and b are finite integers). For $a \le i < b$, the 1 [illegible] or [illegible] made between step i and step $i+1$ of the pseudotrajectory $\{\mathbf{y}_i\}_{i=a}^{b}$ is the vector difference $\mathbf{e}_{i+1} = \mathbf{y}_{i+1} - \varphi(\mathbf{y}_i)$. Thus, an exact trajectory is one whose 1-step errors are identically zero, and a δ-pseudotrajectory is one whose 1-step errors satisfy $\|\mathbf{e}_i\| < \delta$ for $a < i \le b$.

An exact trajectory $\{\mathbf{x}_i\}_{i=a}^{b}$ ε-[illegible] the pseudotrajectory $\{\mathbf{y}_i\}_{i=a}^{b}$ if $\|\mathbf{x}_i - \mathbf{y}_i\| < \varepsilon$ for $a \le i \le b$. The pseudotrajectory $\{\mathbf{y}_i\}_{i=a}^{b}$ has a [illegible] at point $i = G_0 < b$ if for some relevant ε there exists an exact trajectory that ε-shadows $\{\mathbf{y}_i\}_{i=a}^{G_0}$, but no exact trajectory that ε-shadows $\{\mathbf{y}_i\}_{i=a}^{G}$, for $G > G_0$.

For the purpose of generating shadows, we must choose an appropriate time interval across which to compute 1-step errors. The obvious choice is to use the same

timesteps as were used by the original numerical integration. However, as we will see later, it is often more efficient to concatenate many timesteps together into a single larger step, which we call a [illegible].

[illegible] is a process similar to Newton's method that iteratively attempts to reduce the noise across a numerical orbit. A refinement iteration is [illegible] if before the iteration the trajectory has noise δ^0, after the iteration it has noise δ^1, and

$$\delta^1 < \mu\delta^0 \text{ for some reasonable } \mu \in (0,1). \tag{3}$$

Otherwise the refinement iteration is [illegible].

Shadowing was first discussed in relation to [illegible] systems by Anosov [2] and Bowen [6]. In a 2-dimensional hyperbolic system, there are two special directions called the [illegible] (or [illegible]) and the [illegible] (or [illegible]) directions, which may vary with time and generally are not orthogonal. Small perturbations along the stable direction decay exponentially in forward time, while small perturbations in the unstable direction grow exponentially in forward time. The two directions reverse roles in backward time. In addition, in a hyperbolic system, the angle between the stable and unstable directions is uniformly bounded away from 0. In such a system, Anosov and Bowen proved that $\forall\varepsilon > 0$, $\exists\delta > 0$ such that every δ-pseudotrajectory is ε-shadowed.

For nonhyperbolic systems, it seems that we must be satisfied with finite-length shadows. The first studies of shadows for nonhyperbolic systems appear to be by [5] and [28]. In the 1990s, there was a flurry of activity in the study of numerical methods for finding shadows [26, 40, 10, 11, 50, 15, 14], as well as studies of when shadowing tends to break down [21, 43, 45]. In this paper, we concern ourselves with the refinement procedure of [40], which is an extension of the 2-dimensional procedure of [26] to arbitrary-dimensional Hamiltonian systems. These two papers will be referred to as QT and GHYS, respectively.

2. The refinement procedure of GHYS and QT.

2.1. Outline. The refinement procedure of GHYS [26] and QT [40] is similar to Newton's method for finding a zero of a function. Here we provide a heuristic explanation. Let $\mathbf{Y} = \{\mathbf{y}_i\}_{i=0}^{S}$ be a trajectory with S steps that has noise $\delta > \eta\varepsilon_{mach}$, where ε_{mach} is the machine precision and η is some constant significantly greater than 1 that allows room for improvement towards the machine precision. Let $\mathbf{e}_{i+1} = \mathbf{y}_{i+1} - \varphi(\mathbf{y}_i)$ be an estimate of the 1-step error at step $i+1$, where $\|\mathbf{e}_i\| < \delta$ for all i. The set of all 1-step errors is represented by $\mathbf{E} = \{\mathbf{e}_i\}_{i=1}^{S}$ and is estimated by a numerical integration technique that has higher accuracy than that used to compute $\mathbf{Y}$. Let g be the function that computes the set of 1-step errors $\mathbf{E}$, given the entire numerical trajectory $\mathbf{Y}$ as input, i.e., $g(\mathbf{Y}) = \mathbf{E}$. Since the 1-step errors are assumed to be small, $\|\mathbf{E}\|$ is small. That is, $\mathbf{Y}$ is close to a zero of g if one exists. A zero of g would represent an orbit in which the 1-step errors are identically zero, i.e., an exact orbit. This is an ideal situation in which to apply Newton's method. Just as with Newton's method, refinement is [illegible], in that we repeatedly compute and apply a correction $\mathbf{C} = \{\mathbf{c}_i\}_{i=0}^{S}$ to $\mathbf{Y}$, ideally giving a less noisy orbit $\mathbf{Y}' = \mathbf{Y} + \mathbf{C}$. Refinement adds a few technical complications that disallow us from directly using Newton's method. For example, the number of constraints (1-step errors) is less than the number of unknowns (correction points in the orbit), and the computation is ill-conditioned. Both problems are solved by imposing boundary conditions on the corrections at both endpoints of the orbit (described below). In practice, we continue iteration until refinement either stops working or produces 1-step errors near the machine precision.

In the latter case we call the refined orbit a [illegible]. The existence of a numerical shadow supports the existence of an exact shadow of comparable duration [40, 44], although rigorously proving the existence of an exact shadow [44, 15, 32] is much more expensive than refinement. We do not pursue rigorous proofs here.

2.2. The GHYS refinement algorithm. Assume that we have a noisy orbit $\mathbf{Y} = \{\mathbf{y}_i\}_{i=0}^{S}$ and that it has a shadow $\{\mathbf{x}_i\}_{i=0}^{S}$. Then

$$\mathbf{x}_{i+1} = \varphi(\mathbf{x}_i) \quad \text{and} \quad \mathbf{y}_{i+1} = \tilde{\varphi}(\mathbf{y}_i),$$

where $\tilde{\varphi}$ is an approximation to φ with a typical accuracy or [illegible] of δ. Using a more accurate integration, we can estimate the 1-step errors $\mathbf{e}_{i+1} = \mathbf{y}_{i+1} - \varphi(\mathbf{y}_i)$. Then, $\hat{\mathbf{c}}_i \equiv \mathbf{x}_i - \mathbf{y}_i$ represents a correction term that perturbs point $\mathbf{y}_i$ towards the shadow $\mathbf{x}_i$, and the next correction term along the orbit is

$$\hat{\mathbf{c}}_{i+1} \equiv \mathbf{x}_{i+1} - \mathbf{y}_{i+1} = \varphi(\mathbf{x}_i) - \varphi(\mathbf{y}_i) - \mathbf{e}_{i+1} = \frac{\partial \varphi(\mathbf{y}_i)}{\partial \mathbf{y}_i}\hat{\mathbf{c}}_i - \mathbf{e}_{i+1} + O(|\hat{\mathbf{c}}_i|^2). \tag{4}$$

In the spirit of Newton's method, we ignore the $O(|\hat{\mathbf{c}}_i|^2)$ in (4), and so one refinement iteration defines the corrections along the entire orbit

$$\mathbf{c}_{i+1} = L_i \mathbf{c}_i - \mathbf{e}_{i+1}, \tag{5}$$

where $L_i \equiv \frac{\partial \varphi(\mathbf{y}_i)}{\partial \mathbf{y}_i}$ is the linearized perturbation map (we will describe how to initialize the iteration below). For a discrete map, L_i is just the Jacobian of the map at step i. For a system of ODEs, L_i is the Jacobian of the integral of the ODE from step i to step $i+1$, computed by solving the linear variational equation [27]. If we let d be the dimension of the problem, then the resolvent has $O(d^2)$ elements in it, and it takes $O(d^3)$ time to compute, assuming that each element takes time $O(d)$ to compute, as is the case in the N-body problem [29].

For simplicity of explanation, we assume $d = 2$ for the remainder of this subsection, deferring discussion of the higher-dimensional case to the next subsection.

If the problem were not chaotic, the correction terms $\mathbf{c}_i$ could be computed directly from (5). But since L_i will amplify any errors in $\mathbf{c}_i$ not lying in the stable direction, computing the $\mathbf{c}_i$'s by iterating (5) forward will amplify errors and typically produce nothing but noise. Therefore, we split the error and correction terms into components in the stable ($\mathbf{s}_i$) and unstable ($\mathbf{u}_i$) directions at each timestep:

$$\mathbf{e}_i = e_{u_i}\mathbf{u}_i + e_{s_i}\mathbf{s}_i, \qquad \mathbf{c}_i = c_{u_i}\mathbf{u}_i + c_{s_i}\mathbf{s}_i. \tag{6}$$

Since it is not known a priori which direction is unstable at each timestep, the unstable vector $\mathbf{u}_0$ at time t_0 is initialized to an arbitrary unit vector. The linearized map is then iterated forward with

$$\bar{\mathbf{u}}_{i+1} = L_i \mathbf{u}_i, \qquad \mathbf{u}_{i+1} = \bar{\mathbf{u}}_{i+1}/|\bar{\mathbf{u}}_{i+1}|. \tag{7}$$

Since L_i magnifies any component that lies in the unstable direction, $\mathbf{u}_i$ converges to the true unstable direction as i increases. Similarly, the stable unit direction vectors $\mathbf{s}_i$ are computed by initializing $\mathbf{s}_S$ to an arbitrary unit vector and iterating backward,

$$\bar{\mathbf{s}}_i = L_i^{-1}\mathbf{s}_{i+1}, \qquad \mathbf{s}_i = \bar{\mathbf{s}}_i/|\bar{\mathbf{s}}_i|. \tag{8}$$

Substituting (6) into (5) yields

$$c_{u_{i+1}}\mathbf{u}_{i+1} + c_{s_{i+1}}\mathbf{s}_{i+1} = L_i(c_{u_i}\mathbf{u}_i + c_{s_i}\mathbf{s}_i) - (e_{u_{i+1}}\mathbf{u}_{i+1} + e_{s_{i+1}}\mathbf{s}_{i+1}). \tag{9}$$

While L_i magnifies errors in the unstable direction, it damps them in the stable direction. Likewise, L_i^{-1} damps errors in the unstable direction and magnifies errors in the stable direction. Thus the c_u terms should be computed backward, and the c_s terms forward. Taking components of (9) in the unstable direction at step $i+1$, we iterate backward on

$$c_{u_i} = (c_{u_{i+1}} + e_{u_{i+1}})/|\bar{\mathbf{u}}_{i+1}|, \tag{10}$$

and taking components in the stable direction, we iterate forward on

$$c_{s_{i+1}} = |L_i \mathbf{s}_i| c_{s_i} - e_{s_{i+1}}. \tag{11}$$

The initial choices for c_{s_0} and c_{u_S} are arbitrary as long as they are small—smaller than the maximum shadowing distance—because (11) damps initial conditions and (10) damps final conditions. GHYS and QT choose them both as 0, as do we for simplicity. This choice is probably as good as any, but it can be seen here that if one shadow exists, there are infinitely many of them. Another way of looking at these initial choices for c_{s_0} and c_{u_S} is that they "pinch" the growing components at the endpoint, and the backward-growing components at the initial point, to be small. That is, [illegible] are being forced on the problem so that the exponential divergence is forcibly masked, if possible, making the solution of (5) numerically stable.

Note that these boundary conditions demand that the initial condition for the shadow and noisy orbits differ along the unstable direction. In fact, this [illegible] occur if the change in initial conditions is to have any effect. That is, when looking for a shadow, if perturbations were allowed only in the stable direction, those perturbations would die out, leading the perturbed exact orbit to follow the original exact orbit that passes through the initial conditions—the one that is already known to diverge exponentially from the noisy orbit.

Algorithm 1 gives pseudocode for the basic 2-dimensional refinement algorithm.

ALGORITHM 1. Basic two-dimensional refinement algorithm.

Input: noisy orbit $\mathbf{Y} = \{\mathbf{y}_i\}_{i=0}^{S}$.
loop
  estimate 1-step errors $\mathbf{e}_i = \mathbf{y}_i - \varphi(\mathbf{y}_{i-1})$ for each step $i = 1, \ldots, S$.
  exit when 1-step errors either ''blow up'' or stop changing between outer loops.
  compute all resolvent matrices L_i by solving the variational equation for each timestep i.
  compute all unstable and stable vectors $\mathbf{u}_i$, $\mathbf{s}_i$ by iterating (7) and (8), respectively.
  split $\mathbf{e}_i$ into stable and unstable components via (6).
  compute split corrections using (10) and (11).
  recombine correction terms $\mathbf{c}_i$ via equation (6).
  apply corrections to $\mathbf{Y}$: $\mathbf{y}_i := \mathbf{y}_i + \mathbf{c}_i$ for each timestep $i = 0, \ldots, S$.
end loop

2.3. QT's generalization to arbitrary Hamiltonian systems. If the configuration space is d-dimensional, then there are $2d$ dimensions in the phase space. It can be shown that in a Hamiltonian system, the number l of stable and unstable directions is equal, although $l < d$ is possible. At time t_i, let $\{\mathbf{u}_i^j\}_{j=1}^{d}$ represent d unstable unit vectors, and let $\{\mathbf{s}_i^j\}_{j=1}^{d}$ represent d stable unit vectors. For any particular timestep, it will be convenient if the unstable vectors are orthonormal to each other and the stable vectors are orthonormal to each other. However, the stable and unstable vectors together will not in general form an orthogonal system.

The vectors are evolved as in the 2-dimensional case, except using modified Gram–Schmidt orthonormalization to produce two sets of d-orthonormal vectors at each timestep. Arbitrary orthonormal bases are chosen, $\mathbf{u}_0^j$ at time t_0, and $\mathbf{s}_S^j$ at time t_S, and then evolved according to

$$\bar{\mathbf{u}}_{i+1}^j = L_i \mathbf{u}_i^j, \qquad \bar{\mathbf{s}}_i^j = L_i^{-1} \mathbf{s}_{i+1}^j.$$

At each step i, two modified Gram–Schmidt orthonormalizations are done: one on $\{\bar{\mathbf{u}}_{i+1}^j\}_{j=1}^d$ to produce $\{\mathbf{u}_{i+1}^j\}_{j=1}^d$, and another on $\{\bar{\mathbf{s}}_i^j\}_{j=1}^d$ to produce $\{\mathbf{s}_i^j\}_{j=1}^d$. After a few Lyapunov times, $\mathbf{u}_i^1$ lies close to the most unstable direction at step i, $\mathbf{u}_i^2$ lies close to the second most unstable direction, etc. Likewise, $\mathbf{s}_i^1$ lies close to the most stable direction at time i, $\mathbf{s}_i^2$ lies close to the second most stable direction, etc.

The multidimensional generalization of (6) is the obvious

$$\mathbf{e}_i = \sum_{j=1}^{d} (e_{u_i^j} \mathbf{u}_i^j + e_{s_i^j} \mathbf{s}_i^j), \qquad \mathbf{c}_i = \sum_{j=1}^{d} (c_{u_i^j} \mathbf{u}_i^j + c_{s_i^j} \mathbf{s}_i^j). \tag{12}$$

To convert the 1-step error at step i from phase-space coordinates $\mathbf{e}_i' = \{e_i^k\}_{k=1}^{2d}$ to the stable and unstable basis $\mathbf{e}_i = \{\{e_{u_i^j}\}_{j=1}^d, \{e_{s_i^j}\}_{j=1}^d\}$, one constructs the matrix V_i whose columns are the unstable and stable unit vectors, $V_i = (\mathbf{u}_i^1 \mathbf{u}_i^2 \cdots \mathbf{u}_i^d \mathbf{s}_i^1 \mathbf{s}_i^2 \cdots \mathbf{s}_i^d)$, and solves the system $V_i \mathbf{e}_i = \mathbf{e}_i'$.

From (5) and (12) the equation for the correction coefficients in the unstable subspace at step $i+1$ is

$$\sum_{j=1}^{d} (c_{u_{i+1}^j} + e_{u_{i+1}^j}) \mathbf{u}_{i+1}^j = \sum_{j=1}^{d} c_{u_i^j} L_i \mathbf{u}_i^j,$$

which is projected out along $\mathbf{u}_{i+1}^k$ producing

$$c_{u_{i+1}^k} + e_{u_{i+1}^k} = \sum_{j=k}^{d} c_{u_i^j} U_i^{kj},$$

where the scalar $U_i^{kj} = \mathbf{u}_{i+1}^k \cdot L_i \mathbf{u}_i^j = \mathbf{u}_{i+1}^k \cdot \bar{\mathbf{u}}_{i+1}^j$ and the modified Gram–Schmidt process ensures that $U_i^{kj} = 0$ if $j < k$. As stated previously, the the boundary condition requires that the unstable component of the corrections be small at timestep S and their stable components be small at timestep 0. For simplicity we take $\{c_{u_S^j} = 0\}_{j=1}^d$ as did QT, and the coefficients are computed backward using

$$c_{u_i^k} = \frac{1}{U_i^{kk}} \left(c_{u_{i+1}^k} + e_{u_{i+1}^k} - \sum_{j=k+1}^{d} c_{u_i^j} U_i^{kj} \right).$$

We first solve for $\{c_{u_i^d}\}_{i=0}^S$, which does not require knowledge of the other c_u coefficients, and then solve for $\{c_{u_i^{d-1}}\}_{i=0}^S$, etc.

Again from (5) and (12), the equation for the correction coefficients in the stable subspace at timestep i is

$$\sum_{j=1}^{d} (c_{s_{i+1}^j} + e_{s_{i+1}^j}) L_i^{-1} \mathbf{s}_{i+1}^j = \sum_{j=1}^{d} c_{s_i^j} \mathbf{s}_i^j,$$

which is projected out along $\mathbf{s}_i^k$ producing

$$c_{s_i^k} = \sum_{j=k}^{d} (c_{s_{i+1}^j} + e_{s_{i+1}^j}) S_i^{kj},$$

where $S_i^{kj} = \mathbf{s}_i^k \cdot L_i^{-1}\mathbf{s}_{i+1}^j = \mathbf{s}_i^k \cdot \bar{\mathbf{s}}_i^j$ and the modified Gram–Schmidt process ensures that $S_i^{kj} = 0$ if $j < k$. The boundary condition at step 0 is $\{c_{s_0^j} = 0\}_{j=1}^d$, and the co-efficients are computed forward using

$$c_{s_{i+1}^k} = \frac{1}{S_i^{kk}} \left(c_{s_i^k} - \sum_{j=k+1}^{d} (c_{s_{i+1}^j} + e_{s_{i+1}^j}) S_i^{kj} \right) - e_{s_{i+1}^k}.$$

As with the unstable corrections, we first compute $\{c_{s_i^d}\}_{i=0}^S$, which does not require knowledge of the other c_s coefficients, and then we compute $\{c_{s_i^{d-1}}\}$, etc.

Applying the above computed corrections to the noisy orbit, producing a nearby orbit with (ideally) less noise, concludes one refinement iteration.

3. Optimizations to the GHYS/QT refinement algorithm.

3.1. Asymptotic runtimes. Most of the expense of refinement of an N-body orbit is in computing the resolvents L_i. We tested our algorithm on an artificial system of N particles, only M of which move. Manually counting floating-point operations in the N-body Jacobian gives an operation count of roughly $60MN + 50M^2$. The total operation count to compute the right-hand side of the variational equation, including the matrix-matrix multiply and the computation of the Jacobian, is about $110M^3 + 70M^2 + 85MN$. The M^2 term is probably negligible, and the MN term is only relevant if $N \gg M$. Thus, if there are S shadow steps, and the function computing the right-hand side is invoked an average of k times per shadow step, the total cost of computing all the resolvents is about $k \times S \times (110M^3 + 85MN)$. We found empirically that, using an Adams's integrator [34], k seems to be independent of M and roughly equal to 500 for the shadow steps used in our N-body simulations.

A straightforward, unoptimized implementation of the high-dimensional QT algorithm can take a prohibitively long time to find shadows of nontrivial duration. Furthermore, if the dimension of the problem is d, then the time scales as $O(d^3)$, making it virtually impossible to study shadows of high-dimensional systems. However, a vital scientific question is how shadow lengths scale with the dimensionality of the system.

3.2. Brief overview of the optimizations. This paper introduces eight major optimizations to the GHYS/QT refinement procedure. Each provides a constant speedup of roughly between 1.5- and 8-fold, with a cumulative average speedup of about a factor of 100. We briefly introduce all eight optimizations here. The first three are trivial and are not discussed further, while the remaining five are discussed in more detail in the following subsections. Most of the effort is focused on reducing both the number of resolvents to recompute and the time spent recomputing each. This necessitates handling the ensuing complications of when a resolvent [illegible] be recomputed and when it would be worthless to do so. Furthermore, each of the optimizations is independent of all the others. It is conceivable that some optimizations may significantly decrease the reliability of refinement for some systems, although this was not observed for the systems we tested.

Each optimization (except the first) has a name and a single-letter identification for later discussion. We use the acronym [illegible] to mean the set of all [illegible]esolvents, [illegible]nstable, and [illegible]table vectors for the entire trajectory. The RUS at a particular timestep i is referred to as RUS_i.

[illegible] $3M$ [illegible] QT recomputed a new resolvent for each stable and unstable vector; i.e., at each timestep they computed $6M$ resolvents (this is obvious only from

viewing their code). However, a resolvent $R(t_1, t_0)$ is a matrix operator that applies to small perturbations of the orbit from time t_0 to t_1. Thus only two resolvents per timestep need to be computed: one for evolving perturbations forward in time, and another to evolve them backward. Thus QT would have been required to perform $O(M^4)$ work for M moving particles. Since most of the time is spent computing the resolvents, fixing this oversight provides an immediate speedup of a factor of about $3M$. The effect of fixing this oversight is included in the speedup values of Table 1, but it partly explains why QT thought that shadowing is wholly impractical for large N systems.

The above optimization can be extended further by noting that the resolvent matrix L_i that maps perturbations from time t_i to t_{i+1} is precisely the inverse matrix of the resolvent that maps small perturbations from t_{i+1} to t_i. Thus, rather than doing an integration from t_{i+1} backward to t_i to compute L_i^{-1}, L_i can be inverted using matrix operations, or the system $L_i\mathbf{x} = \mathbf{b}$ can be solved, whenever necessary, using standard elimination schemes. This gives a speedup of about 2.

Our experiments show that for smooth problems like the N-body problem, the Jacobian need not be extremely accurate, even in late refinements where the 1-step errors approach the machine precision. In these N-body experiments, when this optimization was used, resolvents were always computed to a fixed tolerance of 10^{-6}. We found that the movement of the orbit during refinement dictates recomputation of a resolvent, not the numerical error in its construction.

When computing the resolvent and 1-step errors during early refinements, it is not necessary to compute them to extremely high accuracy. Since the initial 1-step errors may have magnitudes of, say, 10^{-4}, the resolvents and 1-step errors need only be computed to a tolerance of, say, 10^{-7}, i.e., three extra digits. QT always computed the 1-step errors and resolvents to a tolerance of 10^{-13}. Of course, if the optimization is used, this only affects the 1-step error tolerances.

If a shadow exists, then by definition it cannot be too far away from the original noisy orbit. It is reasonable to assume that sometimes the RUS will change little as the orbit is perturbed towards the shadow. Thus, it may not be necessary to recompute the RUS for every refinement iteration. This is probably the biggest savings, because in combination with the cheaper accurate integrator, it means that the RUS often needs only to be computed once to a lax tolerance. This is analogous to a Newton's method that does not recompute the Jacobian at every iteration.

To find the longest possible shadow of a noisy orbit, we attempt to shadow for longer and longer times until shadowing fails. Assume that shadowing for S shadow steps produces a shadow A. When attempting to shadow $S + k$ timesteps for some integer k, assume that a successful shadow B will be found. Since A and the first S steps of B both shadow the same noisy orbit, they must be close to one another. By the same argument as in the previous paragraph, the RUS that was computed for A can probably be reused for the first S steps of B. Thus only k new RUS_i's need to be computed.

If it can be shown that a particular RUS_i, or a small set of them, is causing Constant RUS refinements to fail, then perhaps it is sufficient only to recompute the "bad" RUS_i's, rather than all of them along the entire orbit. It is not trivial to decide which ones need recomputing, though.

QT used every internal timestep of their integrator's noisy orbit as a shadow step, but this is not necessary. It is reasonable to skip timesteps in the original orbit to build larger shadow steps. This means that fewer resolvents and stable/unstable directions need to be computed and stored. This optimization alone produced speedups of more than an order of magnitude in some cases.

3.3. Constant RUS directions ($\boldsymbol{R}$). For a smooth, continuous, well-behaved function, the Jacobian is also smooth and continuous. Most Hamiltonian systems (that we have seen) are at least piecewise well-behaved in this sense. The N-body problem, in particular, is of this class, assuming that no 0-distance collisions occur, or if the forces are artificially bounded through "softening." This implies that the resolvent along a particular path will not change much if the path is perturbed slightly. Since the unstable and stable unit vectors are computed solely from the resolvents, they will also change only slightly when the path is perturbed. Thus, the RUS computed on one refinement iteration may be reusable on some subsequent iterations. Computing the new 1-step errors is then the only significant work to be performed on each refinement iteration after the first.

We have observed that computing the RUS to a tolerance of between 10^{-6} and 10^{-9} usually suffices to refine the orbit down to 1-step errors near 10^{-15}. If refinement fails using Constant RUS, then perhaps there is a spot in the orbit where some RUS_i's change quickly with small perturbations in the orbit. In that case, the RUS can be recomputed for a refinement or two, after which Constant RUS may be tried again. However, when Constant RUS fails it often suggests that there is a glitch somewhere in the portion of the orbit which is currently being tested for a shadow.

3.3.1. Switching between constant and recomputed RUS. To switch between Constant RUS and Recomputed RUS, we use a running-average "memory" scheme to track the progress of the norm of the maximum 1-step error over the previous few refinements. We originally used a simple algorithm [40] that signals failure after K successive failed refinements, for $\mu = 0.9$ (see (3)) and $K = 3$. However, we found that refinement would sometimes get into a "loop" in which a few successful refinements would be followed by an unsuccessful one that would "undo" the previous improvements. Thus, refinement would be at a standstill even though there would never be more than one consecutive "bad" iteration, but setting $K = 1$ was too stringent, because it aggressively stops refinements that would eventually succeed.

The [illegible] is defined by

$$A_{j+1} = \alpha A_j + (1-\alpha)\nu, \qquad \alpha \in (0,1), \tag{13}$$

where ν is the newest element added to the set and α is the [illegible] constant. The higher the memory constant, the longer the memory—i.e., the less the effect of each new element; A is roughly an average of the most recent $2/(1-\alpha)$ elements. However, (13) is not suited for measuring errors such as those in refinement that can change by many orders of magnitude, and is especially unsuited when smaller means better. A [illegible] equivalent of (13) allows values differing by orders of magnitude to average meaningfully. We define the [illegible] G as

$$G_{j+1} = \sqrt[n+1]{(G_j)^n \nu}, \tag{14}$$

where ν is the new element and $\frac{n}{n+1}$ is analogous to α in (13), so higher N implies longer memory. Both (13) and (14) require initialization to some reasonable starting value A_0 and G_0, respectively. N should not be too large; we found 2 or 3 worked best.

Finally, we want to measure the [illegible] that is being made by successive refinements, rather than the absolute error, because it is the [illegible] in 1-step errors that indicates whether current refinements are succeeding, not their absolute size. Note that the 1-step errors may stop decreasing for two reasons: (a) 1-step errors have gotten as close to machine precision as is possible, or (b) refinement is failing to find a shadow. Using the improvement rather than the absolute value allows us to use the same algorithm to halt refinement in either case. We use the geometric running average (14) of the improvement to measure the progress of refinement, where the improvement I is

$$I = \left| \frac{\text{the maximum 1-step error of this refinement}}{\text{maximum 1-step error of previous refinement}} \right|.$$

If I is close to or greater than 1, then the current refinement did not improve on the previous one; if $I < \mu$ (μ from (3)), then the current refinement is successful.

We use the improvement I to switch between methods of various expense as follows. In general, we continue to use cheap refinement until improvement stops, at which point we either give up or switch to a more expensive refinement method. We currently have only two refinement methods. In order of decreasing cost, they are Recomputed RUS and Constant RUS. Below is the heuristic we have created using much trial and error. Let μ_R be the success value (from (3)) when the RUS is being recomputed, and μ_C the success value when using Constant RUS. We used $\mu_R = 0.1$, $\mu_C = 0.5$, because we expect a Constant RUS iteration not to be as successful as one that recomputes the RUS, but they are much cheaper, so we can afford a lower expected improvement per Constant RUS refinement.

- When using Recomputed RUS, it is safe to switch to Constant RUS when the geometric running average improvement becomes $< \mu_R$. At this time the current orbit and all its statistics must be saved in case Constant RUS refinement fails.
- When using Constant RUS, it is necessary to switch back to Recomputed RUS when the geometric running average improvement stays $> \mu_C$ for three successive refinements. We then discard all progress made by Constant RUS and revert to the previous orbit that used Recomputed RUS. We believe it is advantageous to discard all progress made by Constant RUS, even if significant progress was made, for the following reasons:
  - A refinement that computes the RUS is far more expensive than one that does not, so discarding all progress made by Constant RUS refinements usually makes little difference, percentagewise, in the final runtime.
  - Future Constant RUS refinements, which will be performed after the RUS is recomputed, will converge faster than the current ones that just failed, because the RUS will be more accurate.
  - Recomputing the RUS with small 1-step errors would mean, using the simple "three extra digits of accuracy" heuristic, recomputing it at a much higher accuracy than is necessary. (Unless the [illegible] optimization is used.)
- Finally, after having switched back to Recomputed RUS, it is time to admit failure if the geometric running average improvement stays $> \mu_R$ for three successive refinements; and it is safe to switch again to Constant RUS when the geometric running average improvement becomes less than μ_R.

We found that there are usually no half-measures when using recomputed RUS—refinement either succeeds geometrically or fails miserably. Finally, there may be

a place for other noise-reduction procedures in the universe of expensive and cheap refinement algorithms.

3.4. Reuse RUS from a previous successful shadow (P). This idea is based on the same observation as Constant RUS, and is useful only if Constant RUS is employed. It takes advantage of the proximity of an RUS for an orbit B to the RUS for a nearby orbit A. So, when trying to find a shadow for a segment B which is an extension to segment A, the RUS of A can be reused on the segment of B that overlaps A.

One interesting question is which of A's RUS's to use if A's RUS was ever recomputed. An argument in favor of using the first is that the noisy orbit is exactly the same, since B is just an extension of A. However, if A had to recompute the RUS, then probably so will B if A's first RUS is used. Recall that the RUS needed for the early refinements need not be as accurate as the ones used later. Furthermore, we assume that the segment of B's shadow that overlaps A's shadow will be [illegible] to A's shadow than the first few iterations of B is to the first few iterations of A. Thus, if we use the last RUS that A used, we are less likely to recompute the RUS for B. If B is a [illegible] of A rather than an extension, then obviously no new RUS_i's need to be computed.

3.5. Recompute specific RUS_i's (i). When Constant RUS refinements fail, it may be because some of the RUS_i's are invalid due to the current trajectory drifting too far from the trajectory for which the RUS_i was computed. If the set of RUS_i's that are invalid is small, then it would be advantageous to recompute only those RUS_i's that are causing the failure.

A difficulty arises, however, when trying to pinpoint which RUS_i's are causing the problem. Note that refinement using the GHYS/QT algorithm is a [illegible] method: the correction $\mathbf{c}_j$ is a function of the resolvents and 1-step errors of [illegible] the timesteps, not just L_j and $\mathbf{e}_j$. Thus, it is not trivial to decide which RUS_i's are causing a particular $\mathbf{c}_j$ to be invalid.

What we would like is some measure M_i of how bad an RUS_i is. Then we can insert RUS_i's into a priority queue based on M_i, extract the RUS_i's that are worse than some criteria, and recompute them. Some obvious measures for M_i are the following:

- the 1-step error at step i,
- the distance $\mathbf{y}_i$ has moved since the last time its RUS_i was computed,
- the norm $\|L_i\|$, which is a measure of how sensitive that area of the orbit is to small changes.

Once the M_i's are ordered by some measure, a criterion is needed to decide where to put the dividing line between those RUS_i's that need recomputing and those that don't. Some obvious criteria are the following:

- recompute all RUS_i's for which $M_i > M'$ for some constant M',
- recompute some constant number of the RUS_i's,
- recompute some constant fraction of the RUS_i's,
- recompute all whose $M_i > w(\bar{M})$ for some function w of the geometric mean measure $\bar{M}$.

None of these measures taken alone with any of the above criteria taken alone seem sufficient, since there were cases in which recomputing the entire RUS resulted in a successful refinement, but a single-measure–single-criterion method for recomputing particular RUS_i's resulted in a long sequence of unsuccessful refinements.

After much trial and error, a measure was found which gives a speedup no better than a factor of 2, which is much less than we expected. Let us focus on a particular

timestep i. Let k be the current refinement iteration, and k' be the refinement at which the RUS_i was last computed. Let $L_i^{k'}$ be the resolvent for step i computed during refinement k'. Let $\mathbf{y}_i^{k'}$ be the orbit point at step i from refinement k', and let $\mathbf{y}_i^k$ be the orbit point at step i for the current refinement k. When trying to decide if we need to compute L_i^k, the measure we devised is

$$M_i = \|L_i^{k'}(\mathbf{y}_i^{k'} - \mathbf{y}_i^k)\|.$$

The intent is to combine the effects of the norm of L_i and how much the orbit has moved at that point since L_i was last computed. L_i^k is recomputed if it satisfies [illegible] of the following criteria:

- always recompute the worst K RUS_i's, for some integer K;
- always recompute the worst F RUS_i's, for some fraction F of all of them;
- always recompute RUS_i if $M_i > M'$ for some constant M';
- for each RUS_i satisfying one of the above, also recompute RUS_{i-1}, since L_i starts at $\mathbf{y}_i$, while L_{i-1} ends at $\mathbf{y}_i$.

We used $K = 1$, $F = \frac{1}{8}$, and $M' = 10^{-3}$.

Unfortunately, this set of measures and criteria eventually recomputes most of the RUS_i's except in the final few refinements of a failing search. In other words, this set of criteria gives the best speedups only during shadow searches that will eventually fail to find a shadow. This is a useful speedup, because a large fraction of the time spent trying to find the longest shadow is spent in the failing search for a shadow longer than the longest eventually found. However, it would be better if some criterion could be found that also aids in searches that are eventually successful. It seems plausible that some such measure and criterion should exist. Since the benefits are potentially enormous for orbits with many timesteps, more study seems appropriate.

3.6. Large shadow steps (L). A numerical solution of an ODE is represented by an ordered, discrete sequence of points. Assume that we construct a continuous solution $\mathbf{y}(t)$ from these points, for example by using a suitably smooth and accurate interpolant. Then we could extend the definition of ε-shadowing to continuous systems as follows: if $\mathbf{x}(t)$ is an exact solution, then $\mathbf{x}(t)$ ε-shadows $\mathbf{y}(t)$ on $t_0 \le t \le t_1$ if $\forall t \in [t_0, t_1],\ \|\mathbf{x}(t) - \mathbf{y}(t)\| < \varepsilon$.

Now, it should be clear that we can choose [illegible] representative sequence of points along $\mathbf{y}(t)$ to use in the refinement algorithm; we need not choose the points from which $\mathbf{y}(t)$ was originally constructed. In particular, we can choose a subset of the original set of points, as long as enough points are chosen to be "representative" of $\mathbf{y}(t)$. The steps that are finally chosen are called [illegible].

There are at least two reasons to desire as few shadow steps as possible. First, if Constant RUS is being used, then the RUS needs to be stored. Each RUS_i requires a matrix (the resolvent), and two sets of basis vectors.[1] Second, if the "accurate" integrator has a large startup cost, then we wish to minimize the number of startups. For example, the Adams's method that we used takes extremely small internal timesteps at the beginning of each shadow step.

For the N-body simulations reported in this paper, a set of "standardized" units [33] was used such that the scale of the system in all macroscopic units of interest was of order 1—i.e., the system had a diameter of order 1, the crossing time and total

[1]For example, with $M = 25$ moving particles, an RUS of length $S = 128$ requires about 100 megabytes of memory, and this space scales as $O(SM^2)$. ((25 particles × 6 dimensions per particle)^2× 8 bytes per double precision number × 4 (2 resolvents, 2 sets of basis vectors each covering half the space) × 128 steps).

energy were of order 1, and the N particles each had mass $1/N$. In such a system, the timesteps of QT's integrator averaged about 0.01, and they used each timestep as a shadow step. We found empirically that, in this system, using shadow steps about ten times longer, of size 0.1, works well. Smaller shadow steps use more time and memory but could not find shadows any better; shadow steps of 0.2 were slightly less reliable, and steps of size 0.5 were unreliable. A significant area of further work would be to dynamically determine in an algorithmic fashion what size shadow step is appropriate in the general case.

It might be reasonable to assume that as refinement proceeds to decrease the 1-step errors, it would be advantageous to construct larger-and-larger shadow steps. However, we found that this does not give much of a speedup, because (1) if refinement is working well, then Constant RUS will be invoked, in which case there is no need to recompute the RUS at all; (2) conversely, if refinement is failing, then there is no justification for increasing the size of shadow steps—in fact, it may be advantageous to decrease them. Note that, if refinement is succeeding, it may be advantageous to use larger-and-larger shadow steps in the computation of the 1-step errors, even though the RUS is not being recomputed. We did not do this.

Finally, implementing dynamic shadow step sizes may help in another area. As described above, we currently discard all progress made by Constant RUS when it begins to fail, reverting to the orbit and RUS of the most recent refinement that computed the RUS. However, if Constant RUS works for several refinements, but then starts to fail, perhaps it would be advantageous to use the orbit of the most recent successful refinement to build new shadow steps using the above dynamic algorithm, regardless of whether the most recent successful refinement computed the RUS or not.

3.7. Cheaper accurate integrator (C). When computing the 1-step errors of a noisy orbit, an integrator must be used that has smaller 1-step errors than the integrator used to compute the noisy orbit. The question is, how much more accurate does it need to be? During early refinements when the 1-step errors are large, the errors in the correction factors may be dominated by the first-order approximation of the resolvents, so the 1-step errors do not need to be computed to machine precision. In practice, we found that it is sufficient to estimate the 1-step errors of the noisy trajectory to an accuracy of 10^{-3} times that of the size of the maximum 1-step error of the previous refinement; computing them any more accurately does not speed refinement, although computing them only 10^{-2} times more accurately sometimes results in more iterations of the refinement procedure.[2] In addition, a factor of only 10^{-2} is not enough because some integrators have sufficiently gross control of their errors that requesting only two extra digits will sometimes result in the integrator returning the same result. This is because it did too much work in the less accurate case, so that the solution it computed had at least two more accurate digits than were requested. This is less likely to happen with a difference of 10^{-3}. Note that it is necessary to loosen this criterion when the 1-step errors are within 10^{-3} of the machine precision, in order not to request more accuracy than the machine precision allows.

We have tested several different integrators as "accurate", including a 7/8 order Runge–Kutta pair [23], two Adams's methods [34, 35], and a Bulirsch–Stöer method [39]. Although all integrators gave roughly the same reliability results (that is, the shadows produced did not change significantly based upon which accurate integrator was chosen), we found that LSODE [34] was most efficient. However, it would not be

[2]More iterations, but each iteration takes less time. There is clearly a trade-off here that is probably problem-dependent.

surprising if efficiency were a function of the problem being integrated. In particular, if the shadow steps are small, it may pay to use a less sophisticated routine, such as a high-order explicit Runge–Kutta method. If the shadow steps are large, an Adams or a Bulirsch–Stöer method is probably apt, because even though they both have high startup cost, they can eventually move quickly along the solution if they are not restarted too often. It may also be interesting to attempt using extended precision integration to test the accuracy of the standard (double precision) routines.

Finally, an important factor in problems, like the N-body problem, that have a large variance of scales all occurring at once (i.e., some pairs of stars are several orders of magnitude closer to each other than other pairs) is a concept called [illegible]. The modern hand-coded N-body integrator gives each star a personalized integration timestep; stars that have high accelerations are integrated with smaller timesteps than those with lower accelerations. Perhaps it would be fruitful to attempt shadowing with an integration routine that uses individual timesteps for each star, because currently the timestep of the entire system is restricted to the smallest required timestep.

4. Results on a test case: The gravitational *N*-body problem. To quantify the speedups of the optimizations, we did timing tests while applying the algorithm to trajectories of a simplified gravitational n-body system. The system consists of 100 particles, 99 of which are fixed in 3-dimensional space [40, 31, 30]. Units are scaled so that the gravitational constant is 1, the physical extent of the system and the total mass are both unity, while one particle moves "pinball" fashion among the fixed particles with a velocity of order unity. For our simplified system, the moving particle feels an acceleration $\mathbf{a}$ arising from Newtonian gravitational forces from all the other particles, according to

$$\mathbf{a} = \sum_{j=1}^{99} m_j \hat{\mathbf{r}}_j / r_j^2,$$

where m_j is the mass of particle j, $\hat{\mathbf{r}}_j$ is a unit vector lying along the line between the particle j and the moving particle, and r_j is the scalar distance between the fixed particle j and the moving particle. Thirty-two initial conditions were chosen at random. Each was shadowed using several different combinations of the optimizations. The 32 orbits were chosen by generating random 3-dimensional positions for all particles from the uniform distribution on $(0, 1)$; a 3-dimensional random initial velocity for the moving particle was also chosen uniformly on $(0, 1)$. The standardized units of Heggie and Mathieu [33] were used, in which each particle has mass $1/N$. The pseudorandom number generator was the popular Unix 48-bit `drand48()`, with seeds 1 through 32.

Once the initial conditions were set, each noisy orbit was generated by integrating for 1.28 standard time units (about 1 crossing time) with local errors of about 10^{-6}. This figure agreed well with the magnitude of the initial 1-step errors computed during the first refinement. Although one crossing time sounds short, it is long enough that five of the orbits contained trouble spots.[3] The number of unoptimized QT refinements required to find a shadow that has no trouble spots seems independent of the length of the orbit—each refinement takes much longer, but the convergence is still geometric per refinement. Thus, the timing results below should be independent

[3]If the orbit has a trouble spot, then Constant resolvent and Reuse RUS from previous successful shadow will have little effect, because the RUS will be recomputed in an attempt to find a shadow. The other optimizations—C, L, F, and I—still offer significant performance improvement.

of the length of the orbit. This is what has been observed with the longer orbits we have shadowed, although we do not document them here.

For short shadow steps, a constant shadow step size of 0.01 was used, which approximates the average-sized shadow step in QT. This results in 128 shadow steps. For large shadow steps, 16 shadow steps of size 0.08 were used. As in a usual shadowing attempt, longer and longer segments are shadowed in an attempt to find the longest shadow. Here, each successive segment had twice as many shadow steps as the previous one, up to 16 and 128, for long and short shadow steps, respectively. No attempt was made to isolate glitches more accurately than this factor of two.

The most stringent tolerance requested of the accurate integrator was 10^{-15}. A successful numerical shadow was defined to be one whose 1-step errors were all less than 2×10^{-14}. This number was chosen simply because it was the smallest number that geometrically converging refinement sequences could consistently achieve; 10^{-14} was too small, because many refinement sequences would proceed geometrically until their maximum 1-step error was about 1.5×10^{-14}, and then they would "bounce around" for many refinements until, apparently by chance, the maximum 1-step error would fall below 10^{-14}. The maximum allowed shadow distance was 0.1, although none over 0.0066 were observed with successful shadows.

Table 1 displays the speedups of the various optimizations. All ratios are speedup factors with respect to the time column, which was originally timed on a Sun Sparcstation. However, similar total speedups were recorded (under less rigorous conditions in which only the fully optimized versus unoptimized versions were tested) for many platforms, including Sun Sparcstations using both Sun's C compiler and GCC, Intel machines running Microsoft Windows or Linux, Silicon Graphics machines, a Cray Y-MP, and a Fujitsu VPX vector supercomputer. There are several interesting observations to make about this table. First, note that the run times of the original QT algorithm (after correction of the 3M oversight) are comparable to the run times of our unoptimized version (differing on average by a factor of 1.07), as would be expected. Now looking at each optimization acting alone, we see that using large shadow steps (column L) 8 times longer gives an average speedup of about 5.5. Large shadow steps are trivial to implement, so we would recommend that, even if no other optimizations are adopted, large shadow steps be used in any new shadowing implementation. Third, inverting the forward resolvent to produce the inverse resolvent (column I) produces the expected average speedup of 2.0. Fourth, the cheap accurate integrator (column C) gives an average speedup of 2.36. This is about what is expected, because both the QT and C algorithms on average require just over three refinements to converge, and all C refinements are cheaper than a QT refinement except the last one, which is about equal in expense. Finally, using Constant RUS gives a speedup of almost 3. Again this is about what is expected, because QT requires about three refinements to converge, while R has one RUS computation followed by several cheap Constant RUS refinements. The P, F, and i optimizations were not tested alone.

Next we look at combinations of optimizations. First, it is interesting to note that combining the cheap accurate integrator C with Constant RUS R results in an average speedup that is greater than the product of the two individual speedups ($2.36 \times 2.68 = 6.32 < 7.55$). This is because, when using CR, only $'$ $'$ RUS is computed, and it is computed cheaply. Using R alone requires computing the one RUS to high accuracy; using C alone requires computing at least one RUS (the final one) to high accuracy. Second, reusing the RUS of a previous successful shadow (P) makes sense only when R is also used. This gives an average speedup of 43% over CR. The next three columns show other combinations. An interesting point to note

TABLE 1

Speedups of the optimizations. "Time" represents unoptimized version. For other abbreviations, see text.

Seed	Time(s)	QT	L	I	C	R	CR	CPR	CLR	KR	KRI	KRIF	KRIFi

is that, except for CR, the combinations give a speedup less than the product of appropriate previous columns. Perhaps this is at least partially owing to an effect similar to Ahmdal's law: there still exist parts of the algorithm that have not been sped up, and as the remainder of the program that ▪ ▪ being optimized speeds up, these unoptimized sections take a greater proportion of the time.

Finally, it can be seen that the effect of the last two optimizations, ▪ and ▪, observed cumulatively with other optimizations ▪ ▪ in the last two columns of Table 1, contribute little to the average. This is because most of the systems in this table were shadowable. In fact, F slightly slows down refinement in one case. However, orbits 5, 6, 13, 19, and 29 obtained speedups significantly less than the average in the KRI column, but gain was made in the final two columns of up to a factor of 5. These were precisely the orbits that were most difficult to shadow (as the time column shows), and in fact some of them were not shadowable for their entire lengths. For these orbits, significant time was spent in the failed search to find a shadow lasting 1.28 time units. This indicates that the F and i optimizations are most effective in speeding up failing searches.

The final version of our algorithm corresponds to the combination of all optimizations, as illustrated in the last column of Table 1. However, in our source code, each of the optimizations can be turned on or off at compile time if the user so wishes.

5. Discussion. QT argues that if the refinement algorithm fails, there is good reason to believe that no shadow exists. This seems reasonable for several reasons. First, from the more rigorous study of simpler systems, glitches are known to exist and are not just a failure of any particular refinement algorithm. Second, QT's results are consistent with a conjecture by GHYS on the frequency of glitches [40]. Finally, [44] finds that 1-step errors close to the machine precision are often enough to rigorously imply the existence of an exact shadow (assuming sufficient hyperbolicity). However, in a nonnegligible number of cases, a shadow is not found for shadow steps $0..S$, but a shadow is found for the set $0..2S$. In other words, the algorithm failed to find a shadow of length S even though one exists. This also occurs when all optimizations are disabled, so it is not merely that the optimizations reduce reliability. Thus, in the search for the longest shadow, if our algorithm finds a shadow of length S but none of length $2S$, we also try $4S$ before giving up.

The GHYS/QT refinement algorithm is trivially parallelizable, since the computation of each RUS_i is independent of all the others; for the same reason, it also has excellent locality of reference in a serial implementation, so virtual memory paging is minimized.

There may be further optimizations possible. For example, in the N-body problem, the phase-space dimensions are split into sets of 6, one set for each particle in the system. Instead of computing the $6M \times 6M$ resolvent in $O((6M)^3)$ time, perhaps it may be possible to refine the trajectories of each particle separately, requiring M resolvents each of dimension 6×6, and $O(6^3 M)$ time to compute. This approach was explored with partial success in [31] and [30], but more work is needed to solidify the technique.

That a Hamiltonian system is shadowable for a nontrivial duration of time seems to surprise many people, since it can be shown that Hamiltonian systems are not hyperbolic. However, in practice, a system can hyperbolic for a nontrivial duration of time, before the global nonhyperbolicity inevitably asserts itself. In practice, it is the duration of this interval of "pseudohyperbolicity" [32] that shadowing measures, and in many cases the duration is nontrivial. We intend to apply our shadowing algorithm to a wider variety of problems in the near future. It has already been applied to a simple molecular dynamics test case with interesting results.

The source code can in principle be adapted to any ODE. However, the current major stumbling block is that the Jacobian must be hand-coded by the user, an extremely tedious and error-prone process. We intend in the near future to incorporate automatic differentiation [3, 4], but until then we are reluctant to publicly release the source code. However, individual requests for the source code can be addressed to the first author.

Acknowledgments. We thank Gerry Quinlan and Scott Tremaine for helpful discussions throughout this research, and for providing their original source code. The University of Toronto undergraduate Computing Disciplines Facility generously provided workstation clusters on which we consumed several CPU years during this research.

THREE-LEVEL BDDC IN THREE DIMENSIONS*

XUEMIN TU†

Abstract. Balancing domain decomposition by constraints (BDDC) methods are nonoverlapping iterative substructuring domain decomposition methods for the solution of large sparse linear algebraic systems arising from the discretization of elliptic boundary value problems. Their coarse problems are given in terms of a small number of continuity constraints for each subdomain, which are enforced across the interface. The coarse problem matrix is generated and factored by a direct solver at the beginning of the computation and it can ultimately become a bottleneck if the number of subdomains is very large. In this paper, two three-level BDDC methods are introduced for solving the coarse problem approximately for problems in three dimensions. This is an extension of previous work for the two-dimensional case. Edge constraints are considered in this work since vertex constraints alone, which work well in two dimensions, result in a noncompetitive algorithm in three dimensions. Some new technical tools are then needed in the analysis and this makes the three-dimensional case more complicated. Estimates of the condition numbers are provided for two three-level BDDC methods, and numerical experiments are also discussed.

Key words. BDDC, three-level, three dimensions, domain decomposition, coarse problem, condition number, Chebyshev iteration

1. Introduction.

Balancing domain decomposition by constraints (BDDC) methods, which were introduced and analyzed in [4, 11, 12], are similar to the balancing Neumann–Neumann algorithms. The coarse problem in a BDDC algorithm is given in terms of a set of primal constraints chosen for each subdomain, and the matrix of the coarse problem is generated and factored by using a direct solver at the beginning of the computation. We note that there are now computer systems with more than 100,000 powerful processors, which allow very large and detailed simulations. If there is a one to one or one to several relationship between processors and subdomains, then we can have a large number of subdomains. The coarse component of a two-level preconditioner can therefore become a bottleneck if the number of subdomains is very large. One way to remove this difficulty is to introduce one or more additional levels. In our recent paper [17], two three-level BDDC methods were introduced for two-dimensional problems with vertex constraints. We solve the coarse problem approximately by using the BDDC idea recursively and show that a good rate of convergence still can be maintained. However, in three dimensions, vertex constraints alone are not enough to obtain good polylogarithmic condition number bounds due to much weaker interpolation estimates, and constraints on the averages over edges or faces are needed. The new constraints lead to a considerably more complicated coarse problem and the need for new technical tools in the analysis. In this paper, we extend the two three-level BDDC methods in [17] to the three-dimensional

case using primal edge average constraints. With the help of new technical tools, we are able to provide estimates of the condition numbers of the system with these two new preconditioners.

We note that, since this paper was submitted, several papers have appeared on inexact solvers for BDDC (see [5, 10, 16, 15]) and dual-primal finite element tearing and interconnecting (FETI-DP), which are iterative substructuring algorithms closely related to BDDC (see [6]). For the study of the convergence rates of the BDDC algorithms and their connection with the FETI-DP algorithms, see [11, 12, 9, 2].

The rest of the paper is organized as follows. We first review the two-level BDDC methods briefly in section 2. We introduce our first three-level BDDC method and the corresponding preconditioner $\widetilde{M}^{-1}$ in section 3. We give some auxiliary results in section 4. In section 5, we provide an estimate of the condition number for the system with the preconditioner $\widetilde{M}^{-1}$, which is of the form $C(1+\log\frac{\hat{H}}{H})^2(1+\log\frac{H}{h})^2$, where $\hat{H}$, H, and h are typical diameters of the subregions, subdomains, and elements, respectively. (We decompose the whole domain into subregions and each subregion is then partitioned into several subdomains; see section 3 for details.) In section 6, we introduce a second three-level BDDC method which uses Chebyshev iterations. We denote the corresponding preconditioner by $\widehat{M}^{-1}$. We show that the condition number bound of the system with the preconditioner $\widehat{M}^{-1}$ is of the form $CC(k)\left(1+\log\frac{H}{h}\right)^2$, where $C(k)$ is a function of k, the number of Chebyshev iterations, and also depends on the eigenvalues of the preconditioned coarse problem and on the two parameters chosen for the Chebyshev iteration. $C(k)$ goes to 1 as k goes to ∞; i.e., the condition number approaches that of the two-level case. Finally, some computational results are presented in section 7.

2. The two-level BDDC method. The two-level BDDC methods have been studied extensively; see [4, 11, 12, 9]. In this section, we will briefly review this work and introduce notation which will be used in the rest of the paper.

We will consider a second order scalar elliptic problem in a three-dimensional region Ω as follows: Find $u \in H_0^1(\Omega)$ such that

$$\int_\Omega \rho\nabla u\cdot\nabla v = \int_\Omega fv \quad \forall v \in H_0^1(\Omega), \tag{2.1}$$

where $\rho(x) > 0$ for all $x \in \Omega$. We decompose Ω into N nonoverlapping subdomains Ω_i with diameters H_i, $i = 1,\dots,N$, and set $H = \max_i H_i$. We then introduce a triangulation of all the subdomains. Let Γ be the interface between the subdomains and let the set of interface nodes Γ_h be defined by $\Gamma_h = (\cup_i \partial\Omega_{i,h}) \setminus \partial\Omega_h$, where $\partial\Omega_{i,h}$ is the set of nodes on $\partial\Omega_i$ and $\partial\Omega_h$ is the set of nodes on $\partial\Omega$. The nodes of the different triangulations match across Γ.

Let $\mathbf{W}^{(i)}$ be the standard finite element space of continuous, piecewise trilinear functions on Ω_i; the algorithms and theory developed in this paper work for other lower order finite elements as well. We assume that these functions vanish on $\partial\Omega$. Each $\mathbf{W}^{(i)}$ can be decomposed into a subdomain interior part $\mathbf{W}_I^{(i)}$ and a subdomain interface part $\mathbf{W}_\Gamma^{(i)}$, i.e., $\mathbf{W}^{(i)} = \mathbf{W}_I^{(i)} \bigoplus \mathbf{W}_\Gamma^{(i)}$, where the subdomain interface part $\mathbf{W}_\Gamma^{(i)}$ will be further decomposed into a primal subspace $\mathbf{W}_\Pi^{(i)}$ and a dual subspace $\mathbf{W}_\Delta^{(i)}$, i.e., $\mathbf{W}_\Gamma^{(i)} = \mathbf{W}_\Pi^{(i)} \bigoplus \mathbf{W}_\Delta^{(i)}$. (They are called primal and dual in earlier works on FETI algorithms, where the dual variables are controlled by Lagrange multipliers.) Here, we will consider only edge average constraints over all the edges of all subdomains as primal variables. We change the variables to make the edge average degrees

of freedom explicit; see [7, section 4.2.1] and [9, section 2.3]. From now on, we assume that all the matrices are written in terms of the new variables.

We denote the associated product spaces by $\mathbf{W} := \prod_{i=1}^{N} \mathbf{W}^{(i)}$, $\mathbf{W}_\Gamma := \prod_{i=1}^{N} \mathbf{W}_\Gamma^{(i)}$, $\mathbf{W}_\Delta := \prod_{i=1}^{N} \mathbf{W}_\Delta^{(i)}$, $\mathbf{W}_\Pi := \prod_{i=1}^{N} \mathbf{W}_\Pi^{(i)}$, and $\mathbf{W}_I := \prod_{i=1}^{N} \mathbf{W}_I^{(i)}$. Correspondingly, we have $\mathbf{W} = \mathbf{W}_I \bigoplus \mathbf{W}_\Gamma$, and $\mathbf{W}_\Gamma = \mathbf{W}_\Pi \bigoplus \mathbf{W}_\Delta$.

The elements of $\mathbf{W}$ can be discontinuous across the interface. However, the finite element approximation of the elliptic problem is continuous across Γ. We denote the corresponding subspace of $\mathbf{W}$ by $\widehat{\mathbf{W}}$. Similarly, we denote the corresponding subspaces of $\mathbf{W}_\Gamma$, $\mathbf{W}_\Delta$, and $\mathbf{W}_\Pi$ by $\widehat{\mathbf{W}}_\Gamma$, $\widehat{\mathbf{W}}_\Delta$, and $\widehat{\mathbf{W}}_\Pi$, respectively.

In order to define the BDDC preconditioner, we further introduce an interface subspace $\widetilde{\mathbf{W}}_\Gamma \subset \mathbf{W}_\Gamma$, for which all the edge average primal constraints are enforced. The space $\widetilde{\mathbf{W}}_\Gamma$ can be decomposed into $\widetilde{\mathbf{W}}_\Gamma = \widehat{\mathbf{W}}_\Pi \bigoplus \mathbf{W}_\Delta$. We also have $\widehat{\mathbf{W}}_\Gamma \subset \widetilde{\mathbf{W}}_\Gamma$.

The global problem has the following form: Find $(\mathbf{u}_I, \mathbf{u}_\Delta, \mathbf{u}_\Pi) \in (\mathbf{W}_I, \widehat{\mathbf{W}}_\Delta, \widehat{\mathbf{W}}_\Pi)$ such that

$$\begin{pmatrix} A_{II} & A_{\Delta I}^T & A_{\Pi I}^T \\ A_{\Delta I} & A_{\Delta\Delta} & A_{\Pi\Delta}^T \\ A_{\Pi I} & A_{\Pi\Delta} & A_{\Pi\Pi} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ \mathbf{u}_\Delta \\ \mathbf{u}_\Pi \end{pmatrix} = \begin{pmatrix} \mathbf{f}_I \\ \mathbf{f}_\Delta \\ \mathbf{f}_\Pi \end{pmatrix}. \tag{2.2}$$

This problem is assembled from the subdomain problems

$$\begin{pmatrix} A_{II}^{(i)} & A_{\Delta I}^{(i)^T} & A_{\Pi I}^{(i)^T} \\ A_{\Delta I}^{(i)} & A_{\Delta\Delta}^{(i)} & A_{\Pi\Delta}^{(i)^T} \\ A_{\Pi I}^{(i)} & A_{\Pi\Delta}^{(i)} & A_{\Pi\Pi}^{(i)} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I^{(i)} \\ \mathbf{u}_\Delta^{(i)} \\ \mathbf{u}_\Pi^{(i)} \end{pmatrix} = \begin{pmatrix} \mathbf{f}_I^{(i)} \\ \mathbf{f}_\Delta^{(i)} \\ \mathbf{f}_\Pi^{(i)} \end{pmatrix}. \tag{2.3}$$

We also denote by $\mathbf{F}_\Gamma$, $\widehat{\mathbf{F}}_\Gamma$, and $\widetilde{\mathbf{F}}_\Gamma$ the dual spaces, that is, the spaces of the right-hand sides corresponding to $\mathbf{W}_\Gamma$, $\widehat{\mathbf{W}}_\Gamma$, and $\widetilde{\mathbf{W}}_\Gamma$, respectively.

In order to describe the BDDC algorithms, we need to introduce several restriction, extension, and scaling operators between different spaces.

The restriction operators from the product spaces to the subdomain local spaces are

$$\widehat{\mathbf{W}}_\Gamma \xrightarrow{R_\Gamma^{(i)}} \mathbf{W}_\Gamma^{(i)}, \quad \widehat{\mathbf{W}}_\Gamma \xrightarrow{\widehat{R}_\Delta^{(i)}} \mathbf{W}_\Delta^{(i)}, \quad \widetilde{\mathbf{W}}_\Gamma \xrightarrow{\overline{R}_\Gamma^{(i)}} \mathbf{W}_\Gamma^{(i)}, \quad \widehat{\mathbf{W}}_\Pi \xrightarrow{R_\Pi^{(i)}} \mathbf{W}_\Pi^{(i)}, \quad \text{and} \quad \mathbf{W}_\Delta \xrightarrow{R_\Delta^{(i)}} \mathbf{W}_\Delta^{(i)}.$$

Additionally, there are three restriction operators:

$$\widehat{\mathbf{W}}_\Gamma \xrightarrow{\widehat{R}_\Pi} \widehat{\mathbf{W}}_\Pi, \quad \widetilde{\mathbf{W}}_\Gamma \xrightarrow{R_{\Gamma\Delta}} \mathbf{W}_\Delta, \quad \text{and} \quad \widetilde{\mathbf{W}}_\Gamma \xrightarrow{R_{\Gamma\Pi}} \widehat{\mathbf{W}}_\Pi.$$

We also introduce two extension operators:

$$\widehat{\mathbf{W}}_\Gamma \xrightarrow{\widetilde{R}_\Gamma} \widetilde{\mathbf{W}}_\Gamma \xrightarrow{\overline{R}_\Gamma} \mathbf{W}_\Gamma,$$

where $\widetilde{R}_\Gamma$ is the direct sum of the operators $\widehat{R}_\Delta^{(i)}$ and $\widehat{R}_\Pi$, and $\overline{R}_\Gamma$ is the direct sum of the operators $\overline{R}_\Gamma^{(i)}$.

Multiplying each element of the matrix $\widehat{R}_\Delta^{(i)}$, which corresponds to a node $x \in \partial\Omega_i$, with $\delta_i^\dagger(x)$ gives us $\widehat{R}_{D,\Delta}^{(i)}$. Here, we define the scale factor $\delta_i^\dagger(x)$ as follows: For $\gamma \in [1/2, \infty)$,

$$\delta_i^\dagger(x) = \frac{\rho_i^\gamma(x)}{\sum_{j \in \mathcal{N}_x} \rho_j^\gamma(x)}, \quad x \in \partial\Omega_{i,h} \cap \Gamma_h, \tag{2.4}$$

where $\mathcal{N}_x$ is the set of indices j of the subdomains such that $x \in \partial\Omega_j$, and $\rho_j(x)$ is the coefficient of (2.1) at x in the subdomain Ω_j.

The scaled extension operator $\widetilde{R}_{D,\Gamma}$ is the direct sum of the operators $\widehat{R}^{(i)}_{D,\Delta}$ and $\widehat{R}_{\Pi}$. Equivalently, we can write $\widetilde{R}_{D,\Gamma} = D\widetilde{R}_{\Gamma}$, where D is a diagonal scaling matrix. The diagonal elements of D, corresponding to the primal variables, are 1, and all others are given by $\delta_i^{\dagger}(x)$.

We also use the same restriction, extension, and scaled extension operators for $\mathbf{F}_\Gamma$, $\widehat{\mathbf{F}}_\Gamma$, and $\widetilde{\mathbf{F}}_\Gamma$.

We now reduce the global problem (2.2) to an interface problem. We first introduce the subdomain Schur complement $S_\Gamma^{(i)}$ by eliminating the subdomain interior variables $u_I^{(i)}$ in (2.3) as follows:

$$S_\Gamma^{(i)} = \begin{pmatrix} A^{(i)}_{\Delta\Delta} & A^{(i)^T}_{\Pi\Delta} \\ A^{(i)}_{\Pi\Delta} & A^{(i)}_{\Pi\Pi} \end{pmatrix} - \begin{pmatrix} A^{(i)}_{\Delta I} \\ A^{(i)}_{\Pi I} \end{pmatrix} A^{(i)^{-1}}_{II} \begin{pmatrix} A^{(i)^T}_{\Delta I} & A^{(i)^T}_{\Pi I} \end{pmatrix}$$

and let

$$S_\Gamma = \begin{pmatrix} S_\Gamma^{(1)} & & \\ & \ddots & \\ & & S_\Gamma^{(N)} \end{pmatrix}.$$

The partially assembled Schur complement $\widetilde{S}_\Gamma$ is obtained from S_Γ by assembling the primal variables on the subdomain interface, i.e.,

$$\widetilde{S}_\Gamma = \overline{R}_\Gamma^T S_\Gamma \overline{R}_\Gamma.$$

$\widetilde{S}_\Gamma$ can be further assembled with respect to the variables of the $\mathbf{W}_\Delta^{(i)}$ and the reduced interface problem of (2.2) can be written as follows: Find $\mathbf{u}_\Gamma \in \widehat{\mathbf{W}}_\Gamma$ such that

$$\widetilde{R}_\Gamma^T \widetilde{S}_\Gamma \widetilde{R}_\Gamma \mathbf{u}_\Gamma = \mathbf{g}_\Gamma,$$

where

$$\mathbf{g}_\Gamma = \sum_{i=1}^N R_\Gamma^{(i)^T} \left\{ \begin{pmatrix} \mathbf{f}_\Delta^{(i)} \\ \mathbf{f}_\Pi^{(i)} \end{pmatrix} - \begin{pmatrix} A^{(i)}_{\Delta I} \\ A^{(i)}_{\Pi I} \end{pmatrix} A^{(i)^{-1}}_{II} \mathbf{f}_I^{(i)} \right\}.$$

The preconditioned two-level BDDC equation is of the form

$$M^{-1} \widetilde{R}_\Gamma^T \widetilde{S}_\Gamma \widetilde{R}_\Gamma \mathbf{u}_\Gamma = M^{-1} \mathbf{g}_\Gamma,$$

where the preconditioner $M^{-1} = \widetilde{R}_{D,\Gamma}^T \widetilde{S}_\Gamma^{-1} \widetilde{R}_{D,\Gamma}$ has the following form:

(2.5)
$$\widetilde{R}_{D,\Gamma}^T \left\{ R_{\Gamma\Delta}^T \left(\sum_{i=1}^N \begin{pmatrix} \mathbf{0} & R_\Delta^{(i)^T} \end{pmatrix} \begin{pmatrix} A^{(i)}_{II} & A^{(i)}_{I\Delta} \\ A^{(i)}_{\Delta I} & A^{(i)}_{\Delta\Delta} \end{pmatrix}^{-1} \begin{pmatrix} \mathbf{0} \\ R_\Delta^{(i)} \end{pmatrix} \right) R_{\Gamma\Delta} + \Phi S_\Pi^{-1} \Phi^T \right\} \widetilde{R}_{D,\Gamma}.$$

Here Φ is the matrix given by the coarse level basis functions of minimal energy defined by

$$\Phi = R_{\Gamma\Pi}^T - R_{\Gamma\Delta}^T \sum_{i=1}^N \begin{pmatrix} \mathbf{0} & R_\Delta^{(i)^T} \end{pmatrix} \begin{pmatrix} A^{(i)}_{II} & A^{(i)}_{I\Delta} \\ A^{(i)}_{\Delta I} & A^{(i)}_{\Delta\Delta} \end{pmatrix}^{-1} \begin{pmatrix} A^{(i)^T}_{\Pi I} \\ A^{(i)^T}_{\Pi\Delta} \end{pmatrix} R_\Pi^{(i)}.$$

The coarse level problem matrix S_Π is determined by

(2.6)
$$S_\Pi = \sum_{i=1}^{N} R_\Pi^{(i)^T} \left\{ A_{\Pi\Pi}^{(i)} - \begin{pmatrix} A_{\Pi I}^{(i)} & A_{\Pi\Delta}^{(i)} \end{pmatrix} \begin{pmatrix} A_{II}^{(i)} & A_{I\Delta}^{(i)} \\ A_{\Delta I}^{(i)} & A_{\Delta\Delta}^{(i)} \end{pmatrix}^{-1} \begin{pmatrix} A_{\Pi I}^{(i)^T} \\ A_{\Pi\Delta}^{(i)^T} \end{pmatrix} \right\} R_\Pi^{(i)},$$

which is obtained by assembling subdomain matrices; for additional details, cf. [4, 11, 9].

We know that, under certain assumptions, and for any $\mathbf{u}_\Gamma \in \widehat{\mathbf{W}}_\Gamma$,

$$\mathbf{u}_\Gamma^T M \mathbf{u}_\Gamma \leq \mathbf{u}_\Gamma^T \widetilde{R}_\Gamma^T \widetilde{S}_\Gamma \widetilde{R}_\Gamma \mathbf{u}_\Gamma \leq C \left(1 + \log(H/h)\right)^2 \mathbf{u}_\Gamma^T M \mathbf{u}_\Gamma. \tag{2.7}$$

These estimates can be established directly by using methods very similar to those of certain studies of the FETI-DP algorithms. Denote by E_D and P_D, respectively, the average and jump operators (see [14, Formulas (6.4) and (6.38)]) on the space $\widetilde{\mathbf{W}}_\Gamma$. Central to obtaining the condition number estimate for the preconditioned two-level BDDC operator is a bound for the E_D operators (see [12, Theorem 25]). Since $E_D + P_D = I$ (see [14, Lemma 6.10]), we need only find a bound for the P_D operator. We obtain a bound for the P_D operator by using [14, Lemma 6.36] under [14, Assumption 4.3.1] for the triangulation and using [14, Assumption 6.27.2] for the coefficient $\rho(x)$ of (2.1).

3. A three-level BDDC method. For the three-level cases, as in [17], the coarse problem matrix S_Π defined in (2.6) will not be factored by a direct solver. Instead, a new level is introduced and the coarse problem is solved approximately. Call the new level the subregion level. To distinguish the spaces and operators for the subregion level from those for the subdomain level, we use the subscript c for the former.

We decompose Ω into N_c subregions Ω^j with diameters $\hat{H}^j$, $j = 1, \ldots, N_c$. Each subregion Ω^j is the union of N_j subdomains Ω_i^j with diameters H_i^j. Let $\hat{H} = \max_j \hat{H}^j$ and $H = \max_{i,j} H_i^j$, for $j = 1, \ldots, N_c$, and $i = 1, \ldots, N_j$. Then N, the total number of subdomains, can be written as $N = N_1 + \cdots + N_{N_c}$.

We introduce the subregional Schur complement as

$$S_\Pi^{(j)} = \sum_{i=1}^{N_j} R_\Pi^{(i)^T} \left\{ A_{\Pi\Pi}^{(i)} - \begin{pmatrix} A_{\Pi I}^{(i)} & A_{\Pi\Delta}^{(i)} \end{pmatrix} \begin{pmatrix} A_{II}^{(i)} & A_{I\Delta}^{(i)} \\ A_{\Delta I}^{(i)} & A_{\Delta\Delta}^{(i)} \end{pmatrix}^{-1} \begin{pmatrix} A_{\Pi I}^{(i)^T} \\ A_{\Pi\Delta}^{(i)^T} \end{pmatrix} \right\} R_\Pi^{(i)} \tag{3.1}$$

and note that the coarse problem matrix S_Π can be assembled from the $S_\Pi^{(j)}$.

In the two-level case, S_Π is factored by a direct solver at the beginning of the computation; cf. (2.5). Here, we build $\widetilde{S}_\Pi^{-1}$ to approximate S_Π^{-1}. Replacing S_Π^{-1} in (2.5) with $\widetilde{S}_\Pi^{-1}$ gives us the three-level preconditioner $\widetilde{M}^{-1}$:

$$\widetilde{R}_{D,\Gamma}^T \left\{ R_{\Gamma\Delta}^T \left(\sum_{i=1}^{N} \begin{pmatrix} \mathbf{0} & R_\Delta^{(i)^T} \end{pmatrix} \begin{pmatrix} A_{II}^{(i)} & A_{I\Delta}^{(i)} \\ A_{\Delta I}^{(i)} & A_{\Delta\Delta}^{(i)} \end{pmatrix}^{-1} \begin{pmatrix} \mathbf{0} \\ R_\Delta^{(i)} \end{pmatrix} \right) R_{\Gamma\Delta} + \Phi \widetilde{S}_\Pi^{-1} \Phi^T \right\} \widetilde{R}_{D,\Gamma}.$$

To define $\widetilde{S}_\Pi^{-1}$ in detail, we need to introduce several spaces and operators.

Let Γ_c be the interface between the subregions; note that $\Gamma_c \subset \Gamma$. For each subregion Ω^i, we denote by $\mathbf{W}_c^{(i)}$ the space corresponding to the subdomain edge

average variables in this subregion. Let $\mathbf{W}_c = \prod_{i=1}^{N_c} \mathbf{W}_c^{(i)}$ and let $\widehat{\mathbf{W}}_c$ be the subspace of $\mathbf{W}_c$ of elements that are continuous across Γ_c. $\mathbf{W}_c^{(i)}$ can be decomposed into a subregion interior part $\mathbf{W}_{c,I_c}^{(i)}$ and a subregion interface part $\mathbf{W}_{c,\Gamma_c}^{(i)}$, i.e., $\mathbf{W}_c^{(i)} = \mathbf{W}_{c,I_c}^{(i)} \bigoplus \mathbf{W}_{c,\Gamma_c}^{(i)}$. We further decompose the subregion interface part $\mathbf{W}_{c,\Gamma_c}^{(i)}$ into a primal subspace $\mathbf{W}_{c,\Pi_c}^{(i)}$ and a dual subspace $\mathbf{W}_{c,\Delta_c}^{(i)}$, i.e., $\mathbf{W}_{c,\Gamma_c}^{(i)} = \mathbf{W}_{c,\Pi_c}^{(i)} \bigoplus \mathbf{W}_{c,\Delta_c}^{(i)}$. Here, we will consider only the use of edge average constraints over subregion edges. Again, we should change the variables for all local coarse matrices corresponding to these edge average constraints. We will assume that all matrices are written in the new variables.

We denote the associated subregion interface product space by $\mathbf{W}_{c,\Gamma_c} := \prod_{i=1}^{N_c} \mathbf{W}_{c,\Gamma_c}^{(i)}$. We note that the elements in $\mathbf{W}_{c,\Gamma_c}$ can be discontinuous across the subregion interface Γ_c. Let $\widehat{\mathbf{W}}_{c,\Gamma_c}$ and $\widetilde{\mathbf{W}}_{c,\Gamma_c}$ be two subsets of $\mathbf{W}_{c,\Gamma_c}$. The elements are continuous across Γ_c in $\widehat{\mathbf{W}}_{c,\Gamma_c}$, whereas only the primal variables are continuous across Γ_c in $\widetilde{\mathbf{W}}_{c,\Gamma_c}$. We have $\widehat{\mathbf{W}}_{c,\Gamma_c} \subset \widetilde{\mathbf{W}}_{c,\Gamma_c} \subset \mathbf{W}_{c,\Gamma_c}$. We also need two extension operators $\widetilde{R}_{\Gamma_c}$ and $\overline{R}_{\Gamma_c}$,

$$\widehat{\mathbf{W}}_{c,\Gamma_c} \xrightarrow{\widetilde{R}_{\Gamma_c}} \widetilde{\mathbf{W}}_{c,\Gamma_c} \xrightarrow{\overline{R}_{\Gamma_c}} \mathbf{W}_{c,\Gamma_c},$$

which are similar to $\widetilde{R}_{\Gamma}$ and $\overline{R}_{\Gamma}$, respectively.

We denote by $\widehat{\mathbf{F}}_c$ and $\widehat{\mathbf{F}}_{\Gamma_c}$ the dual spaces of $\widehat{\mathbf{W}}_c$ and $\widehat{\mathbf{W}}_{c,\Gamma_c}$, respectively. We use the same operators for $\widehat{\mathbf{F}}_c$ and $\widehat{\mathbf{F}}_{\Gamma_c}$.

We are now ready to explain how $\widetilde{S}_{\Pi}^{-1}$ works on a vector in $\widehat{\mathbf{F}}_c$. Given a vector $\Psi \in \widehat{\mathbf{F}}_c$, let $\mathbf{y} = S_{\Pi}^{-1}\Psi$ and $\widetilde{\mathbf{y}} = \widetilde{S}_{\Pi}^{-1}\Psi$. We write Ψ, $\mathbf{y}$, and $\widetilde{\mathbf{y}}$ in terms of interior and interface parts, i.e., $\Psi = (\Psi_{I_c}^{(1)}, \ldots, \Psi_{I_c}^{(N_c)}, \Psi_{\Gamma_c})^T$, $\mathbf{y} = (\mathbf{y}_{I_c}^{(1)}, \ldots, \mathbf{y}_{I_c}^{(N_c)}, \mathbf{y}_{\Gamma_c})^T$, and $\widetilde{\mathbf{y}} = (\widetilde{\mathbf{y}}_{I_c}^{(1)}, \ldots, \widetilde{\mathbf{y}}_{I_c}^{(N_c)}, \widetilde{\mathbf{y}}_{\Gamma_c})^T$.

To obtain $\mathbf{y}$, we can solve $S_{\Pi}\mathbf{y} = \Psi$ by block factorization. This vector satisfies

$$\begin{pmatrix} S_{\Pi_{I_c I_c}}^{(1)} & \mathbf{0} & \mathbf{0} & S_{\Pi_{\Gamma_c I_c}}^{(1)^T} R_{\Gamma_c}^{(1)} \\ \mathbf{0} & \ddots & \mathbf{0} & \vdots \\ \mathbf{0} & \mathbf{0} & S_{\Pi_{I_c I_c}}^{(N_c)} & S_{\Pi_{\Gamma_c I_c}}^{(N_c)^T} R_{\Gamma_c}^{(N_c)} \\ R_{\Gamma_c}^{(1)^T} S_{\Pi_{\Gamma_c I_c}}^{(1)} & \cdots & R_{\Gamma_c}^{(N_c)^T} S_{\Pi_{\Gamma_c I_c}}^{(N_c)} & \sum_{i=1}^{N_c} R_{\Gamma_c}^{(i)^T} S_{\Pi_{\Gamma_c \Gamma_c}}^{(i)} R_{\Gamma_c}^{(i)} \end{pmatrix} \begin{pmatrix} \mathbf{y}_{I_c}^{(1)} \\ \vdots \\ \mathbf{y}_{I_c}^{(N_c)} \\ \mathbf{y}_{\Gamma_c} \end{pmatrix} = \begin{pmatrix} \Psi_{I_c}^{(1)} \\ \vdots \\ \Psi_{I_c}^{(N_c)} \\ \Psi_{\Gamma_c} \end{pmatrix},$$

where $R_{\Gamma_c}^{(i)} : \widehat{\mathbf{W}}_{c,\Gamma_c} \to \mathbf{W}_{c,\Gamma_c}^{(i)}$ is a restriction operator.

We solve $\mathbf{y}_{I_c}^{(i)}$ in terms of $\mathbf{y}_{\Gamma_c}$ and have

$$\mathbf{y}_{I_c}^{(i)} = S_{\Pi_{I_c I_c}}^{(i)^{-1}} \left(\Psi_{I_c}^{(i)} - S_{\Pi_{I_c \Gamma_c}}^{(i)} R_{\Gamma_c}^{(i)} \mathbf{y}_{\Gamma_c} \right). \tag{3.2}$$

We then obtain the subregion interface problem

(3.3)
$$\left(\sum_{i=1}^{N_c} R_{\Gamma_c}^{(i)^T}(S_{\Pi_{\Gamma_c\Gamma_c}}^{(i)} - S_{\Pi_{\Gamma_c I_c}}^{(i)} S_{\Pi_{I_c I_c}}^{(i)^{-1}} S_{\Pi_{\Gamma_c I_c}}^{(i)^T}) R_{\Gamma_c}^{(i)}\right) \mathbf{y}_{\Gamma_c} = \Psi_{\Gamma_c} - \sum_{i=1}^{N_c} R_{\Gamma_c}^{(i)^T} S_{\Pi_{\Gamma_c I_c}}^{(i)} S_{\Pi_{I_c I_c}}^{(i)^{-1}} \Psi_{I_c}^{(i)}.$$

Let

$$T^{(i)} = S_{\Pi_{\Gamma_c\Gamma_c}}^{(i)} - S_{\Pi_{\Gamma_c I_c}}^{(i)} S_{\Pi_{I_c I_c}}^{(i)^{-1}} S_{\Pi_{\Gamma_c I_c}}^{(i)^T}$$

be the subregion Schur complement in (3.3).

Denote their direct sum by T:

$$T = \begin{pmatrix} T^{(1)} & & \\ & \ddots & \\ & & T^{(N_c)} \end{pmatrix}.$$

As on the subdomain level case, we introduce a partially assembled Schur complement of S_Π, and denote it by $\widetilde{T}$. $\widetilde{T}$ can be written as

$$\widetilde{T} = \overline{R}_{\Gamma_c}^T T \overline{R}_{\Gamma_c}. \tag{3.4}$$

We define $\mathbf{h}_{\Gamma_c} \in \widehat{\mathbf{F}}_{\Gamma_c}$ by

$$\mathbf{h}_{\Gamma_c} = \Psi_{\Gamma_c} - \sum_{i=1}^{N_c} R_{\Gamma_c}^{(i)^T} S_{\Pi_{\Gamma_c I_c}}^{(i)} S_{\Pi_{I_c I_c}}^{(i)^{-1}} \Psi_{I_c}^{(i)}. \tag{3.5}$$

The reduced subregion interface problem (3.3) can be written as follows: Find $\mathbf{y}_{\Gamma_c} \in \widehat{\mathbf{W}}_{c,\Gamma_c}$ such that

$$\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c} \mathbf{y}_{\Gamma_c} = \mathbf{h}_{\Gamma_c}. \tag{3.6}$$

To obtain the approximation $\widetilde{\mathbf{y}} = \widetilde{S}_\Pi^{-1}\Psi$, we do not solve (3.6) exactly. Instead, we compute $\widetilde{\mathbf{y}}_{\Gamma_c}$ as

$$\widetilde{\mathbf{y}}_{\Gamma_c} = \widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c} \mathbf{h}_{\Gamma_c}. \tag{3.7}$$

Here $\widetilde{R}_{D_c,\Gamma_c}$ is a scaled operator which is similar to $\widetilde{R}_{D,\Gamma}$; we can write $\widetilde{R}_{D_c,\Gamma_c} = D_c \widetilde{R}_{\Gamma_c}$, where D_c is a diagonal scaling matrix. The diagonal elements of D_c, corresponding to the primal variables, are 1, and all others are given by $\delta_{c,i}^\dagger(x)$. Here $\delta_{c,i}^\dagger(x)$ is similar to $\delta_i^\dagger(x)$, which is defined in (2.4), except that $\delta_{c,i}^\dagger(x)$ is defined for the subregion interface instead of the subdomain interface nodes. For an x on the subregion interface, $\delta_{c,i}^\dagger(x)$ is defined as follows: For $\gamma \in [\frac{1}{2}, \infty)$, $\delta_{c,i}^\dagger(x) = \frac{\rho_i^\gamma(x)}{\sum_{j\in\mathcal{N}_x} \rho_j^\gamma(x)}$, where $\mathcal{N}_x$ is the set of indices j of the subregions such that $x \in \partial\Omega^j$ and $\rho_j(x)$ is the coefficient of (2.1) at $x \in \partial\Omega^j$. (In our theory, we assume the ρ_i are constant in the subregions.)

We will maintain the same relation between $\widetilde{\mathbf{y}}_{I_c}^{(i)}$ and $\widetilde{\mathbf{y}}_{\Gamma_c}$as for $\mathbf{y}_{I_c}^{(i)}$ and $\mathbf{y}_{\Gamma_c}$ in (3.2), i.e.,

$$\widetilde{\mathbf{y}}_{I_c}^{(i)} = S_{\Pi_{I_c I_c}}^{(i)^{-1}} \left(\Psi_{I_c}^{(i)} - S_{\Pi_{I_c\Gamma_c}}^{(i)} R_{\Gamma_c}^{(i)} \widetilde{\mathbf{y}}_{\Gamma_c}\right). \tag{3.8}$$

4. Some auxiliary results. In this section, we will collect a number of results which are needed in our theory. In order to avoid a proliferation of constants, we will use the notation $A \approx B$. This means that there are two constants c and C,

independent of any mesh parameter and the coefficients of (2.1), such that $cA \le B \le CA$, where $C < \infty$ and $c > 0$. For the definition of discrete harmonic functions, see [14, section 4.4].

LEMMA 4.1. [illegible] $\mathcal{D}$ [illegible] $A_1 = (0,0,0)$ $B_1 = (H,0,0)$ $C_1 = (H,H,0)$ $D_1 = (0,H,0)$ $A_2 = (0,0,H)$ $B_2 = (H,0,H)$ $C_2 = (H,H,H)$ [illegible] $D_2 = (0,H,H)$ [illegible] h [illegible] v [illegible] $\mathcal{D}$ [illegible] $\bar{v}_{A_1B_1} \approx 1 + \log \frac{H}{h}$ [illegible] $\bar{v}_{A_1B_1}$ [illegible] v [illegible] A_1B_1 $|v|^2_{H^1(\mathcal{D})} \approx H\left(1 + \log \frac{H}{h}\right)$ [illegible] v [illegible]. This lemma follows from a result by Brenner and He [1, Lemma 4.2]. Let N be an integer and G_N the function defined on $(0,1)$ by

$$G_N(x) = \sum_{n=1}^{N} \left(\frac{1}{4n-3} \sin\left((4n-3)\pi x\right) \right).$$

$G_N(x)$ is even with respect to the midpoint of $(0,1)$, where it attains its maximum in absolute value. Moreover, we have

$$|G_N|^2_{H_{00}^{1/2}(0,1)} \approx 1 + \log N \text{ and } \|G_N\|_{L^2(0,1)} \approx 1;$$

see [1, Lemma 3.7].

Let $[-H, 0]$ and $[0, H]$ have a mesh inherited from the quasi-uniform meshes on D_1A_1 and A_1B_1, respectively, and let $g_h(x)$ be the nodal interpolation of $G_N(\frac{x+H}{2H})$. Then, we have

$$\|g_h\|_{L^\infty(-H,H)} \approx 1 + \log \frac{H}{h}, \quad |g_h|^2_{H_{00}^{1/2}(-H,H)} \approx 1 + \log \frac{H}{h}, \tag{4.1}$$
$$\text{and} \quad \|g_h\|_{L^2(-H,H)} \approx H;$$

see [1, Lemma 3.7] or [17, Lemma 1].

Let $\tau_h(x)$ be a function on $[0, H]$ defined as follows:

$$\tau_h(x) = \begin{cases} \frac{x}{h_1}, & 0 \le x \le h_1, \\ 1, & h_1 \le x \le H - h_2, \\ \frac{H-x}{h_2}, & H - h_2 \le x \le H, \end{cases}$$

where h_1 and h_2 are the lengths of the two end mesh intervals of $[0, H]$. Then the following estimates hold:

$$\|\tau_h\|^2_{L^2(0,H)} \approx H \quad \text{and} \quad |\tau_h|^2_{H_{00}^{1/2}(0,H)} \approx 1 + \log \frac{H}{h}; \tag{4.2}$$

see [1, Lemma 3.6].

Define the discrete harmonic function v as 0 everywhere on the boundary of $\mathcal{D}$ except on the two open faces $A_1B_1C_1D_1$ and $A_1B_1B_2A_2$. On these two faces it is defined by

$$v(x_1, x_2, 0) = g_h(x_2)\tau_h(x_1) \quad \text{for } (x_1, x_2) \in A_1B_1C_1D_1,$$

$$v(x_1, 0, x_3) = g_h(-x_3)\tau_h(x_1) \quad \text{for } (x_1, x_3) \in A_1B_1B_2A_2.$$

It is clear that $\bar{v}_{A_1B_1} \approx 1 + \log \frac{H}{h}$ and that v has a zero average over the other edges. Since v is discrete harmonic in $\mathcal{D}$, we have

$$\begin{aligned} |v|^2_{H^1(\mathcal{D})} &\approx |v|^2_{H^{1/2}(\partial\mathcal{D})} \\ &\approx |g_h|^2_{H^{1/2}_{00}(-H,H)} \|\tau_h\|^2_{L^2(0,H)} + |\tau_h|^2_{H^{1/2}_{00}(0,H)} \|g_h\|^2_{L^2(-H,H)} \\ &\approx H\left(1 + \log \frac{H}{h}\right), \end{aligned}$$

where we have used (4.1), (4.2), and [1, Corollary 3.5]. ∎

In Lemma 4.1, we have constructed the function v for a cube $\mathcal{D}$. By using similar ideas, we can construct functions v for other shape-regular polyhedra which will satisfy similar properties and bounds.

LEMMA 4.2. Ω^i_j Ω^i $j = 1, \ldots, N_i$ $V^h_{i,j}$ Ω^i_j h $\mathcal{E}_k$ $k = 1, \ldots, K_j$ Ω^i_j u $\bar{u}_{\mathcal{E}_k}$ $u \in V^h_{i,j}$ Ω^i_j Ω^i_j $j = 1, \ldots, N_i$

$$\left(1 + \log \frac{H}{h}\right) \left(\sum_{j=1}^{N_i} |u|^2_{H^1(\Omega^i_j)}\right) \approx \sum_{j=1}^{N_i} \sum_{k_1,k_2=1}^{K_j} H |\bar{u}_{\mathcal{E}_{k_1}} - \bar{u}_{\mathcal{E}_{k_2}}|^2.$$

Without loss of generality, we assume that the subdomains are hexahedral. Denote the edges of the subdomain Ω^i_j by $\mathcal{E}_k$, $k = 1, \ldots, 12$, and denote the average values of u over these 12 edges by $\bar{u}_{\mathcal{E}_k}$, $k = 1, \ldots, 12$, respectively.

According to Lemma 4.1, we can construct 11 discrete harmonic functions ϕ_m, $m = 2, \ldots, 12$, on Ω^i_j such that

$$(\overline{\phi}_m)_{\mathcal{E}_k} = \begin{cases} (\bar{u}_{\mathcal{E}_m} - \bar{u}_{\mathcal{E}_1})\,(1 + \log \frac{H}{h}), & m = k, \\ 0, & m \neq k, \end{cases}$$

and with

$$|\phi_m|^2_{H^1(\Omega^i_j)} \approx (\bar{u}_{\mathcal{E}_m} - \bar{u}_{\mathcal{E}_1})^2 \, H\left(1 + \log \frac{H}{h}\right), \quad m = 2, \ldots, 12. \tag{4.3}$$

Let $v_j = \frac{1}{1+\log \frac{H}{h}} (\sum_{m=2}^{12} \phi_m) + \bar{u}_{\mathcal{E}_1}$; we then have $(\bar{v}_j)_{\mathcal{E}_k} = \bar{u}_{\mathcal{E}_k}$, for $k = 1, \ldots, 12$, and

$$\begin{aligned} |v_j|^2_{H^1(\Omega^i_j)} &= \Big|\frac{1}{1 + \log \frac{H}{h}} \left(\sum_{m=2}^{12} \phi_m\right) + \bar{u}_{\mathcal{E}_1}\Big|^2_{H^1(\Omega^i_j)} \\ &= \left(\frac{1}{1 + \log \frac{H}{h}}\right)^2 \left|\sum_{m=2}^{12} \phi_m\right|^2_{H^1(\Omega^i_j)} \leq 11 \left(\frac{1}{1 + \log \frac{H}{h}}\right)^2 \sum_{m=2}^{12} |\phi_m|^2_{H^1(\Omega^i_j)} \\ &\leq \left(\frac{1}{c^{1/2}(1 + \log \frac{H}{h})}\right)^2 H\left(1 + \log \frac{H}{h}\right) \sum_{m=2}^{12} (\bar{u}_{\mathcal{E}_m} - \bar{u}_{\mathcal{E}_1})^2 \\ &\leq \frac{1}{c(1 + \log \frac{H}{h})} \sum_{k=1}^{12} H (\bar{u}_{\mathcal{E}_k} - \bar{u}_{\mathcal{E}_1})^2. \end{aligned}$$

Here, we have used (4.3) for the penultimate inequality.

By the definition of u, we have

$$|u|^2_{H^1(\Omega^i_j)} \leq |v_j|^2_{H^1(\Omega^i_j)} \leq \frac{1}{c(1+\log\frac{H}{h})} \sum_{k=1}^{12} H(\bar{u}_{\mathcal{E}_k} - \bar{u}_{\mathcal{E}_1})^2.$$

Summing over all the subdomains in the subregion Ω^i, we have

$$c\left(1+\log\frac{H}{h}\right)\left(\sum_{j=1}^{N_i} |u|^2_{H^1(\Omega^i_j)}\right) \leq \sum_{j=1}^{N_i}\sum_{k=1}^{12} H(\bar{u}_{\mathcal{E}_k} - \bar{u}_{\mathcal{E}_1})^2.$$

This proves one side of the equivalence.

We prove the other side as follows:

$$\begin{aligned}
&\sum_{j=1}^{N_i}\sum_{k=1}^{12} H(\bar{u}_{\mathcal{E}_k} - \bar{u}_{\mathcal{E}_1})^2 = \sum_{j=1}^{N_i}\sum_{k=1}^{12} H|\overline{(u-\bar{u}_{\mathcal{E}_1})}_{\mathcal{E}_k}|^2 \\
&\leq C\left(\sum_{j=1}^{N_i}\sum_{k=1}^{12} H\frac{1}{H}\|u-\bar{u}_{\mathcal{E}_1}\|^2_{L^2(\mathcal{E}_k)}\right) \leq C\left(\sum_{j=1}^{N_i}\left(1+\log\frac{H}{h}\right)|u|^2_{H^1(\Omega^i_j)}\right) \\
&\leq C\left(1+\log\frac{H}{h}\right)\left(\sum_{j=1}^{N_i}|u|^2_{H^1(\Omega^i_j)}\right).
\end{aligned}$$

Here, we have used a standard finite element Sobolev inequality; see [14, Lemma 4.30] for the second inequality and [14, Lemma 4.16] for the penultimate inequality.

We complete the proof of the other side of the equivalence by using the triangle inequality. ∎

We now introduce a new mesh on each subregion; we follow [3, 13]. The purpose of introducing this mesh is to relate the quadratic form of Lemma 4.2 to one for a more conventional finite element space.

Given a subregion Ω^i and subdomains Ω^i_j, $j = 1, \ldots, N_i$, let $\mathcal{T}$ be a quasi-uniform subtriangulation of Ω^i such that its set of vertices includes the vertices and the midpoints of the edges of Ω^i_j. For the hexahedral case, we decomposed each hexahedron into eight hexahedra by connecting the midpoints of the edges. We then partition the vertices of the new mesh $\mathcal{T}$ into two sets. The midpoints of edges are called primary and the other vertices of the new mesh $\mathcal{T}$ are called secondary. We call two vertices in the triangulation $\mathcal{T}$ adjacent if there is an edge of $\mathcal{T}$ between them, as in the standard finite element context; see Figures 1 and 2.

Let $U_H(\Omega)$ be the continuous piecewise trilinear finite element function space with respect to the new triangulation $\mathcal{T}$. For a subregion Ω^i, $U_H(\Omega^i)$ and $U_H(\partial\Omega^i)$ are defined as restrictions:

$$U_H(\Omega^i) = \{u|_{\Omega^i} : \ u \in U_H(\Omega)\}, \qquad U_H(\partial\Omega^i) = \{u|_{\partial\Omega^i} : \ u \in U_H(\Omega)\}.$$

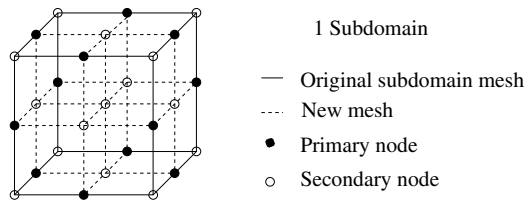

FIG. 1. *The new mesh and primary and secondary nodes in one subdomain of a subregion. (Note that all the lines of the original subdomain mesh are drawn in the same way.)*

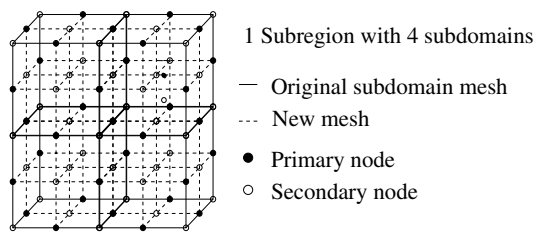

FIG. 2. *The new mesh and primary and secondary nodes in a subregion with four subdomains. (Note that all the lines of the original subdomain mesh are drawn in the same way.)*

We define a mapping $I_H^{\Omega^i}$ of any function ϕ, defined at the primary vertices in Ω^i, to $U_H(\Omega^i)$ by

(4.4)

$$I_H^{\Omega^i}\phi(x) = \begin{cases} \phi(x) \text{ if } x \text{ is a primary node;} \\ \text{the average of the values at all adjacent primary nodes} \\ \text{on the edges of } \Omega^i \text{ if } x \text{ is a vertex of } \Omega^i; \\ \text{the average of the values at two adjacent primary nodes} \\ \text{on the same edge of } \Omega^i \text{ if } x \text{ is an edge secondary node of } \Omega^i; \\ \text{the average of the values at all adjacent primary nodes on the} \\ \text{boundary of } \Omega^i \text{ if } x \text{ is a face secondary boundary node of } \Omega^i; \\ \text{the average of the values at all adjacent primary nodes} \\ \text{if } x \text{ is an interior secondary node of } \Omega^i \text{ with some adjacent} \\ \text{primary nodes;} \\ \text{the average of the values at all adjacent nodes} \\ \text{if } x \text{ is an interior secondary node of } \Omega^i \text{ without any adjacent} \\ \text{primary nodes;} \\ \text{the result of trilinear interpolation using the vertex values} \\ \text{if } x \text{ is not a vertex of } \mathcal{T}. \end{cases}$$

We recall that $\mathbf{W}_c^{(i)}$ is the discrete space of the values at the primary nodes given by the subdomain edge average values. $I_H^{\Omega^i}$ can be considered as a map from $\mathbf{W}_c^{(i)}$ to $U_H(\Omega^i)$ or as a map from $U_H(\Omega^i)$ to $U_H(\Omega^i)$.

Let $I_H^{\partial\Omega^i}$ be the mapping of a function ϕ defined at the primary vertices on the boundary of Ω^i to $U_H(\partial\Omega^i)$ and defined by $I_H^{\partial\Omega^i}\phi = (I_H^{\Omega^i}\phi_e)|_{\partial\Omega^i}$, where ϕ_e is any function in $\mathbf{W}_c^{(i)}$ such that $\phi_e|_{\partial\Omega^i} = \phi$. The map is well defined since the boundary values of $I_H^{\Omega^i}\phi_e$ depend only on the boundary values of ϕ_e.

Finally, let

$$\widetilde{U}_H(\Omega^i) = \{\psi = I_H^{\Omega^i}\phi,\ \phi \in U_H(\Omega^i)\}, \qquad \widetilde{U}_H(\partial\Omega^i) = \{\psi|_{\partial\Omega^i},\ \psi \in \widetilde{U}_H(\Omega^i)\}.$$

$I_H^{\partial\Omega^i}$ also can be considered as a map from $\mathbf{W}_{c,\Gamma_c}^{(i)}$ to $\widetilde{U}_H(\partial\Omega^i)$.

We carefully define the operators $I_H^{\Omega^i}$ and $I_H^{\partial\Omega^i}$ so that, if the edge averages of $w_i \in \mathbf{W}_{c,\Gamma_c}^{(i)}$ and $w_j \in \mathbf{W}_{c,\Gamma_c}^{(j)}$ over an edge $\mathcal{E}$ are the same, we have $(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}} = (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}}$. Here we need to use a weighted average which has a larger weight at the two end points since we consider an edge as an open set and the two end primary points have only one neighboring secondary node on the edge. But this will not affect our analysis. We could also define a weighted edge average of w_i and w_j and obtain $(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}} = (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}}$ for the usual average.

We list some useful lemmas from [3]. For proofs of Lemmas 4.3 and 4.4, see [3, Lemmas 6.1 and 6.2], respectively.

LEMMA 4.3. There exists a constant $C > 0$ such that for any H and $|\Omega^i|$ the

$$|I_H^{\Omega^i}\phi|_{H^1(\Omega^i)} \le C|\phi|_{H^1(\Omega^i)} \quad \text{and} \quad \|I_H^{\Omega^i}\phi\|_{L^2(\Omega^i)} \le C\|\phi\|_{L^2(\Omega^i)} \quad \forall \phi \in U_H(\Omega^i).$$

LEMMA 4.4. For $\hat{\phi} \in \widetilde{U}_H(\partial\Omega^i)$

$$\inf_{\phi \in \widetilde{U}_H(\Omega^i),\ \phi|_{\partial\Omega^i} = \hat{\phi}} \|\phi\|_{H^1(\Omega^i)} \approx \|\hat{\phi}\|_{H^{1/2}(\partial\Omega^i)},$$

$$\inf_{\phi \in \widetilde{U}_H(\Omega^i),\ \phi|_{\partial\Omega^i} = \hat{\phi}} |\phi|_{H^1(\Omega^i)} \approx |\hat{\phi}|_{H^{1/2}(\partial\Omega^i)}.$$

LEMMA 4.5. For $w_i \in \mathbf{W}_{c,\Gamma_c}^{(i)}$

$$\rho_i C_1 |I_H^{\partial\Omega^i} w_i|^2_{H^{1/2}(\partial\Omega^i)} \approx \left(1 + \log\frac{H}{h}\right)(T^{(i)} w_i, w_i),$$

where $(T^{(i)} w_i, w_i) = w_i^T T^{(i)} w_i = |w_i|^2_{T^{(i)}}$ and $T^{(i)} = S^{(i)}_{\Pi_{\Gamma_c\Gamma_c}} - S^{(i)}_{\Pi_{\Gamma_c I_c}} S^{(i)^{-1}}_{\Pi_{I_c I_c}} S^{(i)^T}_{\Pi_{\Gamma_c I_c}}$

By the definition of $T^{(i)}$, we have

$$\begin{aligned}
\left(1+\log\frac{H}{h}\right)(T^{(i)}w_i,w_i) &= \left(1+\log\frac{H}{h}\right)\inf_{v\in\mathbf{W}_c^{(i)},\ v|_{\partial\Omega^i}=w_i}|v|^2_{S_\Pi^{(i)}}\\
&= \inf_{v\in\mathbf{W}_c^{(i)},\ v|_{\partial\Omega^i}=w_i}\rho_i\left(1+\log\frac{H}{h}\right)\left(\sum_{j=1}^{N_i}\inf_{u\in V_{i,j}^h,\ \bar{u}_{\mathcal{E}_l}=v_l,\ \mathcal{E}_l\subset\partial\Omega_j^i}|u|^2_{H^1(\Omega_j^i)}\right)\\
&\approx \inf_{v\in\mathbf{W}_c^{(i)},\ v|_{\partial\Omega^i}=w_i}\rho_i\sum_{j=1}^{N_i}\sum_{k_1,k_2=1}^{K_j}H|\bar{u}_{\mathcal{E}_{k_1}}-\bar{u}_{\mathcal{E}_{k_2}}|^2\\
&\approx \inf_{v\in\mathbf{W}_c^{(i)},\ v|_{\partial\Omega^i}=w_i}\rho_i\sum_{j=1}^{N_i}\sum_{k_1,k_2=1}^{K_j}H|v_{k_1}-v_{k_2}|^2\\
&\approx \inf_{v\in\mathbf{W}_c^{(i)},\ v|_{\partial\Omega^i}=w_i}\rho_i|I_H^{\Omega^i}v|^2_{H^1(\Omega^i)} \approx \inf_{\phi\in\widetilde{U}_H(\Omega^i),\ \phi|_{\partial\Omega^i}=I_H^{\partial\Omega^i}w_i}\rho_i|\phi|^2_{H^1(\Omega^i)}\\
&\approx \rho_i|I_H^{\partial\Omega^i}w_i|_{H^{1/2}(\partial\Omega^i)}.
\end{aligned}$$

We use Lemma 4.2 for the third bound, the definitions of $I_H^{\Omega^i}$ and $I_H^{\partial\Omega^i}$ for the fourth and fifth bounds, and Lemma 4.4 for the final bound. ∎

To be fully rigorous, we assume that there is a quasi-uniform coarse triangulation of each subregion. We can then obtain uniform upper and lower bounds for each subregion as is required in Lemma 4.5.

We define the interface average operator E_{D_c} on $\widetilde{\mathbf{W}}_{c,\Gamma_c}$ as $E_{D_c}=\widetilde{R}_{\Gamma_c}\widetilde{R}^T_{D_c,\Gamma_c}$, which computes the averages across the subregion interface Γ_c and then adopts these averages at the boundary points of the subregions.

The interface average operator E_{D_c} has the following property.

LEMMA 4.6.

$$|E_{D_c}\mathbf{w}_{\Gamma_c}|^2_{\tilde{T}} \le C\left(1+\log\frac{\hat{H}}{H}\right)^2|\mathbf{w}_{\Gamma_c}|^2_{\tilde{T}}$$

$\mathbf{w}_{\Gamma_c}\in\widetilde{\mathbf{W}}_{c,\Gamma_c}$, C $\hat{H}$ H h (2.1) $\widetilde{T}$ (3.4).

Let $w_i=\overline{R}^{(i)}_{\Gamma_c}\mathbf{w}_{\Gamma_c}\in\mathbf{W}^{(i)}_{c,\Gamma_c}$, where $\overline{R}^{(i)}_{\Gamma_c}$ is the restriction operator from $\widetilde{\mathbf{W}}_{c,\Gamma_c}$ to $\mathbf{W}^{(i)}_{c,\Gamma_c}$. We rewrite the formula for $v:=w_{\Gamma_c}-E_{D_c}w_{\Gamma_c}$ for an arbitrary element $\mathbf{w}_{\Gamma_c}\in\widetilde{\mathbf{W}}_{c,\Gamma_c}$, and find that for $i=1,\dots,N_c$,

$$v_i(x):=(\mathbf{w}_{\Gamma_c}(x)-E_{D_c}\mathbf{w}_{\Gamma_c}(x))_i=\sum_{j\in\mathcal{N}_x}\delta^\dagger_{c,j}(w_i(x)-w_j(x)),\quad x\in\partial\Omega^i\cap\Gamma_c. \tag{4.5}$$

Here $\mathcal{N}_x$ is the set of indices of the subregions that have x on their boundaries.

We have

$$|E_{D_c}\mathbf{w}_{\Gamma_c}|^2_{\tilde{T}}=\sum_{i=1}^{N_c}|w_i-v_i|^2_{T^{(i)}}\le 2\sum_{i=1}^{N_c}|w_i|^2_{T^{(i)}}+2\sum_{i=1}^{N_c}|v_i|^2_{T^{(i)}}\text{ and }|\mathbf{w}_{\Gamma_c}|^2_{\tilde{T}}=\sum_{i=1}^{N_c}|w_i|^2_{T^{(i)}}.$$

We can therefore focus on the estimate of the contribution from a single subregion Ω^i and proceed as in the proof of [14, Lemma 6.36].

We will also use the simple inequality

$$\rho_i \delta_{c,j}^{\dagger^2} \leq \min(\rho_i, \rho_j) \text{ for } \gamma \in [1/2, \infty). \tag{4.6}$$

By Lemma 4.5,

$$(T^{(i)} v_i, v_i) \leq C \frac{1}{(1 + \log \frac{H}{h})} \rho_i |I_H^{\partial\Omega^i}(v_i)|^2_{H^{1/2}(\partial\Omega^i)}. \tag{4.7}$$

Let $l_i = I_H^{\partial\Omega^i}(v_i)$. By using a partition of unity as in [14, Lemma 6.36], we have

$$l_i = \sum_{\mathcal{F} \subset \partial\Omega^i} I^H(\theta_{\mathcal{F}} l_i) + \sum_{\mathcal{E} \subset \partial\Omega^i} I^H(\theta_{\mathcal{E}} l_i) + \sum_{\mathcal{V} \in \partial\Omega^i} \theta_{\mathcal{V}} l_i(\mathcal{V}),$$

where I^H is the nodal piecewise linear interpolant on the coarse mesh $\mathcal{T}$. We note that the analysis of face and edge terms is almost identical to that in [14, Lemma 6.36]. But the vertex terms are different because of $I_H^{\partial\Omega^i}$. We need only consider the vertex term when two subregions share at least an edge. This make the analysis simpler than in the proof of [14, Lemma 6.36].

Face terms. First, consider

$$I^H(\theta_{\mathcal{F}} l_i) = I^H(\theta_{\mathcal{F}} I_H^{\partial\Omega^i}(\delta_{c,j}^{\dagger}(w_i - w_j))).$$

Similar to [14, Lemma 6.36], we obtain, by using (4.6),

$$\begin{aligned}
&\rho_i |I^H(\theta_{\mathcal{F}} I_H^{\partial\Omega^i}(\delta_{c,j}^{\dagger}(w_i - w_j)))|^2_{H^{1/2}(\partial\Omega^i)} \\
&\quad = \rho_i \delta_{c,j}^{\dagger^2} |I^H(\theta_{\mathcal{F}} I_H^{\partial\Omega^i}(w_i - w_j))|^2_{H^{1/2}(\partial\Omega^i)} \\
&\quad \leq \min(\rho_i, \rho_j) |I^H(\theta_{\mathcal{F}}((I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}) - (I_H^{\partial\Omega^i} w_j - (\overline{I_H^{\partial\Omega^i} w_j})_{\mathcal{F}}) \\
&\qquad + ((\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}} - (\overline{I_H^{\partial\Omega^i} w_j})_{\mathcal{F}})))|^2_{H^{1/2}(\partial\Omega^i)} \\
&\quad \leq 3 \min(\rho_i, \rho_j) \Big(|I^H(\theta_{\mathcal{F}}(I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}))|^2_{H^{1/2}(\partial\Omega^i)} \\
&\qquad + |I^H(\theta_{\mathcal{F}}(I_H^{\partial\Omega^i} w_j - (\overline{I_H^{\partial\Omega^i} w_j})_{\mathcal{F}}))|^2_{H^{1/2}(\partial\Omega^i)} \\
&\qquad + |\theta_{\mathcal{F}}((\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}} - (\overline{I_H^{\partial\Omega^i} w_j})_{\mathcal{F}})|^2_{H^{1/2}(\partial\Omega^i)} \Big).
\end{aligned} \tag{4.8}$$

By the definition of $I_H^{\partial\Omega^i}$,

$$I^H(\theta_{\mathcal{F}}(I_H^{\partial\Omega^i} w_j)) = I^H(\theta_{\mathcal{F}}(I_H^{\partial\Omega^j} w_j)) \quad \text{and} \quad (\overline{I_H^{\partial\Omega^i} w_j})_{\mathcal{F}} = (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{F}}.$$

By [14, Lemma 4.26], the first and second terms in (4.8) can be estimated as follows:

$$\begin{aligned}
&\min(\rho_i, \rho_j)(|I^H(\theta_{\mathcal{F}}(I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}))|^2_{H^{1/2}(\partial\Omega^i)} \\
&+ |I^H(\theta_{\mathcal{F}}(I_H^{\partial\Omega^i} w_j - (\overline{I_H^{\partial\Omega^i} w_j})_{\mathcal{F}}))|^2_{H^{1/2}(\partial\Omega^i)}) \\
&\quad = \min(\rho_i, \rho_j)(|I^H(\theta_{\mathcal{F}}(I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}))|^2_{H^{1/2}(\partial\Omega^i)} \\
&+ |I^H(\theta_{\mathcal{F}}(I_H^{\partial\Omega^j} w_j - (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{F}}))|^2_{H^{1/2}(\partial\Omega^i)}) \\
&\quad \leq C \left(1 + \log \frac{\hat{H}}{H}\right)^2 \left(\rho_i |I_H^{\partial\Omega^i} w_i|^2_{H^{1/2}(\partial\Omega^i)} + \rho_j |I_H^{\partial\Omega^j} w_j|^2_{H^{1/2}(\partial\Omega^j)} \right).
\end{aligned}$$

Let $\mathcal{E} \subset \partial\mathcal{F}$. Since the edge averages of w_i and w_j are the same, we have, by the definition of $I_H^{\partial\Omega^i}$ and $I_H^{\partial\Omega^j}$, that $(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}} = (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}}$. As we have pointed out before, we use a weighted average which has a larger weight at the two end points.

We then have

$$\begin{aligned}
&|(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}} - (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{F}})|^2 \\
&\quad \leq 2\left(|(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}} - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}|^2 + |(\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}} - (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{F}}|^2\right).
\end{aligned} \tag{4.9}$$

It is sufficient to consider the first term on the right-hand side. Using [14, Lemma 4.30], we find

$$\begin{aligned}
&|(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}} - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}|^2 \\
&\quad = |\overline{(I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}})_{\mathcal{E}}}|^2 \leq C/\hat{H}_i \|I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}\|^2_{L^2(\mathcal{E})},
\end{aligned}$$

and, by using [14, Lemma 4.17] and the Poincaré inequality given as [14, Lemma A.17], we have

$$|(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}} - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}|^2 \leq \frac{C}{\hat{H}_i}\left(1 + \log\frac{\hat{H}}{H}\right)|I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}}|^2_{H^{1/2}(\mathcal{F})}.$$

Combining this with the bound for $\theta_{\mathcal{F}}$ in [14, Lemma 4.26], we have

$$\begin{aligned}
&\min(\rho_i, \rho_j)|\theta_{\mathcal{F}}((\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{F}} - (\overline{I_H^{\partial\Omega^i} w_j})_{\mathcal{F}})|^2_{H^{1/2}(\partial\Omega^i)} \\
&\quad \leq C\left(1 + \log\frac{\hat{H}}{H}\right)^2 \left(\rho_i |I_H^{\partial\Omega^i} w_i|^2_{H^{1/2}(\partial\Omega^i)} + \rho_j |I_H^{\partial\Omega^j} w_j|^2_{H^{1/2}(\partial\Omega^j)}\right).
\end{aligned}$$

Edge terms. We can develop the same estimate as in [14, Lemma 6.34]. For simplicity, we consider only an edge $\mathcal{E}$ common to four subregions Ω^i, Ω^j, Ω^k, and Ω^l. Then,

$$\begin{aligned}
&\rho_i |I^H(\theta_{\mathcal{E}} l_i)|^2_{H^{1/2}(\partial\Omega^i)} \\
&\quad \leq \rho_i \left(|I^H(\theta_{\mathcal{E}} I_H^{\partial\Omega^i}(\delta^\dagger_{c,j}(w_i - w_j)))|^2_{H^{1/2}(\partial\Omega^i)}\right. \\
&\quad + |I^H(\theta_{\mathcal{E}} I_H^{\partial\Omega^i}(\delta^\dagger_{c,k}(w_i - w_k)))|^2_{H^{1/2}(\partial\Omega^i)} \\
&\quad \left. + |I^H(\theta_{\mathcal{E}} I_H^{\partial\Omega^i}(\delta^\dagger_{c,l}(w_i - w_l)))|^2_{H^{1/2}(\partial\Omega^i)}\right).
\end{aligned} \tag{4.10}$$

We recall that $\delta^\dagger_{c,j}$, $\delta^\dagger_{c,k}$, and $\delta^\dagger_{c,l}$ are constants.

By the definition of $I_H^{\partial\Omega^i}$, $I_H^{\partial\Omega^j}$, $I_H^{\partial\Omega^k}$, and $I_H^{\partial\Omega^l}$, we have

$$\theta_{\mathcal{E}}(I_H^{\partial\Omega^i} w_j) = \theta_{\mathcal{E}}(I_H^{\partial\Omega^j} w_j), \quad \theta_{\mathcal{E}}(I_H^{\partial\Omega^i} w_k) = \theta_{\mathcal{E}}(I_H^{\partial\Omega^k} w_k), \quad \theta_{\mathcal{E}}(I_H^{\partial\Omega^i} w_l) = \theta_{\mathcal{E}}(I_H^{\partial\Omega^l} w_l),$$

and

$$(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}} = (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}} = (\overline{I_H^{\partial\Omega^k} w_k})_{\mathcal{E}} = (\overline{I_H^{\partial\Omega^l} w_l})_{\mathcal{E}}.$$

We assume that Ω^i shares a face with Ω^j as well as Ω^l and shares an edge only with Ω^k.

First, we consider the second term in (4.10). By [14, Lemmas 4.19 and 4.17] and (4.6), we have

$$
\begin{aligned}
&\rho_i |I^H(\theta_{\mathcal{E}} I_H^{\partial\Omega^i}(\delta_{c,k}^{\dagger}(w_i - w_k)))|^2_{H^{1/2}(\partial\Omega^i)} \\
&\quad \le C\rho_i \delta_{c,k}^{\dagger^2} \|I^H(\theta_{\mathcal{E}}(I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}}) - \theta_{\mathcal{E}}(I_H^{\partial\Omega^k} w_k - (\overline{I_H^{\partial\Omega^k} w_k})_{\mathcal{E}}))\|^2_{L^2(\mathcal{E})} \\
&\quad \le 2C \Big(\rho_i \|I^H(\theta_{\mathcal{E}}(I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}}))\|^2_{L^2(\mathcal{E})} \\
&\qquad + \rho_k \|I^H(\theta_{\mathcal{E}}(I_H^{\partial\Omega^k} w_k - (\overline{I_H^{\partial\Omega^k} w_k})_{\mathcal{E}}))\|^2_{L^2(\mathcal{E})}\Big) \\
&\quad \le 2C \Big(\rho_i \|I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}}\|^2_{L^2(\mathcal{E})} + \rho_k \|I_H^{\partial\Omega^k} w_k - (\overline{I_H^{\partial\Omega^k} w_k})_{\mathcal{E}}\|^2_{L^2(\mathcal{E})}\Big) \\
&\quad \le 2C \left(1 + \log \frac{\hat{H}}{H}\right) \Big(\rho_i |I_H^{\partial\Omega^i} w_i|^2_{H^{1/2}(\mathcal{F}^i)} + \rho_k |I_H^{\partial\Omega^k} w_k|^2_{H^{1/2}(\mathcal{F}^k)}\Big) \\
&\quad \le 2C \left(1 + \log \frac{\hat{H}}{H}\right) \Big(\rho_i |I_H^{\partial\Omega^i} w_i|^2_{H^{1/2}(\partial\Omega^i)} + \rho_k |I_H^{\partial\Omega^k} w_k|^2_{H^{1/2}(\partial\Omega^k)}\Big),
\end{aligned}
$$

where $\mathcal{F}^i$ is a face of Ω^i, $\mathcal{F}^k$ is a face of Ω^k, and $\mathcal{F}^i$ and $\mathcal{F}^k$ share the edge $\mathcal{E}$.

The first and third terms can be estimated similarly.

Vertex terms. We can apply techniques similar to those of the proof in [14, Lemma 6.36]. We have

$$
\rho_i |\theta_{\mathcal{V}} l_i(\mathcal{V})|^2_{H^{1/2}(\partial\Omega^i)} = \rho_i |\theta_{\mathcal{V}}(I_H^{\partial\Omega^i} v_i)(\mathcal{V})|^2_{H^{1/2}(\partial\Omega^i)}. \tag{4.11}
$$

By (4.5) and the definition of $I_H^{\partial\Omega^i}$, we see that $(I_H^{\partial\Omega^i} v_i)(\mathcal{V})$ is nonzero only when two subregions share one or several edges with a common vertex $\mathcal{V}$.

In the definition of $I_H^{\Omega^i}$, we denote by $\mathcal{E}_{i,m}$, $m = 1, 2, 3, \ldots$, the edges in $\partial\Omega^i$ which share $\mathcal{V}$. Denote by $p_{i,m}$ the primary nodes on the edges $\mathcal{E}_{i,m}$ which are adjacent to $\mathcal{V}$.

By the definition of $I_H^{\Omega^i}$, (4.11), and $|\theta_{\mathcal{V}}|^2_{H^{1/2}(\partial\Omega^i)} \le CH_i$, we have

$$
\begin{aligned}
\rho_i |\theta_{\mathcal{V}}(I_H^{\partial\Omega^i} v_i)(\mathcal{V})|^2_{H^{1/2}(\partial\Omega^i)} &\le C\rho_i |\sum_m v_i(p_{i,m})|^2 |\theta_{\mathcal{V}}|^2_{H^{1/2}(\partial\Omega^i)} \\
&\le C\rho_i H_i \sum_m |v_i(p_{i,m})|^2. \qquad (4.12)
\end{aligned}
$$

Let us look at the first term in (4.12); the other terms can be estimated in the

same way. We find that

$$
\begin{aligned}
&\rho_i H_i |v_i(p_{i,1})|^2 \\
&\quad = \rho_i H_i | \sum_{j,\ \mathcal{E}_{i,1}\subset\partial\Omega^j} \delta^\dagger_{c,j}(w_i(p_{i,1}) - w_j(p_{i,1}))|^2 \\
&\quad \le C \sum_{j,\ \mathcal{E}_{i,1}\subset\partial\Omega^j} \min(\rho_i,\rho_j) H_i |w_i(p_{i,1}) - w_j(p_{i,1})|^2 \\
&\quad = C \sum_{j,\ \mathcal{E}_{i,1}\subset\partial\Omega^j} \min(\rho_i,\rho_j) H_i |I_H^{\partial\Omega^i} w_i(p_{i,1}) - I_H^{\partial\Omega^j} w_j(p_{i,1})|^2 \\
&\quad \le C \sum_{j,\ \mathcal{E}_{i,1}\subset\partial\Omega^j} \min(\rho_i,\rho_j) H_i \left(|I_H^{\partial\Omega^i} w_i(p_{i,1}) - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}_{i,1}}|^2 \right. \\
&\qquad \left. + |I_H^{\partial\Omega^j} w_j(p_{i,1}) - (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}_{i,1}}|^2 \right) \\
&\quad \le C \sum_{j,\ \mathcal{E}_{i,1}\subset\partial\Omega^j} \min(\rho_i,\rho_j) \left(H_i | \left(I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}_{i,1}} \right)(p_{i,1})|^2 \right. \\
&\qquad \left. + H_i | \left(I_H^{\partial\Omega^j} w_j - (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}i,1} \right)(p_{i,1})|^2 \right) \\
&\quad \le C \sum_{j,\ \mathcal{E}i,1\subset\partial\Omega^j} \min(\rho_i,\rho_j) \left(\| I_H^{\partial\Omega^i} w_i - (\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}_{i,1}} \|^2_{L^2(\mathcal{E}_{i,1})} \right. \\
&\qquad \left. + \| I_H^{\partial\Omega^j} w_j - (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}_{i,1}} \|^2_{L^2(\mathcal{E}_{i,1})} \right) \\
&\quad \le C \sum_{j,\ \mathcal{E}i,1\subset\partial\Omega^j} \left(1 + \log \frac{\hat{H}}{H} \right) \left(\rho_i |I_H^{\partial\Omega^i} w_i|^2_{H^{1/2}(\partial\Omega^i)} + \rho_j |I_H^{\partial\Omega^j} w_j|^2_{H^{1/2}(\partial\Omega^i)} \right).
\end{aligned}
$$

For the third equality, we use that $p_{i,1}$ is a primary node. For the fourth inequality, we use that $(\overline{I_H^{\partial\Omega^i} w_i})_{\mathcal{E}_{i,1}} = (\overline{I_H^{\partial\Omega^j} w_j})_{\mathcal{E}_{i,1}}$. We use [14, Lemmas B.5] for the sixth inequality and [14, Lemma 4.17] for the last inequality.

Combining all face, edge, and vertex estimates, we obtain

$$
\rho_i |I_H^{\partial\Omega^i}(v_i)|^2_{H^{1/2}(\partial\Omega^i)} \le C \left(1 + \log \frac{\hat{H}}{H} \right)^2 \sum_{j:\ \partial\Omega^j\cap\partial\Omega^i\neq\emptyset} \rho_j |I_H^{\partial\Omega^i}(w_j)|^2_{H^{1/2}(\partial\Omega^j)}. \tag{4.13}
$$

Using (4.13), Lemma 4.5, and (4.7), we obtain

$$
\begin{aligned}
(T^{(i)} v_i, v_i) = |v_i|^2_{T^{(i)}} &\le C \frac{1}{(1+\log\frac{H}{h})} \rho_i |I_H^{\partial\Omega^i}(v_i)|^2_{H^{1/2}(\partial\Omega^i)} \\
&\le C \frac{\left(1+\log\frac{\hat{H}}{H}\right)^2}{(1+\log\frac{H}{h})} \sum_{j:\ \partial\Omega^j\cap\partial\Omega^i\neq\emptyset} \rho_j |I_H^{\partial\Omega^i}(w_j)|^2_{H^{1/2}(\partial\Omega^j)} \\
&\le \frac{C}{c} \left(1 + \log \frac{\hat{H}}{H} \right)^2 \sum_{j:\ \partial\Omega^j\cap\partial\Omega^i\neq\emptyset} (T^{(j)} w_j, w_j) \\
&= \frac{C}{c} \left(1 + \log \frac{\hat{H}}{H} \right)^2 \sum_{j:\ \partial\Omega^j\cap\partial\Omega^i\neq\emptyset} |w_j|^2_{T^{(j)}}. \qquad \square
\end{aligned}
$$

LEMMA 4.7. [illegible] $\mathbf{u}_\Gamma \in \widehat{\mathbf{W}}_\Gamma$ [illegible] $\Psi = \Phi^T \widetilde{R}_{D,\Gamma} \mathbf{u}_\Gamma$ [illegible]

$$\Psi^T S_\Pi^{-1} \Psi \le \Psi^T \widetilde{S}_\Pi^{-1} \Psi \le C \left(1 + \log \frac{\hat{H}}{H}\right)^2 \Psi^T S_\Pi^{-1} \Psi.$$

[illegible] Using (3.2), (3.5), and (3.6), we have

$$\begin{aligned}
\Psi^T S_\Pi^{-1} \Psi &= \sum_{i=1}^{N_c} {\Psi_{I_c}^{(i)}}^T \mathbf{y}_{I_c}^{(i)} + \Psi_{\Gamma_c}^T \mathbf{y}_{\Gamma_c} \\
&= \sum_{i=1}^{N_c} {\Psi_{I_c}^{(i)}}^T \left({S_{\Pi_{I_c} I_c}^{(i)}}^{-1} (\Psi_{I_c}^{(i)} - S_{\Pi_{I_c}\Gamma_c}^{(i)} R_{\Gamma_c}^{(i)} \mathbf{y}_{\Gamma_c}) \right) + \left(\mathbf{h}_{\Gamma_c} + \sum_{i=1}^{N_c} {R_{\Gamma_c}^{(i)}}^T {S_{\Pi_{\Gamma_c} I_c}^{(i)}} {S_{\Pi_{I_c} I_c}^{(i)}}^{-1} \Psi_{I_c}^{(i)} \right)^T \mathbf{y}_{\Gamma_c} \\
&= \sum_{i=1}^{N_c} {\Psi_{I_c}^{(i)}}^T {S_{\Pi_{I_c} I_c}^{(i)}}^{-1} \Psi_{I_c}^{(i)} + \mathbf{h}_{\Gamma_c}^T \mathbf{y}_{\Gamma_c} = \sum_{i=1}^{N_c} {\Psi_{I_c}^{(i)}}^T {S_{\Pi_{I_c} I_c}^{(i)}}^{-1} \Psi_{I_c}^{(i)} + \mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c} \right)^{-1} \mathbf{h}_{\Gamma_c}.
\end{aligned}$$

Using (3.8), (3.5), and (3.7), we also have

$$\begin{aligned}
\Psi^T \widetilde{S}_\Pi^{-1} \Psi &= \sum_{i=1}^{N_c} {\Psi_{I_c}^{(i)}}^T \widetilde{\mathbf{y}}_{I_c{}^{(i)}} + \Psi_{\Gamma_c}^T \widetilde{\mathbf{y}}_{\Gamma_c} \\
&= \sum_{i=1}^{N_c} {\Psi_{I_c}^{(i)}}^T \left({S_{\Pi_{I_c} I_c}^{(i)}}^{-1} (\Psi_{I_c}^{(i)} - S_{\Pi_{I_c}\Gamma_c}^{(i)} R_{\Gamma_c}^{(i)} \widetilde{\mathbf{y}}_{\Gamma_c}) \right) + \left(\mathbf{h}_{\Gamma_c} + \sum_{i=1}^{N_c} {R_{\Gamma_c}^{(i)}}^T {S_{\Pi_{\Gamma_c} I_c}^{(i)}} {S_{\Pi_{I_c} I_c}^{(i)}}^{-1} \Psi_{I_c}^{(i)} \right)^T \widetilde{\mathbf{y}}_{\Gamma_c} \\
&= \sum_{i=1}^{N_c} {\Psi_{I_c}^{(i)}}^T {S_{\Pi_{I_c} I_c}^{(i)}}^{-1} \Psi_{I_c}^{(i)} + \mathbf{h}_{\Gamma_c}^T \widetilde{\mathbf{y}}_{\Gamma_c} = \sum_{i=1}^{N_c} {\Psi_{I_c}^{(i)}}^T {S_{\Pi_{I_c} I_c}^{(i)}}^{-1} \Psi_{I_c}^{(i)} + \mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c} \right) \mathbf{h}_{\Gamma_c}.
\end{aligned}$$

We need only compare $\mathbf{h}_{\Gamma_c}^T (\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c})^{-1} \mathbf{h}_{\Gamma_c}$ and $\mathbf{h}_{\Gamma_c}^T (\widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c}) \mathbf{h}_{\Gamma_c}$ for any $\mathbf{h}_{\Gamma_c} \in \widehat{\mathbf{F}}_{\Gamma_c}$. We follow the proofs of [8, Theorem 1].

Let

$$\mathbf{w}_{\Gamma_c} = \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c} \right)^{-1} \mathbf{h}_{\Gamma_c} \in \widehat{\mathbf{W}}_{c,\Gamma_c} \text{ and } \mathbf{v}_{\Gamma_c} = \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c} \mathbf{h}_{\Gamma_c} \in \widetilde{\mathbf{W}}_{c,\Gamma_c}. \tag{4.14}$$

Noting the fact that $\widetilde{R}_{\Gamma_c}^T \widetilde{R}_{D_c,\Gamma_c} = \widetilde{R}_{D_c,\Gamma_c}^T \widetilde{R}_{\Gamma_c} = I$ and using (4.14), we have

$$\begin{aligned}
\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c} \right)^{-1} \mathbf{h}_{\Gamma_c} &= \mathbf{h}_{\Gamma_c}^T \mathbf{w}_{\Gamma_c} = \mathbf{h}_{\Gamma_c}^T \widetilde{R}_{D_c,\Gamma_c}^T \widetilde{R}_{\Gamma_c} \mathbf{w}_{\Gamma_c} \\
&= \mathbf{h}_{\Gamma_c}^T \widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{T} \widetilde{R}_{\Gamma_c} \mathbf{w}_{\Gamma_c} = \left(\widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c} \mathbf{h}_{\Gamma_c} \right)^T \widetilde{T} \widetilde{R}_{\Gamma_c} \mathbf{w}_{\Gamma_c} \\
&= \mathbf{v}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c} \mathbf{w}_{\Gamma_c} = \langle \mathbf{v}_{\Gamma_c}, \widetilde{R}_{\Gamma_c} \mathbf{w}_{\Gamma_c} \rangle_{\widetilde{T}} \\
&\le \langle \mathbf{v}_{\Gamma_c}, \mathbf{v}_{\Gamma_c} \rangle_{\widetilde{T}}^{1/2} \langle \widetilde{R}_{\Gamma_c} \mathbf{w}_{\Gamma_c}, \widetilde{R}_{\Gamma_c} \mathbf{w}_{\Gamma_c} \rangle_{\widetilde{T}}^{1/2} \\
&= \left(\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c} \right) \mathbf{h}_{\Gamma_c} \right)^{1/2} \left(\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c} \right)^{-1} \mathbf{h}_{\Gamma_c} \right)^{1/2}.
\end{aligned}$$

We obtain

$$\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c} \right)^{-1} \mathbf{h}_{\Gamma_c} \le \mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c} \right) \mathbf{h}_{\Gamma_c}.$$

On the other hand,

$$\begin{aligned}
&\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c}\right) \mathbf{h}_{\Gamma_c} \;=\; \mathbf{w}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right) \left(\widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c}\right) \mathbf{h}_{\Gamma_c} \\
&= \left\langle \mathbf{w}_{\Gamma_c}, \widetilde{R}_{D_c,\Gamma_c}^T \left(\widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c} \mathbf{h}_{\Gamma_c}\right)\right\rangle_{\left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)} \;=\; \left\langle \mathbf{w}_{\Gamma_c}, \widetilde{R}_{D_c,\Gamma_c}^T \mathbf{v}_{\Gamma_c}\right\rangle_{\left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)} \\
&\le \langle \mathbf{w}_{\Gamma_c}, \mathbf{w}_{\Gamma_c}\rangle_{\left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)}^{1/2} \left\langle \widetilde{R}_{D_c,\Gamma_c}^T \mathbf{v}_{\Gamma_c}, \widetilde{R}_{D_c,\Gamma_c}^T \mathbf{v}_{\Gamma_c}\right\rangle_{\left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)}^{1/2} \\
&= \left(\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)^{-1} \mathbf{h}_{\Gamma_c}\right)^{1/2} \left\langle \widetilde{R}_{\Gamma_c} \widetilde{R}_{D_c,\Gamma_c}^T \mathbf{v}_{\Gamma_c}, \widetilde{R}_{\Gamma_c} \widetilde{R}_{D_c,\Gamma_c}^T \mathbf{v}_{\Gamma_c}\right\rangle_{\widetilde{T}}^{1/2} \\
&= \left(\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)^{-1} \mathbf{h}_{\Gamma_c}\right)^{1/2} |E_{D_c} \mathbf{v}_{\Gamma_c}|_{\widetilde{T}} \\
&\le C \left(1 + \log \frac{\hat{H}}{H}\right) \left(\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)^{-1} \mathbf{h}_{\Gamma_c}\right)^{1/2} |\mathbf{v}_{\Gamma_c}|_{\widetilde{T}} \\
&= C \left(1 + \log \frac{\hat{H}}{H}\right) \left(\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)^{-1} \mathbf{h}_{\Gamma_c}\right)^{1/2} \left(\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c}\right) \mathbf{h}_{\Gamma_c}\right)^{1/2},
\end{aligned}$$

where we use Lemma 4.6 for the penultimate inequality.

We finally obtain

$$\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{D_c,\Gamma_c}^T \widetilde{T}^{-1} \widetilde{R}_{D_c,\Gamma_c}\right) \mathbf{h}_{\Gamma_c} \le C \left(1 + \log \frac{\hat{H}}{H}\right)^2 \left(\mathbf{h}_{\Gamma_c}^T \left(\widetilde{R}_{\Gamma_c}^T \widetilde{T} \widetilde{R}_{\Gamma_c}\right)^{-1} \mathbf{h}_{\Gamma_c}\right). \qquad \square$$

5. Condition number estimate for the new preconditioner. In order to estimate the condition number for the system with the new preconditioner $\widetilde{M}^{-1}$, we compare it to the system with the preconditioner M^{-1}.

LEMMA 5.1. [illegible] $\mathbf{u}_\Gamma \in \widehat{\mathbf{W}}_\Gamma$

$$\mathbf{u}_\Gamma^T M^{-1} \mathbf{u}_\Gamma \le \mathbf{u}_\Gamma^T \widetilde{M}^{-1} \mathbf{u}_\Gamma \le C \left(1 + \log \frac{\hat{H}}{H}\right)^2 \mathbf{u}_\Gamma^T M^{-1} \mathbf{u}_\Gamma. \tag{5.1}$$

[illegible] We have, for any $\mathbf{u}_\Gamma \in \widehat{\mathbf{W}}_\Gamma$,

$$\begin{aligned}
&\mathbf{u}_\Gamma^T M^{-1} \mathbf{u}_\Gamma \\
&= \mathbf{u}_\Gamma^T \widetilde{R}_{D,\Gamma}^T \left\{ R_{\Gamma\Delta}^T \sum_{i=1}^N \begin{pmatrix} \mathbf{0} & R_\Delta^{(i)^T} \end{pmatrix} \begin{pmatrix} A_{II}^{(i)} & A_{I\Delta}^{(i)} \\ A_{\Delta I}^{(i)} & A_{\Delta\Delta}^{(i)} \end{pmatrix}^{-1} \begin{pmatrix} \mathbf{0} \\ R_\Delta^{(i)} \end{pmatrix} R_{\Gamma\Delta} \right\} \widetilde{R}_{D,\Gamma} \mathbf{u}_\Gamma \\
&+ \mathbf{u}_\Gamma^T \widetilde{R}_{D,\Gamma}^T \Phi S_\Pi^{-1} \Phi^T \widetilde{R}_{D,\Gamma} \mathbf{u}_\Gamma
\end{aligned}$$

and

$$\begin{aligned}
&\mathbf{u}_\Gamma^T \widetilde{M}^{-1} \mathbf{u}_\Gamma \\
&= \mathbf{u}_\Gamma^T \widetilde{R}_{D,\Gamma}^T \left\{ R_{\Gamma\Delta}^T \sum_{i=1}^N \begin{pmatrix} \mathbf{0} & R_\Delta^{(i)^T} \end{pmatrix} \begin{pmatrix} A_{II}^{(i)} & A_{I\Delta}^{(i)} \\ A_{\Delta I}^{(i)} & A_{\Delta\Delta}^{(i)} \end{pmatrix}^{-1} \begin{pmatrix} \mathbf{0} \\ R_\Delta^{(i)} \end{pmatrix} R_{\Gamma\Delta} \right\} \widetilde{R}_{D,\Gamma} \mathbf{u}_\Gamma \\
&+ \mathbf{u}_\Gamma^T \widetilde{R}_{D,\Gamma}^T \Phi \widetilde{S}_\Pi^{-1} \Phi^T \widetilde{R}_{D,\Gamma} \mathbf{u}_\Gamma.
\end{aligned}$$

We obtain our result by using Lemma 4.7. ∎

THEOREM 5.2. $\widetilde{M}^{-1}$ $C(1+\log\frac{\hat{H}}{H})^2(1+\log\frac{H}{h})^2$

Combining the condition number bound, given in (2.7) for the two-level BDDC method, and Lemma 5.1, we find that the condition number for the three-level method is bounded by $C(1+\log\frac{\hat{H}}{H})^2(1+\log\frac{H}{h})^2$. ∎

6. Using Chebyshev iterations. Another approach to the three-level BDDC methods is to use an iterative method with a preconditioner to solve (3.6). Here, we consider a Chebyshev method with a fixed number of iterations and use $\widetilde{R}^T_{D_c,\Gamma_c}\widetilde{T}^{-1}\widetilde{R}_{D_c,\Gamma_c}$ as a preconditioner. Denoting the eigenvalues of $(\widetilde{R}^T_{D_c,\Gamma_c}\widetilde{T}^{-1}\widetilde{R}_{D_c,\Gamma_c})(\widetilde{R}^T_{\Gamma_c}\widetilde{T}\widetilde{R}_{\Gamma_c})$ by λ_j, we need two input parameters l and u, which are estimates for the minimum and maximum values of λ_j, for the Chebyshev iterations. From our analysis above, we know that $l=1$ and $\max_j\lambda_j \le C(1+\log\frac{\hat{H}}{H})^2(1+\log\frac{H}{h})^2$. We can use the conjugate gradient method to obtain an estimate for the largest eigenvalue at the beginning of the computation to choose a proper u.

Let $\alpha=\frac{2}{l+u}$, $\mu=\frac{u+l}{u-l}$, and $\sigma_j=1-\alpha\lambda_j$. As for the two-dimensional case in [17, section 6], we have the following theorem. No new ideas are required.

THEOREM 6.1. $\widehat{M}^{-1}$ k $C\frac{C_2(k)}{C_1(k)}(1+\log\frac{H}{h})^2$

$$C_1(k)=\min_j\left(1-\frac{\cosh(k\cosh^{-1}(\mu\sigma_j))}{\cosh(k\cosh^{-1}(\mu))}\right),$$

$$C_2(k)=\max_j\left(1-\frac{\cosh(k\cosh^{-1}(\mu\sigma_j))}{\cosh(k\cosh^{-1}(\mu))}\right),$$

$\frac{C_2(k)}{C_1(k)}\to 1$ $k\to\infty$

7. Numerical experiments. We have applied our two three-level BDDC algorithms to the model problem (2.1), where $\Omega=[0,1]^3$. We decompose the unit cube into $\widehat{N}\times\widehat{N}\times\widehat{N}$ subregions with the side-length $\hat{H}=1/\widehat{N}$ and each subregion into $N\times N\times N$ subdomains with the side-length $H=\hat{H}/N$. Equation (2.1) is discretized, in each subdomain, by conforming piecewise trilinear elements with an element diameter h. The preconditioned conjugate gradient iteration is stopped when the norm of the residual has been reduced by a factor of 10^{-6}.

We have carried out two different sets of experiments to obtain iteration counts and condition number estimates. All the experimental results are fully consistent with our theory.

In the first set of experiments, we use the first preconditioner $\widetilde{M}^{-1}$. We take the coefficient $\rho\equiv 1$ in case 1. In case 2, ρ is constant in one direction with a checkerboard pattern in the cross sections, where we take $\rho=1$ or $\rho=100$. The coefficients in both cases satisfy [14, Assumption 6.27.2]; i.e., for all pairs of subdomains which have a vertex but not an edge in common, there exists an acceptable edge path (see [14, Definition 6.26]) between these two subdomains. Table 1 gives the iteration counts and condition number estimates with a change of the number of subregions. We find that the condition numbers are independent of the number of subregions. Table 2 gives results with a change of the number of subdomains and the size of the subdomain problems.

TABLE 1
Eigenvalue bounds and iteration counts with the preconditioner $\widetilde{M}^{-1}$ with a change of the number of subregions, $\frac{\hat{H}}{H} = 3$ and $\frac{H}{h} = 3$.

TABLE 3
Eigenvalue bounds and iteration counts with the preconditioner $\widehat{M}^{-1}$, $u = 2.3$, $3 \times 3 \times 3$ subregions, $\frac{\hat{H}}{H} = 6$, and $\frac{H}{h} = 3$.

k	Iter.	$C_1(k)$	$\lambda_{\min}$	$\lambda_{\max}$	Cond. #
1	13	0.6061	0.6167	2.3309	3.7797
2	9	0.9159	0.9255	1.8968	2.0496
3	8	0.9827	1.0000	1.8835	1.8836
4	8	0.9964	1.0016	1.8854	1.8825
5	8	0.9993	1.0009	1.8797	1.8780

TABLE 4
Eigenvalue bounds and iteration counts with the preconditioner $\widehat{M}^{-1}$, $u = 3$, $3\times3\times3$ subregions, $\frac{\hat{H}}{H} = 6$, and $\frac{H}{h} = 3$.

k	Iter.	$C_1(k)$	$\lambda_{\min}$	$\lambda_{\max}$	Cond. #
1	15	0.5000	0.5093	2.0150	3.9562
2	10	0.8571	0.8678	1.9744	2.2753
3	8	0.9615	0.9900	1.8821	1.9012
4	8	0.9897	1.0015	1.8955	1.8927
5	8	0.9972	1.0020	1.8903	1.8866

In the second set of experiments, we use the second preconditioner $\widehat{M}^{-1}$ and take the coefficient $\rho \equiv 1$. We use the preconditioned conjugate gradient (PCG) to estimate the largest eigenvalue of $(\widetilde{R}^T_{D_c,\Gamma_c}\widetilde{T}^{-1}\widetilde{R}_{D_c,\Gamma_c})(\widetilde{R}^T_{\Gamma_c}\widetilde{T}\widetilde{R}_{\Gamma_c})$, which is approximately 2.3249. For $18 \times 18 \times 18$ subdomains and $\frac{H}{h} = 3$, we have a condition number estimate of 1.8767 for the two-level preconditioned BDDC operator. We select different values of u, the upper bound eigenvalue estimate of the preconditioned system, and of k to see how the condition number changes. We take $u = 2.3$ and $u = 3$ in Tables 3 and 4, respectively. We also evaluate $C_1(k)$ for $k = 1, 2, 3, 4, 5$. From these two tables, we find that the smallest eigenvalue is bounded from below by $C_1(k)$ and the condition number estimate becomes closer to 1.8767, the value for the two-level case, as k increases. We also see that if we can get a more precise estimate for the largest

eigenvalue of $(\widetilde{R}^T_{D_c,\Gamma_c}\widetilde{T}^{-1}\widetilde{R}_{D_c,\Gamma_c})(\widetilde{R}^T_{\Gamma_c}\widetilde{T}\widetilde{R}_{\Gamma_c})$, we need fewer Chebyshev iterations to get a condition number close to that of the two-level case. However, the iteration count is not very sensitive to the choice of u.

Acknowledgment. The author is grateful to Professor Olof Widlund for suggesting this problem and all the help and time he has devoted to this work.

A CELL-CENTERED LAGRANGIAN SCHEME FOR TWO-DIMENSIONAL COMPRESSIBLE FLOW PROBLEMS*

PIERRE-HENRI MAIRE†, RÉMI ABGRALL‡, JÉRÔME BREIL†, AND JEAN OVADIA§

Abstract. We present a new Lagrangian cell-centered scheme for two-dimensional compressible flows. The primary variables in this new scheme are cell-centered, i.e., density, momentum, and total energy are defined by their mean values in the cells. The vertex velocities and the numerical fluxes through the cell interfaces are not computed independently, contrary to standard approaches, but are evaluated in a consistent manner due to an original solver located at the nodes. The main new feature of the algorithm is the introduction of four pressures on each edge, two for each node on each side of the edge. This extra degree of freedom allows us to construct a nodal solver which fulfills two properties. First, the conservation of momentum and total energy is ensured. Second, a semidiscrete entropy inequality is provided. In the case of a one-dimensional flow, the solver reduces to the classical Godunov acoustic solver: it can be considered as its two-dimensional generalization. Many numerical tests are presented. They are representative test cases for compressible flows and demonstrate the robustness and the accuracy of this new solver.

Key words. Godunov-type schemes, hyperbolic conservation laws, Lagrangian gas dynamics

1. Introduction.

The physical model that is considered throughout this paper is based on the equations of fluid dynamics written in Lagrangian form. This form is well adapted to the simulation of multimaterial compressible fluid flows, such as those encountered in the domain of inertial confinement fusion (ICF); see [19] and [25]. Our aim is to propose a new Lagrangian cell-centered scheme for two-dimensional gas dynamics equations. Before describing our method, let us briefly give a historical overview of the Lagrangian schemes.

Lagrangian schemes are characterized by a mesh that follows the fluid flow. In this way, these methods treat interfaces in a natural manner. The main numerical difficulty lies in the node motion discretization, especially for multidimensional situations. The most natural way to overcome this difficulty is to use a staggered discretization, where the momentum is defined at the nodes and the other variables (density, pressure, and specific internal energy) are cell-centered. This type of scheme was first introduced by von Neumann and Richtmyer in [27] for one-dimensional flows. The bidimensional extension was proposed by Wilkins in [29]. It is based on an internal energy formulation. The entropy production inherent to shock waves is ensured by an artificial viscosity. In its initial version, this scheme was not conservative, and it admitted numerical spurious modes. However, in spite of these drawbacks, this scheme has been widely used in the domain of multimaterial flow simulations during the last forty years. Moreover, in the past decade, many improvements have been made in order to solve the previous problems. In their paper [7], Caramana and Shashkov show

that with an appropriate discretization of the subzonal forces resulting from subzonal pressures, hourglass motion and spurious vorticity can be eliminated. By using the method of support operators proposed in [6], they constructed a staggered scheme which ensures the conservation of total energy. Moreover, the discretization of artificial viscosity has been considerably improved: first, by introducing formulations for multidimensional shock wave computations in [5] and then by using a discretization based on a mimetic finite difference scheme in [4]. With all these improvements, the staggered Lagrangian scheme is an accurate and robust method, which can produce impressive results, even on unstructured polygonal grids; see, for instance, [21].

An alternative to the staggered discretization is to use a conservative cell-centered discretization. This method for Lagrangian gas dynamics in one dimension was introduced by Godunov; see [12] and [24]. The multidimensional extension of this method was performed during the 1980s [2], [11]. This multidimensional scheme is a cell-centered finite volume scheme on moving structured or unstructured meshes. It is constructed by integrating directly the system of conservation laws on each moving cell. The primary variables—density, momentum, and total energy—are defined in the cells. The flux across the boundary of the cell is computed by solving exactly or approximately a one-dimensional Riemann problem in the direction normal to the boundary. The main problem with this type of method lies in the fact that the node velocity needed to move the mesh cannot be directly calculated. In [2], the node velocity is computed via a special least squares procedure. It consists in minimizing the error between the normal velocity coming from the Riemann solver and the normal projection of the vertex velocity. It turns out that it leads to an artificial grid motion, which requires a very expensive treatment [10]. Moreover, with this approach the flux calculation is not consistent with the node motion.

Recently, new cell-centered methods have been proposed in [15] and [1]. These new approaches use a fully Lagrangian form of the gas dynamics equations; that is, the gradient and divergence operators are expressed in the Lagrangian coordinates. This type of discretization needs to compute the Jacobian matrix associated to the map between Lagrangian and Eulerian spaces. However, these methods are purely Lagrangian and cannot be interpreted as moving mesh methods. This drawback has motivated another approach proposed by Després and Mazeran. In [9], they made a theoretical analysis of the Lagrangian gas dynamics equations written in a fully Lagrangian form and they derived a new conservative and entropy consistent two-dimensional Lagrangian scheme of the finite volume type. It is a moving grid scheme based on a nodal solver. The node velocity is computed in a coherent manner with the face fluxes. The numerical results shown in [9] are quite impressive, in particular, those related to the difficult Saltzmann's test case. However, it appears that in the case of one-dimensional flows, this scheme leads to a nodal velocity, which depends on the cell aspect ratio. This drawback has motivated our study to develop a new cell-centered scheme that retains the good feature of the Després–Mazeran scheme but resolves the aspect ratio problem. Here, we propose a new Lagrangian cell-centered scheme in which the vertex velocities and the numerical fluxes through the cell interfaces are not computed independently as usual but in a consistent manner with an original solver located at the nodes. The main new feature of the algorithm is the introduction of four pressures on each edge, two for each node on each side of the edge. This is the main difference from [9]. We show, in the limit of a one-dimensional flow computed by our two-dimensional solver, or for flows in a cylindrical geometry, that the scheme recovers the classical Godunov approximate Riemann solver. Moreover, our scheme locally conserves momentum and total energy and satisfies a local entropy inequality.

The boundary conditions are taken into account in a natural way. This scheme is first order in time and space.

The paper is organized as follows. First we recall the gas dynamics equations written in the Lagrangian form. In section 2 we derive space approximations based on face and node fluxes. Then we build a nodal solver using conservation arguments and a discrete entropy inequality. In section 4 we give the time discretization. Finally, we validate our new scheme with several test cases. They are representative test cases for compressible fluid flows and demonstrate the robustness and the accuracy of this new solver.

2. Derivation of the Euler equations in the Lagrangian formalism. The aim of this section is to recall briefly how the gas dynamics equations are obtained in the Lagrangian formalism. For such a derivation, we follow the approach developed in [8].

Let $\mathcal{D}$ be a region of the two-dimensional space $\mathbb{R}^2$, filled with an inviscid fluid and equipped with an orthonormal frame (O, X, Y). The Lagrangian formalism consists in following the time evolution of fluid particles along their trajectories. Consider a fluid particle which is moving through the point M at time $t > 0$ and whose initial position is point m. The coordinates of point M are denoted by (X, Y) and are named Eulerian coordinates. The coordinates of point m are denoted by (x, y) and are named Lagrangian coordinates. The Eulerian coordinates are obtained from the trajectory equations

$$\begin{aligned} \frac{dX}{dt} &= u(X, Y, t), \quad X(x, y, 0) = x, \\ \frac{dY}{dt} &= v(X, Y, t), \quad Y(x, y, 0) = y, \end{aligned} \tag{2.1}$$

where (u, v) are the coordinates of the fluid velocity $\boldsymbol{V}$. If the velocity field is smooth enough, the system (2.1) admits a unique solution $(X(x, y, t), Y(x, y, t))$. This enables us to define the map

$$\mathcal{M}_t : (x, y) \mapsto (X, Y), \tag{2.2}$$

where (X, Y) is the unique solution of (2.1). With fixed t, this map advances each fluid particle from its position at time $t = 0$ to its position at time t. If ω denotes a region in $\mathcal{D}$, then $\mathcal{M}_t(\omega) = \Omega$ is the volume ω moving with the fluid. We assume that for each $t > 0$, $\mathcal{M}_t$ is invertible. Let us introduce the Jacobian of this map:

$$J(x, y, t) = \begin{vmatrix} \dfrac{\partial X}{\partial x} & \dfrac{\partial X}{\partial y} \\ \dfrac{\partial Y}{\partial x} & \dfrac{\partial Y}{\partial y} \end{vmatrix}. \tag{2.3}$$

We notice that $J(x, y, 0) = 1$ and since $\mathcal{M}_t$ is invertible we have for each $t > 0$, $J(x, y, t) > 0$. Time differentiation of (2.3) gives the classical result

$$\frac{dJ}{dt} - J\nabla \cdot \boldsymbol{V} = 0, \tag{2.4}$$

where $\nabla\cdot$ denotes the divergence operator, namely, $\nabla \cdot \boldsymbol{V} = \frac{\partial u}{\partial X} + \frac{\partial v}{\partial Y}$.

Let us consider a flow variable φ depending on Eulerian coordinates: $\varphi \equiv \varphi(X, Y, t)$. Time differentiation of φ gives

$$\frac{d\varphi}{dt} = \frac{\partial \varphi}{\partial t} + \frac{dX}{dt}\frac{\partial \varphi}{\partial X} + \frac{dY}{dt}\frac{\partial \varphi}{\partial Y},$$

and using (2.1) one obtains

$$\frac{d\varphi}{dt} = \frac{\partial \varphi}{\partial t} + \boldsymbol{\nabla}\varphi \cdot \boldsymbol{V}, \tag{2.5}$$

where $\boldsymbol{\nabla}$ is the gradient operator, namely $\boldsymbol{\nabla}\varphi = (\frac{\partial \varphi}{\partial X}, \frac{\partial \varphi}{\partial Y})^t$. The time derivative of φ depending on Eulerian coordinates is named the material derivative; it represents the variation of φ along a fluid trajectory. Finally, combining (2.4) and (2.5) it is straightforward to write

$$\frac{d}{dt}(\varphi J) = J\left[\frac{\partial \varphi}{\partial t} + \nabla \cdot (\varphi \boldsymbol{V})\right]. \tag{2.6}$$

With this last equation we are able to transform gas dynamics equations written in Eulerian formalism. These equations for an inviscid compressible fluid (see [18]) are

$$\begin{aligned} &\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{V}) = 0, \\ &\frac{\partial}{\partial t}(\rho \boldsymbol{V}) + \boldsymbol{\nabla} \cdot (\rho \boldsymbol{V} \otimes \boldsymbol{V}) + \boldsymbol{\nabla} P = \mathbf{0}, \\ &\frac{\partial}{\partial t}(\rho E) + \nabla \cdot (\rho E \boldsymbol{V}) + \nabla \cdot (P \boldsymbol{V}) = 0. \end{aligned} \tag{2.7}$$

In (2.7), ρ denotes the density, P is the pressure, and E is the specific total energy. We denote by $\varepsilon = E - \frac{1}{2}\|\boldsymbol{V}\|^2$ the specific internal energy. The thermodynamic closure of (2.7) is given by the equation of state, $P \equiv P(\rho, \varepsilon)$.

Now, using (2.6) for the conservative variables $\varphi = 1,\ \rho,\ \rho\boldsymbol{V},\ \rho E$ and after substitution in (2.7), one obtains the gas dynamics system in Lagrangian formalism:

$$\begin{aligned} &\frac{dJ}{dt} - J\nabla \cdot \boldsymbol{V} = 0, \\ &\frac{d}{dt}(\rho J) = 0, \\ &\frac{d}{dt}(\rho J \boldsymbol{V}) + J\boldsymbol{\nabla} P = \mathbf{0}, \\ &\frac{d}{dt}(\rho J E) + J\nabla \cdot (P \boldsymbol{V}) = 0. \end{aligned} \tag{2.8}$$

We notice that these equations are only in a semi-Lagrangian formalism since the gradient and divergence operate on variables which depend on Eulerian coordinates. In order to write these equations in a full Lagrangian way, one has to express the gradient and divergence operators with Lagrangian coordinates using the map $\mathcal{M}_t$. For such an approach, the reader should refer to [15], [20], and [9].

In order to perform the space discretization in the next section, we give the integral form of system (2.8). This form is obtained by integration of (2.8) on the Lagrangian domain ω. Knowing that $\mathcal{M}_t(\omega) = \Omega$ and $J\mathrm{d}\omega = \mathrm{d}\Omega$, using Green's formula one gets

$$\frac{d}{dt}\int_\Omega \mathrm{d}\Omega - \int_{\partial\Omega} \boldsymbol{V}\cdot\boldsymbol{N}\,\mathrm{d}l = 0, \tag{2.9 i}$$

$$\frac{d}{dt}\int_\Omega \rho\,\mathrm{d}\Omega = 0, \tag{2.9 ii}$$

$$\frac{d}{dt}\int_\Omega \rho\boldsymbol{V}\,\mathrm{d}\Omega + \int_{\partial\Omega} P\boldsymbol{N}\,\mathrm{d}l = \boldsymbol{0}, \tag{2.9 iii}$$

$$\frac{d}{dt}\int_\Omega \rho E\,\mathrm{d}\Omega + \int_{\partial\Omega} P\boldsymbol{V}\cdot\boldsymbol{N}\,\mathrm{d}l = 0, \tag{2.9 iv}$$

where $\partial\Omega$ is the boundary of Ω, $\boldsymbol{N}$ is the unit outward normal to $\partial\Omega$, and $\mathrm{d}l$ is the length element on $\partial\Omega$. The equations (2.9 i)–(2.9 iv) are well known and have been used in this form in many papers; see, for example, [14]. Let m_Ω denote the mass of fluid enclosed in Ω. Then (2.9 ii) simply states mass conservation; hence for each time one gets $m_\Omega = m_\omega$. Let us introduce the area of domain Ω:

$$\mathcal{A}_\Omega = \int_\Omega \mathrm{d}\Omega.$$

We define the density $\rho_\Omega = \frac{m_\omega}{\mathcal{A}_\Omega}$ and the specific volume $\tau_\Omega = \frac{1}{\rho_\Omega}$. We also define the mass averaged velocity and total energy

$$\boldsymbol{V_\Omega} = \frac{1}{m_\omega}\int_\Omega \rho\boldsymbol{V}\mathrm{d}\Omega,$$

$$E_\Omega = \frac{1}{m_\omega}\int_\Omega \rho E\mathrm{d}\Omega.$$

With this notation and mass conservation, one gets the final integral form which will be useful for space discretization:

$$m_\omega\frac{d}{dt}\tau_\Omega - \int_{\partial\Omega} \boldsymbol{V}\cdot\boldsymbol{N}\,\mathrm{d}l = 0, \tag{2.10 i}$$

$$m_\omega\frac{d}{dt}\boldsymbol{V_\Omega} + \int_{\partial\Omega} P\boldsymbol{N}\,\mathrm{d}l = \boldsymbol{0}, \tag{2.10 ii}$$

$$m_\omega\frac{d}{dt}E_\Omega + \int_{\partial\Omega} P\boldsymbol{V}\cdot\boldsymbol{N}\,\mathrm{d}l = 0, \tag{2.10 iii}$$

where m_ω is the mass of fluid enclosed initially in ω.

3. Spatial approximation. Using classical finite volume approach, we derive in this section the spatial approximation of the gas dynamics equations written in Lagrangian formalism. Let us introduce some notation.

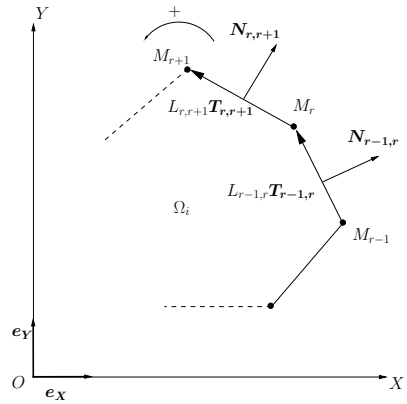

FIG. 3.1. *Notation.*

3.1. Notation, assumptions, and problem statement. Let $\{\omega_i,\ i = 1 \dots I\}$ be a collection of nonoverlapping polygons whose reunion covers ω, the subdomain of $\mathbb{R}^2$ that is initially filled by the fluid. We set $\Omega_i = \mathcal{M}_t(\omega_i)$, where $\mathcal{M}_t$ is the map defined by (2.2). Ω_i is also a polygonal cell[1] whose vertices are denoted by $M_r,\ r = 1, \dots, R(i)$. We denote by $R(i)$ the number of vertices (or faces) of the cell Ω_i. The vertices are indexed counterclockwise; see Figure 3.1. The numbering is also periodic; i.e., $M_{R(i)+1} = M_1$ and $M_0 = M_{R(i)}$. The frame (O, X, Y) is equipped with an orthonormal basis $(\boldsymbol{e_X}, \boldsymbol{e_Y})$ which is completed by the vector $\boldsymbol{e_Z} = \boldsymbol{e_X} \times \boldsymbol{e_Y}$. We denote the Eulerian coordinates of the vertex M_r by (X_r, Y_r). Note that M_r and its coordinates are time dependent. Considering any edge $[M_r, M_{r+1}]$ of Ω_i, $L_{r,r+1}$ denotes its length, $\boldsymbol{T_{r,r+1}}$ represents its unit tangent vector in a counterclockwise orientation, and $\boldsymbol{N_{r,r+1}}$ is its unit outward normal vector. Following these definitions and conventions, we have

$$
\begin{aligned}
&L_{r,r+1}\boldsymbol{T_{r,r+1}} = \boldsymbol{M_r M_{r+1}},\\
&L_{r,r+1}\boldsymbol{N_{r,r+1}} = L_{r,r+1}\boldsymbol{T_{r,r+1}} \times \boldsymbol{e_Z}.
\end{aligned}
\tag{3.1}
$$

The fluid in cell Ω_i is described by the discrete variables $(\tau_i, \boldsymbol{V_i}, E_i)$, respectively, the averaged specific volume, velocity, and specific total energy. A set of discrete equations is written for these discrete unknowns, using the integral formulation (2.10 i) applied for cell Ω_i:

$$
m_i \frac{d}{dt}\tau_i - \int_{\partial\Omega_i} \boldsymbol{V}\cdot\boldsymbol{N}\,\mathrm{d}l = 0,
$$

$$
m_i \frac{d}{dt}\boldsymbol{V_i} + \int_{\partial\Omega_i} P\boldsymbol{N}\,\mathrm{d}l = \boldsymbol{0},
$$

$$
m_i \frac{d}{dt}E_i + \int_{\partial\Omega_i} P\boldsymbol{V}\cdot\boldsymbol{N}\,\mathrm{d}l = 0,
$$

[1]Here, we assume that Ω_i is still a polygon. This means that we implicitly assume that the velocity field variation is linear in space. This is not restrictive here, because the aim of the paper is to develop a scheme that is first order in space.

where m_i denotes the mass of the cell Ω_i. We also introduce the density $\rho_i = \frac{1}{\tau_i}$, the specific internal energy $\varepsilon_i = E_i - \frac{1}{2}\|\boldsymbol{V_i}\|^2$, and the pressure given by the equation of state $P_i = P(\rho_i, \varepsilon_i)$. Since all fluid variables are assumed to be constant in cell Ω_i, we obtain a spatial approximation which is first order accurate.

Finally, we introduce some notation to express the discrete face fluxes. Let us denote by $\boldsymbol{V^\star_{r,r+1}} \cdot \boldsymbol{N_{r,r+1}}$, $P^\star_{r,r+1}\boldsymbol{N_{r,r+1}}$, and $(P\boldsymbol{V})^\star_{r,r+1} \cdot \boldsymbol{N_{r,r+1}}$ the volume, momentum, and total energy fluxes on the face $[M_r, M_{r+1}]$. They are defined by the following equations:

$$
\begin{aligned}
L_{r,r+1}\boldsymbol{V^\star_{r,r+1}} \cdot \boldsymbol{N_{r,r+1}} &= \int_{M_r}^{M_{r+1}} \boldsymbol{V} \cdot \boldsymbol{N}\, \mathrm{d}l,\\
L_{r,r+1}\boldsymbol{P^\star_{r,r+1}}\boldsymbol{N_{r,r+1}} &= \int_{M_r}^{M_{r+1}} P\boldsymbol{N}\, \mathrm{d}l,\\
L_{r,r+1}\,(P\boldsymbol{V})^\star_{r,r+1} \cdot \boldsymbol{N_{r,r+1}} &= \int_{M_r}^{M_{r+1}} P\boldsymbol{V} \cdot \boldsymbol{N}\, \mathrm{d}l.
\end{aligned}
\tag{3.2}
$$

With this notation the previous system is now written in the following manner:

$$
m_i \frac{d}{dt}\tau_i - \sum_{r=1}^{R(i)} L_{r,r+1}\boldsymbol{V^\star_{r,r+1}} \cdot \boldsymbol{N_{r,r+1}} = 0, \tag{3.3 i}
$$

$$
m_i \frac{d}{dt}\boldsymbol{V_i} + \sum_{r=1}^{R(i)} L_{r,r+1}P^\star_{r,r+1}\boldsymbol{N_{r,r+1}} = \boldsymbol{0}, \tag{3.3 ii}
$$

$$
m_i \frac{d}{dt}E_i + \sum_{r=1}^{R(i)} L_{r,r+1}\,(P\boldsymbol{V})^\star_{r,r+1} \cdot \boldsymbol{N_{r,r+1}} = 0. \tag{3.3 iii}
$$

We notice that with this Lagrangian discretization we have to take into account the cell motion. For this purpose we write the node motion equation using the trajectory equation

$$
\begin{aligned}
\frac{d}{dt}X_r &= u^\star_r, \quad X_r(0) = x_r,\\
\frac{d}{dt}Y_r &= v^\star_r, \quad Y_r(0) = y_r,
\end{aligned}
\tag{3.4}
$$

where $(u^\star_r, v^\star_r)$ are the components of the velocity $\boldsymbol{V^\star_r}$ of the vertex M_r.

In order to complete the space approximation, the following important problems arise:

1. How do we compute the face fluxes defined by (3.2)?
2. How do we compute the node velocities $\boldsymbol{V^\star_r}$?
3. These velocities being known, how can we ensure the compatibility between the mesh motion and the volume variation of the cells?

Thus, our task consists in building a numerical solver that can compute the fluxes $\boldsymbol{V^\star_{r,r+1}}$, $P^\star_{r,r+1}$, and $(P\boldsymbol{V})^\star_{r,r+1}$ but also the node velocities $\boldsymbol{V^\star_r}$. Moreover, this must be done coherently. We resolve these questions in the next sections.

3.2. Approximation of the volume equation. Using a geometrical interpretation of (3.3 ii), we can link the volume flux $\boldsymbol{V}^{\star}_{\boldsymbol{r,r+1}} \cdot \boldsymbol{N_{r,r+1}}$ to the node velocity $\boldsymbol{V}^{\star}_{\boldsymbol{r}}$.

First, we notice that $m_i \tau_i = \mathcal{A}_i$, where $\mathcal{A}_i$ is the area of the cell Ω_i. Thus, (3.3 ii) provides the time variation of $\mathcal{A}_i$,

$$\frac{d}{dt}\mathcal{A}_i = \sum_{r=1}^{R(i)} L_{r,r+1} \boldsymbol{V}^{\star}_{\boldsymbol{r,r+1}} \cdot \boldsymbol{N_{r,r+1}}. \tag{3.5}$$

The area of the cell Ω_i can also be evaluated from the location of the vertices M_r using the relation (see [28])

$$\mathcal{A}_i = \frac{1}{2} \sum_{r=1}^{R(i)} \boldsymbol{OM_r} \times \boldsymbol{OM_{r+1}} \cdot \boldsymbol{e_Z}.$$

This amounts to summing the area of the triangles (O, M_r, M_{r+1}) (see Figure 3.1) over all the vertices of the cell. Using the coordinates of the vertices and after time differentiation, we get

$$\frac{d}{dt}\mathcal{A}_i = \frac{1}{2} \sum_{r=1}^{R(i)} \left(Y_{r+1} \frac{d}{dt} X_r - X_{r+1} \frac{d}{dt} Y_r + X_r \frac{d}{dt} Y_{r+1} - Y_r \frac{d}{dt} X_{r+1} \right).$$

We rearrange the last two terms of the sum using the transformation $r \to r-1$ and the periodicity of the indices and get

$$\frac{d}{dt}\mathcal{A}_i = \frac{1}{2} \sum_{r=1}^{R(i)} \left[\left(Y_{r+1} - Y_r + Y_r - Y_{r-1}\right) \frac{d}{dt} X_r - \left(X_{r+1} - X_r + X_r - X_{r-1}\right) \frac{d}{dt} Y_r \right].$$

This formula can be rewritten as

$$\frac{d}{dt}\mathcal{A}_i = \frac{1}{2} \sum_{r=1}^{R(i)} \boldsymbol{V}^{\star}_{\boldsymbol{r}} \cdot \left(L_{r-1,r} \boldsymbol{N_{r-1,r}} + L_{r,r+1} \boldsymbol{N_{r,r+1}} \right), \tag{3.6}$$

and using the change of indices $r-1 \to r$ for the first term of the sum, we have the equivalent formulation

$$\frac{d}{dt}\mathcal{A}_i = \sum_{r=1}^{R(i)} \frac{1}{2} L_{r,r+1} \left(\boldsymbol{V}^{\star}_{\boldsymbol{r}} + \boldsymbol{V}^{\star}_{\boldsymbol{r+1}} \right) \cdot \boldsymbol{N_{r,r+1}}. \tag{3.7}$$

The comparison between (3.5) and (3.7) enables us to give the face velocities in term of the vertex velocities, namely,

$$\boldsymbol{V}^{\star}_{\boldsymbol{r,r+1}} = \frac{1}{2} \left(\boldsymbol{V}^{\star}_{\boldsymbol{r}} + \boldsymbol{V}^{\star}_{\boldsymbol{r+1}} \right). \tag{3.8}$$

This fundamental relation enables us to write two equivalent discretizations of the specific volume variation. It can be given in terms of the flux through the faces, or equivalently, in term of vertex fluxes. Moreover, the two discretizations are [illegible] with the node motion. We get one of the results of [9], but with a much simpler geometrical argument. We note that (3.8) is consistent with the assumption that the velocity field is linear along face $[M_r, M_{r+1}]$.

Hence, one can consider two methods for computing the face velocities:

- The first one relies on the evaluation of the normal velocity $\boldsymbol{V}^{\star}_{\boldsymbol{r,r+1}} \cdot \boldsymbol{N_{r,r+1}}$ using a one-dimensional Riemann solver at faces. The vertex velocities $\boldsymbol{V}^{\star}_{\boldsymbol{r}}$ have to be computed by solving a linear system built from (3.8) written for all the faces. This system is in general singular, which is why we give up this approach and shall adopt a more robust method.
- In the second method, the velocities $\boldsymbol{V}^{\star}_{\boldsymbol{r}}$ are first evaluated using some still-to-be-defined solver. The face velocities are then computed from (3.8). This is the technique we will use in what follows because this method will guarantee the compatibility between vertex motion and cell area variation.

3.3. Approximation of momentum flux. Following the same methodology, we approximate the momentum flux defined at the vertices in such a way that it is compatible with the approximation at faces. Thus, similarly to (3.8) we set

$$P^{\star,i}_{r,r+1} = \frac{1}{2}\left(P^{\star,i}_{r,r+\frac{1}{2}} + P^{\star,i}_{r+\frac{1}{2},r+1}\right), \tag{3.9}$$

where $P^{\star,i}_{r,r+\frac{1}{2}}$ (resp., $P^{\star,i}_{r+\frac{1}{2},r+1}$) represents the pressure on the half-face $[M_r, M_{r+\frac{1}{2}}]$ (resp., $[M_{r+\frac{1}{2}}, M_{r+1}]$) seen from the cell Ω_i; see Figure 3.2. We have added the superscript i to remove any possible ambiguity. Hence, $\frac{1}{2}L_{r,r+1}P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{N_{r,r+1}}$ represents the momentum flux for half-face $[M_r, M_{r+\frac{1}{2}}]$ seen from the cell Ω_i. We observe that at node M_r, seen from the cell Ω_i, there exist two pressures: $P^{\star,i}_{r,r+\frac{1}{2}}$ and $P^{\star,i}_{r-\frac{1}{2},r}$. Because of this, our approach is different from that of [9], where only one pressure is defined at the vertex M_r.

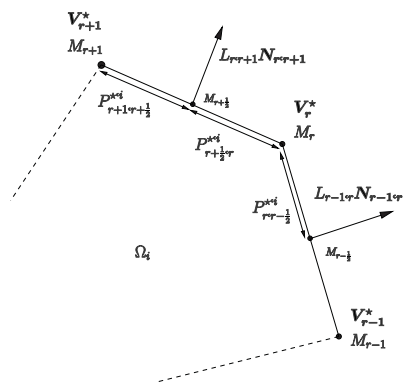

FIG. 3.2. *Pressures at faces.*

Using this definition, the equation for momentum (3.3 iii) is written as

$$m_i \frac{d}{dt}\boldsymbol{V_i} + \sum_{r=1}^{R(i)} \frac{1}{2} L_{r,r+1}\left(P^{\star,i}_{r,r+\frac{1}{2}} + P^{\star,i}_{r+\frac{1}{2},r+1}\right)\boldsymbol{N_{r,r+1}} = \boldsymbol{0}. \tag{3.10}$$

If we shift the index r (i.e., $r \to r-1$) in the second term of the summation, we get

$$m_i \frac{d}{dt}\boldsymbol{V_i} + \sum_{r=1}^{R(i)} \frac{1}{2}\left(L_{r-1,r}P^{\star,i}_{r-\frac{1}{2},r}\boldsymbol{N_{r-1,r}} + L_{r,r+1}P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{N_{r,r+1}}\right) = \boldsymbol{0}. \tag{3.11}$$

It amounts to summing the fluxes over all nodes of the cell. Equations (3.10) and (3.11) are equivalent discretizations. They use either face fluxes or vertex fluxes. The evaluation of these fluxes uses two pressures at a face or at a node for cell Ω_i.

1. We notice that in the case of a one-dimensional Riemann solver at faces, as classically done, only one single pressure is computed for $[M_r, M_{r+1}]$. The conservation of the momentum is a simple consequence of this approximation. Here, this is no longer the case. In fact, if the cell Ω_j shares face $[M_r, M_{r+1}]$ with Ω_i, the pressures on this face seen from Ω_i may be in general different from those seen from Ω_j. That is why we have put the superscript denoting the cell in the definition of edge pressures. This is an important fact, which is one of the key points of our construction: in adding degrees of freedom as here, we will see later in the text that this enables us to build a node solver which simultaneously provides us with the node velocity and the local conservation of momentum and energy.

3.4. Approximation of the energy flux. In order to get an equivalent discretization in terms of face and nodal fluxes for the total energy equation, we set

$$(P\boldsymbol{V})^{\star,i}_{r,r+1} = \frac{1}{2}\left(P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{V_r^\star} + P^{\star,i}_{r+\frac{1}{2},r+1}\boldsymbol{V_{r+1}^\star}\right). \tag{3.12}$$

Using (3.12), the total energy equation in its face flux formulation is written as

$$m_i\frac{d}{dt}E_i + \sum_{r=1}^{R(i)}\frac{1}{2}L_{r,r+1}\left(P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{V_r^\star} + P^{\star,i}_{r+\frac{1}{2},r+1}\boldsymbol{V_{r+1}^\star}\right)\cdot\boldsymbol{N_{r,r+1}} = 0. \tag{3.13}$$

Shifting once more the index r in the second term of the sum, we get the node flux formulation

$$m_i\frac{d}{dt}E_i + \sum_{r=1}^{R(i)}\frac{1}{2}\left(L_{r-1,r}P^{\star,i}_{r-\frac{1}{2},r}\boldsymbol{N_{r-1,r}} + L_{r,r+1}P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{N_{r,r+1}}\right)\cdot\boldsymbol{V_r^\star} = 0. \tag{3.14}$$

3.5. Summary. We obtain an approximation of the Euler equations written in Lagrangian coordinates which relies on approximated vertex fluxes:

$$m_i\frac{d}{dt}\tau_i - \sum_{r=1}^{R(i)}\frac{1}{2}\left(L_{r-1,r}\boldsymbol{N_{r-1,r}} + L_{r,r+1}\boldsymbol{N_{r,r+1}}\right)\cdot\boldsymbol{V_r^\star} = 0,$$

$$m_i\frac{d}{dt}\boldsymbol{V_i} + \sum_{r=1}^{R(i)}\frac{1}{2}\left(L_{r-1,r}P^{\star,i}_{r-\frac{1}{2},r}\boldsymbol{N_{r-1,r}} + L_{r,r+1}P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{N_{r,r+1}}\right) = \boldsymbol{0}, \tag{3.15}$$

$$m_i\frac{d}{dt}E_i + \sum_{r=1}^{R(i)}\frac{1}{2}\left(L_{r-1,r}P^{\star,i}_{r-\frac{1}{2},r}\boldsymbol{N_{r-1,r}} + L_{r,r+1}P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{N_{r,r+1}}\right)\cdot\boldsymbol{V_r^\star} = 0.$$

The system (3.15) is equivalent to (3.3) provided that the face fluxes are defined by

$$\begin{aligned}
\boldsymbol{V^\star_{r,r+1}} &= \tfrac{1}{2}\left(\boldsymbol{V_r^\star} + \boldsymbol{V_{r+1}^\star}\right),\\
P^{\star,i}_{r,r+1} &= \tfrac{1}{2}\left(P^{\star,i}_{r,r+\frac{1}{2}} + P^{\star,i}_{r+\frac{1}{2},r+1}\right),\\
(P\boldsymbol{V})^{\star,i}_{r,r+1} &= \tfrac{1}{2}\left(P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{V_r^\star} + P^{\star,i}_{r+\frac{1}{2},r+1}\boldsymbol{V_{r+1}^\star}\right).
\end{aligned} \tag{3.16}$$

Moreover, this definition is coherent with the vertex motion.

Now, we are going to show how to compute, for each vertex M_r , the velocity $\boldsymbol{V_r^\star}$ and the pressures $P^{\star,i}_{r-\frac{1}{2},r}$ and $P^{\star,i}_{r,r+\frac{1}{2}}$.

4. Construction of a solver at the vertices. The evaluation of $\boldsymbol{V_r^\star}$, $P^{\star,i}_{r-\frac{1}{2},r}$, and $P^{\star,i}_{r,r+\frac{1}{2}}$ relies on the following arguments:

- the global conservation of momentum,
- a local entropy inequality.

The first argument is a consequence of Remark 1: the pressure on the face $[M_r, M_{r+1}]$ is not unique, contrary to the standard finite volume approach. Thus, we lose the automatic conservation of momentum and total energy. Of course, we must guarantee the conservation of momentum and total energy, so we have to add additional constraints on $\boldsymbol{V_r^\star}$, $P^{\star,i}_{r-\frac{1}{2},r}$, and $P^{\star,i}_{r,r+\frac{1}{2}}$.

The second argument is about the thermodynamical consistency of the scheme, which is necessary for a correct computation of the discontinuities. We will build a sufficient condition which will supply a local dissipation of entropy.

The two sets of constraints (conservation and dissipation of entropy) will lead, as we shall see in this section, to a linear system whose unique solution will give us $\boldsymbol{V_r^\star}$, $P^{\star,i}_{r-\frac{1}{2},r}$, and $P^{\star,i}_{r,r+\frac{1}{2}}$.

4.1. Notation around a vertex. In order to exhibit conservation equations for momentum and total energy around a node, let us introduce some new notation. We denote by M_q a generic internal vertex of the mesh, for $q = 1, \dots, Q$, where Q is the total number of internal nodes. The case of the nodes located on the boundary $\partial\Omega$ will be treated in section 4.7. There are $K(q)$ cells around M_q which are denoted by Ω_k; see Figure 4.1. For the cell Ω_k we denote by $[M_q, M_k]$ and $[M_q, M_{k+1}]$ the edges coming from node M_q. The outward normal to these edges are $\boldsymbol{N_k^k}$, $\boldsymbol{N_{k+1}^k}$ and their lengths L_k, L_{k+1}. Let $\boldsymbol{V_q^\star}$ be the velocity of node M_q and $P^{\star,k}_{q,k}$ (resp., $P^{\star,k}_{q,k+1}$), the half-pressures on edge $[M_q, M_k]$ (resp., $[M_q, M_{k+1}]$) seen from cell Ω_k.

4.2. Conservation relations. Omitting the boundary conditions and summing (3.11) on each cell of the domain, we make a global balance of momentum

$$\frac{d}{dt}\left(\sum_{i=1}^{I} m_i \boldsymbol{V_i}\right) = -\sum_{i=1}^{I}\sum_{r=1}^{r(i)} \frac{1}{2}\left(L^i_{r-1,r} P^{\star,i}_{r-\frac{1}{2},r} \boldsymbol{N^i_{r-1,r}} + L^i_{r,r+1} P^{\star,i}_{r,r+\frac{1}{2}} \boldsymbol{N^i_{r,r+1}}\right).$$

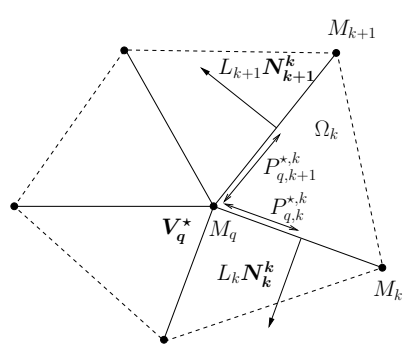

FIG. 4.1. *Notation around the vertex M_q.*

We have added the superscript i for the lengths and normals in order to remove any possible ambiguity. If we replace the global summation over cells by a global summation over nodes, using the notation previously defined, we can rewrite the right-hand side in the following way:

$$\frac{d}{dt}\left(\sum_{i=1}^{I} m_i \boldsymbol{V_i}\right) = -\sum_{q=1}^{Q}\sum_{k=1}^{K(q)} \frac{1}{2}\left(L_k P_{q,k}^{\star,k} \boldsymbol{N_k^k} + L_{k+1} P_{q,k+1}^{\star,k} \boldsymbol{N_{k+1}^k}\right).$$

The (global) conservation of momentum is satisfied provided that the right-hand side vanishes. A sufficient condition is

$$\sum_{k=1}^{K(q)} \frac{1}{2}\left(L_k P_{q,k}^{\star,k} \boldsymbol{N_k^k} + L_{k+1} P_{q,k+1}^{\star,k} \boldsymbol{N_{k+1}^k}\right) = \boldsymbol{0}. \tag{4.1}$$

This summation is done over all the cells k surrounding vertex M_q; see Figure 4.1. The relation (4.1) can be interpreted as the local equilibrium of vertex M_q under pressure forces. This is also a local conservation relation.

It can be checked that condition (4.1) also implies the global conservation of total energy. To do so, we sum (3.14) on each cell, switch the summation for the cells' and the vertices' indices, and get

$$\frac{d}{dt}\left(\sum_{i=1}^{I} m_i E_i\right) = -\sum_{q=1}^{Q}\sum_{k=1}^{K(q)} \frac{1}{2}\left(L_k P_{q,k}^{\star,k} \boldsymbol{N_k^k} + L_{k+1} P_{q,k+1}^{\star,k} \boldsymbol{N_{k+1}^k}\right) \cdot \boldsymbol{V_q^\star} = 0,$$

using (4.1) and because the velocity $\boldsymbol{V_q^\star}$ is single valued at M_q.

The conservation of volume is easily checked. To do so, we sum the first equation of (3.15) for each cell:

$$\frac{d}{dt}\left(\sum_{i=1}^{I} m_i \tau_i\right) = \sum_{q=1}^{Q}\sum_{k=1}^{K(q)} \frac{1}{2}\left(L_k \boldsymbol{N_k^k} + L_{k+1} \boldsymbol{N_{k+1}^k}\right) \cdot \boldsymbol{V_q^\star}.$$

We know that

$$\sum_{k=1}^{K(q)} \frac{1}{2}\left(L_k \boldsymbol{N_k^k} + L_{k+1} \boldsymbol{N_{k+1}^k}\right) = \boldsymbol{0}, \tag{4.2}$$

since the polygon whose vertices are M_k, $k = 1, \ldots, K(q)$, is closed (dotted line in Figure 4.1).

4.3. Entropy inequality. We first compute the time variation of entropy in cell Ω_i. Let us denote it by σ_i. If T_i is the cell average temperature, we have

$$m_i T_i \frac{d}{dt}\sigma_i = m_i\left(\frac{d}{dt}\varepsilon_i + P_i \frac{d}{dt}\tau_i\right). \tag{4.3}$$

This quantity is evaluated in two steps. First, we compute the variation of internal energy $\frac{d}{dt}\varepsilon_i = \frac{d}{dt}E_i - \boldsymbol{V_i} \cdot \frac{d}{dt}\boldsymbol{V_i}$, and then we evaluate the pressure work $P_i \frac{d}{dt}\tau_i$.

- Internal energy: we dot-multiply (3.11) by $\boldsymbol{V_i}$ to get the kinetic energy variation:

$$m_i \boldsymbol{V_i} \cdot \frac{d}{dt}\boldsymbol{V_i} = -\sum_{r=1}^{R(i)} \frac{1}{2}\left(L_{r-1,r} P_{r-\frac{1}{2},r}^{\star,i} \boldsymbol{N_{r-1,r}} + L_{r,r+1} P_{r,r+\frac{1}{2}}^{\star,i} \boldsymbol{N_{r,r+1}}\right) \cdot \boldsymbol{V_i}. \tag{4.4}$$

Then (4.4) is subtracted from the total energy variation equation and we have

(4.5)
$$m_i \frac{d}{dt}\varepsilon_i = -\sum_{r=1}^{R(i)} \frac{1}{2}\left(L_{r-1,r}P^{\star,i}_{r-\frac{1}{2},r}\boldsymbol{N_{r-1,r}} + L_{r,r+1}P^{\star,i}_{r,r+\frac{1}{2}}\boldsymbol{N_{r,r+1}}\right)\cdot\left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right).$$

- Pressure work: we multiply the first relation of (3.15) by P_i:

$$m_i P_i \frac{d}{dt}\tau_i = \sum_{r=1}^{R(i)} \frac{1}{2}\left(L_{r-1,r}P_i\boldsymbol{N_{r-1,r}} + L_{r,r+1}P_i\boldsymbol{N_{r,r+1}}\right)\cdot\boldsymbol{V_r^\star}.$$

An equivalent formulation is

$$m_i P_i \frac{d}{dt}\tau_i = \sum_{r=1}^{R(i)} \frac{1}{2}\left(L_{r-1,r}P_i\boldsymbol{N_{r-1,r}} + L_{r,r+1}P_i\boldsymbol{N_{r,r+1}}\right)\cdot\left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right). \tag{4.6}$$

Knowing that,

$$\sum_{r=1}^{R(i)} \frac{1}{2}\left(L_{r-1,r}\boldsymbol{N_{r-1,r}} + L_{r,r+1}\boldsymbol{N_{r,r+1}}\right) = \boldsymbol{0},$$

because the boundary of Ω_i is a closed polygon.

Last, the summation of (4.5) and (4.6) gives

$$m_i T_i \frac{d}{dt}\sigma_i = \sum_{r=1}^{R(i)} \frac{1}{2}\left[L_{r-1,r}\left(P_i - P^{\star,i}_{r-\frac{1}{2},r}\right)\boldsymbol{N_{r-1,r}} + L_{r,r+1}\left(P_i - P^{\star,i}_{r,r+\frac{1}{2}}\right)\boldsymbol{N_{r,r+1}}\right] \cdot\left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right).$$

A sufficient condition for the right-hand side of this relation to be positive is

$$\begin{cases} P_i - P^{\star,i}_{r-\frac{1}{2},r} = \alpha_i\left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right)\cdot\boldsymbol{N_{r-1,r}}, \quad r = 1,\dots,R(i), \\ \\ P_i - P^{\star,i}_{r,r+\frac{1}{2}} = \alpha_i\left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right)\cdot\boldsymbol{N_{r,r+1}}, \quad r = 1,\dots,R(i), \end{cases} \tag{4.7}$$

where α_i is a positive coefficient that has the dimension of a mass flux. These two relations can be interpreted as (discretized) Riemann invariants along the directions $\boldsymbol{N_{r-1,r}}$ and $\boldsymbol{N_{r,r+1}}$. Our main motivation is to recover the approximate acoustic solver [24] for one-dimensional flows, which is why the parameter α_i is set to the value

$$\alpha_i = \rho_i c_i, \tag{4.8}$$

where $c_i = \sqrt{\left(\frac{\partial P}{\partial \rho}\right)_\sigma}$ represents the isentropic sound speed. Under condition (4.7), the variation of entropy is

(4.9)
$$m_i T_i \frac{d}{dt}\sigma_i = \sum_{r=1}^{R(i)} \frac{1}{2}\rho_i c_i \left\{L_{r-1,r}\left[\left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right)\cdot\boldsymbol{N_{r-1,r}}\right]^2 + L_{r,r+1}\left[\left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right)\cdot\boldsymbol{N_{r,r+1}}\right]^2\right\}.$$

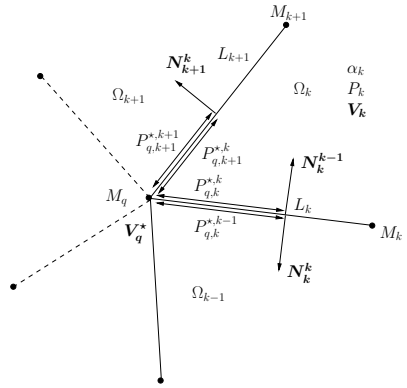

FIG. 4.2. *States around internal node M_q.*

REMARK 2. The relation (4.9) is very similar to the entropy production term resulting from a two-dimensional linear artificial viscosity term; see [5]. We notice that (4.9) implies a positive production of entropy, even in the case of isentropic flows. For such flows our scheme does not conserve entropy. This is typical for Godunov-type schemes. If we rewrite the sufficient condition (4.7) using notation around a generic vertex M_q, we obtain

$$\begin{cases} P_k - P_{q,k}^{\star,k} = \alpha_k \left(\boldsymbol{V_q^\star} - \boldsymbol{V_k} \right) \cdot \boldsymbol{N_k^k}, \quad k = 1, \dots, K(q), \\ \\ P_k - P_{q,k+1}^{\star,k} = \alpha_k \left(\boldsymbol{V_q^\star} - \boldsymbol{V_k} \right) \cdot \boldsymbol{N_{k+1}^k}, \quad k = 1, \dots, K(q), \end{cases} \tag{4.10}$$

where α_k, P_k, and $\boldsymbol{V_k}$ stand for acoustic impedance, pressure, and velocity in cell Ω_k. We point out that for a vertex M_q (not on the boundary of the computational domain), we have to compute $2K(q)$ pressures, that is, together with the velocity $\boldsymbol{V_q^\star}$, to evaluate $2K(q) + 2$ scalar unknowns. Equation (4.1) provides 2 scalar relations, and (4.10) gives $2K(q)$ more. Hence, we can compute the pressures and the velocity at the vertex M_q. This is the topic of the next section.

4.4. Evaluation of the velocity and pressures at the vertices. Using sufficient conditions (4.1) and (4.10), we write the linear system satisfied by the components of the velocity $\boldsymbol{V}_q^\star$ of an internal vertex M_q. This generic vertex is not on the boundary of the domain, so that it is surrounded by the cells Ω_k, $k = 1, \dots, K(q)$; see Figure 4.2. With this new notation, if we shift index $(k \to k-1)$ in the second term of (4.1), we get

$$\sum_{k=1}^{K(q)} L_k \left(P_{q,k}^{\star,k} - P_{q,k}^{\star,k-1} \right) \boldsymbol{N_k^{k-1}} = \boldsymbol{0}, \tag{4.11}$$

where we have used $\boldsymbol{N_k^k} = -\boldsymbol{N_k^{k-1}}$. We proceed in the same way for (4.10):

$$\begin{cases} P_{q,k}^{\star,k} = P_k + \alpha_k \left(\boldsymbol{V_q^\star} - \boldsymbol{V_k} \right) \cdot \boldsymbol{N_k^{k-1}}, \\ \\ P_{q,k}^{\star,k-1} = P_{k-1} - \alpha_{k-1} \left(\boldsymbol{V_q^\star} - \boldsymbol{V_{k-1}} \right) \cdot \boldsymbol{N_k^{k-1}}. \end{cases} \tag{4.12}$$

After substitution of (4.12) into (4.11), we obtain the following equation satisfied by $\boldsymbol{V_q^\star}$:

(4.13)
$$\sum_{k=1}^{K(q)} L_k\left(\alpha_{k-1}+\alpha_k\right) \times \left[\boldsymbol{V_q^\star}\cdot\boldsymbol{N_k^{k-1}} - \frac{P_{k-1}-P_k+\alpha_{k-1}\boldsymbol{V_{k-1}}\cdot\boldsymbol{N_k^{k-1}}+\alpha_k\boldsymbol{V_k}\cdot\boldsymbol{N_k^{k-1}}}{\alpha_{k-1}+\alpha_k}\right]\boldsymbol{N_k^{k-1}} = \mathbf{0}.$$

If we set

$$\mathcal{V}_k^\star = \frac{P_{k-1}-P_k+\alpha_{k-1}\boldsymbol{V_{k-1}}\cdot\boldsymbol{N_k^{k-1}}+\alpha_k\boldsymbol{V_k}\cdot\boldsymbol{N_k^{k-1}}}{\alpha_{k-1}+\alpha_k},$$

$\mathcal{V}_k^\star$ is the normal velocity given by the classical one-dimensional acoustic Riemann solver for face $[M_q, M_k]$. With this notation, we can rewrite (4.13) and give an interesting interpretation of it:

$$\sum_{k=1}^{K(q)} L_k\left(\alpha_{k-1}+\alpha_k\right)\left[\boldsymbol{V_q^\star}\cdot\boldsymbol{N_k^{k-1}} - \mathcal{V}_k^\star\right]\boldsymbol{N_k^{k-1}} = \mathbf{0}.$$

A straightforward calculation shows that the left-hand side of this last equation is the gradient of the following quadratic functional:

$$F(u_q^\star, v_q^\star) = \sum_{k=1}^{K(q)} L_k\left(\alpha_{k-1}+\alpha_k\right)\left[\boldsymbol{V_q^\star}\cdot\boldsymbol{N_k^{k-1}} - \mathcal{V}_k^\star\right]^2, \tag{4.14}$$

where $(u_q^\star, v_q^\star)$ denotes the components of $\boldsymbol{V_q^\star}$. Consequently, the solution of (4.13) reaches the minimum of the functional $F(u_q^\star, v_q^\star)$. Hence, it appears that the nodal velocity $\boldsymbol{V_q^\star}$ is obtained from [illegible]. This least squares procedure corresponds to the overdetermined system equating the projection of the nodal velocity onto the edge normal N_k^{k-1} with the normal velocity $\mathcal{V}_k^\star$ obtained from the acoustic approximate Riemann solver. For each edge impinging on node M_q, the weight is $L_k(\alpha_{k-1}+\alpha_k)$.

Finally, we write the 2×2 linear system satisfied by $(u_q^\star, v_q^\star)$:

$$\begin{cases} Au_q^\star + Cv_q^\star = SM_X, \\ Cu_q^\star + Bv_q^\star = SM_Y, \end{cases} \tag{4.15}$$

where A, B, and C are defined by

$$A = \sum_{k=1}^{K(q)} L_k\left(\alpha_{k-1}+\alpha_k\right)\left(N_{k,X}^{k-1}\right)^2,$$
$$B = \sum_{k=1}^{K(q)} L_k\left(\alpha_{k-1}+\alpha_k\right)\left(N_{k,Y}^{k-1}\right)^2,$$
$$C = \sum_{k=1}^{K(q)} L_k\left(\alpha_{k-1}+\alpha_k\right)N_{k,X}^{k-1}N_{k,Y}^{k-1}.$$

Here, $(N_{k,X}^{k-1}, N_{k,Y}^{k-1})$ are the coordinates of $\boldsymbol{N}_k^k$. The right-hand side (SM_X, SM_Y) of (4.15) are the components of the vector $\boldsymbol{SM}$ defined by

$$\boldsymbol{SM} = \sum_{k=1}^{K(q)} L_k \left(\alpha_{k-1} + \alpha_k\right) \mathcal{V}_k^\star \boldsymbol{N_k^{k-1}}.$$

The determinant Δ of (4.15) is $\Delta = AB - C^2$. We show that it is always positive. In order to simplify notation, let us introduce $\beta_k = \sqrt{L_k \left(\alpha_{k-1} + \alpha_k\right)}$ and $\boldsymbol{N_k} = \boldsymbol{N_k^{k-1}}$ for $k = 1, \ldots, K(q)$. We define

$$\begin{aligned} \boldsymbol{U_X} &= \left(\beta_1 N_{1,X}, \ldots, \beta_K N_{K,X}\right)^t, \\ \boldsymbol{U_Y} &= \left(\beta_1 N_{1,Y}, \ldots, \beta_K N_{K,Y}\right)^t. \end{aligned}$$

We have immediately $A = \|\boldsymbol{U_X}\|^2$, $B = \|\boldsymbol{U_Y}\|^2$, and $C = \langle \boldsymbol{U_X}, \boldsymbol{U_Y} \rangle$, where $\langle , \rangle$ is the inner scalar product of $\mathbb{R}^K$ and $\| \ \|$ its associated norm. From the Cauchy–Schwarz inequality, we know that $\Delta \geq 0$. In fact, $\Delta = 0$ if and only if one of the two vectors is null or $\boldsymbol{U_X}$ and $\boldsymbol{U_Y}$ are colinear. This situation is generally impossible unless the edges around the node merge into a single line.

We have shown that the system (4.15) always has a unique solution which determines the velocity $\boldsymbol{V_q^\star}$. From (4.12), we can get the pressures $P_{q,k}^{\star,k}$ and $P_{q,k}^{\star,k-1}$. Moreover, this nodal solver is invariant under translation, homothety, and rotation of center M_q.

3. If the flow is uniform (i.e., with a uniform velocity $\boldsymbol{V}^0$ and pressure P^0), we can easily check that the solution of (4.15) reduces to $\boldsymbol{V}_q^\star = \boldsymbol{V}^0$

4.5. Summary of the discrete evolution equations. We give in this section the summary of the discrete evolution equations that constitute a closed set of equations for the unknowns $\{\tau_i, \boldsymbol{V_i}, E_i\}$:

$$\begin{aligned} & m_i \frac{d}{dt}\tau_i - \sum_{r=1}^{R(i)} \frac{1}{2} \left(L_{r-1,r} \boldsymbol{N_{r-1,r}} + L_{r,r+1} \boldsymbol{N_{r,r+1}}\right) \cdot \boldsymbol{V_r^\star} = 0, \\ & m_i \frac{d}{dt}\boldsymbol{V_i} + \sum_{r=1}^{R(i)} \frac{1}{2} \left(L_{r-1,r} P_{r-\frac{1}{2},r}^{\star,i} \boldsymbol{N_{r-1,r}} + L_{r,r+1} P_{r,r+\frac{1}{2}}^{\star,i} \boldsymbol{N_{r,r+1}}\right) = \boldsymbol{0}, \\ & m_i \frac{d}{dt}E_i + \sum_{r=1}^{R(i)} \frac{1}{2} \left(L_{r-1,r} P_{r-\frac{1}{2},r}^{\star,i} \boldsymbol{N_{r-1,r}} + L_{r,r+1} P_{r,r+\frac{1}{2}}^{\star,i} \boldsymbol{N_{r,r+1}}\right) \cdot \boldsymbol{V_r^\star} = 0. \end{aligned} \tag{4.16}$$

We note that these equations have been written using a vertex flux formulation (see section 3). Those fluxes are obtained via a nodal solver which is derived in section 4. The edge pressures $P_{r-\frac{1}{2},r}^{\star,i}, P_{r,r+\frac{1}{2}}^{\star,i}$ are computed as follows:

$$\begin{cases} P_i - P_{r-\frac{1}{2},r}^{\star,i} = \rho_i c_i \left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right) \cdot \boldsymbol{N_{r-1,r}}, \ \ r = 1, \ldots, R(i), \\ \\ P_i - P_{r,r+\frac{1}{2}}^{\star,i} = \rho_i c_i \left(\boldsymbol{V_r^\star} - \boldsymbol{V_i}\right) \cdot \boldsymbol{N_{r,r+1}}, \ \ r = 1, \ldots, R(i). \end{cases} \tag{4.17}$$

If q denotes the global index corresponding to the local index r, the nodal velocity $\boldsymbol{V_r^\star} \equiv \boldsymbol{V_q^\star} = (u_q^\star, v_q^\star)$ is given by the solution of the 2×2 linear system

$$\begin{cases} A u_q^\star + C v_q^\star = SM_X, \\ C u_q^\star + B v_q^\star = SM_Y, \end{cases} \tag{4.18}$$

where A, B, and C are defined by

$$A = \sum_{k=1}^{K(q)} L_k \left(\rho_{k-1}c_{k-1} + \rho_k c_k\right) \left(N_{k,X}^{k-1}\right)^2,$$
$$B = \sum_{k=1}^{K(q)} L_k \left(\rho_{k-1}c_{k-1} + \rho_k c_k\right) \left(N_{k,Y}^{k-1}\right)^2,$$
$$C = \sum_{k=1}^{K(q)} L_k \left(\rho_{k-1}c_{k-1} + \rho_k c_k\right) N_{k,X}^{k-1} N_{k,Y}^{k-1},$$

where the index k denotes the label of the cells (edges) that surround the node M_q; see Figure 4.2. The right-hand side of (4.18), $\boldsymbol{SM} = (SM_X, SM_Y)^t$, is given by

$$\boldsymbol{SM} = \sum_{k=1}^{K(q)} L_k \left(\rho_{k-1}c_{k-1} + \rho_k c_k\right) \mathcal{V}_k^\star \boldsymbol{N_k^{k-1}},$$

where $\mathcal{V}_k^\star$ corresponds to the normal velocity given by the classical one-dimensional acoustic Riemann solver

$$\mathcal{V}_k^\star = \frac{P_{k-1} - P_k + \rho_{k-1}c_{k-1}\boldsymbol{V_{k-1}} \cdot \boldsymbol{N_k^{k-1}} + \rho_k c_k \boldsymbol{V_k} \cdot \boldsymbol{N_k^{k-1}}}{\rho_{k-1}c_{k-1} + \rho_k c_k}.$$

Before we detail our implementation of the boundary conditions, we provide in the next section an interpretation of our results in the case of a one-dimensional flow with a planar symmetry and in the case of a flow with a cylindrical symmetry.

4.6. Interpretation of the solver in two simple cases.

4.6.1. One-dimensional flow with planar symmetry. Let us consider M_q surrounded by four quadrangular cells. They are numbered from 1 to 4 in the counterclockwise direction; see Figure 4.3. We consider the frame $(M_q, \boldsymbol{e_X}, \boldsymbol{e_Y})$. The vector $\boldsymbol{N}_k^{k-1}$ is the normal to the edge shared by cells $k-1$ and k. The length of this edge is L_k. The indexing system is periodic with period 4, and the flow is one-dimensional in the $\boldsymbol{e}_X$ direction so that the velocity field in the cell k reduces to $\boldsymbol{V}_k = u_k \boldsymbol{e_X}$. Moreover, any scalar quantity φ satisfies $\varphi_1 \equiv \varphi_4$ and $\varphi_2 \equiv \varphi_3$. The cells 1 and 4 contain the state defined by P_1, c_1, $\boldsymbol{V_1} = u_1 \boldsymbol{e_X}$. The cells 2 and 3 contain the state defined by P_2, c_2, $\boldsymbol{V_2} = u_2 \boldsymbol{e_X}$. Using this notation, the evaluation of the matrix

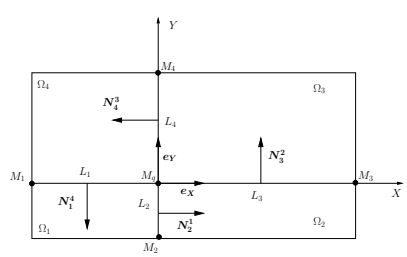

FIG. 4.3. *One-dimensional planar flow.*

coefficients A, B, C is straightforward:

$$A = (L_2 + L_4)(\rho_1 c_1 + \rho_2 c_2),$$

$$B = 2(L_1 \rho_1 c_1 + L_3 \rho_2 c_2),$$

$$C = 0.$$

The calculation of $\boldsymbol{SM}$ gives

$$SM_X = (L_2 + L_4)(P_1 - P_2 + \rho_1 c_1 u_1 + \rho_2 c_2 u_2),$$

$$SM_Y = 0.$$

Therefore $v_q^\star = 0$ and

$$u_q^\star = \frac{P_1 - P_2 + \rho_1 c_1 u_1 + \rho_2 c_2 u_2}{\rho_1 c_1 + \rho_2 c_2}.$$

We recover exactly the acoustic Riemann solver!

4.6.2. One-dimensional flow with cylindrical symmetry. We consider an equiangular cylindrical mesh centered at O. We denote by θ the angle of any sector. The mesh may be nonregular in the radial direction. Any vertex M_q is surrounded by four trapezoidal cells. In order to simplify the algebra, we choose to work in the local orthonormal frame $(M_q, \boldsymbol{e_X}, \boldsymbol{e_Y})$, where $\boldsymbol{e_X}$ is the unit vector colinear to $\boldsymbol{OM_q}$; see Figure 4.4. We use the same conventions as in the previous section. The cells 1 and 4 contain the states defined by P_1, ρ_1, c_1. The cells 2 and 3 contain the states defined by P_2, ρ_2, c_2. Due to cylindrical symmetry, the velocities are defined by $\boldsymbol{V_1} = V_1 \boldsymbol{N_2^1}$, $\boldsymbol{V_2} = V_2 \boldsymbol{N_2^1}$, $\boldsymbol{V_3} = -V_2 \boldsymbol{N_4^3}$, and $\boldsymbol{V_4} = -V_1 \boldsymbol{N_4^3}$. In the frame $(M_q, \boldsymbol{e_X}, \boldsymbol{e_Y})$, the normals are written as

$$\boldsymbol{N_2^1} = \begin{pmatrix} \cos(\theta/2) \\ -\sin(\theta/2) \end{pmatrix}, \quad \boldsymbol{N_2^3} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad \boldsymbol{N_4^3} = \begin{pmatrix} -\cos(\theta/2) \\ -\sin(\theta/2) \end{pmatrix}, \quad \text{and } \boldsymbol{N_1^4} = \begin{pmatrix} 0 \\ -1 \end{pmatrix}.$$

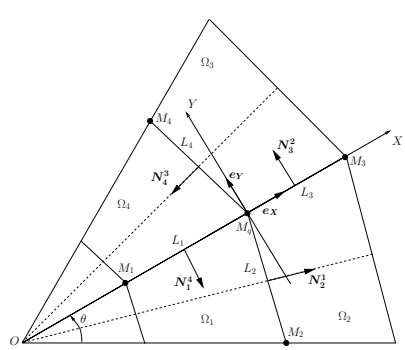

FIG. 4.4. *One-dimensional cylindrical flow.*

After calculations we get

$$A = (L_2 + L_4)\cos^2\left(\frac{\theta}{2}\right)(\rho_1 c_1 + \rho_2 c_2),$$
$$B = 2L_1\rho_1 c_1 + (L_2 + L_4)\sin^2\left(\frac{\theta}{2}\right)(\rho_1 c_1 + \rho_2 c_2) + 2L_3\rho_2 c_2,$$
$$C = (L_4 - L_2)\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{\theta}{2}\right)(\rho_1 c_1 + \rho_2 c_2).$$

We also obtain

$$\boldsymbol{SM} = (P_1 - P_2 + \rho_1 c_1 V_1 + \rho_2 c_2 V_2)\begin{pmatrix}(L_2 + L_4)\cos(\theta/2)\\ (L_4 - L_2)\sin(\theta/2)\end{pmatrix}.$$

Using the symmetry we have $L_2 = L_4$; thus $C = 0$ and $SM_Y = 0$. Therefore $v_q^\star = 0$, and the velocity is of the form $\boldsymbol{V_q^\star} = u_q^\star \boldsymbol{e_X}$. The evaluation of $u_q^\star$ is straightforward:

$$u_q^\star = \frac{P_1 - P_2 + \rho_1 c_1 V_1 + \rho_2 c_2 V_2}{\rho_1 c_1 + \rho_2 c_2}\frac{1}{\cos(\frac{\theta}{2})}.$$

This is once more the acoustic solver modified by a geometrical factor that is a consequence of the projection of $\boldsymbol{V_k}$ on the axis $[O, M_q]$. This term has no consequence since $\cos(\frac{\theta}{2}) \to 1$ when $\theta \to 0$. We also notice that the velocity is radial because the angle between two sectors is uniform. If the mesh does not satisfy this property, therefore $L_2 \neq L_4$ and $C \neq 0$, and consequently, $v_q^\star \neq 0$.

4.7. Boundary conditions. In this section, we explain our implementation of boundary conditions which is consistent with our internal solver. In the Lagrangian formalism, we have to consider two types of boundary conditions on the boundary $\partial\Omega$: either we impose the pressure or we impose the normal component of the velocity. We use the same type of notation as in section 4.1. Let $M_q \in \partial\Omega$. It is surrounded by $K(q) = K$ cells contained in the domain Ω. There are $K + 1$ edges impinging on M_q. They are numbered counterclockwise; see Figure 4.5. The first and last cells Ω_1 and Ω_K have an edge on the boundary $\partial\Omega$. The outward normals to the two boundary edges coming out of M_q are denoted by $-\boldsymbol{N_1^0}$ and $\boldsymbol{N_{K+1}^K}$ coherently with our notation.

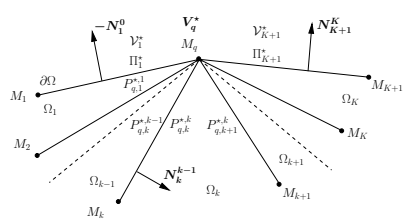

FIG. 4.5. *Notation for the boundary conditions.*

4.7.1. Case of a prescribed pressure. We denote by $\Pi_1^\star$ and $\Pi_{K+1}^\star$ the pressures that are imposed on the boundary edges; see Figure 4.5. We have to compute the $2K$ pressures $P_{q,k}^{\star,k-1}$, $k = 2, \ldots, K+1$, and $P_{q,k}^{\star,k}$, $k = 1, \ldots, K$; adding the velocity $\boldsymbol{V_q^\star}$ of the vertex M_q, we have a total number of $2K + 2$ scalar unknowns. These unknowns satisfy the previous relations (conservation of momentum, entropy

inequality). For the conservation relation, we make a balance around the vertex M_q by counting the pressure forces due to the boundary conditions. We get

$$\begin{aligned} &-L_1 P_{q,1}^{\star,1} \boldsymbol{N_1^0} + \sum_{k=2}^{K} L_k \left(P_{q,k}^{\star,k-1} - P_{q,k}^{\star,k} \right) \boldsymbol{N_k^{k-1}} + L_{K+1} P_{q,K+1}^{\star,K} \boldsymbol{N_{K+1}^K} \\ &\quad = -L_1 \Pi_1^\star \boldsymbol{N_1^0} + L_{K+1} \Pi_{K+1}^\star \boldsymbol{N_{K+1}^K}. \end{aligned} \tag{4.19}$$

The entropy inequality provides

$$\begin{aligned} P_{q,k}^{\star,k} &= P_k + \alpha_k \left(\boldsymbol{V_q^\star} - \boldsymbol{V_k} \right) \cdot \boldsymbol{N_k^{k-1}}, \quad k = 1, \dots, K, \\ P_{q,k}^{\star,k-1} &= P_{k-1} - \alpha_{k-1} \left(\boldsymbol{V_q^\star} - \boldsymbol{V_{k-1}} \right) \cdot \boldsymbol{N_k^{k-1}}, \quad k = 2, \dots, K+1. \end{aligned} \tag{4.20}$$

The use of (4.20) in (4.19) leads to

$$\begin{cases} \tilde{A} u_q^\star + \tilde{C} v_q^\star = \widetilde{SM_X}, \\ \tilde{C} u_q^\star + \tilde{B} v_q^\star = \widetilde{SM_Y}, \end{cases} \tag{4.21}$$

where the coefficients are

$$\begin{aligned} \tilde{A} &= \sum_{k=2}^{K} L_k \left(\alpha_{k-1} + \alpha_k \right) \left(N_{k,X}^{k-1} \right)^2 + L_1 \alpha_1 \left(N_{1,X}^0 \right)^2 + L_{K+1} \alpha_{K+1} \left(N_{K+1,X}^K \right)^2, \\ \tilde{B} &= \sum_{k=2}^{K} L_k \left(\alpha_{k-1} + \alpha_k \right) \left(N_{k,Y}^{k-1} \right)^2 + L_1 \alpha_1 \left(N_{1,Y}^0 \right)^2 + L_{K+1} \alpha_{K+1} \left(N_{K+1,Y}^K \right)^2, \\ \tilde{C} &= \sum_{k=2}^{K} L_k \left(\alpha_{k-1} + \alpha_k \right) N_{k,X}^{k-1} N_{k,Y}^{k-1} + L_1 \alpha_1 N_{1,X}^0 N_{1,Y}^0 + L_{K+1} \alpha_{K+1} N_{K+1,X}^K N_{K+1,Y}^K. \end{aligned}$$

We see that we recover the coefficients A, B and C, where the contribution of the boundary faces are now taken into account. The right-hand side of (4.21) is written as

$$\begin{aligned} \widetilde{\boldsymbol{SM}} = &\sum_{k=2}^{K} L_k \left[P_{k-1} - P_k + (\alpha_{k-1} \boldsymbol{V_{k-1}} + \alpha_k \boldsymbol{V_k}) \cdot \boldsymbol{N_{k-1}^k} \right] \boldsymbol{N_{k-1}^k} \\ &- L_1 \left[P_1 - \Pi_1^\star - \alpha_1 \boldsymbol{V_1} \cdot \boldsymbol{N_1^0} \right] \boldsymbol{N_1^0} \\ &+ L_{K+1} \left[P_K - \Pi_{K+1}^\star + \alpha_K \boldsymbol{V_K} \cdot \boldsymbol{N_K^{K+1}} \right] \boldsymbol{N_K^{K+1}}. \end{aligned}$$

From the Cauchy–Schwartz inequality, we know that $\tilde{C}^2 < \tilde{A}\tilde{B}$. Hence, the linear system (4.21) always has a unique solution $(u_q^\star, v_q^\star)$. The pressures $P_{q,k}^{\star,k-1}, k = 2, \dots, K+1$, and $P_{q,k}^{\star,k}, k = 1, \dots, K$, are obtained from (4.20).

4.7.2. Case of a prescribed normal velocity. Let $\mathcal{V}_1^\star$ and $\mathcal{V}_{K+1}^\star$ be the values of the prescribed normal velocities on the boundary edges coming out of M_q. We distinguish the following two cases:

- $-\boldsymbol{N_1^0}$ and $\boldsymbol{N_K^{K+1}}$ are not colinear: in this case the value of $\boldsymbol{V_q^\star}$ is given by the boundary conditions, and the components of the vertex velocity are the solution of the linear system

$$\begin{cases} -N_{1,X}^0 u_q^\star - N_{1,Y}^0 v_q^\star = \mathcal{V}_1^\star, \\ N_{K,X}^{K+1} u_q^\star + N_{K,Y}^{K+1} v_q^\star = \mathcal{V}_{K+1}^\star. \end{cases}$$

Since the normals are not colinear, this linear system always has a unique solution. The pressures are computed from (4.20).

- $-\boldsymbol{N_1^0}$ and $\boldsymbol{N_K^{K+1}}$ are colinear: in this case, $\boldsymbol{V_q^\star}$ is not given directly, and we need to know the balance of momentum around the vertex M_q which takes the boundary conditions into account:

$$-L_1 P_{q,1}^{\star,1}\boldsymbol{N_1^0} + \sum_{k=2}^{K} L_k\left(P_{q,k}^{\star,k-1} - P_{q,k}^{\star,k}\right)\boldsymbol{N_k^{k-1}} + L_{K+1}P_{q,K+1}^{\star,K}\boldsymbol{N_{K+1}^K} = \left(-L_1\boldsymbol{N_1^0} + L_{K+1}\boldsymbol{N_K^{K+1}}\right)\Pi^\star, \tag{4.22}$$

where $\Pi^\star$ is an average pressure applied on the external side of the edges coming out of M_q. The pressure $\Pi^\star$ is a new unknown, but we have an additional equation corresponding to the boundary condition

$$\left(-L_1\boldsymbol{N_1^0} + L_{K+1}\boldsymbol{N_K^{K+1}}\right)\cdot\boldsymbol{V_q^\star} = L_1\mathcal{V}_1^\star + L_{K+1}\mathcal{V}_{K+1}^\star. \tag{4.23}$$

Using (4.20) in (4.22) combined with (4.23), we get

$$\begin{cases} \tilde{A}u_q^\star + \tilde{C}v_q^\star + D\Pi^\star = \widehat{SM_X}, \\ \tilde{C}u_q^\star + \tilde{B}v_q^\star + E\Pi^\star = \widehat{SM_Y}, \\ Du_q^\star + Ev_q^\star = L_1\mathcal{V}_1^\star + L_{K+1}\mathcal{V}_{K+1}^\star. \end{cases} \tag{4.24}$$

The coefficients $\tilde{A}$, $\tilde{B}$, and $\tilde{C}$ have already been defined in the previous section and we have set $D = -L_1N_{1,X}^0 + L_{K+1}N_{K,X}^{K+1}$, $E = -L_1N_{1,Y}^0 + L_{K+1}N_{K,Y}^{K+1}$. The right-hand side of (4.24) is

$$\widehat{\boldsymbol{SM}} = \sum_{k=2}^{K} L_k\left[P_{k-1} - P_k + (\alpha_{k-1}\boldsymbol{V_{k-1}} + \alpha_k\boldsymbol{V_k})\cdot\boldsymbol{N_{k-1}^k}\right]\boldsymbol{N_{k-1}^k} - L_1\left[P_1 - \alpha_1\boldsymbol{V_1}\cdot\boldsymbol{N_1^0}\right]\boldsymbol{N_1^0} + L_{K+1}\left[P_K + \alpha_K\boldsymbol{V_K}\cdot\boldsymbol{N_K^{K+1}}\right]\boldsymbol{N_K^{K+1}}.$$

The determinant of (4.24) is $\Delta = -\tilde{A}E + 2\tilde{C}DE - \tilde{B}D^2$. Using the fact that $|\tilde{C}| < \sqrt{\tilde{A}\tilde{B}}$, one can show that $\Delta < 0$ provided the mesh is not degenerated: (4.24) always admits a unique solution $(u_q^\star, v_q^\star)$, and then we can always define a unique set of pressures due to (4.20).

4. We have implemented a numerical test in order to determine the colinearity of the unit normal $-\boldsymbol{N_1^0}$ and $\boldsymbol{N_K^{K+1}}$ with a fixed threshold $\varepsilon > 0$. For numerical applications we have set $\varepsilon = 10^{-10}$. Namely, for $|\det(\boldsymbol{N_1^0}, \boldsymbol{N_K^{K+1}})| \leq \varepsilon$, $-\boldsymbol{N_1^0}$ and $\boldsymbol{N_K^{K+1}}$ are almost colinear, and we use the second alternative in order to avoid an ill-conditioned system.

4.8. Some remarks. From conservation arguments and one entropy inequality, we have been able to construct a nodal solver. This scheme shares some characteristics with the method developed in [9] and can be interpreted as a two-dimensional extension of the acoustic solver. It is interesting to realize that we need only the knowledge of the isentropic speed of sound: it is very easy to extend it to more general equation

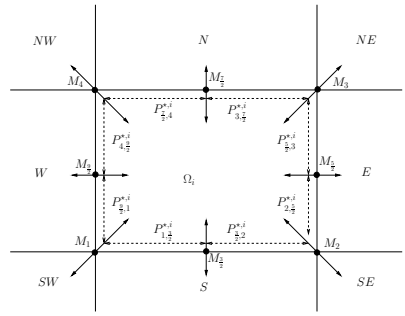

FIG. 4.6. *Stencil for a quadrangular mesh.*

of state. The precise form of the equation of state, analytical or tabulated, does not matter.

We have rigorously shown that the linear system which provides the components of the vertex velocity admits a unique solution, provided that the mesh is not degenerated; see the end of section 4.4. This is also true for vertices located on the boundary, whereas with the method developed in [9] some difficulties have been encountered for vertices located at the corner on the boundary of a rectangular domain.

We have also checked that our solver recovers the one-dimensional acoustic solver in the case of one-dimensional planar and cylindrical flows, contrarily to [9]. More precisely, the calculation of the node velocity with the solver described in [9] gives, for a one-dimensional flow with planar symmetry,

$$u_q^\star = \frac{P_1 - P_2 + \rho_1 c_1 u_1 + \rho_2 c_2 u_2}{\rho_1 c_1 + \rho_2 c_2} \frac{\sqrt{\Delta X^2 + \Delta Y^2}}{\Delta Y},$$

where $L_1 = L_3 = \Delta X$ and $L_2 = L_4 = \Delta Y$ are mesh spacing along directions $\boldsymbol{e_X}$ and $\boldsymbol{e_Y}$. With this nodal solver, one recovers the one-dimensional acoustic solver velocity multiplied by a factor which depends on the aspect ratio of the cells.

Last, our method fully answers the questions raised at the beginning of this paper since it uniquely provides the vertex velocity and the face fluxes. The main new features of our scheme is the introduction of four pressures on each edge, two for each node on each side of the edge, that is, eight pressures at each node for a quadrangular mesh.

We can compute, in a coherent way, the vertex motion as well as the face fluxes. This solver has been constructed delocalizing the fluxes from the faces to the vertices. Consequently, the conservation of momentum and energy is obtained around the node. This implies a fundamental difference with a standard finite volume scheme.

This difference can be illustrated by the consideration of a mesh made of quadrangular cells. We denote by 1, 2, 3, and 4 the vertices of the cell Ω_i and by S, SE, E, NE, N, NW, O, and SW the neighboring cells; see Figure 4.6. In a standard finite volume scheme with an approximate Riemann solver, the cell Ω_i exchanges information only with the neighboring cells having a common face, i.e., the cells S, E, N, and O. This is a 5 point scheme.

With our scheme, the cell Ω_i exchanges momentum and energy with the neighboring cells having a common vertex, i.e., the cells S, SE, E, NE, N, NW, W, and SW. This is a 9 point scheme. The four additional cells reinforce the genuinely multidimensional nature of our scheme.

5. Time discretization. In this section, we time discretize the system that describes the evolution of the physical variables $(\tau_i, \boldsymbol{V_i}, E_i)$ in the cell Ω_i:

$$m_i \frac{d}{dt}\tau_i - \sum_{r=1}^{R(i)} L_{r,r+1} \boldsymbol{V^\star_{r,r+1}} \cdot \boldsymbol{N_{r,r+1}} = 0, \tag{5.1i}$$

$$m_i \frac{d}{dt}\boldsymbol{V_i} + \sum_{r=1}^{R(i)} L_{r,r+1} P^\star_{r,r+1} \boldsymbol{N_{r,r+1}} = \boldsymbol{0}, \tag{5.1ii}$$

$$m_i \frac{d}{dt}E_i + \sum_{r=1}^{R(i)} L_{r,r+1} \left(P\boldsymbol{V}\right)^\star_{r,r+1} \cdot \boldsymbol{N_{r,r+1}} = 0, \tag{5.1iii}$$

where the face fluxes $\boldsymbol{V^\star_{r,r+1}}$, $P^\star_{r,r+1}$ are evaluated by our solver. For the time discretization of (5.1) we use a classical forward Euler scheme. A more sophisticated time discretization is not required here, since the scheme is only first order accurate in space. However, time discretization of (5.1) should be done carefully so that all the properties of the semidiscrete system are kept. They are as follows:

- the variation of volume is coherent with the vertex motion;
- momentum and total energy are conserved;
- the scheme satisfies an entropy inequality.

The first two properties would impose an explicit time discretization; the third would impose an implicit discretization. We choose an explicit time discretization, knowing that the entropy inequality will be a priori satisfied under a CFL-type condition.

We assume to know the physical properties in the cell Ω_i and the geometrical characteristics of the cell at the beginning of the time step t_n, i.e., τ_i^n, $\boldsymbol{V_i^n}$, E_i^n, P_i^n, X_r^n, and Y_r^n. We are going to compute their values at t^{n+1} and we set $\Delta t = t^{n+1} - t^n$.

5.1. Mesh motion and variation of volume. The nodal solver provides the vertex velocities $\boldsymbol{V_r^\star}$ and the face pressures at $P^{\star,i}_{r,r+\frac{1}{2}}$, $P^{\star,i}_{r+\frac{1}{2},r+1}$ from the physical variables and geometry characteristics evaluated at time t^n. The explicit time integration of the trajectory equation provides the location of vertices for any time $t \in [t^n, t^{n+1}]$:

$$\begin{aligned} X_r(t) &= X_r^n + (t - t^n) u_r^\star, \\ Y_r(t) &= Y_r^n + (t - t^n) v_r^\star. \end{aligned} \tag{5.2}$$

In this way, one gets the location of the vertices at time t^{n+1}:

$$\begin{aligned} X_r^{n+1} &= X_r^n + u_r^\star \Delta t, \\ Y_r^{n+1} &= Y_r^n + v_r^\star \Delta t. \end{aligned} \tag{5.3}$$

From this we deduce that $\left(L_{r,r+1}\boldsymbol{N_{r,r+1}}\right)(t) = \left[Y_{r+1}(t) - Y_r(t), -\left(X_{r+1}(t) - X_r(t)\right)\right]^t$ is linear in time, so that

$$\int_{t^n}^{t^{n+1}} \left(L_{r,r+1}\boldsymbol{N_{r,r+1}}\right)(t) \mathrm{d}t = \frac{\Delta t}{2}\left[\left(L_{r,r+1}\boldsymbol{N_{r,r+1}}\right)^n + \left(L_{r,r+1}\boldsymbol{N_{r,r+1}}\right)^{n+1}\right]. \tag{5.4}$$

This last result enables us to write an approximation of the volume equation which is coherent with the mesh motion, namely,

(5.5)
$$m_i\left(\tau_i^{n+1}-\tau_i^n\right)-\frac{\Delta t}{4}\sum_{r=1}^{R(i)}\left[\left(L_{r,r+1}\boldsymbol{N_{r,r+1}}\right)^n+\left(L_{r,r+1}\boldsymbol{N_{r,r+1}}\right)^{n+1}\right]\cdot\left(\boldsymbol{V_r^\star}+\boldsymbol{V_{r+1}^\star}\right)=0.$$

5. We recall that (5.1i) is completely equivalent to the evolution equation of $\mathcal{A}_i$ (area of cell Ω_i), since $m_i\tau_i=\mathcal{A}_i$ and m_i is constant over time; see section 3.2. Knowing that the nodal velocity is computed at time t^n, the right-hand side of (5.1i) is a linear function of time over $[t^n,t^{n+1}]$ thanks to (5.2). Hence, the time integration formula given by (5.4) is exact. Consequently, we can write $\tau_i^{n+1}=\frac{\mathcal{A}_i^{n+1}}{m_i}$. In a nutshell, the second order time integration of the volume flux provides a rigorous compatibility between the specific volume equation and the mesh motion.

5.2. Momentum and total energy. The approximation of the momentum and the total energy equation is fully explicit in order to conserve exactly the momentum and the total energy. The lengths (of edges) and the normals have the same definition as previously. We get

$$m_i\left(\boldsymbol{V_i^{n+1}}-\boldsymbol{V_i^n}\right)+\frac{\Delta t}{2}\sum_{r=1}^{R(i)}L_{r,r+1}^n\left(P^{\star,i}_{r,r+\frac12}+P^{\star,i}_{r+\frac12,r+1}\right)\boldsymbol{N_{r,r+1}^n}=\boldsymbol{0},\tag{5.6}$$

and for the total energy

$$m_i\left(E_i^{n+1}-E_i^n\right)+\frac{\Delta t}{2}\sum_{r=1}^{R(i)}L_{r,r+1}^n\left(P^{\star,i}_{r,r+\frac12}\boldsymbol{V_r^\star}+P^{\star,i}_{r+\frac12,r+1}\boldsymbol{V_{r+1}^\star}\right)\cdot\boldsymbol{N_{r,r+1}^n}=0.\tag{5.7}$$

5.3. Time step limitation. The time step is evaluated following two criteria. The first is a standard CFL criterion which guarantees heuristically the monotone behavior of the entropy. The second is more intuitive, but appears very useful in practice: we limit the variation of the volume of cells over one time step.

5.3.1. CFL criterion. We propose a CFL-like criterion in order to ensure a positive entropy production in cell Ω_i during the time step. At time t_n, for each cell Ω_i we denote by λ_i^n the minimal value of the distance between two nodes of the cell. We define

$$\Delta t_E=C_E\min_{i=1,\dots,I}\frac{\lambda_i^n}{c_i^n},$$

where C_E is a strictly positive coefficient and c_i is the sound speed in the cell. The coefficient C_E is computed heuristically, and we provide no rigorous analysis which allows such formula. However, extensive numerical experiments show that $C_E=0.3$ is a value which provides good numerical results. We have also checked that this value is compatible with a monotone behavior of entropy. The rigorous derivation of this criterion could be obtained by computing the time step which ensures a positive entropy production in cell Ω_i from time t^n to t^{n+1}.

5.3.2. Criterion on the variation of volume. Using (5.2), we can compute the area of the cell i at any time $t \in [t^n, t^{n+1}]$. Indeed, we have

$$\mathcal{A}_i(t) = \frac{1}{2}\sum_{r=1}^{R(i)} \left[X_r^n + (t-t^n)u_r^\star\right]\left[Y_{r+1}^n + (t-t^n)v_{r+1}^\star\right] - \left[Y_r^n + (t-t^n)v_r^\star\right]\left[X_{r+1}^n + (t-t^n)u_{r+1}^\star\right]. \tag{5.8}$$

Simple algebra gives

$$\frac{d}{dt}\mathcal{A}_i(t^n) = \frac{1}{2}\sum_{r=1}^{R(i)} \left(u_r^\star Y_{r+1}^n + v_{r+1}^\star X_r^n - u_{r+1}^\star Y_r^n - v_r^\star X_{r+1}^n\right).$$

After a Taylor expansion we estimate the area at $t = t^{n+1}$ by

$$\mathcal{A}_i^{n+1} = \mathcal{A}_i^n + \frac{d}{dt}\mathcal{A}_i(t^n)\Delta t.$$

Let C_V be a strictly positive coefficient, $C_V \in]0,1[$. We look for Δt such that

$$\frac{|\mathcal{A}_i^{n+1} - \mathcal{A}_i^n|}{\mathcal{A}_i^n} \leq C_V.$$

To do so, we define

$$\Delta t_V = C_V \min_{i=1,\dots,I}\left\{\frac{\mathcal{A}_i^n}{\left|\frac{d}{dt}\mathcal{A}_i(t^n)\right|}\right\}.$$

For numerical applications, we choose $C_V = 0.1$.

Finally, the estimation of the next time step Δt^{n+1} is given by

$$\Delta t^{n+1} = \min\left(\Delta t_E, \Delta t_V, C_M \Delta t^n\right), \tag{5.9}$$

where Δt^n is the current time step and C_M is a multiplicative coefficient, which allows the time step to increase. We generally set $C_M = 1.01$.

5.4. Description of the algorithm.

1. **Initialization**
   At time $t = t^n$ we know in each cell Ω_i, $i = 1, \dots, I$, the fluid variables τ_i^n, $\boldsymbol{V_i^n}$, E_i^n, ρ_i^n, c_i^n, P_i^n and the geometrical characteristics X_r^n,Y_r^n, $L_{r,r+1}^n$, $\boldsymbol{N_{r,r+1}^n}$ for $r = 1, \dots, R(i)$.
2. **Nodal solver**
   - For each internal vertex M_q, $q = 1, \dots, Q$, we first compute the velocity $\boldsymbol{V_q^\star}$ by solving the linear system (4.15). Then we evaluate the edge pressures $P_{q,k}^{\star,k}$ and $P_{q,k}^{\star,k-1}$ with (4.12) for each edge impinging on M_q.
   - For each boundary vertex, we first compute the velocity $\boldsymbol{V_q^\star}$ by solving (4.21) or (4.24). Then we calculate the edge pressures $P_{q,k}^{\star,k}$ and $P_{q,k}^{\star,k-1}$ using (4.20).
3. **Time step limitations**
   We compute Δt_V and Δt_E; then we predict Δt^{n+1} from $\Delta t^{n+1} = \min(\Delta t_E, \Delta t_V, C_M \Delta t^n)$.

4. **Update of the geometrical quantities**
   We compute X_r^{n+1} and Y_r^{n+1} from (5.3); then we deduce $L_{r,r+1}^{n+1}$ and $\boldsymbol{N_{r,r+1}^{n+1}}$.
5. **Update of the physical variables**
   We compute the face fluxes from the vertex velocity and the edge pressures; then we get τ_i^{n+1}, $\boldsymbol{V_i^{n+1}}$, and E_i^{n+1} from (5.5), (5.6), and (5.7).
6. **Equation of state**
   The internal energy is given by $\varepsilon_i^{n+1} = E_i^{n+1} - \frac{1}{2}\|\boldsymbol{V_i^{n+1}}\|^2$; then we get the pressure P_i^{n+1} and the isentropic sound speed c_i from the equation of state.

6. Numerical results. In this section, we present several test cases in order to validate our numerical scheme. For each case we use a perfect gas equation of state, namely $P = (\gamma - 1)\rho\varepsilon$, where γ is the adiabatic index. We begin by several classical one-dimensional test cases characterized by the presence of shock waves, of various strengths, rarefaction waves, and contact discontinuities. We also provide an isentropic compression. For all these test cases an analytical solution is available so that we can make accurate comparisons. Then, we give an original test representative of the domain of hydrodynamic instabilities. The aim of this test is to show the ability of our scheme to reproduce the growth of such instabilities in the linear regime. Last, we propose a two-dimensional test case which consists in imploding a double layer cylindrical shell under an anisotropic pressure load.

6.1. Multimaterial Sod's shock tube problem. We are concerned with a multimaterial variant of Sod's shock tube problem defined in [26]. We consider a shock tube of unity length (see Figure 6.1). At the initial time, the states on the left- and right-hand sides of $x = 0.5$ are constant. The left-hand state is a high pressure fluid characterized by $(\rho_l, P_l, u_l) = (1, 1, 0)$, and the right-hand state is a low pressure fluid defined by $(\rho_r, P_r, u_r) = (0.125, 0.1, 0)$. The equation of state is defined on the left by $\gamma_l = \frac{7}{5}$ and by $\gamma_r = \frac{5}{3}$ on the right. The computational domain is defined by $(x, y) \in [0, 1] \times [0, 0.1]$. The initial mesh is a Cartesian grid, and we denote by n_x and n_y the number of cells in the x and y directions. The boundary conditions are wall boundary conditions: the normal velocity is set to zero. Three simulations are done with $n_y = 10$ and $n_x = 100$, $n_x = 200$, and finally $n_x = 400$ in order to check the mesh convergence of the scheme. The time step is evaluated following (5.9). In Figure 6.2, we compare the profiles of the physical quantities at $t = 0.2$ with the analytical quantities for three different meshes. The profiles are similar to what could be obtained with a one-dimensional first order Lagrangian scheme based on the acoustic solver; see the interpretation of our scheme in section 4.6.1. The shock is smeared on several cells, and the fan is correctly described for a first order scheme. The contact discontinuity is resolved in several cells; this is a consequence of the entropic nature of the solver. We notice an undershoot for the density profile and an overshoot for the internal energy profile which are classical for Lagrangian methods. As expected, the finer the mesh is, the better the results are.

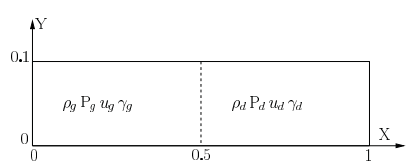

FIG. 6.1. *Initial data for Sod's shock tube test case.*

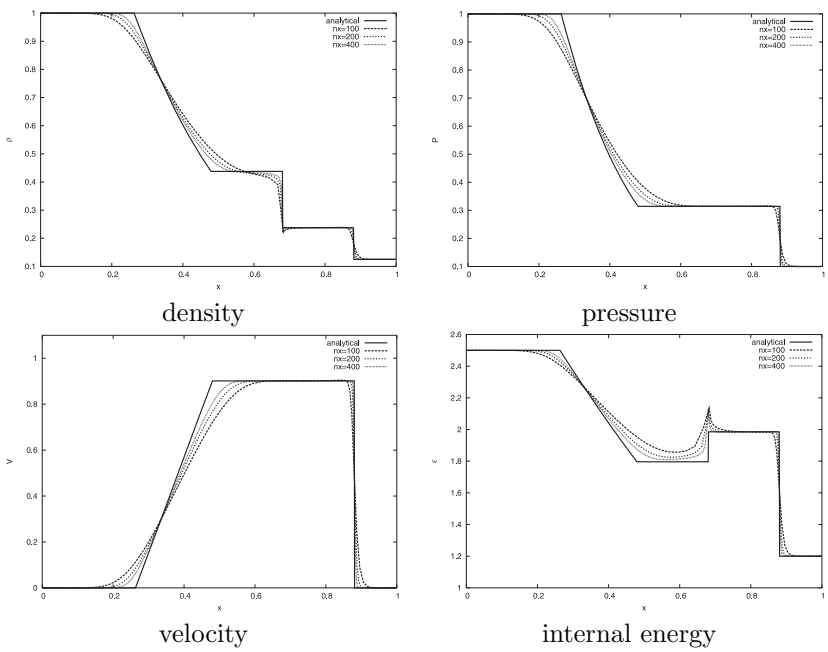

FIG. 6.2. *Cross-section at $t = 0.2$, comparison with the analytical solution.*

6.2. Noh's test case. Noh's test case is the implosion of a cylinder of unit radius. The cylinder is filled with a monoatomic perfect gas ($\gamma = 5/3$). The initial state is $(\rho^0, P^0, \boldsymbol{V^0}) = (1, 0, -\boldsymbol{e_R})$, where $\boldsymbol{e}_R$ represents the radial unit vector. This case, defined by Noh in [23], admits a self-similar solution: a shock wave moves inwards at the constant speed $D = 1/3$. The symmetry of the problem enables us to limit the computational domain to an angular sector of angle Θ; see Figure 6.3. The mesh consists of regular angular sectors, and the domain is meshed with triangles near the center and with quadrangles elsewhere. This enables us to respect the radial symmetry of the solution. We denote by n_x (resp., n_y) the number of layers (resp., angular sectors). In what follows, $\theta = \frac{\Theta}{n_y}$. The test case is initialized with $P^0 = 10^{-6}$. The boundary conditions are wall conditions on the two external edges (hence zero normal velocity), and we impose a constant pressure $P^\star = P^0$ on the external radius $R = 1$. The time step is computed following the condition (5.9). In Figure 6.4 we have represented the results at time $t = 0.6$ for three meshes defined with $\Theta = 12°$ and $(n_x, \theta) = (100, 4°)$, $(200, 2°)$, and $(400, 1°)$. The convergence behavior of the scheme is very satisfactory. The timing, the density levels, and the pressure levels after the shock wave are correct. As for Sod's problem, we notice an overshoot for the internal energy and an undershoot for the density that are characteristic of the wall heating phenomena; see [23]. Figure 6.5 displays the mesh at $t = 0.6$ for $\Theta = 90°$ and $(n_x, \theta) = (100, 2°)$, and one can see that the cylindrical symmetry is perfectly respected.

6.3. Kidder's isentropic compression. In [17], Kidder has analytically computed the solution of the isentropic compression of a cylindrical shell filled with perfect gas. We briefly recall the main features of this solution in order to define the test case. Initially, the shell has the internal (resp., external) radius r_1 (resp., r_2). Let P_1, P_2,

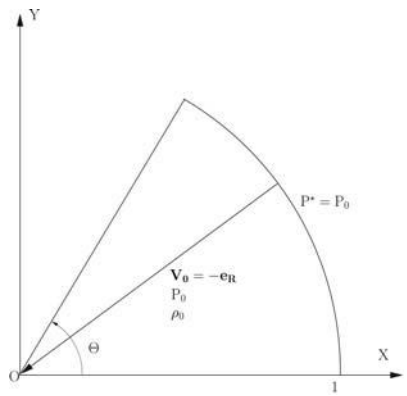

FIG. 6.3. *Noh's case: initial conditions.*

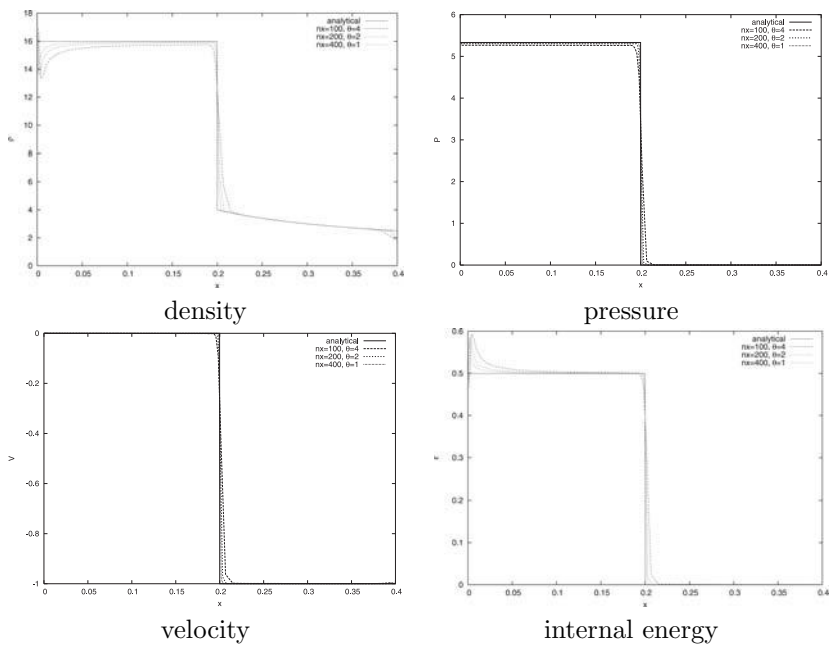

FIG. 6.4. *Cross-section for Noh's case at $t = 0.6$, comparison with the analytical solution.*

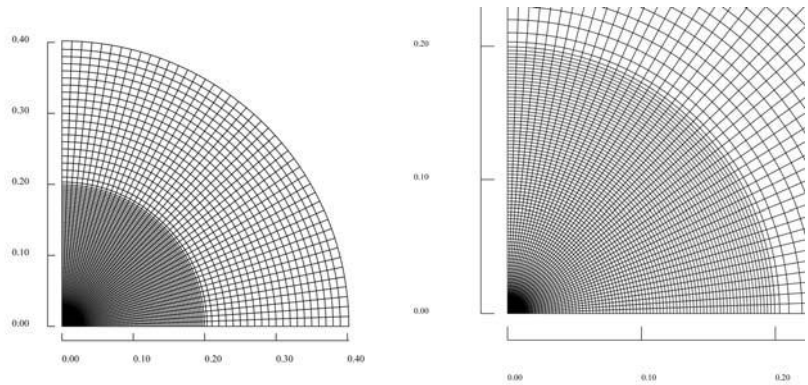
ρ_1, and ρ_2 be the pressures and densities located at r_1 and r_2. Since the compression is isentropic, we define $s = \frac{P_2}{\rho_2^\gamma}$ and we have $\rho_1 = \rho_2(\frac{P_1}{P_2})^{\frac{1}{\gamma}}$. The initial density and pressure profiles are given by (for $r \in [r_1, r_2]$)

$$\rho^0(r) = \left(\frac{r_2^2 - r^2}{r_2^2 - r_1^2} \rho_1^{\gamma-1} + \frac{r^2 - r_1^2}{r_2^2 - r_1^2} \rho_2^{\gamma-1} \right)^{\frac{1}{\gamma-1}},$$

$$P^0(r) = s \left(\rho^0(r) \right)^\gamma.$$

The initial velocity is set to zero: $u_0(r) = 0$. The value of γ is set to $\gamma = 1 + \frac{2}{\nu}$ with $\nu = 1, 2, 3$ whether we have a planar, cylindrical, or spherical symmetry. These values are used in order to obtain a fully analytical solution. In our case we have $\nu = 2$, and



Mesh Zoom near the origin

FIG. 6.5. *Noh's case: mesh at* $t = 0.6$.

therefore $\gamma = 2$. The focusing time τ of the shell is defined (for these parameters) by

$$\tau = \sqrt{\frac{\gamma - 1}{2} \frac{r_2^2 - r_1^2}{c_2^2 - c_1^2}},$$

where $c_i = \sqrt{s\gamma\rho_i^{\gamma-1}}$ for $i = 1, 2$ is the isentropic sound speed at $r = r_i$. The isentropic compression is obtained by imposing the following pressure laws at the internal and external faces of the shell:

$$P(R(r_1, t), t) = P_1 h(t)^{-\frac{2\gamma}{\gamma-1}},$$
$$P(R(r_2, t), t) = P_2 h(t)^{-\frac{2\gamma}{\gamma-1}}.$$

Let $R(r, t)$ be the Eulerian radius (i.e., $R = \sqrt{X^2 + Y^2}$) at $t > 0$ of a fluid particle initially located on the circle of radius r. Looking for a solution of the form $R(r, t) = h(t)r$, we get

$$h(t) = \sqrt{1 - \left(\frac{t}{\tau}\right)^2}.$$

The analytical forms of the physical variables at $t \in [0, \tau[$ are

$$\rho(R(r, t), t) = h(t)^{-\frac{2}{\gamma-1}} \rho^0 \left[\frac{R(r, t)}{h(t)}\right],$$
$$u(R(r, t), t) = \frac{d}{dt} h(t) \frac{R(r, t)}{h(t)},$$
$$P(R(r, t), t) = h(t)^{-\frac{2\gamma}{\gamma-1}} P^0 \left[\frac{R(r, t)}{h(t)}\right].$$

In this test case, we have used the parameters $r_1 = 0.9$, $r_2 = 1$, $P_1 = 0.1$, $P_2 = 10$, and $\rho_2 = 10^{-2}$. From this, we get $\rho_1 = 10^{-3}$, $s = 10^5$, and $\tau = 7.265\ 10^{-3}$. The computational domain consists of the quarter of an annulus; see Figure 6.6. Once

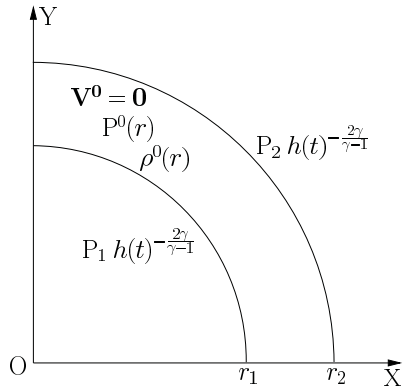


FIG. 6.6. *Initial conditions for Kidder's isentropic compression.*

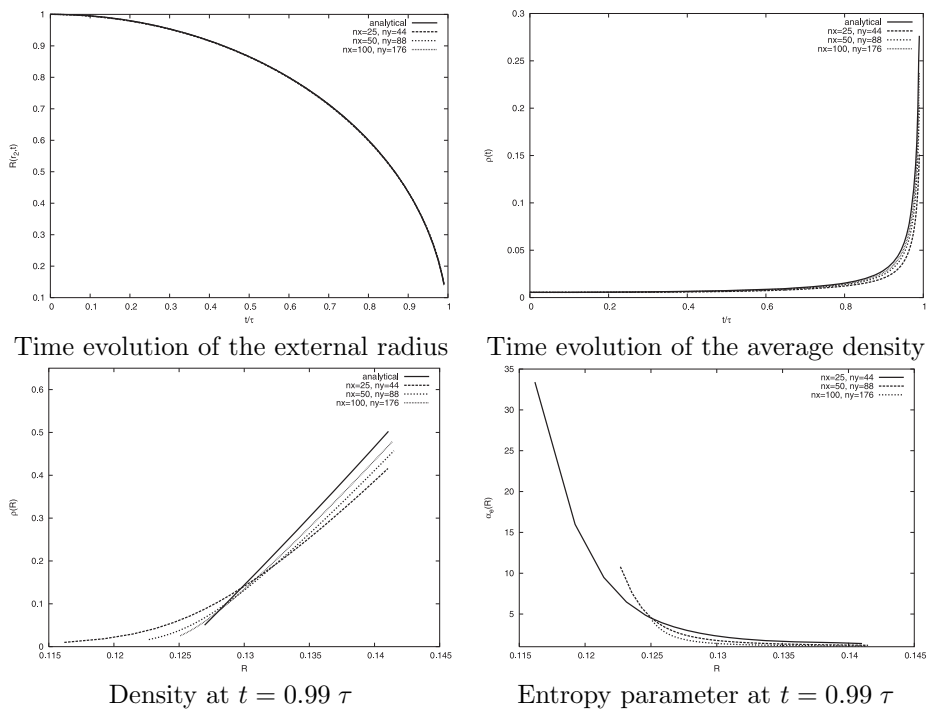

FIG. 6.7. *Kidder's isentropic compression, comparison with the analytical solution.*

more, we impose wall boundary conditions on the axes $X = 0$, $Y = 0$ and the previous pressure laws on the internal and external faces of the domain. The simulations are run on regular polar meshes defined by $(n_x, n_y) = (25, 44),\ (50, 88),\ (100, 176)$. The computations are run up to a final time which is very close to the focusing time, i.e., $t = 0.99\ \tau$. In all that follows, the time is adimensionalized by the focusing time τ.

Figure 6.7, where the variation of the external radius of the shell is plotted, shows the excellent agreement with the analytical solution. The agreement is good for the average density[2] $\bar{\rho}(t)$ near the focusing point; however, the numerical values

[2] $\bar{\rho}(t)$ is evaluated from the analytical formula $\bar{\rho}(t) = 0.5(\rho_1 + \rho_2)h(t)^{-2}$.

are smaller than the exact ones. There exists a gap between numerical and analytical density profiles at the final time. This gap gets smaller and smaller with mesh refinement; thus we believe it is a consequence of the numerical diffusion. This observation is confirmed by the profile of the entropy parameter $\alpha_e = \frac{P}{s\rho^\gamma}$. It indicates the entropy production of the scheme, and we have $\alpha_e = 1$ in the analytical case. The gap between the exact solution and the numerical one is large on the internal face of the shell when the mesh is coarse, and it also gets smaller with mesh refinement. The large entropy production of the scheme degrades the simulated compression, which explains the shape of the density profile on the internal face of the shell.

6.4. Saltzman's shock tube. We consider now the movement of a planar shock wave on a Cartesian grid that has been stretched [10]. This is a well-known difficult test case that enables us to validate the robustness of our scheme when the mesh is not aligned with the fluid flow. The computational domain is the rectangle $(x, y) \in [0, 1] \times [0, 0.1]$. The initial mesh is obtained by transforming a uniform grid of 100×10 cells with the mapping

$$\begin{aligned} x_{str} &= x + (0.1 - y)\sin(x\pi), \\ y_{str} &= y. \end{aligned}$$

For the material we use the equation of state of a monoatomic gas ($\gamma = 5/3$). The initial state is $(\rho^0, P^0, \boldsymbol{V^0}) = (1, 0, 0)$. The boundary condition at $x = 0$ is a normal velocity $V^\star = -1$ (inflow velocity). On all the other boundaries, we set up wall conditions.

The exact solution is a planar shock wave that moves at speed $D = 4/3$ from left to right. The propagation of the shock wave at $t = 0.6$ is displayed in Figure 6.8. The important result is that our scheme preserves the one-dimensional solution very well (except for the first and last layers in the vertical direction, this is an effect of up and down wall boundary conditions). Figure 6.9 shows the mesh at $t = 0.75$ when the shock wave hits the right boundary ($x = 1$). Behind the shock wave, the initial mesh is distorted, and all the horizontal lines stay almost parallel with respect to the others. The density profile at $t = 0.6$ is displayed in Figure 6.10. The shock level is not uniform, but it oscillates around the exact value $\rho = 4$.

The robustness of our scheme is clearly demonstrated by this test case: we are able to reach time $t = 0.93$ which corresponds to two successive rebounds of the shock wave on the vertical boundaries of the domain; see Figure 6.11. After this time, the computation stops because the time step becomes too small (less than 10^{-15}). This too small time step occurs when nodes are too close to each other (see Figure 6.11, top left corner). In order to go beyond this time we have to improve the quality of the mesh by using a rezoning procedure and a remapping phase. This is the arbitrary Lagrangian–Eulerian (ALE) extension of our scheme which is under development; it will be the subject of a forthcoming paper.

6.5. Sedov's test case. We consider the propagation of a high intensity cylindrical shock wave generated by a strong explosion; see, for instance, [30]. All the boundary conditions are wall conditions. The gas of interest is monoatomic ($\gamma = \frac{5}{3}$). It is initially at rest ($(\rho^0, P^0, \boldsymbol{V^0}) = (1, 0, 0)$) and we set up an energy spike at the center. The simulation is done first on a Cartesian grid and then on a polar grid. In order to compare the results, the same amount of energy is added for each computation.

On the Cartesian grids, the computational domain is $(x, y) \in [0, 1] \times [0, 1]$. In the case of the coarsest mesh (i.e., $(n_x, n_y) = (50, 50)$), the internal specific energy of

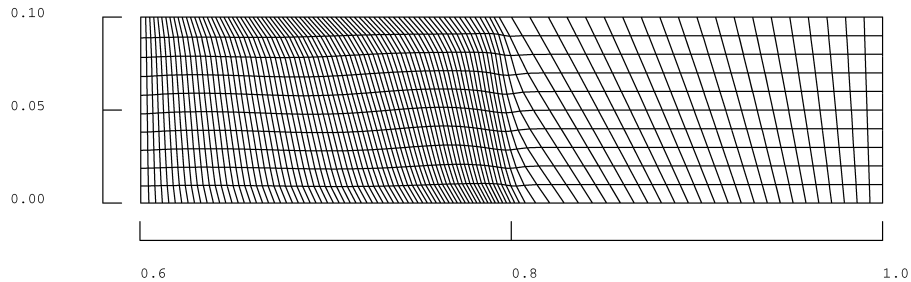

FIG. 6.8. *Saltzman's test: mesh at* $t = 0.6$.

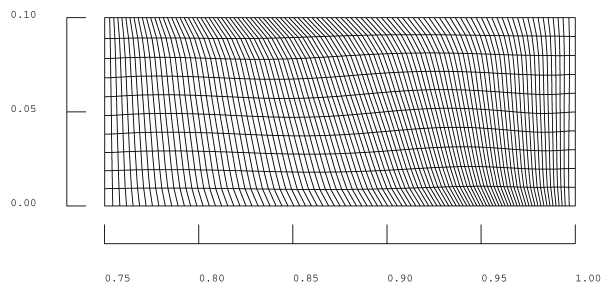

FIG. 6.9. *Saltzman's test: mesh at* $t = 0.75$.

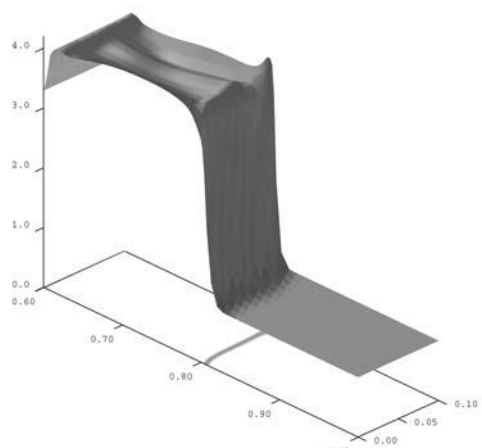

FIG. 6.10. *Saltzman's test: density profile at* $t = 0.6$.

the first cell is set to $\epsilon^0 = 5000$. This corresponds to subdomain $(x, y) \in [0, 1/50] \times [0, 1/50]$. The finer meshes are $(n_x, n_y) = (100, 100)$ and $(n_x, n_y) = (200, 200)$. In order to have the same amount of energy, we also initialize with the specific internal energy $\epsilon^0 = 5000$ in $[0, 1/50] \times [0, 1/50]$.

In the case of the polar grids, the domain is defined by $(r, \theta) \in [0, 1] \times [0, 90°]$. The

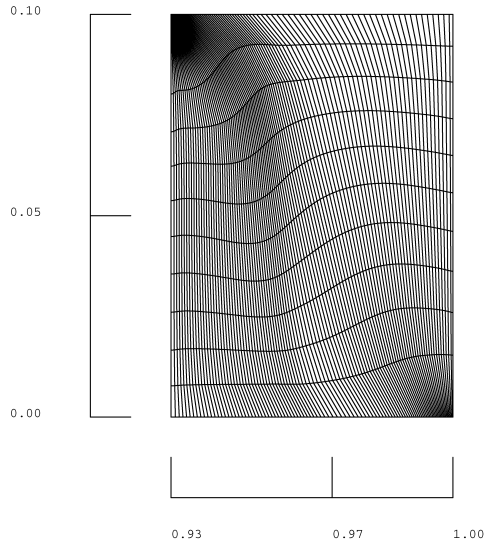

FIG. 6.11. *Saltzman's test: mesh at* $t = 0.93$.

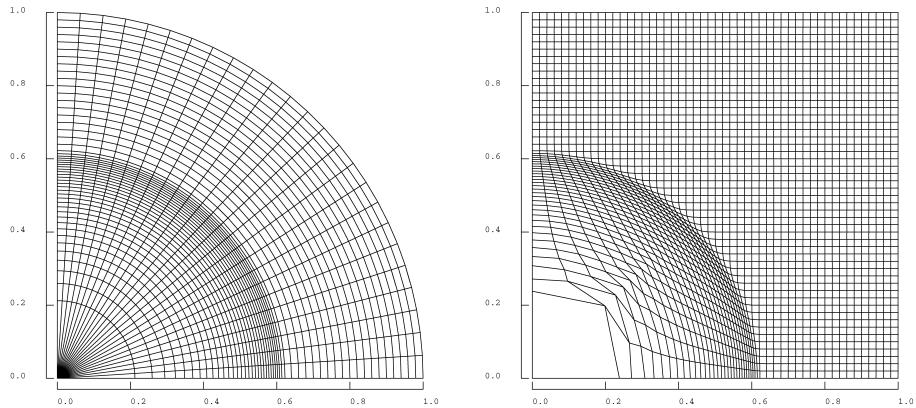
mesh is made of quadrangles with triangles at the center. The parameters (n_x, n_y) correspond to the number of layers in the radial direction and of angular sectors. The coarsest mesh is defined by $(n_x, n_y) = (50, 25)$. We initialize the specific internal energy on triangles and define the subdomain $(r, \theta) \in [0, 1/50] \times [0, 90°]$. As the area to initialize is different in this case, we need to modify the internal energy so that the energy amount is the same as in the case of the Cartesian grid. Thus we choose $\epsilon^0 = 5000\frac{4}{\pi}$. As for the Cartesian mesh, the finest polar grids are $(n_x, n_y) = (100, 50)$ and $(n_x, n_y) = (200, 100)$, and in both cases, the cells to initialize are those in the subdomain $(r, \theta) \in [0, 1/50] \times [0, 90°]$.

Figure 6.12 represents the final mesh at $t = 0.1$ obtained for the two types of meshes. Clearly, our initialization leads to the same results. However, we notice that on the Cartesian grid nonconvex cells appear, but this does not pose any problem to the nodal solver.

The comparison of the density profiles for the two types of grids is done in Figures 6.13, 6.15, and 6.16. We notice that for the polar grid, the cylindrical symmetry of the flow is perfectly preserved; see Figures 6.12 and 6.13. The symmetry is also well preserved on Cartesian grids, as shown in Figure 6.14 on the left, where the density profiles on the diagonal are slightly different from those on the x- and y- axes (which are identical). In Figure 6.14 on the right are represented the density in all cells as function of the centroid radius of each cell. We also observe that the symmetry is well preserved. Consequently, these results on Cartesian grids show the ability of our new scheme to provide good results even when the mesh is not aligned with the flow. Moreover, Figures 6.15 and 6.16 demonstrate that a mesh convergence study for both grids leads to similar results.

6.6. Perturbation of the isentropic Kidder's compression. In this section, we give an original test case representative of the field of hydrodynamic instabilities.



Polar grid Cartesian grid

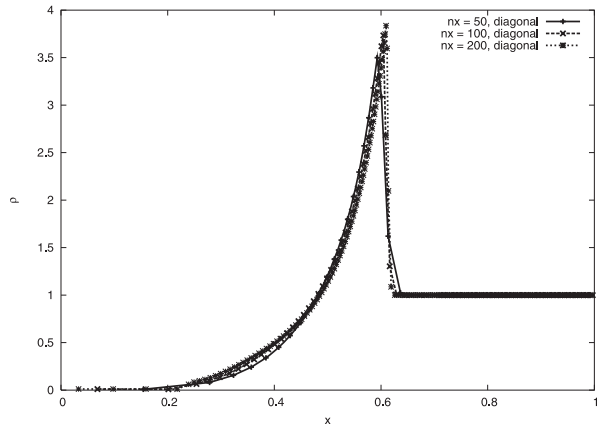

FIG. 6.15. *Sedov's test case: Cartesian grid convergence for density profiles at* $t = 0.1$

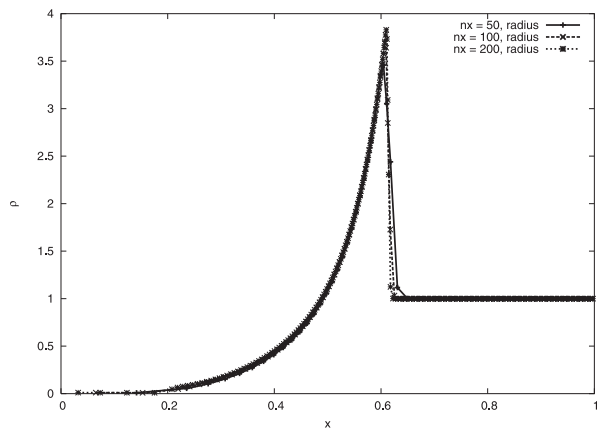

FIG. 6.16. *Sedov's test case: polar grid convergence for density profiles at* $t = 0.1$.

The aim of this test is to show the ability of our new scheme to reproduce the growth of such instabilities. In order to define the test, we consider the isentropic implosion of a cylindrical shell as in section 6.3. We initially perturb the internal and external faces of the shell; see Figure 6.6. Then, we study the time evolution of the perturbations. An approximate analytical solution is available for the perturbation amplification in the linear regime. This solution is obtained with the technique developed in [13]. We briefly recall the main results about the analytical solution in order to set up the test case. More details can be found in [22] and [3].

First we define the mesh perturbation. We are given a Cartesian frame $(0, x, y)$ and polar coordinates (r, θ). The polar coordinates of the vertices are given by

$$\begin{aligned} r^p &= r + a_0 \xi_r(r, \theta), \\ \theta^p &= \theta + a_0 \xi_\theta(r, \theta), \end{aligned}$$

where a_0 is the amplitude of the initial perturbation. The vector $\boldsymbol{\xi} = \binom{\xi_r}{\xi_\theta}$ is defined by

$$\begin{aligned} \xi_r(r, \theta) &= n \left(A_1 r^{-n-1} + A_2 r^{n-1} \right) \cos(n\theta), \\ \xi_\theta(r, \theta) &= -n \left(A_1 r^{-n-1} + A_2 r^{n-1} \right) \sin(n\theta). \end{aligned} \tag{6.1}$$

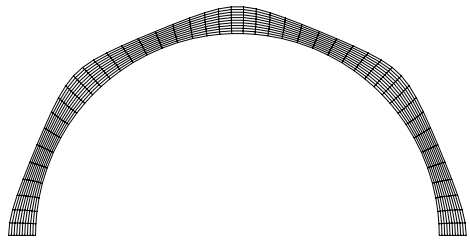

FIG. 6.17. *Perturbed mesh.*

The integer n is the perturbation mode, and A_1, A_2 are constants which are determined by the perturbations ξ_1 and ξ_2 given at the internal and external interfaces, i.e., $\xi_1 = \xi_r(r_1, 0)$ and $\xi_2 = \xi_r(r_2, 0)$. We have

$$\begin{cases} A_1 = -\dfrac{1}{n} \dfrac{\xi_1 r_2^{n-1} - \xi_2 r_1^{n-1}}{r_1^{-n-1} r_2^{n-1} - r_1^{n-1} r_2^{-n-1}}, \\ A_2 = -\dfrac{1}{n} \dfrac{\xi_1 r_2^{-n-1} - \xi_2 r_1^{-n-1}}{r_1^{-n-1} r_2^{n-1} - r_1^{n-1} r_2^{-n-1}}. \end{cases}$$

The analytical form (6.1) is justified by the fact that $\boldsymbol{\xi}$ derives from a potential. We check that $\nabla \cdot \boldsymbol{\xi} = 0$, that is, that the perturbation is incompressible. We have a divergence-free perturbation.

Using the previous results, we get the Cartesian coordinates of the perturbed mesh

$$\begin{aligned} x^p &= \left(1 + \frac{a_0}{r}\xi_r\right) \left[x \cos(a_0 \xi_\theta) - y \sin(a_0 \xi_\theta)\right], \\ y^p &= \left(1 + \frac{a_0}{r}\xi_r\right) \left[x \sin(a_0 \xi_\theta) + y \cos(a_0 \xi_\theta)\right]. \end{aligned} \tag{6.2}$$

This is illustrated by Figure 6.17, which represents the perturbed mesh for the half-annulus of radii $r_1 = 0.9$, $r_2 = 1$, with the following data: perturbation mode $n = 8$, internal and external levels $\xi_1 = 0$, $\xi_2 = 1$, amplitude $a_0 = 0.02$. In [22], we show that the amplification factor $a(\theta, t)$ of the perturbation at the external interface is given by

$$a(\theta, t) = n \left[A_1 r^{-n-1} G_1(t) + A_2 r^{n-1} G_2(t)\right] \cos(n\theta),$$

where $t \in [0, 1[$ is the time.[3] The functions G_1 and G_2 are

$$\begin{aligned} G_1(t) &= \sqrt{1 - t^2} \cos\left[\tfrac{\sqrt{n}}{2} \log\left(\tfrac{1-t}{1+t}\right)\right], \\ G_2(t) &= \tfrac{1}{2}\sqrt{1 - t^2} \left[\left(\tfrac{1-t}{1+t}\right)^{\sqrt{n}/2} + \left(\tfrac{1+t}{1-t}\right)^{\sqrt{n}/2}\right]. \end{aligned}$$

[3]The time is adimensionalized by the focusing time τ.

Next, we present the results for the following cases: modes 4 and 8 with a perturbation of the external interface and mode 8 with a perturbation of the internal and external interfaces. For a given mode, we first define a mesh compatible with this mode, i.e., with enough angular sectors per wave length. Then, we compute the nonperturbed implosion and store the location of the vertex of the external face that corresponds to $\theta = 0$, namely $R(r_2, t)$. Then we perturb the mesh according to (6.2). An implosion simulation is done on this perturbed mesh. Then we store $R_p(r_2, t)$, the location of the same vertex. The amplification factor is defined by the ratio

$$a_{\text{num}}(t) = \frac{R^p(r_2, t) - R(r_2, t)}{a_0}.$$

In each of the perturbed simulations, the initial amplitude is set to $a_0 = 10^{-6}$ in order to stay in the linear phase. The final time of each simulation is $t = 0.99$. The time step follows (5.9).

6.6.1. Mode $n = 4$, $\xi_1 = 0$, $\xi_2 = 1$, $a_0 = 10^{-6}$. The computational domain is defined using the symmetries of mode 4, i.e., $(r, \theta) \in [r_1, r_2] \times [0, \frac{\pi}{2}]$ (see Figure 6.18). We use equiangular meshes defined by $(n_x, n_y) = (25, 44)$, $(n_x, n_y) = (50, 88)$, and $(n_x, n_y) = (100, 176)$.

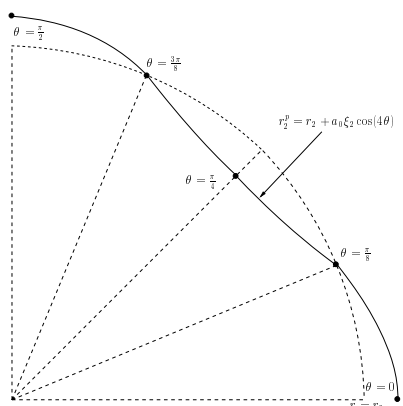

FIG. 6.18. *Mode $n = 4$, location of the vertices of interest.*

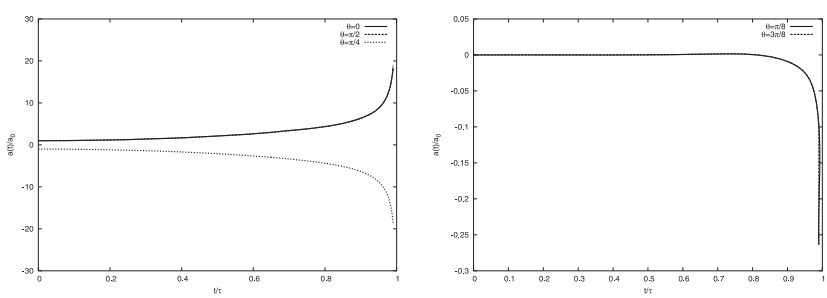

Points of maximal amplitude Points of vanishing amplitude

FIG. 6.19. *Mode $n = 4$, time evolution of the external perturbation for several vertices of interest.*

In Figure 6.19, we show the results for the coarsest mesh. The time evolution of the amplitude for the vertices defined by $\theta = 0,\ \pi/8,\ \pi/4,\ 3\pi/8,\ \pi/2$ (see Figure 6.18)

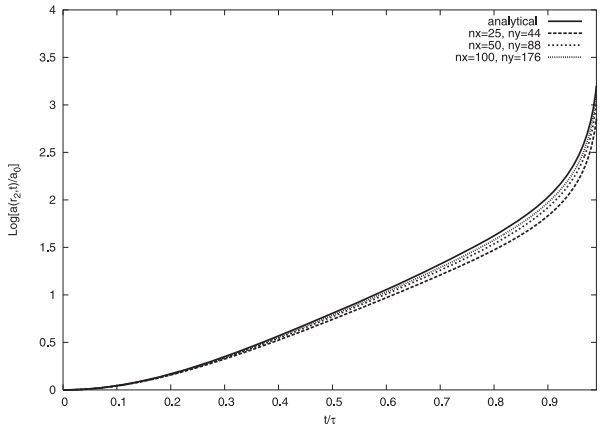

FIG. 6.20. *Mode $n = 4$, time evolution of the amplitude of the external perturbation.*

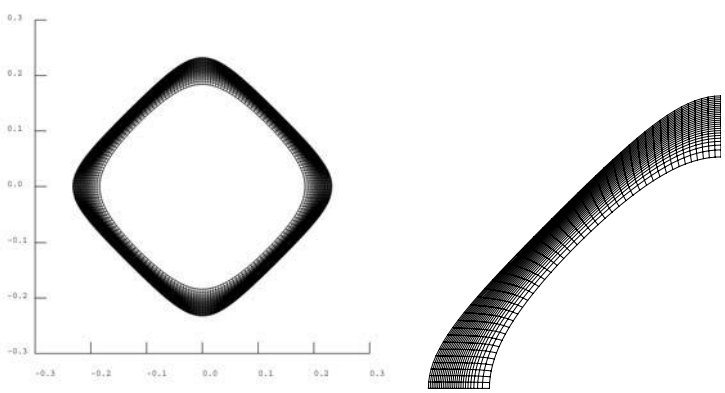
is stored. We see that the expected symmetries for the vertices $\theta = 0,\ \pi/4,\ \pi/2$ are perfectly respected. Moreover, the amplification factor for the vertices defined by $\theta = \pi/8,\ 3\pi/8$ is almost null, but we notice a very small amplification, on the order of 1%, when we are near the focusing. In Figure 6.20, we plot the time evolution of the perturbation obtained numerically for the three meshes and the analytical solution. The comparison is satisfactory since the numerical amplification is coherent with the analytical one. This comparison is even more satisfactory as the scheme is only first order in time and space.



Mesh at $t/\tau = 0.98$ Zoom

FIG. 6.21. *Mode $n = 4$, nonlinear phase $a_0 = 10^{-3}$.*

We present in Figure 6.21 the mesh that corresponds to a perturbed simulation near the focusing time. The initial mesh is defined by $(n_x, n_y) = (25, 176)$. The initial amplitude is set to $a_0 = 10^{-3}$ so that, at the final time, we are in the nonlinear regime.

6.6.2. Mode $n = 8$, $\xi_1 = 0$, $\xi_2 = 1$, $a_0 = 10^{-6}$. The computational domain is defined using the symmetries of the mode 8, i.e., $(r, \theta) \in [r_1, r_2] \times [0, \frac{\pi}{2}]$. We use equiangular meshes with $(n_x, n_y) = (25, 44)$, $(n_x, n_y) = (50, 88)$, and $(n_x, n_y) = (100, 176)$. Figure 6.22 shows a good agreement with the analytical solution for the time evolution

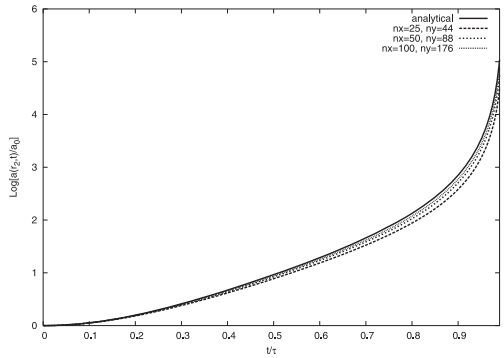


FIG. 6.22. *Mode $n = 8$, time evolution of the amplitude of the external perturbation.*

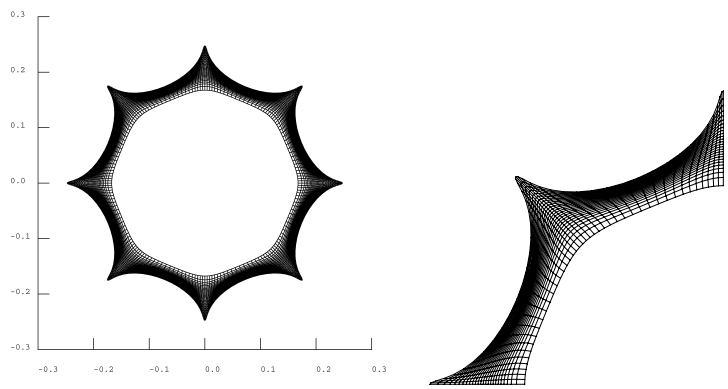
of the amplitude of the external perturbation. As for the $n = 4$ mode case, the scheme converges by lower values.



Mesh at $t/\tau = 0.98$ Zoom

FIG. 6.23. *Mode $n = 8$, nonlinear phase for $a_0 = 10^{-3}$.*

In Figure 6.23 we display the mesh obtained during the nonlinear phase for the flow perturbed on the full geometry. The initial mesh is defined by $(n_x, n_y) = (25, 176)$. The initial amplitude of the perturbation is $a_0 = 10^{-3}$.

6.6.3. Mode $n = 8$, $\xi_1 = 2.565293$, $\xi_2 = 1$, $a_0 = 10^{-6}$. In this case, we have introduced a nonzero initial perturbation on the internal interface. The level of ξ_1 is defined so that at the final time $t = 0.99$, the amplitude of the perturbation on the external face comes back to its initial value. This permits the coupling of the perturbations between the two interfaces. This coupling enables us to get a periodic growth of the perturbation on the internal face. In this case, we use the same meshes and the same domain as in the previous case.

The results are very satisfactory; see Figure 6.24. They show the ability of our scheme to reproduce the coupling of perturbations between the internal and external faces.

6.7. ICF-like test case. In this section, we present a simplified test case of a cylindrical ICF target. The target is made of two materials which have the same

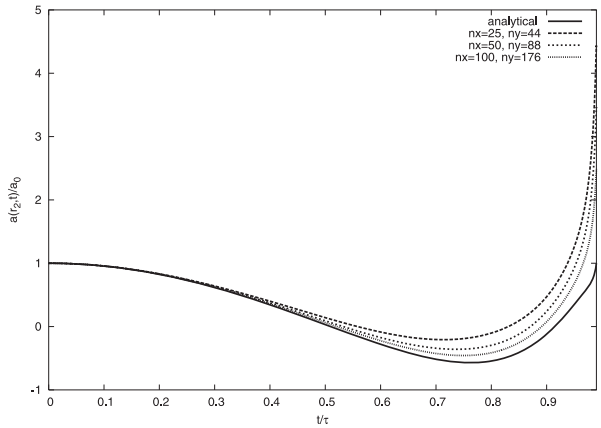


FIG. 6.24. *Coupled mode $n = 8$, growth of the perturbation on the internal interface.*

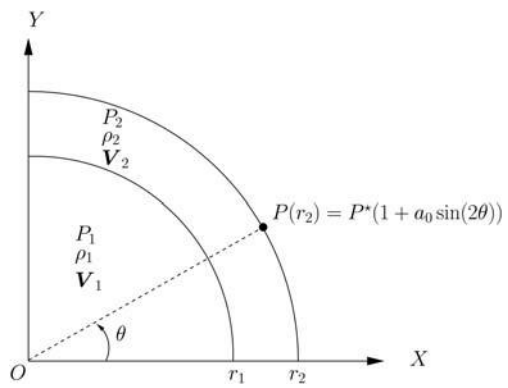

FIG. 6.25. *ICF-like target: initial conditions.*

perfect gas equation of state ($\gamma = 5/3$). The data are chosen to be representative of ICF situations. The interface between the gas and the shell is located at $r_1 = 0.1$, and the external radius of the target is $r_2 = 0.11$; see Figure 6.25. The initial state of the gas is given by $(\rho_1, P_1, \boldsymbol{V_1}) = (0.01, 2.5\ 10^9, 0)$, and the state inside the shell is $(\rho_2, P_2, \boldsymbol{V_2}) = (1, 2.5\ 10^{11}, 0)$. On the external surface of the shell, we apply a pressure law $P^\star = 10^{14}(1 + a_0 \sin(2\theta))$. We study this target in two configurations: the first is monodimensional with $a_0 = 0$, and the second is bidimensional with $a_0 = 0.2$. This second configuration may crudely represent the hydrodynamic part of an ICF flow which results from an inhomogeneous irradiation of the target.

For the monodimensional problem the mesh is made of 25 identical angular sectors on $[0, 90°]$ and 200 layers (100 uniform layers in the gas and 100 layers with a geometrical progression in the shell). A geometrical progression is applied so that we have a good representation of the contact discontinuity between the two materials (we have the same mass in the two cells around the interface). The time evolution of internal interface is displayed in Figure 6.26. This shows the two acceleration periods at $t = 1\ 10^{-9}$ and $t = 3\ 10^{-9}$ of the interface and at the end the deceleration of the interface until the stagnation time at $t = 5\ 10^{-9}$. In order to validate our results for the monodimensional configuration, we compare them to the results obtained with a

monodimensional code named CHIVAS. This code uses a von Neumann–Richtmyer-type scheme; see [16]. In Figure 6.26, we compare the trajectory of the internal interface with our scheme and with CHIVAS. The two curves can be almost superimposed, which demonstrates the quality of our scheme.

For the bidimensional case we use two types of meshes. One is a polar mesh (see Figure 6.27) with 40 angular sectors on $[0, 90°]$ and 100 layers (50 uniform layers in the gas and 50 layers with a geometrical progression in the shell). The other is a multiblock mesh in which we have a square in the central part of the target and nearly the same mesh as the polar grid for the rest of the domain (see Figure 6.27). Figure 6.28 represents the mesh at $t = 4.4\ 10^{-9}$ for both configurations. The nonuniformity of the pressure on the shell boundary leads to a bidimensional deformation of the internal interface.

Figure 6.29 illustrates one of the advantages of using a multiblock mesh. We can see that the time step in the case of the polar mesh reduces to a very small value ($\approx 1\ 10^{-14}$), whereas for the multiblock mesh we keep a reasonable time step ($\approx 1\ 10^{-13}$). The very small value of the time step for the polar mesh is due to the very small size of the triangular cells located at the center. Moreover, the multiblock mesh makes the computation more robust and enables us to deal with higher nonuniformity values for a_0.

7. Conclusion and perspectives. We have developed a new Lagrangian cell-centered conservative scheme. This scheme relies on a genuinely two-dimensional nodal solver. It can be interpreted as the two-dimensional generalization of the Godunov acoustic solver. The main new feature of the algorithm is the introduction of four pressures on each edge, two for each node on each side of the edge. This extra degree of freedom allows us to construct a nodal solver that fulfills two properties. First, the conservation of momentum and total energy is ensured. Second, a semidiscrete entropy inequality is provided. The face fluxes and the nodal velocities are all evaluated in a coherent manner. We have checked that, in the case of one-dimensional problems (with planar or cylindrical symmetry), our solver is exactly equivalent to the one-dimensional Godunov acoustic solver.

The scheme is only first order accurate; however it appears to be quite robust and versatile according to the numerical results obtained for the various test cases presented in this paper.

The next step is to develop the axisymmetric extension of our scheme. Then, in order to improve the accuracy of the scheme we will study its second order extension, probably with a MUSCL-type method. This new Lagrangian method looks promising

both as a stand-alone entity but also as a foundation for a more general method which may include ALE and/or adaptive mesh refinement techniques. The uniform cell centering of the solution variables provides a consistent basis for employing a wide range of well-proven remapping and adaptation schemes.

COPPER MOUNTAIN SPECIAL ISSUE ON ITERATIVE METHODS

The 9th Copper Mountain Conference on Iterative Methods was held April 2–7, 2006, in Copper Mountain, Colorado. The conference is organized by Front Range Scientific Computations, Inc., with co-organizers the Center for Applied Scientific Computing at Lawrence Livermore National Laboratory, and the University of Maryland. Traditionally, the [illegible] (SISC) hosts a special issue on iterative methods that is open to the public and is announced well in advance through both the SISC and the Copper Mountain Conference web sites.

I would like to thank the current members of the program committee for their service as guest editorial board. The committee members are
Xiao-Chuan Cai, University of Colorado
Iain Duff, RAL and CERFACS
Roland Freund, University of California, Davis
Kirk Jordan, IBM, Watson Research Center
Tim Kelley, North Carolina State University
David Keyes, Columbia University
Tom Manteuffel, University of Colorado
Steve McCormick, University of Colorado
David Silvester, University of Manchester
Ray Tuminaro, Sandia National Laboratory
Henk van der Vorst, University of Utrecht
Homer Walker, Worcester Polytechnic Institute
Carol Woodward, Lawrence Livermore National Laboratory
Irad Yavneh, Technion
The committee is chaired by Howard Elman (University of Maryland) and myself.

This issue contains 21 papers that largely reflect the topics presented at the conference, including papers that were part of the student papers competition. More specifically, we have papers covering the more traditional numerical linear algebra topic of preconditioning, including preconditioners for nonsymmetric problems in GMRES, radial basis function interpolation via preconditioned Krylov iterations, preconditioned eigensolvers, graph-based algorithms for preconditioning, and strategies for constructing block preconditioners for systems of PDEs, as well as some emerging new topics, such as preconditioners for stochastic elliptic PDEs and linear systems arising in interior point optimization methods. Most of the papers deal with some aspects of iterative methods for systems of algebraic equations; however, a paper on iterative optimization procedures with application to image registration also found its place in the issue. The overwhelming majority of the papers deal with various aspects of (mostly algebraic) multigrid (or (A)MG), ranging from theory of geometric MG applied to nontraditional formulation of Stokes problems to investigation of a number of algorithmic issues in AMG (such as the construction of the interpolation operator, coarsening strategies including for nonsymmetric problems), as well as the construction of specialized AMG algorithms for Google PageRank-like problems and for problems arising from higher-order spectral elements discretizations.

Many thanks are due to all authors for their valuable contributions. I would like also to thank the SIAM staff for their constant support and efforts to bring this issue to life. Finally, let me acknowledge the traditional support for the conference from

the US Department of Energy, the National Science Foundation, IBM, Los Alamos National Laboratory, Lawrence Livermore National Laboratory, and Sandia National Laboratory.

A GREEDY STRATEGY FOR COARSE-GRID SELECTION*

S. MACLACHLAN† AND YOUSEF SAAD†

Abstract. Efficient solution of the very large linear systems that arise in numerical modeling of real-world applications is often only possible through the use of multilevel techniques. While highly optimized algorithms may be developed using knowledge about the origins of the matrix problem to be considered, much recent interest has been in the development of purely algebraic approaches that may be applied in many situations, without problem-specific tuning. Here, we consider an algebraic approach to finding the fine/coarse partitions needed in multilevel approaches. The algorithm is motivated by recent theoretical analysis of the performance of two common multilevel algorithms, multilevel block factorization and algebraic multigrid. While no guarantee on the rate of coarsening is given, the splitting is shown to always yield an effective preconditioner in the two-level sense. Numerical performance of two-level and multilevel variants of this approach is demonstrated in combination with both algebraic multigrid and multilevel block factorizations, and the advantages of each of these two algorithmic settings are explored.

Key words. iterative methods, algebraic multigrid (AMG), algebraic preconditioners

AMS subject classifications. 65F10, 65N55, 68Q25

DOI. 10.1137/060654062

1. Introduction.

Much of modern scientific computing is driven by the need to solve increasingly large linear systems that arise from discretization of mathematical models of physical systems. The matrices of these linear systems are often not only large but also ill-conditioned. While classical methods may be efficient for smaller systems, the increasing demand for accuracy in numerical models requires a more efficient approach.

When full details of the driving application and its discretization are available, efficient multigrid solvers and multilevel preconditioners may be naturally defined. Coarse-level acceleration ideas were proposed as early as 1935 in the work of Southwell [33], while the potential efficiency of multilevel ideas was first demonstrated in the theoretical work of Fedorenko [16, 17] and Bakhvalov [2] in the 1960s. Geometric multigrid methods [10, 20], first used for computation in the 1970s, can be shown to be optimally efficient for simple problems on regular meshes. Hierarchical basis approaches based on detailed knowledge of the finite-element discretization also lead to effective preconditioners [3]. While techniques based on such complete knowledge are often the most efficient, it is not known how to construct optimal solution strategies for all problems. Further, a good discretization-based preconditioner for one problem may not work at all for a similar problem, without substantial modification.

Algebraic multigrid (AMG) methods, first proposed in [4] and later analyzed and tested in [29], offer performance comparable to geometric multigrid on many problems without requiring as much a priori knowledge. The goal of an AMG algorithm is to use algebraic means to create the multigrid hierarchy based solely on the linear system to be solved. While there are many variants of the original approach, in all cases this amounts to choosing a coarse set of points, and then defining intergrid

transfer operators and a coarse-scale operator that provide a good correction to errors that are slow to be reduced by relaxation. AMG has been successfully applied to many problems but is known to be most effective for those that arise from standard discretizations of elliptic differential equations [12].

The algebraic recursive multilevel solver (ARMS) approach, introduced in [30], is a multilevel block factorization approach based on incomplete LU (ILU) factorizations. The multilevel block factorization approach relies on splitting the matrix into 2×2 block form, then approximately inverting one diagonal block, and then computing a Schur complement to form a preconditioner [1, Chap. 9]. In ARMS, the inversion is accomplished using a threshold-based incomplete LU factorization (ILUT) [31] approach to compute sparse LU factors, which can then be reused in forming an approximation to the needed Schur complement.

Both the AMG and ARMS approaches require a good splitting into fine and coarse grids in order to achieve the best possible performance. To be considered good, a splitting must give a coarse grid that is sufficiently smaller than the original mesh yet still allows an effective preconditioner to be constructed. In AMG, this means that the coarse grid is big enough that the coarse-grid correction can effectively address all errors that are prohibitively slow to be reduced by relaxation. Many heuristics have been proposed to do this, primarily based on independent set algorithms, as were originally used in [29]. For ARMS, the primary goal of the coarse-grid selection algorithm is to allow for an accurate sparse factorization of the fine-grid block, plus an accurate sparse approximation of the coarse-grid Schur complement.

Theoretical convergence analysis of ARMS and AMG give implicit suggestions of ways to choose the coarse grid, but there is no easy explicit connection between the selection of the coarse-grid points and the convergence of the overall scheme. The idea of compatible relaxation (CR) [6, 8, 15, 23] provides a relationship between the properties of the fine-scale block of the matrix and the overall performance of AMG. Similarly, the analysis in [27, 28] provides a relationship between the preconditioning of the fine-scale block within ARMS and the overall quality of the preconditioner. Brief reviews of the AMG and ARMS methodologies and their theoretical analyses are given in section 2.

Here, we use these theoretical results to motivate a coarse-grid selection criterion and algorithm. The optimal coarse-grid selection criterion is seen to lead to an NP-complete coarsening algorithm and, so, a greedy algorithm is proposed to approximately maximize the measure of a good splitting. The resulting algorithm is shown to always satisfy the conditions on the fine-scale block in both AMG and ARMS theory; however no guarantee of reduction in the coarse-grid size is possible. This greedy coarsening strategy and its theoretical analysis are presented in section 3.

Numerical results are given in section 4 that show the algorithm works well for many problems. Of particular interest is the comparison between the performance of AMG and ARMS. Here, it is necessary to distinguish between the efficiency and the robustness of an algorithm. Efficiency is easily measured in terms of error reduction versus computational cost. Robustness, on the other hand, is difficult to quantify precisely. Here, we consider the robustness of an algorithm to be indicated by similar performance on a wide variety of problems. Our numerical results demonstrate the efficiency of the AMG-based algorithm for finite-element discretization of elliptic PDEs. The ARMS-based algorithm is seen to be less efficient than AMG, when AMG works well, but more robust.

2. Background and motivation. The use of multilevel solution techniques has become ubiquitous in the numerical solution of PDEs, and has also begun to

play an important role in more general numerical linear algebraic contexts. While many of these techniques make use of more knowledge than is present in the linear system of equations to be solved (e.g., geometric multigrid [10], hierarchical basis transformations [3]), we concentrate here on purely algebraic approaches, such as the ARMS technique [30] and AMG methods [4, 29]. Such algebraic techniques presume a splitting of the overall set of degrees of freedom into two disjoint sets, typically called the fine- and coarse-level degrees of freedom that are used to partition the given matrix.

Consider the matrix equation, $A\mathbf{x} = \mathbf{b}$, and suppose that the degrees of freedom in $\mathbf{x}$ and $\mathbf{b}$ are partitioned into two disjoint sets, F and C. We consider the matrix, A, to be already reordered, so that

$$\begin{bmatrix} A_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{bmatrix} \begin{pmatrix} \mathbf{x}_f \\ \mathbf{x}_c \end{pmatrix} = \begin{pmatrix} \mathbf{b}_f \\ \mathbf{b}_c \end{pmatrix}. \tag{1}$$

2.1. Multilevel block factorization. Multilevel block factorization techniques [1, Chap. 9] (such as ARMS [30]), make use of this block form to factor A in terms of A_{ff}^{-1}. Writing

$$A = \begin{bmatrix} I & 0 \\ -A_{cf}A_{ff}^{-1} & I \end{bmatrix} \begin{bmatrix} A_{ff} & 0 \\ 0 & \hat{A}_{cc} \end{bmatrix} \begin{bmatrix} I & -A_{ff}^{-1}A_{fc} \\ 0 & I \end{bmatrix}, \tag{2}$$

where $\hat{A}_{cc} = A_{cc} - A_{cf}A_{ff}^{-1}A_{fc}$ denotes the Schur complement of A, we can solve for $\mathbf{x}_f$ and $\mathbf{x}_c$ as in Algorithm 1.

ALGORITHM 1 (block factorization solve).

1. $\mathbf{y}_f = A_{ff}^{-1}\mathbf{b}_f$
2. $\mathbf{y}_c = \mathbf{b}_c + A_{cf}\mathbf{y}_f$
3. $\hat{A}_{cc}\mathbf{x}_c = \mathbf{y}_c$
4. $\mathbf{x}_f = \mathbf{y}_f + A_{ff}^{-1}A_{fc}\mathbf{x}_c$

Such a solution technique is, of course, only useful if we can easily solve systems with A_{ff} and $\hat{A}_{cc}$. In practice, multilevel block factorizations can lead to good preconditioners by approximating these operators by ones that can be inverted in a more computationally efficient manner. The ARMS algorithm [30] utilizes an incomplete LU factorization to approximate A_{ff}^{-1}, both in Steps 1 and 4 of Algorithm 1, and in computing an approximate Schur complement, which is approximately inverted by a recursive application of the ARMS methodology.

The action of the two-level ARMS preconditioner on a residual, $\mathbf{r} = \left(\begin{smallmatrix} \mathbf{r}_f \\ \mathbf{r}_c \end{smallmatrix}\right)$, can be easily explained in terms of a modified block factorization, rewriting (2) as

$$A = \begin{bmatrix} L_{ff} & 0 \\ -A_{cf}U_{ff}^{-1} & I \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & \hat{A}_{cc} \end{bmatrix} \begin{bmatrix} U_{ff} & L_{ff}^{-1}A_{fc} \\ 0 & I \end{bmatrix},$$

where $A_{ff} = L_{ff}U_{ff}$. Taking ILU factors, $L \approx L_{ff}$ and $U \approx U_{ff}$, and letting S^{-1} approximate the action of the inverse of $\hat{A}_{cc}$, we can write the ARMS preconditioner as in Algorithm 2.

ALGORITHM 2 (action of ARMS preconditioner on residual, $\mathbf{r}$).

1. $\mathbf{y}_f = L^{-1}\mathbf{r}_f$
2. $\mathbf{y}_c = \mathbf{r}_c + A_{cf}U^{-1}\mathbf{y}_f$
3. $\mathbf{x}_c = S^{-1}\mathbf{y}_c$
4. $\mathbf{z}_f = \mathbf{y}_f + L^{-1}A_{fc}\mathbf{x}_c$
5. $\mathbf{x}_f = U^{-1}\mathbf{z}_f$

Note that Algorithms 1 and 2 are, in fact, equivalent, if $A_{ff} = LU$ (i.e., if $L = L_{ff}$ and $U = U_{ff}$) and $S^{-1} = \hat{A}_{cc}^{-1}$.

It is apparent that the success of the ARMS preconditioner depends on how well the action of A_{ff}^{-1} can be approximated by the ILU solve. This, in turn, depends directly on the properties of the A_{ff} block of A. Notay relates the condition number of the preconditioned system, $B^{-\frac{1}{2}}AB^{-\frac{1}{2}}$, where B represents the action of the (approximate) multilevel block factorization, as in Algorithms 1 and 2, to the spectral equivalence of A_{ff} and $\hat{A}_{cc}$ and their approximations [27, 28]. Paraphrasing Theorem 9 of [28], we have the following result.

THEOREM 1. [illegible] A [illegible] (1) [illegible] B [illegible]

$$B = \begin{bmatrix} I & 0 \\ -A_{cf}D_{ff}^{-1} & I \end{bmatrix} \begin{bmatrix} D_{ff} & 0 \\ 0 & S \end{bmatrix} \begin{bmatrix} I & -D_{ff}^{-1}A_{fc} \\ 0 & I \end{bmatrix},$$

[illegible] D_{ff} [illegible] S [illegible] $\begin{bmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{bmatrix}$ [illegible] $\lambda_{min}(D_{ff}^{-1}A_{ff}) \geq 1$ [illegible]

$$\frac{\lambda_M}{\lambda_m} \leq \kappa\left(B^{-\frac{1}{2}}AB^{-\frac{1}{2}}\right) \leq \left(1 + \sqrt{1 - \lambda_M^{-1}}\right)^2 \frac{\lambda_M^2 \nu_M}{\min(\lambda_m, \nu_m)}, \tag{3}$$

[illegible]

$$\lambda_m = \lambda_{min}(D_{ff}^{-1}A_{ff}),\ \lambda_M = \lambda_{max}(D_{ff}^{-1}A_{ff}),$$
$$\nu_m = \lambda_{min}(S^{-1}\hat{A}_{cc}),\ \nu_M = \lambda_{max}(S^{-1}\hat{A}_{cc}),$$

[illegible] $D_{ff}^{-1}A_{ff}$ [illegible] $S^{-1}\hat{A}_{cc}$

While [27, 28] provide tighter bounds than those in inequality (3), we emphasize the role that good spectral equivalence to the A_{ff} block plays in these bounds: The overall preconditioner can be no better than the equivalence between D_{ff} and the A_{ff} block, and good equivalence implies the existence of a well-conditioned block factorization preconditioner for the overall system (using $S = \hat{A}_{cc}$). Thus, constructing the partition such that we know a D_{ff} with good equivalence to the A_{ff} block is an attractive approach to realizing an efficient preconditioner for A. A much harder question is achieving good spectral equivalence between the true Schur complement, $\hat{A}_{cc}$, and its approximation, S, especially as $\hat{A}_{cc}$ is, in practice, not explicitly available within the computation.

2.2. Algebraic multigrid. Originally proposed in [4] and further explained in [29], the Algebraic Multigrid (AMG) methodology has, in fact, grown to encompass a number of algorithms focused on the theme of complementing a given relaxation procedure by an algebraically determined correction from a coarser subspace. This collection of algorithms can be roughly parameterized by the choices of the multigrid components: relaxation, intergrid transfer operators, the (nodal) coarse grid, and the coarse-grid operator. Once these choices have been made, the AMG V-cycle can be described as a preconditioner or, more commonly, through its error propagation operator,

$$(I - B_{\text{AMG}}^{-1}A) = (I - M^{-T}A)^{l_2}(I - PA_C^{-1}RA)(I - M^{-1}A)^{l_1},$$

where $I - M^{-1}A$ is the error propagation operator of the chosen relaxation scheme (e.g., Jacobi or Gauss–Seidel), l_1 and l_2 are parameters giving the number of pre- and postrelaxations to be used, R is the restriction operator transferring residuals from the fine grid to the coarse grid, A_C is the coarse-grid operator, and P is the interpolation operator, transferring corrections from the coarse grid to the fine grid.

Choices of the multigrid components can be quite varied. Typical relaxation schemes are the Jacobi and Gauss–Seidel iterations, but other schemes, including symmetric Gauss–Seidel and ILU factorizations, are also possible. Choice of the coarse grid may be done based on the classical AMG definitions of strength of connection [29], using independent set algorithms (possibly modified for parallel processing environments) [14, 21], based on modified strength measures [7], or using CR [6, 8, 15, 23] (as discussed in more detail below). Once the coarse grid has been chosen, the dimensions of the intergrid transfer operators, R and P, are set, and their nonzero structure and values can be determined. Once R and P are chosen, a coarse-grid operator, A_C, may be chosen to solve for the coarse-grid correction.

If A is assumed to be symmetric and positive definite, a variational problem may be defined to simplify the problem of choosing R, P, and A_C. Note the part of the multigrid error propagation operator that is associated with the coarse-grid correction step, $I - PA_C^{-1}RA$. Whatever coarse-grid correction is calculated, error is reduced only within the range of P. Thus, a reasonable goal is to choose the coarse-grid correction to minimize the error after correction, over all corrections in the range of P—that is, to choose $\mathbf{w}_c$, such that $\|\mathbf{e} - P\mathbf{w}_c\|_A = \min$, where $\mathbf{e}$ is the error before the coarse-grid correction step, and the norm, defined as $\|\mathbf{v}\|_A^2 = \langle A\mathbf{v}, \mathbf{v}\rangle$, is chosen so that the minimization is achievable. Choosing this variational approach requires the coarse-grid correction, $\mathbf{w}_c$, to satisfy the equation $P^TAP\mathbf{w}_c = P^TA\mathbf{e}$. Noting that $A\mathbf{e} = \mathbf{r}$, the residual before coarse-grid correction, we see that this prescribes the choices of $R = P^T$ and $A_C = P^TAP$ for any given P. Note that choosing P and exactly computing $A_C = P^TAP$ is similar to Tismenetsky's strategy for computing approximate Schur complements [35], although the usual focus in multigrid is on appropriately complementing relaxation.

Thus, the problem of defining R, P, and A_C is reduced to one of choosing P such that the range of P adequately complements the space over which relaxation is effective. The classical AMG algorithm [29] does this by collapsing certain off-diagonal connections based on the assumption that the near-null space of A is accurately represented by the constant vector. If the nature of errors that are slow to be reduced by relaxation is not known, the adaptive AMG method [9] may be used to expose prototypes of such errors to be used in the definition of interpolation. Energy-minimization principles may also be used to define the multigrid interpolation operators [36, 37].

Even in the variational setting, the overall performance of multigrid depends on the complementarity obtained between the relaxation procedure and the coarse-grid correction. In particular, the key is choosing a coarse grid such that a good definition of interpolation is possible. The principle of compatible relaxation (CR), first introduced by Brandt [6], is based on the idea that the ability to define a good interpolation operator is tied to the relaxation it must complement. In [6], Brandt defines CR as "a modified relaxation scheme which keeps the coarse-level variables invariant" and states that "a general measure for the quality of the set of coarse variables is the convergence rate of the compatible relaxation." Defined in this manner, several possible versions of CR are possible [23], the most common of which is relaxation only on the unknowns associated with the fine grid (so-called F-relaxation [34]).

Falgout and Vassilevski [15] analyze the performance of AMG methods for symmetric and positive-definite matrices, A, based on a measure that accounts for the role of relaxation in complementing the variational coarse-grid correction process. For a relaxation scheme with convergent error propagation operator $I - M^{-1}A$, define the measure

$$\mu(P, \mathbf{e}) = \frac{\langle M(M + M^T - A)^{-1} M^T (\mathbf{e} - P\mathbf{e}_c), (\mathbf{e} - P\mathbf{e}_c)\rangle}{\langle A\mathbf{e}, \mathbf{e}\rangle},$$

where $M + M^T - A$ is invertible because $\|I - M^{-1}A\|_A < 1$. This measure takes into account the performance of relaxation in measuring the effectiveness of a given interpolation operator, P, beyond what is normally considered in the standard eigenvector-approximation criterion for AMG [5, 26]. If, for a given choice of P, $\mu(P, \mathbf{e}) < k$ for all $\mathbf{e} \neq \mathbf{0}$, then it can be shown that $\|I - B_{\mathrm{AMG}}^{-1}A\|_A < 1 - \frac{1}{k}$ [15, Theorem 2.2] for $l_1 = l_2 = 1$. Thus, $\mu(P, \mathbf{e})$ can be seen as a measure of the performance of the resulting AMG scheme for a chosen relaxation, coarse-grid, and interpolation operator.

The idea of CR may be used to bound the optimal value,

$$k^\star = \min_P \max_{\mathbf{e}\neq\mathbf{0}} \mu(P, \mathbf{e}),$$

of k over all possible interpolation operators, P, from the same coarse set. Paraphrasing [15, Theorem 5.1], we have the following result.

THEOREM 2. A $I - M^{-1}A$ ($\|I - M^{-1}A\|_A < 1$) $S_M = \frac{1}{2}(M + M^T)$ M $\omega = \lambda_{max}(S_M^{-1}A)$ Δ M S_M $\mathbf{v}$ $\mathbf{w}$

$$\langle M\mathbf{v}, \mathbf{w}\rangle \leq \Delta \langle S_M\mathbf{v}, \mathbf{v}\rangle^{\frac{1}{2}} \langle S_M\mathbf{w}, \mathbf{w}\rangle^{\frac{1}{2}}.$$

$\rho_{ff} = \|I - M_{ff}^{-1}A_{ff}\|_{A_{ff}}$ M_{ff} M (1)

$$k^\star \leq \frac{\Delta^2}{2 - \omega} \frac{1}{1 - \rho_{ff}},$$

$0 < \omega < 2$

Here, the bound on $k^\star$ gives a bound on the best possible measure of a two-level AMG algorithm with a given relaxation (prescribed by M) and partition into fine and coarse grids. For symmetric smoothers ($M = M^T$), $\Delta = 1$, and this inequality gives an upper bound on the best possible convergence factor for an AMG method with a particular coarse grid, which depends on the relaxation method chosen and the performance of CR. In particular, if CR is quick to converge (and ω is bounded away from 2, meaning that the slowest to converge modes of the symmetric relaxation, $I - S_M^{-1}A$, are the lowest-energy modes of $S_M^{-1}A$), then there exists an interpolation operator, P, that gives good multigrid performance. In general, choosing such a P that also results in an easy-to-invert coarse-grid operator, P^TAP, is difficult, as we seek to retain significant sparsity in P.

The reduction-based AMG algorithm (AMGr) presumes that a partition of the degrees of freedom has been chosen so that CR is fast to converge [24]. In particular,

AMGr is based on the assumption of a close spectral equivalence between A_{ff} and a fine-scale relaxation operator, D_{ff}, as in [24, Theorem 1].

THEOREM 3. [illegible] A [illegible] (1)

[illegible]

$$\langle D_{ff}\mathbf{x}_f, \mathbf{x}_f\rangle \leq \langle A_{ff}\mathbf{x}_f, \mathbf{x}_f\rangle \leq (1+\epsilon)\langle D_{ff}\mathbf{x}_f, \mathbf{x}_f\rangle$$

[illegible] $\mathbf{x}_f$ [illegible] $\left[\begin{smallmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{smallmatrix}\right]$ [illegible]

$$(I - M^{-1}A) = \left(I - \frac{2}{2+\epsilon}\begin{bmatrix} D_{ff}^{-1} & 0 \\ 0 & 0 \end{bmatrix} A\right),$$

[illegible]

$$P = \begin{bmatrix} D_{ff}^{-1}A_{fc} \\ I \end{bmatrix}.$$

[illegible] l [illegible] l [illegible]

$$MG = (I - M^{-1}A)^l(I - P(P^TAP)^{-1}P^TA)(I - M^{-1}A)^l,$$

[illegible]

$$\|MG\|_A \leq \frac{\epsilon}{1+\epsilon}\left(1 + \left(\frac{\epsilon^{2l-1}}{(2+\epsilon)^{2l}}\right)\right) < 1.$$

Now, under the additional assumptions of Theorem 3 (over those of Theorem 2), we can not only say that there exists a P that gives good multigrid convergence, but also give the form of one such P. Notice the similarities between the assumptions for Theorems 1 and 3; both require that $\lambda_{\min}(D_{ff}^{-1}A_{ff}) \geq 1$, and that the matrix, $\left[\begin{smallmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{smallmatrix}\right]$, is semidefinite. The explicit choice of a coarse-grid operator in the AMGr algorithm gives a bound on the multigrid convergence factor dependent solely on the maximum eigenvalue of $D_{ff}^{-1}A_{ff}$, which is also the dominant factor in the bound of Theorem 1.

Thus, for both multilevel block factorizations and (nodal) AMG, tight spectral equivalence between the fine-scale preconditioner or relaxation operator, D_{ff}, and A_{ff} is needed to guarantee good performance of the overall solver. Constructing the fine-grid set so that this is always possible is the subject of the remainder of this paper.

3. The greedy coarsening algorithm. In [32], the strategy of reordering the columns and rows of a nonsymmetric matrix to ensure diagonal dominance of the A_{ff} block was introduced. There, the partitioning was accomplished by ordering the columns and rows of the matrix in order of decreasing dominance, and choosing, as A_{ff}, a subblock of A with sufficiently dominant rows. The algorithm defined here is similar in style, in that it chooses rows for A_{ff} in a greedy manner, but it also takes into account the added dominance within the A_{ff} block that occurs when points are added to the coarse set.

In order to make decisions on dominance to select the A_{ff} block, we must have some sort of measure of the dominance that is sought. We consider choosing D_{ff}

as a simple, diagonal preconditioner or relaxation method, so that we seek classical rowwise diagonal dominance of A_{ff}. Writing the partition of the degrees of freedom into fine and coarse sets as $F \cup C$, we say that row i of A_{ff} has θ dominance if

$$|a_{ii}| \geq \theta \sum_{j \in F} |a_{ij}|.$$

Note that, by this definition, classical diagonal dominance is equivalent to $\theta = \frac{1}{2}$ dominance, as the diagonal, a_{ii}, is included in the sum on the right side. Then, the diagonal dominance associated with row i is given by

$$\theta_i = \frac{|a_{ii}|}{\sum_{j \in F} |a_{ij}|}.$$

Note that the measure, θ_i, depends on the selection of F- and C-points.

Ideally, we would like to choose F as the largest set of degrees of freedom such that for every $i \in F$, $\theta_i \geq \theta$. That is, we would like F to be the largest subset possible such that A_{ff} is θ dominant. This would guarantee good equivalence of a diagonal matrix, D_{ff}, to A_{ff}, as required in the theorems of section 2, but also yield as small a coarse-scale problem as possible. Formally, we would seek to maximize $|F|$ (where $|F|$ denotes the size of the set, F) under the constraint that for every $i \in F$, $\frac{|a_{ii}|}{\sum_{j \in F} |a_{ij}|} \geq \theta$ for a chosen θ. Defining the binary variables

$$f_i = \begin{cases} 1 & \text{if } i \in F, \\ 0 & \text{if } i \in C, \end{cases}$$

the problem can be posed in optimization form:

$$\begin{aligned} &\text{maximize } \sum_{i=1}^{n} f_i, \\ &\text{subject to } f_i \in \{0,1\} \ \forall i, \\ &\qquad |a_{ii}| \geq \theta \sum_{j \in F} |a_{ij}| \text{ if } f_i \neq 0. \end{aligned}$$

Note that the sum over $j \in F$ can be converted into a sum over all j, by weighting the terms by f_j, $\sum_{j \in F} |a_{ij}| = \sum_j |a_{ij}| f_j$. Then, as this is a constrained optimization problem, we convert it to an integer programming problem by adding the term $\theta \|A\|_\infty (1 - f_i)$ to the left side of the inequality constraint,

$$\begin{aligned} &\text{maximize } \sum_{i=1}^{n} f_i, \\ &\text{subject to } f_i \in \{0,1\} \ \forall i, \\ &\qquad \theta \|A\|_\infty (1 - f_i) + |a_{ii}| \geq \theta \sum_j |a_{ij}| f_j. \end{aligned}$$

Note that the modified problem is equivalent to the original, as if $i \in F$, $1 - f_i = 0$, so the original constraint is imposed for all $i \in F$, but if $i \notin F$, $1 - f_i = 1$, and the constraint is automatically satisfied, as $\sum_{j \in F} |a_{ij}| \leq \|A\|_\infty$. Thus, the problem of finding the largest set, F, with the desired dominance is a 0-1 integer programming

problem, known to be NP-complete [38]. As such, we cannot expect to easily find an algorithm that is linear in the number of nonzero entries in A that finds the largest possible set F that has the desired level of diagonal dominance. Instead, we introduce here a greedy algorithm that partitions the unknowns into F and C by iteratively building these sets, adding any sufficiently diagonally dominant points that arise to F, and moving the least diagonally dominant points into C, one at a time.

To accomplish the partitioning, we introduce a third set of points, denoted by the set, U, as those points whose partitioning is, as yet, undecided in the process. Initially, then, U includes all of the degrees of freedom, and sets F and C are both empty. We introduce the dynamic measures,

$$\hat{\theta}_i = \frac{|a_{ii}|}{\sum_{j \in F \cup U} |a_{ij}|},$$

as measures of the diagonal dominance of row i amongst those rows that either are already designated as F-points, or could potentially be so designated. If, at any point, row i is determined to be sufficiently diagonally dominant, that is, $\hat{\theta}_i \geq \theta$ for some preselected threshold θ, then i is automatically added to the set of F-points (as it may only become more dominant as points are moved from U to C or F). If no points are attractive as F-points, then a point that is not attractive as a potential F-point is chosen to be moved to C, in order to make the remaining points in U more diagonally dominant. Thus, the partitioning algorithm, given in Algorithm 3, is a greedy algorithm that, at each step, makes a choice to increase the diagonal dominance of those points in U. In this way, the points in U can be viewed as candidate F-points that are either confirmed or discarded based on the dynamic values of $\hat{\theta}_i$. A common notation, which we use here, is to call $Adj(j)$ the set of nearest neighbors of j, i.e., the set $\{k : a_{jk} \neq 0\}$.

ALGORITHM 3 (greedy partitioning algorithm).

0. $U = \{1, 2, \ldots, n\}; \quad F = \emptyset$. Compute $\hat{\theta}_i, \ i = 1, \ldots, n$
1. For $i = 1, \ldots, n$, if $\hat{\theta}_i \geq \theta$, $\begin{cases} F := F \cup \{i\}, \\ U := U \setminus \{i\} \end{cases}$
2. While $U \neq \emptyset$
   (a) Let $j = \operatorname{argmin}_{i \in U} \{\hat{\theta}_i\}$
   (b) Move j from U to C
   (c) For $i \in U \cap Adj(j)$
   - Recompute $\hat{\theta}_i = \frac{|a_{ii}|}{\sum_{k \in F \cup U} |a_{ik}|}$
   - If $\hat{\theta}_i \geq \theta$, $\begin{cases} F := F \cup \{i\}, \\ U := U \setminus \{i\} \end{cases}$

As the only way for a point to be reclassified from U to F is if $\hat{\theta}_i \geq \theta$, and $\hat{\theta}_i$ is a nondecreasing function (since points are only removed from $F \cup U$), it is immediately apparent that each row within the A_{ff} block created by Algorithm 3 has (at least) θ dominance. This, in turn, suggests the existence of a diagonal preconditioner or relaxation matrix, D_{ff}, that achieves the tight equivalence bounds suggested by Theorems 1, 2, and 3. We now verify this for the case that A is symmetric and positive definite.

THEOREM 4. Let A be symmetric and positive definite, and let $\theta \in (\frac{1}{2}, 1]$ be given. Then

$$\theta \leq \theta_i = \frac{a_{ii}}{\sum_{j \in F} |a_{ij}|} \quad \forall i \in F,$$

$D_{ff} \equiv \mathrm{diag}(A_{ff})$

$$\lambda_m = \lambda_{min}(D_{ff}^{-1}A_{ff}) \geq 2 - \frac{1}{\theta},$$
$$\lambda_M = \lambda_{max}(D_{ff}^{-1}A_{ff}) \leq \frac{1}{\theta}\ .$$

. Let λ be an eigenvalue of $D_{ff}^{-1}A_{ff}$. Clearly, λ is real because $D_{ff}^{-1}A_{ff}$ is similar to the symmetric matrix $D_{ff}^{-\frac{1}{2}}A_{ff}D_{ff}^{-\frac{1}{2}}$. By Gerschgorin's theorem, there is a certain index i such that λ satisfies

$$|\lambda - 1| \leq \sum_{j\in F,\ j\neq i} \left|\frac{a_{ij}}{a_{ii}}\right| = \frac{1}{\theta_i} - 1 \leq \frac{1}{\theta} - 1$$

from which the result follows immediately. □

The results in Theorems 1 and 3 require that the smallest eigenvalue of $D_{ff}^{-1}A_{ff}$ be at least one. By scaling the matrix D_{ff} with the scalar $2 - 1/\theta$ the smallest eigenvalue will be scaled to 1 and the largest to $1/(2\theta - 1)$.

COROLLARY 1. 4
$D_{ff} \equiv (2 - \frac{1}{\theta})\,\mathrm{diag}(A_{ff})$

$$\lambda_m = \lambda_{min}(D_{ff}^{-1}A_{ff}) \geq 1, \qquad \lambda_M = \lambda_{max}(D_{ff}^{-1}A_{ff}) \leq \frac{1}{2\theta - 1}.$$

A similar result may be obtained in the same manner as Theorem 4 using a rowwise scaling of D_{ff} based on the level of dominance in each row.

COROLLARY 2. 4
$(D_{ff})_{ii} = \left(2 - \frac{1}{\theta_i}\right)a_{ii}$ $i \in F$

$$\lambda_m = \lambda_{min}(D_{ff}^{-1}A_{ff}) \geq 1, \qquad \lambda_M = \lambda_{max}(D_{ff}^{-1}A_{ff}) \leq \frac{1}{2\theta - 1}.$$

Recall that the the smallest and largest eigenvalues of $D_{ff}^{-1}A_{ff}$ are the minimum and maximum (resp.) of the Rayleigh quotients $\frac{\mathbf{x}_f^T A_{ff}\mathbf{x}_f}{\mathbf{x}_f^T D_{ff}\mathbf{x}_f}$, so these corollaries are equivalent to saying that, for all $\mathbf{x}_f$,

$$\mathbf{x}_f^T D_{ff}\mathbf{x}_f \leq \mathbf{x}_f^T A_{ff}\mathbf{x}_f \leq \frac{1}{2\theta - 1}\mathbf{x}_f^T D_{ff}\mathbf{x}_f.$$

This, in turn, implies that the parameter ϵ from Theorem 3 may be chosen as $\frac{2-2\theta}{2\theta-1}$. Knowing the extremal Rayleigh quotients also allows definition of an appropriately weighted relaxation scheme, $I - \sigma D_{ff}^{-1}A_{ff}$, with minimal spectral radius for use in the bound in Theorem 2.

Theorems 1 and 3 both require the additional assumption that $\left[\begin{smallmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{smallmatrix}\right]$ be positive semidefinite. In AMGr, this requirement is important as the coarse-level matrix depends on D_{ff} through the variational formulation. For block factorization preconditioners, this condition arises indirectly, in the bounding of the Cauchy–Bunyakowski–Schwarz constant associated with the factorization using D_{ff}. In either case, it is difficult to guarantee this condition for general classes of matrices, although it is easy to construct a matrix, A, for which it holds: simply choose $A = \left[\begin{smallmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{smallmatrix}\right] + \left[\begin{smallmatrix} E_{ff} & 0 \\ 0 & 0 \end{smallmatrix}\right]$ for any semidefinite matrices $\left[\begin{smallmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{smallmatrix}\right]$ and $\left[\begin{smallmatrix} E_{ff} & 0 \\ 0 & 0 \end{smallmatrix}\right]$.

For a given matrix, A, the existence of the decomposition can be proven in the case of diagonal dominance if D_{ff} is chosen as in Corollary 2, as in the following result.

THEOREM 5. A (1)
A D_{ff}
2 $(D_{ff})_{ii} = \left(2 - \frac{1}{\theta_i}\right) a_{ii}$ $\theta_i = \frac{a_{ii}}{\sum_{j \in F} |a_{ij}|}$ $\begin{bmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{bmatrix}$

. As A is diagonally dominant, $\sum_j |a_{ij}| \leq 2a_{ii}$ for every $i \in F$. Splitting the degrees of freedom into $F \cup C$, we then have

$$\begin{aligned} \sum_{j \in C} |a_{ij}| &\leq 2a_{ii} - \sum_{j \in F} |a_{ij}| \\ &= \left(2 - \frac{1}{\theta_i}\right) a_{ii} = (D_{ff})_{ii}. \end{aligned}$$

Thus, all rows in $\begin{bmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{bmatrix}$ associated with an F-point are diagonally dominant. All rows associated with a C-point are also diagonally dominant, as they already were in A. So, $\begin{bmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{bmatrix}$ is diagonally dominant. But then, by Gerschgorin's theorem, it must be positive semidefinite. ∎

1 (relationship to CR). Brandt defines compatible relaxation (CR) as "a modified relaxation scheme which keeps the coarse-level variables invariant" and states that "a general measure for the quality of the set of coarse variables is the convergence rate of the compatible relaxation" [6]. Here, we do not explicitly perform the relaxation in CR, but we achieve a similar result. The construction of the coarse/fine partition, however, is such that the existence of a quickly converging fine-level Jacobi-like relaxation is guaranteed by Theorem 4 and its corollaries. As a result, the partitioning algorithm proposed here may be considered as a new approach to CR, where a property of quickly converging CR is identified (in this case, diagonal dominance) and used to construct a partition for which CR is guaranteed to converge quickly, without actually needing to perform the iteration.

4. Numerical results. To test the approach developed in section 3, we consider a variety of problems and explore some of the different options inherent in the development of multilevel algorithms based on this approach to coarse-grid selection. The results in Theorems 1 and 3 prescribe specific two-level algorithms with bounded convergence properties based only on the fine-scale equivalence of D_{ff} and A_{ff}. Theorems 1 and 2 may also be read as giving indicators of the best possible performance of a two-level algorithm based on the partitioning prescribed. A need for more general (and more expensive) treatment of the interaction between fine and coarse scales is demonstrated and addressed by using the full power of the ARMS and AMG approaches.

4.1. AMG. The reduction-based AMG algorithm discussed in Theorem 3 prescribes a simple two-level scheme that is useful when the coarse-grid selection gives a fine-scale block that is easily relaxed. We first test the diagonal-dominance-based coarse-grid selection scheme in this setting, for PDE-based problems where AMG in general (and AMGr, in particular) is expected to perform reasonably well.

The convergence result of Theorem 3 rests on the requirement that $\begin{bmatrix} D_{ff} & -A_{fc} \\ -A_{fc}^T & A_{cc} \end{bmatrix}$ be positive semidefinite, although this condition is not explicitly enforced in the coarsening algorithm. While established only as a sufficient condition, fast convergence of the AMGr algorithm is typically not found when it is violated. For this reason, we

begin by testing problems where we know the needed definiteness occurs, when A itself is diagonally dominant (as established in Theorem 5). For these tests, we consider the matrices that arise from the bilinear finite-element discretizations of the elliptic operator, $-\nabla \cdot K(x,y)\nabla p(x,y)$, on the unit square, subject to Dirichlet boundary conditions.

There are several relevant measures of the performance of the coarsening algorithm itself and of AMGr coupled with it. We record the required setup time for the algorithm, including computing the coarse grid, partitioning the fine-scale operator, computing the coarse-grid operator, and computing any necessary parameters of the method. For AMGr, we choose a random initial guess and iterate directly on the homogeneous problem, $A\mathbf{x} = \mathbf{0}$. The number of iterations needed to reduce the ℓ^2-norm of the residual by six orders of magnitude and the time taken for these iterations are recorded. These two-level results were computed using MATLAB and, thus, the times presented are intended primarily for comparison purposes; the multilevel results that follow are computed using research C codes compiled with appropriate optimization flags. As always, the reported run times are only accurate to a few hundredths of a second, and so those presented here are rounded to the nearest tenth of a second.

As the coarse grid and D_{ff} determine the convergence bounds for these algorithms, the spectral equivalence properties for A_{ff} and D_{ff} are reported for each problem and each grid resolution. In particular, we report the number of coarse-grid points, n_c, and $\epsilon = \lambda_{\max}(D_{ff}^{-1}A_{ff}) - 1$, computed from the upper spectral equivalence bounds for the fine-scale operators (which is itself computed using a few steps of Arnoldi iteration). The asymptotic convergence factor, ρ, measured in the A-norm, is computed directly using at most 200 steps of the power method. The AMGr cycle used is one with l prerelaxations followed by a coarse-grid correction and no postrelaxation. The analysis of Theorem 3 can also be performed in this setting, yielding the bound, $\|MG\|_A \leq \left(\frac{\epsilon}{1+\epsilon}\left(1+\left(\frac{\epsilon^{2l-1}}{(2+\epsilon)^{2l}}\right)\right)\right)^{\frac{1}{2}}$, where the square-root arises as the convergence of this one-sided cycle is limited by halving the number of relaxation sweeps relative to the symmetric cycle. In the results presented here, we choose $l = 3$, which, for all examples, yielded the fastest solution time for $1 \leq l \leq 5$.

Table 1 shows the performance of the two-level AMGr scheme on matrices that come from bilinear finite element discretizations of the two-dimensional diffusion equation, $-\nabla \cdot K\nabla p$. Three different choices of the diffusion coefficient, $K(x,y)$, are chosen, corresponding to the homogeneous case ($K(x,y) = 1$, the Poisson equation), the smoothly varying case ($K(x,y) = 10^{-8} + 10(x^2 + y^2)$), and the discontinuous case, where $K(x,y)$ is 1 in 80% of the elements, chosen at random, and 10^{-8} in the remaining 20% of the elements. In all three cases, the two-level AMGr algorithm performs well, reducing the A-norm of the error by a factor of 10^6 in at most 20 iterations.

TABLE 1
Performance of two-level AMGr on test matrices from discretizations of $-\nabla \cdot K(x,y)\nabla p(x,y)$.

Coefficient	Grid	n_c	ϵ	t_{setup}	t_{solve}	# iters.	ρ
$K(x,y) = 1$	32×32	225	4.98	0.5	0.2	13	0.37
	64×64	961	4.99	7.2	0.7	13	0.37

random $K(x,y)$	32×32	277	4.61	0.5	0.3	18	0.52
	64×64	1149	4.78	6.4	1.4	19	0.59
	128×128	4715	4.86	109.2	6.7	20	0.62

Grid sizes are effectively reduced, and the resulting asymptotic convergence factors are bounded well away from unity.

In the homogeneous case, the coarsening chosen by Algorithm 3 results in uniform coarse grids. All Dirichlet boundary nodes are automatically chosen as fine-grid points (as they are already diagonally dominant). Nodes neighboring the boundary are also attractive as fine-grid points because of their inherent diagonal dominance (from the algebraic elimination of connections to the boundary nodes). Thus, the 33×33 mesh of unknowns from the 32×32 element grid is coarsened to a uniform 15×15 mesh. Similarly, the 64×64 and 128×128 element meshes are coarsened to meshes of 31×31 and 63×63 degrees of freedom. The parameter, ϵ, of the splitting stays close to 5.0 as the mesh is refined and is theoretically bounded by 9, from Corollary 2, for our choice of $\theta = 0.55$. As expected from a two-level scheme, the setup time does not scale with refinement, nor does the solve time (although this is closer). The resulting convergence factors of approximately 0.37 do not degrade with grid size, as predicted by Theorem 3, although the measured convergence factor is signficantly better than that predicted by the theory.

For the variable coefficient problems, coarsening is less uniform, as is expected given the variations in these operators. The spectral equivalence constant, ϵ, however, remains bounded below 5, leading to effective two-level solvers. Setup times again do not scale, as expected, and the lack of scaling in the iteration times is slightly more pronounced. Asymptotic convergence factors remain nicely bounded below one, and below those predicted by Theorem 3. As a result, iteration counts for reducing the A-norm of the error remain small.

4.1.1. Implementation and cost issues. For multilevel tests, we give more weight to the question of an efficient implementation of Algorithm 3. There are two potential sources of inefficiency in the partitioning algorithm—the selection of the new C-point and the updating of all neighboring F-points. In order to be able to efficiently find the absolute minimal measure, we would need to either keep a sorted list of the measures, which would need updating each time a point was put into C, or search the (unsorted) list of measures. Instead, we implement an incomplete bucket sort [13, section 9.4] based on a doubly linked-list data structure [13, section 11.2] that allows efficient identification of a point with approximately minimal measure as well as fast updates of measures.

For each potential F-point, a standard linked-list data item is created. With each linked-list item, a key for the associated node is assigned as the measure of the node. As measures of potential F-points lie in the interval $[0, \theta)$, this interval is divided into equal-sized subintervals (or buckets), and all list items whose keys lie in the given bucket are added to a single doubly linked list associated with that bucket. The nonempty bucket associated with the smallest key then contains not only the item associated with the absolute minimal measure, but also all items within some small range of the minimal measure. A single element is chosen out of this bucket as an approximately minimal measure and used as the new C-point, j, in Algorithm 3. Taking advantage of the symmetry of A, we then can look over all nonzero columns, i, in row j of A, to update $\hat{\theta}_i$ to account for the removal of j. This is easily accomplished by an indexing array that points to the linked-list item corresponding to node i. Using these structures, we no longer select the absolute minimal-measured node to remove at each iteration, but are rewarded with $O(1)$ update and find-approximate-min operations, and an $O(n)$ amount of storage for partitioning the $n \times n$ matrix, A.

As a multigrid cycle, we consider a mixture of components from the AMGr algorithm and a classical multigrid V-cycle. Full relaxation sweeps, as opposed to the

TABLE 2
Performance of multilevel AMG with AMGr-style interpolation, as in Theorem 3, on test matrices from discretizations of $-\nabla \cdot K(x,y)\nabla p(x,y)$.

F-relaxation used in AMGr, are prevalent in AMG and, so, we use a full sweep of Gauss–Seidel relaxation for both pre- and postrelaxation within the V-cycle, ordered so that coarse points are relaxed first on the downward part of the cycle, but that F-points are relaxed first on the upward part of the cycle. Interpolation is defined as in AMGr (cf. Theorem 3), using the diagonal matrix, D_{ff}, as in Corollary 2. The problem is coarsened until the next coarsest grid would have fewer than 8 degrees of freedom, and the coarsest-grid problem is solved using a (complete) Cholesky factorization.

We first test this AMG approach on the same problems as in Table 1, again with $\theta = 0.55$. The number of subintervals in the bucket sort is taken to be 1000, regardless of the problem size. As we no longer explicitly need the parameter, ϵ, to define relaxation, we do not calculate it for these examples. In Table 2, we show the number of levels created in the multigrid hierarchy for each problem. To measure the efficiency of the multigrid coarsening process, we report both the multigrid grid complexity and operator complexity. The grid complexity, c_G, defined as the sum of the number of grid points on each level divided by the number of grid points on the finest level, is an indicator of the rate at which the problem is coarsened. The multigrid operator complexity, c_A, defined as the sum of the number of nonzero entries in the operator on each level divided by the number of nonzero entries in the finest-grid operator is a measure of both the storage needed and computational cost of a single multigrid cycle. The times required for the setup and solve phases are reported, where solution is taken to mean a reduction in the residual by a factor of 10^6 in solving the homogeneous problem, $A\mathbf{x} = \mathbf{0}$, given a random initial guess. The number of iterations needed for convergence, as well as the asymptotic convergence factor, ρ, measured after at most 200 iterations are also reported.

Performance for the two problems with smooth coefficients is typical of geometric multigrid methods applied to these problems. The number of levels grows by one for each grid refinement, and both grid and operator complexities remain relatively constant as the problem is refined. In fact, because of the approximate minimization in Step (2)(a) of Algorithm 3, a series of fully coarsened grids is chosen for both of these problems, bounding the grid complexity by a factor of $\frac{4}{3}$. That the operator complexity is also bounded by $\frac{4}{3}$ for these problems is a consequence of this regular coarsening, coupled with the fact that, in the variational definition of the coarse-grid operator, the stencil of the coarse-to-fine interpolation operator is that of A_{fc},

resulting in coarse-grid operators that are also nine-point operators on a regular mesh. Setup times roughly scale with matrix size (although there is some slowing, likely due to the indirect indexing operations needed to define interpolation), and the solve times scale nicely with problem size. The resulting convergence factors are bounded well away from unity, although are slightly worse than typical (Ruge–Stüben) AMG performance on these problems, which would lead to convergence factors in the range of 0.1 to 0.2. The simple interpolation operator defined in Theorem 3 allows for efficient computation of the AMG interpolation and coarse-grid operators, but limits its applicability. For these problems, where the AMGr interpolation is effective, setup times for the AMG algorithm can be much lower than those of classical AMG, but typically result in poorer convergence behavior, as seen here.

Performance for the randomly discontinuous coefficient problem, as seen in Table 2, degrades with refinement of the mesh. While the grid complexity does remain nicely bounded, only slightly larger than the factor of $\frac{4}{3}$ seen in the previous examples, there is a notable growth in the operator complexities. This growth is a result of the nonuniform coarsening that is naturally chosen for this problem, coupled with the use of an interpolation stencil that exactly matches that of A_{fc}. In this way, the density of nonzeros in coarse-grid operators grows as the multigrid cycle coarsens. Such growth is compounded in further coarsenings, as new nonzero entries in the stencil of A_{fc} lead to new nonzeros in the variational coarse-grid operator, as well as denser matrix-matrix-matrix products needed to compute these products. This is most noticeable in the dramatic increase in the time needed for the setup stage as the grid is refined, a result of the effectively dense matrix computations needed to coarsen the coarsest few levels of the multigrid hierarchy for the 2048×2048 element grid problem. The obvious solution to this growth is to drop some of the small (or weak) off-diagonal connections in these growing factors, either in the choice of interpolation or in the computation of the coarse-grid operators themselves. Dropping weak off-diagonal connections in the definition of interpolation is, in fact, exactly what is done in the standard AMG approach, discussed below. The slower growth in the solve times is very closely correlated to the combination of the growth in the problem size (by a factor of 4) and the number of iterations needed to reduce the residual appropriately (by a factor of $\frac{3}{2}$ between the 1024×1024 and 2048×2048 problems). This increase in the number of iterations, in turn, is closely linked to the increase in the asymptotic convergence factors as the grids are refined. It is difficult to say (without finer grids to test) if this increase is due to a lack of optimality of the overall multigrid approach (i.e., convergence factors continue to worsen as the grid is refined), or is related to the poorer treatment of the coarsest levels of the multigrid hierarchy.

4.1.2. Importance of theoretical conditions. An even poorer example of the performance of an AMGr-like algorithm can be seen when we violate the assumption that the "reduced" matrix, $\left[\begin{smallmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{smallmatrix}\right]$, be nonnegative definite. In Theorem 5, we note that such an example cannot arise when A is diagonally dominant and, so, we consider another PDE-based example, $-\nabla \cdot K(x,y)\nabla p(x,y)$, where we choose a tensor coefficient, $K(x,y) = \left[\begin{smallmatrix} 1 & 0 \\ 0 & 0.01 \end{smallmatrix}\right]$. As with the continuum operator, the discretization has strong connections between nodes that lie on the same line of fixed y value, but a finite-element discretization of this equation has significant nonzero connections to degrees of freedom that lie off of these lines as well. The greedy coarsening algorithm effectively recognizes these properties of strength of connection and chooses the first coarse grid to be a semicoarsened version of the fine grid, known to be effective for this problem. The AMGr interpolation operator, however, attempts to define an

interpolation that connects a fine-grid point to all of its coarse-grid neighbors. In this case, this includes interpolation from points that are not strongly related to the fine-grid point in question. As a result, the multigrid complexities grow substantially (as A_{fc} is relatively dense) and the overall algorithm performs poorly. For a 32×32 element grid, a grid complexity of 4.69 and operator complexity of 48.16 were recorded, with an asymptotic convergence factor of 0.98989.

A solution to the degradation of performance seen for the randomly discontinuous problems or overall poor performance in the anisotropic case is to combine the coarsening of Algorithm 3 with classical AMG interpolation techniques. While classical AMG [29] limits interpolation to the stencil of A_{fc}, not all nonzero entries in this stencil are used. To compensate for dropping connections in A_{fc}, as well as for strong connections in A_{ff}, the nonzero entries in a row of interpolation are also not necessarily equally proportional to the original entries of A_{fc}. Interpolation is defined based on the principle that the errors remaining after relaxation yield small residuals, so that interpolation needs to be most accurate for vectors, $\mathbf{e}$, such that $A\mathbf{e} \approx \mathbf{0}$ in a pointwise sense. Considering a fine-grid point, i, this means that

$$\begin{aligned} (A\mathbf{e})_i &= 0, \\ \text{or } a_{ii}e_i &= -\sum_{k \in C_i} a_{ik}e_k - \sum_{j \in F_i} a_{ij}e_j, \end{aligned}$$

where the sets C_i and F_i are defined through the localizations of the global coarse and fine sets: $C \cap Adj(i)$, and $F \cap Adj(i)$. Interpolation from coarse neighbors of the point, i, is relatively straightforward, so the main goal is to collapse the connections in F_i onto C_i or i itself in a way to meaningfully define an interpolation operator.

4.1.3. Combination with AMG coarsening. Classical AMG [29] categorizes the off-diagonal connections in row i as strong or weak depending on their suitability for use in interpolation. When the connection between two points is said to be strong, it is treated as an important connection to account for in interpolation, while a weak connection is to be discarded. The classical definition for the set of points that i strongly depends on is $S_i = \{j : -a_{ij} \geq \beta \max_{k \neq i}\{-a_{ik}\}\}$ for a chosen strength threshold, β [10] (other possible algebraic definitions of strong connections include those in [7, 11]). The set C_i is then defined by $C_i = C \cap S_i$, while $F_i = Adj(i) \setminus C_i$. Connections in F_i are then further partitioned into strong connections, $F_i^s = F_i \cap S_i$, and weak connections, F_i^w. Weak connections are not important in interpolation, so they are collapsed directly to the diagonal. Strong connections to fine-grid points are accounted for through an indirect interpolation, based on an assumption on the errors that are slow to be reduced by relaxation (as in [29]) or, possibly, further knowledge of such errors [9]. Making choices consistent with classical AMG gives the interpolation formula [10] for $i \in F$,

$$e_i = -\sum_{k \in C_i} \left(\frac{a_{ik} + \sum_{j \in F_i^s} \left(\frac{a_{ij}a_{jk}}{\sum_{k' \in C_i} a_{jk'}} \right)}{a_{ii} + \sum_{j \in F_i^w} a_{ij}} \right) e_k. \tag{4}$$

TABLE 3
Performance of multilevel AMG with classical AMG-style interpolation and a two-stage coarsening algorithm on test matrices from discretizations of $-\nabla \cdot K(x,y)\nabla p(x,y)$.

Dividing the neighbors of a node, i, into groups of strong and weak connections is necessary to ensure that AMG interpolation does not try to connect points that have no real relationship in the matrix (or governing PDE). In order to define nontrivial interpolation by (4), we now need to ensure that C_i is nonempty. To do this, we use a two-pass coarsening routine based on that used in classical AMG [29], where the coarse grid is first chosen as a maximal independent set over the strong connections of the matrix; then a second pass is made, changing F-points to C-points, to ensure that the strong connections of i are properly accounted for in interpolation. Here, we let Algorithm 3 choose an initial partition into F and C, and then use the AMG second pass algorithm that allows changing F-points to C-points to allow for better use of (4) in defining interpolation [29]. Note that removing points from F can only improve the diagonal dominance of A_{ff}, so Theorem 4 and its corollaries will still hold for the repartitioned system. Our only concern then is to ensure that we do not enlarge C by too much in seeking good approximation properties for the resulting interpolation.

Results for AMG-style interpolation (4), using Algorithm 3 as a first pass for coarsening, augmented by the second pass described above, are shown in Table 3. Here, we choose the AMG strength threshold $\beta = 0.25$ for the isotropic problems and $\beta = 0.3$ for the anisotropic problem. Operator and grid complexities are reported, as are the number of levels in the multigrid hierarchy, showing the deepening hierarchies as the coarsening becomes less uniform. This increase in the number of levels allows AMG to retain the low operator complexities seen in Table 2, yet still address the important need of all fine-grid points for adequate strong connection to the coarse grids.

For all of these problems, we see very effective solvers, with low iteration counts and convergence factors. For the smoothly varying coefficient problems, we see the same grid and operator complexities for the AMG-based approach as for the AMGr-style interpolation, as the second pass of coarsening does not add any points to the coarse grids chosen by Algorithm 3 and the nonzero pattern of interpolation is the same. The setup times for these problems are larger, due both to the second pass of coarsening (which still checks that all points have suitable connection to the coarse grid) and the more complicated definition of interpolation. The AMG-style interpo-

lation, however, produces solvers with lower convergence factors, so the extra setup time is roughly equally offset by the lower solve time. For the randomly discontinuous-coefficient problem, we see slightly higher grid and operator complexities, but these are more evenly distributed throughout the multigrid hierarchy, so there is no longer a significant slowing of the setup stage on finer grids. The resulting solvers are slightly less efficient than those of the smooth coefficient cases but still much better than those shown in Table 2. The anisotropic problem is also well handled by this algorithm, with larger grid and operator complexities consistent with geometric multigrid approaches to this problem. As with all of these examples, setup and solve times scale nicely with the increase in problem size, and the convergence factors grow slightly, but remain bounded well below unity.

4.2. ARMS. Effective two-level block factorizations, as discussed in Theorem 1, rely on good spectrally equivalent preconditioners for both the fine-scale block and Schur complement, $\hat{A}_{cc}$. To test the use of the diagonal-dominance-based coarsening scheme with approximate block-factorization preconditioners, we first consider two-level preconditioners, making use of the equivalence from Corollary 2 to handle the fine-scale preconditioning. Preconditioning of the Schur complement block is considered both exactly and using the variational coarse-grid operator as an approximation to $\hat{A}_{cc}$.

The requirement that $\left[\begin{smallmatrix} D_{ff} & -A_{fc} \\ -A_{fc}^T & A_{cc} \end{smallmatrix}\right]$ be positive semidefinite also arises in the theory for ARMS (cf. Theorem 1), so we begin by testing the two-level ARMS algorithm on the same PDE-based test problems as we did with AMGr. Some of the measures discussed above are again relevant, including the overall setup time (choosing the coarse grid, partitioning the fine-scale operator, computing the fine-scale preconditioner, and computing the coarse-scale operator). We test the two-level ARMS algorithm as a preconditioner for conjugate gradient (CG) by choosing a right-hand side, $\mathbf{b}$, to be the result of the matrix applied to the vector of all ones, $\mathbf{b} = A\mathbf{1}$, and a random initial guess. The number of iterations and time needed to reduce the A-norm of this error by a relative factor of 10^6 are also reported. Once again, these two-level results are computed using MATLAB with the reported times useful only for comparison between themselves and those in Table 1; the multilevel results that follow are computed using research C codes compiled with the appropriate optimization flags. The reported CPU times are accurate only to a few hundredths of a second and, so, are rounded to the nearest tenth of a second.

The coarse grids are selected using the same code and parameters as are used for the runs in Table 1, so the coarse-grid sizes presented here are the same as those (and are presented only for convenient reference). As in Theorem 1, the important quantities in bounding the condition number of the overall preconditioner are $\lambda_M = \lambda_{\max}(D_{ff}^{-1}A_{ff})$ and $\lambda_m = \lambda_{\min}(D_{ff}^{-1}A_{ff})$, the upper and lower spectral equivalence bounds for the fine-scale operators. We also report the condition number of the preconditioned system, $\kappa(B^{-\frac{1}{2}}AB^{-\frac{1}{2}}) = \frac{\lambda_{\max}(B^{-1}A)}{\lambda_{\min}(B^{-1}A)}$, as an indicator of the overall success of the preconditioner.

Table 4 shows details of the performance of two-level ARMS-preconditioned CG, using the exact Schur complement, on these model PDE problems. As observed with AMGr, Algorithm 3 effectively reduces the dimension of the fine-scale problem and produces a diagonal matrix, D_{ff}, that has good spectral equivalence to the fine-scale block, A_{ff}. Setup and solve times scale poorly, as expected, due to the time required to first compute the exact Schur complement and then to invert it for each

iteration. Iteration counts are stable as the problem size grows, and there is only slight growth in the condition numbers as the meshes are refined. The resulting condition numbers satisfy the bounds of Theorem 1, but these bounds are clearly not sharp. In particular, the upper bounds for these condition numbers are at least 100, while the largest observed condition number is just larger than 10. The lower bound, dependant only on the spectral equivalence of D_{ff} and A_{ff}, is a much better predictor of the true performance for these problems.

Table 5 shows details of the performance of two-level ARMS preconditioned CG, using variational approximations to the Schur complement, on these model PDE problems. The variational approximation is formed, as in AMGr, by taking the interpolation operator, $P = \begin{bmatrix} D_{ff}^{-1}A_{fc} \\ I \end{bmatrix}$, and then computing the approximation, $S = P^T AP$. As in Theorem 1, the spectral equivalence between S and $\hat{A}_{cc}$ plays an important role in the upper bound on the condition number of the preconditioned system. Here, we report the upper and lower spectral-equivalence bounds, ν_M and ν_m, along with the usual measures of performance. The fine-scale spectral-equivalence bounds, λ_M and λ_m, for these problems are the same as those appearing in Tables 1 and 4. The coarse-scale spectral-equivalence bounds for these problems are nicely controlled, with the upper bounds close to 1, and the lower bounds away from 0. Setup time again does not scale, as is expected from the increasing cost of computing the partitioning (without an efficient sorted data structure) and coarse-scale operator. Iteration times are very similar to those of two-level AMGr, as in Table 1, with a slightly larger factor of increase over that of the problem size. Iteration counts are steady, as are the condition numbers of the preconditioned operators. Once again, the bounds of Theorem 1 are loose bounds on the actual performance of the preconditioner; the lower bound does not take into account the role of the approximation to the Schur complement and, so, is unchanged from the case of an exact Schur complement, whereas the upper

bound increases slightly (by a factor of $\frac{1}{\nu_m}$) but remains significantly larger than the condition numbers that are observed.

4.2.1. PDE problems. To test the effectiveness of coarsening within ARMS using Algorithm 3 in a multilevel setting, we again consider PDE-based problems where the system matrix is symmetric, positive definite, and diagonally dominant (so that we are certain to satisfy all of the conditions of Theorem 1). As exact computation of the Schur complement on each level is prohibitively expensive, we first test the variational coarsening scheme used in Table 5. Here, GMRES is preconditioned by ARMS, and the number of iterations and time to solution needed to reduce the ℓ^2-norm of the residual by a relative factor of 10^6 are recorded. The time needed to set up the ARMS preconditioner is also reported, including time needed for choosing the coarse grids, computing the variational coarse-grid operators, and computing the exact Schur complement for the coarsest-grid operator, which is taken to be any operator which has dimension less than 10, or which is itself θ dominant. The parameter, θ, is again chosen to be 0.55. The ARMS preconditioner complexity (fill factor), c_B, defined to be the storage required for the ARMS preconditioner on all levels, divided by the number of nonzeros in the matrix A (and, thus, excluding the storage needed for A itself) is also recorded, as is the number of levels in the ARMS hierarchy.

Here, we use GMRES as the Krylov accelerator instead of CG for reasons of consistency. The ARMS algorithm has been developed with a focus on general matrices and not only symmetric problems [32, 30]. As such, GMRES has been the appropriate choice of accelerator. For these symmetric problems, using variational coarse-grid operators, we have chosen to use GMRES to remain consistent with this previous work. Additionally, while effort is made to retain some degree of symmetry in the ILU-based preconditioners to follow, symmetry may be sacrificed in favor of accuracy in the treatment of the coarsest levels (which may be quite large). In these cases, as well, GMRES is the only appropriate choice of Krylov subspace method. Thus, we have chosen to use it here, as well, for ease of comparison between these results. Nonsymmetric extensions of the approaches proposed here are considered (and compared to symmetric approaches) in [25].

Results for the multilevel-ARMS-preconditioned GMRES using variational coarse-grid operators and the greedy coarsening algorithm are shown in Table 6. Coarsening for the constant and smoothly varying cases are again the same, as they were in the multilevel AMGr results of Table 2. Counting the storage needed for the fine-scale operator itself, the operator complexities for all three problems are slightly higher than those of AMGr. Coupled with the added memory requirements of GMRES (storing one fine-scale vector per iteration), the 2048×2048 element mesh problems that were possible with AMGr are no longer tractable on a workstation with 2 Gigabytes of memory. Setup times are, in general, notably larger than AMGr for the same problem, with the only exception being the 1024×1024 mesh for the randomly discontinuous permeability where AMGr performed quite poorly. In all cases, iteration times for ARMS-preconditioned GMRES are larger than those for AMGr.

4.2.2. Combination with ILU-based coarsening. Theorem 1 also requires that $\left[\begin{smallmatrix} D_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{smallmatrix}\right]$ be nonnegative definite for the bounds on the condition number of the preconditioned system to hold. While this is true for all of the PDE problems tested in Table 6, it is not true for an anisotropic problem, such as when $K(x,y) = \left[\begin{smallmatrix} 1 & 0 \\ 0 & 0.01 \end{smallmatrix}\right]$. Testing the variational-coarsening-based ARMS as a preconditioner for GMRES on a 32×32 element mesh for this problem requires 911 iterations

TABLE 6
Performance of multilevel ARMS with variational coarsening on test matrices from discretizations of $-\nabla \cdot K(x,y)\nabla p(x,y)$.

Coefficient	Grid	# levels	c_B	t_{setup}	t_{solve}	# iters.

	1024×1024	9	0.96	11.9	52.8	66

to reduce the residual by a relative factor of 10^6. To achieve the robustness we would like from our preconditioner, we turn to the full power of the ARMS approach [30], using an ILU factorization in place of the diagonal D_{ff}. Because we have partitioned A specifically so that the A_{ff}-block is diagonally dominant, we expect to be able to find a suitably sparse ILU factorization that provides both better spectral equivalence to A_{ff} than is possible with a diagonal matrix and a better approximate Schur complement. This combination should then result in a more robust preconditioner than is possible with a diagonal D_{ff}.

Since the fine-scale operators from these PDE problems are symmetric, certain savings are natural in the coarse-grid selection algorithm. In particular, when a coarse-grid node, j, is selected from the set, U, we need only look at the nonzero elements in row j of the matrix to find the nodes whose measures need updating. This is particularly easy when using a compressed-sparse-row storage format, as these indices and the appropriate updates are easily available. In the general (nonsymmetric) case, the update is not as convenient (when using compressed sparse row storage), as a search for nonzero entries in column j must be done, requiring either extra storage or extra computation. To ensure this advantage is maintained, a modification of the ILUT procedure is used in order to ensure that a symmetric dropping strategy is employed. Here, the ILU factorization of A_{ff} is computed using the ILUT algorithm (dropping based both on size and rowwise fill factors [31]), but the U factor in $A_{ff} \approx LDU$ is replaced by L^T. The matrix product $L^{-1}A_{fc}$ is easily computed at the same time as the factorization of A_{ff}, by applying the elimination to the extended matrix, $[A_{ff},\ -A_{fc}]$. The Schur complement can then be computed rowwise from the matrix equation, $S = A_{fc} - (L^{-1}A_{fc})^T D^{-1}(L^{-1}A_{fc})$. In order to control sparsity directly within S, we precompute the diagonal entries of S, allowing dropping based on size, using the symmetric drop criterion, $s_{ij} \leq \alpha\sqrt{s_{ii}s_{jj}}$. Dropping based on level of fill is also possible [22] but not used in the examples presented here.

Table 7 shows the results for the ARMS-preconditioned GMRES algorithm based on symmetrized ILUs. The drop tolerance, α, is chosen to be either 0.01 or 0.1 for both the ILU factorization of A_{ff} and the approximate Schur complement calculation. Choosing α appropriately requires a balance between accuracy of the ILU approximation to A_{ff} and the fill of the resulting preconditioner. Typically, choosing α to be relatively small results in a more effective preconditioner, but a larger value of α results in a smaller preconditioner complexity, c_B, which is useful for large problems

TABLE 7

*Performance of multilevel ARMS with symmetric ILU-based coarsening on test matrices from discretizations of $-\nabla \cdot K(x,y)\nabla p(x,y)$. Results marked with a * indicate that the residual reduction criterion was a relative factor of 10^4 instead of 10^6.*

where memory limitations are restrictive. A further dropping rule is applied to each row of L, allowing no more than twice the average number of nonzeros in a row of A. Again, $\theta = 0.55$, and the coarsening is continued until either the coarse-grid operator has fewer than 10 degrees of freedom or is itself θ dominant.

The robustness of the ILU-based approach comes at a cost in increased memory consumption, reflected in the higher operator complexities for the results in Table 7, as compared to those in Table 6. For the smooth isotropic coefficients, only one coarsening was performed, because of the resulting θ-dominance of the coarse-grid operator. This behavior is largely independent of the choices of α and the row-based fill threshold, only changing if θ was measurably changed. As a result, the operator complexities for these problems are somewhat large, over 2 when $\alpha = 0.01$. In order to perform any meaningful number of iterations on the 1024×1024 element mesh problems, it is necessary to choose $\alpha = 0.1$ to reduce the fill. Even then, memory limitations prevented reducing the residual by a relative factor of 10^6, and a smaller reduction, by a relative factor of 10^4 is used instead. GMRES performance (residual reduction per iteration) for these problems does tend to get worse as the iterations proceed and, so, the number of iterations recorded for these large problems is significantly fewer than the number that would be needed for a reduction by a relative factor of 10^6.

Comparing performance between these four problems, however, shows the robustness of the combination of the greedy coarsening algorithm with ILU-based ARMS, which will be further demonstrated in section 4.2.3. Preconditioner complexities, a primary factor in memory limitations, are controlled by the parameter, α. Setup times are generally comparable across the different problems (for the same α), as are solution times and iteration counts. In fact, the problems which caused most difficulty for the variational coarse-grid operator approach are now more efficient than the smoothly varying coefficient problems that were most efficient. The structure of these problems appears to naturally lead to deeper ARMS hierarchies, yielding lower preconditioner complexities and, thus, lower costs per iteration.

Comparing the results for AMG (Table 3) to those for ARMS (Table 7), we see that both generally perform well for these PDE-based problems, but that the AMG approach appears to be more efficient. ARMS requires storage of part of the

TABLE 8
Performance of multilevel ARMS with symmetric ILU-based coarsening on test matrices with $\theta = 0.55$, drop tolerance of 0.01, average fill factor of 5, and a maximum of 10 levels of coarsening.

operator on each level, plus the ILU factors of each fine-grid block, while AMG requires storage of only the operators, as relaxation on each level is determined entirely by these operators. The ability of AMG to run as an iteration by itself, instead of as a preconditioner for a Krylov subspace method, also reduces its memory overhead, although the ARMS preconditioners used here could be modified for use with CG instead of GMRES, ameliorating this effect. Overall solve times and iteration counts are also much lower for the AMG approach. This is not surprising, as multigrid techniques are largely focused on solving PDE-based problems such as these. The ARMS approach, on the other hand, is motivated by purely algebraic consideration, and, so, we expect it to not perform as well as AMG on PDE-based problems, but to exhibit robustness that the AMG approach may not have.

4.2.3. General sparse symmetric systems. To further test the robustness of the ARMS approach, we consider a subset of the matrices from the test set of [18, 19]. As we are interested primarily in matrices that are not naturally diagonally dominant, we consider only those symmetric and positive-definite matrices for which full data is available (i.e., we do not consider matrices for which only a nonzero pattern is given). In order to run all tests on a single machine (dual-processor Intel Xeon 3.0 GHz with 2 GBytes of RAM), we test all problems with fewer than 3 million nonzero entries. By using swap space, convergence results for one problem with approximately 3.5 million nonzero entries, `oilpan`, are also obtained.

Results in Table 8 show the performance of ARMS-preconditioned GMRES for these matrices. As a first test, we take the parameters for ARMS to allow significant fill in the preconditioner, B, thus looking at the case where accuracy in computing B is not a significant factor in ARMS performance. Diagonal-dominance parameter θ was chosen to be 0.55, as in the PDE-based problems above. The ILU drop tolerance, α, was taken to be 0.01, and further dropping is done so that no row of the approximate L factor has more than 5 times the average number of nonzeros per row of A_{ff} in it. A maximum of 10 levels is allowed, with the coarsest-grid operator computed using

ILUTP with $\alpha = 0.0001$ and fill per row restricted to 20 times the average number of nonzeros per row of the coarsest-grid operator. ILUTP is a pivoting variant of the ILUT algorithm discussed above [31]; elements in the elimination are again filtered by size and fill per row, but a column pivoting step is added for each row to improve the stability of the factorization. With these parameters, ARMS failed to reduce the norm of the residual by a relative factor of 10^6 before memory limitations were reached for only three of the twenty-two problems.

Table 8 reports the complexities (fill factors), c_B, of the resulting preconditioners, setup and iteration times (in seconds), and number of iterations needed to reduce the norm of the residual by a relative factor of 10^6 for the nineteen problems that did converge. As these problems arise from many different applications, it is difficult to make comparisons across different problems, in particular, between smaller and larger problems. We do see quick convergence with low preconditioner complexities for a number of problems, however. For the problems with slower convergence, those with low preconditioner complexities allow many iterations within a short period of CPU time, making the overall time to solution acceptable. For a few of the problems with preconditioner complexities greater than 3, solution was still possible before running into memory limitations. The three problems for which convergence was not obtained, `bcsstk36` ($nnz = 1143140$, $c_B = 10.63$), `msc23052` ($nnz = 1154814$, $c_B = 9.83$), and `nasasrb` ($nnz = 2677324$, $c_B = 4.80$), the large preconditioner complexities coupled with the large initial problem sizes required termination of the iterations before convergence. Slow but steady convergence was seen for `msc23052` and `nasasrb` before iterations were stopped. Only iteration on `bcsstk36` was ineffective in reducing the residual substantially in 6100 iterations before memory limitations were reached.

Experiments with larger drop tolerances (e.g., $\alpha = 0.05$ or $\alpha = 0.1$) show good decreases in preconditioner complexity, but poor performance of the resulting preconditioners. Thus, in Table 9, we look to reduce the preconditioner complexities by allowing each row of L to have only twice as many nonzeros as an average row of A_{ff}, by allowing more levels (up to 50), and by using a smaller $\theta = 0.51$ in the resulting preconditioners. For some problems, these results are equivalent to those in Table 8, up to measurement errors in the times reported. For the problems with large preconditioner complexities in Table 8, the preconditioner complexities are now lower (although still possibly large). This reduction of complexity, however, is (as expected) correlated with an increase in iteration counts and overall time-to-solution (although this is not always the case; cf. `vanbody` and `cvxbqp1`). Setup and solution times are comparable for the problems with fewer than one million nonzeros, although, in some cases, notable growth in c_B and setup time are also seen. For the larger problems, results are slightly mixed. A few more iterations are needed for `cfd1` and `oilpan`, resulting in slightly higher solution times, whereas a much lower preconditioner complexity results in lower setup and solution times for `vanbody`. The lower preconditioner complexities for `bcsstk36` and `msc23052` result in sufficient residual reduction to meet the convergence criteria before available memory (including swap space) is filled. A slightly lower preconditioner complexity for `nasasrb`, 4.36, was obtained for these parameters, but memory considerations still forced early termination of the run, with a residual reduction by a relative factor of approximately 3.35×10^4 in 2500 iterations.

4.2.4. A comparison with AMG and ILUTP. As discussed in section 4.2.2, AMG is expected to perform better than ARMS in some cases (particularly for ma-

trices arising from discretization of elliptic PDEs), but ARMS is generally expected to be more robust. That is, we expect that the loss in efficiency of ARMS for certain problems will be offset by more consistent performance on a general collection of problems, such as those in Tables 8 and 9. To test this expectation, Table 10 gives the performance of classical AMG on the general problems of the previous section. Here, the two-stage coarsening algorithm using greedy coarsening as a first pass with $\theta = 0.55$ and strength threshold $\beta = 0.3$ is used to select the coarse grid and interpolation stencil, while the classical (Ruge–Stüben) algorithm is used to define the interpolation weights. A single full-grid sweep of Gauss–Seidel relaxation is used on each level descending and ascending the V-cycle. To ensure the multigrid hierarchy fits in available memory, 10 sweeps of relaxation are used to "solve" the coarsest-grid problem, instead of computing the (sometimes large, dense) LU factorization of the coarsest-grid operator.

Comparing the AMG and ARMS results for these problems, we see that AMG results in a faster overall time to solution for only five problems. For problems `obstclae`, `jnlbrng1`, and `minsurfo`, the setup time for AMG is one-third faster and solve times the same as those in Table 8. For these three problems, the AMG operator complexities are also close to the ARMS preconditioner complexities, reflecting similar overall memory costs, especially as the AMG operator complexity includes the storage for the original fine-scale operator, not counted in the ARMS fill factors. AMG outperforms ARMS on matrix `cvxbqp1`, although this really reflects better, but still bad, performance. The low AMG operator complexity for this problem allows AMG to converge in less time than ARMS but, with over ten thousand iterations required to reduce the residual by a relative factor of 10^6, AMG performance can hardly be called acceptable. Finally, the reduced storage costs of AMG compared to ARMS-preconditioned GMRES allows AMG to converge on the `nasasrb` matrix, although with a large operator complexity and many iterations.

TABLE 10
Performance of multilevel AMG V(1,1) cycles on test matrices with full-grid Gauss–Seidel relaxation, two-stage greedy coarsening using $\theta = 0.55$ and $\beta = 0.3$, a maximum of 20 levels of coarsening, with the coarsest-grid problem solved by 10 sweeps of relaxation.

For the remaining problems, AMG is generally worse in terms of both storage factors (or cost per iteration) and iteration count. The operator complexities for AMG are often larger than ten times the storage of the fine-grid operator, and as much as eighty times this storage is needed. Iteration counts are over ten thousand for three problems and are often many times those used for ARMS. Put simply, there is no reason to expect that the assumptions made in classical AMG on the slow-to-converge modes of Gauss–Seidel relaxation are valid for these general problems and, as a result, the AMG interpolation scheme may provide an arbitrarily bad complement to this relaxation. While the parameters of the AMG methodology may be tuned to improve performance on any one of these problems, the results in Table 10 clearly show the lack of robustness of AMG when used as a black-box solver, in comparison to the relatively good results seen in Tables 8 and 9.

For comparison with a single-level preconditioning strategy, we also look at the performance of (nonsymmetrized) ILUTP on these same test problems in Table 11. In order to make fair comparisons between the multilevel ILU strategy in ARMS and that in ILUTP, we choose the parameters of ILUTP, notably α, the drop tolerance, such that the overall preconditioner complexity is roughly the same as those in Table 9. We limit the number of nonzero entries in each row of L and U^T to be no more than 20 times the average number of nonzeros per row of A. This is done so that the choice of α is used as the primary control over the preconditioner complexities; α is varied in increments of 0.0025 to give the operator complexity closest to those of Table 9. We also report the preconditioner complexities, setup and solve times, and number of iterations to reduce the residual by a relative factor of 10^6. For each problem, we allow at most twice the number of iterations that ARMS-preconditioned GMRES took to converge in Table 9, unless that would require too much memory (i.e., for the problems where swapping was required), in which case the limit is the number of iterations that

ARMS-preconditioned GMRES took to converge. The residual reduction factors for the problems that did not converge are reported in the final column of Table 11.

Comparing the results from Tables 9 and 11, we see that the ARMS-preconditioning approach often, but not always, pays off relative to ILUTP-preconditioned GMRES. In terms of total time to solution, the two strategies tie for a single problem (`bcsstk25`), the ARMS-preconditioners are faster for sixteen problems, while ILUTP yields faster solvers for four problems. In terms of number of iterations (closely related to iteration time as the preconditioner complexities are approximately equal for each problem), ILUTP-preconditioned GMRES required fewer iterations for five problems, with one tie and the ARMS preconditioner requiring fewer iterations for fifteen problems. Of these fifteen problems, ILUTP converged before iteration and memory limits were reached for only six problems. For the remaining nine problems, ARMS was significantly better than ILUTP. On three of the test matrices, not only did ILUTP not converge in double the number of iterations that ARMS required, but it did not succeed in reducing the norm of the residual by a factor of even half that required for convergence. On the two most difficult problems for which ARMS was successful, `bcsstk36` and `msc23052`, ILUTP was unable to reduce the residual by a factor of 10 in the same number of iterations that ARMS required for a reduction by a relative factor of 10^6. For the `nasasrb` matrix that caused ARMS the most difficulty, ILUTP reduced the residual by a factor of 2.02 in the same number of iterations it took ARMS to reduce the residual by a factor of 3.4×10^4.

5. Conclusions. Motivated by a theoretical analysis, a new coarsening algorithm for algebraic multigrid and multilevel solvers is proposed. This greedy algorithm partitions the degrees of freedom so that the fine-grid block satisfies some diagonal dominance properties, and, thus, can be easily treated by relaxation or an ILU factorization. Numerical results show that two-level solvers based on this technique exhibit optimal convergence properties. Multilevel solvers based on simple grid-transfer oper-

ators perform well for simple model problems but break down when certain theoretical assumptions are violated. When used in combination with coarsening ideas from the usual AMG and ARMS methodologies, the resulting algorithms achieve improved robustness, demonstrated on both PDE-based problems and test problems from a variety of sources.

A TRUST REGION DIRECT CONSTRAINED MINIMIZATION ALGORITHM FOR THE KOHN–SHAM EQUATION*

CHAO YANG†, JUAN C. MEZA†, AND LIN-WANG WANG†

Abstract. The self-consistent field (SCF) iteration, widely used for computing the ground state energy and the corresponding single particle wave functions associated with a many-electron atomistic system, is viewed in this paper as an optimization procedure that minimizes the Kohn–Sham (KS) total energy indirectly by minimizing a sequence of quadratic surrogate functions. We point out the similarity and difference between the total energy and the surrogate, and show how the SCF iteration can fail when the minimizer of the surrogate produces an increase in the KS total energy. A trust region technique is introduced as a way to restrict the update of the wave functions within a small neighborhood of an approximate solution at which the gradient of the total energy agrees with that of the surrogate. The use of trust regions in SCF is not new. However, it has been observed that directly applying a trust region-based SCF (TRSCF) to the KS total energy often leads to slow convergence. We propose to use TRSCF within a direct constrained minimization (DCM) algorithm we developed in [*J. Comput. Phys.*, 217 (2006), pp. 709–721]. The key ingredients of the DCM algorithm involve projecting the total energy function into a sequence of subspaces of small dimensions and seeking the minimizer of the total energy function within each subspace. The minimizer of a subspace energy function, which is computed by the TRSCF, not only provides a search direction along which the KS total energy function decreases, but also gives an optimal "step length" that yields a sufficient decrease in total energy. A numerical example is provided to demonstrate that the combination of TRSCF and DCM is more efficient than SCF.

1. Introduction. The self-consistent field (SCF) iteration is the most widely used procedure for computing the ground state energy and the corresponding single particle wave functions associated with a many-electron atomistic system. The procedure is often viewed as a fixed point iteration in which a sequence of linear eigenvalue problems is solved approximately. The approximate eigenvectors computed in the jth iteration are used to construct the potential component of the Kohn–Sham (KS) matrix Hamiltonian required in the $(j+1)$th iteration. Convergence is reached when the difference between Hamiltonians formed in two consecutive iterations becomes negligible. At this point, the eigenvalues and eigenvectors of the Hamiltonian become self-consistent and the KS total energy function associated with the system reaches the global minimum.

It has long been observed that the simplest form of SCF iteration often fails to converge. As such, a number of heuristics have been developed to prevent the

SCF from diverging. These heuristics often involve combining either the potential or the charge densities computed in the previous SCF iterations to construct a new Hamiltonian so that the lack of self-consistency can be minimized. These techniques are known either as [illegible] [13, 15] in the material sciences community or as the direct inversion of iterative subspace (DIIS) extrapolation technique [24, 25] in the quantum chemistry community. Although these heuristics work remarkably well in stabilizing the SCF iteration for many problems, they can still fail in others. Even when they work, the reduction in the KS total energy is often not monotonic. Furthermore, no satisfactory theoretical foundation has been established to explain why charge mixing and DIIS work and under what circumstances they can fail. As a result, the convergence of SCF is often unpredictable for large atomistic systems with small (valence/conducting) band gaps.

In this paper, we will examine SCF from an optimization point of view. We view the SCF iteration as an indirect way to minimize the KS total energy function through the minimization of a sequence of quadratic surrogate functions. We point out the similarity and difference between the surrogate and the true objective function and introduce the concept of a [illegible] that can be used to restrict the update of the wave functions within a region in which the gradients associated with the true object and the surrogate differ very little. The trust region technique is a widely used methodology for promoting global convergence in numerical optimization procedures [5, 20]. Trust region-based SCF (TRSCF) iteration has been used in the past in the quantum chemistry community [28, 31], where it is sometimes called [illegible] SCF iteration [28].

By imposing a trust region with an appropriate radius at each SCF iteration, we can show that a monotonic reduction of the KS total energy can be achieved in the SCF procedure. However, it has been observed that for large systems, the use of TRSCF often leads to extremely slow convergence. In [31], the trust region technique is combined with DIIS to accelerate the convergence of SCF. In this paper, we propose a different approach. Instead of applying the trust region technique directly to an SCF iteration, we use it within a direct constrained minimization (DCM) algorithm developed in [36] to generate an effective search direction and step length simultaneously. This scheme is applicable to density functional theory (DFT) calculations in which the number of degrees of freedom in the discretized wave function is much larger than the number of electrons in the atomistic system.

The paper is organized as follows. In section 2, we establish some basic notation required for the discussion of SCF and DCM. In section 3, we examine the SCF iteration from an optimization point of view and provide the motivation for applying the trust region technique in SCF. A TRSCF iteration is presented in section 4. We discuss the use of TRSCF within the DCM algorithm in section 5. A numerical example is provided in section 6 to demonstrate the value of the trust region technique in KS total energy minimization.

2. Background and notation. In this section, we establish the mathematical notation required to describe the SCF and DCM algorithms. We skip the description of the continuous formulation of the KS total energy optimization problem, which has been presented in [36] and many other references [15, 16, 23]. Instead, we will focus on the finite-dimensional version of the problem.

In the following discussion, we will use A^T to denote the transpose of a matrix A, and A^* to denote the complex conjugate of A. A submatrix of A consisting of rows i through j and columns p through q will be denoted by $A(i:j, p:q)$. If the

submatrix contains all rows (columns) of A, it will be denoted by $A(:, p:q)$ (resp., $A(i:j,:)$). The Frobenius norm of a matrix A (defined as the square root of the sum of the absolute squares of all elements in A) is denoted by $\|A\|_F$.

With an appropriate discretization scheme, a single electron wave function can be approximated by a vector $x_i \in \mathbb{C}^n$, where n is the spatial degrees of freedom, i.e., the number of real space grid points. These vectors satisfy the orthonormality constraints

$$x_i^* x_j = \delta_{i,j}, \quad i,j = 1,2,\ldots,k,$$

where k is the number of occupied states. If we let $X = (x_1, x_2, \ldots, x_k)$, the matrix

$$D(X) = XX^* \tag{2.1}$$

is often known as the density matrix, and the charge density associated with the k occupied states can be expressed by

$$\rho(X) = \mathrm{diag}(XX^*), \tag{2.2}$$

where $\mathrm{diag}(A)$ denotes a column vector consisting of diagonal entries of the matrix A.

The KS total energy function consists of several components [23], i.e.,

$$E_{total}(X) = E_{kinetic}(X) + E_{ion}(X) + E_H(X) + E_{XC}(X),$$

where $E_{kinetic}$ is the kinetic energy and E_{ion}, E_H, and E_{XC} are potential energies induced by the electron-ion interaction (ionic potential), the electron-electron interaction (Hartree potential), and the exchange correlation potential, respectively.

Let $L \in \mathbb{C}^{n\times n}$ be a Hermitian matrix representing a discretized Laplacian operator. The kinetic energy is then defined by [23]

$$E_{kinetic}(X) = \frac{1}{2}\mathrm{trace}(X^* L X).$$

The ionic potential energy consists of a local and a nonlocal term. If we let D_{ion} be a real diagonal matrix representing a discretized local ionic potential function, then the local ionic potential energy is defined by [23]

$$E_{ion(local)}(X) = \mathrm{trace}(X^* D_{ion} X).$$

The contribution from the nonlocal ionic potential is defined by [23]

$$E_{ion(nonlocal)}(X) = \sum_i \sum_\ell \left| x_i^* w_\ell \right|^2,$$

where w_ℓ represents a discretized pseudopotential reference projection function.

In practice, appropriate boundary conditions are imposed so that L is nonsingular. If we use S to denote the inverse of the discrete Laplacian operator, then the Hartree potential energy, which is used to model the classical electrostatic average interaction between electrons, can be expressed [23] by

$$E_H(X) = \frac{1}{2}\rho(X)^T S\, \rho(X).$$

The exchange correlation function ϵ_{xc} is used to model the nonclassical interaction between electrons. The potential energy induced by this function is defined by [23]

$$E_{XC}(X) = e^T\big(\epsilon_{xc}[\rho(X)]\big),$$

where e is a column vector of ones.

Using the notation established above, we can state the KS total energy minimization problem as

$$\begin{aligned} \min \quad & E_{total}(X) \\ \text{s.t.} \quad & X^*X = I_k, \end{aligned} \tag{2.3}$$

where I_k denotes a $k \times k$ identity matrix.

The Lagrangian associated with (2.3) is

$$\mathcal{L}(X) = E_{total}(X) - \operatorname{trace}\big[\Lambda^T(X^*X - I_k)\big], \tag{2.4}$$

where Λ is a $k \times k$ matrix containing the Lagrange multipliers associated with the constraints specified by $X^*X = I_k$ [20].

The solution to (2.3) must satisfy the first order necessary conditions

$$\begin{aligned} \nabla_X \mathcal{L}(X) &= 0, \\ X^*X &= I_k. \end{aligned} \tag{2.5}$$

Here, $\nabla_X \mathcal{L}$ represents an $n \times k$ matrix whose (i,j)th entry is the partial derivative of $\mathcal{L}$ with respect to the (i,j)th entry of X.

It is easy to verify that

$$\nabla_X E_{kinetic} = \frac{1}{2}LX, \tag{2.6}$$

$$\nabla_X E_{ion(local)} = D_{ion}X, \tag{2.7}$$

$$\nabla_X E_{ion(nonlocal)} = \sum_{\ell}(w_\ell w_\ell^*)X, \tag{2.8}$$

$$\nabla_X E_H = \operatorname{Diag}(S\rho(X))X, \tag{2.9}$$

$$\nabla_X E_{XC} = \operatorname{Diag}(\mu_{xc}(\rho))X, \tag{2.10}$$

where

$$\mu_{xc}(\omega) \equiv \frac{d\epsilon_{xc}(\omega)}{d\omega}$$

is the derivative of the exchange-correlation function. Here the notation $\operatorname{Diag}(\rho)$ represents a diagonal matrix whose diagonal is determined by the vector ρ, and we have scaled (2.6)–(2.10) by $1/2$ to be consistent with the convention used in the electronic structure community.

Substituting (2.6)–(2.10) into (2.5), we obtain the KS equation

$$H(X)X = X\Lambda_k, \qquad X^*X = I_k, \tag{2.11}$$

where

$$H(X) = \left[\frac{1}{2}L + D_{ion} + \sum_{\ell} w_\ell w_\ell^* + \operatorname{Diag}(S\rho) + \operatorname{Diag}(\mu_{xc}(\rho))\right]. \tag{2.12}$$

Because the vector ρ in (2.12) depends on X, the eigenvalue problem defined by (2.11) is nonlinear. Also note that the solution to (2.3) is not unique. If X is a solution, then XQ is also a solution for any $Q \in \mathbb{C}^{k\times k}$ such that $Q^*Q = I_k$. That is, the solution to the constrained minimization problem, or, equivalently, the nonlinear equations defined by (2.11), is a k-dimensional invariant subspace in $\mathbb{C}^n$ rather than a specific matrix. In particular, Q can be chosen such that Λ_k is diagonal. In this case, X consists of k KS eigenvectors associated with the k smallest eigenvalues of $H(X)$.

3. The optimization view of SCF. Although the nonlinear eigenvalue problem defined by (2.11) may appear easier to solve than (2.3) because of its close connection to a linear eigenvalue problem, there is yet no robust and efficient general-purpose solver for this type of problem with guaranteed convergence. The most widely used technique for solving (2.11) is to reduce it to a sequence of linear eigenvalue problems that can be solved by many numerical linear algebra software packages such as LAPACK [1] or ARPACK [18]. This approach is often known as the SCF iteration. For completeness, we outline the major steps of the basic version of the SCF iteration procedure in Figure 3.1.

SCF ITERATION

Input: The matrices L, D_{ion}, S, and the vectors w_ℓ, $\ell = 1, 2, \ldots$. The derivative of the exchange-correlation function $\mu_{xc}(x)$; an initial guess $X^{(0)}$ for the optimal wave function $X \in \mathbb{C}^{n\times m}$;

Output: $X \in \mathbb{C}^{n\times m}$ such that $X^*X = I_m$ and $E_{tot}(X)$ is minimized, where $E_{tot}(X)$ is defined by (2.6)–(2.10).

1. for $i = 1, 2, \ldots$ until convergence
2. Form $H^{(i)} = H(X^{(i-1)})$;
3. Compute $X^{(i)}$ such that $H^{(i)}X^{(i)} = X^{(i)}\Lambda^{(i)}$, and $\Lambda^{(i)}$ contains the k smallest eigenvalues of $H^{(i)}$;
4. end for

FIG. 3.1. *The SCF iteration.*

Depending on the discretization scheme used, it may not be necessary or possible to form the Hamiltonian $H^{(i)}$ explicitly in the SCF calculation. This is particularly true when the continuous problem is discretized by a spectral method using a plane wave basis. In that case, $H^{(i)}$ exists only in the form of a matrix vector multiplication procedure, and it is not feasible to solve the linear eigenvalue problem $H^{(i)}X^{(i)} = X^{(i)}\Lambda^{(i)}$ by using subroutines provided in LAPACK [1]. Iterative methods such as the Lanczos [17, 18, 35], preconditioned conjugate gradient [14, 12, 27], the Jacobi–Davidson type of method [6, 21, 26, 29], or multigrid accelerated Rayleigh-quotient iterations [3, 8, 11] are often used in this setting.

Because computing the k smallest eigenpairs of the discrete Hamiltonian $H^{(i)}$ is equivalent to solving the trace minimization problem

$$\begin{aligned} \min \quad & q(X) = \tfrac{1}{2}\mathrm{trace}(X^*H^{(i)}X) \\ \text{s.t.} \quad & X^*X = I_k, \end{aligned} \tag{3.1}$$

the SCF iteration can be viewed as an iterative procedure that minimizes the total energy E_{total} indirectly by minimizing a sequence of quadratic functions of

the form (3.1). Note that the discrete Hamiltonian $H^{(i)}$ is formed by using a fixed set of wavefunctions, $X^{(i-1)}$, computed in the previous SCF iteration.

At $X = X^{(i-1)}$, the gradient of the quadratic surrogate agrees with that of E_{total}, i.e.,

$$\nabla E_{total}(X)_{|X=X^{(i-1)}} = \nabla q(X)_{|X=X^{(i-1)}} = H^{(i)}X^{(i-1)}, \tag{3.2}$$

even though $E_{total}(X^{(i-1)})$ may be completely different from $q(X^{(i-1)})$ in general.

The gradient match between $E_{total}(X)$ and $q(X)$ at $X = X^{(i-1)}$ should come as no surprise because such a match is achieved by construction. A direct consequence of (3.2) is that, at least within a small neighborhood of $X^{(i-1)}$, a reduction of $q(X)$ is likely to result in a reduction in $E_{total}(X)$. However, if one moves too far away from $X^{(i-1)}$, $E_{total}(X)$ may actually increase because gradient matching does not hold in general when X is away from $X^{(i-1)}$.

This optimization view of the SCF iteration suggests the danger of minimizing the quadratic surrogate (3.1) by computing the k smallest eigenpairs of $H^{(i)}$. To illustrate this possibility, we will now give a concrete two-dimensional example below to demonstrate how SCF may fail to converge. Consider a simplified total energy function of the form

$$E_{total}(x) = \frac{1}{2}x^T Lx + \frac{\alpha}{4}\rho(x)^T L^{-1}\rho(x), \tag{3.3}$$

where

$$L = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}, \quad x = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}, \quad \text{and} \quad \rho(x) = \begin{pmatrix} x_1^2 \\ x_2^2 \end{pmatrix}$$

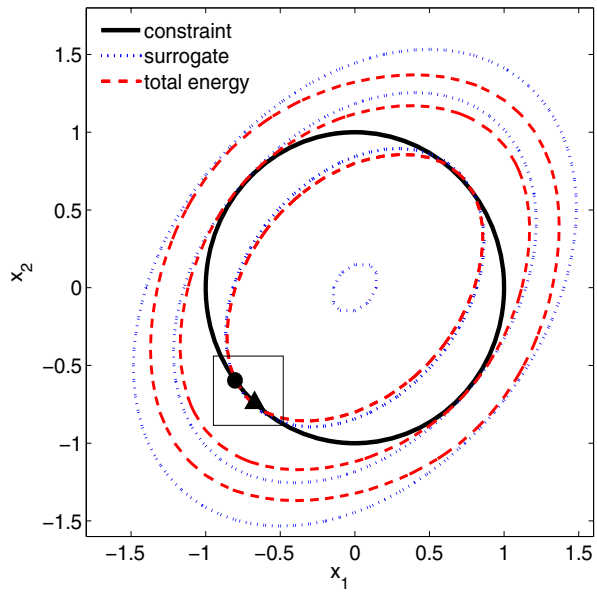
is used as our objective function, to be minimized subject to the constraint

$$x_1^2 + x_2^2 = 1. \tag{3.4}$$

Note that we deliberately ignored the ionic and exchange-correlation potentials to make this example simple enough for testing. As a result, both the total energy and the quadratic surrogate functions are convex, which may not necessarily be the case in general. Nonetheless, these examples exhibit the local convergence behavior of SCF.

When we set $\alpha = 2$ in (3.3), the simplest version of SCF algorithm shown in Figure 3.1 converges in 10 iterations. In Figure 3.2(a), we plot the contour of (3.3) (dashed contour) as well as that of the quadratic surrogate (dotted contour) constructed at the current approximation $\hat{x} = (\hat{x}_1, \hat{x}_2)^T = (-0.8033, -0.5956)^T$. The position of $\hat{x}$ is marked by a small solid circle in the figure. The minimizer of the quadratic surrogate $\hat{x}_q$ is marked by a small solid triangle. Both $\hat{x}$ and $\hat{x}_q$ lie on the large circle which corresponds to the constraint (3.4).

If we zoom into the box shown in Figure 3.2(a), we can see how the total energy changes as we move from $\hat{x}$ (the small solid circle, where the gradient of $E_{total}(x)$ matches the gradient of the quadratic surrogate) to $\hat{x}_q$ (the solid triangle, at which the dotted elliptical contour becomes tangent to the large circle). Figure 3.2(b) shows that the minimizer of the quadratic surrogate, $\hat{x}_q$, lies on the total energy contour (dashed) line that is above and to the right of the dashed contour line that passes $\hat{x}$. Because the total energy in this example is convex, this implies that moving from the current approximation $\hat{x}$ to $\hat{x}_q$ results in a reduction of the total energy. For reference purposes, we also plot the true minimizer of (3.3) as a small solid square in Figure 3.2(b).



(a)

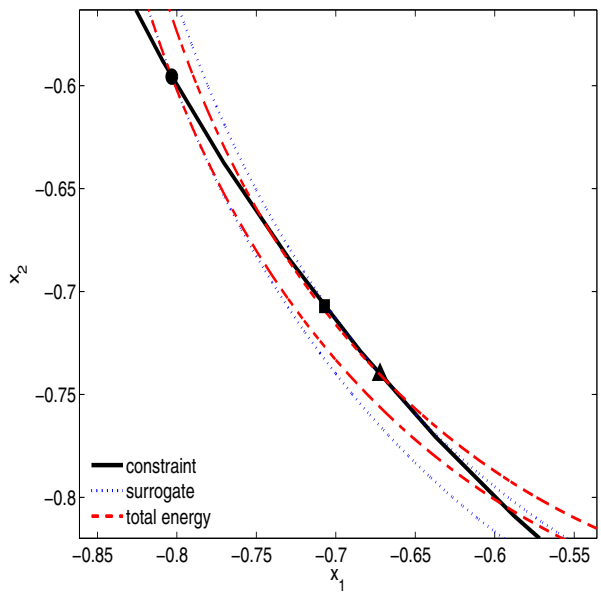
FIG. 3.2. (a) *When $\alpha = 2$ is set in* (3.3)*, the SCF iteration converges. This figure shows the change of $E_{total}(x)$ in a single SCF iteration. The contours of the total energy defined in* (3.3) *and the surrogate $q(x) = \frac{1}{2}x^T(L + \alpha \mathrm{Diag}(L^{-1}\rho(x)))x$ for $\alpha = 2$. The current iterate $\hat{x}$ is marked by the small solid circle at which $\nabla E_{total}(\hat{x}) = \nabla q(\hat{x})$. The minimizer of $q(x)$ is marked by the solid triangle. Both of these points lie on the large circle which defines the orthonormality constraint* (3.4).

When we increase α to 12, the contour of (3.3) becomes less elliptical, as we can see in Figure 3.3(a). Figure 3.3(a) also shows the quadratic surrogate constructed from the current approximation (marked by a small solid circle) $\hat{x} = (\hat{x}_1, \hat{x}_2)^T = (-0.8904,\ -0.4551)^T$, as well as the location of $\hat{x}_q$ (marked by the solid triangle). The small solid square indicates the location of the true minimizer of (3.3) for $\alpha = 12$. All of these three points lie on the orthonormality constraint shown as the large circle in this figure.

As we zoom into the rectangular box shown in Figure 3.3(a), we can see more clearly why a single SCF iteration from $\hat{x}$ leads to an increase in (3.3). In Figure 3.3(b), which provides a zoom-in view, we can clearly see that the dashed contour line that passes through $\hat{x}_q$ lies to the lower left of the curve that passes through $\hat{x}$. This implies an increase in the total energy (3.3) as we move from the current approximation $\hat{x}$ to the minimizer of the surrogate $\hat{x}_q$.

Fortunately, the optimization view of the SCF iteration also suggests at least two ways to improve the convergence of a SCF:

1. develop a better surrogate function,
2. restrict the wave function update in a small neighborhood of the current approximation.

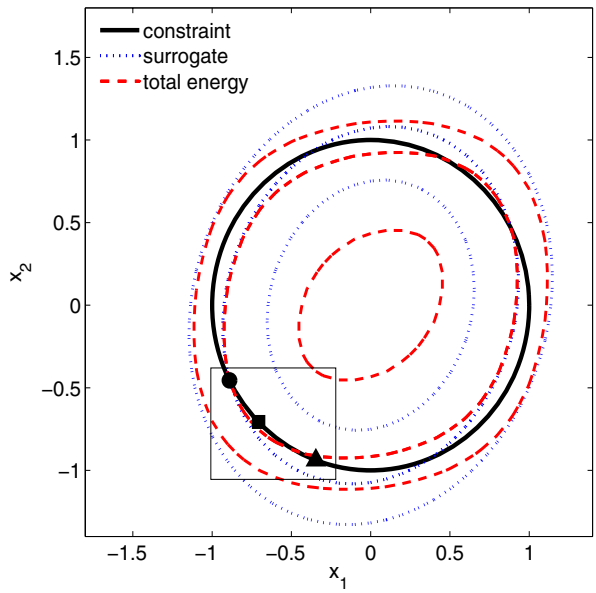


(b)

FIG. 3.2(*continued*). (b) *When* $\alpha = 2$ *is set in* (3.3), *the SCF iteration converges. This figure shows the change of* $E_{total}(x)$ *in a single SCF iteration. A zoom-in view of the boxed area in Figure* 3.2(a). *The minimizer of* $q(x)$ *(the small solid triangle) lies on the inner dashed contour line, indicating a decrease in the total energy. The solid square marks the true minimizer of* E_{total}.

One typical approach is to use the second order Taylor approximation to total energy as the surrogate model. The iterative method based on this quadratic model is the familiar Newton's method. However, due to the high cost associated with Hessian computation, this approach is not practical. Although it is possible to apply a limited memory version of a quasi-Newton method to minimize $E_{total}(X)$ subject to the orthonormality constraint, such an approach, in which only an approximate Hessian is used and updated by taking into account the gradient information computed in previous iterations, is generally not effective because of the large dimensionality of the minimization problem; hence the difficulty of obtaining a good approximation to the Hessian [33].

A technique that is widely used in the current practice of electronic structure calculation is to modify the Hessian of the quadratic surrogate (3.1) so that the [illegible] in KS Hamiltonian $H(X)$ is minimized. The lack of self-consistency in X can be measured in a number of ways. If $X^{(i+1)}$ is the approximate solution to the quadratic minimization problem (3.1), in which H is defined in terms of $X^{(i)}$, then the lack of self-consistency can be directly measured by computing $\delta_H = \|H(X^{(i+1)}) - H(X^{(i)})\|_F$, or simply $\delta_\rho = \|\rho(X^{(i+1)}) - \rho(X^{(i)})\|$, because the change in $H(X)$ is contributed by the last two terms of (2.12), which are both functions of the charge density $\rho(X)$. The minimization of δ_ρ is often achieved approximately by choosing $\rho^{(i+1)}$ to be a linear combination of the charge densities computed in



(a)

FIG. 3.3. (a) *When* $\alpha = 12$ *is set in* (3.3)*, the SCF iteration fails to converge. This figure shows the change of* $E_{total}(x)$ *in a single SCF iteration. the previous SCF iterations and solving an equality constrained quadratic program which returns the "optimal" linear combination. This approach is often referred to as the [illegible] scheme or the DIIS scheme [15, 24, 25]. In the material sciences community, the Pulay mixing scheme is often followed by another procedure in which selected components of the new charge density are modified or scaled. This procedure is sometimes called the [illegible] scheme [13, 15]. These mixing schemes work remarkably well for many problems but can fail for others. To our knowledge, no theoretical analysis of these schemes is yet available. For that reason, we will not go into the details of these mixing schemes but rather refer readers to [15] for more discussions.

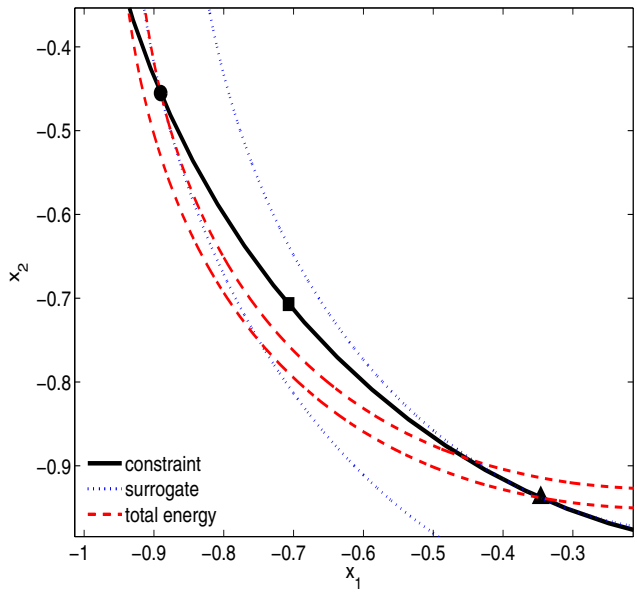
The second way to improve the convergence of SCF, which we will discuss in the next section, is to restrict the minimization of the quadratic surrogate in (3.1) (hence the update of the single particle wave functions) to a small neighborhood of the current approximation $X^{(i)}$. This technique is known as the [illegible] technique in the numerical optimization community [5, 20]. The gradient matching (between the total energy and the surrogate) property of SCF implies that a reduction of the total energy in the SCF iteration can be guaranteed if one imposes a trust region with a sufficiently small radius to (3.1).



(b)

FIG. 3.3(*continued*). (b) *When* $\alpha = 12$ *is set in* (3.3), *the SCF iteration fails to converge. This figure shows the change of* $E_{total}(x)$ *in a single SCF iteration. A zoom-in view of the boxed area in Figure* 3.2(a). *The minimizer of* $q(x)$ *(the small solid triangle) lies on the outer dashed contour line, indicating an increase in the total energy. The solid diamond marks the true minimizer of* E_{total}.

4. Trust region SCF. The simplest type of trust region one may consider for (3.1) is

$$\|X - X^{(0)}\|_F \leq \Delta, \tag{4.1}$$

where Δ is a trust region radius that may be reduced or enlarged depending on the ratio of the actual reduction of $E_{total}(X)$ over the predicted reduction measured in terms of the change in $q(X)$. The constrained optimization problem

$$\begin{aligned} &\min q(X) \\ &X^*X = I, \\ &\|X - X^{(0)}\|_F \leq \Delta, \end{aligned} \tag{4.2}$$

associated with a particular choice of Δ is known as a [illegible].

However, there are two serious drawbacks associated with this type of constraint. First of all, (4.1) is not rotationally invariant; i.e., the inequality (4.1) is not equivalent to

$$\|XQ - X^{(0)}\|_F \leq \Delta$$

for all $Q \in \mathbb{C}^{k\times k}$ such that $Q^*Q = I_k$. As a result, the solution to the trust region subproblem (4.2) is not rotation invariant, whereas the solution to the original total energy minimization problem is.

Secondly, adding (4.1) as a constraint makes the constrained quadratic minimization problem much more difficult to solve. If we introduce the constraint (4.1) as a penalty function and solve

$$\begin{aligned} &\min \hat{q}(X;\sigma) \equiv q(X) + \sigma \|X - X^{(0)}\|_F^2, \\ &X^*X = I_k \end{aligned} \tag{4.3}$$

for an appropriately chosen penalty parameter σ, the first order necessary condition of (4.3) cannot be expressed as a linear eigenvalue problem or other simple form. Thus it cannot be solved easily.

To preserve the rotational invariance property of the solution to (2.3) in a trust region subproblem, we must define the trust region in terms of quantities that are rotationally invariant. Both the charge density $\rho(X)$ defined in (2.2) and the density matrix $D(X)$ defined in (2.1) satisfy this desirable property. However, we will show in the following that a trust region defined in terms of $D(X)$ allows us to reduce the minimizing of the constrained quadratic surrogate function to a linear eigenvalue problem.

Note that $D(X)$ is an orthogonal projector associated with the subspace spanned by columns of X when $X^*X = I_k$. It is well known [10] that

$$\|D(X) - D(X^{(0)})\|_F \tag{4.4}$$

measures the distance between the subspaces defined by columns of X and $X^{(0)}$, where $\|A\|_F$ denotes the Frobenius norm of A. Therefore, we impose the constraint

$$\|D(X) - D(X^{(0)})\|_F \le \Delta$$

on the solution to the quadratic minimization problem. Because $X^*X = {X^{(0)}}^*X^{(0)} = I_k$, it is easy to verify that

$$\begin{aligned} \|D(X) - D(X^{(0)})\|_F^2 &= \|D(X)\|_F^2 + \|D(X^{(0)})\|_F^2 + 2\mathrm{trace}\big[D(X)^*D(X^{(0)})\big] \\ &= 2k - 2\mathrm{trace}\big[X^*X^{(0)}{X^{(0)}}^*X\big]. \end{aligned}$$

If we solve the trust region subproblem by introducing (4.4) as a penalty function in the quadratic objective $q(x)$, i.e., we solve

$$\begin{aligned} &\min \hat{q}(X;\sigma) \equiv \frac{1}{2}\mathrm{trace}\big[X^*H(X^{(0)})X\big] - \frac{\sigma}{2}\mathrm{trace}\big[X^*X^{(0)}{X^{(0)}}^*X\big], \\ &\text{s.t. } X^*X = I_k, \end{aligned} \tag{4.5}$$

where σ is an appropriately chosen penalty parameter, then the first order necessary condition associated with (4.5) becomes

$$\begin{aligned} \big[H(X^{(0)}) - \sigma X^{(0)}{X^{(0)}}^*\big]X &= X\Lambda, \\ X^*X &= I_k, \end{aligned}$$

where Λ (which can be diagonalized by postmultiplying X by an unitary transformation) is a matrix of Lagrange multipliers.

Therefore, when a trust region is defined with respect to $D(X)$, solving the corresponding trust region subproblem is equivalent to computing the eigenvectors associated with the smallest k eigenvalues of the [illegible] Hamiltonian $H(X^{(0)}) -$

$\sigma X^{(0)} X^{(0)^*}$, a problem that we generally know how to solve efficiently, at least when the dimension of $H(X^{(0)})$ is small.

What remains to be determined now is the penalty or trust region parameter σ in (4.5). Choosing a large σ value has the same effect as setting a small trust region radius Δ in (4.2). When σ is sufficiently large, the convergence of the SCF iteration can be guaranteed, although the rate of convergence may be very slow. When σ is too small, the solution to (4.6) may lead to an increase in the total energy. Unfortunately, the optimal choice of σ cannot be obtained analytically in general. The standard recipe for choosing such a parameter is usually dynamic [20]. In an unconstrained optimization problem, one starts with an arbitrary guess Δ_0 bounded by the maximum step length allowed. After the trust region subproblem is solved, the trust region radius may be reduced or increased based on the ratio of reduction in the true objective E_{true} over the predicted reduction E_{pred} measured from the surrogate function. A reduction of the trust region radius implies that the trust region subproblem must be resolved.

Two special features of the SCF iteration require the selection of penalty or trust region parameters to be made in a slightly different manner. First of all, the quadratic surrogate function in (3.1) does not match the true objective, i.e., the KS total energy function, at the current iterate $X^{(i)}$. Recall that the only thing that matches between $E_{total}(X)$ and $q(X)$ at $X^{(i)}$ is their gradients. Hence, the ratio between the changes in $E_{total}(X)$ and $q(X)$ can be difficult to predict. Consequently, an adjustment of the penalty parameter based on this ratio is unlikely to be effective. Secondly, the evaluation of $E_{total}(X)$ tends to be costly. Therefore, the selection of the penalty parameter should avoid repeated evaluation of the total energy.

A heuristic for estimating the penalty parameter is developed in [31] by expressing the change in E_{total} as a function of a matrix built from a linear combination of previous density matrices. The optimal σ is estimated by applying an inexact line search to the approximate model. Such a scheme requires saving wave functions or density matrices obtained in previous SCF iterations; thus is not practical for large problems.

We propose to use a simpler heuristic in this paper. Our heuristic is based on the following observation. As $X^{(i)}$ converges to X in a trust region enabled SCF iteration, the eigenvalues of the level-shifted Hamiltonian $H(X) - \sigma X X^*$ converge to

$$\lambda_1 - \sigma, \lambda_2 - \sigma, \ldots, \lambda_k - \sigma, \lambda_{k+1}, \lambda_{k+2}, \ldots, \lambda_n, \tag{4.6}$$

where

$$\lambda_1 \le \lambda_2 \le \cdots \le \lambda_n$$

are eigenvalues of the KS Hamiltonian $H(X)$ as defined in (2.12). Thus, adding a trust region of the form (4.4) has the effect of increasing the gap between the kth and the $(k+1)$th eigenvalues of the shifted Hamiltonian. Even though (4.6) does not hold in general for eigenvalues of the shifted Hamiltonian $H(X^{(i)})$ before $X^{(i)}$ converges to the solution of (2.3), our numerical experiments and those presented in [31] show an increased gap between the kth and $(k+1)$th eigenvalues of the shifted $H(X^{(i)})$ when σ is sufficiently large.

It is well known [22] that a larger gap between the eigenvalues associated with the desired invariant subspace and the rest of the spectrum generally makes it easier to compute the desired invariant subspace. Thus our heuristic tries to enlarge such a gap when total energy increases in an SCF iteration. To be specific, we set σ to zero

TRSCF

Input: The matrices L, D_{ion}, S, and the vectors w_ℓ, $\ell = 1, 2, \ldots$. The derivative of the exchange-correlation function $\mu_{xc}(x)$; an initial guess $X^{(0)}$ for the optimal wave function $X \in \mathbb{C}^{n\times m}$;

Output: $X \in \mathbb{C}^{n\times m}$ such that $X^*X = I_m$ and $E_{tot}(X)$ is minimized, where $E_{tot}(X)$ is defined by (2.6)–(2.10).

1. Set $\sigma = 0.0$;
2. for $i = 1, 2, \ldots$ until convergence
3. if ($\sigma = 0.0$)
4. Set $H^{(i)} = H(X^{(i-1)})$;
5. else
6. Set $H^{(i)} = H(X^{(i-1)}) - \sigma X^{(i-1)} X^{(i-1)^*}$;
7. endif
8. Compute $X^{(i)}$ such that $H^{(i)}X^{(i)} = X^{(i)}\Lambda^{(i)}$ and $\Lambda^{(i)}$ contains the k smallest eigenvalues of $H^{(i)}$;
9. if ($E_{tot}(X^{(i)}) > E_{tot}(X^{(i-1)})$), set $\sigma \leftarrow \gamma(\lambda_{k+1}^{(i)} - \lambda_k^{(i)})$ for some constant $\gamma > 1$;
10. end for

FIG. 4.1. *A trust region-based SCF iteration.*

initially. If the minimizer of $q(X)$ yields an increase in $E_{total}(X)$, we increase σ by setting it to $\gamma\eta_{\max}$, where $\eta_{\max}$ is the maximum gap defined as

$$\eta_{\max} = \max_{\ell\in\{1,2,\ldots,n-1\}} \lambda_{\ell+1}^{(i)} - \lambda_\ell^{(i)},$$

where $\lambda_\ell^{(i)}$ is the ℓth eigenvalue of $H(X^{(i)})$ and γ is a small constant. Empirically, we found a good choice of γ to be around 2 to 5. This particular strategy for choosing the penalty parameter is somewhat conservative in the sense that σ is never decreased in subsequent SCF iterations to allow a larger reduction in total energy. A more sophisticated and efficient scheme will be described in a separate paper.

The major steps of a TRSCF iteration is summarized in Figure 4.1. We now return to the simple example (3.3) and show the effect of applying the trust region technique in the SCF iteration. The eigenvalues of the Hamiltonian constructed at $\hat{x}$ are

$$\hat{\lambda}_1 = 6.4597 \quad \text{and} \quad \hat{\lambda}_2 = 9.5403.$$

We set $\sigma = \hat{\lambda}_2 - \hat{\lambda}_1$ to increase the gap between the eigenvalues of the shifted Hamiltonian by a factor of two. Figure 4.2 is almost identical to Figure 3.3(b). The only difference is that we plotted the solution to the trust region subproblem (4.5), which is marked by a solid diamond, in addition to the solution to the unpenalized surrogate (3.1), which is marked by a solid triangle. As we can see in this figure, the solution to the trust region subproblem lies inside the inner dashed contour, indicating a reduction in total energy as we move from the small solid circle to the solid diamond. Furthermore, the solid diamond is clearly closer to the minimizer of the total energy

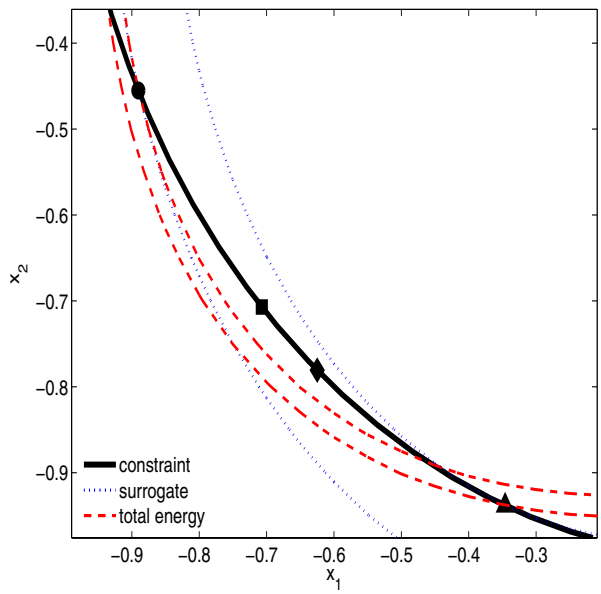


FIG. 4.2. *This is the same contour plot as shown in Figure* 3.3(b)*, except that the figure also shows the effect of applying the trust region technique in SCF. The solution to the trust region subproblem or the penalized problem* (4.5) *is marked by the solid diamond, which lies to the upper right of the inner dashed contour. Clearly, it is closer to the true minimizer (the small solid square) than* $\hat{x}$ *(the small solid circle), indicating a reduction in the total energy in the SCF iteration.*

(the solid square) than either the current approximation $\hat{x}$ (the small solid circle) or the minimizer of the unpenalized surrogate $\hat{x}_q$ (the solid triangle).

5. Direct minimization of the total energy. A monotonic reduction of the total energy can be guaranteed in TRSCF if the penalty parameter σ is sufficiently large. However, choosing a large penalty parameter may lead to a slow convergence rate for large atomistic systems [4] because one is forced to take a shorter step in each TRSCF iteration. In [31], TRSCF is combined with a DIIS-like acceleration scheme to improve the convergence rate. In this paper, we proposed to use TRSCF within a DCM that we developed in [36].

Instead of minimizing $E_{total}(X)$ by minimizing a sequence of quadratic surrogate functions, the DCM algorithm minimizes the $E_{total}(X)$ directly.

This general approach has been discussed in a number of papers [2, 9, 15, 23, 30, 32, 33]. In [23, 30], a conjugate gradient (CG) type of algorithm is used to minimize the total energy. The minimization is carried out "band-by-band"; i.e., the total energy is minimized with respect to one wave function at a time. For the jth band (wavefunction), a search direction $p_j^{(i)}$ is generated from a linear combination of the wavefunction $x_j^{(i)} = X^{(i)} e_j$ and the residual

$$r_j = H^{(i)} x_j^{(i)} - x_j^{(i)} \lambda_j,$$

where λ_j is the jth eigenvalue of the projected Hamiltonian $X^{(i)*} H^{(i)} X^{(i)}$. Note that r_j is simply the jth column of the gradient matrix $\nabla_X \mathcal{L}(X^{(i)})$. Similar to the standard CG algorithm, the linear combination of $x_j^{(i)}$ and r_j is chosen so that $p_j^{(i)}$ is

$H^{(i)}$-conjugate to the previous search direction $p_j^{(i-1)}$. The new wave function $x_j^{(i+1)}$ is then computed by minimizing the KS total energy in the subspace spanned by $x_j^{(i)}$ and $p_j^{(i)}$. To simplify this minimization problem, $p_j^{(i)}$ is first orthogonalized against $x_j^{(i)}$ and normalized so that $\|p_j^{(i)}\| = 1$. The new wave function is then parameterized by

$$x_j^{(i+1)} = x_j^{(i)} \cos\theta + p_j^{(i)} \sin\theta,$$

where the optimal θ is obtained by a standard line search procedure. Instead of using the KS function to perform the line search, Teter, Payne, and Allan [30] proposed using a surrogate function that is cheaper to evaluate. However, this approach was shown in [15] to be less efficient than the SCF iteration. We believe this is primarily due to the "band-by-band" nature of the algorithm.

The methods presented in [9, 2, 33, 32] were designed to minimize the total energy with respect to all wave functions (associated with the occupied state) simultaneously. The method developed in [9] modifies the unconstrained CG search direction so that the orthonormality constraint $X^*X = I_k$ can be satisfied. The approaches taken in [2, 32] reparameterize the search direction so that standard unconstrained minimization can be used directly. The algorithm developed in [33] first computes the search direction via a limited-memory BFGS (Broyden–Fletcher–Goldfarb–Shannon) scheme [19], and the search direction is then modified through a parallel transport technique [7] to ensure that the orthonormality constraint $X^*X = I_k$ is satisfied in the line search procedure. In all of these methods, the search direction is computed first, and a step length is then determined to reduce the total energy along the computed search direction.

The direct minimization algorithm that we presented in [36] also seeks the optimal wave functions associated with all occupied states simultaneously. However, we choose the search direction and the step length simultaneously from a subspace that consists of the existing wave functions $X^{(i)}$, the gradient of the Lagrangian (2.4), and the search direction produced in the previous iteration. A special strategy is developed to minimize the total energy within the search space while maintaining the orthonormality constraint required for $X^{(i+1)}$. This strategy requires us to solve a projected nonlinear eigenvalue problem, as we will illustrate below.

Let $R^{(i)}$ be the preconditioned gradient of the Lagrangian (2.4) with respect to X evaluated at $X^{(i)}$, and let $P^{(i-1)}$ be the search direction obtained in the $(i-1)$th iteration. In our algorithm, the wave function update is performed within the $3k$-dimensional subspace spanned by $X^{(i)}$, $R^{(i)}$, and $P^{(i-1)}$. This is in the same spirit as the locally optimal block preconditioned conjugate gradient (LOBPCG) algorithm proposed in [14] for solving large-scale linear eigenvalue problems. Note that the inclusion of $P^{(i-1)}$ is important. It prevents the search direction constructed at the ith step from being parallel to the steepest descent direction which often results in a tiny change between $X^{(i)}$ and $X^{(i+1)}$ (hence a small reduction in E_{total} from $X^{(i)}$ to $X^{(i+1)}$).

If we let

$$Y = (X^{(i)},\, R^{(i)},\, P^{(i-1)}),$$

we can then express the new approximation, $X^{(i+1)}$, by

$$X^{(i+1)} = YG, \tag{5.1}$$

where $G \in \mathbb{C}^{3k\times k}$ is chosen to minimize $\hat{E}(G) \equiv E_{total}(YG)$; i.e., we must solve

$$\begin{aligned} &\min_G E_{total}(YG) \\ &\text{s.t. } G^*Y^TYG = I_k. \end{aligned} \tag{5.2}$$

The first order necessary condition of (5.2) can be derived by examining the gradient of the Lagrangian associated with $\hat{E}(G)$ (with respect to G). It is easy to verify [36] that

$$\nabla_G \hat{E}(G) = \hat{H}(G)G, \tag{5.3}$$

where

$$\hat{H}(G) = Y^*\left[\frac{1}{2}L + D_{ion} + \sum_\ell w_\ell w_\ell^* + \mathrm{Diag}\Big(S\rho(YG)\Big) + \mathrm{Diag}\Big(\mu_{xc}(\rho(YG))\Big)\right]Y. \tag{5.4}$$

(Note that (5.4) has been scaled by 1/2 to be consistent with the convention used in the electronic structure community.)

Consequently, solving (5.2) is equivalent to solving

$$\hat{H}(G)G = BG\Omega_k, \qquad G^*BG = I_k, \tag{5.5}$$

where $B = Y^*Y$ and the $k \times k$ diagonal matrix Ω_k contains the k smallest eigenvalues of (5.5).

Note that the projected nonlinear eigenvalue problem defined by (5.5) is much smaller than the nonlinear eigenvalue solved in an SCF iteration. The reduction in size provides us with more flexibility in choosing appropriate algorithms to solve the nonlinear eigenvalue problem. In particular, we can apply the TRSCF iteration introduced in section 4 to compute the desired eigenpairs of (5.5). The presence of the mass matrix B does not pose any difficulty in defining a trust region. Through a change of variables (i.e., let $\tilde{G} = RG$, where R is the Cholesky factor of B, i.e., $G = R^H R$), we can easily show that the first order necessary condition of the penalized quadratic surrogate defined at $G^{(i)}$ can be expressed by

$$\big[\hat{H}(G^{(i)}) - \sigma BG^{(i)}{G^{(i)}}^*B\big]G = BG\Omega_k, \qquad G^*BG = I_k. \tag{5.6}$$

The generalized linear eigenvalue problem defined by (5.6) can be solved by calling an appropriate LAPACK [1] subroutine. Choosing a sufficiently large penalty parameter will guarantee that $E_{total}(YG)$ decreases monotonically. Furthermore, it should be noted that it is not necessary to solve (5.5) to full accuracy in the early stage of the direct minimization process, because all we need is a G that yields sufficient decrease in the objective function within the subspace spanned by columns of Y.

Once G is computed, we can update the wave function following (5.1). In addition, we can compute the search direction associated with this update using [14]

$$P^{(i)} \equiv X^{(i+1)} - X^{(i)}G(1:k,:) = Y(:,k+1:3k)G(k+1:3k,:).$$

Because the solution to (5.5) ensures that columns of $X^{(i+1)}$ are orthonormal, there is no need to explicitly orthogonalize $P^{(i)}$ against $X^{(i)}$ in our algorithm.

A complete description of the constrained minimization algorithm is shown in Figure 5.1. We should point out that solving the projected optimization problem

ALGORITHM: A CONSTRAINED MINIMIZATION ALGORITHM FOR TOTAL ENERGY MINIMIZATION

Input: An initial set of wave functions $X^{(0)} \in \mathbb{C}^{n\times k}$, where k is the number of occupied states; the matrices L, D_{ion}, S; the vectors w_ℓ, $\ell = 1, 2, \ldots$. The derivative of the exchange-correlation function $\mu_{xc}(x)$; a preconditioner K;

Output: $X \in \mathbb{C}^{n\times k}$ such that the KS total energy function $E_{total}(X)$ is minimized and $X^*X = I_k$.

1. Orthonormalize $X^{(0)}$ such that ${X^{(0)}}^* X^{(0)} = I_k$;

2. for $i = 0, 1, 2, \ldots$ until convergence

3. Compute $\Theta = {X^{(i)}}^* H^{(i)} X^{(i)}$;

4. Compute $R = K^{-1}\left[H^{(i)}X^{(i)} - X^{(i)}\Theta\right]$,

5. if $(i > 1)$ then
$Y \leftarrow (X^{(i)}, R, P^{(i-1)})$
else
$Y \leftarrow (X^{(i)}, R)$;
endif

6. $B \leftarrow Y^*Y$;

7. Find $G \in \mathbb{C}^{2k\times 2k}$ or $\mathbb{C}^{3k\times 3k}$ that minimizes $E_{total}(YG)$ subject to the constraint $G^*BG = I$;

8. Set $X^{(i+1)} = YG$;

9. if $(i > 1)$ then
$P^{(i)} \leftarrow Y(:, k+1:3k)G(k+1:3k, :)$;
else
$P^{(i)} \leftarrow Y(:, k+1:2k)G(k+1:2k, :)$;
endif

10. end for

FIG. 5.1. *A direct constrained minimization algorithm for total energy minimization.*

in step 7 of the algorithm requires us to evaluate the projected Hamiltonian (5.4) repeatedly as we search for the best G. However, since the first three terms of $\hat{H}$ do not depend on G, they can be computed and stored in advance. Only the last two terms of (5.4) need to be updated. These updates require that the charge density, the Hartree, and the exchange-correlation potentials be recomputed.

6. Numerical examples. In this section, we compare the performance of the DCM algorithm presented in the previous section with that of the SCF iteration implemented in the software package PEtot [34] through two numerical examples. In PEtot, single particle wave functions are discretized by a spectral method using plane waves as the basis. These basis functions are eigenfunction of the Laplacian operator (L) associated with the kinetic energy of the atomistic system. Thus, PEtot stores only the Fourier coefficients of each wave function $x_j = Xe_j$ instead of x_j itself so that $y \leftarrow Lx_j$ can be carried out in $\mathcal{O}(n)$ floating point operations (flops) in the frequency space. However, because the potential terms of the Hamiltonian (with the exception of the nonlocal ionic potential) are diagonal in the spatial domain, PEtot converts the

Fourier space representation of x_j into the real space representation before operations involving these potential terms are performed. The complexity of this conversion is $\mathcal{O}(n \log n)$ when it is carried out by a fast Fourier transform (FFT). We measure the convergence of both algorithms by examining the relative reduction of the total energy computed in each outer iteration. The relative reduction is evaluated by

$$\Delta E_i = E_{total}(X^{(i)}) - E_{min},$$

where E_{min} is a lower bound of the total energy.

In a PEtot SCF iteration, the minimization of the surrogate (3.1) is accomplished by applying a preconditioned conjugate gradient (PCG) algorithm to minimize the Rayleigh quotient $x^* H^{(i)} x / x^* x$. Explicit deflation is put in place to accelerate the convergence of the smallest k eigenpairs. Each PCG iteration requires a single matrix vector (MATVEC) multiplication followed by a preconditioning operation. When n is sufficiently large, the complexity of each MATVEC is dominated by the cost of the FFT calculation used to convert the Fourier space representation of x_j to the real space representation. The Laplacian operator L is used as the preconditioner. Because it is diagonal in the frequency space, the cost of preconditioning is relatively small compared to a MATVEC. If m PCG iterations are taken on average to compute an approximate eigenpair of $H^{(i)}$, then the total number of MATVECs used per SCF iteration is $m \times k$.

In the DCM algorithm, k MATVECs are performed in each outer iteration to obtain the gradient. When TRSCF is used to solve the projected problem (5.5), each outer DCM iteration contains a number of inner TRSCF iterations in which the projected Hamiltonian (5.4) must be updated repeatedly. The update of the projected Hartree potential requires us to compute $S\rho(YG)$. Because S is the inverse of L, this calculation is typically carried out by a fast Poisson solver. The complexity of this computation is approximately $\mathcal{O}(n \log n)$, which is equivalent to a single MATVEC used in the SCF iteration asymptotically. Thus, if p inner TRSCF iterations are taken in the DCM algorithm, the total number of MATVECs used per DCM iteration is $k + p$.

6.1. The PtNiO system. We applied both algorithms to a relatively large system consisting of 9 atoms and 86 valence electrons. It represents a thin PtNi slab with one O atom attached to the surface. The system is used for catalysis to dissociate O_2 molecules. The wave function is defined on a $96 \times 48 \times 48$ real space grid. The number of plane wave basis functions used in the Fourier representation is 15181, and the number of occupied states for this molecule is $k = 43$.

In the SCF calculation, we set the convergence tolerance of each PCG run to $\tau = 10^{-12}$, and the maximum number of PCG iterations allowed to 10. That is, we terminate the PCG iteration when

$$\|H^{(i)} x_j^{(i)} - \lambda_j^{(i)} x_j^{(i)}\| \leq 10^{-12},$$

or when the number of PCG iterations taken reaches 10. In our experiment, the PCG convergence tolerance was never reached before the maximum number of iterations were taken. Thus each outer SCF iteration consumed 43×10 MATVECs. Both Pulay [25] (DIIS) and Kerker [13] charge-mixing schemes were used in the outer SCF iteration to accelerate the convergence.

In the DCM calculation, the projected minimization problem was solved by applying TRSCF iteration to (5.5). We set the number of inner TRSCF iterations to 5.

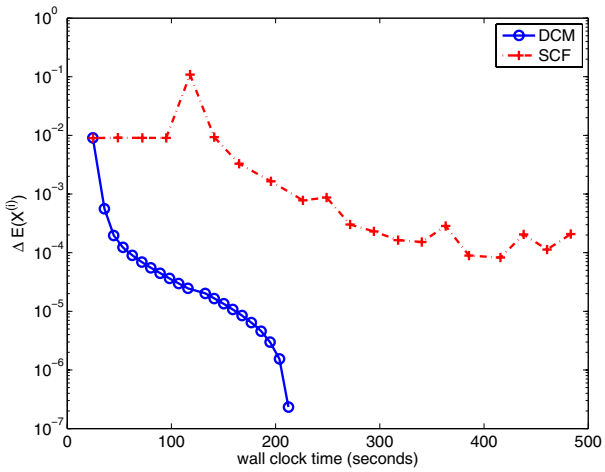

FIG. 6.1. *Comparing the convergence of SCF and DCM when they are applied to the PtNiO system.*

Thus, the number of MATVECs used in each DCM iteration is roughly $5 + 43$, which is significantly smaller than that used in SCF.

Both SCF and DCM have been parallelized using MPI (message passing interface). For the PtNiO system, we ran both codes on the IBM SP maintained at the National Energy Research Scientific Computing (NERSC) Center using 64 CPUs. Each IBM SP node contains 16 Power3 CPUs and 16 GB memory. Each Power3 CPU runs at a 375 MHz clock speed, and has 2 MB L2 cache. Figure 6.1 shows that DCM exhibits monotonic convergence whereas the total energy does not decrease monotonically in SCF even when both Pulay and Kerker charge-mixing schemes are used to stabilize the algorithm. After 20 iterations, DCM was able to reach a much lower KS total energy level.

6.2. The $Si_{29}H_{36}$ cluster. In the second example, we show that the trust region DCM algorithm is more efficient than the SCF iteration (accelerated by charge mixing) for atomistic systems that are "well behaved" (in the sense that the total energy decreases monotonically in SCF). A smaller example was presented in our earlier work [36] in which both DCM and SCF were applied to the SiH_4 system. We showed that DCM was almost four times faster than SCF when both were executed on 16 Power3 CPUs. No trust region was used in that experiment.

In this example, we apply both trust region DCM and SCF (accelerated by charge mixing) to a larger silicon cluster that contains 29 silicon atoms and 36 hydrogen atoms. The total number of valence electrons in the system is 152; i.e., the number of occupied states is $k = 76$. The system is discretized by plane waves on a real space grid of $96 \times 96 \times 96$. The number of plane wave basis functions used is 35585. We ran both DCM and SCF on 128 Power3 CPUs at NERSC. The PCG tolerance and iteration limits used in this example are the same as those set in the PtNiO example. We also set the number of inner TRSCF iterations used in DCM to 5.

Figure 6.2 shows that the total energy decreases monotonically in both the DCM and SCF runs for this problem. However, the reduction of the total energy is much faster in DCM than it is in SCF.

7. Concluding remarks. We viewed the SCF iteration, commonly used for solving the KS equation, as an optimization procedure that minimizes the KS total energy indirectly by minimizing a sequence of quadratic surrogate. Such a viewpoint allows us to easily explain when SCF works and how it can fail. It also allows us to devise techniques that can either stabilize or accelerate the SCF iteration. We showed that the convergence of SCF can be stabilized by introducing a quadratic constraint into the surrogate minimization problem. Such a constraint restricts the wave function update to a small neighborhood of the current iterate at which the gradients of the KS total energy and the surrogate match, hence defining a "trust region." However, applying a trust region-based SCF iteration directly to the KS equation may lead to slow convergence. We proposed using the trust region technique within the DCM algorithm developed in [36] to compute optimal search directions and step lengths simultaneously. We demonstrated through two numerical examples that such a scheme outperforms the SCF iteration combined with charge mixing in terms of both efficiency and reliability. We should point out that our numerical results are still somewhat preliminary. For atomistic systems that are "well behaved," the performance difference between SCF and DCM may be less dramatic if the single vector PCG algorithm used in PEtot to solve the surrogate minimization problem (3.1) is replaced by a block algorithm. Also, it will be interesting to see how these two methods differ in performance when the number of electrons becomes a larger fraction of n. In that case, dense matrix operations will constitute a significant portion of the computational cost in both DCM and SCF. We will undertake a more systematic performance analysis in a future study that will also take into account different discretization schemes.

FAST RADIAL BASIS FUNCTION INTERPOLATION VIA PRECONDITIONED KRYLOV ITERATION*

NAIL A. GUMEROV† AND RAMANI DURAISWAMI‡

Abstract. We consider a preconditioned Krylov subspace iterative algorithm presented by Faul, Goodsell, and Powell (*IMA J. Numer. Anal.* 25 (2005), pp. 1–24) for computing the coefficients of a radial basis function interpolant over N data points. This preconditioned Krylov iteration has been demonstrated to be extremely robust to the distribution of the points and the iteration rapidly convergent. However, the iterative method has several steps whose computational and memory costs scale as $O(N^2)$, both in preliminary computations that compute the preconditioner and in the matrix-vector product involved in each step of the iteration. We effectively accelerate the iterative method to achieve an overall cost of $O(N \log N)$. The matrix vector product is accelerated via the use of the fast multipole method. The preconditioner requires the computation of a set of closest points to each point. We develop an $O(N \log N)$ algorithm for this step as well. Results are presented for multiquadric interpolation in $\mathbb{R}^2$ and biharmonic interpolation in $\mathbb{R}^3$. A novel FMM algorithm for the evaluation of sums involving multiquadric functions in $\mathbb{R}^2$ is presented as well.

Key words. radial basis function interpolation, preconditioned conjugate gradient, cardinal function preconditioner, computational geometry, fast multipole method

1. Introduction.

Interpolation of scattered data of various types using radial-basis functions has been demonstrated to be useful in different application domains [23, 7, 8, 29]. Much of this work has been focused on the use of polyharmonic and multiquadric radial-basis functions (RBF) $\left[\phi : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}\right]$ that fit data as

$$s(\mathbf{x}) = \sum_{j=1}^{N} \lambda_j \phi\left(|\mathbf{x} - \mathbf{x}_j|\right) + \mathcal{P}(\mathbf{x}), \quad \mathbf{x} \in \mathbb{R}^d, \tag{1.1}$$

where several classes of radial-basis functions may be chosen for ϕ. Popular choices include

$$\phi(r) = \begin{cases} r & \text{biharmonic } (\mathbb{R}^3) \\ r^{2n+1} & \text{polyharmonic } (\mathbb{R}^3) \\ \left(r^2 + c^2\right)^{1/2} & \text{multiquadric } (\mathbb{R}^d). \end{cases}$$

Here λ_j are coefficients while $\mathcal{P}(\mathbf{x})$ is a global polynomial function of total degree at most $K-1$. The coefficients $\{\lambda\}$ and the polynomial functions $\mathcal{P}(\mathbf{x})$ are chosen to satisfy the N fitting conditions

$$s(\mathbf{x}_j) = f(\mathbf{x}_j), \quad j = 1, \ldots, N$$

and the constraints

$$\sum_{j=1}^{N} \lambda_j Q(\mathbf{x}_j) = 0,$$

for all polynomials Q of degree at most $K-1$.

Let $\{P_1, P_2, \ldots, P_k\}$ be a basis for the polynomials of total degree $K-1$. Then the corresponding system of equations that needs to be solved to find the coefficients λ and the polynomial $\mathcal{P}$ are

$$\begin{pmatrix} \Phi & P^T \\ P & 0 \end{pmatrix} \begin{pmatrix} \lambda \\ b \end{pmatrix} = \begin{pmatrix} f \\ 0 \end{pmatrix},$$

where

$$\Phi_{ij} = \phi(\mathbf{x}_i - \mathbf{x}_j),\ i,j = 1,\ldots,N; \quad P_{ij} = P_j(\mathbf{x}_i),\ i = 1,\ldots,N;$$
$$j = N+1,\ldots,N+K.$$

Usually the degree K of the polynomial is quite small, and for functions exhibiting linear growth at infinity it can be taken to be 1, in which case the polynomial $\mathcal{P}(\mathbf{x})$ is just a constant, and this is the case that will be considered in what follows. Micchelli [24] has shown that this system of equations is nonsingular.

For large N, as is common in many applications, the computational time and memory required for the solution of the fitting equations is a significant bottleneck. Direct solution of these equations requires $O\left(N^3\right)$ time and $O\left(N^2\right)$ memory. Iterative approaches to solving this set of symmetric equations require evaluations of dense matrix vector products $\Phi\lambda$ which have a $O(N^2)$ computational cost and require $O\left(N^2\right)$ memory. Furthermore, for rapid convergence of the iteration, the system must be preconditioned appropriately.

Considerable progress in the iterative solution of multiquadric and polyharmonic RBF interpolation was made with the development of preconditioners using cardinal functions based on a subset of the interpolating points. This approach was first proposed by Beatson and Powell [1]. Various versions of the idea have since been tried including those based on choosing a set of data near each point, a mix of near and far points, and via modified approximate cardinal functions that have a specified decay behavior [3]. An alternative group of methods that attempt to speed up the algorithm via domain decomposition have also been developed [4].

Recently, an algorithm was published by Faul, Goodsell, and Powell [13], which uses the cardinal function idea, and in which for each point a carefully selected set of q points was used to construct the preconditioner. In informal tests we found that this algorithm appears to achieve a robust performance, and was able to interpolate large problems in a few iterations, where other cardinal function based strategies sometimes took a large number of steps, or failed to converge. In subsequent discussions we will refer to this algorithm as FGP05. This algorithm reduces the number of iterations required; however, its cost remains at $O(N^2)$ and it requires $O(N^2)$ memory. The purpose of this paper is the acceleration of this algorithm.

Similar to many other iterative techniques, the FGP05 algorithm can be accelerated by the use of the fast multipole method (FMM) for the matrix vector product required at each step, making this cost $O(N \log N$ [14]. While the possibility of the use of the FMM was mentioned in [13], results were not reported. Fast multipole methods have been developed for various radial basis kernels including the polyharmonic [5] and multiquadric [11] in $\mathbb{R}^d$, the biharmonic and polyharmonic kernels in

$\mathbb{R}^3$ [19], the polyharmonic [5] kernels in $\mathbb{R}^4$ [6], and Gaussian kernels [17, 26]. Use of the FMM can thus reduce the cost of the matrix vector multiply required in each iteration of the FGP05 algorithm to $O(N \log N)$.

However, there is a further barrier to achieving a truly fast algorithm using the FGP05 algorithm, as there is a precomputation stage that requires the construction of approximate cardinal function interpolants centered at each data point and q of its carefully selected neighbors ($q \ll N$). These interpolants are used to provide a set of directions in the Krylov space for the iteration. The procedure for these preliminary calculations reported in [13] has a formal complexity of $O(N^2)$. Progress towards reducing the cost of this step to $O(N \log N)$ was reported by Goodsell in two dimensions (2D) [18]. However, his algorithm relied on Dirichlet tessellation of the plane and does not extend to higher dimensions.

In this paper we present a modification to this preliminary set up stage, use the FMM for the matrix vector product, and reduce the complexity of the overall algorithm. Section 2 provides some preliminary information on preconditioning with cardinal functions, details of the Faul, Goodsell, and Powell algorithm, and some details of the FMM that are necessary for the algorithms developed in this paper. Section 3 describes the two improvements that let us achieve improved performance in our modified algorithm: finding the q closest points to each point in the set in $O(N \log N)$ time and use of the FMM. Since the latter method is well discussed in other literature, we only provide some details that are unique to our implementation. In particular, we present novel FMM algorithms for the multiquadric (and the inverse multiquadric) in $\mathbb{R}^2$. Section 4 provides results of the use of the algorithm. Section 5 concludes the paper.

2. Background.

2.1. Preconditioning using approximate cardinal functions. A long sequence of papers [1, 3, 4] use approximate cardinal functions to create preconditioners for RBF fitting. The basic iterative method consists at updating at each iteration step the approximation to the function f, $s^{(k)}$

$$s^{(k)}(\mathbf{x}) = \sum_{j=1}^{N} \lambda_j^{(k)} \phi\left(|\mathbf{x} - \mathbf{x}_j|\right) + a^{(k)}, \quad \mathbf{x} \in \mathbb{R}^d, \tag{2.1}$$

by specifying new coefficients $\lambda_j^{(k)}$, $j = 1, \ldots, N$ and the constant $a^{(k)}$. The residual at step k is obtained as

$$r_i^{(k)} = f(\mathbf{x}_i) - s^{(k)}(\mathbf{x}_i), \quad i = 1, \ldots, N,$$

at the data points $\mathbf{x}_i$. To establish notation, and following FGP05, we denote as s^* the function that arises at the end of the iteration process.

The cardinal or Lagrange functions corresponding to any basis play a major role in interpolation theory. The cardinal function z_l corresponding to a particular data point l satisfy the Kronecker conditions

$$z_l(\mathbf{x}_j) = \delta_{lj}, \quad j, l = 1, \ldots, N, \tag{2.2}$$

i.e., z_l takes on the value unity at the lth node, and zero at all other nodes. It can itself be expressed in terms of the radial-basis functions

$$z_l(\mathbf{x}) = \sum_{j=1}^{N} \zeta_{lj} \phi\left(|\mathbf{x} - \mathbf{x}_j|\right) + a_l, \tag{2.3}$$

where the ζ_j^i are the interpolation coefficients and a_l the corresponding constant. If we now form a matrix of all the interpolation coefficients $T_{ji} = \zeta_{ij}$, then we have

$$\begin{pmatrix} \Phi & \mathbf{1}^T \\ \mathbf{1} & 0 \end{pmatrix} \begin{pmatrix} T \\ \mathbf{a} \end{pmatrix} = \begin{pmatrix} I \\ 0 \end{pmatrix}, \tag{2.4}$$

where I is the identity matrix, and $\mathbf{1}$ is a row vector of size N containing ones, and $\mathbf{a}$ a row vector containing the coefficients a_l. Thus the matrix of interpolation coefficients corresponding to the cardinal functions is the inverse of the matrix Φ, and if these coefficients were known, then it would be easy to solve the system. On the other hand, computing each of these sets of coefficients for a single cardinal function z_l (corresponding to a column of T) by a direct algorithm is an $O\left(N^3\right)$ procedure, and there are N of these functions.

The approach pursued by Beatson and Powell [1] was to compute [illegible] to these cardinal functions so that a column ζ_{lj} is approximated by a sparse set of coefficients, say q in number, corresponding to the cardinality condition being satisfied at the point l and $q-1$ other chosen points. Then the matrix $\hat{T}$ corresponding to the approximate cardinal function coefficients is used as a preconditioner in an appropriate Krylov subspace algorithm. In this case the complexity of the preconditioning step is $O(Nq^3)$ and for $q \ll N$, and independent of N, this strategy, provided it converges rapidly, can lead to a fast algorithm.

Early versions of these algorithm were applied to relatively modest sized problems and the points at which the cardinality conditions were satisfied were chosen as neighbors of the point corresponding to the row index. This strategy was observed to not work for larger sets and various modifications were tried. The algorithm of Faul, Goodsell, and Powell [13] presents a variation that works on all tried data sets. It is described in the next section.

[illegible] 2.1. The FMM applies to matrices whose entries can be characterized as radial basis functions. For smoothly varying functions, the approximate cardinal functions are likely to be good approximations to the true cardinal functions. As such, the idea of using approximate cardinal functions to construct preconditioners may be of practical use in a large number of problems where the FMM can be used to accelerate matrix vector products by using the radial basis function itself, or in the singular case, some appropriately mollified version of the FMM radial basis function.

2.2. Algorithm of Faul, Goodsell, and Powell.

2.2.1. Choice of points for fitting cardinal functions. The FGP05 algorithm implements a Krylov method for the solution of (1.1). In this algorithm the point sets on which the approximate cardinal functions are constructed are chosen in a special way, so that a rapidly converging preconditioned conjugate gradient algorithm is achieved. This algorithm was extensively tested in [13] and its convergence properties established theoretically. We also tested our implementation of it practically and found it to exhibit remarkably fast and robust convergence.

Each row of the matrix has associated with it a particular set of q or fewer points. The $N+1 \times N+1$ system of equations (2.4) can be expressed as an equivalent $N-1 \times N-1$ system by eliminating λ_n from the system using

$$\lambda_n = -\sum_{j=1}^{N-1} \lambda_j.$$

To build a preconditioner we need to consider $N-1$ sets of approximate RBF interpolants and associated points $\mathcal{L}_l$, $l = 1, \ldots, N-1$, which we call L-sets. Each set contains the point corresponding to the row index we are working with and other points. To choose the first of these sets, using the interpoint distances, the points that are closest to each other chosen, and one of these points is marked as the first point; $q-2$ further closest neighbors of the marked points are chosen, and the marked point is removed from consideration. In the remaining $N-1$ points, again the closest pair of points is chosen, one of these points is marked, and $q-2$ further closest neighbors of the marked points are chosen. At each step a marked point is selected from the closest pair, a further set of closest points chosen, and a set for the marked point built. In this way the algorithm proceeds to build sets of q points, and the procedure continues till only q points remain, which forms the $(N-q+1)$th set. A further $q-2$ sets of points are constructed from these points by taking $q-1$, $q-2, \ldots, 2$ points from the remaining points, and in each case setting one of these points as the marked point and removing it. In this way a total of $N-1$ groups of points are established.

The procedure described above, though indicated as preferred, was not what is ultimately implemented in FGP05. Rather, an approximate version was used. However, the procedure is nonetheless $O(N^2)$, as it involves computation of pairwise distances between points. A further crucial aspect of the FGP05 procedure is that at each step the algorithm requires deletion of points being considered making the process of constructing the list of closest points a dynamic one.

Now using these point sets, radial-basis function fits of the Lagrange function over these point sets, of the form

$$\hat{z}_l(\mathbf{x}) = \sum_{j \in \mathcal{L}^l} \zeta_{lj} \phi(\mathbf{x} - \mathbf{x}_j) + \text{const.}, \quad \hat{z}_l(\mathbf{x}_j) = \delta_{lj}, \quad l = 1, \ldots, N-1,$$

are constructed. The coefficients of the Lagrange function fit ζ_{lj} are used to define the search directions in a conjugate gradient algorithm that is described below. In this algorithm, the function $\tilde{z}_l$ (defined as $\hat{z}_l$ with the constant part dropped) is used,

$$\tilde{z}_l(\mathbf{x}) = \sum_{j \in \mathcal{L}^l} \zeta_{lj} \phi(\mathbf{x} - \mathbf{x}_j).$$

By construction

$$\sum_{j \in \mathcal{L}^l} \zeta_{lj} = 0.$$

2.2.2. Seminorm and inner product. Given functions s and t at the data interpolation locations $\{\mathbf{x}\}$, and having these functions interpolated using radial basis functions as

$$s(\mathbf{x}) = \sum_{j=1}^{N} \lambda_j \phi(\mathbf{x} - \mathbf{x}_j) + \alpha, \qquad t(\mathbf{x}) = \sum_{i=1}^{N} \mu_i \phi(\mathbf{x} - \mathbf{x}_i) + \beta,$$

FGP05 define the following seminorm

$$\|s\|_\phi = -\left(\lambda^T \Phi \lambda\right)^{\frac{1}{2}}, \qquad \|t\|_\phi = -\left(\mu^T \Phi \mu\right)^{\frac{1}{2}}$$

and inner product between two functions as

$$\begin{aligned}\langle s,t\rangle_\phi &= \frac{1}{2}\left(\|s+t\|_\phi^2 - \left(\|s\|_\phi^2 + \|t\|_\phi^2\right)\right)\\ &= -\frac{1}{2}\left((\lambda+\mu)^T\Phi(\lambda+\mu) - \left(\lambda^T\Phi\lambda\right) - \left(\mu^T\Phi\mu\right)\right)\\ &= -\frac{1}{2}\left(\lambda^T\Phi\mu + \mu^T\Phi\lambda\right) = -\sum_{j=1}^{N}\sum_{i=1}^{N}\lambda_i\phi(\mathbf{x}_i-\mathbf{x}_j)\mu_j = -\sum_{i=1}^{N}\lambda_i t(\mathbf{x}_i)\\ &= -\sum_{j=1}^{N}\mu_j s(\mathbf{x}_j).\end{aligned}$$

If the function values at the interpolation points are known, these inner products can be computed without any matrix-vector products, i.e., in $O(N)$ operations.

2.2.3. Krylov subspace. The Krylov subspace considered is that induced by the operator Ξ acting on functions s that are expressible via a RBF expansion. This operator is defined using the $N-1$ approximations to the cardinal functions centered at the $N-1$ points that are constructed $\tilde{z}_l$ and is given as

$$(\Xi s)(\mathbf{x}) = \sum_{l=1}^{N-1}\frac{\langle\tilde{z}_l, s\rangle_\phi}{\|\tilde{z}_l\|_\phi^2}\tilde{z}_l(\mathbf{x}).$$

2.2.4. The preconditioned conjugate gradient iteration. Let s^* be the function that is sought as the solution. Define an initial guess $s^{(1)}$ as

$$\lambda_j^{(1)} = 0, \quad j=1,\ldots,N; \qquad \alpha_1 = \frac{1}{2}(\min(f)+\max(f)),$$

which leads to the initial residual

$$r_i^{(k)} = f_i - s^{(k)}(\mathbf{x}_i), \qquad \mathbf{r} = \{r_i\}. \tag{2.5}$$

Two functions expressed as RBF sums are used in the iteration:

$$\begin{aligned}t^{(k)} &= \sum_{j=1}^{N}\tau_j^{(k)}\phi(|\mathbf{x}-\mathbf{x}_j|), \quad \sum_{j=1}^{N}\tau_j^{(k)} = 0,\\ d^{(k)} &= \sum_{j=1}^{N}\delta_j^{(k)}\phi(|\mathbf{x}-\mathbf{x}_j|), \quad \sum_{j=1}^{N}\delta_j^{(k)} = 0.\end{aligned}$$

The first function, t, is constructed using the RBF approximation to the cardinal functions on the specially chosen FGP05 points, and the value of the residual at the current iteration at these points is

$$\mu_l^{(k)} = \frac{1}{\zeta_{ll}}\sum_{i\in\mathcal{L}_l}\zeta_{li}r_i^{(k)}, \qquad \tau_j^{(k)} = \mu_l^{(k)}\zeta_{lj}.$$

It is shown that

$$t^{(k)} = \Xi\left(s^* - s^{(k)}\right),$$

while the second function, $d^{(k)}$, satisfies

$$d^{(1)} = t^{(1)}, \quad d^{(k)} = t^{(k)} - \frac{\left\langle t^{(k)}, d^{(k-1)} \right\rangle_\phi}{\left\langle d^{(k-1)}, d^{(k-1)} \right\rangle_\phi} d^{(k-1)}.$$

Because of this definition, the conjugacy criterion holds,

$$\left\langle d^{(k)}, d^{(k-1)} \right\rangle_\phi = \left\langle t^{(k)}, d^{(k-1)} \right\rangle_\phi - \frac{\left\langle t^{(k)}, d^{(k-1)} \right\rangle_\phi}{\left\langle d^{(k-1)}, d^{(k-1)} \right\rangle_\phi} \left\langle d^{(k-1)}, d^{(k-1)} \right\rangle_\phi = 0.$$

The solution is advanced by a step length γ_k along the conjugate direction $d^{(k)}$, so that

$$\lambda_j^{(k+1)} = \lambda_j^{(k)} + \gamma_k d^{(k)}, \qquad \gamma_k = \frac{\sum_{i=1}^{N} \delta_i^{(k)} r_i^{(k)}}{\sum_{i=1}^{N} \delta_i^{(k)} d^{(k)}(\mathbf{x}_i)}$$

while the constant is updated to minimize the maximum element in the new residual vector. The choice γ_k can be shown to be minimize $\left\| s^* - s^{(k+1)} \right\|_\phi$ along $d^{(k)}$.

Crucial to the implementation is the construction of the approximate cardinal functions. It is indicated in [13] that a Fortran implementation is available from Prof. Powell. Our Matlab implementation of the FGP05 algorithm is available online at http://www.umiacs.umd.edu/~ramani/fmm/FGP_RBF.

2.3. The FMM for accelerating matrix vector products. There are several papers and books that introduce the FMM in detail [14, 15, 2, 21], and our purpose is not to reproduce that literature here. However, certain details of geometric data structures in the FMM will be important in the initial computations necessary for the preconditioner. Our implementation of the FMM for polyharmonic radial-basis functions is described in [19], where we also provided operational and memory complexity.

The algorithm consists of two main parts: the preset step and the evaluation step. The preset step, which includes building the FMM data structure (building and storage of the neighbor lists, etc.) and precomputation and storage of all translation data. The data structure is generated using the bit interleaving technique described in [21], which enables spatial ordering, sorting, and bookmarking. While the FMM algorithm is designed for two independent data sets (N arbitrary located sources and M arbitrary evaluation points), for the RBF fitting we will have the same source and evaluation sets of length N. For a problem size N, the cost of building the data structure based on spatial ordering is $O(N \log N)$, where the asymptotic constant is much smaller than the constants in the $O(N)$ asymptotics of the main algorithm. The number of levels could be arbitrarily set by the user or found automatically based on the clustering parameter (the maximum number of sources in the smallest box) for optimization of computations of problems of different size.

Of particular use in developing the $O(N \log N)$ algorithm for the preliminary steps are the octree data structures that are employed in the FMM. A good introduction to these are provided in Greengard's thesis [14]. Fast algorithms for computing neighbor lists, point assignment to boxes and other necessary operation in the FMM using bit-interleaving and deinterleaving operations are described in [21].

3. Fast algorithms. The original form of the FGP05 algorithm has a complexity of $O(N^2)$ due to two reasons: First, the step of setting the data structure requires $O(N^2)$ operations due to pairwise distance search to form $O(N)$ subsets of length $O(q)$ for approximation of cardinal functions centered at each point, and, second, the step of matrix vector multiplication of $O(N \times N)$ matrix by a $O(N)$ vector also requires $O(N^2)$ operations. As mentioned before, the second step can be done using the FMM for $O(N \log N)$ operations. In the subsections below we describe efficient $O(N \log N)$ algorithms for both steps, which bring the FGP iterative method to $O(N \log N)$ complexity.

3.1. Data structure for the FGP05 algorithm. While the problem of determining the closest points in a data set is a relatively well-studied problem in computational geometry, we are unaware of any algorithms that solve the particular problem required in the FGP05 algorithm. As mentioned earlier, a reason for the dramatic performance of the algorithm, as discussed in [13], is the careful selection of the points over which the cardinal function is selected. As such a selection might be useful in the construction of preconditioners with other radial-basis function applications with the FMM, we provide details of this algorithm below.

3.1.1. Problem statement. While the selection of the point sets has been described above in words, we will provide a more precise mathematical statement here, mainly in the interest of establishing notation.

Given a set $\mathbb{X}$ of N points in d dimensional Euclidean space, $\mathbf{x}_i \in \mathbb{R}^d$, $i = 1, \ldots, N$, and $q < N$ build $N-1$ sets $\mathbb{L}_j \subset \mathbb{X}$, $j = 1, \ldots, N-1$ satisfying the following conditions:

- For $j = 1, \ldots, N-q+1$ the sets $\mathbb{L}_j$ consist of q points $\mathbf{x}_{i_{j1}}, \ldots, \mathbf{x}_{i_{jq}} \in \mathbb{X}$ while for $j = N-q+2, \ldots, N-1$ the sets $\mathbb{L}_j$ consist of $N-j+1$ points, $\mathbf{x}_{i_{j1}}, \ldots, \mathbf{x}_{i_{j,N-j+1}} \in \mathbb{X}$. The number of entries in the set is called its "power," so $Pow(\mathbb{L}_j) = q$ for $j = 1, \ldots, N-q+1$ and $Pow(\mathbb{L}_j) = N-j+1$ for $j = N-q+2, \ldots, N-1$.
- Each set $\mathbb{L}_j$ is associated with a point $\mathbf{x}_{i_{j1}} \in \mathbb{L}_j$, called the set center. All set centers are different, $i_{j1} \neq i_{k1}$, for $k \neq j$. Further, we introduce sets of set centers $\mathbb{C}_j = \left\{\mathbf{x}_{i_{11}}, \ldots, \mathbf{x}_{i_{j1}}\right\}$, $j = 1, \ldots, N-1$, $Pow\left(\mathbb{C}_j\right) = j$.
- The set $\mathbb{L}_1$ consists of points $\mathbf{x}_{i_{11}}, \ldots, \mathbf{x}_{i_{1q}} \in \mathbb{X}$ such that

$$|\mathbf{x}_{i_{11}} - \mathbf{x}_{i_{12}}| = \min_{\mathbf{x}_i, \mathbf{x}_k \in \mathbb{X}, i \neq k} |\mathbf{x}_i - \mathbf{x}_k|, \tag{3.1}$$

$$|\mathbf{x}_{i_{11}} - \mathbf{x}_{i_{1l}}| \leq \min_{\mathbf{x}_k \in \mathbb{X} \setminus \mathbb{L}_1} |\mathbf{x}_{i_{11}} - \mathbf{x}_k| \quad \text{for} \quad l = 3, \ldots, q. \tag{3.2}$$

  In other words, the distance between the center of this set and the second element is minimal among all pairwise distances in $\mathbb{X}$. Besides the set center the set consists of the $q-1$ closest points to the set center.
- The set $\mathbb{L}_j$, $j = 1, \ldots, N-1$ consists of points $\mathbf{x}_{i_{j1}}, \ldots, \mathbf{x}_{i_{jp}} \in \mathbb{X} \setminus \mathbb{C}_{j-1}$, $p = Pow(\mathbb{L}_j)$, such that

$$\left|\mathbf{x}_{i_{j1}} - \mathbf{x}_{i_{j2}}\right| = \min_{\mathbf{x}_i, \mathbf{x}_k \in \mathbb{X} \setminus \mathbb{C}_{j-1}, i \neq k} |\mathbf{x}_i - \mathbf{x}_k|, \tag{3.3}$$

$$\left|\mathbf{x}_{i_{j1}} - \mathbf{x}_{i_{jl}}\right| \leq \min_{\mathbf{x}_k \in \mathbb{X} \setminus (\mathbb{L}_j \cup \mathbb{C}_{j-1})} \left|\mathbf{x}_{i_{j1}} - \mathbf{x}_k\right| \quad \text{for} \quad l = 3, \ldots, q. \tag{3.4}$$

  In other words, the distance between the center of this set and the second element is the minimal among all pairwise distances in $\mathbb{X}$ excluding the centers of the sets $\mathbb{L}_1, \ldots, \mathbb{L}_{j-1}$. Besides the set center the set consists of $q-1$ closest

points to the set center for $j = 1, \ldots, N - q + 1$ and $N - j + 1$ closest points to the set center for $j = N - q + 2, \ldots, N - 1$.

3.1. If we construct the complete interpoint distance matrix (requiring computation of $N(N-1)/2$ distances), this problem can be solved simply. However, this requires $O\left(N^2\right)$ time and memory.

3.1.2. General algorithm. There exist fast closest neighbor search algorithms in d dimensional space of complexity $O(\log N)$ per query. These algorithms are based on hierarchical space subdivision using k-d trees or similar ideas [25]. The cost of building a tree data structure is $O(N \log N)$. Furthermore, an initial spatial ordering of the data requires $O(N \log N)$ operations. However, these structures do not enable easy deletion of points.

Deletion is enabled in the heap data structure, which also requires $O(N \log N)$ construction cost [10]. Organization of the data using heaps enables $O(\log N)$ insertion/deletion operations for a single entry. However, even with these preliminary steps the design of the actual algorithm requires several additional data structures which take care of the dynamic nature of the data (the deletions of the set center at each step). These additional structures account for the modifications of the initial set $\mathbb{X}$ due to deletion operations and enable $O(\log N)$ complexity for any operation on the modified data set. Such a performance is needed for these operations, as they must be repeated $O(N)$ times as the cardinal point sets are built for the $N - 1$ centers.

We assume the initial set $\mathbb{X}$ consists of points randomly distributed over the computational domain, which can be enclosed by a d dimensional cube of side D. In practice this set may not be random, as the data may come imbued with a certain order because of the way it was generated. Such an order may not be desirable for the performance of the preconditioner. This is why in [13] the authors suggested an initial random permutation of all initial data. We follow this approach and to avoid additional complexity in notations we assume that such a random permutation is performed as a first step and points in $\mathbb{X}$ are already arranged in random order.

Let $\mathbb{X}'$ be a spatially ordered set of points from $\mathbb{X}$. Spatial ordering in d dimensions, when d is not large (say $d = 2$ or $d = 3$, which is the case for most applications of the FMM) can be performed efficiently using the bit-interleaving technique. We use the same technique to generate the FMM quadtree or octree data structure. A detailed description of the bit-interleaving technique can be found in [22, 21]. The ordered set $\mathbb{X}'$ can be characterized by a permutation index Π. So if $\mathbf{x}_i$ is the ith element of $\mathbb{X}$, then the jth element of $\mathbb{X}'$, where $j = \Pi(i)$ corresponds to the same point. Thus, as Π is available there is no need for additional memory to store $\mathbb{X}'$. The spatially ordered list is needed to provide the following operations with a complexity $O(\log N)$ for any point:

1. deletion, and,
2. q-closest point search in the subset of remaining points after the deletion of previously considered point centers.

These procedures are described below separately.

The second virtual set which we introduce is $\mathbb{H}$, which consists of the elements of $\mathbb{X}$ partially ordered according to some ranking criterion $\mathcal{R}$ using the heap data structure [10]. This set also can be characterized completely by the permutation index H. We will operate only with first k elements of $\mathbb{H}$ which thus form a subset $\mathbb{H}^k \subset \mathbb{H}$. The top ($j = 1$) element of $\mathbb{H}^k$ has the highest rank. Elements below this element are arranged in a binary tree, with each leaf being outranked by its parent ("heap property"). The heap structure is needed to provide the following operations

of complexity $O(\log N)$:

1. find the highest ranked element,
2. delete the highest ranked element,
3. change the rank of an element.

After performing any of these operations, the heap structure (characterized by a permutation index H) can be recovered for a cost of $O(\log N)$ operations. The ranking which we introduce can be applied only to elements of $\mathbb{H}^k$. The rank $\mathcal{R}_i$ of element $\mathbf{x}_i \in \mathbb{H}^k$ is the nearness of the point to the set center. So the closest neighbor to the top element of $\mathbb{H}^k$ is closer (or at the same distance) than the closest neighbors to other points from $\mathbb{H}^k$.

We need to introduce two more lists or indices. The first list can be denoted as C and $C(i)$ is the index of the closest neighbor to $\mathbf{x}_i$ if both these points are in $\mathbb{H}^k$. The second list can be denoted as C^*, where

$$C\left(C^*(j,i)\right) = i \quad \text{for} \quad j = 1, \ldots, M_i^k. \tag{3.5}$$

In some sense this mapping is inverse to $C(i)$. However, as the closeness relationship is not unique, a point $\mathbf{x}_i$ can be the closest neighbor to several points. Since this mapping is not one-to-one, $C^*(:,i)$ provides the indices of all M_i^k points to which $\mathbf{x}_i$ is the closest neighbor. To bound the size of the array (and the memory and operations), we need to bound the quantity M_i^k. There exists a strong bound for M_i^k, which shows that for a given distribution of points in $\mathbb{R}^d$ the number of entries in C^* is $O(N)$. We present this result in the form of the following theorem.

THEOREM 3.2. [illegible] N [illegible] $\mathbb{R}^d$, $(d \geq 1)$ [illegible] $\mathbf{x}_i \in \mathbb{R}^d$ $i = 1, \ldots, N$ [illegible] C [illegible] $i = 1, \ldots, N$ [illegible] M_i [illegible] i [illegible] $M_i \leq K_{(d)}$ [illegible] $K_{(d)}$ [illegible] d [1]

[illegible]. Without any loss of generality we can assign index $i = 1$ to a given point and assign indices $2, \ldots, M+1$ to points for which this point is the closest neighbor. Denote $D_j = |\mathbf{x}_j - \mathbf{x}_1|$ and $D_{\max} = \max_{j=2,\ldots,M+1} D_j$. Consider then a sphere of radius $D_{\max}$ centered at $\mathbf{x}_1$. For each point $\mathbf{x}_j$ we will correspond point $\mathbf{y}_j$ on the sphere surface: $\mathbf{y}_j = \mathbf{x}_1 + (D_{\max}/D_j)(\mathbf{x}_j - \mathbf{x}_1)$, $j = 2, \ldots, M+1$. Let us show that $|\mathbf{y}_j - \mathbf{y}_k| \geq D_{\max}$ for $j, k = 2, \ldots, M+1$, $j \neq k$. Indeed, since for these j and k we have $|\mathbf{x}_j - \mathbf{x}_k| \geq \max(D_j, D_k)$ (otherwise $\mathbf{x}_1$ is not the closest point to $\mathbf{x}_j$ or $\mathbf{x}_k$), we obtain

$$\begin{aligned} 2(\mathbf{x}_j - \mathbf{x}_1) \cdot (\mathbf{x}_k - \mathbf{x}_1) = |\mathbf{x}_j|^2 + |\mathbf{x}_k|^2 - |\mathbf{x}_j - \mathbf{x}_k|^2 &\leq D_j^2 + D_k^2 - [\max(D_j, D_k)]^2 \\ &\leq D_j D_k. \end{aligned}$$

Therefore,

$$\begin{aligned} |\mathbf{y}_j - \mathbf{y}_k|^2 &= |\mathbf{y}_j - \mathbf{x}_1|^2 + |\mathbf{y}_k - \mathbf{x}_1|^2 - 2(\mathbf{y}_j - \mathbf{x}_1) \cdot (\mathbf{y}_k - \mathbf{x}_1) \\ &= 2D_{\max}^2 - \frac{D_{\max}^2}{D_j D_k} 2(\mathbf{x}_j - \mathbf{x}_1) \cdot (\mathbf{x}_k - \mathbf{x}_1) \geq 2D_{\max}^2 - D_{\max}^2 = D_{\max}^2. \end{aligned}$$

Now we see that there are M points on the sphere surface the pairwise distance between which is not less than the radius of this sphere. Introducing spheres of radius $R = D_{\max}/2$ centered at $\mathbf{x}_1$ and $\mathbf{y}_j$, $j = 2, \ldots, M+1$, we can see that this is equivalent

[1] The kissing number is defined as the maximum number of unit spheres which can surround a given unit sphere without intersection (excluding the touching of points on the boundary) [30].

to placing M spheres of radius R around the sphere of the same radius centered at $\mathbf{x}_1$. It is well known that this number cannot exceed the kissing number. □

[illegible] 3.3. The exact kissing number is well known for dimensions $d \leq 9$ and $d = 24$, while for other dimension bounds for $K_{(d)}$ are established. Particularly, we have $K_{(1)} = 2$, $K_{(2)} = 6$, $K_{(3)} = 12$.

The procedure of building sets satisfying the above requirements can then be reduced to procedures of q-closest neighbor search and deletion of found set centers from the data structures.

[illegible]

- Build a hierarchical space subdivision using the 2^d-trees and initialize data structure for neighbor search and deletion procedures.
- Set $k = N$; $M_i^k = 0$, $i = 1, \ldots, N$.
- For $j = 1 : N$
  1. Get the closest neighbor for point j (let this be i). This is provided by the q-neighbor search procedure for $q = 1$.
  2. Set $C(j) = i$, $d(j) = |\mathbf{x}_j - \mathbf{x}_i|$, $M_i^k = M_i^k + 1$, $C^*\left(M_i^k, i\right) = j$.
- Based on ranking $\mathcal{R} = -d$, build the heap permutation index H.

[illegible]

- For $i = 1 : N - 1$
  1. Find the size of set $\mathbb{L}_i$: $q' = \min(q, N - i + 1)$.
  2. Find the index of the set center: $j = H(1)$. This is the top ranked point in the heap. Find the index of the closest to j neighbor: $m = C(j)$.
  3. Find all the entries of $\mathbb{L}_i$. The first entry is $\mathbf{x}_j$ and the rest are $q' - 1$ closest neighbors, provided by the q-neighbor search procedure for $q = q' - 1$.
  4. Delete point j from the hierarchical data structure for neighbor search. Delete point j from the heap. The last procedure sets the heap length to $k = k - 1$ and updates the heap permutation index H.
  5. Modify M_m^k and $C^*\left(M_m^k, m\right)$. As m is the closest to j it is listed in $C^*(:, m)$. So set $M_m^k = M_m^k - 1$ and squeeze $C^*(:, m)$ to exclude j (this will change the indexing in $C^*(:, m)$).
  6. Update lists C and C^* and the heap permutation index H as follows.
  7. For $n = 1 : M_j^k$
     (a) Get the closest neighbor, s, for point $p = C^*(n, j)$. This is provided by the q-neighbor search procedure for $q = 1$.
     (b) Set $C(p) = s$, $d(p) = |\mathbf{x}_p - \mathbf{x}_s|$, $M_s^k = M_s^k + 1$, $C^*\left(M_s^k, s\right) = p$.
     (c) Update the heap permutation index for new rank of point p, $\mathcal{R}(p) = -d(p)$.

3.1.3. Data structure for deletion operation and q-closest neighbor search using 2^d-trees. For fast neighbor search we employ 2^d-tree data structures, which for $d = 2$ and $d = 3$ are known as the quadtree and octree, respectively [27]. In the 2^d-tree we have one box at level 0 (which is a cube including all points from $\mathbb{X}$), 2^d cubical boxes at level 1 obtained by division by half of the initial (parent) box along each dimension, and so on up to level $l_{\max}$, where we have $2^{l_{\max} d}$ boxes. As the data are sorted using the bit-interleaving techniques, they can be easily boxed due to the hierarchical numbering system [21], which also provides a fast way to obtain parents and neighbors for all boxes. Of course, not all the boxes may be occupied, and the "empty" boxes are not listed in the data structure. Selection of $l_{\max}$ is dictated by the parameter q, and one of the possibilities to determine $l_{\max}$ is to define it as the level at

which the finest box contains not more than $q+1$ points. For every box we maintain a list of points which reside in this box. This list is dynamic and provided by an additional data structure described below. The same relates to the list of nonempty boxes neighboring to the given box. For the neighbor search procedure we use the so called 2-neighborhoods [22], which are cubic domains consisting of at most 5^d boxes where $5^d - 1$ neighbor boxes surround the central (given) box.

The selection of 2-neighborhoods is motivated by the space dimensions $d = 2$ and $d = 3$, which are the focus of the present paper. Assume that there are $q + 1$ points located in some box, then for $d = 2, 3$ we can guarantee that for any point in the dataset, its q closest (Euclidean) neighbors are located inside the 2-neighborhood. Indeed, the maximum distance between some point and its qth closest neighbor does not exceed $Dd^{1/2}$, where D is the box size. At the same time the minimum distance from this point to the boundary of the 2-neighborhood is $2D$. As $d^{1/2} \leq 2$ (which also means that the 2-neighborhood can be used for $d = 4$) we have such a guarantee and can use the search algorithm described below.

A complication is that the general algorithm above needs an efficient deletion procedure, so the search required to form the ith set $\mathbb{L}_i$ is performed only on the set $\mathbb{X}\backslash\mathbb{C}_{i-1}$. We resolve this issue by introducing linked lists [10] for all points and boxes in the neighborhood of each box. The point linked list $L_p\,(2, N)$ is an array, where $L_p\,(1, i)$ is the index of point from the ordered set $\mathbb{X}'$ preceding point i and $L_p\,(2, i)$ is the index of point next to i. This list is initialized by setting $L_p\,(1, i) = i - 1$ and $L_p(2, i) = i + 1$ and is updated each time as some point i should be deleted. Note that all points $\{i\}$ residing in box j can be characterized by the indices of the first and last point in this box (bookmarks), as the point linked list is available.

The data structure for handling the neighborhoods is the following. For each box i we have a list of boxes in the 2-neighborhood of this box, $N_{neigh}\,(:, i)$, where the first index takes values from 1 to 5^d. The boxes in this neighborhood are linked in a similar way as the points in the original set. This is provided by the linked lists $L_n\,(:, i)$, where $L_n\,(1, i)$ is the relative index of the first element, $L_n\,(2, i)$ is the link from the first element to the second, and so on. This array is initialized as $L_n\,(m, i) = m$, $m = 1, \ldots, N_n\,(i)$, $i = 1, \ldots N_{b,tot}$, where $N_n\,(i)$ is the number of boxes in the neighborhood of box i and $N_{b,tot}$ is the total number of boxes. For conveniences we also maintain the arrays $N_p\,(i)$, which shows the number of points in box i, $B(j)$, which is the index of the box containing point j, and $N_{pn}\,(i)$, which is the total number of points in the neighborhood of box i.

With these arrays the deletion of point j (index in $\mathbb{X}'$) and the q-closest neighbor search procedures for point j (index in $\mathbb{X}'$) can be described by the following algorithms.

- Set $i = B(j)$; $n_p = N_p(i) - 1$; exit if $n_p < 0$ (nothing to delete), else:
- Update the linked list L_p: $a = L_p\,(1, L_p(j))\,, b = L_p\,(2, L_p(j))$, $L_p\,(1, L_p(j)) = b, L_p\,(2, L_p(j)) = a$ (note that this should be modified for the first and last points; also we need to update the bookmarks if the deleted point is the first or the last point in the box); $N_p(i) = n_p$.
- Set $l = l_{\max}$ and perform the following loop while $l \geq 1$ and $n_p = 0$ (this procedure excludes all boxes, which become empty due to point deletion):
  1. For $m = 1 : N_n(i)$ (go through all boxes which are in the neighborhood of a box i)
     a. $p = N_{neigh}(L_n(m, i), i)$ $(p \neq i)$; $N_{pn}\,(p) = N_{pn}\,(p) - 1$. Update the linked lists $L_n\,(:, p)$.

2. $l = l - 1$; $i = Parent(i)$; $n_p = N_p(i) - 1$; $N_p(i) = n_p$ (also check/update bookmarks for box i if $n_p > 0$).

For the sake of clarity, we drop details of our procedure for updating $L_n(:, p)$, which are rather obvious, as one should reconnect the broken links caused due to the exclusion of box i. Note then that the major complexity of this algorithm is due to the loop over all boxes, for which a given box i lie in its neighborhood. This requires at most $\left(5^d - 1\right)^2$ simple operations (repairing links). Also it may appear that this operation is needed for all parent boxes. If $l_{\max} \sim \log N$ the total cost will be $O(\log N)$, with a remark that the updates of the neighborhood data structure are needed only when the deletion of a point results in an empty box, which then should be deleted. This situation appears relatively rarely. Otherwise, the deletion of point is computationally cheap as it requires just repairing a broken link (2 operations) and a check/update of bookmarks (2 operations).

- Set $i = B(j)$, $l = l_{\max}$, $n_p = N_p(i)$.
- While $k < q + 1$ and $l > 1$ perform the following loop (determine the level at which the box containing point j has at least $q + 1$ entries):
  1. $l = l - 1$; $i = Parent(i)$; $k = N_p(i)$.
- Determine $D_{\max}$ and $D_{\min}$ which are the maximum and minimum distances from j to the boundary of box i.
- Determine all distances from point j to points in box i, which are different from j. Put them into the distance array *dist* and sort in the ascending order.
- If $dist(q) > D_{\min}$, perform the following procedure for boxes $p \neq i$ from the 2-neighborhood of i:
  1. Determine $D'_{\min}$, which is the minimum distance from j to the boundary of box p.
  2. If $D'_{\min} < D_{\max}$, determine all distances from point j to points in box p. Union them with array *dist*. Sort *dist* in the ascending order.

An informal description of the algorithm is the following. First, we are trying to find a box big enough to contain q neighbors of point j. For this purpose we consider the parent of the box, if the box does not contain a sufficient number of points. This procedure is finite (at most $\sim l_{\max} \lesssim \log N$). After such a box is found we introduce two threshold distances $D_{\max}$ and $D_{\min}$ as defined above. It may happen that the closest q points to j occupying box i are closer than $D_{\min}$. In this case there is no need to check points from the neighborhood, since they are further than the q points, which provide the solution to the problem. On the other hand, we know that there are at least q neighbors located at distance smaller than $D_{\max}$. Hence there is no need to check the boxes from the neighborhood with $D'_{\min} \geq D_{\max}$. This constraint substantially reduces the number of boxes to check. For example, for $d = 2$ we should check at most 11 neighbor boxes instead of 24, and for $d = 3$ we have 55 instead of 124 ($5^d - 1$). The numbers in practice are even smaller, as not all points are located in the worst position.

The above algorithm does not have $O(\log N)$ guaranteed complexity for a single point search and an arbitrary distribution. For very nonuniform distributions, additional research is needed as the cost of search can substantially vary from point to point and it is not clear theoretically what is the overall complexity of the above adaptive scheme.[2] However, guarantees can be provided for uniform and some other

[2]This remark applies equally to the FMM, where for carefully contrived distributions the $O(N \log N)$ complexity may not be achieved.

typical distributions. Indeed, in the case of a uniform distribution we can assume that all boxes in the neighborhood has approximately the same number of points $\sim q$. Therefore the search is performed on the set of size $O(5^d q)$, which does not depend on N, and so the $\log N$ complexity arises only from the first step of the procedure (in practice for larger q this step is cheaper than the computation of distances due to its small asymptotic constant).

3.2. Fast multipole acceleration of the matrix vector product.

3.2.1. Polyharmonic kernels in 3D. An approach for efficient computation of sums with biharmonic kernel in $\mathbb{R}^3$, $\phi(r) = r$, using the FMM is described in detail in [19], where we also show how this method can be extended to computation of polyharmonic kernels in $\mathbb{R}^3$, $\phi(r) = r^{2n+1}$. The major result there can be formulated as follows. The FMM for kernels $\phi(r) = r^{2n+1}$, $n = 0, 1, \ldots$, can be efficiently reduced to application of $n+2$ FMMs for the Laplace equation in $\mathbb{R}^3$ (with kernel $\phi(r) = r^{-1}$) for which the FMM is well developed and studied. In practice the cost for the polyharmonic kernel is even smaller, as the same data structure is needed, direct summation in the neighborhood is only needed once, and only a slight modification of the translation operators is needed.

The efficiency of the FMM is determined by the length of function representation, which for polyharmonic kernel $\phi(r) = r^{2n+1}$ can be referred to as $(n+2)\,p^2$, where p is the truncation number for the equivalent Laplace equation determined by the prescribed accuracy of computations, and the cost of a single translation, which for the fastest practical methods available is $O(p^3)$ (with different asymptotic constants [9, 20]); ($O(p^2 \log p)$ methods with larger asymptotic constant are also available, e.g., [16, 12]). In tests used in the present paper we employed our version for summations with the biharmonic kernel [19], where we used rotational-coaxial translation decomposition of the translation operators, which result in $O(p^3)$ complexity for a single translation.

3.2.2. A novel FMM for the multiquadric kernel in $\mathbb{R}^2$. An FMM for the multiquadric kernel, $\phi(r) = \left(r^2 + c^2\right)^{1/2}$, in $\mathbb{R}^n$ was presented in [11]. While this algorithm can be used for the multiquadric function in $\mathbb{R}^2$, we present a new FMM based approach to evaluate sums with the multiquadric kernel.

First, we note that representation of general functions via expansion coefficients or samples in 2D requires double sums or $O(p^2)$ function representation length for a truncation number p (e.g., via truncated Taylor series expansions). In contrast functions that are constrained to satisfy some partial differential equation, such as the harmonic function, can be expressed with just $O(p)$ coefficients in $\mathbb{R}^2$. General translation operators for functions with a $O(p^2)$ representation can then be represented via a $p^2 \times p^2$ truncated matrix, which results in a computational cost of $O(p^4)$ per translation. For large p, methods that employ the convolutional characteristics of the translation can exploit the fast Fourier transform to reduce the asymptotic complexity $O(p^2 \log p)$. However, these methods will in practice not be useful for typical problems and further suffer an inefficiency as they require zero padding. (See [16] for a discussion of this issue.) The proposed method also uses $O(p^2)$ representation; however, the translation cost can be reduced to $O(p^3)$, which is faster than the direct translation for $p \geq 3$.

The essence of the method is to extend the space dimensionality from 2 to 3 and separate the source and receiver points, even though in $\mathbb{R}^2$ these points can be the same. Indeed, let $\mathbf{x}_i$ and $\mathbf{y}_j$ be the source and receiver in 2D. Their interaction is

then described as

$$\phi\left(|\mathbf{y}_j - \mathbf{x}_i|\right) = \left(|\mathbf{y}_j - \mathbf{x}_i|^2 + c^2\right)^{1/2} = \left|\mathbf{y}'_j - \mathbf{x}'_i\right|; \quad \mathbf{y}'_j = \mathbf{y}_j + c\mathbf{i}_z,\ \mathbf{x}'_i = \mathbf{x}_i + 0\mathbf{i}_z,$$

where $\mathbf{y}'_j$ and $\mathbf{x}'_i$ are points in $\mathbb{R}^3$ and $\mathbf{i}_z$ is the unit vector orthogonal to the original plane on which $\mathbf{x}_i$ and $\mathbf{y}_j$ are located. It is seen then that this transform leaves the sources on the original plane, while it shifts the locations of all evaluation points by a constant displacement c, so $\mathbf{y}'_j$ is located on the plane parallel to the original one (the case $c = 0$ is a particular, but not special, case). Therefore the problem of computation of sums with the multiquadric kernel in $\mathbb{R}^2$ is equivalent to the computation of sums with the biharmonic kernel in $\mathbb{R}^3$ with the sources and receivers having special locations (placed on parallel planes).

REMARK 3.4. The use of an increased dimensionality should not frighten us and, in fact, this does not increase either the memory or the computational cost. Indeed, in the FMM that we use all "empty" boxes are skipped.

REMARK 3.5. As the sets of sources and receivers are separated by distance not less than c there is no sense in dividing the space up to levels where the size of the boxes are less than $c/2$ (if the division goes deeper there will be no sources in the neighborhood of the receivers and the computational cost will just increase due to additional translation operations).

REMARK 3.6. This method can also be successfully applied for computations of sums with the inverse multiquadric kernel $\phi(r) = \left(r^2 + c^2\right)^{-1/2}$ in $\mathbb{R}^2$. Sums involving this kernel can be reduced to a summation with the Laplacian kernel $1/r$ in $\mathbb{R}^3$.

4. Numerical tests. To check the accuracy and performance of the fast algorithms and compare them with [13], we implemented the described algorithms and the FGP05 algorithm in Fortran 90 in double precision arithmetic and performed some tests on an Intel Xeon 3.2 GHz processor with 3.5 GB RAM. Performance tests were conducted using two basic random point distributions for $\mathbb{R}^2$ (with the multiquadric kernel) and $\mathbb{R}^3$ (with the biharmonic kernel). The parameter c for the multiquadric kernel was varied from 0 to a value based on the characteristic distance between neighboring points. The first distribution coincides with test case A of [13]. In this case points were uniformly distributed inside a d dimensional unit sphere, we also refer to this case as "A." The second distribution is substantially nonuniform, as the points in this case were uniformly distributed over the surface of a d dimensional unit sphere and so were on manifolds of lower than d dimensions. Such distributions are typical for interpolation of curves and surfaces. We refer to this case as "E." In both cases the entries of the right-hand side vector were generated as random numbers uniformly distributed on $[-1, 1]$. We also performed several illustrative computations for some standard problems appearing in 2D and 3D computer graphics.

4.1. Preconditioner tests. There are new elements in the present algorithm which are related both to construction of the preconditioner (or approximate cardinal functions) and to the approximate FMM based matrix vector multiplication. We first studied the effect of the new preconditioner in isolation in cases where the matrix vector product was performed in the straightforward way.

The first test was to ensure that our implementation of the original FGP05 algorithm is correct. We found that we were able to produce results consistent with those reported in [13]. We next modified the algorithm to use the L-sets produced by our algorithm for selecting the cardinal function interpolation points. The difference between our algorithm and that of [13] is that we impose the selection of closest

points exactly where as this is done approximately in FGP05. Table 4.1 shows the number of iterations required to converge to an accuracy $\epsilon = 10^{-10}$ for the test case A for different N and q. For each case we did several tests trying to find averages, the variation from test to test was rather small (usually within 1 iteration) so we put in the table values for a single random realization. The stability of the number of iterations for different realizations was also pointed out in [13].

The results for case $d = 2, c = 0$ are very close to that reported in [13] (we also checked the $q = 20$ and $q = 40$ reported in [13], with similar results, but do not report them here to conserve space). As one can see from the table, the number of iterations for preconditioners produced by both algorithms are almost the same.

The time required to build the L-sets and compute approximate cardinal function approximation is almost insensitive to parameter c of the multiquadric kernel, while it does depend on the point distribution. Table 4.2 shows the CPU time (in seconds) required to build preconditioners using the original and present algorithm for four cases (A and E, $d = 2$ and $d = 3$) for $q = 30$ and different N. These results are also presented in Figure 4.1. As before, we report the timing for a single random realization, while several entries into the table were recomputed several times to ensure that the variations in timing are rather small (within a couple of percent).

It is clearly seen that for $N < N_b$, which is of order of thousands, the original algorithm performs better, as we incur an additional overhead due to the more complex data structure needed in our algorithm. However, for $N > N_b$ the execution time for the original algorithm scales as $O(N^2)$, while the present algorithm scales almost linearly with N. The scaling constant and the value of N at which the present algorithm starts to perform linearly depends on the problem dimensionality and point distribution. The problem dependence of the present algorithm is stronger than for the original algorithm. We also note that due to large time required by the original al-

gorithm for large N we did not compute the values for $N > 100000$ and put estimated times in parenthesis based on the fit line shown in the figure. It is seen that for large N the ratio of times for the algorithms tested can be several orders of magnitude.

Table 4.1 shows that the number of iterations decreases as the size q of the L-sets increases. Thus, it may be preferable to use a larger q to reduce the iteration time. On the other hand, the time required to build the L-sets and compute cardinal function approximations increases with increasing q, which is the limiting factor to use larger q. This time depends on N and the particular distribution. Theoretically, the time to build the L-sets for a fixed distribution and N should grow almost linearly with

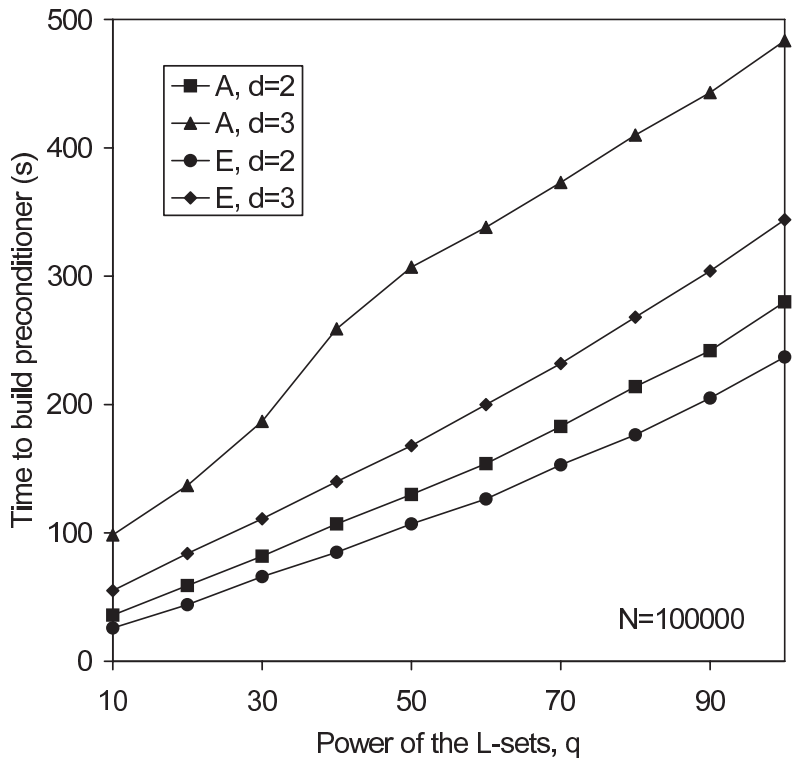

FIG. 4.2. *Dependences of the time required to construct preconditioner for problems A and E on the size of the L-sets q. The number of points for all cases is the same,* $N = 100000$.

q (asymptotically as $q \log q$; the logarithmic complexity appears due to the sorting procedure used for determination of closest neighbors). The time to solve a system of q equations to build the approximate cardinal function grows $\sim q^3$ as we used a standard LAPACK symmetric solver routine for this purpose. Figure 4.2 presents actual computation times for problems A and E and $d = 2$ and 3 at $N = 100000$. It is seen that the time depends on the problem dimensionality and the largest times obtained for $d = 3$. We also note that an effective dimensionality of problem E for large N is $d-1$ rather than d, which explains the smaller times observed for problem E compared to problem A.

4.2. Tests of the algorithm with the FMM. Speeding up the matrix vector product using approximate methods, such as the FMM, raises several issues on the accuracy, convergence, and speed of the algorithm. The accuracy of the FMM is controlled by the truncation number p. For multiquadric functions the error of matrix vector multiplication in the L^∞ norm ϵ_N decays exponentially at growing p, $\epsilon_N \sim N\eta^{-p}$, assuming that they contribute to the error in the worst way (no error cancellation). Actual errors usually are orders of magnitude lower than theoretical bounds and depend on the problem dimensionality and particular point distributions. Concerning convergence of the iterative algorithm we found for given prescribed accuracy empirically numbers $p_*(N)$, $p > p_*(N)$. Here p_* depends on the problem that the number of iterations to converge to any prescribed accuracy is the same as in the case when direct matrix vector multiplication is used. Moreover, the norm of the residuals in this process do not depend on p. Despite this, because of conditioning

of the matrix, the solution may converge to a solution that is not exact. The error of this solution can be evaluated for smaller N as we can check it using one straightforward matrix vector multiplication to evaluate the residual and the results can be extrapolated to larger N as we know qualitatively the dependence of the matrix vector product on N and p. Of course, the error criterion used to stop the iterative process should be selected in some consistent way with this error, and this is an item of current research (see, e.g., [28]). This whole issue is also application dependent since it is often the data to be fit are noisy [8] and the fitting equations may themselves be regularized.

Note then the tuning (optimization) of the overall algorithm is not a simple procedure. Indeed, for some prescribed error, the truncation number should be a function of N (e.g., $p \sim \log CN$). Based on p, the optimal level of space subdivision, $l_{\max}$, for the FMM should be selected. The complexity of the FMM for optimal level depends on the complexity of translation procedures. For example, for the rotational-coaxial translation decomposition in some range of p for 3D problems, this can be $O(p^{3/2}N) = O(N \log^{3/2} N)$. Furthermore, one should select an appropriate q for the preconditioner. As the time to build the preconditioner depends on q and the number of iterations decays with q, one can expect a minimum for the cost. We found that there can be several local minima (e.g., we found four for $N = 100000$, $d = 2$, $c = 0$, problem A in range $15 \leq q \leq 30$). Dependence of the number of iterations on N is also important. An accurate addressing of these issues is outside the scope of this paper. Further fundamental studies of the FMM induced matrix perturbations on the accuracy of the overall solution are required, we will further limit ourselves by presentation of several results of the algorithm performance for some test cases. Further, Faul, Goodsell, and Powell [13] indicate that their intuition is that the choice of q should be independent of problem size.

Table 4.3 shows the CPU times required for computation of some test problems of different size. Here the CPU times include both the time to compute the preconditioner and run the iterative process. In all cases the prescribed error was $\epsilon = 10^{-3}$, and p was increasing for increasing N. For example, for test case A, $d = 2$, $c = N^{-1/2}$, we changed p from 16 to 28 as N changed from 1000 to 1000000. The parameter q in all cases was 30 (the number suggested by [13]), which provided an acceptably small number of iterations, except of case A, $d = 3$, $c = 0$, where a substantial growth in the number of iterations was observed for $N \geq 100000$. For these cases we set $q = 100$, which provided a substantially smaller number of iterations and overall savings in the computational time.

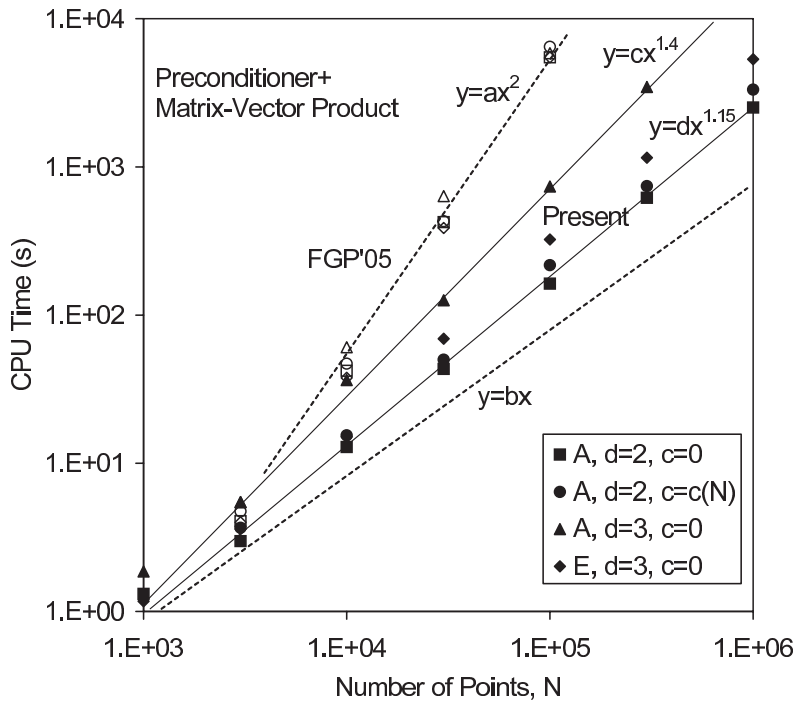

FIG. 4.3. *The total CPU time required for the solution of different problems. The empty markers show computations using algorithm FGP*05*, while the filled markers show computations using the present algorithm. The straight lines with different angular coefficients are plotted for convenience of data analysis.*

Results presented in the table are also plotted in Figure 4.3. The table shows that for all examples the crossover point between the FGP05 and the present algorithm did not exceed $N = 3000$. One can also see that for larger N the CPU time for the FGP05 in the computed range can be fitted by a $O(N^2)$ dependence (in fact, it should be larger than this estimate as the number of iterations does slightly grow with N). We used this fit to estimate the CPU time for the FGP05 algorithm for $N > 100000$, which in fact underestimates the time a bit, and these are shown in Table 4.3 in parentheses. For the present algorithms the data can be fitted by a $O(N^\alpha)$ dependence (one can also use fits of type $O(N \log^\beta N)$, which should hold if the number of iterations grows with N as some power of $\log N$). The constant α for our computations varies from $\alpha = 1.15$ to $\alpha = 1.4$, and as we mentioned there are two basic reasons for this: growth of the truncation number p and of the number of iterations. Also, some computational overhead for larger N contribute to the total CPU time reported. In any case, one can see substantial speed increases achieved using the present method, which make practical computations for million point size sets (larger problems can be computed using parallel computations and larger memory).

Performance of the algorithms for higher accuracy computations is shown in Table 4.4. Here for the FMM computations we set $p = 31$ for all N and the iterative process for both algorithms was terminated when the residual error reached $\epsilon = 10^{-8}$. Other parameters were the same as for cases reported in Table 4.3. For higher accuracy, more iterations are needed and the times reported in Table 4.4 are larger than in Table 4.3. Further, the FMM based algorithms become slower due to an increase of p. This shifts the crossover point for the algorithms towards higher values. Nonetheless,

TABLE 4.4
Total CPU time required by the present and FGP05 algorithms for higher accuracy computations.

the crossover point for the 2D case A is about $N = 3000$, while for the 3D case E it is somewhere between 3000 and 10000, so the present algorithm is more efficient in terms of time than the FGP05 for problems of size $N \geq 10000$.

The effect of the parameter c in the multiquadric RBF on the convergence of iterative processes using the present method (fast preconditioner + FMM with $p = 30$) and the original FGP05 algorithm is shown in Figure 4.4. This parameter has the dimension of length and forces the function to a constant for large values (and thus uninfluenced by neighbors), while it acts as a regularization parameter for derivative evaluation for small values of c. It is seen that, while there are small differences in the norm of the residual after a certain number of iterations, both methods perform approximately in the same manner in terms of the dependence of the number of iterations on c (while the present algorithm is faster). As c increases and q is fixed the number of iterations grows. This growth is not substantial when c is of the order of characteristic distance between the data points, while it is significant for larger c. Moreover, we found that if c is larger than some critical c_c the process, it seems, does not converge (at least after a hundred iterations or so). This critical c depends on q and one of the recipes to compute interpolants with larger c is to use a larger q, which can also be seen in Table 4.1. The same behavior is observed for the original FGP05 algorithm.

Note that for uniform distributions of N points over d dimensional manifolds of volume V the characteristic distance between the points can be evaluated as $d_c = (V/N)^{1/d}$ and the effect of c can be measured in terms of the ratio $\overline{c} = c/d_c$, which for the cases plotted in Figure 4.4 ($d = 2, V = \pi$) are approximately 0.564, 1.69, and 2.82. Also, the number of the L-sets is of order N/q, which provides some mean volume, $V_L = Vq/N$, and some mean size, $d_L = V_L^{1/d}$, of the L-set. One may guess that the convergence rate depends on c/d_L and so the critical c is of the order d_L or $\overline{c}_c \sim q^{1/d}$. The latter quantity for the illustrated case was $q^{1/2} \approx 5.5$ and this is a rough estimate for the value of $\overline{c}_c$, which we observed in our experiments ($4 < \overline{c}_c < 4.5$). However, more detailed study on optimization of parameters c, q, and p, which provide the best performance of the present algorithms is required.

Finally, Figure 4.5 provides illustrations of solutions of some problems from 3D and 2D computer graphics using multiquadric RBFs and the present algorithm. In the first example, bunny (34834 point set) was extended to size 104502 (for points along the normal inside and outside) and after interpolation coefficients were determined the interpolant was evaluated at $\sim 8 \cdot 10^6$ points (regular spatial grid $201 \times 201 \times 201$) from which isosurfaces were found using standard routines. Here we used the same settings as for problem A with $d = 3$ and $c = 0$. The computation of preconditioner took 310 seconds, and the iteration process 283 seconds. Evaluation was made using the FMM (which required one $10^5 \times 8 \cdot 10^6$ matrix-vector multiplication) and took 395 seconds.

In the second example, 86% of 375050 pixels in a 2D color image were removed randomly. The remaining ($N = 51204$) pixels were used to interpolate data back to

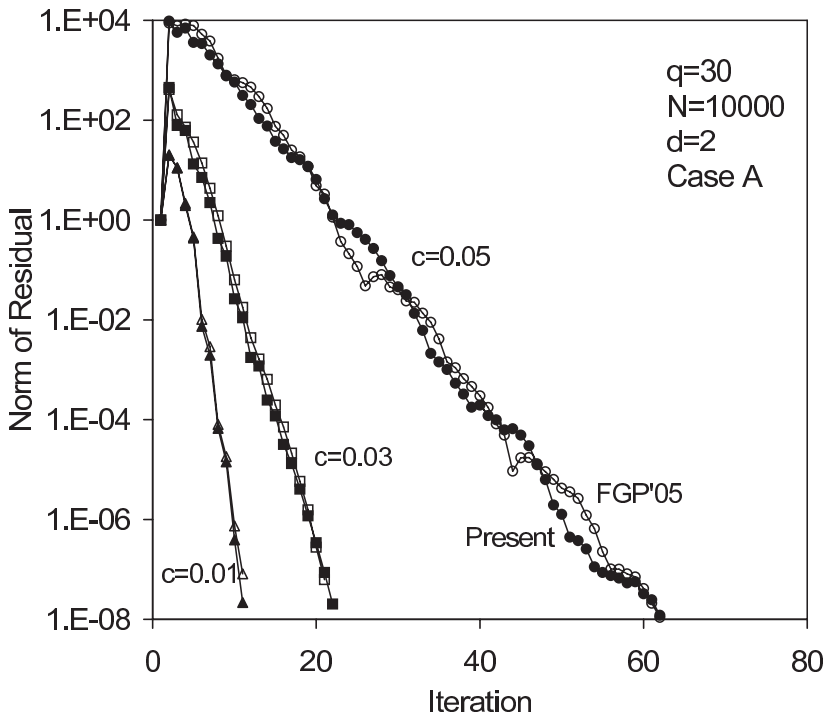

FIG. 4.4. *Convergence of the iterative processes using the present (the dark markers) and the original FGP05 algorithm (the light markers) for different values of parameter c in the multiquadric RBF.*

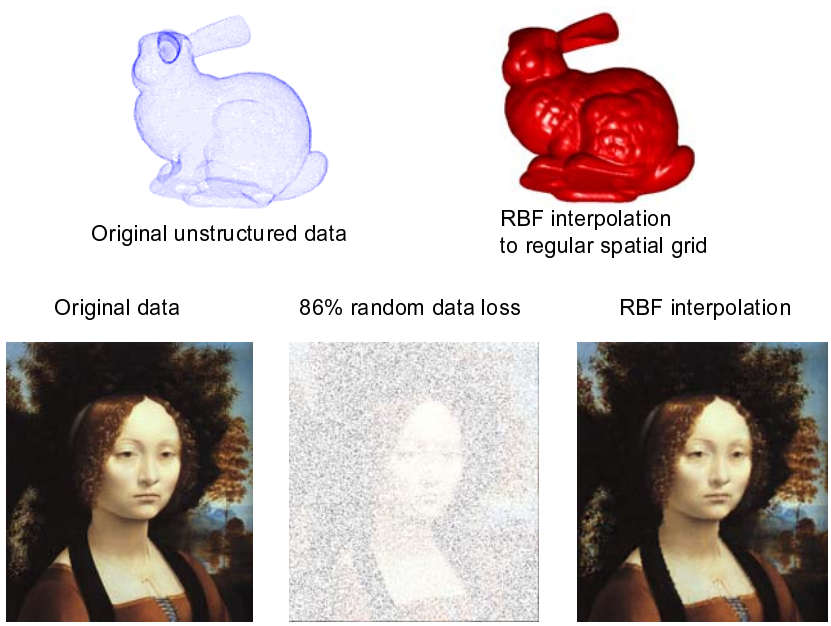

FIG. 4.5. *Illustrations of use of the RBF for 3D and 2D computer graphics problems.*

the grid using the 2D multiqudaric kernel with $c = N^{-1/2}$. The results of recovery are presented in the figure. Here we used the same setting as for problem A with $d = 2$ and $c = N^{-1/2}$. The preconditioner should be built only once as it is suitable for all three RGB channels and took about 30 seconds to perform this task. The iteration process took 75 seconds per channel and the final matrix-vector multiplication took 19 seconds. Note that the three-digit accuracy that we imposed for solution is sufficient to determine the RGB intensities as they vary between 0 to 255 for each channel.

5. Discussion and conclusion. For many dense linear systems of size the availability of an algorithm based on the FMM provides a matrix vector product with time and memory complexity that is $O(N \log N)$. This reduces the cost of the matrix vector product step in the iterative solution of linear systems, and for an iteration requiring k steps, a complexity $O(kN \log N)$ can be expected. To bound k, appropriate preconditioning strategies must be used. However, many conventional preconditioning strategies rely on sparsity in the matrix, and applying them to these dense matrices requires computations that may have a formal time or memory complexity of $O(N^2)$, which negates the advantage of the FMM. For the particular case of the FGP05 algorithm, with our construction, all steps have been accelerated, have a similar formal complexity, and in practice converge in relatively few iterations. The success of this preconditioner based on the geometry of point sets for a matrix that is capable of being accelerated using the FMM should not be surprising, as the FMM itself is based on the use of computational geometry to partition the matrix vector product.

The idea of constructing preconditioned Krylov algorithms based on the cardinal functions may have wider applicability. For any regular FMM kernel function, as the discussion in section 2.1 shows, we can construct an approximate inverse to the cardinal function expressed in terms of the kernel function. This idea bears further exploration.

Finally, we note that our implementation of the algorithm presented in this paper has been recently licensed from the University of Maryland by Fantalgo, LLC (info@fantalgo.com).

6. Acknowledgments. We would like to thank Prof. David Mount for providing us with some pointers to material on computational geometry. We also thank the reviewers for their comments and suggestions to improve the quality of the paper.

SPATIAL MULTIGRID FOR ISOTROPIC NEUTRON TRANSPORT*

B. CHANG†, T. MANTEUFFEL‡, S. MCCORMICK‡, J. RUGE‡, AND B. SHEEHAN‡

Abstract. A spatial multigrid algorithm for isotropic neutron transport is presented in x-y geometry. The linear system is obtained using discrete ordinates in angle and corner balance finite differencing in space. Spatial smoothing is accomplished by a four-color block-Jacobi relaxation, where the diagonal blocks correspond to 4-cell blocks on the spatial grid. A bilinear interpolation operator and its transpose are used for the grid transfer operators. Good convergence factors were observed for homogeneous material properties. Heterogeneous material properties prove more difficult, especially the case of a vacuum region surrounded by a thick, diffusive region. In this case, a small amount of absorption, or "effective absorption" in a time-dependent problem, restores good convergence. Numerical results are presented.

Key words. neutral particle transport, multigrid, S_N approximation, finite difference discretization

1. Introduction.

The purpose of this paper is to present a spatial multigrid algorithm for isotropic neutron transport. The algorithm described here is an extension to two spatial dimensions of the work presented by Manteuffel et al. in [13] and [14]. The partial differential equation (PDE) to be solved is

$$\Omega \cdot \nabla\psi + \sigma_t\psi - \frac{\sigma_s}{4\pi}\int_\Omega \psi \, d\Omega = q, \qquad (x, y, \Omega) \in D \times S^2, \tag{1.1}$$

$$\psi = g, \qquad (x, y) \in \partial D, \quad \mathbf{n} \cdot \Omega < 0. \tag{1.2}$$

$\psi = \psi(x, y, \Omega)$	the angular flux of neutrons
$\Omega \in S^2$	direction of neutron travel on unit sphere
$\sigma_t = \sigma_t(x, y)$	total macroscopic cross section
$\sigma_s = \sigma_s(x, y)$	scattering macroscopic cross section
$q = q(x, y, \Omega)$	interior source of neutrons
$g = g(x, y, \Omega)$	boundary source of neutrons
D, ∂D	unit square, boundary of the unit square
$\mathbf{n}$	outward unit normal

The primary numerical methodology currently in use for solving this PDE is source iteration combined with diffusion synthetic acceleration (DSA) [2, 4, 10, 12]. While DSA has achieved a great deal of success, it also suffers from certain limitations.

The work of these authors was sponsored by the Department of Energy under grants DE-FC02-01ER25479 and DE-FG02-03ER25574, Lawrence Livermore National Laboratory under contract B533502, Sandia National Laboratory under contract 15268, and by the National Science Foundation under DMS-0410318.

One of these limitations is the sensitivity of the method to the spatial discretization [2]. In particular, it is difficult to implement DSA with the discontinuous finite difference method known as [illegible].[1] Fast transport algorithms for the corner balance discretization are an area of active research interest. Other limitations of DSA stem from source iteration, the relaxation step on which it is based [12]. This relaxation is not ideally suited to parallel computing and does not allow for acceleration by spatial multigrid [13, 8, 15]. In contrast, the method outlined below employs the corner balance discretization, acceleration by spatial multigrid, and is well suited to parallel computing.

To explain these concepts further, it is necessary to first discretize the PDE in angle. The angular discretization used in this algorithm is known as discrete ordinates, or S_N [12]. The idea is simply that the PDE is enforced at only a finite number of angles, $\Omega_k, k = 1, \ldots, d$. The angles are chosen so that the angular integral can be replaced by an appropriate quadrature rule, and (1.1)–(1.2) is then written as the following system of coupled PDEs in space. For $k = 1, \ldots, d$,

$$\Omega_k \cdot \nabla \psi_k + \sigma_t \psi_k - \frac{\sigma_s}{4\pi} \sum_{m=1}^{d} w_m \psi_m = q_k, \qquad (x, y) \in D, \tag{1.3}$$

$$\psi_k = g_k, \qquad (x, y) \in \partial D, \quad \mathbf{n} \cdot \Omega_k < 0, \tag{1.4}$$

$\Omega_k,\ w_k$ given direction, quadrature weight,
$\psi_k,\ q_k,\ g_k$ $\psi(x, y, \Omega_k),\ q(x, y, \Omega_k),\ g(x, y, \Omega_k)$.

The spatial discretization of (1.3)–(1.4) is discussed in the next section. For now, assume the problem has been spatially discretized, and write the discrete problem as

$$[\mathbf{D} + \mathbf{\Sigma} - \mathbf{S}]\, \mathbf{\Psi} = \mathbf{Q}, \tag{1.5}$$

where the three terms in brackets represent the discrete versions of the three terms in (1.3). Notice that $\mathbf{D} + \mathbf{\Sigma}$ contains local spatial coupling of the unknowns, and $\mathbf{S}$ contains the angular coupling. Since problems of interest are too large to be solved directly, an iterative approach based on a matrix splitting is used. In the case of transport sweeps, $\mathbf{S}$ is split from the rest of the matrix, and the iteration becomes

$$[\mathbf{D} + \mathbf{\Sigma}]\, \mathbf{\Psi^{i+1}} = [\mathbf{S}]\, \mathbf{\Psi^{i}} + \mathbf{Q}, \tag{1.6}$$

which implies that the error evolves according to

$$\mathbf{e^{i+1}} = [\mathbf{D} + \mathbf{\Sigma}]^{-1}\, [\mathbf{S}]\, \mathbf{e^{i}}. \tag{1.7}$$

This step is computationally inexpensive because $[\mathbf{D} + \mathbf{\Sigma}]$ is triangular, or block triangular, depending on the discretization. However, calculating the action of the inverse of a triangular matrix on a vector is a sequential operation, and this is why transport sweeps are not ideally suited to parallel computing.[2] To see why transport sweeps do

[1] DSA is implemented in [18] for a discretization similar to corner balance. The authors indicate that a fully consistent implementation is computationally expensive, but that similar results can be obtained when an inconsistent DSA is used as a preconditioner for a Krylov method

[2] A domain decomposition method for transport sweeps is described in [19]. This method performs sweeps on local subdomains and avoids the global sequential solve. While this improves the parallel scalability of sweeps, it also significantly changes the performance of the associated DSA algorithm. For the duration of this paper, all references to the performance and parallel scalability of DSA assume an algorithm based on global sweeps.

not allow for acceleration by spatial multigrid, consider the case where $\sigma_s \approx \sigma_t$ and $\sigma_t h \gg 1$, where h is the cell width. In this parameter regime, which is common in real world problems, $[\mathbf{D} + \mathbf{\Sigma}]^{-1} \approx [\mathbf{\Sigma}]^{-1}$. Now imagine an error, $\mathbf{e^i}$, that is independent of angle, so that $\mathbf{Se^i} \approx \mathbf{\Sigma e^i}$. Equation (1.7) now shows $\mathbf{e^{i+1}} \approx \mathbf{e^i}$. Errors that are constant in angle are not significantly changed by transport sweeps in this parameter regime, regardless of their spatial form. Since these errors have no predictable form in space after relaxation, a spatial coarse-grid correction cannot be used to accelerate convergence.

The algorithm described below is based on a different relaxation step, which is well suited to parallel computation and leaves the error with a predictable spatial form. The remainder of this paper is organized as follows. Section 2 describes the spatial discretization, and section 3 gives the details of the relaxation step. Section 4 outlines the multigrid algorithm. Sections 5 and 6 give numerical results for homogeneous and heterogeneous domains. Section 7 examines the computational cost of the method. Sections 8 and 9 compare the parallel scalability and performance of the method to that of DSA, and section 10 contains a brief conclusion.

2. Spatial discretization. As mentioned above, the spatial discretization used in this algorithm is the corner balance finite difference method.[3] The derivation of corner balance is contained in [1]. In this context, it suffices to say that in the case of square cells the solution has four spatial degrees of freedom per cell. Figures 2.1 and 2.2 illustrate the location of the spatial unknowns and a random example solution on a 4-cell grid. It is important to note that these figures represent the grid and solution in only one of the directions.

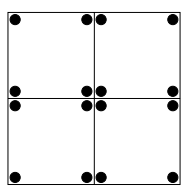

FIG. 2.1. *Location of spatial unknowns.*

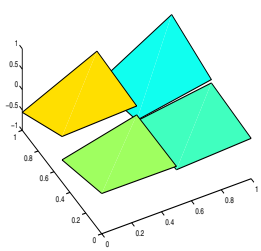

FIG. 2.2. *Bilinear discontinuous example solution.*

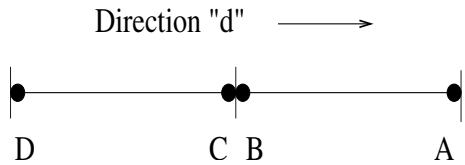
[3]The spatial discretization used in this algorithm is *simple* corner balance, not *upwind* corner balance, both of which are derived in [1].

To describe the relaxation step in section 3, it is necessary to examine the corner balance approximation of a first derivative. The nature of the corner balance approximation of the derivative terms in (1.3) is best explained with a one-dimensional (1-D), 2-cell example:

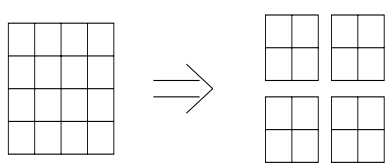


(2.1) At point A in direction d, $$\frac{d\psi}{dx} \approx \frac{\psi_A - \psi_B}{h}.$$

(2.2) At point B in direction d, $$\frac{d\psi}{dx} \approx \frac{\frac{\psi_A+\psi_B}{2} - \psi_C}{\frac{h}{2}} = \frac{\psi_A + \psi_B - 2\psi_C}{h}.$$

Equations (2.1) and (2.2) contain two kinds of spatial coupling. Equation (2.1) contains [illegible] coupling (A to B), while (2.2) contains both within-cell and [illegible] coupling (A and B to C). The distinction between these two categories of spatial coupling is the basis for the matrix splitting described below.

3. Relaxation method. Imagine splitting the two-dimensional domain into 4-cell blocks:



The matrix $\mathbf{D}$ is split as follows: $\mathbf{D} = [\mathbf{D_{wb}} + \mathbf{D_{bb}}]$, where $\mathbf{D_{wb}}$ contains the [illegible] coupling (elements of $\mathbf{D}$ which couple unknowns in a given block to other unknowns in that same block), and $\mathbf{D_{bb}}$ contains the [illegible] coupling (elements of $\mathbf{D}$ which couple unknowns in a given block to unknowns in a separate block). This splitting gives the new relaxation step

(3.1) $$[\mathbf{D_{wb}} + \mathbf{\Sigma} - \mathbf{S}]\, \mathbf{\Psi^{i+1}} = [-\mathbf{D_{bb}}]\, \mathbf{\Psi^{i}} + \mathbf{Q}.$$

The inversion of $[\mathbf{D_{wb}} + \mathbf{\Sigma} - \mathbf{S}]$ is straightforward because, with the appropriate ordering of the unknowns, it is block diagonal and represents a set of unrelated 4-cell transport problems. From this perspective, it is clear that this relaxation is a form of block Jacobi. Since each 4-cell problem can be handled by a different processor, the step is well suited to parallel computing. Equation (3.1) implies that the unknowns corresponding to all the directions within a 4-cell block are solved for simultaneously. This means that the size of the matrix corresponding to each 4-cell block grows with the size of the quadrature set being used. However, since the scattering operator is a low-rank perturbation of the streaming-collision operator, the Sherman–Morrison–Woodbury formula allows the 4-cell inversions to be accomplished at a cost that rises

only linearly with the number of angles. This formula and a more detailed discussion of computational cost are included in section 7.

This relaxation step is designed to spatially smooth the error in the thick diffusive regime, where $\sigma_s \approx \sigma_t$ and $\sigma_t h \gg 1$. In order to see how the smoothing is accomplished, consider applying (3.1) in a diffusive material, with a zero right-hand side and random initial guess. The first iteration calls for the solution of many unrelated 4-cell problems, each with a zero interior source and random inflow boundary conditions. Intuition suggests that in the continuous case, the solution would be random near the boundary but smooth away from the boundary. Therefore, in the discrete 4-cell case, we expect the solution to have the four spatial unknowns at the center of the domain roughly equal. Figures 3.1 and 3.2 show the corner balance solution to a problem with zero interior source, random inflow, and $\sigma_t = \sigma_s = 10^4$. Figure 3.1 is a domain with 64 cells and is intended to be an approximation to the continuous case. Figure 3.2 is a 4-cell domain and shows that the center variables are roughly equal. Once again, these plots show the solution in only one of the directions.

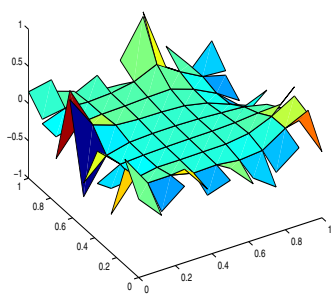


FIG. 3.1. *Zero source, random inflow, on* 64 *cells with* $\sigma_t = \sigma_s = 10^4$.

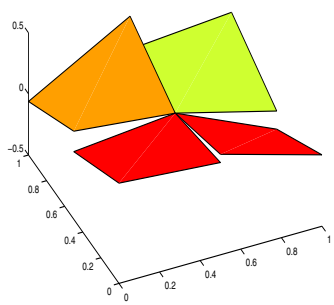

FIG. 3.2. *Zero source, random inflow, on* 4 *cells with* $\sigma_t = \sigma_s = 10^4$.

After one relaxation, the error is no longer random. At the center of each 4-cell block, the four spatial errors are roughly equal in any given direction. Therefore, the error is now "partially continuous." This relaxation step is the extension to two spatial dimensions of the relaxation used by Manteuffel et al. [13, 14], and has been

presented and analyzed in two spatial dimensions by Lansrud [9]. However, the error is not spatially smoothed unless the 4-cell blocks are shifted and the block-Jacobi step is repeated, a total of four times. If the arrangement of the 4-cell blocks is now shifted by one cell, a second relaxation step makes the error continuous at the centers of the new 4-cell blocks. This process of shifting the arrangement of the 4-cell blocks is repeated, and a total of four different arrangements are used. The different 4-cell block patterns are illustrated in Figure 3.3. The iterate is updated before the blocks are shifted, so each of the arrangements below represents a separate block-Jacobi iteration.

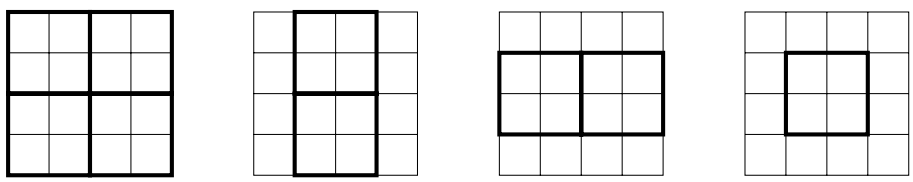

FIG. 3.3. *4-cell block pattern.*

At the end of the complete red-black-orange-white (RBOW) pass, every vertex on the original grid has been at the center of a 4-cell solve once, and the error is nearly continuous over the entire domain. In addition to becoming nearly continuous, the error also tends to become smooth over the entire domain and bilinear over the 4-cell blocks defined by the last color pass. This happens because the center lines of the 4-cell blocks in a given color pass become the boundary conditions for the blocks in the next color pass. Continuous centers become continuous boundary conditions, and continuous boundary conditions produce smoother solutions. Smoother solutions become smoother boundary conditions, and the cycle pushes the error into a form that is not only continuous, but is increasingly smooth and bilinear over the blocks of the last pass.

In practice, it is not necessary to include all spatial points within a 4-cell block in the block solve. The computational cost can be reduced by including only the points which are spatially coupled to the points at the center of the block. Figure 3.4 shows the [illegible] on the left and the [illegible] on the right. Only the 12 points along the "plus sign" of the 4-cell block are included in the reduced block.[4] For the remainder of this paper, the term "4-cell inversion" is taken to mean that the unknowns at the spatial locations of the reduced block, and in all the directions, are solved for simultaneously. Furthermore, the term "RBOW relaxation" implies that the reduced block is being used.

Figure 3.5 shows the evolution of random error on a 256 cell grid, where $\sigma_t = \sigma_s = 10^4$, over five RBOW relaxations. The important feature of the RBOW step is not that it reduces the size of the error, but that it puts the error in a predictable spatial form. The desired spatial form is bilinear over the "red" blocks. This allows a coarse-grid correction based on bilinear interpolation. To leave the error bilinear over the red blocks, the order of the color pass is arranged so that the red pass is last. In

[4]In three spatial dimensions, there would be 64 spatial locations in an 8-cell block. However, only 32 of these would lie along the "three-dimensional plus sign," making the cost savings of using reduced blocks more dramatic than it is in two spatial dimensions.

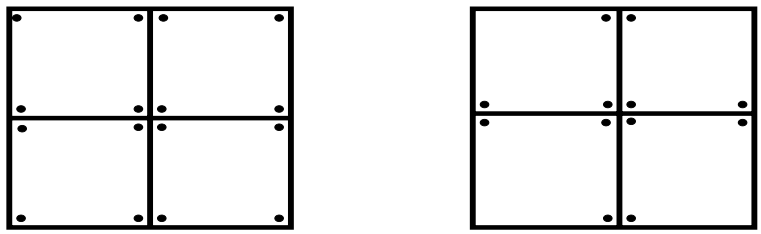

FIG. 3.4. *Spatial unknowns in the full and the reduced block.*

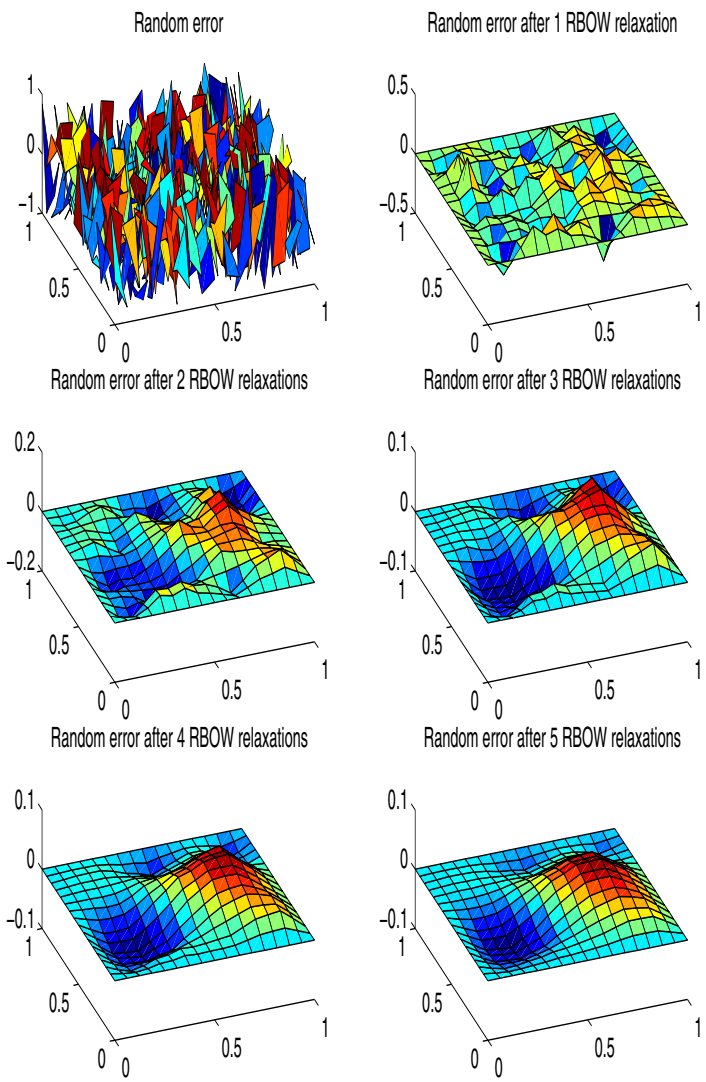

FIG. 3.5. *Evolution of random error.*

Figure 3.5, it is easy to see that the error is nearly bilinear over the red blocks after five RBOW relaxations, and a coarse-grid correction would be very effective at this point. Experiments have shown, however, that the coarse-grid correction is surprisingly effective after just one relaxation.

4. Multigrid algorithm. Since the error after RBOW relaxation is close to being bilinear over the red blocks, it can be approximately represented on a coarse grid. To accomplish this, it is necessary to define the coarse grid, the fine grid, and grid transfer operators that map vectors from one grid to the other. Consider a fine grid with a total of N unknowns, and a coarse grid on which the fine-grid red blocks are single cells. This coarse grid has a total of $\frac{N}{4}$ unknowns. The [illegible] operator, $\mathbf{P}$, is an $N \times \frac{N}{4}$ matrix that maps coarse vectors, denoted by $\mathbf{v^{2h}}$, to fine vectors, denoted by $\mathbf{v^h}$ (the notation h and 2h represent a doubling of the cell width). The interpolation is bilinear, meaning that the spatial unknowns on any coarse cell, which are bilinear by definition, are mapped to the same bilinear over the corresponding fine-grid red block. The [illegible] operator, $\mathbf{R}$, is simply the transpose of $\mathbf{P}$, up to a constant. This restriction operator is often called [illegible].

For the purpose of illustrating the concept of coarse-grid correction, assume that relaxation leaves the error exactly bilinear over the red blocks. This means the fine error lies in the range of bilinear interpolation, and we can write $\mathbf{e^h} = \mathbf{Pe^{2h}}$. The coarse-grid correction then proceeds as follows:

- After relaxation, calculate the fine residual, $\mathbf{r^h} = \mathbf{b} - \mathbf{A\Psi^i}$ ($\mathbf{A}, \mathbf{b}, \mathbf{\Psi^i}$ represent the entire discrete transport operator, the discrete right-hand side, and the current iterate, respectively).
- Write the residual equation $\mathbf{Ae^h} = \mathbf{r^h}$ and use the assumption above to get $\mathbf{APe^{2h}} = \mathbf{r^h}$.
- Solve the $\frac{N}{4} \times \frac{N}{4}$ system $[\mathbf{RAP}]\,\mathbf{e^{2h}} = \mathbf{Rr^h}$.
- Correct the current iterate: $\mathbf{\Psi^{i+1}} = \mathbf{\Psi^i} + \mathbf{Pe^{2h}}$.

In the ideal situation outlined above, the coarse-grid correction would be perfect, and the problem would be solved exactly. In reality, the coarse-grid correction is not perfect because the fine error is not exactly in the range of interpolation. The idea is that if the fine error is close to the range of interpolation, then the coarse-grid correction improves the current iterate at a low computational cost. There are, of course, several other important differences between the ideal example above and the actual algorithm. Since an $\frac{N}{4} \times \frac{N}{4}$ system is still far too large to be solved directly, the procedure is applied recursively. The exact solve does not take place until the coarsest grid, which can be as small as four cells total. The sequence of relaxations and coarse-grid corrections is called a V-cycle [7]. A V-cycle can feature any given number of relaxation steps, called prerelaxations, on each grid level as the grid is being coarsened. It is also common to include some number of additional relaxations, called postrelaxations, after each coarse-grid correction. The optimal number of pre- and postrelaxations to use is often determined experimentally. The notation V(n,m) indicates a V-cycle with n prerelaxations and m postrelaxations. In summary, the spatial multigrid algorithm is a V-cycle with the following features:

- RBOW relaxation,
- bilinear interpolation operator ($\mathbf{P_{BL}}$),
- restriction is full weighting ($\mathbf{R_{FW}}$),
- coarse-grid operator is $\mathbf{R_{FW}AP_{BL}}$.

Notice that the operator for the coarse-grid problem is $\mathbf{R_{FW}AP_{BL}}$. When the corner balance transport operator is multiplied on the left and right by $\mathbf{R_{FW}}$ and

$\mathbf{P_{BL}}$, respectively, its stencil is altered. The evolution of this stencil on coarser and coarser grids is fairly easy to track and heads rapidly to a limit that is equivalent to the bilinear discontinuous Galerkin (BLDG) finite element discretization. The BLDG discretization is very similar to corner balance [1, 2, 3, 16], and the sequence of intermediate stencils also has a similar character. Since the evolution of the stencil is not dramatic, RBOW relaxation is an appropriate smoother for the coarse-grid problems.[5]

5. Results for problems with homogeneous material. The method described above has been coded and tested in two spatial dimensions. In this section, convergence factors are given for the zero right-hand side problem, with zero boundary conditions and random initial guess. The convergence factor is measured by taking a ratio of the vector two-norm of the residual before and after a given V-cycle:

$$\rho^{i+1} = \frac{\|\mathbf{r^{i+1}}\|_2}{\|\mathbf{r^i}\|_2}. \tag{5.1}$$

In most cases, the convergence factor settles to a nearly constant value after a few V-cycles. For consistency, the factors given below were calculated by running fifteen V-cycles and taking the geometric mean of the last five,

$$\rho = \left(\prod_{i=11}^{15} \rho^i \right)^{\frac{1}{5}}. \tag{5.2}$$

All cycles are V(1,1) cycles. In all cases, the domain is the unit square, which is divided into 4,096 square cells. Four directions are used, giving a total of 65,536 unknowns. Table 5.1 gives results for homogeneous, pure scattering domains. In all cases, the results improve with absorption ($\sigma_s < \sigma_t$).

TABLE 5.1
Convergence factors for domains with homogeneous material and pure scattering.

$\sigma_t h$	ρ
10^4	.06
1	.03
10^{-4}	.1

In the case of the thick and medium problem (top two lines), the convergence factors in Table 5.1 do not depend on problem size; using more cells or more directions has no effect on the convergence. The same cannot be said for the thin problem (bottom line). Due to the nature of the thin operator, successive V-cycles create a "marching-style" near exact solve in a pure thin domain. Once the marching process crosses the domain, there is a large drop in the residual. For this reason, thin convergence factors on domains with few cells are better than they would be on domains with many cells. Also, increasing the number of directions degrades the thin convergence factor because, as directions become more grid-aligned, bilinear interpolation is less appropriate for thin regions. While the pure thin problem by itself is not of much interest, it is important to understand how the method might behave in thin regions of domains with heterogeneous material. Domains of this type are discussed further in the next section.

[5]The BLDG stencil is not altered by the coarsening process, i.e., $\mathbf{R_{FW}} \mathbf{A^h_{BLDG}} \mathbf{P_{BL}} = \mathbf{A^{2h}_{BLDG}}$. The algorithm described here can be applied with BLDG instead of corner balance with very similar results.

6. Results for problems with heterogeneous material. This method has been tested on a variety of heterogeneous domains. The domains and coarse grids are set up in such a way that there is no "mixed coarsening." In other words, the case of a 4-cell block composed of multiple materials being coarsened into a single cell does not arise. The idea is to deal with the difficulties of a heterogeneous domain without the added complication of mixed coarsening.[6]

In some cases, the convergence factors for heterogeneous domains are no worse than those for homogeneous domains. The most notable exception to this rule is the case of a thin region surrounded by a thick region, as indicated in Figure 6.1. Tables 6.1 and 6.2 give the convergence factors for this domain with several variations to the cross sections. In Table 6.1, both regions are pure scattering and the values of $\sigma_t h$ are listed for the thick (thin) regions, respectively. While the convergence is still good for fairly large jumps in cross section, it is clear that performance deteriorates completely as the thin region approaches a true vacuum. In Table 6.2, the thin region is always a true vacuum, while the thick region always has $\sigma_t h = 10^4$, with some absorption, as indicated by the scattering ratio ($scat.\ ratio = \frac{\sigma_s}{\sigma_t}$). Clearly, the convergence is improved with the introduction of a small amount of absorption.

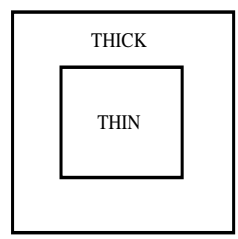

FIG. 6.1. *Heterogeneous model domain.*

It is important to note that a small amount of "effective absorption" will always be present if the steady state problem is being solved at each time step of a time-dependent problem with an implicit time discretization. To see this, let c be the particle speed, and consider the time-dependent problem

$$\frac{1}{c}\frac{\partial \psi}{\partial t} + \Omega \cdot \nabla \psi + \sigma_t \psi - \frac{\sigma_s}{4\pi}\int_\Omega \psi \, d\Omega = q. \tag{6.1}$$

A backward Euler approximation in time yields

$$\frac{1}{c}\frac{\psi^{n+1} - \psi^n}{\Delta t} + \Omega \cdot \nabla \psi^{n+1} + \sigma_t \psi^{n+1} - \frac{\sigma_s}{4\pi}\int_\Omega \psi^{n+1} \, d\Omega = q^{n+1} \tag{6.2}$$

or

$$\Omega \cdot \nabla \psi^{n+1} + \left(\sigma_t + \frac{1}{c\Delta t}\right)\psi^{n+1} - \frac{\sigma_s}{4\pi}\int_\Omega \psi^{n+1} \, d\Omega = q^{n+1} + \frac{1}{c\Delta t}\psi^n. \tag{6.3}$$

The effective absorption cross section is $\sigma_a^* \geq (\frac{1}{c\Delta t})$. This parameter prevents any region from being either pure vacuum or pure scattering. Larsen [11] details a method

[6]Preliminary experiments with mixed coarsening show that the convergence is not adversely affected, provided that the bilinear interpolation is replaced with a kinked-linear interpolation similar to that used by Manteuffel et al. in [14].

TABLE 6.1

Convergence factors for the heterogeneous model domain with a thin pure scattering center and a thick pure scattering perimeter.

$\sigma_t h$ thick (thin)	ρ
10^4 (10^4)	.06
10^4 (10^{-1})	.11
10^4 ($5 * 10^{-2}$)	.23
10^4 (10^{-2})	.61

TABLE 6.3

Convergence factors for the heterogeneous model domain with vacuum center, thick pure scattering perimeter, and time-step-based effective absorption. The thick region always has $\sigma_t h = 10^4$. Parentheses indicate convergence factor for a W-cycle instead of a V-cycle.

$\frac{1}{c\Delta t}$	$\frac{c\Delta t}{\Delta x}$	ρ
nx	1	$7 * 10^{-4}$
$\frac{nx}{10}$	10	.12
$\frac{nx}{100}$	100	.56 (.38)
$\frac{nx}{1000}$	1000	.88 (.69)

for time- and energy-dependent problems that requires the solution of an equation similar to (6.3) in the inner iteration. The algorithm described here has been applied to (6.3) for the model domain with pure vacuum and pure scattering ($\sigma_t h = 10^4$) materials. Naturally, convergence improves with larger values of $\frac{1}{c\Delta t}$. To put this another way, the convergence factor depends on the value of the Courant number, $\frac{c\Delta t}{\Delta x}$, where $\Delta x = \frac{1}{nx}$ and nx is the number of cells in a single dimension (i.e., in two dimensions on a 64×64 grid, $nx = 64$). Table 6.3 shows the convergence factors for various values of $\frac{1}{c\Delta t}$ between $\frac{nx}{1000}$ and nx. The value of $\frac{1}{c\Delta t}$ must be proportional to nx for the results to be independent of grid size. This is because it is the amount of absorption , , , , that affects the convergence of the method. The second column in Table 6.3 gives the Courant number, $\frac{c\Delta t}{\Delta x}$. The values listed in parentheses are for a W-cycle, which requires slightly more work than a V-cycle [7].

7. Computational cost. To put the performance of the method in perspective, it is necessary to discuss computational cost. As mentioned previously, all 4-cell inversions in the relaxation step are accomplished via the Sherman–Morrison–Woodbury formula

$$(\mathbf{H} + \mathbf{U}\mathbf{V}^{\mathbf{T}})^{-1} = \mathbf{H}^{-1} - \left[\mathbf{H}^{-1}\mathbf{U}(\mathbf{I} + \mathbf{V}^{\mathbf{T}}\mathbf{H}^{-1}\mathbf{U})^{-1}\mathbf{V}^{\mathbf{T}}\mathbf{H}^{-1}\right]. \tag{7.1}$$

To see how this formula applies to the discrete transport operator, let $\mathbf{H} = \mathbf{D} + \mathbf{\Sigma}$ be the streaming-collision operator and let $-\mathbf{S} = \mathbf{U}\mathbf{V}^{\mathbf{T}}$ be the scattering operator, where

$$\mathbf{U} = -\begin{bmatrix} \mathbf{\Sigma_s} \\ \mathbf{\Sigma_s} \\ \vdots \\ \mathbf{\Sigma_s} \end{bmatrix} \tag{7.2}$$

and

$$\mathbf{V}^{\mathbf{T}} = \frac{1}{4\pi}\begin{bmatrix} w_1\mathbf{I} & w_2\mathbf{I} & \cdots & w_d\mathbf{I} \end{bmatrix}. \tag{7.3}$$

In (7.3), w_i is a quadrature weight and $\mathbf{I}$ is an $N_{sp} \times N_{sp}$ identity, where N_{sp} is the number of spatial unknowns in the domain. In (7.2), $\mathbf{\Sigma_s}$ is a diagonal matrix of size $N_{sp} \times N_{sp}$, with the values of σ_s at each spatial point in the domain on the diagonal. As before, d is the number of directions, so the total number of unknowns in the problem is $N = N_{sp} * d$, and the sizes of $\mathbf{U}$ and $\mathbf{V}^{\mathbf{T}}$ are $N \times N_{sp}$ and $N_{sp} \times N$, respectively. Notice that $\mathbf{V}^{\mathbf{T}}$ is the discrete integration operator, and $\mathbf{V}^{\mathbf{T}}\mathbf{\Psi} = \mathbf{\Phi}$, where $\mathbf{\Phi}$ is the scalar flux. Now that the discrete system can be written as $(\mathbf{H} + \mathbf{U}\mathbf{V}^{\mathbf{T}})\mathbf{\Psi} = \mathbf{q}$, consider the following algebraic manipulations:

- Multiply $(\mathbf{H} + \mathbf{U}\mathbf{V}^{\mathbf{T}})\mathbf{\Psi} = \mathbf{q}$ by $\mathbf{H}^{-1}$ and rearrange to get

$$\mathbf{\Psi} = \mathbf{H}^{-1}\left[\mathbf{q} - \mathbf{U}\mathbf{\Phi}\right]. \tag{7.4}$$

- Multiply (7.4) by $\mathbf{V}^{\mathbf{T}}$ and rearrange to get

$$(\mathbf{I} + \mathbf{V}^{\mathbf{T}}\mathbf{H}^{-1}\mathbf{U})\mathbf{\Phi} = \mathbf{V}^{\mathbf{T}}\mathbf{H}^{-1}\mathbf{q}. \tag{7.5}$$

In practice, the Sherman–Morrison–Woodbury formula is applied by solving (7.5) and then solving (7.4). The cost of this process is twice the cost of calculating the action of $\mathbf{H}^{-1}$ on a vector, plus the cost of forming and inverting $(\mathbf{I} + \mathbf{V}^{\mathbf{T}}\mathbf{H}^{-1}\mathbf{U})$. By calculating the cost of a single 4-cell inversion this way, the cost of a complete RBOW relaxation can easily be obtained. To minimize the cost per iteration, an LU factorization of the matrix $(\mathbf{I}+\mathbf{V}^{\mathbf{T}}\mathbf{H}^{-1}\mathbf{U})$ corresponding to each 4-cell block is formed and stored in a separate setup phase. To facilitate the calculation of the action of $\mathbf{H}^{-1}$, LU factorizations of the single-cell diagonal blocks of $\mathbf{H}$ are also stored during the setup phase. Table 7.1 gives both the computational cost and storage requirement of one fine-grid RBOW relaxation, including the setup phase. One [illegible] (CU) is the number of operations necessary to compute the fine-grid residual, and one [illegible] (SU) is the memory required to store the current iterate. Notice the cost and storage requirement for the setup phase are given as upper bounds. The setup costs 36 CUs only if every cell in the domain has a different size and/or cross section. Regions of identical cells significantly reduce the setup cost. Similarly, the setup storage is 11 SUs only in the case of a minimal quadrature set (4 directions in two dimensions). Using more directions reduces the setup storage requirement in terms of SUs. The range of 4–6 CUs for the iteration cost is also a function of the quadrature set. Again, if a minimal set of 4 angles is chosen, the iteration cost is 6 CUs. This value decreases to 4 CUs as the number of angles rises.[7]

[7]The cost and storage requirements of the algorithm have a component that is independent of the number of angles, which is trivialized as the number of angles rises. This is why the values in the table are higher for fewer angles, in terms of CU/SU.

TABLE 7.1
Computational cost of one RBOW relaxation including setup phase. One CU is the cost of computing the fine-grid residual. One SU is the memory required to store the current iterate.

Phase	Operations	Storage
Setup	$\leq$ 36 CU	$\leq$ 11 SU
Iteration	4 – 6 CU	1 SU

The cost of the entire V-cycle can easily be obtained based on the cost of one fine-grid relaxation [7]. Let the cost of one fine-grid RBOW relaxation be one work unit (WU). Neglecting the cost of intergrid transfers (10% to 20% of total), the cost of a V(1,1)-cycle is

$$2(1 + 2^{-2} + 2^{-2*2} + \cdots + 2^{-n*2}) < \frac{2}{1 - 2^{-2}} = \frac{8}{3} \text{ WU}. \tag{7.6}$$

Using Table 7.1 and (7.6), the approximate cost of a V(1,1)-cycle in CUs is $\frac{8}{3}(4 -$ 6 CU) $\approx (11 -$ 16 CU).

8. Parallel scalability. The purpose of this section is to compare the time required to complete one RBOW relaxation to the time required to complete one global transport sweep on a parallel machine. In terms of the computational units defined above, a transport sweep requires only 1 CU, while the RBOW relaxation requires 4–6 CUs. Therefore, on a serial machine, the RBOW relaxation takes 4–6 times as long as a sweep. However, the picture is different on a parallel machine. In order to make a time-to-completion comparison, it is necessary to outline a model for the way in which information propagates through the processor grid during a sweep. First, imagine conducting a sweep in only one of the S_N directions, on a domain with only one spatial dimension, using a machine with P processors. The first processor, starting with the inflow boundary conditions, must perform its calculations and send the results to the next processor. Define the time required to complete this number of operations to be one single processor time (SPT). The time required to complete the sweep in this single S_N direction is simply P SPTs. In two spatial dimensions, the time required to complete a sweep in a single S_N direction is $2P^{\frac{1}{2}}$ SPTs. This is because, if one imagines the P processors to be arranged in a $P^{\frac{1}{2}} \times P^{\frac{1}{2}}$ array, the information can be passed through the processor grid on "diagonal bands" in a total of approximately $2P^{\frac{1}{2}}$ steps, as shown in Figure 8.1.

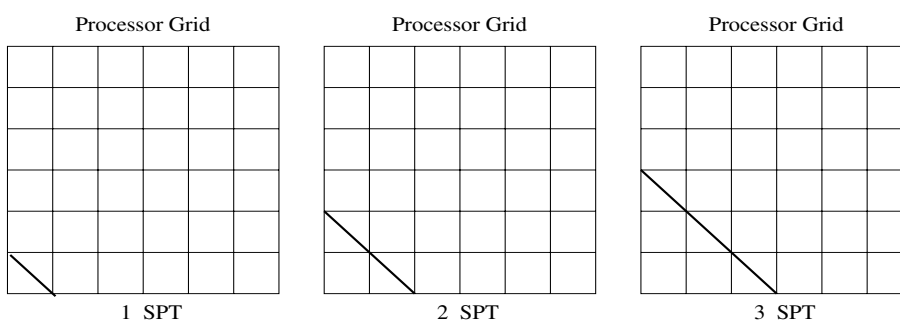

FIG. 8.1. *Transport sweep in one S_N direction and two spatial dimensions through a processor grid. One SPT is the time required for one processor to complete its computations.*

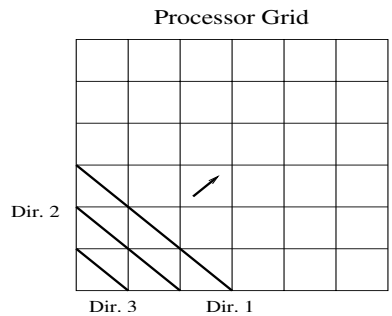

FIG. 8.2. *Transport sweep in multiple S_N directions and two spatial dimensions. The directional sweeps follow each other through the processor grid.*

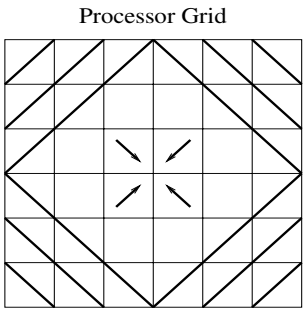

FIG. 8.3. *Transport sweep in multiple S_N directions and two spatial dimensions. Directional sweeps are initiated from the appropriate place in the processor grid.*

In general, if i is the number of spatial dimensions, the time required to complete the sweep in a single S_N direction is $iP^{\frac{1}{i}}$ SPTs. Now consider performing the sweep in all the S_N directions instead of just one. Returning to the 1-D example, once the first processor has completed its calculations and passed the results on to the second processor, it is free to begin a sweep in a second S_N direction. Naturally, this is true with more spatial dimensions as well, and the sweeps for the various S_N directions can follow each other through the processor grid like ducks in a row, as shown in Figure 8.2. If it were possible to begin all of the directional sweeps from the same starting point in the processor grid, it would be easy to see that the total time required to complete a sweep in M directions is $[iP^{\frac{1}{i}} + M]$ SPTs. In reality, in one dimension, half the directional sweeps must begin from the other side of the processor grid, and in two-dimensions, one-quarter of the directional sweeps begin in each of the four corners of the processor grid, as shown in Figure 8.3. This reduces the number of "ducks" in each row, but also creates a delay when processors begin to receive information from multiple directions. A careful analysis reveals that the total time-to-completion is still $[iP^{\frac{1}{i}} + M]$ SPTs even when the various directional sweeps are initiated from the appropriate place in the processor grid.

The number of SPTs required to complete one RBOW relaxation can be obtained more easily by using the serial result given above. In parallel, the number of operations each processor must do to complete its share of the RBOW step is simply (4–6) CU_{local}, where one CU_{local} is the number of operations required to compute the portion of the residual that one processor is responsible for. This is roughly the same number of operations that would be required to do a sweep in $\,,,$ directions on that

TABLE 8.1
Summary of computation time and communication time for one RBOW step and one global sweep on a parallel machine.

	RBOW	Sweep
Computation time	(4-6)M SPT	$[iP^{\frac{1}{i}} + M]$ SPT
Communication time	$4(t_l + k_{rbow}t_b)$	$[iP^{\frac{1}{i}} + M](t_l + k_{sw}t_b)$

processor's portion of the domain, and therefore requires M single processor times, where again, M is the total number of S_N directions. Therefore, the time to complete the RBOW step in parallel is (4–6)M SPTs, regardless of the number of processors being used[8].

The time-to-completion models described above consider only the time required to complete the necessary operations. However, the time required to complete the processor-to-processor communications might also be significant, and the nature of that communication is quite different for the RBOW step than it is for a transport sweep. While numerical tests on a parallel machine are beyond the scope of this paper, it is worthwhile to give a brief outline of the different communication requirements. Basic models of processor communication time describe the total time required to pass a message containing k units of data as [17]

$$t_l + kt_b. \tag{8.1}$$

The time t_l is called the message [illegible], and the reciprocal of t_b is called the [illegible]. In the case of a transport sweep, many small communications are required. Each time information is passed to the next group of processors; the message size is equal to the number of spatial unknowns on half of the processor boundary in only one S_N direction. The total time for all communication in a complete sweep is therefore $[iP^{\frac{1}{i}} + M](t_l + k_{sw}t_b)$, where k_{sw} indicates the relatively small message size associated with sweeps. In the case of the RBOW step, communication only needs to occur four times, once at the beginning of each color pass. However, the message size is larger, including the number of spatial unknowns on half of the processor boundary in all of the inflow directions (half of all the S_N directions). The total time for all communication in an RBOW step is $4(t_l + k_{rbow}t_b)$, where k_{rbow} indicates the larger message size. Clearly, the parallel time-to-completion for a transport sweep or an RBOW relaxation depends on the number of processors and the number of S_N directions, as well as the value of t_l and t_b on a given machine. Table 8.1 summarizes computation and communication time for the models described above.

While the above discussion sheds some light on the parallel scalability issue, it is only a first step towards a parallel performance comparison with DSA. In order to compare performance, one must consider two additional issues. First, the total iteration cost is a multiple of the relaxation cost. As discussed above, the V-cycle cost in two dimensions is approximately $\frac{8}{3}$ times the cost of the RBOW step. In the context of parallel computing, this factor of $\frac{8}{3}$ assumes perfect parallel scalability of the coarse-grid work. In reality, the coarse-grid work does not scale perfectly. It is

[8]This time-to-completion model for the RBOW step assumes no overlap in the spatial regions for which each processor is responsible. In reality, the shifting block process requires that a small overlap exist to facilitate the inversion of 4 cell blocks that straddle the line between two processors. If a significant number of cells are assigned to each processor, the effect of the overlap on time-to-completion is very small.

likely that at some point in the V-cycle, the number of unknowns in the coarse-grid problem will drop below the number of processors, and therefore certain processors will be idle. However, in most applications, the percentage of computational work that takes place while processors are idle is very small, and the effect on parallel scalability is insignificant. This issue is examined in [6]. In the case of an efficient DSA algorithm, the total iteration cost may in fact be close to the cost of the transport sweep. However, if the diffusion solve is accomplished via multigrid, the parallel scalability of the coarse-grid work affects the DSA algorithm just as it does the spatial multigrid algorithm described here. Furthermore, in the case of corner balance and other similar discretizations, a fully consistent DSA cannot be implemented at a computational cost near that of a single sweep. If an inconsistent DSA is used as a preconditioner for a Krylov method [18], the Krylov method itself represents additional computational cost. Second, the convergence factor obtained by the spatial multigrid method for a given problem is different from the convergence factor a DSA algorithm would obtain. Convergence factors for particular problems are discussed below.

9. Comparison to DSA. In order to properly compare spatial multigrid to DSA for a particular problem, one must consider not only the time required to complete an iteration, but also the convergence factor. In the case of a homogeneous thin domain, DSA gives excellent convergence due to the sweeps. For these domains, spatial multigrid struggles, especially if the number of S_N directions is large. For a homogeneous thick domain dominated by scattering, both methods have impressive convergence factors. As indicated above, the spatial multigrid algorithm produces a convergence factor of about .06 in the thick diffusive case. While the exact convergence factor obtainable from a DSA algorithm for the thick diffusive case may depend on the particular implementation, it is likely that it would be near the theoretical value of about 23 obtained from Fourier analysis. Finally, there is the heterogeneous case to consider, especially the case of the thin center. While tests have been done on thin center domains with DSA [18], convergence factors as defined by (5.1) and (5.2) are not given. Therefore, for the purpose of comparison, a DSA algorithm was coded and tested on the heterogeneous model domain described above.

In multigrid terms, DSA can be thought of as a 2-grid scheme in angle. The relaxation method is transport sweeps, and the coarse-grid problem is formed by taking a Galerkin P_1 closure[9] of the residual equation. The simplest way to implement a "fully consistent" DSA scheme is to simply solve the coarse grid system exactly, and this is what we have done. While this strategy is computationally expensive, the goal here is only to get an idea of what convergence factors DSA is capable of producing for certain heterogeneous problems. In [18], Warsa, Wareing, and Morel indicate that an inconsistent DSA used as a preconditioner for a Krylov method is a viable alternative to the fully consistent DSA. Therefore, for the purpose of this comparison, we do not consider the cost of the fully consistent DSA we have implemented, but only use it to get an idea of what convergence factors DSA is capable of producing for the thin center case. Table 9.1 shows the same tests as Table 6.3. The convergence factors for the spatial multigrid method are listed again, and the convergence factors for our implementation of DSA are also given. Clearly the performance of DSA degrades in much the same way as the performance of the spatial multigrid method does for the thin center problem.

[9] P_1 refers to a first order spherical harmonic expansion in angle. One forms the coarse-grid system by assuming the angular flux has a first order spherical harmonic expansion in angle, and then integrating the transport equation against the zeroth and first order spherical harmonics.

TABLE 9.1

Convergence factors for spatial multigrid and DSA on the heterogeneous model domain with vacuum center, thick pure scattering perimeter, and time step–based effective absorption. The thick region always has $\sigma_t h = 10^4$. Parentheses indicate convergence factor for a W-cycle instead of a V-cycle.

$\frac{1}{c\Delta t}$	$\frac{c\Delta t}{\Delta x}$	$\rho_{sp.mg}$	ρ_{dsa}
nx	1	$7 * 10^{-4}$	.03
$\frac{nx}{10}$	10	.12	.41
$\frac{nx}{100}$	100	.56(.38)	.84
$\frac{nx}{1000}$	1000	.88(.69)	.98

The reason for the degraded performance is the same in both cases; the error after relaxation is not sufficiently close to the range of interpolation. Our spatial multigrid method is based on the idea that RBOW relaxation leaves behind bilinear error. For the pure thick domain, this is true, and convergence is excellent. However, in the case of the thin center problem, the error after the RBOW step is not as close to the range of bilinear interpolation, and convergence suffers. Similarly, DSA is based on the idea that a transport sweep leaves behind error that is P_1 in angle. Again, for a pure thick problem, this is true, and convergence is excellent. In the thin center case, the error after the transport sweep in the thin region is much more complicated than P_1 in angle, and therefore the coarse-grid correction loses its effectiveness, and convergence suffers.

In conclusion, while a parallel performance comparison of a state-of-the-art DSA algorithm with our spatial multigrid method is beyond the scope of this paper, the discussion above allows for a rough comparison from which one can identify the types of problems and machines on which one method would likely prove faster than the other. The time required to complete one iteration of either algorithm depends on the number of processors, the number of S_N angles being used, and the speed of processor-to-processor communication. The convergence factors obtained by the two methods are also different and highly problem dependent.

10. Conclusions and future work. The multigrid algorithm presented here gives good convergence factors at a realistic cost for most homogeneous domains and is appropriate for heterogeneous domains in time-dependent applications. Sequential operations associated with global transport sweeps are avoided, making the method suitable for large parallel machines. Future work will focus on improving the convergence factors for heterogeneous domains, reducing computational cost, and applying the methodology to other discretizations.

EFFICIENT PRECONDITIONING OF SEQUENCES OF NONSYMMETRIC LINEAR SYSTEMS*

JURJEN DUINTJER TEBBENS† AND MIROSLAV TŮMA†

Abstract. We present a new approach for approximate updates of factorized nonsymmetric preconditioners for solving sequences of linear algebraic systems. This approach is algebraic and it is theoretically motivated. It generalizes diagonal updates introduced by Benzi and Bertaccini [*BIT*, 43 (2003), pp. 231–244] and Bertaccini [*Electron. Trans. Numer. Anal.*, 18 (2004), pp. 49–64]. It is shown experimentally that this approach can be very beneficial. For example, it is successful in significantly decreasing the number of iterations of a preconditioned iterative method for solving subsequent systems of a sequence when compared with freezing the preconditioner from the first system of the sequence. In some cases, the updated preconditioners offer a rate of convergence similar to or even higher than the rate obtained when preconditioning with recomputed preconditioners. Since the updates are typically cheap and straightforward, their use is of practical interest. They can replace recomputing preconditioners, which is often expensive, especially in parallel and matrix-free environments.

Key words. preconditioned iterative methods, sparse matrices, sequences of linear algebraic systems, incomplete factorizations, factorization updates, Gauss–Jordan transformations, minimum spanning tree

1. Introduction.

We consider the solution of sequences of linear systems

$$A^{(i)}x = b^{(i)},\ i = 1, \ldots, \tag{1.1}$$

where $A^{(i)} \in \mathbb{R}^{n\times n}$ are general nonsingular sparse matrices and $b^{(i)} \in \mathbb{R}^n$ are corresponding right-hand sides. Such sequences arise in many applications such as computational fluid dynamics, structural mechanics, numerical optimization as well as in solving non-PDE problems. For example, a system of nonlinear equations $F(x) = 0$ for $F : \mathbb{R}^n \to \mathbb{R}^n$ solved by a Newton- or Broyden-type method leads to a sequence of problems

$$J(x_i)(x_{i+1} - x_i) = -F(x_i),\ i = 1, \ldots, \tag{1.2}$$

where $J(x_i)$ is the Jacobian evaluated in the current iteration x_i or its approximation [31], [32].

The solution of sequences of linear systems is the main bottleneck in many applications mentioned above. For instance, the solvers may need powerful preconditioners in order to be efficient, and computing preconditioners $M^{(1)}, M^{(2)}, \ldots$ for individual systems separately can be very expensive. There is a strong need for reduction of costs by sharing some of the computational effort among the subsequent linear systems.

A way to reduce the overall costs for solving systems of the type (1.2) is to modify Newton's method by skipping some Jacobian evaluations as in the Shamanskii

combination of Newton's method and the Newton-chord method [11], [54]. In this way we get a sequence of systems with identical matrices, and techniques for solving systems with more right-hand sides may be applied provided that the right-hand sides are available a priori; see, e.g., [45], [25], [55], [60]. However, combinations of Newton's method and the Newton-chord method have much weaker nonlinear convergence properties than the standard Newton method.

A different approach to reducing the overall costs, which is usually more efficient, is based on reusing the preconditioner (using the same preconditioner for a sequence of linear systems), but recomputing (approximate) Jacobians $A^{(i)}$ [12], [37], [38]. This approach is very natural in the context of a matrix-free environment, where the system matrices $A^{(i)}$ may be available only in the form of matrix-vector products (matvecs); see also the overview of matrix-free Newton–Krylov methods in [36].

Another way to avoid efficiency and/or memory related problems connected to algebraic preconditioning is to use conceptually simpler preconditioners derived from the physics of the problem. In some PDE problems the original operator can be replaced by a simpler one. Early results related to preconditioning by fast solvers can be found in [16], [24]. For instance, the simpler operator can be a scaled diffusion operator for a PDE with variable coefficients or a convection-diffusion operator [12], [34], [36]. In the algebraic setting, simple preconditioners derived from stationary iterative methods can be used. Preconditioning by the symmetric part of a nonsymmetric matrix was proposed in [17], [62]; see also [14]. Another popular preconditioning technique for general convection-diffusion-reaction models is based on generalizations of ADI splitting from [48]; see, e.g., [34]. Note that we restrict ourselves here to linear preconditioners; for nonlinear preconditioning techniques we refer, e.g., to [13] and the references therein. In order to make the preconditioning more efficient and to simplify the preconditioner setup even more, reformulations based on nested iterations were introduced; see, e.g., [59]. For instance, the flexible Krylov-subspace framework enables theoretically sound implementations of inner-outer Krylov-subspace methods [51], [56].

Freezing the preconditioner or using simple preconditioning techniques may not be enough for fast convergence in practice. Our contribution proposes new and efficient approximate updates of a preconditioner which is factorized as $LDU \approx A$. The updated preconditioners are then used for solving the subsequent members of the sequence. We do not assume any simple relation among the systems of the sequence. Note that straightforward approximate small rank preconditioner updates can be obtained in case of a sequence of linear systems from a quasi-Newton method, as shown in the symmetric and positive definite case in [44], [8]. It is well known how to compute the updates of sparse decompositions [19], [20], [21]; the techniques for updates starting in early papers, e.g., [27], and having mainly the intent of being applied to the simplex method of linear programming and its extensions are a classical part of numerical mathematics. Another algebraically motivated strategy used in preconditioning sequences of systems is to use adaptive information generated by Krylov-subspace methods [2]. Recent work on recycling explicit information from Krylov subspaces can be found in [41], [47].

In this paper we directly generalize the approximate diagonal updates which are useful for solving the parabolic PDEs proposed in [3]; see also [9]. This generalization consists in modifying general off-diagonal entries. Our numerical experiments show that the generalizations are competitive with recomputing the factorized nonsymmetric preconditioners in terms of achieving similar convergence rates for subsequent systems. Moreover, forming the updates can be significantly cheaper than recomput-

ing the preconditioner. As far as we know, there are no theoretical or experimental results in this direction. We give a couple of theoretical explanations for the good performance of the updates and discuss some unexpected effects which help to improve the convergence and, as far as we know, have not been communicated before. The strategy which we use forms the updated preconditioner from two separate layers: entries of the original factorized preconditioner and scaled entries of the matrix update. For the sake of quality and efficiency we typically need to exploit only a part of the update. This part may result from a Gauss–Seidel type of splitting, or it may be found in a more sophisticated way. In this paper we treat both cases.

The paper is organized as follows. In section 2 we present a brief introduction into preconditioner updates and motivate the basic form of our updated factorizations. In section 3 we describe the new techniques for approximate updating. The results of numerical experiments with the new algorithms are presented and discussed in section 4. Directions for current and future research are given in section 5. Throughout the paper, $\|\cdot\|$ denotes an arbitrary matrix norm.

2. The ideal updated preconditioner. Some of the strategies for updating preconditioners that we mentioned in the introduction are linked with specific classes of linear solvers (e.g., recycling Krylov subspaces) and nonlinear solvers (e.g., Broyden-type methods) or they were designed for symmetric matrices. In this paper we wish to consider sequences of general, nonsymmetric systems that are solved by preconditioned iterative methods. We address here the following problems: First, how can we update, in theory, a preconditioner in such a way that the updated preconditioner is likely to be as powerful as the original one? And second, how can we approximate, in practice, such an update in order to obtain a preconditioner that is inexpensive to apply and yet useful?

In order to simplify the notation, we consider two linear systems of dimension n denoted by $Ax = b$ and $A^+x^+ = b^+$. Denote the difference matrix $A - A^+$ by B and let M be a preconditioner approximating A. Some information about the quality of the preconditioner M can be taken from a norm of the matrix

$$A - M \tag{2.1}$$

or from some norm of the matrix

$$I - M^{-1}A \quad \text{or} \quad I - AM^{-1} \tag{2.2}$$

if we consider preconditioning from the left or right, respectively (see, e.g., [3]). If preconditioners are in factorized form, both (2.1) and (2.2) should be considered in practice since the preconditioners can suffer from two types of deteriorations. While the norm of the matrix (2.1) expresses [illegible] of the preconditioner, the norms of the matrices (2.2) relate to its [illegible] [15]; see also [5]. We will define updated preconditioners M^+ for A^+ whose accuracy and stability are close to the accuracy and stability of M for A. For their derivation we concentrate on the norm of the matrix (2.1) because of its simplicity. Later in this section we present theoretical results demonstrating that both accuracy and stability of the derived updates are comparable to or even better than those of M for A.

We immediately obtain

$$\|A - M\| = \|A^+ - (M - B)\|.$$

Hence $M^+ \equiv M - B$ represents an updated preconditioner for A^+ of the same "level" of accuracy as M represents for A. We will call it the [illegible] updated preconditioner.

Note that there may very well exist different preconditioners that are ideal with respect to a norm of $A^+ - M^+$. Just consider $M^+ = M - C$ for some matrix $C \neq B$ with

$$\|A - M\| = \|A^+ - M^+\| = \|A^+ - M + C\|.$$

Because B is often readily available, we will concentrate on $M^+ = M - B$.

If we want to use M^+ as a preconditioner, we need to multiply vectors with the inverse of M^+ in every iteration of the linear solver. In some problems, the difference matrix B is such that $(M - B)^{-1}$ can be obtained from M^{-1} with low costs. For instance, if B has small rank, M^+ can be easily inverted using the Sherman–Morrison formula; see, e.g., [44, 8]. In general, however, the ideal updated preconditioner cannot be used since multiplication of vectors with $(M - B)^{-1}$ is expensive. Instead, we will consider cheap approximations of $(M - B)^{-1}$.

In this paper we will assume that M is given in the form of a triangular decomposition as $M = LDU \approx A$, where L and U have unit main diagonal. The approximate updates of factorized preconditioners which we will describe below typically assume that the matrices have a strong diagonal. Note that this assumption is very similar to theoretical assumptions which are generally required to get simple incomplete factorizations without a breakdown. For example, standard ILU(0) and AINV preconditioners are proved to be breakdown-free if the system matrix is an H-matrix [43], [6]. In order to extend the breakdown-free property to more general matrices, we need to change the decomposition by modifications which make the diagonal stronger, e.g., by a preliminary shift [43], [40] (see also [33], [1]) or by global modification of the decomposition [57], [35], [4]. The transfer from diagonal dominance of the matrix to diagonal dominance of the factors is discussed, for example, in [7] (cf. [3]) or in the practical reordering strategies based on strong transversals [46], [22], [23]. In the following we tacitly assume matrices are given in such form that the factors L and U more or less approximate the identity matrix.

If $M - B$ is invertible, we can approximate its inverse by a product of more factors which are easier to invert. For example, we can replace $(M - B)^{-1}$ by a product of inverses of triangular matrices and by an inverse of a difference of matrices where a diagonal matrix is used instead of M, as in

$$(M - B)^{-1} = U^{-1}(D - L^{-1}BU^{-1})^{-1}L^{-1} \approx U^{-1}(D - B)^{-1}L^{-1}, \tag{2.3}$$

provided that $D - B$ is nonsingular. Now assume $\overline{D - B}$ is a nonsingular approximation of $D - B$ that can be inverted inexpensively. Then we can define a preconditioner M^+ via the last expression in (2.3) as

$$M^+ = L(\overline{D - B})U. \tag{2.4}$$

In the symmetric case, this preconditioner changes to $M^+ = L(\overline{D - B})L^T$; hence symmetry is preserved if we choose $\overline{D - B}$ appropriately. Here we are primarily interested in the nonsymmetric case, and in this case we can further simplify the update. For example, we can approximate as

$$(M - B)^{-1} = (DU - L^{-1}B)^{-1}L^{-1} \approx (DU - B)^{-1}L^{-1} \tag{2.5}$$

if $DU - B$ is nonsingular. If $\overline{DU - B}$ denotes a nonsingular and easily invertible approximation of $DU - B$, then we define M^+ by

$$M^+ = L(\overline{DU - B}). \tag{2.6}$$

In comparison with (2.4), it seems to be much easier to deal only with two factors. An analogue of (2.5) is approximation through

$$(M-B)^{-1} = U^{-1}(LD - BU^{-1})^{-1} \approx U^{-1}(LD-B)^{-1}. \tag{2.7}$$

In our experiments we choose between approximation with (2.5) or (2.7) adaptively (we explain this later on). We describe our theoretical results for the case (2.5) only.

A first question is whether the update (2.6) has the potential to be more powerful than the frozen preconditioner $M = LDU$ for A^+. In the following simple lemma we express the relation of the frozen preconditioner to the updated form quantitatively.

LEMMA 2.1. [illegible] $\|A - LDU\| = \varepsilon\|A\| < \|B\|$ [illegible] (2.6)

[illegible]

$$\begin{aligned}\|A^+ - M^+\| &\le \frac{\|L(DU - \overline{DU-B}) - B\| + \varepsilon\|A\|}{\|B\| - \varepsilon\|A\|} \cdot \|A^+ - LDU\| \\ &\le \frac{\|L\|\,\|DU - B - \overline{DU-B}\| + \|L-I\|\,\|B\| + \varepsilon\|A\|}{\|B\| - \varepsilon\|A\|} \cdot \|A^+ - LDU\|.\end{aligned}$$

[illegible] We get directly

$$\begin{aligned}\|A^+ - M^+\| &= \|A - B - L(\overline{DU-B})\| = \|(A - LDU) + L(DU - \overline{DU-B}) - B\| \\ &\le \left(\varepsilon\|A\| + \|L(DU - \overline{DU-B}) - B\|\right) \frac{\|B\| - \varepsilon\|A\|}{\|B\| - \varepsilon\|A\|} \\ &\le \left(\varepsilon\|A\| + \|L(DU - \overline{DU-B}) - B\|\right) \frac{\|(A - LDU) - B\|}{\|B\| - \varepsilon\|A\|} \\ &\le \|A^+ - LDU\| \frac{\|L(DU - \overline{DU-B}) - B\| + \varepsilon\|A\|}{\|B\| - \varepsilon\|A\|} \\ &= \|A^+ - LDU\| \frac{\|L(DU - \overline{DU-B} - B) + (L-I)B\| + \varepsilon\|A\|}{\|B\| - \varepsilon\|A\|} \\ &\le \|A^+ - LDU\| \frac{\|L\|\,\|DU - B - \overline{DU-B}\| + \|L-I\|\,\|B\| + \varepsilon\|A\|}{\|B\| - \varepsilon\|A\|}. \qquad \square\end{aligned}$$

The multipliers of $\|A^+ - LDU\|$ in Lemma 2.1 can be smaller than one if $\overline{DU-B}$ is close to $DU - B$ and if $\|L - I\|$ tends to be small. In practice, taking into account preconditioner modifications to improve diagonal dominance, this is often realistic. Note that the assumption $\|A - LDU\| = \varepsilon\|A\| < \|B\|$ is satisfied as soon as we have a strong preconditioner $M = LDU$.

The lemma states, apart from showing a relation to the frozen preconditioner, that for $\varepsilon\|A\|$ small enough a good approximation to $\overline{DU-B}$ combined with a close to diagonal factor L yields an accurate preconditioner which [illegible] be as powerful as a recomputed preconditioner. If we have a recomputed preconditioner M^R with say, $\|A^+ - M^R\| = \delta = \|A - M\|$, then based on (2.5) we expect $\|A^+ - M^+\| \ge \delta$. But the previous lemma shows $\|A^+ - M^+\| < \delta$ is not at all excluded. In section 4 we will show experimentally that the update (2.6) in some cases gives a higher convergence rate than if the preconditioner is recomputed.

The following theorem shows in a different way that, under the given assumptions, the quality of the update may be better than that of recomputed preconditioners if the approximation $\overline{DU-B}$ is favorably chosen. Since Lemma 2.1 is related to the accuracy according to (2.1), the theorem considers its quality with respect to (2.2).

The result is a straightforward generalization of a result from [9]. To simplify the description, the scaled updated approximate factor $D^{-1}(\overline{DU-B})$ will be denoted by $\overline{U-D^{-1}B}$, and $U^{-1}(\overline{U-D^{-1}B})$ will be denoted by $I-\overline{U^{-1}D^{-1}B}$.

THEOREM 2.2. $LDU+E=A$ E $\|\overline{U^{-1}D^{-1}B}\|_2 \le 1/c < 1$ $\|\cdot\|_2$ σ_i

$$(I-L)B + L\left(\overline{DU-B} - (DU+L^{-1}E-B)\right)$$

$$\sigma_1 \ge \sigma_2 \ge \cdots \ge \sigma_t \ge \delta \ge \sigma_{t+1} \ge \cdots \ge \sigma_n$$

t $t \ll n$ $\delta > 0$ $(\overline{DU-B})$ $D=\operatorname{diag}(d_1,\ldots,d_n)$ F Δ

$$(\overline{DU-B})^{-1}L^{-1}A^+ = I+\Delta+F, \tag{2.8}$$

$(\Delta) \le t$

$$\|F\|_2 \le \frac{c}{c-1}\max_i \frac{\delta}{|d_i|}\|L^{-1}\|_2\|U^{-1}\|_2.$$

We have

$$\begin{aligned} L(\overline{DU-B}) - A^+ &= L(DU+L^{-1}E-B+\overline{DU-B}-(DU+L^{-1}E-B)) - A^+ \\ &= (I-L)B + L\left(\overline{DU-B}-(DU+L^{-1}E-B)\right). \end{aligned}$$

By assumption, the SVD of the latter matrix can be written as

$$(I-L)B + L\left(\overline{DU-B}-(DU+L^{-1}E-B)\right) = W\Sigma V^T$$
$$= W\operatorname{diag}(\sigma_1,\ldots,\sigma_t,0,\ldots,0)V^T + W\operatorname{diag}(0,\ldots,0,\sigma_{t+1},\ldots,\sigma_n)V^T \equiv \Delta_1 + F_1,$$

where $\operatorname{rank}(\Delta_1) \le t$ and $\|F_1\|_2 \le \delta$. Hence

$$L(\overline{DU-B}) - A^+ = \Delta_1 + F_1$$

and

$$(\overline{DU-B})^{-1}L^{-1}A^+ = I - (\overline{DU-B})^{-1}L^{-1}\Delta_1 - (\overline{DU-B})^{-1}L^{-1}F_1.$$

By setting

$$F \equiv -(\overline{DU-B})^{-1}L^{-1}F_1, \qquad \Delta \equiv -(\overline{DU-B})^{-1}L^{-1}\Delta_1,$$

we get (2.8), where $\operatorname{rank}(\Delta) \le t$. The matrix F can be bounded by

$$\|F\|_2 \le \|L^{-1}\|_2 \left\|\left(D(\overline{U-D^{-1}B})\right)^{-1}\right\|_2 \delta;$$

hence

$$\begin{aligned} \|F\|_2 &\le \max_i \frac{\delta}{|d_i|}\|L^{-1}\|_2\|(\overline{U-D^{-1}B})^{-1}\|_2 \\ &\le \max_i \frac{\delta}{|d_i|}\|L^{-1}\|_2\|U^{-1}\|_2\|(I-\overline{U^{-1}D^{-1}B})^{-1}\|_2. \end{aligned}$$

By assumption, $\|\overline{U^{-1}D^{-1}B}\|_2 \leq 1/c < 1$, and, consequently,

$$\begin{aligned}\|F\|_2 &\leq \max_i \frac{\delta}{|d_i|}\|L^{-1}\|_2\|U^{-1}\|_2 \left(1 - \|\overline{U^{-1}D^{-1}B}\|_2\right)^{-1} \\ &\leq \frac{c}{c-1}\max_i \frac{\delta}{|d_i|}\|L^{-1}\|_2\|U^{-1}\|_2. \qquad \square\end{aligned}$$

Note that if the matrix F in (2.8) is zero, then the preconditioned system is a rank t update of the identity, and Krylov-subspace methods converge, in exact arithmetics, in at most $t+1$ iterations.

In the following section we propose approximations $\overline{DU-B}$ of $DU-B$ that can be efficiently computed and that lead to preconditioners that are inexpensive to apply. All techniques we present can be analogously formulated for updates of the form $(\overline{LD-B})U$ corresponding to (2.7).

3. Approximate preconditioner updates. We propose the following strategies to approximate $DU-B$ by an easily invertible matrix $\overline{(DU-B)}$. A first obvious but effective strategy is to set $\overline{DU-B} \equiv triu(DU-B)$, where $triu$ denotes the possibly sparsified upper triangular part (including the main diagonal). This results in the preconditioner

$$M^+ = L(DU - triu(B)), \tag{3.1}$$

which can be obtained entirely for free. The additional cost for applying this preconditioner is one triangular sweep with the triangular part of B if we store B and U separately. We may also merge them; then the additional sweep can be virtually free if the sparsity patterns of $triu(B)$ and U are close enough. We will call the update constructed by considering entries only from one triangular part the [illegible]. A trivial structured sparsification is given by

$$\overline{DU-B} \equiv \mathrm{diag}(DU-B),$$

which is a straightforward application of an approach from [3] to nonsymmetric problems.

As we show in the experiments, the simple update (3.1) and its analogue

$$M^+ = (LD - tril(B))U \tag{3.2}$$

seem to be powerful in many problems. One expects them to be particularly suited when one triangular part of B clearly dominates the other. The typical situation of that kind arises when matrices come from upwind/downwind discretization schemes. Nevertheless, as they take into account only one triangular part of the difference matrix B, there may be applications where important information is lost, leading to weak convergence. In the following we present a technique to replace $DU-B$ by an easily invertible matrix which is in general not triangular.

Denote the matrices $\mathrm{diag}(\overline{DU-B})$ by $\tilde{D}$, and $\tilde{D}^{-1}(\tilde{D} - \overline{DU-B})$ by $\tilde{B}$, respectively. Then $\tilde{B}$ has zero diagonal and we can write

$$\overline{DU-B} = \tilde{D}(I - \tilde{B}). \tag{3.3}$$

To motivate the scaling transformation in (3.3) consider for a moment the case when $\tilde{B} = \beta e_i e_j^T$ for some $1 \leq i,j \leq n, i \neq j$, and recall that we assume $\overline{DU-B}$ is nonsingular; hence so is $I - \tilde{B}$. Then we get, with the Sherman–Morrison formula,

$$(I-\tilde{B})^{-1} = I + \beta e_i e_j^T/(1-\beta e_j^T e_i) = I + \beta e_i e_j^T = I + \tilde{B}. \tag{3.4}$$

The matrix in (3.4) is equal to the identity modified by an off-diagonal entry β at the position (i, j). That is, $(I - \tilde{B})$ is a special Gauss–Jordan transformation [28], it is inverted without costs, and it has a fill-in free inverse.

Based on this well-known fact, in the following we will try to find approximations $\overline{DU - B}$ of $DU - B$ such that the scaled matrix $I - \tilde{B}$ can be written as a product of Gauss–Jordan transformations

$$(I - e_{i_1}\tilde{b}_{i_1*})(I - e_{i_2}\tilde{b}_{i_2*}) \dots (I - e_{i_K}\tilde{b}_{i_K*}), \qquad K \leq n-1, \tag{3.5}$$

where $\tilde{B} = (\tilde{b})_{ij}$. Denote the sparsity structure of a row i of $\tilde{B}$ (with zero diagonal) by $row(i)$, that is, $row(i) = \{k | i \neq k \wedge \tilde{b}_{ik} \neq 0\}$. The multiplication $(I - \tilde{B})^{-1}v$ for a given vector v is very cheap, as stated in Observation 3.1.

OBSERVATION 3.1. [illegible] (3.5) [illegible] $2\sum_{j=1}^{K} |row(i_j)|$

It is well known that any unit upper triangular matrix $I - \tilde{B}$ from (3.3) can be trivially written as the product $R_{n-1} \dots R_1$ of $n-1$ elementary triangular matrices $R_i = I - e_i\tilde{b}_{i*}$ for $i = 1, \dots, n-1$. Hence using (3.1) may be considered a special case of (3.5). The following theorem shows a necessary and sufficient condition for the existence of a decomposition of $I - \tilde{B}$ of the form (3.5).

THEOREM 3.1. $I - \tilde{B} = I - \sum_{j_l : l=1,\dots,K} e_{j_l}\tilde{b}_{j_l*}$ [illegible]

$$I - \tilde{B} = (I - e_{i_1}\tilde{b}_{i_1*})(I - e_{i_2}\tilde{b}_{i_2*}) \dots (I - e_{i_K}\tilde{b}_{i_K*}) \tag{3.6}$$

[illegible]

$$i_l \notin \bigcup_{k=1}^{l-1} row(i_k) \text{ for } 2 \leq l \leq K \tag{3.7}$$

[illegible] $i_1, \dots, i_K$ [illegible] $\{j_1, \dots, j_K\} = \{i_1, \dots, i_K\}$ [illegible]. The equivalence of (3.6) and (3.7) follows from the orthogonality of the unit vector e_{i_l} with respect to all $\tilde{b}_{i_k*}$ for $k < l$, $1 \leq l \leq K$. □

Based on Theorem 3.1 we first propose a greedy procedure to find a suitable approximation $\overline{DU - B}$ with $I - \tilde{B}$ satisfying (3.6). Consider a sequential choice of indices $i_1, \dots, i_K$, where $K \leq n-1$ are determined by the algorithm. In each step we keep and update a set of [illegible] $\mathcal{R}$ initialized by $\{1, \dots, n\}$. After choosing a row i we remove from $\mathcal{R}$ all the rows $j \in \mathcal{R}$ for which $\tilde{b}_{ij} \neq 0$.

ALGORITHM 3.1. We use this algorithm to approximate $DU - B$ by a matrix which, scaled by its diagonal, can be written in the form (3.6)

(1) [illegible] $\mathcal{R} = \{1, \dots, n\}$ $K = 0$
(2) [illegible] $k = 1, \dots, n$
(3) [illegible] $row(k) = \{i | i \neq k \wedge |(DU - B)_{ki}| \neq 0\}$
(4) [illegible] $p_k = \sum_{j \in row(k)} |(DU - B)_{kj}|$
(5) [illegible]
(6) [illegible] $\mathcal{R} \neq 0$
(7) [illegible] $i \in \mathcal{R}$ [illegible] $p_i - \sum_{j \in \mathcal{R} \cap row(i)} p_j$
(8) [illegible] $K = K + 1$ $i_K = i$ $\mathcal{R} = \mathcal{R} \backslash \{row(i_K) \cup i\}$
(9) [illegible]

The row indices $i_1, \dots, i_K$ provided by Algorithm 3.1 then determine the approximation in (3.3) with $I - \tilde{B}$ equal to the product (3.5). The heuristic criterion in step (7) aims, on the one hand, to choose the row of $DU - B$ with the largest entries. On

the other hand, it stimulates the choice of a row which results, based on condition (3.7), in removal of candidate rows with small entries. To balance between the two heuristics one may want to introduce a weighting parameter ω and use

(7′) $i \in \mathcal{R}$ $p_i - \omega \cdot \sum_{j \in \mathcal{R} \cap row(i)} p_j$.

Clearly, the algorithm may find more factors of (3.6) if there are fewer nonzero entries in the searched rows. Therefore it may be reasonable to perform some dropping strategy on-the-fly when running the algorithm by substituting step (3) with

(3′) *set* $row(k) = \{i | i \neq k \wedge |(DU - B)_{ki}| > tol\}$

for a predefined drop tolerance *tol*. Apart from tolerance-based dropping, sparsification based on the given mask may enhance the effectiveness of our strategy. Note that sparsification not only helps in covering as many rows as possible by Gauss–Jordan transformations, but it also leads to less expensive matvecs with the inverse of (3.5).

A more elegant and systematic way to get an unstructured update based on Gauss–Jordan transformations can be described by the following bipartite graph model. Let us define the bipartite graph of $(DU - B)$ as $G(DU - B) = (R, C, E)$, where $R = \{1, \ldots, n\}$, $C = \{1', \ldots, n'\}$ and $E = \{(i, j') | (DU - B)_{ij} \neq 0\}$. Then we have the following result.

THEOREM 3.2. $T = (V_T, E_T)$ $G(DU - B)$ $\{(i, i') | 1 \leq i \leq n\} \subseteq E_T$ $\overline{DU - B} \in \mathbb{R}^{n \times n}$

$$\overline{(DU - B)}_{ij} = \begin{cases} (DU - B)_{ij} & \text{if } (i, j') \in E_T, \\ 0 & \text{otherwise,} \end{cases}$$

(3.3) (3.5)

. First consider the case when the spanning forest T is not connected. Components of T induce a block-diagonal splitting of $\overline{DU - B}$, and matrices corresponding to individual blocks can be mutually multiplied in any order without causing any fill-in. Consequently, we can assume without loss of generality that T is connected and that T is a spanning tree. In the following we will show how to form the sequence of Gauss–Jordan transformations from the left to the right.

Our assumption implies that T contains at most $n - 1$ edges (i, j') with $i \neq j$. There exists a free row vertex $i \in R$ in T which is in T incident only to the edge (i, i') such that there is an edge $(k, i') \in E_T$ for some k. Set $i_1 = i$. Then remove from T the vertices $i \in R$, $i' \in C$ and all edges incident to them. Clearly, the updated tree T contains a free row vertex again. By repeating the choice of free row vertices and updates T in this way we get the sequence $i_1, \ldots, i_{n-1}$. If we rewrite as $I - \tilde{B}$ the matrix $\overline{DU - B}$ scaled by its diagonal, we have $I - \tilde{B} = (I - e_{i_1} \tilde{b}_{i_1 *})(I - e_{i_2} \tilde{b}_{i_2 *}) \ldots (I - e_{i_{n-1}} \tilde{b}_{i_{n-1} *})$ which proves the theorem. □

Theorem 3.2 implies the following algorithmic strategy to find a matrix $\overline{DU - B}$ which would approximate $DU - B$ and could be expressed as a product of Gauss–Jordan transformations.

ALGORITHM 3.2. We use this algorithm to find $\overline{DU - B}$ such that (3.6) is satisfied based on a bipartite graph of $DU - B$.

(1) Find a spanning forest $T = (V_T, E_T)$ of $G(DU - B)$ of maximum weight with edge weights $w_{ij} = |(DU - B)_{ij}|$ for $(i, j') \in E_T$ such that $\{(i, i') | 1 \leq i \leq n\} \subseteq E_T$.
(2) Find the entries of $\tilde{B}$ (and corresponding entries of $\overline{DU - B}$) as well as a feasible ordering of Gauss–Jordan factors for $i_1, \ldots, i_{n-1}$ in (3.5) with Theorem 3.2.

(3) For each $k = 2, \ldots, n$ add to $\overline{DU - B}$ all entries $(DU - B)_{i_k l}$ of $DU - B$ such that $l \in \{i_1, \ldots, i_{k-1}\}$.

Note that in the last step of Algorithm 3.2 we possibly put into $\overline{DU - B}$ many more nonzero entries than the $2n - 1$ entries provided by the weighted spanning forest. This is possible because of Theorem 3.1. The complexity of the weighted minimum spanning forest (here we need, in fact, a weighted maximum forest) is $O(m \log m)$ for the Kruskal algorithm [39] and $O(n + m \log m)$ for the Prim algorithm [50], where m is the number of edges in the graph G. Note, in addition, that we start with the partial spanning tree with the set of edges $\{(i, i')|1 \leq i \leq n\}$. While in some cases the algorithms may seem time consuming, this procedure can provide useful updates. As in Algorithm 3.1, we can sparsify $DU - B$ by discarding entries smaller than a certain drop tolerance *tol*, which reduces the value of m and therefore also the computational complexity.

From Lemma 2.1 it is clear that the quality of the approximation of $DU - B$ may play a decisive role in the power of the preconditioner $M^+ = L(\overline{DU - B})$. In practice, the way that the original incomplete decomposition is constructed (scaling L during the construction, pivoting) can strongly support the quality of $\overline{DU - B}$. In order to use the most powerful type of update, in our experiments we switch adaptively between (3.1) and (3.2) based on the weighting of both triangular parts of B and use an unstructured update based on Algorithm 3.1 or 3.2 if its weighting is the most important. More precisely, we compute sums of magnitudes of entries in the triangular parts of the matrices and simulate runs of Algorithms 3.1 and 3.2 to get the sum of magnitudes of entries covered by the unstructured update. We then use the strategy which corresponds to the maximum value among these sums.

It can and often does happen that, in spite of the fact that the updated preconditioner loses some information about the system matrix, it yields a better convergence rate than if the preconditioner would be recomputed from the scratch. There are several possible explanations for this phenomenon. First, note that we showed theoretically in Lemma 2.1 and Theorem 2.2 that our updated preconditioners have the potential to be stronger than recomputed factorizations. In practice, it frequently happens that by updating the preconditioner we relate it to a previous decomposition which is more diagonally dominant than a recomputed decomposition. A part of the stable triangular factors is inherited and the update may even stabilize less stable factors of the initial factorization. Note that a modified old decomposition might be useful in general, but, e.g., in the related strategy [43], the size of the modification should be typically rather small to get a useful preconditioned iterative method. This is exactly what happens when modifying with entries of difference matrices B that are typically small compared to those of $A^{(i)}$. In addition, updates appear to perform better also in cases where there is no instability. We presume this is so because the preconditioner may be favorably modified by the additional structural information given by the update. To our knowledge, this conjecture is stated for the first time. An overlooked fact is that the most powerful dual-threshold incomplete decompositions and inverse decompositions can be very memory-efficient, but they may discard the structure of the problem. Our updates can add to a memory-efficient decomposition cheap and useful information about the structure, as seems to be clear from our experiments. We believe that such a strategy might be used to improve constructing general preconditioners in some cases. We might consider the update as a simple and efficient way to modify off-diagonal entries of the preconditioner, thus getting a generalization of diagonal modifications from [43] or forced diagonal modifications introduced in [33]. It is not unusual that level-based incomplete decompositions are

much better than their sophisticated counterparts. Such a behavior has been observed on some VENKAT matrices from the Harwell–Boeing collection, where powerful and compact dual threshold ILUT [52] preconditioners are less efficient than often very dense but reasonably structured ILU preconditioners using the concept of levels [61], [29].

The next section is devoted to numerical experiments with the most promising updates introduced in the paper.

4. Numerical experiments. In this section we present results of numerical experiments with preconditioned Krylov-subspace methods for solving sequences of systems of linear algebraic equations, where updated preconditioners are compared with recomputed and frozen preconditioners. We consider the sequences in three application problems. The first and second problems were generated with the optimization software UFO [42]. The last application is based on [10]. Software for the problem was kindly provided by Philipp Birken. We present results with several kinds of ILU preconditioners to show that the introduced techniques are quite general. In order to show a larger spectrum of various results, some of the computations were done in MATLAB using its ILU decomposition script. We used MATLAB version 7.0. Most of the tests, in particular for larger problems, were written in Fortran 90 and were compiled by Compaq Visual Fortran 6.6a. The codes were run on a computer with Intel Pentium 4, 3GHz processor, 1GB RAM memory, and 512k L2 cache.

As an accelerator, the BiCGSTAB [58] iterative method with right preconditioning was used. We also performed some experiments with the restarted GMRES [53] method and the transpose-free QMR [26] method. The results were similar, and we do not report on them here. Iterations were stopped when the Euclidean norm of the residual was decreased by seven orders of magnitude. Nevertheless, in our experiments we observed close to linear behavior of convergence curves of the preconditioned iterative method. Therefore, we expect qualitatively the same results for weaker or nonuniform stopping criteria used in nonlinear solvers.

Our first test problem is a two-dimensional nonlinear convection-diffusion model problem which we use to illustrate various aspects of the proposed strategies (general behavior of the strategies, choice of parameters, values of the bounds in Lemma 2.1). It has the form (see, e.g., [31])

$$-\Delta u + Ru\left(\frac{\partial u}{\partial x} + \frac{\partial u}{\partial y}\right) = 2000x(1-x)y(1-y) \tag{4.1}$$

on the unit square, discretized by 5-point finite differences on a uniform 70×70 grid. The initial approximation is the discretization of $u_0(x, y) = 0$. We choose the modest Reynolds number $R = 50$ in order to avoid potential discretization problems which may ask for adding stabilization terms. We obtain a small sequence of 7 matrices with 24220 nonzeros each (in the tables we denote the number of nonzeros by nnz).

Our update techniques are particularly beneficial when recomputing preconditioners is expensive. We start with a typical example given by the so-called ILU(0) incomplete decomposition which has the same sparsity pattern as the matrix it preconditions. This has the obvious advantage that it enables straightforward a priori allocation, but its computation may be time-consuming. In Table 1 we display the total time to solve the whole sequence and the numbers of BiCGSTAB iterations needed to solve the individual linear systems for several preconditioning strategies. In the first, denoted by "Recomp," the ILU(0) preconditioner was computed for each

matrix separately. The strategy "Freeze" used a fixed preconditioner. The strategy denoted by "Str" used structured updates, "Unstr. GJ" stands for unstructured updates based on Gauss–Jordan transformations obtained from Algorithm 3.1, and "Unstr. Kr." stands for those obtained from Algorithm 3.2, where the spanning tree is computed with the Kruskal algorithm. We see that the recomputed ILU(0) decompositions yield powerful preconditioners for our problem, but they are rather slowly computed in MATLAB. Freezing the initial ILU(0) decomposition avoids these slow computations, and although it yields much higher numbers of BiCGSTAB iterations, the overall time to solve the sequence is shorter. Excellent behavior of the structured updates is demonstrated by this table. Here the triangular parts were chosen adaptively based on the magnitudes of their entries. While iteration numbers are nearly as low as with recomputation, significant time savings are achieved by avoiding the recomputation of preconditioners. The iteration counts for unstructured updates from Algorithm 3.1 are a little higher than for structured updates, but they are clearly lower than with the frozen preconditioner. Unstructured updates from Algorithm 3.2 yield iteration numbers comparable to those of structured updates.

Of course, running Algorithm 3.1 or 3.2 to compute the unstructured updates adds a time penalty. However, the timings displayed in Table 1 are pessimistic because they include solving with nontriangular factors of the form (3.5), which cannot compete with the highly optimized implementation of backward and forward solves in MATLAB. The complexity of Algorithm 3.1 or 3.2 alone is not very high for sparse matrices since it is linear in the number of matrix nonzeros. In this context, note that using a drop tolerance in Algorithms 3.1 and 3.2 has an influence on the number of nonzeros and hence also on computational time. We computed the unstructured updates with $tol = 0.3$ in Algorithms 3.1 and 3.2. In practice this parameter should be chosen according to the following considerations for the individual algorithms.

In Algorithm 3.2 we first construct a maximum spanning forest of at most $2n - 1$ entries. Hence we need a value of tol selecting the $2n - 1$ largest entries and as few other entries as necessary to be able to build the spanning forest. We could have optimized the choice of tol according to this rationale, leading to $tol = 0.35$ and an overall time of 10.5 seconds. For Algorithm 3.1 the situation is quite different. Here, an interesting fact is that if we significantly overestimate the parameter, then the

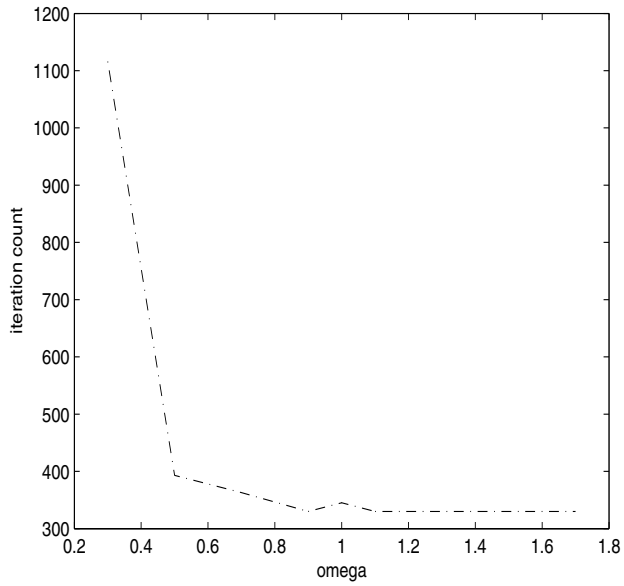

FIG. 1. *Nonlinear convection-diffusion model problem: Iteration counts for Unstr. GJ in dependency of* ω.

unstructured update may be very sparse since a smaller number of nonzeros can be covered by Gauss–Jordan transforms. If we underestimate it, then the update may be very sparse as well since we get only a small number of factors in the unstructured update of the form (3.1). In our case we did not optimize its choice, but a value $tol = 0.1-0.4$ for a reasonably scaled system matrix in order to keep only a few, say up to k, nonzeros in a row, and thus to cover by the unstructured update approximately $k \cdot n$ off-diagonal entries, is fine. This type of behavior is different from what we can sometimes observe in the field of algebraic preconditioners. As for the choice of ω in Algorithm 3.1, its value does not seem to have a crucial influence on the performance of the update either. In Figure 1 we display the total number of BiCGSTAB iterations needed to solve the whole sequence for different values of ω. If the values of ω are smaller than 0.5, criterion $(7')$ of Algorithm 3.1 starts to overemphasize the weight of the chosen candidate row, resulting in bad approximations of $DU - B$. In the other experiments presented here, we always used the choice $\omega = 1$.

In Table 2 the accuracies $\|A^{(i)} - M^+\|$ (in the Frobenius norm) of the preconditioners M^+ for the individual strategies are displayed. For this sequence, where stability of the preconditioners is not an issue, the accuracies correspond nicely to the numbers of BiCGSTAB iterations. We also present some information about the quality of the approximations $\overline{DU - B}$. Table 3 contains the values of the approximations $\|DU - B - \overline{DU - B}\|$ in the Frobenius norm for the considered update techniques. Also these values correspond to the numbers of BiCGSTAB iterations.

In Table 4 we take a closer look at the various update techniques we introduced. Whereas Table 1 suggests that structured updates provide more efficient preconditioners than unstructured updates, this is not apparent from Table 4. Here we use as initial preconditioner the ILU implemented in MATLAB with drop tolerance 0.01. The tol-

erance in Algorithms 3.1 and 3.2 for unstructured updates is 0.3. Clearly, unstructured updates are more powerful than structured updates with this kind of initial factorization. This is caused by the fact that the approximations $\overline{DU - B}$ in (2.6) cover more large entries when we use unstructured updates. In the following we quantify this property for a difference matrix B from the middle of the sequence, $B = A^{(0)} - A^{(4)}$. For other difference matrices from the sequence we would obtain similar numbers. With $B = A^{(0)} - A^{(4)}$, nonzero entries in $DU - B$ are quite evenly distributed over both triangular parts. We have $\|striu(DU - B)\| \approx 80$ and $\|stril(DU - B)\| \approx 38$ in the Frobenius norm. Here $stril(\cdot)$ and $striu(\cdot)$ denote the strict lower and upper triangular matrix part, respectively. Hence the upper triangular part is dominating, but important entries may be found in the lower part, too, and they are lost with structured updates. The unstructured updates take into account both triangular parts. This is reflected by the Frobenius norms $\|striu(\overline{DU - B})\| \approx 70$ and $\|stril(\overline{DU - B})\| \approx 16$ for the approximation $\overline{DU - B}$ from Algorithm 3.1. With Algorithm 3.2 we obtain $\|striu(\overline{DU - B})\| \approx 58$ and $\|stril(\overline{DU - B})\| \approx 32$. Note that Algorithm 3.2 yields more nonzeros, which is explained by step (3) of the algorithm. In this context, also note that the number of nonzeros of the initial factorization and structured updates is about 52000, whereas unstructured updates have smaller numbers of nonzeros, about 39000–46000, which makes application of the unstructured updated preconditioner less expensive. This is one of the reasons why the unstructured updates are competitive, even with respect to timing, with structured ones, in spite of the time penalty to run Algorithm 3.1 or 3.2. The other reason is, of course, lower BiCGSTAB iteration numbers.

In situations as in Table 1, recomputing preconditioners is outperformed by our updates because of the high expenses of recomputing. When, on the other hand, recomputation is straightforward, updates need not be more effective. An example is given in Table 5 with as initial preconditioner the dual-threshold ILUT$(0.1, 5)$ decomposition, implemented in Fortran 90. The number of nonzeros in the incomplete LU decomposition is about 38000 (slightly differing for different matrices). Here the time spent for recomputation is very small due to the simple discretization stencil, and by far the most time is spent while solving with BiCGSTAB. Still, concerning iteration counts, the (adaptively chosen) structured updates perform only slightly worse than recomputation. Note that there is a strong overlap between the location of the nonzeros in B and in the preconditioner, but as above, we did not merge the triangular parts of the updated preconditioner. Table 6 shows similar behavior for a much larger problem with ILUT$(0.1, 3)$ as initial decomposition. Here we discretized (4.1) on a 282×282 grid, the matrices having dimension 79524. While evaluating Tables 5 and 6, it is important to realize that the timings may provide here only partial information. In case of matrix-free implementation we typically need to estimate the matrices first using, for example, graph coloring techniques [18], [49]. Our matrices have five diagonals and this implies that they can be estimated by at most seven matvecs. Namely, the number of matvecs corresponds to the number of colors needed to color the undirected graph of $A^T A$, the so-called intersection graph. Computing some of the standard preconditioners both [illegible] based on matvecs is a state-of-the-art challenging problem and can be very time-consuming. When using updates in a matrix-free environment, only part of the difference matrix needs to be estimated. In our cases the needed part of the difference matrix was always available from at most three matvecs, because the intersection graph of the (possibly permuted) triangular part of the matrix could be colored by only three colors.

In addition to the experiments presented here we also performed some experiments where the nonlinear problems were discretized by upwind schemes, leading to triangular difference matrices. As one can guess from the pattern, the results for solving the linear problems were rather good, but we typically needed more nonlinear iterations. Consequently, discretization by central differences was preferable.

Our second test problem is a smaller but rather difficult problem of dimension 2500. It consists of the two-dimensional driven cavity problem of the form

$$\Delta\Delta u + R\left(\frac{\partial u}{\partial y}\frac{\partial \Delta u}{\partial x} - \frac{\partial u}{\partial x}\frac{\partial \Delta u}{\partial y}\right) = 0$$

on the unit square, discretized by 13-point finite differences on a shifted uniform grid with 50×50 inner nodes [30]. The boundary conditions are given by $u = 0$ on $\partial\Omega$ and $\partial u(0, y)/\partial x = 0$, $\partial u(1, y)/\partial x = 0$, $\partial u(x, 0)/\partial x = 0$, and $\partial u(x, 1)/\partial x = 1$. The initial approximation is the discretization of $u_0(x, y) = 0$.

For the same reason as before, we choose modest Reynolds numbers. Even with

modest Reynolds numbers we obtain sequences of linear systems that are hard to solve for the BiCGSTAB accelerator. As system matrices have 31504 nonzeros, we needed a relatively dense initial ILU preconditioner with 47000 nonzeros and with drop tolerance 0.01 from MATLAB to be able to solve the linear systems at all. Sparser preconditioners caused BiCGSTAB to stagnate for the initial linear system. In Tables 7 and 8 we show experiments executed in MATLAB with the initial ILU(0.01) preconditioner for $R = 50$ and $R = 10$, respectively. As before, by "overall time" we mean the time needed to solve the whole sequence, including preconditioner computations. In the columns "Unstr." we display the performance of unstructured updates computed with Algorithm 3.1 ($tol = 0.05$ for $R = 50$ and $tol = 0.02$ for $R = 10$) and Algorithm 3.2 ($tol = 0.7$ for $R = 50$ and $tol = 0.02$ for $R = 10$).

This problem represents the case where recomputing should be avoided for stability reasons. For instance, with $R = 50$, the recomputation of the incomplete factorization failed for the last 5 linear systems (giving the MATLAB warning "Incomplete upper triangular factor had 1 zero diagonal replaced by local drop tolerance"). In order to quantify instability we computed estimates of the 2-norms of the inverses of the factors of the used factorizations. For the initial decomposition we have $\|U^{-1}\|_2 \approx 41$ and $\|(LD)^{-1}\|_2 \approx 264$, but these norms grow rapidly for subsequent recomputed factorizations. In the second column of Table 9 the norms for $(LD)^{-1}$ are displayed; norms for U^{-1} grow similarly. Clearly, forward and backward substitution have become unstable. In the columns corresponding to updated factorizations we estimated $\|(\overline{LD - B})^{-1}\|_2$. We see that higher estimates correspond in the majority of cases to higher iteration numbers. In the frozen preconditioner strategy, however, instability

$A^{(6)}$	$4 \cdot 10^5$	264	327	290	131

is not the cause of stagnation. We guess the frozen preconditioner fails to provide the structural information contained in updated factorizations. The results for $R = 10$ reflect similar phenomena in a weaker form. Structured and unstructured updates from Algorithm 3.2 yield the best results. In the case $R = 50$ the optimal choice $tol = 0.7$ results in particularly good performance of Algorithm 3.2, with respect to both time and iteration count.

We conclude this section with an application which leads to very large sequences of linear systems. They arise from numerical computation of steady vertical air flow through a level tunnel at a low Mach number subject to the gravitational force. The domain is a two-dimensional longitudinal section of the tunnel with the pressure and density varying only in the horizontal direction such that the gravitational term is balanced out by the pressure gradient. Neumann boundary conditions and Lax–Friedrichs fluxes were used. The gravitation term and the Euler equations were separated by a first-order operator splitting. For the discretization, the implicit Euler method combined with the first-order finite volume discretization in space was used. In every time step, one Newton step is performed in the flow solver only. More details can be found in [10], in particular in section 6.2. Our results were very similar for more variations of the problem.

Table 10 contains the results for two sequences from the linear systems for the described problem with a relatively coarse discretization grid. We used the dual-threshold ILUT$(0.001, 5)$ preconditioner, where the parameters were chosen in order to have a preconditioner size (that is, number of nonzeros) close to the size of the original matrix and such that the total number of matvecs (two in each iteration) to solve the initial system is reasonably small.

Here we show results only for some linear systems from the beginning of the sequences (as given by the superscripts); the whole sequence has more than 1000 linear systems. Three preconditioning strategies were tested: recomputation, freezing and updating. Updates were always related to the first matrix of the sequence. In the first sequence of Table 10, the preconditioner that is being frozen or updated was computed for the matrix $A^{(0)}$, and in the second sequence it was taken from the 30th linear system. The update strategy was implemented as a black-box routine which decides which of the updates (unstructured update from Algorithm 3.1 or 3.2, structured update based on the upper triangular part of the difference matrix, or structured update based on the lower triangular part of the difference matrix) is used, based on the sum of magnitudes of strong matrix entries. The structured updates store the update separately, although merging with the decomposition could provide even better timings. The results are characterized by the number of iterations

of the BiCGSTAB method and by the timings of the preconditioned iterative method required to solve the individual linear systems, including the time required to compute the preconditioner. The average time to compute the preconditioner is denoted by *timep*, and its average number of nonzeros is denoted by *psize*. These last two characteristics differ slightly in individual computations of a sequence of problems. Note that preconditioning this problem was necessary; the unpreconditioned method worked rather poorly.

From Table 10 we can see once more that freezing the preconditioner may not be enough for getting efficiently preconditioned iterative methods for all the systems. Freezing with updating is typically better in terms of the number of matvecs. The additional solve with the update may add a time penalty, but its influence seems to be limited. Clearly, by changing the matrix more and more the gap between the efficiency of freezing and updating gets larger up to some point where, of course, also the update is not sufficient anymore. We included this point in our table, but in practice this would be the moment to recompute a factorization. As in the previous problem, it seems that the update is even more powerful than the recomputed preconditioners in the sense of giving the smallest number of iterations among all three preconditioning strategies. This must be mainly caused by the fact that recomputation becomes less

stable as the sequence proceeds, as can be seen from the iteration numbers around the 75th linear system. However, the role of additional structural information provided by updates should not be underestimated. In Table 12 we will consider a sequence without instability regions where updates are still more powerful than recomputed factorizations.

Table 11 presents qualitatively the same results for a larger matrix. As above, a powerful ILUT preconditioner was chosen in order to provide small iteration counts and to have the number of nonzeros of the preconditioner similar to the number of nonzeros of the original matrix. Note that for most of the more difficult problems, the time needed to solve the linear system is the best for our updates. While, as above, there is a similar behavior of the iteration counts we also show results for more matrices around the point where the original frozen preconditioner stops being useful. Note that for some matrices the updated preconditioner behaves . . . better than the other strategies.

In Table 12 we consider discretization leading to matrices of a dimension about 60000. Most of the remarks on the previous two tables can be made here too, though we note that there are no instability regions anymore. As before, updates achieve an acceleration compared to recomputing of up to 90%. The relation to the freezing strategy is the same as for the corresponding problems of smaller dimension. A noteworthy difference with smaller dimensions is that the ratio of the average time to recompute the preconditioner ("timep") the time to solve the systems is much larger.

Hence avoiding recomputation becomes more important with larger dimensions. To conclude, let us mention the problem of recomputing related to a different preconditioner. This large air flow problem with the standard AINV(0.1) preconditioner with a number of nonzeros close to the number of nonzeros in the first matrix of the sequence converges in 12 iterations on average, the time to compute the preconditioner is 1.67 s, and time for the BiCGSTAB iterations is 0.25 s! We may assume that the role of avoiding frequent recomputations will be significantly increased in this case, but we did not follow this line.

5. Conclusions. In this paper we proposed a couple of algebraic procedures which may be useful for solving sequences of systems of linear equations. The numerical experiments show that our updated preconditioners can be rather successful in practice, and the updates can often replace recomputation of preconditioners. In many cases, one would like to make the overall number of operations smaller with simple updates, and our experiments confirm that this is possible. In particular, the preconditioner update seems to be more advantageous than the other approaches if one of the following cases applies: if preconditioner computation is not cheap, if its recomputation is unstable, or if the update is structurally dominant, that is, if it covers a significant part of the difference matrices from subsequent problems. Nevertheless, there can be also different, and sometimes very strong, reasons for avoiding preconditioner recomputations. In matrix-free and/or parallel environments, which are currently quite common, any recomputation of a preconditioner may be expensive. This is especially true for strong algebraic preconditioners which are used for solving difficult problems. We intentionally used structured updates based on only one trian-

gular part. Part of our motivation was that we concentrated on finding methods for problems where the nonsymmetry is apparent. In addition, we are interested in the structured update since we expect possible cheap estimation of sparsified triangular matrices. This may be important in a matrix-free environment. Note that our unstructured updates are very close to permuted (and sparsified) triangular updates. We intend to present fully matrix-free results in the near future. Another issue which we are currently investigating is combination of approximate factorizations with various Gauss–Seidel type preconditioners to define updates.

An interesting problem which we would like to consider in the future is to find first a nonsymmetric permutation that transforms the system matrices into a form more suitable for one particular structured or unstructured update. In particular, this permutation may make one triangular part of the matrices heavier (in the sense of the sum of magnitudes of its entries) than the other triangular part. This may have a connection to the combinatorial method in Algorithm 3.2 for finding an unstructured update. The use of a weighted spanning tree strongly brings to mind the popular strategy of matchings-based nonsymmetric permutations which has significantly improved algebraic preconditioning in recent years [23], [5].

Acknowledgments. The authors thank Philipp Birken and Ladislav Lukšan for providing the software for solving the nonlinear problems and for useful instructions on working with it. They thank Andreas Meister for initiating application of the proposed techniques to the tunnel problem.

SPECTRAL ANALYSIS OF THE DISCRETE HELMHOLTZ OPERATOR PRECONDITIONED WITH A SHIFTED LAPLACIAN*

M. B. VAN GIJZEN†, Y. A. ERLANGGA‡, AND C. VUIK†

Abstract. Shifted Laplace preconditioners have attracted considerable attention as a technique to speed up convergence of iterative solution methods for the Helmholtz equation. In this paper we present a comprehensive spectral analysis of the Helmholtz operator preconditioned with a shifted Laplacian. Our analysis is valid under general conditions. The propagating medium can be heterogeneous, and the analysis also holds for different types of damping, including a radiation condition for the boundary of the computational domain. By combining the results of the spectral analysis of the preconditioned Helmholtz operator with an upper bound on the GMRES-residual norm, we are able to provide an optimal value for the shift and to explain the mesh-dependency of the convergence of GMRES preconditioned with a shifted Laplacian. We illustrate our results with a seismic test problem.

Key words. Helmholtz equation, shifted Laplace preconditioner, iterative solution methods, GMRES, convergence analysis

1. Introduction.

In this paper we investigate the spectral behavior of iterative methods applied to the time-harmonic wave equation in heterogeneous media. The underlying equation governs wave propagation and scattering phenomena arising in acoustic problems in many areas, e.g., aeronautics, marine technology, geophysics, and optical problems. In particular, we look for solutions of the Helmholtz equation discretized by using finite difference, finite volume, or finite element discretizations. Since the number of grid points per wavelength should be sufficiently large to result in acceptable solutions, for very high frequencies the discrete problem becomes extremely large, prohibiting the use of direct solution methods. Krylov subspace iterative methods are an interesting alternative. However, Krylov subspace methods are not competitive without a good preconditioner.

Finding a suitable preconditioner for the Helmholtz equation is still an area of active research; see, for example, [7]. A class of preconditioners that has recently attracted considerable attention is the class of shifted Laplace preconditioners. Preconditioning of the Helmholtz equation using the Laplace operator without shift was first suggested in [1]. This approach has been enhanced in [8, 9] by adding a positive shift to the Laplace operator, resulting in a positive definite preconditioner. In [2, 3, 4, 13] the class of shifted Laplace preconditioners is further generalized by also considering general complex shifts.

It is well known that the spectral properties of the preconditioned matrix give important insight in the convergence behavior of the preconditioned Krylov subspace methods. Spectral analyses for the Helmholtz equation preconditioned by a shifted

Laplace operator have previously been given in [2, 3, 4]. The analysis in [2], however, is restricted to the homogeneous physical parameters case, for a purely imaginary shift preconditioner. This analysis concerns the singular values of the preconditioned matrix rather than the eigenvalues. Furthermore, only reflecting and pressure release boundary conditions are considered. In [3], a convergence analysis of GMRES is discussed, under the same restriction as in [2]. A more thorough spectral analysis is presented in [4] for the case when the preconditioning operation is performed approximately by using multigrid. The analysis is based on rigorous Fourier analysis (RFA) for homogeneous physical parameters. Results from RFA, however, give little insight into the convergence of Krylov subspace methods.

This paper gives a spectral analysis from an algebraic point of view. Therefore, the results are valid under the following rather general conditions:

- They do not depend on the discretization method;
- inhomogeneous physical parameters (such as sound speed, density, and damping) are allowed;
- the analysis is also valid for various types of boundary conditions (reflecting, radiation, pressure release, and perfectly matched layer (PML) as well).

These generalizations are new, and they allow us to analyze shifted-Laplace preconditioners for a much wider class of discrete Helmholtz problems than in previous publications.

By combining the results of our analysis with a bound on the norm of the GMRES-residual, we are able to derive a "quasi" optimal value for the shift. This result is also new. The shift is derived under the assumption that the preconditioning operations with the shifted-Laplace preconditioner are performed sufficiently accurately. In practice, the preconditioning operations are performed only approximately, for example, by using a multigrid method or by making an ILU decomposition of the shifted-Laplace operator. Of course, our results do not hold unconditionally in these cases. However, the results that are reported in [2, 3, 4], where the preconditioning operations are performed approximately using either a multigrid method or incomplete LU factorization (ILU), are obtained using shifts that are close to the optimal shift that follows from our analysis. This indicates that the optimal shift that we derive in this paper also gives strong guidelines for choosing the shift in the case when the preconditioning operations are performed approximately.

This paper is organized as follows. In section 2 we describe the acoustic wave equation and its discretization. We specify some properties of the matrices (symmetry, complex valued, positive definiteness etc.), which form the coefficient matrix of the resulting linear system. In section 3 we show that for the damped Helmholtz equation with Dirichlet and Neumann boundary conditions, the eigenvalues are located on a line or on a circle with a given parameterization for a special type of damping. For radiation boundary conditions and for general viscous media we show that the eigenvalues are located on one side of the line or within the circle. In section 4 we use a simple bound on the GMRES-residual norm. Using this bound and the results of our spectral analysis we are able to derive the optimal value of the shift in the shifted Laplacian preconditioner. We also show for a number of applications that the convergence of GMRES is independent of the grid size. Section 5 contains numerical experiments to illustrate and verify the theoretical results derived in sections 3 and 4. Finally, section 6 contains the conclusions of this paper.

2. The Helmholtz equation.

2.1. The acoustic wave equation. An acoustic medium with space-varying density $\rho(\mathbf{x})$ and sound speed $c(\mathbf{x})$ occupies the volume Ω, bounded by the boundary $\Gamma = \Gamma_1 \cup \Gamma_2 \cup \Gamma_3$. In addition, the medium is assumed to be viscous with damping coefficient $\gamma(\mathbf{x})$. The wave equation for the acoustic pressure $p(\mathbf{x}, t)$ (with $\mathbf{x}$ spatial coordinates and t time) in such a medium is

$$\frac{1}{\rho c^2}\frac{\partial^2 p}{\partial t^2} + \frac{\gamma}{\rho}\frac{\partial p}{\partial t} - \nabla \cdot \frac{1}{\rho}\nabla p = \frac{s(\mathbf{x}, t)}{\rho} \quad \text{in } \Omega, \tag{1}$$

where ∇ denotes the gradient operator and $\nabla\cdot$ the divergence. Realistic conditions on the physical boundaries of an acoustic medium can be reflecting boundaries, which are described by the homogeneous Neumann condition

$$\frac{\partial p}{\partial n} = 0 \quad \text{on } \Gamma_1; \tag{2}$$

pressure release boundaries, which are described by the homogeneous Dirichlet condition

$$p = 0 \quad \text{on } \Gamma_2; \tag{3}$$

and radiating boundaries, which can be described by

$$\frac{\partial p}{\partial n} = -\frac{1}{\rho c}\frac{\partial p}{\partial t} \quad \text{on } \Gamma_3, \tag{4}$$

where n is the outward pointing normal unit vector.

We will assume that the right-hand side function $s(\mathbf{x}, t)$ is a harmonic point source $s(\mathbf{x}, t) = ae^{2\pi i f t}\delta(\mathbf{x} - \mathbf{x}_s)$, located at $\mathbf{x}_s$, which transmits a signal with amplitude a and frequency f. Here, $i = \sqrt{-1}$.

2.2. The Helmholtz equation. If the source term is harmonic, then the pressure field has the factored form

$$p(\mathbf{x}, t) = \hat{p}(\mathbf{x})e^{2\pi i f t}. \tag{5}$$

Substitution of (5) into (1) yields the so-called Helmholtz equation

$$\left(\frac{-(2\pi f)^2}{\rho c^2} + 2\pi i f\frac{\gamma}{\rho}\right)\hat{p} - \nabla \cdot \frac{1}{\rho}\nabla\hat{p} = \frac{a}{\rho}\delta(\mathbf{x} - \mathbf{x}_s) \quad \text{in } \Omega, \tag{6}$$

with boundary conditions

$$\frac{\partial \hat{p}}{\partial n} = 0 \quad \text{on } \Gamma_1, \tag{7}$$

$$\hat{p} = 0 \quad \text{on } \Gamma_2, \tag{8}$$

and

$$\frac{\partial \hat{p}}{\partial n} = -\frac{2\pi i f}{\rho c}\hat{p} \quad \text{on } \Gamma_3. \tag{9}$$

This latter condition is also known as a Sommerfeld condition of the first kind.

If the damping parameter has the special form

$$\gamma(\mathbf{x}, f) = 2\pi f \frac{\nu}{c^2}, \tag{10}$$

with ν a nonnegative constant, the Helmholtz equation (6) simplifies to

$$\left(-\frac{(2\pi f)^2}{\rho c^2}(1 - i\nu) - \nabla \cdot \frac{1}{\rho}\nabla\right)\hat{p} = a\frac{\delta(\mathbf{x} - \mathbf{x}_s)}{\rho(\mathbf{x}_s)} \quad \text{in } \Omega. \tag{11}$$

Clearly, the assumption holds for nonviscous media, i.e., with $\gamma = 0$.

The above equation can be discretized with a discretization method such as the finite element method, finite volume method, or finite difference method. Discretization of the above equation plus boundary conditions with any of these methods yields a discrete Helmholtz equation of the form

$$(L + iC - z_1 M)x = b \tag{12}$$

in which L is the discretization of $-\nabla \cdot \frac{1}{\rho}\nabla$, M corresponds to the discretized zeroth order term $\frac{1}{\rho c^2}$, C corresponds to the Sommerfeld condition and/or to damping that does not satisfy (10), and b to the source term. The complex number z_1 is defined by

$$z_1 = (2\pi f)^2(1 - i\nu). \tag{13}$$

Both L and C are real symmetric and positive semidefinite, and the matrix M is real symmetric and positive definite. The matrix $L + iC - z_1 M$, however, is complex symmetric and indefinite.

For high frequencies, system (12) can be very large, in particular in three dimensions. This is a consequence of the fact that each wavelength has to be sampled with sufficient grid points. Numbers of unknowns in excess of 10^6 for realistic models are quite common. Fortunately, system (12) is sparse. Krylov-type iterative solvers such as GMRES [12] or Bi-CGSTAB [14] are among the most popular techniques for solving large and sparse linear systems. They have proved to be particularly efficient for systems with an Hermitian positive definite matrix, or more generally, for systems with a matrix with all eigenvalues in the right half of the complex plane. Helmholtz-type systems such as (12), however, are highly indefinite, which means that the system matrix has eigenvalues with both negative and positive real parts, a characteristic that can result in a very slow convergence. In order to overcome this problem a suitable preconditioner has to be applied. A class of promising preconditioners that has attracted a lot of attention is the class of shifted Laplace preconditioners [1, 8, 2, 3, 4]. In the next section we will analyze these preconditioners by locating in the complex plane the spectrum of the preconditioned discrete Helmholtz operator.

3. Spectral analysis of the Helmholtz operator preconditioned with the shifted Laplace preconditioner. Shifted Laplace preconditioners are preconditioners of the form

$$P = L + iC - z_2 M,$$

i.e., the same form as the discrete Helmholtz operator $A = L + iC - z_1 M$. The shift parameter z_2 has to be chosen such that the convergence of GMRES (or another suitable iterative method) applied to the preconditioned system

$$(L + iC - z_2 M)^{-1}(L + iC - z_1 M)x = (L + iC - z_2 M)^{-1} b$$

is considerably faster than GMRES applied to the original system. Moreover, z_2 has to be chosen such that operations with the inverse of $(L + iC - z_2M)$ are easy to perform. In practice this means that z_2 is chosen such that operations with the inverse of the preconditioner can be computed using a fast multigrid method [4]. Note that $L + iC$ is the operator that is being shifted. This means that all boundary conditions, including the Sommerfeld condition, are included in the preconditioner, as recommended in [10].

The complex numbers z_1 and z_2 can be written as

$$z_1 = \alpha_1 + i\beta_1, \qquad z_2 = \alpha_2 + i\beta_2, \tag{14}$$

in which $\alpha_1, \beta_1, \alpha_2$, and β_2 are real. Recall that for our application, z_1 is defined by (13), and hence

$$\alpha_1 > 0, \qquad \beta_1 \leq 0.$$

Choices for the shift z_2 that are considered in the literature are $z_2 = 0$ [1], $z_2 = -\alpha_1$ [8], $z_2 = -i\alpha_1$ [2, 3], and $z_2 = (1 - 0.5i)\alpha_1$ [4].

In this section we will study the spectrum of the preconditioned system. The spectrum governs, to a large extent, the convergence of iterative methods as long as the matrix of the eigenvectors is well conditioned.

3.1. The spectrum of the preconditioned Helmholtz operator without the Sommerfeld condition. We will first assume that $C = 0$, and hence that the damped Helmholtz operator is given by $L - z_1M$. We recall that L is symmetric positive semidefinite, M symmetric positive definite, and z_1 is a complex number. We will consider a shifted Laplace preconditioner, i.e., a matrix of the form $L - z_2M$, as a preconditioner for the Helmholtz operator and analyze how the location of the eigenvalues σ of the preconditioned system depends on the parameters z_1 and z_2. The eigenvalues σ of the preconditioned matrix are solutions of the generalized eigenproblem

$$(L - z_1M)x = \sigma(L - z_2M)x. \tag{15}$$

It is easy to see that the matrices $(L - z_1M)$ and $(L - z_2M)$ share the same eigenvectors, which are the eigenvectors of

$$Lx = \lambda Mx. \tag{16}$$

Since for our problem L is symmetric positive semidefinite and M symmetric positive definite, the eigenvalues λ are real and nonnegative. Substitution of λMx for Lx in (15) yields

$$(\lambda - z_1)Mx = \sigma(\lambda - z_2)Mx,$$

and hence

$$\lambda - z_1 = \sigma(\lambda - z_2), \tag{17}$$

which, if $z_2 \neq \lambda$, gives

$$\sigma = \frac{\lambda - z_1}{\lambda - z_2}. \tag{18}$$

Note that if z_2 coincides with an eigenvalue of (16), i.e., if $z_2 = \lambda$, the preconditioner $P = L - z_2 M$ will be singular, which is a situation that has to be avoided. So in the following we assume that $z_2 \neq \lambda$ for all eigenvalues of (16). The eigenvalues λ can be considered as a real parameterization of the curves (18) in the complex plane on which the eigenvalues σ of the preconditioned system are located.

To determine these curves we write $\sigma = \sigma^r + i\sigma^i$ and substitute this into (17), which yields

$$\lambda - \alpha_1 - i\beta_1 = \sigma^r(\lambda - \alpha_2) - i\sigma^r\beta_2 + i\sigma^i(\lambda - \alpha_2) + \sigma^i\beta_2.$$

We can split this equation into an equation for the real terms and one for the imaginary terms:

$$\lambda - \alpha_1 = \sigma^r(\lambda - \alpha_2) + \sigma^i\beta_2,$$

$$-\beta_1 = -\sigma^r\beta_2 + \sigma^i(\lambda - \alpha_2).$$

If $\beta_1 = \sigma^r\beta_2$, the second equation reduces to $\sigma^i = 0$. If this is not the case, we get for λ that

$$\lambda = \alpha_2 + \frac{\sigma^r\beta_2 - \beta_1}{\sigma^i}.$$

Substitution of λ in the equation for the real terms yields the following result:

$$\beta_2(\sigma^r)^2 - (\beta_1 + \beta_2)\sigma^r + \beta_2(\sigma^i)^2 + (\alpha_1 - \alpha_2)\sigma^i = -\beta_1. \tag{19}$$

This equation is valid for all values of $\alpha_1, \beta_1, \alpha_2$, and β_2, including the case $\beta_1 = \sigma^r\beta_2$.

In the following we will distinguish between the cases $\beta_2 = 0$ and $\beta_2 \neq 0$. Theorem 3.1 deals with the case $\beta_2 = 0$.

THEOREM 3.1. [illegible] $\beta_2 = 0$ [illegible] $\sigma = \sigma^r + i\sigma^i$ [illegible] (15) [illegible]

$$-\beta_1\sigma^r + (\alpha_1 - \alpha_2)\sigma^i + \beta_1 = 0. \tag{20}$$

[illegible] The result follows directly from substituting $\beta_2 = 0$ in (19). ∎

The next theorem characterizes the spectrum in the case when $\beta_2 \neq 0$.

THEOREM 3.2. [illegible] $\beta_2 \neq 0$ [illegible] $\sigma = \sigma^r + i\sigma^i$ [illegible] (15) [illegible]

$$\left(\sigma^r - \frac{\beta_2 + \beta_1}{2\beta_2}\right)^2 + \left(\sigma^i - \frac{\alpha_2 - \alpha_1}{2\beta_2}\right)^2 = \frac{(\beta_2 - \beta_1)^2 + (\alpha_2 - \alpha_1)^2}{(2\beta_2)^2}. \tag{21}$$

[illegible] c [illegible]

$$c = \left(\frac{\beta_2 + \beta_1}{2\beta_2}, \frac{\alpha_2 - \alpha_1}{2\beta_2}\right)$$

[illegible]

$$R = \sqrt{\frac{(\beta_2 - \beta_1)^2 + (\alpha_2 - \alpha_1)^2}{(2\beta_2)^2}}.$$

Proof. Divide (19) by $(2\beta_2)$ and complete the square. ∎

To understand the convergence of iterative methods it is important to know if the origin is enclosed by the circle given in Theorem 3.2. The following theorem gives a simple condition that determines this.

THEOREM 3.3. If $\beta_1\beta_2 > 0$ then (21) does not enclose the origin for the circle given in Theorem 3.2

Proof. The origin is not enclosed by the circle if the distance of the center to the origin is larger than the radius. Hence

$$\frac{(\beta_2+\beta_1)^2+(\alpha_2-\alpha_1)^2}{(2\beta_2)^2} > \frac{(\beta_2-\beta_1)^2}{(2\beta_2)^2}+\frac{(\alpha_2-\alpha_1)^2}{(2\beta_2)^2},$$

which is clearly the case. ∎

The center of the circle can also be written as

$$c = \frac{z_1-\overline{z}_2}{z_2-\overline{z}_2}$$

and the radius as

$$R = \left|\frac{z_2-z_1}{z_2-\overline{z}_2}\right|.$$

3.2. The spectrum of the preconditioned Helmholtz operator with the Sommerfeld condition. We will now study the general damped Helmholtz operator $L+iC-z_1M$. As before, L and C are symmetric positive semidefinite matrices, M is a symmetric and positive definite matrix, and z_1 is a complex number. For our problem, the matrix C stems either from the discretization of the Sommerfeld boundary condition or from damping that does not satisfy (10). This means, for example, that a damping matrix that stems from an absorbing layer is also covered by the theory below. We consider a shifted Laplace preconditioner, i.e., a matrix of the form $L+iC-z_2M$, to precondition the Helmholtz operator. The eigenvalues of this matrix are given by

$$(L+iC-z_1M)x = \sigma_S(L+iC-z_2M)x. \tag{22}$$

Let λ_S be an eigenvalue of the generalized problem

$$(L+iC)x = \lambda_S Mx. \tag{23}$$

As in the previous section it is straightforward to show that (22) and (23) share the same eigenvectors x and that the eigenvalues σ_S of the preconditioned system are related to the eigenvalues λ_S by

$$(\lambda_S-z_2)\sigma_S = \lambda_S - z_1. \tag{24}$$

The main difference from the previous section is that λ_S is *complex*, whereas λ in the previous section was real, which allowed us to consider λ as a real valued parameterization of a curve in the complex plane. Although the eigenvalues σ_S will in general not be located on a straight line or on a circle in the complex plane if λ_S is complex, it is still possible to establish useful results regarding the location of σ_S. To this end, we will distinguish between the three cases $\beta_2 = 0$, $\beta_2 > 0$, and $\beta_2 < 0$. Before we proceed we will formulate the following lemma that we will need in the remainder of this section.

LEMMA 3.1. *L C M* $\lambda_S = \lambda_S^r + i\lambda_S^i$ (23)

We use the fact that any matrix can be split into two Hermitian matrices:

$$A = \frac{1}{2}(A + A^H) + i\frac{1}{2i}(A - A^H) = \Re(A) + i\Im(A), \tag{25}$$

where

$$\Re(A) = \frac{1}{2}(A + A^H) \text{ and } \Im(A) = \frac{1}{2i}(A - A^H)\ . \tag{26}$$

According to Bendixon's theorem (see, e.g., [6, page 69]), we have

$$\lambda_{\min}^{\Re(A)} \le \mathrm{Re}(\lambda^A) \le \lambda_{\max}^{\Re(A)},$$

$$\lambda_{\min}^{\Im(A)} \le \mathrm{Im}(\lambda^A) \le \lambda_{\max}^{\Im(A)}.$$

The eigenvalues λ_S of the generalized problem (23) are also solutions of the standard eigenproblem

$$U^{-1}(L + iC)U^{-T}y = \lambda_S y$$

in which $M = UU^T$. This means that we can take $A = U^{-1}(L + iC)U^{-T}$, in which case $\mathrm{Im}(A) = U^{-1}CU^{-T}$. This latter matrix is positive semidefinite, so by Bendixon's theorem we have $\lambda_S^i \ge 0$. □

As in the previous section we first consider the case $\beta_2 = 0$.

THEOREM 3.4. *$\beta_2 = 0$ L C M* $\sigma_S = \sigma_S^r + i\sigma_S^i$ (22)

$$-\beta_1\sigma_S^r + (\alpha_1 - \alpha_2)\sigma_S^i + \beta_1 \ge 0.$$

Since $\beta_2 = 0$ we have

$$(\lambda_S - \alpha_2)\sigma_S = \lambda_S - z_1.$$

Splitting this equation into an equation for the real terms and one for the imaginary terms yields

$$\lambda_S^r\sigma_S^r - \lambda_S^i\sigma_S^i - \alpha_2\sigma_S^r = \lambda_S^r - \alpha_1$$

and

$$\lambda_S^r\sigma_S^i + \lambda_S^i\sigma_S^r - \alpha_2\sigma_S^i = \lambda_S^i - \beta_1.$$

The second equation gives that either $\sigma_S^i = 0$ or

$$\lambda_S^r = \alpha_2 - \frac{\beta_1}{\sigma_S^i} + \lambda_S^i\frac{1 - \sigma_S^r}{\sigma_S^i}.$$

Substitution in the first equation and some straightforward manipulations yield

$$-\beta_1\sigma_S^r + (\alpha_1 - \alpha_2)\sigma_S^i + \beta_1 = \lambda_S^i((\sigma_S^r - 1)^2 + {\sigma_S^i}^2).$$

By Lemma 3.1, $\lambda_S^i \geq 0$, and hence the right-hand side term is greater than or equal to zero. ∎

If $\beta_2 < 0$, the spectrum of the preconditioned matrix is characterized by Theorem 3.5.

THEOREM 3.5. $\beta_2 < 0$ L C M σ_S (22) $c = \frac{z_1 - \overline{z}_2}{z_2 - \overline{z}_2}$ $R = |\frac{z_2 - z_1}{z_2 - \overline{z}_2}|$

PROOF. We have to prove that $|\sigma_S - c| \leq R$ if $\beta_2 < 0$:

$$
\begin{aligned}
|\sigma_S - c| &= \left| \frac{\lambda_S - z_1}{\lambda_S - z_2} - \frac{z_1 - \overline{z}_2}{z_2 - \overline{z}_2} \right|, \\
&= \left| \frac{(\lambda_S - z_1)(z_2 - \overline{z}_2) - (\lambda_S - z_2)(z_1 - \overline{z}_2)}{(\lambda_S - z_2)(z_2 - \overline{z}_2)} \right|, \\
&= \left| \frac{\lambda_S(z_2 - z_1) + (z_1 - z_2)\overline{z}_2}{(\lambda_S - z_2)(z_2 - \overline{z}_2)} \right|, \\
&= \left| \frac{\lambda_S - \overline{z}_2}{\lambda_S - z_2} \frac{z_2 - z_1}{z_2 - \overline{z}_2} \right|, \\
&= \left| \frac{\lambda_S - \overline{z}_2}{\lambda_S - z_2} \right| R. \qquad (27)
\end{aligned}
$$

What is left to prove is that $|\frac{\lambda_S - \overline{z}_2}{\lambda_S - z_2}| \leq 1$. Writing

$$\lambda_S = \lambda_S^r + i\lambda_S^i$$

we get

$$\left| \frac{\lambda_S - \overline{z}_2}{\lambda_S - z_2} \right|^2 = \frac{(\lambda_S^r - \alpha_2)^2 + (\lambda_S^i + \beta_2)^2}{(\lambda_S^r - \alpha_2)^2 + (\lambda_S^i - \beta_2)^2}. \qquad (28)$$

Since $\beta_2 < 0$ and by Lemma 3.1, $\lambda_S^i \geq 0$, we have

$$\frac{(\lambda_S^r - \alpha_2)^2 + (\lambda_S^i + \beta_2)^2}{(\lambda_S^r - \alpha_2)^2 + (\lambda_S^i - \beta_2)^2} \leq 1,$$

and hence the above condition is satisfied. ∎

If $\beta_2 > 0$, the spectrum of the preconditioned matrix is characterized by Theorem 3.6.

THEOREM 3.6. $\beta_2 > 0$ L C M σ_S (22) $c = \frac{z_1 - \overline{z}_2}{z_2 - \overline{z}_2}$ $R = |\frac{z_2 - z_1}{z_2 - \overline{z}_2}|$

PROOF. This is analogous to the proof of Theorem 3.5. ∎

The results presented above specify regions in the complex plane where the eigenvalues of the preconditioned matrix are located. These regions are completely determined by the parameters z_1 and z_2. Given the definition of z_1, (13), these regions depend only on the frequency f, on the damping parameter ν, and of course on the shift for the preconditioner z_2. It is important to note that the regions in the complex plane where the eigenvalues are located do not depend on other physical parameters, such as the sound speed or density, nor on computational parameters, such as the size of the matrix, or on the mesh size h.

4. Combination of the results of the spectral analysis with an upper bound on the GMRES-residual norm. In this section we will combine the results of the spectral analysis presented in the previous section with a well-known upper bound on the GMRES-residual norm. This upper bound assumes that the spectrum is enclosed by a circle, and hence this bound can be naturally combined with the circle specified in Theorems 3.2 and 3.5.

Let the eigenvalues of the preconditioned matrix be enclosed by a circle with radius R and center c as in Theorem 3.5. Then the GMRES-residual norm after k iterations $\|r^k\|$ satisfies (see, e.g., [12])

$$\frac{\|r^k\|}{\|r^0\|} \leq c_2(X) \left(\frac{R}{|c|}\right)^k . \tag{29}$$

In this equation X is the matrix of eigenvectors and $c_2(X)$ its condition number in the 2-norm. If this condition number is large, the upper bound gives no information about the convergence, since in that case there is no relation between the location of the eigenvalues and the convergence behavior of the preconditioned Krylov method [5]. Fortunately, in our application we may expect that the condition number of the eigenvector matrix is relatively small. If $C = 0$, the eigenvectors of the preconditioned matrix are the same as in (16), and hence independent of the shift parameters. Moreover, since the eigenvectors of (16) are M-orthogonal and M is a (scaled) mass matrix. which is in general well conditioned, we expect that $c_2(X)$ will be small in practice. This can be seen from

$$X^T M X = I \;\Leftrightarrow\; c_2(X^T M X) = 1 \;\Leftrightarrow\; c_2(M^{\frac{1}{2}} X) = 1.$$

Since

$$c_2(X) = c_2(M^{-\frac{1}{2}} M^{\frac{1}{2}} X) \leq c_2(M^{-\frac{1}{2}}) c_2(M^{\frac{1}{2}} X),$$

we get

$$c_2(X) \leq \sqrt{c_2(M)}.$$

If $C \neq 0$, the eigenvectors of the preconditioned system are the same as of (23). These are unfortunately not M-orthogonal, but for many problems we can consider (23) as a relatively small perturbation of (16), in which case we can still expect that $c_2(X)$ is small.

4.1. Optimization of the shift. Although (29) gives only an upper bound on the GMRES-residual norm, it allows us to derive a "quasi" optimal choice for the shift. We derive this shift by minimizing the upper bound. For this it is sufficient to minimize the ratio $\frac{R}{|c|}$, or, using Theorem 3.5, the function

$$f(\alpha_2, \beta_2) = \frac{R^2}{|c|^2} = \frac{(\alpha_2 - \alpha_1)^2 + (\beta_2 - \beta_1)^2}{(\alpha_2 - \alpha_1)^2 + (\beta_2 + \beta_1)^2}.$$

To analyze this function we differentiate with respect to α_2,

$$\frac{\partial f}{\partial \alpha_2} = \frac{8(\alpha_2 - \alpha_1)\beta_1\beta_2}{((\alpha_2 - \alpha_1)^2 + (\beta_2 + \beta_1)^2)^2},$$

and with respect to β_2,

$$\frac{\partial f}{\partial \beta_2} = \frac{4\beta_1((\beta_2^2 - \beta_1^2) - (\alpha_2 - \alpha_1)^2)}{((\alpha_2 - \alpha_1)^2 + (\beta_2 + \beta_1)^2)^2}.$$

Clearly, both derivatives are zero at $\alpha_1 = \alpha_2, \beta_1 = \beta_2$. This choice for the shift minimizes of course the upper bound since this corresponds to using the original operator as a preconditioner, which means that performing the preconditioning operation is as hard as solving the original system.

We are interested in the case when the preconditioning operation is relatively cheap. In particular, we have in mind the situation when preconditioning operations can be efficiently carried out using a fixed number of cycles of a multigrid method for the whole range of shifts under consideration. We therefore restrict our analysis to values for the shift for which multigrid is known to work well. We first consider the purely imaginary shift [2, 3, 4]; this means that α_2 equals zero. In this case, the derivative with respect to β_2 is zero if

$$(\beta_2^2 - \beta_1^2) - \alpha_1^2 = 0, \tag{30}$$

yielding

$$\beta_2 = \pm|z_1|.$$

Since by (13) $\beta_1 = -(2\pi f)^2\nu \leq 0$, we must choose by Theorem 3.3 $\beta_2 \leq 0$, and hence $z_2 = -|z_1|i$ as the shift that minimizes the upper bound (29). This choice is also optimal if we consider all possible shifts for which $\alpha_2 \leq 0$, meaning all possible shifts for which the preconditioner has all its eigenvalues in the right half-plane. By (13), $\alpha_1 = (2\pi f)^2 > 0$, and by Theorem 3.3, $\beta_1\beta_2 \geq 0$, so $\frac{\partial f}{\partial \alpha_2}$ is negative for $\alpha_2 \leq 0$. Therefore $f(\alpha_2, \beta_2)$ takes its minimum on the edge $\alpha_2 = 0$. We conclude that the choice

$$z_2 = -|z_1|i \tag{31}$$

minimizes the upper bound (29) for all $z_2 \in \mathbb{C}$, with $\alpha_2 \leq 0$.

The same methodology for deriving an optimal shift can still be used if we do not restrict ourselves to the case $\alpha_2 \leq 0$. Such a shift still (approximately) minimizes the number of GMRES iterations. However, the performance of a multigrid method for the preconditioning operations will deteriorate if z_2 is too close to z_1, and hence such a shift would no longer minimize the total work of the whole solution process. How to find a shift that minimizes the total work, if the performance of multigrid depends on the shift, is of great practical importance, but is outside the scope of this paper.

4.2. Discussion. The upper bound (29) is meaningful only if the circle does not enclose the origin. This is the case if $\beta_1 < 0$, or equivalently if $\nu > 0$. However, because of continuity arguments, result (31) for the "quasi" optimal shift is still valid if $\beta_1 = 0$.

As was remarked in the previous section, the circle around the spectrum of the preconditioned matrix depends only on z_2, on f, and on ν. Consequently, if $\beta_1 < 0$, inequality (29) yields an upper bound on the GMRES-residual norm that also depends only on the frequency f and on the damping parameter ν. Because of this, the number of GMRES iterations should be bounded from above by a constant that is independent of the mesh size.

By scaling the shift z_2 with the frequency we can make the upper bound on the number of GMRES iterations also independent of frequency. To this end we introduce the scaled shift

$$\tilde{z_2} = \tilde{\alpha}_2 + i\tilde{\beta}_2 = \frac{z_2}{(2\pi f)^2}.$$

Applying Theorem 3.5 and substituting $z_2 = (2\pi f)^2 \tilde{z_2}$ and the definition for z_1 (13) into (29) yield

$$\frac{\|r^k\|}{\|r^0\|} \leq c_2(X) \left(\frac{R}{|c|}\right)^k = c_2(X) \sqrt{\frac{(\tilde{\alpha}_2 - 1)^2 + (\tilde{\beta}_2 + \nu)^2}{(\tilde{\alpha}_2 - 1)^2 + (\tilde{\beta}_2 - \nu)^2}}. \tag{32}$$

Clearly, this upper bound depends only on the damping parameter ν and on the choice for the parameter $\tilde{z}_2$.

5. Experiments. In this section we describe a typical test problem with a variable sound velocity. The location of the eigenvalues of the discretized operators are compared with the theoretically predicted locations. The value of the optimal shift is validated by numerical experiments. Finally, it appears that the convergence behavior of GMRES is independent of the mesh size.

5.1. Description of the test problem. The test problem that we consider mimics three layers with a simple heterogeneity and is taken from [11].

For $\nu \in \mathbb{R}$, find $p \in \mathbb{C}^N$ satisfying

$$\begin{cases} -\Delta p - (1-\nu)(\frac{2\pi f}{c(\mathbf{x})})^2 p = s \quad \text{in } \Omega = (0,600) \times (0,1000) \text{ meter}^2, \\ s = \delta(x_1 - 300, x_2), \quad x_1 = (0,600), \quad x_2 = (0,1000) \\ \text{with Sommerfeld conditions or Neumann conditions on } \Gamma \equiv \partial\Omega. \end{cases} \tag{33}$$

The local sound velocity is given as in Figure 1. The density is assumed to be constant.

We have discretized the above problem with the finite element method using linear triangular elements. The computations that are described in this section have been performed with MATLAB.

5.2. Location of the eigenvalues. The first experiments validate the theorems that are presented in section 3. To this end we have taken as source frequency $f = 2$ and we have discretized the problem with mesh size $h = 100/2$. We have calculated all the eigenvalues of the preconditioned matrix for four typical combinations of values of the scaled parameters $\tilde{z}_1$ and $\tilde{z}_2$. (See Figure 2.) The upper left-hand side subplot shows the spectrum of the preconditioner if a real shift is chosen, as suggested in [8]. As was predicted by Theorem 3.1, the eigenvalues for the Neumann problem, which are indicate with the symbol *, are located on a line. Since the example contains damping, the line does not pass through the origin. The eigenvalues of the Sommerfeld problem, which are indicated with the symbol o, are all on one side of the line, as is predicted by Theorem 3.4. Note that the eigenvalues move away from the origin if the Neumann problem is replaced with the Sommerfeld problem.

The upper right-hand side subplot shows the spectrum of the preconditioner if a purely imaginary shift is chosen. The eigenvalues of the Neumann problem are located on the circle that is given by Theorem 3.2, and the eigenvalues of the Sommerfeld problem are, as predicted by Theorem 3.5, either on or inside this circle. This example does not contain damping (apart from the radiation condition): $\tilde{z}_1$ is real. Consequently, the circle contains the origin.

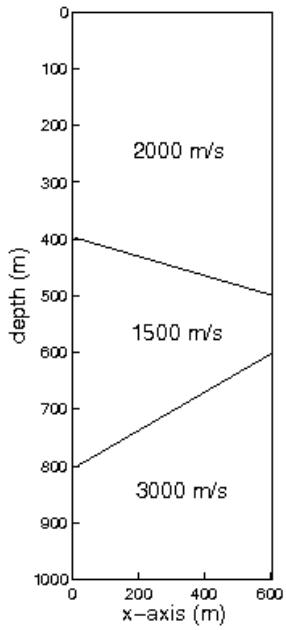

FIG. 1. *Problem geometry with sound velocity profile.*

The lower left-hand side subplot shows another picture of the spectrum of the preconditioner if a purely imaginary (negative) shift is chosen. In this case the problem contains damping since $\tilde{z}_1$ is complex. As a result, the circle is smaller than for the previous example, and the origin is outside the circle.

The lower right-hand side subplot shows for the same z_1 what happens if the sign of the complex shift is wrongly (i.e., positively) chosen. According to Theorem 3.6 the eigenvalues of the Sommerfeld problem should in this case be either on or outside the circle. This is confirmed by the numerical results. Moreover, by Theorem 3.3, the origin should be enclosed by the circle, which is the case.

5.3. Optimization of the shift. The second group of experiments validates the optimal value for the shift z_2 that was found in section 4. This value is given by (31).

The optimal value was determined by minimizing the ratio $\frac{R}{|c|}$. Using the scaled variables $\tilde{z}_2 = z_2/(2\pi f)^2$, this ratio can be written as

$$\frac{R}{|c|} = \sqrt{\frac{(\tilde{\alpha}_2 - 1)^2 + (\tilde{\beta}_2 + \nu)^2}{(\tilde{\alpha}_2 - 1)^2 + (\tilde{\beta}_2 - \nu)^2}}. \tag{34}$$

This function takes values between 0 and 1. A small value of $\frac{R}{|c|}$ indicates fast convergence and a value close to 1 slow convergence. Figure 3 shows, for three different damping parameters ν, how the value of $\frac{R}{|c|}$ depends on $\tilde{\alpha}_2$ and $\tilde{\beta}_2$. The values on the contour lines correspond to the value of $\frac{R}{|c|}$. The three plots show clearly that (34) takes its minimum when $\tilde{\alpha}_2 = 0$, and that the optimal $\tilde{\beta}_2$ becomes more negative when the damping parameter is increased. These observations are of course consistent with the optimal value for the shift parameter (31) that was derived in section 4.

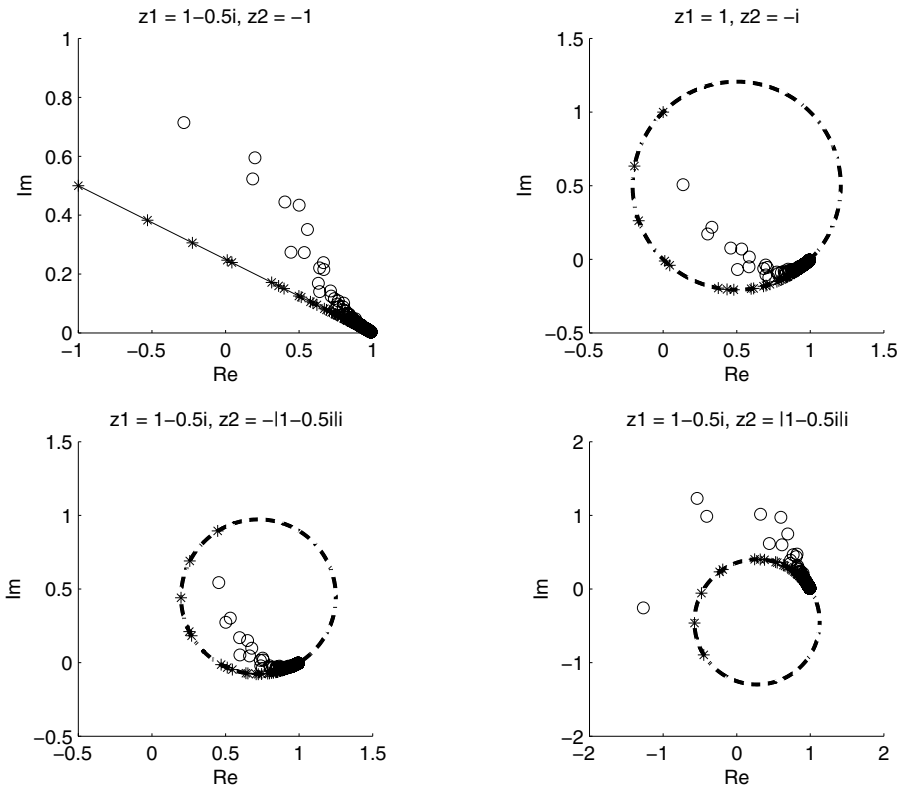

FIG. 2. *Spectra for different values of the complex shift in the preconditioner;* $h = 100/2, f = 2$. *The symbol * denotes eigenvalues for the Neumann problem; o denotes eigenvalues for the Sommerfeld problem.*

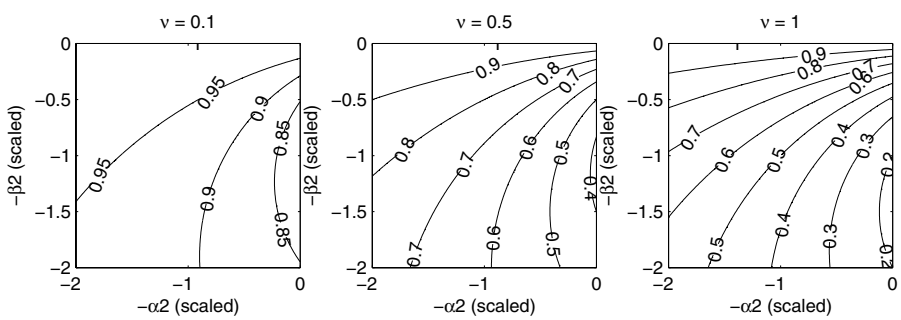

FIG. 3. *Contour plot of the convergence factor as a function of the complex shift.*

To validate that this value is really (sub-) optimal in actual computations we solve the Sommerfeld problem with scaled imaginary shifts ranging from 0 to -2. For the mesh size we take $h = 100/8$ and perform the experiment for four different damping parameters. The result is shown in Figure 4. Clearly, the more damping, the fewer the number of GMRES iterations, and the larger (more negative) the optimal imaginary shift.

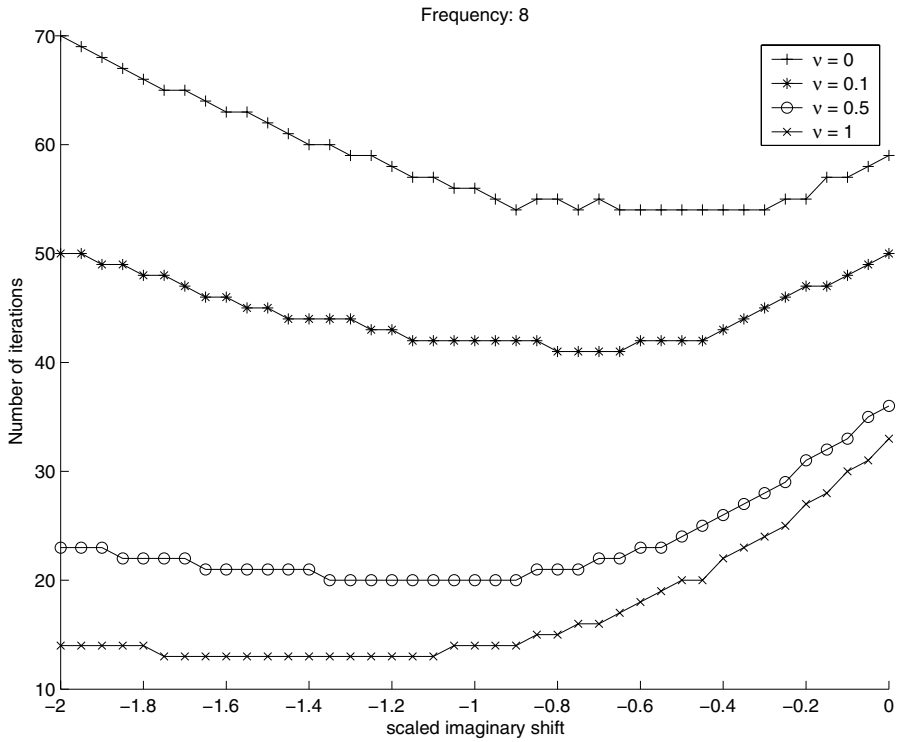

FIG. 4. *Actual number of iteration as a function of the imaginary shift* ($h = 100/8$).

TABLE 1
Number of iterations for "optimal" shift and minimum number of iterations.

Damping	Optimal shift	Iterations "optimal" shift	Min. number of iterations
$\nu = 0$	1	56	54
$\nu = 0.1$	1.005	42	41
$\nu = 0.5$	1.118	20	20
$\nu = 1$	1.4142	13	13

Table 1 shows the minimum number of iterations and compares this with the number of iterations when the "optimal" shift (31) is used. The results show that the shift (31) is nearly optimal with respect to the number of GMRES iterations.

5.4. Mesh dependency. The last set of experiments examines the dependency of the number of iterations of preconditioned GMRES on the mesh size.

Table 2 shows for an increasingly fine step size h the number of iterations for the Sommerfeld problem. The experiment is performed for four different damping parameters, and the frequency is kept fixed to $f = 2$. The results show that for all four different values of the damping parameter the number of iterations is independent of the step size h. Based on the discussion at the end of section 4, this could be expected. The theory that is presented in section 4, however, does not make any predictions about the mesh-dependent performance of preconditioned GMRES for problems with a zero damping parameter.

The results of the same type of experiments, but now with a frequency that scales

TABLE 2
Number of iterations under mesh refinement for a fixed frequency.

	Number of iterations				
h :	100/2	100/4	100/8	100/16	100/32
f :	2	2	2	2	2
$\nu = 0$	14	13	13	13	13
$\nu = 0.1$	13	12	12	12	13
$\nu = 0.5$	11	10	11	11	11
$\nu = 1$	9	9	9	9	9

TABLE 3
Number of iterations under mesh refinement for increasingly high frequencies.

	Number of iterations				
h :	100/2	100/4	100/8	100/16	100/32
f :	2	4	8	16	32
$\nu = 0$	14	25	56	116	215
$\nu = 0.1$	13	22	42	63	80
$\nu = 0.5$	11	16	20	23	23
$\nu = 1$	9	11	13	13	13

with the mesh size, are tabulated in Table 3. These results confirm that if the damping parameter is nonzero, the number of GMRES iterations is bounded by a number that is independent of the mesh size. This is most apparent in the results for $\nu = 0.5$ and $\nu = 1$. The results for $\nu = 0$ seem to indicate that the number of GMRES iterations more or less doubles if the step size is halved. As was remarked above, the theory presented in section 4 does not make any predictions for the case when $\nu = 0$.

To check that $c_2(X)$ is actually small for the above test cases we have also computed the condition numbers of the mass matrices on the five meshes. These condition numbers are equal to 24 for all meshes; hence we have that

$$c_2(X) \leq \sqrt{c_2(M)} = 2\sqrt{3}.$$

6. Conclusions. We have presented a spectral analysis of the Helmholtz operator that is preconditioned with a shifted Laplace operator. We have shown that, depending on the value of the shift, the eigenvalues of the preconditioned matrix are located either in or on a circle, or in a half-plane. Combining these results concerning the spectrum of the preconditioned matrix with a well-known bound on the GMRES-residual norm allowed us to determine a close-to-optimal shift. Furthermore, we have shown for problems with a nonzero damping parameter that there is an upper bound on the number of GMRES iterations that depends only on the damping parameter and hence is independent of the mesh size, the frequency, the sound speed, and the density.

We have derived the close-to-optimal shift for the shifted-Laplace preconditioner in combination with GMRES under the assumption that preconditioning operations are performed exactly. In practice, however, preconditioning operations are performed approximately, for example, using a multigrid method, and another Krylov method, such as Bi-CGSTAB [14], may be used instead of GMRES. In this case the analysis that has been presented in this paper no longer holds. However, experimental results reported in [3], where Bi-CGSTAB is used as a Krylov solver and preconditioning operations are performed approximately with one multigrid cycle, use values for the shift that are close to the predicted value for the optimal shift we present in this

paper. The experimental results are also in these cases quite satisfactory. We therefore conclude that our results provide strong guidelines on how to select the shift parameter for all Krylov methods, as well as for approximate preconditioners.

Acknowledgments. The authors thank Kees Oosterlee for valuable discussions.

AN EFFICIENT SOLVER FOR THE INCOMPRESSIBLE NAVIER–STOKES EQUATIONS IN ROTATION FORM*

MICHELE BENZI† AND JIA LIU‡

Abstract. We consider preconditioned iterative methods applied to discretizations of the linearized Navier–Stokes equations in two- and three-dimensional bounded domains. Both unsteady and steady flows are considered. The equations are linearized by Picard iteration. We make use of the rotation form of the momentum equations, which has several advantages from the linear algebra point of view. We focus on a preconditioning technique based on the Hermitian/skew-Hermitian splitting of the resulting nonsymmetric saddle point matrix. We show that this technique can be implemented efficiently when the rotation form is used. We study the performance of the solvers as a function of mesh size, Reynolds number, time step, and algorithm parameters. Our results indicate that fast convergence independent of problem parameters is achieved in many cases. The preconditioner appears to be especially attractive in the case of low viscosity and for unsteady problems.

1. Introduction.

Iterative Krylov subspace algorithms are popular methods for solving large and sparse linear systems arising in many areas of computational science and engineering [29, 34]. It is well known that in order to be effective, iterative methods must be coupled with preconditioning techniques. In the last several years, much progress has been made in the development of preconditioners tailored to the linear systems arising from linearizations and discretizations of incompressible flow problems; see [5, 36] and especially the recent monograph [12]. As a result of this effort, several effective solvers now exist for important problems like the generalized Stokes problem and the Oseen problem. Nevertheless, the performance of even the best solvers tends to deteriorate for small values of the viscosity. Furthermore, most existing methods for the Oseen problem rely on the availability of efficient solvers for convection-dominated convection-diffusion equations, which are nontrivial to develop for complex flow pattern, especially in three dimensions.

In this paper we study a preconditioning technique that is applicable to various incompressible flow problems. The preconditioner is especially well suited for the so-called [illegible] of the Navier–Stokes equations [14, 21, 27, 37]. We present numerical results on both steady and unsteady problems in two and three space dimensions aimed at assessing the performance of the solver with respect to problem parameters such as mesh size, time step, and viscosity. These experiments indicate that the solver is effective for a wide range of problems. Implementation of the preconditioner is fairly straightforward, and it can take advantage of existing solvers

(and software) for scalar elliptic problems. In addition, the preconditioner does not require the solution of convection-diffusion problems.

The paper is organized as follows. In section 2 we recall the standard and rotation forms of the incompressible Navier–Stokes equations in primitive variables. In section 3 we describe the discrete form of the linearized equations and briefly discuss the structure and spectral properties of the coefficient matrices. Section 4 contains a description of the preconditioning techniques used in this paper and a brief overview of related work. Numerical experiments on a selection of steady and unsteady model problems in two and three space dimensions are presented in section 5. Here we also report on the convergence of the Picard linearization for the rotation form. Some conclusions are given in section 6.

2. Incompressible fluid flow problems. We are concerned with the primitive variables formulation of the Navier–Stokes equations for a viscous, incompressible Newtonian fluid in a bounded domain $\Omega \subset \mathbb{R}^d$ $(d = 2, 3)$ with boundary $\partial\Omega$:

$$\frac{\partial \mathbf{u}}{\partial t} - \nu \quad \mathbf{u} + (\mathbf{u} \cdot \nabla)\,\mathbf{u} + \nabla p = \mathbf{f} \quad \text{in } \Omega \times (0,T]\,, \tag{2.1}$$

$$\operatorname{div} \mathbf{u} = 0 \quad \text{in } \Omega \times [0,T]\,, \tag{2.2}$$

$$\mathcal{B}\mathbf{u} = \mathbf{0} \quad \text{on } \partial\Omega \times [0,T]\,, \tag{2.3}$$

$$\mathbf{u}(\mathbf{x},0) = \mathbf{u}_0 \quad \text{in } \Omega\,, \tag{2.4}$$

where $\mathbf{u} = \mathbf{u}(\mathbf{x},t) \in \mathbb{R}^d$ is the velocity field, $p = p(\mathbf{x},t) \in \mathbb{R}$ is the pressure, $\mathbf{f} \in \mathbb{R}^d$ is a known forcing term, $\nu > 0$ is the kinematic viscosity coefficient ($\nu = O(\mathrm{Re}^{-1})$, where Re denotes the Reynolds number), $\quad$ is the (vector) Laplace operator in d dimensions, ∇ is the gradient, div is the divergence, and $\mathcal{B}$ is some type of boundary operator (e.g., a trace operator for Dirichlet boundary conditions). Equation (2.1) will be referred to as the $\quad$ of the momentum equation. The pressure field, p, is determined up to an additive constant. To uniquely determine p we may impose some additional condition, such as

$$\int_\Omega p\, d\mathbf{x} = 0\,. \tag{2.5}$$

Discretization in time with a fully implicit method (such as backward Euler, although more sophisticated methods are often used in practice) leads to a sequence of semidiscrete systems of the form

$$\sigma\mathbf{u} - \nu \quad \mathbf{u} + (\mathbf{u} \cdot \nabla)\,\mathbf{u} + \nabla p = \mathbf{f} \quad \text{in } \Omega\,, \tag{2.6}$$

$$\operatorname{div} \mathbf{u} = 0 \quad \text{in } \Omega\,, \tag{2.7}$$

$$\mathcal{B}\mathbf{u} = \mathbf{0} \quad \text{on } \partial\Omega\,. \tag{2.8}$$

Here $\sigma \geq 0$ is a constant, with $\sigma > 0$ in the unsteady case and $\sigma = 0$ in the steady case. Due to the presence of the inertial term $(\mathbf{u} \cdot \nabla)\,\mathbf{u}$ in the momentum equation (2.6), the Navier–Stokes equations are nonlinear. They can be linearized in various ways. A widely used scheme is Picard (fixed-point) linearization [12], which leads to a sequence of $\quad$, i.e., linear problems of the form

$$\sigma\mathbf{u} - \nu \quad \mathbf{u} + (\mathbf{v} \cdot \nabla)\,\mathbf{u} + \nabla p = \mathbf{f} \quad \text{in } \Omega\,, \tag{2.9}$$

$$\operatorname{div} \mathbf{u} = 0 \quad \text{in } \Omega\,, \tag{2.10}$$

$$\mathcal{B}\mathbf{u} = \mathbf{0} \quad \text{on } \partial\Omega\,. \tag{2.11}$$

In the momentum equation (2.9), the vector field $\mathbf{v}$ is the approximation of the solution from the previous Picard iteration. For $\mathbf{v} = \mathbf{0}$, equations (2.9)–(2.11) are known as the [illegible] if in addition $\sigma = 0$, they reduce to the usual (steady) Stokes problem.

An alternative linearization can be derived based on the identity

$$(\mathbf{u} \cdot \nabla)\mathbf{u} = (\nabla \times \mathbf{u}) \times \mathbf{u} + \frac{1}{2}\nabla(\mathbf{u} \cdot \mathbf{u}); \tag{2.12}$$

see [14, 21]. The linearization consists in approximating the right-hand side of (2.12) with the linearized expression $(\nabla \times \mathbf{v}) \times \mathbf{u} + \frac{1}{2}\nabla(\mathbf{u} \cdot \mathbf{u})$, where $\mathbf{v}$ represents the approximation of the velocity field from the previous Picard iteration. The linearized equations are

$$\sigma\mathbf{u} - \nu \quad \mathbf{u} + \mathbf{w} \times \mathbf{u} + \nabla P = \mathbf{f} \quad \text{in } \Omega, \tag{2.13}$$

$$\operatorname{div} \mathbf{u} = 0 \quad \text{in } \Omega, \tag{2.14}$$

$$\mathcal{B}\mathbf{u} = \mathbf{0} \quad \text{on } \partial\Omega. \tag{2.15}$$

In (2.13) we have set $P = p + \frac{1}{2}\mathbf{u} \cdot \mathbf{u}$ (the [illegible]). Moreover, in the two-dimensional (2D) case

$$(\mathbf{w}\times) = \begin{pmatrix} 0 & w \\ -w & 0 \end{pmatrix},$$

with $w = \nabla \times \mathbf{v} = -\frac{\partial v_1}{\partial x_2} + \frac{\partial v_2}{\partial x_1}$, where $\mathbf{v}$ is the approximation of the solution from the previous Picard iteration. Similarly, for three-dimensional (3D) problems

$$(\mathbf{w}\times) = \begin{pmatrix} 0 & -w_3 & w_2 \\ w_3 & 0 & -w_1 \\ -w_2 & w_1 & 0 \end{pmatrix},$$

where w_i denotes the ith component of the vector $\nabla \times \mathbf{v}$. Notice that no first-order terms in the velocities appear in (2.13); on the other hand, the velocities in the d scalar equations comprising (2.13) are now coupled due to the presence of the term $\mathbf{w} \times \mathbf{u}$. The disappearance of the convective terms suggests that the [illegible] (2.13) of the momentum equations may be advantageous over the standard form (2.9) from the linear solution point of view; see also [21]. For a discussion of the excellent conservation properties of the linearization based on the rotation form, see [22]; another relevant reference is [27].

3. The discrete equations. In this paper we assume $\Omega = [0,1]^d$, and we use a standard marker-and-cell (MAC) scheme [15] with a uniform grid to discretize either the momentum form of the linearized equations (2.9)–(2.11) or the rotation form (2.13)–(2.15). However, most of what follows holds for more complicated geometries and for a variety of spatial discretization schemes, and in particular for finite elements; see [12].

The discrete system has the form

$$\begin{bmatrix} A & B^T \\ B & O \end{bmatrix} \begin{bmatrix} \mathbf{u} \\ p \end{bmatrix} = \begin{bmatrix} \mathbf{f} \\ 0 \end{bmatrix}, \qquad \text{or} \qquad \mathcal{A}\,u = b, \tag{3.1}$$

where now $\mathbf{u}$, p, and $\mathbf{f}$ are finite-dimensional counterparts of the functions denoted by the same symbols. System (3.1) is often referred to as a generalized saddle point

problem; see [5]. When pressure stabilization is used (e.g., to circumvent the Babuška–Brezzi condition), a nonzero (2,2) block will generally be present in $\mathcal{A}$. Here we assume that a div-stable method (like MAC) is being used, so that no stabilization is needed. However, much of what follows admits a straightforward extension to the case where the (2,2) block of $\mathcal{A}$ consists of a symmetric negative semidefinite matrix.

As is well known, for small values of the viscosity ν velocity stabilization becomes necessary in order to prevent spurious (nonphysical) oscillations in the discrete solution corresponding to all but the finest meshes. For the time being, we sidestep the issue and assume that a sufficiently fine mesh is used. Note that the same assumption is made (for Galerkin FEM discretizations) in [12, p. 327]. We return to this topic in the section on numerical experiments.

The B block in (3.1) represents a discrete divergence operator. In the 2D case, $B = \begin{bmatrix} B_1 & B_2 \end{bmatrix}$, where B_1 is a discretization of $\frac{\partial}{\partial x}$ and B_2 is a discretization of $\frac{\partial}{\partial y}$. The form of the (1,1) block A depends on whether the convection form or the rotation form of the momentum equation is used. For the convection form we have, in the 2D case,

$$A = \begin{bmatrix} \sigma I + \nu L_1 + S_1 & O \\ O & \sigma I + \nu L_2 + S_2 \end{bmatrix},$$

where L_1, L_2 are discrete (negative) Laplacians and S_1, S_2 represent discretizations of the components of the convection term $(\mathbf{v} \cdot \nabla)\,\mathbf{u}$. In this paper we assume that the convective terms are skew-symmetric: $S_1 = -S_1^T$, $S_2 = -S_2^T$. This assumption is satisfied, for example, if the boundary conditions are of Dirichlet type only, or if Neumann boundary conditions are present on the outflow and characteristic boundaries only; see [12] for a detailed discussion of this issue, especially pp. 120–121 and 151. In the 3D case, there will be three diagonal blocks of the same form rather than two.

If the rotation form is used we will have, in the 2D case,

$$A = \begin{bmatrix} \sigma I + \nu L_1 & D \\ -D & \sigma I + \nu L_2 \end{bmatrix},$$

where the matrix D represents multiplication by the discretized function $w = \nabla \times \mathbf{v}$. For MAC discretization, D is a just a diagonal matrix containing on the main diagonal the values of w on the grid edges. In the 3D case,

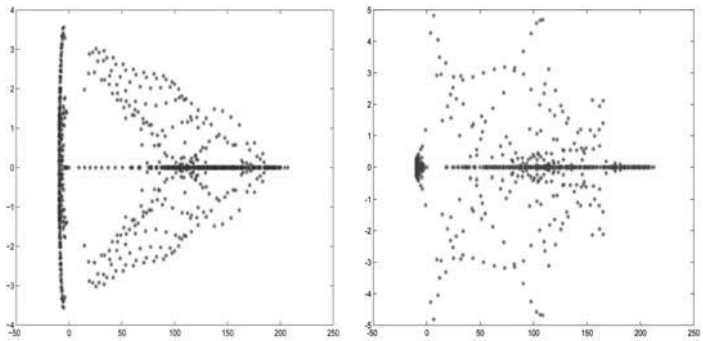
$$A = \begin{bmatrix} \sigma I + \nu L_1 & -D_3 & D_2 \\ D_3 & \sigma I + \nu L_2 & -D_1 \\ -D_2 & D_1 & \sigma I + \nu L_3 \end{bmatrix},$$

where now D_i is the matrix that corresponds to multiplication by w_i, the ith component of $\nabla \times \mathbf{v}$. For finite element discretizations, the I and D matrices will be replaced by appropriate (weighted) mass matrices which may no longer be diagonal.

We observe that for both the convection and the rotation form we can write $A = H + K$, where (2D case)

$$H = \frac{1}{2}(A + A^T) = \begin{bmatrix} \sigma I + \nu L_1 & O \\ O & \sigma I + \nu L_2 \end{bmatrix}$$

is symmetric positive definite for all $\sigma \geq 0$. The matrix $K = \frac{1}{2}(A - A^T)$ is skew-symmetric, and its structure will depend on the form of the momentum equation. In the case of the (generalized) Stokes problem, $K = O$.



(a) Convection form (b) Rotation form

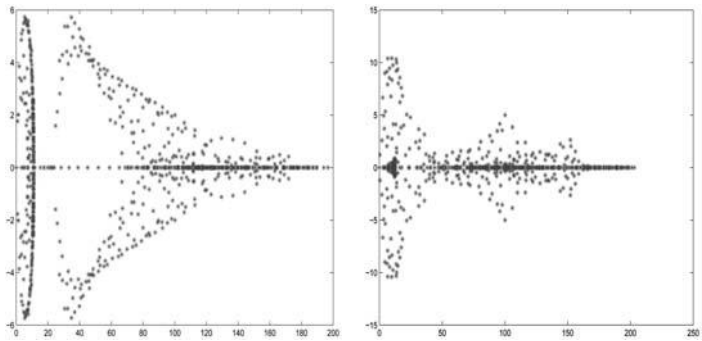
FIG. 3.1. *Eigenvalues for 2D linearized Navier–Stokes problem using MAC discretization (indefinite form).*

With either form of the momentum equation the saddle point matrix $\mathcal{A}$ is highly indefinite, in the sense that it has many eigenvalues on either side of the imaginary axis. Figure 3.1(a) displays the eigenvalues of the discrete steady Oseen operator (convection form, $\nu = 0.01$) obtained from a MAC discretization on $\Omega = [0,1]\times[0,1]$ on a 16×16 grid. As the wind function, we used $\mathbf{v} = (8x(x-1)(1-2y), 8(2x-1)y(y-1))$. Figure 3.1(b) displays the eigenvalues of the discrete operator corresponding to the rotation form on the same grid, with $\nu = 0.01$ and $w = 16x(x-1) + 16y(y-1) = \nabla \times \mathbf{v}$. As can be seen, both matrices have many eigenvalues with negative real part. Additional algebraic properties of saddle point matrices are discussed in [5, sect. 3].

Eigenvalue distributions such as those shown in Figures 3.1(a)–3.1(b) are generally unfavorable for solution by Krylov subspace methods, and, indeed, without preconditioning, Krylov subspace methods converge very slowly (or not at all) when applied to the corresponding linear systems. It has been observed by several authors (see [5, sect. 3.4]) that a simple transformation can be used to obtain an equivalent linear system with a coefficient matrix whose spectrum is entirely contained in the half-plane $\Re(z) > 0$. (Here we use $\Re(z)$ and $\Im(z)$ to denote the real and imaginary parts of $z \in \mathbb{C}$.) Indeed, we can rewrite the saddle point system in the equivalent form

$$\begin{bmatrix} A & B^T \\ -B & O \end{bmatrix} \begin{bmatrix} \mathbf{u} \\ p \end{bmatrix} = \begin{bmatrix} \mathbf{f} \\ 0 \end{bmatrix}, \qquad \text{or} \qquad \hat{\mathcal{A}}\, u = \hat{b}\,. \tag{3.2}$$

Figures 3.2(a)–(b) display the eigenvalues of the matrix $\hat{\mathcal{A}}$ corresponding to the same linearized problems as before (convection and rotation form, respectively). As can be seen, all the eigenvalues lie in the right half-plane. Matrices with this property are said to be [illegible]. A good preconditioner should preserve this property while at the same time clustering the eigenvalues away from the origin. Ideally, most of the eigenvalues should be in the cluster, and the cluster itself should be bounded away from zero independently of the mesh size h and the viscosity ν. A few outliers do not typically constitute a problem. In general, ν-independence is harder to achieve than h-independence; see [12].



(a) Convection form (b) Rotation form

FIG. 3.2. *Eigenvalues for 2D linearized Navier–Stokes problem using MAC discretization (positive definite form).*

4. Preconditioner description. In this section we introduce and motivate our proposed preconditioning strategy for the linearized Navier–Stokes equations in rotation form, including inexact variants. We also (briefly) mention related work by other authors.

4.1. HSS preconditioner and its variants. The Hermitian/skew-Hermitian splitting (HSS) preconditioner is based on the nonsymmetric formulation (3.2). Letting $H \equiv \frac{1}{2}(A + A^T)$ and $K \equiv \frac{1}{2}(A - A^T)$, we have the following splitting of $\hat{\mathcal{A}}$ into its symmetric and skew-symmetric parts:

$$\hat{\mathcal{A}} = \begin{bmatrix} A & B^T \\ -B & O \end{bmatrix} = \begin{bmatrix} H & O \\ O & O \end{bmatrix} + \begin{bmatrix} K & B^T \\ -B & O \end{bmatrix} = \mathcal{H} + \mathcal{K}\,. \tag{4.1}$$

Note that $\mathcal{H}$, the symmetric part of $\hat{\mathcal{A}}$, is symmetric positive semidefinite since H is. Let $\alpha > 0$ be a parameter. Similar in spirit to the classical alternating-direction implicit (ADI) method, we consider the following two splittings of $\hat{\mathcal{A}}$:

$$\hat{\mathcal{A}} = (\mathcal{H} + \alpha\mathcal{I}) - (\alpha\mathcal{I} - \mathcal{K}) \qquad \text{and} \qquad \hat{\mathcal{A}} = (\mathcal{K} + \alpha\mathcal{I}) - (\alpha\mathcal{I} - \mathcal{H})\,.$$

Here $\mathcal{I}$ denotes the identity matrix of order $n + m$. Note that

$$\mathcal{H} + \alpha\mathcal{I} = \begin{bmatrix} H + \alpha I_n & O \\ O & \alpha I_m \end{bmatrix}$$

is symmetric positive definite with eigenvalues bounded below by $\alpha > 0$. Similarly,

$$\mathcal{K} + \alpha\mathcal{I} = \begin{bmatrix} K + \alpha I_n & B^T \\ -B & \alpha I_m \end{bmatrix}$$

is nonsingular and has positive definite symmetric part. Its eigenvalues are of the form $\alpha \pm \mathrm{i}\mu$ with $\mu \in \mathbb{R}$, where $\mathrm{i} = \sqrt{-1}$.

Alternating between these two splittings leads to the stationary HSS iteration:

$$\begin{cases} (\mathcal{H} + \alpha\mathcal{I})\, u_{k+\frac{1}{2}} = (\alpha\mathcal{I} - \mathcal{K})\, u_k + \hat{b}, \\ (\mathcal{K} + \alpha\mathcal{I})\, u_{k+1} = (\alpha\mathcal{I} - \mathcal{H})\, u_{k+\frac{1}{2}} + \hat{b} \end{cases} \tag{4.2}$$

($k = 0, 1, \dots$). Here $\hat{b}$ denotes the right-hand side of (3.2); the initial guess u_0 is chosen arbitrarily. Elimination of $u_{k+\frac{1}{2}}$ from (4.2) leads to a stationary (fixed-point) iteration of the form

$$u_{k+1} = \mathcal{T}_\alpha u_k + c\,, \quad k = 0, 1, \dots,$$

where $\mathcal{T}_\alpha = (\mathcal{K} + \alpha\mathcal{I})^{-1}(\alpha\mathcal{I} - \mathcal{H})(\mathcal{H} + \alpha\mathcal{I})^{-1}(\alpha\mathcal{I} - \mathcal{K})$ is the iteration matrix and c is a certain vector. The iteration converges for arbitrary initial guesses u_0 and right-hand sides $\hat{b}$ to the solution $u_* = \hat{\mathcal{A}}^{-1}\hat{b}$ if and only if $\varrho(\mathcal{T}_\alpha) < 1$, where $\varrho(\mathcal{T}_\alpha)$ denotes the spectral radius of $\mathcal{T}_\alpha$. This stationary iteration was first introduced in [2], where convergence was proved for systems of the form $Ax = b$ with A [illegible] (i.e., the symmetric part of A is positive definite). In the same paper, the authors studied the optimal choice of the parameter α and the effect of inexact solves in (4.2). The extension of this method to saddle point systems (for which the symmetric part is usually singular) was first given in [4]; in this paper it was also observed that the rate of convergence of the stationary HSS iteration is often very slow (even with the optimal choice of the parameter α) and that the method should be used as a preconditioner for a Krylov subspace method rather than as a solver.

It follows from the general theory in [7] that there is a unique splitting $\hat{\mathcal{A}} = \mathcal{P} - \mathcal{Q}$ with $\mathcal{P}$ nonsingular such that the iteration matrix $\mathcal{T}_\alpha$ is the matrix induced by that splitting, i.e., $\mathcal{T}_\alpha = \mathcal{P}^{-1}\mathcal{Q} = \mathcal{I} - \mathcal{P}^{-1}\hat{\mathcal{A}}$. An easy calculation shows that the HSS iteration (4.2) can be written in [illegible] as

$$u_{k+1} = u_k + \mathcal{P}^{-1} r_k, \quad r_k = \hat{b} - \hat{\mathcal{A}} u_k\,,$$

where the preconditioner $\mathcal{P}$ is given by

$$\mathcal{P} \equiv \mathcal{P}_\alpha = \tfrac{1}{2\alpha}(\mathcal{H} + \alpha\mathcal{I})(\mathcal{K} + \alpha\mathcal{I})\,. \tag{4.3}$$

Note that as a preconditioner we can use $\mathcal{P}_\alpha = (\mathcal{H} + \alpha\mathcal{I})(\mathcal{K} + \alpha\mathcal{I})$ instead of the expression given in (4.3), since the factor $\frac{1}{2\alpha}$ has no effect on the preconditioned system. It is just a normalization factor that allows us to conclude that $\varrho(\mathcal{T}_\alpha) < 1$; hence, the eigenvalues of the preconditioned matrix $\mathcal{P}_\alpha^{-1}\hat{\mathcal{A}}$ (or $\hat{\mathcal{A}}\,\mathcal{P}_\alpha^{-1}$, which has the same spectrum) are all contained in the disk $\{z \in \mathbb{C} : |z - 1| < 1\}$. In particular, the spectrum of the preconditioned matrix, like that of $\hat{\mathcal{A}}$, lies entirely in the right half-plane: the preconditioned matrix is positive stable.

Spectral properties of the preconditioned matrix as a function of α have been studied, under different sets of assumptions, in [3, 33]. A Fourier analysis of HSS preconditioning for saddle point formulations of Poisson's equation (including the anisotropic case) was given in [3]. The analysis showed that using a sufficiently small value of α results in h-independent convergence. Furthermore, as $\alpha \to 0+$ the eigenvalues of the preconditioned matrix are all real and fall within two small intervals $(0, \varepsilon_1)$ and $(2 - \varepsilon_2, 2)$, with $\varepsilon_1, \varepsilon_2 > 0$ and $\varepsilon_1, \varepsilon_2 \to 0$ as $\alpha \to 0+$. This clustering result was generalized in [33] to general saddle point systems with $A = A^T$ positive definite using purely algebraic arguments; see also [6]. Numerical experiments show that with an appropriate scaling of the system (such that the nonzero diagonal entries of $\hat{\mathcal{A}}$ are equal to 1), there is a unique value α_* of α for which the number of preconditioned iterations is minimized, and this α_* is usually a small number, between 0 and 1. However, h-independent convergence is not always guaranteed; for example, it does not occur for the [illegible] Stokes problem, as we shall see.

No rigorous analysis exists for the nonsymmetric ($A \neq A^T$) case. Here the only available result is that $\varrho(\mathcal{T}_\alpha) < 1$ for all $\alpha > 0$. Nevertheless, the following informal argument suggests that good performance of the HSS preconditioner applied to linearized Navier–Stokes problems should be expected for sufficiently small ν and α. Let us assume that $A = \nu L + K$, where $\frac{1}{2}(A + A^T) = H = \nu L$ is positive definite and K is skew-symmetric; note that this is certainly the case for the linearizations of the steady Navier–Stokes equations discussed in section 2, where L is a discrete vector Laplacian in $\mathbb{R}^d$, and K contains the skew-symmetric contribution from the convective or rotation terms. We have

$$\mathcal{P}_\alpha = \begin{bmatrix} \nu L + \alpha I & O \\ O & \alpha I \end{bmatrix} \begin{bmatrix} K + \alpha I & B^T \\ -B & \alpha I \end{bmatrix} = \begin{bmatrix} \alpha A + \nu L K + \alpha^2 I & \alpha B^T + \nu L B^T \\ -\alpha B & \alpha^2 I \end{bmatrix}.$$

Therefore, as $\nu \to 0$ the (scaled) preconditioner $\alpha^{-1}\mathcal{P}_\alpha$ approaches the matrix $\hat{\mathcal{A}} + \alpha\mathcal{I}$. For small α this is close to $\hat{\mathcal{A}}$, and we conclude that the HSS preconditioner may be interpreted as an [illegible] of the coefficient matrix $\hat{\mathcal{A}}$, in which the approximation error $\|\alpha^{-1}\mathcal{P}_\alpha - \hat{\mathcal{A}}\|$ decreases as $\nu, \alpha \to 0+$. (This holds true for both the convection and the rotation form of the linearized Navier–Stokes equations.) In practice, however, the shift α should not be taken too small, as the preconditioner becomes singular for $\alpha = 0$. The choice of α is an important issue which we defer until section 5.

In the unsteady case ($\sigma > 0$ in (2.9)), direct computation of $\alpha^{-1}\mathcal{P}_\alpha - \hat{\mathcal{A}}$ shows that the HSS preconditioner does not yield, as ν and α become smaller, a good approximation, except when σ is very small. However, it is possible to remedy the situation by making a small modification to the preconditioner. Observing that $H = \sigma I_n + \nu L$, we consider the following splitting of $\hat{\mathcal{A}}$:

$$\hat{\mathcal{A}} = \begin{bmatrix} \nu L & O \\ O & O \end{bmatrix} + \begin{bmatrix} K + \sigma I & B^T \\ -B & O \end{bmatrix} = \mathcal{H}' + \mathcal{K}'. \tag{4.4}$$

Note that $\mathcal{H}'$ is still symmetric, but $\mathcal{K}'$ is no longer skew-symmetric unless $\sigma = 0$. Now let $\alpha > 0$ be a shift and consider the preconditioner $\mathcal{P}_\alpha = (\mathcal{H}' + \alpha\mathcal{I})(\mathcal{K}' + \alpha\mathcal{I})$. Expanding the product shows that as $\nu, \alpha \to 0+$, the scaled preconditioner $\alpha^{-1}\mathcal{P}_\alpha$ approaches $\hat{\mathcal{A}}$. It can be shown (see [19]) that for this splitting as well, the spectral radius of the corresponding iteration matrix satisfies $\varrho(\mathcal{T}_\alpha) < 1$ for all $\alpha > 0$ and for all $\sigma \geq 0$; this result generalizes Theorem 3.1 in [4]. Furthermore, for $\sigma > 0$ sufficiently large the preconditioner yields a good approximation even for the generalized (i.e., unsteady) Stokes and Oseen-type problems. These observations are corroborated by the numerical results in section 5.

Since for $\sigma = 0$ the preconditioner based on the splitting (4.4) reduces to the standard HSS preconditioner, from now on we will use the name "HSS preconditioner" for the method based on the splitting (4.4), and we will write $\mathcal{H}$, $\mathcal{K}$ instead of $\mathcal{H}'$, $\mathcal{K}'$.

4.1.1. Application of the preconditioner. Application of the HSS preconditioner within a Krylov subspace method (e.g., GMRES [30]) requires solving a linear system of the form $\mathcal{P}_\alpha z_k = r_k$ at each iteration. This is done by first solving the system

$$(\mathcal{H} + \alpha\mathcal{I})\, w_k = r_k \tag{4.5}$$

for w_k, followed by

$$(\mathcal{K} + \alpha\mathcal{I})\, z_k = w_k\,. \tag{4.6}$$

The first system requires solving systems with coefficient matrix $H+\alpha I$. This consists of d $(= 2, 3)$ decoupled subsystems (one for each spatial direction) with symmetric positive definite coefficient matrix, regardless of whether the rotation or the convection form of the equations is used. A number of standard methods can be deployed, including sparse Cholesky factorization, preconditioned conjugate gradient schemes, or multigrid methods, either geometric or algebraic. Iterative methods can be expected to work quite well, since each system consists of a shifted Poisson-type equation. Note that owing to the diagonal scaling used, the addition of a positive shift to the main diagonal of H leads to a condition number

$$\kappa(H+\alpha I) = \frac{\lambda_{\max}(H)+\alpha}{\lambda_{\min}(H)+\alpha} < 1 + \frac{\lambda_{\max}(H)}{\alpha} = O(\alpha^{-1}),$$

since $\lambda_{\max}(H)$ is bounded independently of h. A typical value of α is usually around 0.1 or larger, resulting in well-conditioned systems and consequently fast rates of convergence of iterative methods applied to (4.5).

Solving (4.6) is somewhat more involved. It requires the solution of a linear system of the form

$$\begin{bmatrix} K+\gamma I & B^T \\ -B & \alpha I \end{bmatrix} \begin{bmatrix} x_k \\ y_k \end{bmatrix} = \begin{bmatrix} f_k \\ g_k \end{bmatrix}, \tag{4.7}$$

where we have set $\gamma = \sigma+\alpha$. This system can be solved in several ways. One approach is to eliminate x_k from the second equation using the first one (Schur complement reduction), leading to a smaller (order m) linear system of the form

$$[B(K+\gamma I)^{-1}B^T + \alpha I]y_k = B(K+\gamma I)^{-1}f_k + \alpha g_k. \tag{4.8}$$

Once the solution y_k to (4.8) has been computed, the vector x_k is given by

$$(K+\gamma I)x_k = f_k - B^T y_k\,.$$

When $K = O$, system (4.8) simplifies to

$$(BB^T + \alpha\gamma I)\, y_k = Bf_k + \alpha\gamma g_k, \tag{4.9}$$

and $x_k = \gamma^{-1}(f_k - B^T y_k)$. Note that BB^T is essentially a discrete Laplacian, and that $\gamma > 0$; therefore, system (4.9) can be solved efficiently. When $K \neq O$ the matrix in (4.8) is dense for the convective form of the Navier–Stokes equations but sparse for the rotation form. As this is a crucial point, we discuss it in some detail. Recall that in the 2D case the system matrix for the linearization of the rotation form is

$$\begin{bmatrix} A_1 & D & B_1^T \\ -D & A_2 & B_2^T \\ -B_1 & -B_2 & O \end{bmatrix} = \begin{bmatrix} \nu L_1 & O & O \\ O & \nu L_2 & O \\ O & O & O \end{bmatrix} + \begin{bmatrix} \sigma I & D & B_1^T \\ -D & \sigma I & B_2^T \\ -B_1 & -B_2 & O \end{bmatrix} = \mathcal{H} + \mathcal{K}\,.$$

Here the L_i are discrete Laplace operators with appropriate boundary conditions, and $B = \begin{bmatrix} B_1 & B_2 \end{bmatrix}$; $D = D^T$ is a matrix that corresponds to multiplication by $w = \nabla \times \mathbf{v}$. For finite difference schemes (like MAC) D is a diagonal matrix; for finite elements, it will be a scaled mass matrix. When D is diagonal, the Schur complement $B(K+\gamma I)^{-1}B^T + \alpha I$ is a sparse matrix and can be formed explicitly. This follows from the fact that

$$(I+\gamma^{-1}K)^{-1} = \begin{bmatrix} I & \gamma^{-1}D \\ -\gamma^{-1}D & I \end{bmatrix}^{-1} = \begin{bmatrix} E_1 & -E_2 \\ E_2 & E_3 \end{bmatrix},$$

where E_1, E_2, and E_3 are diagonal matrices given by $E_1 = I - \gamma^{-2} D(I + \gamma^{-2} D^2)^{-1} D$, $E_2 = \gamma^{-1} D(I + \gamma^{-2} D^2)^{-1}$, and $E_3 = (I + \gamma^{-2} D^2)^{-1}$. This can be verified directly, or also by noting that $I + \gamma^{-1} K = PGP^T$, where G is a block diagonal matrix with two-by-two blocks and P is the odd-even permutation matrix. Thus, $(I + \gamma^{-1} K)^{-1} = PG^{-1}P^T$ has exactly the same sparsity structure as $I + \gamma^{-1} K$.

When D is not diagonal, we can replace it with a (spectrally equivalent) diagonal approximation and still have a sparse Schur complement; since we are constructing a preconditioner, the action of $(\mathcal{K} + \alpha \mathcal{I})^{-1}$ need not be computed exactly. Hence, the Schur complement $B(K + \gamma I)^{-1} B^T + \alpha I$ (or the approximation of it obtained by replacing D with a diagonal matrix) is sparse, and system (4.6) can be efficiently solved via (4.8) by explicitly forming the sparse Schur complement system and solving it by appropriate sparse matrix techniques. Standard options include sparse LU factorization or nonsymmetric Krylov subspace methods with an appropriate choice of the preconditioner. It is also possible to use multigrid methods, since the Schur complement can be interpreted as a discretization of a second-order elliptic operator with variable coefficients. Indeed, the matrix $B(I + \gamma^{-1} K)^{-1} B^T$ can be regarded as a discretization of the differential operator

$$\mathcal{L} = -\mathrm{div}\,(k^{-1}\,\nabla)\,, \quad \text{where} \quad k = \begin{pmatrix} 1 & \gamma^{-1} w \\ -\gamma^{-1} w & 1 \end{pmatrix}, \quad w = w(\mathbf{x}). \tag{4.10}$$

This operator is not self-adjoint (except in the case $w =$ constant), but has positive definite symmetric part; in other words, it is strongly elliptic. Efficient multigrid methods exist for this type of problem; see [22] for an approach especially well suited for this problem. Clearly, the larger γ is, the easier it is to solve the Schur complement system.

While we have focused our description on the 2D case, the 3D case can be treated along similar lines. The system matrix is now

$$\hat{\mathcal{A}} = \begin{bmatrix} \nu L_1 & O & O & O \\ O & \nu L_2 & O & O \\ O & O & \nu L_3 & O \\ O & O & O & O \end{bmatrix} + \begin{bmatrix} \sigma I & -D_3 & D_2 & B_1^T \\ D_3 & \sigma I & -D_1 & B_2^T \\ -D_2 & D_1 & \sigma I & B_3^T \\ -B_1 & -B_2 & -B_3 & O \end{bmatrix} = \mathcal{H} + \mathcal{K}\,.$$

The Schur complement is now given by

$$\alpha I + B(I + \gamma^{-1} K)^{-1} B^T = \alpha I + B \begin{bmatrix} F_1 & -E_3 & E_2 \\ E_3 & F_2 & -E_1 \\ -E_2 & E_1 & F_3 \end{bmatrix} B^T,$$

where F_1, F_2, F_3, E_1, E_2, and E_3 are easily computed diagonal matrices. We refer to [19] for additional details. Again, the Schur complement system is sparse and can be solved using standard sparse matrix solvers or a multigrid method.

4.1.2. Inexact variants. In practice, the solves (4.5) and (4.6)–(4.8) need not be performed to high accuracy. Rather than "exact" solves, inexact solves can be performed by inner iterative schemes applied to (4.5) and (4.8). Our experience is that the rate of convergence of the outer Krylov subspace iteration is scarcely affected by the use of inexact inner solves, and that a fairly low accuracy in the inner solves is sufficient to retain good rates of convergence of the outer iteration. This is especially important for very large problems, where exact inner solves would not be feasible.

A distinction has to be made depending on the type of solvers used in the inner iterations. If the inexact inner solves consist of a fixed number of steps of a stationary iterative method (such as multigrid), then the (inexact) HSS preconditioner remains constant from outer iteration to outer iteration and a standard Krylov subspace method, such as GMRES, can be used for the outer iteration. On the other hand, if the inner iterations are terminated when a reduction of the inner residual norms by a prescribed amount has been reached, or if the inner iterations consist of a few steps of a nonstationary method (such as conjugate gradients), then the inexact HSS preconditioner changes from one outer iteration to the next, and a flexible method (such as FGMRES [28]) must be used for the outer iteration.

We reiterate that the linear systems arising from (4.5) are well conditioned and are easy to solve approximately. In particular, approximate solutions of (4.5) can be obtained in $O(n)$ operations using multigrid or preconditioned conjugate gradients. For the Schur complement system (4.9) arising in the case of Stokes and generalized Stokes problems, similar techniques can be used to obtain an approximate solution in $O(m)$ work. For the nonsymmetric (Oseen-type) case, the Schur complement system is the nonsymmetric problem (4.8). In this case one could use GMRES with ILU preconditioning, but multigrid is a viable option here as well; see [22].

The above discussion assumes that the rotation form of the equations is used. For the standard (convective) form of the Navier–Stokes equations, the solution of (4.6), whether exact or inexact, appears to be problematic.

4.2. Related work. Olshanskii has proposed an effective block triangular preconditioner for the rotation form of the (linearized) Navier–Stokes equations; see [21, 22, 23] as well as [24] and [20]. His method is quite robust with respect to both h and ν. The preconditioner has the form

$$\mathcal{P} = \begin{bmatrix} \hat{A} & B^T \\ O & \hat{S} \end{bmatrix}, \tag{4.11}$$

where $\hat{A}$ and $\hat{S}$ are not explicitly computed matrices but implicit approximations to the (1,1) block of the saddle point system and of the Schur complement, respectively. Application of the preconditioner within an outer Krylov subspace iteration requires evaluating the action of $\hat{A}^{-1}$ and of $\hat{S}^{-1}$ on given vectors. For the action of $\hat{A}^{-1}$, a suitable multigrid method has been developed and analyzed in [24]. Note that the (1,1) block A can be interpreted as a coupled system of reaction-diffusion equations for the two (three in three dimensions) components of the velocity field. Clearly, this is a more complicated problem than inverting the uncoupled shifted velocity Laplacians in the HSS approach; see (4.5).

The approximate Schur complement step requires inexact solves for the elliptic problem (4.10) already mentioned in the previous subsection. We refer the reader to [21, 23] for details. The cost of this operation is comparable to the cost of solving the Schur complement system (4.8) in the HSS preconditioner; in the latter method, however, the system to be solved is somewhat easier due to the presence of the shift parameter α, which results in linear systems with eigenvalues that are better separated from the imaginary axis. In particular, for small σ the elliptic problem (4.10) tends to become singular and must be regularized by a suitable diagonal shift in the tensor k appearing in (4.10). In our experience, the performance of the preconditioner can be affected rather strongly by the choice of the shift parameter.

In summary, Olshanskii's preconditioner requires specialized solvers for the subproblems corresponding to both the (1,1) block and the approximate Schur comple-

ment, and applying this preconditioner within one step of an outer Krylov method is somewhat more expensive than with the HSS preconditioner.

It must be noted that several other preconditioners for the discrete Navier–Stokes equations can be cast as approximate (block) factorizations of the system matrix. Furthermore, many algebraic splitting methods for the unsteady Navier–Stokes equations can be interpreted in terms of approximate block factorizations; this is the case, for instance, for the classical fractional step method and for the popular SIMPLE scheme and its variants; see, e.g., the recent references [9, 18, 26, 31, 35, 36]. These splittings naturally lead to preconditioners for Krylov methods, for both steady and unsteady problems [12, Chapter 8.3.5]. While these preconditioners have been designed for the convection form, some of them may be formally extended to the rotation form of the linearized Navier–Stokes equations; this is the case, for instance, for Elman's so-called BFB^T preconditioner [10]. Regardless of which form of the equations is used, however, these preconditioning schemes do not yield better approximations as the viscosity ν approaches zero; on the contrary, the quality of the approximation tends to deteriorate as $\nu \to 0$, especially for stationary problems. This is an important difference between these earlier approaches and the HSS and Olshanskii-type preconditioners.

Furthermore, most of the block preconditioners for the standard form of the Navier–Stokes equations depend on the availability of effective solvers (exact or approximate) for convection-dominated convection-diffusion equations, which are not easily developed. In contrast, no such solvers are needed when the rotation form of the equations is used.

5. Numerical experiments. In this section we report on several numerical experiments meant to illustrate the behavior of the HSS preconditioner on a wide range of model problems. We consider both Stokes and Oseen-type problems, steady and unsteady, in two and three dimensions. The use of inexact solves is also discussed. Our results include iteration counts, as well as some timings and eigenvalue plots. We further include a few experiments illustrating the convergence of Picard's iteration for the rotation form. All results were computed in MATLAB 7.1.0 on one processor of an AMD Opteron with 32 GB of memory. Many additional experimental results can be found in [19]; the results presented here are but a representative sampling of those in [19].

In all experiments, a symmetric diagonal scaling was applied before forming the preconditioner, so as to have all the nonzero diagonal entries of the saddle point matrix equal to 1. We found that this scaling is beneficial to convergence and makes finding (nearly) optimal values of the shift α easier. Of course, the right-hand side and the solution vector were scaled accordingly. We found, however, that without further preconditioning Krylov subspace solvers converge extremely slowly on all the problems considered here. Right preconditioning was used in all cases.

5.1. Oseen-type equations in rotation form. Here we consider linear systems arising from the discretization of the linearized Navier–Stokes equations in rotation form. For lack of a better name we will refer to the linear problem (2.13)–(2.15) as the [illegible]. The computational domain is the unit square $\Omega = [0,1] \times [0,1]$ (or the unit cube $\Omega = [0,1] \times [0,1] \times [0,1]$ for 3D problems). Homogeneous Dirichlet boundary conditions are imposed on the velocities; experiments with different boundary conditions were also performed, with results similar to those reported below. We experimented with different forms of the divergence-free field $\mathbf{v}$ appearing (via $\mathbf{w} = \nabla \times \mathbf{v}$) in (2.13). Here we present results for the choice

TABLE 5.1

$w = 16x(x-1) + 16y(y-1)$ (2D case) and $\mathbf{w} = (-4z(1-2x),\ 4z(2y-1),\ 2y(1-y))$ (3D case). The 2D case corresponds to the choice of $\mathbf{v}$ used in [11]. The equations were discretized with a MAC scheme with a uniform mesh size h. The outer iteration (full GMRES) was stopped when

$$\frac{||r_k||_2}{||r_0||_2} < 10^{-6},$$

where r_k denotes the residual vector at step k. For the results presented in this section, the symmetric positive definite systems (4.5) were solved "exactly" by means of the sparse Cholesky factorization available in MATLAB, in combination with an approximate minimum degree ordering [1] to reduce fill-in. For the sparse, nonsymmetric Schur complement system (4.8) we used the sparse LU solver available in MATLAB with the original (lexicographic) ordering. We found this to be faster than a minimum degree ordering, probably because the need for pivoting makes the fill-reducing ordering ineffective or even harmful. We defer a discussion of the effect of inexact solves to section 5.3.

When working with the usual (convection) form of the Oseen problem, it is well known that care must be taken to avoid potential instabilities in the discrete velocities, either by taking h sufficiently small (compared to ν and $\|\mathbf{v}\|_\infty$), or by adding suitable stabilization terms to the discrete equations. Velocity stabilization is an issue for the rotation form of the equations as well; see [20, 22] for a discussion within the finite element context. For the experiments in this section we ignore the issue of velocity stabilization and assume that a sufficiently fine mesh is used; the same point of view is taken in [12, Chapter 7.3]. Whenever we present results on a sequence of grids, we do so only as a means of investigating the scalability of the linear solver as $h \to 0$, assuming that the finest mesh is sufficiently fine for the computed solution to be meaningful. This has indeed been verified by using test problems with a known solution.

First we consider a 2D steady ($\sigma = 0$) Oseen-type problem. In Table 5.1 we report iteration counts for a sequence of increasingly refined grids and for different values of the viscosity ν. The number of velocity and pressure unknowns (n and m, respectively) is also included. A value of the parameter α close to the optimal one was used in all cases. We found that for steady problems, the best value of α is of the form $\alpha = ch$, where c is independent of h but depends (weakly) on ν. A good rule of thumb is $c = -4 \log_{10} \nu$; that is, $c = 4$ for $\nu = 0.1$, and $c = 16$ for $\nu = 0.0001$. Thus, it is possible to determine a good choice of the shift parameter in this way: first one finds the optimal α by solving a few small problems on a coarse grid with mesh size h; then the optimal value of α for a fine grid with mesh size h/ℓ can be estimated by dividing the value of α by ℓ. We note that for every problem we have solved, there is a unique optimal value of α.

It is clear from the results in Table 5.1 that for this set of (steady) problems, the rate of convergence with HSS preconditioning suffers from some degradation as $h \to 0$; on the other hand, the convergence in all cases is pretty fast and tends to improve (albeit not monotonically) as ν becomes smaller. The robustness of HSS preconditioning with respect to ν has been observed in all the tests we performed, and in our opinion this is enough to justify interest in this preconditioning technique.

In Table 5.2 we present results for a quasi-steady problem with $\sigma = 40$ and $\nu = 0.001$. We can see from this table that HSS preconditioning results in fast convergence in all cases, and that the rate of convergence is virtually h-independent, especially for $\nu \leq 0.01$. Here as in all other unsteady (or quasi-steady) problems that we have tested, the rate of convergence is not overly sensitive to the choice of α, especially for small ν. A good choice is $\alpha \approx 0.5$ for the two coarser grids, and $\alpha \approx 0.25$ for the finer grids. Again, the optimal value of α is a few times larger for $\nu = 0.0001$ than for $\nu = 0.1$. The behavior of the iteration count as a function of α is displayed in Table 5.3 for the case $\nu = 0.001$ on the 256×256 grid.

Table 5.4 shows iteration counts for a set of 3D generalized Oseen problems on a $40 \times 40 \times 40$ grid, for several values of the parameter σ. No attempt was made to find the optimal value of α for each problem; instead, the same value $\alpha = 0.1$ was used in all cases. The discrete problem has $n = 187,200$ and $m = 64,000$, for a total of $N = 251,200$ unknowns. It can be seen that the iteration counts are remarkably stable. When the optimal value of α is used, the rate of convergence improves for increasing σ and decreasing ν.

Virtually optimal (i.e., grid-independent) rates of convergence are obtained when σ is not held constant but is taken to be inversely proportional to h, as in the case of genuinely unsteady flow problems; see [25]. To show this, we use a set of 3D, unsteady Oseen problems with $\nu = 0.001$ and $\sigma = h^{-1}$. The results for HSS preconditioning (with the fixed value $\alpha = 0.5$) are reported in Table 5.5. The total number

FIG. 5.1. *Eigenvalues of discrete generalized Oseen problem preconditioned with HSS.*

of unknowns ranges from 15,616 for the coarsest grid to 2,028,800 for the finest one.

These experiments show the good behavior of HSS preconditioning on Oseen-type problems, in particular for unsteady or quasi-steady problems. The performance is especially good for small values of the viscosity ν. This is in contrast to most other solvers, which tend to deteriorate for small values of ν.

Figures 5.1(a)–(d) display the eigenvalues of the HSS-preconditioned discrete Oseen operator on a 16×16 grid for different values of σ and ν. As predicted by the theory in [4, 19], the eigenvalues lie in the interior of the disk of center $(1, 0)$ and radius 1, except for the zero eigenvalue corresponding to the one-dimensional null space of the discrete gradient B^T. Since this lone zero eigenvalue has no effect on the convergence of preconditioned GMRES, we did not remove it by imposing (2.5) or other auxiliary conditions; see the discussion in [12, Chapter 2.3]. Note that the clustering of the spectrum away from the zero eigenvalue becomes more pronounced as ν gets smaller.

5.2. Stokes flow. Here we consider the generalized Stokes problem on the unit square (or unit cube in three dimensions). The boundary conditions, discretization scheme, and GMRES stopping criterion are the same as in the previous section. HSS preconditioning was carried out with "exact" solves using MATLAB's sparse Cholesky decomposition with an approximate minimum degree reordering; inexact solves are considered in section 5.3.

For the first two sets of experiments, we fix σ and ν and investigate the behavior of the preconditioned iteration for different values of h for a 2D problem. Iteration counts and CPU times (in seconds) are reported in Table 5.6 for $\sigma = 0$ and $\nu = 1$ and in Table 5.7 for $\sigma = 40$ and $\nu = 0.001$. For the steady ($\sigma = 0$) problem the best value of α depends on h; our rule of thumb is to take $\alpha \approx 5h$. The constant value $\alpha = 0.25$ was used for the unsteady problem. As for the Oseen-type case, our experience is that for unsteady problems the best value of α does not depend on h; hence, it can be determined for a coarse grid and used on finer grids with good results. Overall, the rate of convergence is not overly sensitive to the choice of α.

These results show that the rate of convergence with HSS preconditioning suffers some deterioration as $h \to 0$. On the other hand, while not h-independent, the rate convergence is quite good, especially for $\sigma > 0$. (A Fourier analysis of HSS preconditioning for the Stokes case will be presented elsewhere.)

Next we consider a steady 3D Stokes problem. Here we found that a good rule of thumb for the choice of the HSS parameter is $\alpha \approx 2h$. The results are shown in Table 5.8. Again, the convergence rate is reasonable, but not independent of the mesh size.

As in the 2D case, the performance of HSS preconditioning tends to improve as ν gets smaller and as σ gets larger. Table 5.9 shows iteration counts for a set of 3D generalized Stokes problems on a $40 \times 40 \times 40$ grid, for several values of the

parameter σ. The fixed value $\alpha = 0.5$ was used in all cases. The discrete problem has $n = 187,200$ and $m = 64,000$, for a total of $N = 251,200$ unknowns. It can be seen that the iteration counts improve for increasing σ and decreasing ν.

Optimal (i.e., grid-independent) rates of convergence are obtained when σ is not held constant but is taken to be inversely proportional to h (see, e.g., [25]). To show this, we use a set of 3D, unsteady Stokes problems with $\nu = 0.001$ and $\sigma = h^{-1}$. The results for HSS preconditioning (with the fixed value $\alpha = 0.5$) are reported in Table 5.10.

These experiments show the excellent behavior of HSS preconditioning for nonstationary Stokes problems, especially for small values of the viscosity ν and for a wide range of values of σ. On the other hand, the behavior of the preconditioner is suboptimal for steady Stokes problems (as can be verified by Fourier analysis).

It is interesting to note that for the Stokes problem the HSS-preconditioned matrix is diagonalizable and all its eigenvalues are real (and, of course, positive). Hence, there is a nonstandard inner product in which the preconditioned matrix is symmetric positive definite; see [6].

5.3. The effect of inexact solves. In all the results presented so far we have always used "exact" solves (in the form of sparse direct factorizations) for the linear systems that arise in the application of HSS preconditioning. As is well known, the storage and arithmetic complexity of direct solvers scales superlinearly with problem size when they are applied to linear systems arising from the discretization of elliptic PDEs; even with the best fill-reducing orderings currently available, for 3D problems their cost becomes quickly prohibitive as h is decreased. The poor scaling of sparse direct solvers is largely responsible for the superlinear scaling observed in the solution timings reported in the previous two sections. Other factors include (possibly) the nonconstant number of iterations as well as memory traffic issues.

Faster solution and better scalability may be achieved if the exact solves are replaced by inexact ones using inner iterations. We recall that for the (generalized) Stokes problem, all the inner solves correspond to shifted Poisson-type equations, which can be (approximately) solved efficiently by standard multigrid or by preconditioned conjugate gradients. For the Oseen problem, two (or three in three dimensions) of the systems are shifted Poisson-type equations, and one corresponds to a nonsymmetric but strongly elliptic problem. The latter system can be solved by

preconditioned GMRES or by a suitable multigrid method.

In Tables 5.11–5.12 we compare results for HSS-preconditioned FGMRES with inexact solves with those for HSS-preconditioned GMRES with exact solves. The test problems are unsteady 2D Stokes and Oseen problems with $\nu = 0.001$. We used drop tolerance-based incomplete Cholesky factorization preconditioning, available in MATLAB (function `cholinc`), for the two linear systems in (4.5). For (4.8) we used incomplete Cholesky in the Stokes case (where the Schur complement is symmetric and positive definite; see (4.9)) and incomplete LU (function `luinc`) in the Oseen case.

The drop tolerance τ in the incomplete factorizations was chosen so as to ensure that just 1–2 inner PCG iterations sufficed to reduce the inner residuals by at least a factor of 10. This low accuracy is already enough to ensure that the total number of (outer) FGMRES iterations is nearly the same as that of GMRES with exact solves. The use of incomplete factorizations leads to a reduction in memory requirements for the triangular factors, but this is partially offset by the memory overhead induced by the use of a flexible outer iteration. For the two shifted Laplacians in (4.5), which are very well conditioned, we used $\tau = 10^{-2}$. For the Schur complement system (4.9), in the Stokes case we used $\tau = 10^{-3}$ for all grids, except for the 512×512 case, where we used $\tau = 10^{-4}$. The 512×512 problem has a total of $N = 785,408$ unknowns. For the Schur complement in the Oseen problem we set the drop tolerance to 10^{-4} on all grids except for the 512×512 case, where we used $\tau = 10^{-5}$. Larger drop tolerances can be used at the expense of more inner iterations, and this tends to increase solution times.

The first observation to be made is that the use of inexact solves does not lead to a strong increase in the number of outer (FGMRES) iterations, even when a very loose tolerance ($tol = 10^{-1}$) is used for the inner iterations. This is especially true for the Oseen problem, for which the number of outer iterations is exactly the same as with exact solves.

Second, it appears from the results in Tables 5.11–5.12 that replacing the exact inner solves with inexact ones does not typically result in faster solution and may actually lead to higher computing times. Indeed, even for the set-up phase the

advantages of using incomplete factorizations instead of complete ones are small or nonexistent. Inexact solves are clearly counterproductive for the Stokes problem. The situation is somewhat better for the Oseen problem; however, the only case where inexact solves resulted in faster time to solution is in the case of the 512×512 grid. Note that in this case, the savings are entirely a result of reduced set-up costs. It should be kept in mind that the incomplete factorizations and inner iterations used are not very efficient. For the complete factorizations, the MATLAB code makes use of highly optimized sparse direct solvers. Also, the matrices are first reordered with an approximate minimum degree heuristic, which results in relatively low fill-in. In contrast, the implementations of the incomplete Cholesky and incomplete LU factorization functions in MATLAB are not very efficient. Furthermore, minimum degree reordering of the equations tends to have an adverse effect on the rate of convergence of the inner iterations; hence, no reordering was used when computing the incomplete factorizations. Because of this, the incomplete factors are not much cheaper to compute than the complete factors, and the additional costs induced by the (few) inner Krylov subspace iterations needed to satisfy the convergence criteria for the inexact solves lead in almost all cases to increased overall solution costs compared to the case of exact solves.

Nevertheless, the fact that HSS preconditioning does not significantly deteriorate in the presence of inexact solves is encouraging. We expect that with a more optimized implementation, or with the use of more efficient solvers for elliptic problems (i.e., multigrid schemes) it will be possible to achieve faster solutions and better scalability than with exact solves, at least for sufficiently large problems.

Finally, we note that similar conclusions hold for the case of steady problems and problems in three dimensions.

5.4. Comparison with other methods. Extensive experimental comparisons with other solvers have been carried out in [19]. We give here a brief summary of our findings.

To our knowledge, the only other solver explicitly developed for the rotation form of the Navier–Stokes equations is Olshanskii's block triangular preconditioner; see, e.g., [21] or the brief discussion in section 4.2. This preconditioner is very effective for the solution of unsteady Oseen-type problems. For steady problems, the exact variant of the preconditioner appears to be both h- and ν-independent; when inexact inner solves are used, however, a fairly high number of inner iterations may be needed to keep the number of outer iterations from growing as ν becomes smaller.

A possible drawback of this approach is the need to solve linear systems with coefficient matrix A at each iteration. In this system, all components of the velocities are coupled. Standard sparse solvers (direct or iterative) do not perform well on such systems; instead, specialized multigrid solvers have to be used; see [24]. The work involved in the inversion of the (2,2) block is comparable to that required by the Schur complement solve in HSS preconditioning; note, however, that in the case of HSS the eigenvalues of the Schur complement are shifted away from zero (see (4.8)). The diagonal shift in (4.8) helps making the problem arising in HSS preconditioning better conditioned.

Summarizing, for many problems Olshanskii's preconditioner is about as effective as or better than HSS preconditioning on Oseen-type problems in terms of iteration counts. We do not have an efficient implementation of Olshanskii's preconditioner in MATLAB, and therefore we do not have a way to compare timings. The main advantage of HSS preconditioning, in our opinion, is the greater ease of implemen-

tation. Furthermore, the linear systems that needs to be solved with HSS have a more convenient structure and better conditioning than the systems to be solved with Olshanskii's preconditioner, so the cost per iteration is generally lower.

Numerical experiments were also performed comparing HSS with Uzawa-type and SIMPLE preconditioning; see [19]. These techniques exhibit significant deterioration for small ν and were found to be generally inferior to both HSS and Olshanskii's preconditioner.

Concerning the Stokes problem, both steady and generalized, there are many optimal solvers available. In particular, the steady case is best handled by block diagonal preconditioners of the form

$$\mathcal{P} = \begin{bmatrix} \hat{A} & O \\ O & \hat{S} \end{bmatrix}, \tag{5.1}$$

where $\hat{A}$ is spectrally equivalent to A and $\hat{S}$ is spectrally equivalent to $S = BA^{-1}B^T$; see [32]. When using LBB-stable discretizations, finding spectrally equivalent approximations for the Schur complement S is easy: the pressure mass matrix (or a diagonal approximation of it) will do; for MAC, it is enough to take $S = I_m$. We performed some experiments with exact solves for the (1,1) block (i.e., $\hat{A} = A$) and we verified the expected h-independent convergence. The number of iterations for the finer grids settled around 20 in the 2D case. Since this preconditioner is cheaper than HSS, requiring only two Poisson-type solves rather than three at each step, we conclude that HSS cannot be recommended for the [illegible] Stokes problem, since its rate of convergence is not h-independent.

For generalized Stokes problems (case $\sigma > 0$), on the other hand, HSS offers an attractive alternative to existing preconditioners (see [8, 17, 25]). The rates of convergence obtained with HSS and its cost per iteration appear to be competitive with those that have been reported in the literature; furthermore, implementation of the HSS preconditioner is straightforward.

5.5. Behavior of the Picard iteration. An important question that has not been addressed so far in this paper is that of the rate of convergence of the nonlinear Picard iteration for the rotation form of the Navier–Stokes equations. For the standard (convection) form of the steady Navier–Stokes equations, conditions for the (global) convergence of the Picard iteration have been given in [16]. We are not aware of any such analysis for the rotation form of the equations.

Limited numerical experience reported by Olshanskii in [23] suggests that the rate of convergence of Picard's iteration for the rotation form tends to deteriorate for decreasing values of the viscosity ν. Although some deterioration is also observed for the convective form of the equations, the phenomenon appears to be more pronounced for the rotation form. This is probably the price one pays for the avoidance of convection in the linear solves.

Our own experience is in agreement with the results reported by Olshanskii. In particular, we found that Picard's iteration for the rotation form tends to converge fast for relatively large ν (say, between 2 and 6 iterations for $\nu > 0.05$ in a 2D confined flow problem); however, convergence slows down dramatically for smaller ν (for example, 68 iterations for $\nu = 0.03$), and the iteration fails to converge for smaller values of ν.

In contrast, Picard's iteration was found to converge when using the convective form of the equations, even for small values of the viscosity. The number of iterations for solving the same confined flow problem was found to be 4, 18, and 80 for $\nu = 0.1$,

TABLE 5.13
Picard iterations for rotation form with a regularization term $\xi h^2 I$.

Problem	$\nu = 0.1$	$\nu = 0.01$	$\nu = 0.001$
32×32, $\xi = 10$	3	4	6
error	6.21e-04	5.81e-04	5.79e-04
64×64, $\xi = 12$	3	4	6
error	1.49e-04	1.38e-05	1.36e-04

0.01, and 0.001, respectively. All these results are essentially independent of the mesh size, at least for fine enough grids. In these experiments, convergence of the Picard iteration is achieved when the 2-norm of the (nonlinear) residual is reduced below $tol = 10^{-5}$ times the initial residual (see (8.34) in [12]), starting from a zero initial guess. Exact solves were used at each Picard iteration.

Clearly, this is a serious drawback of the rotation form for steady problems. We found, however, that the convergence of Picard's iteration can be greatly improved by adding to the momentum equations (2.13) a term of the form $\xi \mathbf{u}$, where $\xi > 0$ is a moderate constant. Upon discretization, this amounts to the addition of a term of the form $\xi h^2 I$ to the (1,1) block of the system, and can be regarded as a form of [illegible]. Note that this modification changes the solution of the discrete problem; however, the extra term is small and tends to zero as $h \to 0$. The modification can also be interpreted as a kind of (velocity) stabilization. Although we do not have a rigorous justification for this form of regularization, we mention that the technique is similar to the one used in [13] for saddle point problems arising from the discretization of the curl-curl form of Maxwell's equations.

Nonlinear iteration counts for the modified problem on two grids with two different values of ξ are reported in Table 5.13. We also include the discrete L^2-norm of the difference between the velocity field obtained by Picard's iteration on the modified problem and the true (analytical) solution of our test problem. This error is very small in all cases. However, how to choose ξ remains an open question. Choosing too small a value of ξ leads to slow convergence for very small ν; for example, on the 32×32 grid, using $\xi = 7$ results in 3, 6, and 45 iterations for $\nu = 0.1$, 0.01, and 0.001, respectively. On the other hand, choosing ξ too large could in principle lead to a loss of accuracy in the computed solution. In our (admittedly somewhat limited) experience, however, somewhat overestimating ξ does not lead to a noticeable worsening of the error.

6. Conclusions. In this paper we have described a preconditioning technique for the large sparse linear systems arising from discretizations of the Navier–Stokes equations in rotation form. The basic idea is to decouple the symmetric and skew-symmetric components of the linearized Navier–Stokes system and to alternate between the two. The preconditioner contains a parameter which requires some tuning for optimal performance; we described some heuristics that can be used to find good estimates for the optimal parameter. However, in most cases the performance is not overly sensitive to the value of this parameter. The preconditioner can also be interpreted as an approximate block factorization of the (global) system matrix which becomes increasingly accurate in the vanishing viscosity limit $\nu \to 0$.

Implementation of the preconditioner is straightforward (more so than with other methods), and the numerical experiments show good performance on a wide range of cases, especially for unsteady problems and for low-viscosity problems. While the preconditioner cannot be recommended for steady Stokes problems, it performs very

well in the case of quasi-steady and unsteady problems. We remark that these appear to be precisely the kind of problems for which the rotation form is best suited; see [27].

Although our computational experience has been limited to uniform MAC discretizations and simple geometries, the preconditioner should be applicable to more complicated problems and discretizations, including unstructured grids.

Finally, although we have not discussed parallelization issues in this paper, the preconditioner can easily take advantage of existing elliptic solvers for parallel platforms, such as domain decomposition techniques.

Acknowledgments. The authors would like to thank Maxim Olshanskii and Eldad Haber for helpful suggestions.

AN ALGEBRAIC MULTIGRID PRECONDITIONER FOR A CLASS OF SINGULAR M-MATRICES*

ELENA VIRNIK†

Abstract. We apply algebraic multigrid (AMG) as a preconditioner for solving large singular linear systems of the type $(I - T^T)x = 0$ with GMRES. Here, T is assumed to be the transition matrix of a Markov process. Although AMG and GMRES were originally designed for the solution of regular systems, with adequate adaptation their applicability can be extended to problems as described above.

Key words. algebraic multigrid, singular systems, Markov chains

AMS subject classifications. 65C20, 65N55, 65F10

DOI. 10.1137/060659272

1. Introduction. This paper treats the application of an algebraic multigrid (AMG) method [12] as a preconditioner for solving large singular linear systems of the type

$$Ax := (I - T^T)x = 0 \tag{1}$$

using the generalized minimal residual (GMRES) method [13]. Here, T is the transition matrix of a Markov process. The applicability of GMRES to singular systems was examined, e.g., in [1, 4]. Our AMG strategy is based on the classical theory in [12] originally designed for systems involving regular, symmetric, positive definite M-matrices. The approach in [12] was generalized to symmetric positive definite and semidefinite matrices without the M-matrix property, e.g., in [3, 5, 6, 11]. A multigrid-like algorithm based on aggregation and disaggregation of Markov chains can be found in [9]. The main result of this paper is the extension of the AMG approach to a class of singular nonsymmetric M-matrices.

The theory of Markov chains [2, 14] represents an extremely important tool that has a broad variety of applications not only in the sciences, such as biology, physics, and chemistry, but also in business and economics. As an example, we consider a Markov chain model for blood circulation in the human body.

EXAMPLE 1. Let us imagine the organs within a human body as states of a blood particle. Within one time step, it can advance from one organ to another with a certain probability. It is also possible that it stays within the organ and only continues its journey a few time steps later. On the other hand, an organ can also be considered as a set of substates, since the blood does not simply pass an organ but can also recirculate within it in some chaotic way. Hence, if we define a set of (sub)organs as states of the Markov chain and the corresponding transition probabilities, we get a large sparse (row) stochastic matrix. We are interested in the stationary distribution of the Markov chain, which would, e.g., represent the concentration of a dissolved substance after injection into an organ. For a more detailed description, see [16].

2. Preliminaries. We call a vector $v \in \mathbb{R}^n$, and we write $v > 0$ if all entries v_i are positive. A matrix $T \in \mathbb{R}^{n\times n}$, $T = (t_{ij})_{i,j=1,\dots,n}$, is called , and we write $T > 0$ ($T \geq 0$) if all entries t_{ij} are positive (nonnegative). A matrix $T \in \mathbb{R}^{n\times n}$ is called if there exists a permutation matrix $P \in \mathbb{R}^{n\times n}$, such that $PTP^T = \left[\begin{smallmatrix} T_{11} & 0 \\ T_{21} & T_{22} \end{smallmatrix}\right]$. Otherwise it is called .

A scalar $\lambda \in \mathbb{R}$ is called an of the matrix $T \in \mathbb{R}^{n\times n}$ if a vector $v \in \mathbb{R}^n$, $v \neq 0$ exists, such that $Tv = \lambda v$. The vector v is called a of T associated with λ. Accordingly, a vector $w \in \mathbb{R}^n$, $w \neq 0$, with $w^T T = \lambda w^T$ is called a of T. Let $T \in \mathbb{R}^{n\times n}$ have the eigenvalues λ_i, $i = 1, \dots, n$. Then we call $\rho(T) = \max_{1\leq i\leq n} |\lambda_i|$ the T.

A process is called a if it has n states $s_1, \dots, s_n$ and the transition probability $P[s_i \rightsquigarrow s_j] =: t_{ij}$ is time-independent. The matrix $T = [t_{ij}]_{i,j=1,\dots,n}$ satisfies $t_{ij} \geq 0$ and $\sum_{j=1}^n t_{ij} = 1$ for $i, j = 1, \dots, n$, i.e., it is and is called the of a Markov chain. We denote by $x^k = (x_i^k)$ the , where x_i^k is the probability that the system is in state s_i after k steps. We have $x_i^k \geq 0$ and $\sum_{i=1}^n x_i^k = 1$ for each k. A distribution vector x is said to be if $x^T T = x^T$.

The well-known Perron–Frobenius theorem guarantees the existence and uniqueness of a stationary distribution.

THEOREM 1 (Perron–Frobenius theorem [2, p. 27]). $T \geq 0$ $\rho(T)$ $\rho(T)$ T $\rho(T)$

COROLLARY 2 (see [2, p. 28]). x T $\rho(T)$

COROLLARY 3. T

We define by $\mathcal{Z}^{n\times n} = \{A = [a_{ij}] \in \mathbb{R}^{n\times n} : a_{ij} \leq 0, i \neq j\}$ the set of all real matrices with nonpositive off-diagonal entries. Let $B \geq 0$ with spectral radius $\rho(B)$. A matrix A of the form $A = sI - B$, with $s > 0$ and $s \geq \rho(B)$, is called an . If $s > \rho(B)$, then A is a M-matrix, and if $s = \rho(B)$, then A is a M-matrix. Hence, in our case $A = (I - T^T)$ is a singular M-matrix.

3. AMG preconditioning. The GMRES method we use was introduced in [13]. Algorithm 1 shows a version with left preconditioning.

As we will see in the following, the application of AMG in our case requires the property that the matrix A have row sums zero. Since $A = (I - T^T)$ has column sums zero instead, for the construction of the preconditioner we use the matrix A^T and then use M^T for the iteration process.

3.1. Basic framework of AMG. The AMG method that is presented here follows the concept introduced in [12], which is motivated by geometric multigrid, where a sequence of grids is constructed from the underlying geometry with corresponding transfer operators between the grids. The main idea of geometric multigrid is to remove the smooth error, which cannot be eliminated by relaxation on the fine grid, by coarse grid correction. The solution process then as usual consists of presmoothing, transfer of residuals from fine to coarse grids, interpolation of corrections from coarse to fine levels, and optional postsmoothing. In contrast to geometric multigrid, the idea of AMG is to define an sequence of systems of equations decreasing in

ALGORITHM 1: Preconditioned MGS-GMRES.

Input: $A \in \mathbb{R}^{n\times n}$, $b \in \mathbb{R}^n$, starting vector $x_0 \in \mathbb{R}^n$, preconditioner M
Output: $x_m \in \mathbb{R}^n$ solution approximate in the mth step

```
1  Compute r_0 = M^{-1}(b - Ax_0), β := ||r_0||_2 and v_1 := r_0/β
2  Define the (m + 1) × m matrix H̄_m = {h_ij}_{1≤i≤m+1,1≤j≤m}. Set H̄_m = 0.
3  for j = 1, 2, ..., m do
4  |  Compute w_j := M^{-1} A v_j
5  |  for i = 1, ..., j do
6  |  |  h_ij := (w_j, v_i)
7  |  |  w_j := w_j - h_ij v_i
8  |  h_{j+1,j} = ||w_j||_2. If h_{j+1,j} = 0, set m := j and go to 12
9  |  v_{j+1} = w_j / h_{j+1,j}
10 Compute y_m the minimizer of ||βe_1 - H̄_m y||_2
11 Set x_m = x_0 + V_m y_m.
```

size,

$$A^m u^m = b^m, \tag{2}$$

where the superscript m denotes the mth iterate, directly from the underlying matrix. We have $A^1 = A$, and for $m = 1$ the system (2) is identical to (1). We call these equations "coarse grid" equations. The interpolation operator P and the restriction operator R define the transfer from finer to coarser grids and vice versa. More precisely, let $A^m \in \mathbb{R}^{n_m \times n_m}$; then

$$R^m : \mathbb{R}^{n_m} \to \mathbb{R}^{n_{m+1}},$$
$$P^m : \mathbb{R}^{n_{m+1}} \to \mathbb{R}^{n_m},$$

and the operator on the coarser grid is defined by

$$A^{m+1} = R^m A^m P^m \ \in \mathbb{R}^{n_{m+1}\times n_{m+1}}. \tag{3}$$

Thus, we do not need a geometry behind the problem.

The AMG method consists of two main parts: the setup phase and the solution phase. During the setup phase, the coarse grids and the corresponding operators are defined. We describe this in section 3.2. The solution phase consists of a multilevel iteration. Here, as an example, we illustrate a two-level iteration, which involves the combination of a smoothing process (e.g., Gauss–Seidel; see [7]), with a correction on a coarser grid:

$$x^{(k+1)} = x^{(k)} + B^{-1}(b^m - A^m x^{(k)}), \tag{4a}$$
$$x^{(k+2)} = x^{(k+1)} + P^m (A^{m+1})^{-1} R^m (b^m - A^m x^{(k+1)}). \tag{4b}$$

Here, the matrix $(A^{k+1})^{-1}$ is replaced by the recursive application of (4) to the solution of the coarse grid system. The number of recursive calls, which is the number of levels m, depends on the size and structure of the matrix. For our method, we use the V-cycle pattern (see, e.g., [8]), as shown in Figure 1. Other recursive patterns, e.g., the W-cycle that involves two recursive calls per cycle, are presented in [8].

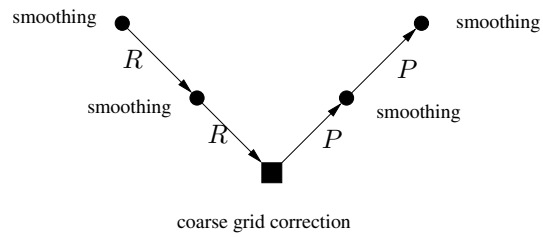

FIG. 1. *V-cycle pattern.*

3.2. Coarsening. The first main step of the coarsening process as introduced in [12] can be read as a permutation of the matrix $A \in \mathbb{R}^{n\times n}$ such that the fine grid nodes come first:

$$A \rightsquigarrow \pi^T A \pi = \left[\begin{array}{c|c} A_{FF} & A_{FC} \\ \hline A_{CF} & A_{CC} \end{array}\right].$$

We choose the fine grid nodes such that the block A_{FF} is close to a diagonal matrix. A further sparsification step is applied in which "small" off-diagonal entries in A_{FF} are added to the diagonal and the remaining off-diagonal entries in A_{FF} are redistributed onto the A_{FC} block:

$$A \rightsquigarrow \tilde{A} = \left[\begin{array}{c|c} \tilde{A}_{FF} & \tilde{A}_{FC} \\ \hline A_{CF} & A_{CC} \end{array}\right]. \tag{5}$$

It is shown in [12] that the "sparsification" process leaves the row sums of the matrix A unchanged.

To obtain the restriction and interpolation operators, we consider the incomplete block LU decomposition of the matrix $\tilde{A}$:

$$\tilde{A} = \left[\begin{array}{c|c} \tilde{A}_{FF} & \tilde{A}_{FC} \\ \hline A_{CF} & A_{CC} \end{array}\right] = \left[\begin{array}{c|c} I & 0 \\ \hline A_{CF}\tilde{A}_{FF}^{-1} & I \end{array}\right] \left[\begin{array}{c|c} \tilde{A}_{FF} & \tilde{A}_{FC} \\ \hline 0 & S \end{array}\right], \tag{6}$$

where $S = A_{CC} - A_{CF}\tilde{A}_{FF}^{-1}\tilde{A}_{FC}$ is the Schur complement with respect to $\tilde{A}_{FF}$. We take S to be the new coarse grid operator. This is the main difference from the classical approach in [12]. For the coarse grid operator we compute the exact Schur complement of an approximated matrix $\tilde{A}$, whereas in the classical approach an approximation to the Schur complement of the exact matrix A is computed. For other choices of restriction, interpolation, and coarse grid operators see, e.g., [5, 6, 12, 15]. Neither of these choices works here, since they do not preserve in our case important properties such as the singular M-matrix property and the row sums zero property; see section 3.3 for details.

The following lemma summarizes the main results for the coarsening process.

LEMMA 4. A (6) N S (6)

1.

$$R = \begin{bmatrix} -A_{CF}\tilde{A}_{FF}^{-1} & I \end{bmatrix} \in \mathbb{R}^{N\times n} \qquad P = \begin{bmatrix} -\tilde{A}_{FF}^{-1}\tilde{A}_{FC} \\ I \end{bmatrix} \in \mathbb{R}^{n\times N},$$

[illegible] S [illegible]

$$S = R\tilde{A}P \in \mathbb{R}^{N\times N}. \tag{7}$$

2. [illegible] P [illegible]
3. [illegible] S [illegible]

[illegible]

1. By straightforward calculation we get

$$\begin{aligned} R\tilde{A}P &= \begin{bmatrix} -A_{CF}\tilde{A}_{FF}^{-1} & I \end{bmatrix} \begin{bmatrix} \tilde{A}_{FF} & \tilde{A}_{FC} \\ A_{CF} & A_{CC} \end{bmatrix} \begin{bmatrix} -\tilde{A}_{FF}^{-1}\tilde{A}_{FC} \\ I \end{bmatrix} \\ &= \begin{bmatrix} -A_{CF}\tilde{A}_{FF}^{-1} & I \end{bmatrix} \begin{bmatrix} -\tilde{A}_{FC} + \tilde{A}_{FC} \\ -A_{CF}\tilde{A}_{FF}^{-1}\tilde{A}_{FC} + A_{CC} \end{bmatrix} \\ &= A_{CC} - A_{CF}\tilde{A}_{FF}^{-1}\tilde{A}_{FC} = S \in \mathbb{R}^{N\times N}. \end{aligned}$$

2. Let $\mathbb{1} = [1, \ldots, 1]^T$ represent the vector containing all entries equal to one. Hence, for all $i \in \{1, \ldots, N\}$ we have

$$0 = e_i^T \tilde{A}\mathbb{1} = \sum_{k\in\mathcal{C}_i} \tilde{a}_{ik} + \tilde{a}_{ii},$$

and thus, as all $\tilde{a}_{ik} \le 0$ for $i \ne k$, we get

$$\frac{\sum_{k\in\mathcal{C}_i} |\tilde{a}_{ik}|}{\tilde{a}_{ii}} = 1,$$

where $\mathcal{C}_i$ is the set of interpolatory connections of i, i.e., we sum up the entries in the ith row of the $\tilde{A}_{FC}$ block. Hence, all row sums of the interpolation operator P are equal to one.

3. From 2. we conclude that

$$e_i^T S\mathbb{1} = e_i^T R\tilde{A}P\mathbb{1} = e_i^T R\tilde{A}\mathbb{1} = 0 \quad \text{for all } i,$$

i.e., the zero row sums property is preserved for the new coarse grid operator S. □

3.3. Multilevel setup. For the setup of a recursive multilevel cycle, it is essential to ensure that the important properties of the finest grid operator carry over to all coarser grids. In our case it is on the one hand the row sums zero property and on the other hand the singular M-matrix property. These are important for an adequate interpolation of the smooth error that needs to be reduced by the coarse grid correction and can be written as

$$e_i \approx \sum_{j\ne i} \frac{|a_{ij}|}{a_{ii}} e_j, \quad \text{where } \sum_{j\ne i} \frac{|a_{ij}|}{a_{ii}} = 1.$$

Here, we can use only significant weights $|a_{ij}|/a_{ii}$ to interpolate e_i. Also the singular M-matrix property is important for the direct solution on the coarsest level; see section 3.5. In Lemma 4 we have shown that the coarsening process leaves the row sums zero. The following theorem states that the singular M-matrix property is preserved after the performance of one coarsening step.

THEOREM 5. [illegible] $A = \left[\begin{smallmatrix} A_{FF} & A_{FC} \\ A_{CF} & A_{CC} \end{smallmatrix}\right]$ [illegible] $\tilde{A} = \left[\begin{smallmatrix} \tilde{A}_{FF} & \tilde{A}_{FC} \\ A_{CF} & A_{CC} \end{smallmatrix}\right]$ [illegible] (5) [illegible] $S = A_{CC} - A_{CF}\tilde{A}_{FF}^{-1}\tilde{A}_{FC}$ [illegible] (7) [illegible]

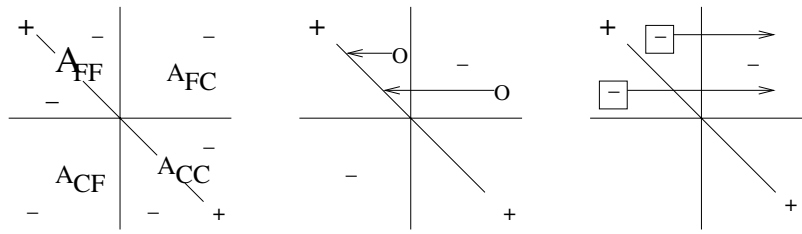

FIG. 2.

1. Show that $\tilde{A}$ is a singular M-matrix:
   A is a singular M-matrix. Therefore, it can be expressed in the form

$$A = sI - T, \qquad \text{where } T \text{ is the transition matrix of a Markov process}$$
$$\rho(T) = 1 = s.$$

   In [12] it was shown that the coarsening process leaves the row sums invariant, i.e., in our case equal to zero. Hence, we can write $\tilde{A} = I - \tilde{T}$, where $\tilde{T}$ has row sums one. Furthermore, we have $\tilde{A} \in \mathcal{Z}^{n\times n}$, i.e., the off-diagonal entries in $\tilde{A}$ are nonpositive and the diagonal is nonnegative (as otherwise the row sums could not be zero). The diagonal entries are also at most one. One can see this by considering the following sparsification steps (see [12] for a detailed description of the "sparsification" process):
   - The initial matrix A has a sign and block structure, as illustrated in Figure 2(a). The sign "−" indicates that all entries in the corresponding section are nonpositive. Accordingly, "+" signifies that the entries in the corresponding section are nonnegative.
   - In the first step, "small" off-diagonal entries in each row are added to the diagonal (see Figure 2(b)). The diagonal entries become smaller but stay nonnegative.
   - Then the remaining off-diagonal entries of the A_{FF}-block are distributed onto the A_{FC}-block (see Figure 2(c)). The entries of the A_{FC}-block become smaller, but remain greater than -1, as otherwise the row sums could not stay zero.

   Thus, $\tilde{T}$ is in addition nonnegative and all entries are at most one. From this we conclude that $\tilde{T}$ is stochastic and thus $\rho(\tilde{T}) = 1 = s$. Consequently, $\tilde{A}$ is a singular M-matrix.
2. Show that S as in (7) is a singular M-matrix:
   In Lemma 4 we have shown that $S\mathbb{1} = 0$, i.e., S has zero row sums. From this and from $A_{CC} \in \mathcal{Z}^{N\times N}$ and $A_{CF}\tilde{A}_{FF}^{-1}\tilde{A}_{FC} \geq 0$, we can conclude that $S = A_{CC} - A_{CF}\tilde{A}_{FF}^{-1}\tilde{A}_{FC} \in \mathcal{Z}^{N\times N}$. Let S now have the representation

$$S = sI - \hat{T}, \qquad \hat{T} \geq 0, \quad s > 0.$$

   Then we get

$$S\mathbb{1} = (sI - \hat{T})\mathbb{1} = s\mathbb{1} - \hat{T}\mathbb{1} = 0$$
$$\Rightarrow \hat{T}\mathbb{1} = s\mathbb{1}.$$

As $\mathbb{1} > 0$ is a positive eigenvector of $\hat{T}$, it follows from Corollary 2 that $s = \rho(\hat{T})$. Hence, S is a singular M-matrix. □

From Theorem 5 we conclude that the singular M-matrix property is preserved on all coarser levels.

3.4. Integration of the side constraint into the solution process. For a badly chosen starting vector x_0 the GMRES method in Algorithm 1 may converge to the trivial solution, instead of the stationary distribution. In fact, for some problems we cannot choose the starting vector randomly but need to employ a specifically fixed starting vector as, e.g., in the case of the blood circulation model. Here, the initial distribution might represent an injection into a certain organ. Therefore, it makes sense to set $x_0 = [0, \ldots, 1, \ldots, 0]^T$, where the only nonzero entry $[x_0]_i = 1$ is positioned to represent the injection into the organ i. In this case the naive application of the preconditioned GMRES algorithm leads to a convergence to the trivial solution.

Hence, we have the side constraint $\mathbb{1}^T x = 1$ that we have to include into the solution process. The idea now is to shift the system such that the trivial solution is excluded as a possible solution. Consider the orthogonal projection matrix $Q := I - \frac{1}{n}\mathbb{1}\mathbb{1}^T$ with respect to $\mathbb{1}$, that is, $\mathbb{1}^T Q = 0$. Any vector x can be decomposed into

$$x := Qy + z$$

such that $z = \alpha\mathbb{1}$ for some constant $\alpha \in \mathbb{R}$. In particular, for a vector $\tilde{x}$ that fulfills $\mathbb{1}^T\tilde{x} = 1$, we obtain $z := \frac{1}{n}\mathbb{1}$.

Now we transform the initial problem as follows:

$$\begin{aligned} & Ax = 0 \\ \Leftrightarrow\ & A(Qy + z) = 0 \\ \Leftrightarrow\ & AQy = -\frac{1}{n}A\mathbb{1}. \end{aligned} \tag{8}$$

By setting $\hat{A} := AQ$ and $b := -\frac{1}{n}A\mathbb{1}$, we get a formulation of the linear system where the side constraint is embedded:

$$\hat{A}y = b. \tag{9}$$

Now, we can solve this system instead of (8) using AMG preconditioned GMRES. The system is still consistent since $b \in \mathrm{im}(A)$. As Q is orthogonal with respect to z, we have $\tilde{x} = Qy + z \neq 0$ for all y.

Note that in the implementation we do not compute the product $\hat{A} := AQ$ explicitly as Q is not sparse and matrix-matrix products are expensive, but rather successively calculate the corresponding matrix-vector products.

3.5. Direct solution on the coarsest level. On the coarsest level we solve the singular system

$$A^m x^m = b^m \tag{10}$$

directly using LU decomposition. From section 3.3 we know that the operator A^m on the coarsest level is still a singular M-matrix. In theory, the coarsening process does not necessarily guarantee irreducibility of A^m, although in our practical examples this is the case. Since the treatment of this problem is beyond the scope of this

paper, in the following discussion we will assume that A^m is irreducible. Then an LU decomposition of A^m with L nonsingular exists [10] and appears as follows:

$$A^m = LU = \begin{bmatrix} 1 & & \\ & \ddots & \\ & & 1 \end{bmatrix} \begin{bmatrix} & & \\ & \ddots & \\ & & 0 \end{bmatrix}.$$

To solve the system (10), we need only prove that it is consistent. That is, we need to ensure that L^{-1} applied to the right-hand side produces a zero in the last entry of the resulting vector. Since the entry in the lower right corner of U is zero, we have a consistent singular system. From the following lemma we conclude that whenever the right-hand side b^m is a zero vector the last entry of $L^{-1}b^m$ will be zero, and thus our system is consistent.

LEMMA 6. [illegible] A [illegible] $A = LU$ [illegible] LU [illegible] A [illegible] L [illegible]

$$e_n^T L^{-1} = \mathbb{1}^T.$$

[illegible] $A = LU \Leftrightarrow L^{-1}A = U$. If we apply the nth unit vector from the left, we get

$$e_n^T L^{-1} A = e_n^T U = [0, \ldots, 0].$$

Thus, it must hold that $e_n^T L^{-1} = \alpha \mathbb{1}^T$ for some scalar α. Yet, as L^{-1} has ones on the diagonal, we get $\alpha = 1$ and hence $e_n^T L^{-1} = \mathbb{1}^T$. □

By construction, the AMG ensures that on any level j, the system (10) satisfies $\mathbb{1}^T b^j = 0$ since this holds for the initial right-hand side in (9), and the new right-hand sides on coarser grids are obtained via restriction of the residual, i.e.,

$$b^{j+1} = R^j(b^j - A^j x^k).$$

Note that Lemma 4 is applied to A^T. Thus, R^j corresponds to $(P^j)^T$ in Lemma 4.

3.6. Numerical tests. For numerical tests, we used MATLAB Version 7.1 run on a PC with an Intel Pentium 4 CPU 3.20GHz processor. The relative machine precision was `eps` $= 2.2204 \times 10^{-16}$. As convergence criterion for GMRES we used the tolerance $t = \|r_0\|\sqrt{\texttt{eps}}$, where r_0 is the initial residual, i.e., GMRES has converged when the residual norm falls under the tolerance t. For the AMG iteration we used the V-cycle with one presmoothing and one postsmoothing sweep; see section 3.1. The time measurement was conducted via the commands `tic` and `toc` and represents an upper bound for the required time. It can be further reduced by a more efficient implementation of the AMG algorithm.

In section 1, we have discussed the Markov chain model of blood circulation in the human body. Table 1 presents some results of the AMG preconditioned GMRES algorithm applied to transition matrices of Markov chains that arise from the blood circulation problem; see Example 1. Here, we consider the case where the blood particles can recirculate in the neighboring organs before passing on. Hence, the considered matrices have about five nonzero entries per row.

In the first column of Table 1 we have the size n of the problem. The second column states the number nnz of nonzero elements in the matrix. The column labeled Grid shows the time required by AMG for the grid construction. In *#level* the

9544	47666	4.08	20	21.05	–	–	162.60	955

number of constructed grids is given. The following Time and Iters. columns represent the computation time of AMG preconditioned GMRES and the corresponding number of iterations. The last column summarizes the total time required by AMG preconditioned GMRES.

In Table 2 we give the results of alternative methods for the same problems as in Table 1. The first two columns as in Table 1 contain the sizes and the numbers of nonzeros of the problems. The following three columns contain the results for AMG as a stand-alone function, where the total required time is given in the third column. The next two columns labeled GS display the time and number of iterations required by Gauss–Seidel iteration. The last two columns present the results for GMRES with Gauss–Seidel as preconditioner. The top times are marked in bold.

As we can see, although for the smallest problem the Gauss–Seidel iteration and the Gauss–Seidel preconditioned GMRES outperform the AMG method, for larger problems AMG preconditioning becomes very effective. The computational effort of AMG preconditioned GMRES grows linearly with the problem size, whereas the number of iterations stays constant. The number of iterations for the Gauss–Seidel preconditioned GMRES, in contrast, grows linearly with the problem size. The effectiveness of AMG preconditioning is due to the fact that the overall computation time of the AMG preconditioned GMRES is dominated by the time required to construct the "algebraic grid." The computational effort required for grid construction, although it also grows linearly, grows much slower with the matrix size than the computational effort for Gauss–Seidel preconditioned GMRES. The AMG algorithm as a stand-alone function also works quite well, although the computational effort is slightly smaller in the AMG preconditioned GMRES due to fewer iterations. This also supports the suitability of the AMG method as a preconditioner for this type of problem.

4. Conclusions. In this paper, the application of the AMG method as a preconditioner for solving large singular linear systems of the type $(I - T^T)x = 0$ with GMRES was examined. In doing so, we concentrated on the case in which T is the transition matrix of a Markov process. The AMG method [12] was originally devel-

oped for regular, symmetric, positive definite M-matrices. In our case, although the matrix $(I - T^T)$ is singular and nonsymmetric, it is a singular M-matrix that possesses a number of useful properties. It turns out that with the adaptation discussed in sections 3.3–3.5, the method becomes applicable to singular matrices such as those in the blood circulation model. Numerical experiments illustrate that preconditioning with the AMG method leads to significant acceleration of the convergence speed.

Acknowledgments. The author thanks M. Bollhöfer for suggesting the problem and for the fruitful discussions throughout the project, as well as V. Mehrmann and D. B. Szyld for reading the manuscript with great care.

A PRECONDITIONER FOR LINEAR SYSTEMS ARISING FROM INTERIOR POINT OPTIMIZATION METHODS*

TIM REES† AND CHEN GREIF‡

Abstract. We explore a preconditioning technique applied to the problem of solving linear systems arising from primal-dual interior point algorithms in linear and quadratic programming. The preconditioner has the attractive property of improved eigenvalue clustering with increased ill-conditioning of the (1,1) block of the saddle point matrix. It fits well into the optimization framework since the interior point iterates yield increasingly ill-conditioned linear systems as the solution is approached. We analyze the spectral characteristics of the preconditioner, utilizing projections onto the null space of the constraint matrix, and demonstrate performance on problems from the NETLIB and CUTEr test suites. The numerical experiments include results based on inexact inner iterations.

1. Introduction.

Interior point methods for solving linear and quadratic programming problems have been gaining popularity in the last two decades. These methods have forged connections between previously disjoint fields and allowed for a fairly general algebraic framework to be used; see, for example, [11] for a comprehensive survey. The size of many problems of interest is very large and the matrices involved are frequently sparse and often have a special structure. As a result, there is an increasing interest in iterative solution methods for the saddle point linear systems that arise throughout the iterations.

The general optimization framework is as follows. Consider the quadratic programming (QP) problem

$$\min_x \frac{1}{2}x^T Hx + c^T x$$
$$\text{subject to}$$
$$Ax = b,\ Cx \geq d.$$

Here $x, c \in \mathbb{R}^n$ and H is an $n \times n$ Hessian, often symmetric positive semidefinite; the constraint matrix A is $m_1 \times n$ with $m_1 < n$, and we assume it has rank m_1. Inequality constraints are expressed in the $m_2 \times n$ matrix C. Often simple bounds on the variables are given, so C could be an identity matrix or its concatenation with a negative identity matrix.

When H is symmetric positive semidefinite and the constraints are linear, satisfaction of the first-order, Karush–Kuhn–Tucker (KKT) conditions is sufficient to

guarantee global optimality of a solution [23, Chap. 16]. If Lagrange multipliers y, z and slack variables s are introduced, the KKT conditions for this problem are

$$\begin{gathered} Hx - A^T y - C^T z = -c, \\ Ax = b, \\ Cx - s = d, \\ s \geq 0,\ z \geq 0,\ s^T z = 0. \end{gathered}$$

Typical interior point methods [23, 28] for QP problems define a function whose roots coincide with the KKT conditions and take Newton steps to progressively approach an optimal solution. One possible way of solving the problem is by performing predictor and corrector solves at each step to ensure sufficient progress towards the optimal point. After elimination of some of the unknowns we obtain the step equations, a saddle point system of the form

$$\begin{pmatrix} H + C^T S^{-1} Z C & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} \Delta x \\ -\Delta y \end{pmatrix} = \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}, \tag{1.1}$$

where S and Z are diagonal and keep changing throughout the QP iteration. The right-hand side vector is related to residual measures of the KKT conditions and depends on whether a predictor or corrector step is being carried out [23, 28].

While we will focus primarily on QP problems, it is also worth considering the linear programming (LP) problem, which is formulated as

$$\begin{aligned} &\min_{x \in \mathbb{R}^n} c^T x \\ &\text{subject to} \\ &Ax = b,\ x \geq d. \end{aligned}$$

LP problems share similarities with QP problems; in fact they can be classified as simple subproblems, with a zero Hessian and further simplifications. It is convenient to present the corresponding linear system in the 2×2 block form

$$\begin{pmatrix} S^{-1} Z & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} \Delta x \\ \Delta \lambda \end{pmatrix} = \begin{pmatrix} v_1 \\ v_2 \end{pmatrix}, \tag{1.2}$$

where $S^{-1}Z$ is diagonal and changes throughout the LP iteration, and the right-hand side vector is constructed in a similar manner to (1.1).

For both LP and QP problems the saddle point matrix becomes highly ill-conditioned as the solution is approached, due to increased ill-conditioning of the $(1,1)$ block. In the typical case when inequality constraints are simple bounds on the primal variables, $H + C^T S^{-1} Z C$ is a diagonal perturbation of H. The complementarity of S and Z gives rise to the simultaneous presence of extremely small and extremely large values in $S^{-1}Z$. For both LP and QP problems the matrices $S^{-1}Z$ and $H + C^T S^{-1} Z C$ will never be exactly singular but will approximate singularity as the solution is approached. This is a key property that must be taken into account.

A detailed description of the theory involved in interior point methods for LP and QP can be found, for example, in [23, 28]. The methodology of using a predictor and corrector step calculation at each iteration of the solve was presented in [21]. These references point out the importance of efficiently solving the step equations and identify the difficulties involved. Many software packages, such as IPOPT [27], LIPSOL [29], and OOQP [13], use direct solvers to solve the step equations. While

this is a sound approach for many problems, it may suffer the combined ailments of poor scaling with problem size and deterioration in conditioning and numerical stability as the QP or LP solution is approached. In particular, special care must be taken in matrix factorizations to deal with the presence of large and small pivots [22]. These factors motivate the study of iterative methods in the context of optimization. Modern solution techniques, such as Krylov subspace methods, rely on the ease of sparse matrix-vector products and converge at a rate dependent on the number of distinct eigenvalues of the preconditioned matrix [7, 25].

In this paper we study a preconditioner which has the property that the more ill-conditioned the (1,1) block of the saddle point matrix is, the faster a minimum residual solver, such as MINRES, converges (in terms of outer iterations). Therefore, the corresponding solver is particularly effective in the last few iterations of the LP or QP solver. Our approach is based on augmentation of the (1,1) block using a weight matrix. Augmentation has been used in several areas of applications and in many flavors (see, for example, [3] and references therein). Our particular methodology extends recent work done by Greif and Schötzau [17, 18] into new directions and introduces a technique that fits well into the algebraic framework of interior point methods for optimization problems.

Our preconditioner is part of a growing set of preconditioned iterative approaches for solving optimization problems. A preconditioning technique that has emerged recently as a popular choice is the class of constraint preconditioners (see Lukšan and Vlček [20] or Keller, Gould, and Wathen [19] and references therein), which rely on leaving the constraints intact and seeking to replace the $(1,1)$ block by a matrix that is much easier to invert. Recent work by Dollar and Wathen [9] introduces implicit factorizations that further facilitate the use of constraint preconditioners. Similar factorizations are applied to regularized saddle point systems by Dollar et al. in [8]. Forsgren, Gill, and Griffin [10] extend constraint-based preconditioners to regularized saddle point systems that use an approximation of the $(1,1)$ block coupled with an augmenting term. The technique is intended for interior point methods for general constrained optimization problems. In [5] Bergamaschi, Gondzio, and Zilli employ constraint preconditioners with diagonal $(1,1)$ blocks, which allow for factoring the preconditioner or its reduced normal equation form. Approximate constraint preconditioners are further explored in [4].

Other block structured preconditioning approaches are also available. For example, Oliveira and Sorensen [24] consider LP and make use of block triangular preconditioners that have the constraint matrix in their $(1,2)$ block and easy-to-invert matrices in the main diagonal. The preconditioned matrix has an eigenvalue $\lambda = 1$ with a high algebraic multiplicity, and since the $(1,1)$ block of the saddle point system is diagonal for linear programs, the preconditioner can be factored and solved for efficiently. The use of iterative methods in constrained optimization also relies on the notion of inexact interior point methods. These have been investigated in [1, 2, 12] and other papers. The findings justify the use of approximate solutions at each step of the method, and we explore this experimentally.

The remainder of this paper is organized as follows. In section 2 the preconditioner and its general form are presented, and algebraic properties are derived. In section 3 the choices of the weight matrix W and inner solves are discussed. This is followed by two schemes for reducing fill-in in the preconditioner when dense rows are present. In section 4 we present numerical results demonstrating performance of the preconditioner. In section 5 we draw some conclusions.

2. The preconditioning approach. We will adopt the general notation

$$\mathcal{A} = \begin{pmatrix} G & A^T \\ A & 0 \end{pmatrix} \tag{2.1}$$

to represent the saddle point matrices of (1.1) and (1.2). We assume that G is symmetric and positive semidefinite with nullity p, and that A is of size $n \times m$ and has full row rank. Note that the assumption that $\mathcal{A}$ is nonsingular implies that $\text{null}(A) \cap \text{null}(G) = \{0\}$, which we use in our analysis below.

2.1. A block triangular preconditioner. Consider the preconditioner

$$\mathcal{M} = \begin{pmatrix} G + A^T W^{-1} A & kA^T \\ 0 & W \end{pmatrix},$$

where k is a scalar and W is an $m \times m$ symmetric positive definite weight matrix. The eigenvalues of the preconditioned matrix $\mathcal{M}^{-1}\mathcal{A}$ satisfy the generalized eigenvalue problem

$$\begin{pmatrix} G & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \lambda \begin{pmatrix} G + A^T W^{-1} A & kA^T \\ 0 & W \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}. \tag{2.2}$$

The second block row gives $y = \frac{1}{\lambda} W^{-1} A x$, and substituting it into the first block equation gives

$$\lambda(\lambda - 1)Gx + (\lambda^2 + k\lambda - 1)A^T W^{-1} A x = 0.$$

Regardless of the choice of k, we see that $\lambda = 1$ with algebraic multiplicity $n - m$. From the nullity of G it follows that there are p linearly independent null vectors of G. For each such null vector we can find two λ values satisfying $\lambda^2 + k\lambda - 1 = 0$. Thus we have

$$\lambda_{\pm} = \frac{-k \pm \sqrt{k^2 + 4}}{2},$$

each with algebraic multiplicity p. The remaining $2(m - p)$ eigenvalues satisfy

$$-\frac{\lambda^2 - \lambda}{\lambda^2 + k\lambda - 1} Gx = A^T W^{-1} A x. \tag{2.3}$$

Since G is positive semidefinite and $A^T W^{-1} A$ is positive definite, we must have

$$-\frac{\lambda^2 - \lambda}{\lambda^2 + k\lambda - 1} > 0,$$

and thus we can write $\frac{\lambda^2 - \lambda}{\lambda^2 + k\lambda - 1} = -\mu^2$ for some $\mu \in \mathbb{R},\ \mu > 0$. We can rearrange this into

$$(1 + \mu^2)\lambda^2 + (k\mu^2 - 1)\lambda - \mu^2 = 0,$$

giving

$$\lambda_{\pm} = \frac{-(k\mu^2 - 1) \pm \sqrt{(k\mu^2 - 1)^2 + 4\mu^2(1 + \mu^2)}}{2(1 + \mu^2)}. \tag{2.4}$$

This expression gives an explicit formula in terms of the generalized eigenvalues of (2.3) and can be used to identify the intervals in which the eigenvalues lie. To illustrate this, we examine the case $k = -1$, which corresponds to setting the $(1, 2)$ block of the preconditioner to be $-A^T$. We have $\lambda = 1$ with multiplicity $n - m$, and $\lambda_\pm = \frac{1\pm\sqrt{5}}{2}$, each with multiplicity p. By (2.4) we have

$$\lambda_\pm = \frac{1 \pm \sqrt{1 + \frac{4\mu^2}{1+\mu^2}}}{2}.$$

Since λ_+ is a strictly increasing function of μ on $(0, \infty)$ (and λ_- are strictly decreasing), the intervals containing the remaining eigenvalues can be found using $\lim_{\mu\to 0,\infty} \lambda_\pm(\mu)$. From this, one finds that the remaining eigenvalues lie in the intervals $(\frac{1-\sqrt{5}}{2}, 0) \cup (1, \frac{1+\sqrt{5}}{2})$. It is worth noting that since G is typically highly singular, many of the generalized eigenvalues are large, in which case the corresponding eigenvalues $\lambda_\pm$ are bounded away from zero. For example, many of the negative eigenvalues will tend to $\frac{1-\sqrt{5}}{2}$. Since the $2p$ eigenvalues $(k \pm \sqrt{k^2 + 4})/2$ are unbounded as k goes to ∞, we conclude that k should be of moderate size.

2.2. A block diagonal preconditioner. The choice $k = 0$ yields a block diagonal symmetric positive definite preconditioner of the form

$$\mathcal{M} = \begin{pmatrix} G + A^T W^{-1} A & 0 \\ 0 & W \end{pmatrix}. \tag{2.5}$$

It is suitable for use with minimal residual methods based on short recurrences, such as MINRES. This preconditioner and its spectral properties in a general algebraic context have been recently studied in [17] and applied (in a slightly different form) to the Maxwell equations in [18]. In the context of optimization, it is useful to examine the behavior on the reduced space generated by projections onto the null space of A. We offer such results below, and prove them using orthogonal transformations, by taking steps similar to those taken in [19].

As before, we assume that G is positive semidefinite with nullity p. Suppose further that A has full rank, and choose W to be symmetric positive definite. It is straightforward to show that if $\mathcal{A}$ is nonsingular, then $G + A^T W^{-1} A$ must be symmetric positive definite. As is shown in [17], the eigenvalues of the preconditioned matrix $\mathcal{M}^{-1}\mathcal{A}$ and their multiplicities can be found directly through the generalized eigenvalue problem

$$\begin{pmatrix} G & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} \bar{x} \\ \bar{y} \end{pmatrix} = \lambda \begin{pmatrix} G + A^T W^{-1} A & 0 \\ 0 & W \end{pmatrix} \begin{pmatrix} \bar{x} \\ \bar{y} \end{pmatrix}. \tag{2.6}$$

Let $QR = A^T$ be an "economy size" QR factorization of A^T, where Q is $n \times m$ and R is $m \times m$. Define Z to be an $n \times (n - m)$ orthogonal basis for the null space of A. Since $Z \cup Q$ forms an orthogonal basis for $\mathbb{R}^n$, any vector $x \in \mathbb{R}^n$ can be written as $x = Zx_z + Qx_q$.

Following the spirit of the proof of [19, Thm. 2.1], we define the $(n+m) \times (n+m)$ matrix

$$P = \begin{pmatrix} Z & Q & 0 \\ 0 & 0 & I \end{pmatrix} \tag{2.7}$$

and perform a similarity transformation as follows. We express $\bar{x} = Z\bar{x}_z + Q\bar{x}_q$, and let $v = (x_z, x_q, y)^T$, where $Pv = (\bar{x}_z, \bar{x}_q, \bar{y})^T$. The generalized eigenvalue problem can then be written as $P^T\mathcal{A}Pv = \lambda P^T\mathcal{M}Pv$. This yields

(2.8)
$$\begin{pmatrix} Z^TGZ & Z^TGQ & 0 \\ Q^TGZ & Q^TGQ & R \\ 0 & R^T & 0 \end{pmatrix} \begin{pmatrix} x_z \\ x_q \\ y \end{pmatrix} = \lambda \begin{pmatrix} Z^TGZ & Z^TGQ & 0 \\ Q^TGZ & Q^TGQ + RW^{-1}R^T & 0 \\ 0 & 0 & W \end{pmatrix} \begin{pmatrix} x_z \\ x_q \\ y \end{pmatrix}.$$

By inspection, we observe that by setting $\lambda = 1$, the system reduces to

$$\begin{pmatrix} 0 & 0 & 0 \\ 0 & -RW^{-1}R^T & R \\ 0 & R^T & -W \end{pmatrix} \begin{pmatrix} x_z \\ x_q \\ y \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

Let e_i denote the ith column of the identity matrix. Evidently there are $n - m$ corresponding eigenvectors that can be written in the form

$$(x_z, x_q, y) = (e_i, 0, 0). \tag{2.9}$$

In addition, m linearly independent eigenvectors can be written in the form

$$(x_z, x_q, y) = (0, e_i, W^{-1}R^Te_i). \tag{2.10}$$

Now consider $\lambda = -1$. Equation (2.8) reduces to

$$\begin{pmatrix} 2Z^TGZ & 2Z^TGQ & 0 \\ 2Q^TGZ & 2Q^TGQ + RW^{-1}R^T & R \\ 0 & R^T & W \end{pmatrix} \begin{pmatrix} x_z \\ x_q \\ y \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

Any vector $x^* = Zx_z^* + Qx_q^*$ in the null space of G satisfies $G(Zx_z^* + Qx_q^*) = 0$. There are p such vectors, so p linearly independent eigenvectors of the form

$$(x_z, x_q, y) = (x_z^*, x_q^*, -W^{-1}R^Tx_q^*) \tag{2.11}$$

will satisfy (2.8) with $\lambda = -1$.

By [17, Thm. 2.2] the remaining eigenvalues, $\lambda \neq \pm 1$, lie in the interval $(-1, 0)$. To derive an expression for the corresponding eigenvectors we reduce (2.8) to an eigenvalue problem in x_q. From the block row in (2.8), $y = \frac{1}{\lambda}W^{-1}R^Tx_q$. The first line of the equation can be reduced to

$$x_z = -(Z^TGZ)^{-1}Z^TGQx_q.$$

Substituting this into the second line of (2.8) and simplifying yields

$$RW^{-1}R^Tx_q = \lambda\left[C^T(Z^TGZ)^{-1}C - Q^TGQx_q - RW^{-1}R^T\right]x, \tag{2.12}$$

where $C = Z^TGQ$. We have actually proved the following theorem.

THEOREM 2.1. [illegible] $\mathcal{M}^{-1}\mathcal{A}$ [illegible] $\lambda = 1$ [illegible] n [illegible] (2.9) [illegible] (2.10) [illegible] $\lambda = -1$ [illegible] p [illegible] (2.11) [illegible] [illegible] $(-1, 0)$ [illegible] (2.12)

Theorem 2.1 illustrates the strong spectral clustering when the $(1,1)$ block of $\mathcal{A}$ is singular. A well-known difficulty associated with interior point methods is the increased ill-conditioning of the $(1,1)$ block as the solution is approached. Our claim is that the preconditioner performs robustly even as the problem becomes more ill-conditioned; in fact the outer iteration count decreases. On the other hand, solving for the augmented (1,1) block may be more computationally difficult and requires an effective approach such as inexact solves.

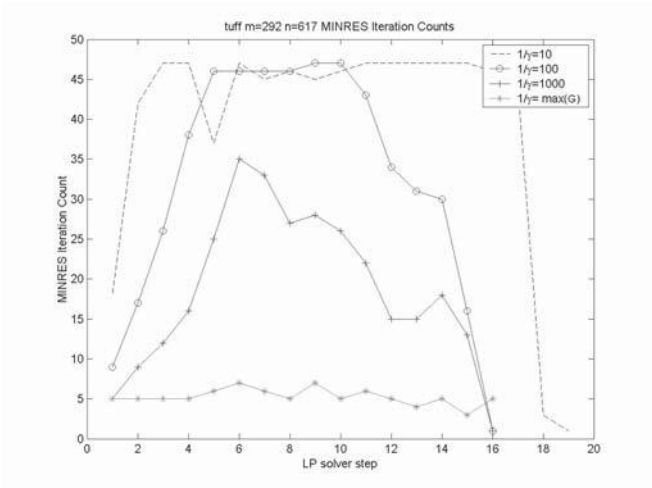

FIG. 3.1. *MINRES iteration counts with various* $W = \gamma I$. *Problem tuff has* $m = 292$, $n = 617$ *after LIPSOL preprocessing. MINRES iteration counts are plotted at each LP step for the various choices of* γ. *MINRES error tolerance was set to* 10^{-8}. *In final iterations,* $\max(G) > 10^8$.

3. Practical considerations and computational cost. In this section we discuss the choice of the weight matrix W and ways of reducing the cost of inner iterations. We also describe procedures for dealing with a dense row.

3.1. The inner iteration and choice of the weight matrix. There are two critical issues to consider in the application of the preconditioner. First, the weight matrix W must be chosen. Then, given a weight matrix, an efficient method of factoring or iteratively solving systems with the preconditioner must be sought. These considerations are motivated by the fact that each iteration of a preconditioned Krylov subspace method requires solutions to linear systems of the form $\mathcal{M}x = b$; based on the block structure of $\mathcal{M}$, this requires solving systems with $G + A^T W^{-1} A$ and W.

The simplest choice of a weight matrix is diagonal, and it clearly makes inverting W trivial. A simple, one-parameter choice is a scaled identity. Letting $W = \gamma I$, γ could be chosen so that the augmenting term $\frac{1}{\gamma} A^T A$ is of a norm comparable to G. See, for example, [14] for a general algebraic discussion. Note that since G changes at each step, γ must also be updated.

For LP problems the matrix G is diagonal, and choosing $1/\gamma$ related to an ordered statistic such as the mean, median, or maximum of the diagonal entries in G has proved to be effective in our experiments in reducing the number of MINRES iterations required at each step. This is illustrated in Figure 3.1 for the NETLIB problem "tuff," where the MINRES residual norms (in the predictor step) are plotted against each step of the LP solve. An arbitrary fixed choice of $1/\gamma$ leads to a "hump" with a large number of intermediate outer iteration counts. As predicted by our theoretical results, close to the solution the near-singularity of the (1,1) block results in fast convergence regardless of the choice of γ. But as is illustrated in the figure, it is the dynamic choice of γ^{-1} as the maximal entry in G that yields rapid convergence of MINRES throughout the LP iteration, and in fact the "hump" is flattened in this case. The choice $1/\gamma = \max(G)$ results in a set of values monotonically increasing from approximately 1 to approximately 10^{10}, and the iteration significantly outperforms

other choices in terms of the number of MINRES iterations, while the cost of each inner solve does not change.

For QP problems, similar approaches are possible. With $W = \gamma I$, a choice of γ such as $\|A\|^2/\|G\|$ (or an approximation thereof) ensures that the norm of the augmenting term is not too small in comparison with G. (See [14] for an analysis of the effect of scaling of this sort on the condition number of the matrix.) For solving $\mathcal{M}x = b$, iterative and direct methods are possible. In an iterative scheme the inner iteration can be solved using the preconditioned conjugate gradient (PCG) method. If a direct solver is preferred, the symmetric positive definiteness of the preconditioner allows for use of a sparse Cholesky factorization.

3.2. Dealing with a dense row in A. The presence of even a single dense row in A can lead to a fully dense augmenting matrix $A^T W^{-1} A$. We present two possible approaches for dealing with dense rows in the situation where it is desirable to explicitly form the $(1,1)$ block of the preconditioner.

First, we present an asymmetric preconditioner, motivated by the analysis of section 2.1. With a_i denoting the dense column i of A^T, and e_i being the ith column of an $m \times m$ identity, we define a preconditioner

$$\hat{\mathcal{M}} = \begin{pmatrix} G + A^T \bar{W} A & -a_i e_i^T \\ 0 & W \end{pmatrix}. \tag{3.1}$$

Suppose $W = \gamma I$ for some $\gamma > 0$, and let $\bar{W} = \frac{1}{\gamma} I - \frac{1}{\gamma} e_i e_i^T$. Assuming $\hat{\mathcal{M}}$ is nonsingular, the eigenvalues of the preconditioned matrix are given by the following theorem.

THEOREM 3.1. [illegible] $\hat{\mathcal{M}}^{-1}\mathcal{A}$ [illegible] $\lambda = 1$ [illegible] $n - 1$ [illegible] $\lambda = -1$ [illegible] p [illegible] A [illegible].

Exactly as in the proof of Theorem 2.1 we define Q, R, Z and transform the generalized eigenvalue problem using P as in (2.7). This yields

$$\begin{pmatrix} Z^TGZ & Z^TGQ & 0 \\ Q^TGZ & Q^TGQ & R \\ 0 & R^T & 0 \end{pmatrix} \begin{pmatrix} x_z \\ x_q \\ y \end{pmatrix} = \lambda \begin{pmatrix} Z^TGZ & Z^TGQ & 0 \\ Q^TGZ & Q^TGQ + \frac{1}{\gamma} RR^T - \frac{1}{\gamma} r_i r_i^T & -r_i e_i^T \\ 0 & 0 & \gamma I \end{pmatrix} \begin{pmatrix} x_z \\ x_q \\ y \end{pmatrix}, \tag{3.2}$$

where r_i denotes the ith column of R.

As before, by inspection we check $\lambda = 1$, which reduces the equation to

$$\begin{pmatrix} 0 & 0 & 0 \\ 0 & -\frac{1}{\gamma} RR^T + \frac{1}{\gamma} r_i r_i^T & R + r_i e_i^T \\ 0 & R^T & -\gamma I \end{pmatrix} \begin{pmatrix} x_z \\ x_q \\ y \end{pmatrix} = 0.$$

Immediately we see $n-m$ corresponding eigenvectors of the form $(x_z, x_q, y) = (u, 0, 0)$ for $(n-m)$ linearly independent vectors u. An additional $m-1$ linearly independent eigenvectors can be seen by finding consistent solutions in the free variables x_q, y to the equation

$$\begin{pmatrix} -\frac{1}{\gamma} RR^T + \frac{1}{\gamma} r_i r_i^T & R + r_i e_i^T \\ R^T & -\gamma I \end{pmatrix} \begin{pmatrix} x_q \\ y \end{pmatrix} = 0.$$

Substituting $y = \frac{1}{\gamma} R^T x_q$, this requires $2\frac{1}{\gamma} r_i r_i^T x_q = 0$. In general we can find exactly $m-1$ eigenvectors orthogonal to r_i. That is, there are $m-1$ eigenvectors of the form $(x_z, x_q, y) = (0, x_q^*, \frac{1}{\gamma} x_q^*)$, where x_q^* is orthogonal to r_i, corresponding to $\lambda = 1$.

The p eigenvectors corresponding to $\lambda = -1$ are also evident by simple inspection. Substituting $\lambda = -1$ requires finding a solution to

$$\begin{pmatrix} 2Z^TGZ & 2Z^TGQ & 0 \\ 2Q^TGZ & 2Q^TGQ + \frac{1}{\gamma}RR^T - \frac{1}{\gamma}r_ir_i^T & R - r_ie_i^T \\ 0 & R^T & \gamma I \end{pmatrix} \begin{pmatrix} x_z \\ x_q \\ y \end{pmatrix} = 0.$$

Vectors x_z, x_q, y can be found to solve this equation. Consider any $x^* = Zx_z^* + Qx_q^*$ in the null space of G. Then $GZx_z^* + GQx_q^* = 0$, and we are left with finding a y such that

$$\begin{pmatrix} \frac{1}{\gamma}RR^T - \frac{1}{\gamma}r_ir_i^T & R - r_ie_i^T \\ R^T & \gamma I \end{pmatrix} \begin{pmatrix} x_q^* \\ y \end{pmatrix} = 0$$

for the fixed x_q^*. The choice $y = -\frac{1}{\gamma}R^Tx_q^*$ correctly cancels the left-hand side, and it becomes apparent why the minus sign was chosen for the $(1,2)$ block of $\hat{\mathcal{M}}$; without it, we could not explicitly find a suitable y value. Since the p vectors in the null space of G are linearly independent, we have constructed a p-dimensional eigenbasis for $\hat{\mathcal{M}}^{-1}\mathcal{A}$, corresponding to $\lambda = -1$. □

Theorem 3.1 shows that $\hat{\mathcal{M}}$ is sparse and at the same time maintains strong spectral clustering. The preconditioner is asymmetric, however, and it is desirable to find a simpler form (that still retains the strong spectral properties).

To this end, consider replacing preconditioner $\hat{\mathcal{M}}$ from (3.1) with

$$\bar{\mathcal{M}} = \begin{pmatrix} G + A^T\bar{W}A & 0 \\ 0 & W \end{pmatrix},$$

where $\bar{W}$ is again an approximation to W^{-1}. Similarly to the asymmetric case, consider the choice

$$\bar{W} = W^{-1} - \frac{1}{\gamma}e_ie_i^T.$$

The matrix $\bar{W}$ is diagonal but singular, since each of its rows that corresponds to a dense row of A is identically zero. As a result, the matrix $A^T\bar{W}A$ no longer experiences fill-in from the product $a_ia_i^T$.

This modification does not result in significant changes in the spectral clustering of the preconditioned matrix. Since $\bar{\mathcal{M}}$ is a rank-1 perturbation of $\mathcal{M}$ by (2.5), it follows that $\bar{\mathcal{M}}^{-1}\mathcal{A}$ is just a rank-1 perturbation of $\mathcal{M}^{-1}\mathcal{A}$ and we can apply interlacing results.

If we let μ_i denote the ith largest eigenvalue of $\bar{\mathcal{M}}^{-1}\mathcal{A}$, and let λ_i be the ith largest eigenvalue of $\mathcal{M}^{-1}\mathcal{A}$, interlacing guarantees that $\lambda_{i-1} \le \mu_i \le \lambda_i$. Since the eigenvalues λ_i are known and have high algebraic multiplicities, so are the eigenvalues μ_i, and for each multiple eigenvalue λ_i the multiplicity of the corresponding μ_i reduces by at most 1, due to interlacing. Thus, if preconditioned MINRES is used, we have strong spectral clustering without introducing any fill-in. We can summarize our findings as follows.

PROPOSITION 3.2. [illegible] $\bar{\mathcal{M}}$ [illegible] $\bar{\mathcal{M}}^{-1}\mathcal{A}$ [illegible] $\lambda = 1$ [illegible] $n - 1$ [illegible] $\lambda = -1$ [illegible] $p - 1$

4. Numerical experiments. Numerical experiments were done on problems from the CUTEr test suite [16], using MATLAB, on an Intel 2.5GHZ processor with 2GB of RAM. In our experiments we focused on QP test problems with a nondiagonal and semidefinite $(1,1)$ block, for which our preconditioner is suitable. In this section we illustrate how the number of iterations required by MINRES drops to its theoretical limit and how inexact inner iterations reduce the overall computational work. (For the latter we settle for experimental observations; see, for example, [15] or [26] for general theory and analysis.) We also include results for the row removal scheme discussed in section 3.2.

We used a variety of methods for solving the inner iteration $\mathcal{M}x = b$, but most of our experiments made use of ILUPACK [6]. This package uses multilevel incomplete LU factorizations as preconditioners for CG and GMRES, and was found to be efficient and easy to use. While we tested a range of values, the results we present here were collected with an ILUPACK backwards error setting of 1e−06.

Tables 4.1–4.4 demonstrate several measures of the work required in applying our method. In these tables, n, m_1, m_2 denote the dimensions of the problem being solved, as defined in the introduction, and N_{QP} denotes the total number of QP steps required for convergence. The average number of Krylov solver iterations per QP steps is given by N_K. The average number of iterations of PCG used by ILUPACK in the inner iteration, and the total number summed over all QP steps, are given by N_I and $Tot(N_I)$, respectively. The time (in seconds) required to solve a problem is given in the column Time(s).

Tables 4.1–4.2 show results for applying BiCG-STAB, once with a tight outer tolerance of 10^{-6} and once with a loose outer tolerance of 10^{-2}. Tables 4.3–4.4 show results, using the same tolerances, for applying MINRES. The following observations can be made. In general, loosening tolerance for the Krylov solver increases the overall number of QP iterations only modestly, and at the same time substantially reduces (in most tested examples) the overall number of solves. We mention here that loosening the convergence tolerance of the innermost iterations did not result in

a similar reduction of computational work. We therefore observe in our experiments that inexactness is more effective on the level of the outer Krylov iterations rather than on the level of the innermost iterations.

Comparing the performance of BiCG-STAB to the performance of MINRES is not within our stated goals, but having results using more than one Krylov solver allows us to confirm the consistency of convergence behavior for most problems. The two solvers do behave in a similar manner, and the modest running times indicate that the proposed preconditioner seems to be efficient and robust.

Next, to demonstrate the application of the row removal scheme proposed in sec-

tion 3.2 we consider the blockqp set of problems. These problems are characterized by a Hessian with two nonzero diagonals, and a constraint matrix with a single nonzero diagonal, a dense row, and a dense column. As a result, if the augmentation preconditioner is fully formed, it will be dense. To avoid this, the symmetric row removal scheme is used. This leads to a preconditioner with a nearly diagonal $(1, 1)$ block, which can be approximately factored with ILUPACK in an efficient manner. Table 4.5 presents results confirming that the row removal scheme can lead to a convergent solution while avoiding the intensive memory requirements of fully forming the augmenting $(1, 1)$ block of the preconditioner.

Theorem 2.1 guarantees increased spectral clustering of the preconditioned matrix $\mathcal{M}^{-1}\mathcal{A}$ when the $(1, 1)$ block of $\mathcal{A}$ is singular. The LP and QP saddle point matrices, however, become approximately singular only as a solution is approached. It is useful to evaluate whether the strong clustering of the preconditioned eigenvalues will be achieved under approximate conditions. To test this, we examined the eigenvalues of the preconditioned matrix at various steps in the process of solving an LP problem. Figure 4.1 depicts the sorted eigenvalues at three different steps of the LP solve for the problem share2b.

Preconditioned eigenvalues at the first, sixth, and tenth LP steps are shown from top to bottom. (The problem took 13 steps to solve.) As expected by Theorem 2.1, all

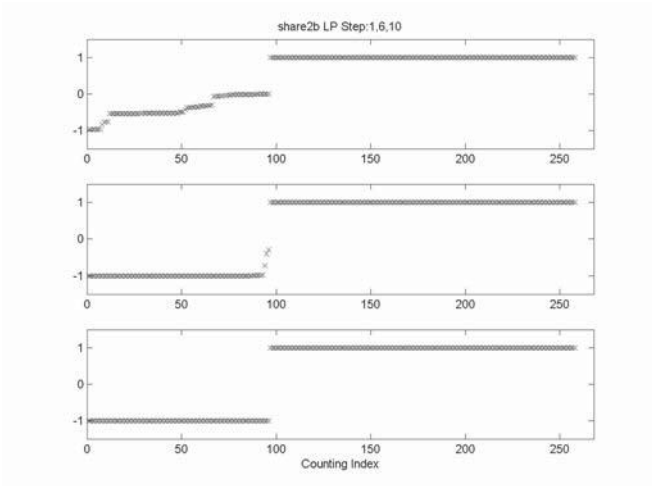

FIG. 4.1. *Eigenvalues of $\mathcal{M}^{-1}\mathcal{A}$ at different steps of the LP solution for share2b. Eigenvalues are plotted in sorted order with values along the y axis. As governed by Theorem* 2.1*, all unclustered eigenvalues lie in the interval* $(-1, 0)$.

eigenvalues lie between -1 and 1. Furthermore, right from the first iteration, $\lambda = 1$ has high multiplicity. It is interesting to note that already by the sixth step (the middle subplot), only a handful of unclustered eigenvalues remains. In the tenth LP step, all eigenvalues appear to be ± 1. These observations all confirm Theorem 2.1 and illustrate how tightly clustered the preconditioned eigenvalues can be when the saddle point system is severely ill-conditioned. This also demonstrates that even in early iterations the preconditioner can be effective.

Next, we present preliminary comparisons with constraint preconditioners. We stress that we have performed only a limited set of tests with a specific simple choice of a (1,1) block for constraint preconditioners; a comprehensive set of tests will be necessary to reach definite conclusions. Our results are mixed, as we illustrate below. Figure 4.2 shows a basic comparison of MINRES iteration counts (of the predictor computation). The plot shows the MINRES iteration counts for each QP step for the problem cvxqp1. The constraint preconditioner used for this plot was chosen to have a $(1, 1)$ block equal to the diagonal of the saddle point system. For both preconditioners, an exact inner solve was applied. For this problem the constraint preconditioner outperformed the augmentation preconditioner in most steps of the QP solve and in terms of overall computational work. In the final few steps, however, where the saddle point matrix was highly ill-conditioned, MINRES iteration counts for our preconditioner dropped significantly and convergence was almost immediate, whereas convergence of the constraint preconditioner was still within approximately 20 iterations. This again confirms Theorem 2.1 and indicates that the proposed preconditioner is most effective when the saddle point matrix is close to singular. This in fact may suggest a hybrid approach in which it may be useful to switch to an augmentation-based preconditioner when iterates approach the solution.

Figure 4.3 shows an example in which our preconditioner is superior to the constraint preconditioner throughout the iteration. For the QP problem cvxqp2, MINRES iteration counts (of the predictor computation) are plotted against the QP step. This is a large problem, but throughout the solve no more than 30 iterations are

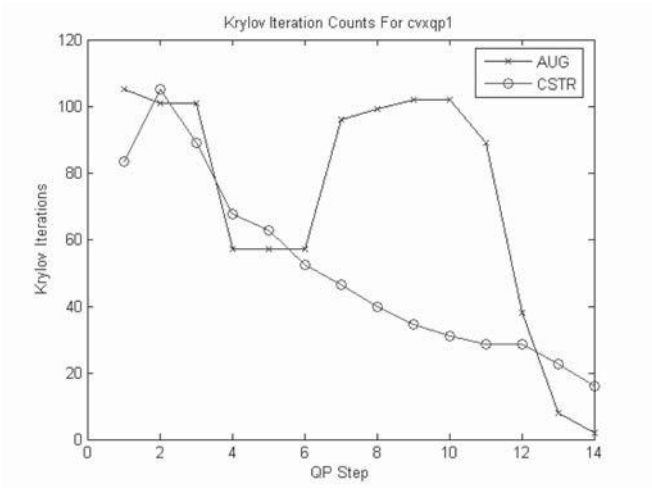

FIG. 4.2. *MINRES iteration counts for cvxqp*1, $n = 1000$, $m_1 = 250$. *Note that in the final few steps, iteration counts for the augmentation preconditioner significantly reduce, as the* $(1, 1)$ *block becomes increasingly rank deficient.*

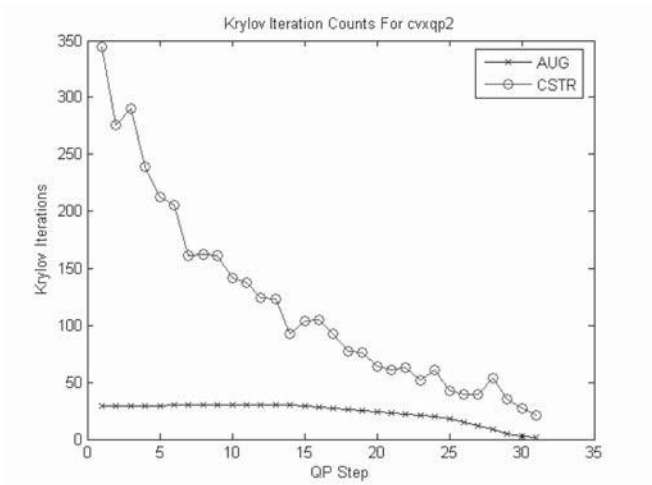

FIG. 4.3. *MINRES iteration counts for cvxqp*2, $n = 10000$, $m_1 = 2500$. *The augmentation preconditioner approaches the rate of convergence predicted by our analysis: the final two iteration counts of MINRES are* 3 *and* 2, *respectively.*

needed per step. In the final few QP steps, the MINRES iteration count approaches its theoretical limit of two. Depicted in the same plot are the corresponding predictor iteration counts for a constraint preconditioner, with the $(1, 1)$ block set to match the diagonal of the saddle point system. The constraint preconditioner consistently requires more MINRES iterations at each QP step.

5. Conclusions. We have studied preconditioners for linear and quadratic programming problems and have demonstrated their merits. The preconditioners are well suited for saddle point systems with a highly singular (1, 1) block. For interior point iterations, as convergence is approached and the $(1, 1)$ block of the saddle point ma-

trix becomes more ill-conditioned, convergence is fastest and can theoretically occur within two outer iterations (in the absence of roundoff errors). We have also provided spectral analysis on the null space of the constraint matrix.

The choice of the weight matrix W is crucial and we have tested with simple scaled identity matrices that incorporate a dynamic choice of the parameter throughout the iteration. A good choice may substantially reduce the iteration counts throughout, as we demonstrate by the "flattened hump" for an LP problem in Figure 3.1. Furthermore, we have shown that applying an inexact version of the Krylov solver throughout the iteration, with a convergence tolerance as low as 0.01, significantly reduces the overall amount of computational work.

The excellent performance of the preconditioner, in particular near the solution of the optimization problem, may suggest that, regardless of what preconditioner is used throughout the iteration, it may be worthwhile to switch to a preconditioner of the form explored here as the iterates approach the solution.

Acknowledgments. We would like to thank the two referees for their constructive comments.

AN OCTREE METHOD FOR PARAMETRIC IMAGE REGISTRATION*

ELDAD HABER†, STEFAN HELDMANN†, AND JAN MODERSITZKI‡

Abstract. Even for reasonably sized three-dimensional (3D) images, image registration becomes a computationally intensive task. Here, we introduce and explore the concept of octrees for registration which drastically reduces the amount of processed data and thus the computational costs. We show how to map the registration problem onto an octree and present a suitable optimization technique. Furthermore, we demonstrate the performance of the new approach by academic (two-dimensional) as well as real life (3D) examples. These examples indicate that the computational time can be reduced by a factor of 3–4 compared with standard approaches.

Key words. image registration, adaptive discretization, octree, nonlinear optimization

1. Introduction.

Image registration is one of today's challenging image processing problems. Given a so-called reference image R and a so-called template image T, the basic idea is to find a [illegible] transformation such that a transformed version of the template image becomes [illegible] to the reference image. Image registration has to be applied whenever images resulting from different times, devices, and/or perspectives need to be compared or integrated; see, e.g., [4, 17] and references therein.

The computation of parametric image registration has two main building blocks. The first is a distance measure $\mathcal{D}$ quantifying distance or similarity of images. The second building block is a typically low dimensional parameterizable search space $\mathcal{V}$ for the desired transformation.

For example, if $\mathcal{V}$ is a linear space, any transformation can be expanded into a sum of basis functions with coefficients γ_j, i.e.,

$$\boldsymbol{\Phi}(\boldsymbol{\gamma})(\mathbf{x}) := \sum_{j=1}^{n} \gamma_j \, \boldsymbol{\psi}_j(\mathbf{x}) \quad \text{with} \quad \boldsymbol{\gamma} := (\gamma_1, \ldots, \gamma_n)^\top \in \mathbb{R}^n. \tag{1.1}$$

Therefore, any transformation in $\mathcal{V}$ is parameterized by a vector $\boldsymbol{\gamma}$.

The choice of the particular subspace can be thought of as a type of regularization, added to the problem to overcome ill-posedness; see, e.g., [17]. Typical examples include rigid, affine linear, and spline transformations [4].

In the following we model the images R and T as smooth functions mapping from $\mathbb{R}^d$ to $\mathbb{R}$ (practically, these functions are obtained by interpolation of the given discrete two-dimensional (2D) or three-dimensional (3D) data). With some abuse of notation, the transformed image is denoted by $T(\boldsymbol{\gamma})$, where

$$T(\boldsymbol{\gamma})(\mathbf{x}) := T(\boldsymbol{\Phi}(\boldsymbol{\gamma})(\mathbf{x})).$$

A common treatment of parametric registration is based on the following minimization problem [23, 20]: Find a parameter $\boldsymbol{\gamma}^*$ minimizing

$$\mathcal{J}(\boldsymbol{\gamma}) := \mathcal{D}(R, T(\boldsymbol{\gamma})). \tag{1.2}$$

Generally, the optimization problem (1.2) cannot be solved analytically, and thus numerical schemes are required. Although the number of unknowns $\boldsymbol{\gamma}$ might be small, computing the transformed image $T(\boldsymbol{\gamma})$ can be computationally expensive for 3D images. For example, the computation of $T(\boldsymbol{\gamma})$ for a 512^3 voxel image results in more than 10^8 interpolation points to be evaluated. Thus, efficient algorithms are required in order to perform the registration in a reasonable amount of time.

In order to keep the computational time reasonable, it is desirable to reduce the amount of data which has to be processed. A simple reduction can be obtained through down-sampling. However, naive down-sampling results in a loss of possibly important image features. Nevertheless, down-sampling can be safely done in parts of the image with low variations. A proper use of this observation can substantially reduce the storage needed to represent the image and the amount of the computation needed for a registration.

Octrees provide a straightforward approach to such a context-driven data sparsification. The octree data presentation uses few voxels for regions with small variability and many voxels for regions with high variability.

Although generating an octree from a known image is a simple task, solving the registration problem on octrees is far less trivial. The main difficulty is that a proper registration requires the octree representation of $T(\boldsymbol{\gamma}^*)$, where γ^* is a minimizer of (1.2). Because this minimizer is unknown a priori, we cannot generate a reliable octree for $T(\boldsymbol{\gamma}^*)$. We overcome this problem by an updating of the current octree using only local refinement. Although these refinement steps require additional computations, the procedure still reduces the computational costs by one order of magnitude.

Using octrees in image processing is not new. Recent efforts have been made in the field of computer graphics [16, 15]. In particular, the work of Losasso and colleagues on octree discretization demonstrates that images of fine-detail flows and smoke can be represented efficiently and reliably with this type of data structure. Other related work on motion estimation using quadtree splines has been proposed in [21, 22, 14]. In [22, 14] the displacement field was discretized using quadtree splines, and in [21] a 2D surface was embedded in three dimensions and represented using an octree.

Our approach can be thought of as an extension of the work proposed in [21], using octrees for 3D rather than 2D volumes. Furthermore, our approach uses more advanced optimization strategy (merit function and backtracking) in order to ensure global convergence.

Our approach is different and extends the previous work to three dimensions and works with global transformation. Furthermore, we use techniques borrowed from numerical PDEs in order to efficiently solve the minimization problem obtained on the octree.

The paper is organized as follows. In section 2, we discuss the mathematical framework and the octree discretization of the problem (1.2). In section 3 we present an effective numerical optimizing procedure based on a Gauss–Newton-type scheme. In section 4, we propose a locally refined multilevel method for a solution of the nonlinear problem with self-adjusting octree refinement. Finally, in section 5, we

present numerical examples for 2D and 3D images that demonstrate the effectiveness of our algorithm.

The presented theory does not depend on a particular dimension, and our implementation supports 2D and 3D images. However, for ease of presentation, we restrict our explanations to the 2D case and comment on the 3D case whenever an extension is not straightforward.

2. Mathematical framework. In the literature we could not find a unique definition of an octree [13]. Here, we consider an octree as a nonuniform but still highly regular and sparse discretization of a domain $\Omega \subset \mathbb{R}^d$, where d denotes the spatial dimension. To this end, we define an octree as a collection of discretization points $\mathbf{x}_j$ and mesh-sizes h_j. Next, we present a formal description of octrees.

2.1. Octree definition. Let $\Omega = (a_1, b_1) \times (a_2, b_2) \times \cdots \times (a_d, b_d) \subset \mathbb{R}^d$ be a rectangular domain and $h \in \mathbb{R}$ such that $(b_j - a_j)/h \in \mathbb{N}$ for all j. We define an [illegible] $\mathcal{S}_h$ [illegible] Ω [illegible] h as

$$\mathcal{S}_h = \{(\mathbf{x}_j, h_j) \,:\, j = 1, 2, \ldots, N\} \;\subset\; \Omega \times \{h \cdot 2^\ell \,:\, \ell \in \mathbb{N}\}$$

such that the subdomains $B_j := B(\mathbf{x}_j, h_j) := \{\mathbf{y} \,:\, \|\mathbf{x}_j - \mathbf{y}\|_\infty < h_j/2\}$ essentially build a partition of Ω, i.e., $B_j \cap B_k = \emptyset$ for $j \neq k$, and $\bigcup_{j=1}^N \overline{B_j} = \overline{\Omega}$.

Furthermore, we make a few auxiliary definitions for neighborhood relations on octrees, regularity of octrees, and nested octrees that will be useful in the following.

For $(\mathbf{x}_j, h_j) \in \mathcal{S}_h$ the set of [illegible] is defined by

$$\mathrm{Adj}(\mathbf{x}_j, h_j) := \{(\mathbf{x}_k, h_k) \in \mathcal{S}_h \,:\, (\mathbf{x}_j, h_j) \neq (\mathbf{x}_k, h_k) \text{ and } \mathcal{H}^{d-1}(\overline{B}_j \cap \overline{B}_k) \neq 0\},$$

where $\mathcal{H}^{d-1}$ denotes the $(d-1)$-dimensional surface measure.

An octree discretization $\mathcal{S}_h$ is called [illegible] if for all $(\mathbf{x}_j, h_j) \in \mathcal{S}_h$ it holds

$$2^{-m} \;\leq\; h_j/h_k \;\leq\; 2^m \qquad \text{for all direct neighbors } (\mathbf{x}_k, h_k) \in \mathrm{Adj}(\mathbf{x}_j, h_j).$$

In the following we refer to an octree $\mathcal{S}_h$ with the implicit understanding of a first order regular octree discretization of finest mesh-size h.

Note that a zeroth order regular octree $\mathcal{S}_h^0$ is a cell-centered equispaced discretization of Ω. In other words, $\mathcal{S}_h^0$ is the richest possible octree of finest mesh-sizes $h_j = h$ given by

$$\mathcal{S}_h^0 := \left\{(\mathbf{x}, h) \,:\, x_\ell = (a_\ell + h(k_\ell - \tfrac{1}{2})_{\ell=1}^d,\; k_\ell = 1, \ldots, \tfrac{b_\ell - a_\ell}{h}\right\}. \tag{2.1}$$

An octree discretization $\mathcal{S}_h$ is [illegible] in an octree discretization $\mathcal{S}_h'$ if for all $(\mathbf{x}, h) \in \mathcal{S}_h$ there exists an $(\mathbf{x}', h') \in \mathcal{S}_h'$, such that

$$B(\mathbf{x}, h) \cap B(\mathbf{x}', h') = B(\mathbf{x}, h).$$

The finest octree $\mathcal{S}_h^0$ is nested in any other octree discretization of Ω.

There are many possible data structures for a given octree. Here, the tree is stored as a sparse d-dimensional array S. The relative size h_j/h of each cell is stored in the upper left corner of the cell; e.g., the octree shown in Figure 1 is represented by

$$S = \begin{pmatrix} 2 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \end{pmatrix}.$$

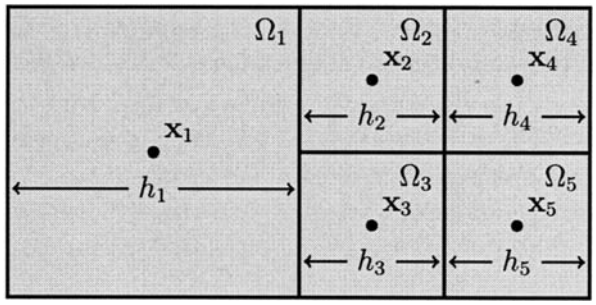

FIG. 1. *An octree discretization $\mathcal{S}_h$ in two dimensions.*

This allows us to use sparse matrix techniques in order to quickly find neighbors, which is the major operation in the discretization process. The data structure is closely related to the one suggested in [13]. As a consequence, all that is needed to address a point of the octree is the sparse array S.

2.2. Octree approximation of discrete images. Consider a discrete 2D image with $m_1 \times m_2$ pixels. Assume that this image has large regions with low variability. Then such an image can be efficiently represented by an octree. An optimal octree is the one that would have the least amount of cells for the given image. However, such an octree is difficult to find (i.e., exponentially difficult) [13]. For practical purposes, we compute a suboptimal octree by Algorithm 1. A similar algorithm is suggested in [13].

ALGORITHM 1. Generate sparse array representation S of an octree for a 2D image T where regions with gray-value differences less than tol are treated as constant.

$[S] \leftarrow$ `generateOctreeFromImage`(T, tol)

set $[m_1, m_2] \leftarrow \text{size}(T)$

Initialize $S(1\!:\!m_1, 1\!:\!m_2) \leftarrow 1$ and $T_{\min} \leftarrow T$, $T_{\max} \leftarrow T$

for $s = 2^{[0:\log_2(\min([m_1,m_2]))]}$

- find $(i_1, i_2) \in [1\!:\!s\!:\!m_1] \times [1\!:\!s\!:\!m_2]$ with $S(i_1, i_2) = s$
- get 4 subblock indices of the superblock stored at (i_1, i_2) with size $2s$: $\mathcal{I} \leftarrow [i_1, i_1 + s] \times [i_2, i_2 + s]$
- compute minimum and maximum in the superblock: $T_{\min}(i_1, i_2) \leftarrow \min(T_{\min}(\mathcal{I}))$ and $T_{\max}(i_1, i_2) \leftarrow \max(T_{\max}(\mathcal{I}))$
- **if** $T_{\max}(i_1, i_2) - T_{\min}(i_1, i_2) \leq \text{tol}$ **then** set $S(i_1, i_2) = 2s$ and $S(\mathcal{I} \setminus (i_1, i_2)) = 0$, **end if**

end for

A central point is that the overall complexity of Algorithm 1 is $\mathcal{O}(N)$, where N is the number of pixels in the image. Furthermore, we added a tolerance parameter tol. It is used as a threshold to decide whether the image is almost constant in a certain region. In our application we have set tol to the estimated noise level in the image.

Although the number of pixels in the octree is image-dependent, we have found that for typical MRI and CT images the number of pixels is reduced to less than 20% of the original size in two dimensions and to less than 10% of the size in three

dimensions, respectively. A representative 2D example, an octree discretization of a CT image, is given in Figure 2. Table 1 shows compression rates and errors obtained for several tolerances.

2.3. Octree image interpolation. For the minimization of (1.2) we must be able to evaluate R and $T(\boldsymbol{\gamma})$ where we model images as smooth functions. Typically, an image comes in digital form as discrete data, and we construct a continuous function by interpolation. Here, we consider the case of linear interpolation where the data is given on an octree. We start our considerations on the full grid $\mathcal{S}_h^0$.

We consider a pixel located at a point $\mathbf{x}$ which is not a grid point and we are interested in the value $T(\mathbf{x})$. To compute this value we use a linear interpolation scheme. In the 2D case, let nw, sw, ne, and se denote the centers of the four adjacent pixels of $\mathbf{x} = (x_1, x_2)$; cf. Figure 3. Then, defining $\xi_j = x_j/h - \lfloor x_j/h \rfloor \in [0,1]$, we have

$$T(\mathbf{x}) \approx \xi_2\Big(T(\mathrm{nw})\xi_1 + T(\mathrm{sw})(1-\xi_1)\Big) + (1-\xi_2)\Big(T(\mathrm{ne})\xi_1 + T(\mathrm{se})(1-\xi_1)\Big). \tag{2.2}$$

Now, assume that we have an octree discretization as plotted in Figure 3(b). In this case we have the octree values of the pixel in SW, SE, NW, and NE = ne, but we do not have values in nw, sw, and se. Nevertheless, since we assume that the image is almost constant over each of the larger cells we can use the prescribed value of the larger cells instead of the values of the original small cell:

$$T(\mathrm{sw}) \approx T(\mathrm{SW}), \quad T(\mathrm{se}) \approx T(\mathrm{SE}), \quad T(\mathrm{nw}) \approx T(\mathrm{NW}), \quad T(\mathrm{ne}) \approx T(\mathrm{NE}). \tag{2.3}$$

Finally, formula (2.2) is used for interpolation.

Our approach can be thought of as a two stage interpolation. First, we prolongate the image to the full grid, and each cell on the full grid obtains the value of its parent octree cell. Next, we use simple bilinear interpolation on the full grid. Note that our image model is continuous, which guarantees continuously differentiable gradients.

LEMMA 1. [illegible] $T \in C^2(\mathbb{R}^d, \mathbb{R})$ [illegible] (2.2) [illegible] (2.3) [illegible] $\mathcal{O}(h)$ [illegible]. We present the proof for $d = 1$; the extension to higher dimensions is straightforward.

Let x be an arbitrary point which lies between two grid points x^- and $x^+ = x^- + h$ such that $x^- \le x \le x^+$ and $\xi := x/h - \lfloor x/h \rfloor \in [0,1]$. From classical interpolation we have

$$T(x) = T(x^- + h\xi) = T(x^-)(1-\xi) + T(x^+)\xi + \mathcal{O}(h^2).$$

Perturbing, for example, the first control point by h, the statement follows from $T(x^- - h) = T(x^-) + \mathcal{O}(h)$ and $0 \le 1 - \xi < 1$. The proof for the perturbed second control point is along the same lines. ∎

A direct consequence of this interpolation scheme is summarized in the next corollary. This corollary suggests picking a nonvanishing tolerance in Algorithm 1 even if the image data is not perturbed by noise.

COROLLARY 2. [illegible] $\mathcal{S}_h^0$ [illegible] $\mathcal{S}_h^m$ [illegible] m [illegible] $\Omega \subset \mathbb{R}^d$ [illegible] $T \in C^2(\overline{\Omega})$ [illegible] T^0 [illegible] T^m [illegible] $\mathcal{S}_h^0$ [illegible] $\mathcal{S}_h^m$ [illegible]

$$|T^m(\mathbf{x}) - T^0(\mathbf{x})| = \mathcal{O}(h).$$

(d) absolute error $|T - \widehat{T}|$ (scaled)

FIG. 2. *Approximation of an image with an octree (cf. Table* 1, tol = 15%*).*

TABLE 1

Octree approximations $\widehat{T}$ of an image T with $N = 256^2$ pixels (cf. Figure 2(a)*), with scaled gray-values between* 0 *and* 100 *for various tolerances, $\#\mathcal{S}_h$ the number of octree points, $\#\mathcal{S}_h/\#\mathcal{S}_h^0$ the ratio between octree and full grid discretization points, average error $\frac{1}{N}\|T-\widehat{T}\|_1$, and maximum error $\|T-\widehat{T}\|_\infty$.*

tol	$\#\mathcal{S}_h$	$\#\mathcal{S}_h/\#\mathcal{S}_h^0$	Average error	Maximum error
0%	28,846	44.02%	0.00%	0.00%
1%	21,703	33.11%	0.02%	0.82%
2%	18,202	27.77%	0.06%	1.43%
5%	10,069	15.36%	0.27%	3.75%
10%	4,138	6.31%	0.59%	7.45%
15%	2,806	4.28%	0.77%	11.49%
20%	1,780	2.72%	1.02%	15.49%

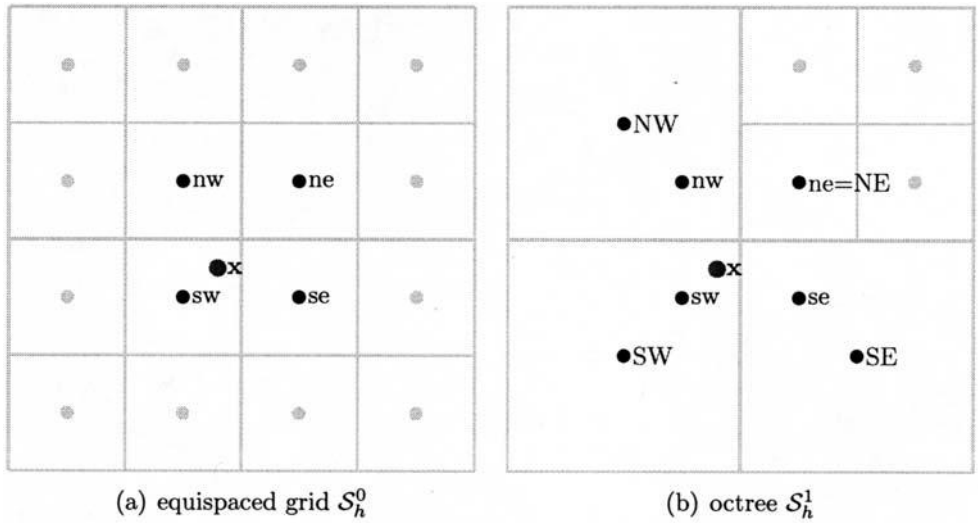

FIG. 3. *Linear interpolation on* $\mathcal{S}_h^0$ (a) *and* $\mathcal{S}_h^1$ (b).

In practice, since the image is noisy anyway, low order interpolation is sufficient. Furthermore, if the image is almost constant over the octree cell, then the coefficient in front of the h^2 term is small and we may not observe deterioration of the interpolation compared with a uniform grid interpolation.

2.4. Octree based distance measures. The octree based distance measure approximation is exemplarily discussed for the L_2-norm based sum of squared differences (SSD) distance measure [4]. Here,

$$\mathcal{D}(R, T(\boldsymbol{\gamma})) = \frac{1}{2}\|T(\boldsymbol{\gamma}) - R\|^2_{L_2(\Omega)} \tag{2.4}$$

$$= \frac{1}{2}\int_\Omega \big(T(\boldsymbol{\gamma})(\mathbf{x}) - R(\mathbf{x})\big)^2 \, d\mathbf{x}$$

$$\approx \frac{1}{2}\sum_{(\mathbf{x}_j, h_j)\in\mathcal{S}_h^0} h_j^d \big(T(\boldsymbol{\gamma})(\mathbf{x}_j) - R(\mathbf{x}_j)\big)^2 \tag{2.5}$$

$$\approx \frac{1}{2}\sum_{(\mathbf{x}_j, h_j)\in\mathcal{S}_h^1} h_j^d \big(T(\boldsymbol{\gamma})(\mathbf{x}_j) - R(\mathbf{x}_j)\big)^2 \tag{2.6}$$

$$= \frac{1}{2}\|T(\boldsymbol{\gamma}) - R\|^2_H =: D(\mathcal{S}_h, R, T(\boldsymbol{\gamma})) \tag{2.7}$$

with a weighted l_2-norm, where the diagonal weighting matrix is given by $H = \mathrm{diag}(h_j^d)$ with the cell sizes h_j^d, where (2.5) is the standard midpoint quadrature rule and (2.6) is its approximation on a first order octree. Note that $h_j = h$ in (2.5), whereas h_j can vary in (2.6). In (2.7), we make the discretized distance measure explicitly dependent on the octree. In our implementation, we use the octree generated for the transformed image $T(\boldsymbol{\gamma})$. Therefore, it is important to note that generally an octree discretization depends on $\boldsymbol{\gamma}$, i.e., $\mathcal{S}_h = \mathcal{S}_h(\boldsymbol{\gamma})$.

3. Optimization. Ideally, our aim is to minimize

$$J(\boldsymbol{\gamma}) := D(\mathcal{S}_h^0, R, T(\boldsymbol{\gamma})), \tag{3.1}$$

where $\mathcal{S}_h^0$ is the full equispaced grid (2.1). To do so efficiently, we replace this problem by a problem on a sparse and computationally less involved octree discretization. A straightforward approach is to substitute (3.1) by

$$J(\boldsymbol{\gamma}) := D(\mathcal{S}_h(\boldsymbol{\gamma}), R, T(\boldsymbol{\gamma})) \tag{3.2}$$

such that a minimizer $\boldsymbol{\gamma}^*$ leads to a transformed image $T(\boldsymbol{\gamma}^*)$ for which (2.5) can be replaced by (2.6) up to a small error.

One approach to minimizing (3.2) is to consider $\boldsymbol{\gamma} = \boldsymbol{\gamma}(t)$ as a time-dependent function and to embed the problem into a time stepping process such as the dynamical system

$$\boldsymbol{\gamma}_t = -\nabla_{\boldsymbol{\gamma}} J(\boldsymbol{\gamma}) = -\nabla_{\boldsymbol{\gamma}} D(\mathcal{S}_h(\boldsymbol{\gamma}), R, T(\boldsymbol{\gamma})).$$

Then, one can use methods that have been developed for adaptive mesh refinement for time-dependent problems when integrating to steady state. At each step one estimates both $\boldsymbol{\gamma}$ and the octree $\mathcal{S}_h(\boldsymbol{\gamma})$. However, such an approach is inefficient in the context of parametric registration since we are not interested in the dynamics of the process and evaluating the octree at each time step is not necessary.

Since the octree in (3.2) depends on $\boldsymbol{\gamma}$, the minimization is far from trivial. Therefore, we propose a two phase procedure similar to coordinate search. Starting with $k = 0$ and an initial parameter vector $\boldsymbol{\gamma}^{(k)}$, the first step is to compute the corresponding octree $\mathcal{S}_h^{(k)} := \mathcal{S}_h(\boldsymbol{\gamma}^{(k)})$. The next step is to compute a minimizer $\boldsymbol{\gamma}^{(k+1)}$ of

$$J^{(k)}(\boldsymbol{\gamma}) := D(\mathcal{S}_h^{(k)}, R, T(\boldsymbol{\gamma}))$$

for the (fixed) octree $\mathcal{S}_h^{(k)}$. These two steps are repeated to convergence. The strategy is very similar to refinement strategies used for adaptive grid problems in ordinary differential equations and partial differential equations; see, e.g., [1, 2, 8] and references therein. The algorithm is summarized in Algorithm 2.
