A crucial point in our method is to ensure decrease towards a solution on the full grid. This is done by a backtracking line search.

Assume that $\mathcal{S}_h^{(k)}$ is an octree valid for $\boldsymbol{\gamma}^{(k)}$ and $\widehat{\boldsymbol{\gamma}}$ is a minimizer of $J^{(k)}$. A naive approach is to continue the iteration by setting $\boldsymbol{\gamma}^{(k+1)} := \widehat{\boldsymbol{\gamma}}$. However, this procedure may not guarantee convergence to a minimizer of 3.1. In fact, while $\widehat{\boldsymbol{\gamma}}$ minimizes $J^{(k)}$, it may increase the value of J. We therefore use a (weak) line search for computing the new transformation and the new octree. Algorithm 2 implies that we use the octree in order to compute a search direction $\delta\boldsymbol{\gamma}$ and then use this direction to decrease the objective function J, i.e., $D(\mathcal{S}_h^0, \cdot)$, on the full grid. Therefore, we refer to Algorithm 2 as outer iteration and we speak of solving for $\widehat{\boldsymbol{\gamma}}$ on a fixed octree as inner iteration.

The obvious question of whether $\delta\boldsymbol{\gamma}$ computed on a coarse octree leads to a descent direction for the full octree is positively answered in the literature [18, 11, 3]. In particular, the work of [3] gives precise conditions on the coarse grid function. Nevertheless, for our problem, it is impossible to verify that these conditions actually are fulfilled. Summarizing the above work, loosely speaking, the essential guideline for constructing a coarse grid approximation is that it must sufficiently approximate the convexity properties of the functional at finest resolution.

Finally, we have two natural stopping criteria. First, if $\mathcal{S}_h^{(k+1)} = \mathcal{S}_h^{(k)}$, we set $\boldsymbol{\gamma}^* \leftarrow \boldsymbol{\gamma}^{(k)}$ and stop. Second, if we are unable to decrease the value of the objective function in the direction $\delta\boldsymbol{\gamma}$, then we set $\boldsymbol{\gamma}^* \leftarrow \boldsymbol{\gamma}^{(k)}$ and stop.

ALGORITHM 2. Outer iteration to minimize $J(\boldsymbol{\gamma}) := D(\mathcal{S}_h^0, R, T(\boldsymbol{\gamma}))$.

$\boldsymbol{\gamma}^* \leftarrow \texttt{minimizeJ}(T, R, \boldsymbol{\gamma}^{(0)}, h)$

while not converged

- for given $\boldsymbol{\gamma}^{(k)}$ generate $\mathcal{S}_h^{(k)}$ such that $D(\mathcal{S}_h^{(k)}, \boldsymbol{\gamma}^{(k)}) \approx J(\boldsymbol{\gamma}^{(k)})$
- compute a minimizer $\widehat{\boldsymbol{\gamma}}$ of $J^{(k)} := D(\mathcal{S}_h^{(k)}, \cdot\,)$
- set $\delta\boldsymbol{\gamma} \leftarrow \widehat{\boldsymbol{\gamma}} - \boldsymbol{\gamma}^{(k)}$
- perform line search on $\mathcal{S}_h^0$: find λ such that $J(\boldsymbol{\gamma}^{(k)} + \lambda\delta\boldsymbol{\gamma}) < J(\boldsymbol{\gamma}^{(k)})$
- update $\boldsymbol{\gamma}^{(k+1)} \leftarrow \boldsymbol{\gamma}^{(k)} + \lambda\delta\boldsymbol{\gamma}$,

end while

return $\boldsymbol{\gamma}^* \leftarrow \boldsymbol{\gamma}^{(k+1)}$.

3.1. Solving for $\boldsymbol{\gamma}$ on an octree. To compute a minimizer $\widehat{\boldsymbol{\gamma}}$ of $D(\mathcal{S}_h, \cdot\,)$ on a given fixed octree $\mathcal{S}_h$, we use a Gauss–Newton-like method. Note that using linear interpolation we obtain a piecewise constant Jacobian. Nevertheless, using the Gauss–Newton method with backtracking we could obtain linear convergence.

Since the octree is constant in this step, we may rewrite the distance function (2.7) by

$$D(R, T(\boldsymbol{\gamma})) = D(\mathcal{S}_h, R, T(\boldsymbol{\gamma})).$$

To use the Gauss–Newton method, we first linearize $T(\boldsymbol{\gamma})$:

$$T(\boldsymbol{\gamma} + \delta\boldsymbol{\gamma}) \approx T(\boldsymbol{\gamma}) + T_{\boldsymbol{\gamma}}(\boldsymbol{\gamma})\ \delta\boldsymbol{\gamma},$$

where $T_{\boldsymbol{\gamma}}$ is the Jacobian matrix of T w.r.t. $\boldsymbol{\gamma}$. To compute $T_{\boldsymbol{\gamma}}$ we use the chain rule. Discretizing (1.1) the displacement everywhere, $\boldsymbol{\phi}$ can be written as

$$\boldsymbol{\phi} = P\boldsymbol{\gamma},$$

where each column of the matrix P holds the discretized grid function of the basis function $\boldsymbol{\psi}_j \quad j = 1, \ldots, n$. To differentiate w.r.t. $\boldsymbol{\phi}$ we differentiate the interpolation formula (2.2) directly. We then multiply with P to complete the evaluating of the Jacobian.

We then use the linearization with the distance function D,

$$D(R, T(\boldsymbol{\gamma} + \delta\boldsymbol{\gamma})) \approx D(R, T(\boldsymbol{\gamma}) + T_{\boldsymbol{\gamma}}(\boldsymbol{\gamma})\delta\boldsymbol{\gamma}).$$

Differentiating w.r.t. $\delta\boldsymbol{\gamma}$, we obtain the following equation which can be solved for $\delta\boldsymbol{\gamma}$:

$$T_{\boldsymbol{\gamma}}(\boldsymbol{\gamma})^\top\ D_T(R, T(\boldsymbol{\gamma}) + T_{\boldsymbol{\gamma}}(\boldsymbol{\gamma})\delta\boldsymbol{\gamma}) = 0, \tag{3.3}$$

where D_T is the gradient of the distance measure w.r.t. T.

For example, for the SSD distance measure discussed in section 2.4, $D(R, T(\boldsymbol{\gamma})) = \frac{1}{2}\|T(\boldsymbol{\gamma}) - R\|_H^2$, we end up with the usual Gauss–Newton scheme [6], where $\delta\boldsymbol{\gamma}$ is obtained by solving the system

$$T_{\boldsymbol{\gamma}}^\top H(T_{\boldsymbol{\gamma}}\ \delta\boldsymbol{\gamma} + T - R) = 0.$$

However, for more complicated distance measures (e.g., mutual information [5, 24] or normalized gradient fields [9]) an inexact solution of this system can be obtained using an inexact Newton method.

After solving for $\delta\boldsymbol{\gamma}$, we update $\boldsymbol{\gamma}$ using a weak line search which ensures sufficient reduction in the value of the objective function [19]. The algorithm for computing a single inner iteration is summarized in Algorithm 3.

ALGORITHM 3. Inner iteration to minimize $D(\mathcal{S}_h, R, T(\boldsymbol{\gamma}))$ w.r.t. $\boldsymbol{\gamma}$.

$\widehat{\boldsymbol{\gamma}} \leftarrow$ `minimizeJonFixedOctree`$(\mathcal{S}_h, R, T, \boldsymbol{\gamma})$

while not converge
- compute $T(\boldsymbol{\gamma})$ and $T_{\boldsymbol{\gamma}}(\boldsymbol{\gamma})$
- approximately solve (3.3) for $\delta\boldsymbol{\gamma}$
- perform line search:
  find λ such that $D(\mathcal{S}_h, R, T(\boldsymbol{\gamma} + \lambda\delta\boldsymbol{\gamma})) < D(\mathcal{S}_h, R, T(\boldsymbol{\gamma}))$
- update $\boldsymbol{\gamma} \leftarrow \boldsymbol{\gamma} + \lambda\delta\boldsymbol{\gamma}$

end while
return $\widehat{\boldsymbol{\gamma}} \leftarrow \boldsymbol{\gamma}$

3.2. Generating an octree for $\boldsymbol{\gamma}$. In the previous subsection we discussed how to compute a minimizer $\boldsymbol{\gamma}$ for a particular given octree. In this subsection we assume that $\boldsymbol{\gamma}$ is given and we discuss how to generate an appropriate octree.

The key for the computation of a new octree is that the transformed image must be well represented on the grid; i.e., we need to sufficiently estimate the distance function $\mathcal{D}(R, T(\boldsymbol{\gamma}))$. In order to be more specific, in this subsection we assume that $\mathcal{D}$ is the SSD distance measure; cf. section 2.4.

Since we try to approximate the integral of the difference between $T(\boldsymbol{\gamma})$ and R, the octree has to be constructed based on both $T(\boldsymbol{\gamma})$ and R. Therefore, we first evaluate $T(\boldsymbol{\gamma})$ and R on the full grid. We then use Algorithm 1 to generate octrees $\mathcal{S}_h^T$ and $\mathcal{S}_h^R$ for $T(\boldsymbol{\gamma})$ and R. Finally, we join the octrees. As a result, we obtain an octree nested in both $\mathcal{S}_h^T$ and $\mathcal{S}_h^R$; cf. section 2.1. The procedure is summarized in Algorithm 4.

ALGORITHM 4. Generate sparse octree representation S (2D).

$S \leftarrow$ `generateJointOctree`$(T, R, \boldsymbol{\gamma})$
- compute $T(\boldsymbol{\gamma})$ and R on the full grid Ω_h
- compute octree representations S_T and S_R for $T(\boldsymbol{\gamma})$ and R using Algorithm 2.2
- join S_T and S_R, i.e.,
  - find (i_1, i_2) where $S_R(i_1, i_2) \neq 0$ and $S_T(i_1, i_2) \neq 0$ and set $S(i_1, i_2) \leftarrow \min\{S_R(i_1, i_2), S_T(i_1, i_2)\}$
  - find (i_1, i_2) where $S_R(i_1, i_2) \neq 0$ and $S_T(i_1, i_2) = 0$ and set $S(i_1, i_2) \leftarrow S_R(i_1, i_2)$
  - find (i_1, i_2) where $S_R(i_1, i_2) = 0$ and $S_T(i_1, i_2) \neq 0$ and set $S(i_1, i_2) \leftarrow S_T(i_1, i_2)$

4. Multilevel continuation. To overcome nonlinearities and accelerate computations, we use a multilevel strategy. A multilevel method for image registration is not new [7, 10, 12]. However, modification of the standard algorithm is required to effectively use the octree grid. Our multilevel algorithm uses the octree structure directly in order to gradually refine the grid only in areas where a refinement is required.

We start on a coarsest octree with finest mesh-size $H = 2^L h$, which is a few multiples of the smallest mesh-size h. We then solve the optimization problem using Algorithm 2 to obtain a coarse grid solution $\boldsymbol{\gamma}_H$. We then move to the next finer

ALGORITHM 5. Multilevel solve for $\boldsymbol{\gamma}$.

$[\boldsymbol{\gamma}] \leftarrow \texttt{MLSolve}(T, R, \boldsymbol{\gamma}, h, L)$

set $H \leftarrow 2^L h$

initialize $\boldsymbol{\gamma}$ and S_H

while $H > h$

- use Algorithm 2 with initial guess $\boldsymbol{\gamma}_{2H}$ to find $\boldsymbol{\gamma}_H$ such that $D(\mathcal{S}_H^0, \boldsymbol{\gamma}_H) =$ min:
  $\boldsymbol{\gamma}_H \leftarrow \texttt{minimizeJ}(T, R, \boldsymbol{\gamma}_{2H}, H)$
- set $H \leftarrow H/2$

end while

level. We set the finest mesh-size H to $H/2$ and use the coarse grid solution $\boldsymbol{\gamma}_H$ as an initial guess to the optimization problem for the finest mesh-size $H/2$. We repeat this procedure until we arrive at the smallest grid size h. The algorithm is summarized in Algorithm 5.

It is important to note that combining our multilevel strategy with the optimization strategy naturally results in only [illegible]. This is because the optimization on every level starts with an [illegible] of the refined previous solution and this automatically refines the grid only in high variability areas.

5. Examples. In this section we demonstrate the effectiveness of our approach on a few examples. We use a 2D example which can be easily visualized and a 3D example to further demonstrate the computational saving when solving registration problems in three dimensions. In both examples we use the SSD distance measure and optimize w.r.t. affine transformations.

5.1. 2D registration of hand CT. Our first numerical experiment is matching 2D images of hands plotted in Figure 4. The reference image is a rotated and shifted version of the template image. Thus, the transformation parameters are explicitly known, and we should generally be able to recover them with registration. In the following we denote the true parameter by $\boldsymbol{\gamma}_{\text{true}}$ and parameters obtained from registration by $\boldsymbol{\gamma}_{\text{opt}}$. As stopping criteria for the optimization, we considered the difference between subsequent iterates where we terminated our algorithm when $\|\boldsymbol{\gamma}^{(k)} - \boldsymbol{\gamma}^{(k+1)}\|_\infty < 10^{-2}$.

The multilevel optimization process is summarized in Table 2, and a few octree grids obtained in the process of optimization are plotted in Figure 5.

For this problem, the gray-values of the image were in the range $[0, 750]$. Therefore, a tolerance of 1% in the gray-value dynamics corresponds to an absolute value of 7.5.

In Table 3 we present our results for several tolerances for the octrees. Basically, we observe that we are able to recover the true parameter. An error in the parameters of $\|\boldsymbol{\gamma}_{\text{opt}} - \boldsymbol{\gamma}_{\text{true}}\|_\infty \approx 10^{-4}$ corresponds to a misalignment of approximately 0.05 pixels which is visually indistinguishable from the reference image. Therefore, the results show that we are able to sufficiently accurately recover the true parameters with approximately only a fifth of a full discretization (cf. Table 3, tol $\leq$ 15%). Nevertheless, we did not observe a speedup in wall-clock time, which suggests that the computation overhead from the regridding and line searches coming from dealing with nonuniform grids is too large compared to the problem size.

In Table 4 we present the outcomes of our algorithm after each level in the multi-

5	128×128	2	3
6	256×256	2	3

level process. As we can see, the results for the octree discretizations and the full grid are almost identical, and the finest resolution is needed to obtain the final accuracy. Furthermore, the accuracy did not improve from the 8×8 to the 32×32 level, which also suggests that we started with a too coarse grid.

5.2. 3D registration of head MRI. In our second experiment we register 3D MRI images of the head. The images were taken from the BrainWeb database and interpolated to a size of $256 \times 256 \times 256$ voxels. To create a template we rotated the reference by 20° around the center of the image in the x-, y-, and z-directions and finally made a diagonal shift by 20 pixels. The reference and template are shown in Figures 6(a) and 6(b), respectively.

The multilevel optimization path with a tolerance of 5% of the gray-value dynamics is plotted in Table 5, Table 6 lists the accuracy for the recovered parameter for various tolerances, and Table 7 shows the outcomes in the multilevel process.

Basically, we observe exactly the same behavior as in the 2D example w.r.t. the accuracy of the recovered parameters. The main difference between the two examples is the problem size. Here, we observe a speedup of a factor 3–4 when using an octree discretization versus the full grid (cf. Table 6, tol = 5–20%). Thus, the problem size is large enough such that the computational saving from the octree approach versus a full grid discretization compensates the introduced algorithmic overhead from a nonregular discretization.

6. Summary and final comments. In this paper we have developed a variational octree image registration technique. We have demonstrated that by using such a technique we are able to substantially accelerate parametric image registration problems.

While we observe major computational savings for parametric registration, we expect to have much better results for nonparametric registration where large sparse linear systems are solved for the displacement.

A NOTE ON GMRES PRECONDITIONED BY A PERTURBED LDL^T DECOMPOSITION WITH STATIC PIVOTING*

M. ARIOLI†, I. S. DUFF‡, S. GRATTON§, AND S. PRALET¶

Abstract. A strict adherence to threshold pivoting in the direct solution of symmetric indefinite problems can result in substantially more work and storage than forecast by a sparse analysis of the symmetric problem. One way of avoiding this is to use static pivoting where the data structures and pivoting sequence generated by the analysis are respected and pivots that would otherwise be very small are replaced by a user defined quantity. This can give a stable factorization but of a perturbed matrix. The conventional way of solving the sparse linear system is then to use iterative refinement, but there are cases where this fails to converge. In this paper, we discuss the use of more robust iterative methods, namely GMRES and flexible GMRES (FGMRES). We show both theoretically and experimentally that both approaches are more robust than iterative refinement and furthermore that FGMRES is far more robust than GMRES and that, under reasonable hypotheses, FGMRES is backward stable. We also show how restarted variants can be beneficial, although again the GMRES variant is not as robust as FGMRES.

Key words. augmented systems, sparse matrices, multifrontal methods, GMRES, flexible GMRES, static pivoting, roundoff error

1. Introduction.

This paper is concerned with solving the set of linear equations

$$Ax = b, \tag{1.1}$$

where the coefficient matrix $A \in \mathbb{R}^{n\times n}$ is a symmetric indefinite sparse matrix. Our hope is to solve this system using a direct method, but sometimes the cost of doing this is too high in terms of time or memory. We have therefore looked at the possibility of using static pivoting to avoid these problems which are particularly acute if the matrix is highly indefinite as, for example, can happen for saddle-point problems.

We will use a multifrontal approach for our direct method. In this approach, we first determine an order for choosing pivots based on the sparsity structure of A and we then accommodate further pivoting for numerical stability during the subsequent numerical factorization phase. When the matrix is highly indefinite, the resulting pivot sequence used in the numerical factorization can differ substantially from that predicted by the analysis step. A simple way to avoid this problem is to force the elimination through static pivoting.

We assume that the matrix A has been factorized using the HSL `MA57` package [7] with the option of using static pivoting [8]. Static pivoting will add a factor τ to a diagonal entry when it is impossible to find a suitable pivot in the fully summed blocks. It is common to choose $\tau \approx \sqrt{\varepsilon}||A||$ (ε machine precision).

Therefore, the computed factors $\hat{L}$ and $\hat{D}$ are, in exact arithmetic, the exact factorization of the perturbed problem

$$A + E = \hat{L}\hat{D}\hat{L}^T, \tag{1.2}$$

where E is a diagonal matrix of rank equal to the number of static pivots used during the factorization and $|E| \leq \tau I$. Hereafter, given the matrix B, we denote by $|B|$ the matrix having entries equal to the absolute values of the entries of B. The nonzero diagonal entries in E correspond to the positions at which static pivoting was performed and are all equal to τ. Note that if τ is chosen too small, then the factorization could be very unstable, whereas if it is chosen too large, the factorization will be stable but will not be an accurate factorization of the original matrix (that is, $|E|$ will be large). In section 2, we give a brief description of the static pivoting strategy used in `MA57`.

Equation (1.2) gives a splitting of A in terms of $M = \hat{L}\hat{D}\hat{L}^T$ and E,

$$A = M - E, \tag{1.3}$$

and the solution of (1.1) can be expressed as the solution of the equivalent systems

$$\begin{cases} (I - EM^{-1})Mx = b, \\ (I - M^{-1}E)x = M^{-1}b. \end{cases} \tag{1.4}$$

Owing to the symmetry of all the matrices in (1.4), $I - EM^{-1} = (I - M^{-1}E)^T$. Moreover, the first system corresponds to a right preconditioning of (1.1), while the second corresponds to a left preconditioning.

If the spectral radius of the matrix $I - M^{-1}E$ (or $I - EM^{-1}$) is less than one, the system (1.4) can be solved using iterative refinement. This has been used by many authors [5, 8, 13, 18] and is successful over a wide range of matrices although it is sensitive to the value of τ. If, however, the spectral radius is greater than or equal to one (or even close to one), it may be necessary to switch to a more powerful method such as GMRES [17]. Although the matrix is symmetric, we choose GMRES since it gives us much more freedom to work with a wide range of preprocessors and preconditionings.

We have found experimentally that using the factorization (1.2) as a right preconditioning for GMRES works in most cases and is, as expected, much more robust than iterative refinement. However, there are cases where we do not get convergence of a scaled residual to machine precision. Moreover, we have found that restarted GMRES performs better and that using flexible GMRES (FGMRES) [15], even though our preconditioner remains constant, does even better.

We illustrate this through numerical experiment (see section 6) and show theoretically that, under reasonable assumptions, FGMRES preconditioned by our static pivoting factorization is backward stable so that a small scaled residual can be achieved (see section 5). Our analysis also holds for the case of restarted FGMRES that we advocate for controlling the memory requirement while still achieving the desired robustness and accuracy. Indeed, we give theoretical arguments for why restarting often greatly improves the convergence.

In the following, we use the MATLAB notation $[A, B]$ to mean the matrix that consists of the columns of matrix A followed by the columns of matrix B. We denote by ε the machine precision of a finite-precision arithmetic satisfying the IEEE standard, and by $fl(\cdot)$ the result of a sequence of floating-point operations. The computed matrices, vectors, and scalars will be identified by a bar over the symbol. Finally, we will denote by $||\cdot||$ the usual Euclidean 2-norm for vectors and the corresponding induced norm for matrices.

2. LDL^T with static pivoting. In the multifrontal context, the factorization can be represented by a tree at each node of which elimination operations are performed on a partially summed frontal matrix

$$\begin{bmatrix} F_{11} & F_{12} \\ F_{12}^T & F_{22} \end{bmatrix}, \tag{2.1}$$

and pivots at that stage can be chosen only from within the fully summed block F_{11}. The problem occurs when it is impossible or numerically suicidal to eliminate all of F_{11}, resulting in more work and storage (sometimes dramatically more) than forecast.

Our mixed pivoting approach is based on two phases. In the first phase, we perform numerical pivoting in the block F_{11} of fully summed variables until no remaining variables satisfy the numerical criterion. In the second phase, we eliminate the remaining fully summed variables, adding 1×1 perturbations defined using a threshold $\mu > 0$. Let us denote by a_{ii} the generic 1×1 pivot and by

$$P = \begin{bmatrix} a_{ii} & a_{ij} \\ a_{ji} & a_{jj} \end{bmatrix}$$

the generic 2×2 pivot.

Then, our pivoting strategy is defined as follows. We define

$$g_1(i) = \frac{\max_{k\neq i} |a_{ki}|}{|a_{ii}|} \tag{2.2}$$

and

$$g_2(i,j) = \left|\left| |P^{-1}| \begin{pmatrix} \max_{k\neq i,j} |a_{ki}| \\ \max_{k\neq i,j} |a_{kj}| \end{pmatrix} \right|\right|_\infty . \tag{2.3}$$

During the first phase of our algorithm, we perform the usual Duff–Reid algorithm. In this approach, a 1×1 pivot a_{ii} is considered to be stable if and only if

$$g_1(i) \leq 1/u, \tag{2.4}$$

and a 2×2 pivot is considered to be stable if and only if

$$g_2(i,j) \leq 1/u. \tag{2.5}$$

During the second phase we preselect a 1×1 and a 2×2 pivot and decide which will be eliminated. The choice between a 1×1 and a 2×2 pivot is done in three stages. First, if we can eliminate a pivot and ensure a growth factor lower than $1 + 1/\mu$,

where $\mu = \sqrt{\varepsilon}$, i.e., if $g_1(i) \leq 1/\mu$ or $g_2(i,j) \leq 1/\mu$, then we select the one with the lower growth factor. Second, if $g_1(i) \geq 1/\mu$ and $g_2(i,j) \geq 1/\mu$ (we cannot ensure a growth factor lower than $1+1/\mu$), then we compare the quantities $1/|a_{ii}|$ and $||P^{-1}||_\infty$ and select the pivot associated with the smallest quantity. This second comparison is guided by the growth factor that would appear if we suppose that the largest off-diagonal entry is bounded by $\max_{ij} |a_{ij}|$. Finally, if no pivot can be chosen, we add some perturbation to make the factorization more stable. More precisely, a 1×1 pivot a_{ii} is selected and perturbed using $\delta = s(a_{ii})(\tau - |a_{ii}|)$, where s is the sign function and $\tau = \mu \max_{ij} |a_{ij}|$.

3. GMRES. The convergence of the GMRES method can be quite problematic for the general case even when we have a favorable distribution of the eigenvalues as in our case of the matrix $I - M^{-1}E$ (or $I - M^{-1}E$) [2].

However, because of the symmetry of A, the spectrum of $I-M^{-1}E$ (or $I-M^{-1}E$) has additional properties that make the behavior more regular. Let us denote by $\widetilde{I}_m$ and $\widetilde{I}_{n-m}$ the $n \times m$ and $n \times (n-m)$ matrices corresponding to the first m columns and the last $n-m$ columns of the $n \times n$ identity matrix, respectively. We assume that the matrices E, M, and A are symmetrically permuted so that the nonzero entries of E are the first m diagonal entries of the matrix E.

We observe that $\widetilde{I}_{n-m}$ is a basis for $Ker(E)$.

THEOREM 3.1. [illegible] E [illegible] $I - M^{-1}E$ [illegible] $I - EM^{-1}$ [illegible]. $M^{-1}Ex = \lambda x$ if and only if $Ex = \lambda Mx$. Since M is symmetric and nonsingular and E is positive semidefinite, λ is either zero or real, and (M, E) is an Hermitian definite pencil (see [3, p. 110]). □

We can introduce the right preconditioned version of GMRES, where we note that, although the vector z_k is computed, it is not stored.

ALGORITHM 3.1.

[illegible] $[x] =$ [illegible]
$x_0 = M^{-1}b$ $r_0 = b - Ax_0$ [illegible] $\beta = ||r_0||$
$v_1 = r_0/\beta$ [illegible] $r = r_0$
[illegible] $||r|| > \varepsilon\,(||b|| + ||A||\,||x_k||)$ [illegible] $k < maxit$
$k = k + 1$.
$z_k = M^{-1}v_k$. $w = Az_k$.
[illegible] $i = 1, \ldots, k$
$h_{i,k} = v_i^T w$.
$w = w - h_{i,k}v_i$.
[illegible]
$h_{k+1,k} = ||w||$.
$v_{k+1} = w/h_{k+1,k}$.
$V_k = [v_1, \ldots, v_k]$.
$H_k = \{h_{i,j}\}_{1 \leq i \leq j+1; 1 \leq j \leq k}$.
$y_k = \arg\min_y ||\beta e_1 - H_k y||$.
[illegible] $||\beta e_1 - H_k y_k|| \leq \varepsilon\,(||b|| + ||A||\,||x_k||)$
$x_k = x_0 + M^{-1}V_k y_k$ [illegible] $r = b - Ax_k$.
[illegible]
[illegible]
[illegible]

4. Flexible GMRES.

4.1. FGMRES versus GMRES.

First, we introduce the right-preconditioned version of FGMRES in Algorithm 4.1.

ALGORITHM 4.1.

$[x] =$

$x_0 = M_0^{-1} b \quad r_0 = b - Ax_0 \quad \beta = ||r_0||$

$v_1 = r_0/\beta \quad r = r_0$

$||r|| > \varepsilon\,(||b|| + ||A||\,||x_k||) \quad k < maxit$

$k = k + 1$

$z_k = M_k^{-1} v_k \quad w = Az_k$

$i = 1, \ldots, k$

$h_{i,k} = v_i^T w$

$w = w - h_{i,k} v_i$

$h_{k+1,k} = ||w||$

$v_{k+1} = w/h_{k+1,k}$

$Z_k = [z_1, \ldots, z_k] \quad V_k = [v_1, \ldots, v_k]$

$H_k = \{h_{i,j}\}_{1 \le i \le j+1; 1 \le j \le k}$

$y_k = \arg\min_y ||\beta e_1 - H_k y||$

$||\beta e_1 - H_k y_k|| \le \varepsilon\,(||b|| + ||A||\,||x_k||)$

$x_k = x_0 + Z_k y_k \quad r = b - Ax_k$

When $M_k = M$ for all k, Algorithms 3.1 and 4.1 differ only in the computation of x_k where in Algorithm 4.1 the vectors z_k are stored in Z_k. Since Algorithm 4.1 needs both V_k and Z_k, it requires additional storage with respect to Algorithm 3.1. In [9, 16], the convergence of FGMRES is analyzed: if each matrix H_k is full rank, the algorithm converges to the solution.

Both algorithms are based on the relations

$$C^{(k)} = [r_0, AZ_k] = V_{k+1} \begin{bmatrix} R_k \\ 0 \end{bmatrix}; \qquad V_j^T V_j = I_j \quad \forall j. \tag{4.1}$$

This corresponds to computing the orthogonal factorization of $C^{(k)}$, where each column $C_i^{(k)}$ is computed after the $(i-1)$th step of the Gram–Schmidt orthogonalization process. Furthermore, we have

$$R_k = \begin{bmatrix} \beta e_1 & H_k \end{bmatrix} \tag{4.2}$$

and

$$AZ_k = V_{k+1} H_k. \tag{4.3}$$

The vector y_k (in both Algorithms 3.1 and 4.1) is computed by a QR algorithm based on Givens rotations using the upper Hessenberg structure of H_k.

5. Roundoff error analysis. In the following, we will denote by $c_p(n, j)$ functions that depend only on the dimension n and the integer j. We will avoid a precise formulation of these dependences, but we assume that each $c_p(n, j)$ grows moderately with n and j. Finally, if $B \in \mathbb{R}^{n\times m}$, $n \geq m$, is a full rank matrix, we denote by $\kappa(B) = ||B||\,||B^+||$ its spectral condition number where $B^+ = (B^TB)^{-1}B$.

The roundoff error analysis of both FGMRES and GMRES can be made in four stages:

1. Error analysis of the Arnoldi–Krylov process. We will analyze in detail the modified Gram–Schmidt approach, but similar results can be achieved using a Householder-based approach as presented in [1, 6, 19].
2. Error analysis of the Givens process used on the upper Hessenberg matrix H_k in order to reduce it to upper triangular form.
3. Error analysis of the computation of x_k in FGMRES and GMRES.
4. Use of the static pivoting properties and of (1.3) in order to have simpler expressions.

The first two stages of the roundoff error analysis are the same for both FGMRES and GMRES, and the last two stages are specific to each algorithm.

5.1. FGMRES roundoff error analysis. In this section, we state the theorem presenting the main result that covers stages 1–3. The proofs are given in the appendices.

THEOREM 5.1. [illegible] 4.1 [illegible] (1.1) [illegible] ε [illegible]

$$\sigma_{\text{[illegible]}}(\bar{H}_k) > c_1(k,1)\varepsilon\,||\bar{H}_k|| + \mathcal{O}(\varepsilon^2) \quad \forall k, \tag{5.1}$$

$$|\bar{s}_k| < 1 - \varepsilon \quad \forall k, \tag{5.2}$$

[illegible] $\bar{s}_k$ [illegible] $\bar{H}_k$ [illegible] $\bar{y}_k$ [illegible]

$$2.12(n+1)\varepsilon < 0.01 \qquad 18.53\varepsilon\, n^{\frac{3}{2}}\kappa(C^{(k)}) < 0.1 \quad \forall k, \tag{5.3}$$

[illegible] $\hat{k}$, $\hat{k} \leq n$ [illegible] $k \geq \hat{k}$ [illegible]

$$||b - A\bar{x}_k|| \leq c_2(n,k)\varepsilon\left(||b|| + ||A||\,||\bar{x}_0|| + ||A||\,||\bar{Z}_k||\,||\bar{y}_k||\right) + \mathcal{O}(\varepsilon^2). \tag{5.4}$$

[illegible] $M_i = M$ [illegible] i [illegible]

$$\rho = 1.3\,||\hat{W}_k|| + c_3(k,1)\varepsilon\,||M||\,||\bar{Z}_k|| < 1 \quad \forall k < \hat{k}, \tag{5.5}$$

[illegible] $\hat{W}_k = [M\bar{z}_1 - \bar{v}_1, \ldots, M\bar{z}_k - \bar{v}_k]$ [illegible]

$$\begin{aligned} ||b - A\bar{x}_k|| \;\leq\; & c_4(n,k)\gamma\varepsilon\left(||b|| + ||A||\,||\bar{x}_0|| \right.\\ & \left. + ||A||\,||\bar{Z}_k||\left(||M(\bar{x}_k - \bar{x}_0)|| + \varepsilon\,||\bar{x}_0||\right)\right) + \mathcal{O}(\varepsilon^2), \\ \gamma = \frac{1.3}{1-\rho}. & \end{aligned} \tag{5.6}$$

[illegible]. See Appendix A. □

[illegible] 1. We point out that if $\bar{x}_0 = 0$ and $M = I$, FGMRES is numerically equivalent to classical GMRES. Moreover, formula (5.6) implies that GMRES is normwise backward stable, and we obtain the result in [14].

5.1.1. Stage 4: Static pivoting case. We remark that the computation of the matrices $\hat{L}$ and $\hat{D}$ by `MA57` with static pivoting in floating-point arithmetic gives the following relations:

$$\begin{cases} A + \delta A + \tau\Delta = M, \\ ||\delta A|| \leq c_5(n)\varepsilon\, ||\, |\hat{L}|\, |\hat{D}|\, |\hat{L}^T|\, ||, \\ ||\Delta|| \leq 1. \end{cases} \tag{5.7}$$

Moreover, we take into account that

$$\begin{cases} (M + \delta M)\bar{x}_0 = b, \qquad \text{where} \\ ||\delta M|| \leq c_6(n)\varepsilon\ ||\, |\hat{L}|\, |\hat{D}|\, |\hat{L}^T|\, ||. \end{cases} \tag{5.8}$$

Relations (5.7) and (5.8) follow by the use of standard techniques similar to those for the roundoff error analysis of Gaussian elimination [12, 13, 20]. We point out that, from (5.7), the perturbation δA must have a norm smaller than τ in order not to dominate the global error that would make the diagonal perturbation ineffective. Therefore, it is reasonable to assume that

$$\max\left(c_5(n), c_6(n)\right)\varepsilon\, ||\, |\hat{L}|\, |\hat{D}|\, |\hat{L}^T|\, || < \tau. \tag{5.9}$$

THEOREM 5.2. [illegible] 5.1 [illegible] (5.9) [illegible]

$$c_7(n,k)\gamma\varepsilon\, ||A||\, ||\bar{Z}_k|| < 1 \quad \forall k < \hat{k} \tag{5.10}$$

[illegible]

$$\max\{||M^{-1}||, ||\bar{Z}_k||\} \leq \frac{\tilde{c}}{\tau}, \tag{5.11}$$

[illegible] $\tilde{c}$ [illegible]

$$||b - A\bar{x}_k|| \leq 2\mu\varepsilon\left(||b|| + ||A||\left(||\bar{x}_0|| + ||\bar{x}_k||\right)\right) + \mathcal{O}(\varepsilon^{\,2}), \tag{5.12}$$

$$\mu = \frac{c_7(n,k)\gamma}{1 - c_7(n,k)\varepsilon\,\gamma||A||\, ||\bar{Z}_k||}.$$

[illegible]. See Appendix B. □

[illegible] 2. We point out that hypothesis (5.11), as we will see in section 6, is satisfied for a moderate value of $\tilde{c}$ by our static pivoting strategy on all our test problems. However, the upper bound (5.6) is more general and also gives a good estimate of the error when $\tau \ll \sqrt{\varepsilon}$. In all our experiments, we have $||\bar{Z}_k||\, ||M(\bar{x}_k - \bar{x}_0)|| < 10^4$.

5.2. GMRES roundoff error analysis. For the sake of simplicity, we make the assumption that the solution of the linear system

$$Mq = fl(\bar{V}_k\bar{y}_k)$$

is followed by a few steps of iterative refinement in order to guarantee a good local backward stability. Under this assumption, we have the following theorem.

THEOREM 5.3. [illegible] 3.1 [illegible] (1.1) [illegible] ε [illegible] (5.1), (5.2) [illegible] (5.3) [illegible] 5.1 [illegible]

$$c_8(n,1)\varepsilon\,\kappa(M) < 1, \tag{5.13}$$

[illegible] $\hat{k}$, $\hat{k} \le n$ [illegible] $k \ge \hat{k}$ [illegible]

$$\begin{aligned} ||b - A\bar{x}_k|| \le\ & c_9(n,k)\chi\varepsilon \Big\{ ||b|| + ||A||\,||\bar{x}_0|| + ||AM^{-1}||\,||M||\,||\bar{x}_k - \bar{x}_0|| \\ & + \Big[\, ||A||\,||\bar{Z}_k|| + ||AM^{-1}||\,||\,|\hat{L}|\,|\hat{D}|\,|\hat{L}^T|\,|| \,\Big] \\ & \times \Big[\, ||M(\bar{x}_k - \bar{x}_0)|| + n\varepsilon\,||M||\,(||\bar{x}_k - \bar{x}_0|| + ||\bar{x}_0||) \,\Big] \Big\} + \mathcal{O}(\varepsilon^2), \end{aligned} \tag{5.14}$$

$$\chi = \frac{1.3}{1 - 1.3k\varepsilon}.$$

[illegible]. See Appendix C. □

[illegible] 3. Both (5.6) and (5.14) do not depend on the special initial choice $\bar{x}_0 = M^{-1}b$. They will be true for any choice of $\bar{x}_0$. In both FGMRES and GMRES, a restart with a new $\bar{x}_0 = \bar{x}_k$ can improve the situation, reducing the upper bounds significantly.

[illegible] 4. Finally, we point out that when we replace the values of $c_4(n,k)\gamma$ and $c_9(n,k)\chi$ in (5.6) and (5.14) with $\hat{c} = \max(c_4(n,k)\gamma, c_9(n,k)\chi)$, (5.14) becomes an upper bound for (5.6). The numerical experiments in section 6 support this observation.

5.2.1. Stage 4: Static pivoting case. From (5.7) and (5.9), taking into account that $\tau = \varepsilon^{\sigma}||A||$ with $0 < \sigma \le 1$, we have

$$||M|| \le ||A|| + \tau + c_{10}(n)\,\varepsilon\ ||\,|\hat{L}|\,|\hat{D}|\,|\hat{L}^T|\,|| \le ||A|| + 2\,\tau \le 3\,||A||. \tag{5.15}$$

From (5.14), we have

$$\begin{aligned} ||b - A\bar{x}_k|| \le\ & c_{11}(n,k)\,\chi\,\varepsilon \Big[\, ||b|| + ||A||\,||\bar{x}_0|| + ||AM^{-1}||\,||A||\,||\bar{x}_k - \bar{x}_0|| \\ & + ||A||\,||\bar{Z}_k||\,||\,M(\bar{x}_k - \bar{x}_0)|| \\ & + ||AM^{-1}||\,||\,|\hat{L}|\,|\hat{D}|\,|\hat{L}^T|\,||\,||A||\,||\bar{x}_k - \bar{x}_0|| \Big] + \mathcal{O}(\varepsilon^2). \end{aligned} \tag{5.16}$$

Moreover, we have

$$AM^{-1} = I - \tau\Delta M^{-1} - c_5(n)\,\varepsilon\ ||\,|\hat{L}|\,|\hat{D}|\,|\hat{L}^T|\,||$$

and, from (5.11) and by assuming (5.9) is satisfied,

$$||AM^{-1}|| \le 1 + \tilde{c}.$$

Thus we have from (5.16)

$$\begin{aligned} ||b - A\bar{x}_k|| \le\ & c_{12}(n,k)\,\chi\,\varepsilon \Big[\, ||b|| + ||A||\,||\bar{x}_0|| + ||A||\,||\bar{Z}_k||\,||\,M(\bar{x}_k - \bar{x}_0)|| \\ & + \Big[\, 1 + ||\,|\hat{L}|\,|\hat{D}|\,|\hat{L}^T|\,|| \,\Big]\,||A||\,||\bar{x}_k - \bar{x}_0|| \Big] + \mathcal{O}(\varepsilon^2), \end{aligned} \tag{5.17}$$

$$\chi = \frac{1.3}{1 - 1.3k\varepsilon}.$$

. . . . 5. Formula (5.17) suggests that we might expect GMRES to have a final residual larger than the final residual in FGMRES. In particular, we could expect that a factor proportional to $\varepsilon\ ||A||\,||\,|\hat{L}|\,|\hat{D}|\,|\hat{L}^T|\,||\,||\bar{x}_k - \bar{x}_0||$ will appear.

6. Numerical experiments.

6.1. Test problems. We have run FGMRES and GMRES on several test problems. For the sake of simplicity, we present only the results obtained on particularly tough problems where iterative refinement fails for several different static pivoting strategies and values of τ [8]. We decided to omit the other results either because they are very similar to our results or because iterative refinement produced a scaled residual that is at rounding error level.

The dimension, the number of nonzero entries, and the origin of the three test problems that we use to illustrate the theory presented in section 5 are shown in Table 6.1.

behavior of $|||L||D||L^T|||$ versus $1/\tau$ for all our test examples. We point out that $|||L||D||L^T|||$ can grow much more than $1/\tau$ because of the threshold pivoting strategy, and this growth is the reason for the poor behavior of GMRES.

In Tables 6.2, 6.3, and 6.4, we present the parameters and the scaled residual

$$\frac{||b - A\bar{x}_k||}{||b|| + ||A||_\infty \, ||\bar{x}_k||} \tag{6.1}$$

for right-preconditioned GMRES (GMRES column) and flexible GMRES (FGMRES column), for the test problems TUMA1, CONT201, and CONT300, respectively. We also show the values of $||\bar{Z}_k||$ and $||M(\bar{x}_k - \bar{x}_0)||$ at convergence, as they are crucial quantities for the residual bounds in Theorems 5.1 and 5.3.

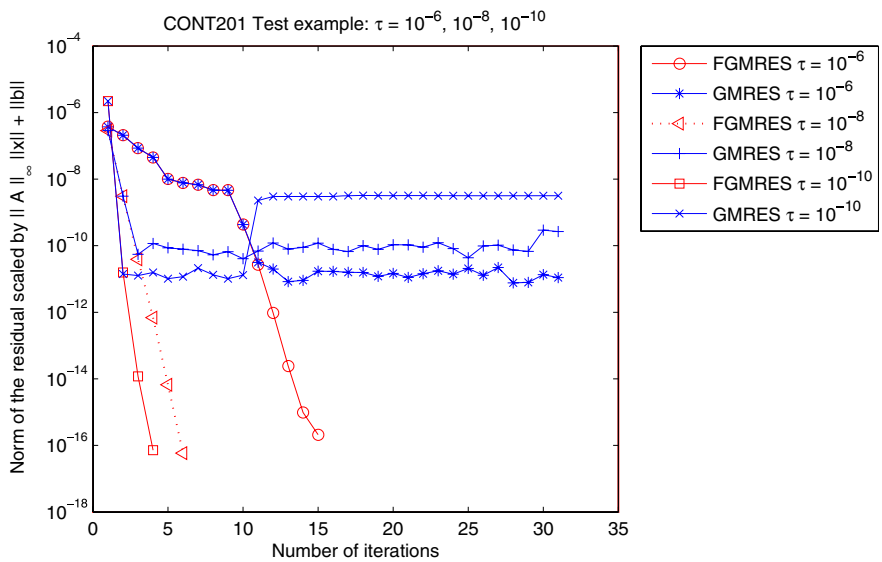

FIG. 6.2. *GMRES versus FGMRES on* CONT201 *test example:* $\tau = 10^{-6}, 10^{-8}, 10^{-10}$.

In all test examples, the values of $||\bar{Z}_k||$ and $||M(\bar{x}_k - \bar{x}_0)||$ for FGMRES show that

$$||\bar{Z}_k||\,||M(\bar{x}_k - \bar{x}_0)|| < 10^4$$

when $\tau = 10^{-9}$ (see Table 6.4). However, for the remaining values of τ the latter product is less than 2×10^2.

In Figures 6.2 and 6.3, we show the convergence histories of the scaled residual (6.1) for FGMRES and the right-preconditioned version of GMRES for the CONT201 and CONT300 test problems.

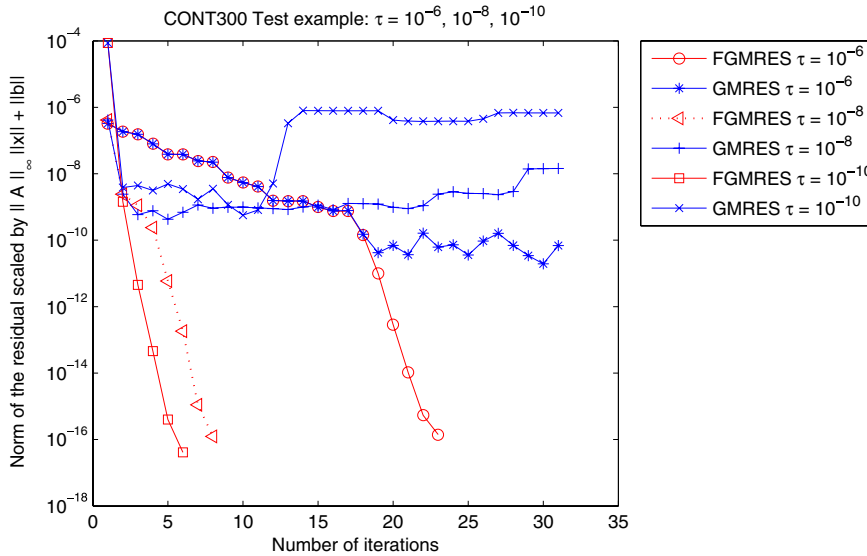

FIG. 6.3. *GMRES versus FGMRES on* CONT300 *test example:* $\tau = 10^{-6}, 10^{-8}, 10^{-10}$.

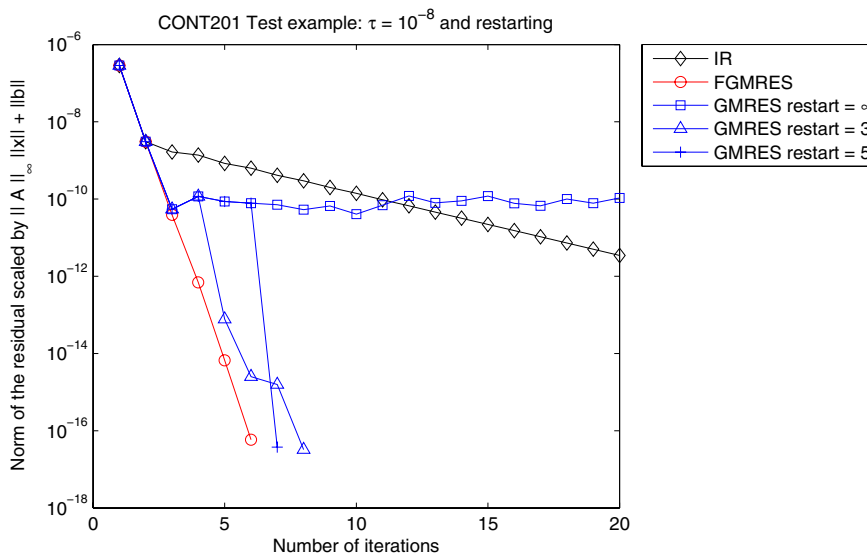

FIG. 6.4. *Restarted GMRES versus FGMRES on* CONT201 *test example:* $\tau = 10^{-8}$.

First, we point out that right-preconditioned GMRES is not backward stable. The FGMRES dependence on τ shows that the best trade-off is obtained for the recommended choice of $\tau = 10^{-8}$, where both iterative refinement and right-preconditioned GMRES are not able to obtain a scaled residual close to ε.

Both FGMRES and right-preconditioned GMRES can benefit from a restarting process. In particular, the restarted right-preconditioned GMRES converges with a scaled residual at machine precision for a small value of the restart parameter. In Figures 6.4 and 6.5, we compare the restarted right-preconditioned GMRES with

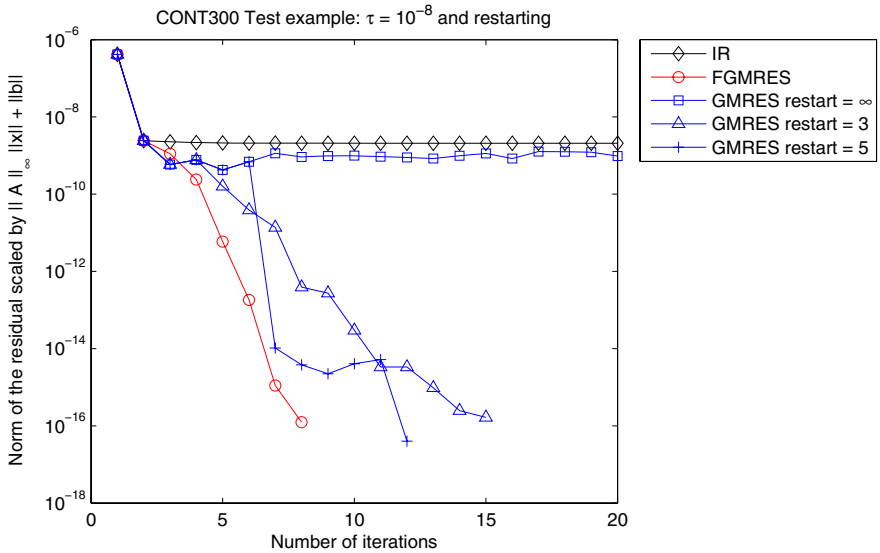

FIG. 6.5. *Restarted GMRES versus FGMRES on* CONT300 *test example:* $\tau = 10^{-8}$.

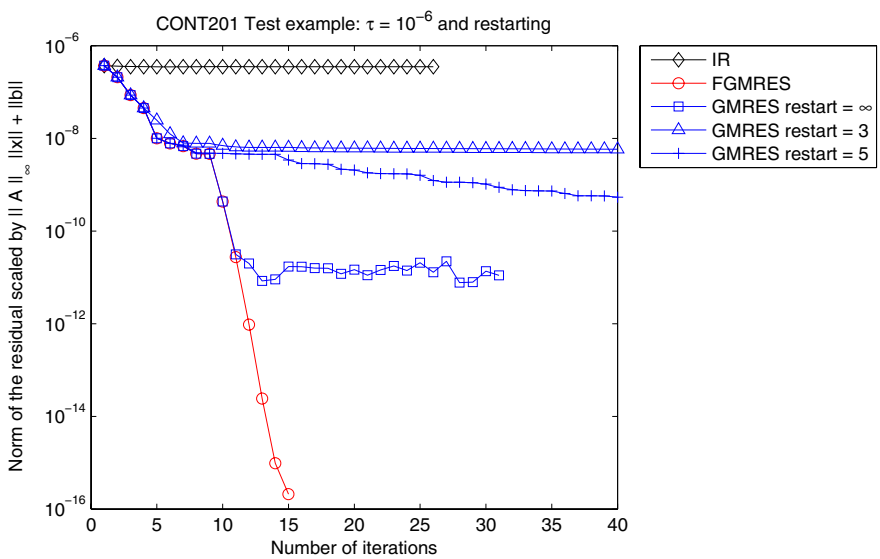

FIG. 6.6. *Restarted GMRES on* CONT201 *test example:* $\tau = 10^{-6}$.

FGMRES for $\tau = 10^{-8}$ for the CONT201 and CONT300 test examples, respectively. In the same figures, we show the behavior of classical iterative refinement which is unable to obtain a scaled residual close to rounding. Furthermore, we show in Figure 6.6 that, even with restarting, the preconditioned GMRES approach is not robust.

7. Conclusions. We have shown by experiment and analysis that FGMRES is a powerful method for obtaining the solution of sets of sparse linear equations when

a direct method using static pivoting has been used to factorize the matrix. This factorization is then used as a preconditioner for an iterative method. In particular, we show that GMRES converges when Richardson's method (iterative refinement) does not, that restarted GMRES performs better, and that FGMRES succeeds when these other methods fail. We also see that the convergence of FGMRES is much less sensitive to the choice of the static pivoting parameter.

Our analysis gives sufficient conditions for convergence, and we observe that FGMRES often converges even when our hypotheses are not satisfied. The main reason for this is that the bound $|||L||D||L^T|||$ on the norm of the solution of the preconditioned system is rather crude. Indeed, taking into account that $||M|| \approx ||A||$, we see that there is severe cancellation in the product and that small entries in D are usually balanced by large entries in L.

However, we see clearly that the analysis showing that stronger hypotheses are required for the convergence of preconditioned GMRES is reflected in the poorer convergence of this method, even when restarting is used.

A great benefit of our analysis and experiments is that the FGMRES iterative method can be used with confidence to solve systems preconditioned with a static pivoting factorization and that the method is far less sensitive to the choice of static pivoting parameter than either GMRES or iterative refinement.

Appendix A: Proof of Theorem 5.1.

1. By standard techniques [13], the computed matrix-by-vector products satisfy the relations

$$fl(r_0) = r_0 + f_1, \qquad ||f_1|| \le c_{13}(n,1)\varepsilon\,(||b|| + ||A||\,||\bar{x}_0||) + \mathcal{O}(\varepsilon^2), \tag{A.1}$$

$$fl(A\bar{Z}_k) = A\bar{Z}_k + F_k, \qquad ||F_k|| \le c_{14}(n,k)\varepsilon\,||A||\,||\bar{Z}_k|| + \mathcal{O}(\varepsilon^2), \tag{A.2}$$

where $\bar{x}_0 = fl(x_0)$.

Following [4, 10], the Gram–Schmidt orthogonalization process applied to $fl(C^{(k)})$ computes an upper triangular matrix $\overline{R}_k$ for which there exists an orthonormal matrix $\hat{V}_{k+1}$ that satisfies the relations

$$\begin{cases} [fl(r_0); fl(A\bar{Z})] + [f_2; E_k] = \hat{V}_{k+1}\overline{R}_k, \qquad \hat{V}_{k+1}^T\hat{V}_{k+1} = I_{k+1}, \\ ||f_2|| \le c_{15}(n,1)\varepsilon\,||r_0|| + \mathcal{O}(\varepsilon^2), \qquad ||E_k|| \le c_{16}(n,k)\varepsilon\,||A\bar{Z}_k|| + \mathcal{O}(\varepsilon^2) \end{cases} \tag{A.3}$$

under the hypothesis (5.3).

By combining (A.1), (A.2), and (A.3), we have

$$\begin{cases} [r_0; A\bar{Z}_k] + [f_1 + f_2; F_k + E_k] = \hat{V}_{k+1}\overline{R}_k, \\ ||f_1 + f_2|| \le c_{17}(n,1)\varepsilon\,(||b|| + ||A||\,||\bar{x}_0||) + \mathcal{O}(\varepsilon^2), \quad \text{and} \\ ||F_k + E_k|| \le c_{18}(n,k)\varepsilon\,(||A\bar{Z}_k|| + ||A||\,||\bar{Z}_k||) + \mathcal{O}(\varepsilon^2). \end{cases} \tag{A.4}$$

2. The second part of FGMRES computes the vector $\bar{y}_k = fl(y_k)$ by Givens or Householder algorithms [11, 12]. The vector $\bar{y}_k$ satisfies the relations

$$\begin{cases} \bar{y}_k = \arg\min_y ||\bar{\beta}e_1 + g^{[k]} - (\bar{H}_k + \Delta\bar{H}_k)y||, \\ ||\Delta\bar{H}_k|| \le c_{19}(k,1)\varepsilon\,||\bar{H}_k|| + \mathcal{O}(\varepsilon^2) \text{ and } ||g^{[k]}|| \le c_{20}(k,1)\varepsilon\,\bar{\beta} + \mathcal{O}(\varepsilon^2), \end{cases} \tag{A.5}$$

where $\bar{\beta} = (\overline{R}_k)_{11} = ||r_0 + f_1 + f_2||$ and the columns of $\bar{H}_k$ are columns $2, \ldots, k+1$ of

$\overline{R}_k$. Note that $\bar{\beta}$ is independent of k because at step k we compute only the kth column of $\overline{R}_k$, leaving the earlier columns unchanged. The computation of $\bar{y}_k$ is performed in two stages, and contributions to the matrix $\Delta\bar{H}_k$ come from two sources.

First, a sequence of Givens (or Householder) rotations $G^{(i)}$ is computed in order to reduce the matrix $\bar{H}$ to the upper triangular form U_k. The floating-point computation of the matrices $G^{(i)}$ gives

$$fl(G^{(i)}) = \bar{G}^{(i)} = \begin{bmatrix} I_{i-1} & & & \\ & \bar{c}_i & -\bar{s}_i & \\ & \bar{s}_i & \bar{c}_i & \\ & & & I_{n-i-1} \end{bmatrix}, \quad i = 1, \ldots, k,$$

$$\bar{c}_i = fl\left(\frac{(\bar{H}_k)_{i,i}}{\sqrt{(\bar{H}_k)_{i,i}^2 + (\bar{H}_k)_{i+1,i}^2}}\right) \qquad \text{and} \qquad \bar{s}_i = fl\left(\frac{(\bar{H}_k)_{i+1,i}}{\sqrt{(\bar{H}_k)_{i,i}^2 + (\bar{H}_k)_{i+1,i}^2}}\right).$$

The $\bar{G}^{(i)}$ matrices are also applied to the vector $\bar{\beta}e_1$, and, from the error analysis presented in [20], the floating-point arithmetic will produce an exact orthogonal matrix $G^{[k]}$ such that

$$\begin{aligned} fl(\bar{G}^{(k)} \cdots \bar{G}^{(1)} \bar{\beta} e_1) &= G^{[k]}(\bar{\beta}e_1 + g^{[k]}), \\ fl(\bar{G}^{(k)} \cdots \bar{G}^{(1)} \bar{H}_k) &= G^{[k]}(\bar{H}_k + \Delta\bar{H}_k^{(1)}), \\ ||\Delta\bar{H}_k^{(1)}|| &\leq c_{21}(k,1)\varepsilon\, ||\bar{H}_k|| + \mathcal{O}(\varepsilon^{\,2}). \end{aligned}$$

Second, the $\bar{y}_k$ vector is computed by solving the upper triangular system. The standard backward substitution algorithm will introduce an additional perturbation $\Delta\bar{H}_k^{(2)}$ of $\bar{H}_k$ but will leave the perturbation $g^{[k]}$ untouched. The perturbation $\Delta\bar{H}_k^{(2)}$ will also have the same upper Hessenberg structure of $\bar{H}_k$ and

$$||\Delta\bar{H}_k^{(2)}|| \leq c_{22}(k,1)\varepsilon\, ||\bar{H}_k|| + \mathcal{O}(\varepsilon^{\,2}).$$

This follows from the upper triangular structure of the perturbation to U_k induced by the backward substitution algorithm and from the structure and orthogonality of $G^{[k]}$. Finally, we point out that in the relations (A.5) we have (see (5.1))

$$\begin{cases} \Delta\bar{H}_k = \Delta\bar{H}_k^{(1)} + \Delta\bar{H}_k^{(2)} \qquad \text{and} \\ c_1(k,1) = c_{21}(k,1) + c_{22}(k,1), \end{cases}$$

where $c_1(k,1)$ is the constant of (5.1). Moreover, because of the special structure of $\bar{\beta}e_1$ and the orthogonality of $G^{[k]}$ we have

$$g_j^{[k]} = 0, \qquad j = k+1, \ldots, n,$$

and, denoting by $\bar{h}^{[k]} = fl(\bar{G}^{(k)} \cdots \bar{G}^{(1)} \bar{\beta} e_1)$, we have

$$\begin{aligned} \alpha_k &= ||G^{[k]}(\bar{\beta}e_1 + g^{[k]} - (\bar{H}_k + \Delta\bar{H}_k)\bar{y}_k)|| \\ &= ||(G^{[k]}(\bar{\beta}e_1 + g^{[k]}))_{k+1}|| = |\bar{h}_{k+1}^{[k]}|. \end{aligned} \tag{A.6}$$

A direct analysis of $\bar{h}^{[k]}$ shows that

$$\begin{cases} \bar{h}_1^{[1]} &= \bar{\beta}\bar{c}_1(1+\mu_1), & |\mu_1| \le \varepsilon\,, \\ \bar{h}_2^{[1]} &= \bar{\beta}\bar{s}_1(1+\rho_1), & |\rho_1| \le \varepsilon\,, \\ \bar{h}_j^{[k]} &= \bar{h}_j^{[k-1]}, & j = 1,\ldots,k-1, \quad k \ge 2, \\ \bar{h}_k^{[k]} &= \bar{h}_k^{[k-1]}\bar{c}_k(1+\mu_k), & |\mu_k| \le \varepsilon\,, \\ \bar{h}_{k+1}^{[k]} &= \bar{h}_k^{[k-1]}\bar{s}_k(1+\rho_k), & |\rho_k| \le \varepsilon\,. \end{cases}$$

Therefore, from using (A.3), (A.4), (A.5), (A.6), and the orthogonality of

$$\widetilde{V}_{k+1} = \hat{V}_{k+1}G^{[k]T},$$

we have

$$\begin{aligned} \alpha_k &= ||\widetilde{V}_{k+1}G^{[k]}(\bar{\beta}e_1 + g^{[k]} - (\bar{H}_k + \Delta\bar{H}_k)\bar{y}_k)|| \\ &= ||r_0 + f_1 + f_2 + \hat{V}_{k+1}g^{[k]} - A(\bar{Z}_k + A^{-1}(F_k + E_k + \hat{V}_{k+1}\Delta\bar{H}_k))\bar{y}_k|| \\ &= ||r_0 + \delta r_0 - A\big(\bar{Z}_k + \hat{Z}_k\big)\bar{y}_k||, \end{aligned}$$

where $\delta r_0 = f_1 + f_2 + f_3$ and $\hat{Z}_k = A^{-1}(F_k + E_k + \hat{V}_k\Delta\bar{H}_k)$. Then

$$\alpha_k = \alpha_{k-1}|\bar{s}_k|(1+\rho_k), \quad |\rho_k| \le \varepsilon\,. \tag{A.7}$$

Thus, under the hypotheses (5.2), (5.1), and (5.3) and from (A.5), the matrices $\big(\bar{Z}_k + \hat{Z}_k\big)$ have full rank for all k; i.e.,

$$\bar{H}_k + \Delta\bar{H}_k$$

is full rank for all k, and the values of α_k converge monotonically to zero for a finite value of $k = \hat{k}$. In the worst case this will happen for $\hat{k} = n$.

3. The last part of FGMRES is the computation of $\bar{x}_k = fl(x_0 + \bar{Z}\bar{y}_k)$. The value $\bar{x}_k$ satisfies the relations

$$\begin{cases} \bar{x}_k = \bar{x}_0 + \bar{Z}_k\bar{y}_k + \delta x_k, \\ ||\delta x_k|| \le c_3(k,1)\varepsilon\,||\bar{Z}_k||\,||\bar{y}_k|| + \varepsilon\,||\bar{x}_0|| + \mathcal{O}(\varepsilon^{\,2}). \end{cases} \tag{A.8}$$

Therefore, we have

$$\alpha_k = ||r_0 + \delta r_0 + A\delta x_k - A\delta x_k - A\bar{Z}_k\bar{y}_k - A\hat{Z}_k\bar{y}_k||. \tag{A.9}$$

From (A.8), we have

$$\begin{cases} \alpha_k = ||b - A\bar{x}_k + w||, \\ w = \delta r_0 + A\delta x_k - A\hat{Z}_k\bar{y}_k, \end{cases} \tag{A.10}$$

and then

$$||b - A\bar{x}_k|| \le ||w|| + \alpha_k. \tag{A.11}$$

From (A.4), (A.5), (A.8), (A.10), and (A.11), we have

$$\text{(A.12)}\qquad \begin{cases} ||\delta r_0|| \le c_{24}(n,1)\varepsilon\,(||b|| + ||A||\,||\bar{x}_0||) + \mathcal{O}(\varepsilon^{\,2}), \\ ||A\delta x_k|| \le c_{25}(n,1)\varepsilon\,||A||\,\Big[\,||\bar{Z}_k||\,||\bar{y}_k|| + ||\bar{x}_0||\Big] + \mathcal{O}(\varepsilon^{\,2}) \end{cases}$$

and, finally,

$$\text{(A.13)}\qquad \begin{aligned} ||w|| \;\le\; c_{26}(n,k)\varepsilon\,\Big(&||b|| + ||A||\,||\bar{x}_0|| + ||\bar{H}_k||\,||\bar{y}_k|| \\ &+ ||A||\,||\bar{Z}_k||\,||\bar{y}_k||\Big) + \mathcal{O}(\varepsilon^{\,2}). \end{aligned}$$

Therefore, under hypothesis (5.1) and from (A.11), we have

$$\text{(A.14)}\qquad \begin{aligned} ||b - A\bar{x}_k|| \;\le\; \alpha_k + c_2(n,k)\varepsilon\,\Big(&||b|| + ||A||\,||\bar{x}_0|| + ||\bar{H}_k||\,||\bar{y}_k|| \\ &+ ||A||\,||\bar{Z}_k||\,||\bar{y}_k||\Big) + \mathcal{O}(\varepsilon^{\,2}) \end{aligned}$$

and, then, taking into account that, from (A.4),

$$\text{(A.15)}\qquad ||\bar{H}_k|| \le ||A\bar{Z}_k|| + \mathcal{O}(\varepsilon\,) \quad \forall k < \hat{k},$$

we have (5.4).

From the analysis of [4, 10], the Gram–Schmidt orthogonalization process applied to $fl(C^{(k)})$ computes matrices $\bar{V}_k = fl(V_k)$ that lose orthogonality quickly. Nevertheless, under the mild hypothesis (5.3) on the matrix $C^{(k)}$ the spectral condition number of each $\bar{V}_k$ is close to one and

$$\begin{aligned} 1 \le ||\bar{V}_k|| \le k, \\ \kappa(\bar{V}_k) \le 1.3 \end{aligned}$$

so that

$$||\bar{V}_k^{+}|| \le 1.3/||\bar{V}_k|| \le 1.3,$$

where $\bar{V}_k^{+} = (\bar{V}^T\bar{V}_k)^{-1}\bar{V}_k^T$ (see [10, Thm. 3.1] and [14]).

Taking into account the previous relations, it is possible to express $\bar{y}_k$ as a function of $\bar{x}_k - x_0$. For each column $\bar{z}_i$ of $\bar{Z}_k$ a matrix $\mathcal{G}_i$ exists and satisfies

$$(M + \mathcal{G}_i)\bar{z}_i = \bar{v}_i, \qquad ||\mathcal{G}_i|| \le c_{27}(n,1)\,\varepsilon\,||\,|\hat{L}|\,|\hat{D}|\,|\hat{L}^T|\,|| + \mathcal{O}(\varepsilon^{\,2}),$$

where $\bar{v}_i$ is the ith column of $\bar{V}_k$. Then, we have the relation

$$\text{(A.16)}\qquad M\bar{Z}_k = \bar{V}_k + \hat{W}_k + \mathcal{O}(\varepsilon^{\,2}).$$

From the relations (A.8) and (A.16), it follows that

$$\begin{aligned} &\bar{x}_k - \bar{x}_0 - \delta x_k = \bar{Z}_k\bar{y}_k, \\ &\bar{V}_k^{+}M(\bar{x}_k - \bar{x}_0 - \delta x_k) = \bar{V}_k^{+}M\bar{Z}_k\bar{y}_k, \\ &\bar{V}_k^{+}(M(\bar{x}_k - \bar{x}_0) - M\delta x_k) = (\bar{V}_k^{+}\bar{V}_k\bar{y}_k + \bar{V}_k^{+}\hat{W}_k\bar{y}_k) + \mathcal{O}(\varepsilon^{\,2}), \\ &\bar{V}_k^{+}(M(\bar{x}_k - \bar{x}_0) - M\delta x_k) - \bar{V}_k^{+}\hat{W}_k\bar{y}_k + \mathcal{O}(\varepsilon^{\,2}) = \bar{y}_k. \end{aligned}$$

Then, we have

$$||\bar{y}_k|| \leq 1.3||M(\bar{x}_k - \bar{x}_0)|| + 1.3||\hat{W}_k||\,||\bar{y}_k|| + ||M||\,||\delta x_k|| + \mathcal{O}(\varepsilon^2)$$

and

$$\begin{aligned}||\bar{y}_k|| \leq\ & 1.3||M(\bar{x}_k - \bar{x}_0)|| + 1.3||\hat{W}_k||\,||\bar{y}_k|| \\ & + c_3(k,1)\varepsilon\,||M||\,||\bar{Z}_k||\,||\bar{y}_k|| + \varepsilon\,||\bar{x}_0|| + \mathcal{O}(\varepsilon^2).\end{aligned}$$

From hypothesis (5.5), we can state the inequality

$$||\bar{y}_k|| \leq \gamma||M(\bar{x}_k - \bar{x}_0)|| + \gamma\varepsilon\,||\bar{x}_0|| + \mathcal{O}(\varepsilon^2), \quad \text{where } \gamma = \frac{1.3}{1-\rho}. \tag{A.17}$$

Finally, by substituting (A.17) into (A.14) and taking into account (A.15), we have the following upper bound for the residual:

$$\begin{aligned}||b - A\bar{x}_k|| \ \leq\ & \alpha_k + c_4(n,k)\gamma\varepsilon\Big[||b|| + ||A||\,||\bar{x}_0|| \\ & + \Big(||A\bar{Z}_k|| + ||A||\,||\bar{Z}_k||\Big)\Big(||M(\bar{x}_k - \bar{x}_0)|| + \varepsilon\,||\bar{x}_0||\Big)\Big] + \mathcal{O}(\varepsilon^2).\end{aligned}$$

Furthermore, hypothesis (5.1) implies that there exists a value $\hat{k}$ (possibly equal to n in the worst case) for which $\alpha_k = 0$. Then, we can conclude that for $k \geq \hat{k}$ we have (5.6).

Appendix B: Proof of Theorem 5.2. We can bound $||M(\bar{x}_k - \bar{x}_0)||$ using (5.7) and (5.8). Under hypothesis (5.9), we have

$$\begin{aligned}||M(\bar{x}_k - \bar{x}_0)|| \ &\leq ||A\bar{x}_k - b|| + \tau\,||\bar{x}_k|| + ||\delta A||\,||\bar{x}_k|| + ||\delta M||\,||\bar{x}_0|| \\ &\leq ||A\bar{x}_k - b|| + 2\tau\big(\,||\bar{x}_k|| + ||\bar{x}_0||\,\big).\end{aligned} \tag{B.1}$$

From the relations (B.1) and (5.6), we have

$$\begin{aligned}||b - A\bar{x}_k|| \ \leq\ & c_4(n,k)\gamma\varepsilon\,(||b|| + ||A||\,||\bar{x}_0|| \\ & + ||A||\,||\bar{Z}_k||\,\big(||A\bar{x}_k - b|| + \tau\,(\,||\bar{x}_k|| + ||\bar{x}_0||\,)\big) + \mathcal{O}(\varepsilon^2).\end{aligned}$$

Under the hypotheses (5.9) and (5.10), we have

$$\begin{cases} ||b - A\bar{x}_k|| \ \leq\ 2\mu\varepsilon\Big(||b|| + ||A||\,||\bar{x}_0|| \\ \qquad\qquad + \tau||A||\,||\bar{Z}_k||\,(||\bar{x}_k|| + ||\bar{x}_0||)\Big) + \mathcal{O}(\varepsilon^2), \\ \mu = \dfrac{c_7(n,k)\gamma}{1 - c_7(n,k)\varepsilon\,\gamma||A||\,||\bar{Z}_k||}. \end{cases} \tag{B.2}$$

Under this final hypothesis (5.11), we obtain (5.12), i.e., the normwise backward stability for FGMRES using as preconditioner the M computed by `MA57` with static pivoting.

Appendix C: Proof of Theorem 5.3. The first two stages of GMRES roundoff error analysis are the same as the first two stages in the proof of Theorem 5.1. Under the assumption of performing a few steps of iterative refinement in solving the final linear system

$$Mq = fl(\bar{V}_k \bar{y}_k),$$

we have the following relations:

$$\text{(C.1)} \qquad \begin{cases} (M+\delta M)\big(I+\Gamma\big)^{-1}\,(\bar{x}_k - (I+\Gamma)\,\bar{x}_0) = \bar{V}_k\,\bar{y}_k + \widetilde{f}, \\ |\Gamma| \le \varepsilon\, I, \\ ||\widetilde{f}|| \le k\varepsilon\ ||\bar{V}_k||\,||\bar{y}_k|| + \mathcal{O}(\varepsilon^{\,2}) \le 1.3k\varepsilon\,||\bar{y}_k|| + \mathcal{O}(\varepsilon^{\,2}), \\ ||\delta M|| \le n\varepsilon\ ||M|| + \mathcal{O}(\varepsilon^{\,2}). \end{cases}$$

Taking into account that

$$(M+\delta M)\,(I+\Gamma)^{-1} = M + \big(\delta M - M\,\Gamma\big)\big(I+\Gamma\big)^{-1} = M + \widetilde{\delta M}$$

with

$$||\widetilde{\delta M}|| \le (n+1)\frac{\varepsilon}{1-\varepsilon}||M|| = c_{28}(n,1)\varepsilon\,||M||,$$

we have, from (C.1), that

$$\text{(C.2)} \qquad (M+\widetilde{\delta M})(\bar{x}_k - \bar{x}_0) = \bar{V}_k\,\bar{y}_k + \widetilde{f} + (M+\widetilde{\delta M})\,\Gamma\,\bar{x}_0.$$

Therefore, we have from (5.13) and (C.2) that (A.8) can be replaced by

$$\text{(C.3)} \qquad \bar{x}_k = \bar{x}_0 + (M+\widetilde{\delta M})^{-1}(\bar{V}_k\,\bar{y}_k + \widetilde{f}) + \Gamma\,\bar{x}_0$$

$$\text{(C.4)} \qquad = \bar{x}_0 + M^{-1}\,\bar{V}_k\,\bar{y}_k + \delta\bar{x}_k$$

with

$$\begin{aligned} \delta\bar{x}_k &= \Gamma\,\bar{x}_0 + M^{-1}\,\widetilde{f} - M^{-1}\,\widetilde{\delta M}\,M^{-1}\,\bar{V}_k\,\bar{y}_k + \mathcal{O}(\varepsilon^{\,2}) \\ &= \Gamma\,\bar{x}_0 + M^{-1}\,\widetilde{f} - M^{-1}\,\widetilde{\delta M}\,(\bar{x}_k - \bar{x}_0 - \delta\bar{x}_k) + \mathcal{O}(\varepsilon^{\,2}) \end{aligned}$$

and

$$\text{(C.5)} \qquad \begin{aligned} \delta\bar{x}_k &= \big(I - M^{-1}\,\widetilde{\delta M}\big)^{-1}\big(\Gamma\,\bar{x}_0 + M^{-1}\,\widetilde{f} - M^{-1}\,\widetilde{\delta M}\,(\bar{x}_k - \bar{x}_0)\big) + \mathcal{O}(\varepsilon^{\,2}) \\ &= \Gamma\,\bar{x}_0 + M^{-1}\,\widetilde{f} - M^{-1}\,\widetilde{\delta M}\,(\bar{x}_k - \bar{x}_0) + \mathcal{O}(\varepsilon^{\,2}). \end{aligned}$$

Under hypotheses (5.3) and (5.13), we obtain from (C.3), (C.4), (C.5), and (A.16)

$$\text{(C.6)} \qquad \begin{cases} \alpha_k = ||b - A\bar{x}_k + w_g||, \qquad \text{where} \\ w_g = \delta r_0 + A\delta x_k - A\hat{Z}_k\bar{y}_k + A(M^{-1}\,\bar{V}_k\,\bar{y}_k - \bar{Z}_k\,\bar{y}_k) \\ \qquad = \delta r_0 + A\delta x_k - A\hat{Z}_k\bar{y}_k + AM^{-1}\,\hat{W}_k\,\bar{y}_k + \mathcal{O}(\varepsilon^{\,2}), \end{cases}$$

and then

$$||b - A\bar{x}_k|| \leq \alpha_k + ||w_g||. \tag{C.7}$$

From (A.4), (A.5), (A.7), (C.3), (C.5), (C.6), and (C.7), we have

$$\begin{cases} ||\delta r_0|| \;\leq\; c_{29}(n,1)\varepsilon\,(||b|| + ||A||\,||\bar{x}_0||) + \mathcal{O}(\varepsilon^{\,2}) \\ ||A\delta x_k|| \;\leq\; c_{30}(n,1)\varepsilon\left[||AM^{-1}||\left(||M||\,||\bar{x}_k - \bar{x}_0|| + ||\bar{y}_k||\right)\right. \\ \qquad\qquad \left. + ||A||\,||\bar{x}_0||\right] + \mathcal{O}(\varepsilon^{\,2}) \end{cases} \tag{C.8}$$

and, finally,

$$\begin{aligned} ||w_g|| \leq c_{31}(n,k)\varepsilon\;\Big[\;&||b|| + ||A||\,||\bar{x}_0|| + ||\bar{H}_k||\,||\bar{y}_k|| + ||A||\,||\bar{Z}_k||\,||\bar{y}_k|| \\ &+ ||AM^{-1}||\left(||M||\,||\bar{x}_k - \bar{x}_0|| + ||\bar{y}_k|| + ||\,|\hat{L}|\,|\hat{D}|\,|\hat{L}^T|\,||\,||\bar{y}_k||\right)\Big] + \mathcal{O}(\varepsilon^{\,2}). \end{aligned} \tag{C.9}$$

From (C.2), we can compute an upper bound for $||\bar{y}_k||$ by multiplying the equation by $\bar{V}_k^+$:

$$\bar{y}_k = \bar{V}_k^+\,(M + \widetilde{\delta M})(\bar{x}_k - \bar{x}_0) - \bar{V}_k^+\,(\widetilde{f} + (M + \widetilde{\delta M})\,\Gamma\,\bar{x}_0) \tag{C.10}$$

$$= \bar{V}_k^+\,M(\bar{x}_k - \bar{x}_0) - \bar{V}_k^+\,(\widetilde{f} - \widetilde{\delta M}(\bar{x}_k - \bar{x}_0) + (M + \widetilde{\delta M})\,\Gamma\,\bar{x}_0), \tag{C.11}$$

and then

$$\begin{aligned} ||\bar{y}_k|| \;&\leq\; 1.3||M(\bar{x}_k - \bar{x}_0)|| + 1.3k\varepsilon\,||\bar{y}_k|| \\ &+\; 1.3n\varepsilon\,||M||\,(||\bar{x}_k - \bar{x}_0|| + ||\bar{x}_0||) + \mathcal{O}(\varepsilon^{\,2}). \end{aligned} \tag{C.12}$$

From hypothesis (5.3), we can assume that $1.3\,k\varepsilon < 1$, and thus we have

$$\begin{cases} ||\bar{y}_k|| \leq \chi||M(\bar{x}_k - \bar{x}_0)|| + \chi n\varepsilon\,||M||\,(||\bar{x}_k - \bar{x}_0|| + ||\bar{x}_0||) + \mathcal{O}(\varepsilon^{\,2}), \\ \chi = \dfrac{1.3}{1 - 1.3k\varepsilon}. \end{cases} \tag{C.13}$$

Furthermore, as in the proof of Theorem 5.1, hypothesis (5.1) implies that there exists a value $\hat{k}$ (possibly equal to n in the worst case) for which $\alpha_k = 0$. Then, under hypotheses (5.1), (5.3) and from (C.13), (C.7), and (C.9), we can conclude that for $k \geq \hat{k}$ we have (5.14).

Acknowledgment. We would like to thank the anonymous referees for their helpful comments that have hopefully made the paper easier to read.

INTERPOLATION OPERATORS FOR ALGEBRAIC MULTIGRID BY LOCAL OPTIMIZATION*

CLARK R. DOHRMANN†

Abstract. An approach is presented to construct interpolation operators for algebraic multigrid (AMG) based on solutions of local optimization problems. The local problems are posed in such a way that the null space can be approximated exactly at each multigrid level. In addition, a condition ensuring nonsingularity of a local matrix highlights the need for special considerations when the null space dimension exceeds the number of unknowns for each node. Numerical examples for the Poisson equation and linear elasticity demonstrate the effectiveness of the approach and the optimal performance of an ensuing AMG preconditioner. Comparisons with a smoothed aggregation approach are also made.

Key words. algebraic multigrid, interpolation operators, energy minimization, iterative methods, smoothed aggregation

DOI. 10.1137/06066103X

1. Introduction.

Several approaches have been proposed recently to construct multigrid interpolation operators (matrices) based on energy minimization concepts. In [12] and [16], minimizing the sum of coarse interpolation energies subject to null space constraints leads to a global optimization problem for the different coarsening strategies considered. This problem is then solved approximately using an iterative method. A global optimization problem is avoided in algebraic multigrid based on elements (AMGe) [2, 9], but local energy minimization problems require individual element matrices. Studies of element-free alternatives to AMGe not requiring access to element matrices appear in [8, 10].

Our approach can be interpreted as a new way of constructing element-free AMGe operators that explicitly incorporates available null space information. We show how the interpolation operators can be obtained conveniently from solutions of local energy minimization problems. The approach ultimately leads to effective multigrid methods, not only for problems like the Poisson equation, but for more complicated systems such as linear elasticity. Other problem types such as plate bending can also be treated using the same framework, but they are not discussed here. We note for elasticity problems that special considerations involving the introduction of nodal rotations are required at the first coarse level.

Another approach used for constructing AMG interpolation operators is smoothed aggregation [15, 14]. In smoothed aggregation, an interpolation called a tentative prolongator is constructed using information about the null space for the problem. Often, the tentative prolongator is then smoothed using damped Jacobi iterations.

Although these iterations can reduce the energy of the interpolations, they increase the support of the aggregates and require spectral estimates. In contrast, coarse node supports are specified beforehand for the present approach and no eigenvalue estimates are needed. Like smoothed aggregation, the present approach uses knowledge about the null space, but it does so in a fundamentally different way. Here, the null space is used to approximate nodal values in a neighborhood around a noncoarse node.

To keep the presentation simple, we assume that the coarse nodes for each level are given. The subject approach for constructing interpolation operators is presented in section 2. Numerical examples and comparisons with a smoothed aggregation approach are provided in section 3. A few concluding remarks are given in section 4.

2. Interpolation operators. Let A denote the stiffness matrix for a given multigrid level. We assume that A is symmetric and at least positive semidefinite. Each row and column of A corresponds to a particular node and local degree of freedom (dof) number of the computational mesh (grid). Let $r(i)$ denote the rows of A corresponding to node i. Two nodes i and j are said to be adjacent if $a_{kl} \neq 0$ for some $k \in r(i)$ and $l \in r(j)$. We also say that dofs k and l are adjacent if $a_{kl} \neq 0$. Each column of the interpolation matrix P corresponds to a particular node called a coarse node.

2.1. Motivation and connections. To begin, let f (fine) denote the set of dofs for a particular noncoarse node. The set of dofs potentially affecting the interpolation of f is denoted by c (coarse). Define $I = f \cup c$ as the set of [illegible] dofs. The set of [illegible] dofs B contains all dofs adjacent to at least one dof in I but not contained in I. Depending on the context, symbols such as f and c can refer to either these dof sets or their associated node sets. The null space matrix associated with the problem operator has the same number of rows as A and is denoted by N.

The vector y_I contains all the dofs in I and is partitioned such that

$$y_I = \begin{bmatrix} y_f \\ y_c \end{bmatrix}, \quad A_{II} = \begin{bmatrix} A_{ff} & A_{fc} \\ A_{cf} & A_{cc} \end{bmatrix}, \quad A_{IB} = \begin{bmatrix} A_{fB} \\ A_{cB} \end{bmatrix}, \quad N_I = \begin{bmatrix} N_f \\ N_c \end{bmatrix}. \tag{2.1}$$

We assume that A_{II} is positive definite. A key part of our approach is constraining y_B to be of the form

$$y_B = N_B q\,. \tag{2.2}$$

The harmonic extension of y_B for y_I is then given by

$$y_{Ih} = -A_{II}^{-1} A_{IB} N_B q. \tag{2.3}$$

For a fixed y_c, we would like (motivated by [8]) to choose y_f and q such that y_I is the best approximation in energy norm to y_{Ih}. Thus, minimizing

$$E = (y_I - y_{Ih})^T A_{II} (y_I - y_{Ih})$$

with respect to y_f and q leads to the linear system

$$\underbrace{\begin{bmatrix} A_{ff} & A_{fB}N_B \\ N_B^T A_{fB}^T & N_B^T A_{IB}^T A_{II}^{-1} A_{IB} N_B \end{bmatrix}}_{\mathcal{A}} \begin{bmatrix} y_f \\ q \end{bmatrix} = - \begin{bmatrix} A_{fc} \\ N_B^T A_{cB}^T \end{bmatrix} y_c\,. \tag{2.4}$$

LEMMA 2.1.

$$A_{II}N_I + A_{IB}N_B = 0\,. \tag{2.5}$$

$\mathcal{A}$ (2.4) N_c . Consider the linear system

$$\mathcal{A}x = d, \quad x = \begin{bmatrix} y_f \\ q \end{bmatrix}, \quad d = \begin{bmatrix} d_1 \\ d_2 \end{bmatrix}.$$

Solving the first block of equations for y_f and substituting the result back into the second block leads to

$$y_f = A_{ff}^{-1}(d_1 - A_{fB}N_B q)$$

and

$$Dq = d_2 + N_B^T A_{fB}^T A_{ff}^{-1} d_1,$$

where

$$D = N_B^T(A_{IB}^T A_{II}^{-1} A_{IB} - A_{fB}^T A_{ff}^{-1} A_{fB})N_B\,.$$

From (2.5) we have

$$A_{II}^{-1}A_{IB}N_B = -N_I \quad \text{and} \quad A_{ff}^{-1}A_{fB}N_B = -(N_f + A_{ff}^{-1}A_{fc}N_c)$$

so that

$$D = N_I^T A_{II} N_I - (N_f + A_{ff}^{-1}A_{fc}N_c)^T A_{ff}(N_f + A_{ff}^{-1}A_{fc}N_c) = N_c^T S N_c,$$

where

$$S = A_{cc} - A_{fc}^T A_{ff}^{-1} A_{fc}\,.$$

Since A_{II} is positive definite, both A_{ff} and the Schur complement S are positive definite. Thus, D is positive definite if the columns of N_c are linearly independent. Since D is the Schur complement of A_{ff} in $\mathcal{A}$, positive definiteness of A_{ff} and D implies positive definiteness of $\mathcal{A}$. Now if the columns of N_c are linearly dependent, then there exists a nonzero vector v such that $N_c v = 0$. It follows that $Dq = 0$ has the nontrivial solution $q = v$, which implies that $\mathcal{A}$ is singular and thus not positive definite. □

Returning for a moment to the proof of Lemma 2.1, by setting $d_1 = -A_{fc}y_c$ and $d_2 = -N_B^T A_{cB}^T y_c$ as in (2.4), we obtain

$$N_c^T S N_c q = N_c^T S y_c \tag{2.6}$$

and

$$y_f = -A_{ff}^{-1}(A_{fc}y_c + A_{fB}N_B q). \tag{2.7}$$

Equation (2.6) means that q gives the coordinates (in the N_c column basis) of the projection of y_c onto the range of N_c in the $(S\cdot,\cdot)$ inner product. Thus, y_B can be

viewed as a weighted projection of y_c onto the null space. This defines an extension mapping in the spirit of [8], which in the simplest case of a Poisson problem is given by a weighted averaging:

$$y_B = \frac{e^T S y_c}{e^T S e} e,$$

where $e = N_c$ is a unit vector with all entries equal to 1. It follows from (2.2) and (2.7) that y_f is a harmonic extension of y_c and y_B. Interpolation operators based on harmonic extensions appear in other approaches such as those in [4] and [8].

LEMMA 2.2. [illegible] (2.5) [illegible] N_c [illegible]

(2.8) $$y_c = N_c p\,,$$

[illegible] $y_f = N_f p$ [illegible] $q = p$ [illegible] (2.4) [illegible]. From Lemma 2.1 we have that $\mathcal{A}$ is nonsingular so that the solution of (2.4) is unique. It remains to show that the stated choices for y_f and q result in the smallest possible value of E. From (2.3) and (2.5) we have $y_{Ih} = N_I p$. We also have $y_I = N_I p$ so that $E = 0$, which is the smallest possible value of E since A_{II} is positive definite. ∎

Let $w = Np$ denote a vector in the range of the null space matrix N. Lemma 2.2 implies that if the problem satisfies a null space relation as in (2.5) and the coarse dofs are chosen such that $y_c = w_c$ as in (2.8), then y_f obtained from the solution of (2.4) equals w_f. In other words, the interpolation for y_f is consistent with the rigid body motion of the coarse nodes. This property is important in ensuring a scalable approach.

2.2. Construction. We assume that the interpolation of each noncoarse node is affected by all adjacent coarse nodes and that each noncoarse node is adjacent to at least one coarse node. Additional details on coarse nodes and their selection are provided in section 3. We now discuss how solutions from (2.4) can be used to construct interpolation operators for y_f. Combining (2.6) and (2.7) gives

$$y_f = -A_{ff}^{-1}(A_{fc} + A_{fB} N_B (N_c^T S N_c)^{-1} N_c^T S) y_c. \tag{2.9}$$

If the columns N_c are linearly independent, then (2.9) could be used as an interpolation formula without modification. Unfortunately, it may be problematic to satisfy this condition in practice for certain problem types such as elasticity.

The number of columns in N_c is one for the Poisson equation. Thus, N_c has full column rank provided that c contains at least one coarse node. For two-dimensional (2D) elasticity problems, the number of columns in N_c is three, but there are at most two dofs for each coarse node. Thus, if c consists of just a single coarse node, then the columns of N_c will be linearly dependent. The situation is potentially even more grave for three-dimensional (3D) elasticity problems for which the number of columns in N_c is six, but each coarse node has at most three dofs. Even if c consists of two coarse nodes, the columns of N_c will be linearly dependent as illustrated in Figure 2.1. We note for structural problems involving plate or shell elements that the columns of N_c will typically be linearly independent even if c consists of just one coarse node. This is true because the coarse nodes have both translational and rotational dofs.

One idea for addressing linear dependence in the columns of N_c is to augment the node set c. Doing so increases the number of rows in N_c and has the potential of

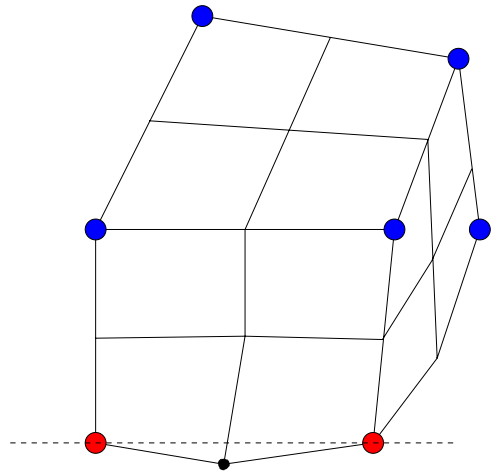

FIG. 2.1. *Simple mesh with eight elements and coarse nodes shown as large filled circles. The two coarse nodes influencing the bottom midedge node are connected by a dashed line. For an elasticity problem, these two coarse nodes do not move for a rotation about the dashed line. However, the midedge node will move unless it is on the line connecting the two coarse nodes. Thus, interpolation of the midedge node based on these two coarse nodes cannot reproduce all rigid body motions. In other words, the columns of N_c are not linearly independent. This problem can be avoided by introducing rotational dofs for the coarse nodes.*

removing linearly dependent columns. For example, if c contains at least two noncoincident coarse nodes, then N_c will have full column rank for 2D elasticity problems. The requirement for 3D elasticity is that c contains at least three noncolinear coarse nodes. Although this option may be easy to implement, it has its drawbacks. Namely, it can lead to significantly more coarse nodes or greater coupling at coarser multigrid levels.

We build on the basic idea of augmenting the set c, but with an important twist. The approach can be viewed as a two-step process in which the coarse node set c is first replaced by its augmented counterpart $\tilde{c}$. The formula in (2.9) then becomes

$$y_f = -A_{ff}^{-1}(A_{f\tilde{c}} + A_{f\tilde{B}}N_{\tilde{B}}(N_{\tilde{c}}^T\tilde{S}N_{\tilde{c}})^{-1}N_{\tilde{c}}^T\tilde{S})y_{\tilde{c}},$$

where $\tilde{}$ indicates that terms are for the augmented set $\tilde{c}$ rather than c. We assume the choice of $\tilde{c}$ ensures that the columns of $N_{\tilde{c}}$ are linearly independent. Since the dimension of $y_{\tilde{c}}$ may be significantly larger than that of y_c, we next impose constraints of the form

$$y_{\tilde{c}} = C\hat{y}_c, \tag{2.10}$$

where $\hat{y}_c$ is associated with the original coarse node set c. The net result is the modified interpolation formula

$$y_f = P_f\hat{y}_c, \tag{2.11}$$

where

$$P_f = -A_{ff}^{-1}(A_{f\tilde{c}} + A_{f\tilde{B}}N_{\tilde{B}}(N_{\tilde{c}}^T\tilde{S}N_{\tilde{c}})^{-1}N_{\tilde{c}}^T\tilde{S})C.$$

We have $\hat{y}_c = y_c$ except at the finest multigrid level for elasticity problems. For that special case the coarse vector $\hat{y}_c$ has rotational dofs whereas y_c does not. In summary,

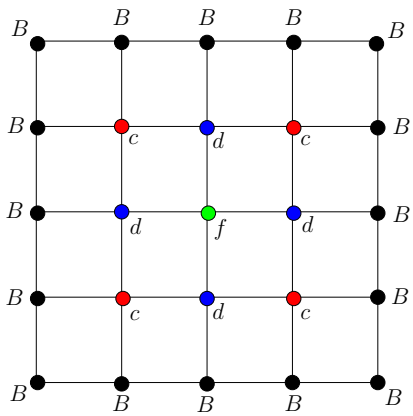

FIG. 2.2. *Example mesh showing node sets c, d, f, and B for a 2D problem.*

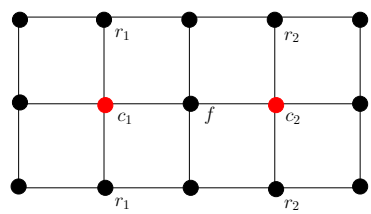

FIG. 2.3. *Example mesh showing node sets c_i, r_i, and f for 2D elasticity.*

the original coarse nodes c are still used for interpolation of y_f, but these coarse nodes now have both translational and rotational dofs for elasticity problems. We note that a different AMG approach for elasticity problems, which can be viewed as a blockwise generalization of classical AMG, is described in [7].

The remainder of this subsection discusses selection of the augmented coarse node set $\tilde{c}$ and the constraint matrix C. To begin, define

$$\tilde{c} = c \cup d \cup r,$$

where node sets d and r are subsets of the set $n(f)$ of noncoarse nodes adjacent to f. Let $c(f)$ denote the set of coarse nodes involved in the interpolation of f and observe that $c(f) = c$. The set of [illegible] nodes $d = \{d_j\}$ consists of all nodes in $n(f)$ for which $c(d_j) \subset c$ (see Figure 2.2). At the finest multigrid level for elasticity problems, we also consider a set of nodes $r = \{r_i\}$ associated with [illegible]. For each coarse node in $c = \{c_i\}$, r_i is defined as the set of all nodes in $n(f) \setminus d$ adjacent to c_i but not adjacent to any other nodes in c. A view of a 2D mesh showing nodes in the sets f, c_i, and r_i is shown in Figure 2.3. Note that $r = \emptyset$ for other multigrid levels or for problem types other than elasticity. It is also worth mentioning that r may be an empty set for certain noncoarse nodes such as the one at the center of the front face in Figure 2.1. This does no harm as long as f is adjacent to a sufficient number of coarse nodes.

Returning to (2.10), constraint equations for [illegible] dofs d_j are based on the interpolation formula (2.11). At the finest multigrid level for elasticity problems, constraint equations for r_i are based on the condition that all nodes in r_i and c_i be in the same rigid body. In order to describe the constraint matrix C in more detail,

we first rewrite (2.10) as

$$\underbrace{\begin{bmatrix} y_c \\ y_d \\ y_r \end{bmatrix}}_{y_{\tilde{c}}} = \underbrace{\begin{bmatrix} C_c \\ C_d \\ C_r \end{bmatrix}}_{C} \underbrace{\begin{bmatrix} \hat{y}_{c_1} \\ \vdots \\ \hat{y}_{c_{|c|}} \end{bmatrix}}_{\hat{y}_c}, \tag{2.12}$$

where

$$y_d = \begin{bmatrix} y_{d_1} \\ \vdots \\ y_{d_{|d|}} \end{bmatrix}, \quad y_r = \begin{bmatrix} s_1 \\ \vdots \\ s_{|c|} \end{bmatrix}, \quad s_i = \begin{bmatrix} y_{r_i^1} \\ \vdots \\ y_{r_i^{|r_i|}} \end{bmatrix}, \quad \hat{y}_{c_i} = \begin{bmatrix} y_{c_i} \\ y_{c_{i\theta}} \end{bmatrix}. \tag{2.13}$$

Except at the finest multigrid level for elasticity problems, C_c is a suitably dimensioned identity matrix I, and the matrix C_r and vectors y_r and $y_{c_{i\theta}}$ are ignored. Recall that the coarse nodes involved in the interpolation of d_j are contained in c. Thus, the interpolation formula (2.11) for y_{d_j} can be expressed as

$$y_{d_j} = P_{d_j} R_{d_j} \hat{y}_c,$$

where each row of the selection matrix R_{d_j} contains exactly one nonzero entry of 1. Note that $R_{d_j}\hat{y}_c$ is simply the vector of coarse dofs involved in the interpolation of y_{d_j}. It then follows from (2.12) and (2.13) that

$$C_d = \begin{bmatrix} P_{d_1} R_{d_1} \\ \vdots \\ P_{d_{|d|}} R_{d_{|d|}} \end{bmatrix}. \tag{2.14}$$

It remains to specify the matrices C_c and C_r for elasticity problems at the finest multigrid level. We restrict our attention to the 3D case since the 2D case is simpler. Let $\mathbf{r}_b$ and $\mathbf{r}_p$ denote position vectors of points b and p. If b and p are in the same rigid body, then for small rotations the displacement of p is given approximately by

$$\mathbf{y}_p = \mathbf{y}_b + \boldsymbol{\theta}_b \times (\mathbf{r}_p - \mathbf{r}_b), \tag{2.15}$$

where $\mathbf{y}_b$ is the displacement of b and $\boldsymbol{\theta}_b$ is a vector of rotations about b. Define $y_{pk} = \mathbf{y}_p \cdot \mathbf{e}_k$, where $\mathbf{e}_k$ is a unit vector in coordinate direction k. In matrix notation, (2.15) can then be expressed as

$$y_p = C(\mathbf{r}_p - \mathbf{r}_b) \begin{bmatrix} y_b \\ \theta_b \end{bmatrix},$$

where

$$y_p = \begin{bmatrix} y_{p1} \\ y_{p2} \\ y_{p3} \end{bmatrix}, \quad C(\mathbf{r}) = \begin{bmatrix} 1 & 0 & 0 & 0 & r_3 & -r_2 \\ 0 & 1 & 0 & -r_3 & 0 & r_1 \\ 0 & 0 & 1 & r_2 & -r_1 & 0 \end{bmatrix}.$$

We then have

$$C_c = \begin{bmatrix} C(\mathbf{0}) R_{c_1} \\ \vdots \\ C(\mathbf{0}) R_{c_{|c|}} \end{bmatrix}, \quad C_r = \begin{bmatrix} C_{s_1} R_{c_1} \\ \vdots \\ C_{s_{|c|}} R_{c_{|c|}} \end{bmatrix}, \quad C_{s_i} = \begin{bmatrix} C(\mathbf{r}_i^1 - \mathbf{c}_i) \\ \vdots \\ C(\mathbf{r}_i^{|r_i|} - \mathbf{c}_i) \end{bmatrix}, \tag{2.16}$$

where **0** denotes a vector of length zero and $\hat{y}_{c_i} = R_{c_i}\hat{y}_c$. In summary, the matrix C_d is based on the interpolation formula in (2.11), while the matrix C_r is based on rigid body constraints.

Noncoarse nodes f are processed in order of increasing $|c|$ so the interpolation matrix P_{d_j} will already be available for use in (2.14). Note in the expression for P_f below (2.11) that factorizations are required for the matrices A_{ff} and $N_{\tilde{c}}^T S N_{\tilde{c}}$. The largest possible dimension of these matrices in this study is 6×6 for 3D elasticity. The interpolation of y_f by coarse dofs is summarized in Algorithm 1.

Recall that each column of the interpolation matrix P corresponds to a particular coarse node. At the finest multigrid level for elasticity problems, it may happen, e.g., due to essential boundary conditions, that the columns of P for such a node are linearly dependent. If this is the case, then the diagonal block of the coarse matrix $P^T A P$ corresponding to this node, call it A_n, will be singular. In order to address such a possibility, consider the eigendecomposition

$$A_n \Phi = \Phi \Lambda,$$

where Φ is a matrix of orthonormal eigenvectors and the diagonal matrix Λ contains the eigenvalues. If any of the eigenvalues are zero, then we make the correction

$$A_n \leftarrow A_n + \alpha \tilde{\Phi} \tilde{\Phi}^T,$$

where α is the trace of A_n and $\tilde{\Phi}$ consists of the columns of Φ corresponding to zero eigenvalues. We have observed for very special case 3D elasticity problems that the above correction may not be sufficient to address a rank-one deficiency of the interpolation matrix P of a more global nature involving rotational dofs. This rank deficiency has only been observed for meshes of identical parallelepipeds and regular arrangements of coarse nodes at the finest level. It has not caused numerical problems for any examples considered thus far, but safeguards could be implemented if the coarse matrix $P^T A P$ is factored in a two-level multigrid for 3D elasticity. Two possible safeguards include scaling the diagonal entries of $P^T A P$ by the factor $1 + \epsilon$ with $0 < \epsilon \ll 1$ and a Laplacian-like stabilization of rotational dofs which is orthogonal to rigid body modes.

REMARK 1. If the null space matrix N is not available, then it may be possible to use a self-correcting method similar to adaptive smoothed aggregation [3] to address this problem. We do not consider such a method here.

3. Numerical examples. Numerical examples are presented in this section for both structured and unstructured meshes. The purpose of these examples is to investigate the effects of problem size, multigrid cycle type, boundary conditions, domain

aspect ratios, material property jumps, and element polynomial degree on AMG performance. All the examples have a random right-hand side and are solved to a relative residual tolerance of 10^{-8} using the preconditioned conjugate gradient algorithm. The AMG preconditioners use nodal Gauss–Seidel relaxation at each level except for the coarsest level where the problem is solved directly. In order to ensure symmetry of the preconditioners, the ordering of nodes for Gauss–Seidel relaxation is reversed in the pre- and postsmoothing steps. Estimated condition numbers are obtained using the connection between conjugate gradients and the Lanczos method [6]. These estimates are lower bounds for the actual condition numbers and are obtained from the extremal eigenvalues of a tridiagonal Lanczos matrix of dimension equal to the number of iterations. The Poisson ratio for all the elasticity examples was set to 0.3.

Coarse nodes at each level are chosen using a maximal independent set algorithm in which nodes of lowest degree are successively added to the coarse set. Thus, none of the coarse nodes are adjacent, and all the remaining noncoarse nodes are adjacent to one or more coarse nodes. We restrict our attention in all the examples to good element aspect ratios and isotropic materials. For elements with poor aspect ratios or materials with large anisotropies, additional coarse nodes would need to be introduced to avoid degraded performance. We do not consider such cases here and only mention that semicoarsening or compatible relaxation [1, 11, 5] could be used to address such problems. We specify that the interpolation of a noncoarse node involves precisely all those coarse nodes that are adjacent to it and no others.

The first examples are for structured meshes of 8-node hexahedral elements on a rectangular parallelepiped domain with dimensions L_1 and $L_2 = L_3 = 1$. In each table refers to the numbers of levels (1 for a direct solution), is the total number of unknowns in the problem, is the number of iterations, is the condition number estimate of the preconditioned operator, and is the operator complexity (sum of number of nonzeros in stiffness matrices at all levels divided by the number of nonzeros at the finest level). Columns headed by $V(m, n)$ and $W(m, n)$ are for symmetric V- and W-cycles with m presmoothing and n postsmoothing steps. For a few examples, results are also shown for symmetric full multigrid V ( ) and W ( ) cycles.

Shown in Table 3.1 are results for a cube domain with essential boundary conditions applied to all six faces. In this case, the coarse node selection algorithm leads to a regular geometric coarsening. Very good performance of both the V and W cycles is evident. Results for the same problem with just one face constrained are shown in Table 3.2. In this case, the coarse nodes do not form a regular grid, and differences between the V- and W-cycles are more pronounced. Results for a domain with an aspect ratio of 8 are shown in Table 3.3. Again, optimal performance of the W-cycle in terms of iterations, condition numbers, and operator complexity is evident. Results for a cube domain with a centered inner cube region of dimension 1/2 are shown in Table 3.4. The elastic modulus has a value of σ in the inner cube region and 1 elsewhere. Although not perfect, the performance of the AMG preconditioner is not greatly sensitive to jumps in material properties for this example.

The next group of examples deals with both 2D and 3D unstructured meshes. Figure 3.1 shows a series of quadrilateral meshes in which the number of elements approximately quadruples with each mesh refinement. Results in Table 3.5 demonstrate the very good performance of the AMG preconditioner for unstructured meshes. The 3D examples are for the unstructured mesh of tetrahedral elements shown in Figure 3.2. Results in Tables 3.6 and 3.7 are for meshes of 4-node and 10-node tetra-

hedral elements, respectively. The 4-node tetrahedron is a linear element, whereas the 10-node tetrahedron is a quadratic element. Here again, the AMG preconditioners exhibit very good performance.

The final group of examples involves comparisons with the smoothed aggregation code called ML [13]. The symmetric Gauss–Seidel smoother in ML does smoothing in both forward and reverse lexicographic order. Thus, for purposes of comparison, the present approach (designated AMG-LO for AMG by local optimization) uses V-

and W-cycles with two rather than one pre- and postsmoothing step. We note the default ML parameter value of 0.67 for [illegible] was increased to 1.0 because ML was run on a single processor and better performance was observed for this value.

Results for AMG-LO and ML applied to elasticity problems appear in Table 3.8. Coarsening for both approaches was stopped once the coarse problem size was less than 1100. For the structured meshes (Tables 3.2–3.4), the number of iterations and condition numbers for the two approaches are comparable, but the operator

complexity for ML is noticeably lower. This is true because smoothed aggregation typically uses a 3-1 coarsening ratio rather than the 2-1 ratio used by the present approach. The number of iterations and condition numbers for the 2D plane stress example with an unstructured mesh are also comparable. Although the performance of the two approaches is comparable for the unstructured mesh of 4-node tetrahedral elements, there is a notable difference for the mesh of 10-node quadratic elements (Table 3.7). Notice that the operator complexity for ML drops from 1.43 for linear elements to 1.14 for quadratic elements. We plan to investigate further the cause for the poorer performance of ML in this case. Although the software for AMG-LO is relatively new, it is competitive with ML in terms of run times reported in Table 3.8.

4. Conclusions. Numerical examples demonstrated that the new approach for constructing interpolation operators results in optimal performance of an ensuing AMG preconditioner. Iterations, condition numbers, and operator complexities all appeared to level off with growing problem size in the examples for W-cycles. In addition, the numerical implementation of the approach was shown to be competitive with an existing smoothed aggregation code for a suite of elasticity problems. The

new approach can be viewed as a classical AMG alternative to smoothed aggregation for elasticity problems.

In order for the new approach to be useful as a general-purpose solver or preconditioner, it must be coupled with an effective method for selecting the coarse nodes. As with other classical AMG approaches, coarse node selection is of great importance for problems with large element aspect ratios or material anisotropies. Future work will focus on developing new approaches for adaptively selecting the coarse nodes to ensure good performance for a broader class of ill-conditioned problems.

Acknowledgment. The author is grateful to the anonymous reviewers for their very helpful comments and suggestions. Their input led to both a clearer presentation and a more efficient numerical implementation of the approach.

PARALLEL SEGREGATED SCHUR COMPLEMENT METHODS FOR FLUID DENSITY FUNCTIONAL THEORIES*

MICHAEL A. HEROUX†, ANDREW G. SALINGER†, AND LAURA J. D. FRINK†

Abstract. Numerical formulations of density functional theories for inhomogeneous fluids (fluid-DFTs) require the solution of large systems of equations with many degrees of freedom (DOF) per node on a computational grid. Historically, solvers for these problems have used simple Picard iterations across DOF or, more recently, fully coupled general algebraic techniques. In this paper we look at fluid-DFTs from a fresh perspective, retaining a fully coupled formulation but segregating variables for the purpose of introducing Schur complement formulations and specialized preconditioners. By viewing fluid-DFTs from this perspective, we develop a mathematical framework and a collection of solution algorithms that have a dramatic impact on the robustness, performance, and scalability of the implicit equations generated by fluid-DFTs.

Key words. inhomogeneous fluids, density functional theories, Schur complement, iterative methods

1. Introduction.

Multiple degrees of freedom (DOF) per node properties are common to many numerical applications. Segregated solvers, which attempt to view each DOF across the grid as a subproblem within the larger fully coupled problem, have been successfully used in many problem domains. Similarly Schur complement methods, which formally eliminate variables by block Gaussian elimination, can reduce the complexity and cost of solution. In this paper we present a combination of these two classes of algorithms applied to density functional theories for inhomogeneous fluids (fluid-DFTs). We will show that viewing fluid-DFTs from a segregated variable perspective yields a rich structure that can be exploited in the development of robust, scalable solution methods. Furthermore, the algorithms we develop can be applied in a similar fashion to all types of problems generated by the target application, showing that our basic approach is a useful general-purpose technique in this problem domain.

Density functional theories (DFTs) have been used to treat a variety of systems at many length scales. For interfacial systems, the fundamental problem is to predict the structure of an inhomogeneous fluid as captured by a density distribution, $\rho(\mathbf{r})$ [36]. At the smallest length scale, the most well known application of DFTs is to predict the electronic structure of materials [23]. More specifically, quantum mechanical DFTs (QM-DFTs) are used to predict the structure of an electron cloud in an external field produced by fixed nuclei. Using a similar mathematical construct, but with nonexact density functionals [13], the structure of atomic [24, 25], molecular [18, 1], and polymer fluids [2, 37, 38, 33] can be computed. Fluid inhomogeneities can result from surfaces (e.g., planar interfaces, porous materials, or large geometrically complex macromolecules [10, 35, 21, 9]) or from competing intramolecular and intermolecular

interactions that can lead to self-assembly [12, 6, 20]. Mesoscale-DFTs have also been developed for colloidal fluids and biological macromolecules [4, 5]. These mesoscale-DFTs are very similar to fluid-DFTs but are based on coarsened models or potentials (e.g., the solvent averaged Yukawa potential).

Our previous efforts to develop numerical methods for fluid-DFTs began with the development of a real space approach using Newton's method that could be solved using parallel iterative solvers optimized for large distributed memory parallel computers [7, 8, 10]. This code was robust, but expensive for 3-dimensional systems. Given those limitations, we then developed a matrix-free method with fast Fourier transforms (FFTs) to compute certain convolutions in the theory [30]. This approach led to a code that could be applied to 3-dimensional problems using very modest computer resources (single processor workstations). However, the FFTs limit the application space of the DFTs to cases with periodic boundary conditions, and since no matrix is stored, matrix-based preconditioning methods cannot be applied to converge difficult nonlinear problems.

In the remainder of this paper we present a new approach to solving fluid-DFTs using a real space method based on segregated Schur complement techniques and we demonstrate the impact of this approach on our ability to solve large, complex problems. Section 2 presents the general mathematical framework of fluid-DFTs. Sections 3 discusses the complexities of the discrete formulation of DFTs with a focus on properties that can be exploited in the design of algorithms. Section 4 contains a discussion of our new block equation framework, and section 5 discusses the block framework for two particular fluid-DFTs. Section 6 presents an analysis of our new solver algorithms compared to generic methods developed for partial differential equations (PDEs) and demonstrates considerable improvement in speed and robustness.

2. Mathematical framework. In fluid-DFTs an approximate free energy functional, $\Omega[\{\rho_i(\mathbf{r})\}]$, depends on a set of density fields, $\{\rho_i(\mathbf{r})\}$. The minimization of this free energy with respect to all fields $\{\rho_i(\mathbf{r})\}$ results in a system of residual equations to be solved for the equilibrium fluid distribution. The residual equations to be solved are written as

$$\frac{\delta\Omega}{\delta\rho_i(\mathbf{r})} = 0, \tag{2.1}$$

where δ is the Fréchet (functional) derivative, leading to an Euler–Lagrange residual equation.

In a perturbation theory, the free energy Ω is typically written as a sum of terms starting with the contributions of a well-known reference fluid (often a hard-sphere fluid). Many terms in these physics-based expansions can be written as

$$F_{phys} = \int f[\{\rho_i\}]g[\{n_\gamma[\{\rho_i\}]\}]dr, \tag{2.2}$$

where f is a functional of the critical density fields, and g is a functional of some nonlocal variables, n. Taking the functional derivative of these terms to set up the residual equations in (2.1), one must apply the chain rule

$$\frac{\delta}{\delta\rho_i(\mathbf{r})}\left(\int f[\{\rho_i\}]g[\{n[\{\rho_i\}]\}]dr\right) = \frac{\partial f}{\partial\rho_i}g[\{n\}] + \int f[\{\rho_i\}]\frac{\partial g}{\partial n}\frac{\delta n(\mathbf{r}')}{\delta\rho_i(\mathbf{r})}d\mathbf{r}', \tag{2.3}$$

where for simplicity (2.3) reflects a problem with only one nonlocal variable, n.

For local terms (e.g., ideal gas contributions), $g[n] = 1$ and the second term drops out. Nonlocal terms can take on various forms. For strict mean field contributions, $g = n_i$, where n_i is a simple linear functional of the set $\{\rho_i\}$,

$$n_i(\mathbf{r}) = \sum_j \int w_{ij}(\mathbf{r}, \mathbf{r}', R_{ij})\rho_j(\mathbf{r}')d\mathbf{r}', \tag{2.4}$$

with a weight function,

$$w_{ij}(\mathbf{r}, \mathbf{r}', R_{ij}) = \theta(|\mathbf{r} - \mathbf{r}'| - R_{ij})\phi_{ij}(|\mathbf{r} - \mathbf{r}'|), \tag{2.5}$$

where θ is a Heaviside step function, ϕ_{ij} denotes a pairwise interaction (i.e., pair potential, direct correlation function, pair correlation function, etc.), and R_{ij} is the characteristic range of the pairwise interaction. On differentiation, $\partial g/\partial n_i = 1$ and $\delta n_i/\delta\rho_j = w_{ij}(\mathbf{r}, \mathbf{r}', R_{ij})$. When forming a matrix problem it is necessary to calculate second derivatives of the free energy (the Hessian). One applies the chain rule in (2.3) a second time. For these strict mean field terms, $\partial^2 g/\partial n^2 = 0$, and thus the Jacobian contribution from these terms is simply

$$J_{ij}(\mathbf{r}, \mathbf{r}') = w_{ij}(\mathbf{r}, \mathbf{r}', R_{ij}). \tag{2.6}$$

While the number of nonzeros in the matrix is determined by the characteristic length, R_{ij}, these terms do not have an integral character at the level of the Hessian.

In contrast, consider a term, F_{phys}, in the free energy expansion with the form $f[\{\rho_i\}] = 1$ and $g[\{n_\gamma\}] = \Phi[n]$, where Φ is a nonlinear functional of a set of $\{n_\gamma\}$. In this case the first term in the chain rule drops out, and the first and second derivatives of these terms will be

$$\frac{\delta F_{phys}}{\delta\rho_i(\mathbf{r})} = \int \sum_\gamma \frac{\partial\Phi}{\partial n_\gamma}\frac{\delta n_\gamma(\mathbf{r}')}{\delta\rho_i(\mathbf{r})}d\mathbf{r}' \tag{2.7}$$

and

$$\frac{\delta^2 F_{phys}}{\delta\rho_i(\mathbf{r})\delta\rho_\mathbf{j}(\mathbf{r}')} = \int \sum_\gamma \sum_\epsilon \frac{\partial^2\Phi}{\partial n_\gamma \partial n_\epsilon}\frac{\delta n_\gamma(\mathbf{r}'')}{\delta\rho_i(\mathbf{r})}\frac{\delta n_\epsilon(\mathbf{r}'')}{\delta\rho_j(\mathbf{r}')}d\mathbf{r}''. \tag{2.8}$$

Often, n_γ is again a linear functional of $\{\rho_i\}$,

$$n_\gamma(\mathbf{r}) = \sum_i \int \omega_{\gamma i}(\mathbf{r}, \mathbf{r}', R_i)\rho_i(\mathbf{r}')d\mathbf{r}', \tag{2.9}$$

and in this case the Hessian contribution may be written

$$\frac{\delta^2 F_{phys}}{\delta\rho_i(\mathbf{r})\delta\rho_\mathbf{j}(\mathbf{r}')} = \int \sum_\gamma \sum_\epsilon \frac{\partial^2\Phi}{\partial n_\gamma \partial n_\epsilon}\omega_{\gamma i}(\mathbf{r}, \mathbf{r}'', R_i)\omega_{\epsilon j}(\mathbf{r}', \mathbf{r}'', R_j)d\mathbf{r}''. \tag{2.10}$$

Note that the weight function, ω, is usually based on either a Heaviside step function, $\theta(|\mathbf{r} - \mathbf{r}'| - R_i)$, or a Dirac delta function, $\delta(|\mathbf{r} - \mathbf{r}'| - R_i)$, where R_i is often a particle radius or diameter.

Computing matrix coefficients based on (2.10) requires a second-order (N^2) operation in order to locate the intersection of the weight functions $\omega_{\gamma i}(\mathbf{r}, \mathbf{r}'', R_i)$ and $\omega_{\epsilon j}(\mathbf{r}', \mathbf{r}'', R_j)$. To reduce the complexity of the matrix fill, the nonlocal variables,

n_γ, can be included as explicit independent variables when taking the second Fréchet derivatives to form the matrix problem. We will refer to this method as a first-order formulation later in this paper, and we note that this approach is akin to the transformation of a higher-order PDE to a system of first-order PDEs by introduction of additional variables in the problem. In this case, the nonzero contributions to the Jacobian will be

$$J_{\gamma\epsilon}(\mathbf{r},\mathbf{r}') = \delta_{\gamma\epsilon}(\mathbf{r},\mathbf{r}'), \tag{2.11}$$

$$J_{\gamma i}(\mathbf{r},\mathbf{r}') = \omega_\gamma(\mathbf{r},\mathbf{r}'), \tag{2.12}$$

$$J_{i\epsilon}(\mathbf{r},\mathbf{r}') = \sum_\gamma \frac{\partial^2 \Psi}{\partial n_\gamma \partial n_\epsilon}(\mathbf{r})\omega_{\gamma i}(\mathbf{r}',\mathbf{r}), \tag{2.13}$$

where the first two contributions arise from the nonlocal variable residual equation defined by (2.9), and the third contribution comes from taking the functional derivative of the Euler–Lagrange equation in (2.7) with respect to the nonlocal variables, n_ϵ. Note that there is no contribution from the derivative of the Euler–Lagrange contribution in (2.7) with respect to the density fields in this case (i.e., $J_{ij}(\mathbf{r},\mathbf{r}') = 0$).

Integral operator terms of the form discussed above are pervasive in DFTs constructed as perturbations to the hard-sphere fluid. However, the general approach of introducing variables to reduce the complexity of the matrix problem is a strategy that can be applied to other classes of fluid-DFTs as well. The polymer-DFT fluids that we discuss later in this paper are based on a second-order density expansion using an ideal chain reference fluid. Although this DFT falls into a different class than hard-sphere perturbation DFTs, the strategy of introducing variables to reduce complexity can also be applied there.

Including nonlocal variables, n in the systems of equations can significantly increase the number of DOF that must be solved at each mesh point. As a result, no advantage was gained from this approach when coupled to a generic PDE optimized solver applied to the full matrix problem [7]. In that case the decrease in the complexity of the matrix fill operation was offset by the increase in problem size for the linear solver. In the current work we demonstrate that when generic PDE solvers are replaced with segregated modeling strategies, fluid-DFTs can be solved with significantly improved efficiency.

3. Discrete formulations. As was mentioned in the introductory section, we have previously developed a code for solving fluid-DFTs on large distributed memory computers. That code was based on a discretization using a uniform structured grid so that the numerical integration stencils for all spatial integrals could be precomputed on a reference grid and then applied anywhere on the grid [7, 8]. Linear interpolation was used for the critical fields between the mesh points, and the equations were discretized using collocation at the mesh points.

The discretized equations were previously solved using a fully coupled Newton method with an analytic Jacobian and algebraic preconditioned Krylov methods. Convergence with these methods is much improved over Picard iteration, reducing nonlinear iterations from $O(100\text{–}1000)$ to $O(10)$. However, these linear solvers were designed for PDE applications and are far from optimal for fluid-DFTs. They sometimes require very expensive preconditioners in order to converge.

The ineffectiveness of the generic methods to efficiently solve the fluid-DFT equations stems primarily from the fact that the systems of equations are very dissimilar to PDEs. Key properties of the fluid-DFTs systems of equations when compared to

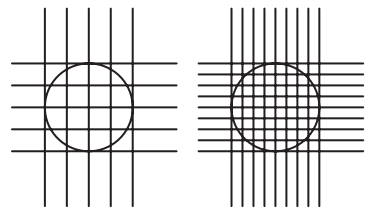

FIG. 3.1. *Stencil support for two mesh densities for integrating the area of the circle. As the mesh is refined, the stencil density increases. This corresponds to more expensive computation of the integrals and more nonzeros per row of the Jacobian matrix.*

PDEs that lead to failure of standard algorithms are as follows:

1. Interphysics versus internodal coupling: While PDEs have a strong spatial coupling, where the equation for a given variable at a given discrete mesh node involves interaction with the same variable at nearby nodes, fluid-DFTs may have remarkably little of this kind of coupling.[1]
2. Stencil support as a function of physical parameter: Unlike PDEs, whose stencils are typically independent of mesh node spacing (e.g., 9 point FEM stencil in two dimensions), the stencils in fluid-DFTs are determined by some characteristic physical parameter in the system (e.g., bead size, bond length). As the mesh is refined, more nodes fall within the range of the integral, and higher fidelity simulations result in larger problem dimensions and many more nonzeros per matrix row (see Figure 3.1).
3. Large number of DOF per node: Most PDE problems have just a handful of DOF in the global system (with the exception of reacting flow problems). First-order formulations of fluid-DFTs, on the other hand, typically have more than 10 DOF per node and may even have 50 or more. Furthermore, the stencils for each DOF can vary greatly in range and complexity.

Since standard algebraic preconditioners, including multilevel methods, incomplete factorizations, and relaxation methods, all have a bias toward internodal coupling, these methods may all miss the mark. Similarly, load balancing tools largely have the same bias and will need to be revisited for fluid-DFTs. The scaling of stencils with mesh density in fluid-DFTs suggests that standard preconditioners, sparse matrix computations, and communication patterns become increasingly inappropriate as mesh fidelity increases. Thus it is critical that a general framework be developed that is more suitable to fluid-DFTs. Because there is a wide variety of fluid-DFTs in current use in the physics community (e.g., various methods for similar fluids, and a wide range of fluids from atomistic neutral particles to polarizable polymers), the framework must be quite flexible and general. We present our current efforts to develop such a framework in section 4.

4. A new block matrix formulation and solution method. The basic framework for all our solver algorithms reflects the importance of interphysics coupling in the first-order formulation of the fluid-DFTs described in section 2. This physics coupling led us to a physics-based block matrix formulation in order to partition critical and nonlocal ancillary variables. The idea is to partition the data into

[1]Exceptions to this property occur when differential operators are part of the system of Euler–Lagrange equations, as with charged fluids [31, 10] or diffusing fluids [11].

blocks that can be optimally managed or solved. The general 2×2 block matrix is

$$\left(\begin{array}{ccc|ccc} A_{11}^{11} & \cdots & A_{11}^{1j} & A_{12}^{1,j+1} & \cdots & A_{12}^{1k} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ A_{11}^{j1} & \cdots & A_{11}^{jj} & A_{11}^{j1} & \cdots & A_{11}^{jj} \\ \hline A_{21}^{j+1,1} & \cdots & A_{21}^{j+1,j} & A_{22}^{j+1,j+1} & \cdots & A_{22}^{j+1,k} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ A_{21}^{k1} & \cdots & A_{21}^{kj} & A_{22}^{k,j+1} & \cdots & A_{22}^{kk} \end{array}\right) \left(\begin{array}{c} x_1^1 \\ \vdots \\ x_1^j \\ \hline x_2^{j+1} \\ \vdots \\ x_2^k \end{array}\right) = \left(\begin{array}{c} b_1^1 \\ \vdots \\ b_1^j \\ \hline b_2^{j+1} \\ \vdots \\ b_2^k \end{array}\right), \tag{4.1}$$

where k is the number of DOF tracked per node and j is the number of DOF associated with the first block equation. The superscript notation $A^{p,q}$ denotes the block of coefficients generated by DOF p interactions with DOF q. The subscripts and partition lines impose a coarser partitioning of the matrix into a 2×2 block system that will be used with a Schur complement approach. We denote by A_{11}, A_{12}, A_{21}, and A_{22} the upper left, upper right, lower left, and lower right submatrix of the coarse 2×2 block matrix, respectively. Similarly, x_1 and x_2 and b_1 and b_2 are the upper and lower parts of x and b, respectively.

Given this two-level structure, the basic strategy for solving each global linear system generated by Newton's method is as follows:

1. Identify and reorder DOF 1 through j such that A_{11}^{-1} (the inverse of A_{11}) is easy to apply (in parallel). The details of this step are given in section 5 for two particular fluid-DFTs.
2. Determine a preconditioner P for $S = A_{22} - A_{21}A_{11}^{-1}A_{12}$, the Schur complement of A with respect to A_{22}. (See Saad [27] for an overview of Schur complement methods.)
3. Solve $Sx_2 = (b_2 - A_{21}A_{11}^{-1}b_1)$ using a preconditioned Krylov method such as generalized minimal residual (GMRES), with preconditioner P. Note that S may or may not be explicitly formed, depending on other problem details.
4. Finally, solve for $x_1 = A_{11}^{-1}(b_1 - A_{12}x_2)$.

The attractive properties of this algorithm from a parallel computing perspective are as follows:

1. The partitioning used to distribute grid nodes can also be effective for partitioning each DOF of the linear system. Because the DOF are segregated, providing a fairly uniform nonzero pattern within each DOF block, this approach typically gives well-balanced data and work distribution for the solver.
2. A_{11}^{-1} can often be applied as a matrix-vector multiplication, or sequence of such. In other cases, A_{11}^{-1} can be explicitly computed. This means that explicitly forming S, or applying it implicitly, is very efficient in parallel.
3. The dimension of S is often a small fraction of the original matrix. Specifically, only the primitive densities, density functionals, and a few scalar DOF are part of the A_{22} block. All other variables, sometimes more than 80% of the total DOF, are part of the A_{11} block. Thus iterative methods such as GMRES will typically converge much faster because of the reduced dimension, independent of other factors such as preconditioning.
4. Assuming nodes of the mesh are equally partitioned on the parallel machine, each matrix block A^{pq} in (4.1) is distributed evenly across the parallel machine. Thus, parallel execution of this solver is well-balanced and produces identical results, independent of the number of processors, up to roundoff error.

5. The new solver applied to two fluid-DFTs. We now describe specifics of this approach for two different fluid-DFTs. The physics description for these two models is included in the appendix. Here we focus on the structure of the matrices, implications for formulating the Schur complement, and suitable preconditioners. We note that while there are other classes of fluid-DFTs, the general strategy of extending the system size to include convenient nonlocal variables and then designing efficient segregated solvers will generalize quite easily to the broader problem space.

5.1. Hard spheres. A hard-sphere fluid is the simplest type of fluid model that is of practical interest (see section A.1). In a first-order numerical formulation, these problems typically have one or more density unknowns (the critical fields) and a set of linear auxiliary variables referred to as nonlocal densities (see (2.9)). In our block matrix formulation, the equations corresponding to the density unknowns (i.e., the Euler–Lagrange equations) are collected in the lower portion of the matrix (densities are the x_2 variables). The nonlocal density equations are collected in the top portion of the matrix (nonlocal densities are the x_1 variables).

We will consider a case when there are $N_{nld} = 4 + 2 * D$ nonlocal densities per node in the problem, where D is the physical dimension (1, 2, or 3) of the problem of interest. If all the nonlocal density variables are independent, the A_{11} block (which is composed of nonlocal density interactions only) is

$$A_{11} = I. \tag{5.1}$$

In this case, the inverse of A_{11} is obviously trivial.

However, for the special case of a single component fluid, some of the nonlocal densities may be trivially dependent on others with

$$n_\gamma(\mathbf{r}) = C n_\epsilon(\mathbf{r}), \tag{5.2}$$

where C is a constant. We generally encode the linear dependency in (5.2). For the case of Rosenfeld's functionals presented in section A.1 [24], this leaves $N_{nld} = 2 + D$ variables that are described by integration stencils (nonzeros in the A_{12} block).

To address these dependencies, we further decompose the A_{11} block into a 2×2 block matrix as follows. The nonlocal density variables that have no dependence on other nonlocal densities are put in the upper left block. The lower right block contains all others, which have a dependence only on variables in the first block. The A_{11} block is then

$$A_{11} = \begin{pmatrix} -I & 0 \\ X & -I \end{pmatrix}, \tag{5.3}$$

where X contains the various proportionality constants, C, in the problem of interest. It is immediately clear from this expression of A_{11} that the inverse is simply

$$A_{11}^{-1} = \begin{pmatrix} -I & 0 \\ -X & -I \end{pmatrix}. \tag{5.4}$$

The simple form of A_{11}^{-1} allows it to be explicitly applied in a matrix-vector multiply for an efficient calculation of S. Very simple preconditioners for S (e.g., Jacobi scaling based on the diagonal of A_{22}) work well to solve hard-sphere systems. Using this approach, we have seen scalable results for 1-, 2-, and 3-dimensional problems. Section 6 provides the details.

5.2. Polymer problems. Polymer and molecular fluid-DFTs that include a deterministic treatment of chain conformations come in several varieties [2, 32, 19, 1].[2] However, they all can be characterized again as a combined system of equations with critical field variables and nonlocal ancillary variables, with the chain structure equations playing the role of the nonlocal ancillary variables. To be more specific we consider the Chandler–McCoy–Singer DFT [2] (CMS-DFT) as it is described in section A.2. In this case, the critical variables $\rho(\mathbf{r})$ and $U(\mathbf{r})$ are the densities and an unknown mean field, respectively. The polymer conformation information is described by Green's function propagator equations, $G(\mathbf{r})$ and $G^{inv}(\mathbf{r})$. The structure of these equations is quite different from the nonlocal densities of the hard-sphere problem, as these equations are significantly coupled to one another through a recursive relationship (see (A.7) and (A.8) in section A.2).

In our new method, the A_{11} block is composed of these propagator equations, and when properly ordered, A_{11} takes the block form

$$A_{11} = \begin{pmatrix} A_{11}^{11} & 0 & 0 & 0 \\ A_{11}^{21} & A_{11}^{22} & 0 & 0 \\ \vdots & \ddots & \ddots & \vdots \\ A_{11}^{j1} & \cdots & A_{11}^{j-1,j} & A_{11}^{jj} \end{pmatrix}, \tag{5.5}$$

where j is two times the length of the polymer chain in the model and each A_{11}^{ii} is diagonal. Because each A_{11}^{pq} is distributed across the parallel machine proportionally to the nodes, and because each A_{11}^{ii} is diagonal, applying A_{11}^{-1} is a sequence of j diagonal scalings and matrix multiplications. Although A_{11}^{-1} cannot be explicitly formed for polymers, we still retain sufficient parallelism to get excellent performance on distributed memory computers, and application of A_{11}^{-1} is invariant under changes in processor count up to roundoff error.

The preconditioner P for polymer problems is more challenging than for hard spheres. The A_{22} block for polymers has the following form:

$$A_{22} = \begin{pmatrix} D_{11} & F \\ D_{21} & D_{22} \end{pmatrix}. \tag{5.6}$$

The first block of equations in A_{22} is associated with the unknown fields $U(\mathbf{r})$ (see (A.6)), and the second block with the primitive densities $\rho(\mathbf{r})$ (see (A.5)). Each of the D_{pq} blocks is diagonal, whereas the F matrix describes the dependence of the unknown field, $U(\mathbf{r})$, on the primitive densities. The density of this block is dictated by the range of the direct correlation function in (A.6). The F block is by far the most dense submatrix in the global matrix. As mentioned in section 3, the density of F increases dramatically with mesh refinement. Also, for the purposes of communicating off-processor values in a distributed memory implementation of the solver, F will have a large overlap and will require the most attention to ensure good parallel communication complexity. It is worth noting that F is the ,,, submatrix block that has these unusual stencil characteristics. It is also worth noting that the values in F do not change between nonlinear iterations.

One final observation is needed to motivate our preconditioner: All values in A_{22} are $O(1)$ except the values in D_{21}, which are $O(10^{-10})$. In other words, the primitive

[2] Note that another approach takes chain conformations from a large number of samples generated with molecular simulations [37, 22].

densities have a very weak direct dependence on the unknown fields, $U(\mathbf{r})$. We take advantage of this by defining an approximation to A_{22} as

$$A_{22} \approx \tilde{A_{22}} = \begin{pmatrix} D_{11} & F \\ 0 & D_{22} \end{pmatrix}. \tag{5.7}$$

We then define a preconditioner P for S that consists of one block Gauss–Seidel (one back-solve) using $\tilde{A_{22}}$. Given that D_{22} and D_{11} are diagonal and well-distributed and that F is also distributed, applying P involves two diagonal scalings, using D_{22} and D_{11}, and a matrix-vector multiplication using F. All these steps are very efficient in parallel. Thus we once again have an effective parallel solver whose results are invariant under changes to processor count, up to roundoff error. This algorithm for CMS-DFT for polymers has attractive features which are similar to those of the hard-sphere solver, except that A_{11}^{-1} cannot easily be explicitly formed.

One additional benefit is that the solver can efficiently handle very long polymer chains, since the chain length increased only the dimension of A_{11}, which has a modest impact on the performance and robustness of the solver. We note that previous approaches to solving polymer problems typically required an incomplete factorization with a fairly high level of fill to solve the linear system of equations. Our new solver requires almost no additional memory for the preconditioner. This reduces the memory requirement for the solver by at least a factor of 2, often a factor of 4 or more.

6. Computational results. In this section, we show results for several cases when the numerical problem is either a 2-dimensional numerical problem (with a third uniform dimension) or a full 3-dimensional problem. We compare a solution via (i) a generic global solver that attempts to solve all equations simultaneously in a single matrix via standard preconditioned Krylov methods, and (ii) the new solvers described in sections 4 and 5. Each solver uses an unscaled residual tolerance of 10^{-4}. Overall the improvement due to the new algorithmic framework is dramatic (up to 10 times better), as well as making some large problems tractable. All results were generated on the Sandia system red squall, a 258-node, dual processor Opteron-based system (2.2 GHz processors with 4 GB memory per node) using a Quadrics Elan4 high-speed interconnect.

6.1. Solver approaches. All the results presented here are from the fluid-DFT application code Tramonto [7]. Tramonto is a parallel, distributed memory application that solves fluid-DFT problems using real space techniques. Early versions of Tramonto used general-purpose preconditioned Krylov solvers from the solver package Aztec [34]. Recently Tramonto was redesigned to utilize the Trilinos solver framework, a large collection of solver packages and parallel linear algebra tools [14, 17].

In this section we use the term to refer to a general-purpose preconditioned Krylov solver applied to the full linear system of equations ordered as described in (4.1). We use an overlapping Schwarz preconditioner with ILUT [26] as the local subdomain solver via the Trilinos package IFPACK [29]. We use nonrestarted GMRES [28] from the Trilinos package AztecOO [16] as the iterative method. Note that the solver is already an improvement over previous work [7] because Trilinos algorithms (an improvement over Aztec solvers) are used, and because the ordering of equations has changed from a node-first ordering to a DOF-first ordering. The DOF-first ordering results in very favorable ILUT fill and robustness properties for the general-purpose solver.

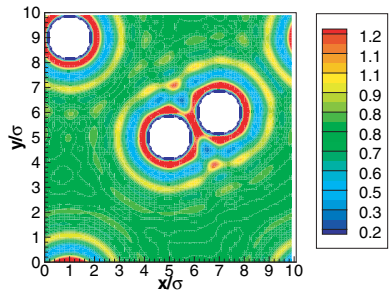

FIG. 6.1. *Fluid density ($\rho\sigma^3$) distribution in the vicinity of* 3 *nanocylinders.*

The segregated Schur solvers presented here will be denoted , , and are based on preconditioned Krylov methods that use our new segregated preconditioners and apply GMRES to the Schur complement system. All preconditioners for the new solvers are constructed and applied using the matrix and vector classes in the Trilinos package Epetra [15]. Due to the number of DOF and the sequencing requirements to apply A_{11}^{-1}, the , , solver preconditioners are composed of several (sometimes more than 100) Epetra distributed sparse matrices. The , , solvers also use GMRES from AztecOO.

6.2. Hard-sphere fluids in two dimensions. This problem considers an inhomogeneous fluid, where there are three cylindrical rod surfaces in the domain. This problem is similar to systems extensively studied previously in a study on adsorption in disordered porous media [9]. Since the solution is uniform perpendicular to the rods, the numerical problem may be solved in two dimensions (with the third dimension treated analytically). Figure 6.1 shows the density profile we compute for this case. The computational domain is $10\sigma \times 10\sigma$ in size, where σ is the diameter of the fluid particles. Periodic boundary conditions were applied in this calculation. The bulk fluid density was $\rho\sigma^3 = 0.75$. The three rods were all quite small with diameters of $2R = 0.5\sigma$ and were located at $(x/\sigma, y/\sigma) = (5,5), (1,9), (7,6)$. Volume exclusion interactions define the rod-fluid interactions, and the corresponding discontinuity in the external field is found at a distance of $R + 0.5\sigma$ from the center of the cylinders.

Table 6.1 compares the , , and , approaches. , solutions were obtained using an ILUT preconditioner with two levels of fill-in. Solves were first attempted with no preconditioning and with an ILU preconditioner. Neither were able to solve the linear problem in less than 100 iterations. As is apparent from the table, the chosen preconditioner is identical to the , , algorithm in nonlinear updates and is similar in the linear solver iteration count. The table shows both parallel scaling and scaling with mesh refinement at a fixed number of processors.

These results clearly demonstrate that the , , method is quite powerful, particularly for smaller numbers of processors. We achieve increased performance with the new algorithms, and the decrease in solve time is on the order of one to two orders of magnitude. Using the solve time data in the second part of the table (excluding data at $\Delta x = 0.2\sigma$) we find that the scaling of the , code with mesh refinement is $T \propto N^{2.7}$, while the new code has $T \propto N^{2.0}$.

6.3. 3-dimensional hard spheres. This problem considers a hard-sphere fluid in a nanotube of finite length, where the nanotube is located in a planar surface (or membrane). This particular choice is the base case for studies on ion channel pro-

teins [10]. Specifically, the domain is of size $18\sigma \times 6\sigma \times 6\sigma$ with the long axis of the nanotube in the x dimension. The diameter of the nanotube is 2.5σ. The length of the nanotube is 10σ. The computational domain has bulk boundary conditions in the x dimension and continuation boundary conditions in the y and z dimensions. In the latter case, when performing integrals we assume that the density profile at the edge of the computational domain persists and is constant beyond the boundary. The bulk fluid density is again set to $\rho_b\sigma^3 = 0.75$ for studies on parallel performance, but is reduced to $\rho_b\sigma^3 = 0.6$ for the mesh refinement studies, as the system of equations becomes difficult to converge at the higher density for the most refined mesh. Figure 6.2 shows the density profile for one slice (at $z = 3\sigma$) in the computational domain.

Performance results are presented in Table 6.2. Overall the results are very similar to the 2-dimensional problem of the previous section. The , , , algorithm improves on the performance of the , , algorithm (ILUT preconditioner with two levels of fill) by up to 18 times for measurable cases. The problems are also amenable to much smaller parallel platforms and a more refined mesh with the new algorithms. These improvements can be attributed to the reduced memory requirements of these algorithms. The scaling with mesh density for this problem using the , , , algorithm is $T \propto N^{1.65}$. For the , , algorithm we find $T \propto N^{2.2}$.

TABLE 6.2

*Results for a 3-dimensional hard-sphere test problem. The second top column now contains the number of nonlinear iterations needed to solve the problem. For a description of all other columns see the Table 6.1 caption. All data in the upper part of the table were generated with a mesh spacing of $\Delta x = \sigma/5$ and with a bulk density of $\rho\sigma^3 = 0.75$. All data in the lower part of the table were generated on 128 processors with a bulk density of $\rho\sigma^3 = 0.6$. The data marked with * indicates that complete convergence was not obtained and timings are extrapolated based on the number of completed nonlinear iterations listed in parentheses.*

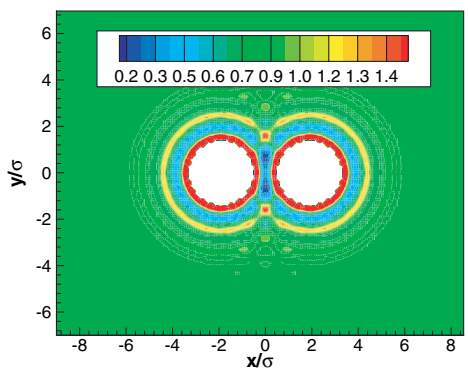

FIG. 6.3. *Density ($\rho\sigma^3$) distribution for a 10-mer homopolymer near two nanocylinders. The computational domain was 1/4 of this image with reflective boundaries at $x = 0$ and $y = 0$.*

6.4. 2-dimensional polymer. Next we consider a 2-dimensional system based on the CMS polymer DFT presented in section A.2. We consider a homopolymer in which there are 10 identical beads on the chain and the size of each segment is σ. There is a pair of infinite cylinders in the problem (diameter 2σ), and we solve for the polymer distribution around these nanocylinders. Both polymer bead interactions and polymer-surface interactions are purely repulsive, as defined by volume exclusions. A series of these calculations at different separations could be performed to compute the force between the cylinders as a function of distance. Studies were performed using a computational domain of size $7\sigma \times 9\sigma$. The initial guess was a uniform solution at the bulk site type density of $\rho\sigma^3 = 0.85$. Figure 6.3 shows the solution we obtain for this problem.

Performance results for this 2-dimensional polymer test problem are shown in Table 6.3. We find very similar behavior to the atomic fluids cases presented in the previous examples with up to a 25-fold improvement in performance. Again the

method was solved using an ILUT preconditioner with two levels of fill. While both methods become more expensive as the polymer chain length increases, we find that the cost of the , , , algorithms increases approximately linearly with chain length, while a steeper performance penalty occurs for the , , method.

6.5. 3-dimensional polymer. Finally, we consider a 3-dimensional system where a self-assembled lipid bilayer is sandwiched between two planar arrays of spheres of diameter 9σ separated by 10σ in a square lattice. The particular chemical model we consider has two components. The first is a model lipid molecule with head group and tail group beads. There are two head group beads on a chain, and 16 tail group beads on a linear chain. The head groups are in the middle, so we have an 8-2-8 morphology on the chain. The head group beads are larger than the tail group beads with $\sigma_h/\sigma_t = 1.44$. The second component in the system is a single site solvent of the same size as the tail beads. The interactions between various species are chosen to favor self-assembly of a lipid bilayer, where the head groups form an interface between the tail beads and the solvent beads. Lipid bilayers formed from this coarse grained model have been shown to be in reasonable agreement with molecular dynamics simulation of the same models and to map reasonably well to fluid experimental bilayers [6].

Figure 6.4 shows one slice through the solution we obtain for this problem. Computing interactions of nanoscale surfaces and colloidal particles with lipid bilayers are needed to provide a molecular theory–based analysis of surface forces experiments (e.g., surface forces apparatus, atomic force microscope, optical tweezers, etc.) for

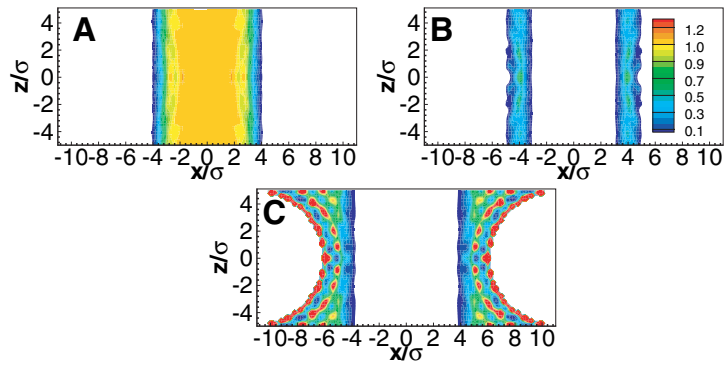

FIG. 6.4. *One slice (at $y = 0$) through a 3-dimensional computational volume. The shaded contours show density ($\rho\sigma^3$) distributions for lipid tail beads* (A)*, lipid head beads* (B)*, and solvent* (C) *for a lipid bilayer assembly sandwiched between planar arrays of large spheres. The computational domain is* 1/4 *of the domain shown in the figure and utilized reflective boundary conditions on all edges. The legend in* B *shows the contour scale for all three figures. Densities less than $\rho\sigma^3 = 0.01$ are shown in white for clarity.*

128	93	190	7.9

these systems. This type of calculation is also needed for studying the interactions of lipid bilayers with proteins.

The computational domain for this problem was $11\sigma \times 5\sigma \times 5\sigma$, and the initial guess for the density distribution is a previously converged uniform bilayer result. Note that this case had 37856 nodes in the computational domain and 44 unknowns per node for a total of 1.66×10^6 unknowns in the problem. Algorithm performance is presented as a function of number of processors only in Table 6.4. In this case, the , , , algorithms provide the ability to solve this difficult problem, as we were not able to solve this problem with the , , approach despite using 128 processors and trying a variety of parameters for solver tolerances and ILUT fill factors. Finally, note that with the , , , approach we find a significant superlinear speedup for this case from 32 to 64 processors.

6.6. Results summary. The results presented in this section are quite promising for the new solvers. In particular there are several observations worth noting.

6.6.1. Memory use. The new solvers use almost no extra memory for the preconditioners. Furthermore, the dimension of the implicit problem that GMRES must solve is 10 to 100 times smaller. Since all solvers are using nonrestarted GMRES and performing 100 or more iterations, the GMRES storage cost is $O(100n)$, where n is the dimension of the GMRES problem. Letting k denote the nonzero count of the global matrix, we see that the memory use for GMRES vectors in the , , solver is comparable to the matrix: from $3k$ to $10k$ storage. The ILUT preconditioner for the

solver requires from $2k$ to $10k$ storage. Thus the solver requires minimally $6k$ storage, up to $20k$ or more. In contrast, the cost of GMRES storage for the new solvers is from $0.1k$ to $0.01k$, and the overall storage is less than $2k$ with the storage cost of the matrix being dominant. The overall reduction in memory use for the solvers over the solver is therefore minimally a factor of 5 and sometimes more than a factor of 20.

6.6.2. Tuning parameters. One difficulty common to preconditioned iterative methods is the presence of tuning parameters. This is true for the solver in that ILUT requires ad hoc parameters to determine fill, and the user must prescribe these parameter values. Furthermore, as is well known, overlapping Schwarz methods tend to lose robustness as the processor count increases, making the choice of ILUT parameters and the maximum number of GMRES iterations a function of processor count. In contrast, the solvers have tuning parameters and have identical convergence behavior independent of processor count. This behavior may be the most important feature to an application user.

6.6.3. Solver scalability in processor count. The processor scalability results for the solver are quite remarkable. In all cases, once the number of processors is large enough for the solver to work at all, the performance improvement as a function of processor count is superlinear. This behavior is often observed in practice and is a function of the following two factors: (i) Increasing processor count increases the amount of cache memory and, for a fixed size problem, reduces the working data set on a processor, and (ii) as processor count increases, the subdomains for overlapping Schwarz decrease in size, resulting in smaller ILUT factors and less work per iteration, even though the number of iterations increases. Some of the solvers scalability results are also superlinear, due to factor (i) above. However, since the solvers are already very efficient in serial cost and apply GMRES to a much smaller problem, there is much less work to distribute as processor counts increase. In effect, the solvers cannot benefit as much as the solver from large processor counts for the same global problem. However, the solvers scale quite well and, because of their low memory usage, can be effective using far fewer processors and can solver much larger problems than the solver.

6.6.4. Scalability in mesh density and chain length. The solvers are not invariant under mesh density changes, but nearly so. In fact, except for the coarsest mesh, the number of solver iterations remains nearly constant as the mesh density increases. The solver iteration count also remains fixed as mesh density increases. However, the overall cost of the solver grows much faster than the solvers.

For polymer problems, the solver has constant iteration count as the chain size increases. Furthermore, the cost of the solver grows approximately linearly with the length of the chain. Again, this is a marked improvement over the solver.

7. Conclusions. In this article we have presented a general mathematical framework for describing fluid-DFT problems and solving them using a new family of segregated Schur complement solvers. By viewing fluid-DFTs from a segregated variable perspective we obtain a rich structure that can be exploited in the development of low-cost, robust, scalable solution methods. We have shown that this approach is very effective for two major classes of fluid-DFTs and is very promising for other classes as well. The improvement in solution time, robustness, and memory use opens the door to easy solution of previously intractable problems and broadens the scope of

applicability for real space fluid-DFT methods.

Although our new solvers are faster and require much less memory than the old solver, perhaps most important is the fact that no tuning parameters are required. This fact makes the routine use of Tramonto much easier for complex applications.

Appendix. Two specific fluid-DFTs. In this section we present the particulars of the two distinctly different fluid-DFTs that we consider explicitly in this paper. The first is used to treat atomic fluids, and in particular hard-sphere systems. The second is a DFT used to treat polymer fluids. We note that many other kinds of DFTs have been developed as well. In fact this field contains a whole collection of disparate approaches that must be analyzed individually from the perspective of optimizing solution algorithms.

A.1. An atomistic fluid model. We first consider the fundamental measures theory DFT (FMT-DFT) that was first developed by Rosenfeld, and that has been modified by others [24, 25]. This theory specifically treats hard-sphere fluids as a reference system with other physical effects (e.g., attractions, Coulomb interactions, and even bond constraints) being treated as a perturbations. The grand free energy functional for a multicomponent hard-sphere fluid is

$$\begin{aligned}\Omega[\{\rho_i(\mathbf{r})\}] = &\sum_i \int \rho_i(\mathbf{r})[ln\rho_i(\mathbf{r}) - 1]d\mathbf{r} \\ &+ \int \Phi(\{n_\gamma[\{\rho_i\}]\})d\mathbf{r} + \sum_i \int \rho_i(\mathbf{r})[V_i(\mathbf{r}) - \mu_i]d\mathbf{r},\end{aligned} \tag{A.1}$$

where V is a one body external field, and μ_i is a constant chemical potential in the case of an equilibrium-DFT, and the set of nonlocal variables n_γ are linear as was defined in (2.9). The Euler–Lagrange equation to be solved is

$$ln\rho_i(\mathbf{r}) - V_i(\mathbf{r}) + \mu_i + \int \sum_\gamma \frac{\partial \Phi}{\partial n_\gamma}(\mathbf{r}')\frac{\delta n_\gamma(\mathbf{r}')}{\delta \rho_i(\mathbf{r})}d\mathbf{r}' = 0. \tag{A.2}$$

The energy density Φ depends on a set of nonlocal variables, $\{n_\gamma\}$, where there are four scalar variables, n_0, n_1, n_2, n_3 and two vector variables, n_{V1}, n_{V2}. In Rosenfeld's original theory [24], the free energy density is

$$\begin{aligned}\Phi(\{n\}) = &-n_0 ln(1-n_3) + \frac{n_1 n_2}{1-n_3} - \frac{\vec{n}_{V1}\cdot\vec{n}_{V2}}{1-n_3} \\ &+ \frac{1}{24\pi(1-n_3)^2}\left(n_2 - \frac{\vec{n}_{V2}\cdot\vec{n}_{V2}}{n_2}\right)^3.\end{aligned} \tag{A.3}$$

The block matrix formulation is built on both the Euler–Lagrange equation (residual denoted R_{EL}) and the definition of the nonlocal density variables (residual denoted R_{NL}), and may be written in the form

$$\begin{bmatrix} -I & w_\gamma(\mathbf{r},\mathbf{r}') \\ \sum_\gamma \dfrac{\partial^2\Phi}{\partial n_\gamma \partial n_\epsilon}(\mathbf{r}) & D_{22}(\mathbf{r}) \end{bmatrix} \begin{bmatrix} \Delta n_\gamma \\ \Delta\rho \end{bmatrix} = -\begin{bmatrix} R_{NL}(\mathbf{r}) \\ R_{EL}(\mathbf{r}) \end{bmatrix}, \tag{A.4}$$

where $D_{22}(\mathbf{r})$ is a diagonal block matrix, and each entry is $1/\rho(\mathbf{r})$.

A.2. A polymer fluid model. The particular DFT for polymers we will consider was developed by Chandler, McCoy, and Singer [2], and our formulation is similar to that of Donely and McCoy [3, 12]. This particular theory is developed by minimization of a free energy functional with respect to both the density and an effective field variable, U. This effective field variable constrains a fluid of ideal chains to have the same density profile as the interacting chains of interest in the real external field V^{ext}. The theory solves simultaneously for critical fields $\rho(\mathbf{r})$ and $U(\mathbf{r})$ for each type of monomer segment α in the system. The two residual equations for these critical fields are

$$\rho_\alpha(\mathbf{r}) = \frac{\rho_{b,\alpha}}{N_\alpha} \sum_{s\in\alpha} \frac{G_s(\mathbf{r})G_s^{inv}(\mathbf{r})}{\exp[-\beta U_\alpha(\mathbf{r})]}, \quad \alpha = 1,\dots,N_\alpha, \tag{A.5}$$

$$U_\alpha(\mathbf{r}) = V_\alpha(\mathbf{r}) - \sum_\beta \int c_{\alpha\beta}(\mathbf{r}-\mathbf{r}')(\rho_\beta(\mathbf{r}') - \rho_{b\beta})d\mathbf{r}', \quad \alpha = 1,\dots,N_\alpha, \tag{A.6}$$

where N_α is the number of segments of type α, $c_{\alpha\beta}$ is the direct correlation function taken from a liquid state theory for bulk fluids, the sum in (A.5) is taken over all N_s monomer segments in the fluid of interest, ρ_b denotes the homogeneous bulk density far from the surface, s is a particular segment on the polymer chain of interest, and the G and G^{inv} functions are propagator functions that describe chain connectivity. Specifically,

$$G_s(\mathbf{r}) = \exp[-\beta U_{\alpha(s)}(\mathbf{r})] \int \omega_{\alpha\beta}(\mathbf{r}-\mathbf{r}')G_{s-1}(\mathbf{r}')d\mathbf{r}', \quad s = 1,\dots,N_s, \tag{A.7}$$

$$G_s^{inv}(\mathbf{r}) = \exp[-\beta U_{\alpha(s)}(\mathbf{r})] \int \omega_{\alpha\beta}(\mathbf{r}-\mathbf{r}')G_{s+1}^{inv}(\mathbf{r}')d\mathbf{r}', \quad s = 1,\dots,N_s, \tag{A.8}$$

where ω is a delta function with a range equal to the bond length between segments s and $s-1$ of types α and β, respectively. We note that for an end bead, only the initial field term is present.

To summarize, we have $2N_\alpha$ critical variables ($\{\rho_\alpha\}$ and $\{U_\alpha\}$, and $2N_s$ nonlocal ancillary variables ($\{G\}$ and $\{G^{inv}\}$). The concrete example we discussed in this paper is for an 18 bead polymer mixed with a single site solvent, where the polymer chain has two types of beads on the chain. For this 3 component, 19 segment problem, we have 6 critical field variables and 38 nonlocal ancillary variables.

This situation is quite extreme with respect to complexity in the integral equations. If the discrete matrix problem were formed only in terms of the critical variables, the nested nonlocal variables would result in multidimensional integrals for each Jacobian entry. Specifically, for a polymer with N_s segments, an $N_s - 1$ dimensional integral would need to be performed. This is clearly out of the question. Thus we form the matrix problem with each of the nonlocal propagator functions treated as independent variables. The structure of the resulting 2×2 block matrix is described more fully in section 4.

A MULTIGRID METHOD FOR THE PSEUDOSTRESS FORMULATION OF STOKES PROBLEMS*

ZHIQIANG CAI† AND YANQIU WANG†

Abstract. The purpose of this paper is to develop and analyze a multigrid solver for the finite element discretization of the pseudostress system associated with the differential operator $\mathcal{A} - \gamma\,\mathbf{grad\,div}$ over 2×2 matrix-valued functions. This system is derived from the pseudostress-velocity formulation [Z. Cai, B. Lee, and P. Wang, *SIAM J. Numer. Anal.*, 42 (2004), pp. 843–859] of two-dimensional Stokes problems through the penalty method or natural time discretization for the respective steady- or unsteady-state problems. Here $\gamma > 0$ is a constant associated with either the penalty parameter or the time-step size, and $\mathcal{A}$ is a singular map. In this paper, we develop a multigrid solver for the discrete problem using both the Raviart–Thomas (RT) and the Brezzi–Douglas–Marini (BDM) finite elements. We show that the multigrid convergence rate is $O(\frac{1+\gamma^{-2}}{1+\gamma^{-2}+m})$, where m is the number of smoothings. This convergence rate is independent of the mesh size and the number of levels used in multigrid. Moreover, numerical results presented in this paper show that the multigrid convergence rate for the BDM elements does not depend on the parameter γ.

Key words. multigrid, mixed finite element, pseudostress-velocity formulation, Stokes problem

1. Introduction.

The stress-velocity-pressure formulation [7, 15] for incompressible Newtonian flows comes from the original physical equations. Recently, this formulation has been gaining consistent attention because of the arising interest in non-Newtonian flows [6, 21]. For some non-Newtonian flows, the stress cannot be eliminated and, hence, a formulation containing the stress as a fundamental unknown is unavoidable. In addition, accurate direct calculation of the stress is important for computing the traction on a fluid-solid interface. Although the stress can be obtained in the velocity-pressure method by differentiating the velocity, this degrades the order of the approximation.

In this paper we are interested in mixed finite element methods for the Stokes problem. Notice that one disadvantage of using the stress-velocity-pressure formulation is that the symmetry constraint of the stress tensor poses extra difficulty in the discretization. For example, stable conforming mixed elements for symmetric matrices, e.g., [3, 5, 20], employ many degrees of freedom and, consequently, lead to large linear systems even for coarse meshes. There are different ways to avoid this difficulty. One way is to use the idea of pseudostress [11] and a pseudostress-velocity formulation. The pseudostress is nonsymmetric and, hence, any stable pairs for the Darcy flows can be adapted to the pseudostress-velocity formulation. This is documented in [13]. Furthermore, the velocity can be eliminated through the penalty method for the steady-state problem or the natural time discretization for the unsteady-state problem. So one need only solve numerically the pseudostress system associated with a differential operator $\mathcal{A} - \gamma\,\mathbf{grad\,div}$ over 2×2 matrix-valued functions. Here, $\gamma > 0$

is a constant depending on either the penalty parameter or the time-step size, and $\mathcal{A}$ is a projection operator whose kernel intersects the kernel of the divergence operator. The purpose of this paper is to construct and analyze a multigrid solver for this pseudostress system. It must be pointed out that this problem is more delicate to handle than a normal $\boldsymbol{H}(\mathbf{div})$ problem because of the complicated kernel structure.

We also mention other methods of circumventing the difficulty posed by the symmetric stress. One is to use a stabilization technique [7]. Another is to use the least-squares method, which does not require stable pairs of finite elements. Least-squares methods with fast multigrid solvers for the stress-velocity-pressure formulation and its variants, stress-velocity and pseudostress-velocity formulations, were studied in [11].

Multigrid methods are efficient for many problems. A vast amount of research has been done in this area, e.g., [8, 18, 22, 25]. However, the classical techniques for the multigrid method do not work for the $\boldsymbol{H}(\mathbf{div})$-type problem since standard smoothers cannot damp out the highly oscillating part of divergence-free components. Hence, special smoothers have to be developed in order to achieve an optimal multigrid convergence rate [1, 2, 19, 24]. An additional difficulty in the multigrid analysis for the pseudostress system is the handling of the kernel of $\mathcal{A}$. To overcome the above difficulties, we employ a Helmholtz-like decomposition of the discrete space, which also utilizes the operator $\mathcal{A}$, so that the analysis can be done on separate subspaces. In this paper we consider multigrid solvers for systems discretized using both the Raviart–Thomas (RT) and the Brezzi–Douglas–Marini (BDM) finite elements. We show that the multigrid convergence rate is bounded above by $\rho = \frac{C(1+\gamma^{-2})}{C(1+\gamma^{-2})+2m} < 1$, where m is the number of smoothings and C is a constant independent of the mesh size or the number of levels used in the multigrid. When $\gamma \gg 1$, which is always true for the penalty method of the stationary problems as the penalty parameter goes to zero, the multigrid convergence for the pseudostress system can be considered independent of γ and, hence, the penalty parameter. When $\gamma \ll 1$, which corresponds to the small time-step size in the time discretization of unsteady-state problems, ρ is close to one. Nevertheless, numerical results presented in this paper show that the multigrid convergence rate for the BDM elements does not depend on the parameter γ even if γ is small.

We give the outline of the paper as follows. In sections 2 and 3, we describe the pseudostress system of the Stokes problem and its finite element discretization. The key Helmholtz-type decomposition of the finite element space is given in section 4. We construct a multigrid solver for the discrete $\boldsymbol{H}(\mathbf{div})$-type problem and give a convergence rate estimate in section 5. Some supporting numerical results are presented in section 6. Finally, in the appendix, we prove an essential inequality needed by the analysis in section 4.

1.1. Notation. Let Ω be a convex polygon. Denote by $\mathbb{R}^2$ the set of two-dimensional vector-valued functions and by $\mathbb{M}_2$ the set of 2×2 matrix-valued functions. Throughout the paper, we adopt the convention that a Greek character denotes a 2×2 matrix and a bold roman character in lower case denotes a vector. Letting $\boldsymbol{\tau} = (\tau_{ij})_{2\times 2} \in \mathbb{M}_2$ and $\boldsymbol{v} = (v_1, v_2)^t \in \mathbb{R}^2$, define

$$\operatorname{div} \boldsymbol{v} = \frac{\partial v_1}{\partial x} + \frac{\partial v_2}{\partial y}, \qquad \mathbf{div}\boldsymbol{\tau} = \begin{pmatrix} \frac{\partial \tau_{11}}{\partial x} + \frac{\partial \tau_{12}}{\partial y} \\ \frac{\partial \tau_{21}}{\partial x} + \frac{\partial \tau_{22}}{\partial y} \end{pmatrix},$$

$$\nabla \boldsymbol{v} = \begin{pmatrix} \frac{\partial v_1}{\partial x} & \frac{\partial v_1}{\partial y} \\ \frac{\partial v_2}{\partial x} & \frac{\partial v_2}{\partial y} \end{pmatrix}, \qquad \mathbf{curl}\, \boldsymbol{v} = \begin{pmatrix} -\frac{\partial v_1}{\partial y} & \frac{\partial v_1}{\partial x} \\ -\frac{\partial v_2}{\partial y} & \frac{\partial v_2}{\partial x} \end{pmatrix}.$$

Define the inner product between vectors and 2×2 matrices by

$$\boldsymbol{u} \cdot \boldsymbol{v} = u_1\, v_1 + u_2\, v_2 \quad \text{and} \quad \boldsymbol{\sigma} : \boldsymbol{\tau} = \sum_{1 \le i,j \le 2} \sigma_{ij}\, \tau_{ij},$$

respectively. We use the usual notation $L^2(\Omega)$ to denote the set of square integrable functions on Ω and $H^s(\Omega)$, where $s > 0$ is a real number, to denote the Sobolev space on Ω with index s. Let $C_0^\infty(\Omega)$ be the space of infinitely differentiable functions on Ω with compact support. Denote by $H_0^s(\Omega)$ the closure of $C_0^\infty(\Omega)$ under the norm of $H^s(\Omega)$ and define $H^{-s}(\Omega) = (H_0^s(\Omega))'$, the dual space of $H_0^s(\Omega)$. It is natural to extend the above definitions to vector- and matrix-valued functions using product spaces. For example, $\boldsymbol{H}^s(\Omega, \mathbb{R}^2)$ and $\boldsymbol{H}^s(\Omega, \mathbb{M}_2)$ denote the Sobolev spaces over the set of vector- and 2×2 matrix-valued functions, respectively. Other notations, such as $\mathbf{L}^2(\Omega, \mathbb{R}^2)$, $\mathbf{L}^2(\Omega, \mathbb{M}_2)$, are defined in the same fashion. For simplicity, denote $\|\cdot\|_{s,\Omega}$ to be the Sobolev norm with index s over scalar-, vector-, or matrix-valued functions, depending on the type of the function. Similarly, denote by $|\cdot|_{s,\Omega}$ the Sobolev seminorm and by $(\cdot, \cdot)$ the $\mathbf{L}^2$ inner product. Define the space

$$\boldsymbol{H}(\mathbf{div}, \Omega, \mathbb{M}_2) = \{\boldsymbol{\sigma} \in \mathbf{L}^2(\Omega, \mathbb{M}_2) \,|\, \mathbf{div}\, \boldsymbol{\sigma} \in \mathbf{L}^2(\Omega, \mathbb{R}^2)\}$$

with the norm $\|\boldsymbol{\sigma}\|^2_{\boldsymbol{H}(\mathbf{div},\Omega,\mathbb{M}_2)} = (\boldsymbol{\sigma}, \boldsymbol{\sigma}) + (\mathbf{div}\boldsymbol{\sigma}, \mathbf{div}\boldsymbol{\sigma})$.

2. Pseudostress system. Consider the two-dimensional steady-state Stokes problem

$$\begin{cases} -\Delta \boldsymbol{u} + \nabla p = -\boldsymbol{f} & \text{in } \Omega, \\ \operatorname{div} \boldsymbol{u} = 0 & \text{in } \Omega, \\ \boldsymbol{u}|_{\partial\Omega} = \mathbf{0}, \end{cases} \tag{2.1}$$

where $\boldsymbol{u}$ is the velocity and p is the pressure which satisfies the compatibility condition $\int_\Omega p\, d\boldsymbol{x} = 0$.

Let $\mathcal{A} : \mathbb{M}_2 \to \mathbb{M}_2$ be a fourth order tensor defined by

$$\mathcal{A}\, \boldsymbol{\tau} = \boldsymbol{\tau} - \frac{1}{2} (\operatorname{tr} \boldsymbol{\tau})\, \mathbf{I},$$

where $\operatorname{tr} \boldsymbol{\tau} = \tau_{11} + \tau_{22}$ is the trace of $\boldsymbol{\tau}$ and $\mathbf{I}$ is the 2×2 identity matrix. We immediately notice that $\mathcal{A}$ is a projection onto the trace-free subspace of $\mathbb{M}_2$ and $Ker(\mathcal{A}) = \{v\, \mathbf{I} \,|\, v \text{ is a scalar function}\}$. Define the pseudostress by

$$\boldsymbol{\sigma} = -p\, \mathbf{I} + \nabla \boldsymbol{u}.$$

Then the Stokes problem (2.1) can be rewritten in the pseudostress-velocity formulation:

$$\begin{cases} \mathbf{div}\boldsymbol{\sigma} = \boldsymbol{f} & \text{in } \Omega, \\ \mathcal{A}\boldsymbol{\sigma} - \nabla \boldsymbol{u} = \mathbf{0} & \text{in } \Omega, \\ \boldsymbol{u}|_{\partial\Omega} = \mathbf{0}. \end{cases} \tag{2.2}$$

The incompressible constraint $\operatorname{div} \boldsymbol{u} = 0$ is enforced through $\operatorname{div} \boldsymbol{u} = \operatorname{tr}(\nabla \boldsymbol{u}) = 0$. Notice that $\operatorname{tr} \boldsymbol{\sigma} = -2p$ also needs to satisfy the compatibility condition $\int_\Omega \operatorname{tr} \boldsymbol{\sigma}\, d\boldsymbol{x} = 0$.

From the well-known regularity estimate of problem (2.1) on convex polygons and the definition of the pseudostress, we have the following regularity results. Let $\boldsymbol{f} \in \mathbf{L}^2(\Omega)$; then the solutions to problem (2.1) and (2.2) satisfy $\boldsymbol{u} \in \boldsymbol{H}^2(\Omega) \cap \boldsymbol{H}_0^1(\Omega)$, $p \in H^1(\Omega)/\mathbb{R}$, $\boldsymbol{\sigma} \in \boldsymbol{H}^1(\Omega, \mathbb{M}_2)$, and

$$\|\boldsymbol{u}\|_{2,\Omega} \le c\|\boldsymbol{f}\|_{0,\Omega}, \quad \|p\|_{H^1(\Omega)/\mathbb{R}} \le c\|\boldsymbol{f}\|_{0,\Omega}, \quad \|\boldsymbol{\sigma}\|_{1,\Omega} \le c\|\boldsymbol{f}\|_{0,\Omega}, \tag{2.3}$$

where c is a positive constant independent of $\boldsymbol{f}$.

REMARK 1. Notice that the symmetric physical stress $\boldsymbol{\sigma}_{phy} = -p\mathbf{I} + (\nabla \boldsymbol{u} + (\nabla \boldsymbol{u})^t)$ and the pressure p can be expressed algebraically in terms of the pseudostress $\boldsymbol{\sigma}$:

$$\boldsymbol{\sigma}_{phy} = \boldsymbol{\sigma} + (\mathcal{A}\boldsymbol{\sigma})^t, \qquad p = -\frac{1}{2}\operatorname{tr}\boldsymbol{\sigma}.$$

Therefore, they can be computed in a postprocessing procedure in the same accuracy as the approximation of $\boldsymbol{\sigma}$.

Denote $\mathbf{V} = \mathbf{L}^2(\Omega, \mathbb{R}^2)$ and

$$\boldsymbol{\Sigma} = \boldsymbol{H}(\mathbf{div}, \Omega, \mathbb{M}_2)/span\{\mathbf{I}\} = \left\{ \boldsymbol{\tau} \in \boldsymbol{H}(\mathbf{div}, \Omega, \mathbb{M}_2) \mid \int_\Omega \operatorname{tr}\boldsymbol{\tau}\, d\boldsymbol{x} = 0 \right\}.$$

Then we have the following variational form for (2.2). [illegible] $\boldsymbol{f} \in \mathbf{V}$ [illegible] $\boldsymbol{\sigma} \in \boldsymbol{\Sigma}$ [illegible] $\boldsymbol{u} \in \mathbf{V}$ [illegible]

$$\begin{cases} (\mathcal{A}\boldsymbol{\sigma}, \boldsymbol{\tau}) + (\mathbf{div}\boldsymbol{\tau}, \boldsymbol{u}) = 0 & \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma}, \\ (\mathbf{div}\boldsymbol{\sigma}, \boldsymbol{v}) = (\boldsymbol{f}, \boldsymbol{v}) & \text{for all } \boldsymbol{v} \in \mathbf{V}. \end{cases} \tag{2.4}$$

Notice that the velocity boundary condition becomes the nature boundary condition in the mixed formulation. According to [10], the existence and uniqueness of problem (2.4) follows from the well-known inf-sup condition $\sup_{\boldsymbol{\tau} \in \boldsymbol{H}^1(\Omega, \mathbb{M}_2)} \frac{(\mathbf{div}\boldsymbol{\tau}, \boldsymbol{v})}{\|\boldsymbol{\tau}\|_{1,\Omega}} \ge \kappa \|\boldsymbol{v}\|_{0,\Omega}$ for all $\boldsymbol{v} \in \mathbf{V}$ and the following lemma [12].

LEMMA 2.1. [illegible] $\boldsymbol{\tau} \in \boldsymbol{\Sigma}$ [illegible]

$$\|\boldsymbol{\tau}\|_{0,\Omega}^2 \le C_A(\|\mathcal{A}^{1/2}\boldsymbol{\tau}\|_{0,\Omega}^2 + \|\mathbf{div}\boldsymbol{\tau}\|_{-1,\Omega}^2),$$

[illegible] $C_A \ge 1$ [illegible] $\boldsymbol{\tau}$

Using the penalty method [10] on problem (2.4) gives a new system

$$\begin{cases} (\mathcal{A}\boldsymbol{\sigma}_\gamma, \boldsymbol{\tau}) + (\mathbf{div}\boldsymbol{\tau}, \boldsymbol{u}_\gamma) = 0 & \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma}, \\ (\mathbf{div}\boldsymbol{\sigma}_\gamma, \boldsymbol{v}) - \frac{1}{\gamma}(\boldsymbol{u}_\gamma, \boldsymbol{v}) = (\boldsymbol{f}, \boldsymbol{v}) & \text{for all } \boldsymbol{v} \in \mathbf{V}, \end{cases} \tag{2.5}$$

where γ is a positive constant which is usually very large. One advantage of using the penalty method is that the mixed system (2.5) can be easily decoupled. Define a bilinear form over $\boldsymbol{H}(\mathbf{div}, \Omega, \mathbb{M}_2)$ by

$$\boldsymbol{\Lambda}(\boldsymbol{\sigma}, \boldsymbol{\tau}) = (\mathcal{A}\boldsymbol{\sigma}, \boldsymbol{\tau}) + \gamma(\mathbf{div}\boldsymbol{\sigma}, \mathbf{div}\boldsymbol{\tau}) \qquad \text{for all } \boldsymbol{\sigma}, \boldsymbol{\tau} \in \boldsymbol{\Sigma}.$$

By eliminating $\boldsymbol{u}_\gamma$, system (2.5) can be reduced to the following $\boldsymbol{H}(\mathbf{div})$ problem:

$$\boldsymbol{\Lambda}(\boldsymbol{\sigma}_\gamma, \boldsymbol{\tau}) = \gamma(\boldsymbol{f}, \mathbf{div}\boldsymbol{\tau}) \quad \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma}. \tag{2.6}$$

By Lemma 2.1, it is easy to see that $\boldsymbol{\Lambda}(\cdot, \cdot)$ is coercive over space $\boldsymbol{\Sigma}$. Hence problem (2.6) is well-posed. Then $\boldsymbol{u}_\gamma$ can be easily calculated through $\boldsymbol{u}_\gamma = \gamma(\mathbf{div}\boldsymbol{\sigma}_\gamma - \boldsymbol{f})$.

Finally, we mention the case of time-dependent Stokes problems. It is not hard to see that the implicit time discretization usually leads to the following pseudostress-velocity form:

$$\begin{cases} \mathbf{div}\boldsymbol{\sigma} - \frac{1}{\gamma}\boldsymbol{u} = \boldsymbol{f} & \text{in } \Omega, \\ \mathcal{A}\boldsymbol{\sigma} - \nabla \boldsymbol{u} = \mathbf{0} & \text{in } \Omega, \\ \boldsymbol{u}|_{\partial\Omega} = \mathbf{0}, \end{cases} \tag{2.7}$$

where $\gamma \ll 1$ is related to the time-step size. Again, problem (2.7) can easily be decoupled and will lead to the pseudostress problem (2.6). The only difference is that γ is small in this case.

3. Finite element approximation. In the remainder of this paper, we will focus on solving problem (2.6) using the finite element method and a multigrid solver. To discretize the problem, we need a good finite element approximation to the space $\boldsymbol{\Sigma}$. There are several well-known conforming elements for the $H(\mathrm{div})$ space over the vector field $\mathbb{R}^2$. We will consider the lowest order RT element [23] and the lowest order BDM element [9]. It should be easy to extend the results to higher order elements.

Let $\mathcal{T}_h$ be a quasi-uniform triangulation of Ω with characteristic mesh size h. On each triangle $T \in \mathcal{T}_h$, denote $P_n(T)$ to be the set of all polynomials with degrees less than or equal to n. Define

$$RT_T = span\left\{ \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \begin{pmatrix} x \\ y \end{pmatrix} \right\}$$

and

$$BDM_T = (P_1(T))^2.$$

The degrees of freedom for the RT element are the zeroth order moments of the normal components on each edge of T. The degrees of freedom for the BDM element are the zeroth order and the first order moments of the normal components on each edge of T.

We use two copies of the RT/BDM element to approximate the space $\boldsymbol{H}(\mathbf{div}, \Omega, \mathbb{M}_2)$. Let

$$\boldsymbol{\Sigma}_T^{RT} = \{\boldsymbol{\tau} \in \mathbb{M}_2 \,|\, (\tau_{i1},\, \tau_{i2}) \in RT_T \text{ for } i = 1,\, 2\},$$

$$\boldsymbol{\Sigma}_T^{BDM} = \{\boldsymbol{\tau} \in \mathbb{M}_2 \,|\, (\tau_{i1},\, \tau_{i2}) \in BDM_T \text{ for } i = 1,\, 2\}.$$

Define the finite element spaces

$$\boldsymbol{\Sigma}_h^{RT} = \{\boldsymbol{\tau} \in \boldsymbol{\Sigma} \,|\; \boldsymbol{\tau}|_T \in \boldsymbol{\Sigma}_T^{RT}\} \quad \text{and} \quad \boldsymbol{\Sigma}_h^{BDM} = \{\boldsymbol{\tau} \in \boldsymbol{\Sigma} \,|\; \boldsymbol{\tau}|_T \in \boldsymbol{\Sigma}_T^{BDM}\}.$$

In later analysis, we use more common properties of the RT and the BDM elements than their differences. Hence we will use $\boldsymbol{\Sigma}_h$ to denote either $\boldsymbol{\Sigma}_h^{RT}$ or $\boldsymbol{\Sigma}_h^{BDM}$. It is well known that the necessary continuity requirement for $\boldsymbol{\Sigma}_h$ to be in $\boldsymbol{\Sigma}$ is that any function in the discrete space should have continuous normal components across each edge of the mesh. Notice that $\boldsymbol{\Sigma}_h$ also inherits the constraint $\int_\Omega \operatorname{tr} \boldsymbol{\sigma}\, d\boldsymbol{x} = 0$ from $\boldsymbol{\Sigma}$.

Consider the discrete problem of (2.6): find $\boldsymbol{\sigma}_h \in \boldsymbol{\Sigma}_h$ such that

$$\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h,\, \boldsymbol{\tau}_h) = \gamma\,(\boldsymbol{f},\, \mathbf{div}\, \boldsymbol{\tau}_h) \quad \text{for all } \boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h. \tag{3.1}$$

Let $\boldsymbol{\sigma}$ and $\boldsymbol{\sigma}_h$ be solutions to problems (2.4) and (3.1), respectively. The following error bound is established in [13] for the RT element with $\gamma = O(h^{-1})$:

$$\|\boldsymbol{\sigma} - \boldsymbol{\sigma}_h\|_{0,\Omega} + \|\mathbf{div}\,(\boldsymbol{\sigma} - \boldsymbol{\sigma}_h)\|_{0,\Omega} \lesssim h\,(\|\boldsymbol{\sigma}\|_{1,\Omega} + \|\boldsymbol{f}\|_{1,\Omega})\,.$$

Here and thereafter, we use $\lesssim$ to denote "less than or equal to" with a factor c independent of the mesh size h or other parameters appearing in the inequality. The above error bound for the BDM element can be obtained in a similar fashion.

Next we give the discretization of problem (2.4) and its error estimate, which will play an important role in later analysis. Define the space $\mathbf{V}_h \subset \mathbf{L}^2(\Omega, \mathbb{R}^2)$ as follows:

$$\mathbf{V}_h = \{(v_1,\, v_2)^t \mid\ v_i|_T \in P_0(T) \text{ for } i = 1,\, 2\}.$$

Since both the RT element and the BDM element satisfy the discrete inf-sup condition [10], we have $\mathbf{div}\boldsymbol{\Sigma}_h = \mathbf{V}_h$. Consider the discrete problem for system (2.4): given $\boldsymbol{f} \in \mathbf{L}^2(\Omega, \mathbb{R}^2)$, find $\boldsymbol{\sigma}_h \in \boldsymbol{\Sigma}_h$ and $\boldsymbol{u}_h \in \mathbf{V}_h$ such that

$$\begin{cases} (\mathcal{A}\boldsymbol{\sigma}_h, \boldsymbol{\tau}_h) + (\mathbf{div}\boldsymbol{\tau}_h, \boldsymbol{u}_h) = 0 & \text{for all } \boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h, \\ (\mathbf{div}\boldsymbol{\sigma}_h, \boldsymbol{v}_h) = (\boldsymbol{f}, \boldsymbol{v}_h) & \text{for all } \boldsymbol{v}_h \in \mathbf{V}_h. \end{cases} \tag{3.2}$$

By Lemma 2.1 and the discrete inf-sup condition of the RT/BDM element space, Problem (3.2) is well-posed and admits a unique solution.

Next, we will give the mixed finite element error estimate for problem (3.2). To do this, we need to show that $\boldsymbol{\Sigma}_h$, under the constraint $\int_\Omega \operatorname{tr}\boldsymbol{\sigma}\, d\boldsymbol{x} = 0$, is a good approximation for $\boldsymbol{\Sigma}$. Denote by $\tilde{\Pi}_h$ the natural interpolation associated with the degrees of freedom onto $\boldsymbol{\Sigma}_h + span\{\mathbf{I}\}$. Let $\mathbf{P}_{\mathbf{V}_h}$ be the $\mathbf{L}^2$ projection onto $\mathbf{V}_h$. Define $\Pi_h : \boldsymbol{\Sigma} \to \boldsymbol{\Sigma}_h$ by

$$\Pi_h \boldsymbol{\tau} = \tilde{\Pi}_h \boldsymbol{\tau} - \frac{\int_\Omega (\operatorname{tr} \tilde{\Pi}_h \boldsymbol{\tau})\, d\boldsymbol{x}}{2\,|\Omega|}\,\mathbf{I} \quad \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma}, \tag{3.3}$$

where $|\Omega| = \int_\Omega d\boldsymbol{x}$. Clearly, Π_h is a linear operator and $\Pi_h \boldsymbol{\tau} \in \boldsymbol{\Sigma}_h$. By the properties of the natural interpolation $\tilde{\Pi}_h$ [10] and the definition of Π_h, it is easy to prove [13] the following lemma.

LEMMA 3.1. [illegible] $\mathbf{div}\Pi_h = \mathbf{P}_{\mathbf{V}_h}\mathbf{div}$ [illegible] $\boldsymbol{\tau} \in \boldsymbol{\Sigma} \cap \boldsymbol{H}^1(\Omega, \mathbb{M}_2)$ [illegible]

$$\|\boldsymbol{\tau} - \Pi_h\boldsymbol{\tau}\|_{0,\Omega} \lesssim h|\boldsymbol{\tau}|_{1,\Omega}, \tag{3.4}$$

$$\|\mathbf{div}\boldsymbol{\tau} - \mathbf{div}(\Pi_h\boldsymbol{\tau})\|_{0,\Omega} \lesssim \|\mathbf{div}\boldsymbol{\tau}\|_{0,\Omega}. \tag{3.5}$$

The following lemma gives error estimates for the mixed finite element approximation (3.2).

LEMMA 3.2. [illegible] $\boldsymbol{f} \in \mathbf{L}^2(\Omega, \mathbb{R}^2)$ [illegible] $(\boldsymbol{\sigma}, \boldsymbol{u})$ [illegible] (2.4) [illegible] $(\boldsymbol{\sigma}_h, \boldsymbol{u}_h)$ [illegible] (3.2) [illegible]

$$\|\boldsymbol{\sigma} - \boldsymbol{\sigma}_h\|_{0,\Omega} \lesssim h|\boldsymbol{\sigma}|_{1,\Omega},$$
$$\|\boldsymbol{u} - \boldsymbol{u}_h\|_{0,\Omega} \lesssim h|\boldsymbol{u}|_{1,\Omega} + h|\boldsymbol{\sigma}|_{1,\Omega}.$$

[illegible] By using the mixed finite element theory and the properties of operator Π_h, it is standard to prove that [10, 5]

$$\|\mathcal{A}(\boldsymbol{\sigma} - \boldsymbol{\sigma}_h)\|_{0,\Omega} \lesssim h|\boldsymbol{\sigma}|_{1,\Omega},$$
$$\|\boldsymbol{u} - \boldsymbol{u}_h\|_{0,\Omega} \lesssim h|\boldsymbol{u}|_{1,\Omega} + h|\boldsymbol{\sigma}|_{1,\Omega}.$$

Next, notice that $\mathbf{div}(\boldsymbol{\sigma}-\boldsymbol{\sigma}_h) = \boldsymbol{f}-\mathbf{P}_{\mathbf{V}_h}\boldsymbol{f}$. By Lemma 2.1 and the approximation property of the $\mathbf{L}^2$ projection, we have

$$\begin{aligned}
\|\boldsymbol{\sigma}-\boldsymbol{\sigma}_h\|_{0,\Omega} &\lesssim \|\mathcal{A}(\boldsymbol{\sigma}-\boldsymbol{\sigma}_h)\|_{0,\Omega} + \|\mathbf{div}(\boldsymbol{\sigma}-\boldsymbol{\sigma}_h)\|_{-1,\Omega} \\
&\lesssim h|\boldsymbol{\sigma}|_{1,\Omega} + \sup_{\boldsymbol{v}\in \boldsymbol{H}_0^1(\Omega,\mathbb{R}^2)} \frac{(\boldsymbol{f}-\mathbf{P}_{\mathbf{V}_h}\boldsymbol{f},\boldsymbol{v})}{\|\boldsymbol{v}\|_{1,\Omega}} \\
&= h|\boldsymbol{\sigma}|_{1,\Omega} + \sup_{\boldsymbol{v}\in \boldsymbol{H}_0^1(\Omega,\mathbb{R}^2)} \frac{(\boldsymbol{f},\boldsymbol{v}-\mathbf{P}_{\mathbf{V}_h}\boldsymbol{v})}{\|\boldsymbol{v}\|_{1,\Omega}} \\
&\lesssim h|\boldsymbol{\sigma}|_{1,\Omega} + h\|\boldsymbol{f}\|_{0,\Omega} = h|\boldsymbol{\sigma}|_{1,\Omega} + h\|\mathbf{div}\boldsymbol{\sigma}\|_{0,\Omega} \\
&\lesssim h|\boldsymbol{\sigma}|_{1,\Omega}.
\end{aligned}$$

This completes the proof of the lemma. ∎

4. A decomposition in $\boldsymbol{\Sigma_h}$. In this section we introduce a Helmholtz-type decomposition of the discrete space $\boldsymbol{\Sigma}_h$. This decomposition and its properties borrowed many ideas from the decomposition presented in the work of Arnold, Falk, and Winther on $H(\mathrm{div})$ problems [1, 2]. The difference is that our decomposition needs to use the projection operator $\mathcal{A}$, which makes the proof more complicated. For the convenience of readers, we give all details of the proof even if some parts are similar to the proof given in [1, 2].

Consider the mixed finite element problem (3.2). Let $(\boldsymbol{\sigma}_h, \boldsymbol{u}_h)$ be the solution to (3.2) with the right-hand side function $\boldsymbol{f} \in \mathbf{L}^2(\Omega,\mathbb{R}^2)$. Denote $\mathbf{div}_h^{-1}\boldsymbol{f} = \boldsymbol{\sigma}_h$. The operator $\mathbf{div}_h^{-1}$ maps $\mathbf{L}^2(\Omega,\mathbb{R}^2)$ to $\boldsymbol{\Sigma}_h$ and can be considered as a pseudoinverse of the $\mathbf{div}$ operator. It is not hard to see that for all $\boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h$ such that $\mathbf{div}\boldsymbol{\tau}_h = \mathbf{0}$,

$$(\mathcal{A}\mathbf{div}_h^{-1}\boldsymbol{f},\boldsymbol{\tau}_h) = -(\mathbf{div}\boldsymbol{\tau}_h,\boldsymbol{u}_h) = 0.$$

Define

$$\boldsymbol{\Sigma}_h^0 = \{\boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h \text{ such that } \mathbf{div}\boldsymbol{\tau}_h = \mathbf{0}\}, \tag{4.1}$$

$$\boldsymbol{\Sigma}_h^1 = \{\boldsymbol{\tau}_h \in \mathbf{div}_h^{-1}\mathbf{V}_h\}. \tag{4.2}$$

Then $\boldsymbol{\Sigma}_h^0$ and $\boldsymbol{\Sigma}_h^1$ are orthogonal under $\boldsymbol{\Lambda}(\cdot,\cdot)$. It is easy to see that $\boldsymbol{\Sigma}_h = \boldsymbol{\Sigma}_h^0 \oplus \boldsymbol{\Sigma}_h^1$.

Define the space $\tilde{\mathbf{U}}_h \subset \boldsymbol{H}^1(\Omega,\mathbb{R}^2)$ as follows: for the RT element, let

$$\tilde{\mathbf{U}}_h = \{(q_1,q_2)^t \in \boldsymbol{H}^1(\Omega,\mathbb{R}^2) \mid q_1,\, q_2 \text{ are } P_1 \text{ polynomials on each } T \in \mathcal{T}_h\}$$

and for the BDM element, let

$$\tilde{\mathbf{U}}_h = \{(q_1,q_2)^t \in \boldsymbol{H}^1(\Omega,\mathbb{R}^2) \mid q_1,\, q_2 \text{ are } P_2 \text{ polynomials on each } T \in \mathcal{T}_h\}.$$

Define

$$\mathbf{U}_h = \tilde{\mathbf{U}}_h / span\left\{\begin{pmatrix}1\\0\end{pmatrix}, \begin{pmatrix}0\\1\end{pmatrix}, \begin{pmatrix}-y\\x\end{pmatrix}\right\}.$$

It is well known that every $\boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h^0$ has a potential $\boldsymbol{q}_h \in \tilde{\mathbf{U}}_h$ such that $\boldsymbol{\tau}_h = \mathbf{curl}\,\boldsymbol{q}_h$ [10]. The constraint $\int_\Omega \operatorname{tr}\boldsymbol{\tau}_h\, d\boldsymbol{x} = 0$ further implies that $\boldsymbol{q}_h$ can be chosen from $\mathbf{U}_h$. In other words, $\boldsymbol{\Sigma}_h^0 = \mathbf{curl}\,(\mathbf{U}_h)$. Hence we have the following exact sequence:

$$0 \longrightarrow \mathbf{U}_h \xrightarrow{\mathbf{curl}} \boldsymbol{\Sigma}_h \xrightarrow{\mathbf{div}} \mathbf{V}_h \longrightarrow 0.$$

For each $\boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h$, we have the decomposition $\boldsymbol{\sigma}_h = \mathbf{curl}\, q_h + \mathbf{div}_h^{-1} v_h$, where $q_h \in \mathbf{U}_h$, $v_h = \mathbf{div}\boldsymbol{\sigma}_h \in \mathbf{V}_h$ and the decomposition is orthogonal under both $(\mathcal{A}\cdot,\cdot)$ and $(\mathbf{div}\cdot,\mathbf{div}\cdot)$. This decomposition is usually referred to as the discrete Helmholtz decomposition.

Next, we study some properties related to the discrete Helmholtz decomposition. Define an operator $\mathbf{grad}_h : \mathbf{V}_h \to \boldsymbol{\Sigma}_h$ as follows:

$$(\mathbf{grad}_h v_h, \boldsymbol{\tau}_h) = -(\mathbf{div}\boldsymbol{\tau}_h, v_h) \quad \text{for all } \boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h.$$

The operator $\mathbf{grad}_h$ is actually the discrete dual operator of $\mathbf{div}$. Notice that for an arbitrary $\boldsymbol{\sigma}_h \in \boldsymbol{\Sigma}_h$, $\mathcal{A}\boldsymbol{\sigma}_h$ is not necessarily in $\boldsymbol{\Sigma}_h$ since it may not satisfy the $\boldsymbol{H}(\mathbf{div}, \Omega, \mathbb{M}_2)$ continuity requirement on normal components. Therefore we need to define discrete operators $A_h : \boldsymbol{\Sigma}_h \to \boldsymbol{\Sigma}_h$ and $\boldsymbol{\Lambda}_h : \boldsymbol{\Sigma}_h \to \boldsymbol{\Sigma}_h$ by

$$\begin{aligned}(A_h\boldsymbol{\sigma}_h, \boldsymbol{\tau}_h) &= (\mathcal{A}\boldsymbol{\sigma}_h, \boldsymbol{\tau}_h) \quad \text{for all } \boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h,\\ (\boldsymbol{\Lambda}_h\boldsymbol{\sigma}_h, \boldsymbol{\tau}_h) &= \boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\tau}_h) \quad \text{for all } \boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h.\end{aligned}$$

It is equivalent to say that $A_h = \mathbf{P}_{\boldsymbol{\Sigma}_h}\mathcal{A}$, where $\mathbf{P}_{\boldsymbol{\Sigma}_h}$ is the $\mathbf{L}^2$ projection onto the finite dimensional space $\boldsymbol{\Sigma}_h$ and $\boldsymbol{\Lambda}_h\boldsymbol{\sigma}_h = A_h\boldsymbol{\sigma}_h - \gamma\mathbf{grad}_h\mathbf{div}\boldsymbol{\sigma}_h$. By the property of the projection operator $\mathbf{P}_{\boldsymbol{\Sigma}_h}$, we have

$$\|A_h\boldsymbol{\tau}_h\|_{0,\Omega} \lesssim \|\mathcal{A}\boldsymbol{\tau}_h\|_{0,\Omega} \qquad \text{for all } \boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h. \tag{4.3}$$

Let $\mathcal{T}_H$ be a quasi-uniform triangulation of Ω with characteristic mesh size H and let $\mathcal{T}_h$ be a refinement of $\mathcal{T}_H$ with characteristic mesh size h. We follow the notation previously introduced with the understanding that spaces and operators with subscript H are defined over the mesh $\mathcal{T}_H$. For example, $\boldsymbol{\Sigma}_H$ is defined on $\mathcal{T}_H$ in the same way that $\boldsymbol{\Sigma}_h$ is defined on $\mathcal{T}_h$. Besides, the RT/BDM finite element spaces are known to be nested; that is, $\boldsymbol{\Sigma}_H \subset \boldsymbol{\Sigma}_h$.

LEMMA 4.1. [illegible] $v_h \in \mathbf{V}_h$ [illegible] $\boldsymbol{\sigma}_h = \mathbf{div}_h^{-1} v_h$ [illegible] $\boldsymbol{\sigma}_H = \mathbf{div}_H^{-1} v_h$ [illegible]

$$\begin{aligned}\|\boldsymbol{\sigma}_h - \boldsymbol{\sigma}_H\|_{0,\Omega} &\lesssim H\|v_h\|_{0,\Omega},\\ \|\mathbf{div}(\boldsymbol{\sigma}_h - \boldsymbol{\sigma}_H)\|_{0,\Omega} &\lesssim H\|\mathbf{grad}_h v_h\|_{0,\Omega}.\end{aligned}$$

[illegible] Let $\boldsymbol{\sigma} \in \boldsymbol{\Sigma}$ be the solution to

$$\begin{cases}(\mathcal{A}\boldsymbol{\sigma}, \boldsymbol{\tau}) + (\mathbf{div}\boldsymbol{\tau}, u) = 0 & \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma},\\ (\mathbf{div}\boldsymbol{\sigma}, w) = (v_h, w) & \text{for all } w \in \mathbf{L}^2(\Omega, \mathbb{R}^2).\end{cases}$$

By the regularity property (2.3), Lemma 3.2, and the fact that $h < H$, we have

$$\|\boldsymbol{\sigma}_h - \boldsymbol{\sigma}_H\|_{0,\Omega} \le \|\boldsymbol{\sigma} - \boldsymbol{\sigma}_h\|_{0,\Omega} + \|\boldsymbol{\sigma} - \boldsymbol{\sigma}_H\|_{0,\Omega} \lesssim H|\boldsymbol{\sigma}|_{1,\Omega} \lesssim H\|v_h\|_{0,\Omega}.$$

Notice that $\mathbf{div}(\boldsymbol{\sigma}_h - \boldsymbol{\sigma}_H) = v_h - \mathbf{P}_{\mathbf{V}_H} v_h$, where $\mathbf{P}_{\mathbf{V}_H}$ is the $\mathbf{L}^2$ projection onto $\mathbf{V}_H$. Define $\tilde{\boldsymbol{\sigma}} \in \boldsymbol{\Sigma}$ by

$$\begin{cases}(\mathcal{A}\tilde{\boldsymbol{\sigma}}, \boldsymbol{\tau}) + (\mathbf{div}\boldsymbol{\tau}, u) = 0 & \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma},\\ (\mathbf{div}\tilde{\boldsymbol{\sigma}}, w) = (v_h - \mathbf{P}_{\mathbf{V}_H} v_h, w) & \text{for all } w \in \mathbf{L}^2(\Omega, \mathbb{R}^2).\end{cases}$$

Recall that Π_h and Π_H satisfy $\mathbf{div}\Pi_h = \mathbf{P}_{\mathbf{V}_h}\mathbf{div}$ and $\mathbf{div}\Pi_H = \mathbf{P}_{\mathbf{V}_H}\mathbf{div}$. By using Lemma 3.1, the Schwarz inequality, and the regularity result (2.3), we have

$$\begin{aligned}
\|\boldsymbol{v}_h - \mathbf{P}_{\mathbf{V}_H}\boldsymbol{v}_h\|_{0,\Omega}^2 &= (\mathbf{div}\tilde{\boldsymbol{\sigma}}, \boldsymbol{v}_h - \mathbf{P}_{\mathbf{V}_H}\boldsymbol{v}_h) \\
&= (\mathbf{div}(\Pi_h\tilde{\boldsymbol{\sigma}} - \Pi_H\tilde{\boldsymbol{\sigma}}), \boldsymbol{v}_h) = -((\Pi_h\tilde{\boldsymbol{\sigma}} - \Pi_H\tilde{\boldsymbol{\sigma}}), \mathbf{grad}_h\boldsymbol{v}_h) \\
&\le \|\Pi_h\tilde{\boldsymbol{\sigma}} - \Pi_H\tilde{\boldsymbol{\sigma}}\|_{0,\Omega}\|\mathbf{grad}_h\boldsymbol{v}_h\|_{0,\Omega} \lesssim H|\tilde{\boldsymbol{\sigma}}|_{1,\Omega}\|\mathbf{grad}_h\boldsymbol{v}_h\|_{0,\Omega} \\
&\lesssim H\|\boldsymbol{v}_h - \mathbf{P}_{\mathbf{V}_H}\boldsymbol{v}_h\|_{0,\Omega}\|\mathbf{grad}_h\boldsymbol{v}_h\|_{0,\Omega}.
\end{aligned}$$

This completes the proof of the lemma. □

LEMMA 4.2. For $\boldsymbol{\sigma}_h \in \boldsymbol{\Sigma}_h$ satisfying $\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\tau}_H) = 0$ for all $\boldsymbol{\tau}_H \in \boldsymbol{\Sigma}_H$, $\boldsymbol{\sigma}_h = \mathbf{curl}\,\boldsymbol{q}_h + \mathbf{div}_h^{-1}\boldsymbol{v}_h$ for some $\boldsymbol{q}_h \in \mathbf{U}_h$ and $\boldsymbol{v}_h = \mathbf{div}\boldsymbol{\sigma}_h \in \mathbf{V}_h$. Let $\boldsymbol{\Lambda}$ be elliptic, and let $\boldsymbol{\sigma}_h^1 = \mathbf{div}_h^{-1}\boldsymbol{v}_h$. Then

$$(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1) \lesssim \gamma^{-1}H^2\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\sigma}_h), \tag{4.4}$$

$$(1 + \gamma H^{-2})\|\boldsymbol{\sigma}_h^1\|_{0,\Omega}^2 \lesssim (1 + \gamma^{-2})\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\sigma}_h), \tag{4.5}$$

$$\|\boldsymbol{q}_h\|_{0,\Omega}^2 \lesssim H^2(\mathcal{A}\mathbf{curl}\,\boldsymbol{q}_h, \mathbf{curl}\,\boldsymbol{q}_h). \tag{4.6}$$

The proof of inequality (4.6) is a little long and hence will be put in the appendix. Here we give the proof of inequalities (4.4) and (4.5). Define $\tilde{\boldsymbol{\sigma}}_h \in \boldsymbol{\Sigma}_h$ by

$$\boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h, \boldsymbol{\tau}_h) = (\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\tau}_h) \quad \text{for all } \boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h. \tag{4.7}$$

It is clear that

$$\boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h, \mathbf{curl}\,\boldsymbol{p}_h) = (\mathcal{A}\boldsymbol{\sigma}_h^1, \mathbf{curl}\,\boldsymbol{p}_h) = 0 \quad \text{for all } \boldsymbol{p}_h \in \mathbf{U}_h.$$

This implies $\tilde{\boldsymbol{\sigma}}_h \in \boldsymbol{\Sigma}_h^1$. In other words, if we denote $\mathbf{div}\tilde{\boldsymbol{\sigma}}_h = \tilde{\boldsymbol{v}}_h$, then $\tilde{\boldsymbol{\sigma}}_h = \mathbf{div}_h^{-1}\tilde{\boldsymbol{v}}_h$. Define $\tilde{\boldsymbol{\sigma}}_H = \mathbf{div}_H^{-1}\tilde{\boldsymbol{v}}_h$. By the Schwarz inequality,

$$\begin{aligned}
(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1) &= \boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h, \boldsymbol{\sigma}_h^1) = \boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h, \boldsymbol{\sigma}_h) \\
&= \boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h - \tilde{\boldsymbol{\sigma}}_H, \boldsymbol{\sigma}_h) \le \boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h - \tilde{\boldsymbol{\sigma}}_H, \tilde{\boldsymbol{\sigma}}_h - \tilde{\boldsymbol{\sigma}}_H)^{1/2}\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\sigma}_h)^{1/2}.
\end{aligned} \tag{4.8}$$

We also notice that (4.7) implies that $\boldsymbol{\Lambda}_h\tilde{\boldsymbol{\sigma}}_h = A_h\boldsymbol{\sigma}_h^1$. Furthermore, by setting $\boldsymbol{\tau}_h = \tilde{\boldsymbol{\sigma}}_h$ in (4.7) and using the Schwarz inequality, we can easily see that $\boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h, \tilde{\boldsymbol{\sigma}}_h) \le (\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1)$. Hence, by the fact that $\mathcal{A}$ is a projection, Lemma 4.1, the triangular inequality, and inequality (4.3), we have

$$\begin{aligned}
\boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h - \tilde{\boldsymbol{\sigma}}_H, \tilde{\boldsymbol{\sigma}}_h - \tilde{\boldsymbol{\sigma}}_H) &\le \|\tilde{\boldsymbol{\sigma}}_h - \tilde{\boldsymbol{\sigma}}_H\|_{0,\Omega}^2 + \gamma\|\mathbf{div}(\tilde{\boldsymbol{\sigma}}_h - \tilde{\boldsymbol{\sigma}}_H)\|_{0,\Omega}^2 \\
&\lesssim H^2\gamma^{-1}(\gamma\|\mathbf{div}\tilde{\boldsymbol{\sigma}}_h\|_{0,\Omega}^2 + \gamma^2\|\mathbf{grad}_h\mathbf{div}\tilde{\boldsymbol{\sigma}}_h\|_{0,\Omega}^2) \\
&\lesssim H^2\gamma^{-1}(\gamma\|\mathbf{div}\tilde{\boldsymbol{\sigma}}_h\|_{0,\Omega}^2 + \|A_h\tilde{\boldsymbol{\sigma}}_h\|_{0,\Omega}^2 + \|(A_h - \gamma\mathbf{grad}_h\mathbf{div})\tilde{\boldsymbol{\sigma}}_h\|_{0,\Omega}^2) \\
&\lesssim H^2\gamma^{-1}(\boldsymbol{\Lambda}(\tilde{\boldsymbol{\sigma}}_h, \tilde{\boldsymbol{\sigma}}_h) + \|\boldsymbol{\Lambda}_h\tilde{\boldsymbol{\sigma}}_h\|_{0,\Omega}^2) \\
&\lesssim H^2\gamma^{-1}((\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1) + \|A_h\boldsymbol{\sigma}_h^1\|_{0,\Omega}^2) \\
&\lesssim H^2\gamma^{-1}(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1).
\end{aligned} \tag{4.9}$$

Combining (4.8) and (4.9) gives $(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1) \lesssim H\gamma^{-1/2}(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1)^{1/2}\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\sigma}_h)^{1/2}$. Thus (4.4) holds.

Next, we prove (4.5). Notice that $\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\tau}_H) = 0$ for all $\boldsymbol{\tau}_H \in \boldsymbol{\Sigma}_H$ implies

$$(\mathbf{div}\boldsymbol{\sigma}_h^1, \mathbf{div}\boldsymbol{\tau}_H) = -\gamma^{-1}(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\tau}_H) - \gamma^{-1}(\mathcal{A}\mathbf{curl}\, \boldsymbol{q}_h, \boldsymbol{\tau}_H). \tag{4.10}$$

By definition,

$$\|\mathbf{div}\boldsymbol{\sigma}_h^1\|_{-1,\Omega} = \sup_{\boldsymbol{v}\in \boldsymbol{H}_0^1(\Omega,\mathbb{R}^2)} \frac{(\mathbf{div}\boldsymbol{\sigma}_h^1, \boldsymbol{v})}{\|\boldsymbol{v}\|_{1,\Omega}}.$$

For $\boldsymbol{v} \in \boldsymbol{H}_0^1(\Omega, \mathbb{R}^2)$, let $\boldsymbol{v}_H$ be the $\mathbf{L}^2$ projection of $\boldsymbol{v}$ onto $\mathbf{V}_H$. Then the following estimates are well known:

$$\|\boldsymbol{v} - \boldsymbol{v}_H\|_{0,\Omega} \lesssim H\|\boldsymbol{v}\|_{1,\Omega},$$
$$\|\boldsymbol{v}_H\|_{0,\Omega} \le \|\boldsymbol{v}\|_{0,\Omega} \le \|\boldsymbol{v}\|_{1,\Omega}.$$

Define $\boldsymbol{\tau}_H = \mathbf{div}_H^{-1}\boldsymbol{v}_H$ and $\boldsymbol{\tau}_h = \mathbf{div}_h^{-1}\boldsymbol{v}_H$. We have $(\mathcal{A}\mathbf{curl}\, \boldsymbol{q}_h, \boldsymbol{\tau}_h) = 0$. Besides, by Lemma 3.2 and the regularity result (2.3), it is not hard to see that $\|\boldsymbol{\tau}_H\|_{0,\Omega} \lesssim \|\boldsymbol{v}_H\|_{0,\Omega}$. Combining the above and using Lemma 4.1 and (4.10), we have

$$\begin{aligned}
\sup_{\boldsymbol{v}\in \boldsymbol{H}_0^1(\Omega,\mathbb{R}^2)} \frac{(\mathbf{div}\boldsymbol{\sigma}_h^1, \boldsymbol{v})}{\|\boldsymbol{v}\|_{1,\Omega}} &\le \sup_{\boldsymbol{v}\in \boldsymbol{H}_0^1(\Omega,\mathbb{R}^2)} \frac{(\mathbf{div}\boldsymbol{\sigma}_h^1, \boldsymbol{v} - \boldsymbol{v}_H)}{\|\boldsymbol{v}\|_{1,\Omega}} + \sup_{\boldsymbol{v}\in \boldsymbol{H}_0^1(\Omega,\mathbb{R}^2)} \frac{(\mathbf{div}\boldsymbol{\sigma}_h^1, \boldsymbol{v}_H)}{\|\boldsymbol{v}\|_{1,\Omega}} \\
&\lesssim H\|\mathbf{div}\boldsymbol{\sigma}_h^1\|_{0,\Omega} + \sup_{\boldsymbol{v}\in \boldsymbol{H}_0^1(\Omega,\mathbb{R}^2)} \frac{(\mathbf{div}\boldsymbol{\sigma}_h^1, \mathbf{div}\boldsymbol{\tau}_H)}{\|\boldsymbol{v}\|_{1,\Omega}} \\
&= H\|\mathbf{div}\boldsymbol{\sigma}_h^1\|_{0,\Omega} + \sup_{\boldsymbol{v}\in \boldsymbol{H}_0^1(\Omega,\mathbb{R}^2)} \frac{-\gamma^{-1}(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\tau}_H) - \gamma^{-1}(\mathcal{A}\mathbf{curl}\, \boldsymbol{q}_h, \boldsymbol{\tau}_H - \boldsymbol{\tau}_h)}{\|\boldsymbol{v}\|_{1,\Omega}} \\
&\lesssim H\|\mathbf{div}\boldsymbol{\sigma}_h^1\|_{0,\Omega} + \gamma^{-1}(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1)^{1/2} + \gamma^{-1}H(\mathcal{A}\mathbf{curl}\, \boldsymbol{q}_h, \mathbf{curl}\, \boldsymbol{q}_h)^{1/2}.
\end{aligned}$$

Using the above result, Lemma 2.1, inequality (4.4), the inequality $2\gamma^{-1} \le 1 + \gamma^{-2}$, and the fact that $H < O(1)$, we have

$$\begin{aligned}
\|\boldsymbol{\sigma}_h^1\|_{0,\Omega}^2 &\lesssim (\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1) + \|\mathbf{div}\boldsymbol{\sigma}_h^1\|_{-1,\Omega}^2 \\
&\lesssim (1+\gamma^{-2})\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1) + \|\mathbf{div}\boldsymbol{\sigma}_h^1\|_{0,\Omega}^2 + \gamma^{-2}(\mathcal{A}\mathbf{curl}\, \boldsymbol{q}_h, \mathbf{curl}\, \boldsymbol{q}_h) \\
&\lesssim (1+\gamma^{-2})\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\sigma}_h)
\end{aligned}$$

and

$$\begin{aligned}
\gamma H^{-2}\|\boldsymbol{\sigma}_h^1\|_{0,\Omega}^2 &\lesssim (1+\gamma^{-2})\gamma H^{-2}(\mathcal{A}\boldsymbol{\sigma}_h^1, \boldsymbol{\sigma}_h^1) + \gamma\|\mathbf{div}\boldsymbol{\sigma}_h^1\|_{0,\Omega}^2 + \gamma^{-1}(\mathcal{A}\mathbf{curl}\, \boldsymbol{q}_h, \mathbf{curl}\, \boldsymbol{q}_h) \\
&\lesssim (1+\gamma^{-2})\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\sigma}_h).
\end{aligned}$$

Adding up the above inequalities gives the estimate (4.5). This completes the proof of the lemma. ∎

5. A multigrid solver. For simplicity, we rewrite problem (3.1) in the following form: find $\boldsymbol{\sigma}_h \in \boldsymbol{\Sigma}_h$ such that

$$\boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \boldsymbol{\tau}_h) = (\boldsymbol{F}, \boldsymbol{\tau}_h) \quad \text{for all } \boldsymbol{\tau}_h \in \boldsymbol{\Sigma}_h, \tag{5.1}$$

where $\boldsymbol{F} \in \boldsymbol{\Sigma}_h$ is defined by $(\boldsymbol{F}, \boldsymbol{\tau}_h) = \gamma(\boldsymbol{f}, \mathbf{div}\boldsymbol{\tau}_h)$.

In this section, we construct and analyze a multigrid solver for the discrete problem (5.1). Let $\mathcal{T}_k$, $k = 1, \ldots, K$, be a series of nested meshes under uniform refinements and assume that $\mathcal{T}_1$ has characteristic mesh size $O(1)$. Denote the characteristic mesh size of $\mathcal{T}_k$ to be h_k. Define $\boldsymbol{\Sigma}_k = \boldsymbol{\Sigma}_{h_k}$, the RT/BDM finite element space based on $\mathcal{T}_k$. Notice that $\boldsymbol{\Sigma}_{k-1} \subset \boldsymbol{\Sigma}_k$. Similarly, we define spaces $\mathbf{U}_k$ and $\mathbf{V}_k$. Denote $\mathbf{div}_k^{-1} = \mathbf{div}_{h_k}^{-1}$. Denote $\mathbf{Q}_{k-1} : \boldsymbol{\Sigma}_k \to \boldsymbol{\Sigma}_{k-1}$ and $\mathbf{P}_{k-1} : \boldsymbol{\Sigma}_k \to \boldsymbol{\Sigma}_{k-1}$ to be the $\mathbf{L}^2$ projection and the $\boldsymbol{\Lambda}$ projection, respectively. Let $\mathbf{R}_k : \boldsymbol{\Sigma}_k \to \boldsymbol{\Sigma}_k$ be a symmetric positive definite operator, which will be defined later. Let m be the smoothing times on each level. Finally, denote A_k to be A_{h_k}.

We define a V-cycle multigrid iteration operator $Mg_k(\cdot,\cdot) : \boldsymbol{\Sigma}_k \times \boldsymbol{\Sigma}_k \to \boldsymbol{\Sigma}_k$ inductively as follows.

ALGORITHM 1. Set $Mg_1(\boldsymbol{\tau}, \boldsymbol{F}) = \boldsymbol{\Lambda}_1^{-1}\boldsymbol{F}$. Assuming that $Mg_{k-1}(\cdot,\cdot)$ has been defined, define $Mg_k(\boldsymbol{\tau}, \boldsymbol{F})$ as follows: set $\boldsymbol{\tau}^0 = \boldsymbol{\tau}$ and define

(1) $\boldsymbol{\tau}^l = \boldsymbol{\tau}^{l-1} + \mathbf{R}_k(\boldsymbol{F} - \boldsymbol{\Lambda}_k\boldsymbol{\tau}^{l-1})$ for $l = 1, \ldots, m$;

(2) $\boldsymbol{\sigma}^m = \boldsymbol{\tau}^m + Mg_{k-1}(\mathbf{0}, \mathbf{Q}_{k-1}(\boldsymbol{F} - \boldsymbol{\Lambda}_k\boldsymbol{\tau}^m))$;

(3) $\boldsymbol{\sigma}^l = \boldsymbol{\sigma}^{l-1} + \mathbf{R}_k(\boldsymbol{F} - \boldsymbol{\Lambda}_k\boldsymbol{\sigma}^{l-1})$ for $l = m+1, \ldots, 2m$.

Set $Mg_k(\boldsymbol{\tau}, \boldsymbol{F}) = \boldsymbol{\sigma}^{2m}$.

The V-cycle multigrid iteration for solving problem (5.1) over $\boldsymbol{\Sigma}_k$ is defined below. Given an initial guess $\boldsymbol{\sigma}^0 \in \boldsymbol{\Sigma}_k$, we defined a sequence approximating the solution $\boldsymbol{\sigma}_h$ by

$$\boldsymbol{\sigma}^{i+1} = Mg_k(\boldsymbol{\sigma}^i, \boldsymbol{F}), \qquad i = 0, 1, \ldots.$$

The error propagation operator $\boldsymbol{\varepsilon} : \boldsymbol{\Sigma}_k \to \boldsymbol{\Sigma}_k$ for the above iteration is [8]

$$\boldsymbol{\sigma}_h - \boldsymbol{\sigma}^{i+1} = \boldsymbol{\varepsilon}(\boldsymbol{\sigma}_h - \boldsymbol{\sigma}^i) = Mg_k(\boldsymbol{\sigma}_h - \boldsymbol{\sigma}^i, 0).$$

Similarly to the proof of Theorem 7.4 in [8] and Theorem 5.1 in [1], one can show that the multigrid solver with $\mathbf{R}_k$ as the smoother and m smoothing times on each level will have the convergence rate

$$\boldsymbol{\Lambda}(\boldsymbol{\varepsilon}\boldsymbol{\tau}, \boldsymbol{\tau}) \le \frac{C_p}{C_p + 2m}\boldsymbol{\Lambda}(\boldsymbol{\tau}, \boldsymbol{\tau}) \quad \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma}_k \tag{5.2}$$

if the following two assumptions are true:

(M.1) The spectrum of $I - \mathbf{R}_k\boldsymbol{\Lambda}_k$ is in $[0, 1)$. That is,

$$0 \le \boldsymbol{\Lambda}((I - \mathbf{R}_k\boldsymbol{\Lambda}_k)\boldsymbol{\tau}, \boldsymbol{\tau}) < \boldsymbol{\Lambda}(\boldsymbol{\tau}, \boldsymbol{\tau}) \qquad \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma}_k.$$

(M.2) There exists a positive constant C_p such that

$$\boldsymbol{\Lambda}((I - \mathbf{P}_{k-1})\boldsymbol{\tau}, \boldsymbol{\tau}) \le C_p\mathbf{R}_k(\boldsymbol{\Lambda}_k\boldsymbol{\tau}, \boldsymbol{\Lambda}_k\boldsymbol{\tau}) \quad \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma}_k.$$

In the remainder of this section, we will construct a smoother $\mathbf{R}_k$ which satisfies assumptions (M.1) and (M.2).

Let $\mathcal{V}_k$ be the set of all vertices in $\mathcal{T}_k$, including the boundary vertices. For each $\boldsymbol{x} \in \mathcal{V}_k$, define $\Omega_{k,\boldsymbol{x}}$ to be the interior of the union of all triangles in $\mathcal{T}_k$ which have $\boldsymbol{x}$ as a vertex. Let $\boldsymbol{\Sigma}_{k,\boldsymbol{x}}$ be the RT/BDM space defined on $\mathcal{T}_k$ such that each function in $\boldsymbol{\Sigma}_{k,\boldsymbol{x}}$ vanishes outside $\Omega_{k,\boldsymbol{x}}$. Notice that $\boldsymbol{\Sigma}_{k,\boldsymbol{x}} \subset (\boldsymbol{\Sigma}_k + span\{\mathbf{I}\})$, but $\boldsymbol{\Sigma}_{k,\boldsymbol{x}} \nsubseteq \boldsymbol{\Sigma}_k$ in general, since $\int_\Omega \operatorname{tr}\boldsymbol{\tau}\, d\boldsymbol{x}$ may not vanish for $\boldsymbol{\tau} \in \boldsymbol{\Sigma}_{k,\boldsymbol{x}}$.

Define operator $\boldsymbol{\Lambda}_{k,\boldsymbol{x}} : \boldsymbol{\Sigma}_{k,\boldsymbol{x}} \to \boldsymbol{\Sigma}_{k,\boldsymbol{x}}$ by

$$(\boldsymbol{\Lambda}_{k,\boldsymbol{x}}\boldsymbol{\sigma}, \boldsymbol{\tau}) = \boldsymbol{\Lambda}(\boldsymbol{\sigma}, \boldsymbol{\tau}) \quad \text{for all } \boldsymbol{\sigma},\ \boldsymbol{\tau} \in \boldsymbol{\Sigma}_{k,\boldsymbol{x}}.$$

Notice that $\mathbf{\Lambda}_{k,\boldsymbol{x}}$ is symmetric and $(\mathbf{\Lambda}_{k,\boldsymbol{x}}\boldsymbol{\sigma},\boldsymbol{\sigma}) = 0$ if and only if $\boldsymbol{\sigma} = c\mathbf{I}$, where c is a constant. Since $c\mathbf{I} \notin \mathbf{\Sigma}_{k,\boldsymbol{x}}$ and $\mathbf{\Sigma}_{k,\boldsymbol{x}}$ is a finite dimensional space, it is easy to see that $\mathbf{\Lambda}_{k,\boldsymbol{x}}$ is symmetric positive definite over $\mathbf{\Sigma}_{k,\boldsymbol{x}}$, although the spectrum of $\mathbf{\Lambda}_{k,\boldsymbol{x}}$ may not have a uniform lower bound independent of all k and $\boldsymbol{x}$.

Let $\mathbf{Q}_{k,\boldsymbol{x}} : (\mathbf{\Sigma}_k + span\{\mathbf{I}\}) \to \mathbf{\Sigma}_{k,\boldsymbol{x}}$ and $\mathbf{P}_{k,\boldsymbol{x}} : (\mathbf{\Sigma}_k + span\{\mathbf{I}\}) \to \mathbf{\Sigma}_{k,\boldsymbol{x}}$ be the $\mathbf{L}^2$ projection and the $\mathbf{\Lambda}$ projection, respectively. Here $\mathbf{P}_{k,\boldsymbol{x}}$ is well defined since the operator $\mathbf{\Lambda}_{k,\boldsymbol{x}}$ is symmetric positive definite. Define operator $\tilde{\mathbf{R}}_k : \mathbf{\Sigma}_k \to (\mathbf{\Sigma}_k + span\{\mathbf{I}\})$ using an additive Schwarz scheme:

$$\tilde{\mathbf{R}}_k = \frac{1}{3}\sum_{\boldsymbol{x}\in\mathcal{V}_k} \mathbf{P}_{k,\boldsymbol{x}}\mathbf{\Lambda}_k^{-1} = \frac{1}{3}\sum_{\boldsymbol{x}\in\mathcal{V}_k} \mathbf{\Lambda}_{k,\boldsymbol{x}}^{-1}\mathbf{Q}_{k,\boldsymbol{x}}. \tag{5.3}$$

Define $\mathbf{R}_k : \mathbf{\Sigma}_k \to \mathbf{\Sigma}_k$ by

$$\mathbf{R}_k = \mathbf{Q}_{\mathbf{\Sigma}_k}\tilde{\mathbf{R}}_k, \tag{5.4}$$

where $\mathbf{Q}_{\mathbf{\Sigma}_k} : (\mathbf{\Sigma}_k + span\{\mathbf{I}\}) \to \mathbf{\Sigma}_k$ is the $\mathbf{L}^2$ projection. It is clear that $\mathbf{R}_k$ is symmetric positive definite over $\mathbf{\Sigma}_k$ under the $\mathbf{L}^2$ inner product.

REMARK 2. For simplicity, in this paper we will analyze only the smoother $\mathbf{R}_k$ as defined in (5.4). The analysis can easily be extended to the Hiptmair smoother [19], which is usually more time-efficient in terms of a single sweep of smoothing process, and the same multigrid convergence rate estimate holds.

Next, we show that $\mathbf{R}_k$ satisfies assumptions (M.1) and (M.2). The proof of assumption (M.1) follows directly from the Schwarz inequality and the fact that each triangle in $\mathcal{T}_k$ is covered by exactly three subdomains in $\{\Omega_{k,\boldsymbol{x}}\}_{\boldsymbol{x}\in\mathcal{V}_k}$. In the following, we concentrate on the proof of assumption (M.2).

First, we state the following result.

LEMMA 5.1.
(R.1) $\boldsymbol{\tau}_k \in \mathbf{\Sigma}_k$

$$(\mathbf{I} - \mathbf{P}_{k-1})\boldsymbol{\tau}_k = \sum_{\boldsymbol{x}\in\mathcal{V}_k} \boldsymbol{\tau}_{k,\boldsymbol{x}}, \qquad \boldsymbol{\tau}_{k,\boldsymbol{x}} \in \mathbf{\Sigma}_{k,\boldsymbol{x}},$$

C_0

$$\sum_{\boldsymbol{x}\in\mathcal{V}_k} \mathbf{\Lambda}(\boldsymbol{\tau}_{k,\boldsymbol{x}},\boldsymbol{\tau}_{k,\boldsymbol{x}}) \le C_0\mathbf{\Lambda}((\mathbf{I} - \mathbf{P}_{k-1})\boldsymbol{\tau}_k,\boldsymbol{\tau}_k).$$

(M.2) $C_p = 3C_0$

Assume (R.1) holds. By using the Schwarz inequality, we have

$$\begin{aligned}
\mathbf{\Lambda}((\mathbf{I} - \mathbf{P}_{k-1})\boldsymbol{\tau}_k,\boldsymbol{\tau}_k) &= \sum_{\boldsymbol{x}\in\mathcal{V}_k} \mathbf{\Lambda}(\boldsymbol{\tau}_{k,\boldsymbol{x}},\boldsymbol{\tau}_k) = \sum_{\boldsymbol{x}\in\mathcal{V}_k} \mathbf{\Lambda}(\boldsymbol{\tau}_{k,\boldsymbol{x}},\mathbf{P}_{k,\boldsymbol{x}}\boldsymbol{\tau}_k) \\
&\le \left(\sum_{\boldsymbol{x}\in\mathcal{V}_k} \mathbf{\Lambda}(\boldsymbol{\tau}_{k,\boldsymbol{x}},\boldsymbol{\tau}_{k,\boldsymbol{x}})\right)^{1/2} \mathbf{\Lambda}^{1/2}\left(\sum_{\boldsymbol{x}\in\mathcal{V}_k} \mathbf{P}_{k,\boldsymbol{x}}\boldsymbol{\tau}_k,\boldsymbol{\tau}_k\right) \\
&\le \sqrt{3}C_0^{1/2}\mathbf{\Lambda}^{1/2}((\mathbf{I} - \mathbf{P}_{k-1})\boldsymbol{\tau}_k,\boldsymbol{\tau}_k)\mathbf{\Lambda}^{1/2}(\tilde{\mathbf{R}}_k\mathbf{\Lambda}_k\boldsymbol{\tau}_k,\boldsymbol{\tau}_k) \\
&= \sqrt{3}C_0^{1/2}\mathbf{\Lambda}^{1/2}((\mathbf{I} - \mathbf{P}_{k-1})\boldsymbol{\tau}_k,\boldsymbol{\tau}_k)\mathbf{\Lambda}^{1/2}(\mathbf{R}_k\mathbf{\Lambda}_k\boldsymbol{\tau}_k,\boldsymbol{\tau}_k).
\end{aligned}$$

The last step comes from the fact that $span\{\mathbf{I}\}$ is in the kernel of $\mathbf{\Lambda}_k$. This completes the proof of the lemma. ∎

Finally, we need to prove that condition (R.1) holds.

LEMMA 5.2. [illegible] (R.1) [illegible] $C_0 = c(1+\gamma^{-2})$ [illegible] c [illegible] k [illegible] γ

[illegible] Let $\boldsymbol{\sigma}_k = (\mathbf{I} - \mathbf{P}_{k-1})\boldsymbol{\tau}_k$, where $\boldsymbol{\tau}_k \in \boldsymbol{\Sigma}_k$. We decompose $\boldsymbol{\sigma}_k$ into $\boldsymbol{\sigma}_k = \mathbf{curl}\, \boldsymbol{q}_k + \mathbf{div}_k^{-1}\boldsymbol{v}_k$, where $\boldsymbol{q}_k \in \mathbf{U}_k$ and $\boldsymbol{v}_k = \mathbf{div}\boldsymbol{\sigma}_k$. Denote $\boldsymbol{\sigma}_k^1 = \mathbf{div}_k^{-1}\boldsymbol{v}_k$. Clearly,

$$\boldsymbol{\Lambda}(\mathbf{curl}\, \boldsymbol{q}_k, \mathbf{curl}\, \boldsymbol{q}_k) + \boldsymbol{\Lambda}(\boldsymbol{\sigma}_k^1, \boldsymbol{\sigma}_k^1) = \boldsymbol{\Lambda}(\boldsymbol{\sigma}_k, \boldsymbol{\sigma}_k).$$

Therefore we can consider the decomposition of $\mathbf{curl}\, \boldsymbol{q}_k$ and $\boldsymbol{\sigma}_k^1$ separately.

Next we need a partition of unity. Let $\theta_{\boldsymbol{x}}$ be a continuous piecewise linear function defined on $\mathcal{T}_k$ such that the support of each $\theta_{\boldsymbol{x}}$ is in $\Omega_{k,\boldsymbol{x}}$ and

$$|\theta_{\boldsymbol{x}}|_{W^{j,\infty}(\Omega)} \lesssim h_k^{-j}, \quad j = 0, 1,$$

where $W^{j,\infty}(\Omega)$ is the Sobolev space with index (j, ∞) [14]. This kind of partition of unity exists and has been widely used in the analysis of overlapping Schwarz domain decomposition methods.

Clearly we have the decomposition $\mathbf{curl}\, \boldsymbol{q}_k = \sum_{\boldsymbol{x}\in\mathcal{V}_k} \mathbf{curl}\, (\Pi_{\mathbf{U}_k}(\theta_{\boldsymbol{x}}\boldsymbol{q}_k))$, where $\Pi_{\mathbf{U}_k}$ is the natural interpolation onto $\mathbf{U}_k$ associated with the degrees of freedom. By the standard scaling argument, it is not hard to see that

$$\|\mathbf{curl}\, (\Pi_{\mathbf{U}_k}(\theta_{\boldsymbol{x}}\boldsymbol{q}_k))\|_{0,\Omega} \lesssim \|\mathbf{curl}\, (\theta_{\boldsymbol{x}}\boldsymbol{q}_k)\|_{0,\Omega}.$$

Combining the above, Lemma 4.2, and the fact that $h_k = h_{k-1}/2$, we have

$$\begin{aligned}
&\sum_{\boldsymbol{x}\in\mathcal{V}_k} \boldsymbol{\Lambda}(\mathbf{curl}\, (\Pi_{\mathbf{U}_k}(\theta_{\boldsymbol{x}}\boldsymbol{q}_k)), \mathbf{curl}\, (\Pi_{\mathbf{U}_k}(\theta_{\boldsymbol{x}}\boldsymbol{q}_k))) \\
&\qquad = \sum_{\boldsymbol{x}\in\mathcal{V}_k} (\mathcal{A}\mathbf{curl}\, (\Pi_{\mathbf{U}_k}(\theta_{\boldsymbol{x}}\boldsymbol{q}_k)), \mathbf{curl}\, (\Pi_{\mathbf{U}_k}(\theta_{\boldsymbol{x}}\boldsymbol{q}_k))) \\
&\qquad \le \sum_{\boldsymbol{x}\in\mathcal{V}_k} \|\mathbf{curl}\, (\Pi_{\mathbf{U}_k}(\theta_{\boldsymbol{x}}\boldsymbol{q}_k))\|_{0,\Omega}^2 \le \sum_{\boldsymbol{x}\in\mathcal{V}_k} \|\mathbf{curl}\, (\theta_{\boldsymbol{x}}\boldsymbol{q}_k)\|_{0,\Omega} \\
&\qquad \lesssim \|\mathbf{curl}\, \boldsymbol{q}_k\|_{0,\Omega}^2 + h_k^{-2}\|\boldsymbol{q}_k\|_{0,\Omega}^2 \lesssim (\mathcal{A}\mathbf{curl}\, \boldsymbol{q}_k, \mathbf{curl}\, \boldsymbol{q}_k) \\
&\qquad \le \boldsymbol{\Lambda}(\boldsymbol{\sigma}_k, \boldsymbol{\sigma}_k).
\end{aligned} \tag{5.5}$$

Next, for $\boldsymbol{\sigma}_k^1$, we consider the decomposition $\boldsymbol{\sigma}_k^1 = \sum_{\boldsymbol{x}\in\mathcal{V}_k} \Pi_{\boldsymbol{\Sigma}_k}(\theta_{\boldsymbol{x}}\boldsymbol{\sigma}_k^1)$, where $\Pi_{\boldsymbol{\Sigma}_k}$ is the interpolation operator as defined in (3.3) on the mesh $\mathcal{T}_k$. This decomposition is well defined since $\Pi_{\boldsymbol{\Sigma}_k}$ is a linear operator. By the standard scaling argument, we have

$$\|\Pi_{\boldsymbol{\Sigma}_k}(\theta_{\boldsymbol{x}}\boldsymbol{\sigma}_k^1)\|_{0,\Omega} \lesssim \|\theta_{\boldsymbol{x}}\boldsymbol{\sigma}_k^1\|_{0,\Omega}.$$

Therefore, by Lemma 4.2 and the fact that $2h_k = h_{k-1}$,

$$\begin{aligned}
&\sum_{\boldsymbol{x}\in\mathcal{V}_k} \boldsymbol{\Lambda}(\Pi_{\boldsymbol{\Sigma}_k}(\theta_{\boldsymbol{x}}\boldsymbol{\sigma}_k^1), \Pi_{\boldsymbol{\Sigma}_k}(\theta_{\boldsymbol{x}}\boldsymbol{\sigma}_k^1)) \\
&\qquad \lesssim \sum_{\boldsymbol{x}\in\mathcal{V}_k} (\|\Pi_{\boldsymbol{\Sigma}_k}(\theta_{\boldsymbol{x}}\boldsymbol{\sigma}_k^1)\|_{0,\Omega}^2 + \gamma\|\mathbf{div}(\Pi_{\boldsymbol{\Sigma}_k}(\theta_{\boldsymbol{x}}\boldsymbol{\sigma}_k^1))\|_{0,\Omega}^2) \\
&\qquad \lesssim \|\boldsymbol{\sigma}_k^1\|_{0,\Omega}^2 + \gamma(\|\mathbf{div}\boldsymbol{\sigma}_k^1\|_{0,\Omega}^2 + h_k^{-2}\|\boldsymbol{\sigma}_k^1\|_{0,\Omega}^2) \\
&\qquad \lesssim (1+\gamma^{-2})\boldsymbol{\Lambda}(\boldsymbol{\sigma}_k, \boldsymbol{\sigma}_k).
\end{aligned} \tag{5.6}$$

Finally, we define the decomposition

$$\boldsymbol{\sigma}_k = \sum_{\boldsymbol{x}\in\mathcal{V}_k} (\mathbf{curl}\,(\Pi_{\mathbf{U}_k}(\theta_{\boldsymbol{x}}\boldsymbol{q}_k)) + \Pi_{\boldsymbol{\Sigma}_k}(\theta_{\boldsymbol{x}}\boldsymbol{\sigma}_k^1)).$$

The stability of this decomposition comes from (5.5) and (5.6). This completes the proof of the lemma. □

By inequality (5.2) and Lemmas 5.1 and 5.2, the convergence rate of the multigrid solver is $O(\frac{1+\gamma^{-2}}{1+\gamma^{-2}+m})$.

6. Numerical results. We report some numerical results for the multigrid solver for the $\boldsymbol{H}(\mathbf{div})$-type problem (5.1). Let Ω be the unit square $(0,1)\times(0,1)$. The multigrid solver with a smoother as defined in section 5 is used. The coarsest mesh is as shown in Figure 6.1. We solve problem (5.1) on the 2nd–5th multigrid levels. The right-hand side $\boldsymbol{F} \in \boldsymbol{\Sigma}_h$ is selected randomly.

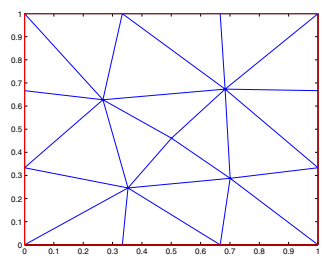

FIG. 6.1. *The coarsest mesh.*

Both the lowest order RT element and the lowest order BDM element are used in the discretization. The experiments are done for $\gamma = 10^{-4}$, 10^{-2}, 1, 10^2, 10^4. We tested the iteration numbers needed for reaching a relative residual 10^{-6}. The results are listed in Tables 6.1 and 6.2.

TABLE 6.1
Iteration numbers using the RT element.

Level	$\gamma = 10^{-4}$	$\gamma = 10^{-2}$	$\gamma = 1$	$\gamma = 10^2$	$\gamma = 10^4$
2	22	13	11	11	11
3	62	18	14	14	14
4	132	19	16	15	16
5	200	19	16	16	16

TABLE 6.2
Iteration numbers using the BDM element.

Level	$\gamma = 10^{-4}$	$\gamma = 10^{-2}$	$\gamma = 1$	$\gamma = 10^2$	$\gamma = 10^4$
2	6	6	6	6	6
3	7	7	7	7	7
4	7	7	8	7	7
5	8	7	7	7	7

From the tables we can see that when γ is large, the iteration numbers seem to be independent of γ and the number of levels, which agrees with the theory. When γ is

small, the theory suggests that the convergence rate deteriorates. From the numerical results we can see that this is true for the RT element. However, for the BDM element, the convergence rate still seems to be independent of γ.

Appendix. Proof of (4.6).

As stated before, we assume that Ω is a convex polygon. Let $\boldsymbol{\sigma}_h$ and $\boldsymbol{q}_h$ be defined as in Lemma 4.2. Then $\boldsymbol{q}_h$ is in $\boldsymbol{H}^1(\Omega,\mathbb{R}^2)/\mathbb{R}^2$ and for all $\boldsymbol{p}_H \in \tilde{\mathbf{U}}_H$, we have

$$(\mathcal{A}\mathbf{curl}\,\boldsymbol{q}_h, \mathbf{curl}\,\boldsymbol{p}_H) = \boldsymbol{\Lambda}(\mathbf{curl}\,\boldsymbol{q}_h, \mathbf{curl}\,\boldsymbol{p}_H) = \boldsymbol{\Lambda}(\boldsymbol{\sigma}_h, \mathbf{curl}\,\boldsymbol{p}_H) = 0. \tag{A.1}$$

Denote $\boldsymbol{n}$ and $\boldsymbol{t}$ to be the unit outer normal vector and the unit tangential vector along $\partial\Omega$. Define the curl operator for all $\boldsymbol{\tau} \in \boldsymbol{H}^1(\Omega,\mathbb{M}_2)$ by

$$\operatorname{curl}\boldsymbol{\tau} = \begin{pmatrix} -\frac{\partial \tau_{11}}{\partial y} + \frac{\partial \tau_{12}}{\partial x} \\ -\frac{\partial \tau_{21}}{\partial y} + \frac{\partial \tau_{22}}{\partial x} \end{pmatrix}.$$

First we notice that the following lemma holds.

LEMMA A.1. [illegible] $\boldsymbol{\sigma} \in \boldsymbol{H}^1(\Omega,\mathbb{M}_2)$ [illegible] $\boldsymbol{q}_h = \operatorname{curl}\boldsymbol{\sigma}$ [illegible]

(S1) $\mathcal{A}\boldsymbol{\sigma} = \boldsymbol{\sigma}$ [illegible] $\boldsymbol{\sigma}$ [illegible]

(S2) $(\boldsymbol{\sigma}\boldsymbol{t})|_{\partial\Omega} = \mathbf{0}$;

(S3) $\|\boldsymbol{\sigma}\|_{1,\Omega} \lesssim \|\boldsymbol{q}_h\|_{0,\Omega}$

[illegible] (4.6) [illegible]

Define $\boldsymbol{\sigma}^1$ by

$$\begin{cases} (\mathcal{A}\boldsymbol{\sigma}^1, \boldsymbol{\tau}) + (\mathbf{div}\boldsymbol{\tau}, \boldsymbol{u}) = 0 & \text{for all } \boldsymbol{\tau} \in \boldsymbol{\Sigma}, \\ (\mathbf{div}\boldsymbol{\sigma}^1, \boldsymbol{v}) = (\mathbf{div}\boldsymbol{\sigma}, \boldsymbol{v}) & \text{for all } \boldsymbol{v} \in \mathbf{V}. \end{cases}$$

The regularity result (2.3) implies $\|\boldsymbol{\sigma}^1\|_{1,\Omega} \lesssim \|\mathbf{div}\boldsymbol{\sigma}\|_{0,\Omega}$. Since $\boldsymbol{\sigma} - \boldsymbol{\sigma}^1 \in \boldsymbol{H}^1(\Omega,\mathbb{M}_2)$ and $\mathbf{div}(\boldsymbol{\sigma} - \boldsymbol{\sigma}^1) = \mathbf{0}$, there must exist a potential function $\boldsymbol{p} \in \boldsymbol{H}^2(\Omega,\mathbb{R}^2)$ such that $\mathbf{curl}\,\boldsymbol{p} = \boldsymbol{\sigma} - \boldsymbol{\sigma}^1$ and

$$|\boldsymbol{p}|_{2,\Omega} \le \|\boldsymbol{\sigma}\|_{1,\Omega} + \|\boldsymbol{\sigma}^1\|_{1,\Omega} \lesssim \|\boldsymbol{\sigma}\|_{1,\Omega} \lesssim \|\boldsymbol{q}_h\|_{0,\Omega}.$$

Let $\boldsymbol{p}_H$ be the natural interpolation of $\boldsymbol{p}$ onto $\tilde{\mathbf{U}}_H$. Then by the assumptions on $\boldsymbol{\sigma}$, (A.1), and integration by parts,

$$\begin{aligned} \|\boldsymbol{q}_h\|_{0,\Omega}^2 &= (\operatorname{curl}\boldsymbol{\sigma}, \boldsymbol{q}_h) = -(\boldsymbol{\sigma}, \mathbf{curl}\,\boldsymbol{q}_h) = -(\mathcal{A}\boldsymbol{\sigma}, \mathbf{curl}\,\boldsymbol{q}_h) \\ &= -(\mathcal{A}\mathbf{curl}\,\boldsymbol{p}, \mathbf{curl}\,\boldsymbol{q}_h) = -(\mathcal{A}\mathbf{curl}\,(\boldsymbol{p} - \boldsymbol{p}_H), \mathbf{curl}\,\boldsymbol{q}_h) \\ &\lesssim H|\boldsymbol{p}|_{2,\Omega}\|\mathcal{A}\mathbf{curl}\,\boldsymbol{q}_h\|_{0,\Omega} \lesssim H\|\boldsymbol{q}_h\|_{0,\Omega}\|\mathcal{A}\mathbf{curl}\,\boldsymbol{q}_h\|_{0,\Omega}. \end{aligned}$$

This completes the proof of (4.6). ∎

In the remainder of this section, we will construct a $\boldsymbol{\sigma}$ that satisfies the assumptions in Lemma A.1.

For any scalar function f, define $\mathbf{curl}\,f = (-\frac{\partial f}{\partial y}, \frac{\partial f}{\partial x})^t$. Then there exists an $\mathbf{L}^2$-orthogonal Helmholtz decomposition (see [16]) $\boldsymbol{q}_h = \mathbf{curl}\,\phi + \nabla\psi$, where $\phi \in H_0^1(\Omega)$ and $\psi \in H^1(\Omega)/\mathbb{R}$ satisfy $\|\phi\|_{1,\Omega} \le \|\boldsymbol{q}_h\|_{0,\Omega}$ and $\|\psi\|_{1,\Omega} \le \|\boldsymbol{q}_h\|_{0,\Omega}$. Then

$$\boldsymbol{q}_h = \operatorname{curl}\begin{pmatrix} \phi & \psi \\ -\psi & \phi \end{pmatrix} = \operatorname{curl}\begin{pmatrix} \phi & (\psi + C) \\ -(\psi + C) & \phi \end{pmatrix} + \operatorname{curl}\nabla\boldsymbol{u}$$

for all $C \in \mathbb{R}$ and $\boldsymbol{u} \in \boldsymbol{H}^2(\Omega, \mathbb{R}^2)$. Define

$$\boldsymbol{\sigma} = \begin{pmatrix} \phi & (\psi + C) \\ -(\psi + C) & \phi \end{pmatrix} + \nabla \boldsymbol{u}. \tag{A.2}$$

Clearly $\boldsymbol{\sigma} \in \boldsymbol{H}^1(\Omega, \mathbb{M}_2)$, and we need only find C and $\boldsymbol{u}$ such that $\boldsymbol{\sigma}$ satisfies (S1), (S2), and (S3) in Lemma A.1, which can be translated to

$$\begin{aligned} \operatorname{div} \boldsymbol{u} &= -2\phi, & \frac{\partial \boldsymbol{u}}{\partial \boldsymbol{t}}|_{\partial\Omega} &= (\psi + C)\boldsymbol{n}|_{\partial\Omega}, \\ |C| &\lesssim \|\boldsymbol{q}_h\|_{0,\Omega}, & \|\boldsymbol{u}\|_{2,\Omega} &\lesssim \|\boldsymbol{q}_h\|_{0,\Omega}. \end{aligned} \tag{A.3}$$

Since $\boldsymbol{q}_h \in \boldsymbol{H}^1(\Omega, \mathbb{R}^2)/\mathbb{R}^2$ and $\phi \in H_0^1(\Omega)$, we have

$$\begin{aligned} \int_{\partial\Omega} \psi \boldsymbol{n}\, ds &= \int_\Omega \nabla\psi\, d\boldsymbol{x} = \int_\Omega (\boldsymbol{q}_h - \mathbf{curl}\,\phi)\, d\boldsymbol{x} \\ &= -\int_\Omega \mathbf{curl}\,\phi\, d\boldsymbol{x} = \int_{\partial\Omega} \phi \boldsymbol{t}\, ds = \boldsymbol{0}. \end{aligned} \tag{A.4}$$

Recall that Ω is a convex polygon. Denote $\boldsymbol{z}_i$, $i = 1, \ldots, N$, to be the corners of Ω. To close the polygon, we set $\boldsymbol{z}_0 = \boldsymbol{z}_N$ or $\boldsymbol{z}_{N+1} = \boldsymbol{z}_1$. Denote Γ_i to be the edge of Ω connecting $\boldsymbol{z}_i$ and $\boldsymbol{z}_{i+1}$. Define $\boldsymbol{n}_i = (n_{1,i}, n_{2,i})^t$ and $\boldsymbol{t}_i = (n_{2,i}, -n_{1,i})^t$ to be the unit outer normal vector and the unit tangential vector on Γ_i, respectively. According to the trace theorem on polygons (see Theorem 1.4.6 in [17]), we have

$$\int_0^\varepsilon s^{-1} \left| -\psi(\boldsymbol{z}_i + s\boldsymbol{t}_i) + \psi(\boldsymbol{z}_i - s\boldsymbol{t}_{i-1}) \right|^2 ds \le \infty \tag{A.5}$$

for all $\varepsilon < min_{i=1,\ldots,N} |z_i - z_{i-1}|$.

Let s_0, s be points on $\partial\Omega$ and $\int_{s_0}^s dt$ be the line integral from s_0 to s along $\partial\Omega$ in counterclockwise direction. Define

$$C = \frac{-\int_\Omega 2\phi\, d\boldsymbol{x} - \int_{\partial\Omega} (\int_{s_0}^s \psi \boldsymbol{n}\, dt) \cdot \boldsymbol{n}\, ds}{\int_{\partial\Omega} (\int_{s_0}^s \boldsymbol{n}\, dt) \cdot \boldsymbol{n}\, ds} \tag{A.6}$$

and

$$\boldsymbol{g}(s) = \int_{s_0}^s (\psi + C)\boldsymbol{n}\, dt. \tag{A.7}$$

By (A.4) and Green's formula, we immediately see that $\boldsymbol{g}$ is continuous on $\partial\Omega$. Furthermore, we clearly have $\boldsymbol{g}|_{\Gamma_i} \in \boldsymbol{H}^{3/2}(\Gamma_i, \mathbb{R}^2)$ and

$$\begin{aligned} |C| &\lesssim \|\phi\|_{0,\Omega} + \|\psi\|_{0,\partial\Omega} \lesssim \|\phi\|_{0,\Omega} + \|\psi\|_{1,\Omega} \lesssim \|\boldsymbol{q}_h\|_{0,\Omega}, \\ \|\boldsymbol{g}\|_{3/2,\Gamma_i} &\lesssim \|\psi\|_{1/2,\partial\Omega} + |C| \lesssim \|\phi\|_{0,\Omega} + \|\psi\|_{1,\Omega} \lesssim \|\boldsymbol{q}_h\|_{0,\Omega}. \end{aligned}$$

By (A.5), (A.6), and (A.7), it is not hard to see that $\int_\Omega -2\phi\, d\boldsymbol{x} = \int_{\partial\Omega} \boldsymbol{g} \cdot \boldsymbol{n}\, ds$ and

$$\begin{aligned} &\int_0^\varepsilon s^{-1} \left| \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{t}}(z_i + s\boldsymbol{t}_i) \cdot \boldsymbol{n}_{i-1} - \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{t}}(z_i - s\boldsymbol{t}_{i-1}) \cdot \boldsymbol{n}_i \right|^2 ds \\ &= \int_0^\varepsilon s^{-1} \left| (\psi + C)(z_i + s\boldsymbol{t}_i) - (\psi + C)(z_i - s\boldsymbol{t}_{i-1}) \right|^2 (\boldsymbol{n}_{i-1} \cdot \boldsymbol{n}_i)^2\, ds \\ &< \infty \end{aligned}$$

for all $\varepsilon < \min_{i=1,\ldots,N}|z_i - z_{i-1}|$. Recall that $\phi \in H_0^1(\Omega)$. Combining all the above and according to Theorem 7.1 in [4], there exists $\boldsymbol{u} \in \boldsymbol{H}^2(\Omega, \mathbb{R}^2)$ such that $\operatorname{div} \boldsymbol{u} = -2\phi$, $\boldsymbol{u}|_{\partial\Omega} = \boldsymbol{g}$, and

$$\|\boldsymbol{u}\|_{2,\Omega} \lesssim \|\phi\|_{1,\Omega} + \sum_{i=1,\ldots,N} \|\boldsymbol{g}\|_{3/2,\Gamma_i} \lesssim \|\phi\|_{1,\Omega} + \|\psi\|_{1,\Omega} \lesssim \|\boldsymbol{q}_h\|_{0,\Omega}.$$

Clearly $\boldsymbol{u}$ defined above and C defined in (A.6) satisfy (A.3), and hence $\boldsymbol{\sigma}$ defined as in (A.2) satisfies (S1), (S2), and (S3). This completes the proof for (4.6). ∎

PARALLEL DOMAIN DECOMPOSITION METHODS FOR STOCHASTIC ELLIPTIC EQUATIONS*

CHAO JIN†, XIAO-CHUAN CAI‡, AND CONGMING LI†

Abstract. We present parallel Schwarz-type domain decomposition preconditioned recycling Krylov subspace methods for the numerical solution of stochastic elliptic problems, whose coefficients are assumed to be a random field with finite variance. Karhunen–Loève (KL) expansion and double orthogonal polynomials are used to reformulate the stochastic elliptic problem into a large number of related but uncoupled deterministic equations. The key to an efficient algorithm lies in "recycling computed subspaces." Based on a careful analysis of the KL expansion, we propose and test a grouping algorithm that tells us when to recycle and when to recompute some components of the expensive computation. We show theoretically and experimentally that the Schwarz preconditioned recycling GMRES method is optimal for the entire family of linear systems. A fully parallel implementation is provided, and scalability results are reported in the paper.

Key words. stochastic elliptic equations, domain decomposition, recycling Krylov subspace method, parallel scalability

1. Introduction.

Many physical phenomena are modeled by partial differential equations whose coefficients are measured through experiments which often contain some levels of uncertainty. To understand the model accurately, the randomness must be considered in the differential equations. In the last decade, many researchers have studied the so-called stochastic partial differential equation (SPDE). One of the approaches for solving SPDEs numerically is known as the stochastic Galerkin method; see, for example, [1, 2, 11, 12, 17, 22, 25, 30] and references therein. The method expands the random field in the equation. Several such expansions are available; for example, [1, 2, 9, 13, 20] use the Karhunen–Loève (KL) expansion introduced in [21], [17, 29, 30] use the Wiener chaos expansion [31], and [29] uses the generalized chaos expansion. With the expansion, the SPDE is reduced to a high-dimensional deterministic equation, which can be solved by different numerical methods. Based on the solution, the statistics of the physical solution of the original SPDE, such as the mean and the variance, can be derived.

In this paper, we focus on elliptic problems with stochastic diffusion coefficients. For this type of SPDEs, we use the double orthogonal basis [3, 16] to decouple the high-dimensional equation in the probability space and produce a sequence of independent equations. After the discretization, we obtain a large number of linear systems:

$$A_i x_i = b_i, \quad i = 1, 2, \ldots, \tag{1.1}$$

where the matrices A_i and right-hand sides b_i are closely related but independent from each other. There are a number of techniques for solving a sequence of related linear systems of equations. In this paper, we focus on the recently introduced recycling Krylov subspace method [24], which retains a Krylov subspace generated while solving a previous system with GMRES and uses it to reduce the cost of solving the current system. In our implementation, we extend the original algorithm in [24] to the flexible version of GMRES, which allows the change of preconditioner during the iteration.

Mathematically we prove, under certain assumptions, that all these linear systems from the KL expansion are spectrally equivalent; however, we also show numerically that it is generally not a good idea to recycle or reuse the same Krylov subspace and/or preconditioner for the entire sequence of linear systems, since some of the spectrally equivalent systems are quite different. Based on some analysis of the KL expansion and the lower bounds of the elliptic coefficients, we propose a grouping algorithm which partitions the large number of systems into several groups, and our tests show that within each group, recycling Krylov subspaces and recycling preconditioners can be safely and efficiently applied.

For preconditioning, we use an overlapping additive Schwarz domain decomposition method [27]. Our parallel implementation is based on the portable extensible toolkit for scientific computation (PETSc) package from Argonne National Laboratory [4]. The scalability and parallel performance of the algorithm are studied theoretically and experimentally.

The rest of the paper is organized as follows. In section 2, we describe the stochastic Galerkin method including the stochastic weak formulation, the KL expansion, the double orthogonal basis, and the discretization. Section 3 presents the additive Schwarz preconditioned recycling Krylov subspace method. A grouping algorithm for efficiently recycling the Krylov subspace and the preconditioner is also introduced. Some experimental results are reported in section 4, and some concluding remarks are given in section 5.

2. Stochastic Galerkin method. In this section, we briefly describe how to transform a stochastic elliptic partial differential equation to a sequence of independent deterministic partial differential equations. We use an elliptic equation with a stochastic diffusion coefficient as a model problem. See [16] for a complete description of the methodology.

2.1. The stochastic weak formulation. We begin with a brief review of notation. Given a probability space $(\Omega, \mathcal{A}, \mathcal{P})$ with sample space Ω, σ-algebra $\mathcal{A}$, and probability measure $\mathcal{P}$, a real-valued random variable is a function $\xi(\omega)$: $\Omega \to \mathbf{R}$. The probability distribution measure of ξ is defined on the Borel set $\mathcal{B}$ as $\mu(\mathcal{B}) = \mathcal{P}(\xi^{-\infty}(\mathcal{B}))$. The mean, or expected value of $\xi(\omega)$, is

$$\langle \xi \rangle = \int_\Omega \xi(\omega) d\mathcal{P}(\omega) = \int_{\mathbf{R}} z d\mu(z) = \int_{\mathbf{R}} z\rho(z) dz, \tag{2.1}$$

where ρ is the probability density function of ξ. We also define the space

$$L^2(\Omega) = \left\{ \xi(\omega) \,\middle|\, \int_\Omega |\xi|^2 d\mathcal{P}(\omega) < \infty \right\}.$$

Let $D \subset R^2$ be the domain of the variable x. A random field $a(x, \omega)$: $D \times \Omega \to \mathbf{R}$ is a real-valued function jointly measurable with respect to the Lebesgue measure on

D and the probability measure $\mathcal{P}$ on Ω. Define the space

$$L^2(D \times \Omega) = \{u(x,\omega) |\ \langle \|u(x,\omega)\|_{L^2(D)} \rangle < \infty\}.$$

The stochastic Sobolev space $H_0^1(D \times \Omega)$ is defined analogously. Now recall that for the classical deterministic two-dimensional elliptic equation

$$\begin{cases} -\nabla \cdot (a(x)\nabla u(x)) = f(x) & \text{in } D, \\ u(x) = 0 & \text{on } \partial D, \end{cases} \tag{2.2}$$

the weak form of the problem is to find $u(x) \in H_0^1(D)$ such that

$$B[u,v] = (f,v) \quad \forall v \in H_0^1(D), \tag{2.3}$$

where

$$B[u,v] = \int_D a(x)\nabla u(x) \cdot \nabla v(x) dx, \qquad (f,v) = \int_D f(x)v(x)dx.$$

If the diffusion coefficient is a random field $a(x,\omega) \in L^2(D \times \Omega)$, so is the solution u. Consequently, we have the stochastic elliptic equation

$$\begin{cases} -\nabla \cdot (a(x,\omega)\nabla u(x,\omega)) = f(x), & x \in D,\ \ \omega \in \Omega, \\ u(x,\omega) = 0, & x \in \partial D,\ \ \omega \in \Omega. \end{cases} \tag{2.4}$$

The weak form of (2.4) is to find $u(x,\omega) \in H_0^1(D \times \Omega)$ such that

$$\langle B[u,v] \rangle = \langle (f,v) \rangle \quad \forall v \in H_0^1(D \times \Omega). \tag{2.5}$$

We assume that $a(x,\omega) \in L^\infty(D \times \Omega)$ is strictly positive, with lower and upper bounds α and β, respectively,

$$0 < \alpha \le a(x,\omega) \le \beta. \tag{2.6}$$

Under this assumption, the existence and uniqueness of a solution u to (2.4) follow from the Lax–Milgram lemma. Note that we assume the source term f is deterministic. This condition can be relaxed to include randomness.

2.2. The KL expansion. Here, we use the KL expansion [21] of the random field $a(x,\omega)$ to separate the deterministic and stochastic components. We assume that the mean and the covariance of $a(x,\omega)$ are known, respectively, as

$$\begin{aligned} a_0(x) &= \int_\Omega a(x,\omega) dP(\omega) \quad \text{and} \\ C_a(x,x') &= \int_\Omega (a(x,\omega) - a_0(x))(a(x',\omega) - a_0(x')) dP(\omega). \end{aligned} \tag{2.7}$$

By the KL expansion, $a(x,\omega)$ can be represented in the form of a series as follows:

$$a(x,\omega) = a_0(x) + \sum_{j=1}^{\infty} \sqrt{\lambda_j}\, k_j(x)\, y_j(\omega), \tag{2.8}$$

where λ_j and $k_j(x)$ are the eigenvalues and orthogonal eigenfunctions of $C_a(x,x')$; i.e.,

$$\int_D C_a(x,x') k_j(x') d(x') = \lambda_j k_j(x). \tag{2.9}$$

This series converges in the mean-square sense.

By definition, $C_a(x,x')$ is symmetric and positive semidefinite. This implies that there exists a countable sequence of eigenpairs $\{(\lambda_j,k_j)\}$, where the eigenvalues $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n \geq \cdots \to 0$ are nonnegative and the eigenfunctions $\{k_j(x)\}$ are orthogonal in $L^2(D)$. Moreover, $\{y_j\}$ is a set of uncorrelated random variables with mean value zero. If the eigenfunctions are normalized, y_j all have unit variance; i.e., $\langle y_j(\omega)\rangle = 0$, $\langle y_i(\omega)y_j(\omega)\rangle = \delta_{ij}$. For the computation, we approximate $a(x,\omega)$ by a truncation of (2.8),

$$a_M(x,\omega) = a_0(x) + \sum_{j=1}^{M} \sqrt{\lambda_j}\; k_j(x)\; y_j(\omega),$$

where M denotes the number of terms in the truncation.

In this paper, we also assume that the $\{y_j\}_{j=1}^M$ are independent. The probability density function of y_j is denoted as ρ_j. The joint probability density function of $y = (y_1,\ldots,y_M)$ is $\rho = \rho_1 \times \cdots \times \rho_M$. Let Γ_j denote the image of y_j and $\Gamma = \Gamma_1 \times \cdots \times \Gamma_M$. We treat a_M: $D \times \Gamma \to R$ as

$$a_M(x,y) = a_0(x) + \sum_{j=1}^{M} \sqrt{\lambda_j}\; k_j(x)\; y_j(\omega). \tag{2.10}$$

Now, we arrive at the following deterministic elliptic problem:

$$-\nabla(a_M(x,y)\nabla u_M(x,y)) = f(x), \qquad u_M(x,y) \text{ in } H_0^1(D) \times L^2(\Gamma,\rho). \tag{2.11}$$

2.3. Double orthogonal basis. For $y \in \Gamma$, we use the double orthogonal polynomial function space [3, 16] to approximate $L^2(\Gamma,\rho)$, which decouples the equation in the y-space, yielding a sequence of uncoupled equations. The double orthogonal basis is constructed as follows. For any $r \in \mathbf{N}$, the space of single-variable polynomials of degree at most r is

$$P_r := \operatorname{span}\{1, t, t^2, \ldots, t^r\}. \tag{2.12}$$

For $\mathbf{r} = (r_1, r_2, \ldots, r_M) \in \mathbf{N}^M$ we construct the multivariable polynomial space

$$P_{\mathbf{r}} := P_{r_1} \otimes P_{r_2} \otimes \cdots \otimes P_{r_M} \in L^2(\Gamma,\rho). \tag{2.13}$$

For the space $P_{r_j}, j = 1,2,\ldots,M$, we use the double orthogonal functions, denoted as $\{\psi_{k,j}(t)\}_{k=0}^{r_j}$, as the basis instead of $\{1,t,t^2,\ldots,t^{r_j}\}$. We require that $\psi_{k,j}(t)$, $k = 0,\ldots,r_j$, satisfy two orthogonality conditions:

$$\begin{cases} \displaystyle\int_{\Gamma_j} \psi_{p,j}(t)\psi_{q,j}(t)\rho_j(t)dt = \delta_{p,q}, \quad p,q = 0,\ldots,r_j, \\ \displaystyle\int_{\Gamma_j} t\psi_{p,j}(t)\psi_{q,j}(t)\rho_j(t)dt = C_{p,j}\delta_{p,q}, \quad p,q = 0,\ldots,r_j, \end{cases} \tag{2.14}$$

where $\{C_{p,j}\}_{p=0}^{r_j}$ are nonzero constants. Next we construct a basis function of $P_{\mathbf{r}}$ by selecting one polynomial basis function from each $P_{r_j}, j = 1,\ldots,M$, and then multiply these selected M basis functions together. So given an $\mathbf{r} = (r_1, r_2, \ldots, r_m) \in \mathbf{N}^M$, there are in total $N_y = \prod_{j=1}^{M}(r_j+1)$ basis functions for $P_{\mathbf{r}}(y_1, y_2, \ldots, y_M)$.

Let $\mathbf{i} = \{i_1, i_2, \ldots, i_M\}$. If $0 \le i_j \le r_j \ \forall 1 \le j \le M$, we say that $\mathbf{i} \le \mathbf{r}$. It is obvious that there are N_y multi-indices $\mathbf{i}$, which are less than or equal to $\mathbf{r}$. Each $\mathbf{i}$ corresponds to one basis function of $P_{\mathbf{r}}$. We denote all the basis functions of $P_{\mathbf{r}}$ as the set

$$\left\{ \psi_{\mathbf{i}}(y) \,\middle|\, \psi_{\mathbf{i}}(y) = \prod_{j=1}^{m} \psi_{i_j,j}(y_j), \ \ i_j \in \{0, 1, \ldots, r_j\} \right\}_{\mathbf{i} \le \mathbf{r}}. \tag{2.15}$$

Finding $\{\psi_{k,\,j}(y_j)\}_{k=0}^{r_j}$ for spaces P_{r_j}, $j = 1, \ldots, M$, results in an eigenproblem (cf. section 8.7.2 in [18]). For the probability space of y, generally we do not need high order polynomials. So the computational work for these eigenproblems is negligible compared with the cost required to solve the coupled equations.

2.4. Discretization. We use a Galerkin method with a double orthogonal basis for the discretization of (2.11) in the y-space. Let

$$u_M(x, y) = \sum_{\mathbf{i} \le \mathbf{r}} u_{\mathbf{i}}(x) \psi_{\mathbf{i}}(y)$$

such that for any $v(x, y) = h(x)\psi_{\mathbf{j}}(y) \in H_0^1(D) \times P_{\mathbf{r}}(\Gamma)$ we have

$$\left\langle \int_D a_M(x, y) \nabla u_M(x, y) \cdot \nabla v(x, y) dx \right\rangle = \left\langle \int_D f(x) v(x, y) dx \right\rangle. \tag{2.16}$$

Writing in an explicit form,

$$\begin{aligned} &\left\langle \int_D a_M(x, y) \nabla u_M(x, y) \cdot \nabla v(x, y) dx \right\rangle \\ &= \sum_{j=1}^{M} \sum_{\mathbf{i} \le \mathbf{r}} \sqrt{\lambda_j} \left(k_j(x) \nabla u_{\mathbf{i}}(x), \nabla h(x) \right) \int_\Gamma y_j \psi_{\mathbf{i}}(y) \psi_{\mathbf{j}}(y) \rho(y) dy. \end{aligned}$$

The two orthogonality conditions (2.14) imply that

$$\int_\Gamma y_j \psi_{\mathbf{i}}(y) \psi_{\mathbf{j}}(y) \rho(y) dy = C_{i_j,j} \delta_{\mathbf{i},\,\mathbf{j}}.$$

Consequently,

$$\begin{aligned} &\left\langle \int_D a_M(x, y) \nabla u_M(x, y) \cdot \nabla v(x, y) dx \right\rangle \\ &= \sum_{j=1}^{M} \sum_{\mathbf{i} \le \mathbf{r}} \sqrt{\lambda_j} \left(k_j(x) \nabla u_{\mathbf{i}}(x), \ \ \nabla h(x) \right) C_{i_j,j} \, \delta_{\mathbf{i},\mathbf{j}}. \end{aligned}$$

On the other hand,

$$\left\langle \int_D f(x) v(x, y) dx \right\rangle = \int_D f(x) h(x) dx \langle \psi_{\mathbf{j}}(y) \rangle.$$

Now it is easy to see that the variational form of (2.11),

$$\langle B[u_M, v] \rangle = \langle (f, v) \rangle,$$

implies that

$$-\nabla\left(a_{M,\mathbf{i}}(x)\nabla u_{M,\mathbf{i}}(x)\right) = f_{\mathbf{i}}(x) \qquad \text{in } H_0^1(D), \text{ with} \tag{2.17}$$

$$\begin{cases} a_{M,\mathbf{i}}(x) := a_0(x) + \displaystyle\sum_{j=1}^{M} \sqrt{\lambda_j}\, k_j(x) C_{i_j,j}, \\ f_{\mathbf{i}}(x) := f(x) \cdot \displaystyle\prod_{j=1}^{M} \int_{\Gamma_j} \psi_{i_j,j}(t)\rho_j(t)dt. \end{cases} \tag{2.18}$$

Thus, we have decoupled (2.11) into N_y deterministic diffusion problems (2.17) and (2.18) in D. The stochastic solution is

$$u_M(x,y) = \sum_{\mathbf{i}\le\mathbf{r}} u_{M,\mathbf{i}}(x)\psi_{\mathbf{i}}(y). \tag{2.19}$$

We discretize the left-hand side of (2.17) and obtain a sequence of matrices $A_i, i = 1,\ldots,N_y$. It can be shown that these systems are positive definite if M is large enough. The following result is useful.

LEMMA 2.1. [illegible] $D \times D$ [illegible] $y_j, j = 1,\ldots,M$ [illegible] $\mathbf{i}$

$$\frac{\alpha}{2} \le a_{M,\mathbf{i}}(x) \le 2\beta$$

[illegible] M [illegible] α [illegible] β [illegible] (2.6) [illegible]. By Proposition 4.3 in [16], $\alpha/2 \le a_M(x,y) \le 2\beta$ for any x, y. The constant $C_{i_j,j}$ in (2.18) and (2.14) is bounded by $|y_j|$ in (2.10):

$$|C_{i_j,j}| \le \int_{\Gamma_j} |y_j|\psi_{i_j j}(y_j)^2 dy_j \le \max|y_j| \int_{\Gamma_j} \psi_{i_j,j}(y_j)^2 dy_j = \max|y_j|.$$

This implies that $a_{M,\mathbf{i}}$ are also bounded in $[\alpha/2, 2\beta]$. ∎

The statistics of the solution can be found from the approximate solutions. For example, the mean of $u(x,y)$ can be approximated by

$$\langle u_M\rangle = \sum_{\mathbf{i}\le\mathbf{r}} u_{M,\mathbf{i}}(x) \int_\Gamma \psi_{\mathbf{i}}(y)\rho(y)dy = \sum_{\mathbf{i}\le\mathbf{r}} u_{M,\mathbf{i}}(x) \prod_{j=1}^{M} \int_{\Gamma_j} \psi_{i_j,j}(t)\rho_j(t)dt.$$

3. Numerical method. After the discretization of (2.18) we obtain a sequence of independent linear systems of the form (1.1). In this section we propose an additive Schwarz preconditioned recycling Krylov subspace method for solving these systems. The recycling Krylov subspace method, called generalized conjugate residual with implicit inner orthogonalization and deflated restarting (GCRO-DR) [24], reduces some of the work in constructing the Krylov subspace for a new system, and the additive Schwarz algorithm [27] provides a preconditioner and a data structure for a parallel implementation. Note that we also reuse the preconditioner to further save the computational time.

3.1. Recycling Krylov subspace method. There are several recycling Krylov subspace methods; see, for example, [8, 14, 15, 19, 23, 26] and references therein. In our case, which has a sequence of linear systems with changing left-hand side matrices and right-hand side vectors, we use GCRO-DR. Here, we present only the main steps of this method. For a detailed description and derivation of the algorithm, we refer the reader to [24].

The idea of GCRO-DR is to retain a Krylov subspace for subsequent restarted GMRES cycles, or for solving other linear systems. For generality, we extend the GMRES framework introduced in [24] to include the flexible version of GMRES (FGMRES). Suppose we have solved the ith system with FGMRES. We retain k vectors

$$\tilde{Y}_k = [\tilde{y}_1, \tilde{y}_2, \ldots, \tilde{y}_k]. \tag{3.1}$$

Let $C_k = Q$, $U_k = \tilde{Y}_k R^{-1}$, where Q and R are from the reduced QR decomposition of $A_{i+1}\tilde{Y}_k$. U_k, $C_k \in R^{n\times k}$ satisfy

$$A_{i+1}U_k = C_k, \quad C_k^H C_k = I_k. \tag{3.2}$$

Let x_0 and r_0 be the initial guess and initial residual of $A_{i+1}x_{i+1} = b_{i+1}$. We update the solution as $x = x_0 + U_k C_k^H r_0$, and set $r = r_0 - C_k C_k^H r_0$. In our numerical experiment, we find that for some systems this updated solution x already satisfies the error tolerance, so that we do not need any more iterations after the initial step.

However, if the x is still not good enough, we continue to generate a Krylov subspace of dimension $m - k + 1$ with $(I - C_k C_k^H)A_{i+1}$, where m is the maximum number of iterations before restarting. In the case of recycling FGMRES, it produces the Arnoldi relation

$$(I - C_k C_k^H)A_{i+1}Z_{m-k} = V_{m-k+1}\bar{H}_{m-k}, \tag{3.3}$$

where the columns of Z_{m-k} are the preconditioned orthogonal vectors V_{m-k}. In the case of GMRES, Z_{m-k} should be replaced by V_{m-k} everywhere in the algorithm.

Each of the Arnoldi vectors $V_{m-k+1} = [v_1, v_2, \ldots, v_{m-k+1}]$ is orthogonal to the range of C_k. We can rewrite (3.3) as

$$A_{i+1}[U_k \;\; Z_{m-k}] = [C_k \;\; V_{m-k+1}] \begin{bmatrix} I_k & B_{m-k} \\ 0 & \bar{H}_{m-k} \end{bmatrix}, \tag{3.4}$$

where $B_{m-k} = C_k^H A_{i+1} Z_{m-k}$. For numerical reasons, we normalize the column vectors of U_k and replace the identity matrix I_k above with a diagonal matrix D_k such that $U_k D_k$ has unit columns denoted as $\tilde{U}_k$. We define

$$\hat{V}_m = [\tilde{U}_k \;\; Z_{m-k}], \qquad \hat{W}_{m+1} = [C_k \;\; V_{m-k+1}], \qquad \bar{G}_m = \begin{bmatrix} D_k & B_{m-k} \\ 0 & \bar{H}_{m-k} \end{bmatrix} \tag{3.5}$$

and write (3.4) more compactly as

$$A_{i+1}\hat{V}_m = \hat{W}_{m+1}\bar{G}_m.$$

Note that $\bar{G}_m = \hat{W}_{m+1}^H A_{i+1}\hat{V}_m$ is upper Hessenberg with diagonal D_k. The columns of $\hat{W}_{m+1}$ are orthogonal, but this is not true for the columns of $\hat{V}_m$.

In each cycle, we need to find y to minimize

$$\begin{aligned}\|r - A_{i+1}\hat{V}_m y\|_2 &= \|r - \hat{W}_{m+1}\bar{G}_m y\|_2 \\ &= \|\hat{W}_{m+1}^H r - \bar{G}_m y\|_2 \\ &= \|e_{k+1}\|r\|_2 - \bar{G}_m y\|_2.\end{aligned}$$

Once we have y, the residual and solution are updated by

$$r := r - A_{i+1}\hat{V}_m y = r - \hat{W}_{m+1}\bar{G}_m y \quad \text{and} \quad x := x + \hat{V}_m y. \tag{3.6}$$

Next, we solve the generalized eigenvalue problem

$$\bar{G}_m^H \bar{G}_m z_i = \theta_i \bar{G}_m^H \hat{W}_{m+1}\hat{V}_m z_i. \tag{3.7}$$

The k vectors $\tilde{Y}_k$ are chosen from $\tilde{y}_i = \hat{V}_m z_i, i = 1, 2, \ldots, m$. Theoretically, any k eigenvectors z_i can be used to compute $\tilde{Y}_k$. In our implementation, we choose the eigenvectors corresponding to the eigenvalues of smallest magnitude [24]. For more details in computing the recycling Krylov subspace between cycles and systems, we refer to [24].

3.2. Additive Schwarz preconditioning. In this section, we show that all matrices in the sequence of linear systems are spectrally equivalent, and therefore an optimal preconditioner for any one of the matrices is also optimal for the whole sequence. Here "optimal" means that the number of iterations is independent of the mesh size and the number of subdomains. Note that optimal does not mean that the number of iterations is small or the computing time is small, which is of course more important. In the next section, we will introduce a method that partitions the sequence of linear systems into groups, and within each group we apply the preconditioning techniques to be discussed briefly below.

We start with a coarse triangulation $\mathcal{T}^H = \{\tau_i^H\}$ and a fine triangulation $\mathcal{T}^h = \{\tau_i\}$ of the domain D. Let $\mathcal{N}(\mathcal{T}^H)$ be the set of nodal points of $\mathcal{T}^H$. Let $h_i =$ diameter of τ_i, and $h = \max_i\{h_i\}$. We assume that the coarse and fine triangulation are shape regular in the sense common to finite element theory. We then partition D into nonoverlapping subdomains $\{D_i\}$, $i = 1, \ldots, N$. Let $H_i =$ diameter of D_i, $H = \max_i\{H_i\}$. We extend each D_i to a larger region $D_i^{'} \subset D$. We assume that the distance between the boundaries ∂D_i and $\partial D_i^{'}$ inside D is bounded from below by a fixed fraction of H_i, and that $\partial D_i^{'}$ does not cut through any elements.

Let V^h and V_0 be the finite element spaces of continuous piecewise linear functions associated with the triangulations $\mathcal{T}^h$ and $\mathcal{T}^H$, respectively. Let $V_i = \{v \in V^h : v(x) = 0,\ x \notin D_i^{'}\}$, $i \geq 1$. Our finite element space V^h can be represented as

$$V^h = I_H^h V_0 + V_1 + \cdots + V_N,$$

where I_H^h is a coarse to fine mesh interpolation operator [7]. We approximate $H_0^1(D)$ by V^h and define the finite element problem of (2.17) as: Find $u_h \in V^h$ such that

$$\int_D a_{M,\mathbf{i}}(x)\nabla u_h \nabla v_h dx = \int_D f_{\mathbf{i}} v_h dx \quad \forall\ v \in V^h. \tag{3.8}$$

For simplicity, we denote $a_{M,\mathbf{i}}(x)$ and $f_{\mathbf{i}}$ for system i, where $i = 1, 2, \ldots, N_y$, as $a_i(x)$ and $f_i(x)$, respectively. $a_0(x)$ is still the mean of $a(x)$. We define the bilinear form, for any $u, v \in H_0^1(D)$,

$$A(u, v) = \int_D a_1(x)\nabla u \nabla v dx,$$

$$B_i(u,v) = \int_D a_i(x)\nabla u \nabla v dx, \quad i = 1, 2, \ldots, N_y.$$

We now define the projection operators, which are the main building blocks of the additive Schwarz methods.

DEFINITION 3.1. P_0: $V^h \longrightarrow V_0$

$$B_i(P_0 u, v) = B_i(u, v) \quad \forall\, v \in V_0.$$

$i = 1, 2, \ldots, N$ P_i: $V^h \longrightarrow V_i$

$$A(P_i u, v) = B_i(u, v) \quad \forall\, v \in V_i.$$

Note that for subdomain problems we define the preconditioners using a bilinear form defined by a system usually different from the one being solved. But for the coarse problem, the preconditioner is defined by using the bilinear form of the same linear system. If we view the additive Schwarz method (ASM) as a preconditioner, the matrix form of P_i is

$$P_i = R^T K_i^{-1} R K, \tag{3.9}$$

where K_i is the stiffness matrix from system 1 associated with subdomain $D_i^{'}$ and K is the stiffness matrix from system i, $i = 1, 2, \ldots, N_y$, associated with D. R is a restriction matrix. The additive Schwarz operator is defined by

$$P = \sum_{i=0}^{N} P_i. \tag{3.10}$$

Using the standard techniques [27, 28], we easily show the following result.

THEOREM 3.2. c_p C_p h H $u \in V^h$

$$c_p A(u,u) \le A(u, Pu), \quad A(Pu, Pu) \le C_p A(u,u). \tag{3.11}$$

According to [5, 6, 7, 10], the convergence rate of the additive Schwarz preconditioned GMRES is bounded by the ratio C_p/c_p, and the theorem implies that the convergence rate is independent of the mesh size h and the number of subdomains N.

3.3. Some analysis of the sequence of linear systems and a grouping algorithm. In this section we provide some analysis of the linear systems. Although mathematically we can prove that all of the matrices are spectrally equivalent, in practice some of the systems are quite different from the others, and the same preconditioner may not work well for all the systems. Similarly, simple recycling of the Krylov subspace from the previous system may not work well for these "bad" systems. Therefore it is very important to identify these bad systems and exclude them from the rest of the systems that can be solved with the recycling of Krylov subspaces and preconditioners.

It is easy to see that the matrices depend on the diffusion coefficients $a_{M,\mathbf{i}}(x), \mathbf{i} \le \mathbf{r}$. From (2.18), it is obvious that the differences among these coefficients $a_{M,\mathbf{i}}(x)$ are determined by the eigenvalues, the eigenfunctions, and the constants $C_{i_j,j}$. If any of them change drastically, the diffusion coefficient changes drastically.

We note that the eigenfunctions are normalized in (2.18) and the eigenvalues $\lambda_j, j = 1, 2, \ldots, M$, are not increasing and converge to zero as j goes to infinity.

Therefore, the changes of the constants $C_{i_j,j}, j = 1, 2, \ldots, M$, play the main role in the perturbation of $a_{M,\mathbf{i}}$ for the terms corresponding to larger values of λ_j, i.e., when j is small. Based on the eigenvalues and the constants $C_{i_j,j}$, we provide an estimate of when the diffusion coefficients $a_{M,\mathbf{i}}$ have a relatively large change. If the constants $C_{i_j,j}$, corresponding to large eigenvalues, change drastically, the corresponding systems may become very different from the previous systems. In this case the recycled Krylov subspace and the preconditioner should not be used.

Following the index of the diffusion coefficient $a_{M,\mathbf{i}}(x)$, the sequence of systems is currently labeled by the M-dimensional index $\mathbf{i}$, which is not too convenient for the purpose of putting the systems into different groups. We next turn the M-dimensional index $\mathbf{i}$ into a one-dimensional array. Given $\mathbf{r} = \{r_1, r_2, \ldots, r_M\}$, the index set $\{\mathbf{i} = \{i_1, i_2, \ldots, i_M\} \le \mathbf{r}\}$ is ordered as follows.

Reordering scheme for the multi-index i.

```
k = 1;
for i_1 = 0, 1, ..., r_1
   for i_2 = 0, 1, ..., r_2
      ...
         for i_M = 0, 1, ..., r_M
            "system k" := "system i," with i = {i_1, i_2, ..., i_M};
            k = k + 1;
end
```

An important characteristic of this ordering is that i_k changes only after all possible ordering of $\{i_{k+1}, \ldots, i_M\}$. Following this one-dimensional reindex of $\mathbf{i}$, the set of basis functions $\psi_{\mathbf{i}}$ has a new index.

As it is known that there is a decay of the eigenvalues, consequently the first few terms in the KL expansion carry a lot more weight in perturbing the diffusion coefficient. Using the eigenvalue information and the values of $C_{i_j,j}$, we derive a heuristic algorithm that puts the matrices into several groups.

We first use the mean value of the diffusion coefficient to determine which eigenvalues should be considered to carry more weight. For this purpose, we choose a parameter

$$\theta = \frac{1}{3} \max_{x \in \mathcal{N}(\mathcal{T}^H)} \{a_0(x)\}, \tag{3.12}$$

where $\mathcal{N}(\mathcal{T}^H)$ is the set of coarse mesh nodes of the domain D. If an eigenvalue is greater than θ, we consider that the change in the term associated with this eigenvalue causes large change in the diffusion coefficient. Assume, by this criterion, that we have decided that the first p terms may cause large perturbation. Then the sequence of linear systems is divided into $(r_1+1) \times (r_2+1) \times \cdots \times (r_p+1)$ groups. In each group, there are $(r_{p+1}+1) \times \cdots \times (r_M+1)$ systems. The systems in different groups have different constants $C_{i_j,j}, j = 1, 2, \ldots, p$, in the first p terms of the KL expansion. The systems in the same group have the same first p terms of the KL expansion.

In most situations, the systems in the same group have small differences such that we can use one of the systems to construct a Krylov subspace and a preconditioner that can be reused for solving systems in the whole group. However, in some cases, a subset of systems in the group may be close to being singular, and this subgroup of systems needs to be treated separately. More precisely, for certain systems in a given group of systems, we note that when the minimum value of the diffusion coefficient is close to zero, these systems are more sensitive to small perturbations.

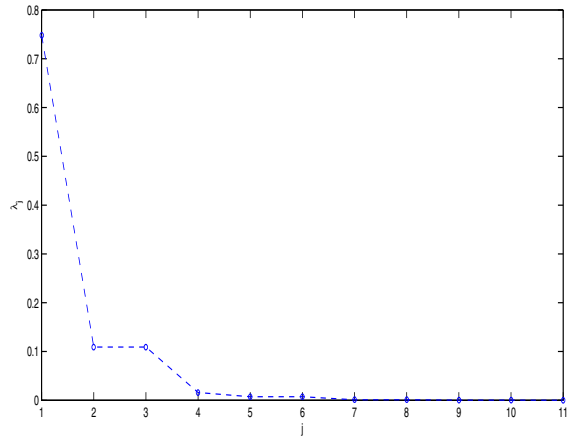

FIG. 3.1. *The decay of eigenvalues when* $C_a(x, x') = e^{-|x-x'|^2}, x \in [0,1]^2$.

The iterative solver may not converge well even when the preconditioner is constructed from another system in the same group. To single out these bad systems, we choose a cutoff parameter $\delta > 0$, and if

$$\min_{x \in \mathcal{N}(\mathcal{T}^H)} \{a_i(x)\} \leq \delta, \tag{3.13}$$

we consider the system as nearly singular. In our numerical experiments, $\delta = 0.03$. In the heuristic estimate, there is no need to compute the minimum value too accurately, and we use a coarse mesh to find the minimums of the diffusion coefficients. If the minimum is less than δ, we consider this system too sensitive to be preconditioned by any other systems that are not close to being singular. We collect these sensitive systems together into a subgroup. Experiences show that systems in the subgroup have similar lower bounds, and therefore we can solve them by recycling the Krylov subspace, recycling the symbolic factorizations of the subdomain matrices, but not the preconditioner, within the subgroup. We note that these sparse matrices have the same nonzero pattern, and by using this fact, certain data structures and communication information can be recycled.

Furthermore, based on the eigenfunctions and the values of $C_{i_j,j}, j = 1, 2, \ldots, M$, we may narrow down the interval to which the sensitive systems belong without searching through every group of systems.

To help the discussion, we consider an example with the mean and covariance functions

$$a_0(x) = 3 + \sin(\pi x_1), \qquad C_a(x, x') = e^{-|x-x'|^2}, \quad x \in [0,1]^2. \tag{3.14}$$

$M = 11$ and $\mathbf{r} = (3, 2, 2, 1, 1, 1, 1, 1, 1, 1, 1)$. This implies that there are 9216 systems of form (2.18). We assume that y_j in the KL expansion is uniformly distributed in $\Gamma_j = [-\sqrt{3}, \sqrt{3}]$.

In Figure 3.1 we show the decay of the eigenvalues. With the above ordering, for the example (3.14), Figure 3.2 illustrates how the upper and lower bounds of the diffusion coefficient $a_{M,\mathbf{i}}$ change with $\mathbf{i}$. Note that some of the lower bounds are quite close to zero.

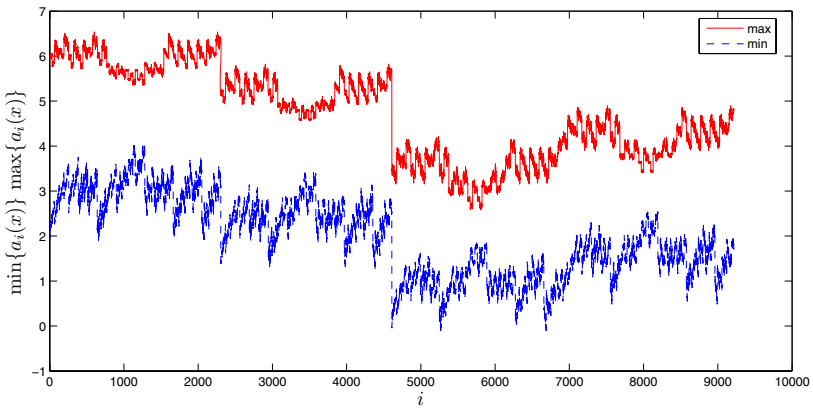

FIG. 3.2. *Top curve is the maximum of the diffusion coefficient* $\max_{x\in\mathcal{N}(\mathcal{T}^H)}\{a_{M,\mathbf{i}}(x)\}$, *and the bottom curve is the minimum of the diffusion coefficient* $\min_{x\in\mathcal{N}(\mathcal{T}^H)}\{a_{M,\mathbf{i}}(x)\}$, $M = 11$, $\mathbf{r} = \{3, 2, 2, 1, 1, 1, 1, 1, 1, 1, 1\}$, $a_0(x) = 3 + \sin(\pi x)$.

Since λ_1 is dominantly large compared with other eigenvalues, we consider that the first term has more weight in perturbing the diffusion coefficient. $r_1 = 3$ implies there are four possible corresponding constants: $C_{i_1,1}, i_1 = 0, 1, 2, 3$. The four constants $C_{i_1,1}, i = 0, 1, 2, 3$, evenly divide all the systems into four groups. According to the reordering scheme for the multi-index $\mathbf{i}$, the first group includes systems 1 to 2304, in which all the systems' diffusion coefficients share the constant $C_{i_1,1}, i_1 = 0$, in the first term of the KL expansion. Similarly, the second group from 2305 to 4608 corresponds to $C_{i_1,1}, i_1 = 1$; the third group corresponds to $C_{i_1,1}, i_1 = 2$; and the last group corresponds to $C_{i_1,1}, i_1 = 3$. We can see clearly that the bounds of the diffusion coefficient have a dramatic change for systems 2305, 4609, 6913. This matches with the change of $C_{i_1,1}, i_1 = 0, 1, 2, 3$, which are $1.49, 0.59, -1.49, -0.59$, respectively, by numerical computation. $C_{i_j,j}$ decreases from 1.49 to 0.59 and then to -1.49. In the end, it increases to -0.59. Correspondingly, the bounds of the last group in Figure 3.2 increase too compared with the third group. In particular, since the third constant -1.49 is the smallest value among the first four constants, the minimum values of some diffusion coefficients, which are close to zero, are all in the third group 4609–6912. These systems are the bad cases, for which the iterative solver does not converge well if using a preconditioner not in the same subgroup.

Figure 3.3 shows the surface plots of the diffusion coefficients of systems 4608 to 4613. We can see clearly that the plot for system 4608 is significantly different from those of the other systems. The plots for systems 4609 to 4613 have very small differences. In particular, the minimum values of the diffusion coefficients of systems 4609 to 4613 are close to zero.

Generally speaking, we would like to recycle both the Krylov subspace and the preconditioner as much as possible. For the preconditioner, there are two ways to recycle, namely, (1) recycle the symbolic factorization of the subdomain matrices to save the computational work in the construction of the preconditioners for the next system; and (2) recycle the preconditioner for the next system. Obviously, the second choice saves more work than the first. However, when the matrices have significant differences from each other, the number of iterations can be large if we reuse the old

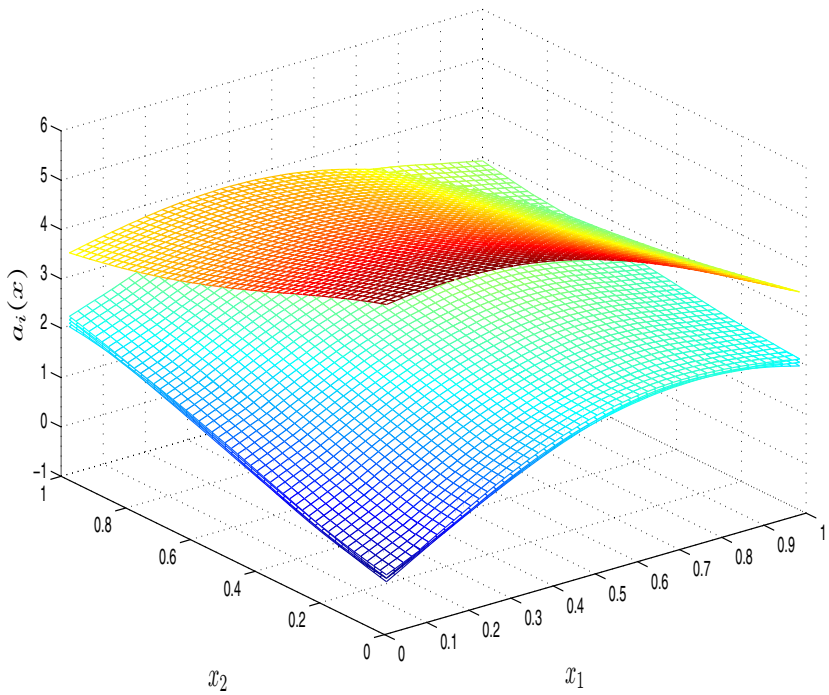

FIG. 3.3. *Surface plots of diffusion coefficients of systems* 4608–4613. *The top surface is for system* 4608, *and the bottom cluster of surfaces is for systems* 4609–4613.

preconditioner, and therefore a new preconditioner is preferred.

We summarize our analysis in term of a grouping algorithm which provides an estimate of when the systems have relatively large change and when the systems are close to being singular.

A GROUPING ALGORITHM.

- Choose M and $\mathbf{r} = \{r_1, r_2, \ldots, r_M\}$. Generate a new index for $\mathbf{i} \leq \mathbf{r}$ according to the reordering scheme. Compute the double orthogonal basis and obtain the corresponding constants $C_{i_j,j}, j = 1, 2, \ldots, M$. Compute the eigenvalues λ_j and eigenfunctions k_j, $j = 1, 2, \ldots, M$. Choose the parameters $\delta > 0$ and $\theta > 0$. (In our example we choose $\theta = 1/3 \max_{x \in \mathcal{N}(\mathcal{T}^H)}\{a_0(x)\}$ and $\delta = 0.03$.)
- Compute $p = \max\{i \mid |\lambda_i| > \theta,\ i = 1, 2, \ldots, M\}$. Divide the systems into $(r_1 + 1) \times \cdots \times (r_p + 1)$ groups. In each group, there are $q = (r_{p+1} + 1) \times \cdots \times (r_M + 1)$ systems.
- Compute the approximate minimum value of each diffusion coefficient on the coarse mesh, $\min_{x \in \mathcal{N}(\mathcal{T}^H)}\{a_i(x)\}$. If the minimum is less than or equal to δ, the corresponding system is labeled as nearly singular, or a "bad case."
- Put these bad cases into a subgroup. Construct a Krylov subspace and a preconditioner from one system in the subgroup and then recycle the Krylov subspace and recycle the symbolic factorization of the subdomain matrices for other systems in the subgroup.

- For the other systems in each group, construct a Krylov subspace and a preconditioner from one system and then recycle the Krylov subspace and recycle the preconditioner for other systems in this group.

4. Numerical experiments. We test the performance of the additive Schwarz preconditioned recycling FGMRES algorithm for solving the model problem (2.4) on a two-dimensional domain $D = [0,1]^2$. The source term $f(x) = 1$. The mean and covariance functions are explicitly given as

$$a_0(x) = 3 + \sin(\pi x_1), \qquad C_a(x,x') = e^{-|x-x'|^2}.$$

For the KL expansion of $a(x,\omega)$, we choose $M = 11$ truncation terms as the approximation. This implies that the dimension for the y-space is 11. By the selecting algorithm provided in [16], we choose $\mathbf{r} = (3,2,2,1,1,1,1,1,1,1,1)$. Consequently, we have 9216 systems of form (2.18). At the same time, we assume that y_j, $j = 1,2,\ldots,11$, are uniformly distributed in $\Gamma_j = [-\sqrt{3},\sqrt{3}]$. Thus the probability density function $\rho_j = 1/(2\sqrt{3})$. Note that this implies that the variance of y_j is unity. We compute the eigenpairs $(\lambda_j, k_j(x))$ using MATLAB. $k_j(x)$ is saved as a step function together with eigenvalues into a file to be used in the main program. The computation of the orthogonal polynomials (2.14) involves the generalized eigenvalue problem $Ax = \lambda Bx$ with symmetric and positive semidefinite matrices A, B of size $r_j, j = 1,2,\ldots,11$. These are solved with MATLAB and saved in a file to be read by the main program.

The main program implements the additive Schwarz preconditioned recycling FGMRES. PETSc [4] is employed for the parallel computation. Both the relative tolerance and absolute tolerance for all the tests are set to 10^{-6}.

4.1. Comparison of different recycling schemes. In this section, we study the following four schemes:

1. No recycling of Krylov subspace and no recycling of preconditioner.
2. Recycle Krylov subspace and recycle symbolic factorizations of subdomain matrices for the entire sequence of systems.
3. Recycle Krylov subspace and recycle the preconditioner for the entire sequence of systems.
4. An algorithm based on the grouping algorithm introduced in the previous section.

Scheme 1 is used as a basis of comparison for the other schemes. To take advantage of the fact that all the matrices have the same nonzero pattern, we recycle the symbolic factorization of subdomain matrices and call this Scheme 2. In PETSc this ensures that certain data structures and communication information are reused (instead of being regenerated) during successive steps, thereby increasing the efficiency of the software. For example, for a parallel preconditioner such as incomplete factorization, matrix colorings and communication patterns are determined only once and then reused throughout the solution process. Scheme 3 uses the same preconditioner for all systems. It saves almost all the preconditioner construction work for all the matrices. However, this causes a steep increase in iteration numbers for some of the systems. We can see in Figures 4.1, 4.2, 4.3, and 4.4 that, for Scheme 2, all the iteration numbers of the following systems are about half of the iteration of the first system. But for Scheme 3, there are sudden increases of iteration numbers for some systems. The reason was discussed in the previous section. Scheme 4 combines the advantages of Schemes 2 and 3. It adaptively recycles the Krylov subspace and the preconditioner according to the grouping algorithm.

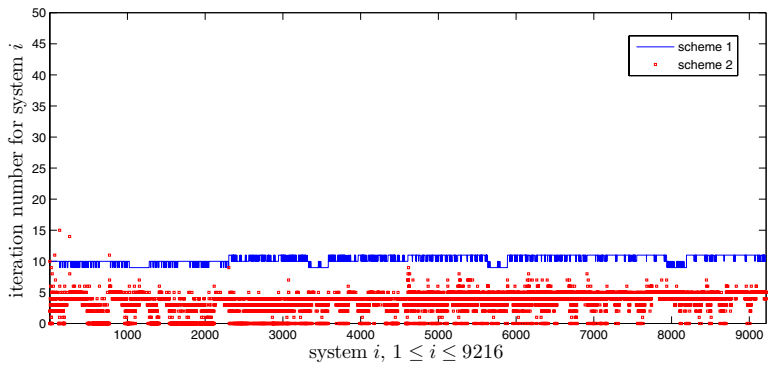

FIG. 4.1. *One-level ASM, iteration number comparison of schemes* 1 *and* 2.

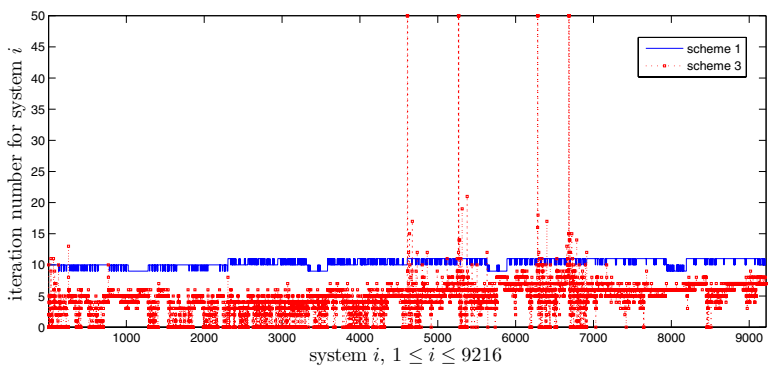

FIG. 4.2. *One-level ASM, iteration number comparison of schemes* 1 *and* 3.

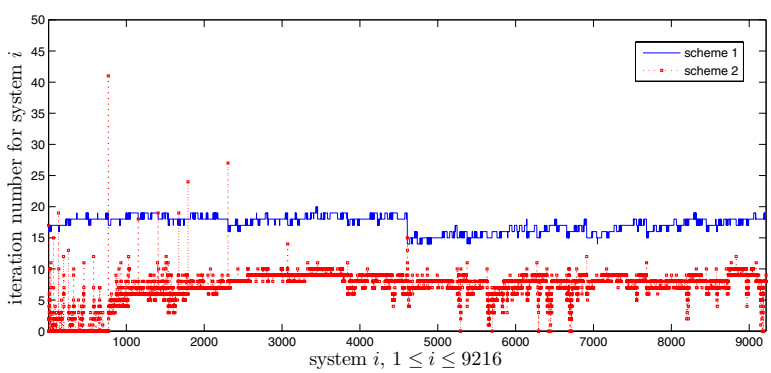

FIG. 4.3. *Two-level ASM, iteration number comparison of schemes* 1 *and* 2.

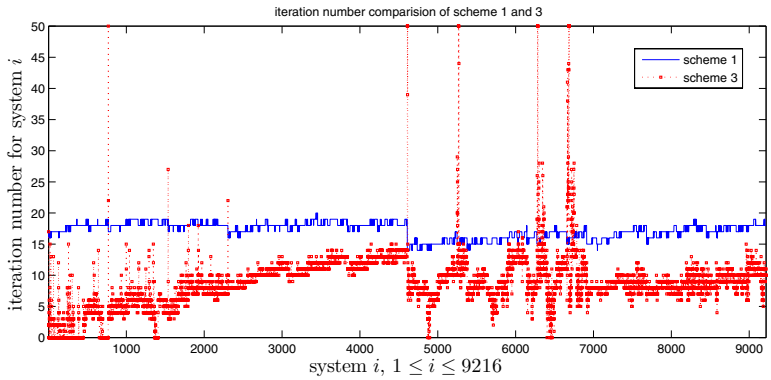

FIG. 4.4. *Two-level ASM, iteration number comparison of schemes* 1 *and* 3.

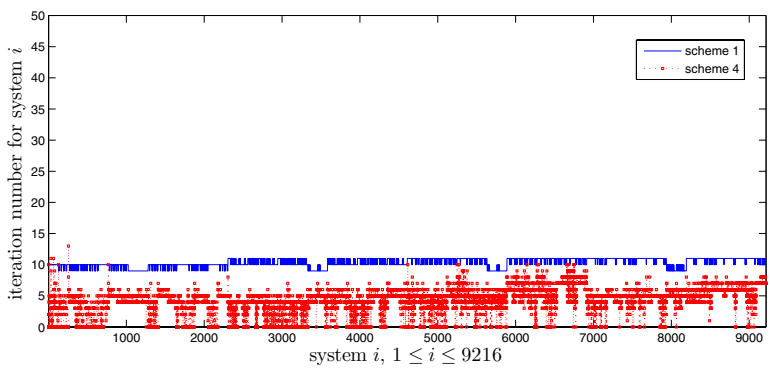

FIG. 4.5. *One-level ASM, iteration number comparison of schemes* 1 *and* 4.

TABLE 4.1
Running time for different schemes and preconditioning (seconds).

Preconditioner	Scheme			
	1	2	3	4
One-level ASM	12030	7693	4205	3882
Two-level ASM	20980	14130	10740	8476

We first study the one-level additive Schwarz method, i.e., without the coarse level preconditioning. The mesh size is 256×256. The number of processors is 16. Figures 4.1, 4.2, and 4.5 show the comparisons. The running times for both one-level and two-level ASM are in Table 4.1.

From Figure 4.1, we see that most of the iteration numbers of Scheme 2 are less than half of those obtained using Scheme 1. Many systems even have zero iterations, which means that the solution generated from the recycled Krylov subspace is already good enough for the current system. This leads to big savings in the running time. In Figure 4.2, we use the same preconditioner for all systems. The iteration numbers increase a little for most systems, but still less than those of Scheme 1. In a few cases,

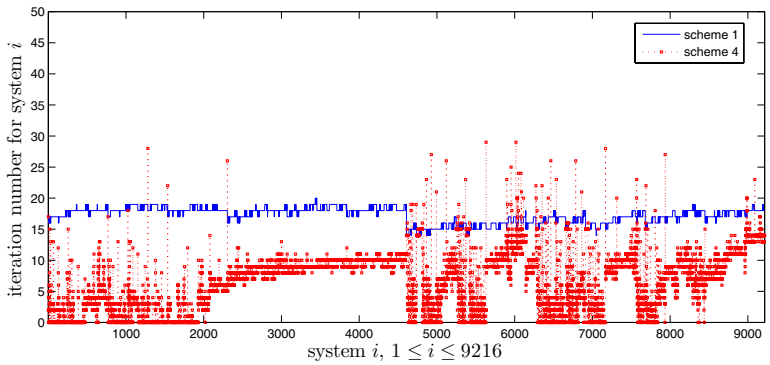

FIG. 4.6. *Two-level ASM, iteration number comparison of schemes* 1 *and* 4.

TABLE 4.2
Average iteration numbers, one-level additive Schwarz preconditioner.

Mesh	Overlap	Number of subdomains			
		1	4	16	64
128×128	4	5.89	5.81	5.83	6.83
256×256	8	3.79	5.52	4.28	7.76
512×512	16	2.08	5.46	4.10	5.78

the number of iterations even reaches 50, which is the maximum iteration number we set in the implementation. These are the bad cases we discussed in the previous section. Notice that the systems with high iteration numbers in Figure 4.2 are exactly the systems of which the minima of the coefficients are close to zero. Unsurprisingly, the running time of Scheme 3 is much less than that of Scheme 2 and only about 1/3 that of Scheme 1. In Figure 4.5, we recycle the Krylov subspace and the preconditioner by the grouping algorithm. The running time is about the same as for Scheme 3. The iteration numbers required for solving those few systems are also controlled.

Figures 4.3, 4.4, and 4.6 are for the comparison of the schemes when we use two-level additive Schwarz preconditioner in the implementation. The coarse mesh is 16×16. It shows the same effects as in the one-level case. In particular, we can see that in Scheme 4 there are more systems requiring zero iteration numbers.

4.2. Scalability of the additive Schwarz method. In this section, we study the scalability of the additive Schwarz methods. We use recycling Scheme 4 for these experiments. Table 4.2 shows the results of the one-level additive Schwarz method. Table 4.3 shows the results of the two-level additive Schwarz method. The iteration numbers in the tables are the average iteration numbers for solving all systems.

From Table 4.2, we can see that, for the one-level ASM, as the mesh size increases, the average iteration numbers actually decrease a little. As the number of processors increases, the average iteration numbers increase except for the 16 processor case. To conclude, with the one-level ASM, the method is scalable with respect to mesh size but not to the number of processors.

TABLE 4.3
Average iteration numbers, two-level additive Schwarz preconditioner, coarse mesh 16×16.

Mesh	Overlap	Number of subdomains			
		1	4	16	64
136×136	4	7.66	8.53	8.82	8.99
256×256	8	3.93	9.04	6.39	4.14
496×496	16	2.52	2.59	4.59	3.44

From Table 4.3, we can see that the two-level ASM is scalable with respect to both the mesh size and the number of processors. Actually, the average iteration numbers decrease a little as the mesh size increases as in the one-level case. When the number of processors increases, the average iteration numbers decrease too, except for the mesh 136×136. The number of iterations is higher than expected; more research is still needed to fully understand the situation.

5. Conclusion. In this paper, we introduced a parallel domain decomposition preconditioned recycling Krylov subspace method for stochastic elliptic partial differential equations. By recycling the Krylov subspace and the preconditioner, the overall computational cost and time can be saved by as much as 50%. We carefully analyzed the KL expansion and derived a useful algorithm that tells us when to recompute and when to recycle some of the expensive components of the computation. We showed theoretically and experimentally that the multilevel additive Schwarz preconditioned recycling GMRES method is optimal for the entire family of linear systems arising from the discretization of the stochastic elliptic partial differential equation. A fully parallel implementation was provided and tested with up to 64 processors, and scalability results were also reported.

GREEDY COARSENING STRATEGIES FOR NONSYMMETRIC PROBLEMS*

SCOTT MACLACHLAN† AND YOUSEF SAAD†

Abstract. The solution of large-scale linear systems in computational science and engineering requires efficient solvers and preconditioners. Often, the most effective such techniques are those based on multilevel splittings of the problem. In this paper, we consider the problem of partitioning both symmetric and nonsymmetric matrices based solely on algebraic criteria. A new algorithm is proposed that combines attractive features of two previous techniques proposed by the authors. It offers rigorous guarantees of certain properties of the partitioning, yet is naturally compatible with the threshold based dropping known to be effective for incomplete factorizations. Numerical results show that the new partitioning scheme leads to improved results for a variety of problems. The effects of further matrix reordering within the fine-scale block are also considered.

Key words. preconditioning, algebraic multigrid (AMG), multilevel ILU, matrix partitioning, nonsymmetric matrices

1. Introduction.

Recent advances in the solution of linear systems of equations have been driven by the ever-increasing problem sizes required in computational science and engineering applications. Matrices of interest arise both from discretizations of differential equations that govern physical systems, where accuracy considerations demand fine meshes, and from naturally discrete problems with many degrees of freedom. These systems are typically not only large but also ill conditioned, requiring advanced techniques for efficient solution.

For many such large-scale linear systems, the most efficient solution techniques utilize multilevel frameworks. For elliptic PDE based problems, multigrid [12] and algebraic multigrid (AMG) [8, 25] methods have been demonstrated to have optimal efficiency. For more general problems, however, classical multigrid approaches do not perform as well without more expensive approaches to the multigrid setup phase [9, 10]. While purely algebraic approaches, such as the algebraic recursive multilevel solver (ARMS) [30] and other multilevel ILU techniques [4, 7], do not typically match the performance of multigrid for discretizations of elliptic PDEs, their robustness across many problems makes them an attractive option when complete knowledge of a problem's origin cannot be guaranteed.

When the system matrix is symmetric and positive definite, theoretical analysis gives insight into the requirements on the partitioning into fine-scale and coarse-scale degrees of freedom. Analysis of multilevel block factorization preconditioners, such as ARMS, shows that it is crucial that the fine-scale submatrix be well approximated, in a spectral sense, by the fine-scale part of the preconditioner in order to achieve effective results [24]. Motivated by this analysis and corresponding theory for multigrid for symmetric and positive-definite matrices [16, 21], we have previously developed a

partitioning algorithm for the symmetric case [22]. In this approach, the optimal partition is defined in terms of a diagonal-dominance property of the fine-scale block. Exactly achieving the optimal coarsening was shown to be an NP-complete problem, and so an $O(N)$ approach to approximately achieve this objective, based on a greedy strategy, was used instead.

In this paper, we consider the extension of the approach from [22] to nonsymmetric problems. A direct generalization using symmetric permutations is quite natural although may not be effective when the nonsymmetry in the matrix dominates its properties. In particular, when defining a multilevel preconditioner, the partitioning algorithm must be applied recursively; the symmetric approach of [22], however, requires stricter constraints on the coarse-grid problem than are natural to ensure that recursion is possible. While the extension to nonsymmetric matrices is simple in principle, it is quite powerful. Multilevel ILU factorizations are most effective when combined with threshold based dropping criteria. The symmetric partitioning approach [22] requires symmetric operators on all levels; however, threshold based dropping in IKJ-ordered factorizations is naturally nonsymmetric. In [22], the upper-triangular factor was discarded, and the incomplete factor, L^T, was used instead to ensure symmetry. Here, no information must be lost.

A natural approach for nonsymmetric problems is to consider a nonsymmetric permutation strategy, as was done in [28]. Here, we extend our earlier, greedy approach to such nonsymmetric permutations, seeking a permutation where the fine-scale block is row diagonally dominant. The algorithms proposed in [28], while compatible with threshold based dropping, do not necessarily guarantee the diagonal-dominance of the fine-grid subblock and, thus, may result in less accurate factors. By carefully extending the symmetric partitioning algorithm of [22], we seek to gain the best of both worlds: the robustness of nonsymmetric permutations coupled with the computational efficiency gained by large, diagonally dominant fine-grid blocks. The partitioning approaches are compared on a variety of nonsymmetric matrices. Additionally, we consider the effectiveness of the nonsymmetric approaches discussed here on the symmetric test problems of [22], without looking to exploit symmetry. This allows the ILU factors to be used as given and compares the utility of enforcing symmetry versus exploiting the full power of the incomplete factorization approach.

Another important question in the ARMS technique is the ordering of the fine-scale block, A_{ff}, so that it may be efficiently approximated by its ILUT factors. Here, we consider various approaches to reordering the fine-scale block based on standard techniques such as those of Sparspak [17] and METIS [20]. The effects of reordering on the performance of incomplete factorization preconditioners has been considered previously [5, 11, 15]. Here, we extend the work of [29] and examine the effects of reordering on multilevel ILU preconditioners, such as ARMS.

This paper is organized as follows. In section 2, we present the ARMS algorithm and the greedy partitioning strategy. Section 3 details the extension of these approaches to nonsymmetric problems, with particular focus on nonsymmetric permutations. Numerical results, for both symmetric and nonsymmetric problems, are presented in section 4. A discussion of reordering of the fine-scale block is given in section 5, followed by conclusions in section 6.

2. Background.

2.1. The algebraic recursive multilevel solver (ARMS) algorithm. The ARMS algorithm [30] arises from considering the block factorization of a given matrix, A. Partitioning the degrees of freedom of A into two sets, F and C, referred to as

the fine-grid and coarse-grid degrees of freedom (respectively), the (reordered) matrix can then be written as a block 2×2 system,

$$A = \begin{bmatrix} A_{ff} & -A_{fc} \\ -A_{cf} & A_{cc} \end{bmatrix}.$$

This block form can be directly factored as

$$A = \begin{bmatrix} I & 0 \\ -A_{cf}A_{ff}^{-1} & I \end{bmatrix} \begin{bmatrix} A_{ff} & 0 \\ 0 & \hat{A}_{cc} \end{bmatrix} \begin{bmatrix} I & -A_{ff}^{-1}A_{fc} \\ 0 & I \end{bmatrix}, \tag{1}$$

where $\hat{A}_{cc} = A_{cc} - A_{cf}A_{ff}^{-1}A_{fc}$ denotes the Schur complement of A. From this factored form, an algorithm for the direct solution of $A\mathbf{x} = \mathbf{b}$ is apparent (partitioning the vectors, $\mathbf{x} = \left(\begin{smallmatrix} \mathbf{x}_f \\ \mathbf{x}_c \end{smallmatrix}\right)$ and $\mathbf{b} = \left(\begin{smallmatrix} \mathbf{b}_f \\ \mathbf{b}_c \end{smallmatrix}\right)$).

ALGORITHM 1 (block factorization solve of $A\mathbf{x} = \mathbf{b}$).

1. $\mathbf{y}_f = A_{ff}^{-1}\mathbf{b}_f$
2. $\mathbf{y}_c = \mathbf{b}_c + A_{cf}\mathbf{y}_f$
3. Solve $\hat{A}_{cc}\mathbf{x}_c = \mathbf{y}_c$
4. $\mathbf{x}_f = \mathbf{y}_f + A_{ff}^{-1}A_{fc}\mathbf{x}_c$

For a general F/C partition, there is no advantage in using Algorithm 1 over directly factoring A. The advantage of the block factorization approach occurs when considering preconditioners, however, if the partition is chosen so that the diagonal-block matrices, A_{ff} and $\hat{A}_{cc}$, are easily (approximately) inverted. In this case, solution with an approximate block factorization can be a good preconditioner for a Krylov subspace method. Many variations on this approach have been considered; see, for example, [2, 3, 7].

In the ARMS methodology, the inversion of A_{ff} is approximated through its ILUT factors. That is, we write $A_{ff} \approx LU$, where the L and U factors are truncated based on size and number of nonzeros per row [26], and approximate A as in (1) by

$$B = \begin{bmatrix} I & 0 \\ -A_{cf}U^{-1}L^{-1} & I \end{bmatrix} \begin{bmatrix} LU & 0 \\ 0 & S \end{bmatrix} \begin{bmatrix} I & -U^{-1}L^{-1}A_{fc} \\ 0 & I \end{bmatrix}.$$

The application of the preconditioner, B, to a residual, $\mathbf{r}$, is then given by Algorithm 2.

ALGORITHM 2 (action of ARMS preconditioner on residual, $B^{-1}\mathbf{r}$).

1. $\mathbf{y}_f = L^{-1}\mathbf{r}_f$
2. $\mathbf{y}_c = \mathbf{r}_c + A_{cf}U^{-1}\mathbf{y}_f$
3. Solve $S\mathbf{x}_c = \mathbf{y}_c$
4. $\mathbf{z}_f = \mathbf{y}_f + L^{-1}A_{fc}\mathbf{x}_c$
5. $\mathbf{x}_f = U^{-1}\mathbf{z}_f$

Here, S is an approximation to $\hat{A}_{cc} = A_{cc} - A_{cf}A_{ff}^{-1}A_{fc}$, computed using $A_{ff}^{-1} \approx U^{-1}L^{-1}$ and similar truncation strategies to those of ILUT. While the solution of $S\mathbf{x}_c = \mathbf{y}_c$ in step 3 could be considered directly, the set, C, is generally still large enough that this is quite costly. Instead, the ARMS methodology is applied recursively to solve the system with S, stopping only when the dimension of the coarsest-scale problem is small enough that direct solution is practical, or when S^{-1} is seen to be easily approximated (for example, when S itself is strongly diagonally dominant).

It is then apparent that the success of Algorithm 2 as a preconditioner is dependent on the accuracy of the factorization, $A_{ff} \approx LU$. The accuracy of this factorization, in turn, depends on the partition chosen to define F. If the partition allows

direct factorization of A_{ff} with no fill (if the graph of A_{ff} is, for example, a tree), then the factorization may be done very accurately at low cost. Unfortunately, this is usually not possible without choosing F to be prohibitively small. In contrast, however, choosing C to be small often leads to an A_{ff} block whose inverse is difficult to approximate in a sparse manner. The contrasting goals of sparse factorization and effective coarsening lead to partitioning algorithms that aim at a compromise.

2.2. Original ARMS partitioning. The original ARMS algorithm [30] is a natural extension of the ILUM, BILUM, and BILUTM algorithms. The ILUM (multi-elimination ILU) algorithm [27] is a block-factorization preconditioner, where the partitioning is chosen so that the fine-scale block, A_{ff}, is diagonal (that is, F is an independent set of the degrees of freedom). As A_{ff} is diagonal, it is easily inverted, and the block-factorization solve may be easily implemented (although it is often useful to allow some dropping in the computation of the Schur complement to limit fill). The BILUM (block ILUM) algorithm [31] extends this idea using small block-independent sets to form F, yielding a block-diagonal matrix, A_{ff}. In BILUTM (block multilevel ILUT) [32], the block-independent sets used to form F were allowed to be much larger, leading to inefficiency in computing the exact inverse of the diagonal blocks of A_{ff}. Instead, the ILUT algorithm was used to compute approximate inverses of the large diagonal blocks in A_{ff}, where the block-independent sets are formed using a domain decomposition approach.

In [30], the idea of diagonal dominance was first introduced into the partitioning stage. Row-wise diagonal-dominance coefficients of A are initially computed as $\hat{w}(i) = \frac{|a_{ii}|}{\sum_{j=1}^{n} |a_{ij}|}$, and then scaled by the maximum dominance ratio, giving $w(i) = \frac{\hat{w}(i)}{\max_j \hat{w}(j)}$. An initial fine-scale block is then chosen using a similar approach as before, either by choosing an independent set of the degrees of freedom, or by choosing block-independent sets (using, for example, nested dissection [17]). Points from this set are, however, rejected based on thresholding of the diagonal-dominance ratios, $w(i)$. If a row, i, chosen to be in F is not sufficiently diagonally dominant (if $w(i) < \theta$ for some predetermined θ), then row i is rejected from the fine set and switched to a coarse-grid point. Note that the use of relative diagonal-dominance measures here implies that the fine-grid block, A_{ff}, can no longer be said to be (block) diagonally dominant—only that it tends to be, as its rows were chosen from the most diagonally dominant rows of A.

The introduction of a measure based on diagonal dominance is motivated by considering the ILUT employed in approximating the inverse of A_{ff} in the ARMS algorithm (Algorithm 2). The accuracy of the overall preconditioning depends on how accurately A_{ff} is represented by its ILUT factors. The efficiency, however, depends on how sparse these factors are. To best balance these competing concerns, we seek to choose F so that A_{ff} is well approximated by sparse ILUT factors. To achieve this balance, we reject rows from F that are poorly diagonally dominant, as these are rows in which we expect many significant off-diagonal entries in the ILUT factors. Put another way, we can most easily compute accurate, sparse ILUT factors of A_{ff} when it is strongly diagonally dominant; thus, we reject rows from F that are more likely to cause fill.

2.3. Greedy partitioning. While the use of a diagonal-dominance measure as in [30] is an important improvement in the ARMS algorithm, the approach used there is static; that is, the evolving fine/coarse partition plays no role in the computation or use of these measures. A dynamic approach to diagonal dominance was recently

introduced in [22], based on the observation that it is the dominance strictly within A_{ff} that determines how well A_{ff} may be approximated by its ILUT factors, and not just the dominance of the F rows of A (as is measured by the ratios in [30]).

In [22], the static measures, $w(i)$, are replaced by dynamic measures, $\hat{\theta}_i = \frac{|a_{ii}|}{\sum_{j \in F \cup U} |a_{ij}|}$, where the degrees of freedom of A are assumed either to have been already partitioned into F and C, or to be in U, the set of undecided points. Thus, $\hat{\theta}_i$ is a measure of the dominance of row i over all points that either are in F or have the potential to be in F. If row $i \in U$ is dominant over this set ($\hat{\theta}_i \geq \theta$ for some predetermined θ), then i is added to set F. If there are no such points, then at least one column from U must be added to C in order to determine if the dominance of the rows in U can be improved to the point where they make good F points, or if they should also be discarded into C. For the case of symmetric and positive-definite matrices, as considered in [22], the partition of rows and columns into F and C was also symmetric (that is, if row $i \in C$, then so is column i); so, the row/column pair associated with the least diagonally dominant row is chosen to be the new C point. Measures for all neighboring U rows are then updated, with any rows whose measures are now large enough added to F.

This greedy approach (so named because at each step, all sufficiently dominant rows are added to F and the least dominant row is discarded into C) is considered as an approximation to the "ideal" partitioning of the degrees of freedom of A. If diagonal dominance of A_{ff} is all that we need to ensure a good approximation of A_{ff} by its ILUT factors (in terms of both accuracy and sparsity), then the ideal partitioning is the one which maximizes the size of F, given the constraint that for all rows, $i \in F$, $\theta_i = \frac{|a_{ii}|}{\sum_{j \in F} |a_{ij}|} \geq \theta$, for some predetermined θ. In [22], we showed that finding the ideal partitioning for arbitrary A is an NP-complete problem. This greedy approach approximates the ideal partitioning in such a way that we are guaranteed that the A_{ff} block is diagonally dominant and led to effective ARMS performance for a number of symmetric problems.

It is important, however, to realize that the approach proposed in [22] is strictly limited in its applicability to symmetric problems. In particular, the decision as to which elements of A to partition into F and C is made using a solely row based criterion. A symmetric partition may be effective for a given nonsymmetric matrix; however, in general, an appropriate measure for making such a decision should take the nonsymmetry into account. This is particularly important in the multilevel setting considered here, where a naturally nonsymmetric factorization (such as the ILUT) may be used to approximate A_{ff}^{-1} within the calculation of the approximate Schur complement. If this nonsymmetry is not appropriately taken into account, the partitioning of the coarse-grid operator is no longer guaranteed to satisfy the desired diagonal-dominance property and may fail altogether.

3. Nonsymmetric partitioning approaches. While the symmetric partitioning approaches described above work well for many symmetric (and some nonsymmetric) problems, they do not always effectively partition the rows and columns of A. Consider, for example, taking a diagonally dominant tridiagonal matrix and cyclically permuting all entries two columns to the right. The resulting matrix is no longer diagonally dominant (indeed, the diagonal entries are all zero), and either of the above algorithms would fail to find any F points. A more robust approach is to define separate left and right permutation matrices, allowing large off-diagonal entries to be moved to the diagonal of the reordered system and used as pivots in the ILUT factorization.

3.1. Two-stage algorithm. In [28], a two-stage approach is used to find a nonsymmetric permutation that results in an A_{ff} block that is expected to have its largest entries on the diagonal. A preselection stage is used to first identify rows that are good potential rows for A_{ff} and then sort these rows based on a measure of their likelihood to produce sparse ILUT factors. In the second stage, the nonsymmetric permutations are defined by traversing this list (in order), permuting the dominant element for the row to the diagonal, if possible, and discarding rows for which a suitable permutation cannot be defined. In this way, a nonsymmetric permutation pair is constructed that yields an A_{ff} block that is expected to yield sparse ILUT factors based on a simple greedy strategy.

The preselection stage itself first discards rows with no significant dominant element, and then orders the remaining rows based on evaluating their potential to yield sparse ILUT factors. For each row, i, the dominant element in row i, $k_i = \text{argmax}_k |a_{ik}|$, is first calculated, along with the row's ℓ_1 norm, $t_i = \sum_j |a_{ij}|$. If t_i is small enough, relative to $|a_{ik_i}|$, measured by a preselected tolerance, then row i is admitted as a candidate row for A_{ff}. Diagonal dominance alone is not enough, however, to guarantee sparse ILUT factors. Indeed, a row with only two equal-sized nonzero entries may be more attractive than a row with one large entry and many small entries (as it tends to introduce less fill into the subsequent rows of the factors). To address this issue, the dominance ratios, $\frac{|a_{ik_i}|}{\sum_j |a_{ij}|}$, are then multiplied by $\frac{1}{|\text{Adj}(i)|}$, where $\text{Adj}(i) = \{j \neq i : a_{ij} \neq 0\}$, and $|S|$ denotes the number of elements in set S. These weighted dominance ratios are then sorted in decreasing order to establish a ranking of the attractiveness of row i to be included in A_{ff}.

Many possible strategies exist for selecting which of the rows passed by the preselection algorithm described above are then included in A_{ff} [28]. A simple greedy approach is to scan these rows in order, building a nonsymmetric permutation by accepting row i and column k_i into the F block if neither has already been accepted. As rows appear at most once in the preselection list, this requires only checking if column k_i has already been used as a diagonal by another row already selected for F. If so, row i is discarded to C; otherwise it is accepted, and node (i, k_i) is permuted to the diagonal.

While this approach is successful for many problems, it does not always yield an effective preconditioner. Adding constraints on A_{ff} such that it is diagonally dominant may yield a smaller block but a better overall preconditioner (as the ILUT factors of A_{ff} are both sparser and more accurate). Note, however, that this approach relies on static measures (i.e., measures that are not influenced by the evolving partition) and does not guarantee the diagonal dominance of the resulting A_{ff} block. A second strategy proposed in [28] is based on a dynamic measure and, thus, guarantees row diagonal dominance within the A_{ff} block of the reordered matrix. In this approach, for each row i accepted by the preselection algorithm, if column k_i has not already been reordered and element $|a_{ik_i}|$ dominates row i over those columns already added to F, row i and column k_i are added to A_{ff}. Additionally, for each remaining column $j \in \text{Adj}(i)$ that has not already been added to F or C, if a_{ij} is large enough such that row i would fail to be diagonally dominant in A_{ff} if $|\text{Adj}(i) \setminus (F \cup C)|$ entries of size a_{ij} are added to it, column j is rejected from possibly becoming an F column, and is added to C. In this way, the A_{ff} block of the reordered system is guaranteed to be row diagonally dominant, but columns that may have been acceptable choices for the A_{ff} block are rejected based on an averaged expectation and not their unique contribution. Notice also that the performance is strongly dependent on the ordering

produced by the preselection algorithm. If row i is strongly dominated by column k_i, but there are many large entries in that column, the resulting partition may suffer from accepting row i too early.

3.2. Single-stage greedy nonsymmetric partitioning. Here, we propose a technique that combines the nonsymmetric permutation approach of [28] (described in section 3.1) with the single-stage greedy algorithm approach of [22] (described in section 2.3). The resulting algorithm once again guarantees that the A_{ff} block of the reordered system is diagonally dominant but is much more reluctant to move columns into C. As such, we expect the resulting algorithm to form similar partitions to those chosen by [28] when that algorithm performs well (i.e., when the chosen F blocks are not too small) but to show improved performance when the average dominance criterion described above is too aggressive at removing columns. The practical benefit of such an approach is an expected improvement in the complexity of the resulting preconditioners; increasing the size of the A_{ff} blocks while retaining similar diagonal dominance properties should not degrade convergence of the preconditioners but should result in a sparser approximate factorization that is less expensive to apply.

Extending the diagonal-dominance measure from [22], row i of matrix A is defined to be θ-dominated by column k if $\frac{|a_{ik}|}{\sum_j |a_{ij}|} \geq \theta$. As before, we seek to find a partitioning of the rows and columns of A so that each row in A_{ff} is θ-dominated by its diagonal. To do this, consider the three sets of undecided points, U, fine points, F, and coarse points, C, but now we will maintain different sets for both rows and columns. A point in U_{row} is made into an F-row if, at any point,

$$\frac{|a_{ik_i}|}{\sum_{j \in F_{\text{col}} \cup U_{\text{col}}} |a_{ij}|} \geq \theta,$$

where $k_i = \text{argmax}_{k \in U_{\text{col}}} |a_{ik}|$. If row i is put into F_{row}, then column k_i must also be put into F_{col}, so that the entry, a_{ik_i}, may be permuted into a diagonal position in A_{ff}. If, at any point, row i is zero over all columns in U_{col}, then it is placed in C_{row}, as it is no longer possible to θ-dominate this row with any valid pivot element.

Rows and columns are always moved into the F sets in pairs, defining a nonsymmetric permutation with a square A_{ff} block. Eliminating rows and columns from the U sets into the C sets, however, should occur independently, as if row i is no longer sufficiently dominated by an eligible pivot to be put in F_{row}; it does not necessarily mean that any of the columns in $\text{Adj}(i) \cap U_{\text{col}}$ would not make a good pivot for another row in U_{row}. Thus, the elimination of rows and columns from U_{row} and U_{col} into the C sets occurs independently, as follows. If, at some point in the algorithm, no row in U_{row} is sufficiently dominated by a column in U_{col} such that another row/column pair can be added to F, a single column, $j^\star \in U_{\text{col}}$, that is deemed to be least attractive as a column in A_{ff} is selected to be added to C_{col}. For each $i \in U_{\text{row}}$ such that $a_{ij^\star} \neq 0$, the dominance ratio of row i is updated by decrementing the ℓ_1 norm by $|a_{ij^\star}|$ and, possibly, recomputing the dominant column, $k_i \in U_{\text{col}}$. If $a_{ij^\star}$ is the last nonzero entry in row i's restriction to U_{col}, then row i is added to C_{row}. Otherwise, if the updated $\hat{\theta}_i = \frac{|a_{ik_i}|}{\sum_{j \in F_{\text{col}} \cup U_{\text{col}}} |a_{ij}|} \geq \theta$, then the pair (i, k_i) is added to the F sets. If, at any point when a column is moved into F_{col} or C_{col}, a row, i, is no longer sufficiently dominated over F_{col} by some $k \in U_{\text{col}}$, that is, $\frac{|a_{ik}|}{\sum_{j \in F_{\text{col}}} |a_{ij}|} < \theta$ for all $k \in \text{Adj}(i) \cap U_{\text{col}}$, then there is no possible pivot column for row i that would result in a diagonally dominant

A_{ff}, and row i is discarded into C. This pattern continues until either U_{row} or U_{col} is empty.

There are many possible measures of which the column, $j^\star$, is chosen as the least attractive potential F column. In the symmetric permutation case considered in [22], $j^\star$ was chosen based on the attractiveness of row $j^\star$ as an F-row. Here, we consider the row diagonal-dominance measures,

$$\hat{\theta}_i = \frac{|a_{ik_i}|}{\sum_{j \in F_{\text{col}} \cup U_{\text{col}}} |a_{ij}|},$$

from which the decrease of $\hat{\theta}_i^{-1}$that occurs when column $j^\star$ is moved from U_{col} to C_{col} is easily quantified as $\frac{|a_{ij^\star}|}{|a_{ik_i}|}$. The column that is most attractive as a C column, then, is the one that brings about the greatest cumulative change in the measures, $\hat{\theta}_i$, for $i \in U_{\text{row}}$ measured, for example, as $\sum_{i \in U_{\text{row}}} \frac{|a_{ij}|}{|a_{ik_i}|}$ for each $j \in U_{\text{col}}$.

The resulting algorithm is then summarized as follows, where we ignore the important question of computational complexity and suppress the updating of k_i for $i \in U_{\text{row}}$, which is assumed to always reference the largest entry, a_{ik}, over $k \in U_{\text{col}}$. In Algorithm 3, all second-order updates are also suppressed, particularly the elimination of rows to C when new dominating columns, k_i, are computed. For full details of the implementation, see the discussion in section 3.3.

ALGORITHM 3 (single-stage greedy nonsymmetric partitioning algorithm).

1. Initialize $U_{\text{row}} = U_{\text{col}} = \{1, 2, \ldots, n\}$
2. Initialize $C_{\text{row}} = C_{\text{col}} = \emptyset$ and $F_{\text{row}} = F_{\text{col}} = \emptyset$
3. For all $i \in U_{\text{row}}$,
   (a) Compute $k_i = \text{argmax}_{k \in U_{\text{col}}} |a_{ik}|$
   (b) Compute $l_i = \sum_{j \in F_{\text{col}} \cup U_{\text{col}}} |a_{ij}|$
   (c) Compute $r_i = \sum_{j \in F_{\text{col}}} |a_{ij}|$
   (d) If $a_{ik_i} = 0$, then $C_{\text{row}} = C_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$.
   (e) If $\frac{|a_{ik_i}|}{l_i} \geq \theta$, then make (i, k_i) a diagonal element of A_{ff}:
      - $F_{\text{row}} = F_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$
      - $F_{\text{col}} = F_{\text{col}} \cup \{k_i\}$, $U_{\text{col}} = U_{\text{col}} \setminus \{k_i\}$
   (f) If $\frac{|a_{ik_i}|}{r_i} < \theta$, then $C_{\text{row}} = C_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$.
4. While $U_{\text{col}} \neq \emptyset$ and $U_{\text{row}} \neq \emptyset$,
   (a) For each $j \in U_{\text{col}}$, compute $w_j = \sum_{i \in U_{\text{row}}} \frac{|a_{ij}|}{|a_{ik_i}|}$
   (b) Let $j^\star = \text{argmax}_{j \in U_{\text{col}}} \{w_j\}$ and make $j^\star$ a C-column: $C_{\text{col}} = C_{\text{col}} \cup \{j^\star\}$, $U_{\text{col}} = U_{\text{col}} \setminus \{j^\star\}$
   (c) For $i \in U_{\text{row}} \cap \{i : a_{ij^\star} \neq 0\}$,
      i. Update $l_i = l_i - |a_{ij^\star}|$
      ii. If $a_{ik_i} = 0$, then $C_{\text{row}} = C_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$.
      iii. If $\frac{|a_{ik_i}|}{l_i} \geq \theta$, then
         - $F_{\text{row}} = F_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$
         - $F_{\text{col}} = F_{\text{col}} \cup \{k_i\}$, $U_{\text{col}} = U_{\text{col}} \setminus \{k_i\}$
5. $C_{\text{row}} = C_{\text{row}} \cup U_{\text{row}}$
6. $C_{\text{col}} = C_{\text{col}} \cup U_{\text{col}}$

Steps 1 and 2 in Algorithm 3 simply initialize the sets U, F, and C for both columns and rows. Step 3 is an initial pass over the rows, which finds the largest entry in each row and computes the total and fine-grid row sums of each row. If the

row is zero over U_{col}, it is immediately discarded into C_{row}. If the row is already θ-dominated by its largest entry, then that entry is permuted to the diagonal and its row and column are moved into the F sets. If no θ-dominance by a column in U_{col} is possible for the row, it is also immediately discarded into C_{row}.

The main elimination loop occurs in step 4. For each undecided column, j, a measure, w_j, of column j's fitness as an F-column is computed. The larger the measure, the more large entries there are in column j, relative to the largest in the eligible part of each row. Thus, we select the column, $j^\star$, with the largest measure to be eliminated from U_{col} (and added to C_{col}) in step 4(b). For rows i such that $j^\star \in \text{Adj}(i)$, the removal of column $j^\star$ increases the dominance of a_{ik_i} over the portion of row i that is in $F_{\text{col}} \cup U_{\text{col}}$; thus, we check each adjacent row to see if it is now sufficiently dominated to be included in F.

Finally, note that the termination condition for the main loop (in step 4) allows the algorithm to stop without a full partitioning of both rows and columns. This is reasonable, as step 4(a) could be trivial in two ways: either U_{col} is empty, in which case there are no weights to be calculated, or U_{row} is empty, in which case all the weights are zero. This is possible because columns and rows are moved individually into their respective C blocks, so that while $|F_{\text{col}}| = |F_{\text{row}}|$ must always hold, there is no such constraint on the growth of the C blocks. Thus, iteration of the main loop stops whenever either the rows or the columns are completely partitioned into C and F. Steps 5 and 6 ensure that whatever rows or columns are left are placed into C, so that both the A_{ff} and A_{cc} blocks are square.

The column measures computed in step 4(a) are chosen to reflect how much of a roadblock column j poses to finding a diagonally dominant A_{ff} block. If column j has many entries that are large relative to the largest in their row, then it does, indeed, make dominance hard to achieve. One possible downside to this particular measure, however, is the inability to distinguish between good potential pivots (entries in column j that are the largest in their rows) and entries that effectively block dominance (entries that are very close to, but slightly smaller than, the largest in their rows). It may be possible to neglect entries identified as potential pivots in this algorithm, leading to a more effective measure, but we have not experimented with this option. Another option apparent from the discussion above is that this choice of measure is simply one of many possible averages of the changes in the $\hat{\theta}_i$. Other measures (including other ℓ_p norms, or other averages, such as the harmonic average) are also possible but have not been experimented with.

3.3. Implementation details. While Algorithm 3 describes the important features of the partitioning algorithm, it is intended only to convey the general outline of the scheme. Here, we provide full details of the scheme, as implemented, and as tested in section 4. In particular, we consider the choices made in order to achieve low computational complexity, as well as the details of updating the row-wise quantities k_i, l_i, and r_i. By tracking when these updates are made, the first opportunities to move a row from U_{row} to F_{row} or C_{row} are more easily identified when the relevant quantities are updated. This detailed implementation described here is presented as Algorithm 4 in the appendix.

For ease of computation, two preprocessing stages are added. First, the transpose of A is computed (step 3 of Algorithm 4). While not explicitly necessary, this is convenient because of our use of a compressed sparse row (CSR) storage scheme for the matrix A (and A^T). Thus, for loops such as in step 4(c) of Algorithm 3, we have easy access to the set, $\{i : a_{ij^\star} \neq 0\}$, as the adjacency list of row $j^\star$ in A^T. For this

reason, we use the notation $\text{Adj}^T(j) = \{i : a_{ij} \neq 0\}$ in Algorithm 4. Additionally, the adjacency lists for each row i in A are sorted in decreasing order by $|a_{ij}|$ (step 4(a)). This is done for convenience in updating k_i; instead of needing to search over all entries in $\text{Adj}(i)$ for the next smallest entry that is eligible to dominate row i when the previous k_i is removed from U_{col}, the sorted adjacency lists allow us to simply scan the list from the entry for the old k_i onward, until we find the next column in $\text{Adj}(i) \cap U_{\text{col}}$. In this manner, the adjacency list for row i is scanned from start to finish at most once over all of the updates to k_i before row i is removed from U_{row}.

The extra operations needed to update k_i, l_i, and r_i first arise in step 3(e) of Algorithm 3 (step 4(f) of Algorithm 4). Now, instead of just removing row i and column k_i to their respective F sets, the unsorted rows, m, in $\text{Adj}^T(k_i)$ are also examined. If column k_i dominated row m, then a new dominating column for row m is found from those still in U_{col}. If no such column exists, then row m is easily discarded to C_{row}, as there is no pivot that can pair with it to give a diagonally dominant row in A_{ff}. The A_{ff} row-norm for row m, r_m, is incremented by the value in the added column, and if row m is no longer sufficiently dominant relative to its F columns, it is also moved into C_{row}.

The initial computation of the column measures w_j for $j \in U_{\text{col}}$ is now broken into a separate loop (step 5), and these measures are then updated in the main loop whenever a row is sorted. To manage these measures efficiently and enable easy approximation of the column with maximal measure, a bucket-sort style data structure is used. Within the first loop (step 4 of Algorithm 4), an upper bound on the measures is calculated as the maximum length of an adjacency list in U_{row}. The interval from 0 to this upper bound is then divided equally into a fixed number of buckets, where each bucket corresponds to a doubly linked list of elements representing columns from U_{col} whose measures lie in the appropriate subinterval. A separate list of pointers is maintained, indexed by column, pointing to the list element corresponding to each column. In this way, columns are easily removed from the data structure when they are moved into C_{col} or F_{col}, by accessing the element through the column-indexed pointer list and updating the bucket from which it came using the doubly linked list properties. Columns are also easily moved when their measure is updated by removing the corresponding element from its previous list and adding it to the head of its new list. An approximately maximal column is also easily found as the first item in the nonempty bucket with largest index.

The most significant changes to the algorithm occur in the main loop, step 4 (step 6 and, in particular, step 6(b) of Algorithm 4). Now, when column $j^\star$ is removed, we first check if it dominated any row $i \in U_{\text{row}} \cap \text{Adj}^T(j^\star)$. If so, we update k_i as before and check if the new k_i is large enough to continue considering row i as a potential F row. If not, row i is moved into C_{row}. If, however, the intersection of $\text{Adj}(i)$ and U_{col} is nonempty, removing row i from U_{row} necessitates an update to the column measures for each $j \in \text{Adj}(i) \cap U_{\text{col}}$. Even if row i is not to be removed, these column weights change whenever the dominating column changes, and so, in step 6(b)ii.D of Algorithm 4, the measures for updating any columns are adjusted. The final major step, step 6(b)iii, makes row i and column k_i a pivot in A_{ff} if row i is sufficiently dominated by column k_i. Here, we again update the measure of any column in U_{col} that is affected by the removal of row i from U_{row}. Additionally, for any row that is dominated by column k_i, a new dominating column is found, the intersecting column weights are adjusted, and the row is tested for suitability as a potential F row.

4. Numerical results. We consider several sets of test problems for the proposed partitioning scheme, building on problems tested in previous papers. For each set of tests, we compare the performance of ARMS preconditioners based on the new nonsymmetric partitioning scheme to other effective preconditioners, including ARMS with other choices of partitioning schemes. All tests were run on a dual-processor 3.0GHz Intel Xeon workstation with 2GB of RAM.

In all of these examples, parameters are chosen (whenever possible) to allow easy comparison with previous work [22, 28]. It is important to realize, however, that there is some sensitivity in the performance to these choices of parameters. In general, we find that the choice of θ has a strong influence over the complexity of the algorithm but a milder influence on iteration counts. As complexity is generally lowest when the fine-grid block is largest, but still retains some diagonal dominance, θ should be taken close to 0.5, as it is in the results that follow. As in classical dual-threshold ILUT factorizations [26], the best performance is seen when the maximum fill-per-row parameter plays only a small role in keeping the factors sparse. Thus, we aim to adjust the drop tolerance in such a way as to control both accuracy and sparsity of the factors, while using the maximum fill parameter only to ensure against catastrophic fill-in. Finally, our goal is to coarsen until the coarsest-grid problem is quite small; thus, we demand high accuracy in its incomplete factorization for all test problems. While these guidelines also apply to the symmetric partitioning algorithm [22], the parameter choices for the two-stage partitioning algorithm are quite different. We refer the reader to [28] for a discussion of these choices in that context.

4.1. Symmetric PDE based problems. To compare the nonsymmetric partitioning schemes with their symmetric counterpart (as described in section 2.3), we first consider some test problems from [22]. These matrices, bilinear finite-element discretizations of the second-order elliptic PDE $-\nabla \cdot K(x,y)\nabla p(x,y)$ on regular rectangular meshes of $[0,1]^2$, are sparse, symmetric, and positive-definite. Aside from confirming that the nonsymmetric partitioning scheme preserves the desired properties of the symmetric and definite case, these tests allow another observation. The classical approach to designing solvers for symmetric problems has been to take advantage of symmetry as much as possible. The threshold based incomplete factorizations considered here are, however, naturally nonsymmetric (as thresholding is performed row-wise). Thus, comparing ARMS performance using the symmetric partitioning approach (where symmetrized ILUT factorizations are necessary) and using the nonsymmetric partitioning approach (with full (nonsymmetric) ILUT factorizations) may be done to compare the benefits of retaining symmetry versus taking full advantage of a naturally nonsymmetric factorization.

We consider four choices for the diffusion coefficient, $K(x,y)$. Constant $K(x,y) = 1$, the Poisson equation, is a standard test problem for sparse matrix solvers, particularly for multigrid and its algebraic variants. A smoothly varying, but nonconstant, isotropic coefficient, $K(x,y) = 10^{-8} + 10(x^2+y^2)$, is also considered. A more difficult problem, where $K(x,y) = 10^{-8}$ on 20% of the elements of the grid, chosen randomly, and $K(x,y) = 1$ on the remainder, results in degradation of performance of standard geometric multigrid approaches, but is typically solved efficiently by AMG and multilevel approaches. Finally, we consider the case of a constant, but anisotropic, diffusion coefficient, $K(x,y) = \left[\begin{smallmatrix} 1 & 0 \\ 0 & 0.01 \end{smallmatrix}\right]$, which causes difficulty for many algebraic solvers and preconditioners, including the two-level ARMS preconditioner considered in [22].

Results for the symmetric ARMS preconditioner based on the symmetric greedy coarsening strategy of [22] are shown in Table 1 (Table 7 of [22]). For each choice of

the coefficients, $K(x,y)$, we consider several levels of uniform mesh refinement. For these results, θ is chosen to be 0.55, a symmetrized ILUT algorithm is used where the L factors on all grids but the coarsest are computed with drop tolerance α, as reported in Table 1, and a maximum of twice the average number of nonzeros-per-row of A_{ff} are allowed in each row of its L factor. Coarsening is continued until either the coarsest-grid operator is θ-dominated by its diagonal or has fewer than 10 degrees of freedom. The coarsest-grid operator is then factored using ILUTP, with a drop tolerance of 10^{-5} and a maximum of twenty times the average number of nonzeros per row of this coarsest Schur complement allowed per row of its L factor. For these examples, a more efficient solver results from not rescaling the A_{ff} matrices prior to computing their ILUT factors, as discussed in [28]. In Table 1, we report the number of levels used by the symmetric ARMS preconditioner, the complexity, c_B, of the preconditioner (defined as the total number of nonzeros stored on all levels of the ARMS preconditioner divided by the number of nonzeros in the original fine-scale operator, A), the setup and solve times, and the number of iterations for preconditioned GMRES to reduce the residual by a relative factor of 10^6 (or, for the problems marked by a *, 10^4).

Table 2 shows results for the new nonsymmetric partitioning based ARMS preconditioners on these problems. For the first three problems, the same parameters are used for the nonsymmetric partitioning as are used for the symmetric partitioning. For the anisotropic $K(x,y)$, using the same parameters as the symmetric partitioning resulted in very slow convergence of ARMS with nonsymmetric partitioning. This is likely related to the fact that the average size of the nonzero offdiagonal entries for the discrete anisotropic operator is much closer to the size of its diagonal than for the isotropic problems, and only a very particular choice of coarse degrees of freedom leads to the semicoarsened grids that are known to be most effective for this problem. So, in Table 2, we use $\theta = 0.5$ instead of $\theta = 0.55$ for the anisotropic problem, which results in much better performance. Table 2 also includes two extra data points, detailing the performance of the preconditioners for the two cases from Table 1 where

memory limitations required the choice of $\alpha = 0.1$. For these problems, we include results for both $\alpha = 0.01$ and $\alpha = 0.1$.

For the first two problems (with smooth isotropic coefficients), using ARMS based on nonsymmetric partitioning is slightly more efficient than the symmetric partitioning scheme. This can be seen, in particular, on the larger meshes, where the solve times for the 512×512 grid examples are slightly better than those of the symmetric approach, but the setup times scale much better. As a result, the overall performance of the nonsymmetric partitioning based approach with $\alpha = 0.01$ is significantly better than the performance of either partitioning scheme with $\alpha = 0.1$. For these two problems with $\alpha = 0.01$, the preconditioner complexity is better across all grids using the nonsymmetric partitioning scheme. For the second two problems, however, the performance of ARMS using the symmetric partitioning scheme is slightly better than that of ARMS using the nonsymmetric partitioning approach. In particular, the lower operator complexities for these two problems lead to notably faster solve times even though the iteration counts are comparable (in fact, the nonsymmetric partitioning algorithm results in fewer iterations for all grid sizes for the randomly selected coefficient problem). In any case, the slight difference between these results indicates that there is little benefit in abandoning the inherent advantages of a symmetric preconditioner.

An additional comparison is made with the two-stage nonsymmetric permutation algorithm of [28], as described in section 3.1. For this method, the parameters are chosen as in [28, section 6.1]; namely, a dominance threshold of 0.1 (now relative to the maximum dominance ratio), and drop tolerances of 0.001 in the computation of the ILUT factors, L and U, of A_{ff}, 0.01 in the computation of $L^{-1}A_{fc}$ and $A_{cf}U^{-1}$, 0.001 in the Schur complement computation, and 0.01 on the coarsest level are used. Fill-in is restricted to ten times the average number of nonzeros per row of A_{ff} in all thresholded computations on the fine scales, and five times the average number of

nonzeros per row of the Schur complement on the coarsest scale. Results for the same four model problems and grid sizes are shown in Table 3.

The performance of the two-stage algorithm, shown in Table 3, is interesting because of its contrast to the other results. For each problem, the two-stage algorithm creates hierarchies with more levels, yet results in preconditioner complexities that are, in all cases, bigger than those of either of the other two methods. The setup times clearly do not scale linearly with the increases in problem sizes, yet the iteration counts are similar (and, in some cases, better) than those of the other approaches. Because the LU solves require more operations, however, iteration times with this approach are generally larger than those of the others.

4.1.1. Performance profiles. Comparing the raw results, such as those shown in Tables 1, 2, and 3, gives a good picture of the performance of these preconditioners on individual problems; however, a better sense of the overall performance may be obtained by considering performance profiles, as in [14], instead of tables to present the results in a more compact manner.

Given a measurable solver performance characteristic, such as total time to solution, number of iterations, or preconditioner complexity, performance profiles are a useful tool for comparing different solvers in terms of their measured characteristics for a given set of problems. Let S be the set of solvers and P be the set of problems. For a solver, $i \in S$, and a problem, $j \in P$, take s_{ij} to be the performance characteristic measured for solver i on problem j (e.g., the total time taken by solver i to reduce the residual of problem j by a relative factor of 10^6). For a particular problem, j, the best observed performance, in terms of this chosen characteristic, is

$$\hat{s}_j = \min_{i \in S}\{s_{ij}\}.$$

For each solver, i, we can then define

$$p_i(\alpha) = \frac{|\{j : s_{ij} \leq \alpha \hat{s}_j\}|}{|P|}$$

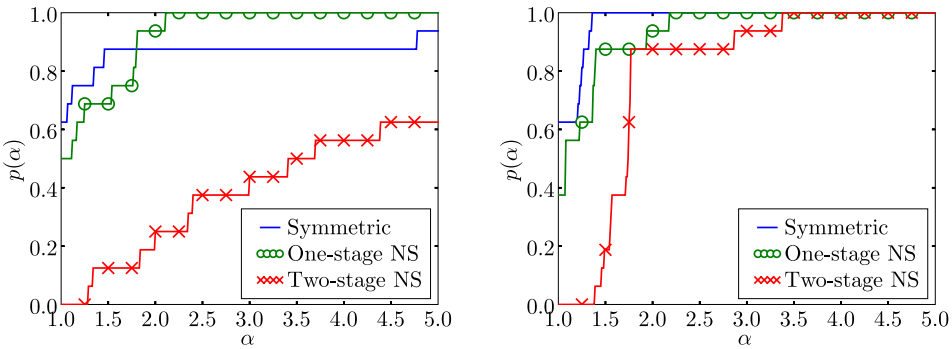

FIG. 1. *Performance profiles for total time to solution (left) and preconditioner complexity (right) for the ARMS preconditioners based on the three partitioning algorithms on the symmetric PDE based problems. Solution is taken to mean a reduction of the residual by a relative factor of* 10^6 *on all grids but* 1024×1024*, where a reduction by a relative factor of* 10^4 *is used.*

as the fraction of the problems in P for which the measured characteristic of solver i is within a relative factor of α of the optimal. If, for any reason, solver i fails on problem j, we take $s_{ij} = \infty$ (and, further, if $s_{ij} = \infty$ for all i, we take $\hat{s}_j = 0$, as no solver can be said to be "optimal"). Thus, $p_i(1)$ is the fraction of problems for which solver i is the best, and $\lim_{\alpha \to \infty} p_i(\alpha)$ is the fraction of problems for which solver i succeeded. A very good solver (relative to the chosen characteristic) is then one for which $p_i(\alpha)$ is largest (closest to one) for small values of α.

Performance profiles for the preconditioners based on the three partitioning algorithms, whose results are given in Tables 1, 2, and 3, are shown in Figure 1. At left is the profile for total time to solution, including setup time plus time required to reduce the residual by a relative factor of 10^6 (10^4 for 1024×1024 grid problems). While ARMS based on symmetric partitioning is the fastest overall in 10 of 16 cases, the new single-stage nonsymmetric partitioning algorithm is seen to be competitive, solving 8 of 16 problems in the fastest time (2 ties in overall time occur). The preconditioner based on the nonsymmetric partitioning solves all problems within a factor of just over 2 of the individual optimal times. The slow setup times of the two-stage nonsymmetric partitioning approach are reflected in the slow growth of its profile. On the right of Figure 1 is the profile for the preconditioner complexities, c_B. While the best overall complexities are seen for the symmetric partitioning approach, the single-stage nonsymmetric partitioning algorithm offers the best complexity for six problems and is seen to be quite competitive with the symmetric approach. The two-stage nonsymmetric partitioning algorithm is seen to yield complexities that are, in all cases, at least 40% larger than the best complexity.

4.2. General sparse symmetric systems. The second set of test problems considered in [22] was drawn from the collection of general, sparse, symmetric, and positive-definite matrices considered in [18, 19]. This set of matrices is the subset of the positive definite problems considered in [18] for which full data is available (discounting problems for which only a nonzero pattern is available) with fewer than 3 million nonzero entries (plus the problem, OILPAN, which has 3.5 million nonzeros, but for which a low preconditioner complexity made convergence possible). Here, we consider the same test set; matrix names, dimensions, and numbers of nonzero entries are listed in Table 4.

Solver parameters are chosen consistently with previous work. For the symmetric permutation scheme, $\theta = 0.55$, drop tolerances are 0.01 with the number of nonzeros per row of the symmetrized ILUT factor limited to five times the average number of nonzeros per row in A_{ff} on all but the coarsest scale, where the drop tolerance is 0.0001 and twenty times the average number of nonzeros per row of the coarsest Schur complement are allowed in each row of its symmetrized ILUT factor. A maximum of 10 levels (plus the coarsest) are allowed, and the A_{ff} blocks are not rescaled before the ILUT. For the single-stage nonsymmetric partitioning approach, θ is chosen as 0.51, and a maximum of 50 levels are allowed; this partitioning scheme tends to choose smaller coarse grids than the symmetric partitioning, and so these parameters are chosen to allow a better comparison. Otherwise, parameters for the single-stage nonsymmetric partitioning approach are the same as for the symmetric partitioning scheme. For the two-stage nonsymmetric partitioning scheme, parameters are chosen to be the same as in the previous section and in [28, section 6.1]. A maximum of 100 levels are allowed, with a dominance threshold of 0.1 (relative to the most dominant row). Diagonal rescaling before the ILUT of A_{ff} is used, and drop tolerances of 0.01 and 0.001 with maximum fill factors of 10 are used on fine scales. On the coarsest scale, the drop tolerance is 0.01, with five times the average number of nonzeros per row of the coarsest Schur complement matrix allowed in each row of its symmetrized ILUT factor.

Performance profiles for total time to solution (at left) and complexity (at right) for the preconditioners resulting from using the symmetric and one- and two-stage nonsymmetric partitioning algorithms are shown in Figure 2. For these profiles, a problem is deemed to have been solved if the ℓ_2 norm of the residual is reduced by a relative factor of 10^6 within 1000 iterations. For problems that failed to meet this criteria, the solution time is taken to be infinite. Notice that each method is fastest for several problems and that, in general, the symmetric partitioning based approach is most successful. In particular, while the one-stage nonsymmetric partitioning approach is close to the fastest for about 20% of the total problems (noting that none of the solvers is successful on 4 of the problems), the symmetric and two-stage nonsymmetric partitioning schemes showed about equal overall performance. In terms of complexity (as seen on the right of Figure 2), there is little differentiation between the methods. The symmetric partitioning is generally the best, followed by the one-stage algorithm, but the difference is small.

Performance of classical AMG [8, 25] for these problems was considered in [22].

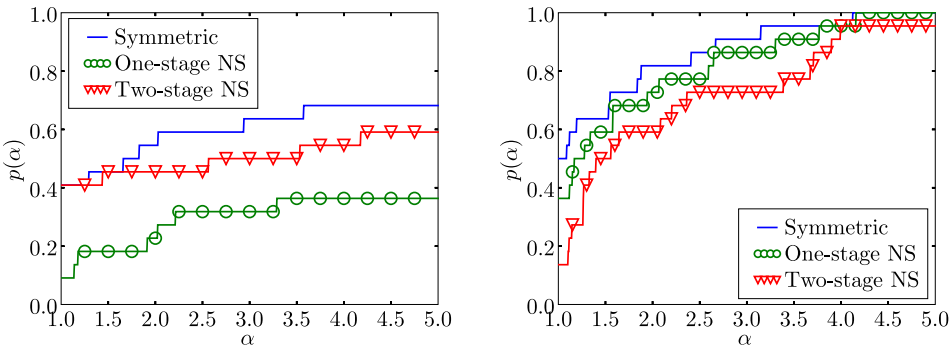

FIG. 2. *Performance profiles for total time to solution (left) and complexity (right) for the preconditioners resulting from using the three partitioning algorithms on the general spare symmetric problems. Solution is taken to mean a reduction of the residual by a relative factor of* 10^6*, within* 1000 *iterations.*

There, it was shown that a naive application of AMG performs quite poorly for this general selection of problems (only 4 of 22 problems converged in fewer than 150 iterations). This behavior emphasizes the benefits of the ARMS approach over AMG; while AMG is typically faster when it works well (including for problems such as those considered in section 4.1), ARMS is more robust as a black-box solver. For this reason, we do not include a detailed comparison of our approach with AMG for general sparse matrices.

4.3. Convection-diffusion problems. As a first set of nonsymmetric test problems, we consider simple finite difference discretizations of the convection-diffusion operator in two dimensions,

$$-\Delta u + a u_x = f,$$

for a variable wind-speed a. Using the standard second-order five-point stencil for the Laplacian term, performance should be close to that seen in section 4.1 for small values of a, no matter how the lower-order derivative has been discretized. For large values of a, however, it is important to discretize the u_x term using an upwind differencing (as opposed to a central-difference approximation) both for accuracy of the solution and to maintain nice (i.e., M-matrix) properties of the linear system.

Table 5 shows the results for both the single-stage partitioning algorithm presented here and the two-stage partitioning algorithm of [28] applied to upwind finite difference discretizations of this problem for values of a ranging from 1.0 to 10^4 on grids of 129×129, 257×257, and 513×513 degrees of freedom. For the single-stage partitioning algorithm, we see low computational complexities for all winds, on all grids. There is some growth in iteration count as grid sizes increase, but performance appears to improve as a increases. Setup times for the two-stage partitioning are much higher—sufficiently so that even though the solve times are, in general, shorter, the overall time to solution is longer for every problem than using the new partitioning algorithm. Furthermore, for all but 3 problems, the preconditioner complexities, c_B, for the two-stage partitioning algorithm are more than twice those for the single-stage partitioning.

Similar results are seen for the unstable discretization, as shown in Table 6. Once again, setup times and preconditioner complexities for the two-stage approach are

much worse than those for the new, single-stage partitioning algorithm of section 3.2. Interestingly, neither solver seems overly affected by the poor-quality discretization, which leads to non-M-matrices for $ah > 2.0$.

Comparison with a single-level ILUT preconditioner shows the efficiency of the ARMS approach. For the central-difference discretization, with $a = 10^4$, an ILUT factorization with drop tolerance of 10^{-3} and a maximum fill-in factor of 20 leads to preconditioner complexities of 14.85 on a 129×129 grid, 18.26 on a 257×257 grid, and 18.99 on a 513×513 grid. While such a preconditioner may be effective on a small grid (only 5 iterations are required to reduce the residual by a factor of 10^6 on the 129×129 grid), its effectiveness quickly diminishes. On the 257×257 grid, 182 iterations are necessary for the same reduction, while a reduction in residual of

only 0.64% was reached in 500 iterations on the 513×513 mesh.

Because of the PDE nature of these systems, a comparison with the AMG algorithm is also appropriate. Results for AMG applied to both the upwind and central-difference discretizations are given in Table 7. Comparing this performance with that in Tables 5 and 6, we see that this performance is consistent with common perception. When AMG works, its performance far exceeds that of ARMS. For these problems, the discrete operators remain M-matrices for all a in the upwind discretization, and so AMG generally outperforms ARMS with either partitioning. For the central-difference discretization, however, AMG performance suffers significantly when ah is large, leading to divergence in the worst cases, whereas ARMS performance was insensitive to this change.

4.4. General sparse nonsymmetric systems. Another interesting nonsymmetric test set is from [28, section 6.1]. This collection of 58 matrices is taken from the Harwell–Boeing collection; those selected are all square matrices from the RUA (real, unsymmetric, assembled) collection that have a dimension of 500 or higher. Matrix names, dimensions, and numbers of nonzero entries are listed in Table 8.

As a comparison for these problems, we consider the performance of a single-level ILUTP preconditioner within GMRES, in addition to the two nonsymmetric partitioning based ARMS preconditioners. For the ILUTP solver, a drop tolerance of 0.0001 is used, with the number of nonzeros per row of L and U^T limited to twenty times the average number of nonzeros per row of A. For the ARMS codes, we use the same parameters as in the previous section, with the exception that A_{ff} is now always diagonally rescaled before it is factored by ILUT. An attempt was made to compare the performance of AMG with that of ARMS for these problems; however, applying a standard AMG algorithm to these matrices did not lead to a single instance of a converging solver.

Figure 3 shows the performance profiles for total time to solution (at left) and complexity (at right) for the problems of Table 8 using these three preconditioning strategies. It should be noted that for many of the smaller problems in this set, all

three preconditioners require very little time, so that a relative difference of 50% may reflect only 0.01 seconds of CPU time.

For all three approaches, we see similar profiles for total time to solution. For the parameters chosen, ILUTP tends to require more significant setup time, while the ARMS approaches are more balanced between their setup and solve times. A

significant difference, however, is seen in terms of the preconditioner complexities for these problems, on the right of Figure 3. Here, we see that the single-stage partitioning algorithm results in the least fill for nearly 70% of the problems considered. The longer setup times of ILUTP are reflected in its slowly increasing profile in this figure; it required more than twice the minimum memory on more than half of the problems in this set.

4.5. Circuit and semiconductor simulation matrices. As a final test set, we consider matrices arising in semiconductor and circuit simulation, obtained from the University of Florida Sparse Matrix collection [13]. The matrices are taken from five sets within this collection: Bomhof [6], Hamm, Schenk_IBMSDS [33], Schenk_ISEA [33], and Wang [23]. The dimensions and numbers of nonzero entries for these problems are listed in Table 9; the matrices range in dimension from 2395 to 181343, and in number of nonzero entries from 17 thousand to 11 million.

For these matrices, as in the previous section, we compare the preconditioners produced by the ARMS methodology using both the new single-stage nonsymmetric partitioning approach and the two-stage nonsymmetric partitioning approach of [28], along with an ILUTP approach. For the single-stage partitioning, $\theta = 0.5$ is chosen, along with a drop tolerance of 0.01 and maximum fill per row in the ILUT factors of five times the average number of nonzeros per row of A_{ff} on all but the coarsest level, where a drop tolerance of 0.0001 and a fill factor of ten are used. For the two-stage partitioning approach, we use the parameters from [28, section 6.5], with a relative diagonal-dominance threshold of 0.1, a drop tolerance of 0.01, and an allowable fill factor of three on all but the coarsest grid, where a drop tolerance of 10^{-5} and fill factor of twenty is used. For both preconditioners, we allow rescaling of A_{ff} on all

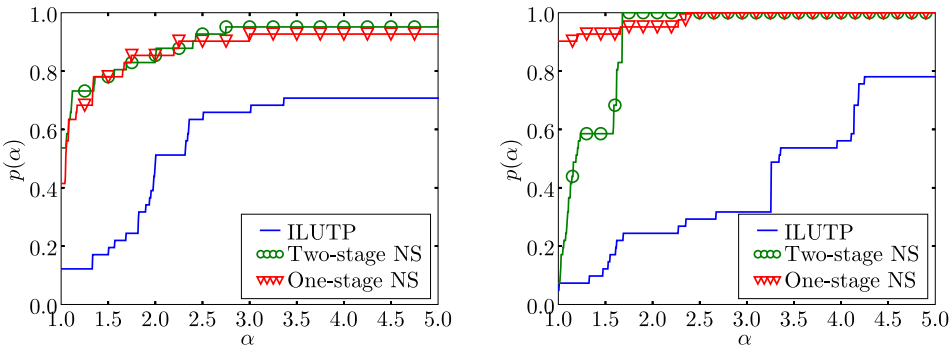

FIG. 4. *Performance profiles for total time to solution (left) and complexity (right) for the three nonsymmetric preconditioning strategies with the circuit and semiconductor device simulation matrices. Solution is taken to mean a reduction of the residual by a relative factor of* 10^6*, within* 1000 *iterations.*

grids before the ILUT factors are computed. For the ILUTP preconditioner, a drop tolerance of 0.0001 and a maximum fill factor of twenty are used.

The performance profiles for these problems, shown in Figure 4, indicate a much bigger gap between the ARMS approaches and the ILUTP preconditioner than is seen for the smaller problems of section 4.4. In terms of total time, the performance profiles for the two ARMS based approaches are quite similar, with the single-stage approach being fastest for roughly 40% of the test problems, while the two-stage partitioning yields the fastest solver for approximately 55% of the test problems. The ILUTP preconditioner is notably slower in terms of total time to solution, primarily because of its increased setup costs.

Looking at these results in more detail than is shown in the performance profiles, we see that the difference between the two ARMS based approaches is significant for some of the problems in this test set. On the matrix circuit_3, from the Bomhof set, the preconditioner based on the single-stage approach failed to converge within 1000 iterations, while the two-stage preconditioner converged, but slowly, in 723 iterations. For the matrix circuit_4, both approaches converged in 9 iterations (in about 0.3 seconds), but the single-stage approach needed only 0.5 seconds for setup, compared to 1.2 seconds for the two-stage approach. For the matrix 3D_28984_Tetra, from the Schenk_IBMSDS set, the two-stage preconditioner did not converge within 1000 iterations, yet the single-stage preconditioner converged in only 1 iteration, requiring 0.5 seconds to set up a successful preconditioner, compared to 0.4 seconds for the unsuccessful approach. On the matrix scircuit, from the Hamm set, the new partitioning approach yielded a preconditioner that converged in 32 iterations (and 3.8 seconds) compared to 60 iterations (and 9.3 seconds) for the two-stage approach, yet required only slightly more setup time, 1.4 seconds versus 1.2 seconds. For the wang3 and wang4 matrices, the single-stage partitioning approach yielded preconditioners that are faster both in setup and iteration, yielding a total speedup of over 25%. For many of the problems, however, the differences are less significant, with the single-stage preconditioner being approximately 10% faster on the barrier2 problems, and the two-stage preconditioner approximately 10% faster on the para problems, both from the Schenk_ISEI set.

Some of the speedup seen in iteration times for the single-stage partitioning pre-

conditioners is due to improved preconditioner complexities, as seen on the right of Figure 4. For both ARMS based approaches, the preconditioner complexities are quite good, below one for many problems, but the new partitioning scheme leads to overall lower complexities. Once again, the memory requirements of the ILUTP preconditioners are much higher; for this test set, ILUTP required over three times the amount of memory of the optimal solver on over two-thirds of the problems. These increased memory requirements do not result in large iteration times, as the constructed preconditioners require only a few iterations to sufficiently reduce the residual, but are reflected in the large gap in setup times (and, thus, total solution times) between the ILUTP and ARMS approaches shown on the left of Figure 4. While overall time to solution is an important measure of these preconditioners, the increased memory requirements of the ILUTP approach should not be ignored, especially for large matrices such as these, where the feasibility of storing such large preconditioners must be considered.

5. Ordering the A_{ff} block. While much effort has been focused on the partitioning of rows and columns within the ARMS algorithm, little consideration has been given to the ordering of the rows within the partitions. While ordering of the coarse-scale block has little practical effect, reordering of the A_{ff} block could result in a significant change in the sparsity of the resulting ILUT factors, as is the case in sparse direct methods (see, for example, [17]). Here, we extend the initial study of [29], where it was seen that the use of standard reordering techniques from sparse direct solvers may also result in improvements to the overall efficiency of the ARMS algorithm.

The efficiency of the ARMS process rests on the accurate approximation of the action of the inverse of A_{ff} by its ILUT factors. While diagonal dominance of A_{ff} is an important consideration in being able to find sparse, accurate ILUT factors, it is not the only requirement. Indeed, even if the graph of A_{ff} allows exact LU factors to be defined with no fill beyond its nonzeros, this can occur only if A_{ff} is appropriately ordered. As in sparse direct methods, then, the sparsity of the ILUT factors depends somewhat on the ordering of the A_{ff} block, and reordering this block may be an effective remedy if the ARMS algorithm performs well but has a high complexity.

In this section, experiments with several standard techniques for reordering the A_{ff} block within ARMS are given. As a baseline for comparison, we consider the order in which the F rows are selected by whatever selection procedure is used, as is used in the results of section 4. There are two possible ways to evaluate the success of these reorderings. If the same ILUT tolerances are used for both the ordered and unordered systems, we can compare the combination of the ARMS fill factor (or preconditioner complexity, defined as the total number of nonzeros stored in the ARMS preconditioner on all levels divided by the number of nonzero entries in A) and iteration counts for the resulting solvers. Of particular interest, of course, is the total time to solution, which is, in effect, the product of these two values when computer architecture considerations are neglected. Alternately, the tolerances used to form the ILUT factors could be adjusted so that the ARMS preconditioner complexity using reordering (approximately) matches that of the preconditioner without reordering. In this situation, the relative performance of the two preconditioners can easily be compared based solely on iteration counts, as each iteration has roughly the same cost for both preconditioners. Because of the number of problems and variety of approaches considered, only the first sort of comparison is used here.

Several common reordering techniques are considered. From the METIS tool-

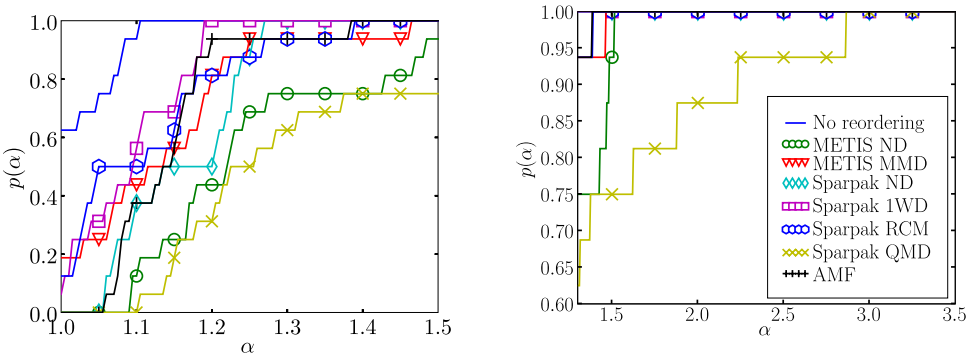

FIG. 5. *Performance profiles for total time to solution of the symmetric PDE based problems, using various reordering techniques with the single-stage nonsymmetric partitioning algorithm. Solution is taken to mean a reduction of the residual by a relative factor of* 10^6 *on all grids but* 1024×1024*, where a reduction by a relative factor of* 10^4 *is used. At right are profiles for* $\alpha \in [1.3, 3.5]$*; the detail at left shows* $\alpha \in [1.0, 1.5]$*; each reordering algorithm is denoted by the same line color and marker in both figures.*

kit [20], we consider the Nodal Nested Dissection and Multiple Minimum Degree orderings. From the SPARSPAK package [17], we consider both Nested and One-way Dissections, along with Reverse Cuthill–McKee and Quotient Minimum Degree reorderings. Finally, we consider the Approximate Minimum Fill technique of [1].

Adding these reorderings to the ARMS setup procedure requires very little change to the overall ARMS algorithm. The partitioning stage in ARMS already defines reorderings of the rows and columns of A (for any partitioning, and not just that described in Algorithm 3) and, implicitly, defines the fine-scale block, A_{ff}. The adjacency graph of A_{ff} is then extracted from that of A, symmetrized (nodes i and j are deemed to be adjacent if either $i \in \text{Adj}(j)$ or $j \in \text{Adj}(i)$), and passed to the reordering algorithm. The ordering computed here is then compounded with that from ARMS over the fine-grid rows and columns, after which the ARMS setup and iterations proceed as usual. In particular, no changes are needed to the partitioning algorithm itself other than the call to compute the reordering, and no changes are needed within the solve phase. The effects of reordering the A_{ff} block on a given level, however, compound on coarser scales; reordering the A_{ff} block affects both the sparsity and entries in the ILUT factors, which are then used to compute the approximate Schur complement on the coarse scale.

Performance profiles for the total time to solution (setup plus solve times) for the symmetric PDE based problems including reordering are shown in Figure 5. The plot at right shows the performance profile for $1.3 \leq \alpha \leq 3.5$, by which point all methods have $p(\alpha) = 1$. In general, the total times to solution using reordering are slightly larger than those without reordering, but almost all of the methods have total time within a factor of 1.5 of the fastest, as seen in the detail at left. Notice that while using the standard ARMS ordering is fastest for many problems, using the METIS Multiple Minimum Degree, Sparspak One-way Dissection, and Reverse Cuthill–McKee reorderings are each the fastest for some problems.

Results for iteration time and complexity are shown in Figure 6. For iteration time (at left), the performance curves are quite similar for all of the different methods. Using the standard ARMS ordering is fastest for only half of the problems, while the METIS Multiple Minimum Degree reordering results in the fastest solver for five

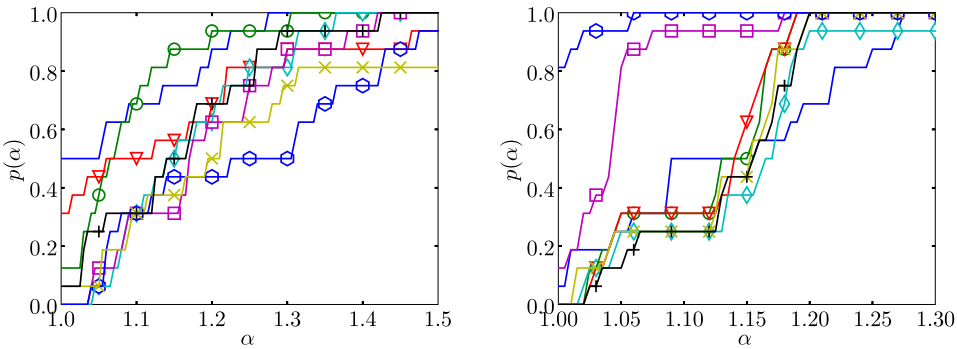

FIG. 6. *Performance profiles for solution time excluding setup (at left) and complexity (at right) for the symmetric PDE based problems, using various reordering techniques with the single-stage nonsymmetric partitioning algorithm. Solution is taken to mean a reduction of the residual by a relative factor of* 10^6 *on all grids but* 1024×1024*, where a reduction by a relative factor of* 10^4 *is used. Each reordering algorithm is denoted by the same line color and marker as in Figure* 5.

problems. Considering total time and iteration time separately distinguishes between solvers that have a slow overall time (as shown in Figure 5) because of the costs of the reordering stage and those that are slow because of some deficiency in the resulting preconditioner. In particular, note that the METIS ND reordering is one of the slowest in terms of total time to solution yet is among the fastest in iteration time. The added setup costs for this reordering obscure the actual performance gains in the solve phase.

On the right in Figure 6 are the performance profiles for preconditioner complexity, a measure of the memory requirements of the preconditioner itself. Overall, the effect of reordering is seen to be small (all preconditioner complexities are within 40% of the minima), but not trivially so. In the detail, we see that the Sparspak Reverse Cuthill–McKee and One-way Dissection algorithms are most effective in reducing the fill, but that all reorderings showed some benefit, in terms of lower complexity, over the original ordering by the ARMS process.

For the circuit and semiconductor problems, the single-stage partitioning scheme already results in low ARMS preconditioner complexities (below one for all but 10 of these problems and below one-half for 17 of them); very slight performance improvements can be expected from any of the reorderings considered. The SPARSPAK One-Way Dissection and Reverse Cuthill–McKee reorderings are most effective in terms of reducing total time to solution, and performance profiles for these two reorderings are shown in Figure 7. These results again highlight the importance of a fast reordering algorithm; nearly all preconditioner complexities are within 10% of the optimal approach for each problem, resulting in only a small possible savings in iteration time. The most effective approaches are those with low overhead in terms of setup costs.

The results in Figures 5, 6, and 7 suggest that there is little practical benefit in compounding the reordering produced by the ARMS partitioning algorithm with one of these techniques. Similar results are seen in [15], where reorderings for a single-level ILU preconditioner for the discrete Poisson problem were considered. Reordering in a multilevel procedure, such as ARMS, potentially has more significant consequences than in a single-level ILU or ILUT preconditioner, as the reordering and factors computed at one level affect choices made at coarser levels; however, no significant benefit

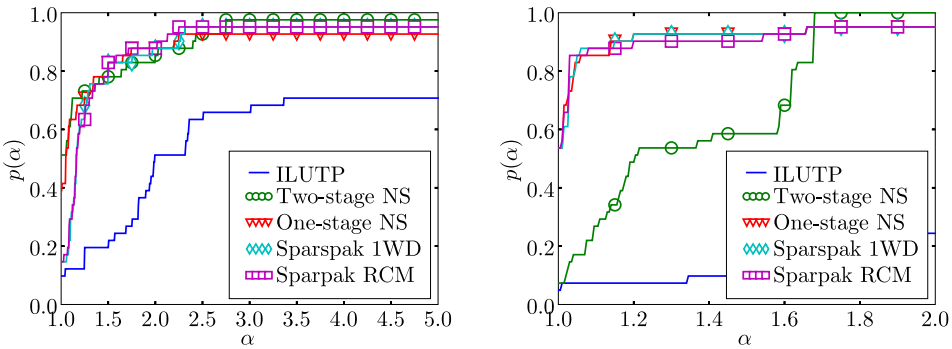

FIG. 7. *Performance profiles for total time to solution (left) and complexity (right) for the ILUTP-preconditioned GMRES and preconditioners using the nonsymmetric partitioning schemes for ARMS, possibly with reordering, on the circuit and semiconductor device simulation problems. Solution is taken to mean a reduction of the residual by a relative factor of* 10^6*, within* 1000 *iterations.*

(direct or indirect) was observed in our tests. In [5], it is observed that the benefit of reordering in incomplete factorizations depends on how far the matrix is from being symmetric and diagonally dominant. With our partitioning, the matrix A_{ff}, whose ILUT factors are computed, is always diagonally dominant, and thus our findings are consistent with those of [5].

6. Conclusions. We present a new greedy algorithm for partitioning matrices within a multilevel preconditioner such as ARMS. This algorithm combines the attractive features of two previous works, in that it is based on a direct greedy approach to finding the largest diagonally dominant A_{ff} block (as in [22]) but allows for nonsymmetric permutations, as these are known to be appropriate for problems with significant nonsymmetry in the operator [28]. We also demonstrate that further reordering of the fine-scale block of the partitioned system, in order to achieve a better approximation of this block by its ILUT factors while emphasizing sparsity, leads to little practical benefit because of the guarantee that our technique offers on the structure of this block.

The new partitioning approach generalizes the symmetric approach introduced previously but does not rely on relative diagonal dominance measures as a previous nonsymmetric partitioning approach does. The setup algorithm is somewhat more complicated than that of the two-stage approach, often resulting in longer times for the preconditioner construction, but generally giving preconditioners with lower complexities. In many cases, the improved performance of the preconditioner compensates for the added expense in forming it, but this is not always so. For problems where memory considerations are more important than total time, the new technique offers better complexity than previous approaches, without a significant impact on solver performance.

Appendix: Detailed implementation of Algorithm 3. The following is a detailed description of the implementation of the single-stage greedy coarsening algorithm sketched in Algorithm 3. These details are discussed in section 3.3.

ALGORITHM 4 (detailed single-stage greedy nonsymmetric partitioning algorithm).

1. Initialize $U_{\text{row}} = U_{\text{col}} = \{1, 2, \ldots, n\}$

2. Initialize $C_{\text{row}} = C_{\text{col}} = \emptyset$ and $F_{\text{row}} = F_{\text{col}} = \emptyset$
3. Compute A^T
4. For all $i \in U_{\text{row}}$,
   (a) Sort $\text{Adj}(i)$ by decreasing $|a_{ij}|$
   (b) Compute $k_i = \text{argmax}_{k \in U_{\text{col}}} |a_{ik}|$
   (c) Compute $l_i = \sum_{j \in F_{\text{col}} \cup U_{\text{col}}} |a_{ij}|$
   (d) Compute $r_i = \sum_{j \in F_{\text{col}}} |a_{ij}|$
   (e) If $a_{ik_i} = 0$, then $C_{\text{row}} = C_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$.
   (f) If $\frac{|a_{ik_i}|}{l_i} \geq \theta$, then make (i, k_i) a diagonal element of A_{ff}:
      i. Make i an F-row: $F_{\text{row}} = F_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$
      ii. Make k_i an F-column: $F_{\text{col}} = F_{\text{col}} \cup \{k_i\}$, $U_{\text{col}} = U_{\text{col}} \setminus \{k_i\}$
      iii. For $m \in U_{\text{row}} \cap \text{Adj}^T(k_i)$,
         - If k_m has already been defined and $k_m = k_i$,
           – Compute new $k_m = \text{argmax}_{k \in U_{\text{col}}} |a_{mk}|$
           – If $a_{mk_m} = 0$, then $C_{\text{row}} = C_{\text{row}} \cup \{m\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{m\}$
         - Update $r_m = r_m + |a_{mk_i}|$
         - If $\frac{|a_{mk_m}|}{r_m} < \theta$, then $C_{\text{row}} = C_{\text{row}} \cup \{m\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{m\}$
   (g) If $\frac{|a_{ik_i}|}{r_i} < \theta$, then $C_{\text{row}} = C_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$
5. For $j \in U_{\text{col}}$, compute $w_j = \sum_{i \in U_{\text{row}}} \frac{|a_{ij}|}{|a_{ik_i}|}$
6. While $U_{\text{col}} \neq \emptyset$ and $U_{\text{row}} \neq \emptyset$,
   (a) Let $j^\star \approx \text{argmax}_{j \in U_{\text{col}}} \{w_j\}$ and remove $j^\star$ from U_{col}: $C_{\text{col}} = C_{\text{col}} \cup \{j^\star\}$, $U_{\text{col}} = U_{\text{col}} \setminus \{j^\star\}$
   (b) For $i \in U_{\text{row}} \cap \text{Adj}^T(j^\star)$,
      i. Update $l_i = l_i - |a_{ij^\star}|$
      ii. If $k_i = j^\star$,
         A. Compute new $k_i = \text{argmax}_{k \in U_{\text{col}}} |a_{ik}|$
         B. If $a_{ik_i} = 0$, then make i a C-row: $C_{\text{row}} = C_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$
         C. If $a_{ik_i} \neq 0$ and $\frac{|a_{ik_i}|}{r_i} < \theta$, then,
            - For each $j \in U_{\text{col}} \cap \text{Adj}(i)$, update column weight, $w_j = w_j - \frac{|a_{ij}|}{|a_{ik_i^{\text{old}}}|}$
            - Make i a C-row: $C_{\text{row}} = C_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$
         D. If $a_{ik_i} \neq 0$ and $\frac{|a_{ik_i}|}{r_i} \geq \theta$, then, for $j \in U_{\text{col}} \cap \text{Adj}(i)$, update column weight,

$$w_j = w_j - \frac{|a_{ij}|}{|a_{ik_i^{\text{old}}}|} + \frac{|a_{ij}|}{|a_{ik_i^{\text{new}}}|}$$

      iii. If $i \in U_{\text{row}}$ and $\frac{|a_{ik_i}|}{l_i} \geq \theta$, then make (i, k_i) a diagonal element of A_{ff}:
         A. Make i an F-row: $F_{\text{row}} = F_{\text{row}} \cup \{i\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{i\}$
         B. Make k_i an F-column: $F_{\text{col}} = F_{\text{col}} \cup \{k_i\}$, $U_{\text{col}} = U_{\text{col}} \setminus \{k_i\}$
         C. For $j \in U_{\text{col}} \cap \text{Adj}(i)$, update column weight, $w_j = w_j - \frac{|a_{ij}|}{|a_{ik_i}|}$
         D. For $m \in U_{\text{row}} \cap \text{Adj}^T(k_i)$
            - If k_m has already been defined and $k_m = k_i$,
              – Compute new $k_m = \text{argmax}_{k \in U_{\text{col}}} |a_{mk}|$
              – If $a_{mk_m} = 0$, then make i a C-row: $C_{\text{row}} = C_{\text{row}} \cup \{m\}$,

$U_{\text{row}} = U_{\text{row}} \setminus \{m\}$
- If $a_{mk_m} \neq 0$, then for each $j \in U_{\text{col}} \cap \text{Adj}(m)$, update column weight,

$$w_j = w_j - \frac{|a_{ij}|}{|a_{ik_i^{\text{old}}}|} + \frac{|a_{ij}|}{|a_{ik_i^{\text{new}}}|}$$

- Update $r_m = r_m + |a_{mk_i}|$
- If $m \in U_{\text{row}}$ and $\frac{|a_{mk_m}|}{r_m} < \theta$,
  - Make m a C-row, $C_{\text{row}} = C_{\text{row}} \cup \{m\}$, $U_{\text{row}} = U_{\text{row}} \setminus \{m\}$.
  - For $j \in U_{\text{col}} \cap \text{Adj}(m)$, update column weight, $w_j = w_j - \frac{|a_{mj}|}{|a_{mk_m}|}$

7. $C_{\text{row}} = C_{\text{row}} \cup U_{\text{row}}$
8. $C_{\text{col}} = C_{\text{col}} \cup U_{\text{col}}$

EXTENSIONS OF CERTAIN GRAPH-BASED ALGORITHMS FOR PRECONDITIONING*

DAVID FRITZSCHE†, ANDREAS FROMMER‡, AND DANIEL B. SZYLD†

Abstract. The original TPABLO algorithms are a collection of algorithms which compute a symmetric permutation of a linear system such that the permuted system has a relatively full block diagonal with relatively large nonzero entries. This block diagonal can then be used as a preconditioner. We propose and analyze three extensions of this approach: We incorporate a nonsymmetric permutation to obtain a large diagonal, we use a more general parametrization for TPABLO, and we use a block Gauss–Seidel preconditioner which can be implemented to have the same execution time as the corresponding block Jacobi preconditioner. Experiments are presented showing that for certain classes of matrices, the block Gauss–Seidel preconditioner used with the system permuted with the new algorithm can outperform the best ILUT preconditioners in a large set of experiments.

Key words. block partitioning, PABLO, TPABLO, preconditioning, block Gauss–Seidel, ILU decomposition

1. Introduction.

We consider a nonsingular linear system

$$Ax = b,\ A \in \mathbb{R}^{n\times n},\ x, b \in \mathbb{R}^n, \tag{1.1}$$

with n large and A sparse. We do not assume A to be symmetric. Direct methods, based on Gaussian elimination, have reached a mature state for this general system; see, e.g., [18], [19], [22]. They may, however, suffer from severe fill-in so that memory resources may become insufficient and/or execution times may become too large.

Modern iterative methods for the solution of (1.1) work best with a good preconditioner, and at each step, the basic operation is usually one matrix-vector multiplication with A and one application of the preconditioner. A good preconditioner contains as much information about the matrix A as possible. Incomplete factorizations of A (ILU preconditioners) have proven to work well in many cases [4].

The PABLO (parametrized block ordering) and TPABLO (threshold PABLO) approaches to preconditioning proceed in the following manner: a permutation matrix $P \in \mathbb{R}^{n\times n}$ is computed such that the permuted matrix $\widehat{A} = PAP^T$ has a (relatively) dense block diagonal; see [5], [13], [14], [30]. Block sizes are determined dynamically. In the simplest case the preconditioner is taken as the block diagonal $\widehat{D}$ with respect to these blocks; i.e., one solves the permuted system

$$\widehat{A}\widehat{x} = \widehat{b}, \quad \text{where} \quad \widehat{A} = PAP^T,\ \widehat{x} = Px,\ \text{and}\ \widehat{b} = Pb,$$

iteratively using GMRES (or some other Krylov subspace method) with preconditioner $\widehat{D}$; see, e.g., [29], [34], [36] for their description. To solve the preconditioning

system $\widehat{D}s = r$, a (complete) LU decomposition $\widehat{D} = \widehat{L}\,\widehat{U}$ is computed. Since this reduces to an LU decomposition on each of the diagonal blocks, we can use readily available packages. For small and dense blocks we use level 3 BLAS-based LAPACK [2] routines and for large and sparse blocks we use UMFPACK [16]. Moreover, the LU decomposition of $\widehat{D}$ could be done in parallel.

Whereas PABLO determines the blocks for $\widehat{D}$ by just using structural information of A given through its associated directed graph, the TPABLO variants also take the numerical values in A into account.

In the present paper, which builds upon [28], we propose three extensions of the PABLO and TPABLO preconditioners. First, we apply a nonsymmetric permutation to put large entries on the diagonal. We discuss this in section 2. In section 3 we introduce new parametrizations to be used with PABLO and TPABLO. We describe the resulting algorithmic framework, termed XPABLO, in detail and analyze its computational complexity. In other words XPABLO is more general, it includes new different criteria to produce the blocking permutation, and it reduces to the previous versions for specific parametrizations. In section 4 we discuss how one can use either the lower or the upper block triangular part of the matrix as a preconditioner at the same cost as the block diagonal preconditioner.

After reviewing several practical issues related to the implementation in section 5, we finally give results of numerical experiments in section 6, including a comparison with ILU preconditioning. In section 7, we present some concluding remarks and an outlook to further development.

In addition to the references already mentioned, several authors have explored reorderings and partitioning techniques to improve the robustness and performance of different types of preconditioners. Among them, we cite [6], [7], [8], [9], [24]; see also the sections on the effect of orderings in the survey [4].

We conclude this introduction by noting that PABLO variants have been applied successfully in the construction of preconditioners in settings that are different from the one presented in this paper. A slightly modified version of PABLO has been used successfully in a parallel computing setting to build block diagonal preconditioners for difficult problems in computational fluid dynamics (CFD) and chemical engineering; see, e.g., [23]. The threshold variants TPABLO and XPABLO can be used as a method to find blocks with large entries in dense or sparse matrices. Specifically, in [26] and [27], XPABLO is used to find such blocks to build preconditioners for the CSYM method [12] for solving systems with complex symmetric matrices. The situation there is that an efficient preconditioner has to be factorized into its complex symmetric singular value decomposition, so that block diagonal preconditioners seem to be the only practical way. In the examples presented in [26] the iteration count is reduced by up to 30% when using this approach.

2. Nonsymmetric permutations and diagonal scalings. Let σ be the permutation associated with the permutation matrix $Q \in \mathbb{R}^{n\times n}$; i.e., for all $x \in \mathbb{R}^n$

$$(Qx)_i = x_{\sigma(i)}, \quad i = 1, \ldots, n.$$

A [illegible] of the nonsingular matrix $A \in \mathbb{R}^{n\times n}$ is any permutation σ for which

$$(QA)_{ii} = a_{\sigma(i),i} \neq 0, \quad i = 1, \ldots, n.$$

A maximum transversal exists for the class of structurally nonsingular matrices which contains the class of nonsingular matrices; see, e.g., [19]. In [20], two different types of

transversals with respect to different notions of a "weight" were introduced according to the following definition.

DEFINITION 2.1. [illegible] σ

(i) [illegible] bottleneck transversal [illegible]

$$\min_{i=1,\ldots,n} |a_{\sigma(i),i}|$$

(ii) [illegible] maximum product transversal [illegible]

$$\prod_{i=1}^{n} |a_{\sigma(i),i}|$$

The paper [20] proposes and analyzes various algorithms to compute bottleneck transversals. Extensive testing shows that in practice the computational complexity of these algorithms is reported to behave like $\mathcal{O}(n+nz)$, where nz is the total number of nonzeros in the matrix, although the theoretical worst case upper bound may be much larger. Algorithms for computing bottleneck and maximum product transversals have been incorporated in the HSL-library as algorithm MC64; see [20], [21] for their description. As a by-product, when computing a maximum product transversal, MC64 also delivers diagonal scaling matrices $\hat{C}$ and $\hat{R}$ such that

$$\hat{A} = Q(\hat{R}A\hat{C}) \tag{2.1}$$

is an I-matrix; i.e., $|\hat{A}_{ij}| \leq 1$ for all i, j and $\hat{A}_{ii} = 1$, $i = 1, \ldots, n$.

The rationale for these different approaches to obtaining diagonals with large weight is heuristic: Large diagonals tend to decrease the need for pivoting in a direct elimination method. ILU-type preconditioners can also benefit greatly [6], [35]. Moreover, an iterative method with diagonal preconditioner may be expected to converge more rapidly if the diagonal is large compared to the off-diagonal part of the matrix.

In this paper, we use maximum product transversals and we always apply the scaling computed by MC64; i.e., we always transform A to an I-matrix. For our test problems in section 6 this always gave us better results than using the usually cheaper bottleneck transversal.

3. XPABLO: An extension of PABLO and TPABLO. PABLO, TPABLO, and XPABLO compute a (symmetric) permutation for A, and a block partition of it, based on information of the (directed) graph of A and the size of the entries of A. Let us quickly recall that the directed graph or digraph $G(A) = (V, E)$ associated with A is given as

$$V = \{1, \ldots, n\}, \quad E = \{(i, j) : a_{ij} \neq 0\}.$$

Let $nz = |E|$, the cardinality of E. Using a somewhat nonstandard terminology, we say that vertex $i \in V$ is [illegible] with edge $e = (k, \ell)$ if $i = k$ or $i = \ell$. This terminology makes no distinction between the starting point k and the end point ℓ of the edge e. The two vertices k and ℓ incident to (k, ℓ) are called [illegible]. Given a set of vertices $W \subseteq V$, the adjacency set $\mathrm{adj}(W)$ contains all vertices which are not in W but which are adjacent to a vertex in W; i.e.,

$$\mathrm{adj}(W) = \big\{j \in V : j \notin W \text{ and } j \text{ is adjacent to some } i \in W\big\}.$$

To describe the PABLO algorithms, we need additional notation for subgraphs. If $G = (V, E)$ and $V' \subseteq V$, the induced subdigraph $G|_{V'}$ is $G' = (V', E')$ with $E' = \{(i, j) \in E : i, j \in V'\}$. Frequently, we use quantities that refer to an induced subdigraph $G' = G|_{V'}$. We indicate this using the [illegible] $|_{V'}$. For example, $\mathrm{adj}|_{V'}(W)$ refers to the adjacency set in the subdigraph induced by V'. We write $|E|_{V'}$ to denote the cardinality of E'.

PABLO, TPABLO, and XPABLO produce a partitioning of V into m disjoint, nonempty subsets V_κ, $\kappa = 1, \ldots, m$ (the "blocks"). These blocks are built one at a time. We now describe how this is done, assuming the following situation: Blocks $V_1, \ldots, V_{\nu-1}$ have already been built. Given the current block V_ν and a candidate vertex $i \in \mathrm{adj}|_{\overline{V}}(V_\nu)$ with $\overline{V} = V \setminus \bigcup_{\kappa=1}^{\nu-1} V_\kappa$, the algorithms decide whether or not to incorporate i into the current block using a criterion τ. The following definitions describe some basic criteria. They can be combined logically to yield a variety of different criteria, including, as we shall see, the traditional PABLO and TPABLO criteria. Algorithm 1 toward the end of the section shows how candidate vertices are selected; see also [30].

DEFINITION 3.1. [illegible] $G = (V, E)$ [illegible] $V' \subseteq V$ [illegible] $G' = (V', E')$ [illegible] fullness $\varphi(V')$ [illegible] V' [illegible]

$$\varphi(V') = \begin{cases} \dfrac{|E'|}{|V'|^2 - |V'|} & \text{if } |V'| > 1, \\ 0 & \text{if } |V'| \leq 1. \end{cases}$$

The fullness thus defined measures the number of edges in G' compared to the maximally possible number $|V'|^2 - |V'|$ for a complete digraph. The definition of $\varphi(\{v\}) = 0$ follows PABLO in the interpretation that a graph with only one vertex is empty, but other definitions may be useful depending on the problems one needs to solve.

Given $\alpha > 0$, in our generic situation, we say (see [30]) that vertex i satisfies the [illegible] (with fullness parameter α) if

$$\varphi(V_\nu \cup \{i\}) \geq \alpha \varphi(V_\nu). \tag{FC}$$

Note that (FC) can be fulfilled even when $\alpha > 1$.

DEFINITION 3.2. [illegible] degree $\deg(i)$ [illegible] i [illegible] $G = (V, E)$ [illegible] [illegible] i

$$\deg(i) = \big|\{e \in E : i \text{ [illegible] } e\}\big|.$$

[illegible] $V' \subseteq V$ [illegible] $\deg|_{V'}(i)$ [illegible] $\deg(i)$ [illegible] $V' \cup \{i\}$

DEFINITION 3.3. [illegible] i [illegible] $G = (V, E)$ [illegible] $\deg(i) > 0$ [illegible] $V' \subseteq V$ [illegible] connectivity [illegible] i [illegible] V' [illegible]

$$\frac{\deg|_{V'}(i)}{\deg(i)}.$$

In our generic situation, given $\beta > 0$, we say that vertex i satisfies the [illegible] (with connectivity parameter β) if

$$\deg|_{V_\nu}(i) \geq \beta \deg|_{\overline{V}}(i). \tag{CC}$$

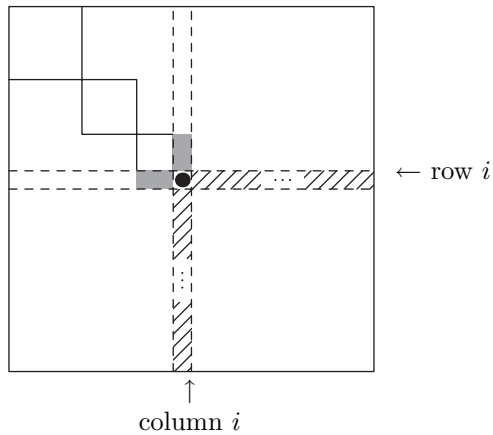

FIG. 3.1. *Illustration of the fullness criterion (FC) and the connectivity criterion (CC).*

The connectivity criterion means that in $G|_{\overline{V}}$ at least a fraction β of all edges incident with i have their other incident vertex in V_ν. The criterion is never met if $\beta > 1$ (and $\deg(i) > 0$).

Figure 3.1 illustrates the fullness and the connectivity criterion for the digraph $G(A)$ in terms of the pattern of the matrix A. The matrix is assumed to be already symmetrically permuted such that the blocks built up so far (there are three such blocks) appear first. The black diagonal entry corresponds to the candidate vertex to be included into the third block. The fullness criterion requires that the grey parts of row i and column i must not be too empty. The connectivity criterion means that the hatched parts of these rows and columns should not contain too many elements as compared to the grey parts. Row and column i are considered only together—not individually. The white parts of row i and column i are not taken into consideration when deciding on vertex i.

The PABLO algorithm of [30] adds a candidate vertex $i \in \mathrm{adj}|_{\overline{V}}(V_\nu)$ to the current block V_ν if and only if v satisfies the fullness , the connectivity criterion for some prechosen parameters α and β. We formulate this by saying that PABLO uses the criterion τ defined as

$$\tau = \mathrm{FC} \vee \mathrm{CC}. \tag{PABLO}$$

This combined PABLO criterion uses only structural information of A.

In its threshold counterparts TPABLO1 and TPABLO2 (see [5], [13]), numerical values of the matrix entries are also taken into account. For a precise statement, and also to formulate our generalization XPABLO, we introduce additional notation and terminology. From now on we consider the digraph $G(A)$ as an edge-weighted digraph where edge $e = (i, j)$ has weight $w(e) = |a_{ij}|$.

DEFINITION 3.4. , $A \in \mathbb{R}^{n\times n}$, $\gamma > 0$, $A^{>\gamma} \in \mathbb{R}^{n\times n}$,

$$(A^{>\gamma})_{ij} = \begin{cases} a_{ij} & , |a_{ij}| > \gamma, \\ 0 & , \end{cases}$$

We use the superscript notation $^{>\gamma}$ in an intuitive manner at various places. For example, if $G = G(A)$ is the digraph of A, then $G^{>\gamma} = G(A^{>\gamma})$. Another example is the following definition.

DEFINITION 3.5. [illegible] $G = (V, E)$ [illegible] $V' \subseteq V$ [illegible] $\gamma \geq 0$ [illegible] threshold fullness $\varphi^{>\gamma}(V')$ [illegible] V' [illegible] $\varphi(V')$ [illegible] V' [illegible] $G^{>\gamma}$

In our generic situation, given a threshold parameter $\gamma > 0$ and a threshold fullness parameter $\theta \in [0, 1]$, we say that i satisfies the [illegible] if

$$\varphi^{>\gamma}(V_\nu \cup \{i\}) \geq \theta. \tag{TFC}$$

In contrast to the plain fullness criterion, the threshold fullness criterion just measures the fullness the new block $V_\nu \cup \{i\}$ has in $A^{>\gamma}$ without relating it to the fullness of V_ν.

DEFINITION 3.6. [illegible] $G = (V, E)$ [illegible] $V' \subseteq V$ [illegible] $\gamma \geq 0$ [illegible] i [illegible] $\deg|_{V'}(i) > 0$ [illegible] threshold connectivity [illegible] i [illegible] V' [illegible]

$$\frac{\deg|^{>\gamma}_{V'}(i)}{\deg|_{V'}(i)}.$$

Threshold connectivity compares the number of heavy edges of i in $G|_{V'}$ to all such edges. As opposed to plain connectivity according to Definition 3.3, it does not consider any edges going to nodes outside V'.

In our generic situation, given a threshold connectivity parameter ζ, we say that the [illegible] holds if

$$\deg|^{>\gamma}_{V_\nu}(i) \geq \zeta \deg|_{V_\nu}(i). \tag{TCC}$$

This criterion measures how many of the new entries of the current block are large. A useful choice for the threshold connectivity parameter is $\zeta = 1/2n$. For this value of ζ the right-hand side of (TCC) is always strictly less than one since $\deg|_{V_\nu}(i) < 2n$ for all $i \in V$. Hence the threshold connectivity criterion holds if and only if $\deg|^{>\gamma}_{V_\nu}(i) \geq 1$.

In addition to the threshold parameter γ, XPABLO also accepts an additional threshold parameter δ, which is used to filter out nonzero matrix entries with very small magnitude, both from the graph $G(A)$ and from the threshold graph $G(A^{>\gamma})$; i.e., XPABLO really works on the graphs $G(A^{>\delta})$ and $G(A^{>\max(\gamma,\delta)})$. So we have $0 \leq \delta < \gamma$ in any useful application. Note that δ changes only the graphs on which XPABLO is operating and not the underlying matrix.

We now have four criteria at hand upon which we can decide whether to include a new vertex to a current block or not. These criteria can be logically combined resulting in various XPABLO criteria, denoted by τ. The following list shows how XPABLO is reduced to PABLO or TPABLO by choosing a specific criterion τ and specific values for some of the parameters.

1. With $\tau = \text{FC} \vee \text{CC}$, XPABLO is equivalent to PABLO.
2. With $\tau = (\text{FC} \vee \text{CC}) \wedge \text{TCC}$ and $\zeta = 1/(2n)$, XPABLO is equivalent to TPBALO1.
3. With $\tau = (\text{FC} \vee \text{CC}) \wedge \text{TFC}$ and $\theta = 1$, XPABLO is equivalent to TPABLO2.

The default criterion for XPABLO is $\tau = \text{FC} \vee \text{CC} \vee \text{TCC}$ with $\zeta = 1/(2n)$; see section 5.2 for a more detailed discussion of XPABLO default parameters.

Once XPABLO has determined a partitioning of V into blocks $V_1, \ldots, V_m$, let π be a permutation that groups the vertices $1, \ldots, n$, from V into these blocks; i.e., $V_1 = \{\pi(1), \ldots, \pi(k_1)\}$, $V_2 = \{\pi(k_1 + 1), \ldots, \pi(k_2)\}, \ldots, V_m = \{\pi(k_{m-1} + 1), \ldots, \pi(k_m)\}$, with $k_j = \sum_{i=1}^{j} |V_j|$. Then the permuted matrix PAP^T is naturally partitioned

input: a digraph $G(A) = (V, E)$ and a criterion τ
output: a partitioning $\{V_1, \ldots, V_m\}$ of V
set $C := V$, $Q := \emptyset$, $B := \emptyset$ and set $\kappa := 1$
set $\deg|_B(i) := 0$ and $\deg|_B^{>\gamma}(i) := 0$ for all $i \in V$
while $C \neq \emptyset$ **do**
  remove a vertex i from C, and place it in B
  set $|E|_B := 0$, $|E|_B^{>\gamma} := 0$, $\varphi(B) := 0$, $\varphi^{>\gamma}(B) := 0$
  for all vertices j adjacent to i **do**
    move j from C to Q if $j \in C$
    $\deg|_B(j) := \deg|_B(j) + \mathrm{mult}(i, j)$
    $\deg|_B^{>\gamma}(j) := \deg|_B^{>\gamma}(j) + \mathrm{mult}^{>\gamma}(i, j)$
  end for
  while $Q \neq \emptyset$ **do**
    remove a vertex i from Q
    if i fulfills the XPABLO criterion τ **then**
      insert i into B
      set $|E|_B := |E|_B + \deg|_B(i)$
      set $|E|_B^{>\gamma} := |E|_B^{>\gamma} + \deg|_B^{>\gamma}(i)$
      update $\varphi(B)$ and $\varphi^{>\gamma}(B)$ {this requires $|E|_B$ and $|E|_B^{>\gamma}$}
      for all vertices j adjacent to i **do**
        move j from C to Q if $j \in C$
        $\deg|_B(j) := \deg|_B(j) + \mathrm{mult}(i, j)$
        $\deg|_B^{>\gamma}(j) := \deg|_B^{>\gamma}(j) + \mathrm{mult}^{>\gamma}(i, j)$

ALGORITHM 1. *XPABLO with criterion τ based on (CC), (FC), (TCC), and (TFC).*

into m blocks of size $|V_j|$, the jth diagonal block corresponding to the vertex set V_j. The threshold criteria may now be interpreted as placing large entries on these diagonal blocks. This is made more precise in the following proposition which follows immediately upon inspection of the various criteria.

PROPOSITION 3.7.

1. $\tau = (_ \vee _) \vee$ $\zeta = 1/(2n)$ PAP^T γ
2. $\tau = (_ \vee _) \wedge$ $\zeta = 1$ PAP^T $\geq \gamma$

Algorithm 1 now describes the XPABLO algorithm in more detail. It uses three data structures C, Q, and B to manage the vertices. The set B denotes the current block being built. During the algorithm, quantities needed for τ, such as $\deg|_{V'}(i)$, $\deg|_{V'}^{>\gamma}(i)$, etc., are always updated immediately. The notation $\mathrm{mult}(i, j)$ ($\in \{0, 1, 2\}$) for two nodes i, j refers to the number of directed edges between i and j.

The time complexity of Algorithm 1 is given in the following result.

PROPOSITION 3.8. $\mathcal{O}(n + |E|)$ τ $\mathcal{O}(1)$

We assume that $G = G(A)$ is given stored in an adjacency list representation including the values for $\mathrm{mult}(i,j)$; see, e.g., [19]. Note that for the common sparse matrix formats $G(A)$ can be obtained with cost $\mathcal{O}(n+|E|)$.

Scanning the adjacency list representation, we build up $G^{>\gamma}$ and $\mathrm{mult}^{>\gamma}(i,j)$ with complexity $\mathcal{O}(|E|)$. Taking Q as a queue, C as a doubly linked list with an external index, and B as a singly linked list, all insert and remove operations we use with these lists as well as their flushing can be done with cost $\mathcal{O}(1)$. As was already shown in [30], the entire PABLO algorithm has then complexity $\mathcal{O}(n+|E|)$. The main observation to obtain this result is to realize that each node i is inserted into Q at most $\deg(i)$ times.

By assumption, the cost for testing criterion τ is $\mathcal{O}(1)$ as it is in PABLO. Therefore, the additional work in XPABLO as compared to PABLO is that we have to update the new quantities $|E|_B^{>\gamma}$, $\varphi^{>\gamma}(B)$, and $\deg|_B^{>\gamma}$ used in (TCC) and (TFC). These updates follow the ones to be done for $|E|_B$, $\varphi(B)$, and $\deg|_B$ by PABLO. In total, this means $\mathcal{O}(n)$ extra operations to update $|E|_B^{>\gamma}$ and $\varphi^{>\gamma}(B)$ and $\mathcal{O}(|E|)$ extra operations to update $\deg|_B^{>\gamma}$. So this is an additional cost of $\mathcal{O}(n+|E|)$, which establishes the proposition. ∎

Let us note that in our practical implementations we indeed build up $G^{>\gamma}$ explicitly. This is in contrast to the implementation of TPABLO in [13]. As is explained in [13], the implementation there is not more than d times as costly as PABLO when d is the maximum degree in G. We prefer to build up $G^{>\gamma}$ explicitly, since then TPABLO requires only about twice the work that PABLO does, so that our implementation is in most cases faster than that in [13].

We defer a detailed discussion on how to choose an XPABLO criterion τ and the various parameters (α, β, γ, θ, ζ) to the sections on practical issues and on numerical results (sections 5 and 6).

4. Efficient block Gauss–Seidel preconditioning. Let A denote the matrix obtained after the preprocessing steps and after applying the XPABLO permutation P of section 3, i.e., $A \leftarrow PQ(RAC)P^T$. Then A has a block structure

$$A = \begin{bmatrix} A_{11} & \cdots & A_{1m} \\ \vdots & \ddots & \vdots \\ A_{m1} & \cdots & A_{mm} \end{bmatrix}, \qquad A_{ij} \in \mathbb{R}^{n_i \times n_j},$$

with $n_i = |V_i|$ being the size of the blocks corresponding to the XPABLO permutation P. Each diagonal block $D_i = A_{ii}$ in the block diagonal $D = \mathrm{diag}(D_1, \ldots, D_m)$ should be (relatively) full and should have (relatively) large nonzero entries. Even with A nonsingular, some of the diagonal blocks D_i can be singular; see section 5.1 for a discussion of this issue. For the moment we assume all D_i to be nonsingular.

We can compute the (row pivoted) LU factorization $D_i = \Pi_i L_i' U_i'$ for each block, so that $D = \Pi\, L'\, U'$, $\Pi = \mathrm{diag}(\Pi_i)$, $L' = \mathrm{diag}(L_i')$, and $U' = \mathrm{diag}(U_i')$, and we use this LU factorization of D when it comes to solving linear systems of the form

$$Ds = r$$

in a preconditioned iterative method with preconditioner D. This block diagonal preconditioning approach (with PABLO, TPABLO1, and TPABLO2) was used in [14], where the numerical results were quite encouraging. Note that when the diagonal block D_i is dense, we can use the optimized dense matrix linear algebra code from

LAPACK to perform these factorizations very efficiently [2]. When they are sparse, a sparse factorization is performed; we use the package UMFPACK [16].

An obvious extension of this idea is to use block Gauss–Seidel preconditioning, i.e., to include a block triangular part of A into the preconditioner. In the following discussion we will use the lower block triangular part, i.e., a forward block Gauss–Seidel iteration, as the preconditioner. It is easy to see that Proposition 4.1 below also holds when the preconditioner M is the upper block triangular part of A.

Note that block Gauss–Seidel iteration without acceleration by a Krylov subspace method was used in the original PABLO paper [30]. Using the established block structure the block Gauss–Seidel preconditioner M can be written as

$$M = \begin{bmatrix} D_1 & 0 & \cdots & 0 \\ A_{21} & D_2 & & \vdots \\ \vdots & & \ddots & 0 \\ A_{m1} & A_{m2} & \cdots & D_m \end{bmatrix}. \tag{4.1}$$

The usual interfaces for (left) preconditioned sparse iterative solvers separate the operation $z = M^{-1}Ax$ into a matrix-vector multiplication $y = Ax$ and a solve operation $z = M^{-1}y$. Viewed in this way, computing $M^{-1}Ax$ seems to be much more expensive than computing $D^{-1}Ax$. But it is not more expensive at all if we do not separate the operations, as we show in the next result. This result is basically a form of the well-known Eisenstat trick [25], [31], [32, pp. 208, 225]. Using this trick, we could also implement efficient block SOR preconditioners, but this is not pursued in this paper.

PROPOSITION 4.1. [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $m \times m$ [illegible] $D_i = A_{ii}$ $i = 1, \ldots, m$ [illegible] $D = \operatorname{diag}(D_i)$ [illegible] M [illegible] A [illegible] $D^{-1}Ax$ [illegible] $M^{-1}Ax$ [illegible]. Let $z = M^{-1}Ax$ and $\tilde{z} = D^{-1}Ax$. For any vector $w \in \mathbb{R}^n$ we write w_i to denote the ith block, conformal with the block structure of A. We split A as $A = D - L - U$ into the block diagonal part $D = \operatorname{diag}(D_i)$ (same as before), the block lower triangular part L with $L_{ij} = -A_{ij}$ for $i > j$, and the block upper triangular part U with $U_{ij} = -A_{ij}$ for $i < j$. Both L and U have a zero block diagonal.

Using this notation the block triangular preconditioner is $M = D - L$, and we can rewrite the preconditioned matrix-vector multiplication as

$$\begin{aligned} M^{-1}Ax &= (D-L)^{-1}(D-L-U)x \\ &= (D-L)^{-1}(D-L)x - (D-L)^{-1}Ux \\ &= x - (D-L)^{-1}Ux. \end{aligned}$$

If we set $y = Ux$ and $v = (D-L)^{-1}y$, we get $z_i = x_i - v_i$, $i = 1, \ldots, m$, where

$$v_i = D_i^{-1}\left(y_i + \sum_{j=1}^{i-1} L_{ij}v_j\right) \qquad \text{and} \qquad y_i = \sum_{j=i+1}^{m} U_{ij}x_j.$$

We can further simplify the formula for v_i to

$$v_i = -D_i^{-1}\left(\sum_{j=1}^{i-1} A_{ij}v_j + \sum_{j=i+1}^{m} A_{ij}x_j\right). \tag{4.2}$$

Following the same procedure, we write $\tilde{z} = D^{-1}Ax = x - \tilde{v}$ and get $\tilde{z}_i = x_i - \tilde{v}_i$, where

$$\tilde{v}_i = -D_i^{-1}\left(\sum_{j=1}^{i-1} A_{ij}x_j + \sum_{j=i+1}^{m} A_{ij}x_j\right). \tag{4.3}$$

But the computations (4.2) and (4.3) use the exact same number of operations if we assume that dense vectors are used. ∎

5. Practical issues. Before reporting on our numerical experiments, we address some practical issues when using XPABLO in a preconditioning framework. We concentrate on the two main issues, namely, numerical stability and the choice of a good set of values for all the different XPABLO parameters.

5.1. Robustness. We consider the issue of numerical instability (or even the singularity) of the diagonal blocks D_ν in the block triangular preconditioner M. If A is a general nonsingular matrix, there is no guarantee that all the blocks D_i are nonsingular, nor that M is nonsingular. We mention that difficulties with singular blocks were very rare in our numerical experiments using the recommended parameters, as described in section 5.2. Problems with singular and nearly singular blocks are handled as follows: If a diagonal block D_ν happens to be singular or numerically singular, i.e., if the numerical factorization fails, we modify the diagonal entries such that the block becomes diagonal dominant.

The problems described cannot occur for the class of H-matrices. Recall that a matrix A is termed an H-matrix if there exist weights u_j, $j = 1, \ldots, n$, $u_j > 0$ such that for all $j = 1, \ldots, n$

$$|a_{ii}| \cdot u_i > \sum_{\substack{j=1,\ldots,n \\ j \neq i}} |a_{ij}| \cdot u_j.$$

The class of H-matrices contains the class of M-matrices, and they arise, e.g., in certain discretizations of (elliptic) boundary value problems; see, e.g., [10]. We have the following result.

PROPOSITION 5.1. [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] H [illegible] A [illegible] M [illegible] (4.1) [illegible] D_ν [illegible] $\nu = 1, \ldots, m$ [illegible]. Assume first that A is an H-matrix. Then M is also an H-matrix (with the same weights u_j as for A). Therefore, the diagonal blocks D_ν of M are H-matrices as well and they are thus nonsingular. Moreover, their LU factorizations can be performed without pivoting; see, e.g., [1].

If A is symmetric positive definite, each of the blocks D_ν, which are principal submatrices of A, are symmetric positive definite as well. In particular, they are all nonsingular and they admit a Cholesky factorization and an LU factorization without pivoting. ∎

In view of the maximum transversal transformation $A \to Q(RAC)$ and the two-sided XPABLO permutation $A \to PAP^T$, it is important to notice that the H-matrix property, symmetry, and positive definiteness are preserved under the XPABLO permutation. In general, however, these properties will not be conserved under the transversal transformation, although the I-matrix scaling of MC64 will have a tendency to preserve the H-matrix property.

TABLE 5.1
Recommended XPABLO criterion τ and parameter values for block Jacobi and block Gauss–Seidel preconditioning.

Preconditioner	τ	α	β	γ	δ	ζ
Block Jacobi	FC $\vee$ CC $\vee$ TCC	1.1	0.6	$\frac{\sum \lvert a_{ij} \rvert}{nz}$	0.05	$1/(2n)$
Block Gauss–Seidel	FC $\vee$ TCC		–			

5.2. Choosing parameters. We also have to consider carefully the choice of the XPABLO parameters and the actual criterion τ. A first important point in practice is that of fixing a maximum block size in Algorithm 1. Indeed, it may happen that with the criteria and the parameters in use, the algorithm would produce only one block, the whole matrix, and this is clearly not useful. We therefore fix a maximum block size, and we modify Algorithm 1 so that it closes the current block B as soon as it reaches this maximum size. We often also fix a minimum block size. This block size is achieved by merging adjacent blocks which are too small. Note that we do not merge blocks if we would exceed the maximum block size, even if we retain small blocks. For block Jacobi or block Gauss–Seidel preconditioning we recommend setting the minimum block size to 200 and the maximum block size to 1000.

The next, very crucial, issue is that of finding adequate parameters and a suitable XPABLO criterion τ. Good parameters for each given matrix could be found by trying a variety of different parameter settings and then choosing the best one (with respect to the resources being used, time, and storage). Of course, this is too costly in practice. We performed a long series of computations on many test problems, and we can give suggested values for most of the parameters resulting in run times of the preconditioned iterative methods which are quite close to the individually best ones. The suggested choices for both block Jacobi and block Gauss–Seidel preconditioning are presented in Table 5.1. If these recommendations are used, the only difference between XPABLO and TPABLO1 is a small change in τ. XPABLO has $\tau =$ FC $\vee$ CC $\vee$ TCC and TPABLO1 has $\tau =$ (FC $\vee$ CC) $\wedge$ TCC. Nevertheless, in almost all cases XPABLO is clearly to be preferred compared to TPABLO1.

As a last issue, we further discuss our choice for γ, the threshold parameter used in (TCC) and (TFC). Of all the parameter recommendations, the one for γ is the weakest in the sense that it is the most likely candidate for not being a good choice for a particular problem. Therefore, we present a different recommendation, which also gives good overall results and for some problems even better results than the default choice. After having scaled (and permuted) the matrix according to (2.1), it seems reasonable to use γ as a "percentage" parameter; i.e., we chose γ such that a given fraction $\gamma' \in [0, 1]$ of the nonzero elements are dropped when passing from A to $A^{>\gamma}$. Since we know the number $|E|$ of nonzeros in A, finding the corresponding γ is an instance of the k[illegible] : γ is the value of the kth largest element of A with $k = \lfloor \gamma' |E| \rfloor$. Note that the kth largest element problem can be solved with linear complexity; i.e., its cost is $\mathcal{O}(|E|)$; see, e.g., [15]. In practical computations, finding the average of the magnitude of the nonzeros is much simpler and faster.

6. Numerical experiments. In this section we present numerical results using XPABLO as a tool for preconditioning. We start by showing the improvements of XPABLO over PABLO and TPABLO, and then provide a detailed comparison of XPABLO and ILUT as a tool for preconditioning. All experiments were run on an Intel Core 2 processor. The test programs are written in C, C++, and Fortran and were compiled using the GNU Compiler Collection (GCC). Identical optimization

flags were used in all cases. This allows us to compare the execution times and not only the iteration counts. The test matrices are from the University of Florida Sparse Matrix collection [17]. Some basic properties of our test matrices are summarized in Table 6.1. For most matrices we use the provided right-hand side b. If no right-hand side is provided, we use $b := Ae$, where $e = (1, \ldots, 1)^T$ is the vector of all ones.

Preliminary tests had shown that the XPABLO framework can perform well for problems stemming from CFD and semiconductor device simulation. Therefore, the test matrices were specifically chosen from these application areas. In Table 6.1 the matrices above the horizontal line are CFD problems, and the matrices below the line are device simulation problems. We note that PABLO was not designed specifically to solve these kinds of problems. As noted in section 1, a modified version of PABLO has been used before for problems in CFD [23]. More information on solving systems from semiconductor device simulation can be found in [35].

To illustrate the different phases of the XPABLO framework, Figure 6.1 shows matrix plots of the matrix GARON1 during four different phases. The bottom right plot shows the matrix of the system we are actually solving. The structure of this system is shown in more detail in Figure 6.2.

Table 6.2 shows how the execution times and iteration counts using the XPABLO framework compare to PABLO- and TPABLO1-based preconditioning. Additionally the improvements gained by using MC64 instead of the default row-column scaling (RCS) is shown. RCS just scales the largest entry in each row and column to one. The following scaling and permutation algorithms are used:

- P: RCS + PABLO,
- T: RCS + TPABLO1,
- X: RCS + XPABLO,
- MX: MC64 + XPABLO.

All parameters are set to the values described in section 5; in particular, γ is set to the average of all nonzero entries. Only the criterion τ is varied. For MX

Bottom right: The matrix after the XPABLO permutation. Note the difference in scale between the top left and the other plots.*

we additionally use XPABLO in conjunction with MC64. GMRES(50) is used as the solver. The preconditioner is the lower block triangular part of the scaled and permuted matrix, using the blocks found by (T/X)PABLO. A dash indicates that we did not observe convergence after 20 cycles of GMRES(50), i.e., after 1000 iterations. For each matrix the numbers in bold indicate the smallest execution time and the lowest iteration number. More details on the stopping criterion are given later. The robustness of XPABLO can be readily appreciated.

We now describe how we compare XPABLO with ILUT as a tool for preconditioning. We use ILUPACK [11] for our experiments with ILUT. The ILUT implementation has two parameters—the drop tolerance τ and the elbow space ℓ. We write ILUT(τ, ℓ) to denote ILUT preconditioning with the specified parameters. In the experiments the elbow space is chosen large enough so that no overflow occurs. We denote this by writing ILUT(τ, ∞). In preliminary tests the three drop tolerances have been found to be good values for the selected problems. We use both XPABLO and ILUT in conjunction with MC64; see section 2. We precede ILUT additionally with a reverse Cuthill–McKee ordering (RCM); this follows the recommendations in [7], [8], and [35]. We mention here that RCM is the default ordering in several software packages, e.g., in [37]. We do not use RCM together with XPABLO as our experiments have shown that it does not further improve the convergence.

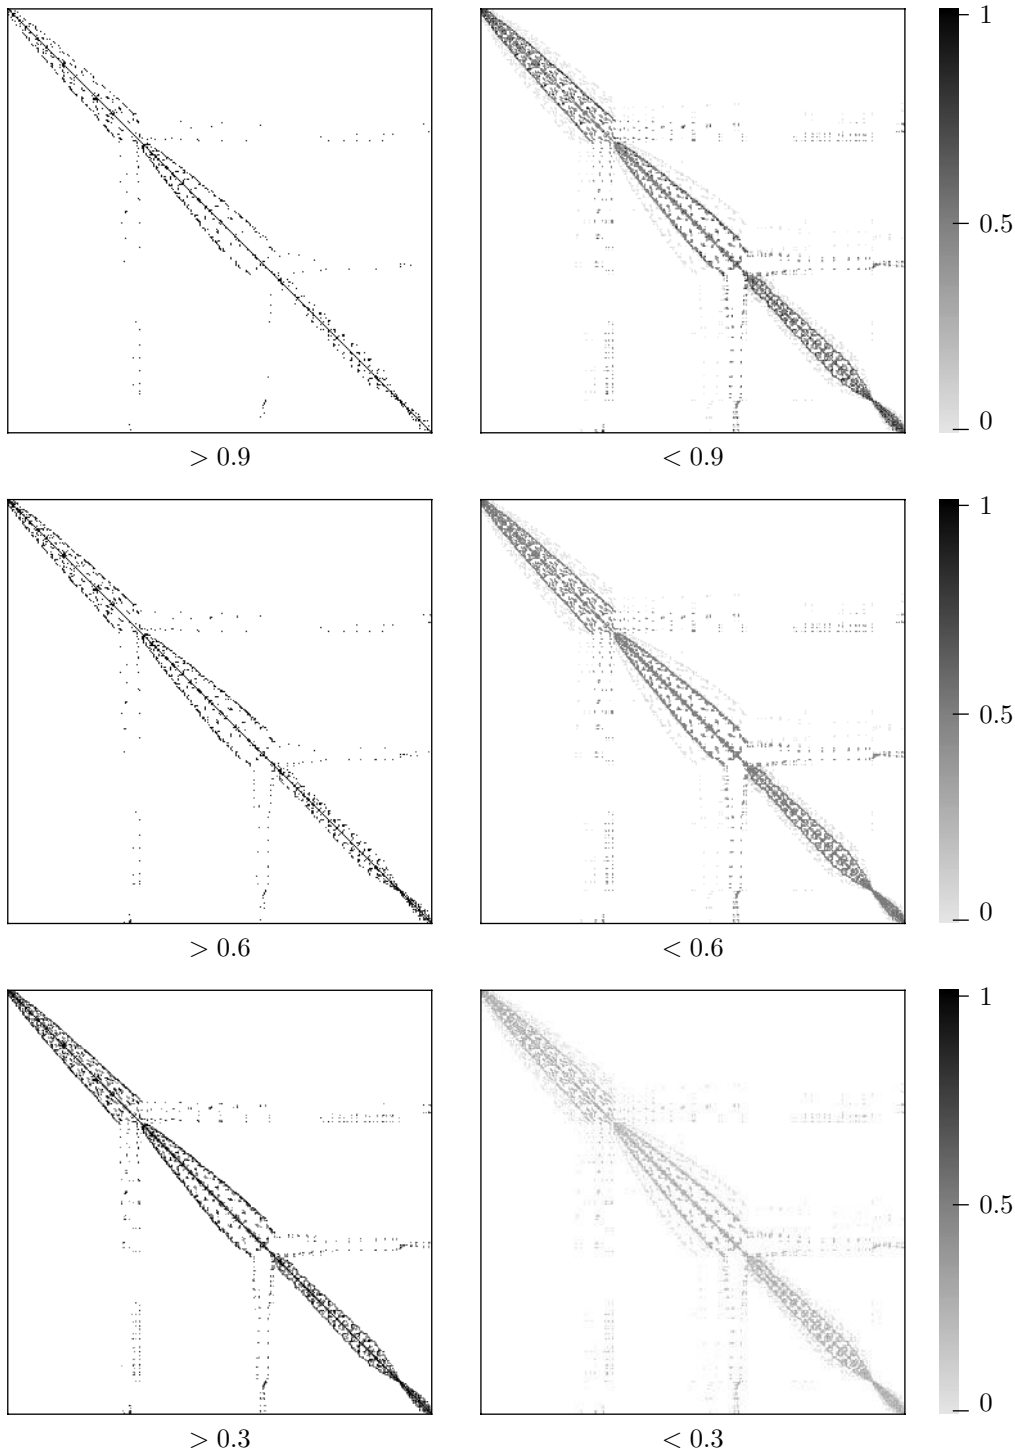

FIGURE 6.2. *Matrix plots of* GARON1 *after scaling and permutation by* MC64 *and XPABLO. Left column: The plots show only matrix entries with a magnitude greater than the given value (*0.9, 0.6 *or* 0.3*). Right column: The plots show the matrix entries less than the given magnitude.*

IBM_MATRIX_2	–	–	**4.6**	4.7	–	–	49	**47**
MATRIX_9	–	–	22	**16**	–	–	176	**100**

As already mentioned, we use GMRES(50) as the iterative solver in all our experiments. The stopping criterion is

$$\|r_k\|/\|b\| < \sqrt{\epsilon}, \tag{6.1}$$

where r_k is the residual at the kth iteration and ϵ is the machine epsilon, i.e., $\sqrt{\epsilon} \approx 10^{-8}$ since we use IEEE 754 double precision arithmetic. We also did tests with the alternative stopping criterion

$$\frac{\|r_k\|_2}{\sqrt{\|A\|_\infty \|A\|_1}\,\|x_k\|_2 + \|b\|_2} \le \sqrt{\epsilon},$$

which is the default criterion in ILUPACK [11], based on the analysis in [3]; see also [33]. Since the results were very similar and the full test cannot be done at each iteration, we show only results using the relative residual stopping criterion (6.1). The solver was stopped if no convergence is reached after 20 cycles of GMRES(50), i.e., after 1000 iterations. We use the following preconditioners:

- J: MC64 + XPABLO + block Jacobi,
- LX: MC64 + XPABLO + forward block Gauss–Seidel,
- UX: MC64 + XPABLO + backward block Gauss–Seidel,
- I1: MC64 + RCM + ILUT($10^{-2}, \infty$),
- I2: MC64 + RCM + ILUT($10^{-3}, \infty$),
- I3: MC64 + RCM + ILUT($10^{-4}, \infty$).

The results are summarized in Table 6.3. For XPABLO-based preconditioners we use the recommended parameters described in section 5. A dash indicates that we did not observe convergence. For each matrix the bold numbers indicate the smallest execution time and the lowest iteration number.

As it can be observed, the XPABLO-based preconditioners can perform better than the ILUT-based ones in many cases, and in some cases much better. In some

examples the XPABLO-based preconditioners perform better, although the iteration counts of the ILUT-based preconditioners are lower. The reason for this is that times for finding and, more importantly, factorizing the preconditioner are not the same in both cases.

7. Conclusion. While XPABLO is not always competitive with sophisticated ILU preconditioners like ILUT, we have seen that XPABLO can perform better than ILUT for many CFD and semiconductor device simulation problems. Furthermore, XPABLO-based preconditioners have much more parallelization potential than ILU-based preconditioners.

Acknowledgments. We thank Michele Benzi and the anonymous referee for their constructive comments. Their help and suggestions are very much appreciated.

NEARLY OPTIMAL PRECONDITIONED METHODS FOR HERMITIAN EIGENPROBLEMS UNDER LIMITED MEMORY. PART II: SEEKING MANY EIGENVALUES*

ANDREAS STATHOPOULOS† AND JAMES R. MCCOMBS†

Abstract. In a recent companion paper, we proposed two methods, GD+k and JDQMR, as nearly optimal methods for finding one eigenpair of a real symmetric matrix. In this paper, we seek nearly optimal methods for a large number, nev, of eigenpairs that work with a search space whose size is $O(1)$, independent from nev. The motivation is twofold: avoid the additional $O(nevN)$ storage and the $O(nev^2N)$ iteration costs. First, we provide an analysis of the oblique projectors required in the Jacobi–Davidson method and identify ways to avoid them during the inner iterations, either completely or partially. Second, we develop a comprehensive set of performance models for GD+k, Jacobi–Davidson type methods, and ARPACK. Based both on theoretical arguments and on our models we argue that any eigenmethod with $O(1)$ basis size, preconditioned or not, will be superseded asymptotically by Lanczos-type methods that use $O(nev)$ vectors in the basis. However, this may not happen until $nev > O(1000)$. Third, we perform an extensive set of experiments with our methods and against other state-of-the-art software that validates our models and confirms our GD+k and JDQMR methods as nearly optimal within the class of O(1) basis size methods.

1. Introduction.

The numerical solution of large, sparse, Hermitian, or real symmetric eigenvalue problems is one of the most computationally intensive tasks in a variety of applications. The challenge is twofold. First, the matrix size, N, is routinely more than a million, while an order of a billion has also been tried [43]. Second, many applications, including electronic structure calculations, require the computation of hundreds or even thousands of extreme eigenpairs. Often the number of required eigenpairs, nev, is described as a small percentage of the problem size. In such cases, orthogonalization of nev vectors, an $O(nev^2N)$ task, becomes $O(N^3)$, making the scaling to larger problem sizes practically infeasible.

Iterative methods are the only means of addressing these large problems. Yet, iterative methods may converge slowly, especially as the problem size grows, and must store the iteration vectors for computing eigenvector approximations. Beyond challenges in execution time, the storage demands of these applications can be staggering. Over the last decade, iterative methods have been developed [14, 51, 54, 30, 29, 49, 41, 57] that can effectively use the large arsenal of preconditioners for linear systems and converge nearly optimally to an eigenpair under limited memory requirements.

The quest for optimality under limited memory is a natural one. On symmetric linear systems, Krylov methods such as conjugate gradient (CG) achieve optimal convergence through a three term recurrence. For eigenvalue problems, the Lanczos method can produce the optimal space through a three term recurrence, but the

vectors must be stored or recomputed. With preconditioning, traditional Lanczos does not apply directly. Restarting techniques can be employed so that approximations are obtained from a search space of limited size, but at the expense of convergence.

When seeking one eigenpair, a useful way to approach the problem is by considering it as a nonlinear problem, where both the eigenvalue and eigenvector are unknown. In [57], we studied the problem from two nonlinear viewpoints: the inexact Newton and the limited memory quasi-Newton [40]. The two methods we have developed, the JDQMR and the GD+k, can be related to the above respective viewpoints, which allowed us to argue for their near-optimal convergence. The former is a Jacobi–Davidson (JD) method where the inexact inner iteration is stopped dynamically and optimally. The latter is a generalized Davidson (GD) method with a recurrence-based restarting that delivers convergence extremely close to, and sometimes indistinguishable from, the optimal method (i.e., without restarting).

When seeking many eigenpairs, it is an open question whether optimality can be achieved under limited memory. If one eigenvalue is known exactly, the corresponding eigenvector can be obtained optimally through a CG iteration [30, 57]. If nev eigenvalues are known, one may think that the analogue optimality is to run nev separate CG iterations. This is the approach taken by most limited memory, preconditioned eigensolvers for small nev values. Yet, it is clearly suboptimal because a method that stores the CG iterates from each run would converge in much fewer iterations. For example, when the number of CG iterations is $O(N)$, the former approach takes $O(nev\ N)$, while an unrestarted Lanczos would take no more than N.

In this paper, we focus on methods that do not allow their memory requirements to grow unbounded. We further distinguish between two "classes" of these methods: The first allows the size of the search space to be a small multiple of nev, typically $2nev$ or $1.5nev$. This class concedes the $O(nev^2)$ factor in the hope of much fewer iterations. The second class restricts the search space to a constant size (e.g., 20 vectors) and uses locking to obtain all nev eigenvectors. Although the number of iterations increases, orthogonalization and iteration costs decrease dramatically. This memory-based classification is slightly different from the one in [5], but it better captures the performance characteristics of solvers for large nev. The holy grail in this area has been to obtain nev eigenpairs in linear to nev scaling.

We make three contributions in this paper. First, after discussing the merits of current state-of-the-art methods for finding many eigenvalues, we analyze the effects of projecting against converged eigenvectors in the correction equation of the JD method, and we propose variants that avoid both the extra storage and the second orthogonalization. In particular, the unpreconditioned JDQMR-000 variant requires no orthogonalization during inner iterations and thus has the potential of overcoming the $O(nev^2)$ scaling barrier.

Second, we perform a detailed complexity analysis of the two classes of methods, and, based also on experimental observations, we develop a complete set of models that describes the relative performance between JD variants, GD+k, and implicitly restarted Lanczos (IRL) as implemented in ARPACK. The analysis not only reveals the relative asymptotic behavior but also provides performance crossover points between methods that can be used for dynamic method selection within a multimethod software, such as PRIMME, which we have recently developed [34].

Third, we conduct an extensive set of experiments, with and without preconditioning, which complements the ones in [5] by comparing our GD+k and JDQMR variants against software that implements current state-of-the-art methods such as JDBSYM,

BLOPEX, and ARPACK. The experiments show that our proposed JDQMR variants and GD+k are clearly the best methods in their class and confirm the crossover points and the asymptotic behaviors from our models. They also demonstrate the almost linear scaling of the JDQMR-000 variant without preconditioning up to several hundreds of eigenvalues.

2. State-of-the-art eigenmethods for many eigenvalues. Throughout this paper we assume that we seek the nev algebraically smallest eigenvalues λ_i and their corresponding eigenvectors $\mathbf{x}_i$, $i = 1, \ldots, nev$, of a symmetric matrix A of size N.

2.1. Lanczos-based methods. It should be no surprise that unrestarted Lanczos is still considered a state-of-the-art method without preconditioning. It is the optimal method in terms of number of iterations, for one or more eigenvalues, it is theoretically well understood, and it has several efficient, highly robust implementations [58, 45, 21, 9]. For finding one eigenvalue JD methods are now preferred to Lanczos, not only because of preconditioning, but also because of nearly optimal convergence that does not require unlimited storage [57]. For many eigenvalues, however, the ability of unrestarted Krylov spaces to capture large parts of the extremes of the spectrum of A remains unparalleled. This optimal convergence comes with several drawbacks. Frequent selective and/or partial orthogonalizations are required to avoid dealing with ghost eigenvalues. Also, besides storing or recomputing the vector iterates, the method needs to store a tridiagonal matrix of a size equal to the number of iterations, which can be tens of thousands, and solve for nev of its eigenpairs. Finally, Lanczos has difficulty obtaining multiple eigenvalues. Block versions of Lanczos have been proposed as a robust and cache efficient alternative [8, 19] but usually increase the total execution time (see [22] for a recent survey).

In the rest of the paper, we do not consider unrestarted Lanczos methods, because they do not satisfy our limited memory criterion and cannot use preconditioning without some form of inner-outer iteration [57, 38]. In doing so, we realize that there could be cases where the unrestarted methods are faster than the alternatives we present. In addition, we do not discuss the powerful shift-and-invert Lanczos [45], because it requires the exact inversion of the matrix.

To reduce storage and iteration costs, the Lanczos method can be restarted through the implicit restarting [53] or the equivalent thick restarting [36, 56, 59] technique. When the maximum size m_{max} for the search space is reached, the nev required Ritz vectors are computed and replace the search space. The ARPACK software is a high quality, efficient implementation of the implicitly restarted Arnoldi and Lanczos methods [33], and it has become the default eigensolver in many applications.

Restarting impairs the optimality of Lanczos. Implicit (or thick) restarting with nev (or more) vectors improves convergence but may not be sufficient with small basis sizes. Indeed, it is known that IRL is a polynomially accelerated simultaneous iteration with a polynomial of degree $m_{max} - nev$ [32]. Hence, inner-outer methods can be more effective for small nev. On the other hand, ARPACK requires that $m_{max} > nev$ (and typically $m_{max} = 2nev$), which implies that for really large nev the algorithm approaches again an unrestarted Lanczos with full orthogonalization, with its convergence benefits but high iteration costs.

2.2. Newton approaches. We can view the eigenvalue problem as a constrained minimization problem for minimizing the Rayleigh quotient $\mathbf{x}^T A\mathbf{x}$ on the unit sphere or equivalently minimizing $\mathbf{x}^T A\mathbf{x}/\mathbf{x}^T\mathbf{x}$ [14]. For many eigenpairs, the same formulation applies for minimizing the trace of a block of vectors [48], working with nev-

dimensional spaces [2]. As we discussed in [57], most eigenmethods can be interpreted through the inexact Newton viewpoint or the quasi-Newton viewpoint.

2.2.1. The inexact Newton approach. The exact Newton method for eigenproblems, applied on the Grassmann manifold to enforce normalization of the eigenvectors, is equivalent to Rayleigh quotient iteration (RQI) [14]. It is well known that solving the Hessian equation to full accuracy is not needed at every Newton step. Inexact Newton methods attempt to balance good convergence of the outer Newton method with an inexact solution of the Hessian equation. Extending inexact Newton methods to RQI has attracted a lot of attention in the literature [46, 31, 52, 20, 49].

In [57] we argued that a more appropriate representative of the inexact Newton minimization for eigenvalue problems is the JD method [51]. See also [1] for a theoretical discussion on Newton variants. Given an approximate eigenvector $\mathbf{u}^{(m)}$ and its Ritz value $\theta^{(m)}$, the JD method obtains an approximation to the eigenvector error by approximately solving the correction equation

$$(I - \mathbf{u}^{(m)}\mathbf{u}^{(m)T})(A - \eta I)(I - \mathbf{u}^{(m)}\mathbf{u}^{(m)T})\mathbf{t}^{(m)} = -\mathbf{r}^{(m)} = \theta^{(m)}\mathbf{u}^{(m)} - A\mathbf{u}^{(m)}, \tag{2.1}$$

where η is a shift close to the wanted eigenvalue. The next (inexact) Newton iterate is then $\mathbf{u}^{(m+1)} = \mathbf{u}^{(m)} + \mathbf{t}^{(m)}$. The pseudoinverse of the Hessian is considered to avoid the singularity when $\eta \approx \lambda$ and also to avoid yielding back $\mathbf{t}^{(m)} = \mathbf{u}^{(m)}$ when the equation is solved accurately with $\eta = \theta^{(m)}$. The latter problem could cause stagnation in the classical or the GD methods [10, 37, 55, 42, 61]. The GD method obtains the next iterate as $\mathbf{t}^{(m)} = K^{-1}\mathbf{r}^{(m)}$, where the preconditioner K approximates $(A - \eta I)$ directly—not as an iterative solver.

JD and GD mehods are typically used with subspace acceleration, where the iterates $\mathbf{t}^{(m)}$ are accumulated in a search space from which eigenvector approximations are extracted through Rayleigh–Ritz or some other projection technique [44, 35, 25]. This is particularly beneficial, especially when looking for more than one eigenpair.

The challenge in the JD method is to identify the optimal accuracy to solve each correction iteration. In [41] Notay proposed a dynamic stopping criterion based on monitoring the growing disparity in convergence rates between the eigenvalue residual and linear system residual of CG. The norm of the eigenvalue residual was monitored inexpensively through a scalar recurrence (see [24] for recent extensions). In [57] we proposed JDQMR that extends JDCG by using symmetric QMR [16] as the inner method. The advantages are as follows: (a) The smooth convergence of sQMR allows for robust and efficient stopping criteria. (b) It can handle indefinite correction equations, which is important also for large *nev*. (c) sQMR, unlike MINRES, can use indefinite preconditioners, which are often needed for interior eigenproblems. We also argued that JDQMR-type methods cannot converge more than three times more slowly than the optimal method and usually are significantly less than two times slower. Coupled with the very low sQMR costs, JDQMR has proven to be one of the fastest and most robust methods for $nev = 1$.

When seeking many eigenvalues, the Newton method can be applied on the *nev*-dimensional Grassmann manifold to compute directly the invariant subspace (see [48] and [2] for a more recent review). Practically, however, the Grassmann RQI approach proposed in [2] is simply a block JD method. To see this, note first that the JD search space is kept orthonormal; second, a Rayleigh–Ritz is performed at every outer step, and therefore the Sylvester equations stemming from the Newton approach are decoupled as *nev* independent correction equations for each vector in the block. The

open computational question is how to solve these *nev* linear systems most efficiently, and whether to use a block method at all.

The problem is highly related to ongoing linear systems research for multiple right-hand sides [50, 7, 26, 23]. It could be argued that seed methods that build one large Krylov space and reuse it to solve all the *nev* equations are the best choice. In our case, the disadvantage of seed methods is that they need to store this large space, which is exactly what we try to avoid by restarting the outer JD iteration and by using short term recurrence methods for the correction equation. Moreover, the multiple right-hand sides are not related in any way, so it is unclear how much one system can benefit from the Krylov space of another.

Block methods that solve all the correction equations simultaneously do not consistently improve the overall runtime. On some occasions, however, when the eigenvalues are multiple or highly clustered, certain JD implementations may benefit from a small block size, because the fast, targeted convergence of Newton could cause eigenvalues to converge out of order and thus the required ones to be missed.

With large *nev*, however, the near optimal convergence of the JDQMR has to be repeated *nev* times, much like the *nev* independent CGs we mentioned in the introduction. In this case, and assuming a very small block size, the role of a larger subspace acceleration is to obtain better approximations for nearby eigenpairs while JD converges to the targeted eigenpair. Although the convergence rate of QMR cannot improve further, increasing the basis size gives increasingly better initial guesses for the eigenpairs to be targeted next. In this paper, we avoid this continuum of choices and focus only on constant, limited memory basis sizes.

2.2.2. The quasi-Newton approach. An alternative to Newton is the use of the nonlinear conjugate gradient (NLCG) method for eigenproblems [14]. It is natural to consider a method that minimizes the Rayleigh quotient on the whole space $L = \left\{\mathbf{u}^{(m-1)}, \mathbf{u}^{(m)}, \mathbf{r}^{(m)}\right\}$ instead of only along one search direction. The method

$$\mathbf{u}^{(m+1)} = \text{RayleighRitz}\left(\left\{\mathbf{u}^{(m-1)}, \mathbf{u}^{(m)}, \mathbf{r}^{(m)}\right\}\right), \ m > 1, \tag{2.2}$$

is often called locally optimal conjugate gradient (LOCG) [13, 28] and seems to consistently outperform other NLCG-type methods. For numerical stability, $\mathbf{u}^{(m)} - \tau^{(m)}\mathbf{u}^{(m-1)}$ for some weight $\tau^{(m)}$ can be used instead of $\mathbf{u}^{(m-1)}$. When used with multivectors $\mathbf{u}^{(m)}, \mathbf{r}^{(m)}$, this is the well-known LOBPCG method [30].

LOCG can be accelerated by minimizing over the subspace of more iterates $\mathbf{u}^{(m)}$. When the subspace reaches its maximum size we must restart. If we restart through IRL, however, we lose the single important direction ($\mathbf{u}^{(m-1)}$) that offers the excellent convergence to LOCG. This was first observed in [39] for the Davidson method, although under a different viewpoint. In [54] we offered a theoretical justification and an efficient implementation that combined this technique with thick restarting for the GD method. In [57], we noted the connection of our method, which we call GD+k, to the quasi-Newton and in particular to the limited memory BFGS method [18, 40].

GD(m_{min}, m_{max})+k uses a basis of maximum size m_{max}. When m_{max} is reached, we compute the m_{min} smallest Ritz vectors, $\mathbf{u}_i^{(m)}$, and also k of the corresponding Ritz vectors $\mathbf{u}_i^{(m-1)}$ from step $m-1$. An orthonormal basis for this set of m_{min}+k vectors becomes the restarted basis. If the block size in GD/JD is b, it is advisable to keep k $\geq b$ to maintain good convergence for all block vectors. The special case of block GD(b, $3b$)+b is equivalent mathematically to LOBPCG with the same block size. In [57], we showed that convergence of the GD+k for one eigenvalue is often

ALGORITHM 2.1.

indistinguishable from the optimal method. Yet, higher iteration costs than JDQMR make it less competitive for very sparse operators.

When seeking many eigenvalues, we have never found the use of a block size $b > 1$ beneficial, even with a small subspace acceleration. Then, as with JDQMR, each eigenpair has to be targeted and converged independently. The role of subspace acceleration is perhaps more important for GD+k than for JDQMR, as it provides both its local optimal convergence and the initial guesses for nearby eigenvalues.

2.3. The GD+k and the JDQMR algorithms. The GD algorithm can serve as the basic framework for implementing both JDQMR and GD+k. Algorithm 2.1

depicts a version of the basic GD+k algorithm for finding *nev* smallest eigenpairs. It implements Rayleigh–Ritz and locking and is the basis for the performance models in section 4. The implementation of +k restarting is shown at steps numbered with decimal points. Both steps (20.0) and (20.1) apply on vectors of size m_{max}, and therefore the cost of the GD(m_{min}, m_{max})+k implementation is the same as that of GD(m_{min}+k, m_{max}). In our experience, k = 1 or 2 is always sufficient, obviating the use of larger m_{min} and hence being less expensive. Although not explored here, Algorithm 2.1 can be viewed as a block method by implementing vectors as multivectors.

Step (27) differentiates between eigenmethods. By returning $\mathbf{t}^{(m)} = \mathbf{r}^{(m)}$ or the preconditioned residual, $\mathbf{t}^{(m)} = K^{-1}\mathbf{r}^{(m)}$, we have the GD+k method. Step (27) can also return a JD correction vector. Without inner iterations, a preconditioner K can be inverted orthogonally to the space $Q = [X, \mathbf{u}^{(m)}]$ and applied to $\mathbf{r}^{(m)}$. Assuming $(Q^T K^{-1} Q)$ is invertible, the pseudoinverse of this preconditioner can be written as

$$\left((I - QQ^T)K(I - QQ^T)\right)^+ = (I - K^{-1}Q(Q^T K^{-1}Q)^{-1}Q^T)K^{-1}(I - QQ^T) \tag{2.3}$$

$$= K^{-1}(I - Q(Q^T K^{-1}Q)^{-1}Q^T K^{-1})(I - QQ^T). \tag{2.4}$$

When this preconditioner is used in an iterative method on (2.1), a significant extra storage for $K^{-1}Q$ is required to avoid doubling the number of preconditioning operations. In [15, 51, 6] it is shown that the JD method can be implemented with one projection with Q per iteration. In the following section we show that this may not be sufficient with right preconditioning and high convergence tolerance. Our JDQMR algorithm uses the GD+k as the underlying outer method and, at step (27), calls the symmetric, right preconditioned QMR as described in detail in [57].

3. Avoiding the JD oblique projectors. When eigenvectors converge in the JD method, they are locked in the array X, and the algorithm targets the next higher eigenpair. As the shift in the correction equation moves inside the spectrum, the equation becomes increasingly indefinite. Although this is not prohibitive for the QMR solver, it usually is unnecessarily expensive, as QMR has to rebuild the lower eigendirections in X sufficiently so that it can converge to the correction which should be orthogonal to X. The JD authors have observed that it is always beneficial to project X from the correction equation. They also mention that the preconditioner needs also to be projected in the same way, so that the image of its operation matches the domain of the projected matrix A. This reasoning, however, is not of practical use because the vectors can be considered embedded in $\Re^N$. A better approach would be to consider the effect of these projectors on the conditioning of the correction equation, and whether it justifies the significant additional expense—either a second preconditioning operation per iteration or an array that stores $K^{-1}X$.

There is little doubt that the skew projection of (2.3) should be used for the Ritz vector $\mathbf{u}^{(m)}$. First, there is a constant additional cost to QMR, which is independent from *nev*. More importantly, an extremely accurate preconditioner may cause the problems seen in Davidson. A recent analysis by Notay [42] shows that, although such problems are rare, they could arise. The Davidson problem is specific to the vector $\mathbf{u}^{(m)}$ and cannot occur if orthogonality to the converged eigenvectors X is not enforced in the correction equation. However, the effectiveness of the preconditioner may change. To simplify notation in this section, we assume that the matrix A and the preconditioner K encapsulate both the shifting with η and the projection (2.3) for $\mathbf{u}^{(m)}$, and focus on $Q = X$. Define also the projector for any matrix B for which

TABLE 3.1
Projection alternatives to the classical JD correction equation (with right preconditioning). The 0/1 *string characterizes whether there is a projection on the left of A, on the right of A, and whether the right projection is skew projection or not. Theoretically JD corresponds to* (111) *although it is typically implemented as* (011).

(Left skew right)	Operator	(Left skew right)	Operator
111	$PAP_{K^{-1}}K^{-1}$	011	$AP_{K^{-1}}K^{-1}$
101	$PAPK^{-1}$	001	APK^{-1}
100	PAK^{-1}	000	AK^{-1}

Q^TBQ is not singular,

$$P_B = (I - BQ(Q^TBQ)^{-1}Q^T), \tag{3.1}$$

and note that if $P = (I - QQ^T)$, in addition to (2.3), (2.4) it holds that

$$PP_BBP = P_BB = BP_B^T = PBP_B^TP. \tag{3.2}$$

Based on the above, the appropriate formulation for right preconditioning of the JD projected operator in the correction equation is

$$PAP(PKP)^+ = PAP_{K^{-1}}K^{-1} \tag{3.3}$$

$$= PAK^{-1}P_{K^{-1}}^T. \tag{3.4}$$

Computationally the above formulation is expensive because at every QMR step it requires two orthogonalizations with Q, from both left and right of A, and a backsolve with the factors of the small matrix $(Q^TK^{-1}Q)^{-1}$. Moreover, to avoid an extra preconditioning operation per iteration, the vectors $K^{-1}Q$ must be stored, which is a very unreasonable storage requirement for a large number of eigenvalues. Naturally, the question is whether some projectors can be avoided, in their skew form or altogether.

Equation (3.3) suggests several variants of a projected operator based on whether we operate with a projector on the left and/or on the right of A, and whether we relax the requirement for a right skew projector, replacing it with P. Table 3.1 summarizes the variants. Note that the cases $PAK^{-1}P_{K^{-1}}^T$ and $AK^{-1}P_{K^{-1}}^T$ (from (3.4)) are equivalent to (111) and (011), respectively, so they are not included. Additionally, when the QMR iterates are orthogonal to Q, a P projection on the right of the preconditioner is unnecessary; hence we have not included the case $PAK^{-1}P$. Finally, we do not include the variant $AK^{-1}P$ because it maintains no orthogonality of the QMR iterates. We discuss each column of the table separately.

3.1. No *P* projection on the left of *A*. Case (000) does not work orthogonally to Q, and it is expected to require a sharply increasing number of inner iterations as more eigenvalues are locked, especially with less effective preconditioners. There is a notable exception. When K has the same eigenvectors as A (e.g., if K is a polynomial of A or simply $K = I$), QMR starts with the residual $\mathbf{r}^{(m)} \perp Q$ and thus all its iterates will stay in $Q^\perp$. This property is sometimes exploited in methods with polynomial acceleration [60] (see also [4] in the context of an a priori known null space in Maxwell's equations). Floating point arithmetic and the fact that the eigenvectors in Q are converged to *tol*, not to machine precision, will eventually introduce Q components that QMR will have to remove by additional iterations. However, a few additional iterations are a small price to pay for removing the limiting scalability factor

$O(nev^2N)$ of orthogonalization. In all our experiments, unpreconditioned JDQMR-000 (no projections) achieves an almost linear scaling with nev, both in convergence and in time.

Case (011) is the recommended way to implement right preconditioning in JD. For any vector v, we have $P_{K^{-1}}K^{-1}v \in Q^{\perp}$, and thus $AP_{K^{-1}}K^{-1}v \in Q^{\perp}$, requiring no additional left orthogonalization. This formulation, however, may have disadvantages when the required relative convergence tolerance is much larger than machine precision (e.g., $tol \geq \|A\|\sqrt{\epsilon_{\text{machine}}}$). In such cases, large Q components may appear early in the QMR iterations, delaying its convergence. Finally, we note that the same concern holds for the (001) case, which we do not examine further because even if we fixed this concern, for example, by using case (101), it would still not be competitive for the reason described in section 3.2.2.

3.2. P projection on the left of A. Cases that project with P on the left of A guarantee that all QMR iterates will be exactly in $Q^{\perp}$, regardless of how close Q is to an A-invariant subspace. Case (111) implements accurately the JD projection, but it is very expensive and storage demanding. Cases (101) and (100) approximate equations (3.3) and (3.4), respectively, by replacing the skew projectors with P, thus avoiding the additional storage. In addition, (100) does not require the right projector, so it is the least expensive method that can maintain the QMR iterates in $Q^{\perp}$. If conditioning of the matrix in (100) does not differ much from the matrix in (111), case (100) should be preferred.

To examine the condition numbers of the projected matrices, we note first that when B has a nontrivial null space, its condition number is defined in its range as $\kappa(B) = \|B\|\|B^{+}\|$. We also need the following elementary property for pseudoinverses.

PROPOSITION 3.1. [illegible] A B [illegible]

$$(AB)^{+} = B^{+}A^{+}.$$

[illegible] The pseudoinverse of a matrix A is defined as $A^{+} = V\Sigma^{-1}U^{T}$, where $A = U\Sigma V^{T}$ is the economy size SVD of A which consists only of the nonzero singular values and vectors. Similarly, the pseudoinverse for $B = YMZ^{T}$ is $B = ZM^{-1}Y^{T}$. Let $X \in \Re^{N,k}$, $k < N$, be an orthonormal basis for the range of A and B. Because A, B are symmetric, their SVDs can be described as $A = U\Sigma(XQ_A)^{T}$ and $B = XQ_BMZ^{T}$ for some orthogonal matrices $Q_A, Q_B \in \Re^{k,k}$. By substituting $Y = XQ_B$ and $V = XQ_A$ and using a known property of pseudoinverses, we have

$$\begin{aligned}(AB)^{+} &= (U\Sigma V^{T}YMZ^{T})^{+} = Z(\Sigma V^{T}YM)^{-1}U^{T} \\ &= ZM^{-1}Y^{T}Y(V^{T}Y)^{-1}\Sigma^{-1}U^{T} = B^{+}Y(V^{T}Y)^{-1}\Sigma^{-1}U^{T} \\ &= B^{+}XQ_B(Q_A^{T}Q_B)^{-1}\Sigma^{-1}U^{T} = B^{+}XQ_A\Sigma^{-1}U^{T} = B^{+}A^{+}. \qquad \square\end{aligned}$$

Using Proposition 3.1 with a two norm and (3.3), (3.4), we can derive the condition numbers for cases (111), (101), and (100):

$$\begin{aligned}\kappa_{111} &= \|PAP(PKP)^{+}\|\|PKP(PAP)^{+}\| = \|PAK^{-1}P_{K^{-1}}^{T}\|\|PKA^{-1}P_{A^{-1}}^{T}\|, \\ \kappa_{101} &= \|PAPK^{-1}P\|\|(PK^{-1}P)^{+}(PAP)^{+}\| = \|PAPK^{-1}P\|\|P_KKPA^{-1}P_{A^{-1}}^{T}\|, \\ \kappa_{100} &= \|PAK^{-1}P\|\|(PAK^{-1}P)^{+}\| = \|PAK^{-1}P\|\|P_{KA^{-1}}KA^{-1}\|.\end{aligned}$$

There are obvious similarities between the condition numbers, but no one emerges as the default winner. The effect of the projectors $P_{K^{-1}}^{T}, P_{A^{-1}}^{T}$, and $P_{KA^{-1}}$ depends on how close A, K, K^{-1}, and KA^{-1} are to Q-invariant. We therefore examine the following two special, extreme cases.

3.2.1. Special case: Q are exact eigenvectors of A. This assumption leads to $PA = AP$, $P_{KA^{-1}} = P_K$, $P^T_{A^{-1}} = P$, and, by considering (3.2), to the following simplifications:

$$\kappa_{111} = \|PAK^{-1}P^T_{K^{-1}}\|\|PKA^{-1}P\|,$$
$$\kappa_{100} = \kappa_{101} = \|PAK^{-1}P\|\|P_KKA^{-1}P\|.$$

The differences between κ_{111} and κ_{100} may be better understood if we consider how close Q is to an invariant subspace of K. If we denote as $R_K = KQ - Q(Q^TKQ)$ the residual of Q in K, we have $P_K = P - R_K(Q^TKQ)^{-1}Q^T$, and κ_{100} becomes

$$\begin{aligned}\kappa_{100} &= \|PAK^{-1}P\|\|PKA^{-1}P - R_K(Q^TKQ)^{-1}Q^TKPA^{-1}\| \\ &= \|PAK^{-1}P\|\|PKA^{-1}P - R_K(Q^TKQ)^{-1}R_K^TA^{-1}\|. \end{aligned} \tag{3.5}$$

Similarly, with $R_{K^{-1}} = K^{-1}Q - Q(Q^TK^{-1}Q)$ and $P^T_{K^{-1}} = P - Q(Q^TK^{-1}Q)^{-1}R_{K^{-1}}$,

$$\kappa_{111} = \|PAK^{-1}P - AR_{K^{-1}}(Q^TK^{-1}Q)^{-1}R^T_{K^{-1}}\|\|PKA^{-1}P\|. \tag{3.6}$$

Moreover, let $\delta_0 = \|R_K(Q^TKQ)^{-1}R_K^TA^{-1}\|$ and $\delta_1 = \|AR_{K^{-1}}(Q^TK^{-1}Q)^{-1}R^T_{K^{-1}}\|$. Then, $\delta_0 = O(\|R_K\|^2)$ and $\delta_1 = O(\|R_{K^{-1}}\|^2)$, and through some basic algebra we can derive

$$|\kappa_{111} - \kappa_{000}| \le \delta_0\|P_KKA^{-1}P\| + \delta_1\|PAK^{-1}P^T_{K^{-1}}\| = O(\|R_K\|^2 + \|R_{K^{-1}}\|^2). \tag{3.7}$$

Equation (3.7) implies that the differences between the two methods disappear with better preconditioners, when Q becomes close to K-invariant (depending on the squares of the residuals). When Q is far from K-invariant the two condition numbers may not be close. However, there is no reason why κ_{111} should be smaller than κ_{100}. If we assume, according to (3.5), (3.6), that smaller residuals may lead to smaller condition numbers, then obtaining $\|R_K\| \ll \|R_{K^{-1}}\|$ would depend on the norms of $\|K\|$ and $\|K^{-1}\|$ and on what part of the K spectrum is approximated by Q and how well. In extensive experiments on practical cases we have noticed negligible differences between cases (111) and (100).

3.2.2. Special case: Q inexact eigenvectors but $K = A$. In this extreme case, $\kappa_{111} = \kappa_{100} = 1$, but κ_{101} can be much worse. To see why, let the residuals $R_A = AQ - Q(Q^TAQ)$ and $R^T_{A^{-1}} = Q^TA^{-1} - (Q^TA^{-1}Q)Q^T$, and consider the norms for κ_{101}:

$$\begin{aligned}\|PAPK^{-1}P\| &= \|P(A - AQQ^T)A^{-1}P\| \\ &= \|P(I - (R_A + Q(Q^TAQ))Q^TA^{-1})P\| \\ &= \|P - P(R_A + Q(Q^TAQ))(R^T_{A^{-1}} + (Q^TA^{-1}Q)Q^T)P\| \\ &= \|P - R_AR^T_{A^{-1}}\|, \\ \|P_KKPA^{-1}P^T_{A^{-1}}\| &= \|P + R_A(Q^TAQ)^{-1}(Q^TA^{-1}Q)^{-1}R^T_{A^{-1}}\|. \end{aligned}$$

Obviously, interleaving an inaccurate eigenprojector between A and K can cause κ_{101} to be far from 1, despite the double orthogonalization expense. The same effects remain, only exaggerated, if the left projection is avoided as in the (001) case.

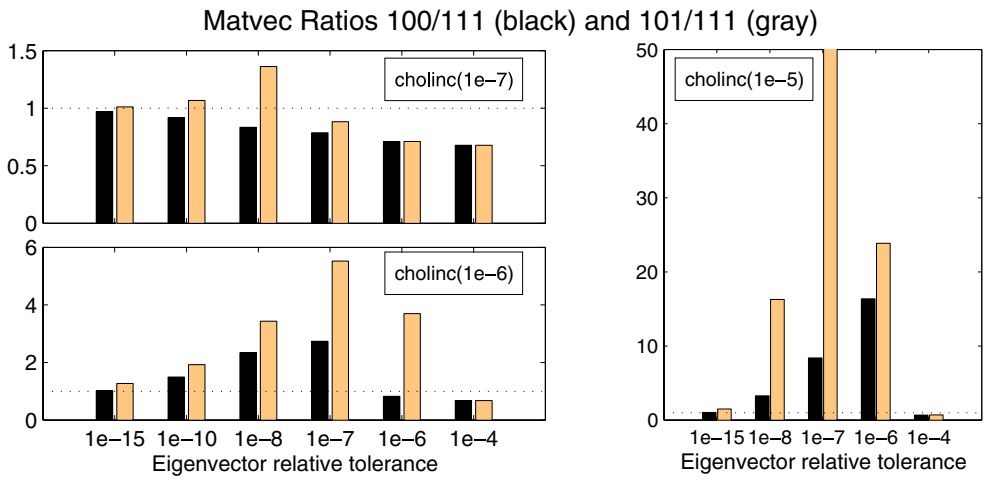

FIG. 3.1. *We look for* 20 *lowest eigenpairs of the matrix PLAT*362 *from Harwell Boeing. We show the ratios of the number of matrix-vector products (including the preconditioner application) of method* (100) *over* (111) *(black bars), and* (101) *over* (111) *(gray bars). The three boxes depict results from preconditioning with the MATLAB* `cholinc`*, with thresholds* `1e-7, 1e-6`*, and* `1e-5`*, respectively. In each box, the x-axis varies the relative tolerance for computed eigenvectors; i.e., the residual of* Q *is less than* $\|A\|_F tol$*. The example was picked because it shows two possible anomalies. First, decreasing both eigenvector accuracy (around* $\sqrt{\epsilon_{machine}}$*) and the quality of the preconditioner could necessitate the use of* (111)*. Second, case* (101) *shows a much higher sensitivity than* (100) *to the accuracy of the eigenvalues. Even in this "anomaly" case, with very good or very bad eigenvector accuracy, method* (100) *takes fewer iterations than* (111)*.*

3.2.3. General case. When both Q and K are not accurate, it is hard to quantify the relative merits of κ_{111} and κ_{100}. However, the Q are not random vectors but approximate eigenvectors to a certain threshold (typically at least as good as single precision). Therefore, we expect our results of section 3.2.1 to apply in general. In particular, (3.5), (3.6) suggest that method (100) should be preferred over the expensive (111) with good preconditioners. This is in contrast to the situation for the Ritz vector $\mathbf{u}^{(m)}$, where skew projectors are especially needed when $K \approx A$.

In our extensive experiments, we never found it necessary to use method (111) when the eigenvectors were computed relatively accurately. In fact, method (100) consistently gave lower iteration numbers. Despite the lack of theoretical assurance, we have observed similar behavior even with smaller eigenvector accuracy (10^{-7} relative tolerance in the next section). Situations can arise, however, where (111) could be beneficial. We have been able to identify only one such case. Figure 3.1 shows the results from this "anomaly" case. Even so, method (100) is still competitive and often better than (111) except for a small range of carefully picked parameters. The figure also demonstrates the disadvantages of method (101).

4. Modeling the relative asymptotic behavior between methods. The challenge in relative modeling is that practical models must include information about time complexity, type of operations and their performance on certain hardware, and cost of the operators (matvec and preconditioner), but most importantly they must capture the relative convergence behavior of the methods. Insight on the latter arises from lengthy experimentation with the methods on a variety of problems. In the following, we do not separate the experimentation from the modeling process as the two

are complementary. Instead, for each pair of methods, we first model their observed relative convergence behavior. Then, we couple it with time complexity models to predict their relative asymptotic behavior for large *nev*. Because the meaning of iteration differs among methods, we normalize all models as cost per operator application (that includes matvec and preconditioner, if available).

4.1. Experimentation environment. In our experiments we use actual production codes, not prototypes, that implement state-of-the-art methods. Our GD+k and JDQMR methods are implemented in C, in the package PRIMME: PReconditioned Iterative MultiMethod Eigensolver [34]. From various methods available in PRIMME, we compare only GD+k and the following JDQMR variants (following notation from the previous section): JDQMR-000, JDQMR-100, JDQMR-011, JDQMR-111. With the exception of forcing these projector configurations, the default parameters provided by PRIMME are used in all the experiments. These defaults include the use of locking, block size of 1, $m_{min} = 6$, $m_{max} = 18$, k = 1 with preconditioning, and k = 2 without it. The methods converge when the residual norm of each of the *nev* required eigenpairs is less than $\|A\|_F tol$, where $\|A\|_F$ is the Frobenius norm of A.

The only other symmetric JD implementation available is JDBSYM [17]. It is also written in C, it is a block method, but it stops the inner iteration using the scheme proposed in [51, 12]. JDBSYM provides several choices of inner iterative methods. We opt for the symmetric QMR to facilitate a comparison with JDQMR. We use the same m_{min}, m_{max} for the JD basis, block size of 1, a maximum number of 200 inner iterations, TOLDECAY = 1.5, symmetric preconditioning OPTYPE, and strategy = 0. In certain cases strategy = 1 was necessary to achieve convergence. JDBSYM finds only eigenvalues closest to a shift τ—not extreme ones. In all our tests, we provide τ as a small, left perturbation of the precomputed λ_1 and let JDBSYM switch to using the Ritz values as shifts when EPS_TR $= 10^{-3}\|A\|_F/\sqrt{N}$. Convergence is declared when all residual norms fall below $\|A\|_F tol$.

From the class of Lanczos methods we use the ARPACK software [33]. The basis size for ARPACK is chosen as $\max(40, 2nev)$ for $nev < 400$ and $1.5nev$ for $nev \geq 400$. The tolerance *tol* is provided directly to ARPACK.

Finally, we compare against BLOPEX, a C implementation of LOBPCG [27]. We chose to implement a wrapper around BLOPEX(b) that uses locking to compute *nev* eigenvalues a block, b, at a time. After some experimentation, we found $b = 10$ to be the best choice for most problems. For large *nev*, BLOPEX(*nev*) was several times slower than BLOPEX(10). We ask for convergence tolerance of $\|A\|_F tol$.

All methods start with the same random initial guess. We have run experiments for two different tolerances: *tol* = 1e-15 and *tol* = 1e-7. For BLOPEX we report only results for *tol* = 1e-7, as it could not produce results with the lower tolerance. We run experiments on an Apple G5 with 1 GB of memory and two 2GHz processors, each with 512 MB L2 cache. The C codes are compiled using the gcc-4.0.0 compiler with -O3 flag, and the ARPACK is compiled with the g77 compiler. We link with the Apple vecLib library that includes optimized versions of BLAS/LAPACK libraries.

We use eight matrix problems (as shown in Table 4.1), six from the University of Florida [11] and the FEAP [3] collections, and two standard seven-point three-dimensional Laplacian matrices generated by SPARSKIT [47] with zero Dirichlet boundary conditions. The matrix sizes are far beyond toy problems, yet they make finding hundreds or thousands of eigenvalues tractable on a workstation. They also represent different applications, operators, and sparsities. The smallest side of the spectrum is hard to obtain for all matrices, while the largest side is easier for several

TABLE 4.2
The parameters used to model the various methods, their meaning, and range of values.

Name	Description	Value
$OP(OP_p)$	Cost of the matvec (matvec+preconditioner)	
c_a	ARPACK iteration cost per eigenvalue	$14N$
c_g	Cost of reorthogonalizing locked vectors in GD	$4N$
c_p	Cost of projecting the locked vectors in QMR	$2N$
c_q	Symmetric QMR cost per step	$21N$
c_{qr}, c_{gr}	Outer iteration costs for JDQMR/GD+1	(see section 4.5)
C	$MV_{jdqmr000}/(MV_{arp}nev)$	[0.1, 0.25]
f	$f = c_g/c_a$	4/14
f_p	$f_p = MV_{jdqmr100}/MV_{jdqmr000}$	
k_{inn}^{xyz}	Number of inner iterations in JDQMR-xyz	> 1
γ	$\gamma = MV_{jdqmr100}/MV_{GD+1}$	[1.1, 2.4]

of them. Finally, Table 4.2 provides a look-up reference for the parameters used in our modeling, their meaning, and their typical range of values.

4.2. JDQMR-000 versus ARPACK. Because the size of the ARPACK basis increases with nev, so does its effectiveness. Thus, the number of matrix vector operations per eigenvalue found by ARPACK is expected to decrease rapidly with nev. In contrast, the number of matvecs per eigenvalue found for JDQMR-000 is expected to be at least constant or increase slightly for highly interior eigenpairs because of the loss of implicit orthogonality during inner iterations. Although it is difficult to model this decrease/increase of matvecs for the two methods, surprisingly, we can relate empirically the ratio of their number of matvecs. The left graph in Figure 4.1 shows that for sufficiently large nev, the matvec ratio between ARPACK and JDQMR follows a power law. Interestingly, fitting the ratios to a power law curve results in the model

$$MV_{jdqmr000} = C\ nev\ MV_{arp}, \tag{4.1}$$

with $0.1 < C < 0.25$. The same observations hold for the experiments in Figure 4.2.

ARPACK obtains this excellent asymptotic convergence with nev, at the expense of increasing orthogonalization and restarting costs. Based solely on flop counts as a measure of performance and considering only higher order terms and their constants, we have that between restarts ARPACK requires $\sum_{k=nev}^{2nev} 8kN = 3/2nev^2 8N$ flops for (re)orthogonalization and $2nev^2N$ flops for restarting. Averaging over the nev steps between restarts, we obtain $14nevN$ flops per matrix-vector operation. Let $c_a = 14N$ be the constant capturing these costs independently from nev. This facilitates a more general model, as the constants in the flop counts may change depending on implementation and hardware platform. Letting OP denote the cost of the matrix vector operator, the approximate cost function per step for ARPACK is

$$ArpPerMV = c_a\ nev + OP.$$

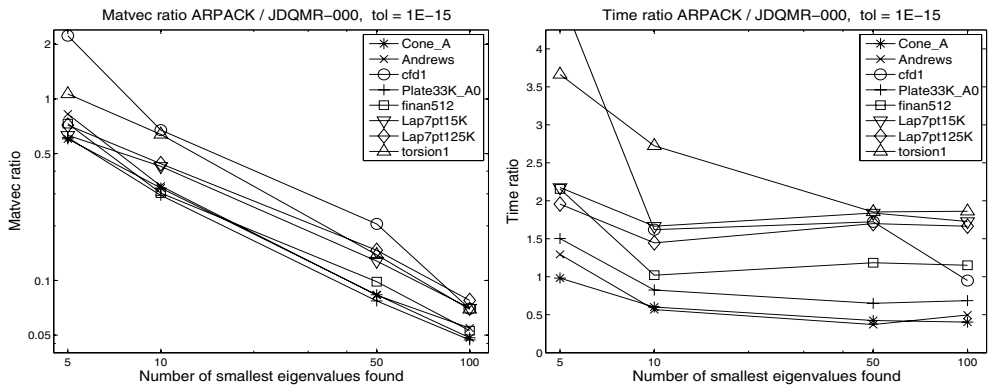

FIG. 4.1. *Relative performance of ARPACK over JDQMR-000 for finding nev smallest eigenvalues of 8 matrices. The left graph shows the matvec ratios. The right graph shows time ratios.*

For JDQMR-000 the cost of the inner iteration is that of the QMR method,

$$InnerPerMV = c_q + OP.$$

If flop count is used as a performance measure, $c_q = 21N$. The outer JD step, which includes orthogonalization against all $l = 1, \ldots, nev$ converged eigenvalues, occurs only every k_{inn} inner iterations. To avoid counting the matvec of the outer step twice, we include it in the cost of the inner method. Then, we have the following approximate cost model per operator application:

$$OuterPerMV = c_g \; nev/k_{inn}.$$

To provide insight on the size of the constant c_g we can use an accounting method to analyze the average cost per step over all $l = 1, \ldots, nev$. Because the outer iteration is an inexact Newton method, each eigenvalue is obtained with roughly the same number of outer iterations. Then, if m_{op} is the total number of matvecs, one eigenvalue is found every $m_{op}/(k_{inn}nev)$ outer iterations. Therefore, the total orthogonalization cost throughout the execution of the method is $m_{op}/(k_{inn}nev)\sum_{l=0}^{nev-1} 8lN = m_{op}4(nev - 1)N/k_{inn}$. Averaging over all m_{op} matvecs, we obtain $c_g = 4N$.

The outer JD step also incurs costs for orthogonalization of the basis, restarting, and residual computation. These can be twice as expensive as the ARPACK costs if the basis sizes were the same. But with locking, these outer JD costs do not scale with nev, so they are not included in c_g. Thus, asymptotically, $f = c_g/c_a = 4/14 < 1$, but f increases for small nev.

Considering the ratio of the overall JDQMR-000 and ARPACK costs and substituting the matvec model from (4.1), we have

$$r_{arp}^{j000} = \frac{MV_{jdqmr000}(c_q + OP + c_g \; nev/k_{inn})}{MV_{arp}\;(c_a nev + OP)} = \frac{C(c_q + OP)}{c_a + OP/nev} + \frac{Cnev\; c_g/k_{inn}}{c_a + OP/nev}. \tag{4.2}$$

Asymptotically, for large nev and not too dense operators, we have $OP/nev \ll c_a$, and the ratio can be approximated as

$$r_{arp}^{j000} \approx C\;\frac{c_q + OP}{c_a} + \frac{f\; C\; nev}{k_{inn}}. \tag{4.3}$$

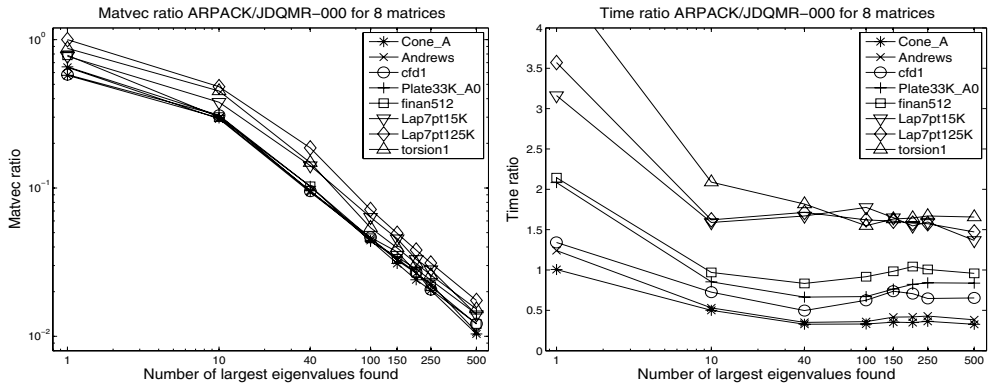

FIG. 4.2. *Relative performance of ARPACK over JDQMR-000 for finding nev largest eigenvalues for tol* $= 1e-15$. *The left graph shows the matvec ratios. The right graph shows time ratios.*

The first summand in (4.3) determines when JDQMR-000 cannot be faster than ARPACK, regardless of k_{inn}, because of too expensive an operator. The first summand, and thus the ratio, is always greater than 1 if $OP > c_a/C - c_q$. In our experiments $C \in [0.1, 0.25]$, [illegible] 000 [illegible] $OP < 119N$ [illegible] $OP < 35N$ (for $C = 0.1$ or $C = 0.25$, respectively). Yet, for many important problems stemming from finite difference or finite element discretizations of PDEs, the matrices are sufficiently sparse to favor JDQMR-000.

Equation (4.3) states that even for those sufficiently sparse matrices, [illegible] 000 [illegible] *nev* Initially, when only some of the eigenvectors have converged, JDQMR-000 spends most of its time in the inner iteration. As more eigenvectors converge, the orthogonalization of the outer step becomes increasingly expensive and will eventually dominate.

Some intuition can be gained by two extreme examples. First, consider a hypothetical case with the least competitive choice of parameters for JDQMR, $C = 0.25$ and $k_{inn} = 10$. The second summand of (4.3) remains less than 0.8 for $nev < 112$. Second, consider an actual experiment with the Lap7pt15K matrix, as shown in Figure 4.3. This case is favorable for JDQMR-000, but it also demonstrates how well the model captures the relative behavior of the two methods. For this case, we empirically measure $C = 0.1$, $k_{inn} = 50$. Also, because of the seven point three-dimensional Laplacian, the operator cost is $14N$. With these values, the model becomes $r = 0.25 + 0.00057\ nev$, dictating that JDQMR-000 is faster than ARPACK for $nev < 1313$, which is close to the crossover point in the experiment. Moreover, for smaller nev values, the first summand dominates, and this is the reason why in Figures 4.1 and 4.2 the time ratio of the two methods for this matrix looks constant for $40 < nev < 500$.

When seeking only a few eigenvalues, JDQMR-000 is always faster than ARPACK, not so much because it avoids the projectors, but because of the nearly optimal convergence for one eigenpair and the cheaper QMR iteration ($21N$ versus $14N$ nev). In (4.2) the second summand is negligible if $nev \ll k_{inn}$, and so $r_{arp}^{j000} < 1$ for $nev = 1$, and r_{arp}^{j000} increases monotonically with nev. Then, $r_{arp}^{j000} \to Cnev$ as $OP \to \infty$, and so, assuming a worst case $C = .25$, JDQMR-000 should always be faster for $nev < 4$, regardless of operator cost. In practice, this model is not meant to be accurate for

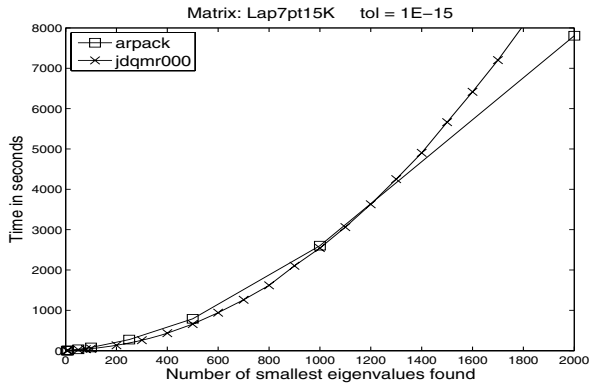

FIG. 4.3. *Time for finding nev smallest eigenvalues for ARPACK and JDQMR*-000. *Although much faster initially, JDQMR*-000 *succumbs to orthogonalization costs of the outer step at* 1100.

small nev, but the intuition it provides agrees with all the experiments we have performed. Moreover, for very high cost operators, GD+k provides a more efficient choice than JDQMR.

In summary, JDQMR-000 is faster than ARPACK for sufficiently sparse matrices and up to a certain nev, which can be $O(100s)$. Beyond that nev, using a larger basis with ARPACK is preferable. For very small nev, JDQMR-000 is always preferable.

4.3. Preconditioned JDQMR-100 versus unpreconditioned JDQMR-000. With a "good" preconditioner, JDQMR-000 can converge quickly on the indefinite correction equation, similarly to an exact shift and invert, obviating the projection with locked eigenvectors. With less accurate preconditioners, our results have been inconclusive. JDQMR-000 would sometimes converge quickly to many extreme eigenvalues, only to slow down appreciably, and unpredictably, on the next unconverged one. For this reason, we do not consider the preconditioned JDQMR-000 further.

Depending on the preconditioner, JDQMR-100 reduces the number of matvecs over unpreconditioned JDQMR-000 by a factor $f_p < 1$: $MV_{jdqmr100} = f_p MV_{jdqmr000}$. The number of matvecs per eigenvalue found by JDQMR-100 may increase with nev because as the shift in the correction equation moves inside the spectrum, the preconditioner, which usually does not change, may not be equally effective. A commensurate increase in matvecs of the unpreconditioned JDQMR-000, however, keeps the f_p roughly constant for different nev. This is depicted for a sample matrix in Figure 4.4, where JDQMR-100 requires 12 times fewer matvecs than the unpreconditioned JDQMR-000 for any nev. Moreover, since the number of outer iterations does not vary substantially, we assume that $k_{inn}^{100} = f_p k_{inn}^{000}$.

In addition to the c_q QMR cost, each JDQMR-100 inner iteration involves a projection with locked eigenvectors (c_p nev) and an operator OP_p which includes matvec and preconditioning. In our flop count model, $c_p = 2N$, which is half of c_g, because we do not reorthogonalize when applying the projector. Reorthogonalization against locked eigenvectors occurs at every outer step for a total of $c_g nev$ cost. Hence, we arrive at the model for the time ratio of the two methods:

$$r_{j000}^{j100} = \frac{MV_{jdqmr100}\ (c_q + OP_p + c_p nev + c_g\ nev/k_{inn}^{100})}{MV_{jdqmr000}\ (c_q + OP + c_g\ nev/k_{inn}^{000})}$$

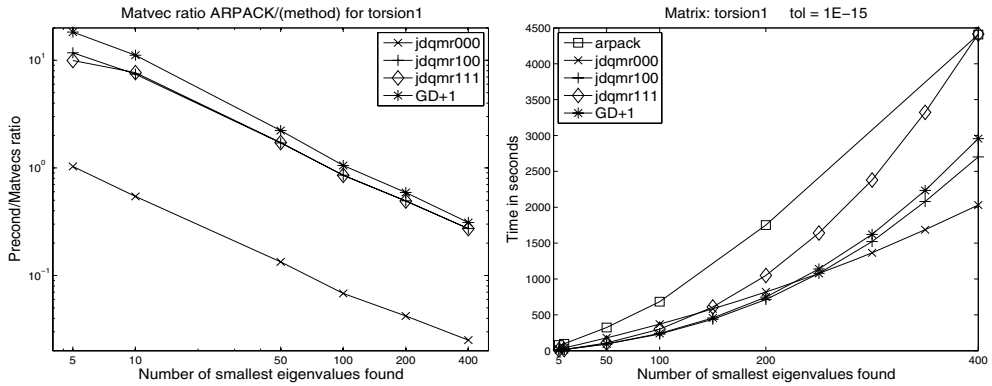

FIG. 4.4. *Matvec ratio of ARPACK over five methods (left graph) and time (right graph) for finding nev smallest eigenvalues. All methods use ILUT*$(40, 1e-3)$ *preconditioning, except for ARPACK and JDQMR-000. Methods that avoid projections are better—even unpreconditioned.*

$$= \frac{f_p(c_q + OP_p + c_p nev) + c_g\ nev/k_{inn}^{000}}{c_q + OP + c_g\ nev/k_{inn}^{000}}. \tag{4.4}$$

For small nev and for preconditioners that are not disproportionally expensive, the ratio is close to f_p, and JDQMR-100 delivers the benefits of preconditioning. For large nev, orthogonalization becomes dominant: $r_{j000}^{j100} \to f_p + f_p k_{inn}^{000}/2 = f_p + k_{inn}^{100}/2$, so since $k_{inn}^{100} > 1$, [illegible] 000 [illegible] 100

Intuitively, the more effective and relatively cheaper the preconditioner, the more eigenvalues JDQMR-100 finds faster before JDQMR-000 becomes beneficial. Figure 4.4 shows an example of this behavior for the torsion1 matrix.

4.4. Preconditioned JDQMR-100 versus ARPACK. Multiplying (4.2) with (4.4) we obtain a time ratio for JDQMR-100 over ARPACK as follows:

$$r_{arp}^{j100} = C f_p\ \frac{c_q + OP_p}{c_a} + C f nev \left(\frac{f_p}{2} + \frac{1}{k_{inn}^{000}} \right), \tag{4.5}$$

where $f = c_g/c_a$ as previously, and OP/nev is negligible. In the example in Figure 4.4, the preconditioned JDQMR-100 has not crossed the ARPACK curve for $nev = 400$, but at that value their growth rates have become similar. For this example, we empirically obtained $f_p = 1/12$, $k_{inn}^{000} = 45$, and $C = 0.1$. Then, according to the model the curves will cross at $nev = 511$, although it is the approximate asymptotic behavior which is of interest here and not the exact crossover point. The curve for the two-projection JDQMR-111 already crosses the ARPACK curve at $nev = 400$.

The last two models suggest that [illegible], for which it may be preferable to switch to unpreconditioned JDQMR-000 (if the matrix operator is inexpensive) or ARPACK (if the matrix operator is expensive). The crossover for that switch, however, depends on the preconditioner and may be a very large nev number.

4.5. JDQMR-100 versus GD+1. We conclude this section with a discussion on the relative performance behavior of GD+1 and JDQMR-100. As we observed in all our experiments and conjectured in [57], the ratio of matvecs $\gamma = MV_{jdqmr1000}/MV_{GD+1}$ is typically $\gamma \in [1, 2.4]$ and usually closer to 1.5. Because

TABLE 4.3

JDQMR-100 versus GD+1: The crossover cost in flops of the combined matrix and preconditioner (OP_p). JDQMR-100 is faster for OP_p costs less than the given values. GD + 1 is faster otherwise. For a certain γ and k_{inn} we also provide the crossover as a function of nev.

	k_{inn} :	10	30	∞
$\gamma = 1.5$	$OP_P <$	$(323 + 0.8nev)N$	$(363 + 1.6nev)N$	$(383 + 2nev)N$
	$nev = 10$	$331N$	$379N$	$403N$
	$nev = 100$	$403N$	$523N$	$583N$
$\gamma = 2$	$OP_P <$	$(141 - 0.8nev)N$	$(168 - 0.3nev)N$	$(181 - 8\frac{nev}{k_{inn}})N$
	$nev = 10$	$133N$	$165N$	$181N$
	$nev = 100$	$61N$	$141N$	$181N$

of similar costs, to compare the two methods for small nev, we must complement the asymptotic model with the outer JD costs that do not depend on nev (residual computation and restarting).

We use the accounting method of section 4.2 to extend the flop-count cost model in [57] to $nev > 1$. The remaining costs that do not depend on nev are given for GD+1 by $c_{gr} = (11.4m_{max} + 18)N$, and for the outer iteration of JDQMR-100 by $c_{qr} = (11.4m_{max} - 3)N$. Hence, the time ratio can be modeled as

$$r_{GD+1}^{j100} = \gamma \frac{(c_q + OP_p + c_p nev + (c_{qr} + c_g\ nev)/k_{inn})}{(c_{gr} + c_g\ nev + OP_p)} \longrightarrow \gamma \left(\frac{1}{2} + \frac{1}{k_{inn}} \right).$$

JDQMR-100 is faster than GD+1 asymptotically if $\gamma \in [1, 2)$ and $k_{inn} > 2\gamma/(2 - \gamma)$, which is the most typical case. For example, for $\gamma = 1.5$ and $k_{inn} = 10$, JDQMR-100 is 10% faster than GD+1, while with $k_{inn} = \infty$ it can be up to 25% faster. If $\gamma > 2$, then GD+1 is always faster. It is important to note that in either case, [illegible]

This asymptotic performance comparison is valid only for nev that are significantly larger than OP_p/N, which includes the cost of both the matrix and the preconditioning operators and thus can be very expensive. Moreover, in the realm of such large nev, JDQMR-000 is always better than JDQMR-100, and ARPACK is eventually faster than JDQMR-000, so the asymptotic comparison is less relevant. In Figure 4.4, using an expensive preconditioner, the two methods are very close, with GD+1 winning slightly for $nev < 150$, and JDQMR-100 winning slightly for $nev > 200$.

For small nev, the winner is determined by the cost of the operator and the number of inner iterations that JDQMR-100 performs. Considering our flop model for the above constants, including the c_{gr} and c_{qr}, and a typical basis size $m_{max} = 18$, we can obtain [illegible] 100 [illegible] +1

$$OP_p < \frac{1}{\gamma - 1} \left(223.2 - \gamma(21 + 202.2/k_{inn}) + (4 - 2\gamma - 4\gamma/k_{inn})nev\right) N.$$

Table 4.3 shows the cost for OP_p beyond which GD+1 becomes faster than JDQMR-100. Despite the asymptotic behavior, with expensive preconditioners the case for GD+1 is compelling even for 100 eigenvalues. Our experiments in the next section use an ILUT preconditioner with a rather large fill-in, and as expected the GD+1 is the fastest method.

We emphasize that we do not advocate the use of flop-counts in the models. They serve only to obtain qualitative information on the trade-offs between methods. Yet, our models are built on top of much more general cost variables (such as c_g or c_q) and operator costs (OP, OP_p) that depend on the implementation and hardware platform.

More importantly, they can be measured not only a priori but also at runtime, thus enabling a dynamic and possibly autonomic method selection that depends on the problem at hand. This is a direction of future research.

5. Comparisons with other methods. In this section we provide further experiments with and without preconditioning, for high and low tolerances, and for both sides of the spectrum. We have already demonstrated the relative asymptotic strengths between GD+k, JDQMR-100, and JDQMR-000. The goals of the following experiments are (a) to show that by avoiding the oblique projector in JDQMR-100, convergence is almost identical to (and sometimes better than) JDQMR-011, and JDQMR-111, but in significantly less time and/or storage, (b) to compare with JDBSYM and BLOPEX, and (c) to confirm some modeling predictions in various cases.

5.1. Without preconditioning. We look for the smallest 100 eigenvalues, and ask for *tol*=1e-15. In Figure 5.1 the left graph shows the linear scaling of matvecs with the number of eigenvalues found for all JDQMR and GD+k methods, except for a slight increase in JDQMR-000. JDBSYM has problems scaling to many eigenvalues for this matrix. The right graph shows the quadratic $O(nev^2)$ behavior in methods with projections, while JDQMR-000 achieves (at least up to 100 eigenvalues) what was designed for: almost linear scaling with *nev*. The matrix, however, has 65 elements per row, yielding an expensive $130N$ operator. Thus, the significant reduction in matvecs from the large ARPACK basis is hard to match. Notice also that JDQMR-100 and JDQMR-011 converge identically.

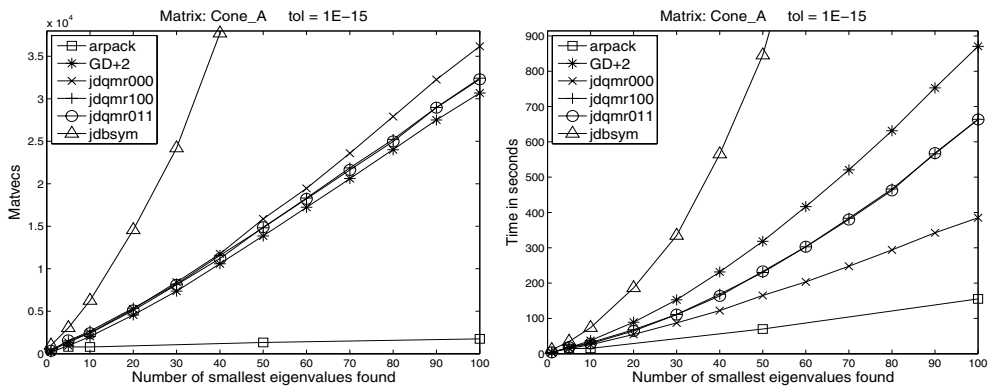

FIG. 5.1. *Matvecs (left graph) and time (right graph) of six methods for nev smallest eigenvalues.*

In Figure 5.2, all JD/GD methods converge very similarly, which means that the stopping criteria of JDBSYM work well in this case. Most methods, particularly JDQMR-000, are better than ARPACK up to 50 eigenvalues, but for $nev = 100$ the much larger ARPACK basis captures some parts of the spectrum that smaller bases could not. ARPACK takes fewer matvecs to find 100 eigenpairs than 50, matching the time of JDQMR-000. This spectrum dependent behavior is hard to model in general.

In Figure 5.3, a sparser matrix, finan512, is considered, and so JDQMR-000 is several times faster than any other JD/GD method and better than ARPACK, exactly as predicted by our model. Again JDBSYM is only slightly slower than JDQMR-100 and JDQMR-011. The last two are again identical.

In Figure 5.4, we consider the largest matrix in the group, whose eigenvalues are all of multiplicity 3 or 6. JDBSYM cannot converge in tractable time for this matrix

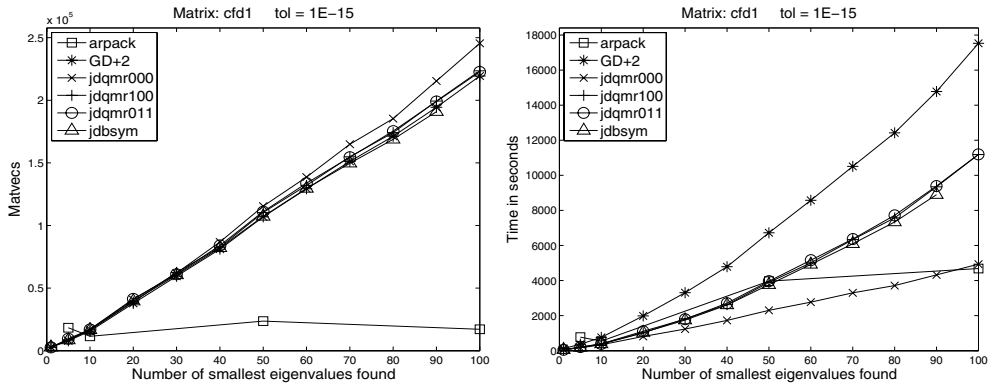

FIG. 5.2. *Matvecs (left graph) and time (right graph) of six methods for nev smallest eigenvalues.*

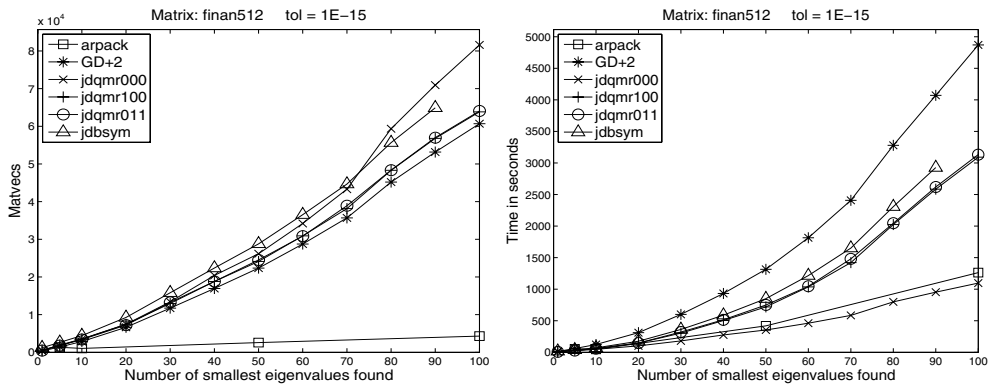

FIG. 5.3. *Matvecs (left graph) and time (right graph) of six methods for nev smallest eigenvalues.*

with strategy = 1, and strategy = 0 performed worse. The sparsity of this Laplacian makes JDQMR-000 significantly faster than all other methods. In all four examples, GD+2 offers the fastest convergence among JD methods in terms of matvecs but not execution time because of its more expensive iteration. Results for the 100 smallest eigenvalues from all matrices were summarized in Figure 4.1.

In the previous examples BLOPEX could not reach the required *tol*. Figure 5.5 shows results from the Cone_A matrix, but with *tol*=1e-7. As with *tol* =1e-15, JDBSYM does not converge well for this matrix. BLOPEX with block size of 10 not only is slower than GD+2/JDQMR methods, but its convergence does not scale linearly with *nev*. For this matrix, the relative behavior of the rest of the methods is similar to *tol* =1e-15 (Figure 5.1).

In Figure 5.6 we observe a significant deterioration of the performance of ARPACK over the *tol* =1e-15 case in Figure 5.2. Closer scrutiny of the iterations between the two figures reveals they are about the same. ARPACK does not benefit from the higher threshold, still computing almost all 100 eigenpairs to full accuracy. We observed this behavior of ARPACK with high tolerances in the majority of our experiments. Surprisingly, JDBSYM is much slower for *tol*=1e-7 than with full accuracy (compare with Figure 5.2). BLOPEX now scales linearly with *nev*, but it is significantly worse than any GD+k/JDQMR method, even for the smallest 10 eigenpairs.

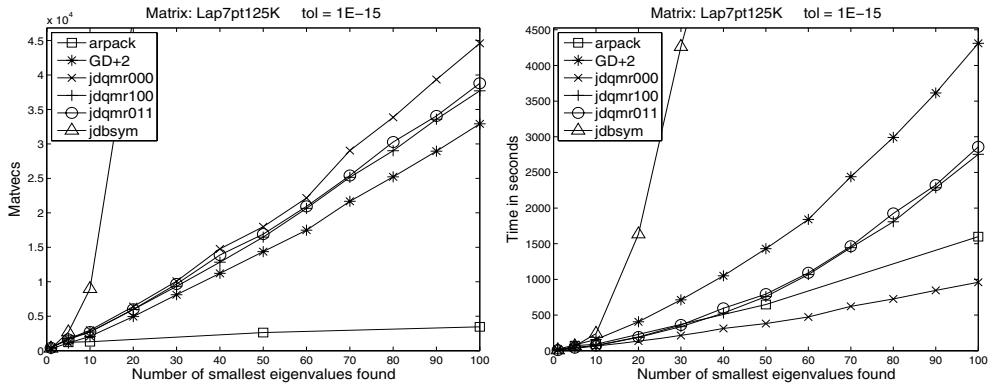

FIG. 5.4. *Matvecs (left graph) and time (right graph) of six methods for nev smallest eigenvalues.*

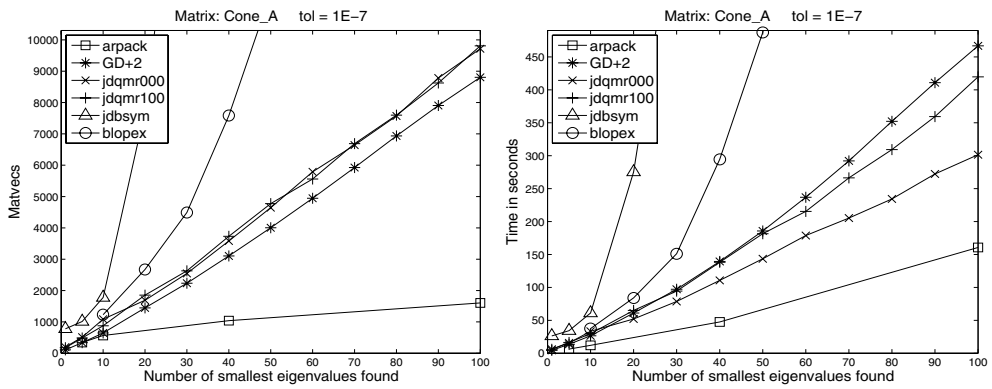

FIG. 5.5. *Matvecs (left) and time (right) of six methods with* $tol = 1e-7$ *for smallest eigenvalues.*

Figure 5.7 reports similar results in execution time for the finan512 and Lap7pt125K matrices. For the finan512, BLOPEX fails to converge to more than 10 eigenpairs, and JDBSYM is again far slower than the *tol* =1e-15 case. The JDQMR and GD+k methods are consistent both in robustness and their relative behavior.

To see whether BLOPEX would perform better on easier spectra, we run experiments with *tol*=1e-7, seeking the 500 largest eigenvalues of the matrices. In Figure 5.8 we give sample results from two matrices. For Plate33K_A0, the largest side of the spectrum is slightly easier to compute, but BLOPEX is still not competitive. For Cone_A, the largest side is much easier. In terms of matvecs (not shown in the figure) BLOPEX is competitive with JDQMR-000 up to 100 eigenvalues, then convergence deteriorates slowly, and the method fails for the 350th eigenvalue. In terms of time, the orthogonalization penalty is apparent on the BLOPEX method.

5.2. With preconditioning. For our preconditioning experiments, we use the ILUT preconditioner from the SPARSKIT library [47]. We have observed that although matvecs always decreased with ILUT, for some matrices execution time did not. Next, we report results from the three matrices on which unpreconditioned JDQMR/GD+k methods were slower than the ARPACK method. For these three cases, ILUT resulted in gains. Also, for the ILUT factorization to complete successfully, we had to shift the matrices slightly away from singularity.

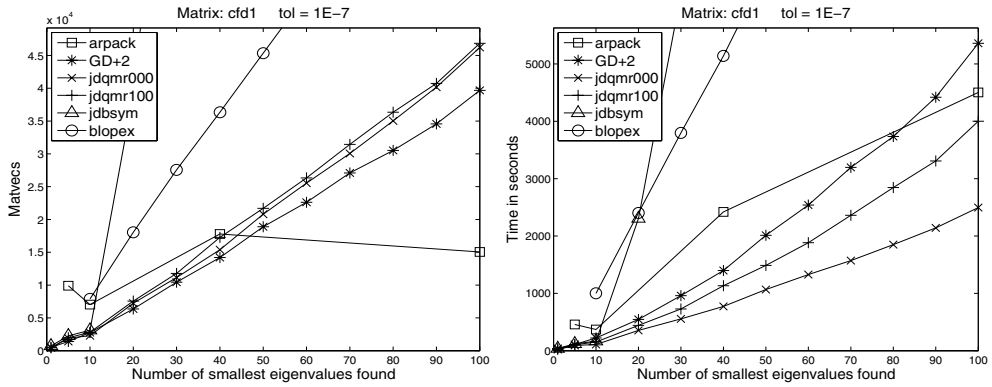

FIG. 5.6. *Matvecs (left) and time (right) of six methods with* $tol = 1e-7$ *for smallest eigenvalues.*

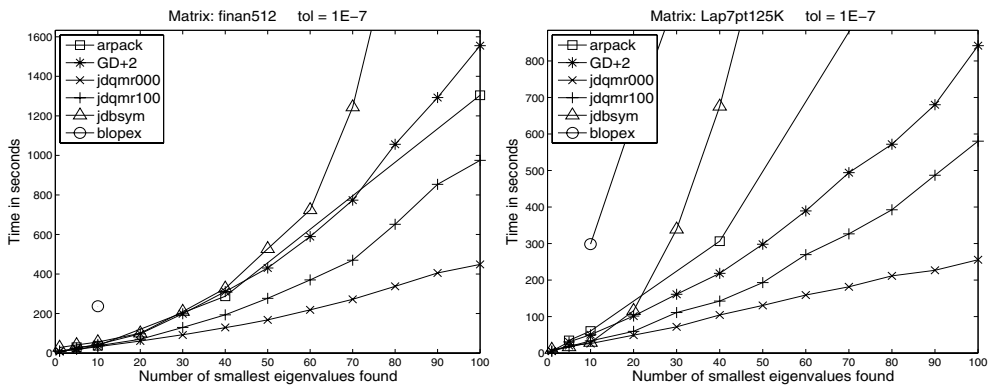

FIG. 5.7. *Execution times of six methods on two matrices with* $tol = 1e-7$ *for smallest eigenvalues.*

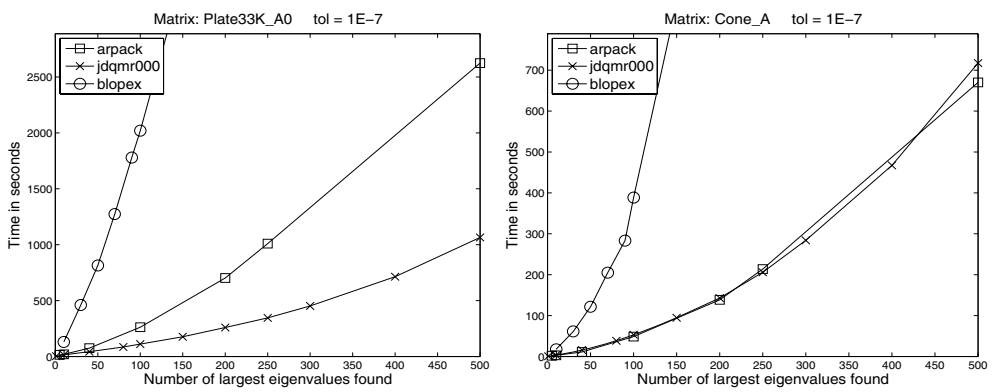

FIG. 5.8. *Times for three methods on two matrices with* $tol = 1e-7$ *for nev largest eigenvalues.*

In Figure 5.9, the ILUT(80,1e-4) of the shifted cfd1 matrix $A+0.01I$ is computed. All preconditioned methods improve and become much better than ARPACK. All JDQMR-100/111/011 variants converge identically, but the 111 takes more time for

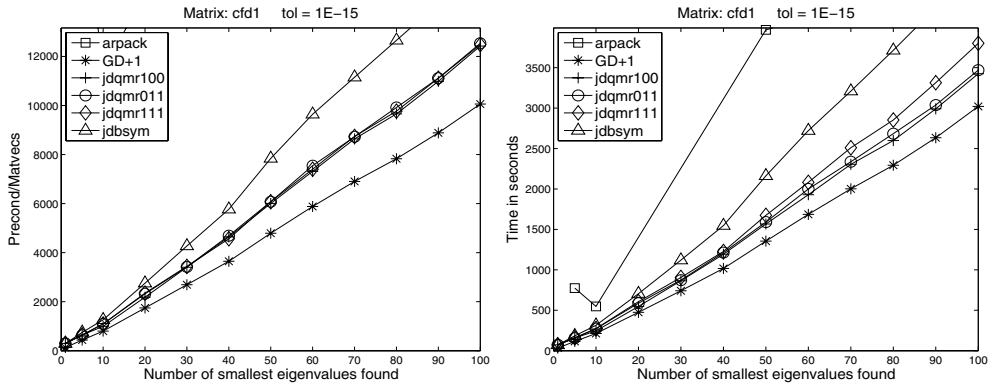

FIG. 5.9. *Matvecs (left) and time (right) with* $ILUT(80, 1e-4)$ *preconditioner. Smallest nev.*

large *nev*. JDBSYM also improves but less than JDQMR-100. Because of large fill-in, the ILUT preconditioner is expensive, and therefore the method with smallest matvecs wins, i.e., GD+1. The number of matvecs for ARPACK is large and out of scale.

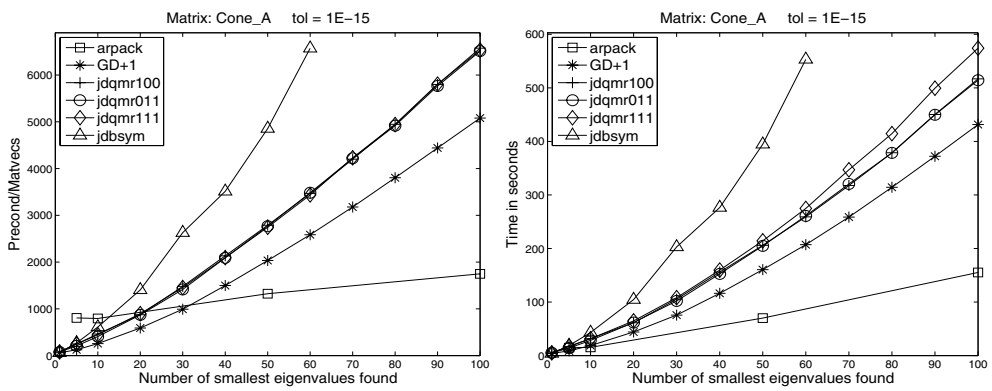

FIG. 5.10. *Matvecs (left) and time (right) with* $ILUT(40, 1e-6)$ *preconditioner. Smallest nev.*

In Figure 5.10, the ILUT(40,1e-6) of the shifted Cone_A matrix $A + 3e6I$ is computed. Although preconditioning reduces matvecs appreciably for JD methods, they still grow linearly with *nev*. As a consequence, the time graph for this experiment shows that ARPACK is faster than any other method beyond $nev = 10$. Observations about the relative behavior of the other methods hold in this example, too. Experiments with the Plate33K_A0 matrix have shown similar convergence behaviors and crossover points, so they are not reported.

Despite the use of preconditioning, BLOPEX was not able to reach convergence to *tol* =1e-15 in any of the previous cases. Therefore, we conclude this section with three experiments that include preconditioning but use a higher tolerance, 1e-7.

In Figure 5.11, with an ILUT(20,1e-6) of the unshifted Laplacian, neither JDBSYM nor BLOPEX were competitive. The graphs also include the unpreconditioned JDQMR-000, the time of which is identical to preconditioned JDQMR-100.

Figure 5.12 shows timing results from Cone_A with the same preconditioner as

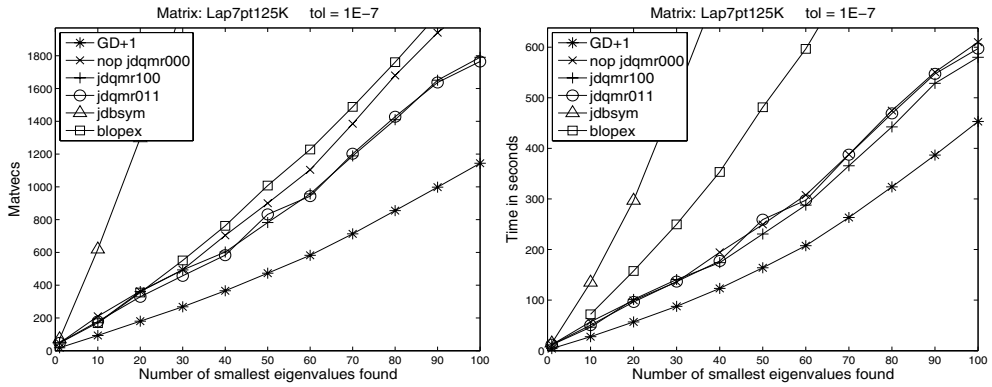

FIG. 5.11. *Matvecs (left) and time (right) with* $ILUT(20, 1e-6)$. *Smallest nev and tol* $= 1e-7$.

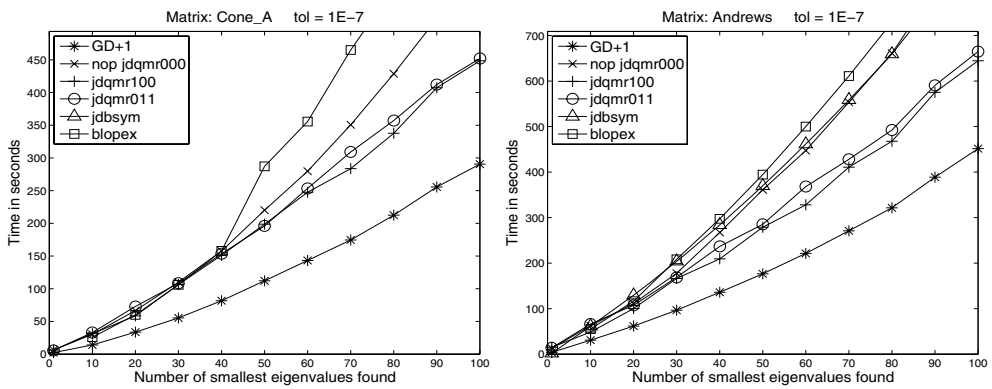

FIG. 5.12. *Times for two matrices, smallest nev, and tol* $= 1e-7$. $ILUT(40, 1e-6)$ *for both matrices.*

before and from the matrix Andrews shifted as $(A-1\text{e-}6I)$. For Cone_A, BLOPEX is marginally faster than JDQMR-100 for 10 eigenvalues, but its convergence deteriorates slowly beyond that and more rapidly after $nev = 40$. JDBSYM converged very slowly for this example. For the Andrews matrix, BLOPEX and JDBSYM are competitive with JDQMR-100 for 10 eigenvalues, but they grow appreciably slower with *nev*, following the curve of the unpreconditioned JDQMR-000. In all our preconditioning experiments, the heavier operators made GD+1 the fastest method.

6. Conclusions. In our research we seek nearly optimal methods for obtaining one or many eigenpairs of Hermitian or real symmetric matrices under limited memory. In an earlier companion paper we identified GD+k and JDQMR as two nearly optimal methods with complementary strengths for obtaining one eigenvalue. In this paper, we offer arguments for why the same near-optimality is not achievable when looking for many eigenpairs.

We have also offered ways to alleviate the quadratic scaling bottleneck stemming from the orthogonalization against converged eigenvectors. Specifically, without preconditioning, our JDQMR-000 method performs no projections during the inner JD iteration and thus achieves nearly linear scaling with *nev* up to the point where *nev* becomes much larger than the number of inner iterations performed, shifting the bot-

tleneck to the outer step. JDQMR-000 outperforms all other JD/GD variants, and for sparse enough matrices even outperforms ARPACK up to thousands of eigenvalues. With preconditioning, our analysis suggests that the oblique projection in the JD correction equation is unnecessary for converged eigenvectors. The resulting method, JDQMR-100, is faster and requires half the storage of other JD variants.

Based on a detailed complexity analysis and extensive experimental observations, we have developed a comprehensive set of models that describes the relative performance between JD variants, GD+k, and ARPACK. The asymptotic analysis has provided the following valuable insight: $O(1)$ $O(nev)$ In practice, $O(1)$ basis sizes with or without preconditioning can be used extremely effectively up to hundreds or thousands of eigenvalues (as our JDQMR-000 shows). Our models also provide performance crossover points between methods that can be used for dynamic, and possibly autonomic, method selection within a multimethod software, such as PRIMME.

Finally, we have provided a large set of experiments on a variety of problems and conditions and have compared these against state-of-the-art methods and software, such as JDBSYM and BLOPEX. Invariably, our GD+k and JDQMR methods are far more efficient and robust and seem to be nearly optimal within the class of $O(1)$ basis size.

Acknowledgments. The comments from the referees have contributed to a clearer and more concise presentation. We thank M. Hochstenbach for pointing out some connections with a method in [4].

ALGEBRAIC MULTIGRID PRECONDITIONING OF HIGH-ORDER SPECTRAL ELEMENTS FOR ELLIPTIC PROBLEMS ON A SIMPLICIAL MESH*

LUKE OLSON†

Abstract. Algebraic multigrid is investigated as a solver for linear systems that arise from high-order spectral element discretizations. An algorithm is introduced that utilizes the efficiency of low-order finite elements to precondition the high-order method in a multilevel setting. In particular, the efficacy of this approach is highlighted on simplexes in two and three dimensions with nodal spectral elements up to order $n = 11$. Additionally, a hybrid preconditioner is also developed for use with discontinuous spectral element methods. The latter approach is verified for the discontinuous Galerkin method on elliptic problems.

Key words. spectral element, discontinuous Galerkin, algebraic multigrid

1. Introduction.

In recent years spectral element methods have increased in popularity [18, 9]. Their success is often attributed to the ability to approximate solutions to partial differential equations (PDEs) efficiently by requiring fewer degrees-of-freedom than low-order approaches (e.g., bilinear finite elements). Moreover, high-order methods yield more accurate solutions in problems with long time integration [14] and are also beneficial in multiscale simulation [17]. Combined with a compatible discretization method such as the discontinuous Galerkin (DG) method, the method is used successfully in a variety of applications [20, 15].

The overall efficiency of high-order methods, however, remains an open question, particularly when a solution to a system of equations is needed. While fewer degrees-of-freedom are required to achieve a certain accuracy in the solution compared with low-order methods, the degrees-of-freedom are more intimately coupled, and the resulting matrix is more dense. The reduced locality impacts both the amount of storage and the complexity of the solver.

The use of high-order elements also changes many matrix properties, impacting the success of an iterative method. The condition of the matrix is high compared to that of low-order methods resulting in slower convergence (e.g., $\mathcal{O}(N^4/h^{-2})$ for two dimensional (2D) elliptic problems [26]), and the systems are not M-matrices, a valuable theoretical property for algebraic multigrid.

The multigrid method has found success for a variety of applications [32], particularly in the scope of elliptic problems. Algebraic-based multigrid methods [30] in particular have emerged as robust solvers, relying only on the graph of the matrix to achieve a scalable algorithm. The primary goal of this paper is to investigate the use of algebraic multigrid (AMG) with low-order finite elements as a preconditioner of high-order spectral element discretizations of elliptic problems.

The contributions of this paper are twofold. First, an AMG algorithm for solving systems arising from nodal spectral elements on simplexes in two and three dimensions is highlighted. The solution technique utilizes a low-order finite element preconditioner based on a local Delaunay triangulation of the interpolatory nodes. Scalable performance of the multigrid preconditioner is verified. Second, a new hybrid preconditioner is identified for use in a nonconforming setting. In particular, we extend the successful AMG preconditioner in the continuous setting to an effective solution method in the discontinuous framework and highlight the necessary components for achieving a scalable algorithm.

The remainder of the paper is organized as follows. Sections 1.1 and 1.2 briefly detail the spectral element method and the common AMG framework used throughout the paper. In section 1.3, previous results are summarized which provide a basis for the algorithmic details and performance outlined in section 2. The preconditioner for the discontinuous method is introduced in section 3, and we summarize the scope of this research in section 4.

1.1. Discretization. The focus of this paper is on spectral elements of nodal type: basis functions defined by Lagrange interpolating polynomials over a set of nodes. While this framework has many benefits, including direct representation of the solution as coefficients and a decoupling of degrees-of-freedom in the case of inter-element connectivity, it does not possess a direct hierarchical representation. Spectral methods of modal type often do form a hierarchical set and are more directly amenable to multilevel solution techniques. The so-called spectral multigrid method developed computationally and theoretically in [22, 27, 23] has proven to be efficient, yielding bounded convergence factors in one dimension and only marginal growth in two dimensions. The results in [12] highlight the versatility of the p-multigrid approach. As discussed in section 1.3, we follow an approach that also utilizes a low-order basis, but we do so through well-established theory on the spectral equivalence of the low-order finite element and high-order spectral element operators.

Let $\Omega \in \mathbb{R}^d$ denote the domain for $d = 2, 3$. Initially we focus on the elliptic PDE

$$-\nabla \cdot \nabla u(\mathbf{x}) = f(\mathbf{x}) \quad \text{in } \Omega, \tag{1.1a}$$

$$u(\mathbf{x}) = g(\mathbf{x}) \quad \text{on } \partial\Omega, \tag{1.1b}$$

where AMG has been successful for low-order finite element methods. The associated weak problem for the Galerkin method becomes the following: Find $u_{h,n} \in V$ so that

$$a(u_{h,n}, v_{h,n}) = \ell(v_{h,n}) \quad \forall\, v_{h,n} \in V, \tag{1.2}$$

where

$$a(u, v) = \int_\Omega \nabla u \cdot \nabla v \, d\mathbf{x}, \quad \ell(v) = \int_\Omega f(\mathbf{x}) v \, d\mathbf{x}, \tag{1.3}$$

and V denotes the spectral element basis. The system of equations $Au = b$ that results from (1.3) is the focus of the first portion of this paper.

As explained above, the basis functions V are nodal. As a reference element, we use the d-simplex $\hat{\kappa}_d = \{(\xi_1, \ldots, \xi_d) \in \mathbb{R}^d : \xi_i \in [-1, 1], \sum_{i=1}^d \xi_i < 0\}$ and denote the complete space of n-degree polynomials on $\hat{\kappa}_d$ with minimal dimension as P_n^d. The dimension of this space [13] is $\dim P_n^d \equiv N_n^d = \binom{d+n}{d}$. Over $\hat{\kappa}$ we define $\phi_{n,i}(\mathbf{x}) \in \hat{V}$ as a Lagrange interpolating polynomial with the property $\phi_{n,i}(\mathbf{x}_j) = \delta_{ij}$, where δ_{ij} is the Kronecker delta function, $\mathbf{x}_i$ are nodal locations, and i ranges from 1 to $N = N_n^d$.

FIG. 1.1. *Nodal sets with* $n = 10$ (1.1(a)) *and* $n = 6$ (1.1(b)) *on the reference elements.*

In one dimension, the Gauss–Legendre–Lobatto (GLL) nodes offer a highly stable and complete set interpolation points for a Lagrange basis. For higher dimensions, a natural set of nodal locations is not available. Much progress has been made in defining stable and accurate nodal sets [31, 33]; we employ nodal locations based on electrostatics [13] due to their availability and near-optimal numerical properties. The results in this paper were largely invariant with respect to small variations in the nodal locations, namely using the Fekete nodal set [31] or Warp&Blend nodes [33]. In two dimensions, the electrostatic nodal set we use enforces GLL nodes on each edge of $\hat{\kappa}_2$, letting the remaining $N_n^2 - 3N_n^1 - 3$ interior nodes be determined by symmetry and electrostatic distribution. Similarly, in three dimensions, we impose the 2D distribution on each face of the tetrahedron and allow the remaining nodal locations in the interior to be determined also from electrostatics. The values are determined in preprocessing or from a library and only for the reference element $\hat{\kappa}_d$. An example is illustrated in Figure 1.1. As with GLL nodes in one dimension, the electrostatic nodes (equal to GLL nodes in one dimension) are clustered in the corners.

1.2. Algebraic multigrid. We consider the solution of high-order $A_{sp}u = b$ using algebraic-based multigrid methods together with standard Krylov acceleration methods such as the conjugate gradient (CG). The AMG algorithm we adhere to is the classical Ruge–Stüben (RS) [30] algorithm, with a few modifications, which are mentioned throughout this paper. The MG cycling we use is the familiar V-cycle summarized for two levels by the following:

1.	Presmooth ν_1 times on the fine grid Ω^0	$u^0 \leftarrow S(u^0; \nu_1)$.
2.	Restrict residual $r^0 = b^0 - Au^0$ to the coarse grid Ω^1	$r^1 = Rr^0$.
3.	Solve the coarse grid problem $A^1e^1 = r^1$ on Ω^1	$e^1 \approx (A^1)^{-1}r^1$.
4.	Interpolate the coarse-grid error to Ω^0	$e^0 = Pe^1$.
5.	Correct the previous approximation on Ω^0	$u^0 \leftarrow u^0 + e^0$.
6.	Postsmooth ν_2 on the fine grid Ω^0	$u^0 \leftarrow S(u^0; \nu_1)$.

The setup phase is more tedious and impacts on the application to high-order discretizations. Unknown u_i is connected to u_j if $a_{ij} \neq 0$. The size of a_{ij} indicates the impact of this connection, relating how much influence the error at j has on the error at i in the relaxation process. We say that u_i is strongly connected [30] to u_j if

$$-a_{ij} \geq \theta \max_{k \neq i} -a_{ik}, \tag{1.4}$$

where a threshold of $\theta = 0.25$ is used in our computations, a typical selection for

elliptic problems. We refer to [30] for details on the selection of coarse grids.

For a given C/F splitting of Ω^0, the next step in the setup phase is to define interpolation. The θ parameter in the definition of the strength-of-connection controls the density of coarse grids. Likewise, in the definition of interpolation, we need to ensure that corresponding coarse-grid operators A^k are sufficiently sparse. In section 2, long-range connections are not used in interpolation: only direct connections are used in the definition. However, it does not yield effective interpolation for all problems, as highlighted in section 3.

Although AMG is well suited as a solution technique, it is also used for many problems as an effective preconditioner. This process can be viewed as acceleration since Krylov steps can often reduce error components that the multigrid cycle is unable to annihilate. Furthermore, each step of the Krylov method is relatively inexpensive, requiring on the order of one matrix-vector multiply.

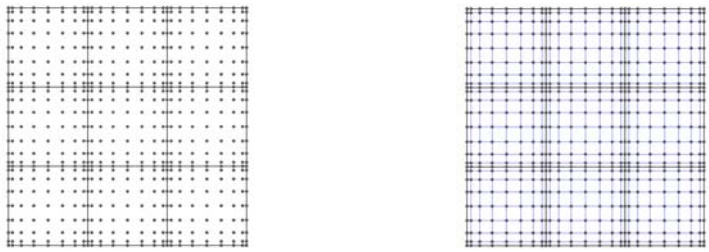
ALGORITHM 1. AMG-PCG ALGORITHM.

1 $r_{new} = r_0 = b - Ax_0$
2 $MG_{\text{setup}}(\hat{A})$
3 $p = z = MG_{\text{cycle}}(\hat{A}, r_0)$
4 while $\|r_{new}\|/\|r_0\| > \delta$
5 $\quad \alpha := (r, z)/(Ap, p)$
6 $\quad x_{new} := x + \alpha p$
7 $\quad r_{new} := r - \alpha Ap$
8 $\quad z_{new} := MG_{\text{cycle}}(\hat{A}, r_{new})$
9 $\quad \beta := (r_{new}, z_{new})/(r, z)$
10 $\quad p_{new} := z_{new} + \beta p$
11 $\quad$ update r, z, p

The construction of $\hat{A}$ in Algorithm 1 is central to the algorithm introduced in sections 2 and 3. Specifically, steps 2, 3, and 8 require the formulation of $\hat{A}$ along with the definition of the associated multigrid process. The reference to MG_{cycle} in Algorithm 1 consists of one V-cycle for the computations reported in this paper, but the use of multiple cycles or W-cycles may be easily incorporated.

1.3. AMG vis-à-vis high order. The strategy proposed in this paper relies on the ability of low-order finite element operators to precondition the high-order spectral element discretization. Let A_s be the matrix from a spectral element discretization, and let A_f be the resulting matrix from a low-order method defined over a tessellation of the nodal set in the spectral element discretization. The concept is well developed with early contributions in [24]. In [24], it is shown that using a finite-difference operator to precondition a matrix from a *spectral* method is effective in one dimension. The use of finite elements is detailed in [8] for one dimension, and the effectiveness for two dimensions is detailed in [10]. Norm dependent bounds on $A_f^{-1}A_s$ are further developed in [25], the impact of advection and reaction terms are studied in [25, 11], and the 2D and 3D Helmholtz problem is studied in [4]. The condition number in higher dimensions, however, does not in general remain bounded, and the effectiveness of preconditioning is decreased when using simplexes [10]. Still, the condition of the system is improved and is suitable for Krylov iterative methods. An extensive study focusing on Schwarz methods in this context can be found in [21] and has motivated much the effort here.

As an example of the low-order preconditioner, consider the 3×3 spectral element mesh of order $n = 10$ displayed in Figure 1.2(a). The nodal set used in each element is a tensor set of the one dimensional (1D) GLL nodes. An effective preconditioner



(a) A_s (b) A_f

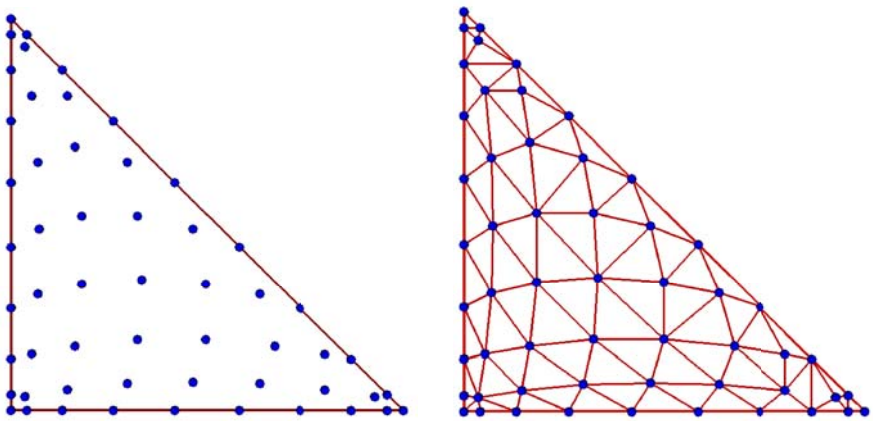
FIG. 1.2. *Meshes corresponding to the spectral element operator A_s and to the finite element preconditioner A_f, respectively.*

utilizes the nodal locations, forming a bilinear finite element mesh resulting in A_f. The effect is illustrated in Figure 1.2(b). The performance using low-order finite element preconditioning with AMG is studied for quadrilaterals in [16]. One AMG V-cycle is used to approximate the action of A_f^{-1} to precondition the spectral element matrix.

Two aspects are highlighted in [16] which motivate the algorithms developed in this paper. First, for both Poisson's equations and Stoke's flow (H^1-elliptic least-squares form), the use of a bilinear finite element preconditioner with AMG as illustrated in Figure 1.2 scales with spectral element order. The preconditioner is known to be effective; however, the inexact and inexpensive preconditioning of AMG is sufficient. More precisely, CG iterations exhibit a linear increase with spectral order n, while AMG preconditioned CG (AMG-PCG) iterations remain invariant, needing only 12–14 iterations in the cases tested. Furthermore, the average convergence factor of the AMG-PCG iterations also scaled with n, remaining constant at around 0.34. Also notable regarding this simulation is that the AMG complexity (detailed below in section 2) remains bounded, although somewhat high.

The subtle nature of complexities is the basis of the second observation in [16]. While AMG-PCG applied directly to the spectral operator A (i.e., $\hat{A} = A$) yields attractive convergence factors of around 0.1 for all spectral orders, the cost of each AMG cycle heavily depends on n. The overall cost associated in preconditioning with $\hat{A} = A$ scales as $\mathcal{O}(n^4)$, whereas preconditioning with $\hat{A} = A_f$ scales only as $\mathcal{O}(n^2)$. The underlying statement of [16] is that AMG-PCG iterations can be performed directly on the spectral element operator when $n < 4$ and that $\hat{A} = A_f$ preconditioning is beneficial if $n \geq 4$. The later case is even more remarkable since explicit construction of the spectral element operator A is not needed, saving memory and reducing the $\mathcal{O}(n^4)$ construction cost.

The algorithms proposed in this paper follow a similar process; however, we extend the results, implementation, and analysis in a number of directions. The methodology is extended to simplexes and for nontensor nodal sets—based on electrostatics introduced in section 1.1—requiring an unstructured local tessellation utilizing a reference Delaunay triangulation. Additionally, the quality of the meshes is considered and simulations are performed both in two and in three dimensions. A new complexity measure is also introduced to account for the use of a low-complexity, low-order preconditioner in the context of a high-order solver. The new measure highlights the efficacy of low-order finite element AMG preconditioning. Discontinuous spectral elements are also considered, and a novel multilevel preconditioner is introduced.



(a) $n = 10$ (b) $n = 1$

FIG. 2.1. *Local Delaunay tessellation of the reference element for* $n = 10$.

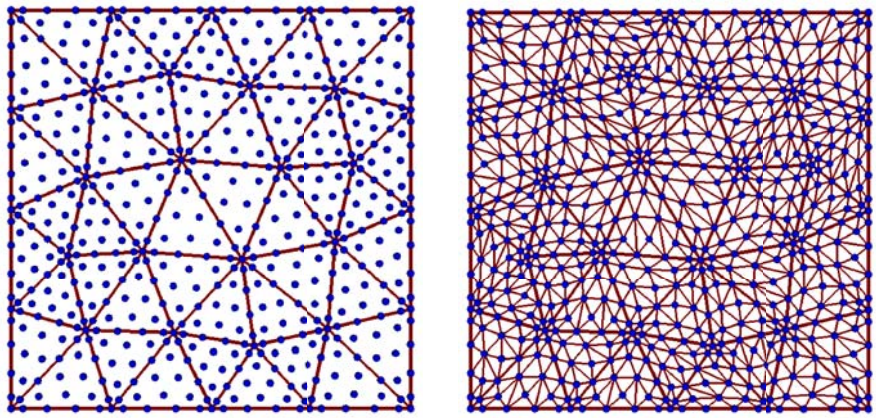
2. Continuous methods. In this section we investigate the use of Algorithm 1 for high-order spectral elements on triangular and tetrahedral meshes. A continuous Galerkin method is used (1.3) to discretize the model problem (1.1).

Central to the algorithm is the ability to use a low-order finite element operator as a preconditioner: $\hat{A} = A_f$. For triangles and for tetrahedrons, the nontensor nodal locations (see Figure 1.1) require additional attention, whereas in the case of quadrilaterals, a straightforward structured mesh is used to locally tessellate the nodal set (see Figure 1.2). Here, we use a Delaunay triangulation of the nodal set on the reference element, mapping the local tessellation to each element in the spectral element mesh to construct the global finite element mesh. The Delaunay triangulation is used since it maximizes the minimum angle of the local elements as depicted in Figure 2.1. Moreover, since the Delaunay operation is executed in preprocessing over just the reference element, it does not add to the complexity of the algorithm. The nonuniqueness of tetrahedral tessellations did not result in problematic elements for the nodal sets tested, although postprocessing could easily be included to ensure the exclusion of so-called sliver elements. Since the quality of the tessellation is enforced only on the reference element, the area ratios and minimum angles are not preserved over the global grid. Yet, given a reasonable initial spectral element mesh, we can assume for d-simplexes that the mesh qualities are preserved since the map Jacobian is constant. On the other hand, as with quadrilaterals, the aspect ratio of the mesh can become skewed particularly at high order due to the grouping of nodes in corners. An example is illustrated in Figure 2.2.

2.1. AMG measures. A classical Ruge–Stüben implementation of AMG is used (see section 1.2). We assume a C/F splitting and define interpolation by considering $Ae \approx 0$ for smooth error. That is,

$$a_{ii}e_i \approx -\sum_{j\in C_i^s} a_{ij}e_j - \sum_{j\in F_i^s} a_{ij}e_j - \sum_{j\in N_i^w} a_{ij}e_j, \tag{2.1}$$

where C_i^s are C-points that strongly influence F-point i, F_i^s are F-points that strongly influence i, and N_i^w are points that weakly influence i. First, weak connections N_i^w



(a) $n = 6$ (b) $n = 1$

FIG. 2.2. *Meshes corresponding to the spectral element operator A and to the finite element preconditioner A_f, respectively.*

are distributed to the diagonal as in the original RS description [30] (cf. [3]):

$$\left(a_{ii} + \sum_{j \in N_i^w} a_{ij}\right) e_i \approx - \sum_{j \in C_i^s} a_{ij} e_j - \sum_{j \in F_i^s} a_{ij} e_j. \tag{2.2}$$

Intuitively this is compatible with the high-order discretization as weak connections may be large in magnitude but of the same sign as the diagonal, thus preserving the dominance of the F-point i in the interpolation process. Numerically the performance is only slightly improved.

The remaining term in (2.2) is perhaps more important than the weak connections: F-points strongly influencing i. We also adhere to the original algorithm and distribute direct strong connections along all nodes in C_i^s to ensure that interpolation is reasonable in the event that a strength of an edge has been misidentified for a positive off-diagonal entry.

The remaining parameters in the AMG algorithm are standard and largely invariant with spectral order for the problems tested. We run V(1,1)-cycles in all tests performed, using pointwise Gauss–Seidel over C-points followed by F-points in prerelaxation and the reverse ordering for postrelaxation in order to preserve symmetry of the AMG preconditioner, a necessary attribute for PCG.

Measuring the performance of Algorithm 1 is not straightforward. Typical tools in analyzing the performance of multigrid include the convergence factor, ρ, which is computed as the average reduction in the residual in each iteration. In each test, we drive Algorithm 1 until the relative residual is reduced by a factor of 10^{-6}. One component of a scalable algorithm is to maintain a constant convergence factor (as low as 0.05 for some problems). The other key element is the complexity of each step in the process. For AMG we consider the *operator complexity* for a matrix A^0:

$$\chi_{\text{op}} = \frac{\sum_{\ell=0}^{\ell_{max}} \aleph(A^\ell)}{\aleph(A^0)}, \tag{2.3}$$

where $\aleph(A)$ is the number of nonzeros in matrix A and ℓ_{max} is the number of levels to be visited in the AMG cycle. The operator complexity is more instructive than

the *grid complexity*, which similarly measures the number of variables on all levels compared with the finest. Additionally, we define the *cycle complexity* as

$$\chi_{\text{cyc}} = \frac{\sum_{\ell=0}^{\ell_{max}} \nu_\ell \cdot \aleph(A^\ell)}{\aleph(A^0)}, \tag{2.4}$$

where ν_ℓ is the number of relaxation sweeps on level ℓ. If we consider one relaxation sweep on the fine grid as one work unit, then χ_{cyc} approximates the amount of work per cycle; for a V(1,1)-cycle, χ_{op} and χ_{cyc} differ by a factor of approximately 2. As we intend to iterate on both spectral and finite element matrices, we denote by χ^s_{cyc} and χ^f_{cyc} the respective cycle complexities.

The results listed in [16] indicate that the cycle complexities χ^f_{cyc} using finite element preconditioning are much larger than the complexities of AMG applied directly to the spectral element operator χ^s_{cyc}. Moreover, χ^s_{cyc} scales with polynomial order, while χ^f_{cyc} grows slightly. If we consider the complexity of the overall algorithm, the results are even more compelling. The fundamental difficulty with χ^f_{cyc} is that $A_f u = b$ is not the target system and does not dominate the process. Rather, the matrix-vector multiply in the CG wrapper involves spectral element operator A_s and comprises much of the cost. This identifies the suboptimal performance indicated by χ^f_{cyc}. Additionally, due to the extreme density of the high-order operator on the finest level, the spectral complexity χ^s_{cyc} is deceptively small. To extend these definitions, we propose the following hybrid operator complexity which accounts for the finite element operator within the spectral PCG wrapper (Algorithm 1):

$$\chi^\star_{\text{op}} = \frac{\aleph(A^0) + \sum_{\ell=0}^{\ell_{max}} \aleph(A^\ell_f)}{\aleph(A^0)} \tag{2.5}$$

$$= \frac{\aleph(A^0) + \chi^f_{\text{op}} \cdot \aleph(A^0_f)}{\aleph(A^0)}. \tag{2.6}$$

A similar definition for $\chi^\star_{\text{cyc}}$ follows.

Combining the work per cycle (2.6) with the convergence factor ρ, we define the overall work as the number of work units to reduce the residual by a factor of 10:

$$W = -\frac{\chi_{\text{cyc}}}{\log_{10} \rho} \tag{2.7}$$

or

$$W^\star = -\frac{\chi^\star_{\text{cyc}}}{\log_{10} \rho}. \tag{2.8}$$

2.2. Numerical tests. In this section we present numerical results validating the scalability of Algorithm 1 with the measures introduced in the previous section. In particular, we refer to four situations listed in Table 2.1.

The performance results in Figures 2.3(c) and 2.4 are for a spectral element unstructured triangulation of the unit square with 574 elements. The mesh quality is high, with a normalized minimum angle of 0.7 (over a scale of 0.0 to 1.0) and an area ratio of approximately 0.5. The solver performance was consistent for both coarser and finer spectral element meshes, with nearly constant element diameters across the tessellation; for brevity we present only this particular case.

TABLE 2.1
List of methods.

CG-A_s	The classical CG method applied to the target system of equations $A_s u = b$.
AMG-A_s	AMG V(1,1)-cycles as a solver for $A_s u = b$, rather than used as a preconditioner.
PCG-AMG-A_s	AMG-A_s with acceleration. Algorithm 1 with $\hat{A} = A$.
PCG-AMG-A_f	AMG preconditioned CG using low-order finite element preconditioning. Algorithm 1 with $\hat{A} = A_f$.

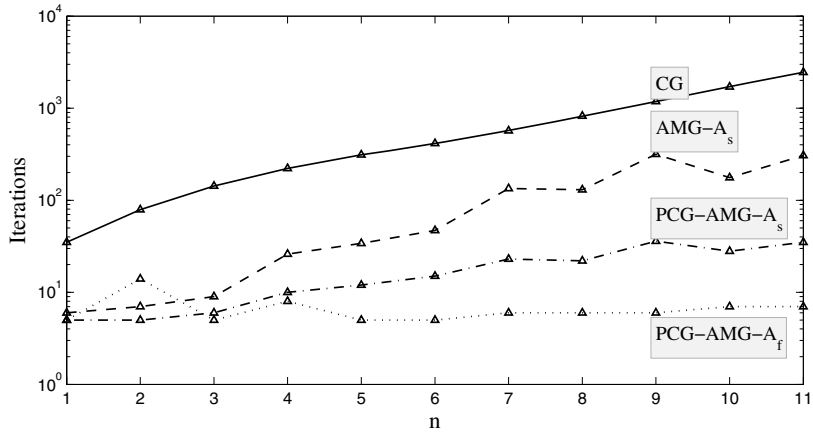
The methods in Table 2.1 are compared as the order of the spectral element is increased from linear ($n = 1$) to very high-order ($n = 11$). Figures 2.3(a)–2.3(c) highlight the efficiency of low-order preconditioning with AMG. As a benchmark, pure CG iterations (CG-A_s) are also listed in the first figure. From Figure 2.3(b) it is evident that AMG alone is unable to handle orders beyond $n = 6$. This is consistent with previous attempts where direct application of AMG was found to become ineffective at $n \approx 4$ [29]. Furthermore, both Figures 2.3(a) and 2.3(b) confirm the scalability (in spectral order) for low-order preconditioning. Krylov acceleration alone is unable to effectively capture problematic eigenmodes in the faulty AMG-A_s. The level curve for PCG-AMG-A_f compared with the nontrivial slope in the PCG-AMG-A_s approach confirms that the low-order operator A_f combined with AMG is accurately preconditioning the spectral operator in the CG algorithm.

Figures 2.3(a) and 2.3(b) do not fully address the complexity of the algorithm. The complexity of steps 2 and 8 in Algorithm 1 will vary depending on $\hat{A}$. For both AMG-A_s and PCG-AMG-A_s, we base the work (2.7) on complexity χ^s_{cyc} as in (2.4). The PCG-AMG-A_f algorithm with $\hat{A} = A_f$ requires the hybrid complexity $\chi^\star_{\text{cyc}}$ defined by $\chi^\star_{\text{op}}$ in (2.6), and the associated work is defined in (2.8). The work is presented in Figure 2.3(c). Since AMG is able to maintain a modest level of complexity for the low-order operator as n increases, the overall complexity remains close to 1.0, while the work increases significantly when AMG is applied to the spectral operator A_s.

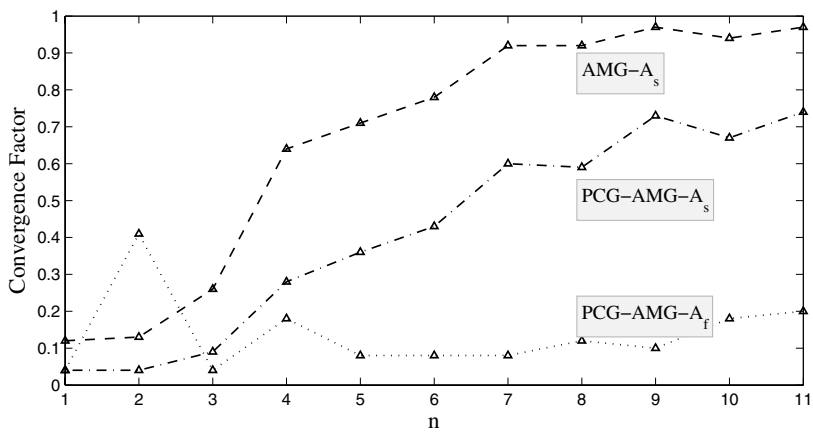
The low complexity associated with AMG applied to A_f is predictable, as the density of the operator is much less than that of the spectral operator A_s (cf. Figure 2.4): the number of connections per node in the graph of A_f was on average 6, and the maximum number of connections increases from 8 to 12 with n. The notable AMG advantage is the ability to handle large variations in the size of the elements. The area ratios of the finite element mesh decrease with $\mathcal{O}(n^4)$ (cf. Figure 2.4) as the polynomial order increases, while the minimum angle degrades only slightly, being preserved by the local Delaunay process. This view captivates the necessity of using an algebraic-based solver in the context of low-order preconditioning on unstructured grids.

We extend this approach to three dimensions in a similar manner over a spectral element unstructured mesh of 188 elements. The performance for the methods listed in Table 2.1 are presented in Figure 2.5 and reveal a trend similar to that of two dimensions. AMG combined with CG acceleration effectively preconditions the spectral element operator A_s when combined with A_f, while use of AMG with A_s yields both poor convergence and high complexities.

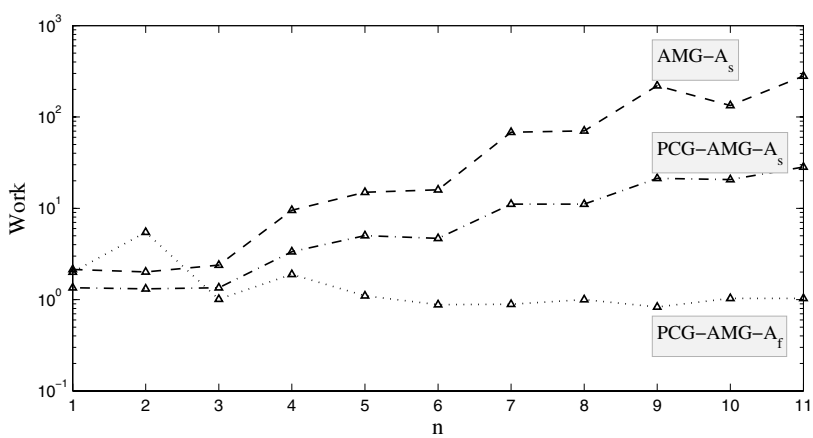
Similar to the case of quadrilaterals [16], AMG should be used directly with A_s when the spectral order is low $n \leq 4$, while low-order preconditioning is beneficial for high-order $n > 4$. When matrix-free application of the spectral operator A_s is available, then $\hat{A} = A_f$ gains even more appeal, although construction and management



(a) Iterations



(b) Convergence Factors



(c) Total Work

FIG. 2.3. *Performance measures in two dimensions: The convergence factors (ρ), iterations to convergence, and work per digit of accuracy are listed for the methods in Table* 2.1.

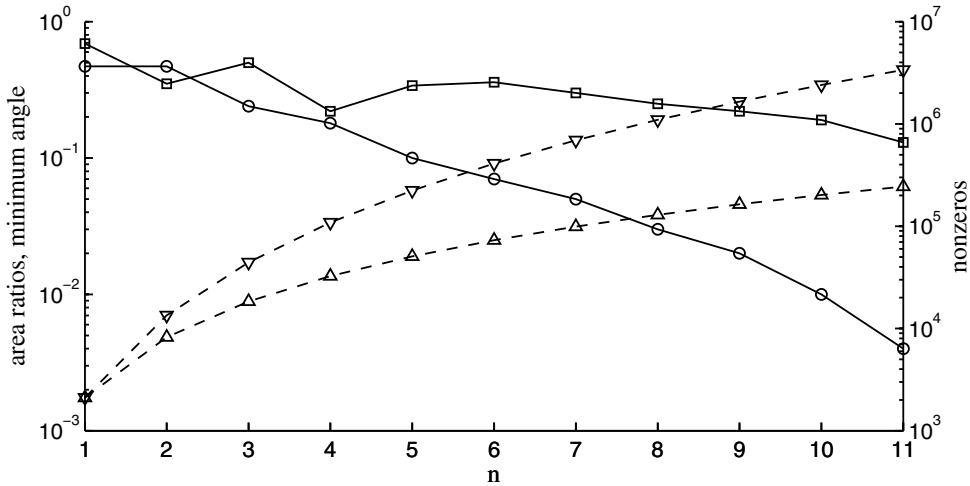


FIG. 2.4. *Mesh diagnostics: The number of connections in both A_s (∇) and in A_f ($\triangle$) along with the normalized minimum angle ($\square$) and the area ratio ($\circ$) in the finite element mesh.*

of the low-order finite element operator should be considered. From Figure 2.3(c), we notice a similar separation at $n = 4$, with PCG-AMG-A_f remaining relatively inexpensive. Moreover, the 3D simulations show this threshold to be at slightly lower orders—at $n \approx 2$ or 3—as illustrated in Figure 2.5(c).

The deterioration in convergence for classical AMG applied directly to A_s is largely due to the underlying M-matrix assumptions of the method. Both strength-of-connection and interpolation construction in RS-AMG are motivated through principles based on an M-matrix. Indeed, much of the early convergence theory on AMG relies on the system being an M-matrix [30], and the high-order matrices A_s considered here do not have this property: $a_{ij} > 0$ for some (i, j) (apart from the linear case). A well-known theoretical tool to generalize the theory is the concept of an *essentially positive* matrix [2]. For positive off-diagonal connections a_{ij}, if there exists a d-path with sufficiently large negative weight, then the AMG convergence results still hold [32]. Computationally, however, the adjustments for essentially positive matrices (i.e., basing coarse-grid selection and interpolation on negative weights only) have little impact. The results vary little whether positive connections are ignored or collapsed.

The notable change in performance for AMG at certain polynomial orders (e.g., $n = 4$ in two dimensions) is that the matrices are no longer essentially positive (with a path length of two). As an example, in the 2D case with a effective grid size of $h \approx 1/4$, the matrix is heavily populated with off-diagonals from $n = 2$, but the essentially positive property is not lost until $n = 5$ (see Figure 2.6). The number of positive edges in the graph of A_s grows with $\mathcal{O}(n^4)$, making classical AMG strength measures increasingly less effective. The $n = 4$ case coincides also with the deterioration of AMG convergence, thus confirming these M-matrix diagnostics. One common problem in utilizing very long-range connections in interpolation is that the computation is overwhelmed by the operator complexities.

3. Discontinuous methods. The DG method was initially introduced as a solution method for solving hyperbolic and convection dominated problems [6]. More recently, the DG methodology has successfully been extended to a variety of problems, becoming a robust and popular framework. In this section we describe the DG approach followed throughout this paper.

A variety of DG methods have been proposed in recent years for various problems [1]; we follow a *local* DG method (LDG) [7], which is described as follows. Recalling the model elliptic problem (1.1), let $\mathbf{q} = \nabla u$ and rewrite the problem as a first-order system:

$$\mathbf{q} - \nabla u = 0 \quad \text{in } \Omega, \tag{3.1a}$$

$$-\nabla \cdot \mathbf{q} = f \quad \text{in } \Omega, \tag{3.1b}$$

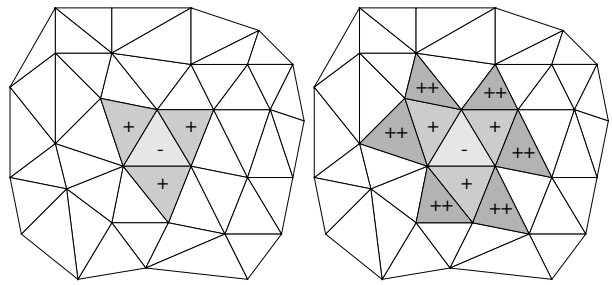
$$u(\mathbf{x}) = g \quad \text{on } \partial\Omega. \tag{3.1c}$$

Central to the DG methodology is the discontinuity in the approximation between elements; the DG varieties are distinguished by the way interelement connectivity is imposed. Let $\mathcal{K}^h$ be a tessellation of Ω, and consider the weak form of (3.1) over each $\kappa \in \mathcal{K}^h$:

$$\int_\kappa \mathbf{q} \cdot \psi \, d\mathbf{x} + \int_\kappa u \nabla \cdot \psi \, d\mathbf{x} = \oint_{\partial\kappa} u\psi \cdot \mathbf{n}_\kappa \, d\mathbf{x}, \tag{3.2a}$$

$$\int_\kappa \mathbf{q} \cdot \nabla\phi = \oint_{\partial\kappa} \mathbf{q} \cdot \mathbf{n}_\kappa \, d\mathbf{x} + \int_\kappa f\phi \, d\mathbf{x}, \tag{3.2b}$$

where $\phi(\mathbf{x})$ and $\psi(\mathbf{x})$ are scalar and vector test functions, respectively, and $\mathbf{n}_\kappa$ is the outward normal on κ. The interelement connectivity is now determined by definition of numerical flux on each edge. On element κ, define u^- to be the value of u interior to the element, and define u^+ to be the value of u in the adjacent neighboring element. For a scalar function u and vector function $\mathbf{q}$, the *jump* and the *average* between neighboring elements are respectively defined as $[\![u]\!] = u^-\mathbf{n}^- + u^+\mathbf{n}^+$, $\{\!\{u\}\!\} = \frac{1}{2}(u^- + u^+)$, $[\![\mathbf{q}]\!] = \mathbf{q}^- \cdot \mathbf{n}_{k^-} + \mathbf{q}^+ \cdot \mathbf{n}_{k^+}$, $\{\!\{\mathbf{q}\}\!\} = \frac{1}{2}(\mathbf{q}^- + \mathbf{q}^+)$. We define the numerical fluxes u^* and $\mathbf{q}^*$ independently of ∇u, allowing the formulation of the weak problem (3.2) independently of the flux $\mathbf{q}(\mathbf{x})$. In general, the numerical fluxes for the



(a) LDG (b) Brezzi

FIG. 3.1. *Stencil width for the LDG method compared with Brezzi and related DG methods. The width is one for the case of LDG, while dependence extends to two layers (++) for other common DG methods.*

LDG method are defined as [1]

$$u^* = \{\!\{u\}\!\} + \beta \cdot [\![u]\!], \qquad \mathbf{q}^* = \{\!\{\mathbf{q}\}\!\} - \beta [\![\mathbf{q}]\!] - \eta_k [\![u]\!], \tag{3.3}$$

which replace u and $\mathbf{q}$ in the elemental boundary terms of (3.2). With this, we strengthen the weak problem slightly using an additional integration-by-parts to arrive at

$$\int_\kappa \mathbf{q} \cdot \psi \, d\mathbf{x} - \int_\kappa \nabla u \cdot \psi \, d\mathbf{x} = \oint_{\partial\kappa} (u^* - u)\psi \cdot \mathbf{n}_\kappa \, d\mathbf{x}, \tag{3.4a}$$

$$- \int_\kappa \nabla \cdot \mathbf{q}\phi = \oint_{\partial\kappa} (\mathbf{q}^* - \mathbf{q}) \cdot \mathbf{n}_\kappa \, d\mathbf{x} + \int_\kappa f\phi \, d\mathbf{x} \tag{3.4b}$$

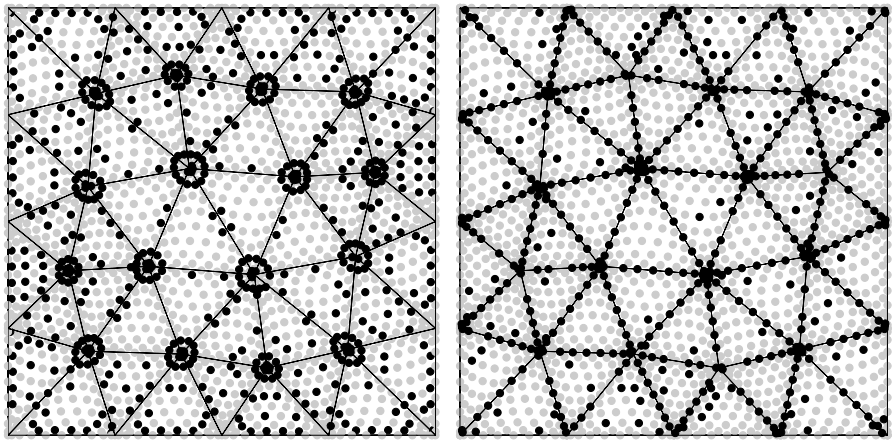
for all $\kappa \in \mathcal{K}$. The construction leads to the linear system $A^{dg}u = b$, which is the focus of the section.

Choosing $\beta = \mathbf{n}_\kappa/2$ ensures symmetry and locality of the associated stiffness matrix [1] and is a standard choice which leads to the *local* DG method.

3.1. AMG modification. While the LDG method does exhibit many advantageous properties in terms of the approximation both mathematically and computationally, it introduces additional complexities in the algebraic system. The issues concerning AMG are illustrated in this section, including modifications to the basic RS algorithm.

A key component of the LDG formulation is the so-called penalty term, identified by the coefficient η_κ in (3.3). From an approximation standpoint, η_κ offers stability control as it moderates the effect of the jump in u, $[\![u]\!]$. Moreover, it is well known that the spectrum of the linear system is influenced by the η_κ parameter, impacting many iterative solution methods. For elliptic problems, we can expect a relationship of $\text{cond}(A) = \mathcal{O}(\eta)$ between the condition number and η_κ, with $\eta_\kappa = \eta$ for all $\kappa \in \mathcal{K}$ [5]. With a well-balanced penalty term of $\eta_\kappa = \frac{n}{h^2}$ (cf. [34]), the preconditioner proposed below performed well and exhibited no dependence on slight variations in η_κ. This may be partly due to the results reported in [5] indicating less variability with respect to the penalty parameter in the condition number at higher orders.

Our choice in DG schemes was partly based on the fact that LDG limits the breadth of dependence. Figure 3.1 illustrates this effect. The result is that (1) the locality of AMG interpolation will be more effective for tighter stencils and (2) a low-order preconditioner will be more easily identified since construction can be arguably constrained in the first level to interelement connectivity only.



(a) Continuous Galerkin (b) Discontinuous Galerkin

FIG. 3.2. *AMG C/F splitting for $n = 11$. The C-points are represented by gray circles and the F points by black circles.*

Still, central to DG is the concept of additional degrees-of-freedom along element boundaries. AMG applied directly to the spectral operator in the continuous Galerkin method yields adequate results; we cannot expect such straightforward application in the context of DG methods, as the connections between degrees of freedom along a boundary play a much different role than connectivity with interior nodes. Indeed, Figure 3.2(a) identifies this subtlety for the case of $n = 11$. Figure 3.2(a) is the C/F splitting for the continuous methods analyzed in the previous section, while 3.2(b) depicts the C/F splitting for the first-level. The latter case results in a nonconvergent method and, more notably, very high complexities.

The solution is to extend the definition of "strong connections" in the AMG setup phase. In the classical RS algorithm presented earlier, only *direct* connections in the graph of the matrix are considered as possible interpolation nodes. In the DG framework, this results in element boundary nodes being interpolated only from nodes interior to the element and from nodes on adjacent element boundaries. Conversely, in the continuous Galerkin setting, the scope of interpolation extends into both elements for points along an edge. We accomplish this extension by considering long-range connections in the graph for interpolation (see Figure 3.3).

To consider long-range influence, we use an approach based on relaxation in defining the strong connections since using relaxation circumvents the need for an M-matrix. The implementation was introduced in [28] but has not been used extensively in practice. For node i, we seek a measure of influence from some node j (not necessarily connected to i). There are three cases in which we would like to account for long-range influence; three examples are illustrated in Figure 3.4. In Figure 3.4(a), we account for the strength of the direct connection i to j. In Figure 3.4(b), we see that i will benefit from having two connections to a pair $\{j, k\}$ with a strong connection. The influence of k on j will either strengthen the existing connection to i or possibly balance the connection, leaving the influence of j on i as weak. Finally, Figure 3.4(b) identifies the most common example of long-range influence: no connection between i and j, but a common connection to node k.

To identify the influence in the cases of Figure 3.4 we employ the following algo-

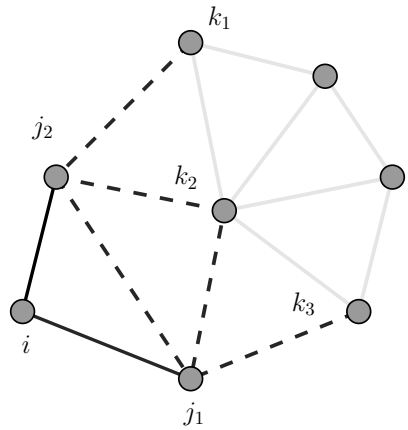


FIG. 3.3. *Long-range connections: Node i is directly connected to j indices, while having long-range connections to k indices. The direct connections are solid black, and the long-range (or direct-direct) connections are dashed black.*

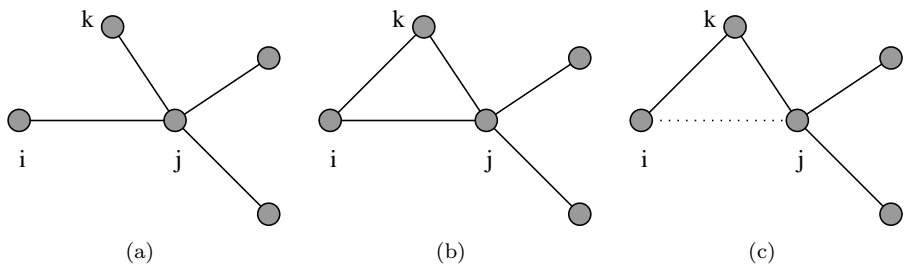

FIG. 3.4. *Three cases for long-range influence: only direct, common direct, and indirect.*

rithm:

1. Initialize vector v to be 1 at node j and zero otherwise.
2. Relax at i.
3. Relax at each k.
4. Relax again at i.

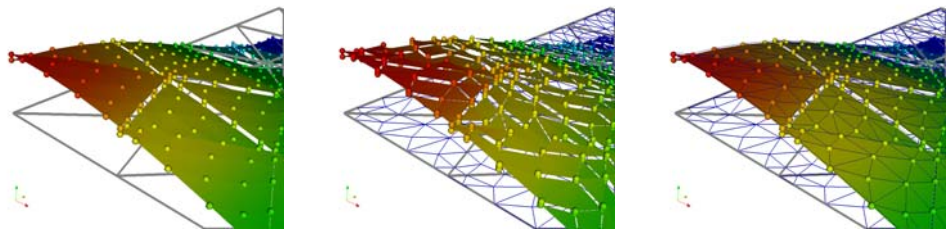
Since we consider smooth error to have little variation in the direction of a strong connection, a large value of v_i will indicate a strong connection between i and j. Classical RS interpolation is then implemented.

3.2. Hybrid preconditioner. The construction of a low-order preconditioner resembles the low-order finite element preconditioner studies in section 2; however, we introduce several modifications to account for the discontinuity. Coupled with the modified AMG algorithm in section 3.1, the process yields a scalable method.

The preconditioner we present is motivated by three components:

1. Low-order preconditioning is effective in the simplex (cf. section 2).
2. Continuous, linear finite elements are effective coarse spaces in domain decomposition for low-order DG methods [19].
3. Interelement connectivity in the spectral element DG method is closely associated with the spectrum of the matrix (cf. (3.4)).

Combining steps 1–3 into a suitable algorithm provides the basis of our approach. Given the bilinear form $a^{dg}(u, v)$ defined by the LDG method (3.4), we have the



(a) Spectral Element (b) Finite Element (c) Hybrid

FIG. 3.5. *Grid vectors in a spectral element, finite element, and locally projected (hybrid) space.*

following weak problem defined: Find $u, v \in V^{dg}$ so that

$$a^{dg}(u,v) = \ell(v) \qquad \forall\, v \in V^{dg}, \tag{3.5}$$

where $V^{dg} = V_s^{dg}$ defines the discontinuous nodal spectral element basis—Lagrange interpolating polynomials over electrostatic nodes as defined in section 1.1—over the spectral element mesh $\mathcal{K}_s = \mathcal{K}$. This leads to the matrix equation $A_s^{dg} u = f$. Similarly, we define (3.5) with a discontinuous linear finite element space V_f^{dg} over the locally constructed finite element mesh $\mathcal{K}_f$ of section 2 (cf. Figure 2.2), resulting in a (low-order) matrix equation $A_f^{dg} u = b$.

Motivated by [19] we construct operator C to project the LDG problem into a locally *continuous* finite element space. Denote by $V^\star$ a hybrid space of continuous finite elements within each spectral element. $V^\star$ is defined as

$$V^\star = \{u \in V_f^{dg} \,:\, u \in H_0^1(\kappa) \,\forall\, \kappa \in \mathcal{K}_s\}. \tag{3.6}$$

Functions in $V^\star$ are continuous across local elements but remain discontinuous across spectral elements $\kappa \in \mathcal{K}_s$. Defining $C : V_f^{dg} \to V^\star$ by averaging the jump, $u \leftarrow (u^+ + u^-)/2$, we arrive at the hybrid preconditioner matrix

$$A^\star = C A_f^{dg}. \tag{3.7}$$

The preconditioner is illustrated in Figure 3.5 using an example grid vector. The underlying spectral element mesh with for $n = 5$ is apparent in Figure 3.5(a), while the discontinuous finite element problem $A_f^{dg} u = b$ is evident by the jumps and locally refined mesh in Figure 3.5(b). Figure 3.5(c) highlights the hybrid preconditioner, where jumps are maintained between spectral elements and the local finite element space is continuous.

With the hybrid preconditioner defined, the advantage of using long-range connections as proposed in section 3.1 can be seen in Figure 3.6. The connectivity between an element boundary node i and nodes in adjacent elements (e.g., j) is limited in the case of direct connections. However, with long-range connections, the possible influence is more extensive, mimicking the case of continuous elements.

3.3. Numerical tests. We confirm the efficacy of the hybrid preconditioner proposed in the previous section by considering the model problem (1.1) in two dimensions. An LDG method is constructed based on (3.4), and we test the performance as the order of the spectral elements increases by considering the complexity measures presented in section 2.1.

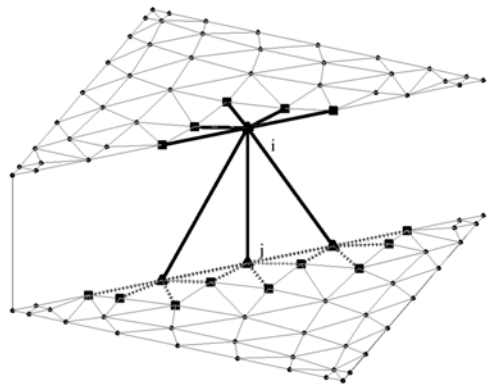


FIG. 3.6. *Long-range connections in the hybrid preconditioner: node i and node j with direct connections (solid) and additional long-range connections (dotted).*

TABLE 3.1

AMG preconditioning for DG: Polynomial order n is compared with the number of iterations of Algorithm 1, the average convergence factor ρ, the total work per digit accuracy $W^\star$, the number of nonzeros in the matrices, and the total number of degrees-of-freedom in the spectral element problem N.

n	Iterations	ρ	$W^\star$	$\aleph(A_s^{dg})$	$\aleph(A^\star)$	N
1	19	0.46	9.77	3420	3420	138
2	8	0.18	3.33	13680	14076	276
3	9	0.21	3.19	38000	35100	460
4	9	0.20	2.57	85500	59184	690
5	6	0.09	1.61	167580	98244	966
6	9	0.18	1.87	297920	141408	1288
7	11	0.26	2.05	492480	194508	1656
8	12	0.29	2.02	769500	251712	2070
9	12	0.29	1.88	1149500	321372	2530
10	13	0.34	2.05	1655280	399312	3036
11	12	0.30	1.68	2311920	478908	3588

We present in Table 3.1 the performance measures for Algorithm 1 with $\hat{A} = A^\star$. As the polynomial order increases, the number of iterations needed to converge along with the average convergence factor remain generally bounded. Furthermore, the complexity measure $\chi^\star_{\text{op}}$ justified in section 2.1 combined with the average convergence factor yields a low, bounded work measure $W^\star$, confirming the scalability of the method with respect to spectral order. Additional simulations on both coarser and finer spectral element grids generated nearly identical trends.

The performance listed in Table 3.1 is encouraging,[1] particularly in view of the number of nonzeros in the matrix. The ratios of nonzeros (columns 5 and 6) to problem size N (column 7) is plotted in Figure 3.7. The complexity of the fine grid preconditioning operator $A^\star$ remains low, while the density in the spectral operator A_s^{dg} grows with n, as expected.

Finally, the C/F splitting in AMG for the fine-grid hybrid preconditioner is presented in Figure 3.8. Comparing with Figure 3.2, the long-range connections used for

[1]The case of $n = 1$ is trivial. The additional and unnecessary work in constructing the preconditioner is evident in the results, which are provided for completeness.

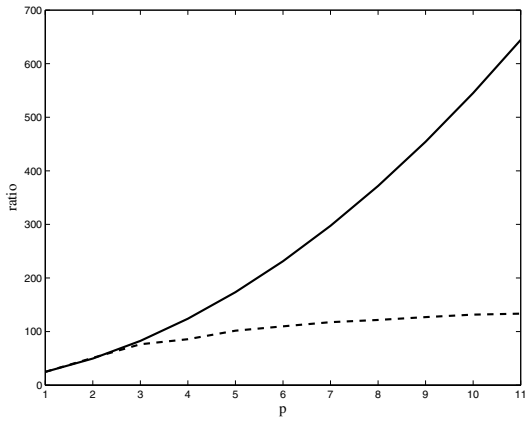

FIG. 3.7. *The ratio of nonzeros in matrix A_s^{dg} (solid) and in matrix $A^\star$ (dashed) to the matrix size N.*

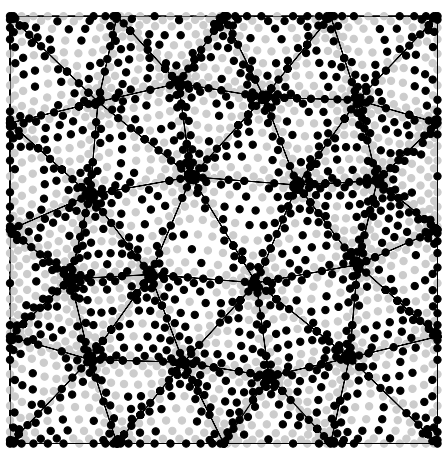

FIG. 3.8. *AMG C/F splitting for $n = 11$ for the matrix of the hybrid discontinuous preconditioner. The C-points are represented by gray circles and the F points by black circles.*

the hybrid preconditioner are able to produce a more compatible splitting, resulting in both better convergence and lower complexity.

4. Summary. The proposed computational framework is shown to be an effective approach for solving high-order spectral element methods. The algorithm, based on low-order preconditioning, provides a straightforward way of combining two highly successful methodologies: algebraic multigrid and high-order spectral element discretizations.

The present work contributes to the development of scalable solvers for high-order discretizations in several ways. A low-order preconditioner is extended to d-simplexes using a local Delaunay triangulation, while hybrid measures are proposed to accurately weigh the cost of using a low-order multilevel preconditioner in the context of a high-order spectral element discretization. Both 2D and 3D results highlight the efficacy for continuous methods and provide a motivational basis in moving toward discontinuous discretizations.

A new multilevel preconditioner for discontinuous methods is introduced. The approach utilizes an extension to the classical Ruge–Stüben AMG which accounts for long-range connections in the coarse-grid selection phase and in construction of the intergrid transfer operators. The AMG modifications are used in combination with a local low-order continuous finite element preconditioner to efficiently solve the spectral element problem.

Acknowledgment. The author thanks the developers of Sledge++, a discontinuous spectral element library [35], which provided the basis for the numerical results presented in this paper. Additionally, portions of the RS implementation and modifications were developed by John Ruge; the author is appreciative of the many helpful discussions.

APPLYING AUTOMATED MEMORY ANALYSIS TO IMPROVE ITERATIVE ALGORITHMS*

J. M. DENNIS† AND E. R. JESSUP‡

Abstract. In this paper, we describe automated memory analysis, a technique to improve the memory efficiency of a sparse linear iterative solver. Our automated memory analysis uses a language processor to predict the data movement required for an iterative algorithm based upon a MATLAB implementation. We demonstrate how automated memory analysis is used to reduce the execution time of a component of a global parallel ocean model. In particular, code modifications identified or evaluated through automated memory analysis enable a significant reduction in execution time for the conjugate gradient solver on a small serial problem. Further, we achieve a 9% reduction in total execution time for the full model on 64 processors. The predictive capabilities of our automated memory analysis can be used to simplify the development of memory-efficient numerical algorithms or software.

1. Introduction and motivation.

Many important scientific and engineering computations involve the solution of a set of partial differential equations formulated as a large sparse system of linear equations. The solution of the linear system by an iterative linear solver is often the single most costly component of the application [13, 26]. Historically, iterative solvers have been designed to achieve the best numerical accuracy for a given number of floating-point operations [18, 24, 25]. This approach is based on the assumption that the time to perform those operations dominates the cost of the solver. This assumption is no longer true because, while advances in computer architecture have significantly reduced the cost of a floating-point operation, the memory access cost has not seen nearly as rapid an improvement [21]. We must therefore take a memory-centric approach to the design and implementation of efficient algorithms. To that end, we propose the use of memory analysis as an integral component of the design process. Memory analysis evaluates the interaction of the algorithm with the memory hierarchy by calculating the amount of data that must be loaded from the memory hierarchy for each component of the iterative algorithm. We have developed the Sparse Linear Algebra Memory Model (SLAMM) language processor to automate memory analysis. The SLAMM language processor analyzes an

algorithm written in MATLAB code. Unlike a cache monitoring tool which only measures actual data movement of an existing implementation, a SLAMM analysis gives a prediction of the minimum required data movement for an efficient implementation of the algorithm in a compiled language.

Automated memory analysis provides both the ability to rapidly evaluate the memory efficiency of a particular design choice during the design phase and the ability to improve the memory efficiency of a preexisting solver. We illustrate both applications by using SLAMM to reduce the execution time of the Parallel Ocean Program (POP) [27]. In section 2, we provide the background for memory-efficient programming and review related work. In section 3, we describe POP, a parallel ocean model developed at Los Alamos National Laboratory. We describe the two-dimensional (2D) data structure it currently uses and an alternative one-dimensional (1D) data structure in section 3. In section 4, we describe memory analysis, a technique to calculate the amount of data that must be moved through the memory hierarchy for each component of an iterative algorithm. We describe manual memory analysis in section 4.1 and automated memory analysis using SLAMM in section 4.2. Finally, in section 5, we demonstrate how SLAMM is used to increase the memory efficiency of the POP iterative solver and reduce execution time.

2. Background and related work. We propose a technique to simplify the design and implementation of memory-efficient software through automated memory analysis. Our automated memory analysis uses compiler techniques to evaluate an algorithm implemented in MATLAB. The SLAMM language processor inputs MATLAB code marked with SLAMM directives and outputs the same code with additional code blocks to perform memory analysis. Our work differs from the compilers described in [1, 10, 14, 23] because we do not convert MATLAB to another language but rather analyze the code to determine its potential memory efficiency before implementation in a compiled language.

We focus our efforts on improving the execution rate of linear algebra algorithms that are sensitive to the amount of bandwidth between the memory hierarchy and the CPU. Bandwidth is the rate that data is moved through the memory hierarchy in units of cache-lines. We quantify the impact of the memory hierarchy bandwidth on a particular algorithm by comparing the total storage requirement of an algorithm as well as its working set size to the size of the cache. The total storage requirement is the total size in bytes of all variables required by an algorithm. The working set size is the size in bytes of all variables accessed during a particular section or phase of the algorithm. Different implementations of the same algorithm may have the same total storage requirement but may have significantly different working set sizes. The results of matching an algorithm's working set size to cache size can result in significant performance gains. For example, loop blocking [5, 17] of dense linear algebra, which breaks up larger code blocks or loops into smaller blocks in order to match working set size and cache size, is used in the optimized level 2 and 3 BLAS routines [11].

Several researchers have used compiler techniques to predict serial and parallel performance. Cascaval et al. [6] use the Polaris compiler to predict the performance of serial Fortran and C codes. Polaris-based predictions for execution time and cache miss-rates, which are fed back into the compiler to improve code optimization, are accurate to within an average of 20% error. Van Gemund [31] uses the PAMELA compiler to add symbolic cost expressions for data parallel problems, which, in combination with a simple machine model, allow it to predict execution time to within

10% error. Fahringer [12] developed the Parameter-based Performance Prediction Tool (P^3T) which is integrated with the Vienna Fortran compiler [3].

Unlike these previous approaches [6, 12, 31], SLAMM does not analyze Fortran or C source code but rather analyzes MATLAB code. The use of MATLAB allows the analysis of an algorithm before implementation in a compiled language. Analyzing an algorithm written in an interpreted high level language like MATLAB avoids the bias of the implementation details present in a Fortran or C version. The SPIRAL project [22] has a similar basis. Recognizing that information is lost when an algorithm is implemented in Fortran or C, SPIRAL generates optimized code based on mathematical descriptions of FFT and DFT algorithms. The use of a high level description of an algorithm allows SLAMM to accurately predict the minimum possible data movement needed by an algorithm and compares it to the existing data movement. We do not develop a sophisticated analytical model of memory performance because the consumer of SLAMM's analysis is the developer of the algorithm. While it is possible to study the amount of memory that is loaded between the multiple components of the memory hierarchy, we find that a simple model, which is described in section 4, accurately correlates to the amount of data loaded from L2 to L1 cache ($Mbytes_{L1}$) and is sufficient to provide valuable insight into the algorithm developer.

The performance of POP has been analyzed by several groups. Kerbyson and Jones [16] develop an analytical model of expected parallel performance. Snavely et al. [28] employ a convolution-based framework that uses hardware performance counts and MPI library traces to predict parallel performance. Our work does not specifically address parallel performance but rather concentrates on reducing data movement for a single component of the POP model.

3. Parallel Ocean Program. The Parallel Ocean Program (POP) [27] is a global ocean model developed at Los Alamos National Laboratory that is used extensively as the ocean component of the Community Climate System Model [7]. POP uses finite-difference for the baroclinic component of the timestep and a preconditioned conjugate gradient solver to solve for surface pressure in the barotropic component. Parallelism on distributed memory computers is supported through the Message Passing Interface (MPI) [29] standard.

We use POP version 2.0.1 [20] to examine data movement in the barotropic solver using the *test* and $gx1v3$ grids. The test grid is a coarse grid provided with the source code to facilitate the porting of POP to other compute platforms. The gx1v3 grid is higher resolution than the test grid with one degree resolution at the equator. POP using the gx1v3 grid represents 20% of the total compute cycles at the National Center for Atmospheric Research (NCAR) [4].

3.1. Existing data structure. POP uses a three-dimensional (3D) computational mesh. The horizontal dimensions are decomposed into logically rectangular 2D blocks [15]. The computational mesh is distributed across multiple processors by placing one or more 2D blocks on each processor. There are km vertical levels associated with each 2D horizontal block. Blocks that do not contain any ocean points, or land blocks, are eliminated. Table 1 contains the dimensions of the test and gx1v3 grids. The variables nx and ny are the global numbers of points in the x and y directions of the grid, respectively. Table 1 also contains the block sizes $bsize_x$ and $bsize_y$, the number of blocks $nblocks$, and the numbers of ocean, land, and total points in the barotropic solver for several block size configurations. The block size parameters $bsize_x$ and $bsize_y$ correspond to the number of points in the x and y directions for each 2D block. Note that land block elimination reduces the number of 20×24

TABLE 1
Description of POP grids.

Name	Grid $nx \times ny \times km$	$bsize_x \times bsize_y$	*nblocks*	# points Ocean	Land	Total
test	$192 \times 128 \times 20$	16×16	92	15378	8174	23552
gx1v3	$320 \times 384 \times 40$	40×48	64	86354	36526	122880
		20×24	246	86354	31726	118080

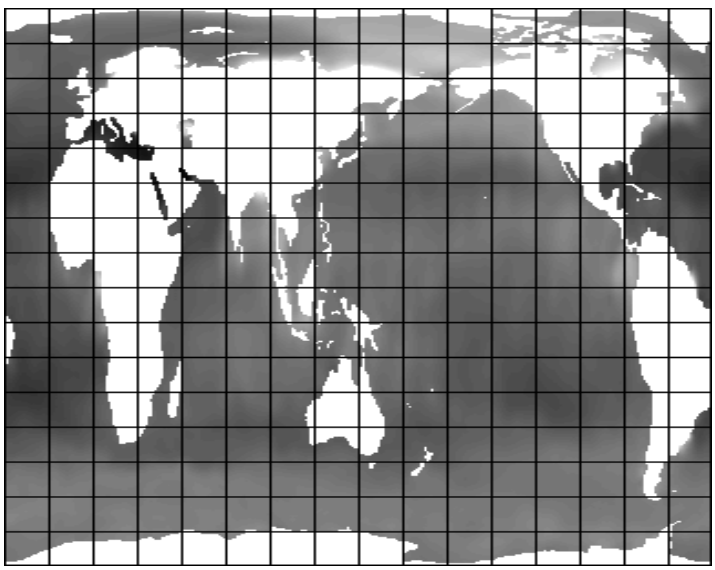

FIG. 1. *The POP gx1v3 grid, where white corresponds to land points, gray to ocean points, and superimposed lines indicate* 20×24 *blocks. Reprinted from* [9] *with permission from IEEE.* ©2007 *IEEE.*

blocks to 246, resulting in a reduction in the number of land points versus the 40×48 configuration.

Figure 1 illustrates the gx1v3 grid decomposed into 2D blocks of size 20×24. The white area in Figure 1 represents land, while ocean is indicated by gray. The black lines in Figure 1 indicate the boundaries of the 20×24 blocks. We next describe the form of the 2D data structure in greater detail.

Each 2D block contains $bsize_x \times bsize_y$ internal grid points and a halo region of width *nghost*. The halo region is used to store grid points that are located in neighboring 2D blocks. Figure 2 illustrates the 2D data structure within the source code for the block from Figure 1 containing the Iberian peninsula. Note that the large white structure on the upper right side of the block in Figure 2 is the Iberian peninsula, while the white structure in the lower right side is the northern coast of Africa. For this particular block, only about 60% of the grid points represent ocean.

We next describe the form of matrix-vector multiply within the conjugate gradient solver. The matrix-vector multiply within the conjugate gradient solver is applied via a 9-point stencil. The code for the 9-point stencil is illustrated in Figure 3. To calculate point $Y(i,j)$, the nine points $X(i,j)$, $X(i,j+1)$, $X(i,j-1)$, $X(i+1,j)$,

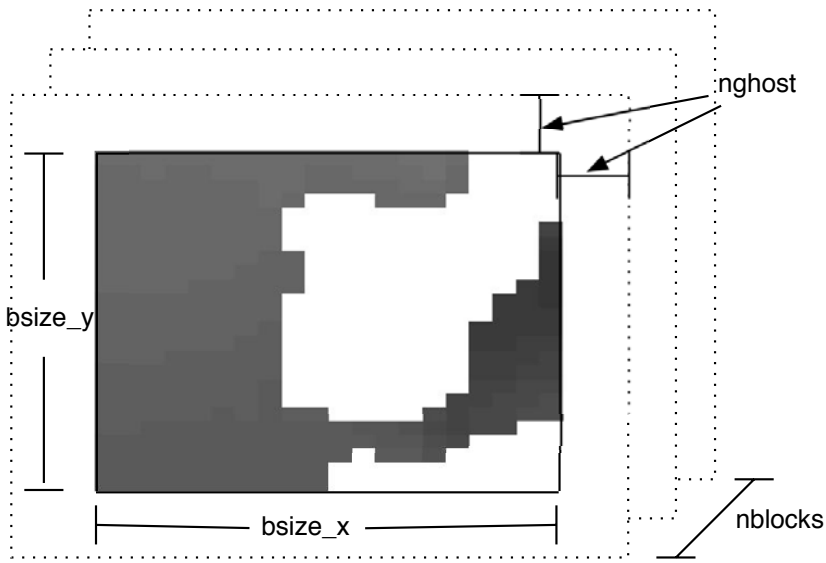

FIG. 2. *A* 20×24 *block of the* $gx1v3$ *grid over the Iberian peninsula. Note the presence of land and ocean points within the block.*

```
do j=this_block%jb,this_block%je
do i=this_block%ib,this_block%ie
   Y(i,j) = A0 (i  ,j  )*X(i  ,j  ) + &
            AN (i  ,j  )*X(i  ,j+1) + &
            AN (i  ,j-1)*X(i  ,j-1) + &
            AE (i  ,j  )*X(i+1,j  ) + &
            AE (i-1,j  )*X(i-1,j  ) + &
            ANE(i  ,j  )*X(i+1,j+1) + &
            ANE(i  ,j-1)*X(i+1,j-1) + &
            ANE(i-1,j  )*X(i-1,j+1) + &
            ANE(i-1,j-1)*X(i-1,j-1)
end do
end do
```

FIG. 3. *The barotropic operator in POP, implemented as a* 9*-point stencil using the* 2*D data structure.*

$X(i-1,j)$, $X(i+1,j+1)$, $X(i+1,j-1)$, $X(i-1,j+1)$, and $X(i-1,j-1)$ are required along with the associated coefficient arrays $A0$, AN, AE, and ANE. The need for a halo region is apparent if we consider the calculation of the corner point $Y(1,1)$. We need among other points $X(0,0)$, which is contained within the halo region. The primary advantage of the 2D data structure is that it provides a regular stride-one access for the matrix-vector multiply. The disadvantage of the 2D data structure is that it includes a large number of grid points that represent land. In effect, a number of explicitly stored zeros are added to the matrix. While it is possible to reduce the number of excessive land points by reducing the block size, smaller blocks have a larger percentage of their total size dedicated to halo points. We present an alternative to the 2D data structure in the next section.

```
is = Mat%Ia(1)
do i=1,n2
  ie = Mat%Ia(i+1)
  tmp = 0.0
     do j=is,ie-1
        tmp = tmp + Mat%A(j)*X(Mat%Ja(j))
     enddo
  Y(i) = tmp
  is = ie
enddo
```

FIG. 4. *The barotropic operator in POP, implemented as compressed sparse row matrix-vector multiply using the* 1*D data structure.*

3.2. An alternate data structure. We next describe a 1D data structure that enables the elimination of a potentially large number of land points present in the 2D data structure. The 1D data structure consists of a 1D array of extent n. The first $nActive$ elements in the 1D array correspond to active ocean points, while the remaining $n - nActive$ points correspond to the off-processor halo needed by the 9-point stencil. In removing the excessive land points, the 1D data structure changes the form of the matrix-vector multiply. Indirect-addressing is now necessary to apply the operator matrix which is stored in a compressed sparse row format. The code for the matrix-vector multiply for the 1D data structure is provided in Figure 4. The need for the $Mat\%Ia$ and $Mat\%Ja$ index arrays has the potential to negate any reduction in data movement achieved by the elimination of land points. We demonstrate in the next section how memory analysis is used to evaluate the impact of alternative data structures on data movement.

4. Memory analysis. We next examine the process of memory analysis. Memory analysis examines the amount of data that must be loaded from the memory hierarchy to the CPU to perform an operation. Consider two fundamental linear algebra operations, a dot product and an AXPY. The dot product of two vectors $\alpha = u'v$, where $v, u \in \mathbb{R}^n$ and $\alpha \in \mathbb{R}$, requires two vectors of length n. The amount of data that must be loaded from the memory hierarchy, or working set load size (WSL), is

$$WSL^{DOT} = 2\,n\,L_d, \tag{1}$$

where L_d is the size of a double precision floating-point value in bytes. The AXPY operation $u = u + \alpha v$, where $v, u \in \mathbb{R}^n$ and $\alpha \in \mathbb{R}$, requires two vectors of length n and a scalar. The working set size for an AXPY operation is

$$WSL^{AXPY} = (2\,n + 1)\,L_d. \tag{2}$$

The derivation of (1) and (2) is an example of manual memory analysis. While manual memory analysis is trivial for simple linear algebra operations, its complexity grows if we extend the technique to an entire iterative algorithm. We describe manual memory analysis of a complete iterative algorithm in section 4.1, followed by our automated memory analysis procedure in section 4.2.

4.1. Manual memory analysis. We focus on the preconditioned conjugate gradient iterative solver used by POP [27] to update the ocean surface pressure at

```
1. r_0 = b − Ax_0, p_0 = 0, φ_0 = (r_0, r_0)
2. for j = 0, 1, ... until convergence
3.         Mz = r_j                      /* Apply Precon */
4.         φ_{j+1} = (r_j, z)            /* dot product */
5.         β = φ_{j+1}/φ_j
6.         p_{j+1} = z + βp_j            /* AXPY */
7.         q = Ap_{j+1}                  /* MxV */
8.         δ = (p_{j+1}, q)              /* dot product */
9.         α = φ_{j+1}/δ
10.        x_{j+1} = x_j + αp_{j+1}      /* AXPY */
11.        r_{j+1} = r_j − αp_{j+1}      /* AXPY */
12. end
```

FIG. 5. *Preconditioned conjugate gradient algorithm with two inner products (PCG2).*

TABLE 2

Working set sizes (WSL) for each line of the preconditioned conjugate gradient algorithm in Figure 5.

Line	Operation	WSL (bytes)
3	Precon	varies
4	$DOT()$	$2\,n\,L_d$
6	$AXPY()$	$(2\,n+1)\,L_d$
7	$MxV()$	varies
8	$DOT()$	$2\,n\,L_d$
10	$AXPY()$	$(2\,n+1)\,L_d$
11	$AXPY()$	$(2\,n+1)\,L_d$
2–12	TOTAL	$(10\,n+3)\,L_d$
		$+\,WSL^{MxV}$
	for 1 iteration	$+\,WSL^{Precon}$

each timestep. In Figure 5, we provide a common form of the preconditioned conjugate gradient solver which uses two products (PCG2). Iterative solvers are composed of basic linear algebra operations. Thus, we compute the working set load size of the solver from the working set load size of its constituent operations. In Table 2, we provide the working set sizes for each line of the PCG2 algorithm in Figure 5. Note that the PCG2 algorithm requires several dot products (DOT) and AXPY operations (AXPY), a single sparse matrix-vector product (MxV), and the application of the preconditioner (Precon) for each iteration.

We first determine the working set load size for the sparse matrix-vector multiply for the 2D and 1D data structures followed by the application of the preconditioner. Consider the matrix-vector multiply for the 2D data structure. The working set load size of a matrix-vector multiply $y = Ax$, where A is a sparse coefficient matrix, is

$$WSL = sizeof(y) + sizeof(x) + sizeof(A), \tag{3}$$

where $sizeof()$ is a function that returns the size of its argument in bytes. An examination of Figure 3, which contains the code for the matrix operator for the 2D data structure, indicates that arrays $A0$, AN, AE, and ANE form the coefficient matrix A. Because $sizeof(A) = 4 \cdot sizeof(x)$, we use (3) to calculate working set load size for the 2D matrix-vector product

$$WSL_{2D}^{MxV} \equiv (2\,n_{2D} + 4\,n_{2D})\,L_d = 6\,n_{2D}\,L_d, \tag{4}$$

```
%SLM start caseStudy;              % line 1
n=200; u=rand(n,1); v=rand(n,1);   % line 2
%SLM start dotprod;                % line 3
alpha=u'*v                         % line 4
%SLM end dotprod;                  % line 5
%SLM print dotprod;                % line 6
%SLM end caseStudy;                % line 7
```

FIG. 6. *MATLAB code that computes the dot product of two vectors with SLAMM directives.*

where

$$n_{2D} = nblocks \cdot (bsize_x + 2 \cdot nghost)\,(bsize_y + 2 \cdot nghost).$$

The working set load size for the matrix-vector multiply for the 1D data structure is different than for the 2D data structure because $sizeof(A)$ is different. In the case of the 1D data structure, we must account for both the number of nonzero entries and the size of the indirect-addressing arrays. The WSL_{1D}^{MxV} is therefore

$$WSL_{1D}^{MxV} \equiv (nnz_{1D} + 2\,n_{1D})\,L_d + (nnz_{1D} + n_{1D})\,L_i, \tag{5}$$

where n_{1D} is the number of ocean points from column 5 of Table 1, nnz_{1D} is the number of nonzero values in the matrix $Mat\%A$ in Figure 4, and L_i is the size of an integer in bytes.

We next calculate the working set load size for the application of the preconditioner. Because POP uses a scaled diagonal preconditioner,

$$WSL^{Precon} = 2\,n\,L_d. \tag{6}$$

Using (4), (5), and (6) and the equations provided in Table 2 we can calculate the working set load sizes for both the 2D- and 1D-based solvers. Deriving and evaluating the analytical expression for data movement in this way is a time-consuming, laborious, and error-prone process that can be automated using language processing techniques. In the next section we describe the automated memory analysis procedure, which greatly simplifies memory analysis.

4.2. Automated memory analysis. We next describe how the Sparse Linear Algebra Memory Model (SLAMM) language processor is used to automate the memory analysis procedure. We use the dot product described in section 4 as an example. Figure 6 contains MATLAB code that calculates the dot product of two vectors $u, v \in \mathbb{R}^n$. Note that lines 2 and 4 in Figure 6 are the MATLAB code to initialize and calculate the dot product, respectively. The remaining lines in Figure 6 with the prefix $\%SLM$ are directives that control the SLAMM language processor. Lines 1 and 7 delineate the beginning and end of a body of MATLAB code. Lines 3 and 5 also delineate a body of code and identify it with the symbolic name *dotprod*. Line 6 is a SLAMM directive requesting the printing of the memory analysis of the dotprod code block.

Based on the input MATLAB code in Figure 6, the SLAMM language processor analyzes and generates modified output code which contains both the original code and new blocks of code that calculate memory usage properties. Figure 7 shows the resulting automated memory analysis of code body dotprod from Figure 6. Note that the total storage requirement (SR) and the working set load size (WSL) are printed

```
SLAMM Memory Analysis for Body: dotprod
       TOTAL: Storage Requirement  Kbytes (SR) : 3.13
       TOTAL: Loaded from L2 -> L1 Kbytes (WSL): 3.12 +- 0.00
                           DGEMM    Kbytes      : 0.00 +- 0.00
                     Sparse Ops     Kbytes      : 0.00 +- 0.00
```

FIG. 7. *The SLAMM generated predictions for dot product code in Figure* 6.

in Kbytes. SLAMM separately indicates the component of data movement due to dense matrix-matrix multiplication, indicated by DGEMM, as well as sparse matrix operations. We differentiate between the different components of WSL to indicate the fraction of the algorithm that might benefit from specific optimization techniques like the use of an optimized DGEMM subroutine. Fundamentally, the SLAMM language processor derives and evaluates (1) automatically. While automated memory analysis is certainly not necessary for a simple operation like a dot product, its advantages become apparent when it is applied to a complete iterative algorithm that may contain a large number of linear algebra operations. We demonstrate the application of automated memory analysis to evaluate the memory efficiency of the POP preconditioned conjugate gradient solver in the next section.

5. Results. Automated memory analysis can be used to evaluate a design decision before implementation in a compiled language and to evaluate the quality of a particular implementation. We first describe the methodology and compute platforms used to validate the accuracy of the SLAMM-based predictions. We instrumented each version of the solvers with a locally developed performance profiling library (Htrace), which is based on the PAPI [19] hardware performance counter API. Htrace calculates data movement by tracking the number of cache-lines moved through the different components of the memory hierarchy. We focus on three primary microprocessor compute platforms that provide counters for cache-lines loaded from the memory hierarchy to the L1 cache: Sun Ultra II [30] (Ultra II), IBM POWER 4 [2] (POWER4), and MIPS R14K [32] (R14K). A description of the cache configuration for each compute platform is provided in Table 3.

TABLE 3
Description of the microprocessor compute platforms and their cache configurations.

CPU	Ultra II	POWER4	R14K
Company	SUN	IBM	SGI
MHz	400	1300	500
L1 data-cache	32KB	32KB	32KB
L2 cache	4 MB	1440 KB	8 MB
L3 cache	–	32 MB	–

We first demonstrate how automated memory analysis is used to evaluate the choice of data structure for POP. We implemented the PCG2 algorithm of Figure 5 in MATLAB using both the 2D and 1D data structures described in sections 3.1 and 3.2, respectively. Using the SLAMM directives described in the previous section, we delineate one iteration of each of the PCG2 algorithms. The predicted data movement (WSL_P) for the 2D data structure (PCG2+2D) and the 1D data structure (PCG2+1D) versions for the test grid are provided in the second column of Table 4. SLAMM predicts that the use of the 1D data structure would reduce the amount of data loaded from the L2 to the L1 cache ($Mbytes_{L1}$) by 34% versus the existing 2D

data structure.

TABLE 4

$Mbytes_{L1}$ for a single iteration of the preconditioned conjugate gradient solver in POP using the test grid. The values of WSL_P and WSL_M are in Kbytes.

Solver implementation	WSL_P	vers.	Ultra II		POWER4		R14K	
			WSL_M	error	WSL_M	error	WSL_M	error
PCG2+2D	4902	v1	5163	5.3%	5068	3.4%	5728	16.9%
		v2	4905	0.1%	4865	−0.7%	4854	−1.0%
PCG2+1D	3218		3164	−1.7%	3335	3.7%	3473	7.9%
Reduction	34%		39%		34%		39%	

The measured data movement (WSL_M) or $Mbytes_{L1}$ the amount of data loaded from the L2 to the L1 cache for the existing 2D data structure implementation (PCG2+2D v1), an optimized 2D version (PCG2+2D v2), and the 1D version are provided for each of the compute platforms in Table 4. We measure 10 iterations and report the average measured data movement. While the discrepancies between the measured and predicted working set load sizes for the PCS2+2D v1 solver are minimal for both the Ultra II and POWER4 platforms, the measured value of 5728 Kbytes for the R14K is 17% greater than the predicted value of 4902 Kbytes. The difference in data movement between the three compute platforms may be due to additional code transformations performed by the Ultra II and POWER4 compilers. That the PCG2+2D v1 solver is loading 17% more data from the memory hierarchy than necessary on the R14K is an indication that it is possible to improve the quality of the implementation.

An examination of the source code for the PCG2+2D v1 solver indicates that a minor change to the dot product calculation reduces data movement. Code blocks that correspond to lines 6 to 8 of the PCG2 algorithm in Figure 5 for the v1 and v2 versions of the solver are provided in Figure 8. The function *operator* applies the 9-point stencil from Figure 3, and the array *LMASK* is an array that masks out points that correspond to land points. In version v1 of the do loop, a temporary array WORK0 is created that contains the pointwise product of two vectors Q and P. Outside the do loop, the dot product of LMASK and the WORK0 array is calculated by *global_sum*. If the size of data accessed in the do loop is larger than the L1 cache, then a piece of the WORK0 array at the end of the do loop is no longer located in the L1 cache and must be reloaded to complete the calculation.

In version v2 of the do loop, in Figure 8, a scalar temporary *delta_local* is added to accumulate each block's contribution to the dot product of Q and P. An additional function *local_sum* is used that applies the land mask to complete the dot product. Finally, we replace the function global_sum with a call to *gsum*. The subroutine gsum, when executed on a single processor, is an assignment of delta_local to delta. Because version v2 of the code block does not access WORK0 outside the do loop, it potentially reduces data movement.

Both dot product calculations (lines 4 and 8 of Figure 5) in the PCG2 algorithm were rewritten to create the v2 solver. The WSL_M values in Table 4 for the v1 and v2 versions of the PCG2+2D solver on the R14K indicate that the rearranged dot product calculations reduce data movement by 18%. Note that data movement is also reduced on the Ultra II and POWER4 platforms but to a lesser extent.

The previous description is a demonstration of how SLAMM is used to guide performance tuning. Table 4 also provides the relative error between predicted and measured data movement for the solvers. SLAMM predicts data movement to within an

```

```

FIG. 8. *A code block that implements lines* 6 *to* 8 *of the preconditioned conjugate gradient algorithm in Figure* 5 *for the* $v1$ *and* $v2$ *solvers.*

average error of 0.6% for the PCG2+2D v2 solver and within 4.4% for the PCG2+1D solver. We provide the actual percentage reductions in data movement for the 1D versus 2D solver for each compute platform. Table 4 indicates that the actual percentage reductions in data movement are very similar to the predicted reductions. Table 4 clearly demonstrates that it is possible for automated memory analysis to accurately predict the amount of data movement required for an algorithm. Such a capability provides a priori knowledge of the memory efficiency of a particular design choice before implementation in a compiled language.

We next examine the impact of reducing data movement on execution time. The timestep of POP includes a baroclinic and a barotropic component. The barotropic component is composed of a single linear solver for surface pressure. We execute POP using the test grid on a single processor of each compute platform for a total of 20 timesteps. This configuration requires an average of 69 iterations of the PCG2 algorithm per timestep. In Table 5, we provide the barotropic execution time in seconds using the three implementations of the solver. We include the execution time for the initial implementation of the solver using 2D data structures to accurately reflect the overall impact automated memory analysis has on execution time. Note that the PCG1+1D solver consistently has a lower execution time than either of the 2D data structure–based solvers. The last row in Table 5 contains the percentage reduction in barotropic execution time for the PCG2+2D v1 versus the PCG2+1D solver. Table 5 indicates that code modifications either evaluated or identified by automated memory analysis reduce execution time by an average of 46%. Curiously, a comparison of Tables 4 and 5 indicates that the percentage reduction in execution time is even larger than the percentage reduction in data movement. The reason for the discrepancy is unclear.

We next examine the impact of the 1D data structures on parallel execution time

TABLE 5
Barotropic execution time for 20 *timesteps of POP in seconds using the test grid on a single processor.*

Solver implementation	Ultra II	POWER4	R14K
PCG2+2D v1	21.17	4.57	8.58
PCG2+2D v2	20.49	4.01	7.97
PCG2+1D	12.74	2.11	4.61
Reduction	39%	54%	46%

TABLE 6
Total execution time for 200 *timesteps with the gx*1*v*3 *grid on* 64 *POWER*4 *processors.*

	Solver implementation			
	PCG2+2D v1	PCG1+2D v1	PCG2+1D	PCG1+1D
Total time (sec)	86.2	81.5	78.8	73.9

using the gx1v3 grid. We wrote a generalized gather-scatter routine to provide parallel execution under MPI for the 1D version of the solver. Recently, an alternative preconditioned conjugate gradient algorithm which uses a single dot product (PCG1) [8] was added to POP. The PCG1 algorithm provides a performance advantage for parallel execution because it eliminates one of the distributed dot product calculations. Because we want to realistically estimate the impact the 1D data structure has on execution time, we provide timing results for both PCG2 and PCG1 algorithms using the 2D and 1D data structures in Table 6.

We configure POP such that the computational costs of a production run are accurately characterized. We measure a total of 200 timesteps on 64 IBM POWER4 processors, with an average of 151 iterations per timestep. The execution time for the time stepping loop in seconds for the four solver implementations is provided in Table 6. These results indicate that use of the PCG1+1D solver versus the PCG1+2D solver reduces total POP execution time by 9%. A 9% reduction in total execution time of POP is significant because it has been extensively studied and optimized [15, 28]. Further, POP consumes approximately 2.4 million CPU hours every year at NCAR. A 9% reduction in execution time eliminates the need for 216,000 CPU hours per year.

6. Conclusion. We demonstrate how automated memory analysis is used to performance tune the Parallel Ocean Program. We automate memory analysis using the SLAMM language processor, which accurately predicts the amount of data loaded from the L2 cache to the L1 cache to within a relative error of 10%. The accurate predictive capability of SLAMM enables the identification of excessive data movement in the existing 2D data structure–based solver, and it allows us to evaluate the use of an alternative 1D data structure. We observe that the reduction in data movement predicted by SLAMM for the 1D versus the 2D solver is 34% and compares favorably with a measured 36% reduction. The reduction in data movement results in a similar reduction in single processor execution time. Finally we demonstrate how use of the 1D data structure reduces total execution time of POP on 64 processors using a one degree resolution grid by 9%, which represents a substantial savings in compute time.

BLOCK LOCALLY OPTIMAL PRECONDITIONED EIGENVALUE XOLVERS (BLOPEX) IN HYPRE AND PETSC*

A. V. KNYAZEV†, M. E. ARGENTATI†, I. LASHUK†, AND E. E. OVTCHINNIKOV‡

Abstract. We describe our software package Block Locally Optimal Preconditioned Eigenvalue Xolvers (BLOPEX) recently publicly released. BLOPEX is available as a stand-alone serial library, as an external package to PETSc (Portable, Extensible Toolkit for Scientific Computation, a general purpose suite of tools developed by Argonne National Laboratory for the scalable solution of partial differential equations and related problems), and is also built into *hypre* (High Performance Preconditioners, a scalable linear solvers package developed by Lawrence Livermore National Laboratory). The present BLOPEX release includes only one solver—the Locally Optimal Block Preconditioned Conjugate Gradient (LOBPCG) method for symmetric eigenvalue problems. *hypre* provides users with advanced high-quality parallel multigrid preconditioners for linear systems. With BLOPEX, the same preconditioners can now be efficiently used for symmetric eigenvalue problems. PETSc facilitates the integration of independently developed application modules, with strict attention to component interoperability, and makes BLOPEX extremely easy to compile and use with preconditioners that are available via PETSc. We present the LOBPCG algorithm in BLOPEX for *hypre* and PETSc. We demonstrate numerically the scalability of BLOPEX by testing it on a number of distributed and shared memory parallel systems, including a Beowulf system, SUN Fire 880, an AMD dual-core Opteron workstation, and IBM BlueGene/L supercomputer, using PETSc domain decomposition and *hypre* multigrid preconditioning. We test BLOPEX on a model problem, the standard 7-point finite-difference approximation of the 3-D Laplacian, with the problem size in the range of 10^5–10^8.

1. Introduction.

We describe a new software package, Block Locally Optimal Preconditioned Eigenvalue Xolvers (BLOPEX) revision 1.0, recently publicly released. BLOPEX is available as a stand-alone serial library, which can be downloaded from http://math.cudenver.edu/~aknyazev/software/BLOPEX/, as an external package to the Portable, Extensible Toolkit for Scientific Computation (PETSc) (see Balay et al. [2]), and is built into the High Performance Preconditioners (*hypre*) library (see Falgout, Jones, and Yang [8, 9]). Jose Roman has also written a Scalable Library for Eigenvalue Problem Computations (SLEPc) (see Hernandez, Roman, and Vidal [10]) interface to our *hypre* BLOPEX.

*Received by the editors May 31, 2006; accepted for publication (in revised form) July 2, 2007; published electronically September 28, 2007. Preliminary results of this work have been presented at the 11th and 12th Copper Mountain Conferences on Multigrid Methods and Preconditioning (2003), the SIAM Conference on Parallel Processing for Scientific Computing (2004), and the 16th International Conference on Domain Decomposition Methods (2005), and have appeared in Knyazev and Argentati [20] and Lashuk et al. [23].

The native *hypre* BLOPEX version takes advantage of powerful *hypre* multigrid preconditioners, both algebraic multigrid (AMG, called BoomerAMG in *hypre*) and geometric or structured multigrid (SMG). BLOPEX in PETSc gives the PETSc community easy access to the customizable code of a preconditioned eigensolver.

Currently, BLOPEX includes only one solver—the Locally Optimal Block Preconditioned Conjugate Gradient (LOBPCG) method (see Knyazev [17, 18]) for eigenproblems $Ax = \lambda Bx$ with large, possibly sparse, symmetric matrix A and symmetric positive definite matrix B. Preconditioned eigenvalue solvers in general (see Knyazev [16, 17]) and in particular the LOBPCG method have recently attracted attention as potential competitors to (block-) Lanczos methods. LOBPCG has been implemented using different computer languages in a number of other software packages such as: C++ in Anasazi Trilinos (see Arbenz et al. [1] and Heroux et al. [11]) and in NGSolve (see Zaglmayr [30, sections 7.2–7.4]); C in PRIMME (see Stathopoulos and McCombs [25]); FORTRAN 77 in PLTMG (see Bank [3]); FORTRAN 90 in ABINIT (see Bottin et al. [5]) and in PESCAN (see Tomov et al. [26]); and Python in SciPy by Robert Cimrman and in PYFEMax by Peter Arbenz and Roman Geus. LOBPCG has been independently tested in Yamada et al. [27, 28] for the Fermion–Habbard model on earth simulator CDIR/MPI; in Arbenz et al. [1] and Borzí and Borzí [4] using AMG preconditioning for vibration problems; and in Tomov et al. [26] and Yang, Meza, and Wang [29] for electronic structure calculations. Our *hypre* BLOPEX version has been used in Bramble, Kolev, and Pasciak [6] for the Maxwell problem.

Section 2 contains a complete and detailed description of the LOBPCG algorithm as implemented in BLOPEX. We discuss our specific abstract implementation approach in section 3. Parallel performance on distributed and shared memory systems using domain decomposition and multigrid preconditioning is discussed in section 4. Technical information, in the appendices, includes descriptions of variables, installation and testing instructions, a list of computers used for testing, and acronyms.

2. LOBPCG and its implementations. In subsection 2.1, we briefly describe the ideas behind the LOBPCG method, mostly following Knyazev [17, 18]. In subsection 2.2, we present a complete description of the LOBPCG algorithm as implemented in BLOPEX. Deflation by hard and soft locking is suggested in subsection 2.3.

2.1. LOBPCG ideas and description.

2.1.1. The problem and the assumptions. We consider the problem of computing the m smallest eigenvalues and the corresponding eigenvectors of the generalized eigenvalue problem $Ax = \lambda Bx$, with symmetric (Hermitian in the complex case) matrices A and B, the latter assumed to be positive definite. For a given approximate eigenvector x, we use the traditional Rayleigh quotient $\lambda(x) = (x, Ax)/(x, Bx)$ in the standard scalar product as an approximation to the corresponding eigenvalue. We emphasize that only matrix B is assumed to be positive definite. There is no such requirement on A; moreover, in all formulas in this section we can replace A with $A + \alpha B$ and the formulas are invariant with respect to a real shift α.

To accelerate the convergence, we introduce a preconditioner T, which is typically a function that for a given vector x produces Tx. The existing theory (see, e.g., [18, 21]) of the LOBPCG method is based on several assumptions: T needs to be linear, symmetric, and positive definite. Under these assumptions a specific convergence rate bound is proved in [18, 21]. Numerical tests suggest that *all these requirements on T are necessary* in order to guarantee this convergence rate. The use of preconditioning that does not satisfy the requirements above not only can slow down the convergence,

but may also lead to a breakdown of the method and severe instabilities in the code, resulting in incorrect results—however, this should not be mistakenly interpreted as bugs in the code.

2.1.2. Single-vector LOBPCG. For computing only the smallest eigenpair, i.e., if $m = 1$, the LOBPCG method takes the form of a 3-term recurrence:

$$\begin{array}{l} x^{(i+1)} = w^{(i)} + \tau^{(i)} x^{(i)} + \gamma^{(i)} x^{(i-1)}, \\ w^{(i)} = T(Ax^{(i)} - \lambda^{(i)} Bx^{(i)}),\ \lambda^{(i)} = \lambda(x^{(i)}) = (x^{(i)}, Ax^{(i)})/(Bx^{(i)}, x^{(i)}) \end{array} \tag{2.1}$$

with properly chosen scalar iteration parameters $\tau^{(i)}$ and $\gamma^{(i)}$. The easiest, and perhaps the most efficient, choice of parameters is based on an idea of *local optimality* (see Knyazev [14, 17, 18]), namely, select $\tau^{(i)}$ and $\gamma^{(i)}$ that minimize the Rayleigh quotient $\lambda(x^{(i+1)})$ by using the Rayleigh–Ritz procedure in the 3-D trial subspace spanning $x^{(i)}$, $w^{(i)}$, and $x^{(i-1)}$. We do not describe the Rayleigh–Ritz procedure using an arbitrary basis of the trial subspace here and assume that the reader is familiar with it.

If $\gamma^{(i)} = 0$, method (2.1) turns into the classical preconditioned locally optimal steepest descent method, so one can think of method (2.1) as an attempt to accelerate the steepest descent method by adding an extra term to the iterative recurrence; see, e.g., Knyazev [14, 17]. The general idea of accelerating an iterative sequence by involving the previous approximation is very natural and is well known. Let us note here that if instead of the previous approximation $x^{(i-1)}$ we use the previous preconditioned residual $w^{(i-1)}$ in formula (2.1), we get a different method that in practical tests does not converge as fast as method (2.1).

When implementing the Rayleigh–Ritz procedure in the trial subspace spanning $x^{(i)}$, $w^{(i)}$, and $x^{(i-1)}$, we need to be careful in choosing an appropriate basis that leads to reasonably conditioned Gram matrices. The current eigenvector approximation $x^{(i)}$ and the previous eigenvector approximation $x^{(i-1)}$ get closer to each other in the process of iterations, so special measures need to be taken in method (2.1) to overcome the potential numerical instability due to the round-off errors. Using both vectors $x^{(i)}$ and $x^{(i-1)}$ as basis vectors of the trial subspace leads to ill-conditioned Gram matrices, and the Rayleigh–Ritz method can produce spurious eigenpairs.

A simple fix is suggested in [18]: the 3-term recurrence that contains the current eigenvector approximation, the preconditioned residual, and the implicitly computed difference between the current and the previous eigenvector approximations:

$$\begin{array}{lcll} x^{(i+1)} & = & w^{(i)} + \tau^{(i)} x^{(i)} & + \gamma^{(i)} p^{(i)},\ w^{(i)} = T(Ax^{(i)} - \lambda^{(i)} Bx^{(i)}), \\ p^{(i+1)} & = & w^{(i)} & + \gamma^{(i)} p^{(i)},\ p^{(0)} = 0,\ \lambda^{(i)} = \lambda(x^{(i)}). \end{array} \tag{2.2}$$

We have $x^{(i+1)} \in \mathrm{span}\{w^{(i)},\ x^{(i)},\ p^{(i)}\} = \mathrm{span}\{w^{(i)},\ x^{(i)},\ x^{(i-1)}\}$ as the directions $p^{(i+1)} = x^{(i+1)} - \tau^{(i)} x^{(i)}$; therefore, the new formula (2.2) is mathematically equivalent to (2.1) in exact arithmetic. We choose in (2.2) the scalar iteration parameters $\tau^{(i)}$ and $\gamma^{(i)}$ as above, i.e., minimizing the Rayleigh quotient $\lambda(x^{(i+1)})$.

We note that formula (2.2) is not quite the ultimate fix; e.g., it is possible in principle that at the initial stage of the iterations $\tau^{(i)}$ is small, so that $p^{(i+1)}$ is too close to $x^{(i+1)}$, and the Rayleigh–Ritz procedure may fail. The proper choice of the basis in the trial subspace $\mathrm{span}\{w^{(i)}, x^{(i)}, p^{(i)}\}$ for the Rayleigh–Ritz procedure in (2.2), having in mind that vectors $w^{(i)}$ and $p^{(i)}$ converge to zero, is not a trivial issue; see Hetmaniuk and Lehoucq [12] for possible causes of LOBPCG instability.

The locally optimal choice of the step sizes in the LOBPCG allows an easy generalization from the single-vector version (2.1) or (2.2) to the block version described next in subsection 2.1.3, where a block of m vectors is iterated simultaneously. We return to the discussion of the choice of the basis in subsection 2.2, where it becomes even more vital with the increase of the block size m.

2.1.3. The LOBPCG basics. A block version of LOBPCG for finding the $m \geq 1$ smallest eigenpairs is suggested in Knyazev [16, 17]:

$$x_j^{(i+1)} \in \operatorname{span}\left\{x_1^{(i-1)},\ x_1^{(i)},\ T(A-\lambda_1^{(i)}B)x_1^{(i)},\ldots,\ x_m^{(i-1)},\ x_m^{(i)},\ T(A-\lambda_m^{(i)}B)x_m^{(i)}\right\},$$

where $x_j^{(i+1)}$ is computed as the jth Ritz vector, $j = 1,\ldots,m$, corresponding to the jth smallest Ritz value in the Rayleigh–Ritz procedure on a $3m$-dimensional trial subspace. The block method has the same problem of having close vectors in the trial subspace as the single-vector version (2.1) discussed in the previous subsection, for which [18] suggested the same fix using the directions p.

As in other block methods, the block size should be chosen, if possible, to provide a large gap between first m eigenvalues and the rest of the spectrum, as this typically leads to a better convergence; see [18, 21, 24]. Block methods generally handle clusters in the spectrum and multiple eigenvalues quite well, and the LOBPCG is no exception. An attempt should be made to include the whole cluster of eigenvalues in the block, while for multiple eigenvalues this is not essential at all. The smallest eigenvalues often converge faster, and the few eigenvalues with the noticeably slower convergence usually are the largest in the block and typically correspond to a cluster of eigenvalues that is not completely included in the block. A possible cure is to use a flexible block size a bit larger than the number of eigenpairs actually wanted and to ignore poorly converging eigenpairs.

The block size m should not be so big that the costs of the Rayleigh–Ritz procedure in the $3m$-dimensional trial subspace dominate the costs of iterations. If a large number of eigenpairs is needed, deflation is necessary; see subsection 2.3. The optimal choice of the block size m is problem-, software-, and computer-dependent; e.g., it is affected by such details as the amount of the CPU cache and the use of optimized BLAS library functions in the multivector implementation; see section 3.

2.2. The detailed description of the LOBPCG algorithm. The description of the LOBPCG algorithm as implemented in our BLOPEX-1.0 code follows:

Input: m starting linearly independent vectors in $X \in \mathbb{R}^{n\times m}$, l linearly independent constraint vectors in $Y \in \mathbb{R}^{n\times l}$, devices to compute $A*X$, $B*X$, and $T*X$.

1. Allocate memory $W, P, Q, AX, AW, AP, BX, BW, BP \in \mathbb{R}^{n\times m}$, $BY \in \mathbb{R}^{n\times l}$.
2. Apply the constraints to X:
   $BY = B*Y$; $X = X - Y*\left(Y^T*BY\right)^{-1}*((BY)^T*X)$.
3. B-orthonormalize X: $BX = B*X$; $R = \mathrm{chol}(X^T*BX)$; $X = X*R^{-1}$;
   $BX = BX*R^{-1}$; $AX = A*X$. (Note: "chol" is the Cholesky decomposition.)
4. Compute the initial Ritz vectors: solve the eigenproblem
   $(X^T*AX)*TMP = TMP*\Lambda$;
   and compute $X = X*TMP$; $AX = AX*TMP$; $BX = BX*TMP$.
5. Define the index set J of active iterates to be $\{1,\ldots,m\}$.
6. **for** $k = 0,\ldots,MaxIterations$:
7. Compute the residuals: $W_J = AX_J - BX_J*\Lambda_J$.
8. Exclude from the index set J the indices that correspond to residual

vectors for which the norm has become smaller than the tolerance.
If J, then becomes empty; exit loop.
9. Apply the preconditioner T to the residuals: $W_J = T * W_J$.
10 Apply the constraints to the preconditioned residuals W_J:
$W_J = W_J - Y * \left(Y^T * BY\right)^{-1} * ((BY)^T * W_J)$.
11. Compute BW_J and B-orthonormalize W_J: $BW_J = B * W_J$;
$R = \text{chol}(W_J^T * BW_J)$; $W_J = W_J * R^{-1}$; $BW_J = BW_J * R^{-1}$.
12. Compute AW_J: $AW_J = A * W_J$.
13. **if** $k > 0$
14. B-orthonormalize P_J: $R = \text{chol}(P_J^T * BP_J)$; $P_J = P_J * R^{-1}$;
15. Update $AP_J = AP_J * R^{-1}$; $BP_J = BP_J * R^{-1}$.
16. **end if**
Perform the Rayleigh–Ritz procedure:
Compute symmetric Gram matrices:
17. **if** $k > 0$
18. $$gramA = \begin{bmatrix} \Lambda & X^T * AW_J & X^T * AP_J \\ \cdot & W_J^T * AW_J & W_J^T * AP_J \\ \cdot & \cdot & P_J^T * AP_J \end{bmatrix}.$$
19. $$gramB = \begin{bmatrix} I & X^T * BW_J & X^T * BP_J \\ \cdot & I & W_J^T * BP_J \\ \cdot & \cdot & I \end{bmatrix}.$$
20. **else**
21. $$gramA = \begin{bmatrix} \Lambda & X^T * AW_J \\ \cdot & W_J^T * AW_J \end{bmatrix}.$$
22. $$gramB = \begin{bmatrix} I & X^T * BW_J \\ \cdot & I \end{bmatrix}.$$

37. **end for**

Output: The eigenvectors X and the eigenvalues Λ.

For description of all LOBPCG BLOPEX variables see Appendix A.

In the complex case, the transpose needs to be replaced by the adjoint. Only double-precision real arithmetic is supported in the current release 1.0 of BLOPEX.

The algorithm is *matrix-free* in the sense that the matrices A and B are not needed in the algorithm and not stored in the code, but rather are accessed only through matrix-vector product functions provided by the user. Matrix-free codes are needed in applications where the matrices A and B are never explicitly formed, e.g., in finite element method software packages for partial differential equations.

The algorithm uses only one block application of the preconditioner T (step 9) and one block matrix-vector product Bx (step 11) and Ax (step 12) per iteration. This is achieved by storing and manipulating $9m$ vectors ($6m$ vectors if $B = I$). If there is not enough memory for $9m$ vectors, or if m is so large that linear algebra operations with $9m$ vectors are more costly than multiplication by A and B, e.g., if A and B are very sparse, the algorithm can be modified so that only $3m$ vectors are stored, but then additional block matrix-vector products Ax and Bx are required per iteration. Such a modification currently is not yet available in BLOPEX.

Choosing a good basis for the Rayleigh–Ritz method becomes even more delicate with a larger number m of vectors in the block. Ill-conditioned Gram matrices in the Rayleigh–Ritz procedure may result in algorithm failure, inaccurate computations of the Ritz pairs, or spurious Ritz pairs. As it can be seen in the LOBPCG algorithm in steps 11–22, we explicitly compute X, P, and W and form the basis of the Rayleigh–Ritz procedure in the following way: X is left untouched since it already has B-orthonormal columns, made of the Ritz vectors, while the vectors inside both W and P are B-orthonormalized in steps 11 and 14, correspondingly, so we put the identities on the block diagonal of the matrix $gramB$ (steps 19 and 22).

For the B-orthonormalization of W and P in steps 11 and 14, the cheapest orthonormalization technique, using the Cholesky decomposition of the Gram matrix, has been chosen. This technique is known to be of poor quality in the presence of the round-off errors. Nevertheless, in our experience, the Cholesky-based B-orthonormalization of W and P reduces the risk of the Rayleigh–Ritz procedure failure while being considerably cheaper than the stable B-orthonormalization of all $3m$ vectors in the basis described, e.g., in Hetmaniuk and Lehoucq [12].

Let us note that matrices P and W converge to zero; what is even worse is that different columns of P and W converge to zero with different speeds, so matrices plugged into the Cholesky decomposition are extremely poorly scaled. It is crucial for the stability that the code of the Cholesky decomposition used here is numerically invariant with respect to matrix scaling; otherwise, the explicit normalization of columns of P and W is necessary prior to the call of the Cholesky decomposition. Such a subtle property as scaling invariance, which we rely on here, apparently may be affected by aggressive optimization flags during the compilation of the Cholesky decomposition code.

We also have tested (in MATLAB) a version in which we explicitly compute the block diagonal of the matrix $gramB$ instead of just setting the blocks to be the identities. Such an approach is similar to a known idea of repeated orthonormalization and results in more attainable accuracy. However, in our tests we have found that the attainable accuracy of our Algorithm 2.2 is already adequate, so this is not implemented in our BLOPEX LOBPCG.

Numerical software development is often an act of a balanced compromise between performance, reliability, and accuracy. Performance has been our main priority in

BLOPEX release 1.0, but we preserve reasonable reliability for common situations and achieve the accuracy typical for large-scale applications in engineering. Design of efficient and reliable implementations of the LOBPCG algorithm for BLOPEX is underway.

2.3. LOBPCG deflation by hard and soft locking. When several eigenvectors are computed simultaneously, it is often the case that some eigenvectors converge faster than others. To avoid the unnecessary computational work, one "locks" the eigenvectors that have already converged within a required tolerance while continuing to iterate the others. Locking approximately computed eigenvectors is not well studied theoretically. In this subsection, we introduce hard and soft locking and explain how locking is used in the LOBPCG algorithm, following the presentation of Knyazev [19]. The idea of soft locking is very natural and may have been known to some practitioners, developing codes for symmetric eigenvalue problems, even prior to Knyazev [19], where the term "soft locking" was apparently first introduced, but we are not aware of any earlier references.

A commonly used locking technique, known as deflation by restriction, is to keep the locked eigenvectors unchanged and those that are still iterated orthogonal to the locked ones. This technique is usually called "locking," but here it is referred to as "hard locking" to distinguish it from a new type of locking described next.

A different technique, called here "soft locking," can be used in simultaneous iterations combined with the Rayleigh–Ritz procedure. The idea of this technique is to remove the residuals of the locked vectors from the computation but continue using the vectors themselves in the Rayleigh–Ritz procedure, which can change them. The orthogonality of the soft locked vectors to iterative vectors follows from the well-known fact that the Ritz vectors corresponding to different Ritz values are orthogonal, and those corresponding to multiple Ritz values can be chosen to be orthogonal.

Compared to hard locking, soft locking is computationally more expensive. The advantage of soft locking is that it provides more accurate results. First and foremost, as the number of hard locked vectors increases, the attainable accuracy of the iterated ones may decrease, which may prevent them from reaching the required tolerance. With soft locking, the attainable accuracy of the iterated vectors does not depend on the number and the accuracy of soft locked ones. Second, if the Rayleigh quotient of kth locked vectors is less than the $(k+1)$th exact eigenvalue, then the accuracy of the first k locked vectors will increase in the course of the iterations, owing to the participation in the Rayleigh–Ritz procedure, even though their role in the iterative loop is now reduced to only this procedure. Soft-locking accuracy can be analyzed using known error bounds for the Rayleigh–Ritz method (see, e.g., [13, 15, 22]).

Below we describe the hard and soft locking as used in the BLOPEX implementation of LOBPCG and present preliminary numerical results demonstrating the effectiveness of soft locking compared to traditional hard locking.

Let us consider the single-vector LOBPCG method with no locking as described by (2.1), which we repeat here for the reader's convenience:

$$x^{(i+1)} = w^{(i)} + \tau^{(i)}x^{(i)} + \gamma^{(i)}x^{(i-1)},\ w^{(i)} = T(Ax^{(i)} - \lambda^{(i)}Bx^{(i)}).$$

Let P be a projector on the complement to the span of already computed eigenvectors. In LOBPCG with hard locking, we redefine $w^{(i)} = PT(Ax^{(i)} - \lambda^{(i)}Bx^{(i)})$ so that all iterates are now within the range of P if the initial guess in chosen within the range. Traditionally, P is orthogonal in the B-based scalar product and the complement is orthogonal also in the B-based scalar product, since this allows the easiest

and most inexpensive implementation. This is what we use in step 10 of the LOBPCG algorithm in subsection 2.2. The constraints, given by the columns of the matrix Y, are in this case the already approximately computed eigenvectors that we want to deflate.

If the locked eigenvectors are computed exactly, then it is easy to analyze the influence of classical hard locking and to show that it is equivalent to simply removing the locked eigenpairs from consideration. If the locked eigenvectors are only approximate, the range of P is not exactly an invariant subspace of the matrix pencil $A-\lambda B$, and the analysis of the influence of the approximation quality on locking becomes much more complicated; see, e.g., D'yakonov and Knyazev [7].

As the number of locked vectors increases, their inaccuracy may affect the attainable accuracy of iterated vectors. To avoid this, we use soft locking in the LOBPCG algorithm in subsection 2.2. We denote by X_J the matrix that contains only the active (not soft locked) iterative eigenvector approximations as columns, while all m iterative vectors X are included in the Rayleigh–Ritz procedure. Only X_J participates in iterations; i.e., having $\Lambda_J^{(i)}$ and $X_J^{(i)}$ we compute only $W_J^{(i)} = T(AX_J^{(i)} - BX_J^{(i)}\Lambda_J^{(i)})$, where $\Lambda_J^{(i)}$ is a diagonal matrix of approximate eigenvalues corresponding to $X_J^{(i)}$. We include the complete X, but only W_J and P_J, in the basis of the Rayleigh–Ritz procedure in steps 18–22 and 26–32 of the LOBPCG algorithm in subsection 2.2.

The positive influence of soft locking is especially noticeable when the stopping tolerance is not so small. Figure 2.1 presents the results of soft locking when the residual norm reaches 10^{-1} in LOBPCG with $m = 10$ for a model problem. We observe that the active eigenpairs continue to converge and that the eigenpairs, which are already soft locked, still improve in accuracy.

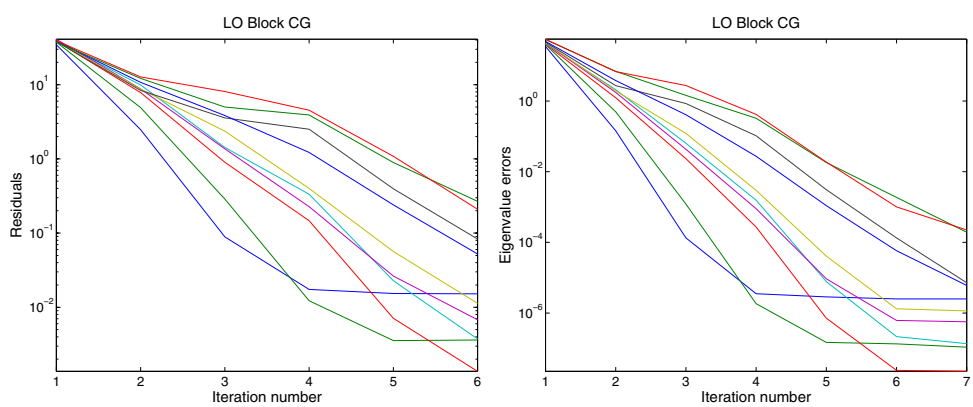

FIG. 2.1. *Residual norms (left) and eigenvalue errors (right) for* 10 *eigenpairs in LOBPCG with soft locking. Soft locked (the bottom* 6*) eigenpairs continue to improve.*

To summarize, we use the classical hard locking in LOBPCG through the constraints and soft locking inside the LOBPCG code. If the user wants to compute so many eigenpairs that it is not reasonable to include all of them at once in the block, the user should determine an appropriate block size m for the given hardware and call LOBPCG with the block size m several times, putting the previously computed eigenvectors into the constraints for the next LOBPCG call. The LOBPCG MATLAB code includes an example of such a call in the help information.

3. Abstract BLOPEX implementation for PETSc and *hypre*. PETSC and *hypre* are software libraries for solving large systems on massively parallel computers. Our native PETSc BLOPEX version gives the PETSc user community easy access to the customizable code of a modern preconditioned eigensolver and an opportunity to easily call *hypre* preconditioners from PETSc. The BLOPEX built-in *hypre* version efficiently takes direct advantage of powerful *hypre* AMG preconditioner BoomerAMG and its geometric multigrid preconditioners.

The BLOPEX library currently includes only the LOBPCG eigensolver. The BLOPEX code is written in C-language and calls a few LAPACK subroutines for dense matrix operations. The matrix-vector multiply and the preconditioner call are done through user-supplied functions. The main LOBPCG code is abstract in the sense that it works only through an interface that determines the particular software environment, e.g., PETSc or *hypre*, in order to call parallel (multi)vector manipulation routines. A block diagram of the main modules is given in Figure 3.1.

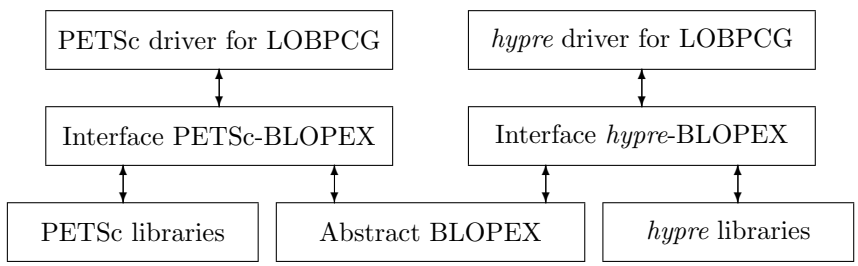

FIG. 3.1. *BLOPEX hypre and PETSc software modules.*

In the abstract part of BLOPEX, the blocks of vectors (X, P, etc.) are represented by an abstract data object we call "multivector." A particular implementation of the multivector is outside of our code, so we only provide an interface to it. Ideally, all operations involving multivectors should be implemented in a block fashion to minimize the number of exchanges between the processors and to take advantage of a highly optimized matrix-matrix multiplication routine `dgemm` in BLAS when computing Gram matrices and updating multivectors. However, to our knowledge such an object is currently not available to users in PETSc and *hypre*, so we had to temporarily use the multivector interfaces as references to individual vectors. When properly implemented multivectors become available in PETSc and *hypre*, we plan to change our interface codes to use the true multivectors, which is expected to lead to greater speed-up due to a smaller number of communications and efficient use of BLAS.

4. BLOPEX LOBPCG numerical results in PETSc and *hypre*. Here we present results which were accumulated over a considerable length of time. Despite our efforts, the reader may still notice some inconsistency, e.g., some tests may use different tolerances. All tests are performed in double-precision real arithmetic.

4.1. The basic accuracy of the algorithm. In these tests BLOPEX LOBPCG computes the smallest 50 eigenvalues of 3-D 7-point $200\times200\times200$ and $200\times201\times202$ Laplacians using a direct application of the *hypre* BoomerAMG preconditioning. In the first case we have eigenvalues with multiplicity, and in the second case the eigenvalues are distinct but clustered. The initial approximations are chosen randomly. We set the stopping tolerance (the norm of the maximum residual) equal to 10^{-6}. The

numerical output (for the complete data, see Knyazev and Argentati [20]) is compared to the exact eigenvalues

$$\lambda_{i,j,k} = 4\left[\sin\left(\frac{i\pi}{2(n_x+1)}\right)^2 + \sin\left(\frac{j\pi}{2(n_y+1)}\right)^2 + \sin\left(\frac{k\pi}{2(n_z+1)}\right)^2\right]$$

of the 3-D 7-point Laplacians on the $n_x \times n_y \times n_z$ cube with $1 \le i \le n_x$, $1 \le j \le n_y$, and $1 \le k \le n_z$. In both tests for all eigenvalues the maximum relative error is less than 10^{-8}, so LOBPCG is cluster robust, i.e., it does not miss (nearly) multiple eigenvalues, which supports the conclusion of Borzí and Borzí [4].

4.2. Performance versus number of inner iterations. We can execute a preconditioner $x = Tb$ either directly or by calling PCG to solve a linear system, which in our tests is $Ax = b$, so T approximates A^{-1}. Increasing the number of "inner" iterations of the PCG will accelerate the overall convergence, but only if we do not make too many iterations, since even if $T = A^{-1}$, the convergence of the LOBPCG method is still linear. In other words, for a given matrix A and a particular choice of a preconditioner T, there should be an optimal finite (maybe zero, corresponding to the direct application of T) number of inner iterations.

We try to find this optimal number for the Schwarz-PCG and BoomerAMG-PCG preconditioners in *hypre* and PETSc for the 7-point 3-D $100 \times 100 \times 100$ Laplacian with block size $m = 1$. We measure the execution time as we vary the quality of the preconditioner by changing the maximum number of inner iterations in the corresponding PCG solver. PETSc and *hypre* built-in Schwarz algorithms are different but demonstrate similar behavior. The *hypre* multigrid BoomerAMG and PFMG preconditioners are called from *hypre* test drivers. The *hypre* BoomerAMG preconditioner in addition is called through PETSc. The results for these tests involving different multigrid preconditioners are also similar.

We find that for this problem the optimal number of inner iterations is approximately 10–15 for Schwarz-PCG, but BoomerAMG-PCG works best if BoomerAMG is applied directly as a preconditioner, without even initializing the PCG solve function. Our explanation of this behavior is based on two facts. First, the Schwarz method with the default parameters used here is somewhat cheaper, but not of such good quality when compared to BoomerAMG in these tests. Moreover, the costs for matrix-vector and multivector linear algebra in LOBPCG are relatively small compared to the costs of the BoomerAMG application but is comparable to the costs of applying the Schwarz preconditioner here. Second, one PCG iteration is less computationally expensive compared to one LOBPCG iteration because of the larger number of linear algebra operations with vectors in the latter. A single direct application of BoomerAMG as the preconditioner in LOBPCG results in enough improvement in convergence to make it the best choice, while Schwarz requires more iterations that are less time consuming if performed using PCG rather than directly in LOBPCG.

In the next set of numerical tests for the same eigenproblem, we use the block size $m = 10$, and we vary the type of PCG preconditioner available in the *hypre* IJ interface together with the number of inner PCG iterations. For the complete test data, see Knyazev and Argentati [20]; here we provide only a summary. We observe that both the number of outer iterations and the execution time can be decreased significantly by choosing the maximum number of inner iterations optimally. For this problem, the BoomerAMG preconditioner applied directly has the fastest run time and converges in the smallest number of iterations, 31. If we use no preconditioning,

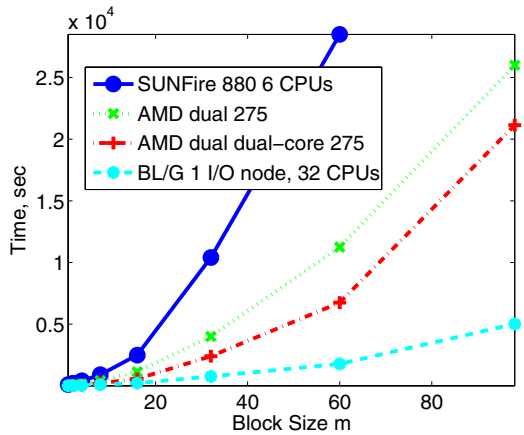

FIG. 4.1. *LOBPCG performance versus block size. Preconditioner: hypre BoomerAMG.*

then in 500 iterations, which take 10 times longer, we still do not reach the required tolerance 10^{-10}, which illustrates the importance of preconditioning.

4.3. LOBPCG performance versus block size. We test *hypre* and PETSc LOBPCG on a 7-point 3-D Laplacian with $128 \times 128 \times 128 \approx 2M$ unknowns using the *hypre* BoomerAMG preconditioner by increasing the block size m from 1 to 98. We run the tests on a shared memory SUN Fire880 system, dual- and single-core AMD Opterons Dual 275 CPUs servers, and a single I/O node of IBM BG/L with 32 CPUs. We find that the *hypre* and PETSc LOBPCG run times are very close and use the same tolerance 10^{-8}; with PETSc the extra overhead is less than a few percent of the total times compared to a direct use of *hypre*, as expected. The growth of the CPU time with the increase of the block size m is approximately linear for this problem up to $m = 16$; then the complexity term $m^2 n$ becomes visible and the slower convergence rate for larger eigenvalues starts noticeably affecting the overall timing, as shown in Figure 4.1. An efficient implementation of the multivector, e.g., such as that used in the ABINIT version of the LOBPCG (see Bottin et al. [5]), is expected to significantly improve performance of the LOBPCG with respect to the block size.

4.4. Scalability. For the 7-point 3-D Laplacian we vary the problem size proportionally to the number of processors. We directly apply *hypre* BoomerAMG or PFMG multigrid preconditioner. First, on the MCR cluster the eightfold increase in the number of dual-CPU nodes does not noticeably increase the LOBPCG CPU time, which is approximately 50 sec for BoomerAMG and 180 sec for PFMG with $m = 1$ and tolerance 10^{-8}. The PFMG takes more time overall compared to BoomerAMG because of the larger convergence factor, but each iteration of the former is 50% faster than that of the latter, as we observe in Figure 4.2, which displays the CPU time per iteration for LOBPCG *hypre* code with *hypre* BoomerAMG and PFMG preconditioners in our second test on the Beowulf cluster. We see that the 32-fold increase in the number of dual-CPU nodes just slightly increases the CPU time.

Finally, we solve the 7-point 3-D Laplacian eigenvalue problems for large matrix sizes and for a variety of block sizes m on the BG/L system. We observe a 10–20% variability in the iteration numbers, and thus in the wall clock, due to the randomness of the initial approximations, so we report here typical average results. Tables 4.1 and 4.2 contain information about LOBPCG runs using *hypre* SMG geometric multigrid and tolerance 10^{-6}.

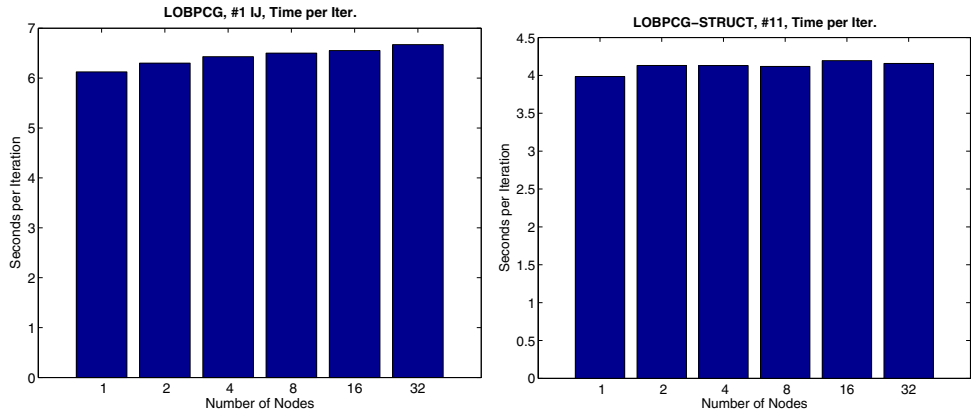

FIG. 4.2. *LOBPCG scalability, 1M unknowns per node on Beowulf.*

TABLE 4.1
Scalability for $80 \times 80 \times 80 = 512{,}000$ *mesh per CPU,* $m = 1/6$.

5. Conclusions. The BLOPEX software is integrated into the *hypre* library and is easily available in PETSc as an external package. BLOPEX is the only currently available software that solves eigenvalue problems by directly using high quality existing *hypre* and PETSc preconditioners. Our abstract C implementation of the LOBPCG in BLOPEX allows easy deployment with different software packages. Our interface routines are based on *hypre* and PETSc standard interfaces and give the user an opportunity to provide matrix-vector multiply and preconditioned solver functions. The code scalability is tested for model problems of large sizes on parallel systems.

Appendix A. Description of all LOBPCG BLOPEX variables.

X (multivector). The iterative approximation to eigenvectors.

A (function). Multiplies the function argument, which is a multivector, by the first matrix of the eigenproblem.

B (function). Multiplies the function argument, which is a multivector, by the second matrix of the eigenproblem.

T (function). Applies the preconditioner to the function argument, a multivector.

Y (multivector). The given constraint that can be used for hard locking. Iterations run in the B-orthogonal complement to the span of Y.

Λ (diagonal matrix, in the actual code given by a vector of the diagonal entries). The iterative approximation to eigenvalues.

W (multivector). Used to store the residuals (step 7), the preconditioned residuals (step 9), and the preconditioned constrained residuals (step 10 and later).

J (index vector). Denotes the set of indexes of active iterates. The starting value for J is $\{1, \ldots, m\}$. If the norm of the residual r_j for some $j \in J$ has become smaller than the tolerance, this index j is excluded from the set J. By X_J we denote a submatrix of X with the columns, the indexes of which are present in the set J—these are the active iterates. The indexes from $\{1, \ldots, m\}$ that are not present in the set J correspond to iterative approximations to eigenvectors, which have been "soft locked."

P (multivector). The LOBPCG "directions."

gramA and *gramB* (matrices). The Gram matrices in the Rayleigh–Ritz procedure.

C (matrix). The matrix of *gramB*-orthonormalized eigenvectors in the Rayleigh–Ritz procedure, used as the matrix of coefficients to compute the Ritz vectors, the new multivectors X, as linear combinations of the basis X, W_J, and P_J.

AX, BX, AP, BP, etc. (multivectors). Implicitly computed results of the application of the corresponding functions to the corresponding vectors. In the absence of the round-off errors, they would be identical to their targets, e.g., $AX = A \star X$.

R (matrix). The upper triangular matrix of the Cholesky factorization, used for the B-orthogonalization via Cholesky.

Appendix B. Installing and testing BLOPEX with PETSc and *hypre*. Here we give brief but specific information for the reader who wants to install and test our BLOPEX software. This information concerns the current BLOPEX-1.0, PETSc-2.3.2, and *hypre*-2.0.0 releases. We refer to Appendix D for the acronyms and other names not explained here and suggest reading the software manuals for more details.

To install and test BLOPEX and *hypre* in PETSc, download the PETSc source and follow the standard installation procedure with the external packages option. The present procedure is to add "--download-blopex=1 --download-hypre=1" options to the PETSc configuration. BLOPEX and *hypre* sources are then downloaded and compiled automatically. The BLOPEX test driver is already included in PETSc at the src/contrib/blopex/driver directory. For example, in

```
driver -da_grid_x 128 -da_grid_y 128 -da_grid_z 128 -ksp_type preonly -pc_type
hypre -pc_hypre_type boomeramg -n_eigs 10 -seed 2 -tol 1e-6 -itr 5 -full_out 1
```

the eigenproblem for the 7-point 3-D Laplacian is solved by directly using the *hypre* BoomerAMG preconditioner. The last five parameters are self-explanatory.

BLOPEX LOBPCG is built into *hypre* and requires no special configuration options. *hypre* supports four conceptual interfaces: STRUCT, SSTRUCT, FEM, and IJ. LOBPCG has been tested with all but the FEM interface. *hypre*-2.0.0 test drivers for LOBPCG are in the src/test directory. The following are examples with the same options as in the PETSc call above using IJ and STRUCT test drivers:

```
ij -lobpcg -n 128 128 128 -pcgitr 0 -vrand 10 -seed 2 -tol 1e-6 -itr 5 -verb 1
struct -lobpcg -n 128 128 128 -pcgitr 0 -vrand 10 -seed 2 -tol 1e-6 -itr 5 -verb 1
```

Our code can, but is not really intended to, be used with the popular shift-and-invert strategy, since its main advantage compared to traditional eigensolvers is that it uses preconditioning. Our test drivers can call preconditioning directly ("-ksp_type preonly" PETSc option and "-pcgitr 0" *hypre* option) as well as through calls to the *hypre*/PETSc PCG method. In the latter case the action $x = Tb$ of the preconditioner T on a given vector b is performed by calling a few steps of PCG to solve $Ax = b$. The BLOPEX LOBPCG code has been tested with all available *hypre* PCG-capable preconditioners in STRUCT, SSTRUCT, and IJ interfaces, with the PETSc native additive Schwarz, and with the PETSc linked BoomerAMG from *hypre*.

Appendix C. Computers used for testing.

AMD workstations Several single- and dual-core AMD two 64 bit 275 CPUs with 16GB shared memory, running Linux, at CCM CU-Denver.

SUN Fire 880 SUN Solaris 9, 6 UltraSPARC III 64 bit CPUs, 24GB shared memory, at CCM CU-Denver.

Beowulf cluster Linux, 36 nodes, dual PIII 933MHz processors and 2GB memory per node with 7.2SCI Dolphin interconnect, at CCM CU-Denver.

MCR cluster Linux, dual Xeon 2.4GHz 4 GB nodes with Quadrics, at LLNL.

Blue Gene/L (BG/L) IBM single-rack with 1024 compute nodes, organized in 32 I/O nodes with 32 compute nodes each. Every compute node is a dual-core chip, containing two 700MHz PowerPC-440 CPUs and 512 MB of memory. We run using the default 1 CPU for computing and 1 CPU for communication on every compute node. Location: NCAR.

Appendix D. Acronyms and other names.

D.1. Organizations.

CCM CU-Denver Center for Computational Mathematics, University of Colorado at Denver and Health Sciences Center, Downtown Denver Campus.

LLNL Lawrence Livermore National Laboratory.

NCAR National Center for Atmospheric Research.

D.2. Software packages.

BLOPEX Block Locally Optimal Preconditioned Eigenvalue Xolvers, a library for large-scale eigenvalue problems, developed by the authors of the paper.

PETSc Portable, Extensible Toolkit for Scientific Computation, tools for the scalable solution of partial differential equations and related problems developed by Argonne National Laboratory; see Balay et al. [2].

hypre High Performance Preconditioners, scalable linear solvers package developed by LLNL; see Falgout, Jones, and Yang [8, 9].

SLEPc Scalable Library for Eigenvalue Problem Computations, a library for large eigenvalue problems, an extension of PETSc; see Hernandez, Roman, and Vidal [10].

D.3. *hypre* interfaces and preconditioners.

IJ A Linear-Algebraic Interface for applications with sparse matrices.

BoomerAMG a parallel implementation of an algebraic multigrid.

Schwarz Agglomeration-based domain decomposition preconditioner.

STRUCT A structured grid interface for applications with logically rectangular grids.

SMG A parallel semicoarsening multigrid solver for the linear systems arising from finite difference, finite volume, or finite element discretiza-

tions of the diffusion equation on logically rectangular grids. The code solves both 2-D and 3-D problems with discretization stencils of up to 9-point in 2-D and up to 27-point in 3-D. The algorithm semicoarsens in the z-direction and uses plane smoothing.

PFMG A parallel semicoarsening multigrid solver similar to SMG. The main difference between the two methods is in the smoother: PFMG uses simple pointwise smoothing. As a result, PFMG is not as robust as SMG, but is much more efficient per V-cycle.

SSTRUCT A semistructured grid interface that targets applications with grids that are mostly structured but with some unstructured features.

FEI An unstructured grid interface designed for Finite Element applications.

D.4. Methods.

PCG Preconditioned Conjugate Gradient.

LOBPCG Locally Optimal Block Preconditioned Conjugate Gradient.

AMG Algebraic Multigrid.

D.5. Computer terms.

CPU Central Processing Unit.

MPI Message Passing Interface.

BLAS Basic Linear Algebra Subprograms are routines that provide standard building blocks for performing basic vector and matrix operations.

Acknowledgments. We are grateful to all members of the Scalable Algorithms Group of the Center for Applied Scientific Computing, Lawrence Livermore National Laboratory, and, in particular, to Ulrike Yang, Rob Falgout, Edmond Chow, Charles Tong, and Panayot Vassilevski for their patient support and help. We thank Matthew Knepley and other members of the PETSc team for their help with incorporating our BLOPEX as an external package into the PETSc library. We thank Jose Roman, a member of the SLEPc team, for writing the SLEPc interface to our *hypre* LOBPCG.

EFFICIENT NUMERICAL SOLUTION OF CAHN–HILLIARD–NAVIER–STOKES FLUIDS IN 2D*

DAVID KAY† AND RICHARD WELFORD‡

Abstract. A finite element discretization of the variable density Cahn–Hilliard–Navier–Stokes system is presented. This system is then decoupled with the Cahn–Hilliard part solved via the nonlinear multigrid method proposed by the authors in [*J. Comput. Phys.*, 212 (2006), pp. 288–304] and the Navier–Stokes part via a multigrid preconditioned GMRES scheme. This new solver is examined numerically and is shown to be efficient with respect to mesh refinement and robust with respect to the problem parameters.

Key words. Cahn–Hilliard equation, Navier–Stokes equation, finite element, nonlinear multigrid

DOI. 10.1137/050648110

1. Introduction.

The Cahn–Hilliard equation [6, 8] is a phenomenological model of phase transitions; see the survey work of Elliott [10] for details. When coupled to the Navier–Stokes equations it provides a model for the dynamics of multiphase fluids that is used to model phenomena such as hydrodynamic effects during spinodal decomposition and the behavior of polymer fluids. The numerical simulation of this model is an area of research currently undergoing intense study (see, for example, [2], [5], [15], [19], [20]), with the majority of the work so far concentrating on finite difference discretizations. However, the *efficient* solution of these equations has yet to be studied in depth. Kim, Kang, and Lowengrub [20] have developed a finite difference multigrid scheme based on FAS (full approximation storage) multigrid for the Cahn–Hilliard part and a projection method for the Navier–Stokes part. The multigrid solver has convergence rates independent of the mesh size h with a slight time-step restriction dependent on the problem parameters.

In this paper we introduce a robust efficient nonlinear multigrid scheme for a finite element discretization of the Cahn–Hilliard–Navier–Stokes (CHNS) problem. The model is well suited to finite elements because of their flexibility and capacity for adaptivity.

Set $c \in [-1, 1]$ to be the concentration order parameter so that $c(x) \approx 1$ (resp., $c(x) \approx -1$) if and only if fluid 1 (resp., fluid 2) is present at the point x. Defining the mean velocity field by

$$\mathbf{u} = \frac{1+c}{2}\mathbf{u}_1 + \frac{1-c}{2}\mathbf{u}_2, \tag{1.1}$$

where $\mathbf{u}_i$ is the velocity field of fluid i, and the total density by

$$\rho = \rho_1 + \rho_2, \qquad \rho_1 = \rho_1^0 \frac{1+c}{2}, \qquad \rho_2 = \rho_2^0 \frac{1-c}{2}, \tag{1.2}$$

where ρ_i^0 is the density of fluid i, mass conservation ensures that the velocity is divergence free; that is,

$$\nabla \cdot \mathbf{u} = 0. \tag{1.3}$$

We note that the velocity defined by $\rho\mathbf{u} = \rho_1\mathbf{u}_1 + \rho_2\mathbf{u}_2$ which is considered by some authors (e.g., [22]) does not have this property.

Let Ω be a bounded convex polygonal domain in $\mathbb{R}^2$. The variable density CHNS problem is the following [4]:

(**P**) Find $\{c(x,t), w(x,t), \mathbf{u}(x,t), p(x,t)\}$ such that

$$\frac{\partial c}{\partial t} + \mathbf{u}\cdot\nabla c - \frac{1}{Pe}\nabla\cdot\left(\frac{b(c)}{\rho(c)}\nabla\left(\frac{w}{\rho(c)}\right)\right) = 0 \quad \text{in } \Omega_T := \Omega\times(0,T), \tag{1.4a}$$

$$-w + \frac{1}{\epsilon}\Phi'(c) - \epsilon\Delta c = 0 \quad \text{in } \Omega_T, \tag{1.4b}$$

$$\rho(c)\left(\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\cdot\nabla)\mathbf{u}\right) - \nu\Delta\mathbf{u} + \nabla p = Kw\nabla c + \delta K\frac{1-c^2}{4}\nabla\left(\frac{w}{\rho(c)}\right) + \rho(c)\mathbf{g} \quad \text{in } \Omega_T, \tag{1.4c}$$

$$\nabla\cdot\mathbf{u} = 0 \quad \text{in } \Omega_T, \tag{1.4d}$$

$$c(x,0) = c^0(x), \quad \mathbf{u}(x,0) = \mathbf{u}^0(x) \quad \forall\, x\in\Omega, \tag{1.4e}$$

$$\frac{\partial c}{\partial \hat{n}} = \frac{\partial w}{\partial \hat{n}} = 0, \quad \mathbf{u} = \mathbf{f} \quad \text{on } \partial\Omega\times(0,T), \tag{1.4f}$$

where the density is given by

$$\rho(c) = 1 + \frac{\delta}{2}(c-1) \tag{1.5}$$

and $\hat{\mathbf{n}}$ is the outward pointing unit normal to the boundary $\partial\Omega$. Here w represents the chemical potential and p the pressure. The given constants are Pe, ϵ, ν, K, and $\mathbf{g}$, where the Péclet number Pe and viscosity ν are measures of the relative rates of diffusion, the interface parameter ϵ determines the width of the interface separating the two fluids (the interface is of width $O(\epsilon)$), the capillary (or Cahn) number K is a nondimensional measure of the dispersion, and $\mathbf{g}$ is the gravitational field; cf. [22].

The contrast between the two densities is given by $\delta = (\rho_1^0 - \rho_2^0)/\rho_1^0$, where we have assumed throughout that $\rho_1^0 \geq \rho_2^0$. The mobility function b and double well potential Φ are given by

$$b(c) = ([1-c^2]_+)^2 = (\max(1-c^2, 0))^2, \tag{1.6}$$

$$\Phi(c) = \frac{1}{4}(1-c^2)^2. \tag{1.7}$$

Existence and uniqueness for this problem have been studied by Boyer [3]. Some fully discrete finite element discretizations of the equal density problem are analyzed in [13].

REMARK 1.1. *Using the identity* $\nabla(wc) = c\nabla w + w\nabla c$, *the term* $-Kw\nabla c$ *in the Navier–Stokes equation* (1.4c) *can be replaced by* $Kc\nabla w$, *where the additional term has been absorbed into the pressure term. Alternatively using* (1.4b), $-Kw\nabla c$ *can be replaced by* $K\epsilon\nabla c\Delta c$, *where again the extra terms are absorbed into the pressure term.*

These equations are very challenging to solve numerically. Typically the interfacial region separating the two fluids is very narrow, and a high spatial resolution is

required to accurately capture the interface dynamics, which leads to a large nonlinear matrix problem to be solved at each time step. Thus finite elements are a good choice for a discretization scheme as they can easily be used in adaptive meshes which have high interfacial resolution. This will be explored further in future work.

The matrix problem that arises from the discretization is very stiff so an implicit time discretization must be used. Additionally the solution may have several time scales over which it evolves. Thus we are led to seek fast and efficient solvers for the problem. We propose a multigrid scheme for the finite element discretization of the problem (**P**) based upon the multigrid scheme for the Cahn–Hilliard equation given in [18] and the F_p preconditioned GMRES solver for the Navier–Stokes equations of Kay, Loghin, and Wathen [17]. We show via numerical examples the robustness of this solver with respect to the problem parameters, in particular that the convergence rate of the scheme is independent of mesh size h.

The layout of this paper is as follows. We start by defining our notation for use below. In section 2 the finite element discretization is described. The solution method is given in section 3, where the multigrid scheme given in [18] and the F_p preconditioner [17] are summarized. Numerical examples demonstrating the efficiency of the proposed scheme are given in section 4. Finally, our conclusions are drawn in section 5.

1.1. Notation. Let $L^2(\Omega)$ denote the space of square integrable functions with norm denoted by $\|\cdot\|$ and inner product $(\cdot,\cdot)$, and let $L^2_0(\Omega) = \{v \in L^2(\Omega) : \int_\Omega v\, dx = 0\}$. Let $H^s(\Omega)$ be the usual Sobolev space. Let $\mathbb{H}^s(\Omega) := (H^s(\Omega))^2$ and $H^1_0(\Omega) := \{u \in H^1(\Omega) : u = 0 \text{ on } \partial\Omega\}$, and similarly for $\mathbb{H}^1_0(\Omega)$.

2. Finite element discretization. For ease of notation we define the four forms

$$a_1(c,u,w) := \left(\frac{b(c)}{\rho(c)}\nabla u, \nabla w\right), \qquad a_2(\mathbf{u},v,w) := (\mathbf{u}\cdot\nabla v, w),$$

$$a_3(\mathbf{u},\mathbf{v},\mathbf{w}) := ((\mathbf{u}\cdot\nabla)\mathbf{v},\mathbf{w}), \qquad a_4(c,u,\mathbf{v}) := \left(\frac{1-c^2}{4}\nabla u, \mathbf{v}\right),$$

and we additionally define $\hat{w} := w/\rho(c)$. Using these, a weak formulation of (1.4a)–(1.4f) can be written as

($\mathbf{P}^{weak}$) Find $\{c(x,t), w(x,t), \mathbf{u}(x,t), p(x,t)\} \in H^1(\Omega)\times H^1(\Omega)\times \mathbb{H}^1_f(\Omega)\times L^2_0(\Omega)$ such that

$$\left(\frac{\partial c}{\partial t}, \eta\right) + a_2(\mathbf{u},c,\eta) + \frac{1}{Pe}a_1(c,\hat{w},\eta) = 0 \quad \forall\, \eta \in H^1(\Omega), \tag{2.1a}$$

$$-(w,\eta) + \frac{1}{\epsilon}(\Phi'(c),\eta) + \epsilon(\nabla c, \nabla\eta) = 0 \quad \forall\, \eta \in H^1(\Omega), \tag{2.1b}$$

$$\begin{aligned}\left(\rho(c)\frac{\partial \mathbf{u}}{\partial t}, \chi\right) + a_3(\rho(c)\mathbf{u},\mathbf{u},\chi) + \nu(\nabla\mathbf{u},\nabla\mathbf{u}) - (p, \nabla\cdot\chi)\\ = Ka_2(\chi,c,w) + \delta K a_4(c,\hat{w},\chi) + (\rho(c)\mathbf{g},\chi) \qquad \forall\, \chi \in \mathbb{H}^1_0(\Omega),\end{aligned} \tag{2.1c}$$

$$(\nabla\cdot\mathbf{u},\xi) = 0 \quad \forall\, \xi \in L^2(\Omega). \tag{2.1d}$$

REMARK 2.1. *Using the incompressibility constraint* (2.1d) *and the boundary conditions for c, we can integrate the convection term in* (2.1a) *to get an equivalent weak form* ($\widetilde{\mathbf{P}}^{weak}$) *to* ($\mathbf{P}^{weak}$)*, where* (2.1a) *is replaced by*

$$\left(\frac{\partial c}{\partial t}, \eta\right) - a_2(\mathbf{u},\eta,c) + \frac{1}{Pe}a_1(c,\hat{w},\eta) = 0 \qquad \forall\, \eta \in H^1(\Omega). \tag{2.2}$$

Both of these formulations will be considered below.

We make the following assumptions on the finite element mesh: let $\mathcal{T}_h$ be a quasi-uniform partitioning of Ω into disjoint open simplices $\{\kappa\}$ with $h_\kappa := diam(\kappa)$ and $h := \max_{\kappa\in\mathcal{T}^h} h_\kappa$, so that $\overline{\Omega} = \cup_{\kappa\in\mathcal{T}^h}\overline{\kappa}$. This triangulation has been refined from an initial coarse macrotriangulation to a refinement level l, leading to a sequence of nested meshes. Additionally we assume that $\mathcal{T}^h$ is weakly acute; that is, for any pair of adjacent triangles the sum of opposite angles relative to the common side does not exceed π. The mesh is then refined once more to produce a finer triangulation $\mathcal{T}^{h/2}$ which also has these properties. We also need the space associated with the triangulation $\mathcal{T}^{2h}$ which is one level coarser than the triangulation $\mathcal{T}^h$.

Associated with $\mathcal{T}^h$, $\mathcal{T}^{h/2}$, and $\mathcal{T}^{2h}$ are the finite element spaces

$$
\begin{aligned}
S^h &:= \{v \in C(\overline{\Omega}) : v|_\kappa \text{ is a polynomial of degree at most } 1\ \forall\,\kappa \in \mathcal{T}^h\} \subset H^1(\Omega),\\
Y^h &:= \{v \in S^h : (v,1) = 0\},\\
X^h &:= \Big\{v \in C(\overline{\Omega}) : v|_\kappa \text{ is a polynomial of degree at most } 1\ \forall\,\kappa \in \mathcal{T}^{h/2}\\
&\qquad \text{and } v = 0 \text{ on } \partial\Omega\Big\} \subset H^1_0(\Omega),\\
V^h &:= \{v \in C(\overline{\Omega}) : v|_\kappa \text{ is a polynomial of degree at most } 1\ \forall\,\kappa \in \mathcal{T}^{2h},\\
&\qquad\qquad (v,1) = 0\} \subset H^1(\Omega).
\end{aligned}
$$

Let $\pi^h : C(\overline{\Omega}) \mapsto S^h$ be the piecewise linear Lagrange interpolation operator such that $(\pi^h v)(x_j) = v(x_j)$ for all $j = 1,\dots,J$, and similarly for $\pi^{h/2} : C(\overline{\Omega}) \mapsto X^h$.

We define a discrete $L^2(\Omega)$ inner product on $C(\Omega)$ via

$$
(u,v)_h := \int_\Omega [\pi^h(uv)](x_j)\,\mathrm{d}\mathbf{x} \equiv \sum_{j=1}^{J} \hat{M}_{jj} u(x_j) v(x_j) \quad \forall\, u, v \in C(\Omega), \tag{2.3}
$$

where $\hat{M}_{jj} := (\phi_j, 1) \equiv (\phi_j, \phi_j)_h$. It is easy to verify that

$$
(\pi^h \eta, \chi)_h = (\eta, \chi)_h \qquad \forall\, \eta, \chi \in C(\overline{\Omega}). \tag{2.4}
$$

Finally for the discrete time derivative we shall write

$$
\partial\eta^n := \frac{\eta^n - \eta^{n-1}}{\tau}.
$$

We can now discretize the system using continuous piecewise linear elements for the Cahn–Hilliard part (2.1a)–(2.1b) and P1-iso-P2/P1 elements for the Navier–Stokes part (2.1c)–(2.1d). These elements are linear in both the velocity and pressure parts but with the pressures being evaluated on the nodes of $\mathcal{T}^h$ and the velocity on the nodes of $\mathcal{T}^{h/2}$; see Figure 2.1.

These elements are known to satisfy the inf-sup stability condition [9],

$$
\inf_{q\in S^h} \sup_{\mathbf{v}\in(X^h)^2} \frac{(q, \nabla\cdot\mathbf{v})}{\|\mathbf{v}\|_{X^h}\|q\|_{S^h}} \geq k_h \geq k_0 > 0 \quad \forall\, \mathbf{v} \in (X^h)^2,\ q \in S^h, \tag{2.5}
$$

where k_0 is independent of h, with similar results if we replace X^h with S^h and S^h with V^h.

The fully discrete problem that we are left to solve is the following:

($\mathbf{P}^{h,\tau}$) Given $c^{h,0}(x) = \pi^h c_0(x)$, $\mathbf{u}^{h,0}(x) = \pi^{h/2}\mathbf{u}_0(x)$, for $n = 1,\dots,N_T$ find

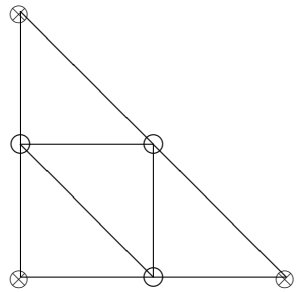

FIG. 2.1. *P1-iso-P2/P1 element:* ∘ = *velocity node,* × = *velocity and pressure node.*

$\{c_h^n, w_h^n, \mathbf{u}_h^n, p_h^n\} \in S^h \times S^h \times (X^h)^2 \times Y^h$ such that

$$(\partial c_h^n, \eta)_h + a_2(\mathbf{u}_h^{n-1}, c_h^n, \eta) + \frac{1}{Pe} a_1(c_h^{n-1}, \hat{w}_h^n, \eta) = 0 \quad \forall\, \eta \in S^h, \tag{2.6a}$$

$$-(w_h^n, \eta)_h + \frac{1}{\epsilon}(\phi(c_h^n) - c_h^{n-1}, \eta)_h + \epsilon(\nabla c_h^n, \nabla \eta) = 0 \quad \forall\, \eta \in S^h, \tag{2.6b}$$

$$(\rho(c_h^n)\partial \mathbf{u}_h^n, \chi) + a_3(\rho(c_h^n)\mathbf{u}_h^{n-1}, \mathbf{u}_h^n, \chi) + \nu(\nabla \mathbf{u}_h^n, \nabla \chi)$$
$$-(p_h^n, \nabla \cdot \chi) = \tilde{\mathbf{f}} \quad \forall\, \chi \in (X^h)^2, \tag{2.6c}$$

$$(\nabla \cdot \mathbf{u}_h^n, \xi) = 0 \quad \forall\, \xi \in S^h \tag{2.6d}$$

with

$$\tilde{\mathbf{f}} = Ka_2(\chi, c_h^n, w_h^n) + \delta K a_4(c_h^n, \hat{w}_h^n, \chi) + (\rho(c_h^n)\mathbf{g}, \chi) \tag{2.7}$$

and where we have used the splitting

$$\Phi'(c_h^n) = (c_h^n)^3 - c_h^{n-1} =: \phi(c_h^n) - c_h^{n-1}. \tag{2.8}$$

This splitting is chosen to ensure the stability of the Cahn–Hilliard part; see [11]. We note that using this discretization scheme on the problem $(\widetilde{\mathbf{P}}^{weak})$ leads to the following discrete scheme:

$(\widetilde{\mathbf{P}}^{h,\tau})$ Given $c^{h,0}(x) = \pi^h c_0(x)$, $\mathbf{u}^{h,0}(x) = \pi^h \mathbf{u}_0(x)$, for $n = 1, \ldots, N_T$ find $\{c_h^n, w_h^n, \mathbf{u}_h^n, p_h^n\} \in S^h \times S^h \times (S^h \cap H^1(\Omega))^2 \times V^h$ such that

$$(\partial c_h^n, \eta)_h - a_2(\mathbf{u}_h^{n-1}, \eta, c_h^n) + \frac{1}{Pe} a_1(c_h^{n-1}, \hat{w}_h^n, \eta) = 0 \quad \forall\, \eta \in S^h, \tag{2.9a}$$

$$-(w_h^n, \eta)_h + \frac{1}{\epsilon}(\phi(c_h^n) - c_h^{n-1}, \eta)_h + \epsilon(\nabla c_h^n, \nabla \eta) = 0 \quad \forall\, \eta \in S^h, \tag{2.9b}$$

$$(\rho(c_h^n)\partial \mathbf{u}_h^n, \chi) + a_3(\rho(c_h^n)\mathbf{u}_h^{n-1}, \mathbf{u}_h^n, \chi) + \nu(\nabla \mathbf{u}_h^n, \nabla \chi)$$
$$-(p_h^n, \nabla \cdot \chi) = \tilde{\mathbf{f}} \quad \forall\, \chi \in (S^h \cap H_0^1)^2, \tag{2.9c}$$

$$(\nabla \cdot \mathbf{u}_h^n, \xi) = 0 \quad \forall\, \xi \in V^h. \tag{2.9d}$$

The discrete schemes $(\mathbf{P}^{h,\tau})$ and $(\widetilde{\mathbf{P}}^{weak})$ are not equivalent since by integrating the convection term in the Cahn–Hilliard equation in $(\widetilde{\mathbf{P}}^{weak})$ by parts we have that

$$\begin{aligned} a_2(\mathbf{u}_h^{n-1}, \eta, c_h^n) &= -(\eta, \nabla \cdot (\mathbf{u}_h^{n-1} c_h^n)) \\ &= -a_2(\mathbf{u}_h^{n-1}, c_h^n, \eta) - (\eta, c_h^n \nabla \cdot \mathbf{u}_h^{n-1}) \\ &\neq -a_2(\mathbf{u}_h^{n-1}, c_h^n, \eta), \end{aligned}$$

as $c_h^n \eta \notin V^h$, so we cannot use (2.9d) to eliminate this term. Thus these two discretizations will give different results, so will investigate both options with respect to the efficiency of the solver.

Since we use a multigrid solver for the convection term in the Navier–Stokes equations we stabilize (2.6c) with a streamline-diffusion method [16]. This involves adding an additional term of the form

$$\gamma(\mathbf{u}_h^{n-1} \cdot \nabla \mathbf{u}_h^n, \mathbf{u}_h^{n-1} \cdot \nabla \chi)$$

into the left-hand side of (2.6c) where γ is the regularization parameter. The local parameter γ_κ is determined by the local mesh Péclet number

$$Pe_\kappa = Re \|\mathbf{u}_h^{n-1}\|_{\infty,\kappa} h_\kappa$$

using

$$\gamma_\kappa = \begin{cases} \frac{1}{2} h_\kappa (1 - \frac{1}{Pe_\kappa}) & \text{if} \quad Pe_\kappa > 1, \\ 0 & \text{if} \quad Pe_\kappa \leq 1. \end{cases}$$

This choice of stabilization aids the convergence of the iterative solver used in the Navier–Stokes equations; see [14], where this choice of parameter is shown to be optimal.

One of the important features of the Cahn–Hilliard equation without flow ($\mathbf{u} \equiv \mathbf{0}$) is that it conserves mass, that is, $\partial c / \partial t = 0$ (take $\eta = 1$ in (2.1a) to show this), and we wish this to be carried over to the discrete case. Both of the discretizations given here can be shown to retain this property as shown in the following lemma.

LEMMA 2.2. *The schemes* $(\mathbf{P}^{weak})$, $(\widetilde{\mathbf{P}}^{weak})$, $(\mathbf{P}^{h,\tau})$, *and* $(\widetilde{\mathbf{P}}^{h,\tau})$ *all conserve mass.*

Proof. For $(\widetilde{\mathbf{P}}^{weak})$ and $(\widetilde{\mathbf{P}}^{h,\tau})$ this comes trivially by taking $\eta = 1$ in the Cahn–Hilliard equation. For $(\mathbf{P}^{weak})$ take $\eta = 1$ in (2.1a), integrate by parts, and use the boundary conditions and the incompressibility constraint (2.1d) to yield the desired result. For $(\mathbf{P}^{h,\tau})$ we take $\eta = 1$ in (2.6a) and, noting that $c_h^n \in S^h$, we can integrate by parts and use (2.6d) to get the desired result. ∎

REMARK 2.3. *We note that if the concentration and velocities were evaluated at the same mesh in scheme* $(\mathbf{P}^{h,\tau})$*, then the pressure would be evaluated on a coarser mesh,* V^h*, so the concentration would not belong to the pressure space, and thus mass would not be conserved. This can be observed in practice and leads to incorrect numerical results. However, such a restriction does not apply for scheme* $(\widetilde{\mathbf{P}}^{\mathbf{h},\tau})$*, which is therefore computationally faster as* c *and* $\mathbf{u}$ *are evaluated on the same mesh of size* h *rather than the velocity being evaluated on the mesh of size* $h/2$*.*

3. Solution of the discrete system. We describe only the scheme $(\mathbf{P}^{h,\tau})$ here; the solution method for $(\widetilde{\mathbf{P}}^{h,\tau})$ is similar, with the relevant changes of finite dimensional spaces.

The system (2.6a)–(2.6d) is solved via a two-stage process. By taking the velocity term in (2.6a) explicitly, the Cahn–Hilliard equations decouple from the Navier–Stokes equations, allowing them to be solved separately. First the Cahn–Hilliard part is solved via a nonlinear multigrid solver (cf. [18]) and then the Navier–Stokes part is solved using these new values for c and w.

3.1. The Cahn–Hilliard solver. The Cahn–Hilliard part requires us to solve the following system:

$$(\partial c_h^n, \eta)_h + a_2(\mathbf{u}_h^{n-1}, c_h^n, \eta) + \frac{1}{Pe} a_1(c_h^{n-1}, \hat{w}, \eta) = 0, \tag{3.1a}$$

$$-(w_h^n, \eta)_h + \frac{1}{\epsilon}(\phi(c_h^n) - c_h^{n-1}, \eta)_h + \epsilon(\nabla c_h^n, \nabla \eta) = 0. \tag{3.1b}$$

Using the stiffness matrix A, mobility dependent stiffness matrix D, convection matrix N, and lumped mass matrix $\hat{M}$ given by

$$A(i,j) := \int_\Omega \nabla\psi_i \cdot \nabla\psi_j \ \mathrm{d}\mathbf{x}, \qquad D(i,j) := \int_\Omega \frac{b}{\rho} \nabla\psi_i \cdot \nabla\psi_j \ \mathrm{d}\mathbf{x},$$

$$N(i,j) := \int_\Omega \mathbf{u}_h^{n-1} \cdot \nabla\psi_i \ \psi_j \ \mathrm{d}\mathbf{x}, \qquad \hat{M}(i,i) := \int_\Omega \psi_i \, \mathrm{d}\mathbf{x},$$

where $S^h = span\{\psi_i\}_{i=1}^{N_p}$, the discrete Cahn–Hilliard problem can be written as

$$\hat{M}c^n + \tau N(\mathbf{u}^{n-1})c^n + \frac{\tau}{Pe} D\hat{w}^n = b, \tag{3.2a}$$

$$-\hat{M}w^n + \frac{1}{\epsilon}\hat{M}\boldsymbol{\phi}(c^n) + \epsilon A c^n = \frac{1}{\epsilon} b, \tag{3.2b}$$

where $b = \hat{M}c^{n-1}$ and $\boldsymbol{\phi}$ is understood to operate pointwise. This problem is solved using the nonlinear successive subspace correction multigrid scheme described in [18]. The mass matrices have been lumped so that the nonlinear term $\hat{M}\boldsymbol{\phi}(c^n)$ is diagonal.

Decompose the finite element space such that

$$S^h = \sum_{l=1}^{L} S_l^h, \tag{3.3}$$

where the $S_l^h \subset S_{l+1}^h$ are obtained by successive (not necessarily uniform) refinements of the triangulation and $S_L^h = S^h$. Project the basis functions for each of these spaces onto the finest grid, given by S^h, using standard prolongation operators (e.g., [27]). The algorithm is then as follows: looping over all of the basis functions η update c and w by

$$c^{n,k+1} = c^{n,k} + \alpha\eta, \quad w^{n,k+1} = w^{n,k} + \beta\eta,$$

where α, β are the solution of

$$(M(c^{n,k} + \alpha\eta), \eta) + \tau(Nc^{n,k}, \eta) + \tau(D(\hat{w}^{n,k} + \beta\hat{\eta}), \eta) - (b, \eta) = 0, \tag{3.4a}$$

$$\epsilon(A(c^{n,k} + \alpha\eta), \eta) + \left(\frac{1}{\epsilon} M\boldsymbol{\phi}(c^{n,k} + \alpha\eta) - \frac{1}{\epsilon} b - M(w^{n,k} + \beta\eta), \eta\right) = 0, \tag{3.4b}$$

with $(x, y) = x^T y$ the Euclidean inner product.

We can eliminate β from these equations to obtain a cubic polynomial in α which is solved using a Newton iteration. This is repeated until all the basis functions have been used in an update and then repeated until the relative residual of (2.6a) has been decreased by a set tolerance, *tol*. One multigrid iteration numerically costs about the same as one Gauss–Seidel iteration [18]; thus any decrease in iteration counts represents a speedup in computational time. This method is seen to be optimally efficient with respect to the problem parameters; see [18], where many numerical examples are presented.

3.2. The Navier–Stokes solver. For the Navier–Stokes part of the scheme we need to solve the following problem at each time step:

$$\frac{1}{\tau}(\mathbf{u}_h^n\chi) + a_3(\rho(c_h^n)\mathbf{u}_h^{n-1}, \mathbf{u}_h^n, \chi) + \nu(\nabla\mathbf{u}_h^n, \nabla\chi) - (p_h^n, \nabla\cdot\chi) = \mathbf{f}, \tag{3.5a}$$

$$(\nabla\cdot\mathbf{u}_h^n, \xi) = 0, \tag{3.5b}$$

where

$$\mathbf{f} := Ka_2(\chi, c_h^n, w_h^n) + \delta Ka_4(c_h^{n-1}, \hat{w}_h^n, \chi) + \left(\rho(c_h^n)\left[\mathbf{g} + \frac{1}{\tau}\mathbf{u}_h^{n-1}\right], \chi\right).$$

This is a generalized Oseen problem, for which solution methods have been extensively studied. We choose the F_p preconditioned GMRES method developed by Kay, Loghin, and Wathen [17].

The F_p preconditioner. Using the stiffness matrix A, convection matrix N, divergence matrices B_x and B_y, and mass matrix M given by

$$A(i,j) := \int_\Omega \nabla\varphi_i\cdot\nabla\varphi_j \ \mathrm{d}\mathbf{x}, \qquad N(i,j) := \int_\Omega \mathbf{u}_h^{n-1}\cdot\nabla\varphi_i \ \varphi_j \ \mathrm{d}\mathbf{x},$$
$$B_x(i,j) := -\int_\Omega \frac{\partial\varphi_i}{\partial x}\psi_j \ \mathrm{d}\mathbf{x}, \qquad B_y(i,j) := -\int_\Omega \frac{\partial\varphi_i}{\partial y}\psi_j \ \mathrm{d}\mathbf{x},$$
$$M(i,j) := \int_\Omega \varphi_i\varphi_j \ \mathrm{d}\mathbf{x},$$

where $X^h = span\{\varphi_i\}_{i=1}^{N_v}$, and additionally letting the matrix N absorb the streamline diffusion term, we can write the Navier–Stokes system as the following matrix problem:

$$\mathcal{A}\mathbf{x} = \hat{\mathbf{f}}, \tag{3.6}$$

where

$$\mathcal{A} = \begin{pmatrix} \mathcal{F} & B^T \\ B & 0 \end{pmatrix}, \qquad \mathcal{F} = \begin{pmatrix} F & 0 \\ 0 & F \end{pmatrix}, \qquad B = (B_x \ B_y),$$
$$F = \frac{1}{\tau}\rho M + \nu A + \rho N, \qquad \mathbf{x} = (\mathbf{u}^n, p^n)^t, \qquad \hat{\mathbf{f}} = (\mathbf{f}, \mathbf{f}_{bc})^t,$$

and the extra term $\mathbf{f}_{bc}$ arises from the imposition of the Dirichlet boundary conditions.

This is a difficult problem to solve as it is a large nonsymmetric indefinite system. We will use GMRES (see [25]) with right preconditioning; i.e., we solve the problem

$$(\mathcal{A}\mathcal{P}^{-1})(\mathcal{P}\mathbf{x}) = \hat{\mathbf{f}}, \tag{3.7}$$

where the preconditioner $\mathcal{P}$ is chosen such that its eigenvalues are clustered and it is easily invertible. The optimal choice of preconditioner is given by [23]

$$\mathcal{P}^{-1} = \begin{pmatrix} \mathcal{F}^{-1} & \mathcal{F}^{-1}B^tS^{-1} \\ 0 & -S^{-1} \end{pmatrix}, \tag{3.8}$$

with $S = B\mathcal{F}^{-1}B^t$, so that

$$\mathcal{A}\mathcal{P}^{-1} = \begin{pmatrix} I & 0 \\ B\mathcal{F}^{-1} & 0 \end{pmatrix}, \tag{3.9}$$

and $\sigma(\mathcal{A}\mathcal{P}^{-1}) = \{1\}$ so the GMRES algorithm converges in at most two iterations. Then at each step we need to solve $\mathcal{P}y = r$, i.e., find v, q such that

$$\begin{pmatrix} v \\ q \end{pmatrix} = \begin{pmatrix} \mathcal{F}^{-1} & \mathcal{F}^{-1}B^tS^{-1} \\ 0 & -S^{-1} \end{pmatrix} \begin{pmatrix} r \\ s \end{pmatrix}. \tag{3.10}$$

This is a two-stage process: first solve for q: $Sq = -s$, then for v: $\mathcal{F}v = r - B^tq$. In practice we replace S and $\mathcal{F}$ with approximations S_* and $\mathcal{F}_*$. The difficulty lies in obtaining a good yet simple approximation for the Schur complement S. Kay, Loghin, and Wathen [17] developed the F_p preconditioner for this purpose. This replaces the inverse of the Schur complement with

$$S_*^{-1} = M_{p*}^{-1}F_pA_{p*}^{-1}, \tag{3.11}$$

where M_{p*}^{-1}, A_{p*}^{-1} are approximations to the inverses of the mass and stiffness matrices on the pressure grid, respectively. M_{p*}^{-1} is obtained by five diagonally scaled conjugate gradient iterations, while A_{p*}^{-1} is obtained via a single multigrid v-cycle applied to A_p, the pressure Laplacian.

This choice of preconditioner is made because it has convergence rates that are independent of mesh size h with only a mild dependence on ν; see [17]. For further details on this scheme see [12, 26].

4. Numerical examples. All of the examples presented were performed on the domain $\Omega = [0,1]^2$, with a solver tolerance of $tol = 1 \times 10^{-6}$. They all use scheme $(\mathbf{P}^{h,\tau})$ except for the final section, where $(\widetilde{\mathbf{P}}^{h,\tau})$ is used.

In the tables of iteration counts the first number is the maximum number of v-cycles for the Cahn–Hilliard solver that were obtained over the course of the simulation, and the second number is the maximum number of GMRES iterations obtained for the Navier–Stokes solver over the course of the simulation. The figures given below illustrate the concentration field c and the velocity streamlines.

4.1. Spinodal decomposition under constant shear. We start by considering the case of two fluids with equal density undergoing spinodal decomposition in a constant shear. The initial data for c is given by a random perturbation of magnitude 0.1 about a mean composition of 0; see Figure 4.1. The velocity is taken to be either $(1,0)^t$ or $(10,0)^t$ throughout. This leads to the stripes forming, and the faster velocity yields more stripes; see Figure 4.2. This first example does not satisfy the boundary conditions for $\mathbf{u}$, but it gives an insight into the performance of the Cahn–Hilliard solver when a velocity is introduced.

The iteration counts for the Cahn–Hilliard solver are given in Table 4.1. It is clear that the iteration counts do not depend on the velocity and are independent of the mesh size, showing that the solver is mesh independent.

4.2. Rayleigh–Taylor instability. Rayleigh–Taylor instability is caused when a heavier fluid is placed upon a lighter one; see Figure 4.3. We examine several cases of this to show how the proposed solver performs during this complex simulation. Since the interesting stages of the evolution do not occur while the solution remains of the form of Figure 4.3, we run this until the initial condition shown in Figure 4.4 is achieved. This is where the most interesting characteristics of the evolution occur such as coalescence and pinch-off. From this initial condition a fixed number of time steps for each problem were calculated, with the various problem parameters varied.

First we examine the effect of the interface width; see Table 4.2. Recalling that the interface width is $O(\epsilon)$, we see that this parameter does not affect the performance

of the solver. The iteration counts for both the Cahn–Hilliard and Navier–Stokes equations are unaffected by mesh refinement and interface width. Thus with respect to these parameters we can see that the solver performs optimally.

For the second test the viscosity ν was varied; see Table 4.3. Again, with respect to mesh refinement the solver performs well. The increase in iteration counts for the GMRES solver as ν is decreased is due to the Reynolds number increasing; see Table 4.4. This is to be expected, as it is known that the F_p preconditioner has a slight dependence on the Reynolds number [17].

The third test involved varying the densities of the two fluids. The values of δ chosen for this test were 0.5, 0.9, 0.99, and 0.999, representing ratios of fluid densities of 2 : 1, 10 : 1, 100 : 1, and 1000 : 1, respectively. Again we see that the solver performed well with respect to mesh refinement, especially for the higher ratios which are of more practical interest; see Table 4.5.

TABLE 4.5

1/128	9(33)	9(33)	9(33)	9(32)

The final test involved the capillary number K; see Table 4.6. The solvers were the most robust with respect to this parameter, showing that although it plays a vital part in the evolution of the flow (see [4] for an examination of this) it does not affect the solution method proposed here.

For completeness we conclude this section by giving the following figures showing a full example of Rayleigh–Taylor instability with $Pe = 1000$, $\epsilon = 0.02$, $\nu = 0.01$, $\delta = 0.99$, $K = 0.001$. These figures show the concentration field and streamlines of the velocity at the given times. The maximum velocity at each time is also shown to demonstrate how the velocity field evolves.

$\|\mathbf{u}\|_\infty = 1.35$

$t = 2$
$\|\mathbf{u}\|_\infty = 0.82$

$t = 2.5$
$\|\mathbf{u}\|_\infty = 0.66$

$t = 25$
$\|\mathbf{u}\|_\infty = 0.14$

4.3. Spinodal decomposition. For the second experiment we perform spinodal decomposition under a gravitational field. The initial data for c is again given by a random perturbation of magnitude 0.1 about a mean composition of 0 with $\mathbf{u}^0 = \mathbf{0}$; see Figure 4.1. For this problem we took $\epsilon = 0.02$, $\nu = 0.01$, $Pe = 1000$, $K = 0.001$, $\delta = 0.99$.

Following [18, 21] we set the time step to be $\tau = 0.001t^{1/4}$ to see how the solver can cope with variable time-step size. This scaling of the time-step size is based on the late stage growth law $l(t) \sim t^{1/4}$ that is followed by the evolution of surfaces undergoing motion by surface diffusion (Laplacian of the curvature). Motion by surface diffusion is the sharp-interface limit (that is, $\epsilon \to 0$) of the Cahn–Hilliard equation [7]. In the early stages of spinodal decomposition the solution rapidly evolves into regions where $c \approx \pm 1$. Then over much slower time scales, these "bulk" regions evolve and conglomerate into larger regions.

The iteration counts obtained (see Figure 4.5) show that as in [18] the Cahn–Hilliard part counts remain fixed. However the GMRES iteration counts grow as $t^{1/4}$, suggesting a relationship of number of iterations $\sim \tau$. The iteration count reaches a maximum that is dependent on the Reynolds number of the problem. It is known that the number of iterations for the F_p preconditioned GMRES grows with the time-step size (see [12]) so this behavior is expected.

The evolution of this problem is presented following Figure 4.5. We note that in the fourth image ($t = 9.5$) there is a small bubble of the lighter fluid trapped in the bottom right-hand corner of the domain. Such bubbles evolve over extremely long time scales [1], and therefore numerically we expect this to remain for all sensible computational times.

$t = 9.5$
$\|\mathbf{u}\|_\infty = 0.15$

4.4. Scheme $(\widetilde{\mathbf{P}}^{h,\tau})$. In this section we return to the Rayleigh–Taylor example of section 4.2 but with discretization scheme $(\widetilde{\mathbf{P}}^{h,\tau})$. The results are given in Table 4.7. We can see that the solver performs just as well with this discretization, retaining its optimality with respect to mesh refinement.

TABLE 4.7
$\tau = 0.005$, $Pe = 1000$, $\nu = 0.01$, $K = 0.001$, $\delta = 0.99$.

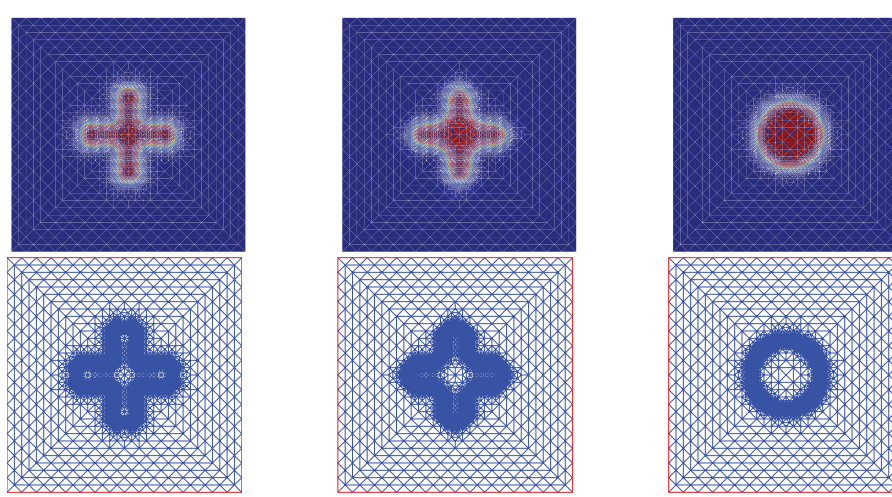
1/64	7(26)	8(29)	7(33)	8(41)
1/128	8(29)	8(30)	8(33)	8(38)

4.5. Adaptivity. The final example is calculated using an adaptive mesh refinement scheme. Coupling the multigrid solver to an adaptive mesh refinement scheme provides us with a very efficient solution method for this problem. The evolution of the concentration and the mesh are shown below. Figure 4.6 shows the numbers of degrees of freedom (NDOFS), divided by 100, and the iteration counts for the Cahn–Hilliard and the Navier–Stokes solvers. Again we see that the solver performs well with this adaptive mesh scheme.



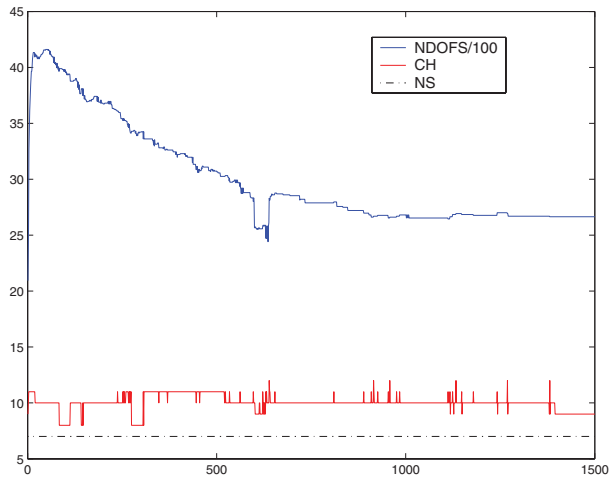


FIG. 4.6. *Number of degrees of freedom and iteration counts for the evolution of a cross.*

5. Conclusions. A new multigrid finite element solver for density-dependent Cahn–Hilliard fluids has been presented that exhibits iteration counts that are independent of mesh size h. Two discretizations of the system have been given, and the solver has been shown via numerical examples to be robust and efficient with respect to the problem parameters. In particular we note that the solver can be used in conjunction with an adaptive mesh refinement scheme to provide a greater increase in efficiency of the scheme.

Acknowledgment. The authors would like to thank the referees for their comments and suggestions.

A DISCONTINUOUS GALERKIN MOVING MESH METHOD FOR HAMILTON–JACOBI EQUATIONS*

J. A. MACKENZIE† AND A. NICOLA‡

Abstract. In this paper we consider the numerical solution of first-order Hamilton–Jacobi equations using the combination of a discontinuous Galerkin finite element method and an adaptive r-refinement (mesh movement) strategy. Particular attention is given to the choice of an appropriate adaptivity criterion when the solution becomes discontinuous. Numerical examples in one and two dimensions are presented to demonstrate the effectiveness of the adaptive procedure.

Key words. adaptivity, moving meshes, discontinuous Galerkin finite elements, Hamilton–Jacobi equations

1. Introduction.

In this paper we consider the adaptive numerical solution of Hamilton–Jacobi (HJ) equations

$$\phi_t + H(\phi_{x_1}, \ldots, \phi_{x_d}) = 0, \quad \phi(\boldsymbol{x}, 0) = \phi_0(\boldsymbol{x}), \tag{1.1}$$

where $\boldsymbol{x} = (x_1, \ldots, x_d) \in \mathbb{R}^d$, $t > 0$. HJ equations arise in many practical areas such as differential games, mathematical finance, image enhancement, and front propagation. It is well known that solutions of (1.1) are Lipschitz continuous, but derivatives can become discontinuous even if the initial data is smooth. Since generalized solutions are not unique, a selection principle is required to pick out the physically relevant solution. For HJ equations the most commonly used condition is the vanishing viscosity condition, which requires that the correct solution should be the vanishing viscosity limit of smooth solutions of corresponding viscous problems. The notion of viscosity solutions was introduced by Crandall and Lions [8], where the questions of existence, uniqueness, and stability of solutions were addressed.

Crandall and Lions were also the first to study numerical approximations of (1.1) and introduced the important class of monotone finite difference methods which were shown to converge to the viscosity solution [7]. However, monotonic schemes are well known to be at most first-order accurate.

There is a close relation between HJ equations and hyperbolic conservation laws (see section 2.1 below). With this in mind, it is not surprising to find that many of the numerical methods used to solve HJ equations are motivated by conservative finite difference or finite volume methods for conservation laws. Methods that have been proposed include high-order essentially nonoscillatory (ENO) schemes [22], [23], weighted ENO schemes [15], and high-resolution central schemes [21].

An increasingly popular approach to solving hyperbolic conservation laws is the discontinuous Galerkin (DG) finite element method [5], [6]. Recently, Hu and Shu

[11] proposed a DG method to solve HJ equations by first rewriting (1.1) as a system of conservation laws

$$(w_i)_t + (H(\boldsymbol{w}))_{x_i} = 0, \quad i = 1, \ldots, d, \quad \boldsymbol{w}(\boldsymbol{x}, 0) = \nabla\phi_0(\boldsymbol{x}), \tag{1.2}$$

where $\boldsymbol{w} = \nabla\phi$. The usual DG formulation would be obtained if $\boldsymbol{w}$ belonged to a space of piecewise polynomials. However, we note that w_i, $i = 1, \ldots, d$, are not independent due to the restriction that $\boldsymbol{w} = \nabla\phi$. In [11] a least squares procedure was used to enforce this condition. More recently it was shown that it is possible to enforce the gradient condition using a smaller solution space [19]. Theoretical analysis of the accuracy and stability of the method was performed in [18].

One of the often cited advantages of DG methods is that since the numerical solution is not continuous across interelement boundaries, this, in theory, makes solution adaptive strategies much easier to implement. This has led to the development of a number of adaptive methods based on *hp*-refinement strategies for hyperbolic conservation laws [4], [10].

An alternative adaptive strategy that has worked well for time-dependent problems is to use moving meshes. A useful way to construct an adaptive moving mesh is to regard it as the image of a uniform mesh covering a computational domain under a time-dependent transformation that clusters mesh elements towards areas where improved spatial resolution is required. The transformation is often found through a variational formulation where the mapping is the minimizer of a functional involving properties of the mesh and the solution (see, e.g., [17], [29]). To improve the stability and smooth the evolution of the moving mesh, Russell, Huang, and coworkers [14], [12] found it useful to obtain the mapping as the solution of parabolic moving mesh PDEs (MMPDEs) which are modified gradient flow equations for the minimization of a suitable mesh functional.

For problems where solution discontinuities exist, the correct choice of an adaptivity criterion, or monitor function, is problematic [30]. It is not unusual to find in the literature that many grid adaptation criteria are singular at solution discontinuities. To prevent singularities from producing degenerate meshes, either some form of smoothing procedure is employed or a regularized functional is used in the variational formulation [1].

There are two main ways to solve PDEs using moving meshes. The first is to reformulate the governing equations with respect to the moving reference frame. If conservation is important, then this reformulation must be done carefully. Examples of this approach are arbitrary Lagrangian–Eulerian (ALE) methods which are commonly used for problem with moving domains. Alternatively one may evolve the numerical solution over one time step using a stationary mesh. Thereafter, the mesh is moved, and some form of interpolation procedure is used to transfer the solution values from one mesh to another. This approach has been used successfully in the work of Tang and coworkers [20], [31], [27] to solve hyperbolic problems where a suitable conservative form of interpolation was proposed.

The aim of this paper is to consider the use of the DG method of Hu and Shu [11] to solve HJ equations using a moving mesh method based on the solution of MMPDEs. The governing equation is transformed to include the effect of the movement of the mesh and this is done in such a way that the conservation properties of the original equation are not lost. The adaptive mesh is driven by a monitor function which is shown to be nonsingular in the presence of solution discontinuities. To produce an acceptable mesh we smooth the monitor function before it is used to drive the adaptive procedure.

The layout of the rest of this paper is as follows: in the next section we present the governing HJ equations and their discretization using a moving mesh and a DG formulation. In section 3 we present the MMPDEs and their discretization and we discuss the choice of the monitor function. Finally, in section 4 we conduct a number of numerical experiments in one and two dimensions.

2. DG discretization of HJ equations.

2.1. HJ equation in one dimension. Let us consider the HJ equation in one dimension:

$$\begin{cases} \phi_t + H(\phi_x) = 0, \quad (x,t) \in (a,b) \times (0,T], \\ \phi(x,0) = \phi_0(x), \end{cases} \tag{2.1}$$

with appropriate boundary conditions. If $u = \phi_x$ and we differentiate (2.1) with respect to x, then u satisfies the hyperbolic conservation law

$$\begin{cases} u_t + H(u)_x = 0, \quad (x,t) \in (a,b) \times (0,T], \\ u(x,0) = u_0(x). \end{cases} \tag{2.2}$$

We assume that the physical domain $\Omega_p = [a,b]$ is the image of a computational domain $\Omega_c = [0,1]$ which is obtained via the time-dependent mapping $x = x(\xi,t)$. If (2.2) is considered with respect to the moving coordinate frame, then

$$\dot{u} - \dot{x} u_x + H(u)_x = 0, \quad (x,t) \in (a,b) \times (0,T], \tag{2.3}$$

where $\dot{(\cdot)}$ represents differentiation with respect to time keeping ξ fixed. Note that the transformed equation is not in conservation form. Therefore, a discretization of (2.3) will not be conservative in general, even if the $H(u)_x$ term is treated conservatively, and this will lead to problems in convergence towards discontinuous solutions of (2.2) (see [24]). Therefore, instead we will consider a discretization of the conservative form in computational coordinates:

$$\begin{cases} \dot{(x_\xi} u) + (H(u) - \dot{x}\, u)_\xi = 0, \quad (\xi,t) \in (0,1) \times (0,T], \\ u(\xi,0) = u_0(\xi). \end{cases} \tag{2.4}$$

The aim is to discretize (2.4) in space using a DG method.

2.2. The DG discretization. For each partition $\{\xi_{j+\frac{1}{2}}\}_{j=0}^{N}$ of Ω_c, we denote

$$I_j = \left(\xi_{j-\frac{1}{2}}, \xi_{j+\frac{1}{2}}\right), \quad \Delta_j = \xi_{j+\frac{1}{2}} - \xi_{j-\frac{1}{2}}, \quad j = 1, \ldots, N.$$

We use a uniform mesh to cover the computational domain such that

$$h = \xi_{j+\frac{1}{2}} - \xi_{j-\frac{1}{2}} = \frac{1}{N}, \quad \xi_j = \frac{1}{2}\left(\xi_{j+\frac{1}{2}} + \xi_{j-\frac{1}{2}}\right), \quad j = 1, \ldots, N. \tag{2.5}$$

If we multiply (2.4) by an arbitrary smooth function v, then integrating by parts over the interval I_j we obtain

$$\int_{I_j} (\dot{x_\xi} u)\, v \, d\xi - \int_{I_j} \widetilde{H}(u, \dot{x})\, v_\xi \, d\xi + \widetilde{H}(u, \dot{x})\, v \Big|_{I_j} = 0, \tag{2.6}$$

where

$$\widetilde{H}(u,\dot{x}) = H(u) - \dot{x}\,u, \tag{2.7}$$

and

$$\widetilde{H}(u,\dot{x})v\Big|_{I_j} = \widetilde{H}(u(\xi_{j+\frac{1}{2}},t),\dot{x}(\xi_{j+\frac{1}{2}}))\,v(\xi_{j+\frac{1}{2}}) - \widetilde{H}(u(\xi_{j-\frac{1}{2}},t),\dot{x}(\xi_{j-\frac{1}{2}}))\,v(\xi_{j-\frac{1}{2}}). \tag{2.8}$$

In this paper we will approximate the exact solution u of (2.6) and the smooth function v locally by linear polynomials. The numerical approximations u_h and v_h belong to the finite dimensional space

$$V_h^1 = \left\{v : v|_{I_j} \in P^1(I_j), \quad j = 1,\dots,N\right\}, \tag{2.9}$$

where $P^1(I_j)$ denotes the space of polynomials on I_j of degree at most one. In the discontinuous Galerkin numerical method u_h and v_h are discontinuous at the points $\xi_{j+\frac{1}{2}}$, $j = 0,\dots,N$, and the question is how to evaluate their values in (2.8). We set

$$v_{h_{j+\frac{1}{2}}}^- = \lim_{\xi\to\xi_{j+\frac{1}{2}}^-} v_h(\xi) \quad \text{and} \quad v_{h_{j-\frac{1}{2}}}^+ = \lim_{\xi\to\xi_{j-\frac{1}{2}}^+} v_h(\xi). \tag{2.10}$$

Furthermore, we replace the nonlinear flux function $\widetilde{H}(u_h,\dot{x})$ defined in (2.7) by a numerical flux function that depends on the values of u_h from the left and right at the point $\left(\xi_{j+\frac{1}{2}},t\right)$, that is,

$$\widetilde{H}(u_h,\dot{x})_{\xi_{j+\frac{1}{2}}}(t) \approx \overline{H}_{j+\frac{1}{2}}\left(u_h\left(\xi_{j+\frac{1}{2}}^-,t\right),u_h\left(\xi_{j+\frac{1}{2}}^+,t\right),\dot{x}_{\xi_{j+\frac{1}{2}}}(t)\right). \tag{2.11}$$

In this paper we have used the local Lax–Friedrichs flux

$$\overline{H}(p,q,\dot{x}) = \frac{1}{2}\left(\widetilde{H}(p,\dot{x}) + \widetilde{H}(q,\dot{x}) - c(q-p)\right), \tag{2.12}$$

where

$$c = \max_{\min(p,q)\le u\le\max(p,q)}\left|\frac{\partial\widetilde{H}}{\partial u}\right|.$$

It is well known that some form of slope or flux limiting procedure is necessary to prevent oscillations at solution discontinuities when high-order methods are used to solve nonlinear hyperbolic conservation laws [25]. For example, if u_j^0 denotes the cell average of u_h in I_j, then we have

$$u_h(\xi) = u_j^0 + u_j^1(\xi - \xi_j), \quad j = 1,\dots,N, \tag{2.13}$$

and

$$\frac{du_h}{d\xi} = u_j^1, \quad j = 1,\dots,N,$$

is the slope of the numerical solution. One formula for limiting the slope in the numerical approximation is the minmod function

$$m(q,r,s) = \begin{cases} \operatorname{sgn}(q)\,\min(|q|,|r|,|s|) & \text{if } \operatorname{sgn}(q) = \operatorname{sgn}(r) = \operatorname{sgn}(s), \\ 0 & \text{otherwise,} \end{cases} \tag{2.14}$$

where sgn is the usual sign function. The initial linear expression for u_h is then replaced by

$$u_h(\xi) = u_j^0 + (u_j^1)^{\mathrm{mod}}(\xi - \xi_j), \quad j = 1, \ldots, N, \tag{2.15}$$

where $(u_j^1)^{\mathrm{mod}}$ is the limited slope computed as

$$(u_j^1)^{\mathrm{mod}} = m(u_j^1,\, \Delta_+ u_j^0/\Delta_j,\, \Delta_- u_j^0/\Delta_j),$$

in which Δ_+ and Δ_- are the usual forward and backward difference operators.

The discontinuous Galerkin space approximation is given as the solution of the weak formulation

$$\int_{I_j} (x_\xi \dot{u}_h) v_h \, d\xi - \int_{I_j} \widetilde{H}(u_h, \dot{x})(v_h)_\xi \, d\xi + \overline{H}_{j+\frac{1}{2}} v^-_{h_{j+\frac{1}{2}}} - \overline{H}_{j-\frac{1}{2}} v^+_{h_{j-\frac{1}{2}}} = 0, \tag{2.16}$$

and the initial condition is given by the projection

$$\int_{I_j} u_h(\xi, 0) v_h(\xi) \, d\xi = \int_{I_j} u_0(\xi) v_h(\xi) \, d\xi, \quad j = 1, \ldots, N, \tag{2.17}$$

for all $v_h \in V_h^1$.

It remains to describe how the gradient of the mesh mapping x_ξ is approximated. We will assume that the map $x = x(\xi, t)$ is piecewise linear so that

$$x(\xi, t) = x_{j-\frac{1}{2}}(t) + N\,(\xi - \xi_{j-\frac{1}{2}})\left(x_{j+\frac{1}{2}}(t) - x_{j-\frac{1}{2}}(t)\right) \tag{2.18}$$

for

$$\xi_{j-\frac{1}{2}} \le \xi \le \xi_{j+\frac{1}{2}}, \quad j = 1, \ldots, N.$$

It then follows that x_ξ used in the weak formulation (2.16) is given by

$$x_\xi(\xi, t) = N(x_{j+\frac{1}{2}}(t) - x_{j-\frac{1}{2}}(t)), \quad j = 1, \ldots, N. \tag{2.19}$$

2.2.1. Temporal integration. The discontinuous Galerkin discretization gives rise to a system of ODEs which can be written as

$$\begin{cases} \dfrac{d}{dt}(x_\xi \mathbf{u}_h) = L_h(\dot{x}, x_\xi, \mathbf{u}_h) \quad \text{in } (0, T], \\ \mathbf{u}_h(0) = \mathbf{u}_{0h}, \end{cases} \tag{2.20}$$

where $\mathbf{u}_{0h}$ is the initial approximation for the vector of the degrees of freedom $\mathbf{u}_h$. To integrate (2.20) numerically we use the second-order TVD Runge–Kutta method

$$\begin{cases} x_\xi^{n+1}\mathbf{u}_h^{(1)} = x_\xi^n \mathbf{u}_h^n + \Delta t\, L(\dot{x}^n, x_\xi^n, \mathbf{u}_h^n), \\ x_\xi^{n+1}\mathbf{u}_h^{n+1} = \dfrac{1}{2} x_\xi^n \mathbf{u}_h^n + \dfrac{1}{2} x_\xi^{n+1}\mathbf{u}_h^{(1)} + \dfrac{1}{2}\Delta t\, L(\dot{x}^{n+1}, x_\xi^{n+1}, \mathbf{u}_h^{(1)}). \end{cases} \tag{2.21}$$

For the temporal approximation of $x(\xi, t)$ we will assume that we have a set of grid points at time level t^n and at t^{n+1} which have been obtained using the MMPDE

described in section 3. The map will be assumed to be piecewise linear in time so that

$$x_{j+\frac{1}{2}}(t) = x^n_{j+\frac{1}{2}} + (t - t^n)\left(\frac{x^{n+1}_{j+\frac{1}{2}} - x^n_{j+\frac{1}{2}}}{t^{n+1} - t^n}\right), \quad t^n \le t \le t^{n+1}, \tag{2.22}$$

and hence

$$\dot{x}_{j+\frac{1}{2}}(t) = \frac{x^{n+1}_{j+\frac{1}{2}} - x^n_{j+\frac{1}{2}}}{t^{n+1} - t^n}, \quad j = 0, \ldots, N. \tag{2.23}$$

Therefore, $\dot{x}(\xi, t)$ will be piecewise linear in space and piecewise constant in time.

As the time integrator is explicit, the time step Δt has to be chosen to satisfy an appropriate CFL condition $\nu \le 1$, where the CFL number is

$$\nu = \Delta t \max_j \left\{ \frac{|(H_u)_{j+\frac{1}{2}} - \dot{x}_{j+\frac{1}{2}}|}{x_{j+1} - x_j} \right\}. \tag{2.24}$$

Note that the time step restriction on a moving mesh is different from that arising on a fixed nonuniform mesh due to the use of a modified wave speed. If the mesh velocity is close to the same speed as a solution discontinuity, then the shifted wave speed will be small where the mesh spacing is small, leading to global relaxation of the CFL condition. On the other hand, if the mesh is stationary and is highly graded towards large solution gradients, then stability requires the use of a globally small time step. The use of local time-stepping procedures can mitigate against this problem, but this certainly makes the overall algorithm more complicated (see, e.g., [26]).

2.2.2. Recovery of ϕ_h. If $(\phi_h)_x = u_h$, then ϕ_h will be determined on each interval I_j up to a constant. Following [11], the constant can be retrieved in two ways:

1. Require that

$$\int_{I_j} (\dot{\phi}_h + \tilde{H}(u_h, \dot{x}))\, \mathrm{d}\xi = 0, \quad j = 1, \ldots, N. \tag{2.25}$$

   The ODE (2.25) is again solved using the second-order TVD Runge–Kutta method (2.21).
2. Use (2.25) to update only the leftmost element I_1, and then since $(\phi_h)_x = u_h$ we have

$$\phi_h(x_j, t) = \phi_h(x_1, t) + \int_{x_1}^{x_j} u_h(x, t)\, \mathrm{d}x. \tag{2.26}$$

In section 4 we compare the performance of both recovery procedures.

2.3. HJ equations in two dimensions. In two dimensions we have

$$\phi_t + H(\phi_x, \phi_y) = 0, \quad (x, y) \in \Omega_p, \quad t > 0, \tag{2.27}$$

where $\Omega_p \subseteq \mathbb{R}^2$ is the physical domain. To generate an adaptive mesh we have seen earlier that it is useful to regard the physical domain Ω_p as the image of a computational domain Ω_c under the invertible maps

$$x = x(\xi, \eta, t), \quad y = y(\xi, \eta, t), \quad \text{and} \quad \xi = \xi(x, y, t), \quad \eta = \eta(x, y, t), \tag{2.28}$$

where $\boldsymbol{x} = (x, y)^T$ and $\boldsymbol{\xi} = (\xi, \eta)^T$ are the physical and computational coordinates, respectively. A mesh covering Ω_p is obtained by applying the mapping given by (2.28) to a partitioning of Ω_c.

Given that the mesh can move, it is necessary to express the Eulerian ($\boldsymbol{x}$-fixed) temporal derivative in (2.27) in terms of the Lagrangian derivative along the trajectory of the moving mesh. If a dot denotes differentiation with respect to time with (ξ, η) fixed, then (2.27) becomes

$$\dot{\phi} - \dot{x}\phi_x - \dot{y}\phi_y + H(\phi_x, \phi_y) = 0, \tag{2.29}$$

where $(\dot{x}, \dot{y})$ represents the mesh velocity. If we let $u = \phi_\xi$ and $v = \phi_\eta$, then by differentiating (2.29) with respect to ξ and η we arrive at the system

$$\dot{u} + \bar{H}_\xi(u, v, \dot{x}, \dot{y}) = 0, \tag{2.30}$$

$$\dot{v} + \bar{H}_\eta(u, v, \dot{x}, \dot{y}) = 0, \tag{2.31}$$

where

$$\bar{H}(u, v, \dot{x}, \dot{y}) = H(\xi_x u + \eta_x v, \xi_y u + \eta_y v) - \dot{x}(\xi_x u + \eta_x v) - \dot{y}(\xi_y u + \eta_y v). \tag{2.32}$$

Using the vectorial notation

$$\boldsymbol{u} = \begin{pmatrix} u \\ v \end{pmatrix}, \quad \boldsymbol{F}_1 = \begin{pmatrix} \bar{H} \\ 0 \end{pmatrix}, \quad \boldsymbol{F}_2 = \begin{pmatrix} 0 \\ \bar{H} \end{pmatrix},$$

we can rewrite (2.30) and (2.31) as the system of conservation laws

$$\dot{\boldsymbol{u}} + [\boldsymbol{F}_1(\boldsymbol{u})]_\xi + [\boldsymbol{F}_2(\boldsymbol{u})]_\eta = 0. \tag{2.33}$$

We apply a discontinuous Galerkin method to solve this coupled system (2.33) for $(u, v) = \nabla_{\boldsymbol{\xi}}\phi$, where the discretization takes place in the computational domain Ω_c. A recovery procedure will then be used to obtain an approximation of ϕ.

2.4. The DG discretization in two dimensions. Let $\mathcal{T}_h$ denote a partition of the computational domain Ω_c and K an arbitrary element in this partition. We consider the space of all polynomials of degree k restricted on the element K to be

$$V_h(K) = \{p \in P^k(K) : p \text{ is a polynomial of degree at most } k \text{ on } K\}. \tag{2.34}$$

To obtain a weak formulation we take the inner product of (2.33) with a test function $\boldsymbol{v}_h \in V_h$, integrate over $K \in \mathcal{T}_h$, and replace $\boldsymbol{u}$ by its approximation $\boldsymbol{u}_h \in V_h$. That is,

$$\frac{d}{dt}\int_K \boldsymbol{u}_h(\boldsymbol{\xi}, t) \cdot \boldsymbol{v}_h(\boldsymbol{\xi})\, d\boldsymbol{\xi} + \int_K \left[(\boldsymbol{F}_1)_\xi \cdot \boldsymbol{v}_h + (\boldsymbol{F}_2)_\eta \cdot \boldsymbol{v}_h\right]\, d\boldsymbol{\xi} = 0, \tag{2.35}$$

and using integration by parts we obtain

$$\begin{aligned} &\frac{d}{dt}\int_K \boldsymbol{u}_h(\boldsymbol{\xi}, t) \cdot \boldsymbol{v}_h(\boldsymbol{\xi})\, d\boldsymbol{\xi} \\ &+ \sum_{e \in \partial K} \int_e \left\{(n_{e,K})_1 \boldsymbol{F}_1 \cdot \boldsymbol{v}_h(\boldsymbol{\xi}^{\text{int(K)}}) + (n_{e,K})_2 \boldsymbol{F}_2 \cdot \boldsymbol{v}_h(\boldsymbol{\xi}^{\text{int(K)}})\right\} ds \\ &- \int_K \left[\boldsymbol{F}_1 \cdot (\boldsymbol{v}_h)_\xi + \boldsymbol{F}_2 \cdot (\boldsymbol{v}_h)_\eta\right]\, d\boldsymbol{\xi} = 0, \end{aligned} \tag{2.36}$$

where $n_{e,K} = [(n_{e,K})_1, (n_{e,K})_2]$ is the unit normal to the edge e of the element K, $\mathrm{int}(K)$ denotes the value taken from the interior of the element K, and $\mathrm{ext}(K)$ denotes the value taken from the exterior of the element K. Next we define the normal flux

$$\boldsymbol{F}_{e,K}(\boldsymbol{u}, \dot{x}, \dot{y}) = (n_{e,K})_1 \boldsymbol{F}_1 + (n_{e,K})_2 \boldsymbol{F}_2 = \begin{bmatrix} (n_{e,K})_1 \bar{H} \\ (n_{e,K})_2 \bar{H} \end{bmatrix}. \tag{2.37}$$

Note that $\boldsymbol{F}_{e,K}$ is not well defined on the element edge as $\boldsymbol{u}_h$ is discontinuous there. Therefore, we replace it by the numerical flux function

$$\widehat{\boldsymbol{F}}_{e,K}\left(\boldsymbol{u}_h(\boldsymbol{\xi}^{\mathrm{int(K)}}), \boldsymbol{u}_h(\boldsymbol{\xi}^{\mathrm{ext(K)}}), \dot{x}, \dot{y}\right). \tag{2.38}$$

Again we will use the Lax–Friedrichs flux

$$\widehat{\boldsymbol{F}}_{e,K}(\boldsymbol{a}, \boldsymbol{b}, \dot{x}, \dot{y}) = \frac{1}{2}\left[\boldsymbol{F}_{e,K}(\boldsymbol{a}) + \boldsymbol{F}_{e,K}(\boldsymbol{b}) + \alpha_{e,K}(\boldsymbol{a} - \boldsymbol{b})\right], \tag{2.39}$$

where

$$\alpha_{e,K} = \rho\left((n_{e,K})_1 \frac{\partial \boldsymbol{F}_1}{\partial \boldsymbol{u}} + (n_{e,K})_2 \frac{\partial \boldsymbol{F}_2}{\partial \boldsymbol{u}}\right) \tag{2.40}$$

and $\rho(\cdot)$ denotes the spectral radius of $(\cdot)$.

In this paper we will consider only the case that $\boldsymbol{u}_h \in (P^1)^2$. In particular we now discuss the basis used when $\boldsymbol{u}_h$ is a discontinuous bilinear function defined on a topologically rectangular mesh covering Ω_c. We will assume that $\Omega_c = [0,1]^2$ is covered by a uniform $N \times N$ element mesh. Following Hu and Shu [11], we assume that the approximate solution of the HJ equation ϕ_h is piecewise discontinuous and quadratic. Therefore, in the cell $K_{ij} = (\xi_{i-1/2}, \xi_{i+1/2}) \times (\eta_{j-1/2}, \eta_{j+1/2})$ we assume

$$\begin{aligned} \phi_h(t) = \overline{\phi}(t) &+ \phi_\xi(t)\mu_i + \phi_\eta(t)\nu_j + \phi_{\xi\eta}(t)\mu_i\nu_j \\ &+ \phi_{\xi\xi}(t)\left(\mu_i^2 - \frac{1}{3}\right) + \phi_{\eta\eta}(t)\left(\nu_j^2 - \frac{1}{3}\right), \end{aligned} \tag{2.41}$$

where

$$\mu_i(\xi) = \frac{2(\xi - \xi_i)}{\Delta\xi} \quad \text{and} \quad \nu_j(\eta) = \frac{2(\eta - \eta_j)}{\Delta\eta}.$$

The gradient in computational space $\nabla_{\boldsymbol{\xi}}\phi_h$ therefore takes the form

$$\nabla_{\boldsymbol{\xi}}\phi_h = \begin{bmatrix} \frac{2}{\Delta\xi}\phi_\xi(t) + \frac{2}{\Delta\xi}\phi_{\xi\eta}(t)\nu_j + \frac{4}{\Delta\xi}\phi_{\xi\xi}(t)\mu_i \\ \frac{2}{\Delta\eta}\phi_\eta(t) + \frac{2}{\Delta\eta}\phi_{\xi\eta}(t)\mu_i + \frac{4}{\Delta\eta}\phi_{\eta\eta}(t)\nu_j \end{bmatrix}, \tag{2.42}$$

and hence there are five unknowns that determine $\nabla_{\boldsymbol{\xi}}\phi_h$. A suitable basis for

$$V_2^1 = \{(v_1, v_2, v_3, v_4, v_5) : \boldsymbol{v}|_K = \nabla_{\boldsymbol{\xi}}\phi, \quad \phi \in P^2(K) \quad \forall K \in \mathcal{T}_h\}$$

is given by

$$\boldsymbol{b}_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \boldsymbol{b}_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad \boldsymbol{b}_3 = \begin{bmatrix} \mu_i \\ 0 \end{bmatrix}, \quad \boldsymbol{b}_4 = \begin{bmatrix} 0 \\ \nu_j \end{bmatrix}, \quad \boldsymbol{b}_5 = \begin{bmatrix} \frac{\nu_j}{\Delta\xi} \\ \frac{\mu_i}{\Delta\eta} \end{bmatrix}. \tag{2.43}$$

The local basis functions (2.43) can easily be shown to be orthogonal, and hence the mass matrix is diagonal.

The evaluation of the edge and element integrals in (2.36) is achieved using quadrature. For the edges,

$$\int_e \widehat{\boldsymbol{F}}_{e,K} \cdot \boldsymbol{v}_h(\boldsymbol{\xi}^{\mathrm{int}(K)}) \approx \sum_{l=1}^{q} \omega_l \widehat{\boldsymbol{F}}_{e,K} \left(\boldsymbol{u}_h(\boldsymbol{\xi}_l^{\mathrm{int(K)}}), \boldsymbol{u}_h(\boldsymbol{\xi}_l^{\mathrm{ext(K)}}), \dot{x}_l, \dot{y}_l \right) \cdot \boldsymbol{v}_h(\boldsymbol{\xi}_l^{\mathrm{int(K)}}) |e|,$$

where ω_l are the weights and $\boldsymbol{\xi}_l$ are the quadrature points along the edge. To estimate these integrals we use the two-point Gauss quadrature rule. Similarly, for the element integrals appearing in (2.36) we use the 2×2 Gauss product rule.

The mesh mapping $\boldsymbol{x}(\boldsymbol{\xi}, t)$ is assumed to vary bilinearly in space based on the position of the four grid nodes defining each element.

After carrying out the integrations and inverting the mass matrix, we finally arrive at the system of ODEs

$$\dot{\boldsymbol{u}} = L(\dot{\boldsymbol{x}}, \boldsymbol{u}), \quad \boldsymbol{u} = (u_1, u_2, u_3, u_4, u_5)^T, \tag{2.44}$$

which will be solved using the explicit two-stage explicit TVD Runge–Kutta scheme (2.21) to evolve $\boldsymbol{u}$, where $\dot{\boldsymbol{x}}$ is assumed to be piecewise constant in time.

The solution of (2.44) allows us to evolve $\nabla_{\boldsymbol{\xi}} \phi_h$. To calculate ϕ_h, we note from (2.41) that we require a procedure to calculate the cell average ϕ_{av}. Following Hu and Shu [11], we project the original HJ equation onto piecewise constants. That is, for any element K we set

$$\int_K (\dot{\phi}_h + \bar{H}(u_h, v_h, \dot{x}, \dot{y}))\, d\xi d\eta = 0. \tag{2.45}$$

We note from (2.41) that

$$\phi_{av}(t) = \frac{1}{|K|} \int_K \phi_h \, d\xi \, d\eta,$$

and hence

$$\dot{\phi}_{av} = -\frac{1}{|K|} \int_K \bar{H}(u_h, v_h, \dot{x}, \dot{y})\, d\xi d\eta. \tag{2.46}$$

We approximate the integral on the right-hand side of (2.46) using a 2×2 Gauss quadrature rule so that

$$\dot{\phi}_{av} = -\frac{1}{|K|} \sum_{l=1}^{4} \frac{\omega_l}{4} \bar{H}((u_h)_l, (v_h)_l, \dot{x}_l, \dot{y}_l)\, |K|. \tag{2.47}$$

The ODE (2.47) is again solved using the second-order TVD Runge–Kutta method (2.21). One possibility is to solve (2.47) for each element of the mesh. However, numerical experience reported in [11] indicates that this approach does not work well when there are singularities in the derivatives and the integral path in time passes

through the singularities at earlier times. Alternatively, one can solve (2.47) for only one element, where there are no derivative singularities, and use the formula

$$\phi(B,t) = \phi(A,t) + \int_A^B (\phi_x\, dx + \phi_y\, dy) \tag{2.48}$$

to update all of the remaining elements.

3. Moving mesh equations.

3.1. MMPDEs in one and two dimensions. Let us consider $\boldsymbol{x} = (x_1, x_2)^T$ to be a point in the physical domain Ω_p and $\boldsymbol{\xi} = (\xi_1, \xi_2)^T$ to be a point in the computational domain Ω_c. The mapping from the computational domain to the physical domain is assumed to minimize the energy functional

$$I[\xi_1, \xi_2] = \frac{1}{2} \int_{\Omega_p} \left((\nabla \xi_1)^T G^{-1} \nabla \xi_1 + (\nabla \xi_2)^T G^{-1} \nabla \xi_2 \right) dx\, dy, \tag{3.1}$$

where G is a symmetric positive-definite monitor matrix which involves various properties of the mesh and physical solution, and ∇ is the gradient operator with respect to $\boldsymbol{x} = (x_1, x_2)^T$.

A two-dimensional MMPDE is given by the gradient flow equations

$$\frac{\partial \boldsymbol{\xi}}{\partial t} = -\frac{P}{\tau} \frac{\delta I}{\delta \boldsymbol{\xi}} = \frac{P}{\tau} \nabla \cdot \left(G^{-1} \nabla \boldsymbol{\xi} \right), \tag{3.2}$$

where $\tau > 0$ is a temporal smoothing parameter and P is an operator with positive spectrum used to regularize the evolution of the mesh. The parameter τ determines how quickly the mesh adapts in time in an attempt to minimize (3.1). The value of τ should be chosen to be small in relation to the time scale of the physical PDE to ensure that the mesh adapts quickly enough to follow important solution features. On the other hand, it is important to make sure that τ is not too small; otherwise the mesh can evolve in an erratic manner, and this can have an adverse effect on accuracy. Further discussion on the choice of τ can be found in [13].

In practice we work directly with the map $\boldsymbol{x} = \boldsymbol{x}(\boldsymbol{\xi}, t)$ because it defines explicitly the location of the physical mesh points. Following [13] and [12], we switch the roles of the dependent and independent variables in (3.2) to obtain

$$\tau \frac{\partial \boldsymbol{x}}{\partial t} = P \left(\sum_{i,j=1}^{2} (\boldsymbol{a}^i \cdot G^{-1} \boldsymbol{a}^j) \frac{\partial^2 \boldsymbol{x}}{\partial \xi_i \partial \xi_j} - \sum_{i,j=1}^{2} \left(\boldsymbol{a}^i \cdot \frac{\partial G^{-1}}{\partial \xi_j} \boldsymbol{a}^j \right) \frac{\partial \boldsymbol{x}}{\partial \xi_i} \right), \tag{3.3}$$

where $\boldsymbol{a}^i = \nabla \xi_i$. In [12], Huang proposed choosing P in order to limit the variation over the domain of the coefficients in (3.3). To do this we choose

$$P = \left(\sum_{i=1}^{2} a_{i,i}^2 + b_i^2 \right)^{-\frac{1}{2}}, \tag{3.4}$$

where

$$a_{i,j} = \boldsymbol{a}^i \cdot G^{-1} \boldsymbol{a}^j, \quad b_i = -\sum_{i,j=1}^{2} \left(\boldsymbol{a}^i \cdot \frac{\partial G^{-1}}{\partial \xi_j} \boldsymbol{a}^j \right). \tag{3.5}$$

Dirichlet boundary conditions for the above system are obtained by solving a one-dimensional MMPDE. If $\partial_p \in \partial\Omega_p$ and $\partial_c \in \partial\Omega_c$ denote the physical and computational boundary segments with arc-lengths l and l_c, respectively, then the mesh on ∂_p is the solution of

$$\tau \frac{\partial s}{\partial t} = \frac{1}{\sqrt{(M^2 + (M_\zeta)^2}} \frac{\partial}{\partial \zeta}\left(M \frac{\partial s}{\partial \zeta}\right), \qquad \zeta \in (0, l_c), \tag{3.6}$$

with $s(0) = 0$ and $s(l_c) = l$. Here M is the one-dimensional projection of the two-dimensional monitor function along the boundary. That is, if $\boldsymbol{t}$ is a unit tangent vector along the boundary, then $M(s,t) = \boldsymbol{t}^T G \boldsymbol{t}$.

3.2. Discretization and boundary conditions. The temporal discretization of (3.3) is achieved using a semi-implicit method where

$$(\boldsymbol{x}^{n+1} - \boldsymbol{x}^n) = \frac{\Delta t P^n}{\tau}(a_{11}^n \boldsymbol{x}_{\xi\xi}^{n+1} + 2a_{12}^n \boldsymbol{x}_{\xi\eta}^{n+1} + a_{22}^n \boldsymbol{x}_{\eta\eta}^{n+1} + b_1^n \boldsymbol{x}_{\xi}^{n+1} + b_2^n \boldsymbol{x}_{\eta}^{n+1}). \tag{3.7}$$

Freezing the coefficients a_{ij}, b_i, and P has two very important effects. The first is that it linearizes the equations that define the mesh $\boldsymbol{x}^{n+1}$. Moreover, the system of PDEs represented by (3.7) for $x^{n+1}(\xi,\eta)$ and $y^{n+1}(\xi,\eta)$ decouples into two scalar equations which have the same spatial derivatives. For simplicity, the spatial discretization of (3.7) is performed using second-order central finite differences on an $N \times N$ uniform partition of $\Omega_c = (0,1) \times (0,1)$. Since the spatial derivatives are identical, the same coefficient matrix needs to be inverted to find the x and y coordinates. We therefore solve first (3.7) for the x coordinates using an ILU-preconditioned BiCGStab method until the mean-squared-root residual is less than 10^{-8}. The same preconditioner is then used to solve (3.7) for the y coordinates. In general, we have found that convergence of the iterative solver is achieved in around 3–4 iterations per time step. Additional details about the spatial discretization of the MMPDEs and the performance of the ILU-preconditioned BiCGStab routine can be found in [3].

3.3. Choice of monitor function. The choice of a suitable adaptivity criterion for problems which develop shocks is highly nontrivial. It is important that the mesh points move smoothly towards regions where discontinuities exist so that the $O(1)$ error at the shock is localized within one or two mesh elements. For robustness, it is also important that the rate of convergence of the method is not severely impaired by the nonuniformity of the moving mesh.

A popular choice of monitor function is the scaled solution arc-length

$$M = \sqrt{1 + \frac{1}{\alpha}|u_x|^2}, \tag{3.8}$$

where $\alpha > 0$ is a user-chosen parameter. The role of this parameter when $\alpha > 1$ is to reduce the local value of the monitor function when $|u_x|$ is large. This then leaves the issue of the proper choice of α. The simplest approach is to set $\alpha =$ constant. However, this procedure is unsatisfactory as the ideal value of α will be problem dependent and any a priori choice of α will never prevent $M \to \infty$ as $|u_x| \to \infty$.

A more sophisticated approach is to make α solution dependent. For example, in [9], $\alpha \approx \max |u|^2$. However, for problems where u becomes discontinuous, this choice of α will be ineffective in again stopping M from becoming unbounded. Another popular choice is

$$M(x,t) = \left(1 + \frac{|u_x|^2}{\alpha}\right)^{1/2}, \qquad \alpha = \frac{1}{\beta(b-a)} \int_a^b |u_x|^2 dx. \tag{3.9}$$

If $\beta = 1$, then (3.9) is exactly a regularization of the monitor function used in [24]. For this monitor function the local derivative term is scaled by its average value over the domain. It is not obvious that this monitor function is bounded above in the presence of a solution discontinuity. Let us assume an idealized situation where

$$|u_x| \simeq \mathcal{O}\left(\frac{1}{\Delta x_{\min}}\right) \tag{3.10}$$

in the cell where $|u_x|$ is large and is constant $|u_x| \simeq C$ everywhere else. If the mesh is obtained from an equidistribution principle, then

$$\int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} M(x,t)\,dx = \frac{1}{N}\int_a^b M(x,t)\,dx, \quad j = 1,\dots,N. \tag{3.11}$$

If we expand the integral in (3.9), we get

$$\alpha = \frac{1}{\beta(b-a)}\left(\int_a^{x^*-\frac{1}{2}\Delta x_{\min}} C^2\,dx + \int_{x^*-\frac{1}{2}\Delta x_{\min}}^{x^*+\frac{1}{2}\Delta x_{\min}} \frac{1}{\Delta x_{\min}^2}\,dx + \int_{x^*+\frac{1}{2}\Delta x_{\min}}^{b} C^2\,dx\right), \tag{3.12}$$

and hence

$$\alpha \simeq \frac{1}{\beta}\left((1-\Delta x_{\min})\,C^2 + \frac{1}{\Delta x_{\min}(b-a)}\right) \approx (\Delta x_{\min})^{-1}. \tag{3.13}$$

It is clear from (3.13) that $\alpha \to \infty$ as $\Delta x_{\min} \to 0$. If we examine the behavior of M, we observe that the monitor function is approximately 1 away from the shock as $|u_x|$ is bounded and α tends to infinity. Close to the shock,

$$M \simeq \mathcal{O}\left(1 + \frac{\frac{1}{\Delta x_{\min}^2}}{\frac{1}{\Delta x_{\min}}}\right)^{\frac{1}{2}} \simeq \mathcal{O}\left(\sqrt{\frac{1}{\Delta x_{\min}}}\right),$$

which is not bounded as $\Delta x_{\min}$ tends to zero. The problem with this monitor function is that the maximum value of $|u_x|^2$ and its average value do not scale in the same way as N increases.

To obtain a bounded monitor function we consider

$$M(x,t) = \left(1 + \frac{|u_x|^2}{\alpha}\right)^{\frac{1}{2}}, \qquad \alpha = \frac{1}{\beta^2}\max_x |u_x|^2, \tag{3.14}$$

and β is a user-chosen parameter. It is clear that this monitor function satisfies the bounds

$$1 \le M(x,t) \le \sqrt{1+\beta^2}.$$

If we have a location x^* where $|u_x|$ becomes large (such as at a shock) and the solution elsewhere is smooth, then the monitor function will have a localized peak at x^*. It is clear that the transition from the smooth to the nonsmooth region of the domain will be almost discontinuous. This leads to an extremely rapid change in the mesh size which might be far from ideal in practice and can lead to a loss in accuracy. Again if

the mesh is found by equidistribution of the monitor function, then if $M \simeq 1$ except in the cell containing x^*, we have

$$\sqrt{1+\beta^2}\Delta x_{\min} \simeq \frac{1}{N}\left((b-a) + \sqrt{1+\beta^2}\,\Delta x_{\min}\right). \tag{3.15}$$

Therefore, the minimum mesh spacing is

$$\Delta x_{\min} \simeq \frac{(b-a)}{(N-1)\sqrt{1+\beta^2}}, \tag{3.16}$$

which is approximately a factor of $\sqrt{1+\beta^2}$ smaller than the spacing that occurs when using a uniform mesh. This is the monitor function that we will use in the following one-dimensional examples.

For two-dimensional problems the monitor function used is of Winslow type, where

$$G = \begin{bmatrix} w & 0 \\ 0 & w \end{bmatrix}$$

and

$$w = \sqrt{1 + \frac{|\nabla u|^2}{\alpha}}, \quad \text{where} \quad \alpha = \frac{1}{\beta^2}\max_{\Omega_p} |\nabla u|^2.$$

This monitor function behaves in a similar fashion to the one-dimensional monitor in the presence of solution discontinuities since the maximum of the solution gradient is used rather than its average.

3.3.1. Smoothing of the monitor function. If the underlying problem involves large solution variations, then the monitor function will be nonsmooth in space, and this will affect the smoothness of the coordinate transformation. In practice, the monitor function is smoothed before it is used in the numerical approximation of the MMPDE.

A smooth transformation can be achieved using a boundary value problem (see [13]) which involves an artificial diffusion term for smoothing the monitor function. The smoothed monitor function $\widetilde{M}$ satisfies the boundary value problem

$$\widetilde{M} - \frac{1}{\lambda^2}\widetilde{M}_{\xi\xi} = M, \tag{3.17}$$

with the boundary conditions

$$\widetilde{M}_\xi(0,t) = \widetilde{M}_\xi(1,t) = 0, \tag{3.18}$$

where λ is a positive parameter. Equation (3.17) is discretized using central differences as

$$\widetilde{M}^n_{j+\frac{1}{2}} - \frac{1}{\lambda^2 h^2}\left(\widetilde{M}_{j+\frac{3}{2}} - 2\widetilde{M}_{j+\frac{1}{2}} + \widetilde{M}_{j-\frac{1}{2}}\right) = M_{j+\frac{1}{2}}, \quad j = 1,\ldots,N-1, \tag{3.19}$$

where $h = 1/N$. The boundary conditions are discretized as

$$\widetilde{M}_{-\frac{1}{2}} = \widetilde{M}_{\frac{1}{2}}, \quad \widetilde{M}_{N+\frac{1}{2}} = \widetilde{M}_{N-\frac{1}{2}}. \tag{3.20}$$

It can be shown that the smoothed monitor function so obtained is bounded and equidistribution leads to a locally quasi-uniform mesh [13]. In particular it can be shown that

$$\nu < \frac{x_{j+\frac{3}{2}}(t) - x_{j+\frac{1}{2}}(t)}{x_{j+\frac{1}{2}}(t) - x_{j-\frac{1}{2}}(t)} < \nu^{-1}, \qquad j = 1, \ldots, N-1,$$

where

$$\nu = \frac{\sqrt{1+4\gamma}-1}{\sqrt{1+4\gamma}+1} \quad \text{and} \quad \gamma = \frac{1}{\lambda h^2}.$$

We can therefore see that the mesh becomes less smooth as we increase the parameter λ. A similar procedure is used to smooth the monitor function in two dimensions.

3.3.2. Complete algorithm. If we assume that at time $t = t^n$ we have an approximation of the physical solution u_h^n and a mesh $\boldsymbol{x}^n$, then we integrate forward in time using the algorithm below.

1. Compute the monitor matrix $G^n(\boldsymbol{x}) = G(\boldsymbol{x}^n, t^n)$ using u_h^n and $\boldsymbol{x}^n$.
2. Integrate the discretized MMPDE to get the mesh $\boldsymbol{x}^{n+1}$.
3. Integrate the physical PDEs to obtain u_h^{n+1} using the meshes $\boldsymbol{x}^n$ and $\boldsymbol{x}^{n+1}$ to form $\dot{\boldsymbol{x}}$.
4. Goto the next time step.

In theory this algorithm could be modified to return to step 1 after u_h^{n+1} has been obtained in step 3 and the coefficients a_{ij}, b_i in (3.5) have been evaluated at t^{n+1} and $\boldsymbol{x}^{n+1}$. A new estimate of the mesh $\boldsymbol{x}^{n+1}$ could then be found by resolving the MMPDEs. This process could be repeated a fixed number of times or until some measure of grid convergence is reached. A similar approach was investigated in [2] and [3], where it was found that larger time steps could be used without affecting accuracy and that the gain in efficiency outweighed the additional cost of performing the additional steps. In the numerical experiments in the next section we have, however, considered only the use of one pass of the algorithm above.

4. Numerical examples.

4.1. One-dimensional problems.

4.1.1. Example 1. The first example considered is the Burgers equation

$$\begin{cases} \phi_t + \dfrac{(\phi_x + 1)^2}{2} = 0, & -1 < x < 1,\ t > 0, \\ \phi(x, 0) = -\cos(\pi(x - 0.85)) \end{cases} \tag{4.1}$$

with periodic boundary conditions. This problem has also been considered in [28] and [15]. As the solution evolves from the smooth initial condition, a discontinuity in the derivative appears and propagates across the domain.

We first test the rate of convergence of the moving mesh DG method when the solution is still smooth. In all of the following results we set CFL = 0.1, $\beta = 10$, $\lambda = 25$, and $\tau = 0.001$. Table 1 shows that the DG solution maintains its second-order accuracy. Note that slope limiting was not needed for this example.

Figure 1 shows the computed DG solutions on a fixed and moving mesh at $t = 0.99/\pi^2$, which is just before the solution becomes discontinuous. We can see that the moving mesh results are a considerable improvement over the fixed mesh results

TABLE 1
Convergence of moving mesh DG solution at $t = 0.5/\pi^2$.

N	$\|\|e_u\|\|_{L_\infty}$	Rate	$\|\|e_\phi\|\|_{L_\infty}$	Rate	$\|\|e_u\|\|_{L_1}$	Rate	$\|\|e_\phi\|\|_{L_1}$	Rate

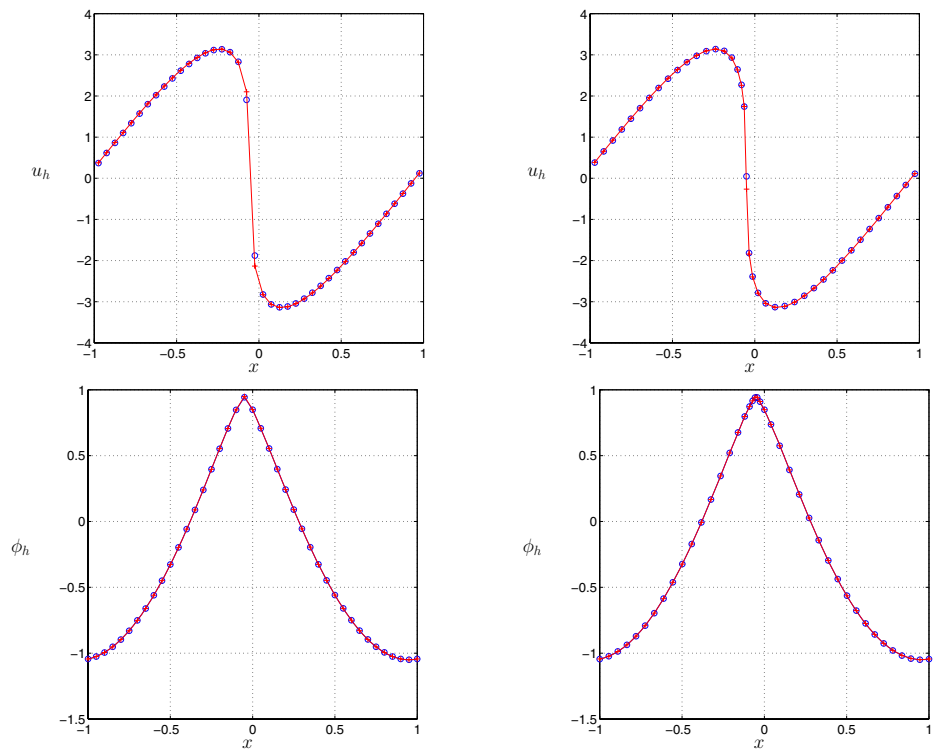

FIG. 1. *DG numerical solution (∘) and exact solution (+) obtained on a uniform stationary mesh (left) and on a moving mesh (right) at time* $t = 0.99/\pi^2$.

as the shock in u and the corner in ϕ are much better resolved. Figure 2 shows the solutions at $t = 3/\pi^2$, where we can see that the shock in u is resolved over one or two cell widths that are much smaller around the shock than those used with the uniform mesh.

The computed mesh trajectories shown in Figure 3 are quite smooth, which is the result of the smoothing of the monitor function. We observe that once the discontinuity forms, the mesh points cluster around it to resolve it more accurately. Numerical experience shows that as long as the numerical solution is smooth, both recovery procedures (2.25) and (2.26) give similar results. In Figure 3 we also compare the two recovery procedures at $t = 1.5/\pi^2$ when the solution is nonsmooth. We can see that the recovery procedure (2.25) does not perform well, whereas (2.26) appears to perform much better and hence is the procedure we use for all further examples.

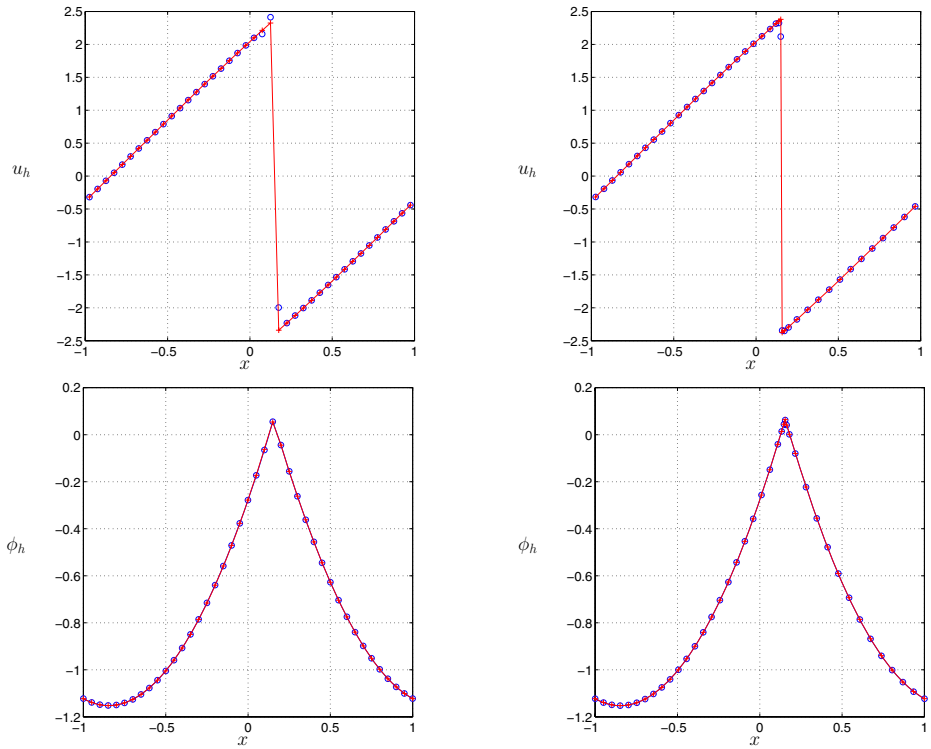

FIG. 2. *DG solution (∘) and exact solution (+) obtained on a uniform stationary mesh (left) and on a moving mesh (right) at time* $t = 3/\pi^2$.

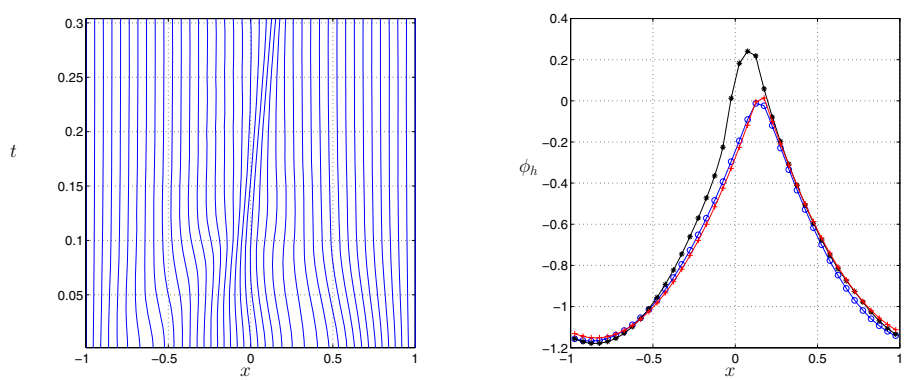

FIG. 3. *Mesh trajectories and comparison between recovery procedures at* $t = 1.5/\pi^2$, (2.25) *(*),* (2.26) *(∘), and exact solution (+), with* $N = 40$.

In Figure 4 we plot the evolution of the time step using a uniform stationary mesh and the adaptive moving mesh. We can see that the time step used with the adaptive mesh is not considerably smaller than that used with the uniform mesh even though the mesh cells close to the shock region are much smaller than those occurring with the uniform mesh.

4.1.2. Example 2. The second example considered is the following Riemann problem with a nonconvex flux:

$$\begin{cases} \phi_t + \frac{1}{4}(\phi_x^2 - 1)(\phi_x^2 - 4) = 0, \quad -1 < x < 1,\ t > 0, \\ \phi(x,0) = -2|x|. \end{cases} \tag{4.2}$$

This problem has been considered in [11] and [28]. This test problem has an initial discontinuity in the derivative of the solution u, and in time this develops into two discontinuities moving in opposite directions. In [11] the authors point out that the DG method fails to "open up" the initial single discontinuity in the derivative to generate the correct entropy solution. Therefore, for this example we used the slope limiting procedure as outlined earlier.

A comparison of the DG solutions using a uniform fixed mesh and a moving mesh is shown in Figure 5. Again there is considerable improvement in the resolution of u_h and ϕ_h using the moving mesh. In Figure 6 we show the computed mesh trajectories and we can see that the monitor function is able to both track discontinuities and concentrate points in regions where more accuracy is needed.

4.1.3. Example 3. The third example considered is

$$\begin{cases} \phi_t - \left(1 + \phi_x^2\right)^{1/2} = 0, \quad -1 < x < 1,\ t > 0, \\ \phi(x,0) = \dfrac{1}{2}\cos(6\pi x), \end{cases} \tag{4.3}$$

with periodic boundary conditions. This is an example of front propagation in one dimension and has also been considered in [22]. As the numerical solution evolves in time, the solution develops corners since the graph of the initial solution moves in its normal direction with unit speed. For this example we found it necessary to use the slope limiting procedure.

In Figure 7 we show a comparison between ϕ_h obtained with DG using a stationary mesh and a moving mesh. The differences between the numerical solutions can be seen more clearly in Figure 8. It can be observed that the adaptive mesh does a much better job of resolving the corner which has developed in the numerical solution ϕ_h. Furthermore, the smooth part of the solution also appears to be much better resolved using the moving mesh. In Figure 9 we plot mesh trajectories of the DG moving mesh solution with $N = 81$ mesh points. We can see that the monitor function drives mesh points towards the discontinuities in the first derivative of the solution. In Figure 9 we also plot the evolution of the numerical solution ϕ_h at time intervals of $\Delta t = 0.01$, up to the final time $t = 0.1$. We can see clearly the initial function evolving with unit speed in its normal direction and that the moving mesh DG method resolves well the evolution of the corner singularities.

4.2. Two-dimensional problems.

4.2.1. Example 4. We consider the two-dimensional Burgers equation

$$\phi_t + \frac{1}{2}(1 + \phi_x + \phi_y)^2 = 0, \quad (x,y) \in (-2,2)^2, \tag{4.4}$$

$$\phi(x,y,0) = -\cos(\pi(x+y)/2), \tag{4.5}$$

with periodic boundary conditions. This problem was proposed in [23] and has also been used as a test case in [28], [11], and [16]. From the smooth initial condition the solution develops a discontinuity in $\nabla\phi$ which propagates across the domain from the bottom left to the top right. Figure 10 shows the results calculated at $t = 1.5/\pi^2$ when $\nabla\phi$ has become discontinuous. Note that flux limiting was not necessary for this example, highlighting the additional stability properties of the DG formulation. We can see that while there seem to be some slight oscillations in the moving mesh calculations of ϕ_x, these seem to be damped out by the recovery procedure used to calculate ϕ_h. The computed adaptive meshes at $t = 0.5/\pi^2$ and $t = 1.5/\pi^2$ are shown in Figure 11, where we can see that the meshes have indeed clustered towards the areas where the gradient is largest. Finally, Figure 12 shows a comparison of the moving and fixed mesh results compared with a fine grid reference solution. We can see that the adaptive mesh results are a considerable improvement on the fixed grid results both in the corner region of the solution and in regions where the solution is smooth.

4.2.2. Example 5. We next consider a problem with a nonconvex flux

$$\phi_t - \cos(1 + \phi_x + \phi_y) = 0, \quad (x, y) \in (-2, 2)^2, \tag{4.6}$$

$$\phi(x, y, 0) = -\cos(\pi(x + y)/2), \tag{4.7}$$

with periodic boundary conditions. The numerical results for this case are shown in Figures 13 and 14. We again can see that the adaptive moving mesh algorithm does a good job of clustering elements towards the discontinuities in the solution gradient. The numerical results are comparable to the adaptive calculations presented in [28].

4.2.3. Example 6. Our final example is a prototype model in geometric optics [16], [22]. The governing equation is

$$\phi_t + \sqrt{1 + \phi_x^2 + \phi_y^2} = 0, \quad (x, y) \in (0, 1)^2, \tag{4.8}$$

$$\phi(x, y, 0) = 0.25(\cos(2\pi x) - 1)(\cos(2\pi y) - 1) - 1, \tag{4.9}$$

with periodic boundary conditions. The viscosity solution for this problem is a surface with its maximum focusing into a peak which opens up. The surface moves downward

with a unit speed, asymptotically approaching a flat sheet. Figure 15 shows the computed approximations of ϕ using a uniform and adaptive mesh with $N = 40$. We can see that the adaptive moving mesh does a better job of resolving the focusing of the solution. The mesh at the final time is shown in Figure 16, where we can see that the mesh has been concentrated towards the focusing of the solution at the center of the domain.

5. Conclusions. We have presented a DG method for the solution of nonlinear HJ equations using an adaptive moving mesh refinement strategy. A suitable mesh refinement criterion was used which does not become singular when the solution become nonsmooth. Numerical experiments in one and two dimensions show that this method works well and efficiently delivers high-resolution solutions using relatively coarse meshes.

Although we have focused here on HJ equations, the moving mesh DG method can also be applied to other hyperbolic problems such as the compressible Euler equations, and work is progressing in this direction. Finally, solution adaptivity was achieved in this paper using mesh movement. Future work will include a study of the combination of mesh movement along with additional refinement strategies such as

h and p refinement. The DG framework should hopefully make this combination of strategies easier to implement.

SIMULTANEOUS HIGHER-ORDER OPTICAL FLOW ESTIMATION AND DECOMPOSITION*

JING YUAN†, CHRISTOPH SCHÖRR†, AND GABRIELE STEIDL‡

Abstract. We study the estimation and decomposition of optical flows from highly nonrigid motions. To this end, recent methods from image decomposition into structural and textural parts are combined with variational optical flow estimation. The approaches we suggest amount to minimizing discrete convex functionals using second-order cone programming. Higher-order regularization is necessary in order to accurately recover important flow structure like vortices, and to incorporate key physical properties such as vanishing divergence. For proper discretization, we apply the finite mimetic difference method, which preserves the identities fulfilled by the continuous differential operators. Numerical examples demonstrate the feasibility of the complex approaches.

Key words. optical flow estimation, optical flow decomposition, divergence-free flows, higher-order regularization, mimetic finite difference method, convex optimization, dual optimization techniques, second-order cone programming

1. Introduction.

The representation, estimation, and analysis of nonrigid motion is relevant to many scenarios in computer vision, medical imaging, remote sensing, and experimental fluid dynamics. Especially in fluid dynamics, sophisticated measurement techniques including pulsed laser light sheets and modern CCD cameras, as well as dedicated hardware, enable the recording of high-resolution image sequences that reveal the evolution of spatio-temporal structures of unsteady flows [25]. In this connection, an important research problem is to develop variational approaches that render flow estimation from image sequences into a well-posed and numerically stable problem while preserving small-scale flow structures that are important for empirical investigations of turbulent phenomena.

To this end, we investigate a novel class of variational flow estimation schemes by combining higher-order flow regularization with recent techniques developed for nonsmooth image decomposition–see below for a more detailed exposition. As a result, we obtain variational approaches that not only allow for estimating fluid flow from image sequences but simultaneously yield a decomposition of the flow into coherent spatio-temporal flow patterns and small-scale structures.

In the following, we briefly describe the respective basic ideas in a continuous setting. In the remainder of the paper, we will derive and investigate discrete approaches using the so-called mimetic finite difference method developed by Hyman and Shashkov [17], which preserves the integral identities fulfilled by the corresponding continuous integral operators.

Image decomposition. In image denoising one is typically interested in removing noise without destroying important structures such as edges. This goal cannot be

achieved with linear filters, e.g., by minimizing

$$J(f) := \|g - f\|^2_{L_2(\Omega)} + \lambda \int_\Omega |\nabla f|^2 \,\mathrm{d}x\mathrm{d}y \tag{1.1}$$

for a given noisy image $g(x, y)$ in $\Omega \subset \mathbb{R}^2$. The regularizer incorporates the quadratic function $\Phi(s) = s^2$ with $s = |\nabla f|$. Via the Euler–Lagrange equation this variational approach can be related to a linear diffusion equation. As a consequence, the solution f smooths g in a completely homogeneous way and therefore blurs semantically important signal structures. To overcome this drawback a variety of nonlinear methods have been proposed. One of the frequently applied approaches replaces the function in the regularization term by $\Phi(s) = s$ and thus penalizes larger deviations of $|\nabla f|$ not as hard as the quadratic function:

$$J(f) := \frac{1}{2} \|g - f\|^2_{L_2(\Omega)} + \lambda \int_\Omega |\nabla f| \,\mathrm{d}x\mathrm{d}y. \tag{1.2}$$

This functional was first considered by Rudin, Osher, and Fatemi [26]. For f having partial derivatives in L_1 the regularizer coincides with the TV seminorm of f,

$$\|f\|_{\mathrm{TV}} := \int |\nabla f| \,\mathrm{d}x\mathrm{d}y.$$

In contrast to the *linear approach* (1.1) we will refer to this method as the *TV approach*. Based on the dual TV norm, the so-called G norm, this denoising model was enlarged for the decomposition of given images g into a structural (cartoon) part f^s and a textural part f^t as

$$\begin{aligned} J(f^s, f^t) &= \|g - (f^s + f^t)\|^2_{L_2(\Omega)} + \lambda \int_\Omega |\nabla f^s| \,\mathrm{d}x\mathrm{d}y, \\ &\text{s.t.} \quad \|f^t\|_{\mathrm{G}} \le \delta. \end{aligned} \tag{1.3}$$

For a more sophisticated treatment of the TV and G norms, we refer to [11, 21]. Meanwhile there exist various numerical realizations of (1.3), e.g., [3, 24, 32, 34]. Although not considered in this paper, we note that there exist other models including other than Gaussian white noise by using the L_1 norm in the data fitting term [5, 23], noise as a third decomposition component by applying Besov norms [4], or frame and TV/frame approaches [10, 28] from harmonic analysis. Moreover, second-order derivatives were incorporated into the regularizer to avoid, for example, staircasing effects; see, e.g., [8, 29].

In this paper, we are interested in the decomposition of vector fields rather than scalar images. Specifically, we want to deal with optical flow fields arising, e.g., in experimental fluid dynamics.

Optical flow estimation. Instead of a single image let us consider an image sequence $\{g(x, y, t) : t \in [0, T]\}$ with a time parameter t. A common assumption is that image intensities are preserved over time:

$$g\big(x(t_1), y(t_1), t_1\big) = g\big(x(t_2), y(t_2), t_2\big), \quad t_2 > t_1. \tag{1.4}$$

Generalizations to other constraints exist but are not relevant for our present investigation. The linearized version of the gray value constancy assumption (1.4) yields the *optical flow constraint*

$$g_x u_1 + g_y u_2 + g_t = \nabla g \cdot u + g_t = 0, \tag{1.5}$$

where the optical flow field $u = (u_1, u_2)^\top := (\dot{x}, \dot{y})^\top$ denotes the instantaneous velocities of image elements.

Obviously, (1.5) cannot be solved pointwise because at each location and time point it consists of solving a single scalar equation for two scalar unknowns. To overcome this so-called *aperture problem* additional requirements have to be imposed. Instead of (1.5) we consider the least squares approximation

$$F(u) := \|\nabla g \cdot u + g_t\|^2_{L_2(\Omega)}. \tag{1.6}$$

In 1981, Horn and Schunck [16] pioneered the field of regularization methods for optical flow computation by suggesting minimization of the functional

$$J(u) = F(u) + \lambda \int_\Omega |\nabla u_1|^2 + |\nabla u_2|^2 \,\mathrm{d}x\mathrm{d}y. \tag{1.7}$$

We will refer to this widely used approach as the *Horn–Schunck model*. Obviously, the Horn–Schunck model suffers from the same drawbacks as the linear image filtering model (1.1). The solution creates blurry optic flow fields where the blur appears also across important flow discontinuities. One way to overcome this limitation consists again if using another function in the regularizer, e.g.,

$$J(u) = \frac{1}{2} F(u) + \lambda \int_\Omega (|\nabla u_1|^2 + |\nabla u_2|^2)^{\frac{1}{2}} \,\mathrm{d}x\mathrm{d}y, \tag{1.8}$$

as counterpart to the TV model (1.2); cf. [2, 13, 15].

In this paper we focus on nonrigid motion analysis. In particular, we are interested in the representation of motion by components that capture different physical aspects, e.g., solenoidal (divergence-free) flows. Referring again to experimental fluid dynamics, for example, the extraction of coherent flow structures which are immersed into additional motion components at different spatial scales [19] poses a challenge for image sequence analysis. However, this goal cannot be achieved using first-order derivatives in the regularizer. Rather, based on early work on second-order regularizers constraining the gradients of the flows' divergence and curl [1, 9, 14, 30], instead of (1.7) we deal with the functional

$$J(u) = F(u) + \lambda_d \int_\Omega |\nabla \mathrm{div}\, u|^2 \,\mathrm{d}x\mathrm{d}y + \lambda_c \int_\Omega |\nabla \mathrm{curl}\, u|^2 \,\mathrm{d}x\mathrm{d}y + \gamma \int_{\partial\Omega} (\partial_{\mathrm{n}} u)^2 \,\mathrm{d}s, \tag{1.9}$$

where the boundary is incorporated for stability reasons; cf. [35, 37]. A key property of this approach is that due to the second order of the flow derivatives involved, the regularizing terms do *not* penalize the magnitude of the basic flow components involving first-order derivatives, i.e., divergence and curl. To further motivate this approach consider Figure 1.1, which shows the estimation of a solenoidal flow field by first- and second-order approaches. The figure clearly demonstrates the superiority of the div-curl model.

Finally, related to the TV model (1.8), we deal with

$$J(u) = \frac{1}{2} F(u) + \lambda_d \int_\Omega |\nabla \mathrm{div}\, u| \,\mathrm{d}x\mathrm{d}y + \lambda_c \int_\Omega |\nabla \mathrm{curl}\, u| \,\mathrm{d}x\mathrm{d}y + \frac{\gamma}{2} \int_{\partial\Omega} (\partial_{\mathrm{n}} u)^2 \,\mathrm{d}s, \tag{1.10}$$

involving regularizing terms that are of second order, as in (9), and that are additionally suited to preserve jumps of the divergence and the curl of a flow field,

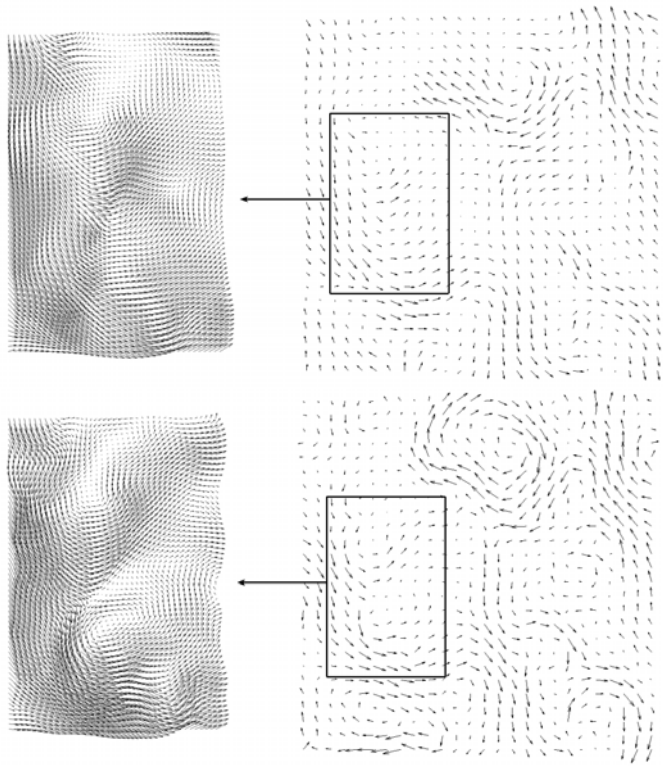

FIG. 1.1. *Estimation of a typical solenoidal flow field u. Top: Restored flow based on the Horn–Schunck model* (1.7). *Bottom: Restored flow based on the second-order model* (1.9). *Vortex structures are better recovered by the div-curl approach (bottom); cf.* [35].

respectively, by utilizing the TV-norm. As in image decomposition we will extend this estimation approach to the decomposition of motion vector fields into physically relevant components at different scales by using a discrete equivalent of the G norm. Moreover, we will study the feasibility of an extension to the *simultaneous* estimation and decomposition of optical flows.

Organization of the paper. We start by introducing our discrete setting based on the mimetic finite difference method in section 2. We define scalar and vector fields on primal and dual grids together with appropriate norms. Then we introduce the first-order operators, where we focus on their matrix representation using tensor product notation. We show how integral identities such as the Gaussian integral identity and the Helmholtz decomposition carry over to the discrete situation. Finally, we define discrete TV and G norms with respect to the primal and dual grid. Based on these definitions and results we consider the flow estimation task in section 3. Here we are interested in the linear versus the TV approach. While the linear method was already treated in [35], the higher-order TV approach is novel. In section 4, we deal with flow decomposition by the TV-G norm model. To this end we have to introduce a decomposition of the optical flow into components with constant divergence and curl and variable components which can be further decomposed into a "structural" part and a "textural" part. In fact, these parts comprise flow patterns at different scales. In section 5, we combine the flow estimation and the decomposition model in

order to solve both tasks simultaneously. In sections 3, 4, and 5 we especially focus on the practically relevant case of solenoidal flows. Some parts of sections 4 and 5 were previously announced at a conference [36]. Section 6 provides the numerical algorithms to solve the convex optimization problems posed in sections 3, 4, and 5. We use second-order cone programming (SOCP) [12, 20]. Finally, we demonstrate the feasibility of our approaches by numerical examples in section 7.

2. Discretization. For our discrete versions of the functionals we need a careful discretization which preserves the identities satisfied by the continuous operators as, e.g., $\operatorname{div} = -\nabla^*$, $\operatorname{curl}\nabla = 0$, the Gaussian integral identity, and the Helmholtz decomposition. For discretizing the relevant spaces and differential operators we apply the *mimetic finite difference method* introduced by Hyman and Shashkov in [17]. This method defines the corresponding discrete operators of ∇, div, and curl simultaneously on two grids. These grids, which we call the *primal* and *dual grid*, are shifted with respect to each other by half a pixel.

Primal and dual scalar/vector fields. Corresponding to the grids, we define the following scalar fields and vector fields:

H_P: space of scalar fields on vertices,
H_S: space of vector fields defined normal to sides,
H_V: space of scalar field on cells,
H_E: space of vector fields defined tangential to sides.

By H_P^o, H_S^o, and H_E^o we denote the corresponding spaces with zero boundary elements. Finally, let $H_{V+\partial V}$ and $H_{E+\partial E}$ be the extended version of H_V and H_E, respectively, to the boundary. If our primal grid consists of $m \times n$ vertices, then $\dim H_P = mn$, $\dim H_V = (m-1)(n-1)$, $\dim H_S = m(n-1)+n(m-1)$, and $\dim H_E = (m-1)(n-2)+(n-1)(m-2)$. The fields are illustrated in Figure 2.1.

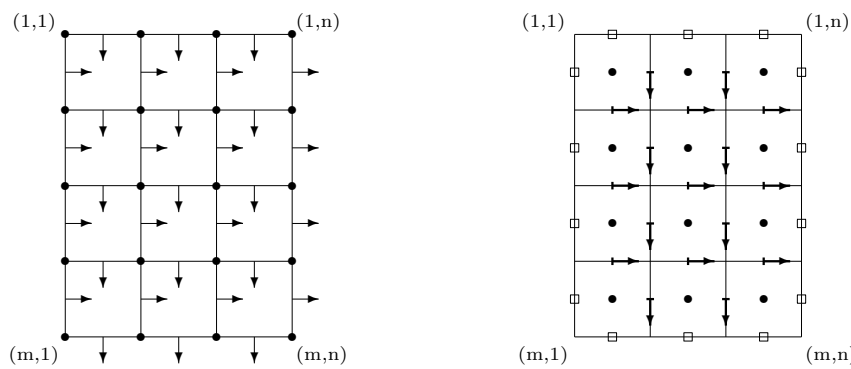

FIG. 2.1. *Primal and dual grid. Left: Spaces H_P (dots) and H_S (arrows). Right: Spaces H_V (dots), $H_{\partial V}$ (squares), and H_E (arrows) for $m = 5$ and $n = 4$.*

While H_P and H_V are equipped with the usual ℓ_2 inner product, the inner products on H_S and H_E are defined with respect to the cells. To this end, we consider the elements of H_S associated with the elements of H_V by

$$u_{V_{i+\frac{1}{2},j+\frac{1}{2}}} := \frac{1}{\sqrt{2}} \left(u_{i,j+\frac{1}{2}}, u_{i+1,j+\frac{1}{2}}, u_{i+\frac{1}{2},j}, u_{i+\frac{1}{2},j+1}\right)^{\mathrm{T}}$$

for $i = 1, \ldots, m-1, j = 1, \ldots, n-1$. Then we define a dotproduct $\cdot : H_S \times H_S \to H_V$

by

$$u \cdot v := \Big((u \cdot v)_{i+\frac{1}{2},j+\frac{1}{2}}\Big)_{i,j=1}^{m-1,n-1} = \left(\left\langle u_{V_{i+\frac{1}{2},j+\frac{1}{2}}}, v_{V_{i+\frac{1}{2},j+\frac{1}{2}}} \right\rangle\right)_{i,j=1}^{m-1,n-1},$$

where $\langle \cdot, \cdot \rangle$ denotes the usual inner product on ℓ_2. Now the inner product on the vector field H_S is given by

$$\langle u, v \rangle_{H_S} := \sum_{i=1}^{m-1} \sum_{j=1}^{n-1} (u \cdot v)_{i+\frac{1}{2},j+\frac{1}{2}}$$

and the corresponding norm by

$$\begin{aligned} \|u\|_{H_S}^2 &:= \left\| \big(\|u_{V_{i+\frac{1}{2},j+\frac{1}{2}}}\|_2 \big)_{i,j=1}^{m-1,n-1} \right\|_2^2 \\ &= \frac{1}{2} \sum_{i=1}^{m-1} \sum_{j=1}^{n-1} (u_{i,j+\frac{1}{2}}^2 + u_{i+1,j+\frac{1}{2}}^2 + u_{i+\frac{1}{2},j}^2 + u_{i+\frac{1}{2},j+1}^2). \end{aligned}$$

Related to the ℓ_1 norm we define

$$\begin{aligned} |u|_{H_S} &:= \left\| \big(\|u_{V_{i+\frac{1}{2},j+\frac{1}{2}}}\|_2 \big)_{i,j=1}^{m-1,n-1} \right\|_1 \\ &= \frac{1}{\sqrt{2}} \sum_{i=1}^{m-1} \sum_{j=1}^{n-1} \sqrt{u_{i,j+\frac{1}{2}}^2 + u_{i+1,j+\frac{1}{2}}^2 + u_{i+\frac{1}{2},j}^2 + u_{i+\frac{1}{2},j+1}^2}. \end{aligned}$$

Similarly, we associate elements of $u \in H_E$ with elements of H_P^o by

$$u_{P_{i,j}} := \frac{1}{\sqrt{2}} \left(u_{i,j-\frac{1}{2}}, u_{i,j+\frac{1}{2}}, u_{i-\frac{1}{2},j}, u_{i+\frac{1}{2},j}\right)^{\mathrm{T}}$$

for $i = 2, \ldots, m-1, j = 2, \ldots, n-1$, and set

$$\|u\|_{H_E}^2 := \left\| \big(\|u_{P_{i,j}}\|_2 \big)_{i,j=2}^{m-1,n-1} \right\|_2^2, \qquad |u|_{H_E} := \left\| \big(\|u_{P_{i,j}}\|_2 \big)_{i,j=2}^{m-1,n-1} \right\|_1.$$

Primal and dual operators. We use the following discrete versions of the first-order operators ∇, div, and curl with respect to the primal and dual grid:

$$\mathbb{G}rad : H_P \to H_{E+\partial E}, \qquad \mathbb{G}rad^{\perp} : H_P \to H_S$$

and

$$\begin{array}{lll} \mathbb{G} : H_P^o \to H_E^o, & \mathbb{D}iv : H_S \to H_V, & \mathbb{G}^{\perp} : H_P^o \to H_S^o, \\ \overline{\mathbb{G}} : H_V \to H_S^o, & \overline{\mathbb{D}iv} : H_E^o \to H_P^o, & \overline{\mathbb{C}url} : H_S^o \to H_P^o. \end{array}$$

Reshaping the scalar/vector fields columnwise into vectors of appropriate lengths, these operators act on the corresponding vector spaces as matrices which can be described by using the first-order forward difference matrix

$$D_m := \begin{pmatrix} -1 & 1 & 0 & \ldots & 0 & 0 & 0 \\ 0 & -1 & 1 & \ldots & 0 & 0 & 0 \\ & & \ddots & \ddots & \ddots & & \\ 0 & 0 & 0 & \ldots & -1 & 1 & 0 \\ 0 & 0 & 0 & \ldots & 0 & -1 & 1 \end{pmatrix} \in \mathbb{R}^{m-1,m}$$

and the tensor product $\otimes$ of matrices. Then we have

$$\mathbb{G}rad = \begin{pmatrix} I_n \otimes D_m \\ D_n \otimes I_m \end{pmatrix}, \quad \mathbb{G}rad^{\perp} = \begin{pmatrix} -D_n \otimes I_m \\ I_n \otimes D_m \end{pmatrix},$$

which explains the notation $^{\perp}$. The operator $\mathbb{G}^{\perp}$ is just the restriction of $\mathbb{G}rad^{\perp}$ to H_P^o. Although $\mathbb{G}$ is not the restriction of $\mathbb{G}rad$ to H_P^o, we will again use the notation $^{\perp}$. More precisely, we define

$$\mathbb{G} = \begin{pmatrix} I_{n-2} \otimes D_{m-2} \\ D_{n-2} \otimes I_{m-2} \end{pmatrix}, \quad \mathbb{G}^{\perp} = \begin{pmatrix} D_{n-1}^{\mathrm{T}} \otimes I_{m-2} \\ -I_{n-2} \otimes D_{m-1}^{\mathrm{T}} \end{pmatrix},$$

$$\mathbb{D}iv \ = \begin{pmatrix} I_{n-1} \otimes D_m, D_n \otimes I_{m-1} \end{pmatrix},$$

where I_n denotes the $n \times n$ identity matrix and the matrices are considered without the zero rows/columns due to embedding. Then we have on the dual grid

$$\overline{\mathbb{G}} = -(\mathbb{D}iv \,_{|_{H_S^o}})^*, \quad \overline{\mathbb{D}iv} = -\mathbb{G}^*, \quad \overline{\mathbb{C}url} = (\mathbb{G}^{\perp})^*, \tag{2.1}$$

where the adjoint operator corresponds to the transposed matrices. Using properties of the tensor product of matrices, we obtain that $\operatorname{curl} \nabla = 0$ reads as

$$\overline{\mathbb{C}url}\ \overline{\mathbb{G}} = 0, \quad \mathbb{D}iv\ \mathbb{G}^{\perp} = -\overline{\mathbb{G}}^{\,*}\, \overline{\mathbb{C}url}^{\,*} = 0. \tag{2.2}$$

We extend the operator $\overline{\mathbb{G}}$ to $H_{V+\partial V}$ by incorporating the boundary elements $H_{\partial V}$ into the forward differences. Since the distance of a boundary point to its neighboring inner point is only $\frac{1}{2}$, we have to multiply the difference filter $(-1, 1)$ at the boundary by 2. The matrix of the resulting operator,

$$\overline{\mathbb{G}}_1 : \ H_{V+\partial V} \to H_S,$$

is given in the appendix. Finally, we define another extension of $\overline{\mathbb{G}}$ in one of the following ways:

- apply a linear extrapolation operator from H_V to $H_{V+\partial V}$ and then $\overline{\mathbb{G}}_1$,
- apply $\overline{\mathbb{G}}$ and then a constant extrapolation from H_S^o to H_S.

Both procedures result in the same operator,

$$\overline{\mathbb{G}}_2 : \ H_V \to H_S,$$

given in matrix form in the appendix.

Discrete integral identities. Next we are interested in a discrete version of the *Gaussian integral identity* $\int_\Omega \operatorname{div} u \, \mathrm{d}x = \int_{\partial\Omega} n \cdot u \, \mathrm{d}s$. To this end, we introduce the boundary operator

$$\mathbb{B} := \begin{pmatrix} I_{n-1} \otimes B_m & 0 \\ 0 & B_n \otimes I_{m-1} \end{pmatrix},$$

where 0 are zero matrices of appropriate sizes and

$$B_m := \begin{pmatrix} -1 & 0 & \dots & 0 & 0 \\ 0 & 0 & \dots & 0 & 1 \end{pmatrix} \in \mathbb{R}^{2,m}.$$

Then the *mimetic Gaussian integral identity* becomes

$$1^{\mathrm{T}}_{\dim H_V}\,\mathbb{D}iv\;u = 1^{\mathrm{T}}_{\dim \partial H_V}\,\mathbb{B}u. \tag{2.3}$$

We will apply the following discrete version of the Helmholtz decomposition.

PROPOSITION 2.1 (mimetic Helmholtz decomposition). *Any $u \in H_S$ can be decomposed into an irrotational part u_{irr} and a soleniodal part u_{sol} by*

$$u = u_{\mathrm{irr}} + u_{\mathrm{sol}} = \overline{\mathbb{G}}_1\psi + \mathbb{G}^{\perp}\varphi, \tag{2.4}$$

where $\varphi \in H^o_P$ is uniquely determined and $\psi \in H_{V+\partial V}$ is uniquely determined up to an additive constant. Moreover, the decomposition is orthogonal in the sense that $\langle \overline{\mathbb{G}}_1\psi, \mathbb{G}^{\perp}\varphi\rangle_{H_S} = 0$.

Proof. By (2.2) and since $\overline{\mathbb{G}}_1$ considered as mapping onto H^o_S equals $\overline{\mathbb{G}}$, we see that

$$\overline{\mathbb{C}url}\,u_{\mathrm{irr}} = \overline{\mathbb{C}url}\;\overline{\mathbb{G}}_1\,\psi = 0, \quad \mathbb{D}iv\;u_{\mathrm{sol}} = \mathbb{D}iv\;\mathbb{G}^{\perp}\varphi = 0.$$

Therefore we have indeed an irrotational and a solenoidal part.

By definition of the matrices it is easy to check that $\dim\mathcal{R}(\overline{\mathbb{G}}_1) = \dim H_{V+\partial V} - 1 = mn + m + n - 4$, and $\dim\mathcal{R}(\mathbb{G}^{\perp}) = \dim H^o_P = (m-2)(n-2)$ so that $\dim\mathcal{R}(\overline{\mathbb{G}}_1) + \dim\mathcal{R}(\mathbb{G}^{\perp}) = \dim H_S$. Here $\mathcal{R}$ denotes the range of the operator. By (2.1) and (2.2) we obtain that

$$\langle \overline{\mathbb{G}}_1\psi, \mathbb{G}^{\perp}\varphi\rangle_{H_S} = \langle \overline{\mathbb{C}url}\;\overline{\mathbb{G}}_1\psi, \varphi\rangle_{H^o_P} = 0,$$

and consequently $H_S = \mathcal{R}(\overline{\mathbb{G}}_1) \oplus \mathcal{R}(\mathbb{G}^{\perp})$ with the orthogonal sum $\oplus$.

Since $\mathbb{G}^{\perp}$ has full rank, the potential φ is uniquely determined by u_{sol}. Since the kernel of $\overline{\mathbb{G}}_1$ is given by $\mathcal{N}(\overline{\mathbb{G}}_1) = \{c1_{\dim H_{V+\partial V}} : c \in \mathbb{R}\}$ we have that ψ is uniquely determined by u_{irr} up to an element from the kernel. This completes the proof. ∎

Conversely, assume for $u \in H_S$ that

$$\begin{aligned} \rho = \mathbb{D}iv\;u &= \triangle_d\,\psi, \\ \omega = \overline{\mathbb{C}url}\,u &= \triangle_c\,\varphi, \end{aligned}$$

where

$$\triangle_d := \mathbb{D}iv\;\overline{\mathbb{G}}_1, \quad \triangle_c := \overline{\mathbb{C}url}\,\mathbb{G}^{\perp}$$

are given. Since $\triangle_c : H^o_P \to H^o_P$ is invertible, the potential φ is uniquely determined by ω, while ψ (and u) are given only up to a laminar flow u_{lam} with vanishing $\mathbb{D}iv$ and $\overline{\mathbb{C}url}$. The laminar flow can be determined by boundary conditions where we have to take the mimetic Gaussian integral identity (2.3) into account. More precisely, we have the following proposition; cf. [36].

PROPOSITION 2.2. *The operator*

$$\mathcal{H} := \begin{pmatrix} \mathbb{D}iv \\ \hline \overline{\mathbb{C}url} \\ \hline \mathbb{B} \end{pmatrix} \in \mathbb{R}^{\dim H_S + 1, \dim H_S}$$

provides a bijection between the spaces H_S and

$$V_S := \{(\rho, \omega, \nu)^T : 1^T_{\dim H_V}\,\rho = 1^T_{\dim H_{\partial V}}\,\nu\}.$$

More precisely, if $(\rho,\omega,\nu)^T = \mathcal{H}u$, *then* $u = \mathcal{H}^\dagger(\rho,\omega,\nu)^T$; *i.e., the inverse mapping on* V_S *is given by the pseudoinverse* $\mathcal{H}^\dagger := (\mathcal{H}^T\mathcal{H})^{-1}\mathcal{H}^T$ *of* $\mathcal{H}$.

In case of a solenoidal flow field from $\{u \in H_S : \mathbb{D}iv\, u = 0\}$, we have by Proposition 2.1 that $\mathbb{D}iv\, \overline{\mathbb{G}}_1\psi = 0$ and $\overline{\mathbb{C}url}\, \overline{\mathbb{G}}_1\psi = 0$. Hence $\overline{\mathbb{G}}_1\psi = u_{\text{lam}}$ is a laminar flow and

$$u = u_{\text{lam}} + u_{\text{sol}} = \overline{\mathbb{G}}_1\psi + \mathbb{G}^\perp\varphi, \quad \mathcal{H}u = (0,0,\nu)^{\text{T}} + (0,\omega,0)^{\text{T}}. \tag{2.5}$$

Further we have the following proposition.

PROPOSITION 2.3. *Every soleniodal flow field* $u \in H_S$ *can be written as*

$$u = \mathbb{G}rad^\perp\phi \tag{2.6}$$

for some $\phi \in H_P$.

Proof. By properties of the tensor product it is easy to check that $\mathbb{D}iv\, \mathbb{G}rad^\perp = 0$ so that the right-hand side of (2.6) is indeed solenoidal.

By Proposition 2.2 we obtain that $\dim(\{u \in H_S : \mathbb{D}iv\, u = 0\}) = mn - 1$. On the other hand, we have $\dim(\mathcal{R}(\mathbb{G}rad^\perp)) = \dim H_P - 1 = mn - 1$. ∎

Primal and dual TV/G norms. For our optical flow decomposition and estimation we need discrete versions of the TV norm $\|f\|_{\text{TV}} := \int |\nabla f|\, dxdy$ and the G norm $\|f\|_{\text{G}} := \inf_{f=\text{div}p} \| |p| \|_{L_\infty}$, where $|p| := (p_1^2 + p_2^2)^{1/2}$ for a vector field $p = (p_1, p_2)$, $p_1, p_2 \in L_\infty$. For a more sophisticated treatment of these norms in the continuous setting, see, e.g., [11, 21].

For $\omega \in H_P^o$ we set

$$\|\omega\|_{\text{TV}} := |\mathbb{G}\,\omega|_{H_E^o}.$$

This defines a seminorm on H_P^o. As usual we will skip the prefix "semi" in the following. Let $N := \dim H_P^o$. According to the norm in H_E^o let $S : \mathbb{R}^{\dim H_E^o} \to \mathbb{R}^{4N}$ be the matrix which assigns the four appropriate elements of H_E^o to each point of H_P^o; cf. the appendix. For $w := (w^1, w^2, w^3, w^4)^{\text{T}} \in \mathbb{R}^{4N}$ with $w^r := (w_j^r)_{j=1}^N$, $r = 1, \ldots, 4$, we define the vector

$$|w| := \left(\|(w_j^r)_{r=1}^4\|_2\right)_{j=1}^N. \tag{2.7}$$

Then the TV norm can be rewritten as

$$\|\omega\|_{\text{TV}} = \| \, |S\,\mathbb{G}\,\omega| \, \|_1.$$

Now the G norm of ω is defined by

$$\|\omega\|_{\text{G}} := \min_{\omega = \mathbb{G}^* S^* w} \| \, |w| \, \|_\infty = \min_{\omega = \mathbb{D}iv\ S^* w} \| \, |w| \, \|_\infty.$$

Similarly, we can define the TV and the G norm on H_V. For $\rho \in H_V$ let

$$\|\rho\|_{\overline{\text{TV}}} := \left|\overline{\mathbb{G}}_2\,\rho\right|_{H_S}.$$

We focus on the second way of extending $\overline{\mathbb{G}}$ to $\overline{\mathbb{G}}_2$ and introduce the operator $\overline{S} : \mathbb{R}^{\dim H_S^o} \to \mathbb{R}^{4N}$ with $N := \dim H_V$, which constantly extrapolates from H_S^o to H_S and assigns the elements of H_S to those of H_V. For the matrix structure of $\overline{S}$, see the appendix. Then we obtain that

$$\|\rho\|_{\overline{\text{TV}}} = \| \, |\overline{S}\,\overline{\mathbb{G}}\,\rho| \, \|_1$$

and

$$\|\rho\|_{\overline{\mathrm{G}}} := \min_{\rho=\overline{\mathbb{G}}*\overline{S}*p} \| \, |p| \, \|_\infty = \min_{\rho=\mathbb{D}iv\,\overline{S}*p} \| \, |p| \, \|_\infty. \tag{2.8}$$

The G norm ($\overline{\mathrm{G}}$ norm) can be considered as dual to the TV norm ($\overline{\mathrm{TV}}$ norm) in the following sense.

PROPOSITION 2.4. *For $\tilde{\omega} \in \mathcal{R}(\mathbb{G}^* S^*)$ the following relation holds true:*

$$\sup_{\|\omega\|_{\mathrm{TV}} \neq 0} \frac{|\langle \tilde{\omega}, \omega \rangle|}{\|\omega\|_{\mathrm{TV}}} = \|\tilde{\omega}\|_{\mathrm{G}}. \tag{2.9}$$

Proof. 1. Set

$$L := S\mathbb{G} : \mathbb{R}^N \to \mathbb{R}^{4N}, \quad N := \dim H_E^o.$$

Then, using the notation (2.7), the relation (2.9) can be rewritten as

$$\sup_{\| \, |L\omega| \, \|_1 \neq 0} \frac{|\langle \tilde{\omega}, \omega \rangle|}{\| \, |L\omega| \, \|_1} = \min_{\tilde{\omega}=L^{\mathrm{T}} v} \| \, |v| \, \|_\infty, \qquad \tilde{\omega} \in \mathcal{R}(L^{\mathrm{T}}).$$

Let $\nu(\tilde{\omega}) := \sup_{\| \, |L\omega| \, \|_1 \neq 0} \frac{|\langle \tilde{\omega}, \omega \rangle|}{\| \, |L\omega| \, \|_1}$. By applying the Schwarz inequality to the four parts of the corresponding vectors in $\mathbb{R}^{4N}$, we obtain for all $v \in \mathbb{R}^{4N}$ with $L^{\mathrm{T}} v = \tilde{\omega}$ that

$$\langle \tilde{\omega}, \omega \rangle = \langle v, L\omega \rangle \leq \langle |v|, |L\omega| \rangle \quad \forall \omega \in \mathbb{R}^N,$$

and then obviously

$$\langle |v|, |L\omega| \rangle \leq \| \, |L\omega| \, \|_1 \| \, |v| \, \|_\infty \qquad \forall \omega \in \mathbb{R}^N.$$

Consequently, we have

$$\nu(\tilde{\omega}) \leq \min_{\tilde{\omega}=L^{\mathrm{T}} v} \| \, |v| \, \|_\infty.$$

To show the reverse direction we consider the subspace $\mathcal{B} := \mathcal{R}(L)$ of $\mathbb{R}^{4N}$ equipped with the norm $\| \, |\cdot| \, \|_1$. Let $\tilde{w}$ with $L^{\mathrm{T}} \tilde{w} = \tilde{\omega}$ be fixed. Then the mapping $l_{\tilde{w}}(L\omega) := \langle \tilde{w}, L\omega \rangle$ is a linear functional on $\mathcal{B}$ which has exactly the norm $\nu(\tilde{\omega})$. By the Hahn–Banach theorem this functional can be extended to a linear functional l on $(\mathbb{R}^{4N}, \| \, |\cdot| \, \|_1)$ with $\|l\| = \|l_{\tilde{w}}\|$. Then there exists $\tilde{v} \in \mathbb{R}^{4N}$ such that $l(v) = \langle \tilde{v}, v \rangle$ for all $v \in \mathbb{R}^{4N}$ and

$$\langle \tilde{v}, L\omega \rangle = \langle \tilde{w}, L\omega \rangle \quad \forall \omega \in \mathbb{R}^N.$$

Since this can be rewritten as

$$\langle L^{\mathrm{T}} \tilde{v}, \omega \rangle = \langle L^{\mathrm{T}} \tilde{w}, \omega \rangle \quad \forall \omega \in \mathbb{R}^N$$

the vector $\tilde{v}$ must fulfil $L^{\mathrm{T}} \tilde{v} = L^{\mathrm{T}} \tilde{w} = \tilde{\omega}$. Then

$$\nu(\tilde{\omega}) = \|l_{\tilde{w}}\| = \|l\| = \| \, |\tilde{v}| \, \|_\infty,$$

where the last equality follows from the fact that $\| \, |\cdot| \, \|_1$ and $\| \, |\cdot| \, \|_\infty$ are dual norms on $\mathbb{R}^{4N}$. Thus, $\nu(\tilde{\omega}) \geq \min_{\tilde{\omega}=L^{\mathrm{T}} v} \| \, |v| \, \|_\infty$, and we obtain the assertion. ∎

3. Flow estimation. Assume now that we are given an image sequence $\{g(\cdot, j) \in H_V : j = 1, \dots, T\}$. For fixed $j \in \mathbb{N}$, we set $g_t = g_t(j) := g(\cdot, j+1) - g(\cdot, j)$. Then the data fitting functional (1.6) can be discretized by

$$F(u) = \|\overline{\mathbb{G}}_2 g \cdot u + g_t\|^2_{H_V}$$

with the dotproduct on H_S and by applying the mimetic Helmholtz decomposition (2.4) by

$$F(\psi, \varphi) = \|\overline{\mathbb{G}}_2 g \cdot \overline{\mathbb{G}}_1 \psi + \overline{\mathbb{G}}_2 g \cdot \mathbb{G}^{\perp} \varphi + g_t\|^2_{H_V}.$$

This further decomposition can be useful from two points of view. First the vectors ψ and φ have only approximately half the lengths of the vector u. Second this approach allows for efficiently handling solenoidal flows, which are very common in computational fluid dynamics.

To discretize the boundary integral $\int_{\partial\Omega} (\partial_{\mathrm{n}} u)^2 \, \mathrm{d}s$ in (1.9) and (1.10) we use the operator

$$\mathbb{B}^{\mathrm{n}} := \begin{pmatrix} I_{n-1} \otimes B^{\mathrm{n}}_m & 0 \\ 0 & B^{\mathrm{n}}_n \otimes I_{m-1} \end{pmatrix}$$

with

$$B^{\mathrm{n}}_m := \begin{pmatrix} -1 & 1 & \dots & 0 & 0 \\ 0 & 0 & \dots & -1 & 1 \end{pmatrix} \in \mathbb{R}^{2,m}.$$

For the smoothing penalizer we distinguish between the linear and the TV approach.

Linear approach. The discrete version of the functional (1.9) becomes

$$J(u) = F(u) + \lambda_d \left\|\overline{\mathbb{G}}_2 \, \mathbb{D}iv \, u\right\|^2_{H_S} + \lambda_c \left\|\mathbb{G} \, \overline{\mathbb{C}url} \, u\right\|^2_{H^o_E} + \gamma \left\|\mathbb{B}^{\mathrm{n}} u\right\|^2_{\partial H_S}. \tag{3.1}$$

The minimizer u of (3.1) can be obtained by solving the corresponding normal equation.

Using the Helmholtz decomposition together with $u_{|_{\partial H_S}} = (\overline{\mathbb{G}}_1 \psi)_{|_{\partial H_S}}$ and (2.2), problem (3.1) can be rewritten as

$$J(\psi, \varphi) = F(\psi, \varphi) + \lambda_d \left\|\overline{\mathbb{G}}_2 \triangle_d \psi\right\|^2_{H_S} + \lambda_c \left\|\mathbb{G} \triangle_c \varphi\right\|^2_{H^o_E} + \gamma \left\|\mathbb{B}^{\mathrm{n}} \overline{G}_1 \psi\right\|^2_{\partial H_S}. \tag{3.2}$$

Since ψ is determined only up to a constant, we add the additional condition

$$1^{\mathrm{T}}_{\dim H_{V+\partial V}} \psi = 0$$

to make the functional strictly convex. This problem can be solved by subspace correction methods [31, 33]. More precisely, we iterate the following process: we consider φ as given and find the solution ψ of (3.2) via the normal equation. Then we fix this solution as ψ and compute φ.

In case of a solenoidal flow field $u \in H_S$ we can apply (2.5), and our variational problem reduces to

$$\begin{aligned} J(\psi, \varphi) &= F(\psi, \varphi) + \lambda_c \left\|\mathbb{G} \triangle_c \varphi\right\|^2_{H^o_E} + \gamma \left\|\mathbb{B}^{\mathrm{n}} \overline{G}_1 \psi\right\|^2_{\partial H_S} \\ \text{s.t.} \quad & \overline{\mathbb{G}}_2 \triangle_d \psi = 0, \quad 1^{\mathrm{T}}_{\dim H_{V+\partial V}} \psi = 0. \end{aligned}$$

The linear case was more extensively treated by some of the authors in [35].

TV approach. Functional (1.10) becomes

$$J(u) = \frac{1}{2}\,F(u) + \lambda_d\,\|\mathbb{D}iv\;u\|_{\overline{\mathrm{TV}}} + \lambda_c\,\left\|\overline{\mathbb{C}url}\;u\right\|_{\mathrm{TV}} + \frac{\gamma}{2}\;\|\mathbb{B}^{\mathrm{n}}u\|^2_{\partial H_S}\,, \tag{3.3}$$

and by applying the Helmholtz decomposition,

$$J(\psi,\varphi) = \frac{1}{2}\,F(\psi,\varphi) + \lambda_d\,\|\triangle_d\,\psi\|_{\overline{\mathrm{TV}}} + \lambda_c\,\|\triangle_c\,\varphi\|_{\mathrm{TV}} + \frac{\gamma}{2}\;\left\|\mathbb{B}^{\mathrm{n}}\overline{G}_1\psi\right\|^2_{\partial H_S}\,, \tag{3.4}$$

where $1^{\mathrm{T}}_{\dim H_{V+\partial V}}\psi = 0$. In case of solenoidal flows the functional further reduces as in the linear case.

To solve (3.3) we propose using SOCP; cf. section 6.

Alternatively, we can again apply a splitting algorithm in (3.4) which iteratively fixes φ as previously computed and finds the minimizer ψ and conversely. Then any of the subproblems with fixed φ or fixed ψ can be written in the form

$$\frac{1}{2}\|Ax-b\|_2^2 + \lambda\|\,|Lx|\,\|_1, \tag{3.5}$$

where $A : \mathbb{R}^{\dim H_{V+\partial V}} \to \mathbb{R}^{\dim H_V}, L : \mathbb{R}^{\dim H_{V+\partial V}} \to \mathbb{R}^{4\dim H_V}$ in case of fixed φ and $A : \mathbb{R}^{\dim H_P^o} \to \mathbb{R}^{\dim H_V},\ L : \mathbb{R}^{\dim H_P^o} \to \mathbb{R}^{4\dim H_P^o}$ in case of fixed ψ. The minimizer of (3.5) can be found by applying dual optimization techniques as proposed by Chambolle and coworkers [3, 7, 6].

4. Flow decomposition. In this section, we want to decompose a given flow vector $u \in H_S$ in a meaningful way. To this end we have to compute some basic decomposition of u first. We apply Proposition 2.2 and consider $\mathcal{H}u = (\rho,\omega,\nu)^{\mathrm{T}}$. Let

$$c_\rho := \frac{1^{\mathrm{T}}_{\dim H_V}\,\rho}{\dim H_V}\,, \quad c_\omega := \frac{1^{\mathrm{T}}_{\dim H_P^o}\,\omega}{\dim H_P^o}$$

be the discrete versions of $|\Omega|^{-1}\int_\Omega \operatorname{div} u\,\mathrm{d}x\mathrm{d}y$ and $|\Omega|^{-1}\int_\Omega \operatorname{curl} u\,\mathrm{d}x\mathrm{d}y$ and

$$\rho_{\mathrm{const}} := c_\rho\,1_{\dim H_V}\,, \quad \omega_{\mathrm{const}} := c_\omega\,1_{\dim H_P^o}. \tag{4.1}$$

Then we can decompose $(\rho,\omega,\nu)^{\mathrm{T}} \in V_S$ as

$$(\rho,\omega,\nu) = (\rho_{\mathrm{const}},\omega_{\mathrm{const}},\nu) + (\rho_{\mathrm{var}},\omega_{\mathrm{var}},0), \tag{4.2}$$

where $1^{\mathrm{T}}_{\dim H_V}\rho_{\mathrm{var}} = 1^{\mathrm{T}}_{\dim H_P^o}\omega_{\mathrm{var}} = 0$. Obviously, both summands are in V_S again, so that

$$u = u_{\mathrm{const}} + u_{\mathrm{var}}$$

is the corresponding basic decomposition of $u \in H_S$, where

$$u_{\mathrm{const}} = \mathcal{H}^\dagger((\rho_{\mathrm{const}},\omega_{\mathrm{const}},\nu)^{\mathrm{T}}, \quad u_{\mathrm{var}} = \mathcal{H}^\dagger(\rho_{\mathrm{var}},\omega_{\mathrm{var}},0)^{\mathrm{T}}.$$

We call vector u_{const} (resp., $(\rho_{\mathrm{const}},\omega_{\mathrm{const}},\nu)$) the basic pattern of the nonrigid flow and its boundary behavior, while u_{var} (resp., $(\rho_{\mathrm{var}},\omega_{\mathrm{var}},0)$) is related to the variable (oscillating) flow pattern.

We are interested in further decomposing the intrinsic flow variation u_{var} into a structural part u^s and a texture part u^t, i.e.,

$$u_{\mathrm{var}} = u^s + u^t.$$

This can be done in two ways. The *first approach* uses Proposition 2.2. Given $u \in H_S$, we compute $(\rho, \omega, \nu)^{\mathrm{T}} = \mathcal{H}u$ and then $\rho_{\mathrm{var}} = \rho - \rho_{\mathrm{const}}$ and $\omega_{\mathrm{var}} = \omega - \omega_{\mathrm{const}}$ by (4.1). Next we decompose $\rho_{\mathrm{var}} = \rho^s + \rho^t$ and $\omega_{\mathrm{var}} = \omega^s + \omega^t$ by minimizing separately

$$J(\rho^s, \rho^t) = \frac{1}{2}\,\|\rho_{\mathrm{var}} - \rho^s - \rho^t\|_2^2 \;+\; \lambda_d \|\rho^s\|_{\overline{\mathrm{TV}}} \;+\; \mu_d \|\rho^t\|_{\overline{\mathrm{G}}},$$
$$J(\omega^s, \omega^t) = \frac{1}{2}\,\|\omega_{\mathrm{var}} - \omega^s - \omega^t\|_2^2 \;+\; \lambda_c \|\omega^s\|_{\mathrm{TV}} \;+\; \mu_c \|\omega^t\|_{\mathrm{G}}.$$

The minimizers can be computed as proposed in [3]. By (2.8) we see that $\rho^t \in \mathcal{R}(\overline{\mathbb{G}}^*) = \mathcal{R}(\mathbb{D}iv_{|_{H_S^o}})$, and since $1^{\mathrm{T}}\mathbb{D}iv_{|_{H_S^o}} = 0$ we have that $(\rho^t, \omega^t, 0)^{\mathrm{T}} \in V_S$ and further by (4.2) that $(\rho^s, \omega^s, 0)^{\mathrm{T}} \in V_S$. Thus we can finally compute u^s and u^t by

$$u^s = \mathcal{H}^\dagger(\rho^s, \omega^s, 0)^{\mathrm{T}}, \quad u^t = \mathcal{H}^\dagger(\rho^t, \omega^t, 0)^{\mathrm{T}}.$$

In this paper, we prefer a *second approach* that computes the components of u directly. This variational approach extends Meyer's model for the decomposition of scalar-valued functions to the *simultaneous* decomposition of vector fields into basic and variable (structural and textural) flow patterns. Moreover, it also fits into our flow estimation-decomposition model in the next section. For $u \in H_S$ we propose to to find $u_{\mathrm{const}} \in H_S$ and $u^s, u^t \in H_S^o$ by minimizing

$$\begin{aligned} J(u_{\mathrm{const}}, u^s, u^t) &= \lambda_d \,\|\mathbb{D}iv\; u^s\|_{\overline{\mathrm{TV}}} + \lambda_c \left\|\overline{\mathbb{C}url}\; u^s\right\|_{\mathrm{TV}} \\ \text{s.t.}\quad & \|\mathbb{D}iv\; u^t\|_{\overline{\mathrm{G}}} \le \delta_d\,, \quad \|\overline{\mathbb{C}url}\; u^t\|_{\mathrm{G}} \le \delta_c, \\ & u_{\mathrm{const}} + u^s + u^t = u, \\ & \overline{\mathbb{G}}\mathbb{D}iv\; u_{\mathrm{const}} = 0, \quad \mathbb{G}\overline{\mathbb{C}url}\; u_{\mathrm{const}} = 0, \\ & 1^{\mathrm{T}}_{\dim H_P^o}\overline{\mathbb{C}url}\; u^s = 0. \end{aligned} \tag{4.3}$$

Concerning the last three constraints we note the following: to obtain the desired decomposition we have to ensure that $\mathbb{D}iv\; u_{\mathrm{const}}$ and $\overline{\mathbb{C}url}\; u_{\mathrm{const}}$ are constant vectors $c\,1$ and that $1^{\mathrm{T}}_{\dim H_V}\mathbb{D}iv\;(u^s + u^t) = 0$, $1^{\mathrm{T}}_{\dim H_P^o}\overline{\mathbb{C}url}\,(u^s + u^t) = 0$. The first two conditions are fulfilled by the fourth and fifth constraint. The third condition is fulfilled by the mimetic Gaussian integral identity and since u^s, $u^t \in H_S^o$. The last condition follows by the last constraint and since $\overline{\mathbb{C}url}\; u^t \in \mathcal{R}(\overline{\mathbb{D}iv}\,)$ and $1^{\mathrm{T}}\overline{\mathbb{D}iv} = 0$.

The solution of (4.3) can be found by SOCP, as shown in section 6.

5. Flow estimation and decomposition. In this section, we combine optical flow estimation with structure-texture flow decomposition. Given image sequence $\{g(\cdot, j) \in H_V : j = 1, \ldots, T\}$, we want to compute the components u_{const} with constant divergence and curl, the large scale patterns $u^s \in H_S^o$ of divergence and curl with bounded TV norms, and the small scale patterns $u^t \in H_S^o$ of divergence and curl with bounded G norms. To this end, we introduce the fitting functional

$$F(u_{\mathrm{const}}, u^s, u^t) = \|\overline{\mathbb{G}}_2 g \cdot (u_{\mathrm{const}} + u^s + u^t) + g_t\|_2^2.$$

Then, with respect to the previous section, one can consider minimizing

$$\begin{aligned} J(u_{\mathrm{const}}, u^s, u^t) = \frac{1}{2}\,F(u_{\mathrm{const}}, u^s, u^t) &+ \lambda_d\|\mathbb{D}iv\; u^s\|_{\overline{\mathrm{TV}}} + \lambda_c\|\overline{\mathbb{C}url}\; u^s\|_{\mathrm{TV}} + \frac{\gamma}{2}\|\mathbb{B}^n u\|^2_{\partial H_S} \\ \text{s.t.}\quad & \|\mathbb{D}iv\; u^t\|_{\overline{\mathrm{G}}} \le \delta_d\,, \quad \|\overline{\mathbb{C}url}\; u^t\|_{\mathrm{G}} \le \delta_c, \\ & \overline{\mathbb{G}}\mathbb{D}iv\; u_{\mathrm{const}} = 0, \quad \mathbb{G}\overline{\mathbb{C}url}\; u_{\mathrm{const}} = 0, \\ & 1^{\mathrm{T}}_{\dim H_P^o}\overline{\mathbb{C}url}\; u^s = 0. \end{aligned}$$

Unfortunately, this approach is not well posed. For the image areas where $\nabla g = 0$, the data term disappears, and the local constraints on the G norms will lead to unbounded solutions. Therefore, we propose to replace the G norm by the L_2 norm, which leads to

$$\begin{aligned} J(u_{\text{const}}, u^s, u^t) = \frac{1}{2} F(u_{\text{const}}, u^s, u^t) + \lambda_d \|\mathbb{D}iv\ u^s\|_{\overline{\text{TV}}} + \lambda_c \|\overline{\mathbb{C}url}\ u^s\|_{\text{TV}} \\ + \mu_d \|\mathbb{D}iv\ u^t\|_2^2 + \mu_c \|\overline{\mathbb{C}url}\ u^t\|_2^2 + \frac{\gamma}{2} \|\mathbb{B}^n u\|_{\partial H_S}^2, \\ \text{s.t.} \quad \overline{\mathbb{G}}\mathbb{D}iv\ u_{\text{const}} = 0, \quad \mathbb{G}\overline{\mathbb{C}url}\ u_{\text{const}} = 0, \\ 1_{\dim H_P^o}^{\text{T}} (\overline{\mathbb{C}url}\ u^s + \overline{\mathbb{C}url}\ u^t) = 0. \end{aligned} \tag{5.1}$$

We will see in our experiments that this approach works well, although the superiority of the G norm over the L_2 norm in capturing (scalar) oscillating patterns was experimentally shown in [4].

Finally, we are interested in solenoidal flows $u \in H_S$. Coupling the mimetic Helmholtz decomposition and the basic decomposition, we obtain with the laminar flow $\overline{\mathbb{G}}_1 \psi$ and $\varphi = \varphi_{\text{const}} + \varphi^s + \varphi^t$ that

$$u = u_{\text{const}} + u^s + u^t = (\overline{\mathbb{G}}_1 \psi + \mathbb{G}^{\perp} \varphi_{\text{const}}) + \mathbb{G}^{\perp} \varphi^s + \mathbb{G}^{\perp} \varphi^t.$$

By Proposition 2.3 and since $\mathbb{G}rad^{\perp}_{|H_P^o} = \mathbb{G}^{\perp}$ this can be rewritten as

$$u = \mathbb{G}rad^{\perp}(\phi_{\text{const}} + \varphi^s + \varphi^t), \qquad \phi \in H_P, \varphi^s, \varphi^t \in H_P^o.$$

Then the fitting term reads

$$F(\phi_{\text{const}}, \varphi^s, \varphi^t) = \|\overline{\mathbb{G}}_2 g \cdot \mathbb{G}rad^{\perp}(\phi_{\text{const}} + \varphi^s + \varphi^t) + g_t\|_2^2,$$

and (5.1) can be rewritten as

$$\begin{aligned} J(\phi_{\text{const}}, \varphi^s, \varphi^t) = &\frac{1}{2} F(\phi_{\text{const}}, \varphi^s, \varphi^t) + \lambda_c \|\triangle_c \varphi^s\|_{\text{TV}} + \mu_c \|\triangle_c \varphi^t\|_2^2 \\ &+ \frac{\gamma}{2} \|\mathbb{B}^n \mathbb{G}rad^{\perp} \phi_{\text{const}}\|_{\partial H_S}^2 \\ \text{s.t.} \quad &\mathbb{G}\,\overline{\mathbb{C}url}\ \mathbb{G}rad^{\perp} \phi_{\text{const}} = 0,\ 1_{\dim H_P^o}^{\text{T}} \triangle_c (\varphi^s + \varphi^t) = 0, \\ &1_{\dim H_P}^{\text{T}} \phi_{\text{const}} = 0, \end{aligned} \tag{5.2}$$

where the last constraint appears since ϕ_{const} is determined only up to an additive element from the kernel of $\mathbb{G}rad^{\perp}$, which consists of constant vector fields.

6. Algorithmic aspect—SOCP. Our computational approach to flow estimation via (4.3) and to simultaneous flow estimation and decomposition via (5.2) is based on SOCP [20]. This amounts to minimizing a linear objective function subject to the constraints that several affine functions of the variables have to lie in a *second-order cone* $\mathcal{L}^{n+1} \subset \mathbb{R}^{n+1}$ defined by the convex set

$$\mathcal{L}^{n+1} = \left\{ \begin{pmatrix} x \\ t \end{pmatrix} = (x_1, \ldots, x_n, t)^{\top} : \|x\|_2 \le t \right\}.$$

With this notation, the general form of an SOCP is given by

$$\inf_{x \in \mathbb{R}^n} f^{\top} x, \quad \text{s.t.} \begin{pmatrix} A_i x + b_i \\ c_i^T x + d_i \end{pmatrix} \in \mathcal{L}^{n+1}, \quad i = 1, \ldots, r. \tag{6.1}$$

Problem (6.1) is a convex program for which efficient large-scale solvers are available [22]. In connection with TV-based image decomposition the application of SOCPs was recently suggested in [12, 34].

We reformulate the variational approach (4.3) as the SOCP

$$
\begin{aligned}
&J(u_{\text{const}}, u^s, u^t) = \lambda_d 1^{\mathrm{T}}_{\dim H_V} v + \lambda_c 1^{\mathrm{T}}_{\dim H_P^o} w,\\
&\text{s.t. } u_{\text{const}} + u^s + u^t = u\,, \quad \overline{\mathbb{G}}\mathbb{D}iv\, u_{\text{const}} = 0\,, \quad \mathbb{G}\overline{\mathbb{C}url}\, u_{\text{const}} = 0,\\
&1^{\mathrm{T}}_{\dim H_P^o} \overline{\mathbb{C}url}\, u^s = 0\,, \quad \mathbb{D}iv\, u^t = \mathbb{D}iv\, p_d\,, \qquad \overline{\mathbb{C}url}\, u^t = \mathbb{D}iv\, p_c,\\
&\begin{pmatrix} (\overline{\mathbb{G}}\mathbb{D}iv\, u^s)_{V_{i+\frac12,j+\frac12}} \\ v_{V_{i+\frac12,j+\frac12}} \end{pmatrix} \in \mathcal{L}^5\,, \qquad \begin{pmatrix} (\overline{\mathbb{G}\mathbb{C}url}\, u^s)_{P_{i,j}} \\ w_{P_{i,j}} \end{pmatrix} \in \mathcal{L}^5,\\
&\begin{pmatrix} (p_d)_{V_{i+\frac12,j+\frac12}} \\ \delta_d \end{pmatrix} \in \mathcal{L}^5\,, \qquad \begin{pmatrix} (p_c)_{P_{i,j}} \\ \delta_c \end{pmatrix} \in \mathcal{L}^5.
\end{aligned}
$$

In order to incorporate the quadratic terms of the variational approaches to optical flow estimation, we use the following rotated version of the standard cone:

$$
\mathcal{R}^{n+2} := \left\{ \left(x, x_{n+1}, x_{n+2}\right)^\top \in \mathbb{R}^{n+2} : \frac{1}{2}\|x\|_2^2 \le x_{n+1}x_{n+2},\, x_{n+1}, x_{n+2} \ge 0 \right\}.
$$

Fixing $x_{n+2} = 1/2$, we have $\|x\|_2^2 \le x_{n+1}$. Now we can rewrite (5.2) as follows:

$$
\begin{aligned}
&J(\phi_{\text{const}}, \varphi^s, \varphi^t) = v + \mu_c t + \lambda_c 1^{\mathrm{T}}_{\dim H_P^o} w,\\
&\text{s.t.} \quad \mathbb{G}\overline{\mathbb{C}url}\, \mathbb{G}rad^{\perp}\phi_{\text{const}} = 0\,, \qquad 1^{\mathrm{T}}_{\dim H_P}\phi_{\text{const}} = 0,\\
&1^{\mathrm{T}}_{\dim H_P^o} \triangle_c(\varphi^s + \varphi^t) = 0,\\
&\begin{pmatrix} (\overline{\mathbb{G}}\triangle_c\varphi^s)_{V_{i+\frac12,j+\frac12}} \\ w_{V_{i,j}} \end{pmatrix} \in \mathcal{L}^5, \quad \begin{pmatrix} \triangle_c\varphi^t \\ t \\ 1/2 \end{pmatrix} \in \mathcal{R}^{\dim H_P+2},\\
&\begin{pmatrix} \overline{\mathbb{G}}_2 g \cdot \mathbb{G}rad^{\perp}(\phi_{\text{const}} + \varphi^s + \varphi^t) + g_t \\ v \\ 1/2 \end{pmatrix} \in \mathcal{R}^{\dim H_V+2}.
\end{aligned}
$$

7. Numerical examples. In this section we verify our approaches by numerical examples. The programs were written in MATLAB and used the software package SeDuMi for SOCP [27]. Unfortunately, we do not have an automatized choice of parameter values. Parameter values were chosen by hand following two general rules: (i) choose the weights as small as possible in order to not smooth out turbulent motion, (ii) for TV terms, smaller values than in the linear case (e.g., (21)) are appropriate, because these regularizers return larger values than their linear counterparts (assuming that image data are scaled to the range $[0, 1]$). Rule (ii) leads to parameter values of the order $\propto e^{-4}$. Thanks to the mimetic discretization, this suffices for numerical stability

Flow estimation. We start by comparing flow estimations obtained by the linear approach (3.2) and the TV approach (3.4). We consider the artificial example in Figure 7.1 with the groundtruth on top of Figure 7.2. Figure 7.2 (middle) was obtained by solving the linear systems of equations resulting from (3.2) with parameters

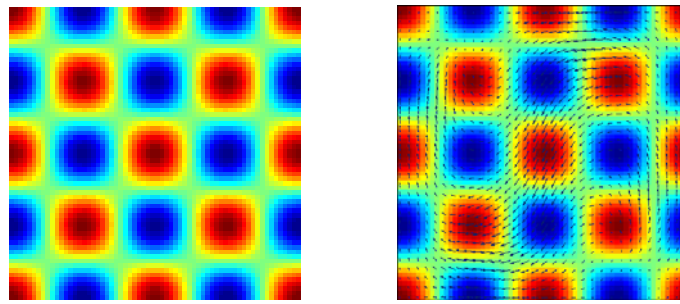

FIG. 7.1. *Frame g (left) and its warping with the groundtruth flow (right) for flow estimation by the linear approach and the TV approach.*

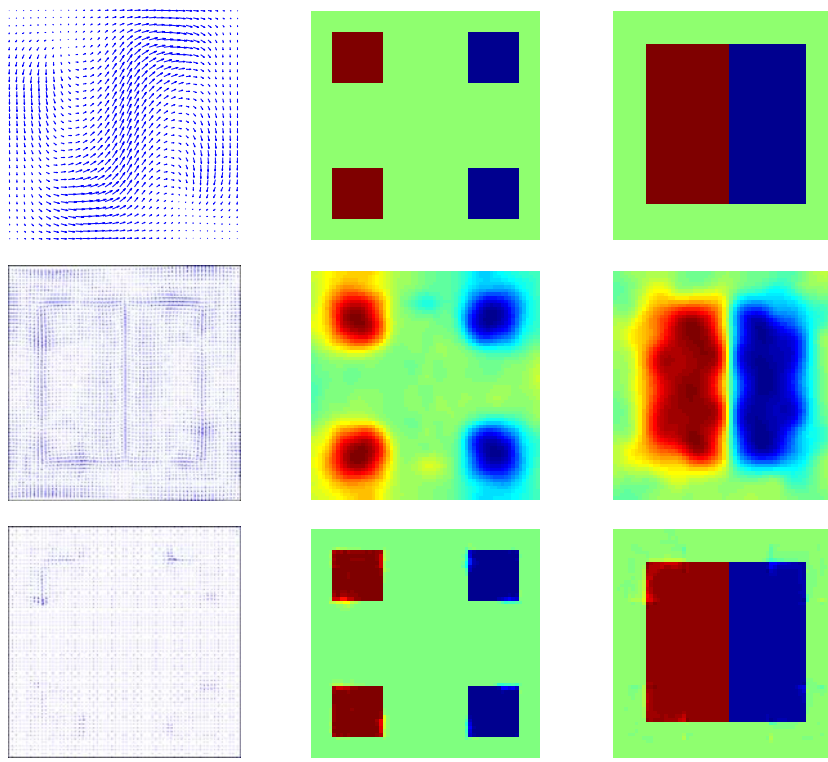

FIG. 7.2. *Top: The groundtruth flow u, its div and curl (left to right). Middle: Linear reconstruction by* (3.1)*, difference between u and its estimation, reconstructed div and curl (left to right). Bottom: TV reconstruction by* (3.3)*, difference between u and its estimation, reconstructed div and curl (left to right).*

$\lambda_d = 0.06$, $\lambda_c = 0.048$. As the boundary parameter we have used $\gamma = 0.04$. The result shows the typical blurring effects at the edges. If we decrease the parameter values, the rectangular shape of div and curl becomes easier to see, but the artifacts always visible in Figure 7.2 (middle) increase too. The bottom of Figure 7.2 contains the solution of (3.3) with the parameters $\lambda_d = e^{-6}$, $\lambda_c = e^{-6}$, and $\gamma = e^{-5}$ by SOCP and 17 iterations. As expected for this example, the TV approach gives very good results by preserving discontinuities of the flow derivatives (div, curl).

Flow decomposition. Figure 7.3 shows a turbulent flow field u as groundtruth along with its divergence ρ and curl ω. Applying the variational method (4.3) with $\lambda_d = 0.2\,,\ \lambda_c = 0.5$, and $\delta_d = 0.05\,,\ \delta_c = 0.1$, we obtain the decompositions depicted in Figures 7.4 and 7.5. The structural and textural components recovered the interesting motion patterns at different scales, which are not easily visible in the flow u itself.

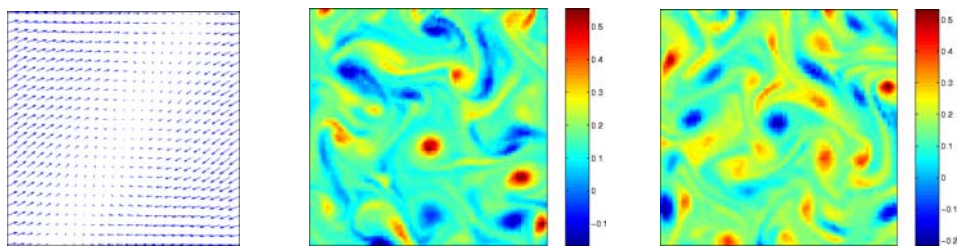

FIG. 7.3. *Groundtruth data to be decomposed: flow field u (left), its divergence field ρ (middle), and its curl field ω (right).*

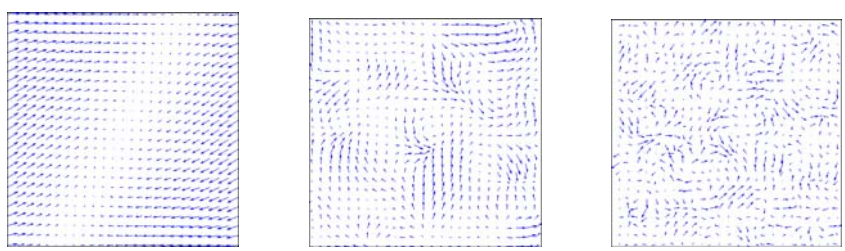

FIG. 7.4. *The components of the flow u from Figure* 7.3*: u_{const} (left), u^s (middle), and u^t (right). The vectors of u^s, u^t are scaled up for better visibility. Note that despite $|u| \approx |u_{\text{const}}|$, the structural and texture parts u^s and u^t are recovered well.*

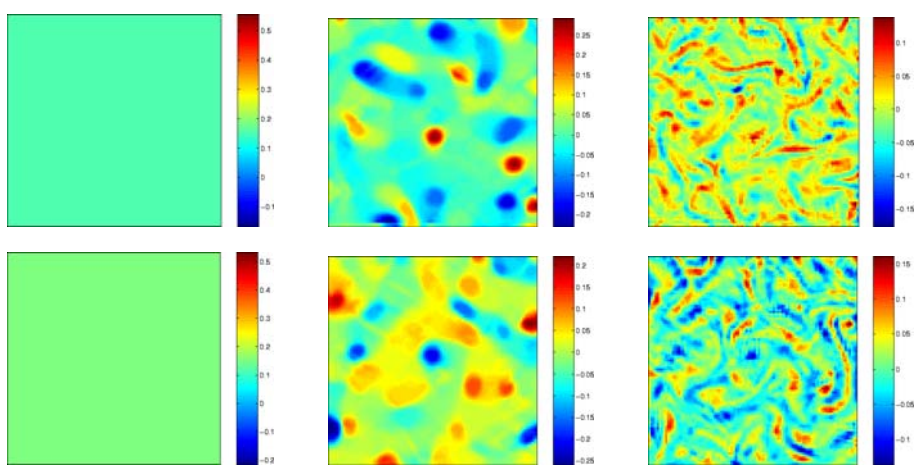

FIG. 7.5. *Decomposition of u from Figure* 7.3 *with the approach* (4.3)*. Top: $\rho_{\text{const}}, \rho^s, \rho^t$ (left to right). Bottom: $\omega_{\text{const}}, \omega^s, \omega^t$ (left to right). The structure and texture components reveal turbulent flow patterns at different scales, which are not easily visible in the flow u itself.*

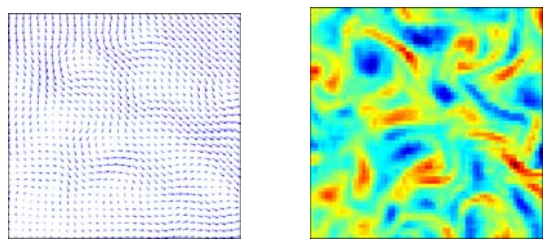

FIG. 7.6. *Groundtruth data u (left) and its curl (right) to be estimated from a corresponding artificially created image sequence. Here u is a superposition of a laminar flow and turbulent vortices.*

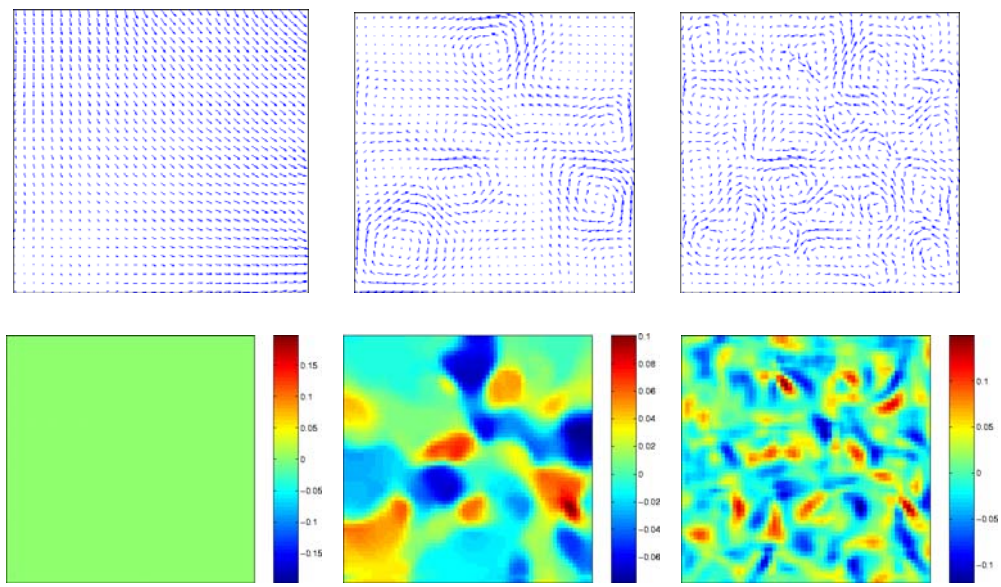

FIG. 7.7. *Estimated and decomposed flow corresponding to Figure* 7.6 *using the $TV - L_2$ approach* (5.2). *Top: u_{const}, u^s, and u^t (left to right). Bottom: ω_{const}, ω^s, and ω^t (left to right).*

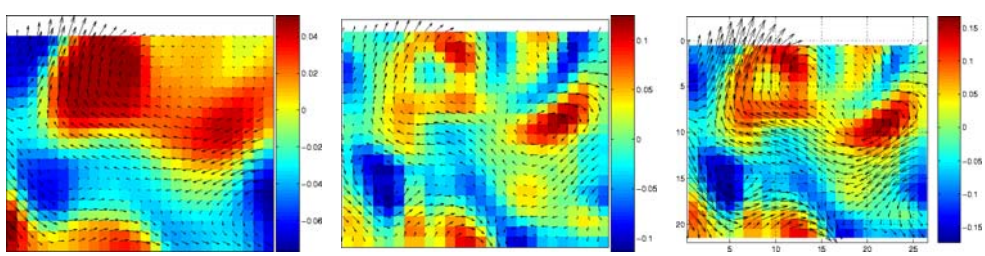

FIG. 7.8. *Close-up view of a section of Figure* 7.7. *From left to right: $\omega^s, \omega^t, \omega^s + \omega^t$ with the corresponding flows as overlays.*

Flow estimation and decomposition. In this section we will validate the flow estimation-decomposition model (5.2). First we create a divergence-free groundtruth flow field u by superimposing a dominant laminar flow with some turbulent vortex structures; see Figure 7.6. Using this flow, an artificial image sequence $\{g\}$ was created.

Figures 7.7 and 7.8 show the decomposition-based optical flow estimates, where

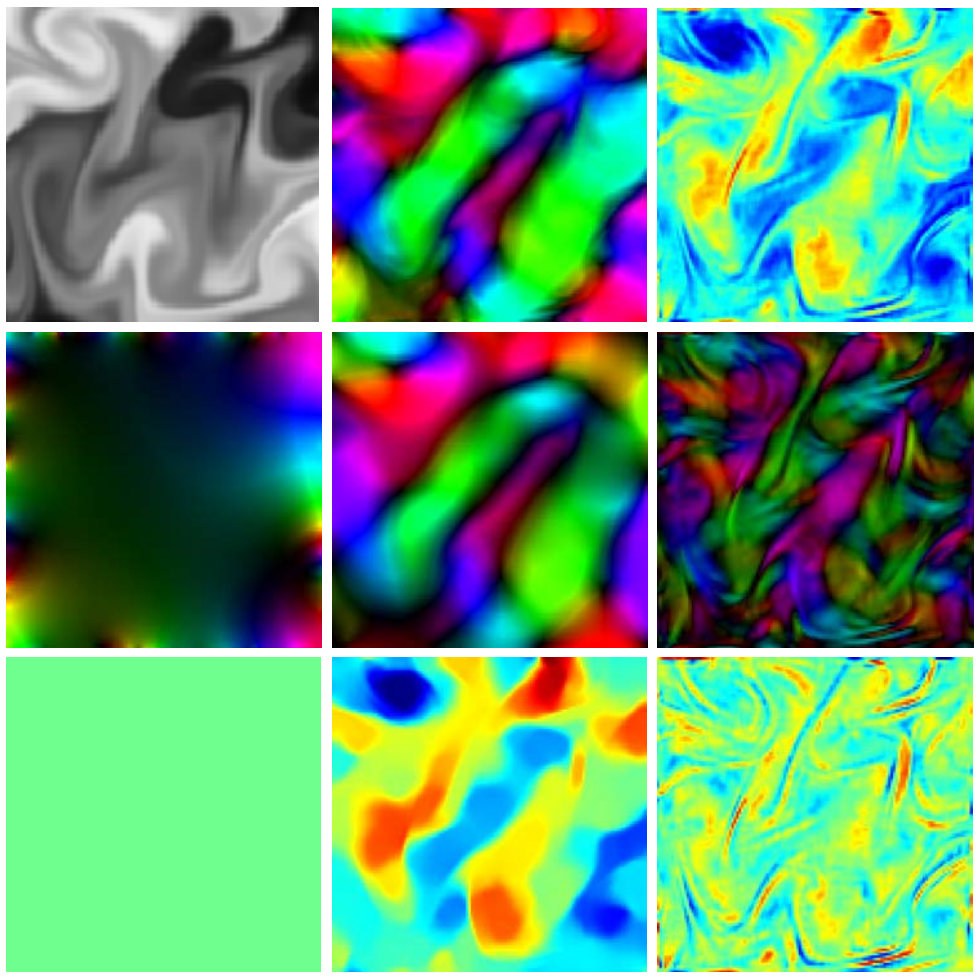

FIG. 7.9. *Top-left: frame of a real image sequence depicting the mixture of fluorescein and water* [18]. *Top-center: the turbulent solenoidal flow estimated by minimizing* (5.2). *Flow vectors are color-coded for better visibility (color* $\simeq$ *direction, magnitude* $\simeq$ *brightness). Top-right: the curl field comprising large-scale patterns immersed in turbulent oscillations. Middle, from left to right:* $u_{\text{const}}, u^s, u^t$. *Note that* u_{const} *contains the (nonvanishing) boundary values, and that* u^s *and* u^t *separate coherent motion patterns and turbulent fluctuations, respectively. Bottom, from left to right: the curl fields* ω_{const}, ω^s, *and* ω^t.

we have used $\lambda_c = 6e^{-5}$ and $\mu_c = 3e^{-4}$. The boundary parameter was chosen slightly smaller than λ_d. The u_{const} component nicely recovers the laminar flow, whereas the structural and textural components reveal the turbulent curl field. Finally, Figure 7.8 gives a close-up view of a section of Figure 7.7.

A real-world example. Figure 7.9 (top-left) shows a sample image of the experimental evaluation of the spreading of a low-diffusivity dye in a two-dimensional turbulent flow, forced at a large scale. The passive scalar is a mixture of fluorescein and water. The divergence of the corresponding flow vanishes. For more details about the experimental setup, we refer to [18].

Figure 7.9 shows the components of the flow and curl field estimated in terms of $\phi_{\text{const}}, \varphi^s, \varphi^t$ by minimizing (5.2) (parameter values: $\lambda_c = 1e^{-4}$, $\mu_c = 3e^{-4}$, $\gamma = 5e^{-4}$). This result clearly demonstrates how the convex constrained optimization

approach allows for estimating complex flows while simultaneously separating large-scale coherent motion patterns from turbulent fluctuations.

Appendix. Additional matrix notation. The extensions $\overline{\mathbb{G}}_1$, $\overline{\mathbb{G}}_2$ of $\overline{\mathbb{G}} = -(\mathbb{D}iv\,_{|H_S^o})^* = \left(\begin{smallmatrix} I_{n-1}\otimes D_{m-1} \\ D_{n-1}\otimes I_{m-1}\end{smallmatrix}\right)$ are given as follows. Let

$$D_m^1 := \begin{pmatrix} -2 & 2 & 0 & \dots & 0 & 0 & 0 \\ 0 & -1 & 1 & \dots & 0 & 0 & 0 \\ & & \ddots & \ddots & \ddots & & \\ 0 & 0 & 0 & \dots & -1 & 1 & 0 \\ 0 & 0 & 0 & \dots & 0 & -2 & 2 \end{pmatrix} \in \mathbb{R}^{m,m+1}$$

and

$$D_m^2 := \begin{pmatrix} -1 & 1 & 0 & \dots & 0 & 0 & 0 \\ -1 & 1 & 0 & \dots & 0 & 0 & 0 \\ 0 & -1 & 1 & \dots & 0 & 0 & 0 \\ & & \ddots & \ddots & \ddots & & \\ 0 & 0 & 0 & \dots & -1 & 1 & 0 \\ 0 & 0 & 0 & \dots & 0 & -1 & 1 \\ 0 & 0 & 0 & \dots & 0 & -1 & 1 \end{pmatrix} \in \mathbb{R}^{m+1,m},$$

and let the diagonal matrices Z_1 and Z_2 be defined by

$$Z_1 := \left(0_{(n-1)m,m-1}, I_{(n-1)(m+1)}, 0_{(n-1)m,m-1}\right),$$

$$Z_2 := \begin{pmatrix} I_{m-1} & 0_{m-1,(n-1)(m+1)} & 0_{m-1,m-1} \\ 0_{(n-1)(m-1),m-1} & I_{n-1}\otimes(0_{m-1,1}, I_{m-1}, 0_{m-1,1}) & 0_{(n-1)(m-1),m-1} \\ 0_{m-1,m-1} & 0_{m-1,(n-1)(m+1)} & I_{m-1} \end{pmatrix},$$

where $0_{m,n}$ is the matrix consisting of $m \times n$ zeros. Then

$$\overline{\mathbb{G}}_1 := \begin{pmatrix} (I_{n-1}\otimes D_m^1)Z_1 \\ (D_n^1\otimes I_{m-1})Z_2 \end{pmatrix}, \quad \overline{\mathbb{G}}_2 := \begin{pmatrix} I_{n-1}\otimes D_{m-1}^2 \\ D_{n-1}^2\otimes I_{m-1} \end{pmatrix}.$$

The matrices S and $\overline{S}$ for the computation of the TV and G norm can be defined using

$$L_m(a) := \begin{pmatrix} \frac{1}{\sqrt{2}}a & 0_{1,m-1} \\ \frac{1}{\sqrt{2}}I_m \end{pmatrix}, \quad R_m(a) := \begin{pmatrix} \frac{1}{\sqrt{2}}I_m \\ 0_{1,m-1} & \frac{1}{\sqrt{2}}a \end{pmatrix}$$

as

$$S := \begin{pmatrix} I_{n-2}\otimes L_{m-3}(0) & 0 \\ I_{n-2}\otimes R_{m-3}(0) & 0 \\ 0 & L_{n-3}(0)\otimes I_{m-2} \\ 0 & R_{n-3}(0)\otimes I_{m-2} \end{pmatrix},$$

$$\overline{S} := \begin{pmatrix} I_{n-1}\otimes L_{m-2}(1) & 0 \\ I_{n-1}\otimes R_{m-2}(1) & 0 \\ 0 & L_{n-2}(1)\otimes I_{m-1} \\ 0 & R_{n-2}(1)\otimes I_{m-1} \end{pmatrix}.$$

A SPARSE DISCRETIZATION FOR INTEGRAL EQUATION FORMULATIONS OF HIGH FREQUENCY SCATTERING PROBLEMS *

DAAN HUYBRECHS† AND STEFAN VANDEWALLE†

Abstract. We consider two-dimensional scattering problems, formulated as an integral equation defined on the boundary of the scattering obstacle. The oscillatory nature of high-frequency scattering problems necessitates a large number of unknowns in classical boundary element methods. In addition, the corresponding discretization matrix of the integral equation is dense. We formulate a boundary element method with basis functions that incorporate the asymptotic behavior of the solution at high frequencies. The method exhibits the effectiveness of asymptotic methods at high frequencies with only few unknowns, but retains accuracy for lower frequencies. New in our approach is that we combine this hybrid method with very effective quadrature rules for oscillatory integrals. As a result, we obtain a sparse discretization matrix for the oscillatory problem. Moreover, numerical experiments indicate that the accuracy of the solution actually increases with increasing frequency. The sparse discretization applies to problems where the phase of the solution can be predicted a priori, for example in the case of smooth and convex scatterers.

Key words. integral equations, high-frequency scattering, oscillatory integrals, steepest descent

1. Introduction.

The accurate numerical modeling of physical problems involving strong oscillations is a challenging problem. Scattering problems in unbounded domains are often modeled by an integral equation defined on the boundary of the scattering obstacle. As such, the problem on an unbounded domain is reduced to a lower-dimensional problem on a bounded domain. Numerically, these are two important advantages. Still, the method has its drawbacks, and difficulties arise as the frequency of the problem increases. Contrary to the case for partial differential equations, the discretization matrix of an integral equation is dense. Furthermore, in order to represent an oscillatory solution, the number of unknowns in a boundary element approach has to be large. Typically, one chooses a fixed number of unknowns per wavelength per dimension. This results in a linear system with a very large and dense discretization matrix. Hence, classical solution methods for scattering problems rapidly become prohibitively expensive [4].

Substantial efforts have been made over the last two decades to overcome these difficulties. One direction has been to improve on the solution time required to solve the dense linear system. The fast multipole method achieves a fast matrix-vector product in $O(N \log N)$ operations, when the number of unknowns N increases at least linearly with the wavenumber [30]. The fast matrix-vector product can be combined with a preconditioned iterative technique for an efficient overall solution algorithm [10]. Another direction is given by a number of asymptotic methods, such as geometrical optics, physical optics, and the geometrical theory of diffraction [17, 23]. A common

characteristic of asymptotic methods is that they have an error of the order $O(k^{-n})$, where k is the wavenumber and where the exponent n is typically equal to 1 or 2. This means that the accuracy of such methods improves with increasing frequencies. Asymptotic methods break down for low to moderate frequencies, however.

A more recent trend is the combination of finite element methods with asymptotic methods. This is achieved by considering basis functions that are, e.g., piecewise polynomial, multiplied by the asymptotic form of the solution at large frequencies. The asymptotic behavior of the solution to the problem of scattering by smooth convex obstacles was analyzed in [27]. Motivated by these results, a hybrid scheme was considered in [1]. The authors report an overall solution method that requires $O(k^{1/3})$ operations as a function of the wavenumber, a huge improvement over the linear dependence on k. The basis functions are piecewise polynomials, multiplied by plane waves in a number of directions. Similar hybrid methods with even better results are proposed in [2, 7, 25, 24, 15, 12]. A number of operations that is independent of the wavenumber, for a fixed error, is achieved by Bruno et al. in [7] for the scattering by smooth convex obstacles, and by Langdon and Chandler-Wilde in [25] for scattering on a half-plane. In the present paper, we combine a similar approach with recent insights into the behavior of oscillatory integrals [21, 19]. As a result, we obtain a small and highly sparse discretization matrix. In addition, the accuracy of the solution actually increases with increasing frequency.

We start the paper in section 2 with a brief review of a suitable quadrature rule for the evaluation of oscillatory integrals that have the general form

$$I[f] := \int_a^b f(x) e^{ikg(x)} \, \mathrm{d}x, \tag{1.1}$$

where both f and g are smooth functions and where the wavenumber k determines the frequency of the oscillations. The review is based on results by Iserles and Nørsett in [21] and by the authors in [19]. We show how Filon-type quadrature rules using derivatives can be constructed that have the form

$$I[f] \approx Q[f] := \sum_{l=0}^{n} \sum_{j=1}^{d_l} w_{l,j} f^{(j)}(x_l) \tag{1.2}$$

such that the accuracy of the rule improves with increasing frequency. This is quite contrary to the rapid deterioration of classical quadrature rules, based on polynomial interpolation, for increasingly oscillatory integrals. The asymptotic order of accuracy as a function of the frequency is $O(k^{-s-1})$, where the value of s depends on the number of derivatives used. This is much like the behavior of truncated asymptotic expansions. However, due to the nature of the constructed rules, the result is exact for an arbitrarily large family of functions regardless of the frequency. The main difference with asymptotic expansions therefore is that there is no breakdown at low frequencies. In general, one can also expect a smaller error for moderate frequencies.

The results of [19] are generalized in section 3 to an appropriately chosen model form

$$I_H[f] := \int_a^b f(x) H_\nu^{(1)}(kg_1(x)) e^{ikg_2(x)} \, \mathrm{d}x,$$

where f, g_1, and g_2 are assumed to be smooth functions. The function $H_\nu^{(1)}(z)$ is the Hankel function of the first kind and order ν; it is an oscillatory function for large

arguments. The model form is chosen to represent the integrals that will appear later in the solution of scattering problems. The resulting quadrature rule has the same form as (1.2). The scattering problem is introduced in section 4. The quadrature rules are subsequently used in the discretization of the oscillatory integral equation in section 5. We identify a setting in which each row of the discretization matrix corresponds to the discretization of a specific one-dimensional oscillatory integral with a known phase. Owing to the small number of quadrature points required for the evaluation of such integrals, the discretization matrix is sparse. The accuracy of the solution improves because the quadrature rules themselves improve for increasing frequencies.

We illustrate the method with numerical results in section 6. We consider the scattering of a plane wave and of a circular wave, by a circle and by an ellipse, respectively. We end the paper with some concluding remarks in section 7.

2. The efficient evaluation of oscillatory integrals. The classical approach for the evaluation of oscillatory integrals is to use a fixed number of quadrature points per wavelength. This automatically leads to a number of operations that scales linearly with the frequency. However, the asymptotic expansion of an oscillatory integral for large frequencies reveals that the value of the integral is actually determined by the behavior of the integrand near a small set of special points [31, 5]. These are the boundary points of the interval, and the so-called *stationary points*.

Consider the oscillatory integral (1.1), where both f and g are smooth functions. We call f the *amplitude*, and g the *oscillator*, of the integral. The stationary points of (1.1) are all solutions ξ to the equation $g'(\xi) = 0$, $\xi \in [a, b]$. A stationary point is said to have *order* r if $g^{(j)}(\xi) = 0$, $j = 1, \ldots, r$, but $g^{(r+1)}(\xi) \neq 0$. The importance of such points lies in the fact that, locally, the integrand does not oscillate near a stationary point. Away from all stationary points and the boundary points a and b, the oscillations of the integrand increasingly cancel out. Hence, such regions do not contribute much to the value of the integral.

Mathematically, this property is reflected in the asymptotic expansion of (1.1). It can be shown that integral (1.1) with one interior stationary point of order r has an asymptotic expansion of the form (see [31])

$$I[f] \sim \sum_{j=0}^{\infty} \frac{c_j[f]}{k^{(j+1)/(r+1)}}, \qquad k \to \infty. \tag{2.1}$$

It is proved in [21] that the first few coefficients $c_j[f]$ of the asymptotic expansion depend only on the first few derivatives of f and g, evaluated at the boundary points and at the stationary points. A number of recent methods exploit this behavior in order to obtain an approximation of $I[f]$ that improves with increasing k [21, 19, 26, 29]. We recall one particularly useful approach, which leads to a quadrature rule with a classical form. We refer the reader to [20] for a more general overview.

2.1. A numerical steepest descent method. A well-known technique for obtaining the asymptotic expansion (2.1) is the method of steepest descent [5, 33]. Justified by Cauchy's integral theorem for analytic functions, the integration path is deformed into a complex integration path that has more desirable properties. Specifically, the new path is chosen such that the integrand is not oscillatory along the path and has exponential decay. The asymptotic expansion can then be derived from the resulting line integrals in the complex plane. Asymptotic expansions have the disadvantage, however, that the error is not controllable for low values of k. Rather than

forming the asymptotic expansion, the line integrals can also be evaluated numerically. This numerical approach leads to a method that improves with increasing k, but that retains accuracy for small values of k [19].

Assume that both f and g are analytic functions. Subdivide the integration interval $[a,b]$ into subintervals $[a_l,b_l]$, $l=1,\dots,L$, such that $g'(x)\neq 0$, $x\in(a_l,b_l)$, i.e., the oscillator g is a monotonic function on $[a_l,b_l]$. Then the inverse of g exists uniquely on $[a_l,b_l]$, and it is also analytic. We denote it by g_l^{-1}. The integral over $[a_l,b_l]$ is evaluated by deforming the integration path into the complex plane. Define the path $h_{x,l}(p)$ by

$$h_{x,l}(p)=g_l^{-1}(g(x)+ip),\qquad x\in[a_l,b_l]. \tag{2.2}$$

This path is called the *path of steepest descent*. It follows immediately from the definition that $e^{ikg(h_{x,l}(p))}=e^{-kp}e^{ikg(x)}$. Hence, the line integral along the new integration path, originating in the point x and terminating in the point $h_{x,l}(P)$, can be written as

$$S_l[f;x]=e^{ikg(x)}\int_0^P f(h_{x,l}(p))h'_{x,l}(p)e^{-kp}\,\mathrm{d}p,\qquad P>0. \tag{2.3}$$

The integrand of (2.3) is not oscillatory and decays exponentially fast. The integral over $[a_l,b_l]$ can now be approximated by $S_l[f;a_l]-S_l[f;b_l]$. In general, the value of $I[f]$ can be approximated by a sum of nonoscillatory line integrals with exponentially small error,

$$I[f]=\sum_{l=1}^{L}\left(S_l[f;a_l]-S_l[f;b_l]\right)+O(e^{-kP}), \tag{2.4}$$

with $P>0$. The larger P, the better the approximation, but for all finite P the error decays exponentially fast as the frequency parameter k increases. In many cases of practical interest, the limit case $P\to\infty$ is possible, and the error $O(e^{-kP})$ vanishes. In that case, decomposition (2.4) is exact.

2.2. A quadrature rule for oscillatory integrals. The decomposition (2.4) can be used to obtain a quadrature rule for $I[f]$ with a classical form. Approximating f by its truncated Taylor series at each point a_l and b_l, we find a quadrature rule using derivatives of the form

$$Q[f]:=\sum_{l=0}^{L}\sum_{j=0}^{d_l}w_{l,j}f^{(j)}(x_l), \tag{2.5}$$

with $x_0=a$, $x_l=b_l$, $l=1,\dots,L$, and with the weights given by

$$\begin{aligned}
w_{0,j}&=S_1\left[\frac{(x-a)^j}{j!};a\right],\\
w_{l,j}&=-S_l\left[\frac{(x-x_l)^j}{j!};x_l\right]+S_{l+1}\left[\frac{(x-x_l)^j}{j!};x_l\right],\quad l=1,\dots,L-1,\\
w_{l,j}&=-S_l\left[\frac{(x-b)^j}{j!};b\right].
\end{aligned}$$

Note that this rule uses only local information of f: its values and derivatives at the endpoints a and b of the integration region and at all the stationary points in

between. Yet the approximation $I[f] \approx Q[f]$ is very accurate and becomes increasingly accurate with increasing values of the frequency parameter k. It can be shown that the first few terms of the asymptotic expansion of the error $I[f] - Q[f]$ vanish. This is due to the fact that these terms depend only on the derivatives of f at exactly the points we consider in the quadrature rule. Hence, the approximation has a high asymptotic accuracy. The exact order depends on the number of derivatives d_l that are used and on the order of the stationary points involved [19].

3. Specialized quadrature rules. The quadrature rule of the previous section applies only to the model integral (1.1). Intuitively, however, one sees that the ideas can be readily generalized to any oscillatory integral. The value of an oscillatory integral is determined by the behavior of the integrand near the endpoints of the integration interval, and near the points where the integrand locally does not oscillate. In order to construct similar quadrature rules, one requires knowledge of the phase of the integral. In this section, we will construct such rules for a family of integrals that will arise in the scattering problem discussed later. In particular, the integrand involves an oscillatory Hankel function.

3.1. A generalized model form. Consider the oscillatory integral

$$I_H[f] = \int_a^b f(x) H_\nu^{(1)}(k g_1(x)) e^{ikg_2(x)} \, \mathrm{d}x, \tag{3.1}$$

where f, g_1, and g_2 are smooth functions and $H_\nu^{(1)}(z)$ is the Hankel function of the first kind of order ν. The Hankel function of order zero, $H_0^{(1)}(z)$, has a logarithmic singularity at $z = 0$. Hankel functions of higher order have algebraic singularities of the form $1/z^\nu$, $z \to 0$ [3].

For large arguments, the Hankel functions behave like an oscillatory complex exponential with a decaying amplitude,

$$H_\nu^{(1)}(z) \sim \sqrt{\frac{2}{\pi z}} e^{i(z - \frac{1}{2}\nu\pi - 1/4\pi)}, \qquad -\pi < \arg z < \pi, \quad |z| \to \infty. \tag{3.2}$$

Hence, the oscillator of the integrand of (3.1) is approximately given by

$$g(x) = g_1(x) + g_2(x), \tag{3.3}$$

up to the addition of a constant. The Hankel function decays exponentially fast for complex arguments with a positive imaginary part, as can be seen from the asymptotic behavior (3.2). This means that the approach of section 2.2 using the path of steepest descent is applicable. Hence, we conjecture that a quadrature rule exists of the form

$$I_H[f] \approx Q_H[f] := \sum_{l=0}^{L} \sum_{j=0}^{d_l} w_{l,j}^H f^{(j)}(x_l). \tag{3.4}$$

In the remainder of the section, we will prove this conjecture, determine the quadrature abscissae x_l, and show how the weights can be computed efficiently.

3.2. Construction of the quadrature rule. We start by stating some assumptions on the functions f and g, which are needed to guarantee the integrability and analyticity of the integrand in (3.1). First, we assume that f is analytic in an open complex neighborhood D of $[a, b]$, so that $[a, b] \subset \operatorname{int} D$. Likewise, we assume

that g_1 and g_2 are nonsingular and analytic in D, except possibly along a branch cut that extends from a or b to the boundary of the region D; i.e., a and b may be branch points but not singular points. We assume furthermore that $g(x)$, defined by (3.3), is strictly monotonic on the open interval (a, b) and hence invertible, but possibly $g'(a) = 0$ or $g'(b) = 0$. Also, we assume that $g_1(x) \neq 0$, $x \in (a, b)$. Finally, if $\nu > 0$ and $g_1(\xi) = 0$, we assume that f behaves like

$$f(x) \sim (x - \xi)^{\nu - 1 + \epsilon}, \quad x \to \xi, \quad \text{with} \quad \epsilon > 0. \tag{3.5}$$

Condition (3.5) guarantees that the integrand of $I_H[f]$ is integrable. Subject only to condition (3.5) and the analyticity requirements, the integration interval of (3.1) can always be split into a number of subintervals that satisfy the conditions. The assumptions guarantee that the integrand of $I_H[f]$ is analytic on $[a, b]$ except possibly in the points a and b. In particular, this will allow us to apply Cauchy's integral theorem to select the integration path of (3.1).

THEOREM 3.1. *Under the assumptions stated above, the integral $I_H[f]$ can be approximated by a sum of contributions*

$$I_H[f] = S^H[f; a] - S^H[f; b] + O(e^{-kP}), \tag{3.6}$$

with $P > 0$, and with the contributions given by the integrals

$$S^H[f; x] = \int_0^P f(h_x(p)) H_\nu^{(1)}(k g_1(h_x(p))) e^{ikg_2(h_x(p))} h_x'(p) \, \mathrm{d}p, \tag{3.7}$$

where $h_x(p)$ satisfies

$$g(h_x(p)) = g(x) + ip. \tag{3.8}$$

The proof is almost identical to the proof of Lemma 4.1 in [18] and is omitted; it differs mainly in the special treatment of the Hankel function based on the asymptotic expression (3.2).

We note from the asymptotic behavior (3.2) that the integrand of the line integral $S^H[f; x]$ in (3.7) is nonoscillatory and exponentially decaying in the integration variable p,

$$H_\nu^{(1)}(k g_1(h_x(p))) e^{ikg_2(h_x(p))} \sim \sqrt{\frac{2}{\pi k g_1(h_x(p))}} e^{ikg(x)} e^{i(-\frac{1}{2}\nu\pi - 1/4\pi)} e^{-kp}, \qquad k \to \infty.$$

The size of the constant P is related to the size of the region of analyticity of f and g [18]. In the numerical examples of the scattering problem, given in section 6, we can in fact consider the limit case $P = \infty$. The error of decomposition (3.6) then vanishes even at low frequencies.

We proceed in a way similar to that in section 2.2. Since f is analytic in D, it has an absolutely convergent Taylor series. By the linearity of S^H, we may write

$$S^H[f; x_0] = \sum_{j=0}^{\infty} f^{(j)}(x_0) S^H \left[\frac{(x - x_0)^j}{j!}; x_0 \right].$$

Now, consider a subdivision of $[a, b]$ into subintervals $[a_l, b_l]$, $l = 1, \ldots, L$, such that on each subinterval the conditions of Theorem 3.1 are satisfied. Truncating the Taylor

series of f at each special point a_l and b_l after a finite number of terms, we arrive at a quadrature rule $Q_H[f]$ of the form (3.4), with weights given by

$$w_{0,j}^H = S_1^H \left[\frac{(x-a)^j}{j!}; a \right], \tag{3.9}$$

$$w_{l,j}^H = -S_l^H \left[\frac{(x-x_l)^j}{j!}; x_l \right] + S_{l+1}^H \left[\frac{(x-x_l)^j}{j!}; x_l \right], \quad l = 1, \ldots, L-1, \tag{3.10}$$

$$w_{l,j}^H = -S_l^H \left[\frac{(x-b)^j}{j!}; b \right]. \tag{3.11}$$

The weights can be explicitly computed very efficiently, by using Gauss–Laguerre quadrature or similar techniques [11]. The accuracy of these methods improves rapidly as a function of k, due to the faster decay of the integrands as k increases. For the purposes of our application, this advantageous characteristic is not needed. It suffices already that the number of operations for a fixed accuracy is bounded with respect to k. We therefore choose to focus on the convergence properties of the quadrature rule itself, rather than on the convergence of methods to compute the weights.

3.3. Convergence properties of the quadrature rule. We discuss the properties of the quadrature rule $Q_H[f]$, with weights given by (3.9)–(3.11), as a function of k. The rule is exact by construction for polynomials of degree less than or equal to

$$p = \min_l d_l. \tag{3.12}$$

For more general functions, the accuracy as a function of k is determined by the asymptotic size of the weights. We will show that the size of the weights decreases both with increasing frequency and with increasing order of the corresponding derivative. The order of accuracy of the quadrature rule is therefore equal to the asymptotic size of the first weight that is discarded by truncation. In order to quantify this size, we require a few technical lemmas.

LEMMA 3.2. *Assume that x_0 is a stationary point that has order r. The parameterization of the path* (3.8) *behaves as*

$$h_{x_0}(p) = x_0 + O(p^{1/(r+1)}), \qquad p \to 0, \tag{3.13}$$

$$h'_{x_0}(p) = O(p^{1/(r+1)-1}), \qquad p \to 0. \tag{3.14}$$

Proof. Since $g^{(j)}(x_0) = 0$, $j = 1, \ldots, r$, we can write the Taylor series of g as

$$g(x) = g(x_0) + g^{(r+1)}(x_0) \frac{(x-x_0)^{r+1}}{(r+1)!} + O((x-x_0)^{r+2}).$$

The path $h_{x_0}(p) = g^{-1}(g(x_0) + ip)$ solves $g(h_{x_0}(p)) = g(x_0) + ip$, and hence

$$h_{x_0}(p) \sim x_0 + \sqrt[r+1]{\frac{ip(r+1)!}{g^{(r+1)}(x_0)}}, \qquad p \to 0. \tag{3.15}$$

The second result follows by differentiation. Note that the complex root is multivalued: the correct root is selected by using the analytic continuation of the inverse g_i^{-1} that satisfies $g_i^{-1}(g(x)) = x$ on $[a_i, b_i]$ in expression (3.8). ∎

The size of the weights follows from the size of the line integrals $S^H[\frac{(x-x_0)^j}{j!}; x_0]$. Recall that the integral may be singular if $g_1(x) = 0$. We will assume for the sake

of brevity that, in that case, $g_1'(x) \neq 0$. This condition is always satisfied by the applications in section 6.

LEMMA 3.3. *Let $S^H, [f;x]$ be defined by* (3.7) *with $P = \infty$, and g defined by* (3.3). *Assume that $g'(x_0) \neq 0$; i.e., x_0 is not a stationary point. If $g_1(x_0) \neq 0$, we have*

$$\left|S^H[(x-x_0)^j; x_0]\right| = O(k^{-j-3/2}), \qquad k \to \infty.$$

If $g_1(x_0) = 0$ and $g_1'(x_0) \neq 0$, the integral is singular and we have

$$\left|S^H[(x-x_0)^j; x_0]\right| = O(k^{-j-1}), \qquad j \geq \nu, \quad k \to \infty.$$

Proof. We write the integral $S^H[(x-x_0)^j; x_0]$ as

$$S^H[(x-x_0)^j; x_0] = \int_0^\infty u(p) e^{-kp}\, \mathrm{d}p = \frac{1}{k} \int_0^\infty u(q/k) e^{-q}\, \mathrm{d}q, \tag{3.16}$$

with

$$u(p) = (h_{x_0}(p) - x_0)^j h_{x_0}'(p) H_\nu^{(1)}(k g_1(h_{x_0}(p))) e^{ikg_2(h_{x_0}(p))} e^{kp}. \tag{3.17}$$

It is a consequence of Watson's lemma that the asymptotic expansion of the integral can be obtained by integrating the asymptotic expansion of $\frac{1}{k}u(q/k)$ as $k \to \infty$, term by term in (3.16) [5, 32]. Generalizing Watson's lemma, this remains true for integrals of the form $\int_0^\infty u(p)h(kp)dp$, where $h(z) \sim \log(z)^n z^s e^{-z}$, $n \geq 0$, $s \in \mathbb{Z}$, $z \to 0$, if the integrand is integrable [6]. This means that the singularity of the Hankel function has no influence on the asymptotic expansion.

First, consider the case $g_1(x_0) \neq 0$. Then, combining the asymptotic behavior of the Hankel function for large arguments, (3.2), with the results (3.13)–(3.14) of Lemma 3.2 for $r = 0$, we have $u(q/k) \sim k^{-j-1/2}$. From (3.16) we can conclude $|S^H[(x-x_0)^j; x_0]| = O(k^{-j-3/2})$.

Next, consider the case $g_1(x_0) = 0$. If $g_1'(x_0) \neq 0$, then we have $g_1(h_{x_0}(p)) \sim p^{1/(r+1)} = p$. It follows that $H_\nu^{(1)}(k g_1(h_{x_0}(q/k))) = O(1)$, $k \to \infty$. Hence, by the generalization of Watson's lemma, we may conclude $|S^H[(x-x_0)^j; x_0]| = O(k^{-j-1})$, $j \geq \nu$. ∎

The corresponding lemma for stationary points is very similar. The difference is due to the different behavior of the parameterization as described by Lemma 3.2.

LEMMA 3.4. *Let $S^H[f;x]$ be defined by* (3.7) *with $P = \infty$, and g defined by* (3.3). *Assume that x_0 is a stationary point of order r. If $g_1(x_0) \neq 0$, then we have*

$$x\left|S^H[(x-x_0)^j; x_0]\right| = O(k^{-(j+1)/(r+1)-1/2}), \qquad k \to \infty.$$

If $g_1(x_0) = 0$ and $g_1'(x_0) \neq 0$, then we have

$$\left|S^H[(x-x_0)^j; x_0]\right| = O(k^{-(j+1+r/2)/(r+1)}), \qquad j \geq \nu, \quad k \to \infty.$$

Proof. Consider again the function $u(p)$, given by (3.17). Assume first that $g_1(x_0) \neq 0$. We have $(h_{x_0}(q/k) - x_0)^j \sim k^{-j/(r+1)}$ and $h_{x_0}'(q/k) \sim k^{r/(r+1)}$. Since $k g_1(h_{x_0}(q/k)) \sim k g_1(h_{x_0}(0)) = k g_1(x_0)$, we also have $H_\nu^{(1)}(k g_1(h_{x_0}(q/k))) \sim k^{-1/2}$. Combined in (3.16), and by applying Watson's lemma, this yields the first result.

The case where $g_1(x_0) = 0$ is slightly different. Since $g_1'(x_0) \neq 0$, we have $g_1(h_{x_0}(q/k)) \sim k^{-1/(r+1)}$ and hence $k g_1(h_{x_0}(q/k)) \sim k^{r/(r+1)}$. The Hankel function therefore yields the factor $k^{-(r/2)/(r+1)}$ instead of $k^{-1/2}$ as in the first case. ∎

TABLE 3.1
Absolute error of the approximation of $I_H[f]$ by $Q_H[f]$, with $f(x) = \cos(x-1)$, $g_1(x) = x$, and $g_2(x) = x^2 + x^3 - x$. The last row shows the value of $\log_2(e_{400}/e_{800})$: this value should approximate $d_0/2 + 5/4$ (shown in parentheses).

$k \setminus d_0$	0	1	2	3
100	$1.2E-3$	$2.8E-5$	$1.3E-6$	$2.6E-8$
200	$5.1E-4$	$8.6E-6$	$2.9E-7$	$4.1E-9$
400	$2.2E-4$	$2.6E-6$	$6.4E-8$	$6.2E-10$
800	$9.3E-5$	$7.8.1E-7$	$1.4E-8$	$9.7E-11$
rate	1.23 (1.25)	1.73 (1.75)	2.20 (2.25)	2.68 (2.75)

The convergence of the quadrature rule (3.4) as a function of k can now be established. Note that the results of Lemma 3.3 agree with those of Lemma 3.4 if we take the order of a regular point to be $r = 0$. Hence, we need not distinguish between stationary points and regular (end)points.

LEMMA 3.5. *The error of the approximation of $S_l^H[f; x_0]$, $x_0 \in [a_l, b_l]$, is*

(3.18)
$$\left|S_l^H[f;x_0] - Q_l^S[f;x_0]\right| := \left|S_l^H[f;x_0] - \sum_{j=0}^{d_l} w_{l,j}^H f^{(j)}(x_0)\right| = O(k^{-\alpha_l}), \qquad k \to \infty.$$

If $g_1(x_0) \neq 0$, then $\alpha_l := (d_l + 2)/(r+1) - 1/2$. If $g_1(x_0) = 0$ and $g_1'(x_0) \neq 0$, then $\alpha_l := (d_l + 2 + r/2)/(r+1)$.

Proof. Since the weights decay as a function of k, and as a function of the order of derivative j, the error of the quadrature scheme is asymptotically determined by the size of the first discarded weight. The result follows from Lemmas 3.3 and 3.4 by setting $j = d_l + 1$. ∎

The theorem that characterizes the accuracy of the complete quadrature rule follows immediately.

THEOREM 3.6. *Consider the approximation of $I_H[f]$ by $Q_H[f]$. The error has asymptotic order $\alpha = \min_l \alpha_l$, where α_l is specified in Lemma 3.5.*

As an example, we consider the integral $\int_0^1 \cos(x-1) H_0^{(1)}(kx) e^{ik(x^2+x^3-x)}\,\mathrm{d}x$. The total oscillator for this integral is $g(x) = x^2 + x^3$. There are two quadrature points: there is a singularity and a stationary point of order 1 at $x = 0$, and a regular endpoint at $x = 1$. The weights $w_{0,j}^H$ and $w_{1,j}^H$ are given by (3.9) and (3.11), respectively. From Lemma 3.4 we have $|w_{0,j}^H| = O(k^{-(j+1)/2-1/4})$, and from Lemma 3.3 we have $|w_{1,j}^H| = O(k^{-j-3/2})$. Using d_0 and d_1 derivatives, the error has order $\min\{O(k^{-(d_0+2)/2-1/4}), O(k^{-(d_1+1)-3/2})\}$ by Theorem 3.6. We choose $d_1 = \max\{0, \lceil (2d_0 - 5)/4 \rceil\}$ to match the errors. Table 3.1 shows the convergence of the quadrature rule $Q_H[f]$ as a function of k and d_0.

4. High-frequency scattering problems.

4.1. Problem statement. We are interested in the solution of the two-dimensional Helmholtz equation

$$\Delta u + k^2 u = 0 \tag{4.1}$$

in the domain $\Omega^+ = \mathbb{R}^2 \setminus \overline{\Omega}$ that is exterior to the open domain Ω, subject to a Dirichlet boundary condition $u = 0$ on the boundary $\Gamma = \partial\Omega$. We assume that a periodic parameterization for Γ is given by

$$\kappa(\tau) : [0,1] \to \Gamma \subset \mathbb{R}^2, \tag{4.2}$$

with $|\nabla\kappa(\tau)| > 0$. The Helmholtz equation models the scattering of time-harmonic waves of the form $u(x)e^{-i\omega t}$. In the absence of damping we have $k = \omega/c$, with c the speed of propagation. For the scattering of an incoming acoustic or electromagnetic wave $u^i(x)$ by the obstacle Ω, the solution can be written as $u = u^i + u^s$. The function $u^s(x)$ represents the scattered wave; it satisfies the Helmholtz equation with the Dirichlet boundary condition $u^s(x) = -u^i(x)$ on Γ.

The scattered wave can be represented in terms of the *single-layer potential*,

$$(Sq)(x) = \int_\Gamma K(x,y)q(y)\,\mathrm{d}s_y, \qquad \text{with} \quad K(x,y) = \frac{i}{4}H_0^{(1)}(k|x-y|), \tag{4.3}$$

where $q(x)$ is the *density function* defined on the boundary Γ, and where $K(x,y)$ is the Green's function of the two-dimensional Helmholtz equation. The scattered wave due to an incoming wave u^i is given by $u^s = -Sq$ if the density function $q(x)$ is found as the solution to the combined potential integral equation

$$\frac{q(x)}{2} + \int_\Gamma \left(\frac{\partial K}{\partial n_x}(x,y) + i\eta K(x,y)\right) q(y)\,\mathrm{d}s_y = \frac{\partial u^i}{\partial n}(x) + i\eta u^i(x), \quad x \in \Gamma, \tag{4.4}$$

where n_x is used to denote the normal with respect to the variable x. Equation (4.4) is uniquely solvable for all values of the wavenumber k [8].

An important observation is that $q(x) = \frac{\partial u}{\partial n}(x)$; i.e., the density function is exactly the (exterior) normal derivative of the solution to the Helmholtz problem. This means that the solution to (4.4) is directly related to a physical property of the problem. For example, in electromagnetics, the normal derivative of the electric field is proportional to the induced current on the surface of the conducting obstacle [28].

4.2. High-frequency integral equation formulation. The density function $q(x)$ is highly oscillatory for large values of the wavenumber k. The solution of (4.4) therefore generally requires a large number of unknowns. In some cases, however, one has a priori information about the phase of the solution. For example, if the obstacle is convex, and if the incoming wave is a plane wave, then the phase of the solution q is approximately the same as the phase of the incoming wave. Assume that the incoming wave is given by $u^i(x) = u_s^i(x)e^{ikg^i(x)}$. Then we can write

$$q(\kappa(t)) = q_s(t)e^{ikg^i(\kappa(t))}, \qquad t \in [0,1], \tag{4.5}$$

where $q_s(t)$ is a function that is less oscillatory than $q(\kappa(t))$, in a sense that will be made more precise in section 4.3. In physical terms, the oscillations of the induced current on a perfectly conducting surface tend to follow the oscillations of the incoming electromagnetic wave. This is the main reason why the problem is formulated such that the solution $q(x)$ corresponds to a physical variable—only in that case is the phase known in the form of (4.5). This was noted in [7]; the integral equation formulation of this section follows the same pattern as in [7].

Substituting the ansatz (4.5) into (4.4) leads to the integral equation of the second kind

$$\frac{1}{2}q_s(t)e^{ikg^i(\kappa(t))} + \int_0^1 G(t,\tau)q_s(\kappa(\tau))e^{ikg^i(\kappa(\tau))}\,\mathrm{d}\tau = v^i(\kappa(t)), \tag{4.6}$$

with

$$G(t,\tau) := \left(\frac{\partial K}{\partial n_x}(\kappa(t),\kappa(\tau)) + i\eta K(\kappa(t),\kappa(\tau))\right)|\nabla\kappa(\tau)|,$$

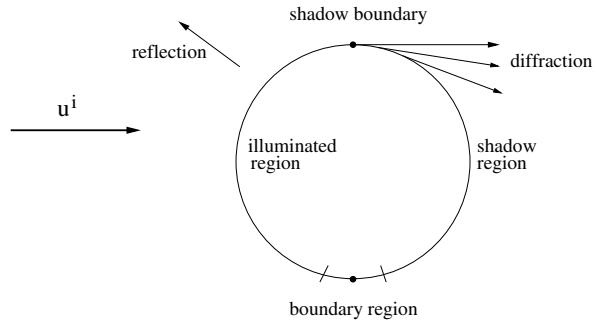

FIG. 4.1. *Reflection and diffraction effects in the scattering of an incoming wave u^i by a smooth and convex obstacle.*

and with the right-hand side given by

$$v^i(x) := \frac{\partial u^i}{\partial n}(x) + i\eta u^i(x).$$

The unknown in (4.6) is the function $q_s(t)$. Since $q_s(t)$ is less oscillatory than the original density function $q(\kappa(t))$, one can solve (4.6) using a coarser discretization. In the next section, we discuss the remaining oscillatory behavior of $q_s(t)$.

4.3. Asymptotic behavior of the solution. In the past decades, a lot of effort has been invested in studying the asymptotic behavior of the solution $q(x)$ to (4.4) as a function of the wavenumber, concentrating mainly on the scattering of a plane wave (see, e.g.,[23, 27] and references therein). For smooth and convex obstacles, there are three important regions with different properties, illustrated in Figure 4.1: the illuminated region, the shadow region, and the transitional shadow boundary region. In the illuminated region, the scattered wave is described asymptotically by geometrical optics: a wave is reflected such that the angle of incidence and the angle of reflection are identical. A wave tangential to the shadow boundary is diffracted. The density function decays rapidly away from the shadow boundary into the shadow region, due to the continuous emission of diffracted waves. In the shadow region the function $q(x)$ approaches zero as k increases.

The asymptotic expansion of $q_s(t)$ for large k reflects these three regions. Assume an incoming plane wave in the direction α of the form $u^i(x) = e^{ik\alpha\cdot x}$, with $|\alpha| = 1$. It was proved in [27] that $q_s(t)$ has a uniform asymptotic expansion of the form

$$q_s(t) \sim \sum_{m,n\geq 0} k^{2/3-n-2m/3} b_{m,n}(\alpha,t)\Psi^{(n)}(k^{1/3}Z(\alpha,t)), \tag{4.7}$$

which remains valid as t crosses the shadow boundaries. The shadow boundary points can be characterized here by $\alpha\cdot\nu = 0$, with ν the exterior normal to Ω. For a thorough discussion and analysis of this expansion, we refer the reader to [12]. Here, we only recall the main characteristics of the expansion, as a means to motivate the choices that are made later on.

The function $Z \in C^\infty$ is infinitely smooth and has a simple root at the two shadow boundary points. The function Z is positive when $\alpha\cdot\nu < 0$, i.e., in the illuminated region, and it is negative in the shadow region. The function $\Psi(z)$ is smooth for positive arguments, with

$$\Psi(z) \sim z, \qquad z \to \infty, \tag{4.8}$$

and it is decaying rapidly but in an oscillatory manner for large negative arguments. It follows that the function $q_s(t)$ is smooth in the illuminated region but may be oscillatory in the shadow region, corresponding to the behavior of $\Psi(z)$ for large positive arguments and large negative arguments, respectively. One can also deduce the following asymptotic properties from the leading order of (4.7):

$$|q_s(t)| = \begin{cases} O(k), & \text{illuminated region,} \\ O(k^{2/3}), & \text{shadow boundary.} \end{cases} \tag{4.9}$$

There is a k-dependent transition region near the shadow boundary. Motivated by (4.7), we introduce a transition region of size $O(k^{-1/3})$ around the shadow boundary points, and define the shadow boundary regions as

$$T_{B1}(k) = [t_{sb1} - D_1 k^{-1/3}, t_{sb1} + C_1 k^{-1/3}], \tag{4.10}$$

$$T_{B2}(k) = [t_{sb2} - C_2 k^{-1/3}, t_{sb2} + D_2 k^{-1/3}], \tag{4.11}$$

with constants $C_1, C_2, D_1, D_2 > 0$ independent of k, but small enough such that $T_{B1}(k)$ and $T_{B2}(k)$ are nonoverlapping, and with t_{sb1} and t_{sb2} the locations of the two shadow boundary points in the parameter domain $[0, 1]$. The illuminated region is defined as

$$T_I(k) = (t_{sb1} + C_1 k^{-1/3}, t_{sb2} - C_2 k^{-1/3}). \tag{4.12}$$

The shadow region is the remaining part of the interval $[0, 1]$.

The size of the transition region is related to the behavior of the argument $k^{1/3} Z(\alpha, t)$ of the function $\Psi(z)$ in (4.7). Because $Z(\alpha, t)$ has a simple zero at t_{sb1}, we have

$$Z(\alpha, t) \approx Z'(\alpha, t_{sb1})(t - t_{sb1}), \qquad t \to t_{sb1}.$$

Hence, there exists a constant c such that for sufficiently large k we have

$$|k^{1/3} Z(\alpha, t)| \leq c \qquad \text{if } t \in T_{B1}(k). \tag{4.13}$$

A similar bound holds for the region $T_{B2}(k)$. Since the oscillations of $q_s(t)$ originate in the oscillatory behavior of $\Psi(z)$ for negative arguments, the meaning of the bound (4.13) is that the number of oscillations of $q_s(t)$ in the shadow boundary region $T_{B1}(k)$ is bounded in k.

Remark 4.1. The remaining oscillatory behavior of $q_c(t)$ in the shadow boundary region indicates that the oscillations of the incoming wave do not completely describe the oscillatory behavior of $q(x)$. Still, we will see that the ansatz (4.5) is suitable for further computations.

5. A hybrid high-frequency boundary element method. The collocation of integral equation (4.6) in a point x_n leads to a one-dimensional and oscillatory integral in the integration variable τ. In this section, we show how an efficient quadrature rule can be used for the discretization of that collocation integral. First, we discuss the classical boundary element approach in section 5.1. The application of specialized quadrature rules, leading to a highly sparse discretization matrix, is described in section 5.2. We comment on the location of the quadrature points section 5.3 and on the limitations of the approach in section 5.4. It turns out that the quadrature rule can not be applied everywhere. Finally, we arrive at a method combining a sparse discretization with a dense part in section 5.5.

5.1. Collocation approach for the discretization. Consider a collocation scheme for integral equation (4.6), with a set of N distinct collocation points $x_n = \kappa(t_n)$, $t_n \in [0,1]$, $n = 1,\dots,N$. The classical way to proceed is to look for an approximation q_c to solution q_s in the form

$$q_c(t) = \sum_{m=1}^{N} c_m \phi_m(t), \tag{5.1}$$

where the ϕ_m functions are a set of linearly independent basis functions with support $\Omega_m := \mathrm{supp}(\phi_m)$. The number of basis functions may be small, since the exact solution q_s is not very oscillatory. Collocating (4.6) in the points t_n, with q_s replaced by q_c, leads to the equations

$$\frac{1}{2} q_c(t_n) e^{ikg^i(x_n)} + \int_0^1 G(t_n,\tau) q_c(\tau) e^{ikg^i(\kappa(\tau))}\,\mathrm{d}\tau = v^i(x_n), \qquad n = 1,\dots,N. \tag{5.2}$$

The collocation approach therefore leads to a linear system $Ac = b$ of size $N \times N$, where the elements of the discretization matrix A are given by

$$A_{n,m} = \frac{1}{2}\phi_m(t_n) e^{ikg^i(\kappa(t_n))} + \int_{\Omega_m} G(t_n,\tau) e^{ikg^i(\kappa(\tau))} \phi_m(\tau)\,\mathrm{d}\tau, \tag{5.3}$$

and the right-hand side by $b_n = v^i(x_n)$. The discretization matrix A is dense, but small compared to the classical boundary element discretization for the original equation. Hence, this is a big improvement over the direct discretization of (4.4). Since the elements (5.3) are given by oscillatory integrals, they can be computed efficiently using the numerical steepest descent technique described in section 2.1. This would yield an efficient total solution method, which remains efficient when k increases, but that is also accurate for small values of k.

However, there are still some issues associated with this approach. Since the matrix is dense, the method requires the evaluation of N^2 integrals. Although N may be rather small, the computational cost can still be high. Interestingly, it was observed in [16] that many of the elements are small and can in fact be discarded, reducing the computation time. A second, more important issue is that the results of [16] indicate that the error of the scheme increases with increasing wavenumber. Here, we examine a different discretization of (5.2) that aims to address these issues, based on the quadrature rule developed in section 3 and motivated by the accuracy of this rule for high wavenumbers. Owing to the small number of required quadrature points, the resulting discretization matrix will be highly sparse.

5.2. The application of specialized quadrature rules. Based on the collocation integral (5.2), we define the following general oscillatory integral:

$$I_c[f;t_n] := \int_0^1 f(\tau) G(t_n,\tau) e^{ikg^i(\kappa(\tau))}\,\mathrm{d}\tau. \tag{5.4}$$

The oscillatory function $G(t,\tau)$ in the integrand is given explicitly by

$$\begin{aligned} G(t,\tau) = &-\frac{i}{4} k \frac{\nabla\kappa(\tau)\cdot(\kappa(t)-\kappa(\tau))}{|\kappa(t)-\kappa(\tau)|} |\nabla\kappa(\tau)| H_1^{(1)}(k|\kappa(t)-\kappa(\tau)|) \\ &-\frac{\eta}{4} |\nabla\kappa(\tau)| H_0^{(1)}(k|\kappa(t)-\kappa(\tau)|). \end{aligned}$$

Choosing $\eta = k$, this function can further be written as

$$G(t,\tau) = a(\tau)kH_0^{(1)}(k|\kappa(t)-\kappa(\tau)|) + b(t,\tau)kH_1^{(1)}(k|\kappa(t)-\kappa(\tau)|), \tag{5.5}$$

with functions $a(\tau)$ and $b(t,\tau)$ that are independent of k. Hence, integral (5.4) can be written as a sum of two model integrals of the form $I_H[f]$, involving Hankel functions, multiplied by k. Both model integrals have the same oscillator,

$$g(\tau;t_n) := |\kappa(t_n)-\kappa(\tau)| + g^i(\kappa(\tau)). \tag{5.6}$$

In particular, this means that one can find a quadrature rule such that

$$I_c[f;t_n] \approx Q_c[f;t_n] := \sum_{l=0}^{L_n}\sum_{j=0}^{d_{n,l}} w^c_{n,l,j} f^{(j)}(\tau_{n,l}). \tag{5.7}$$

The rule $Q_c[f;t_n]$ is computed as follows:

- The weights $w^c_{n,l,j}$ are given by the expressions (3.9)–(3.11) for the weights $w^H_{l,j}$ of the model integral, with the line integrals $S^H[f;x]$ replaced by

$$S^c[f;x] := \int_0^P f(h_x(p))G(t_n,h_x(p))e^{ikg^i(\kappa(h_x(p)))}h_x'(p)\,\mathrm{d}p, \tag{5.8}$$

  where the integration path is the path of steepest descent corresponding to the oscillator (5.6). Compared to $S^H[f;x]$, we have included the additional factors $ka(\tau)$ and $kb(t,\tau)$ from (5.5) into the weight function of the integral. We note that it implies the assumption that $\kappa(\tau)$ is analytic. The scaling by a factor k reduces the asymptotic order, based on the absolute error, by 1.
- The quadrature points $\tau_{n,l}$ are found from the oscillator (5.6). They are the points where the integrand becomes singular (and hence nonanalytic) and the stationary points of the oscillator $g(\tau;t_n)$. These points are derived by a straightforward but technical analysis of $g(\tau;t_n)$. There are no contributing endpoints, as the integrand is periodic on the closed curve Γ.

We now describe how the quadrature rule (5.7) can be used in the discretization. The derivatives of q_c can be written in terms of the basis functions ϕ_m,

$$q_c^{(j)}(\tau) = \sum_{m=1}^{N} c_m \phi_m^{(j)}(\tau). \tag{5.9}$$

Hence, applying the quadrature rule to q_c yields a matrix B with entries

$$B_{n,m} = \begin{cases} \sum_{l:\tau_{n,l}\in\Omega_m}\sum_{j=0}^{d_{n,l}} w^c_{n,l,j}\phi_m^{(j)}(\tau_{n,l}), & \exists l\in[0,L_n]:\tau_{n,l}\in\Omega_m, \\ 0 & \text{otherwise.} \end{cases} \tag{5.10}$$

The entry $B_{n,m}$ is nonzero only if at least one quadrature point $\tau_{n,l}$ exists that lies in the support of the basis function ϕ_m. The number of nonzero points therefore depends on the size of the supports of the basis functions. If all basis functions are local, then the matrix B is highly sparse.

Remark 5.1. The asymptotic order of quadrature rule (5.7) is limited by the number of derivatives $d_{n,l}$ that are used, as described by Theorem 3.6. In turn, note from (5.9) that $d_{n,l}$ is limited by the number of derivatives that exist for the chosen basis functions.

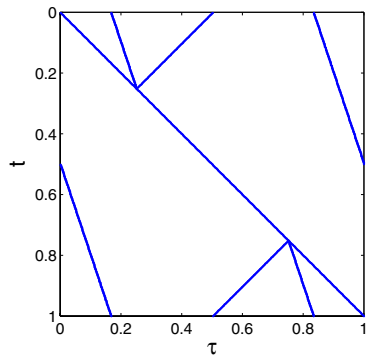

FIG. 5.1. *The location of the contributing points of the collocation integral for the scattering of a plane wave by a circular obstacle. Each row corresponds to a fixed value* $t \in [0, 1]$*, with the shadow boundary points at* 0.25 *and* 0.75*, and the illuminated region in between. The singular points are located along the diagonal. The off-diagonal points correspond to stationary points.*

5.3. Location of the quadrature points. The location of the quadrature points is illustrated in Figure 5.1 for the scattering of a plane wave by a circular obstacle. There is one stationary point if t_n lies in the illuminated region, and there are three stationary points if t_n lies in the shadow region. Two of these points coalesce into one stationary point of order $r = 2$ exactly at the shadow boundary. Using local basis functions, the structure of the discretization matrix B closely resembles that of Figure 5.1.

The coalescence of two stationary points at the shadow boundary is a general property for convex obstacles [22]. The quadrature points on the diagonal reflect the general principle of localization of high-frequency scattering, which states that the scattering of a ray is asymptotically determined by properties local to the point of incidence [13]. As such, Figure 5.1 is illustrative for more general convex shapes.

Remark 5.2. Figure 5.1 shows the existence of a stationary point in the shadow region when $t \in T_I(k)$ is a point in the illuminated region. This seems to contradict the localization principle. Indeed, this stationary point has no physical relevance for the scattering problem. Following Remark 4.1, it is an artifact of the incorrect ansatz in the shadow region.

5.4. Limitations of the sparse discretization. The convergence of quadrature rule $Q_c[f; t_n]$ as a function of k is described by the corresponding results for $Q_H[f]$ discussed in section 3.3. In particular, the results imply that the accuracy of the approximation increases with increasing k, at a rate that depends on the number of derivatives that are used in the quadrature rule. For example, for $t \in T_I(k)$, we have

$$|I_c[f; t_n] - Q_c[f; t_n]| = O\left(k^{-\min\{d_{n,0}+1,(d_{n,1}+2)/2-3/2\}}\right), \tag{5.11}$$

where $\tau_{n,0} = t_n$ and $\tau_{n,1}$ is the stationary point of order $r = 1$ in the shadow region. Hence, the sparse discretization matrix B is very well suited for computing the application of the integral operator under consideration to a function of the form $f(t)e^{ikg^i(\kappa(t))}$.

The convergence results in section 3.3 were derived, however, with the assumption that the function f is independent of k. No statements can therefore be made

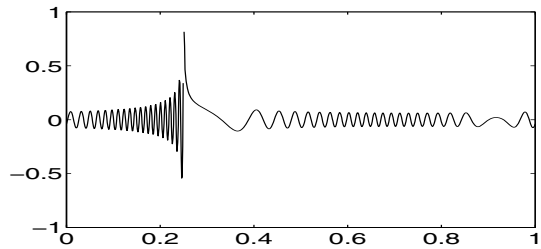

FIG. 5.2. *The real part of the integrand for $t_n = t_{sb1}$ for a circular obstacle and $k = 100$.*

regarding the computed solution of an integral equation using the sparse discretization matrix B, because the solution generally depends on k. Moreover, it was shown that the assumed oscillatory behavior $e^{ikg^i(\kappa(t))}$ in the ansatz (4.5) does not fully describe the oscillatory behavior of the exact solution $q(x)$. Therefore, $Q_c[q_s; t_n]$ might not be a good approximation to $I_c[q_s; t_n]$. It is important that the quadrature rule be accurate when applied to the exact solution q_s. Otherwise, one cannot expect that solving the system with the sparse representation matrix B can yield a good approximation of the exact solution.

It can be verified that $Q_c[q_s; t_n]$ is accurate when $t_n \in T_I(k)$, i.e., when t_n lies in the illuminated region. The cases $t \in T_{sb1}(k)$ and $t \in T_{sb2}(k)$ are more problematic. Figure 5.2 shows the real part of the integrand of the collocation integral $I_c[1; t_{sb1}]$, where $t_n = t_{sb1}$ coincides with the first shadow boundary. This integral has a stationary point of order $r = 2$ at t_{sb1}, but only to the right of the singularity. The integral is highly oscillatory to the left of the shadow boundary, and not oscillatory to the right. It turns out that a quadrature rule similar to $Q_c[f; t_n]$ can be used on the left interval $[0, t_{sb1}]$ and in the illuminated region $T_I(k)$. It is not suited for the intermediate interval $[t_{sb1}, t_{sb1} + C_1 k^{-1/3}]$. Due to the stationary point, however, the integrand is not oscillatory in that interval. In the following section, we will construct a sparse approximation matrix that is based on the use of specialized quadrature rules in the regions where they apply. They are combined with a classical dense discretization in the remaining part of the integration domain.

Remark 5.3. The failure of $Q_c[q_s; t_{sb1}]$ for the exact solution q_s can be seen as follows: the asymptotic decay of the quadrature weights $w_{n,l,j}$ for increasing k is cancelled exactly by the growth of the derivatives $q_s^{(j)}(t_{sb1})$ for increasing k. Hence, the rule does not converge.

5.5. A sparse discretization for the scattering problem.

Basis functions and collocation points. The basis functions for the discretization are chosen corresponding to the behavior of the solution in the three different regions identified in section 4.3. Recall that the solution is smooth in the illuminated region $T_I(k)$, and oscillatory but rapidly decaying in the shadow region. First, following [7], we approximate the solution by zero in the shadow region. We choose a fixed number of basis functions in the illuminated region $T_I(k)$. Finally, we also choose a fixed number of basis functions in the transitional shadow boundary regions $T_{B1}(k)$ and $T_{B2}(k)$, independently of k. This corresponds to using a fixed number of basis functions per oscillation of the solution in these regions.

The collocation points V are chosen equidistantly in the regions $T_{B1}(k)$, $T_{B2}(k)$,

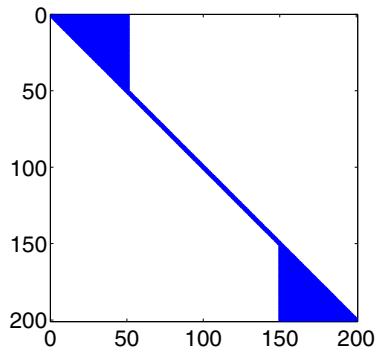

FIG. 5.3. *Illustration of the sparse discretization matrix using cubic B-splines for the scattering of a plane wave by a circular obstacle. The middle part of the matrix is tridiagonal.*

and $T_I(k)$. We have $V = V_1 \cup V_2 \cup V_3$, where

$$V_1 := \{t_{sb1} - D_1 k^{-1/3} + j h_1\}_{j=0}^{N_1}, \quad \text{with } h_1 := \frac{(C_1 + D_1)k^{-1/3}}{N_1},$$

$$V_2 := \{t_{sb1} + C_1 k^{-1/3} + j h_2\}_{j=1}^{N_2-2}, \quad \text{with } h_2 := \frac{(t_{sb2} - t_{sb1} - (C_1 + C_2)k^{-1/3})}{N_2 - 1},$$

$$V_3 := \{t_{sb2} - C_2 k^{-1/3} + j h_3\}_{j=0}^{N_3}, \quad \text{with } h_3 := \frac{(C_2 + D_2)k^{-1/3}}{N_3}.$$

These are $N = N_1 + N_2 + N_3$ points. As basis functions, we choose B-splines of odd degree s with knots U given by

$$U := V \cup \{t_{sb1} - D_1 k^{-1/3} - j h_1\}_{j=1}^{(s+1)/2} \cup \{t_{sb2} + D_1 k^{-1/3} + j h_3\}_{j=1}^{(s+1)/2}. \tag{5.12}$$

These $N + s + 1$ points uniquely determine N distinct B-splines. The basis functions are $s-1$ times continuously differentiable. The nodes in the shadow region are added in order to ensure a smooth transition into the shadow region where the solution is approximated by zero.

Discretization. For the discretization, we propose the following scheme. If $t_n \in T_I(k)$, a collocation point in the illuminated region, then

- the quadrature rule $Q_c[f; t_n]$ is applied for the singular point t_n,
- the stationary points lie in the shadow region, and they are discarded.

For splines of degree s, the singular point t_n lies in the support of only s separate basis functions. The corresponding matrix entries are given by (5.10). The contributions of the stationary points are discarded because the solution is approximated by zero in the shadow region. Recall that in the context of the scattering problem, following Remark 5.2, these are only spurious stationary points.

If $t_n \in T_{B1}(k)$, corresponding to the first shadow boundary region, then

- a specialized quadrature rule for oscillatory integrals is applied on the interval $[0, t_n]$,
- a classical dense discretization is used on the interval $[t_n, t_{sb1} + C_1 k^{-1/3}]$,
- a specialized quadrature rule for oscillatory integrals is again applied on the interval $[t_{sb1} + C_1 k^{-1/3}, 1]$.

The quadrature rule on $[0, t_n]$ reduces to the contribution of the singular point t_n. The corresponding weights have the form of (3.11) with S_l^H replaced by S_l^c,

$$w_{n,l_n,j}^c = -S_{l_n}^c \left[\frac{(x-t_n)^j}{j!}; t_n \right],$$

where l_n is the index such that $t_n = \tau_{n,l_n}$. The quadrature rule on $[t_{sb1} + C_1 k^{-1/3}, 1]$ consists of the contributions of the stationary points $\tau_{n,l}$ outside the shadow boundary region, and of the endpoint $t_r := t_{sb1} + C_1 k^{-1/3}$. The weights corresponding to that endpoint have the form of (3.9),

$$w_{n,l_r,j}^c = S_{l_r+1}^c \left[\frac{(x-t_r)^j}{j!}; t_r \right],$$

where l_r is the index such that $t_r \in [\tau_{n,l_r}, \tau_{n,l_r+1}]$. Finally, the dense discretization in the interval $[t_n, t_r]$ leads to elements of the form

$$\sigma_{n,m} = \frac{1}{2}\phi_m(t_n) e^{ikg^i(x_n)} + \int_{\Omega_m \cap [t_n, t_r]} G(t_n, \tau) e^{ikg^i(\kappa(\tau))} \phi_m(\tau)\, \mathrm{d}\tau. \tag{5.13}$$

The only difference compared to (5.3) is that the integration domain may be cut at the boundaries of $[t_n, t_r]$. Summarizing, the elements of the discretization matrix for $t_n \in T_{B1}(k)$ can be written as

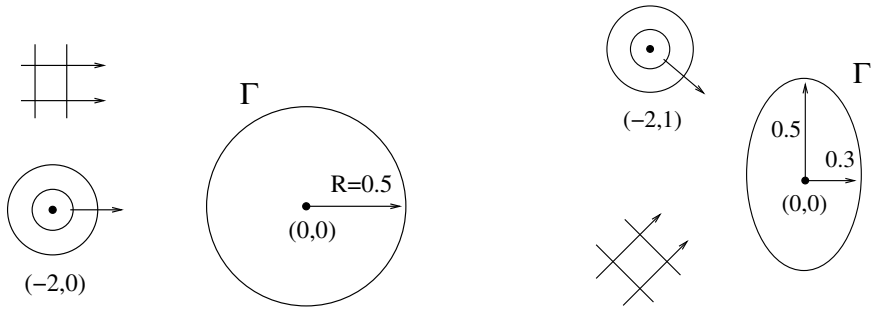
$$C_{n,m} = \begin{cases} \sigma_{n,m} & \text{if } \Omega_m \cap [t_n, t_r] \neq \varnothing \\ \quad + \sum_{j=0}^{d_{n,l_n}} w_{n,l_n,j}^c \phi_m^{(j)}(t_n) & \text{if } t_n \in \Omega_m \\ \quad + \sum_{j=0}^{d_{n,l_r}} w_{n,l_r,j}^c \phi_m^{(j)}(t_r) & \text{if } t_r \in \Omega_m \\ \quad + \sum_{l: t_r < \tau_{n,l} \in \Omega_m} \sum_{j=0}^{d_{n,l}} w_{n,l,j}^c \phi_m^{(j)}(\tau_{n,l}), & \exists l \in [0, L_n] : t_r < \tau_{n,l} \in \Omega_m, \\ \sum_{l: t_r < \tau_{n,l} \in \Omega_m} \sum_{j=0}^{d_{n,l}} w_{n,l,j}^c \phi_m^{(j)}(\tau_{n,l}), & \exists l \in [0, L_n] : t_r < \tau_{n,l} \in \Omega_m, \\ 0 & \text{otherwise.} \end{cases}$$

The case $t_n \in T_{B2}(k)$ can be treated similarly. The structure of the sparse matrix C is illustrated in Figure 5.3. The two small dense parts correspond to the dense discretization in the intervals $[t_n, t_{sb1} + C_1 k^{-1/3}]$ and $[t_{sb2} - C_2 k^{-1/3}, t_{sb2}]$. For simplicity, we have chosen the constant C_1 large enough such that, for $t_n \in T_{B1}$, all stationary points $\tau_{n,l} \in T_{B1}(k)$ also lie in the shadow boundary region. The constant C_2 was chosen similarly.

One can verify that the required integrals of the form (5.13) are not oscillatory. Due to the stationary point of order $r = 2$, the integrand behaves as $e^{ikc(\tau - t_{sb1})^3}$ near the shadow boundary. The argument of the exponential is bounded in k, since by construction we have

$$|\tau - t_{sb1}| \leq \max\{C_1, D_1\} k^{-1/3}.$$

Hence, there is only a bounded number of oscillations in the integrals for increasing k. It is therefore reasonable to expect that the integrals can be evaluated with a number of operations that is independent of k. Since the weights of the quadrature rule can be evaluated efficiently as well, and because the number of unknowns is fixed, the matrix in Figure 5.3 can be computed with a total number of operations that is independent of k.



(a) Circle (b) Ellipse

FIG. 6.1. *Illustration of two smooth convex scattering obstacles. The boundary conditions are plane waves, or circular waves originating from a point source.*

6. Numerical results. We consider the scattering by two convex obstacles, a circle and an ellipse, shown in Figure 6.1. We use two types of boundary conditions: a plane wave, modeled in the form $u^i(x) = e^{ik\alpha\cdot x}$, and a point source, modeled by $u^i(x) = H_0^{(1)}(|x - x_0|)$, with x_0 a point in the exterior Ω^+ of the obstacle. The circle and ellipse are parameterized by

$$\kappa(t) = \begin{cases} R\cos(2\pi t), \\ R\sin(2\pi t), \end{cases} \quad \text{and} \quad \kappa(t) = \begin{cases} R_1\cos(2\pi t), \\ R_2\sin(2\pi t), \end{cases}$$

respectively.

In all examples, we have chosen the constants C_1 and C_2 large enough (w.r.t. D_1 and D_2) such that the sparse matrix has the form shown in Figure 5.3. The highest order of the derivative used in the specialized quadrature rule for oscillatory integrals is kept fixed, $d_{n,l} = d$, $\forall n, l$, with $d \leq s - 1$, where s is the degree of the piecewise polynomial spline basis. The integrals (5.13) for the elements of the dense parts that are singular were evaluated using Cubpack [9].

6.1. Total solution time. The smooth function $q_c(t)$ is illustrated in Figure 6.2 as it was computed for the different scattering problems. The mild oscillatory behavior of the function near the shadow boundary is illustrated in the left panel of Figure 6.3, showing only the real part of the solution. Two spikes are present near the shadow boundary, with a peak value that scales as $O(k^{2/3})$, as predicted by the estimate (4.9). The dashed line shows the effect of doubling k. The $O(k)$ behavior in the illuminated region is clear from the imaginary part illustrated in the right panel of Figure 6.3.

Table 6.1 shows the timings for an implementation of the algorithm of section 5.5 in Matlab. In all the examples considered, the time actually decreases with increasing wavenumber k. This is due to the fact that, at larger frequencies, the weights of the specialized quadrature rule $Q_c[f; t_n]$ are easier to compute. Also, the integrals (5.13) that determine the elements of the dense parts do not become more oscillatory. In a classical boundary element method, and using 10 unknowns per wavelength, the case $k = 10^5$ would correspond to a dense matrix with approximately $N = 0.5 \times 10^6$ unknowns.

6.2. Error and convergence. In this section, we present numerical results evaluating the error of the proposed scheme. First, we investigate the absolute and

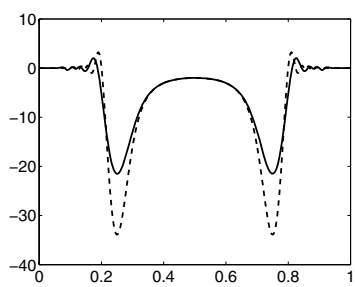

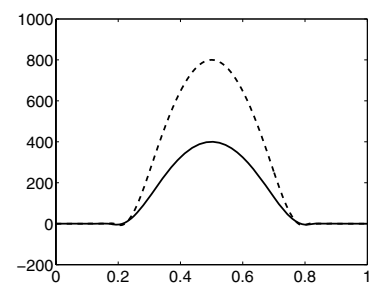

FIG. 6.3. *The real part (left) and imaginary part (right) of* $q_c(t)$ *for the scattering of a plane wave by a circle. The solid lines correspond to* $k = 200$, *the dashed lines to* $k = 400$.

relative error for increasing values of k. Next, we show that the accuracy is improved by increasing the number of derivatives d that are used in the specialized quadrature rules. We then illustrate the influence of the constants C_1, C_2, D_1, and D_2 that determine the size of the shadow boundary region. Finally, we illustrate the influence of the parameters N_1, N_2, and N_3 that determine the total degrees of freedom.

In applications, one is usually interested in the quantity q_s/k. For example, in electromagnetics, this quantity is proportional to the induced current on the surface of the obstacle with a proportionality constant that is independent of k. One can see from (4.9) that q_s/k corresponds to a normalization of q_s for different k. For this

(a) Absolute error E_a (b) Relative error E_r

FIG. 6.4. *Absolute and relative error for the scattering of a plane wave by a circle for different values of k. We have used $d = 1$ derivative in the specialized quadrature rules. The other parameters correspond to those in Table* 6.1.

reason, in all following results we evaluate the absolute error in a point t as

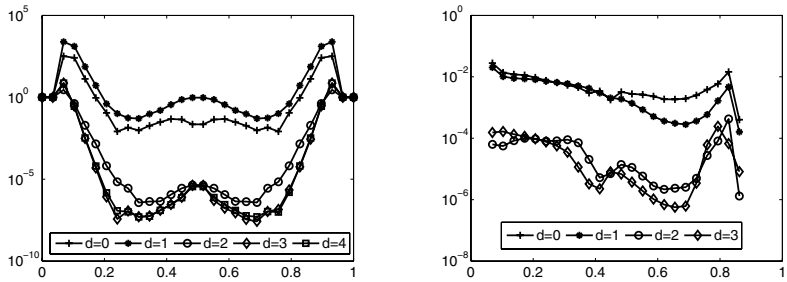
$$E_a(t) = \frac{|q_s(t) - q_c(t)|}{k}, \tag{6.1}$$

and the relative error as

$$E_r(t) = \frac{|q_s(t) - q_c(t)|}{|q_s(t)|}. \tag{6.2}$$

The exact solution q_s of the scattering problem is known analytically only for the case of scattering of a plane wave by a circle. For the other cases, the error is estimated by comparing computed solutions to each other.

The relative and absolute error for the scattering of a plane wave by the circle is shown in Figure 6.4 for increasing values of k. We have chosen to use cubic spline basis functions and derivatives up to order $d = 1$ in each specialized quadrature rule. The figures show that both the absolute error and the relative error decrease with increasing k. This is due to the higher accuracy of the quadrature rule $Q_c[f; t]$ at larger frequencies. The relative error tends to 100% in the deep shadow region because we have approximated the solution by 0 in that region. One can verify from



(a) Relative error for the case of a circle

(b) Absolute error for the case of an ellipse

FIG. 6.5. *Comparison of the absolute and relative error at $k = 200$ for different values of d, the number of derivatives used in the specialized quadrature rules. The left panel corresponds to the case of column 1 in 6.1, the right panel corresponds to the case of column 4.*

the figures that the absolute error in that region is still quite small compared to the average value of the function $q_s(t)$. At $k = 1600$, a relative error of order 10^{-5} is achieved in the illuminated region and near the shadow boundary.

The accuracy shown in Figure 6.4 for the smaller value $k = 200$ is quite poor, however. The accuracy is much improved by increasing the number of derivatives used in the quadrature rules. This is illustrated in Figure 6.5(a) for the same scattering example with $k = 200$. The number of derivatives d ranges from 0 to 4. We used cubic spline basis functions for $d = 0, 1, 2$ and splines of degree 5 for $d = 3, 4$. A relative error of order 10^{-8} is achieved in the shadow boundary region, and a relative error of order 10^{-5} in the illuminated region. A similar experiment is illustrated in Figure 6.5(b), corresponding to an incident circular wave on an ellipse-shaped boundary. The error for $d = 0, \ldots, 3$ in this case was estimated by comparing to the results of using $d = 4$.

The constants C_1, C_2, D_1, and D_2 determine the size of the transitional shadow boundary regions. Since the solution is approximated by zero in the shadow region outside these intervals, it can be expected that increasing the value of these parameters results in smaller errors. This is confirmed by the results in Table 6.2, which show the maximum of the absolute error E_a. The maximum is reached in the points $t_{sb1} - D_1 k^{-1/3}$ and $t_{sb2} + D_2 k^{-1/3}$, i.e., on the border of the shadow region. It is also shown that the accuracy of a point in the shadow boundary region increases if the size of that region is increased. The accuracy of the points in the illuminated region is unaffected by this change.

Finally, Table 6.3 shows the result of increasing the total number of degrees of

TABLE 6.3
Maximal absolute error as a function of the number of degrees of freedom.

$N_1 = N_2 = N_3$	20	30	40	50	60

freedom for the same scattering example. The accuracy initially increases rapidly, but remains stable as N increases further.

In conclusion, the accuracy of the proposed method is influenced by a number of factors: the value of k, the accuracy of the specialized quadrature rules, the size of the shadow boundary region, and the number of degrees of freedom. The results show that the error is quite small and can be improved by changing the parameters. However, the experiments do not indicate that arbitrary accuracy can be achieved for a given value of k. For achieving high accuracy at very low values of k, the use of specialized quadrature rules is not recommended; one can instead employ the dense discretization described in section 5.1.

7. Concluding remarks. The method presented in this paper achieves a sparse discretization matrix for an integral equation, which is made possible by the presence of strong oscillations. The method is based on a classical boundary element technique near the shadow boundary, and uses a new quadrature formula that is very effective for oscillatory integrals in the illuminated region. The a priori knowledge of the phase of the solution allows a discretization with a fixed small number of unknowns. Since the new quadrature rule requires only few quadrature points, a sparse discretization matrix is obtained. Moreover, numerical results indicate that the accuracy of the solution increases with increasing frequency.

The method can still be improved in a number of ways. For example, we have only considered a localized Filon-type method, while numerical experiments indicate that regular Filon-type methods are typically more accurate for the same frequency. One could also add additional quadrature points besides the singular and stationary points to improve the accuracy. The small densely discretized part near the shadow boundary may possibly be avoided by using a more elaborate ansatz for the asymptotic behavior of the solution, such as those described by the geometric theory of diffraction [17, 23, 16].

The method is limited to smooth convex obstacles. The approach of [7] for smooth convex obstacles can be extended to multiple scattering configurations using an iterative approach [14]. We expect the same will hold for our approach. The extension to three-dimensional problems is the subject of future research. This might be based on suitable cubature rules for multivariate highly oscillatory integrals which have recently been constructed [18].

ON THE PERFORMANCE OF TENSOR METHODS FOR SOLVING ILL-CONDITIONED PROBLEMS*

BRETT W. BADER† AND ROBERT B. SCHNABEL‡

Abstract. This paper investigates the performance of tensor methods for solving small- to large-scale systems of nonlinear equations where the Jacobian matrix at the root is ill-conditioned or singular. This condition occurs on many classes of problems, such as identifying or approaching turning points in path-following problems. The singular case has been studied more than the highly ill-conditioned case, for both Newton and tensor methods. It is known that Newton-based methods do not work well with singular problems because they converge linearly to the solution and, in some cases, with poor accuracy. On the other hand, direct tensor methods have performed well on singular problems and have superlinear convergence on such problems under certain conditions. This behavior originates from the use of a special, restricted form of the second-order term included in the local tensor model that provides information lacking in a (nearly) singular Jacobian. With several implementations available for large-scale problems, tensor methods now are capable of solving larger problems. We compare the performance of tensor methods and Newton-based methods for small- to large-scale problems over a range of conditionings, from well-conditioned to ill-conditioned to singular. Previous studies with tensor methods concerned only the ends of this spectrum. Our results show that tensor methods are increasingly superior to Newton-based methods as the problem grows more ill-conditioned.

1. Introduction.

This paper examines two classes of methods for solving the following nonlinear equations problem:

$$\text{given } F : \mathbb{R}^n \to \mathbb{R}^n, \quad \text{find } x_* \in \mathbb{R}^n \text{ such that } F(x_*) = 0, \tag{1.1}$$

where it is assumed that $F(x)$ is at least once continuously differentiable. General systems of nonlinear equations defined by (1.1) arise in many practical situations, including systems produced by finite-difference or finite-element discretizations of boundary value problems for ordinary differential equations (ODEs) and partial differential equations (PDEs).

As a subset of the general nonlinear equations problem (1.1), there is a class of important problems where $F'(x_*)$ is singular or, at least, very ill-conditioned. Such examples arise in bifurcation tracking and path-following problems where the goal is to locate turning points, such as the ignition and extinction points in chemical combustion. Resolving these features is important to engineers, who, for instance, may

be designing control systems for such applications and may need to know important operating boundaries.

Standard methods for solving (1.1), such as Newton's method, base each iteration upon a local, linear model $M(x_k + d)$ of the function $F(x)$ around the current iterate $x_k \in \mathbb{R}^n$. Standard methods work well for problems where the Jacobian at the solution, $F'(x_*)$, is well-conditioned, but they face difficulties when the Jacobian is singular, or even nearly singular, at the solution. Many authors have analyzed the behavior of Newton's method on singular problems and have proposed acceleration techniques as remedies (see, e.g., Decker, Keller, and Kelley [9]; Decker and Kelley [10, 11, 12]; Griewank [19]; Griewank and Osborne [20]; Kelley and Suresh [22]; and Reddien [28]). Their collective analysis shows that, from many starting points, Newton's method is locally q-linearly convergent with constant converging to $\frac{1}{2}$ on singular problems where the second-order term $F''(x_k)$ contains appropriate null space information. Acceleration techniques can improve this behavior; however, they require a priori knowledge that the problem is singular, which is not practical for general problem solving.

Tensor methods, however, do not require a priori knowledge of whether the problem is singular or not. These methods were introduced by Schnabel and Frank in [34] and base each iteration on a simplified quadratic model of $F(x)$ such that the quadratic term is a low-rank secant approximation that augments the standard linear model. Tensor methods also have been extended by other authors to utilize iterative solvers, making the methods appropriate for solving large-scale problems (see [1], [4], and [17]).

The analysis in [16] proves that direct tensor methods have quadratic convergence on nonsingular problems and a superlinear convergence rate on problems where the Jacobian matrix at the solution is singular. Specifically, when the rank of the Jacobian at the root is $n-1$, "practical" tensor methods (i.e., those using secant approximations for the tensor term) have three-step superlinear convergence behavior with q-order $\frac{3}{2}$. In practice, one-step superlinear convergence frequently is observed on these problems, which makes the method even more attractive. The second-order term provides higher order information in recent step directions, which aids in cases where the Jacobian is (nearly) singular at the solution. As the iterates approach the solution, the Jacobian lacks information in the null space direction, and the second-order term supplies useful information for a better quality step. Computational evidence in [34] on small problems shows that tensor methods show 21–23% average improvement (in terms of nonlinear iterations and function evaluations) over standard methods on nonsingular problems and 40–43% improvement on singular problems with $\text{rank}(F'(x_*)) = n - 1$.

While tensor methods have encouraging theoretical and computational results on singular problems, less is known about their performance relative to Newton's method on ill-conditioned problems. Do tensor methods outperform Newton's method due to the close relationship of ill-conditioned matrices with singular matrices? Or do tensor methods exhibit superior behavior only when the problem is truly singular? Does the computational performance of Newton's method degrade gradually as the problem becomes more singular, or sharply at the singularity? The performance comparison over a spectrum of ill-conditioned problems was previously unknown. Thus, this paper examines the performance of tensor methods versus standard methods as the problem becomes more ill-conditioned. We consider tensor methods using direct factorizations of the Jacobian matrix for small-scale problems in addition to Krylov-based iterative tensor methods for large-scale problems.

The organization of this paper is as follows. Because this research involves meth-

ods for solving small- to large-scale problems, this paper includes background for both types in section 2. Specifically, we review direct methods for solving small-scale problems, and we review Krylov-based iterative methods for solving large-scale problems, including the relevant algorithms from [1] and [17]. Section 3 presents numerical results on several small- and large-scale ill-conditioned test problems to examine the performance of tensor methods on problems over a range of conditionings, from well-conditioned to singular. Finally, section 4 summarizes the numerical results and provides some concluding remarks.

Throughout this paper, a subscript k refers to the current iterate of a nonlinear solver. We denote the Jacobian $F'(x)$ by $J(x)$ and abbreviate $J(x_k)$ as J_k. Similarly, $F(x_k)$ is abbreviated often as F_k. When the context is clear, we may drop the subscript k while still referring to the "current" values at an iteration.

2. Algorithms. In this section, we introduce the relevant methods for solving systems of nonlinear equations. We start with methods that use a direct factorization of the Jacobian matrix, and then we discuss inexact methods that use Krylov subspace projection techniques. General references for these topics in nonlinear solvers include [14], [21], [26], and [30].

2.1. Standard methods. In this paper, we denote by standard methods the class of methods for solving (1.1) that uses a linear approximation to $F(x)$ at each iterate around the current iterate $x_k \in \mathbb{R}^n$. Most notable among these methods is Newton's method, which uses the linear local model

$$M_N(x_k + d) = F_k + J_k d, \tag{2.1}$$

where $d \in \mathbb{R}^n$ is the step and $J_k \in \mathbb{R}^{n\times n}$ is either the current Jacobian matrix or an approximation to it. A root of this local model provides the Newton step

$$d_N = -J_k^{-1} F_k,$$

which is used to reach the next trial point. Thus, Newton's method is defined when J_k is nonsingular and consists of updating the current point with the Newton step,

$$x_+ = x_k + d_N. \tag{2.2}$$

If the Jacobian $J(x_k)$ is Lipschitz continuous in a neighborhood containing the root x_* and $J(x_*)$ is nonsingular, then the sequence of iterates produced by (2.2) converges locally and q-quadratically to x_*. That is, there exist constants $\delta > 0$ and $c \geq 0$ such that the sequence of iterates x_k produced by Newton's method obeys

$$\|x_{k+1} - x_*\| \leq c \|x_k - x_*\|^2$$

if $\|x_0 - x_*\| \leq \delta$.

When these standard approaches use direct factorizations of the Jacobian matrix, we will refer to these methods as direct methods. Due to the storage and linear algebra costs, direct methods are practical only for solving small, dense problems. If the matrix is sparse, then sparse linear algebra techniques may be used to solve larger problems but are still limited by the size of the problem.

2.2. Tensor methods. Tensor methods [34] solve (1.1) by including a second-order term in the local model at each iteration. The local tensor model has the general form

$$M_T(x_k + d) = F_k + J_k d + \tfrac{1}{2} T_k dd, \tag{2.3}$$

where $T_k \in \mathbb{R}^{n\times n\times n}$ is the tensor term at x_k and is selected so that the model interpolates a small number p of function values in the recent history of iterates. By choosing the smallest T_k in the Frobenius norm, T_k has rank p and $T_k dd$ is both simple in form and inexpensive to find. Because (2.3) may not have a root, one solves the minimization subproblem

$$\min_{d\in\mathbb{R}^n} \|M_T(x_k + d)\|_2 , \tag{2.4}$$

and a root or minimizer of the model is the tensor step.

The additional cost of forming, storing, or solving the model is minor compared to Newton's method. Specifically, the additional cost of a direct tensor method is about n^2p multiplications (QR implementation) and $2p$ vectors of length n in storage. For our numerical experiments, we will consider only the simplest case of $p = 1$. Computational evidence in [34] suggests that additional past iterates add little benefit to the computational performance of the tensor method.

2.3. Newton–Krylov methods. Up to this point, we have discussed direct methods for the solution of small, dense problems, such that the local model is solved with direct factorizations of the Jacobian matrix. Standard direct methods, such as Newton's method, are impractical on large-scale problems because of their high linear algebra costs and large memory requirements. Thus, most large systems often are solved successfully using a class of "inexact" Newton methods [13]:

$$x_{k+1} = x_k + d_k, \quad \text{where} \quad F'(x_k)d_k = -F(x_k) + r_k, \quad \|r_k\| \le \eta_k \|F(x_k)\| , \tag{2.5}$$

such that the local model typically is solved only approximately at each step using a less expensive approach. These "inexact" steps then locate the next trial point. The convergence rate of inexact Newton methods depends on the forcing sequence η_k [13]. If η_k is constant, then convergence is linear. Successively better approximations to the linear model at each iteration (i.e., η_k getting smaller as k increases) preserve the rapid convergence behavior of Newton's method when nearing the solution. The computational savings reflected in this less expensive inner iteration is usually partially offset with more outer iterations, but the overall savings still is quite significant on large-scale problems by avoiding the direct methods that solve the local model exactly.

The most common methods for approximately solving the local Newton model are Krylov-based methods, which iteratively solve the linear system projected onto the Krylov subspace $\mathcal{K}$. A linear Krylov subspace method is a projection method that seeks an approximate solution x_m to the linear system $Ax = b$ from an m-dimensional affine subspace $x_0 + \mathcal{K}_m$. Here $\mathcal{K}_m$ is the subspace

$$\mathcal{K}_m(A, r_0) = span\{r_0, Ar_0, A^2r_0, \ldots, A^{m-1}r_0\},$$

where $r_0 = b - Ax_0$ is the residual at an initial guess x_0. A popular Krylov subspace method is the generalized minimum residual method (GMRES), which computes a solution $x_m \in x_0 + \mathcal{K}_m$ such that the residual norm over all vectors in $x_0 + \mathcal{K}_m$ is minimized. That is, at the mth step, GMRES finds x_m such that $\|b - Ax_m\|_2$ is minimized for all $x_m \in x_0 + \mathcal{K}_m$.

Newton-GMRES is one specific method in the class of Newton–Krylov methods. Here, the linear system is the Newton equation $J_k d = -F_k$, and the system is solved via GMRES according to the tolerance η_k in (2.5). Krylov subspace methods have

the appeal of not requiring an explicit Jacobian due to their exclusive use of Jacobian-vector products, which may be calculated by a finite-difference directional derivative. For this reason and others, Newton-GMRES is a popular algorithm for solving large-scale problems, and it will be the standard large-scale Newton-based algorithm for comparisons in our numerical experiments.

Newton–Krylov methods have been considered by many authors, including Brown and Saad [6, 7], Chan and Jackson [8], and Brown and Hindmarsh [5]. Their computational results show that Newton–Krylov methods can be quite effective for many classes of problems in the context of systems of PDEs and ODEs.

2.4. Tensor-Krylov methods. To accommodate large problems and avoid the expensive direct solution of the local model, the three tensor-Krylov methods described in [1] combine the concepts from direct tensor methods with concepts from inexact Newton methods [13] using Krylov-based linear solvers. The tensor-Krylov methods calculate an inexact tensor step from a specially chosen Krylov subspace that facilitates the solution of a minimization subproblem at each iteration. Here, we give a very brief overview of these methods.

All large-scale tensor methods in this paper consider only a rank-one tensor model, which only interpolates the function value at the previous iterate. Thus, the rank-p model of (2.3) reduces to

$$M_T(x_k + d) = F_k + J_k d + \tfrac{1}{2} a_k (s_k^T d)^2, \tag{2.6}$$

such that

$$a_k \in \mathbb{R}^n = \frac{2(F_{k-1} - F_k - J_k s_k)}{(s_k^T s_k)^2}, \tag{2.7}$$

$$s_k \in \mathbb{R}^n = x_{k-1} - x_k. \tag{2.8}$$

In each of the tensor-Krylov methods, the tensor step is found by approximately solving the minimization subproblem

$$\min_{d \in \mathcal{K}_m} \left\| F_k + J_k d + \tfrac{1}{2} a_k (s_k^T d)^2 \right\|_2, \tag{2.9}$$

where $\mathcal{K}_m$ is a specially chosen Krylov subspace that facilitates the solution of the quadratic model. The three methods described in [1] differ in their choice of $\mathcal{K}_m$, and they are identified by this characteristic difference. TK2 and TK2+ use a Krylov-based local solver that starts with an initial block of two vectors (TK2+ also augments the Krylov subspace in a special way). Similarly, TK3 uses an initial block of size three. The three methods share the ability to calculate an approximate tensor step that satisfies the tensor model to within a specified tolerance. Their cost per nonlinear iteration exceeds that of Newton-GMRES by at most $10n+4mn+6m^2$ multiplications (in comparison, GMRES costs $\mathcal{O}(nm^2)$ multiplications). The methods can be readily combined with either left or right preconditioning. More details of these Krylov-subspace methods for solving the tensor model may be found in [1].

2.5. Tensor-GMRES method. Another large-scale tensor method is that of Feng and Pulliam [17], which uses Krylov subspace projection techniques for solving the local tensor model. In particular, it uses GMRES to first find the approximate Newton step $d_N = d_0 + V_m y_m$. The columns of V_m form an orthonormal basis for the Krylov subspace $\mathcal{K}_m$ generated by the corresponding Arnoldi process, and the Hessenberg matrix H_m is also generated from the Arnoldi process. Given these key

matrices, their tensor-GMRES algorithm proceeds to solve a projected version of the tensor model (2.6) along a subspace that spans the Newton step direction and the Krylov subspace from the Newton step solution. (That is, the approximate tensor step is in the span of the Krylov subspace $\mathcal{K}_m^N$ and d_0, or, equivalently, the span of the matrix $[V_m, d_0]$.) Thus, their algorithm solves the least-squares problem

$$\min_{d \in \{d_0\} \cup \mathcal{K}_m^N} \left\| F_k + J_k d + \tfrac{1}{2} P a (s^T d)^2 \right\|, \tag{2.10}$$

where P is the projection matrix

$$P = Y(Y^T Y)^{-1} Y^T, \quad \text{where } Y = J_k[V_m, d_0]. \tag{2.11}$$

The analysis in [17] shows that the same superlinear convergence properties for the unprojected tensor model considered in [16] also hold for the projected tensor model (2.10). The complete tensor-GMRES algorithm for solving (2.10) at the kth nonlinear iteration is listed in [17].

Despite the algorithm's difficult algebra, the design actually is rather straightforward. The algorithm may be viewed as an extension of Newton-GMRES, where the inexact Newton step is calculated via GMRES in the standard way. The tensor step is calculated subsequently using the Krylov subspace information generated for the Newton step. In this way, the method also is consistent with preconditioning techniques and a matrix-free implementation, which makes it appealing for general use.

The extra work and storage beyond GMRES for computing the tensor step are quite small. The extra work is at most $4mn + 5n + 2m^2 + \mathcal{O}(m)$ multiplications plus a single Jacobian-vector product for evaluating the tensor term a_k. The extra storage amounts to two extra n-vectors for a and s plus a few smaller working vectors of length m.

The results in [17] show the superlinear convergence behavior of tensor-GMRES on three singular and nearly singular problems, where the Newton-GMRES method exhibits linear convergence due to a lack of sufficient first-order information. The margin of improvement (in terms of reduction of nonlinear iterations over Newton's method) varied from 20% to 55% on the simpler problems and from 32% to 60% on the more difficult Euler problem. Running times and the total number of Jacobian-vector products for each method were not reported in [17], but from our own experience with the algorithm, we assume that these performance metrics are correlated with the number of nonlinear iterations.

3. Numerical experiments on ill-conditioned problems.

3.1. Small problems solved with direct methods. This section investigates the performance of direct tensor methods as well as Newton's method on a set of small problems that include a parameter for adjusting the ill-conditioning of the Jacobian matrix at the root. The results show that Newton's method requires increasingly more iterations as the problem ill-conditioning grows, whereas the direct tensor methods are only mildly affected.

Following the approach in [34], we created ill-conditioned problems by modifying nonsingular test problems to be of the form

$$\hat{F}(x, \lambda) = F(x) - \lambda F'(x_*) A (A^T A)^{-1} A^T (x - x_*), \tag{3.1}$$

where $F(x)$ is the standard nonsingular test function, x_* is its root, $A \in \mathbb{R}^{n \times j}$ is an arbitrary matrix that has full column rank with $1 \leq j \leq n$, and $\lambda \in [0, 1]$ is a

parameter for ill-conditioning. We denote $\hat{J}(x,\lambda)$ as the Jacobian matrix of $\hat{F}(x,\lambda)$ with respect to x:

$$\hat{J}(x,\lambda) \equiv \frac{\partial}{\partial x}\hat{F}(x,\lambda).$$

These new test problems are similar to problems in continuation or homotopy methods, except that $\hat{F}(x,\lambda)$ has the same root as $F(x)$ (i.e., x_*) for all values of λ. While the problem becomes harder to solve as λ approaches 1, the idea is not to follow the path over a sequence of values of λ. Rather, we solve the modified problem for each value of λ from the same starting point across all tests and record the number of iterations required to reach the solution.

One special quality of this modified problem is that if $\lambda = 1$ and $F'(x_*)$ has full rank, then the rank of $\hat{J}(x_*,\lambda)$ equals $\operatorname{rank}(F'(x_*)) - \operatorname{rank}(A) = n - \operatorname{rank}(A)$. Thus, as λ approaches 1, the rank deficiency of $\hat{J}(x_*,\lambda)$ approaches the rank of A. Stated another way, a set of the smallest singular values of $\hat{J}(x_*,\lambda)$ equal to the rank of A will approach 0 as λ approaches 1.

Different sets of singular and ill-conditioned problems may be created using the matrix A in (3.1); adding more independent columns to A serves to decrease the rank of $\hat{J}(x_*,1)$. We routinely used the matrices

$$A \in \mathbb{R}^{n\times 1}, \quad A^T = \begin{pmatrix} 1 & 1 & 1 & \dots & 1 \end{pmatrix},$$

$$A \in \mathbb{R}^{n\times 2}, \quad A^T = \begin{pmatrix} 1 & 1 & 1 & \dots & 1 \\ 1 & -1 & 1 & \dots & \pm 1 \end{pmatrix},$$

and

$$A \in \mathbb{R}^{n\times 3}, \quad A^T = \begin{pmatrix} 1 & 1 & 1 & \dots & 1 \\ 1 & -1 & 1 & \dots & \pm 1 \\ 1 & 1 & -1 & \dots & \pm 1, \end{pmatrix}$$

because they provide "balanced" problems by acting equally on the whole Jacobian $F'(x_*)$. Letting A equal the unit vector e_1, for example, would operate only on the $(1,1)$ element of $F'(x)$.

We chose six problems for testing from the standard small-dimensional test set of Moré, Garbow, and Hillstrom [25] and modified them according to (3.1). Table 3.1 lists the problems used in our numerical tests, along with the corresponding dimensions. For all problems, the starting vector x_0 was the standard starting point for each problem published in [25]. Except for the cases mentioned below, these starting points did not require a global strategy to reach the solution (i.e., the full step was accepted at all iterations).

We chose the parameter λ in (3.1) to asymptotically approach $\lambda = 1$ by using the values $\lambda = 1 - 10^{-j}$, $j = 0, 1, 2, \dots$. Thus, for $j = 0$ the problem is the original, unmodified problem, and each subsequent value of j makes the problem more ill-conditioned. At some point, round-off errors in the evaluation of $\hat{F}(x,\lambda)$ as well as the numerical precision of the root x_* make the numerical solution indistinguishable from the case of $\lambda = 1$. All subsequent values of λ would produce the same result, so we collected only the results up to these points and indicated the case of $\lambda = 1$ at the rightmost extent of our plots. Due to the numerical precision of the solutions, the Jacobian at x_* may not be fully singular.

TABLE 3.1
Ill-conditioned test problems.

Problem	Size
Broyden tridiagonal	50
Broyden banded	50
Discrete integral equation	50
Discrete boundary value function	50
Rosenbrock's function	2
Brown almost linear	10

We used the following two stopping conditions in all these tests: $\|F(x_k)\|_\infty \leq 10^{-12}$ and $\|x_k - x_{k-1}\|_\infty \leq 10^{-12}$, which are the same conditions Eisenstat and Walker used when analyzing inexact Newton methods in [15]. In many practical applications, less stringent convergence tolerances are commonly used, but these tight tolerances were used in this experiment (and later experiments) to differentiate results at higher condition numbers and to allow asymptotic convergence behavior to become evident. To help gauge what can be expected with looser stopping tolerances, we have included convergence histories for a few problems (see, e.g., Figure 3.1) where the performance difference is still present but less striking.

As a prelude to these results and to help explain what is happening in these experiments, we first provide a graphical description. Figure 3.1 shows the typical iteration profiles for different values of λ that we observed. This figure graphs the function value at each iteration for the tensor and Newton methods on a typical problem approaching rank $n-1$ with various values of $\lambda = 0, 0.9, 0.99, 0.999, \ldots, 1$. All of the tensor method profiles are bunched together on the left, requiring few iterations even as λ nears 1, whereas the profiles of Newton's method are spread out and require increasingly more iterations for convergence as the problem becomes more ill-conditioned. This plot of iteration profiles is typical for all problems. Thus, while all of the tensor runs display superlinear convergence throughout the iterations, it is evident that Newton's method converges linearly for a number of iterations before accelerating to quadratic convergence. With increasing ill-conditioning, the region of quadratic convergence for Newton's method shrinks in size, acting as if the problem were singular outside of this region.

Figure 3.2 shows the relative performance of Newton's method versus a rank-one tensor method on the six problems, in the case where each Jacobian at the solution approaches rank $n-1$. The condition number $\hat{J}(x_*, \lambda)$ is plotted on the abscissa, while the number of iterations for both methods is plotted on the ordinate axis. One tensor method iteration is just slightly more expensive than a Newton iteration. There were no linesearches in all cases except on Rosenbrock's function at $\lambda = 0$, which explains the unusual spike on the left in that plot. Also, both methods arrived at different solutions in the Brown almost linear problem at $\lambda = 0$, and thus these points were not included in that plot. For all other points, both methods arrived at the same x_*.

The six plots of Figure 3.2 show that as the ill-conditioning of a particular problem grows, Newton's method requires more iterations, whereas the tensor method is very mildly affected. This is a key result. Previously, it was suggested that tensor methods behave reasonably well on ill-conditioned problems, but there was no numerical testing of this conjecture.

However, because the condition number is just a single value representing the ratio of the largest to the smallest magnitude singular values, it does not capture the singular value spectrum of the Jacobian. Say, for instance, that there are multiple

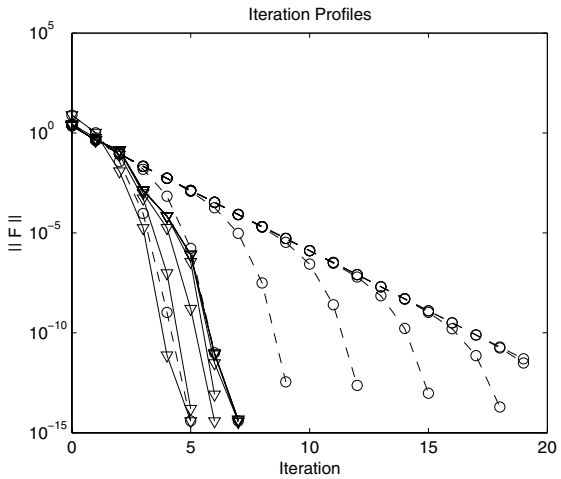

FIG. 3.1. *Superimposed iteration profiles of the tensor method (∇, solid lines) and Newton's method (∘, dashed lines) when solving the modified Broyden tridiagonal function as it approaches rank $n-1$. For both methods and their corresponding set of iteration profiles, problem difficulty (λ) increases from left to right, making the problem more ill-conditioned and requiring more iterations to solve.*

singular values approaching zero, creating a very ill-conditioned matrix. One might speculate that a tensor method using a rank-one tensor term would be less advantageous in this case because it could "handle" only one direction, perhaps the direction associated with the smallest singular value, leaving other (near) singular directions to impede convergence. Figures 3.3 and 3.4 consider exactly these cases where the Jacobians approach rank $n-2$ and $n-3$, respectively, while still using a rank-one tensor model. Two problems were not included in these figures for different reasons. The modified Rosenbrock function had excessive linesearches that obscured the results in the rank $n-2$ problems, and the rank $n-3$ problem is not possible with the Rosenbrock function due to its small dimension of $n=2$. For the Brown almost linear problem, each method arrived at a solution that was different from the root x_* used in (3.1). For these reasons, these two problems were not included in Figures 3.3 and 3.4.

It is evident that the results for higher rank deficiencies are not as striking as in Figure 3.2, but the general trend still remains—tensor methods perform better than Newton's method on ill-conditioned problems, even when the Jacobian approaches a rank deficiency greater than the rank of the tensor term. A few peculiarities exist in the results that warrant explanation. We attribute the "humps" in both curves to the random paths each method takes to arrive at the solution, and we believe this shape is coincidental. The "spikes" in both methods for the two discrete problems in Figure 3.4 are due to linesearches occurring at a specific value of λ. The linesearches force a few more outer iterations to eventually solve the problems.

3.2. Medium-scale problems solved with inexact methods. This subsection investigates the performance of the Newton-GMRES, tensor-GMRES, and tensor-Krylov methods on three ill-conditioned problems of moderate size and complexity: the Bratu problem, a modified discrete boundary value function, and a modified Broyden tridiagonal problem. The tests on the ill-conditioned problems have a design

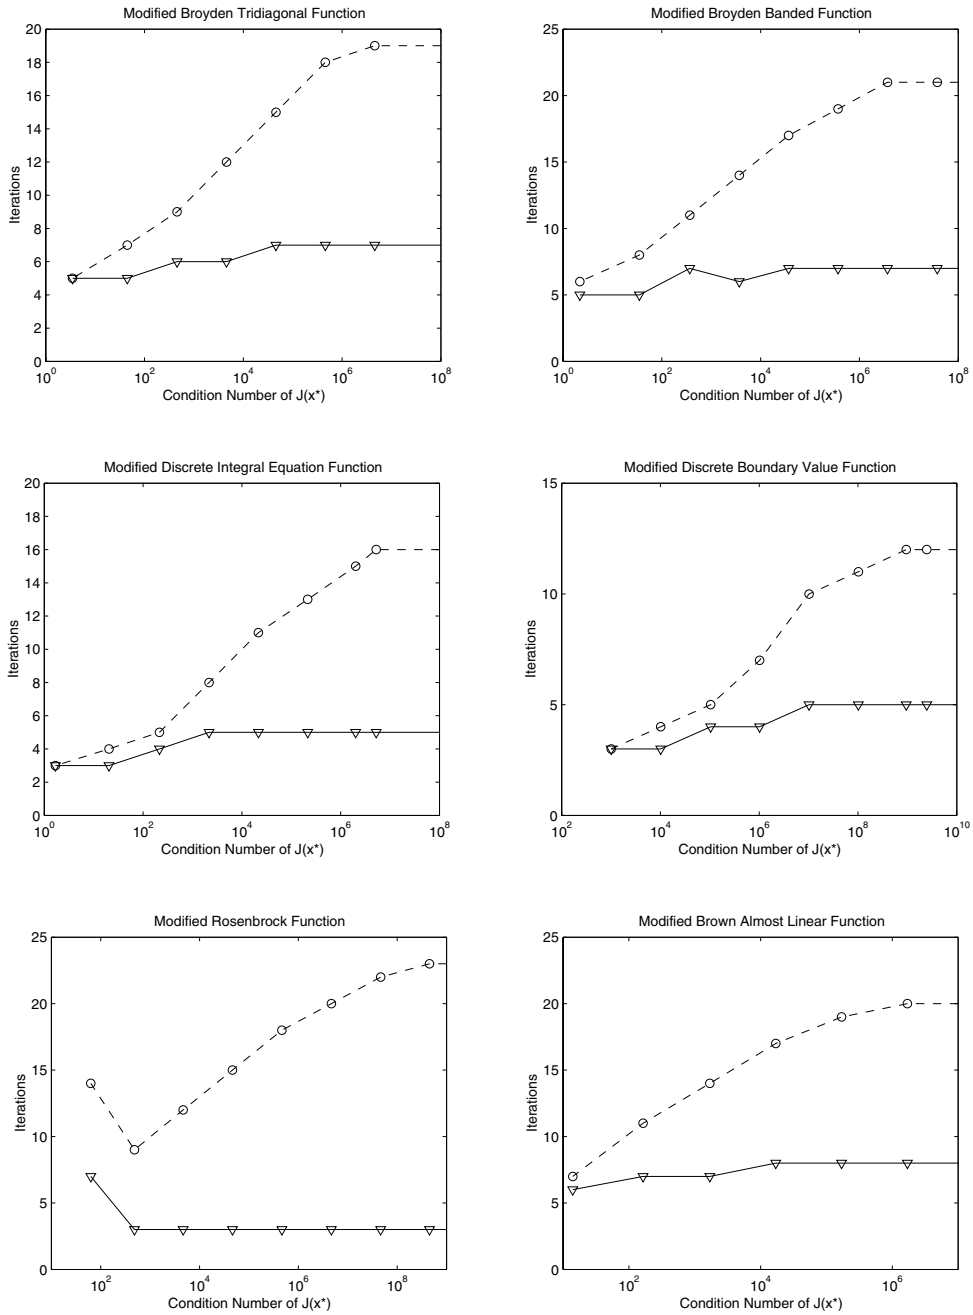

FIG. 3.2. *Comparison of a rank-one tensor method (∇, solid line) with Newton's method (○, dashed line) on variably ill-conditioned test problems that approach rank* $n-1$.

similar to that of the study performed in section 3.1, and we investigate to what extent the benefits of using direct tensor methods for solving small ill-conditioned/singular problems that were shown in section 3.1 extend to inexact versions of tensor methods for larger problems.

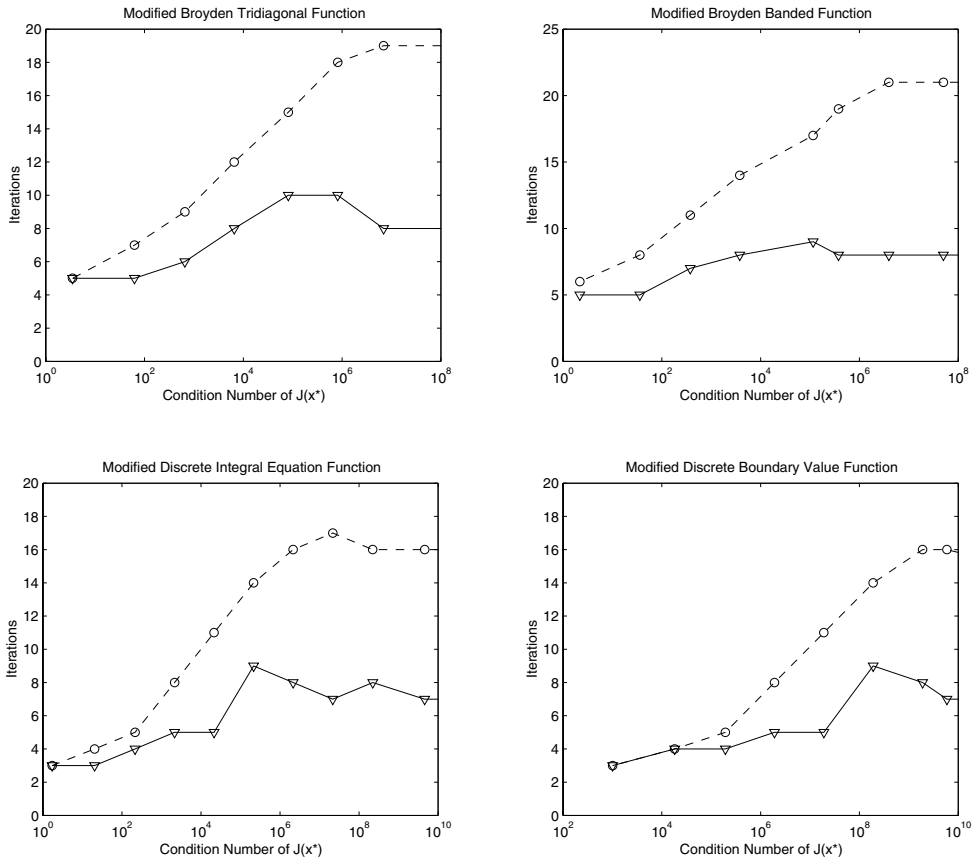

FIG. 3.3. *Comparison of a rank-one tensor method (∇, solid line) with Newton's method (○, dashed line) on variably ill-conditioned test problems that approach rank* $n-2$.

We implemented all of the methods in MATLAB using double precision arithmetic. For objective comparisons, we used the same level of basic linear algebra routines in MATLAB in all of our tests. Thus, the results in this section do not reflect the most efficient implementations that are available, but the statistics that we collected (nonlinear iterations, function evaluations) are invariant to optimal implementations.

For the numerical tests, we used the same stopping conditions and parameters as in section 3.1. For the inner method, we solved the local model to a constant relative tolerance of 10^{-4}, which requires uniformly close approximations to Newton and/or tensor steps at each iterate and results in fast local q-linear convergence. Using a constant relative tolerance may not be ideal in practice (see [15] for alternatives), but it provides for more unbiased comparisons among the methods. Changing this tolerance affects the fastest eventual convergence rate that may be achieved (linear convergence for inexact Newton methods [13]). Specifically, a tighter (or looser) tolerance leads to a faster (slower) convergence rate and does not change the relative performance of these methods with respect to each other. The effect may be seen in the steepest slope that the convergence curve may achieve as the nonlinear iterates near the solution.

In practice, the Krylov subspace dimension should be kept small to reduce arithmetic and storage costs, which may be accomplished via restarted Krylov methods

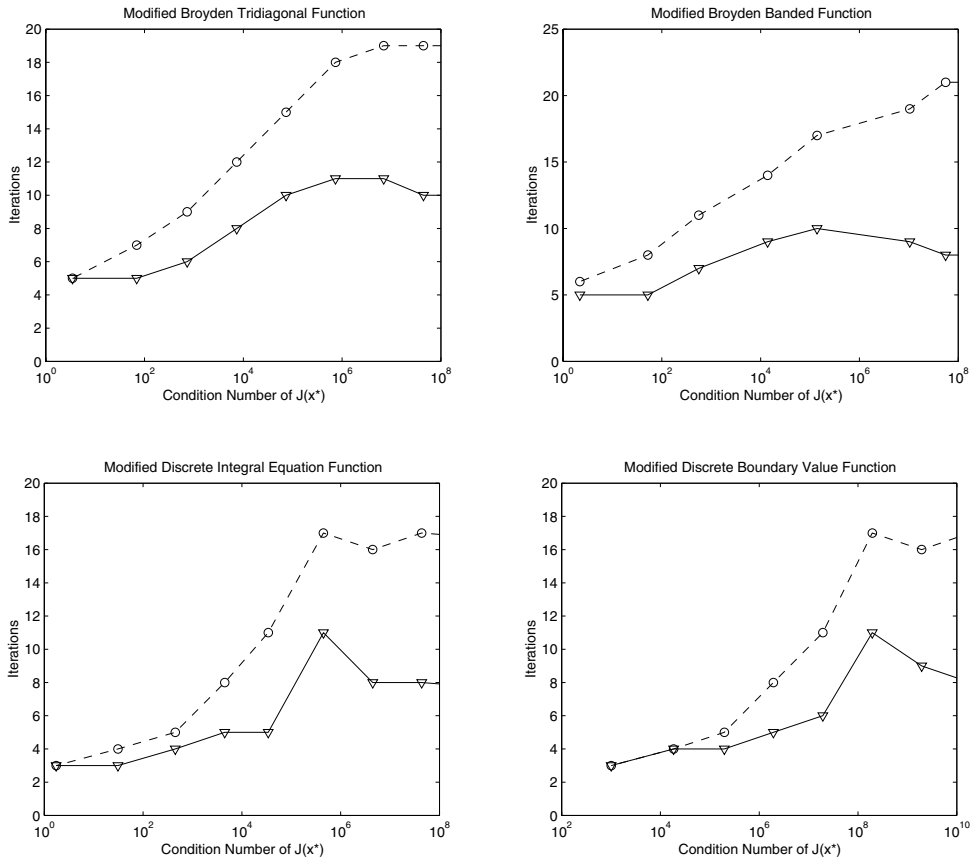

FIG. 3.4. *Comparison of a rank-one tensor method (∇, solid line) with Newton's method (○, dashed line) on variably ill-conditioned test problems that approach rank* $n-3$.

and preconditioning. However, to eliminate any ill effects of small Krylov subspaces preventing convergence in the local model and affecting the outer iterations, the maximum Krylov subspace was set to the problem dimension, $m_{max} = n$, and the solver was not restarted. We used preconditioners that are appropriate for the problem, and they will be discussed with each problem.

In the next three subsections, we present numerical results on the ill-conditioned problems. The results of the tensor-Krylov method TK2 are virtually identical to those of TK2+, so we do not include them here.

3.2.1. Bratu problem. The Bratu problem is a simplified model for nonlinear diffusion phenomena occurring, for example, in semiconductors and combustion, where the source term is related to the Arrhenius law for modeling exothermic reactions. The following version is taken from the set of nonlinear model problems collected by Moré [24]. The problem is the nonlinear PDE in u,

$$-\nabla^2 u = \lambda e^u \text{ in } \Omega, \quad u = 0 \text{ on } \partial\Omega, \tag{3.2}$$

where $\nabla^2 = \sum_{i=1}^{n} \partial^2/\partial x_i^2$ is the Laplace operator, $\lambda \in \mathbb{R}$ is a parameter, Ω is the bounded domain $(0,1) \times (0,1)$, and $\partial\Omega$ is the boundary of Ω.

Problem (3.2) has a unique solution for $\lambda \leq 0$, but for $\lambda > 0$, there may be zero, one, or two solutions (cf. [18]). The critical value $\lambda^* = 6.80812$ is a limit point such that for $0 < \lambda < \lambda^*$, problem (3.2) has two solutions and for $\lambda > \lambda^*$, it has no solutions. Also, the problem at the limit point is singular with a rank of $n - 1$, and as λ approaches the limit point, the discretized problem becomes harder to solve. To investigate the effects of ill-conditioning on the inexact algorithms, we increased λ over the range $\lambda \in [5, 6.806652]$, which increased the condition number of $J(x_*)$ from about 10^3 to 10^6.

When testing the Bratu problem, the initial approximate solution was zero on a uniform grid of size 31×31. The Laplace operator was discretized using centered differences (5-point stencil), and our preconditioner was also the centered differences discretization of the Laplace operator. Note that the preconditioner is not exact due to omitting the forcing term in (3.2). We computed Jacobian-vector products using first-order forward differences. Hence, the number of function evaluations is the sum of the total number of Arnoldi iterations, the number of linesearch backtracks (if any), and the total number of nonlinear iterations. Thus, the number of function evaluations provides a relative measure of overall work for each algorithm.

Figure 3.5 presents the results of these tests, comparing the number of function evaluations computed for each method using the three choices of preconditioning (none, left, and right preconditioning). If one considers the condition number of the preconditioned Jacobian at the root (i.e., $M^{-1}J(x_*)$ or $J(x_*)M^{-1}$), then the condition numbers in the bottom two plots span the range of 3×10^0 to about 10^4 instead of 10^3 to 10^6 for the Jacobian itself. The results in the figure are similar to those in figures in section 3, where Newton-GMRES requires increasingly more function evaluations as the problem becomes more ill-conditioned and difficult. The tensor-Krylov methods required from four to seven outer iterations, whereas Newton-GMRES required from four to 13 outer iterations. That is, Newton-GMRES required almost double the number of tensor-Krylov iterations on the most ill-conditioned problem. The three plots in Figure 3.5 uphold the prior conclusion that increased ill-conditioning only mildly increases the number of outer iterations for tensor methods.

In all cases, when the problem is not overly difficult (e.g., the experiments at a condition number of 10^3 in Figure 3.5), Newton-GMRES is more efficient in terms of nonlinear iterations than the tensor methods. Here, the number of iterations for all of the methods is equal, but GMRES is more efficient at solving the local Newton model, which results in fewer total function evaluations. When the problem is more difficult, however, the tensor methods are superior to Newton-GMRES by a factor of up to 1.9. Approaching the limit point even more closely would have given even more of an advantage to the tensor-Krylov methods.

When comparing only the tensor methods, the tensor-GMRES method of Feng and Pulliam [17] is more efficient than the TK3 and TK2+ methods. It appears that the step produced from the projected tensor model of the Feng–Pulliam method is nearly the same as the steps calculated from the more precise local models of the tensor-Krylov methods, and it is less expensive to compute. This behavior may be understood more clearly by investigating the iteration history of all of the methods, which we describe next.

To investigate the step quality of each tensor-Krylov method, we tested the Bratu problem with $\lambda = 6.806652$, which has a condition number of roughly 1.5×10^6. Using right preconditioning, the results in the first plot of Figure 3.6 show the faster outer (nonlinear) iterations of the three tensor methods, which display very similar performance. All methods start by exhibiting linear convergence until the respective

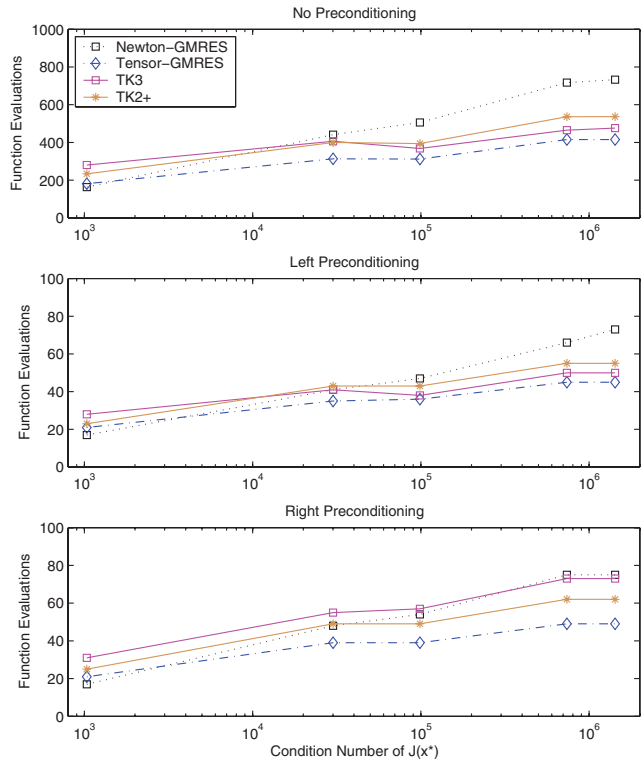

FIG. 3.5. *Effects of ill-conditioning on the inexact algorithms as seen in the Bratu problem.*

method can overcome the near singularity and accelerate convergence. The tensor methods accelerate convergence sooner than Newton-GMRES (iteration 2 versus iteration 5), and this is typical behavior for ill-conditioned problems—Newton-type methods branch into superlinear convergence later and later as the ill-conditioning grows. Because the forcing term for the inner iterative method is constant (instead of decreasing each iteration), all methods exhibit asymptotic linear convergence, as evidenced by their straight trajectories near the solution.

When we consider function evaluations in the bottom plot, the tensor-Krylov methods separate from the Feng–Pulliam method. The block size of the method is a clear indicator of the relative efficiency of the method. Specifically, tensor-GMRES, which uses the scalar (block size one) implementation of GMRES, is more efficient than TK2+ (block size two) and TK3 (block size three). The Bratu problem is unique among our tests in that the steps computed from a projected local tensor model are of roughly the same quality as the steps from TK2+ and TK3. Therefore, the number of outer iterations is the same, but because tensor-GMRES is more efficient in solving the local model, tensor-GMRES has the advantage.

3.2.2. Modified discrete boundary value problem. The discrete boundary value problem is a simple test problem from [25]. The standard discrete boundary value problem is

$$f_i(x) = 2x_i - x_{i-1} - x_{i+1} + \tfrac{1}{2}h^2(x_i + t_i + 1)^3, \quad 1 \le i \le n, \tag{3.3}$$

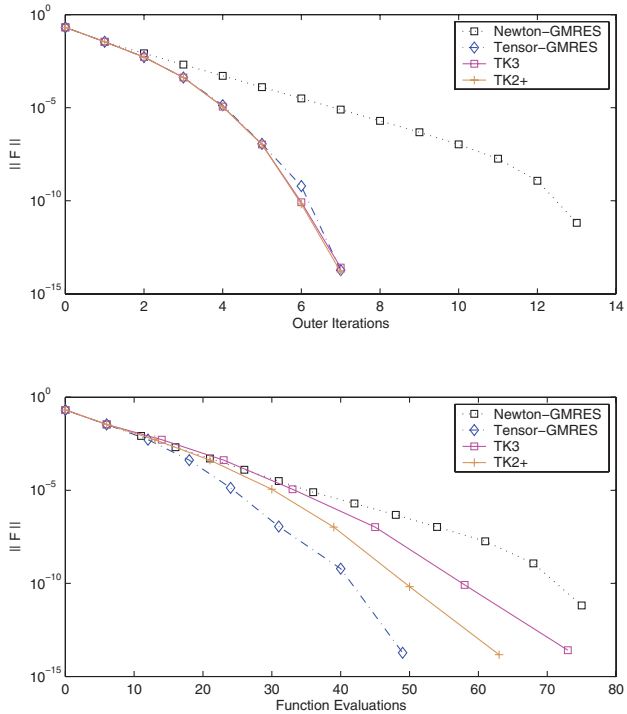

FIG. 3.6. *Example iteration history on the Bratu problem at* $\lambda = 6.806652$.

where $h = \frac{1}{n+1}$, $t_i = ih$, and $x_0 = x_{n+1} = 0$. The initial approximate solution is zero on a problem size of $n = 100$ equations. For our tests, we have modified (3.3) in accordance with (3.1) of section 3.1.

When testing this problem, we used a preconditioner that corresponds to the Jacobian of (3.3) but without the term t_i. We computed Jacobian-vector products using an analytic evaluation of the Jacobian, and we tallied the number of "function evaluation equivalents," which is the sum of function evaluations and Jacobian-vector products. If these products were approximated by first-order forward differences, as is generally the case with complex problems, then "function evaluation equivalents" would be equal to the number of function evaluations. This number also provides a relative measure of overall work for each algorithm.

Figure 3.7 presents the results of these tests, comparing the number of function evaluation equivalents computed for each method using the three choices of preconditioning (none, left, and right preconditioning) for the various values of $\lambda = 1 - 10^{-j}$, $j = 0, 1, 2, \ldots$, in (3.1). If one considers the condition number of the preconditioned Jacobian at the root (i.e., $M^{-1}J(x_*)$ or $J(x_*)M^{-1}$), then the condition numbers in the bottom two plots span the range of 1×10^0 to about 2×10^6 (left preconditioning) or 2×10^8 (right preconditioning) instead of 4×10^3 to 2×10^9 for the Jacobian, not counting the singular case.

The results for the modified discrete boundary value problem are similar to those of the Bratu problem in Figure 3.5: Newton-GMRES requires increasingly more function evaluations as the problem becomes more ill-conditioned, whereas the number of function evaluations required by the tensor methods increases to a lesser extent. It

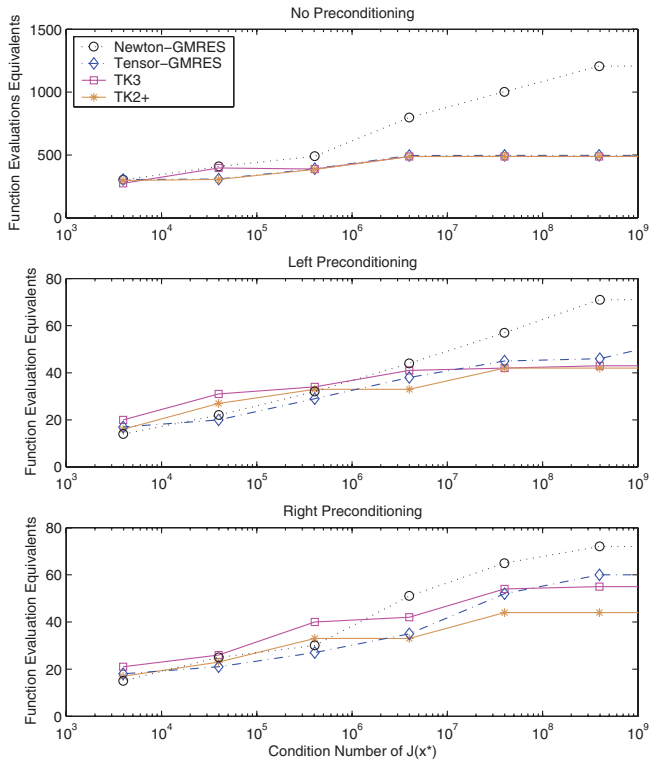

FIG. 3.7. *Effects of ill-conditioning on the inexact algorithms as seen in the discrete boundary value problem.*

is interesting to note that the tensor methods are virtually identical in performance without preconditioning and resemble the results in section 3.1. However, once preconditioning is used, the tensor methods are affected by the ill-conditioning of the problem, yet still to a lesser extent than Newton-GMRES.

When comparing only the tensor methods while using left and right preconditioning, the tensor-GMRES method of Feng and Pulliam is more efficient than the TK3 and TK2+ methods on the easier problems but less efficient on the hardest problems, which is different from the experience with the Bratu problem above. We explain this relative difference by noting that tensor-GMRES required more nonlinear iterations as the problem grew more ill-conditioned. Because the tensor-Krylov methods generally require more Arnoldi (inner) iterations to solve the local tensor model due to the less efficient block-Arnoldi process, any computational savings must come from fewer nonlinear (outer) iterations.

To better illustrate this behavior, Figure 3.8 presents the iteration history of all methods for one test case in Figure 3.7. We present the results of the modified problem using right preconditioning with $\lambda = 1$, which corresponds to the rightmost set of points in the bottom plot of Figure 3.7. Here, the top plot of Figure 3.8 shows that Newton-GMRES has linear convergence, and after one good step on the second iteration, tensor-GMRES appears to have linear convergence that is slightly faster than that of Newton-GMRES. The TK2+ and TK3 methods appear to have superlinear convergence with nearly the same steps. This profile indicates that the

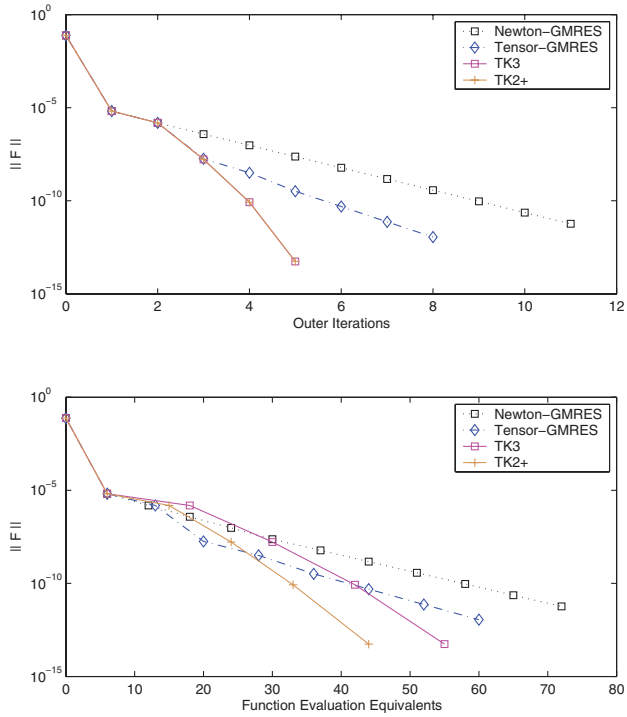

FIG. 3.8. *Example iteration history on the discrete boundary value problem at* $\lambda = 1$.

tensor step found from a projected tensor model is not as good for this problem as the tensor-Krylov steps which use the full tensor model. That is, the projection of the tensor model loses some information that is important for achieving superlinear convergence.

When we consider function evaluations in the bottom plot of Figure 3.8, two features are evident. First, the slopes of the Newton-GMRES and tensor-GMRES lines are nearly identical, which indicates that the cost of solving the projected tensor model in terms of function evaluations is roughly the same as the cost of solving the Newton model in Newton-GMRES. Second, the TK2+ and TK3 trajectories separate, which indicates that the block-2+ local solver in TK2+ is more efficient than the block-3 solver in TK3.

3.2.3. Modified Broyden tridiagonal problem. The Broyden tridiagonal problem is another test problem from [25]. The function is defined as

$$f_i(x) = (3 - 2x_i)x_i - x_{i-1} - 2x_{i+1} + 1, \quad 1 \le i \le n, \tag{3.4}$$

where $x_0 = x_{n+1} = 0$. Here again, we have modified the problem to be ill-conditioned, but in this case, we modify the last function to be

$$f_n(x) = (1 - \lambda)\left[(3 - 2x_n)x_n - x_{n-1} + 1\right] + \lambda\left[(3 - 2x_n)x_n - x_{n-1} + 1\right]^2.$$

This modification is similar to the problem studied by Feng and Pulliam in [17] and makes the problem more ill-conditioned as λ asymptotically approaches one, and singular at $\lambda = 1$ with a rank $n - 1$. We used the values $\lambda = 1 - 10^{-j}$, $j = 0, 1, 2, \ldots,$

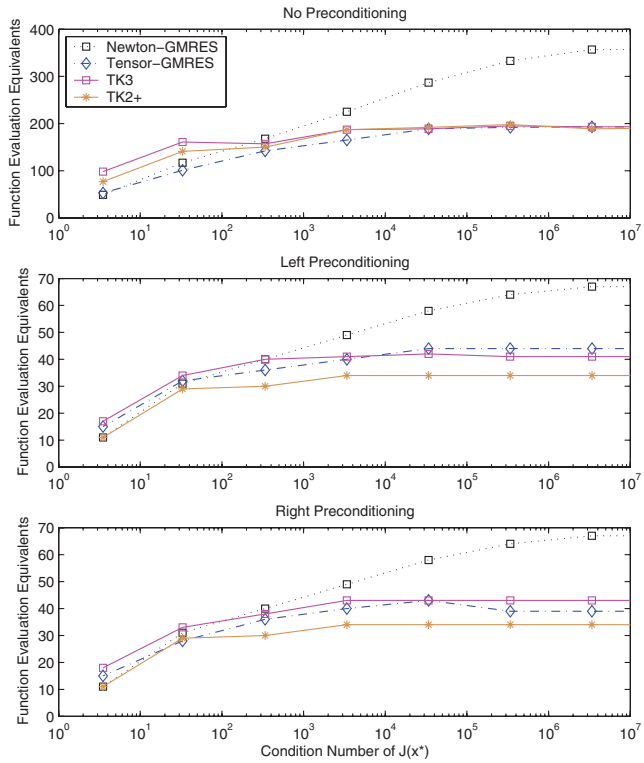

FIG. 3.9. *Effects of ill-conditioning on the inexact algorithms as seen in the modified Broyden tridiagonal problem.*

until the results were indistinguishable from $\lambda = 1$ due to round-off error, at which point we just use $\lambda = 1$. For our tests, we set $n = 100$ and used $(-1, \ldots, -1)^T$ as the starting vector. We used the Jacobian of (3.4) as our preconditioner for all values of λ.

Figure 3.9 presents the results of the ill-conditioning tests over the span of problems using $\lambda \in [0, 1]$, which affects the condition number of $J(x_*)$. The three plots represent the three choices of preconditioning (none, left, and right preconditioning), and each compares the number of function evaluation equivalents computed for the different methods. If one considers the condition number of the preconditioned Jacobian at the root (i.e., $M^{-1}J(x_*)$ or $J(x_*)M^{-1}$), then the condition numbers in the bottom two plots (not counting the singular case) span the range of 1×10^0 to 2×10^6 instead of 3×10^0 to 3×10^6 for the Jacobian.

Here again the results show that Newton-GMRES requires increasingly more function evaluations as the problem becomes more ill-conditioned. The tensor methods are affected somewhat at the low condition numbers, but there is a plateau where the number of function evaluations required by the tensor methods are no longer affected by the ill-conditioning of the problem. Near $\lambda = 1$, Newton-GMRES requires almost twice the number of function evaluations as the tensor methods.

When comparing only the tensor methods while using left and right preconditioning, the tensor-GMRES method of Feng and Pulliam is roughly comparable to TK3. The TK2+ method is more efficient on all problems except one, where tensor-GMRES is the best. In comparison with Newton-GMRES on the easier problems with left or

right preconditioning, TK2+ requires the same number of or fewer function evaluation equivalents.

Figure 3.10 presents the iteration history of all methods for the rightmost test case ($\lambda = 1$) in the right preconditioning plot in Figure 3.9. The top plot of Figure 3.10 shows that Newton-GMRES has linear convergence on this singular problem, and the tensor methods have superlinear convergence. Once again, the two tensor-Krylov methods have the same quality of steps, but the tensor-GMRES method no longer shares the same trajectory as TK2+ and TK3, which indicates that the projected tensor model loses some critical directional information.

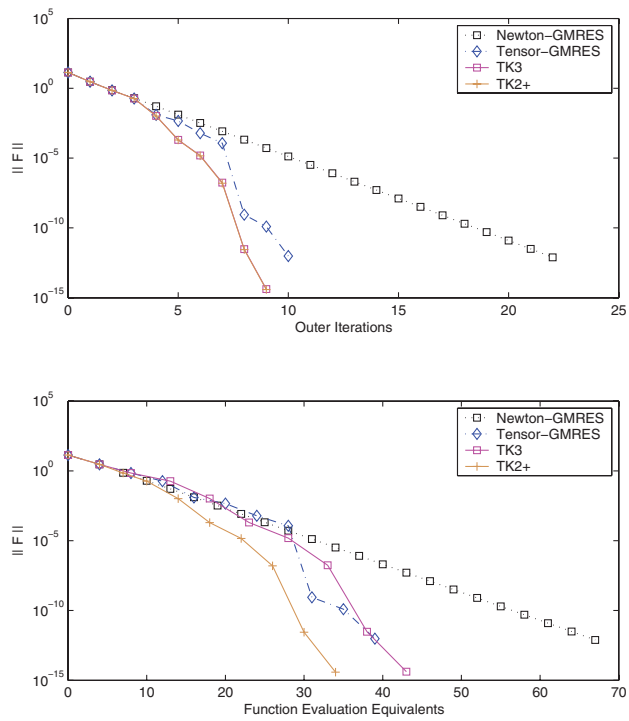

FIG. 3.10. *Example iteration history on the modified Broyden tridiagonal problem at* $\lambda = 1$.

The bottom plot of Figure 3.10 considers the function evaluation equivalents on the x-axis. It shows that tensor-GMRES is generally more efficient than TK3 at solving the local model. Thus, while TK3 is more efficient in total nonlinear iterations, tensor-GMRES is more efficient at solving the local model, which accounts for the difference. Another feature evident in the bottom plot is that the TK2+ and TK3 trajectories separate. As with the discrete boundary value problem above, this indicates that the block-2+ local solver in TK2+ is more efficient than the block-3 solver in TK3.

3.3. Large-scale problem solved with inexact methods. For our largest, most difficult problem, we consider the counterflow jet problem described in [27]. This fluid flow problem offers steady-state multiplicity and exhibits a pitchfork bifurcation, where the Jacobian is singular (rank $n - 1$).

The two-dimensional planar counterflow jet problem consists of a rectangular channel with two opposing inlet flows on the y-axis and two outlet flows on the x-axis. This fluid flow problem is set up using a particular spatial discretization of the continuity and Navier–Stokes equations describing laminar, isothermal flow of an incompressible Newtonian fluid. The particular spatial discretization that we use is from the finite element reacting flow code MPSalsa [33].

The finite-element discretization utilized 6,321 bilinear elements corresponding to 18,963 unknowns and had a fixed aspect ratio of 1.0. For reasons related to coupling external solvers to MPSalsa, the aspect ratio was constrained to the geometry in the original mesh file and could not be scaled with a parameter to achieve different aspect ratios as was done in [27]. Consequently, not all experimental conditions are the same.

As the Reynolds number of the injected fluid changes, multiple steady states may exist. The point at which a single steady state changes to multiple steady states is a bifurcation. We used the Library of Continuation Algorithms (LOCA) [32, 31] to identify a pitchfork bifurcation at $Re^* = 872.20306885$ for our particular geometry and mesh. To investigate the effects of ill-conditioning on the methods, we increased Re from 100 to Re^*, which increased the condition number of $J(x_*)$ from about 10^4 to 10^{15}. Differences in performance among the algorithms were not seen until $Re = 872.19$.

We implemented the algorithms in NOX [23], which is a C++ object-oriented nonlinear solver package developed at Sandia National Laboratories. For objective comparisons, all of the methods, including Newton-GMRES and tensor-GMRES, used the same Arnoldi process (modified Gram–Schmidt) as the tensor-Krylov methods.

We used an explicit Jacobian, which our PDE code computed efficiently by a combination of analytic evaluation and numerical differentiation, and enabled the option for maximum accuracy in the Jacobian. We employed right preconditioning in all cases using an ILUT preconditioner [29].

We used a standard backtracking linesearch procedure for Newton-GMRES and used the complete tensor-GMRES algorithm in [17], including their globalization. For the tensor-Krylov methods, we report results of the standard linesearch, but the curvilinear linesearch [3] provided similar performance. For selecting the linesearch parameter at each trial step, we used interval halving (dividing the search direction in half at each inner iteration).

To get the Jacobian as close to singular as possible, the problem was solved as accurately as possible. We used the following stopping condition: $\|F(x_k)\|_2 \leq 10^{-15} \|F(x_0)\|_2$. In all other respects, we used the same conditions and parameters as before. The initial approximation was the zero vector for all cases.

Figure 3.11 shows that the tensor-Krylov methods require 6–10 iterations to solve the range of problems. On the other hand, Newton-GMRES requires nearly twice the iterations at the pitchfork bifurcation, and tensor-GMRES failed to solve that problem. All methods had identical performance until very near the pitchfork bifurcation as the condition exceeded 10^{10}. TK2+ required four linesearch iterations at 10^{11}, hence the higher number of function evaluations.

Figure 3.12 shows the convergence history for all methods at the pitchfork bifurcation. The tensor-Krylov methods share roughly the same level of performance. Tensor-GMRES, on the other hand, stalls after about 12 orders of magnitude improvement in $\|F\|$. This is not due to excessive linesearches because in most instances a full step is taken; tensor-GMRES just loses directional information here. Newton-GMRES behaves as we have seen previously with smaller problems—roughly linear

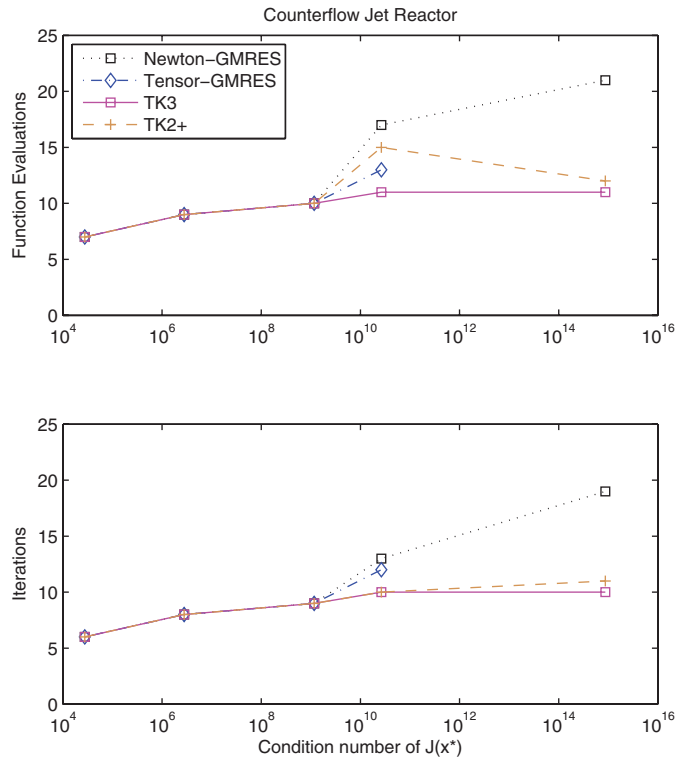

FIG. 3.11. *Effects of ill-conditioning in the counterflow jet reactor problem.*

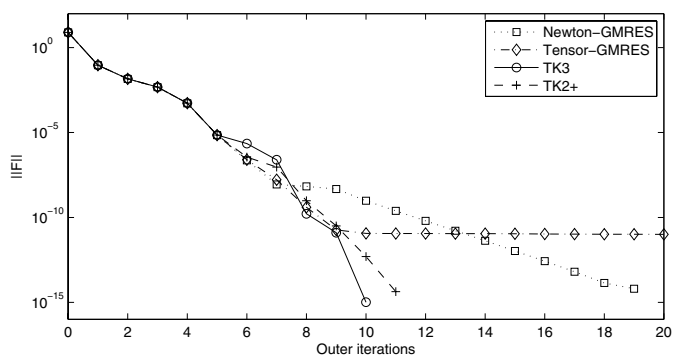

FIG. 3.12. *Iteration history of the counterflow jet reactor problem at the pitchfork bifurcation.*

convergence that is slower than that of the tensor methods (tensor-GMRES notwithstanding).

4. Summary and conclusions. This paper has investigated the performance of tensor methods (both direct and Krylov-based inner solvers) on small- to large-scale problems over a range of conditionings, from well-conditioned to ill-conditioned to singular. Our results showed that tensor methods outperform Newton-based methods as the problems become more ill-conditioned. Prior to this investigation, studies on

direct tensor methods focused only on singular problems or on general problems that are well-conditioned.

Specifically, our results show that, eventual quadratic convergence notwithstanding, the performance of Newton's method will degrade as the ill-conditioning grows, whereas tensor methods appear to be relatively unaffected or only mildly affected (in the case of larger rank deficiencies). Newton-based methods do not handle these singular problems well because they converge linearly to the solution and, in some cases, with poor accuracy.

For the large-scale methods, despite the use of an iterative inner method with an approximate solve, the tensor-Krylov methods appear to retain superlinear convergence properties on ill-conditioned problems. On the other hand, Newton-GMRES is affected by the ill-conditioning and branches into superlinear convergence later and later as the problems become more ill-conditioned. Thus, tensor methods are especially useful for large-scale problems that are highly ill-conditioned or singular, where Newton-based algorithms exhibit very slow convergence.

In terms of the various tensor methods, TK3 and TK2+ generally have the best performance in terms of nonlinear iterations. When considering total function evaluations, then TK2 and TK2+ outperform TK3. Feng and Pulliam's tensor-GMRES method is very competitive but could not solve the large-scale problem at the bifurcation point. A thorough comparison of these methods on other fluid flow problems is in [2].

There are many important and practical problems that have ill-conditioned or singular Jacobian matrices at the solution, such as large PDE problems that exhibit shocks, turning points, and/or pitchfork bifurcations. The conclusions of this research indicate that concepts from tensor methods may benefit algorithms for bifurcation tracking and stability analysis. We intend to investigate these applications in future research.

Acknowledgments. We thank Roger Pawlowski for the counterflowing jet problem in MPSalsa, and we are grateful to Eric Phipps for assistance with finding the pitchfork bifurcation using LOCA. We also thank the two anonymous referees for carefully reading the manuscript and suggesting important improvements.

NUMERICAL SIMULATION OF ACOUSTIC STREAMING ON SURFACE ACOUSTIC WAVE-DRIVEN BIOCHIPS*

DANIEL KÖSTER†

Abstract. A novel type of microfluidic biochip employs acoustic surface waves as a pumping mechanism for fluids. Piezoelectric substrate materials in the chip efficiently convert an electromagnetic input signal into an elastic wave confined to the surface layer of the substrate, hence the surface acoustic wave. The interaction of these waves with an adjoining fluid volume leads to streaming patterns in the fluid or of the motion of the fluid as a whole. In this work we study this acoustic streaming effect. We present a two-scale mathematical model, some theoretical results on the well-posedness of the model problem, as well as numerical simulations based on the finite element method. The model will include the case of free capillary fluid boundaries.

1. Introduction.

The past decades have seen unprecedented advances in the production of miniaturized electronic circuits, from the leviathan computers filling entire rooms in the humble beginnings to the powerful and omnipresent microchips of today. A similar revolution under the motto "smaller is better" is currently taking place in the life sciences regarding the manipulation of fluids, with the transition from test tubes and beakers to micropipettes and microtitre plates.

In contrast to the field of microelectronics, where the aim is still to reduce the size of transistors, in microfluidics the main concern nowadays is to manufacture increasingly complex systems of channels with sophisticated pumps, valves, mixers, separators, and filters, all on a scale of micrometers. A popular concept today is known as *lab-on-a-chip*. The goal of a lab-on-a-chip is the integration of a complete analysis and reaction system on a small surface (≈ 1 cm^2 or less). A sample device is shown in Figure 1.1.

There are many reasons for desiring a small scale. Less energy and lesser amounts of expensive reagents are needed, reducing costs. Devices can be used in parallel and with automatic control, useful in applications such as gene sequencing. From the physical point of view we have more efficient heat and material transport, leading to better yields and faster analysis.

Despite all of these promising aspects there are certain technical difficulties arising in the production of microfluidic components. Specifically, the task of performing controlled pumping or mixing of nano- or picoliter quantities of fluids becomes difficult. For instance, the low Reynolds number of typical flows on this scale signifies that flows in this regime are laminar and not turbulent. This is an obstacle in designing a component to mix reagents.

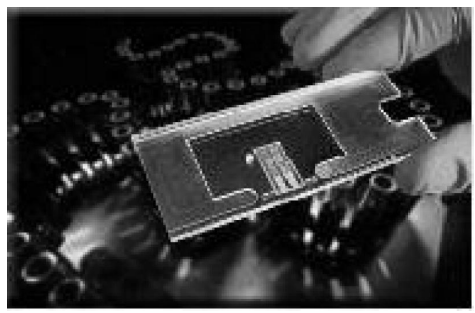

FIG. 1.1. *Example of a biochip.*

A novel type of microfluidic biochip employs surface waves as a driving force. The key of this technology is a pump able to position reagents on the surface of chips or in microfluidic channels without mechanical contact. This is achieved using surface acoustic waves induced using radio frequency electric signals. The waves arise through the use of piezoelectric substrate materials in the chip, e.g., lithium niobate. The electromagnetic signal is efficiently converted into an elastic wave confined to the surface layer of the substrate, the hence surface acoustic wave (SAW).

The interaction of these waves with the fluid leads to streaming patterns in the fluid or of the motion of the fluid as a whole. It is thus possible to mix minute amounts of fluid or conduct chemical reactions through precisely controlled transport of reagents. See, e.g., [48, 21] for further details. Microfluidic pumps based on this technology are already available on the market; see [49].

In this work we will use the compressible Navier–Stokes equations as a starting point to describe fluid flow. This is justified since the typical value of the Knudsen number, defined as the ratio of the characteristic physical length scale to the molecular mean free path length, is much less than 1. Due to the presence of widely different time scales in the physical problem we will derive further model equations to describe the fluid behavior.

The resulting two subproblems describe fluid flow at a microscopic time scale, where acoustic effects are dominant, and at a macroscopic time scale, where the streaming effects are observable. The solution of the microscopic model is necessary to calculate the effective force terms in the macroscopic model. Our model fits into the formal framework of *heterogeneous multiscale methods* as described in [14, 15]. This general approach attempts to formalize the idea of performing microscale simulations to close macroscale models.

Furthermore, we will consider the case of free capillary fluid boundaries. This problem is of interest because some biochip models do not employ closed fluid channels. Instead these chips are constructed with a virtual channel geometry defined by planar regions with different wetting properties on the chip surface. Fluids adhere to the hydrophilic regions by surface tension and are thus contained; see [49]. Another use of free capillary boundaries is for the passive filling of small cavities by surface tension; see [10].

1.1. Prior work and aims of the paper. The mathematical modeling and numerical simulation of the interaction between SAWs and surrounding fluids is a mostly unexplored field. This is mainly due to the novelty of the applied technology. The book [24] may serve as a recent overview of small-scale fluid-streaming phenomena.

Many numerical studies of acoustic streaming effects are already available. However, most of these use the older streaming force approach by Nyborg [32] as a model. As an example we cite [40], where the authors simulated acoustic streaming in microfluidic channels induced by disk actuators.

Another work of interest is [5] since SAWs are also employed there and simulated with true fluid-structure interaction. However, the focus of that work is the simulation of first order acoustic effects and not of acoustic streaming. Hence, the problem of different time scales does not appear there.

The model used in this work was introduced by Bradley [6]. It provides a rigorous treatment of boundary conditions often neglected in other works. As far as we know, the present work contains the first numerical simulation based on this improved model. In this work we have extended this model to include the effect of free capillary fluid boundaries which complicates the numerical algorithm considerably. We note that relatively few works exist which treat the simulation of *compressible* flows with free capillary surfaces.

The main contribution of this paper is a viable numerical algorithm to predict the deformation of free droplet shapes under the influence of acoustic streaming. The numerical results suggest that the method possesses good stability properties, although much numerical effort is currently invested for solving the microscale subproblem. Alternative approaches for the microscale subproblem are current work.

1.2. Outline of this work. We start by presenting the physical fundamentals in section 2. The classical Navier–Stokes equations of hydrodynamics serve as a basis to develop the numerical model. The model consists of two separate systems of partial differential equations to describe the flow variables at pressure p and velocity $\boldsymbol{v}$ on two different time scales.

Section 3 presents an analysis of the central mathematical problems arising in the model. The problem can be characterized as a generalized instationary, compressible Stokes problem, supplied with initial and boundary conditions. We study several different solution concepts: general instationary solutions, periodic solutions, and time-harmonic solutions. We define suitable function spaces as well as the used concept of weak solutions within these spaces.

We will prove the existence and uniqueness of weak solutions, as well as continuous dependence on the problem data. We will additionally introduce a result demonstrating the relationship between the different solution concepts.

Section 4 will introduce the extension of the prior problems to problems incorporating free capillary boundaries. Due to the complexity of the problem we restrict ourselves to the study of appropriate numerical algorithms.

Section 5 presents an overview of the practical algorithms used to solve the discretized problems. We have used standard Lagrange-type conforming triangular and tetrahedral finite elements.

The final section presents results of numerical experiments. Academic test problems are formulated which serve to validate the software implementation. Problems with realistic physical parameters are also defined which demonstrate the applicability to real-life situations.

1.3. Notation and function spaces. In what follows we will denote by Ω a bounded domain in $\mathbb{R}^d$. We will use standard notation from Lebesgue and Sobolev space theory.

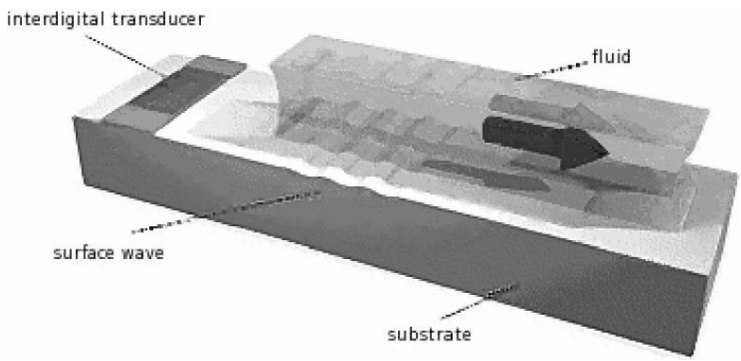

FIG. 2.1. *Working principles of a SAW-driven fluidic device.*

2. Derivation of the model. The biochips treated in this work contain a substrate layer consisting of a piezoelectric material, e.g., lithium niobate. Embedded on the substrate surface are fine electrodes known as *interdigital transducers* (IDTs) due to their comblike structure. When a radio frequency signal (typical frequencies are 100 MHz) is applied to the IDTs, the inverse piezoelectric effect causes a distortion of the substrate layer. Using special crystal cuts one obtains coupled elastic-electromagnetic waves in the substrate.

The chips used for manipulating fluid are designed to favor a special type of wave known as SAWs, also called *Rayleigh waves*. These waves spread out along the surface of the substrate in the fashion of a miniature earthquake. The wavelength is defined by the IDT geometry, and typical amplitudes of displacement are in the nanometer regime. Rayleigh waves are restricted to a thin layer of several wavelengths on the surface of the chip.

If the surface of the substrate is in contact with fluid and if the normal component of displacement is nonzero, part of the energy will be radiated into the fluid. The thus damped SAW is known as a *leaky SAW* (LSAW). The interaction between the LSAW and the fluid causes an internal streaming effect as explained below; see Figure 2.1 for an illustration. This streaming can be used to mix the fluid or as a contact-free pump. It is even possible [49] to define a virtual fluidic network on the chip surface using hydrophobic and/or hydrophilic materials etched onto the substrate using photolithographic techniques. Here we are interested in the effect of the streaming on free capillary boundaries.

Our approach is based on a splitting into two subproblems, with coupling being either neglected or treated empirically. The analysis and numerical simulation of the elastic/electromagnetic subproblem describing the creation of SAWs was treated in [17]. In this work we will focus on the coupling of LSAWs with the fluid. This interaction will be modeled in only one direction. To be precise, we use an empiric LSAW displacement as the input parameter for the streaming effect and neglect the backward coupling of the fluid on the elastic substrate.

2.1. Overview of the fluidics problem. For the modeling of the fluid flow we use the compressible Navier–Stokes equations; see [27, 6]. Assume a bounded fluid domain $\Omega(t)$ with the boundary $\Gamma_d(t) \subseteq \partial\Omega(t)$ in contact with elastic walls partially

traversed by SAWs.

$$
\begin{aligned}
\rho\left(\frac{\partial \boldsymbol{v}}{\partial t} + (\nabla \boldsymbol{v})\boldsymbol{v}\right) &= \nabla \cdot \Sigma && \text{in } \Omega(t),\ t > 0,\\
\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) &= 0 && \text{in } \Omega(t),\ t > 0,\\
\boldsymbol{v}(t, \boldsymbol{x} + \boldsymbol{u}(t, \boldsymbol{x})) &= \frac{\partial \boldsymbol{u}}{\partial t}(t, \boldsymbol{x}) && \text{on } \Gamma_d(t),\ t > 0,\\
\boldsymbol{v} = 0, \quad p = p_0, \quad \Omega(0) &= \Omega_0 && \text{for } t = 0,
\end{aligned}
\tag{2.1}
$$

with the Newtonian stress tensor $\Sigma = \Sigma(\boldsymbol{v}, p)$ defined as

$$
\Sigma_{ij}(\boldsymbol{v}, p) = -p\delta_{ij} + \eta\left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i}\right) + \left(\zeta - \frac{2}{3}\eta\right)(\nabla \cdot \boldsymbol{v})\delta_{ij}.
$$

The quantities that appear are

$\boldsymbol{v}$	fluid velocity,
p	fluid pressure,
ρ	fluid density,
η, ζ	standard and bulk viscosity coefficients,
$\boldsymbol{u}$	SAW displacement from equilibrium position, typically a harmonic function of time,
$\boldsymbol{n}$	outer unit normal vector on $\partial\Omega$.

The divergence of the stress tensor yields

$$
\nabla \cdot \Sigma = -\nabla p + \eta \Delta \boldsymbol{v} + \left(\zeta + \frac{\eta}{3}\right)\nabla(\nabla \cdot \boldsymbol{v}).
$$

We will need a constitutive equation to close this system. We use an equation of state arising from the assumption of constant entropy in time and space (see [11]). This leads to a simple relation of the form

$$
p - p_0 = a(\rho - \rho_0)^\gamma, \tag{2.2}
$$

where p_0, ρ_0 are equilibrium states and $a, \gamma > 0$. We assume a linear dependence for liquids such as water; thus, $\gamma = 1$.

2.2. Physical origin of acoustic streaming. As discussed above we assume that flow in the fluid region arises exclusively from the harmonic oscillation of the solid boundary. When using standard acoustics theory, where nonlinear effects are neglected and low frequencies and amplitudes are assumed, we expect the propagation of acoustic waves in the fluid. An additional effect observed in real life, however, is that of a *stationary* average flow field, not accounted for by standard acoustic theory.

This effect, known as *acoustic streaming*, was first studied by Lord Rayleigh [35]. Further contributions to the study of this phenomenon were made by Lighthill, Eckart, Nyborg, Riley, and others [36, 37, 31, 32, 28, 38, 16]. Two types of acoustic streaming are generally distinguished today:

- *Rayleigh streaming* is associated with the boundary layers of a fluid near solid surfaces.

- *Quartz wind* is associated with the dissipation of acoustic energy in the main body of the fluid.

Acoustic streaming effects are a result of the nonlinearity of the Navier–Stokes equations (2.1) in combination with the viscosity. The main problem for the numerical treatment of acoustic streaming is that extremely different time scales are involved. Typical frequencies of the harmonic oscillation are 100 MHz, requiring a time discretization on the order of 10^{-8} s. The acoustic streaming relaxation times are of the order 10^{-3}–10^{-1} s.

2.3. Acoustic subproblem. We assume an expansion of the unknowns $\boldsymbol{v}$, p, and ρ of the form

$$\begin{aligned} p &= p^{(0)} + \epsilon p' + \epsilon^2 p'' + \mathcal{O}\big(\epsilon^3\big)\,, \\ \rho &= \rho^{(0)} + \epsilon \rho' + \epsilon^2 \rho'' + \mathcal{O}\big(\epsilon^3\big)\,, \\ \boldsymbol{v} &= 0 + \epsilon \boldsymbol{v}' + \epsilon^2 \boldsymbol{v}'' + \mathcal{O}\big(\epsilon^3\big)\,. \end{aligned} \tag{2.3}$$

The small parameter $0 < \epsilon \ll 1$ is later fixed as the ratio $\boldsymbol{u}_0/L$, with $\boldsymbol{u}_0$ being the maximal SAW displacement of the domain boundary and L being the typical length scale used for a dimensionless formulation.

Set $p^{(1)} := \epsilon p'$, $p^{(2)} := \epsilon^2 p''$, and analogously ρ, $\boldsymbol{v}$, Σ. All terms with index 0 are constant in time and space and represent the known equilibrium state without SAW driving. By gathering all terms of order $\mathcal{O}(\epsilon)$ we arrive at

$$\rho^{(0)} \frac{\partial \boldsymbol{v}^{(1)}}{\partial t} - \nabla \cdot \Sigma^{(1)} = 0 \qquad \text{in } \Omega(t),\ t > 0, \tag{2.4a}$$

$$\frac{\partial \rho^{(1)}}{\partial t} + \rho^{(0)} \nabla \cdot \boldsymbol{v}^{(1)} = 0 \qquad \text{in } \Omega(t)\ t > 0, \tag{2.4b}$$

$$p^{(1)} = c_0^2 \rho^{(1)}, \tag{2.4c}$$

$$\boldsymbol{v}^{(1)}(t, \boldsymbol{x}) = \frac{\partial \boldsymbol{u}}{\partial t}(t, \boldsymbol{x}) \qquad \text{on } \Gamma_d(t),\ t > 0, \tag{2.4d}$$

$$\boldsymbol{v}^{(1)} = 0, \quad p^{(1)} = 0 \qquad \Omega(0) = \Omega_0 \qquad \text{for } t = 0, \tag{2.4e}$$

where c_0 is the small signal sound velocity in the fluid. The boundary condition is derived by observing that $\boldsymbol{u} = \mathcal{O}(\epsilon)$ and performing a Taylor expansion:

$$\boldsymbol{v}(t, \boldsymbol{x} + \boldsymbol{u}) = \boldsymbol{v}(t, \boldsymbol{x}) + (\nabla \boldsymbol{v})\boldsymbol{u} + \mathcal{O}(\|\boldsymbol{u}\|^2) = \frac{\partial \boldsymbol{u}}{\partial t}(t, \boldsymbol{x}).$$

In the future we will neglect the time dependence of Ω arising through the SAW oscillation. This is possible since the SAW displacement $\boldsymbol{u}$ is much smaller than the typical length L, equivalent to the fact that $\epsilon \ll 1$.

This linear system describes the *damped* propagation of acoustic waves. These arise solely as a reaction to the time-harmonic boundary values (2.4d), since the right-hand sides are zero. Due to the parabolic character of the system and the boundedness of Ω we expect the solution to converge into a time-harmonic quasi-equilibrium state for large t. Since the goal is the solution of the system (2.1) on the large time scale, the startup effects are of less interest than this equilibrium state.

2.4. Acoustic streaming subproblem. Assuming that the above first order system (2.4) is solved we proceed to gather terms of second order in ϵ while treating

the solution of (2.4) as given data. The result is

$$\rho^{(0)}\frac{\partial \boldsymbol{v}^{(2)}}{\partial t} - \nabla\cdot\Sigma^{(2)} = -\rho^{(1)}\frac{\partial \boldsymbol{v}^{(1)}}{\partial t} - \rho^{(0)}(\nabla \boldsymbol{v}^{(1)})\boldsymbol{v}^{(1)} \qquad \text{in } \Omega(t),\ t>0, \tag{2.5a}$$

$$\frac{\partial \rho^{(2)}}{\partial t} + \rho^{(0)}\nabla\cdot\boldsymbol{v}^{(2)} = -\nabla\cdot(\rho^{(1)}\boldsymbol{v}^{(1)}) \qquad \text{in } \Omega(t),\ t>0, \tag{2.5b}$$

$$p^{(2)} = c_0^2\rho_2, \tag{2.5c}$$

$$\boldsymbol{v}^{(2)} = -(\nabla \boldsymbol{v}^{(1)})\boldsymbol{u} \qquad \text{on } \Gamma_d(t),\ t>0, \tag{2.5d}$$

$$\boldsymbol{v}^{(2)} = 0, \quad p^{(2)} = 0, \quad \Omega(0) = \Omega_0 \qquad \text{for } t = 0. \tag{2.5e}$$

This system can be interpreted as an instationary Stokes problem describing creeping flow and containing mass sources and body forces.

Define $T := 2\pi\omega$ as the period of the harmonic SAW oscillation. Since we are interested in the acoustic streaming effects observable on the larger time scale, we take a temporal average of the right-hand sides. More precisely, we apply the operation

$$\langle a\rangle := \frac{1}{T}\int_{t_0}^{t_0+T} a(t)\,dt.$$

We thereby obtain the system

$$\begin{aligned}
\rho^{(0)}\frac{\partial \bar{\boldsymbol{v}}^{(2)}}{\partial t} - \nabla\cdot\bar{\Sigma}^{(2)} &= \left\langle -\rho^{(1)}\frac{\partial \boldsymbol{v}^{(1)}}{\partial t} - \rho^{(0)}(\nabla \boldsymbol{v}^{(1)})\boldsymbol{v}^{(1)}\right\rangle && \text{in } \Omega(t),\ t>0,\\
\frac{\partial \bar{\rho}^{(2)}}{\partial t} + \rho^{(0)}\nabla\cdot\bar{\boldsymbol{v}}^{(2)} &= \left\langle -\nabla\cdot(\rho^{(1)}\boldsymbol{v}^{(1)})\right\rangle && \text{in } \Omega(t),\ t>0,\\
\bar{p}^{(2)} &= c_0^2\bar{\rho}_2, &&\\
\bar{\boldsymbol{v}}^{(2)} &= -\left\langle(\nabla \boldsymbol{v}_1)\boldsymbol{u}\right\rangle && \text{on } \Gamma_d(t),\ t>0,\\
\bar{\boldsymbol{v}}^{(2)} = 0, \quad p^{(2)} &= 0, \quad \Omega(0) = \Omega_0 && \text{for } t = 0.
\end{aligned} \tag{2.6}$$

In the following we will deal only with the averaged terms $\bar{\boldsymbol{v}}^{(2)}$, $\bar{p}^{(2)}$, $\bar{\rho}^{(2)}$ and therefore denote these without the bars for simplicity. The corresponding stationary problem is also of interest when performing simulations without free capillary boundaries.

$$-\nabla\cdot\Sigma^{(2)} = \left\langle -\rho^{(1)}\frac{\partial \boldsymbol{v}^{(1)}}{\partial t} - \rho^{(0)}(\nabla \boldsymbol{v}^{(1)})\boldsymbol{v}^{(1)}\right\rangle \qquad \text{in } \Omega, \tag{2.7a}$$

$$\rho^{(0)}\nabla\cdot\boldsymbol{v}^{(2)} = \left\langle -\nabla\cdot(\rho^{(1)}\boldsymbol{v}^{(1)})\right\rangle \qquad \text{in } \Omega, \tag{2.7b}$$

$$p^{(2)} = c_0^2\rho_2, \tag{2.7c}$$

$$\boldsymbol{v}^{(2)} = -\left\langle(\nabla \boldsymbol{v}_1)\boldsymbol{u}\right\rangle \qquad \text{on } \Gamma_d. \tag{2.7d}$$

2.5. Free capillary boundaries. In addition to the problems with fixed channel geometries we will also treat the case of free capillary surfaces along parts of the boundary. To prepare this we first rewrite (2.1) using additional boundary conditions which are valid on a free capillary boundary $\Gamma_f(t)$ between liquid and air. The new boundary conditions are necessary to determine the normal velocity of the moving

interface as well as the stress acting due to capillary forces.

$$\rho\left(\frac{\partial \boldsymbol{v}}{\partial t} + (\nabla \boldsymbol{v})\boldsymbol{v}\right) = \nabla \cdot \Sigma \qquad \text{in } \Omega(t),\ t > 0, \tag{2.8a}$$

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) = 0 \qquad \text{in } \Omega(t),\ t > 0, \tag{2.8b}$$

$$\boldsymbol{v}(t, \boldsymbol{x} + \boldsymbol{u}(t, \boldsymbol{x})) = \frac{\partial \boldsymbol{u}}{\partial t}(t, \boldsymbol{x}) \qquad \text{on } \Gamma_d, \tag{2.8c}$$

$$\Sigma \boldsymbol{n} = \sigma(d-1)\boldsymbol{\kappa} \qquad \text{on } \Gamma_f(t),\ t > 0, \tag{2.8d}$$

$$\boldsymbol{v} \cdot \boldsymbol{n} = V \qquad \text{on } \Gamma_f(t),\ t > 0, \tag{2.8e}$$

$$\boldsymbol{v} = 0, \quad p = p_0, \quad \Omega(0) = \Omega_0 \qquad \text{for } t = 0. \tag{2.8f}$$

Here we have σ as the constant of surface tension between water and vacuum, the difference to the conditions of water/air interfaces being negligible, (cf. [27]), $\Gamma_f \subset \partial\Omega(t)$ as the free boundary, and V as the normal velocity component of the free boundary. Furthermore we have $\boldsymbol{\kappa}$ as the vector of curvature. By definition this vector has magnitude H (mean curvature of $\partial\Omega(t)$) and points in the direction of $\boldsymbol{n}$ (outer unit normal vector of $\partial\Omega(t)$).

The location of $\Gamma_f(t)$ will change significantly in time and now represents one of the unknowns of the problem. To adapt the two-scale model for the inclusion of capillary boundary effects, we include the capillary stress condition (2.8d) in both subproblems.

For the sake of consistency we will continue to neglect the motion of the domain when solving the first order acoustics problem (2.4). However, we will need to take it into account when solving the large time scale acoustic streaming subproblem (2.7).

3. Analytical results. In this section we will analyze a mathematical model of the acoustics and acoustic streaming subproblems introduced in section 2 for a fixed domain without free boundaries. Both subproblems (2.4) and (2.7) have the following general form: Given right-hand sides $\boldsymbol{f}_v$, f_p, boundary values $\boldsymbol{g}$, and initial values $\boldsymbol{v}_0, p_0$, find $\boldsymbol{v}$ and p satisfying

$$\mu_v \frac{\partial \boldsymbol{v}}{\partial t} - \nu_1 \Delta \boldsymbol{v} - \nu_2 \nabla(\nabla \cdot \boldsymbol{v}) + \nabla p = \boldsymbol{f}_v \qquad \text{in } \Omega,\ t > 0, \tag{3.1a}$$

$$\mu_p \frac{\partial p}{\partial t} + \nabla \cdot \boldsymbol{v} = f_p \qquad \text{in } \Omega,\ t > 0, \tag{3.1b}$$

$$\boldsymbol{v} = \boldsymbol{g} \qquad \text{on } \partial\Omega,\ t > 0, \tag{3.1c}$$

$$\boldsymbol{v} = \boldsymbol{v}_0, \quad p = p_0 \qquad \text{in } \Omega,\ t = 0, \tag{3.1d}$$

with positive constant parameters μ_v, μ_p, ν_1, ν_2. We will consider both the time-dependent and the stationary cases $\mu_v = \mu_p = 0$ which requires different methods.

As before, we assume Ω to be a bounded Lipschitz domain. We will use the following variational formulation of (3.1):

$$\mu_v \int_\Omega \frac{\partial \boldsymbol{v}}{\partial t} \cdot \boldsymbol{w} + \nu_1 \int_\Omega \nabla \boldsymbol{v} : \nabla \boldsymbol{w} + \nu_2 \int_\Omega (\nabla \cdot \boldsymbol{v})(\nabla \cdot \boldsymbol{w}) - \int_\Omega p \nabla \cdot \boldsymbol{w} = \int_\Omega \boldsymbol{f}_v \cdot \boldsymbol{w} \qquad \text{for all } \boldsymbol{w} \in \boldsymbol{C}_0^\infty(\Omega),$$

$$\mu_p \int_\Omega \frac{\partial p}{\partial t} q + \int_\Omega q \nabla \cdot \boldsymbol{v} = \int_\Omega f_p q \qquad \text{for all } q \in C_0^\infty(\Omega).$$

In our analysis we will assume $\mu_v = \mu_p$.

To deal with the instationary problem we will introduce three different solution concepts, each requiring a separate theoretical treatment and numerical implementation. The validity of each approach is determined by the form of the problem data (right-hand sides $\boldsymbol{f}_v$, f_p and boundary conditions $\boldsymbol{g}$):

- general time-dependent solutions, requiring no assumptions on the form of the problem data,
- time-periodic solutions, requiring periodic problem data,
- time-harmonic solutions, requiring problem data given as a superposition of sine and cosine terms.

Periodic solutions are of interest, since the application to SAW-driven acoustic streaming often involves time-periodic data $\boldsymbol{f}_v$, f_p, $\boldsymbol{g}$. In the case of time-harmonic problem data it is possible to eliminate the time dependence altogether and reduce the problem to an equivalent stationary system. This so-called *quasi-stationary approach* is treated later in this section.

3.1. Solution spaces and variational formulation. For the variational formulation we define the following spaces:

$$\begin{aligned}
\boldsymbol{V} &= \boldsymbol{H}_0^1(\Omega),\\
Q &= L_0^2(\Omega),\\
U &= \boldsymbol{H}_0^1(\Omega) \times L_0^2(\Omega),\\
H &= \boldsymbol{L}^2(\Omega) \times L_0^2(\Omega),\\
U' &= \boldsymbol{H}^{-1}(\Omega) \times L_0^2(\Omega) \qquad \text{as the dual space of } U.
\end{aligned}$$

This yields a Gelfand triple

$$U \subset H \subset U' \tag{3.2}$$

with each space continuously embedded and dense in the subsequent space; see e.g., [50].

For a given bounded time interval $[0,T] \subset \mathbb{R}$ we define the Hilbert space

$$W(0,T) = \{f \in H^1(0,T;U') \mid f \in L^2(0,T;U)\},$$

with the scalar product

$$(f_1, f_2)_{W(0,T)} = \int_0^T (f_1(t), f_2(t))_U \, dt + \int_0^T (f_1'(t), f_2'(t))_{U'} \, dt$$

for all $f_1, f_2 \in W(0,T)$.

Thanks to well-known continuity properties of this space we will be able to justify the specification of initial values in H. We now define the following bilinear forms:

$$a : \boldsymbol{V} \times \boldsymbol{V} \to \mathbb{R}, \tag{3.3a}$$

$$a(\boldsymbol{v}, \boldsymbol{w}) = \nu_1 \int_\Omega \nabla \boldsymbol{v} : \nabla \boldsymbol{w} + \nu_2 \int_\Omega (\nabla \cdot \boldsymbol{v})(\nabla \cdot \boldsymbol{w}), \tag{3.3b}$$

$$b : Q \times \boldsymbol{V} \to \mathbb{R}, \tag{3.3c}$$

$$b(p, v) = -\int_\Omega p \nabla \cdot \boldsymbol{v}, \tag{3.3d}$$

$$s : U \times U \to \mathbb{R}, \tag{3.3e}$$

$$s((\boldsymbol{v}, p), (\boldsymbol{w}, q)) = a(\boldsymbol{v}, \boldsymbol{w}) + b(q, \boldsymbol{v}) - b(p, \boldsymbol{w}). \tag{3.3f}$$

LEMMA 3.1. *The following properties hold for the bilinear forms defined in* (3.3)*:*

1. *The form a is $\boldsymbol{V}$-*elliptic*, meaning that there exist constants $c_a, C_a > 0$ so that for all $\boldsymbol{v}, \boldsymbol{w} \in \boldsymbol{V}$*

$$|a(\boldsymbol{v}, \boldsymbol{w})| \leq C_a \|\boldsymbol{v}\|_1 \|\boldsymbol{w}\|_1 ,$$
$$a(\boldsymbol{v}, \boldsymbol{v}) \geq c_a \|\boldsymbol{v}\|_1^2 .$$

2. *There exist constants $c_b, C_b > 0$ so that for all $\boldsymbol{v} \in \boldsymbol{V}$ and $p \in Q$*

$$|b(p, \boldsymbol{v})| \leq C_b \|p\|_0 \|v\|_1 , \tag{3.4}$$

$$\inf_{p \in Q \setminus \{0\}} \sup_{\boldsymbol{v} \in \boldsymbol{V} \setminus \{0\}} \frac{b(p, \boldsymbol{v})}{\|p\|_0 \|\boldsymbol{v}\|_1} \geq c_b. \tag{LBB}$$

The inequality (LBB) *is the well-known Ladyzhenskaya-Babuška-Brezzi condition.*

3. *The form s is U-*coercive *(see, e.g.,* [29]*); in other words, there are constants $c_s, C_s > 0$, $k_s \in \mathbb{R}$ so that for all $f, g \in U$*

$$|s(f, g)| \leq C_s \|f\|_U \|g\|_U , \tag{3.5}$$

$$s(f, f) + k_s \|f\|_H^2 \geq c_s \|f\|_U^2 . \tag{3.6}$$

We can choose $c_s = k_s = c_a$.

DEFINITION 3.2. *Using Lemma* 3.1 *we define the following bounded linear operators. Let $\boldsymbol{v}, \boldsymbol{w} \in \boldsymbol{V}$, $p, q \in Q$, $f, g \in U$.*

$$\begin{aligned} A \in L(\boldsymbol{V}, \boldsymbol{V}') : &\qquad \langle A\boldsymbol{v}, \boldsymbol{w} \rangle_{\boldsymbol{V}' \times \boldsymbol{V}} = a(\boldsymbol{v}, \boldsymbol{w}), \\ B \in L(Q, \boldsymbol{V}') : &\qquad \langle Bp, \boldsymbol{v} \rangle_{\boldsymbol{V}' \times \boldsymbol{V}} = b(p, \boldsymbol{v}), \\ B^* \in L(\boldsymbol{V}, Q) : &\qquad \langle B^* \boldsymbol{v}, p \rangle_{Q \times Q} = b(p, \boldsymbol{v}), \\ S \in L(U, U') : &\qquad \langle Sf, g \rangle_{U' \times U} = s(f, g), \\ K \in L(Q, Q) : &\qquad K = B^* A^{-1} B. \end{aligned} \tag{3.7}$$

Also useful will be the bilinear form corresponding to the Schur complement operator K:

$$k : Q \times Q \to \mathbb{R},$$
$$k(p, q) = (Kp, q)_0.$$

3.2. Instationary solutions. We can now formulate the variational formulation of (3.1).

Problem 3.3 (weak formulation of the instationary problem). Let $u_0 = (\boldsymbol{v}_0, p_0) \in H$ and $f = (\boldsymbol{f}_v, f_p) \in L^2(0, T; U')$. Find $u = (\boldsymbol{v}, p) \in W(0, T)$ so that

$$\begin{aligned} \langle w, u'(t) \rangle_{U \times U'} + s(w, u(t)) = \langle w, f(t) \rangle_{U \times U'} &\quad \text{for all } w \in U, \text{ f.a.a.}^1 \ \ t \in (0, T), \\ u(0) = u_0 &\quad \text{in } H. \end{aligned} \tag{P}$$

We remark that Problem 3.3 is well-posed due to the properties of the solution space $W(0, T)$.

[1]The abbreviation "f.a.a." will stand for "for almost all" with respect to the used Lebesgue measure.

LEMMA 3.4. *The problem* (P) *can be equivalently formulated as*
Find $(\boldsymbol{v}, p) \in W(0,T)$ *so that*

$$
\begin{aligned}
\langle \boldsymbol{w}, \boldsymbol{v}'(t)\rangle_{\boldsymbol{V}\times\boldsymbol{V}'} + a(\boldsymbol{w}, \boldsymbol{v}(t)) + b(p(t), \boldsymbol{w}) &= \langle \boldsymbol{w}, \boldsymbol{f}_v(t)\rangle_{\boldsymbol{V}\times\boldsymbol{V}'} && \text{for all } \boldsymbol{w} \in \boldsymbol{V},\\
(q, p'(t))_0 - b(q, \boldsymbol{v}(t)) &= (q, f_p(t))_0 && \text{for all } q \in Q,\\
& && \text{f.a.a. } t \in (0,T),\\
\boldsymbol{v}(0) &= \boldsymbol{v}_0 && \text{in } \boldsymbol{L}^2(\Omega),\\
p(0) &= p_0 && \text{in } Q.
\end{aligned}
\tag{P$'$}
$$

Proof. Assume (P$'$) holds. Set $w = (\boldsymbol{w}, q)$, $u_0 = (\boldsymbol{v}_0, p_0)$, and sum the first two equations to get (P). Now assume (P) holds. Select first $\psi = (\boldsymbol{w}, 0)$ to obtain the first variational equality in (P$'$) and then $\psi = (0, q)$ for the second one. The initial condition is clear. ∎

The stationary problem corresponding to (3.1) can be interpreted as a compressible Stokes system.

Problem 3.5 (weak formulation of the stationary problem). Let $f = (\boldsymbol{f}_v, f_p) \in U'$. Find $u = (\boldsymbol{v}, p) \in U$ so that

$$
\begin{aligned}
a(\boldsymbol{w}, \boldsymbol{v}) + b(p, \boldsymbol{w}) &= \langle \boldsymbol{w}, \boldsymbol{f}_v\rangle_{\boldsymbol{V}\times\boldsymbol{V}'} && \text{for all } \boldsymbol{w} \in \boldsymbol{V},\\
-b(q, \boldsymbol{v}) &= (q, f_p)_0 && \text{for all } q \in Q.
\end{aligned}
\tag{P$_{stat}$}
$$

An equivalent reformulation of (P$_{stat}$) using the form s is also possible using the same methods as in Lemma 3.4.

Remark 3.6. The choice of Q as pressure space is a real restriction as the following example shows.

Given $\Omega = (0,1)^2$, solve the problem

$$
\begin{aligned}
\frac{\partial \boldsymbol{v}}{\partial t}(t) - \Delta \boldsymbol{v} - \nabla(\nabla \cdot \boldsymbol{v}) + \nabla p &= 0 && \text{in } \Omega,\\
\frac{\partial p}{\partial t}(t) + \nabla \cdot \boldsymbol{v} &= 1 && \text{in } \Omega,\\
\boldsymbol{v}(x,t) &= 0 && \text{on } \partial\Omega,\\
\boldsymbol{v}_0(x) = 0, \quad p_0(x) &= 0.
\end{aligned}
\tag{3.8}
$$

We immediately verify that a solution is given by $\boldsymbol{v}(x,t) = 0$, $p(x,t) = t$, which does not lie in $W(0,T)$.

This shows that working with $Q = L_0^2(\Omega)$ is too restrictive in this setting. However, we use this space for simplicity in this presentation. An extension of the existence and uniqueness theorems presented later to the case of generalized solutions $(\boldsymbol{v}, p)$ sought in the larger space $\boldsymbol{H}^1(\Omega) \times L^2(\Omega)$ may be found in [26].

Since the Ladyzhenskaya-Babuška-Brezzi condition (LBB) is fulfilled we can deduce the existence and uniqueness of solutions of Problem 3.5.

LEMMA 3.7. *Problem* (P$_{stat}$) *has a unique solution* $(\boldsymbol{v}, p) \in U$. *The following a priori estimate holds:*

$$\|\boldsymbol{v}\|_1 + \|p\|_0 \le C(\|\boldsymbol{f}_v\|_{\boldsymbol{V}'} + \|f_p\|_0),$$

with a constant $C > 0$.

Proof. Given the properties of the bilinear forms in Lemma 3.1, we can use the saddle point theory specified in [34]. Additional references are [19, 25, 7]. ∎

We observe that (P) defines a parabolic problem due to the properties of $s(\cdot,\cdot)$ explained in Lemma 3.1. We cite the following theorem.

THEOREM 3.8 (existence and uniqueness of (P)). *For $0 < T < \infty$ the problem* (P) *possesses a unique solution $(\boldsymbol{v}, p) \in W(0,T)$. Furthermore, we have the following stability estimate:*

$$\|(\boldsymbol{v},p)\|_{W(0,T)} \le C\left(\|(\boldsymbol{v}_0,p_0)\|_H + \|(\boldsymbol{f}_v,f_p)\|_{L^2(0,T;U')}\right).$$

The constant C will generally depend on T.

Proof. [50, Theorem 26.1]. ∎

We also state the following result for time regularity of the solution.

THEOREM 3.9 (time regularity of the solution of (P)). *Assume $u = (\boldsymbol{v}, p)$ as the solution of the parabolic problem* (P) *stated in the following form:*

$$\begin{aligned} u' + Su &= f && \text{a.e. in } (0,T),\\ u(0) &= u_0 && \text{for } t = 0. \end{aligned}$$

Let $0 < k \in \mathbb{N}$. We assume $f \in H^k(0,T;U')$ and u_0 fulfilling the following compatibility conditions:

$$\begin{aligned} w_0 &:= u_0 \in U,\\ w_j &:= \frac{d^{j-1}f}{dt^{j-1}}(0) - Sw_{j-1} \in U,\ j = 1,\dots,k-1,\\ w_k &:= \frac{d^{k-1}f}{dt^{k-1}}(0) - Sw_{k-1} \in H. \end{aligned}$$

We then have

$$u \in H^k(0,T;U) \qquad \text{and} \qquad \frac{d^{k+1}u}{dt^{k+1}} \in L^2(0,T;U').$$

Proof. [50, Theorem 27.2]. ∎

3.3. Periodic solutions. For the acoustics subproblem (2.4) we generally have a time-periodic driving force $\boldsymbol{u}$. It is therefore of interest to reformulate Problem 3.3 for right-hand sides f which have period T and search for periodic solutions. This changes the character of the problem from an initial value problem to a periodic problem, where $u(0)$ and $u(T)$ are unknown a priori.

Later in this section we will compare the solution u of the initial value problem (P) supplied with a periodic forcing f to the solution u_{per} of the corresponding periodic problem. We expect the solution of the initial value problem to converge in some sense towards a periodic equilibrium state, that is, u_{per}, for large times. This phenomenon is known as *forced oscillation* in physics. In [26] we present a theorem confirming this convergent behavior.

We first specify what is meant by a periodic solution. The definition may be surprising at first since periodicity is not mentioned explicitly. The characterization given in Proposition 3.11 will justify the terminology.

Problem 3.10 (periodic solutions). Let $0 < T < \infty$ and $f = (\boldsymbol{f}_v, f_p) \in L^2(0,T;H)$. Find $u = (\boldsymbol{v}, p) \in W(0,T)$ so that

$$(\mathrm{P}_{per}) \qquad \begin{aligned} \langle w, u'(t)\rangle_{U\times U'} + s(w,u(t)) &= (w,f(t))_H && \text{for all } w \in U, \text{ a.e. in } (0,T),\\ u(0) &= u(T) && \text{in } H. \end{aligned}$$

Note that $u(0)$ and $u(T)$ are unknowns, not data of the problem. We demand more regularity in space, i.e., $f(t) \in H$. This will enable us to use elementary results of Fourier analysis (see [1]) for the derivation of a priori estimates.

PROPOSITION 3.11. *Assume that the right-hand side f is extended to a periodic function $\widetilde{f}$ by*

$$\widetilde{f}(t+kT) = f(t) \qquad \text{for } t \in [0,T),\ k \in \mathbb{Z}.$$

A solution u of (P_{per}) can then be uniquely extended to a periodic solution $\widetilde{u}$ fulfilling

$$\langle w, \widetilde{u}'(t)\rangle_{U\times U'} + s(w, \widetilde{u}(t)) = (w, \widetilde{f}(t))_H \qquad \text{for all } w \in U,\ \text{f.a.a. } t \in \mathbb{R}.$$

Proof. The existence and uniqueness Theorem 3.8 implies that the solution u with initial values $u(0)$ is well defined for an arbitrarily large interval $[0,\tau]$. Define $z(t) := u(T+t) - u(t)$. The function z is a solution of the following initial value problem:

$$\begin{aligned} z'(t) + Sz(t) &= 0, \\ z(0) &= 0. \end{aligned}$$

The a priori estimate of Theorem 3.8 then implies $z = 0$, and therefore $u(t) = u(T+t)$. A similar argument shows that the solution can be uniquely extended backwards in time. ∎

THEOREM 3.12 (existence and uniqueness of (P_{per})). *The problem (P_{per}) has a unique solution $(\boldsymbol{v}, p) \in W(0,T)$. We have the stability estimate*

$$\|(\boldsymbol{v}, p)\|_{W(0,T)} \le C \,\|(\boldsymbol{f}_v, f_p)\|_{L^2(0,T;H)}.$$

The constant C will generally depend on the period T.

The idea of the proof is to use the standard Galerkin method. In a first step we establish stability properties of corresponding finite-dimensional problems. These are extended to the full problem using standard compactness results. For the finite-dimensional problem we used Fourier analysis to eliminate the time dependence of the periodic problem. The key elements of the stability proof are elaborate estimates on the eigenvalues of the compressible Stokes operator S defined in (3.7). These were taken from [4]. For the complete proof see [26, Theorem 3.2.6].

3.4. Quasi-stationary approach. In the physical applications the forcing terms are typically given by a harmonic signal:

$$\begin{aligned} \boldsymbol{f}_v(t,\boldsymbol{x}) &= \widehat{\boldsymbol{f}}_{vc}(\boldsymbol{x})\cos(\omega t) + \widehat{\boldsymbol{f}}_{vs}(\boldsymbol{x})\sin(\omega t), \\ f_p(t,\boldsymbol{x}) &= \widehat{f}_{pc}(\boldsymbol{x})\cos(\omega t) + \widehat{f}_{ps}(\boldsymbol{x})\sin(\omega t), \\ \boldsymbol{g}(t,\boldsymbol{x}) &= \widehat{\boldsymbol{g}}_{c}(\boldsymbol{x})\cos(\omega t) + \widehat{\boldsymbol{g}}_{s}(\boldsymbol{x})\sin(\omega t), \end{aligned} \tag{3.9}$$

with a frequency $\omega = 2\pi/T > 0$. As proven in [26, Theorem 3.2.10] the solution of the acoustic system will converge against a periodic equilibrium state for $t \to \infty$. As will become clear later this periodic equilibrium state must also be time-harmonic. Since the equilibrium state is what we are interested in when solving the full problem, we may attempt to split the spatial and temporal dependence of the acoustic field solution. This eliminates the need for a time discretization. To be precise, we consider the following ansatz:

$$\begin{aligned} \boldsymbol{v}(t,\boldsymbol{x}) &= \widehat{\boldsymbol{v}}_{c}(\boldsymbol{x})\cos(\omega t) + \widehat{\boldsymbol{v}}_{s}(\boldsymbol{x})\sin(\omega t), \\ p(t,\boldsymbol{x}) &= \widehat{p}_{c}(\boldsymbol{x})\cos(\omega t) + \widehat{p}_{s}(\boldsymbol{x})\sin(\omega t), \end{aligned} \tag{3.10}$$

with a frequency ω equal to the driving frequency of the boundary conditions and right-hand sides in (3.9). This idea is standard for solving time-harmonic problems, although a decomposition using the complex terms $\exp(i\omega t)$, $\exp(-i\omega t)$ is usually used instead.

After substituting these formulas for $\boldsymbol{v}$ and p in system (3.1) and using the linear independence of sine and cosine functions, we arrive at four new field equations in the unknowns $\widehat{\boldsymbol{v}}_i$, $\widehat{p}_i$, $i = c, s$:

$$
\begin{aligned}
\omega\mu_v\widehat{\boldsymbol{v}}_s - \nu_1\Delta\widehat{\boldsymbol{v}}_c - \nu_2\nabla(\nabla\cdot\widehat{\boldsymbol{v}}_c) + \nabla\widehat{p}_c &= \widehat{\boldsymbol{f}}_{vc},\\
-\omega\mu_v\widehat{\boldsymbol{v}}_c - \nu_1\Delta\widehat{\boldsymbol{v}}_s - \nu_2\nabla(\nabla\cdot\widehat{\boldsymbol{v}}_s) + \nabla\widehat{p}_s &= \widehat{\boldsymbol{f}}_{vp},\\
\omega\mu_p\widehat{p}_s + \nabla\cdot\widehat{\boldsymbol{v}}_c &= \widehat{f}_{pc},\\
-\omega\mu_p\widehat{p}_c + \nabla\cdot\widehat{\boldsymbol{v}}_s &= \widehat{f}_{ps} \qquad \text{in } \Omega,\\
\widehat{\boldsymbol{v}}_c &= \widehat{\boldsymbol{g}}_c,\\
\widehat{\boldsymbol{v}}_s &= \widehat{\boldsymbol{g}}_s \qquad \text{on } \partial\Omega.
\end{aligned}
\tag{3.11}
$$

We are now faced with solving only one stationary system at the price of twice as many unknowns as before. A variational formulation of this system is derived as before. This variational formulation can be analyzed using well-known results for saddle point problems; see [34, Theorem 2.2], [25], and also [7].

4. Methods for free boundary problems. This section will treat the discretization of free capillary problems associated with (3.1). Most of the available literature for free capillary boundary problems concentrates on the incompressible (nonlinear) Navier–Stokes system; see [3] and references therein. It is interesting to note that the nonlinear convection term, together with the assumption of incompressibility, may actually serve to prove the stability of numerical schemes; see [3, p. 6]. Analytical results of existence and uniqueness, even for the more well known case of incompressible Navier–Stokes, are applicable only to special domains or small times or rely on function spaces with high regularity properties unsuitable for a finite element method (FEM) discretization; see [30, 45, 42].

We will treat the case of Dirichlet and free capillary boundary conditions specified on subsets Γ_d (resp., Γ_f) of $\partial\Omega$, $\Gamma_d \cup \Gamma_f = \partial\Omega$. We will assume that Γ_d is a topologically closed surface, implying that the contact line between the free surface and walls remains fixed. We note that this hypothesis is not always valid in physical situations. However, moving contact lines cause problems in mathematical formulations due to the incompatibility of boundary conditions; see the first section of [45].

This yields the following system:

$$\mu_v\frac{\partial\boldsymbol{v}}{\partial t} - \nabla\cdot\Sigma = \boldsymbol{f}_v \qquad \text{in } \Omega(t), t > 0, \tag{4.1a}$$

$$\mu_p\frac{\partial p}{\partial t} + \nabla\cdot\boldsymbol{v} = f_p \qquad \text{in } \Omega(t),\ t > 0, \tag{4.1b}$$

$$\boldsymbol{v} = \boldsymbol{g} \qquad \text{on } \Gamma_d, \tag{4.1c}$$

$$\Sigma\boldsymbol{n} = \sigma(d-1)\boldsymbol{\kappa} \qquad \text{on } \Gamma_f(t),\ t > 0, \tag{4.1d}$$

$$\boldsymbol{v}\cdot\boldsymbol{n} = V \qquad \text{on } \Gamma_f(t),\ t > 0, \tag{4.1e}$$

$$\Omega(0) = \Omega_0, \tag{4.1f}$$

$$\boldsymbol{v}(t=0,\boldsymbol{x}) = \boldsymbol{v}_0 \qquad \text{in } \Omega_0, \tag{4.1g}$$

$$p(t=0,\boldsymbol{x}) = p_0 \qquad \text{in } \Omega_0, \tag{4.1h}$$

with

$$\Sigma_{ij} = -p\delta_{ij} + \nu_1 \left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) + (\nu_2 - \nu_1)(\nabla \cdot \boldsymbol{v})\delta_{ij} \qquad \text{the stress tensor,}$$

V the normal velocity of $\Gamma_f(t)$,

$\boldsymbol{\kappa}$ the vector of mean curvature,

$\sigma > 0$ the coefficient of surface tension.

We are interested in a sharp interface arbitrary Lagrangian Eulerian (ALE) approach, where the domain essentially follows the motion of the fluid; see [23, 22] and references therein. This seems most promising because of its simplicity, at the price of not being able to deal with domain topology changes, for example, due to the formation of cusps. Examples of more general methods are volume-of-fluid [20] or the more recent level set methods [33, 47, 44, 46, 43]. In the standard physical situations considered we do not expect topology changes.

4.1. Variational formulation including curvature. To incorporate free capillary boundaries in the finite element framework, we will need a variational formulation of the curvature term [12, 13].

We assume $\Gamma \subset \mathbb{R}^d$ to be a subset of an orientable $(d-1)$-dimensional smooth manifold M and $\boldsymbol{\chi} : U \to \Gamma$, U an open subset of $\mathbb{R}^{d-1}$, as a local parameterization of Γ. We define $g_{ij} = \partial_i \boldsymbol{\chi} \cdot \partial_j \boldsymbol{\chi}$ as the metric tensor of Γ and $g^{ij} = (g^{-1})_{ij}$ as its inverse.

For functions $f : \Gamma \to \mathbb{R}$, $\boldsymbol{f} : \Gamma \to \mathbb{R}^d$ we introduce the following differential operators on Γ:

$$(\nabla_\Gamma f) \circ \boldsymbol{\chi} := \sum_{i,j=1}^{d-1} g^{ij} \partial_i (f \circ \boldsymbol{\chi}) \partial_j \boldsymbol{\chi}$$

as the tangential derivative of f,

$$(\nabla_\Gamma \cdot \boldsymbol{f}) \circ \boldsymbol{\chi} := \sum_{i,j=1}^{d-1} g^{ij} \partial_i (\boldsymbol{f} \circ \boldsymbol{\chi}) \cdot \partial_j \boldsymbol{\chi}$$

as the tangential divergence of $\boldsymbol{f}$, and

$$(\Delta_\Gamma f) \circ \boldsymbol{\chi} := (\nabla_\Gamma \cdot \nabla_\Gamma f) \circ \boldsymbol{\chi} = \sum_{i,j=1}^{d-1} \frac{1}{\sqrt{\det g}} \partial_i \left(\sqrt{\det g}\, g^{ij} \partial_j (f \circ \boldsymbol{\chi}) \right)$$

as the Laplace–Beltrami operator of f; see, for instance, [2, 9]. We have the following identity:

$$\Delta_\Gamma \operatorname{id}_\Gamma = \boldsymbol{\kappa},$$

where $\boldsymbol{\kappa}$ is the mean curvature vector on Γ. Let $\boldsymbol{\psi}$ be a smooth vector valued function defined on Γ, with $\boldsymbol{\psi} = 0$ on the relative boundary $\operatorname{relbd}(\Gamma)$ in M. Using partial integration on Γ we get

$$\begin{aligned} \int_\Gamma \boldsymbol{\kappa} \cdot \boldsymbol{\psi}\, d\mathcal{H}^{d-1} &= \int_\Gamma (\Delta_\Gamma \operatorname{id}_\Gamma) \cdot \boldsymbol{\psi}\, d\mathcal{H}^{d-1} \\ &= -\int_\Gamma \nabla_\Gamma \operatorname{id}_\Gamma : \nabla_\Gamma \boldsymbol{\psi}\, d\mathcal{H}^{d-1} = -\int_\Gamma \nabla_\Gamma \cdot \boldsymbol{\psi}\, d\mathcal{H}^{d-1}. \end{aligned} \tag{4.2}$$

There is no boundary term in the partial integration because $\boldsymbol{\psi} = 0$ on relbd(Γ). We now return to the system (4.1). If we test (4.1a) with a smooth function $\boldsymbol{\psi}$ defined on $\bar{\Omega}(t)$ and fulfilling $\boldsymbol{\psi} = 0$ on Γ_d, we get

$$\begin{aligned}\mu_v \int_\Omega \boldsymbol{\psi} \cdot \frac{\partial \boldsymbol{v}}{\partial t} - \int_\Omega \boldsymbol{\psi} \cdot \boldsymbol{f}_v &= \int_\Omega \boldsymbol{\psi} \cdot (\nabla \cdot \Sigma) \\ &= \int_\Omega \nabla \cdot (\Sigma \boldsymbol{\psi}) - \int_\Omega \Sigma : \nabla \boldsymbol{\psi} \\ &= \int_{\partial\Omega} (\Sigma \boldsymbol{\psi}) \cdot \boldsymbol{n} \, d\mathcal{H}^{d-1} - \int_\Omega \Sigma : \nabla \boldsymbol{\psi}.\end{aligned}$$

Thanks to (4.2) and the boundary condition (4.1d) the boundary integral is equal to

$$\int_{\partial\Omega} (\Sigma \boldsymbol{\psi}) \cdot \boldsymbol{n} \, d\mathcal{H}^{d-1} = \int_{\partial\Omega} (\Sigma \boldsymbol{n}) \cdot \boldsymbol{\psi} \, d\mathcal{H}^{d-1} = -\sigma(d-1) \int_{\Gamma_f} \nabla_\Gamma \cdot \boldsymbol{\psi} \, d\mathcal{H}^{d-1}.$$

The second integral evaluates to

$$\begin{aligned}-\int_\Omega \Sigma : \nabla \boldsymbol{\psi} = \int_\Omega p(\nabla \cdot \boldsymbol{\psi}) - \frac{\nu_1}{2} \int_\Omega D(\boldsymbol{v}) : D(\boldsymbol{\psi}) \\ - (\nu_2 - \nu_1) \int_\Omega (\nabla \cdot \boldsymbol{v})(\nabla \cdot \boldsymbol{\psi}),\end{aligned}$$

with the *deformation tensor* $D(\boldsymbol{v}) := \nabla \boldsymbol{v} + \nabla \boldsymbol{v}^T$. Combining the last equations finally yields

$$\begin{aligned}(4.3)\quad \mu_v \int_\Omega \boldsymbol{\psi} \cdot \frac{\partial \boldsymbol{v}}{\partial t} + \frac{\nu_1}{2} \int_\Omega D(\boldsymbol{v}) : D(\boldsymbol{\psi}) + (\nu_2 - \nu_1) \int_\Omega (\nabla \cdot \boldsymbol{v})(\nabla \cdot \boldsymbol{\psi}) \\ - \int_\Omega p(\nabla \cdot \boldsymbol{\psi}) = \int_\Omega \boldsymbol{\psi} \cdot \boldsymbol{f}_v - \sigma(d-1) \int_{\Gamma_f} \nabla_\Gamma \cdot \boldsymbol{\psi} \, d\mathcal{H}^{d-1}.\end{aligned}$$

This will be the starting point of the discrete formulation of the free boundary problem in the following section.

We will first review the ALE approach used to treat the motion of the free capillary surface. The basic idea is to use a special finite element space defined on a reference triangulation which will contain the coordinate function defining the mesh nodes at any time step. We will use a time-marching procedure as before to calculate the evolution of the velocity and pressure fields. The velocity at the free capillary boundary will be used to update the mesh position for the next time step.

4.2. ALE formulation. For the beginning we consider the extension of the evolution problem (P) to a time-dependent but given domain $\Omega(t)$. Let $\hat{\Omega} \subset \mathbb{R}^d$ be a bounded reference domain. We define a time-dependent continuous transformation to map $\hat{\Omega}$ to the current domain $\Omega(t)$:

$$\begin{aligned}\boldsymbol{\Phi} : [0,T] \times \hat{\Omega} &\to \mathbb{R}^d, \\ \boldsymbol{\Phi}(t, \hat{\Omega}) &= \Omega(t), \\ G &= \{(t, \boldsymbol{x}) \in [0,T] \times \mathbb{R}^d \mid \boldsymbol{x} \in \Omega(t)\}.\end{aligned}$$

We define a reverse transformation $\mathbf{\Psi}$ as follows:

$$\begin{aligned}&\mathbf{\Psi} : G \to \hat{\Omega},\\ &\mathbf{\Psi}(t, \mathbf{\Phi}(t, \hat{\boldsymbol{x}})) = \hat{\boldsymbol{x}}.\end{aligned}$$

We will assume that the following natural requirements for a proper space-time domain G are fulfilled.

Assumption 4.1 (admissible transformation). Let $t \in [0, T]$. Then

- $\mathbf{\Phi}(t, \cdot) : \hat{\Omega} \to \Omega(t)$ is injective, and
- $\inf_{\hat{x} \in \hat{\Omega}} \det D_{\hat{x}} \mathbf{\Phi}(t, \hat{x}) > 0$.

Here $D_{\hat{x}} \mathbf{\Phi}(t, \hat{x})$ stands for the Jacobian of $\mathbf{\Phi}$ with respect to the space variable.

For a given function $\varphi : G \to \mathbb{R}$ we can therefore define a related reference function as

$$\begin{aligned}&\hat{\varphi} : [0, T] \times \hat{\Omega} \to \mathbb{R},\\ &\qquad \hat{\varphi}(t, \hat{x}) = \varphi(t, \mathbf{\Phi}(t, \hat{x})).\end{aligned}$$

Let $\mathbf{\Phi}$ and $\varphi : G \to \mathbb{R}$ be sufficiently smooth to apply the chain rule of differentiation. We have

$$\begin{aligned} D_t \hat{\varphi}(t, \hat{x}) &= D_t \varphi(t, \mathbf{\Phi}(t, \hat{x})) + D_x \varphi(t, \mathbf{\Phi}(t, \hat{x})) D_t \mathbf{\Phi}(t, \hat{x}) \\ &= D_t \varphi(t, x) + D_x \varphi(t, x) D_t \mathbf{\Phi}(t, \hat{x}), \end{aligned} \tag{4.4}$$

where $x = \mathbf{\Phi}(t, \hat{x})$. The second term containing spatial derivatives of φ is actually omitted in the numerical discretization, as it is of higher order with respect to the expansion parameter ϵ and since we are mostly interested in a stationary limit. See [26] for details.

For a discretization in space as well as in time we assume that we have a finite-dimensional reference subspace $\hat{U}_h \subset \hat{U}$ defined on $\hat{\Omega} = \Omega_0$. Furthermore, we assume that a sequence of discrete time steps $0 = t_0 < t_1 < \cdots < t_N = T$ are given with corresponding mesh transformations $\mathbf{\Phi}_h^n : \hat{\Omega} \to \Omega_n$, $\mathbf{\Psi}_h^n : \Omega_n \to \hat{\Omega}$.

We now seek the discrete solution

$$u_h^n \in U_{h,n} = \{\hat{\varphi}_h \circ \mathbf{\Psi}_h^n \mid \hat{\varphi}_h \in \hat{U}_h\}$$

for $n = 1, \dots, N$.

4.3. Algorithm. We will now define an algorithm to discretize the free boundary problem (4.1). We assume that a reference domain $\hat{\Omega}$ with a conforming triangulation $\hat{\mathcal{T}}$ is given. We define $\hat{\Gamma}_f \subset \partial\hat{\Omega}$ as the part of the boundary where free capillary boundary conditions are prescribed and $\hat{\Gamma}_d \subset \partial\hat{\Omega}$ as the part with Dirichlet boundary conditions. We choose $\hat{\Gamma}_d$ to be a relatively closed surface in $\partial\hat{\Omega}$ and require $\partial\hat{\Omega} = \hat{\Gamma}_f \cup \hat{\Gamma}_d$, $\hat{\Gamma}_f \cap \hat{\Gamma}_d = \emptyset$.

We assume that $\hat{\mathcal{T}}$ is chosen in such a way that the boundary faces of the simplices $\hat{S} \in \hat{\mathcal{T}}$ induce a conforming triangulation $\hat{\mathcal{R}}$ of dimension $d-1$ of $\hat{\Gamma}_f$. We split the simplices of $\hat{\mathcal{T}}$ into two sets

$$\begin{aligned}&\hat{\mathcal{T}}_i := \{S \in \hat{\mathcal{T}} \mid S \cap \hat{\Gamma}_f = \emptyset\},\\ &\hat{\mathcal{T}}_f := \hat{\mathcal{T}} \setminus \hat{\mathcal{T}}_i.\end{aligned}$$

We thus have the property

$$\hat{\mathcal{R}} = \{\hat{T} \mid \hat{T} \text{ is } d-1 \text{ dim. simplex}, \ \hat{T} = \hat{S} \cap \partial\hat{\Omega}, \ \hat{S} \in \mathcal{T}_f\}.$$

We define the finite element spaces for the discrete velocity, pressure, and mesh position in the interior and at the free boundary as follows:

$$\begin{aligned}
\hat{\boldsymbol{V}}_h &= \{\boldsymbol{w}_h \in C^0(\overline{\hat{\Omega}})^d \mid \boldsymbol{w}_h|_S \in \mathbb{P}_2(S)^d \text{ for all } S \in \hat{\mathcal{T}}, \boldsymbol{w}_h|_{\Gamma_d} = 0\},\\
\hat{Q}_h &= \{q_h \in C^0(\overline{\hat{\Omega}}) \mid q_h|_S \in \mathbb{P}_1(S) \text{ for all } S \in \hat{\mathcal{T}}\},\\
\hat{M}_h &= \{\boldsymbol{\Phi}_h \in C^0(\overline{\hat{\Omega}})^d \mid \boldsymbol{\Phi}_h|_S \in \mathbb{P}_1(S)^d \text{ for } S \in \hat{\mathcal{T}}_i \text{ and } \boldsymbol{\Phi}_h|_S \in \mathbb{P}_2(S)^d \text{ for } S \in \hat{\mathcal{T}}_f\},\\
\hat{R}_h &= \{\boldsymbol{x}_h \in C^0(\overline{\hat{\Gamma}}_f)^d \mid \boldsymbol{x}_h|_T \in \mathbb{P}_2(T)^d \text{ for } T \in \hat{\mathcal{R}}\}.
\end{aligned}$$

In other words, we use the Taylor–Hood element of order 1 for velocity and pressure, piecewise linears for the interior simplices, and piecewise quadratics for the boundary simplices. The choice of piecewise quadratics implies the use of curved simplices at the free boundary which is desirable for precise modeling of discrete curvature; cf. [3].

Given a transformation $\boldsymbol{\Phi}_h^n \in \hat{M}_h$ at time step n, we define the transformed mesh and spaces as follows:

$$\begin{aligned}
\Omega_n &:= \boldsymbol{\Phi}_h^n(\hat{\Omega}), & \Gamma_d &:= \boldsymbol{\Phi}_h^0(\hat{\Gamma}_d) \text{ (stays fixed)},\\
\Gamma_{f,n} &:= \boldsymbol{\Phi}_h^n(\hat{\Gamma}_f), & \mathcal{T}^n &:= \{\boldsymbol{\Phi}_h^n(S) \mid S \in \hat{\mathcal{T}}\},\\
\mathcal{T}_i^n &:= \{\boldsymbol{\Phi}_h^n(S) \mid S \in \hat{\mathcal{T}}_i\}, & \mathcal{T}_f^n &:= \{\boldsymbol{\Phi}_h^n(S) \mid S \in \hat{\mathcal{T}}_f\},\\
\mathcal{R}^n &:= \{\boldsymbol{\Phi}_h^n(T) \mid T \in \hat{\mathcal{R}}\}, & \boldsymbol{\Psi}_h^n &:= (\boldsymbol{\Phi}_h^n)^{-1} : \Omega_n \to \hat{\Omega},\\
\boldsymbol{V}_{h,n} &:= \{\hat{\boldsymbol{w}}_h \circ \boldsymbol{\Psi}_h^n \mid \hat{\boldsymbol{w}}_h \in \hat{\boldsymbol{V}}_h\}, & Q_{h,n} &:= \{\hat{q}_h \circ \boldsymbol{\Psi}_h^n \mid \hat{q}_h \in \hat{Q}_h\},\\
M_{h,n} &:= \{\hat{\boldsymbol{x}}_h \circ \boldsymbol{\Psi}_h^n \mid \hat{\boldsymbol{x}}_h \in \hat{M}_h\}, & R_{h,n} &:= \{\hat{\boldsymbol{x}}_h \circ \boldsymbol{\Psi}_h^n \mid \hat{\boldsymbol{x}}_h \in \hat{R}_h\}.
\end{aligned} \tag{4.5}$$

Since the domain will change with time, we define time-dependent bilinear forms on the domain $\Omega_n = \boldsymbol{\Phi}_h^n(\hat{\Omega})$ for a variational formulation:

$$\begin{aligned}
&a_n : \boldsymbol{V}_{h,n} \times \boldsymbol{V}_{h,n} \to \mathbb{R},\\
&a_n(\boldsymbol{v}_h, \boldsymbol{w}_h) = \frac{\nu_1}{2} \int_{\Omega_n} D(\boldsymbol{v}_h) : D(\boldsymbol{w}_h) + (\nu_2 - \nu_1) \int_{\Omega_n} (\nabla \cdot \boldsymbol{v}_h)(\nabla \cdot \boldsymbol{w}_h),\\
&b_n : Q_{h,n} \times \boldsymbol{V}_{h,n} \to \mathbb{R},\\
&b_n(q_h, \boldsymbol{v}_h) = -\int_{\Omega_n} q_h \nabla \cdot \boldsymbol{v}_h,\\
&d_n : R_{h,n} \times R_{h,n} \to \mathbb{R},\\
&d_n(\boldsymbol{v}_h, \boldsymbol{w}_h) = \tau_n \sigma (d-1) \int_{\Gamma_{f,n}} \nabla_{\Gamma_{f,n}} \boldsymbol{v}_h \cdot \nabla_{\Gamma_{f,n}} \boldsymbol{w}_h \, d\mathcal{H}^{d-1}.
\end{aligned} \tag{4.6}$$

Two more tools are needed to define the discretized free boundary algorithm: a discrete outer unit normal vector $\boldsymbol{n}_h^n \in R_{h,n}$ to the mesh boundary $\Gamma_{f,n}$ and a suitable extension operator $E_h : \hat{R}_h \times \hat{M}_h \to \hat{M}_h$.

The function $\boldsymbol{n}_h^n \in R_{h,n}$ is defined by setting the values in the nodes of the quadratic Lagrange mesh G_2 of $\Gamma_{f,n}$. If $T \in \mathcal{R}_n$ is a $d-1$-dimensional simplex, we set

$$\begin{aligned}
\widetilde{\boldsymbol{n}}_T &:= \boldsymbol{n}_T \mathcal{H}^{d-1}(T),\\
P(x) &:= \{T' \in \mathcal{R}_n \mid x \in T'\}.
\end{aligned}$$

Here $\boldsymbol{n}_T$ is the (well-defined) outer unit normal vector on T. Now define $\boldsymbol{n}_h^n \in R_{h,n}$ as

$$\boldsymbol{n}_h^n(\overline{x}) := \begin{cases} \frac{\sum_{T\in P(\overline{x})} \tilde{\boldsymbol{n}}_T}{|\sum_{T\in P(\overline{x})} \tilde{\boldsymbol{n}}_T|} & \text{if } \overline{x} \in \Gamma_{f,n}, \\ 0 & \text{otherwise} \end{cases}$$

for all nodes $\overline{x}$ of G_2. This means that the (well-defined) normal on faces is averaged to define values on corners or edges.

The extension operator E_h is used to define the interior nodes of Ω_n, based on the position of $\Gamma_{f,n}$ and the old mesh Ω_{n-1}:

$$\boldsymbol{\Phi}_h^n = E_h(\boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f}, \boldsymbol{\Phi}_h^{n-1}).$$

This is necessary, since the boundary condition (4.1e) prescribes only the motion of the free boundary. The interior nodes should be selected in such a manner as to guarantee a good quality of the mesh triangulation $\mathcal{T}^n$.

ALGORITHM 4.2 (free boundary discretization). *Let $\boldsymbol{\Phi}_h^0 \in \hat{M}_h$ and $\boldsymbol{v}_h^0 \in \boldsymbol{V}_{h,0}$, $p_h^0 \in Q_{h,0}$, as well as $\boldsymbol{f}_v^n$, f_p^n as locally integrable functions on $\mathbb{R}^d$, $n \in \mathbb{N}$, and $\boldsymbol{g}_h$ as the extension by zero of given Dirichlet boundary conditions for the velocity. Loop over $n = 1, 2, \ldots$:*

1. *Solve for $(\tilde{\boldsymbol{v}}_h^n, \tilde{p}_h^n) \in (\boldsymbol{g}_h + \boldsymbol{V}_{h,n-1}) \times Q_{h,n-1}$:*

$$\begin{aligned} (4.7)\quad \frac{1}{\tau_n}\int_{\Omega_{n-1}} \boldsymbol{\psi}_h \cdot \tilde{\boldsymbol{v}}_h^n + a_{n-1}(\boldsymbol{\psi}_h, \tilde{\boldsymbol{v}}_h^n) + d_{n-1}(\boldsymbol{\psi}_h, \tilde{\boldsymbol{v}}_h^n) + b_{n-1}(\tilde{p}_h^n, \boldsymbol{\psi}_h) \\ = \frac{1}{\tau_n}\int_{\Omega_{n-1}} \boldsymbol{\psi}_h \cdot \boldsymbol{v}_h^{n-1} + \int_{\Omega_{n-1}} \boldsymbol{\psi}_h \cdot \boldsymbol{f}_v^{n-1} \\ - \sigma(d-1)\int_{\Gamma_{f,n-1}} \nabla_{\Gamma_{f,n-1}} \cdot \boldsymbol{\psi}_h \, d\mathcal{H}^{d-1} \end{aligned}$$

for all $\boldsymbol{\psi}_h \in \boldsymbol{V}_{h,n-1}$ and

$$\begin{aligned} (4.8)\quad \frac{1}{\tau_n}\int_{\Omega_{n-1}} \varphi_h \cdot \tilde{p}_h^n - b_{n-1}(\varphi_h, \tilde{\boldsymbol{v}}_h) \\ = \frac{1}{\tau_n}\int_{\Omega_{n-1}} \varphi_h \cdot p_h^{n-1} + \int_{\Omega_{n-1}} \varphi_h f_p^{n-1} \end{aligned}$$

for all $\varphi_h \in Q_{h,n-1}$.

2. *Update the position of the free boundary as follows: Define*

$$\begin{aligned} \boldsymbol{\Delta}_h^{n-1} &:= \tau_n(\tilde{\boldsymbol{v}}_h^n|_{\Gamma_{f,n}} \cdot \boldsymbol{n}_h^{n-1})\boldsymbol{n}_h^{n-1} \in R_{h,n-1}, \\ \boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f} &:= \left(\mathrm{id}_{\Gamma_{f,n-1}} + \boldsymbol{\Delta}_h^n\right) \circ \boldsymbol{\Phi}_h^{n-1}|_{\hat{\Gamma}_f}. \end{aligned}$$

3. *Now update the position of the entire mesh:*

$$\boldsymbol{\Phi}_h^n := E_h(\boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f}, \boldsymbol{\Phi}_h^{n-1}),$$

with a suitable extension operator E_h. If $\boldsymbol{\Phi}_h^n$ is not an admissible mesh transformation according to Assumption 4.1, then STOP.

4. *Finally, set*

$$\begin{aligned}
\Omega_n &:= \boldsymbol{\Phi}_h^n(\hat{\Omega}),\\
\Gamma_{f,n} &:= \boldsymbol{\Phi}_h^n(\hat{\Gamma}_f),\\
\mathcal{T}^n &:= \{\boldsymbol{\Phi}_h^n(S) \mid S \in \hat{\mathcal{T}}\},\\
\mathcal{R}^n &:= \{\boldsymbol{\Phi}_h^n(T) \mid T \in \hat{\mathcal{R}}\},\\
\boldsymbol{\Psi}_h^n &:= (\boldsymbol{\Phi}_h^n)^{-1},\\
\boldsymbol{v}_h^n &:= \tilde{\boldsymbol{v}}_h^n \circ \boldsymbol{\Phi}_h^{n-1} \circ \boldsymbol{\Psi}_h^n,\\
p_h^n &:= \tilde{p}_h^n \circ \boldsymbol{\Phi}_h^{n-1} \circ \boldsymbol{\Psi}_h^n.
\end{aligned}$$

Remark 4.3. Several remarks about the free boundary algorithm are in order.

- The algorithm employs a decoupling of the bulk equations and the geometry updates, which would otherwise be coupled in a nonlinear way.
- The discretization has the following property:

(4.9)
$$\begin{aligned}
&-d_{n-1}(\boldsymbol{\psi}_h, \tilde{\boldsymbol{v}}_h^n) - \sigma(d-1)\int_{\Gamma_{f,n-1}} \nabla_{\Gamma_{f,n-1}} \cdot \boldsymbol{\psi}_h \, d\mathcal{H}^{d-1}\\
&\quad = -\sigma(d-1)\int_{\Gamma_{f,n-1}} \nabla_{\Gamma_{f,n-1}} \boldsymbol{\psi}_h \cdot \nabla_{\Gamma_{f,n-1}} (\mathrm{id}_{\Gamma_{f,n-1}} + \tau_n \tilde{\boldsymbol{v}}_h^n) \, d\mathcal{H}^{d-1},\\
&\quad \approx \sigma(d-1)\int_{\Gamma_{f,n}} \boldsymbol{\psi}_h \cdot \boldsymbol{\kappa} \, d\mathcal{H}^{d-1};
\end{aligned}$$

  cf. (4.3). The capillary boundary condition is thus treated in a semi-implicit manner, since information about the new boundary position $\Gamma_{f,n}$ enters the definition of the curvature term. Furthermore, note that the term d_n adds additional coercivity on the left-hand side.
  The idea for this discretization of curvature was taken from [3], where it is crucial for proving stability of a discontinuous Galerkin scheme for the free boundary incompressible Navier–Stokes equations.
- We have defined the update of the free boundary as

$$\boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f} := \big(\mathrm{id}_{\Gamma_{f,n-1}} + \tau_n (\tilde{\boldsymbol{v}}_h^n|_{\Gamma_{f,n}} \cdot \boldsymbol{n}_h^{n-1}) \boldsymbol{n}_h^{n-1}\big) \circ \boldsymbol{\Phi}_h^{n-1}|_{\hat{\Gamma}_f}.$$

  A simpler formula, motivated by (4.9), is

$$\boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f} := \big(\mathrm{id}_{\Gamma_{f,n-1}} + \tau_n \tilde{\boldsymbol{v}}_h^n|_{\Gamma_{f,n}}\big) \circ \boldsymbol{\Phi}_h^{n-1}|_{\hat{\Gamma}_f}. \tag{4.10}$$

  This method is actually used during the mesh update Algorithm 4.4 below. However, in the case of large variations of the tangential velocity at the boundary (4.10) may lead to a quick distortion of the mesh, making the definition of a suitable mesh extension E_h even more difficult. Moving the free boundary only in the normal direction is justified since the set $\Gamma_{f,n}$ remains essentially the same—only the nodes defining the triangulation $\mathcal{R}_n$ are placed differently.

We conclude the discussion of the algorithm by presenting two implemented algorithms to define the mesh extension $E_h^n : \hat{R}_h \times \hat{M}_h \to \hat{M}_h$.

ALGORITHM 4.4 (mesh update algorithm 1). *Given old mesh positions* $\boldsymbol{\Phi}_h^{n-1} \in \hat{R}_h$ *and the velocity field* $\tilde{\boldsymbol{v}}_h^n \in \boldsymbol{V}_{h,n-1}$ *of step* 1 *in Algorithm* 4.2*, define* $\boldsymbol{\Phi}_h^n =$

$E(\boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f}, \boldsymbol{\Phi}_h^{n-1})$ as follows:

$$\boldsymbol{\Phi}_h^n|_{\hat{\Omega}\cup\hat{\Gamma}_f} := \left(\mathrm{id}_{\Omega_{n-1}} + \tau_n \tilde{\boldsymbol{v}}_h^n\right) \circ \boldsymbol{\Phi}_h^{n-1}|_{\hat{\Omega}\cup\hat{\Gamma}_f},$$
$$\boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_d} := \boldsymbol{\Phi}_h^0|_{\hat{\Gamma}_d}.$$

In other words, all interior nodes as well as the nodes on the free boundary are moved with the velocity field $\tilde{\boldsymbol{v}}_h^n$.

ALGORITHM 4.5 (mesh update algorithm 2). *Given are old mesh positions $\boldsymbol{\Phi}_h^{n-1} \in \hat{R}_h$ as well as the new positions of the free boundary $\boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f}$. Determine $\boldsymbol{\Xi}_h \in M_{h,n-1}$ (see (4.5)) as the solution of the elliptic system*

$$\int_{\Omega_{n-1}} \nabla\boldsymbol{\psi}_h : \nabla\boldsymbol{\Xi}_h = 0 \qquad \text{for all } \boldsymbol{\psi}_h \in M_{h,n-1},$$
$$\boldsymbol{\Xi}_h = \boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f} \circ \boldsymbol{\Psi}_h^{n-1} \quad \text{on } \Gamma_{f,n-1},$$
$$\boldsymbol{\Xi}_h = \mathrm{id}_{\Gamma_d} \qquad \text{on } \Gamma_d.$$

Now set $\boldsymbol{\Phi}_h^n = E(\boldsymbol{\Phi}_h^n|_{\hat{\Gamma}_f}, \boldsymbol{\Phi}_h^{n-1})$ as

$$\boldsymbol{\Phi}_h^n := \boldsymbol{\Xi}_h \circ \boldsymbol{\Phi}_h^{n-1}.$$

This idea of using the Laplace operator to smooth the mesh nodes was taken from [3]. Although simple and efficient to implement, this method has certain drawbacks; e.g., it cannot deal with nonconvex domains without modifications. Nevertheless, this algorithm was sufficient for our purposes. We refer to [39] for more sophisticated ideas on mesh smoothing.

5. Discretization. The simulation of acoustic streaming induced by SAWs was realized by the two-stage model already introduced in section 2. We used the second order Taylor–Hood finite element for the spatial discretization of the Stokes-like acoustic and acoustic streaming subproblems. The resulting discrete saddle point problem is solved using a CG iteration to invert the corresponding Schur complement of the system. For details we refer to [8]. To achieve a temporal discretization we employed either backward Euler or the Crank–Nicolson scheme.

We now present detailed algorithms to calculate solutions. We differentiate between the fixed mesh case and the case of free capillary boundaries.

5.1. Fixed meshes.

ALGORITHM 5.1 (acoustic streaming, fixed domain). *Given is a computational domain $\Omega \subset \mathbb{R}^d$, physical parameters, and a periodic function $\boldsymbol{u}$ as the SAW displacement on $\Gamma_d = \partial\Omega$.*

1. *Solve the acoustics subproblem (2.4) for $(\boldsymbol{v}^{(1)}, p^{(1)})$. We are interested in the periodic equilibrium state corresponding to the periodic forcing terms. Two methods are implemented:*
   (a) *Perform a time discretization with fixed time step size $\tau^{(1)} > 0$ together with Taylor–Hood finite elements with mesh parameter h. We perform either a fixed number of time steps or iterate until a given periodicity condition is fulfilled at a time t_{end}.*
   (b) *Employ the quasi-stationary approach (no time discretization) as described in section 3.4.*
2. *Calculate the right-hand terms and boundary conditions for (2.7).*

3. *Solve the acoustic streaming subproblem for* $(\boldsymbol{v}^{(2)}, p^{(2)})$. *Here we have the following alternatives:*
   (a) *We solve the stationary problem* (2.7).
   (b) *We solve the instationary variant* (2.6) *with fixed time step size* $\tau^{(2)}$. *This is primarily of interest when determining the relaxation time of the acoustic streaming flow.*

5.2. Free capillary boundaries. For the simulation of acoustic streaming with free capillary boundaries, we will need physical parameters as before and additionally a coefficient σ of surface tension. A typical value would be $\sigma = 7.3 \cdot 10^{-2}$ N/m.

The basis of this algorithm was already presented as Algorithm 4.2. It remains to specify the right-hand sides $\boldsymbol{f}_v^n$, f_p^n for each time step. These are now determined by solving the acoustics subproblem as above.

ALGORITHM 5.2 (acoustic streaming, free boundaries). *Given is a starting domain* $\Omega_0 \subset \mathbb{R}^d$ *and a periodic function* $\boldsymbol{u}$ *as the SAW displacement on* $\Gamma_d \subset \partial\Omega$. *Loop over* $n = 0, 1, 2, \ldots$:

1. *Solve the acoustics subproblem* (2.4) *for* $(\boldsymbol{v}^{(1)}, p^{(1)})$ *on the domain* Ω_n *up to the periodic equilibrium state. This is done as above in Algorithm* 5.1, *with either a time discretization or the quasi-stationary approach. In the former case iterate until periodicity is reached.*
2. *Calculate right-hand terms* $\boldsymbol{f}_v^{(2),n}$, $f_p^{(2),n}$ *and boundary conditions for the acoustic streaming solution at time step* t_n *using* $\boldsymbol{v}^{(1)}$ *and* $p^{(1)}$ *as above.*
3. *Perform step* 1 *of Algorithm* 4.2 *to determine the acoustic streaming solution* $(\boldsymbol{v}^{(2),n}, p^{(2),n})$ *at time step* t_n *with* $\tau_n := \tau^{(2)}$.
4. *Update the position of the mesh to determine* Ω_{n+1}, *as described in steps* 2 *and* 3 *of Algorithm* 4.2. *We have the alternatives* 4.4 *and* 4.5 *as mesh smoothing methods.*

Remark 5.3. Recalculating the acoustics solution $(\boldsymbol{v}^{(1)}, p^{(1)})$ in each time step t_n of the main iteration is extremely costly. In practice we have relaxed this requirement by continuing to use $\boldsymbol{f}_v^{(2),n}$, $f_p^{(2),n}$ for several time steps before recomputing. Numerical experiments show that the additional error involved does not have a significant effect on the equilibrium state of the solution $(\Omega_n, \boldsymbol{v}^{(2),n}, p^{(2),n})$ reached for large n.

6. Numerical results. The goal of this section is to present simulation results of SAW-induced streaming with realistic physical parameters. The computational effort for solving fixed domain problems is still acceptable for our 3D setup—the simulation of streaming effects including free capillary boundaries, however, is possible only in a simple two-dimensional (2D) configuration using the current implementation. The reason for this is that the change of the domain in each time step necessitates the recalculation of the acoustic field solution; see below.

All calculations were performed on AMD Opteron$^{\text{TM}}$ 64 bit 2.6 GHz dual-head processors with 8 GB memory. We used the freely available ALBERTA finite element toolbox, [41].

6.1. Fixed domains.

6.1.1. 2D simulation. We refer to (2.1) for the notation. The 2D simulation setting is a fluid-filled square cavity $\Omega = [0, 1 \text{ mm}]^2$ with SAW displacements $\boldsymbol{u}$ prescribed on the bottom edge. The velocity $\boldsymbol{v}$ is set to zero on the other three edges. The SAW propagates from left to right with exponential attenuation. The exact shape assumed in this work is based on wavelengths, wave velocities, amplitudes,

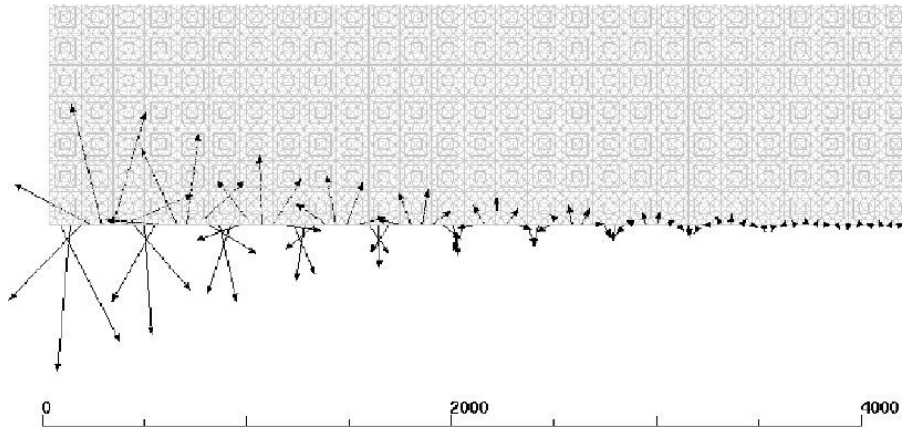

FIG. 6.1. *Detail of computational mesh and SAW displacement field in the bottom left corner of the domain with a computational length scale (*1 *unit* $\equiv 10^{-1}\mu$m*).*

TABLE 6.1
Numerical and physical parameters for the 2*D SAW simulation.*

Parameter	Value and units	Description
V	$1.0 \cdot 10^{-1}$ m/s	Dimensionless velocity scale
L	$1.0 \cdot 10^{-7}$ m	Dimensionless length scale
T	$1.0 \cdot 10^{-8}$ s	Dimensionless time scale
f	$1.0 \cdot 10^{8}$ Hz	Frequency of the SAW device
$c_{0,l}$	$1.484 \cdot 10^{3}$ m/s	Small signal sound speed in water
$c_{0,s}$	$3.8 \cdot 10^{3}$ m/s	Small signal sound speed in solid
ρ_0	$1.0 \cdot 10^{3}$ kg/m^3	Density of liquid
u_0	$1.0 \cdot 10^{-9}$ m	Maximal SAW displacement
C_d	$8.06 \cdot 10^{3}$ 1/m	Damping parameter of the LSAW
ν_1	$1.002 \cdot 10^{-6}$ m^2/s	Kinematic viscosity of water
ν_2	$1.002 \cdot 10^{-6}$ m^2/s	Kinematic bulk viscosity of water

and damping parameters of a typical lithium niobate crystal as described in [18]; see Figure 6.1.

This setup approximates the case of a vertically oriented thin slice of water trapped in a container and touching the SAW-traversed solid surface at the bottom. The fluid is assumed to be initially at rest, i.e., $\boldsymbol{v}_0 = 0$, $p_0 = 0$.

Data of the 2*D SAW device simulation.* The function $\boldsymbol{u}$ to describe the SAW displacement at the lower edge is defined in dimensionless form as

$$
\begin{aligned}
u_1(t, \boldsymbol{x}) &= 0.6\epsilon \exp(-\widehat{C}_d x_1) \sin(2\pi(-\widehat{k} x_1 + \widehat{f} t)), \\
u_2(t, \boldsymbol{x}) &= -\epsilon \exp(-\widehat{C}_d x_1) \cos(2\pi(-\widehat{k} x_1 + \widehat{f} t))
\end{aligned}
\tag{6.1}
$$

for $\boldsymbol{x} \in \partial\Omega$, $x_2 = 0$ with parameters $\epsilon = u_0/L$, $\widehat{C}_d = C_d L$, $\widehat{k} = L/\lambda$, $\widehat{f} = fT$. Note that the discretization parameter ϵ is 0.1; confer (2.3). Additional damping terms, not mentioned here, serve to avoid sharp jumps of the function $\boldsymbol{u}$ at $\boldsymbol{x} = 0$ and $t = 0$. The other parameters used in the simulation are given in Table 6.1.

As described in section 2 the acoustic streaming field $(\boldsymbol{v}^{(2)}, p^{(2)})$ is calculated via a two-stage algorithm using the intermediate acoustics field solution $(\boldsymbol{v}^{(1)}, p^{(1)})$. We use the standard Crank–Nicolson time discretization algorithm for parabolic problems

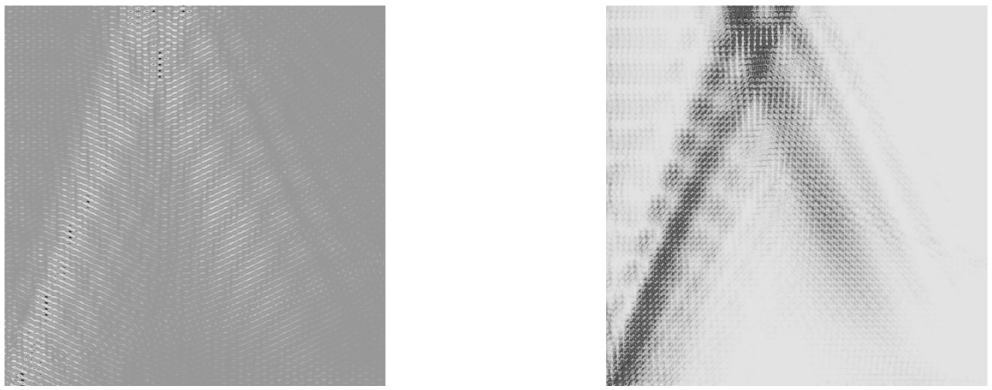

FIG. 6.2. *Left: Acoustics subproblem solution: pressure field* $p^{(1)}$ *at time* $t = 142 \equiv 1.42$ μs. *Right: Plot of effective force* f_v *for the acoustic streaming solution. Clearly visible is the reflection of the pressure wave at the top boundary of the domain as well as the typical Rayleigh angle corresponding to the ratio of sound speeds in liquid and substrate.*

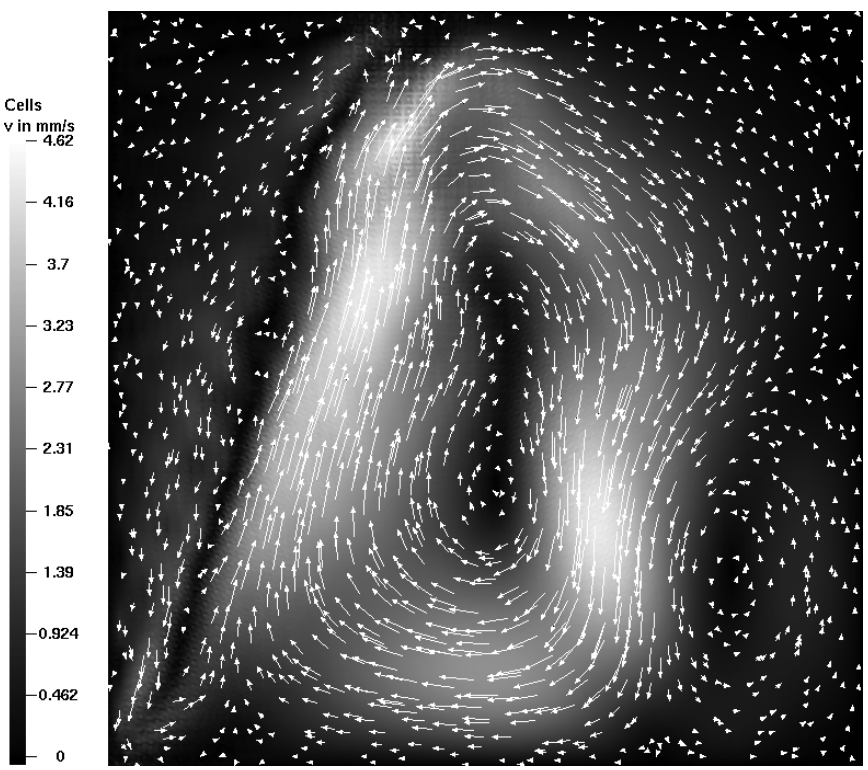

FIG. 6.3. *Acoustic streaming solution: velocity field* $v^{(2)}$ *in* mm/s.

to solve for the acoustics field $(\boldsymbol{v}^{(1)}, p^{(1)})$ at each time step. We calculate a sufficient number of time steps in order to reach an oscillating equilibrium state.

Results of the 2D SAW device simulation. The CPU time necessary for the full calculation was approximately two hours. See Figures 6.2 and 6.3.

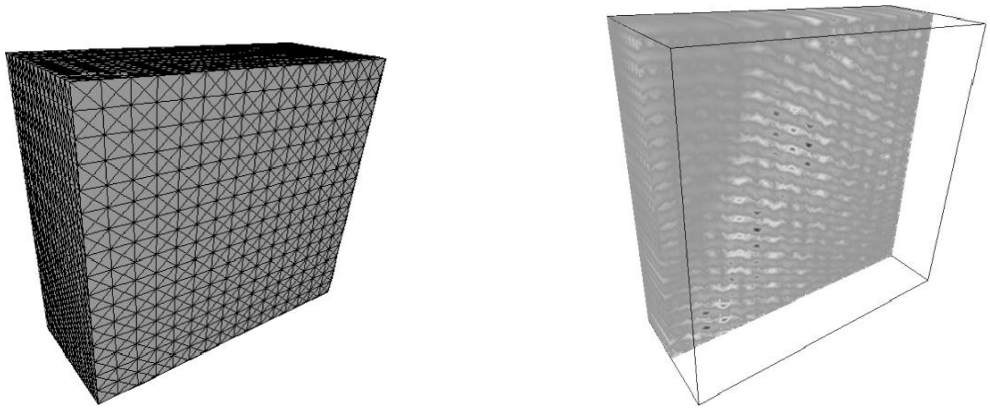

FIG. 6.4. *Left: Domain for the 3D simulation runs. Right: Acoustics subproblem solution: slab* $x_3 \geq 0$ *of the pressure field* $p^{(1)}$ *at time* $t = 200 \equiv 2$ *μs.*

6.1.2. 3D simulation. The parameters used for the 3D simulation are similar to the 2D case. The domain will again be a fluid-filled rectangular cavity. We set $\Omega = [0, 250\ \mu\text{m}]^2 \times [-50\ \mu\text{m}, 50\ \mu\text{m}]$; see Figure 6.4. The SAW traverses the bottom face; on the other walls, we again prescribe zero Dirichlet boundary conditions for fluid velocity.

Data of the 3D SAW device simulation. The parameters are set to the same values as before. The function $\boldsymbol{u}$ is defined in dimensionless form as

$$\begin{aligned} u_1(t, \boldsymbol{x}) &= 0.6\epsilon \exp(-\widehat{C}_d x_1) \sin(2\pi(-\widehat{k}x_1 + \widehat{f}t)) d(x_3), \\ u_2(t, \boldsymbol{x}) &= -\epsilon \exp(-\widehat{C}_d x_1) \cos(2\pi(-\widehat{k}x_1 + \widehat{f}t)) d(x_3), \\ u_3(t, \boldsymbol{x}) &= 0. \end{aligned} \tag{6.2}$$

The terms have the same meaning as in (6.1) above. What is new is the term $d(x_3)$, defined as

$$d(x_3) = 4 \cdot 10^{-6}(x_3 - 500)(x_3 + 500).$$

Observing that the domain depth 100 μm corresponds to the dimensionless depth of 1000 units, we have thus extended the SAW shape of the 2D simulation to a parabolic profile over the bottom face.

Results of the 3D SAW device simulation. The CPU time necessary for the full calculation was approximately six days. The acoustic streaming velocity values $\boldsymbol{v}^{(2)}$ are shown in Figure 6.5.

We additionally took a vertical cross section of the 3D mesh to define a 2D mesh, together with values of the SAW displacement field $\boldsymbol{u}$ along the cross section. This permits a comparison of a 3D solution with a corresponding 2D solution. Figure 6.6 shows that the result is qualitatively close to the 3D field.

6.2. Free boundaries. As described above, we will restrict ourselves to performing a 2D simulation. We will describe the deformation of an originally semicircular drop of water of radius $2500 \equiv 0.25$ mm posed above a SAW wave of the same shape as in the fixed domain 2D simulations. The maximal SAW amplitude was $\boldsymbol{u}_0 = 100$ nm, a much higher value compared to the fixed domain simulations.

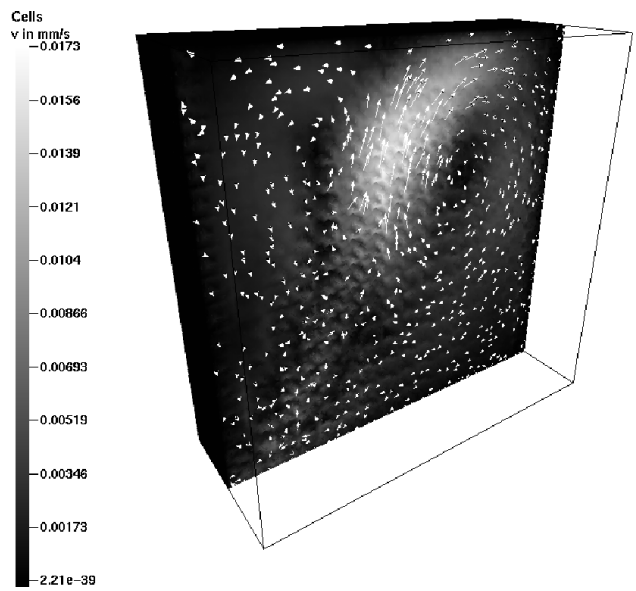

FIG. 6.5. *Acoustic streaming solution: slab* $x_3 \geq 0$ *of the velocity field* $v^{(2)}$.

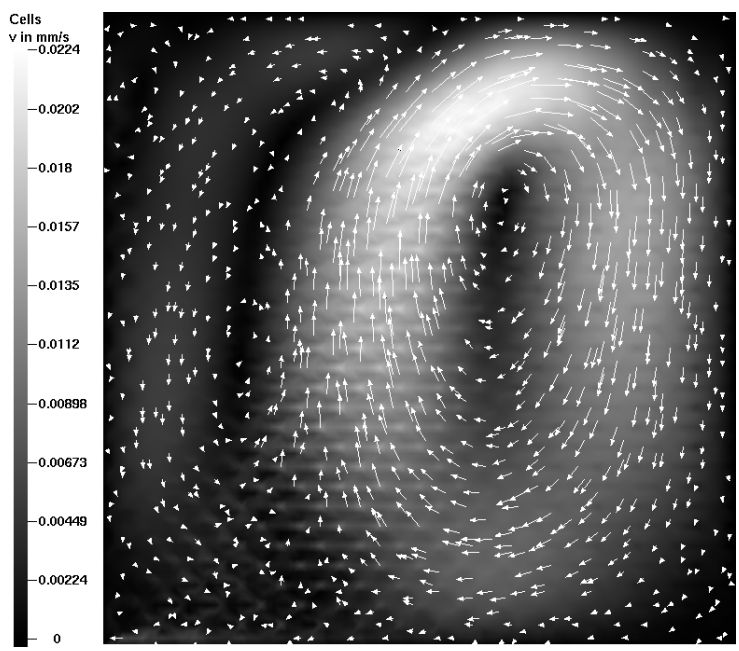

FIG. 6.6. *Comparison with the corresponding* $2D$ *simulation: acoustic streaming velocity field* $v^{(2)}$.

The coefficient of surface tension assumed in the simulations is $\sigma = 7.3 \cdot 10^{-2}$ N/m corresponding to a water/vacuum interface.

We solved 200 microscopic time steps of length $\tau^{(1)} = 0.1 \equiv 1.0 \cdot 1$ ns to determine the equilibrium acoustics solution needed for each macroscopic time step. The acoustic streaming solution was calculated using macroscopic time steps of length $\tau^{(2)} = 1000 \equiv 10$ μs.

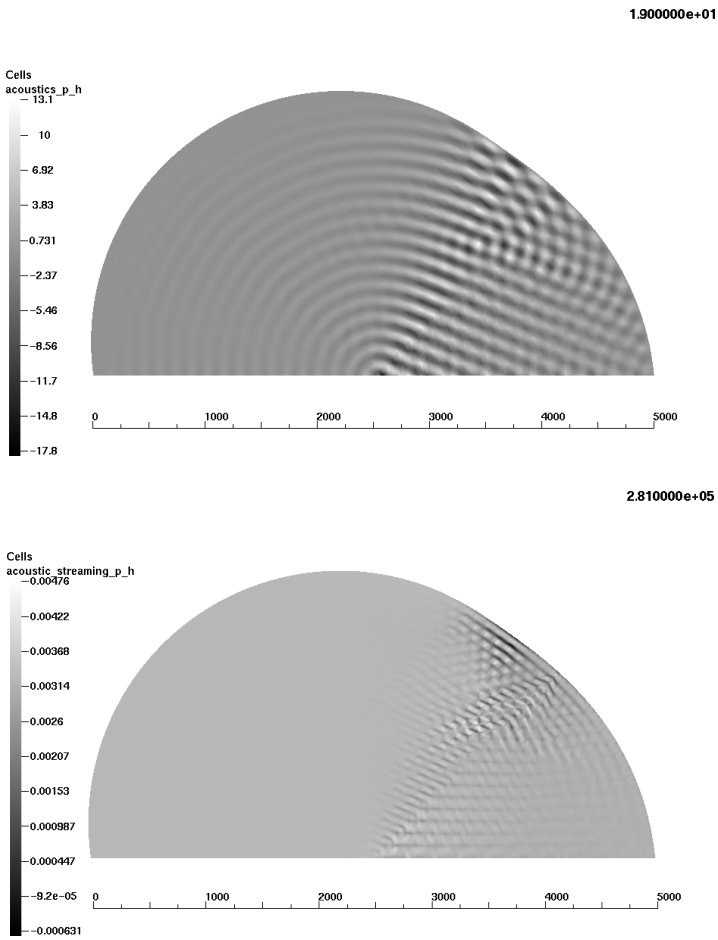

FIG. 6.7. *Free boundary solution. Top: acoustic pressure field* $p^{(1)}$ *at microscopic time* $t^{(1)} = 19$ *and macroscopic time* $t^{(2)} = 2.81 \cdot 10^5$. *Bottom: acoustic streaming pressure field* $p^{(2)}$ *at macroscopic time* $t^{(2)} = 2.81 \cdot 10^5$.

One important change was done in the calculations. The mass generation rate $f_p^{(2),n}$ and outflow $\boldsymbol{g}^{(2),n} \cdot \boldsymbol{n}$ used in step 3 of Algorithm 4.2 will, in general, not be balanced. This implies a change in the pressure mean over time. In the presence of free capillary boundaries a change in the overall pressure leads to a change in volume—this is undesirable and nonphysical behavior. We therefore restored the balance between outflow and mass generation in the numerical calculations by multiplying $\boldsymbol{g}^{(2),n}$ with a correction factor. Numerical experiments performed without this correction indeed displayed a continuously decreasing volume of the droplets.

Results of the free boundary SAW simulation. The maximal CPU time for the calculation of 10 time steps was approximately five hours. The observed behavior of the drop is characterized by initial damped oscillations. A deformed equilibrium position is obtained after a short period of time.

Figure 6.7 shows the acoustic and acoustic streaming pressure fields $p^{(1)}$ (resp., $p^{(2)}$) in the droplet at different times.

ADAPTIVE SEMIDISCRETE CENTRAL-UPWIND SCHEMES FOR NONCONVEX HYPERBOLIC CONSERVATION LAWS*

ALEXANDER KURGANOV†, GUERGANA PETROVA‡, AND BOJAN POPOV‡

Abstract. We discover that the choice of a piecewise polynomial reconstruction is crucial in computing solutions of nonconvex hyperbolic (systems of) conservation laws. Using semidiscrete central-upwind schemes, we illustrate that the obtained numerical approximations may fail to converge to the unique entropy solution or the convergence may be so slow that achieving a proper resolution would require the use of (almost) impractically fine meshes. For example, in the scalar case, all computed solutions seem to converge to solutions that are entropy solutions for some entropy pairs. However, in most applications, one is interested in capturing the unique (Kruzhkov) solution that satisfies the entropy condition for all convex entropies. We present a number of numerical examples that demonstrate the convergence of the solutions, computed with the dissipative second-order minmod reconstruction, to the unique entropy solution. At the same time, more compressive and/or higher-order reconstructions may fail to resolve composite waves, typically present in solutions of nonconvex conservation laws, and thus may fail to recover the Kruzhkov solution. In this paper, we propose a simple and computationally inexpensive adaptive strategy that allows us to simultaneously capture the unique entropy solution and to achieve a high resolution of the computed solution. We use the dissipative minmod reconstruction near the points where convexity changes and utilize a fifth-order weighted essentially nonoscillatory (WENO5) reconstruction in the rest of the computational domain. Our numerical examples (for one- and two-dimensional scalar and systems of conservation laws) demonstrate the robustness, reliability, and nonoscillatory nature of the proposed adaptive method.

Key words. hyperbolic systems of conservation laws, semidiscrete central-upwind schemes, piecewise polynomial reconstructions, nonconvex flux

DOI. 10.1137/040614189

1. Introduction.

We consider initial-value problems (IVPs) for hyperbolic (systems of) conservation laws in one and two space dimensions:

$$\mathbf{u}_t + \nabla_{\mathbf{x}} \cdot \mathbf{f}(\mathbf{u}) = \mathbf{0}, \tag{1.1}$$

$$\mathbf{u}(\mathbf{x}, 0) = \mathbf{u}_0(\mathbf{x}), \tag{1.2}$$

whose entropy solutions may admit composite waves. Such examples are scalar conservation laws with nonconvex fluxes and systems of conservation laws, for which (at least) one of the structure coefficients, defined in (2.7) in section 2, changes sign. Further, we refer to all these cases as *nonconvex* hyperbolic (systems of) conservation laws.

An important example of such a system is the Euler equations of gas dynamics with a nonconvex equation of state (EOS). In general, in this case, anomalous wave structure should be expected near a phase transition, because the wave speed need

not be monotonic along Hugoniot loci and isentropes, and the usual construction of the wave curves for the Riemann problem must be modified (see [27] and the references therein). Another important example of a nonconvex system of conservation laws is the polymer system used to model polymer flooding processes in enhanced oil recovery (see, e.g., [29]). The solution of the Riemann problem for these two systems is known (see, for example, [2], [23], [24], [27], [36], [38], [39], and [11], [13], respectively). However, designing reliable and robust high-order numerical methods for general initial data remains a challenging problem.

Many classical numerical schemes have been extended to solve nonconvex (systems of) conservation laws. We refer the reader to [1], [4], [5], [6], [10], [31], [37], [40] for several upwind Godunov-type schemes based on both the exact and approximate Riemann problem solvers. A low dissipative front tracking method for the polymer system was proposed in [9]. At the same time, note that the "simplest" extensions of the Roe scheme typically cannot be applied in practice to nonconvex systems of conservation laws. We would also like to point out that many of the aforementioned schemes may require computationally expensive evaluation of integrals or a very careful estimation of the CFL number, since otherwise the computed solution may converge to a weak solution that is not the unique entropy solution (see, for example, [19]).

In this paper, we apply the Godunov-type semidiscrete central-upwind schemes from [15] to numerically solve nonconvex hyperbolic (systems of) conservation laws. These schemes are an attractive alternative to other existing methods because they are simple (no Riemann problem solvers are employed), universal, and efficient, and can be used as a "black-box solver." They consist of three steps: projection (averaging), a piecewise polynomial reconstruction, and evolution of the reconstructed interpolant to the next time level according to the integral form of the conservation law (obtained by integrating (1.1) over the control volume). Assuming the exact averaging and evolution operators are used, the nonoscillatory nature of the computed solution is guaranteed provided the piecewise polynomial reconstruction is nonoscillatory, which is typically achieved with the help of nonlinear limiters. When solving the nonconvex problem (1.1)–(1.2) using the semidiscrete central-upwind schemes from [15], necessary adjustments, related to the estimation of the local speeds of propagation, have to be made. Moreover, it turns out that the choice of reconstruction is crucial for capturing of the unique entropy solution. One may expect that, as in the convex case, the use of more compressive and/or higher-order reconstruction will result in sharper resolution of the computed solution. However, this is not the case here, where sharper reconstructions may lead to the convergence of the computed solutions toward a weak solution, which satisfies the entropy condition for only some, but not all, convex entropies. At the same time, the use of more dissipative reconstructions typically results in computing the unique entropy solution, but with relatively low resolution. For example, the implementation of the dissipative minmod reconstruction (see, e.g., [35], [22], [28], [34]) seems to ensure the convergence toward the unique entropy solution, while more compressible reconstructions based on the generalized minmod [22], [28], [34] or superbee [22], [30], [34] limiters as well as the fifth-order essentially nonoscillatory (WENO5) [3], [12], [26], [32], [33] reconstruction may lead to capturing another weak solution (at least in the case when the mesh is of the reasonably coarse size typically used in practical computations).

In this paper, we introduce a simple scheme adaption strategy for solving nonconvex problems, which utilizes the advantages of both the compressive/high-order and the dissipative reconstructions, namely, computing the entropy solution with high

resolution. This is achieved by the proposed *adaptive semidiscrete central-upwind scheme*. In the new scheme, the choice of reconstruction is based on the so far computed solution and switches adaptively from one type to another at or near the points where the flux convexity changes.

The paper is organized as follows. In section 2, we briefly describe the semidiscrete central-upwind schemes. Several piecewise polynomial reconstructions and their impact on the computed solutions are discussed in section 3. Our scheme adaption strategy is presented in section 4. The numerical examples are shown in section 5, where we test our method on one-dimensional (1-D) and two-dimensional (2-D) nonconvex conservation laws, including scalar equations, the Euler equations of gas dynamics, and the polymer system.

2. Semidiscrete central-upwind schemes—an overview. In this section, we briefly describe the semidiscrete central-upwind schemes proposed in [15]. Here we emphasize the details needed for their implementation for nonconvex conservation laws.

For simplicity, we will focus on the 1-D case, where we consider a uniform spatial grid $x_\alpha = \alpha\Delta x$, and assume that the computed cell averages of the solution at some time level t,

$$\bar{\mathbf{u}}_j(t) \approx \frac{1}{\Delta x}\int_{x_{j-\frac12}}^{x_{j+\frac12}} \mathbf{u}(x,t)\,dx,$$

are already available. Using these values, we reconstruct a (nonoscillatory) piecewise polynomial interpolant (from now on, we will omit the time-dependence of all computed and reconstructed quantities), $\sum_j \mathbf{p}_j(x)\chi_j(x)$, where χ_j is the characteristic function of $[x_{j-\frac12}, x_{j+\frac12}]$ and $\mathbf{p}_j(x)$ are the corresponding polynomial pieces. For example, conservative linear pieces have the following form:

$$\mathbf{p}_j(x) = \bar{\mathbf{u}}_j + \mathbf{s}_j(x - x_j). \tag{2.1}$$

Piecewise polynomial reconstructions are, in general, discontinuous at the cell interfaces, $x = x_{j+\frac12}$, and therefore their evolution is locally described by the solutions of generalized Riemann problems. The sizes of the corresponding Riemann fans are determined by the right- and left-sided local speeds of propagation, $\{a^{\pm}_{j+\frac12}\}$, which can be estimated as follows:

$$\begin{aligned} a^+_{j+\frac12} &:= \max_{\boldsymbol{\omega}\in C(\mathbf{u}^-_{j+\frac12},\mathbf{u}^+_{j+\frac12})}\left\{\lambda_N\left(\frac{\partial \mathbf{f}}{\partial \mathbf{u}}(\boldsymbol{\omega})\right),0\right\},\\ a^-_{j+\frac12} &:= \min_{\boldsymbol{\omega}\in C(\mathbf{u}^-_{j+\frac12},\mathbf{u}^+_{j+\frac12})}\left\{\lambda_1\left(\frac{\partial \mathbf{f}}{\partial \mathbf{u}}(\boldsymbol{\omega})\right),0\right\}. \end{aligned} \tag{2.2}$$

Here, $\lambda_1 < \cdots < \lambda_N$ are the eigenvalues of the Jacobian $\frac{\partial \mathbf{f}}{\partial \mathbf{u}}$, and $C(\mathbf{u}^-_{j+\frac12}, u^+_{j+\frac12})$ is the curve in the phase space that connects the left and right values of the reconstruction at $x = x_{j+\frac12}$:

$$\mathbf{u}^-_{j+\frac12} := \mathbf{p}_j(x_{j+\frac12}), \quad \mathbf{u}^+_{j+\frac12} := \mathbf{p}_{j+1}(x_{j+\frac12}). \tag{2.3}$$

The cell averages $\{\bar{\mathbf{u}}_j\}$ are then evolved in time according to the semidiscrete central-upwind scheme:

$$\frac{d}{dt}\bar{\mathbf{u}}_j(t) = -\frac{\mathbf{H}_{j+\frac{1}{2}}(t) - \mathbf{H}_{j-\frac{1}{2}}(t)}{\Delta x}, \tag{2.4}$$

where the numerical fluxes $\mathbf{H}_{j+\frac{1}{2}}$ are

$$\mathbf{H}_{j+\frac{1}{2}}(t) = \frac{a^+_{j+\frac{1}{2}}\mathbf{f}(\mathbf{u}^-_{j+\frac{1}{2}}) - a^-_{j+\frac{1}{2}}\mathbf{f}(\mathbf{u}^+_{j+\frac{1}{2}})}{a^+_{j+\frac{1}{2}} - a^-_{j+\frac{1}{2}}} + \frac{a^+_{j+\frac{1}{2}}a^-_{j+\frac{1}{2}}}{a^+_{j+\frac{1}{2}} - a^-_{j+\frac{1}{2}}}\left[\mathbf{u}^+_{j+\frac{1}{2}} - \mathbf{u}^-_{j+\frac{1}{2}}\right]. \tag{2.5}$$

Notice that a practical implementation of (2.4)–(2.5) requires the following:

(i) A stable, preferably a strong stability preserving (SSP) [7], solver for the ODE system (2.4). In all numerical experiments presented below, we have used the third-order SSP Runge–Kutta method. To guarantee that no wave interaction occurs during each time step, the CFL number has been set to 0.5.

(ii) A choice of a piecewise polynomial reconstruction (see the discussion in section 3). Notice that the spatial order of the resulting scheme is determined by the order of the reconstruction.

(iii) A practical version of formula (2.2) for computing the one-sided local speeds of propagation. It is well known that in the convex case, they can be computed by

$$\begin{aligned} a^+_{j+\frac{1}{2}} &= \max\left\{\lambda_N\left(\frac{\partial\mathbf{f}}{\partial\mathbf{u}}(\mathbf{u}^-_{j+\frac{1}{2}})\right), \lambda_N\left(\frac{\partial\mathbf{f}}{\partial\mathbf{u}}(\mathbf{u}^+_{j+\frac{1}{2}})\right), 0\right\},\\ a^-_{j+\frac{1}{2}} &= \min\left\{\lambda_1\left(\frac{\partial\mathbf{f}}{\partial\mathbf{u}}(\mathbf{u}^-_{j+\frac{1}{2}})\right), \lambda_1\left(\frac{\partial\mathbf{f}}{\partial\mathbf{u}}(\mathbf{u}^+_{j+\frac{1}{2}})\right), 0\right\}. \end{aligned} \tag{2.6}$$

In the nonconvex case, however, this simple formula is incorrect if the flux convexity changes near $\mathbf{u}^\pm_{j+\frac{1}{2}}$, and one has to use a more accurate estimate of $a^\pm_{j+\frac{1}{2}}$ there.

In the scalar case, the speeds in (2.2) can be easily evaluated exactly:

$$a^+_{j+\frac{1}{2}} = \max_{u\in[u^{\min}_{j+\frac{1}{2}}, u^{\max}_{j+\frac{1}{2}}]}\{f'(u), 0\}, \quad a^-_{j+\frac{1}{2}} = \min_{u\in[u^{\min}_{j+\frac{1}{2}}, u^{\max}_{j+\frac{1}{2}}]}\{f'(u), 0\},$$

where $u^{\min}_{j+\frac{1}{2}} = \min\{u^-_{j+\frac{1}{2}}, u^+_{j+\frac{1}{2}}\}$ and $u^{\max}_{j+\frac{1}{2}} = \max\{u^-_{j+\frac{1}{2}}, u^+_{j+\frac{1}{2}}\}$.

In the case of a system, we follow the approach in [37] if the structure coefficients,

$$\kappa_i = \nabla_{\mathbf{u}}\lambda_i \cdot \mathbf{r}_i, \quad i = 1, \ldots, N, \tag{2.7}$$

change sign near $\mathbf{u}^\pm_{j+\frac{1}{2}}$ (here $\mathbf{r}_i$ is the ith right eigenvector, corresponding to the ith eigenvalue λ_i). The left and right local speeds are then estimated by

$$\begin{aligned} a^+_{j+\frac{1}{2}} &= \max\left\{\lambda_N\left(\frac{\partial\mathbf{f}}{\partial\mathbf{u}}(\mathbf{u}^-_{j+\frac{1}{2}})\right), \lambda_N\left(\frac{\partial\mathbf{f}}{\partial\mathbf{u}}(\mathbf{u}^+_{j+\frac{1}{2}})\right), \widetilde{\mathcal{H}}_N, 0\right\},\\ a^-_{j+\frac{1}{2}} &= \min\left\{\lambda_1\left(\frac{\partial\mathbf{f}}{\partial\mathbf{u}}(\mathbf{u}^-_{j+\frac{1}{2}})\right), \lambda_1\left(\frac{\partial\mathbf{f}}{\partial\mathbf{u}}(\mathbf{u}^+_{j+\frac{1}{2}})\right), \widetilde{\mathcal{H}}_1, 0\right\}. \end{aligned} \tag{2.8}$$

Here, the notation is

$$\widetilde{\mathcal{H}}_N := \max_{\sigma\in[0,1]} \mathcal{H}(\lambda_N(\mathbf{u}^-_{j+\frac12}),\lambda_N(\mathbf{u}^+_{j+\frac12}),\kappa^-_N,\kappa^+_N;\sigma),$$

$$\widetilde{\mathcal{H}}_1 := \min_{\sigma\in[0,1]} \mathcal{H}(\lambda_1(\mathbf{u}^-_{j+\frac12}),\lambda_1(\mathbf{u}^+_{j+\frac12}),\kappa^-_1,\kappa^+_1;\sigma),$$

where

$$\kappa^\pm_i := \nabla_{\mathbf{u}}\lambda_i(\mathbf{u}^\pm_{j+\frac12})\cdot\mathbf{r}_i(\mathbf{u}^{\rm mid}_{j+\frac12}),\quad \mathbf{u}^{\rm mid}_{j+\frac12}=\frac{\mathbf{u}^+_{j+\frac12}+\mathbf{u}^-_{j+\frac12}}{2},\qquad i=1,N, \tag{2.9}$$

are the left and right structure coefficients at $x_{j+\frac12}$, and $\mathcal{H}(a,b,a',b';\sigma)$ is the unique Hermite cubic polynomial that satisfies the following interpolation conditions:

$$\mathcal{H}(a,b,a',b';0)=a,\ \ \mathcal{H}(a,b,a',b';1)=b,\ \ \mathcal{H}'(a,b,a',b';0)=a',\ \ \mathcal{H}'(a,b,a',b';1)=b'.$$

Away from the regions where the convexity changes, the local speeds are computed by (2.6).

Remark. In the 2-D case, we use a higher-order version of the central-upwind scheme from [15], where a fourth-order central-upwind numerical flux was obtained. Proceeding along the lines of the numerical flux derivation in [15] and replacing Simpson's rule with the 3-point Gaussian quadrature in the evaluation of the spatial flux integrals, we arrive at the following semidiscrete central-upwind scheme:

$$\frac{d}{dt}\bar{\mathbf{u}}_{j,k}(t)=-\frac{\mathbf{H}^x_{j+\frac12,k}(t)-\mathbf{H}^x_{j-\frac12,k}(t)}{\Delta x}-\frac{\mathbf{H}^y_{j,k+\frac12}(t)-\mathbf{H}^y_{j,k-\frac12}(t)}{\Delta y}, \tag{2.10}$$

where the numerical fluxes are

(2.11)

$$\begin{aligned}\mathbf{H}^x_{j+\frac12,k} :=\ & \frac{a^+_{j+\frac12,k}}{18(a^+_{j+\frac12,k}-a^-_{j+\frac12,k})}\Big[5\mathbf{f}(\mathbf{u}^{\rm E1}_{j,k})+8\mathbf{f}(\mathbf{u}^{\rm E2}_{j,k})+5\mathbf{f}(\mathbf{u}^{\rm E3}_{j,k})\Big]\\ &-\frac{a^-_{j+\frac12,k}}{18(a^+_{j+\frac12,k}-a^-_{j+\frac12,k})}\Big[5\mathbf{f}(\mathbf{u}^{\rm W1}_{j+1,k})+8\mathbf{f}(\mathbf{u}^{\rm W2}_{j+1,k})+5\mathbf{f}(\mathbf{u}^{\rm W3}_{j+1,k})\Big]\\ &+\frac{a^+_{j+\frac12,k}a^-_{j+\frac12,k}}{18(a^+_{j+\frac12,k}-a^-_{j+\frac12,k})}\\ &\times\Big[5(\mathbf{u}^{\rm W1}_{j+1,k}-\mathbf{u}^{\rm E1}_{j,k})+8(\mathbf{u}^{\rm W2}_{j+1,k}-\mathbf{u}^{\rm E2}_{j,k})+5(\mathbf{u}^{\rm W3}_{j+1,k}-\mathbf{u}^{\rm E3}_{j,k})\Big]\end{aligned}$$

and

(2.12)

$$\begin{aligned}\mathbf{H}^y_{j,k+\frac12} :=\ & \frac{b^+_{j,k+\frac12}}{18(b^+_{j,k+\frac12}-b^-_{j,k+\frac12})}\Big[5\mathbf{g}(\mathbf{u}^{\rm N1}_{j,k})+8\mathbf{g}(\mathbf{u}^{\rm N2}_{j,k})+5\mathbf{g}(\mathbf{u}^{\rm N3}_{j,k})\Big]\\ &-\frac{b^-_{j,k+\frac12}}{18(b^+_{j,k+\frac12}-b^-_{j,k+\frac12})}\Big[5\mathbf{g}(\mathbf{u}^{\rm S1}_{j,k+1})+8\mathbf{g}(\mathbf{u}^{\rm S2}_{j,k+1})+5\mathbf{g}(\mathbf{u}^{\rm S3}_{j,k+1})\Big]\end{aligned}$$

$$+\frac{b^+_{j,k+\frac12}b^-_{j,k+\frac12}}{18(b^+_{j,k+\frac12}-b^-_{j,k+\frac12})}$$

$$\times\Big[5(\mathbf{u}^{\mathrm{S}1}_{j,k+1}-\mathbf{u}^{\mathrm{N}1}_{j,k})+8(\mathbf{u}^{\mathrm{S}2}_{j,k+1}-\mathbf{u}^{\mathrm{N}2}_{j,k})+5(\mathbf{u}^{\mathrm{S}3}_{j,k+1}-\mathbf{u}^{\mathrm{N}3}_{j,k})\Big].$$

Here, the Cartesian grid is assumed to be uniform with $x_\alpha=\alpha\Delta x$, $y_\beta=\beta\Delta y$; the point values $\mathbf{u}^{\mathrm{E}i}_{j,k}$, $i=1,2,3$, are the values of the polynomial piece over the cell $[x_{j-\frac12},x_{j+\frac12}]\times[y_{k-\frac12},y_{k+\frac12}]$, evaluated at the corresponding Gaussian nodes along the eastern edge ($x=x_{j+\frac12}$, $y_{k-\frac12}<y<y_{k+\frac12}$); the point values $\mathbf{u}^{\mathrm{N}i}_{j,k}$, $i=1,2,3$, are the values of the polynomial piece over the same cell evaluated at the corresponding Gaussian nodes along the northern edge ($x_{j-\frac12}<x<x_{j+\frac12}$, $y=y_{k+\frac12}$); and the rest of the point values, $\mathbf{u}^{\mathrm{W}i}_{j,k}$, $\mathbf{u}^{\mathrm{S}i}_{j,k}$, $i=1,2,3$, are calculated at the Gaussian nodes along the remaining two edges. Recall that the Gaussian nodes G_i, $i=1,2,3$, on an arbitrary segment AB with $A=(a_1,a_2)$ and $B=(b_1,b_2)$ have the following coordinates: $G_1=(\alpha_+a_1+\alpha_-a_2,\alpha_+b_1+\alpha_-b_2)$, $G_2=((a_1+a_2)/2,(b_1+b_2)/2)$, and $G_3=(\alpha_-a_1+\alpha_+a_2,\alpha_-b_1+\alpha_+b_2)$, where $\alpha_\pm=\frac12(1\pm\sqrt{3/5})$.

The local speeds of propagation in the x- and y-direction, $a^\pm_{j+\frac12,k}$ and $b^\pm_{j,k+\frac12}$, respectively, are computed at the midpoint of each cell interface in a dimension-by-dimension manner according to the above 1-D recipe.

If the point values in (2.11)–(2.12) are computed using an rth-order piecewise polynomial reconstruction, the resulting spatial order of the semidiscrete central-upwind scheme (2.10)–(2.12) will be $\min(r,6)$ due to the accuracy limitation of the Gaussian formula. When a second-order piecewise linear reconstruction is utilized, the sixth-order fluxes (2.11)–(2.12) can be replaced by their simpler second-order versions (see, e.g., [15], [17]).

3. Piecewise polynomial reconstructions. In this section, we discuss the effect of different piecewise polynomial reconstructions on the numerical solution, computed by the central-upwind schemes. We will consider several second-order reconstructions and the fifth-order WENO5 reconstruction, each of which will be applied to the conservative variables componentwise (therefore, all the variables used in this section are scalar). In the nonconvex case, the choice of reconstruction is particularly important for computing the unique entropy solution, especially when composite waves are present.

In general, in order to achieve high resolution, the piecewise polynomial reconstruction should be of an appropriate order of accuracy and nonoscillatory. For second-order piecewise linear reconstructions (see (2.1)), the first requirement can be easily achieved by ensuring $s_j=u_x(x_j,t)+\mathcal{O}(\Delta x)$, while to satisfy the nonoscillatory property, the reconstruction has to utilize a nonlinear limiter. A library of such reconstructions is available (see, e.g., [35], [19], [8], [22], [28], [30], [34]). In the numerical experiments, reported in section 5, we have tested several well-known limiters, such as the generalized minmod limiter ([8], [22], [28], [34]),

$$s_j=\mathrm{minmod}\left(\theta\frac{\bar u_j-\bar u_{j-1}}{\Delta x},\ \frac{\bar u_{j+1}-\bar u_{j-1}}{2\Delta x},\ \theta\frac{\bar u_{j+1}-\bar u_j}{\Delta x}\right),\quad \theta\in[1,2], \tag{3.1}$$

where the minmod function is defined by

$$\text{minmod}(z_1, z_2, \ldots) := \begin{cases} \min_j\{z_j\} & \text{if } \ z_j > 0 \ \ \forall j, \\ \max_j\{z_j\} & \text{if } \ z_j < 0 \ \ \forall j, \\ 0 & \text{otherwise,} \end{cases}$$

and the superbee limiter ([19], [22], [30], [34]),

$$s_j = \frac{\bar{u}_j - \bar{u}_{j-1}}{\Delta x} \max\left\{0, \min(2r, 1), \min(r, 2)\right\}, \quad r = \frac{\bar{u}_{j+1} - \bar{u}_j}{\bar{u}_j - \bar{u}_{j-1}}. \tag{3.2}$$

Note that the generalized minmod limiter (3.1) with $\theta = 1$ reduces to the standard (dissipative) minmod limiter, which will be referred to as the MM1 limiter. The other limiting case ($\theta = 2$) corresponds to the most compressive minmod limiter, which from now on, will be denoted by MM2. The superbee limiter will be denoted by SB.

In many cases, especially when smooth parts of the solution have a complicated structure, it may be advantageous to use higher (than second)-order reconstructions. We refer the reader to [3], [16], [19], [20], [21], [25] for numerous examples of higher-order reconstructions. A very popular family of such reconstructions are the so-called WENO reconstructions. They were first introduced in [26] and since have been extended to higher orders, multiple numbers of dimensions, and finite-difference setting (see, e.g., [3], [12], [32], [33] and the references therein). In our numerical experiments, we have used the fifth-order finite-volume WENO5 reconstruction, applied componentwise and extended to the 2-D case in a dimension-by-dimension manner as described in [32].

In practice, the reconstruction selection depends on the problem at hand. When the entropy solution does not admit composite waves, the implementation of a compressive second-order reconstruction or a higher-order one typically results in a high quality numerical solution, since both smooth and discontinuous (shocks, contacts) parts of the solution are approximated more accurately than by a more dissipative reconstruction, such as the MM1 one. However, the situation is more complicated in the nonconvex case, in which a formation of composite waves is possible. This problem is best understood in the case of a 1-D scalar equation, which is the simplest conservation law whose solutions admit composite waves.

3.1. One-dimensional scalar conservation laws. Composite waves (see [19]) consist of a sequence of joined rarefactions and shocks. A generic case is a shock adjacent to a rarefaction wave, in the computation of which the reconstruction selection seems to be crucial. As we illustrate below, a numerical scheme that uses the generalized minmod limiter (3.1) with $\theta > 1$ or even the more compressive SB may result in capturing a numerical solution that converges to a weak solution, consisting of a shock, adjacent to an artificial constant state, followed by a rarefaction wave. Moreover, the rarefaction may be completely missing (see Figure 3.4), and the shock location and strength may be totally different from those in the unique entropy solution.

We now consider a particular example: a Riemann problem for the 1-D scalar equation

$$u_t + f(u)_x = 0 \tag{3.3}$$

with the C^1 monotone increasing flux, whose convexity changes at $u = 1/2$:

$$f(u) = \begin{cases} \dfrac{u(1-u)}{4}, & u < \dfrac{1}{2}, \\ \dfrac{1}{2}u^2 - \dfrac{1}{2}u + \dfrac{3}{16}, & u \geq \dfrac{1}{2}. \end{cases} \tag{3.4}$$

While the Kruzhkov entropy solution can be easily obtained for any (nonconvex) smooth flux function (see, e.g., [18]), numerically solving (3.3) by a high-order scheme may be quite a challenging problem.

We apply the central-upwind semidiscretization (2.2)–(2.5) to (3.3)–(3.4). Due to the monotonicity of the flux (3.4), $a^-_{j+\frac{1}{2}} = 0$, and thus the central-upwind scheme (2.2)–(2.5) reduces to a simple semidiscrete upwinding:

$$\frac{d}{dt}\bar{u}_j(t) = -\frac{f(u^-_{j+\frac{1}{2}}) - f(u^-_{j-\frac{1}{2}})}{\Delta x}. \tag{3.5}$$

We first solve (3.3)–(3.4) subject to the initial condition:

$$u(x,0) = \begin{cases} 0, & x < 0.25, \\ 1, & 0.25 < x. \end{cases} \tag{3.6}$$

In Figure 3.1, we show the solutions computed at time $t = 1$ on a uniform grid with $\Delta x = 1/1600$ using the second-order upwind scheme (3.5), (2.1), (2.3) with compressive MM2 and SB reconstructions. One can clearly see that in both cases, the captured solution is not the Kruzhkov entropy solution, which consists of a shock, located at $x = (\sqrt{6} - 1)/4$, followed by a rarefaction wave. Moreover, we have performed a numerical convergence study which clearly indicates that both numerical approximations fail to converge to the entropy solution.

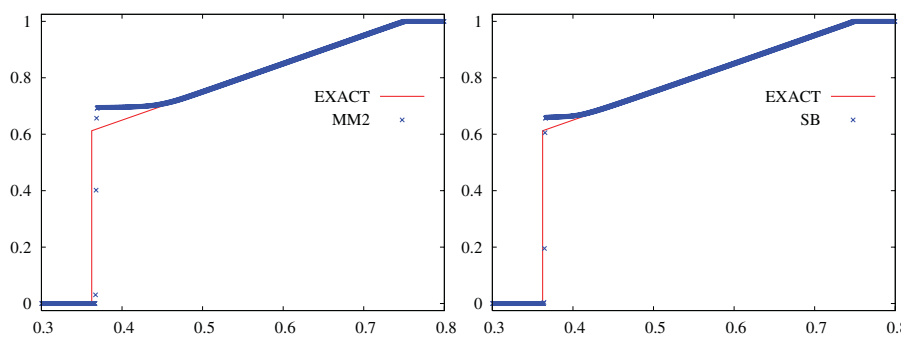

FIG. 3.1. *Solutions of* (3.3)–(3.4), (3.6) *computed with MM2 (left) and SB (right).*

At the same time, we observe that the same method, but with the dissipative MM1 reconstruction, leads to the convergence of the computed solutions toward the unique entropy solution; see Figure 3.2 (left) and Figure 3.2 (right), where a mesh refinement study is performed.

In this example, the evolution step is performed using the semidiscrete upwind scheme (3.5), (2.1), (2.3) and the third-order SSP Runge–Kutta ODE solver. A natural question to ask is whether the observed effect is due to the particular spatial

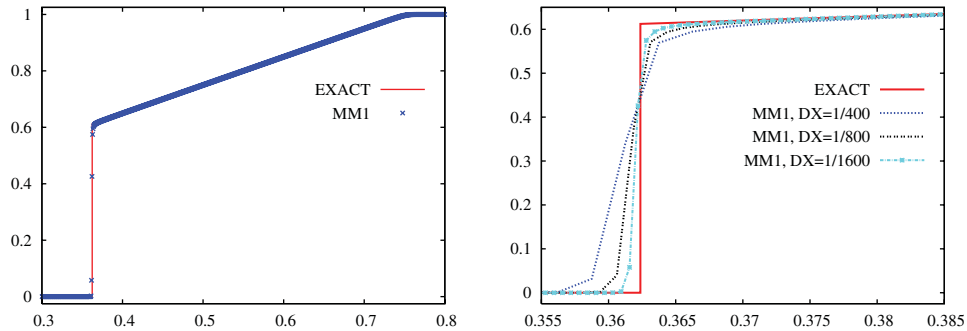

FIG. 3.2. *Solutions of* (3.3)–(3.4), (3.6) *computed with MM*1 *(left) and its convergence test (right, zoom at the composite wave area).*

discretization and time integration used or is a consequence of the implemented reconstruction. It turns out that if we start with a compressive piecewise linear reconstruction at time $t = t^n$ and evolve it exactly to the next time level $t = t^{n+1}$, according to the integral formulation of (3.3),

(3.7)
$$\bar{u}_j(t^{n+1}) = \bar{u}_j(t^n) - \frac{1}{\Delta x}\left[\int_{t^n}^{t^{n+1}} f(u(x_{j+\frac{1}{2}},\tau))\,d\tau - \int_{t^n}^{t^{n+1}} f(u(x_{j-\frac{1}{2}},\tau))\,d\tau\right],$$

the same behavior persists. Here, we only need to exactly compute the temporal integrals in (3.7), which can be done analytically when $\Delta t \le 0.5\Delta x$, since the formulae for both the flux function and the exact solution are available (we have taken $\Delta t = 0.5\Delta x$, but smaller time steps lead to the same results).

Snapshots at times $t = 0.1, 0.2, \ldots, 1.0$ of the exactly evolved solutions of the IVP (3.3)–(3.4), (3.6) are presented in Figure 3.3, where the MM1 and MM2 reconstructions are used. In the case of the MM2 reconstruction, the wrong shock location as well as the formation of an artificial constant state between the shock and the rarefaction wave can be clearly seen, while the MM1 solution accurately approximates the composite wave.

Here, the implementation of the MM2 reconstruction (or another compressive reconstruction, for example, the generalized minmod with any $\theta > 1$ or the SB) leads to an initial overshoot in a single cell—the last cell with a cell-average value less than 1. As time progresses, the overshoot persists and, because of the error propagation, spreads over neighboring cells. At the same time, the moving shock cannot balance the effect of the overshoot, because (i) the overshoot speed is higher than the shock speed, and (ii) the large jumps from the shock feed the overshoot and thus oppose its smearing by the rarefication process and the numerical diffusion. As a result, an artificial constant state between the shock and rarefaction wave is formed. In the case of a generalized minmod reconstruction, its value depends on the value of θ and the size of the initial shock.

The above problem seems to get resolved if we use the dissipative MM1 reconstruction. The successful resolution of composite waves in this case is due to the fact that the smaller of the jumps, $\bar{u}_{j+1} - \bar{u}_j$ or $\bar{u}_j - \bar{u}_{j-1}$, is used to determine the corresponding slope s_j in (2.1). The calculation of the new local cell averages over/near the border between the shock and rarefaction is mostly based on the information from

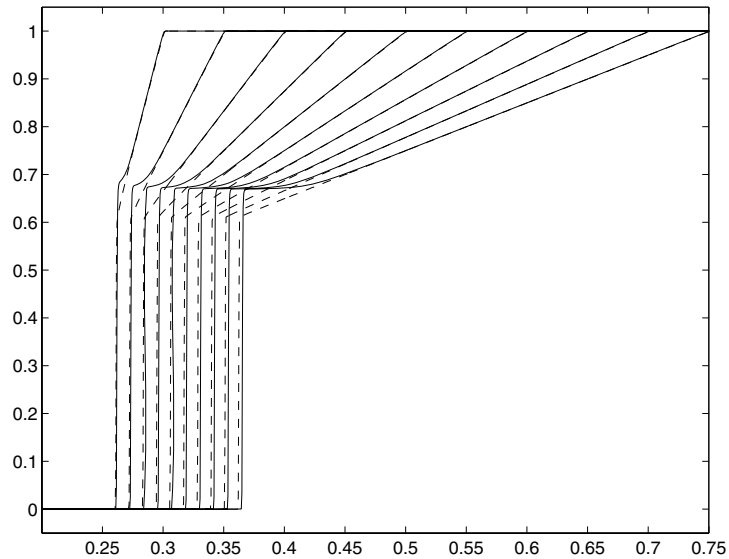

FIG. 3.3. *Exact evolution of the MM*1 *and MM*2 *reconstructions;* $\Delta x = 1/2000$.

the rarefaction part of the computed solution (where the jumps are smaller), and thus the shock impact on the evaluation of these averages is substantially reduced.

So far, the discussion has been restricted to second-order piecewise linear reconstructions since in this case one can relatively easily understand the effects of different reconstructions on the computed solutions. The situation gets much more complicated when a higher-order (for example, the fifth-order WENO5) reconstruction is employed. In the scalar 1-D case, we were unable to find an example in which the WENO5 reconstruction leads to capturing a non-Kruzhkov weak solution. However, our example of a 1-D system (section 5.2) and the 2-D scalar example (section 5.3) clearly illustrate that the WENO5-based scheme may fail to resolve composite waves; see Figures 5.4, 5.7, and 5.10, respectively.

We conclude this section with yet another numerical example, which illustrates that if a compressive reconstruction is employed, a rarefaction part of the composite wave can be completely missed, while the use of the dissipative MM1 reconstruction leads to capturing the unique entropy solution. We compute the solution of the same equation (3.3)–(3.4) subject to different initial data:

$$u(x,0) = \begin{cases} 1, & x < 0.25, \\ 0, & 0.25 < x. \end{cases} \tag{3.8}$$

In Figure 3.4, we show the solutions computed at time $t = 2$ on a uniform grid with $\Delta x = 1/1600$ using the second-order upwind scheme (3.5), (2.1), (2.3) with compressive MM2 and SB reconstructions. One can clearly see that in both cases, the captured solution is a simple shock wave—not the Kruzhkov entropy solution, which consists of a shock, located at $x = (2\sqrt{3}-1)/4$, followed by a rarefaction wave. In Figure 3.5, we present the solution, computed by the same method but with the dissipative MM1 reconstruction. As in the previous example, one can observe the convergence of the numerical solutions toward the unique entropy solution.

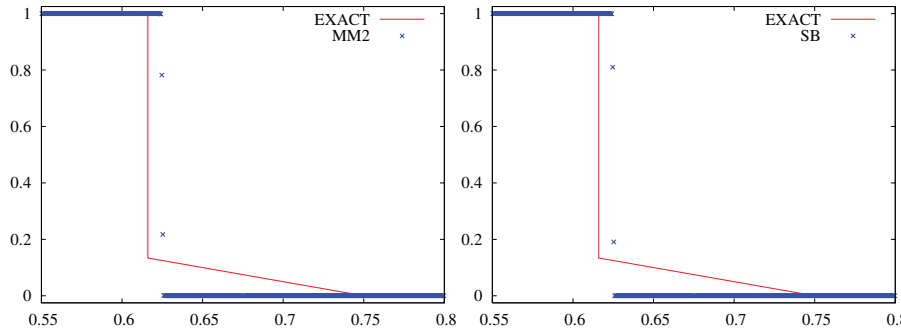

FIG. 3.4. *Solutions of* (3.3)–(3.4), (3.8) *computed with MM*2 *(left) and SB (right).*

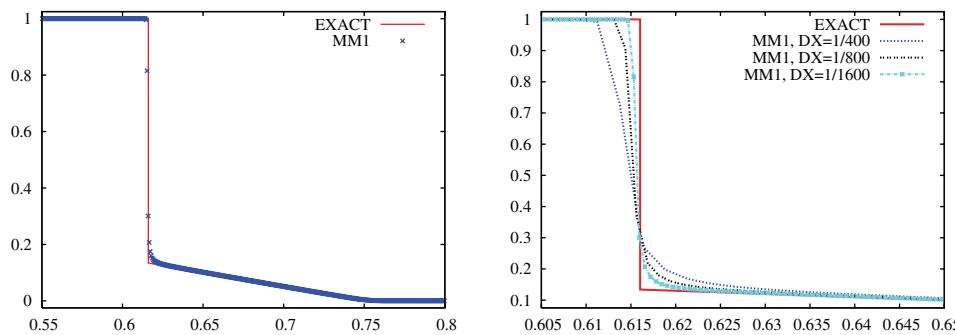

FIG. 3.5. *Solutions of* (3.3)–(3.4), (3.8) *computed with MM*1 *(left) and its convergence test (right, zoom at the composite wave area).*

4. Scheme adaption algorithm. It is a well-known fact that more compressive second-order and/or higher-order piecewise polynomial reconstructions typically lead to a higher resolution than the one that can be achieved with the help of the dissipative MM1 reconstruction. However, as observed in the previous section, the use of higher resolution reconstructions may be dangerous at the presence of composite waves, while the use of the MM1 reconstruction seems to ensure the convergence toward these waves.

We now describe a simple adaption strategy that will utilize the advantages of higher resolution reconstructions away from the composite waves, which, in turn, will be locally approximated using the MM1 reconstruction.

• Use the MM1 reconstruction only in the transition zones—in a small number of cells around points where the flux convexity changes (that is, where f'' or one of the κ_i's in (2.9) changes sign).

• Use a higher resolution reconstruction otherwise.

Remarks.

1. In all numerical experiments presented below, we have used the finite-volume WENO5 reconstruction—applied componentwise to the 1-D systems and in a dimension-by-dimension manner in the 2-D case—as a higher resolution component of our adaptive algorithm.
2. Our extensive numerical experiments suggest that in order to ensure convergence to the unique entropy solution, the number of cells where the MM1

reconstruction is used should be relatively small and could be taken proportional to $|\ln(\Delta x)|$ as the grid is refined.

5. Numerical examples. In this section, we numerically solve nonconvex 1-D hyperbolic systems of conservation laws and a 2-D scalar conservation law with nonconvex fluxes. We apply the semidiscrete central-upwind schemes described in section 2 with different piecewise polynomial reconstructions including the adaptive reconstruction proposed in section 4.

5.1. One-dimensional Euler equations of gas dynamics. We consider the 1-D Euler equations of gas dynamics,

$$\frac{\partial}{\partial t}\begin{bmatrix}\rho\\ m\\ E\end{bmatrix}+\frac{\partial}{\partial x}\begin{bmatrix}m\\ \rho u^2+p\\ u(E+p)\end{bmatrix}=0, \tag{5.1}$$

with the following nonconvex EOS (see [37]):

$$p=p(\rho,e)=((\gamma-1)\rho+f(\rho))e,\quad e=\frac{E}{\rho}-\frac{1}{2}u^2,\quad \gamma=1.4, \tag{5.2}$$

where the function f is given by

$$f(\rho)=\begin{cases}10\exp\left(\dfrac{\rho^2}{1-2\rho+0.75\rho^2}\right), & \dfrac{2}{3}<\rho<2,\\ 0 & \text{otherwise,}\end{cases} \tag{5.3}$$

and ρ, u, $m=\rho u$, p, and E are the density, velocity, momentum, pressure, and total energy, respectively. It can be shown that system (5.1) with the EOS given by (5.2)–(5.3) is hyperbolic.

The computation of the numerical solution of (5.1)–(5.3), using the scheme (2.4)–(2.5), (2.3), (2.8), combined with different piecewise polynomial reconstructions requires the calculation of the one-sided local speeds of propagation, and therefore the computation of the corresponding structure coefficients (2.9). Here, we have

$$\kappa_1^{\pm}=\left(-\frac{m^{\pm}}{(\rho^{\pm})^2}-c_\rho^{\pm}\right)+\left(\frac{1}{\rho^{\pm}}-c_m^{\pm}\right)(u_{mid}-c_{mid})-c_E^{\pm}\left(\frac{E_{mid}+p_{mid}}{\rho_{mid}}-u_{mid}c_{mid}\right),$$

$$\kappa_3^{\pm}=\left(-\frac{m^{\pm}}{(\rho^{\pm})^2}+c_\rho^{\pm}\right)+\left(\frac{1}{\rho^{\pm}}+c_m^{\pm}\right)(u_{mid}+c_{mid})+c_E^{\pm}\left(\frac{E_{mid}+p_{mid}}{\rho_{mid}}+u_{mid}c_{mid}\right),$$

where c is the sound speed,

$$c^2=p_\rho+\frac{pp_e}{\rho^2},$$

and

$$\mathcal{R}_{mid}:=\frac{\mathcal{R}^{+}+\mathcal{R}^{-}}{2}$$

for $\mathcal{R}$ being ρ, u, c, p, or E. The corresponding partial derivatives are

$$c_m=-\frac{m}{2\rho^2}T,\qquad c_E=\frac{1}{2\rho}T,$$

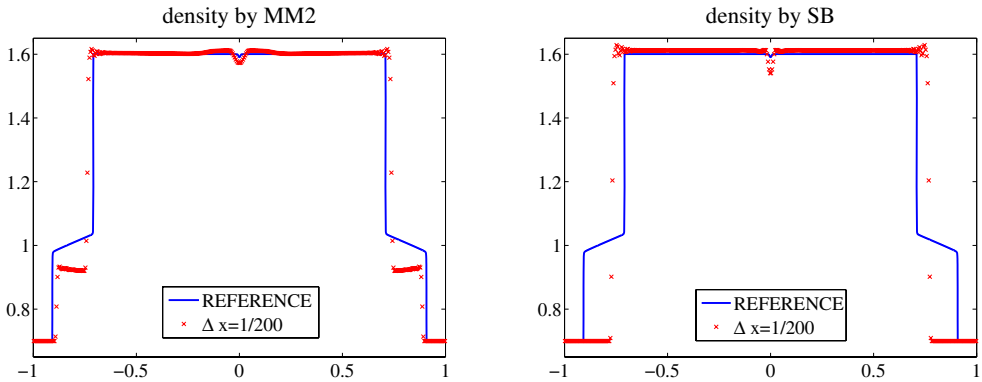

FIG. 5.1. *Solutions of* (5.1)–(5.4), *computed with MM*2 *(left) and SB (right).*

$$c_\rho = \frac{m^2 - E\rho}{2\rho^3}T + \frac{1}{2T}\left(f''(\rho) + \frac{(0.8\rho + 2f(\rho))(f'(\rho)\rho - f(\rho))}{\rho^3}\right),$$

where

$$T = \left(\frac{0.4 + f'(\rho) + (0.4 + f(\rho)\rho^{-1})^2}{E\rho^{-1} - 0.5m^2\rho^{-2}}\right)^{\frac{1}{2}}.$$

We solve the system (5.1)–(5.3) subject to the initial data (see [37]):

$$(p, \rho, u)_L = (0.5, 0.6998, 1), \quad (p, \rho, u)_R = (0.5, 0.6998, -1), \tag{5.4}$$

using the MM1, MM2, SB, and the adaptive reconstruction proposed in section 4. To apply the adaptive strategy from section 4, we need to know where the structure coefficients change sign, which in this case is the same as checking where $p_{\tau\tau}$, $\tau = \rho^{-1}$, changes sign. In this example, $p_{\tau\tau}$ has two isolated zeros $\tau^* = 1/\rho^* = 0.862$ and $\tau^{**} = 1/\rho^{**} = 1.21$. We perform the adaption in the following way. First, we mark all cell pairs with indexes $j, j+1$, for which either $(\rho_{j+1} - \rho^*)(\rho_j - \rho^*) < 0$ or $(\rho_{j+1} - \rho^{**})(\rho_j - \rho^{**}) < 0$. Then we use the MM1 reconstruction in the marked cells and in the cells located within $K\Delta x$ from them, while the WENO5 reconstruction is used in the rest of the computational domain.

We compare the density profiles of the numerical solutions, calculated at time $t = 1$ on a uniform grid with $\Delta x = 1/200$, with the profile of a reference solution, obtained with the "reliable" MM1 limiter and $\Delta x = 1/5000$. The results are presented in Figures 5.1–5.3, where one can clearly see that the composite waves are incorrectly resolved when a compressive piecewise linear reconstruction (either MM2 or SB) is employed, while the central-upwind scheme based on the dissipative MM1 reconstruction accurately captures their structure. Note that in this example, the use of the higher-order WENO5 reconstruction also leads to capturing the entropy solution (see Figure 5.2 (right)). However, the obtained numerical approximation is quite oscillatory, which, together with the failure of the WENO5-based scheme to resolve composite waves in the examples from sections 5.2 and 5.3, makes one doubt the reliability of a pure WENO5 reconstruction.

The solutions, computed by our adaptive central-upwind scheme, are shown in Figure 5.3. When the adaption constant $K = 1$, the obtained solution is basically

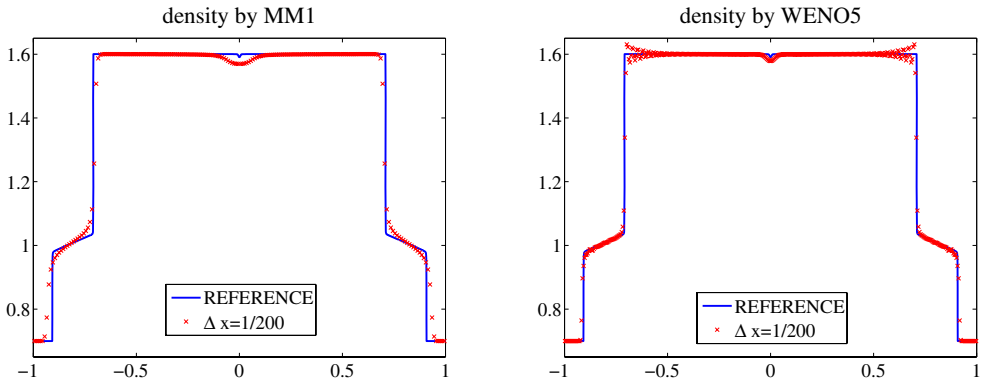

FIG. 5.2. *Solutions of* (5.1)–(5.4), *computed with MM*1 *(left) and WENO*5 *(right).*

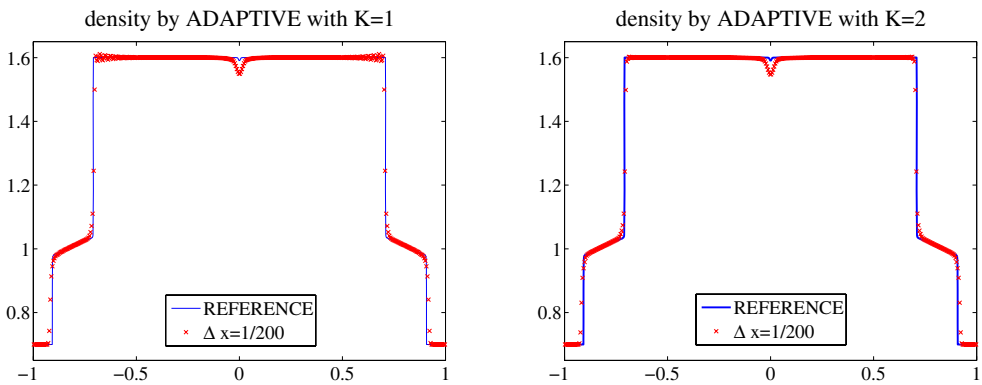

FIG. 5.3. *Solutions of* (5.1)–(5.4), *computed adaptively with* $K = 1$ *(left) and* $K = 2$ *(right).*

as well resolved as that obtained by the WENO5-based scheme, but it still has some oscillations, which are completely removed when a larger ($K = 2$) adaption constant is used. As expected, the adaptive reconstruction offers a better overall resolution of the numerical solution, and thus the adaptive strategy is preferable.

5.2. The polymer system. We consider the 1-D polymer system

$$\frac{\partial}{\partial t}\begin{bmatrix} s \\ b \end{bmatrix} + \frac{\partial}{\partial x}\begin{bmatrix} f(s,c) \\ cf(s,c) \end{bmatrix} = \mathbf{0}, \tag{5.5}$$

where s is the water saturation, c is the polymer concentration in the water, $f(s,c)$ is the fractional flow function of water, $b(s,c) = sc + a(c)$, and $a(c)$ is the adsorption function. Here, we take (see, e.g., [9])

$$f(s,c) = \frac{s^2}{s^2 + (0.5+c)(1-s)^2}, \qquad a(c) = \frac{c}{5(1+c)}. \tag{5.6}$$

Notice that the system (5.5)–(5.6) can be rewritten in the nonconservative form

$$\mathbf{u}_t + A(\mathbf{u})\mathbf{u}_x = \mathbf{0},$$

where $\mathbf{u} = (s, c)^T$ and $A(\mathbf{u})$ has eigenvalues $\lambda_s = f_s(s, c)$ and $\lambda_c = f(s, c)(s + a'(c))^{-1}$ with right eigenvectors $\mathbf{r}_s = (1, 0)^T$, $\mathbf{r}_c = (f_c(s, c), \lambda_c - \lambda_s)^T$ for $s \in (0, 1)$ and $\mathbf{r}_c = (0, 1)^T$ for $s = 0, 1$, respectively. The computation of the one-sided local speeds of propagation (2.8) requires the calculation of the corresponding structure coefficients

$$\kappa_s^{\pm} = f_{ss}(s^{\pm}, c^{\pm}),$$

$$\kappa_c^{\pm} = \frac{f_c^{mid}(f_s^{\pm}(s^{\pm} + a'(c^{\pm})) - f^{\pm})}{(s^{\pm} + a'(c^{\pm}))^2} + \frac{(f^{mid}(s_{mid} + a'(c_{mid}))^{-1} - f_s^{mid})(f_c^{\pm}(s^{\pm} + a'(c^{\pm})) - a''(c^{\pm})f^{\pm})}{(s^{\pm} + a'(c^{\pm}))^2}$$

if $s_{mid} \neq 0, 1$, and

$$\kappa_c^{\pm} = \frac{f_c^{\pm}(s^{\pm} + a'(c^{\pm})) - a''(c^{\pm})f^{\pm}}{(s^{\pm} + a'(c^{\pm}))^2}$$

for $s_{mid} \in \{0, 1\}$. Here, we have used the notation $\mathcal{R}^{mid} := \mathcal{R}(s_{mid}, c_{mid})$, where $s_{mid} := (s^+ + s^-)/2$ and $c_{mid} := (c^+ + c^-)/2$, and $\mathcal{R}^{\pm} := \mathcal{R}(s^{\pm}, c^{\pm})$ for $\mathcal{R}$ being f_s, f_c, or f.

We consider the system (5.5)–(5.6) subject to the Riemann initial data taken from [14]:

$$(s(x, 0), c(x, 0)) = \begin{cases} (0.45, 0), & x \leq 0.252, \\ (0.20, 1), & x > 0.25. \end{cases} \tag{5.7}$$

The exact solution of this IVP is rather complicated and consists of both simple and composite waves (see [13]).

We numerically solve the IVP (5.5)–(5.7) using the central-upwind scheme (2.4)–(2.6), (2.8) with different piecewise polynomial reconstructions of the conserved variables s and b.

For adaption, we check at every grid cell whether a point, where one of the structure coefficients, either

$$\kappa_s = f_{ss}$$

or

$$\kappa_c = \begin{cases} a''f(s + a')^{-3}(f_s(s + a') - f), & 0 < s < 1, \\ (s + a')^{-2}(f_s(s + a') - a''f), & s \in \{0, 1\}, \end{cases}$$

changes sign, is nearby. If this is the case, namely, if the distance between the current grid point and one of the aforementioned points is smaller than $K\Delta x$, then the MM1 reconstruction is used; otherwise the WENO5 reconstruction is used.

In Figure 5.4, we plot the numerical solutions at time $t = 1$, calculated using the MM1 reconstruction with $\Delta x = 1/250$ and $\Delta x = 1/8000$ (the latter is used as a reference solution in all other figures shown in this section).

In Figure 5.5, we compare the c-component of the numerical solutions, computed using the MM1, MM2, SB, and WENO5 reconstructions on three different uniform meshes with $\Delta x = 1/250$, $1/500$, and $1/1000$. As one can clearly see in this figure, only the MM1 numerical solution recovers the correct structure of the composite

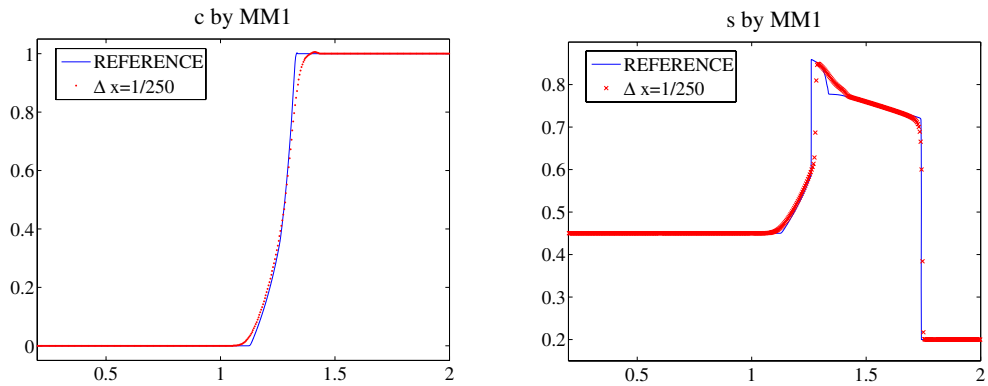

FIG. 5.4. *Solutions of* (5.5)–(5.7), *computed with MM*1*; (left) c- and (right) s-components.*

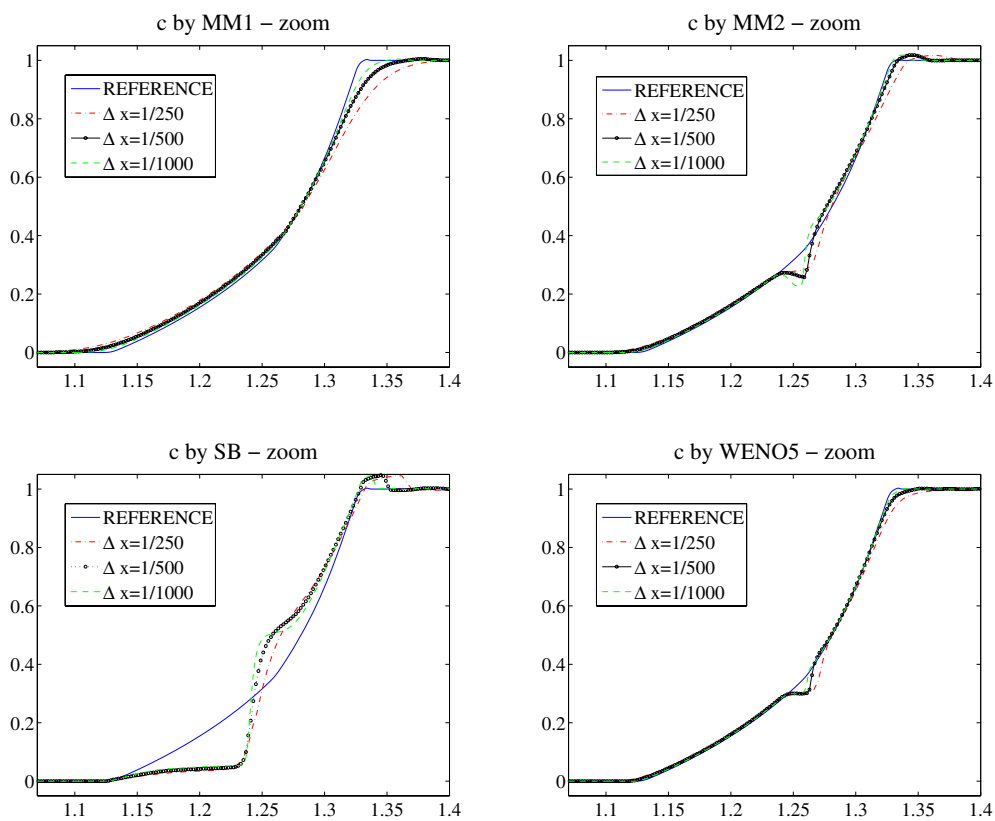

FIG. 5.5. *Solutions (c-component) of* (5.5)–(5.7), *computed with MM*1*, MM*2*, SB, and WENO*5*.*

wave, while the MM2, SB, and WENO5 reconstructions consistently fail to achieve this goal. Note that $\Delta x = 1/1000$ is a reasonably small mesh size that one usually uses in practical computations for such a problem (in the 2-D case, one would have to use an even coarser grid). To perform a numerical convergence study, we have computed the solution with even smaller Δx. It turns out that the numerical approximation

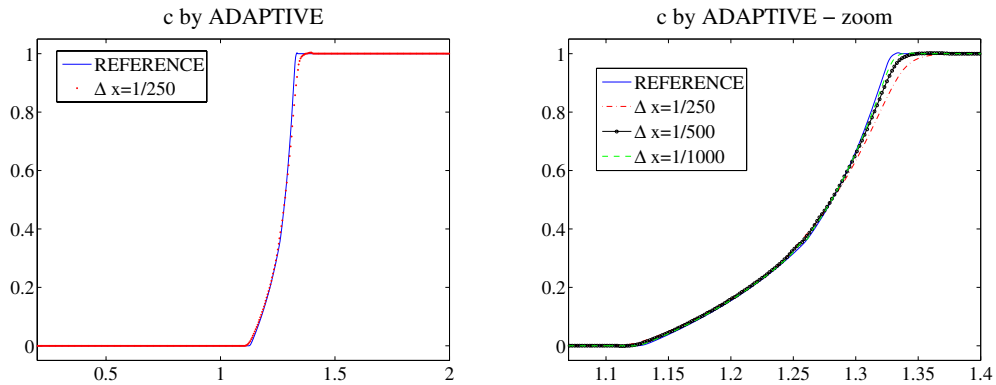

FIG. 5.6. *Solutions (c-component) of* (5.5)–(5.7), *computed adaptively with* $K = 2$ *(left) and its mesh refinement study (right).*

obtained with the WENO5 reconstruction seems to slowly converge to the reference solution, but the values of Δx, required in order to be able to observe this convergence, are so small that this positive result is not of practical interest. On the other hand, the results shown in Figure 5.6 demonstrate that our adaptive strategy both achieves a very high resolution and accurately captures the structure of the composite wave, and thus it is superior to both the lower resolution MM1 solution and the less reliable WENO5 solution.

Next, in Figures 5.7–5.8, we present the s-component of the computed solutions. While the wave structure of the s-component is quite different from that of the c-component, we observe the same effect as before: The central-upwind scheme based on either MM2, SB, or WENO5 reconstruction fails to recover the reference solution even when a very fine mesh with $\Delta x = 1/1000$ is used. At the same time, the schemes based on the MM1 and the adaptive reconstructions perform well. However, as expected, the overall resolution achieved by the adaptive scheme is higher than that achieved by the more dissipative MM1 scheme.

5.3. Two-dimensional scalar conservation law. In this section, we numerically solve the 2-D scalar conservation law

$$u_t + (\sin u)_x + (\cos u)_y = 0, \tag{5.8}$$

subject to the initial data

$$u(x, y, 0) = \begin{cases} 3.5\pi, & x^2 + y^2 < 1, \\ 0.25\pi, & \text{otherwise}, \end{cases} \tag{5.9}$$

using the scheme (2.10)–(2.12) and the piecewise polynomial reconstructions described in sections 3 and 4.

We have computed the solution at time $t = 1$ on a uniform grid with $\Delta x = \Delta y = 1/100$ using the MM1, MM2, SB, WENO5, and the adaptive reconstructions. For adaption, we mark the cells where the convexity of the flux changes, which occurs at $u = k\pi/2$, $k \in \mathbb{Z}$. In these cells and in all cells located within $K \max(\Delta x, \Delta y)$ from them, we use the MM1 reconstruction; otherwise the WENO5 reconstruction is employed.

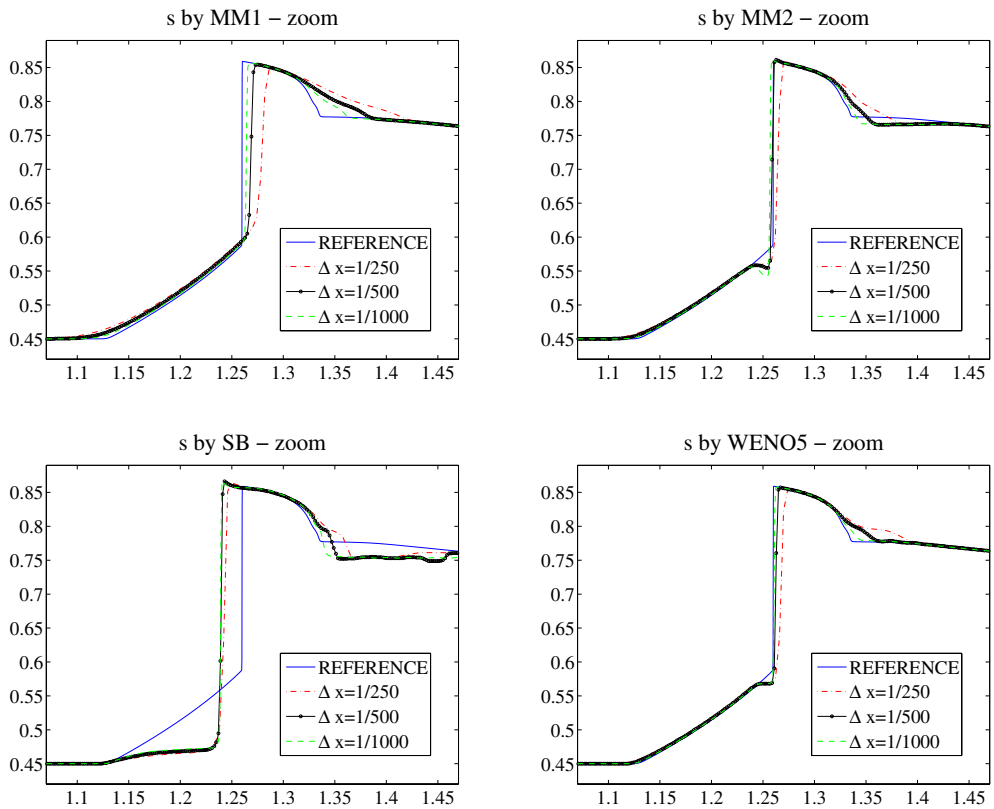

FIG. 5.7. *Solutions (s-component) of* (5.5)–(5.7)*, computed with MM*1*, MM*2*, SB, and WENO*5*.*

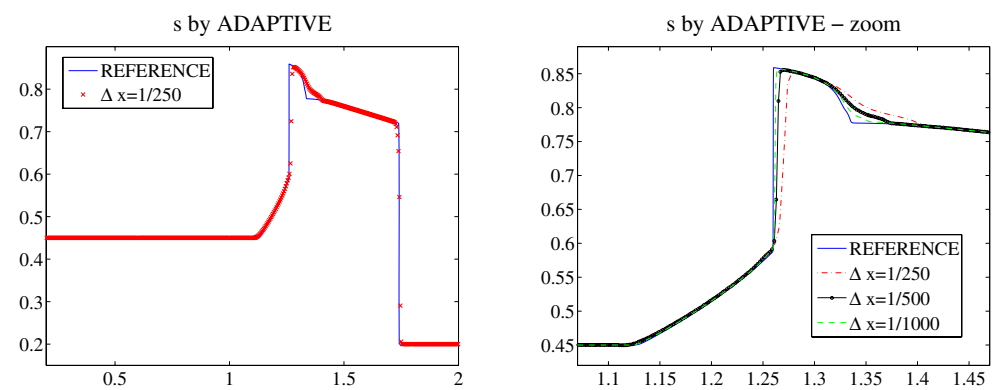

FIG. 5.8. *Solutions (s-component) of* (5.5)–(5.7)*, computed adaptively with* $K = 2$ *(left) and its mesh refinement study (right).*

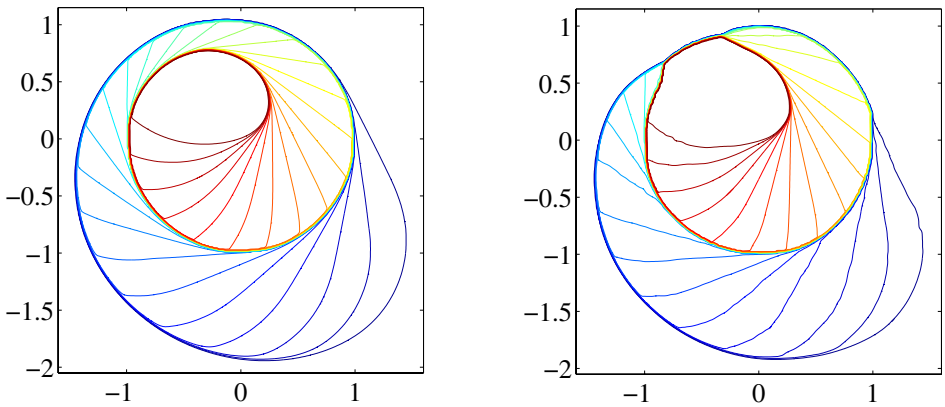

FIG. 5.9. *Solution of* (5.8)–(5.9), *computed with MM*1 *(left) and MM*2 *(right).*

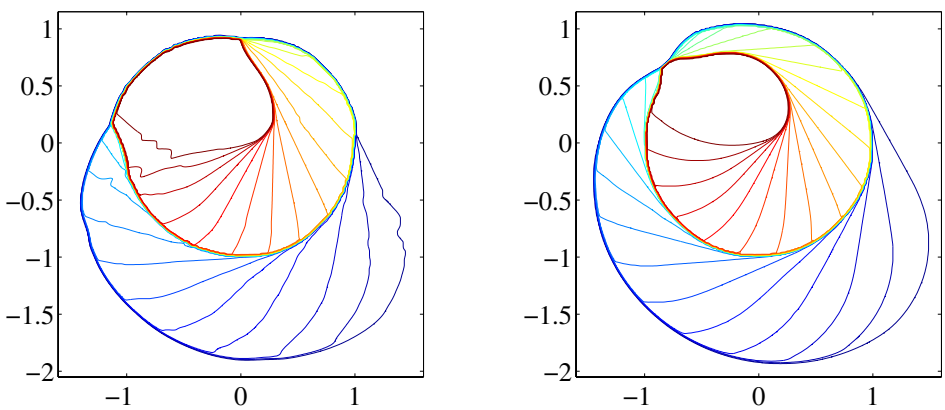

FIG. 5.10. *Solution of* (5.8)–(5.9), *computed with SB (left) and WENO*5 *(right).*

We present our results in Figures 5.9–5.11, where we observe the same effects as in the 1-D case. The central-upwind schemes based on the MM2, SB, and WENO5 reconstructions fail to resolve the composite wave structure, while the use of the MM1 or the adaptive reconstruction leads to capturing the accurate solution. We would like to point out that the adaptive strategy does not seem to be sensitive to the choice of the adaption constant K. We also show (see Figure 5.11 (right)), the areas where the MM1 (white) and the WENO5 (black) reconstructions were used. It can be clearly seen that the MM1 limiter is turned on only at or around transition areas.

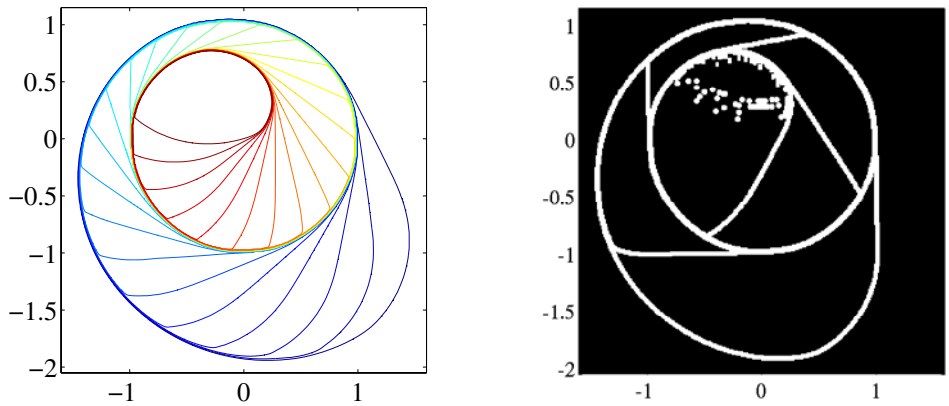

FIG. 5.11. *Solution of* (5.8)–(5.9), *computed adaptively with* $K = 2$ *(left) and the corresponding MM1/WENO5 regions (right).*

Acknowledgments. Part of this work was done in the Fall of 2005, when A. Kurganov visited the Department of Mathematics at the University of Michigan during the semester following Hurricane Katrina. A. Kurganov thanks the chairman, Professor A. Bloch, and all members of the department for their extremely warm hospitality.

OPTIMIZED MULTIPLICATIVE, ADDITIVE, AND RESTRICTED ADDITIVE SCHWARZ PRECONDITIONING*

A. ST-CYR†, M. J. GANDER‡, AND S. J. THOMAS§

Abstract. We demonstrate that a small modification of the multiplicative, additive, and restricted additive Schwarz preconditioner at the algebraic level, motivated by optimized Schwarz methods defined at the continuous level, leads to a significant reduction in the iteration count of the iterative solver. Numerical experiments using finite difference and spectral element discretizations of the positive definite Helmholtz problem and an idealized climate simulation illustrate the effectiveness of the new approach.

Key words. domain decomposition, restricted additive Schwarz method, optimized Schwarz methods, multiplicative Schwarz, spectral elements, high-order methods

1. Introduction.

The classical Schwarz method employs Dirichlet transmission conditions between subdomains. By introducing a more general Robin transmission condition, it is possible to optimize the convergence of the original algorithm; see [9] and the references therein. In this paper, general results are derived for using optimized transmission conditions at the algebraic level of restricted additive Schwarz (RAS), multiplicative Schwarz (MS), and additive Schwarz (AS) on an augmented system. These methods are then applied to the positive definite Helmholtz problem $(\eta - \Delta)u = f$, $\eta > 0$, discretized with finite differences and spectral finite elements, by a simple modification of already existing classical implementations of RAS, MS, and AS, with and without overlap.

Optimized Schwarz methods were originally derived from Fourier analysis of the continuous elliptic partial differential equation (PDE); see [9] and references therein. Until now, it was not clear how to introduce optimized transmission conditions in the classical forms of the AS, MS, and RAS preconditioners at the algebraic level. The present work closes this gap by showing that small modifications of the subdomain matrices in these preconditioners lead to optimized Schwarz methods. The modified preconditioners must satisfy specific compatibility conditions. For optimized RAS

(ORAS), an overlap condition must be satisfied. In the case of optimized MS (OMS), there is no such condition on the overlap. Optimized AS (OAS) requires an augmented system, permitting the use of nonoverlapping regions, where the common unknowns at subdomain boundaries are duplicated. Because these results are algebraic, they readily apply to any space discretization of continuous PDEs for which optimized Schwarz methods have been analyzed in the literature; see [9] for positive definite Helmholtz problems, [12, 10] for indefinite Helmholtz problems, and [14, 6] for advection diffusion problems. Greatly enhanced convergence factors have been shown for one-level optimized Schwarz methods in these references at the continuous level, with much weaker dependence on the overlap than for classical one-level Schwarz methods. There are also first attempts to directly construct algebraically good transmission conditions, which are related to approximations of Schur complement matrices; see [22, 17, 28, 11]. There are, however, no two-level variants yet for optimized Schwarz methods.

Schwarz algorithms are reviewed in the following section, and the link between the discrete and continuous problems is established. The equivalence of the iterative forms of optimized Schwarz methods with ORAS and OMS is demonstrated for multiple domains, as well as with OAS applied to an augmented system. These results are then applied to the positive definite Helmholtz problem using finite difference and spectral element discretizations. The size of the overlap region is varied for finite differences, whereas nonoverlapping subdomains are considered for spectral elements. We finally apply the new techniques to a spectral element climate model [27].

2. Classical Schwarz methods. Schwarz methods for elliptic PDEs subdivide the physical domain into subdomains and iterate the subdomain solutions in order to obtain the global solution. When the subdomain problems are discretized, Schwarz methods can be formulated at the discrete or algebraic level.

2.1. Schwarz methods at the algebraic level. Discretization of the elliptic PDE

$$\mathcal{L}u = f \quad \text{in } \Omega, \quad \mathcal{B}u = g \quad \text{on } \partial\Omega, \tag{2.1}$$

where $\mathcal{L}$ is an elliptic differential operator, $\mathcal{B}$ is a boundary operator, and Ω is a bounded domain, leads to a linear system of equations

$$A\boldsymbol{u} = \boldsymbol{f}. \tag{2.2}$$

A stationary iterative method for (2.2) is given by

$$\boldsymbol{u}^{n+1} = \boldsymbol{u}^n + M^{-1}(\boldsymbol{f} - A\boldsymbol{u}^n). \tag{2.3}$$

An initial guess $\boldsymbol{u}^0$ is required to start the iteration. Algebraic domain decomposition methods group the unknowns into subsets, $\boldsymbol{u}_j = R_j\boldsymbol{u}$, $j = 1, \ldots, J$, where R_j are rectangular restriction matrices such that each entry u_i of the vector $\boldsymbol{u}$ is contained in at least one $\boldsymbol{u}_j$. Coefficient matrices for subdomain problems are defined by $A_j = R_j A R_j^T$. The classical MS method is a stationary iteration (2.3), where the preconditioner M is

$$M_{MS}^{-1} = \left[I - \prod_{j=1}^{J} \left(I - R_j^T A_j^{-1} R_j A \right) \right] A^{-1}. \tag{2.4}$$

MS is often written using fractional steps as

$$\boldsymbol{u}^{n+\frac{j}{J}} = \boldsymbol{u}^{n+\frac{j-1}{J}} + R_j^T A_j^{-1} R_j(\boldsymbol{f} - A\boldsymbol{u}^{n+\frac{j-1}{J}}), \quad j = 1, \ldots, J, \tag{2.5}$$

which shows that it is equivalent to a Gauss–Seidel iteration on the subdomains [25]. It thus corresponds to the original alternating method introduced by Schwarz at the continuous level [23]. A more parallel variant is the AS preconditioner introduced in [5],

$$M_{AS}^{-1} = \sum_{j=1}^{J} R_j^T A_j^{-1} R_j. \tag{2.6}$$

In general, the AS iteration (2.3), (2.6) does not converge, nor does it correspond to a classical iteration per subdomain [7]. The RAS method [3] corrects this problem by introducing prolongation operators $\tilde{R}_j^T$, corresponding to a nonoverlapping decomposition. Each entry u_i of the vector $\boldsymbol{u}$ occurs in $\tilde{R}_j\boldsymbol{u}$ for exactly one j. The RAS preconditioner is

$$M_{RAS}^{-1} = \sum_{j=1}^{J} \tilde{R}_j^T A_j^{-1} R_j. \tag{2.7}$$

Another way to alleviate the convergence problems of AS is to apply M_{AS} as a preconditioner in a Krylov iteration. In general, MS and RAS also will be accelerated by Krylov iteration.

The algebraic formulation of Schwarz methods has an important feature: a subdomain matrix A_j is not necessarily the restriction of A to a subdomain j. For example, if A represents a spectral element discretization of a differential operator, then A_j can be obtained from a finite element discretization on the Gaussian quadrature points. Furthermore, subdomain matrices A_j can be chosen to accelerate convergence, and this is the focus of the next section.

2.2. Schwarz methods at the continuous level. Historically, domain decomposition methods were formulated at the continuous level. Consider a decomposition of the original domain Ω into two overlapping subdomains Ω_1 and Ω_2, and denote the interfaces by $\Gamma_{ij} = \partial\Omega_i \cap \Omega_j$, $i \neq j$, and the outer boundaries by $\partial\Omega_j = \partial\Omega \cap \bar{\Omega}_j$.

The original alternating Schwarz method introduced in [23] for (2.1) is

$$\begin{array}{rclll} \mathcal{L}u_1^{n+1} & = & f & \text{in } \Omega_1, & \mathcal{L}u_2^{n+1} = f \quad \text{in } \Omega_2, \\ \mathcal{B}(u_1^{n+1}) & = & g & \text{on } \partial\Omega_1, & \mathcal{B}(u_2^{n+1}) = g \quad \text{on } \partial\Omega_2, \\ u_1^{n+1} & = & u_2^n & \text{on } \Gamma_{12}, & u_2^{n+1} = u_1^{n+1} \quad \text{on } \Gamma_{21}, \end{array} \tag{2.8}$$

corresponding to Gauss–Seidel traversal of the subdomains. The Jacobi variant of the algorithm introduced in [16] is

$$\begin{array}{rclll} \mathcal{L}u_1^{n+1} & = & f & \text{in } \Omega_1, & \mathcal{L}u_2^{n+1} = f \quad \text{in } \Omega_2, \\ \mathcal{B}(u_1^{n+1}) & = & g & \text{on } \partial\Omega_1, & \mathcal{B}(u_2^{n+1}) = g \quad \text{on } \partial\Omega_2, \\ u_1^{n+1} & = & u_2^n & \text{on } \Gamma_{12}, & u_2^{n+1} = u_1^n \quad \text{on } \Gamma_{21}. \end{array} \tag{2.9}$$

It was shown in [7] that the discrete form of (2.8), represented by

$$A_1\boldsymbol{u}_1^{n+1} = \boldsymbol{f}_1 + B_{12}\boldsymbol{u}_2^n, \quad A_2\boldsymbol{u}_2^{n+1} = \boldsymbol{f}_2 + B_{21}\boldsymbol{u}_1^{n+1}, \tag{2.10}$$

is equivalent to MS in (2.4), and that the discrete form of (2.9),

$$A_1 \boldsymbol{u}_1^{n+1} = \boldsymbol{f}_1 + B_{12}\boldsymbol{u}_2^n, \quad A_2 \boldsymbol{u}_2^{n+1} = \boldsymbol{f}_2 + B_{21}\boldsymbol{u}_1^n, \tag{2.11}$$

is equivalent to RAS in (2.7).

3. Optimized Schwarz methods. Optimized Schwarz methods were developed at the continuous level using Fourier analysis and led to significantly faster convergence rates than classical Schwarz methods [9]. However, an algebraic formulation of optimized Schwarz methods is lacking. Here it is shown how optimized Schwarz methods can be embedded within the framework of RAS, MS, and AS.

3.1. Optimized Schwarz methods at the continuous level. In optimized Schwarz methods, the Dirichlet transmission conditions on the interfaces Γ_{ij} in (2.8) and (2.9) are replaced by more effective conditions including derivatives. The latter permits the use of nonoverlapping domains. The optimized algorithm for the classical case is

$$\begin{array}{rclll rcll} \mathcal{L}u_1^{n+1} & = & f & \text{in } \Omega_1, & \mathcal{L}u_2^{n+1} & = & f & \text{in } \Omega_2, \\ \mathcal{B}(u_1^{n+1}) & = & g & \text{on } \partial\Omega_1, & \mathcal{B}(u_2^{n+1}) & = & g & \text{on } \partial\Omega_2, \\ \tilde{\mathcal{B}}_{12}u_1^{n+1} & = & \tilde{\mathcal{B}}_{12}u_2^n & \text{on } \Gamma_{12}, & \tilde{\mathcal{B}}_{21}u_2^{n+1} & = & \tilde{\mathcal{B}}_{21}u_1^{n+1} & \text{on } \Gamma_{21}, \end{array} \tag{3.1}$$

where the transmission operators $\mathcal{B}_{12}$ and $\mathcal{B}_{21}$ are chosen to obtain faster convergence. Similarly, the more parallel Jacobi version of the optimized Schwarz method is

$$\begin{array}{rclll rcll} \mathcal{L}u_1^{n+1} & = & f & \text{in } \Omega_1, & \mathcal{L}u_2^{n+1} & = & f & \text{in } \Omega_2, \\ \mathcal{B}(u_1^{n+1}) & = & g & \text{on } \partial\Omega_1, & \mathcal{B}(u_2^{n+1}) & = & g & \text{on } \partial\Omega_2, \\ \tilde{\mathcal{B}}_{12}u_1^{n+1} & = & \tilde{\mathcal{B}}_{12}u_2^n & \text{on } \Gamma_{12}, & \tilde{\mathcal{B}}_{21}u_2^{n+1} & = & \tilde{\mathcal{B}}_{21}u_1^n & \text{on } \Gamma_{21}. \end{array} \tag{3.2}$$

The interface formulation was extensively tested in [9] for $\mathcal{L} = \eta - \Delta$, and optimized transmission conditions of Robin and second-order type were developed, leading to significantly faster convergence rates.

A discretization with optimized transmission conditions leads to discrete versions of the form (2.10) and (2.11). The subdomain matrices A_j are replaced by $\tilde{A}_j$, and the transmission operators B_{jk} are replaced by $\tilde{B}_{jk}$, corresponding to the optimized transmission conditions derived at the continuous level for various types of PDEs; see [9, 12, 10, 14, 6] and references therein.

3.2. Optimized restricted additive Schwarz methods. The ORAS method is based on the RAS method (2.3) and (2.7) but uses different subdomain matrices, which come from the optimized Jacobi–Schwarz method

$$\tilde{A}_j \boldsymbol{u}_j^{n+1} = \boldsymbol{f}_j + \sum_{k=1}^{J} \tilde{B}_{jk}\boldsymbol{u}_k^n, \quad j = 1, \ldots, J, \tag{3.3}$$

where $\tilde{B}_{jj} = 0$ to simplify the notation. We show that, for sufficient overlap, the subdomain matrices A_j in the RAS algorithm (2.3) and (2.7) can be replaced by the optimized subdomain matrices $\tilde{A}_j$ from (3.3) to obtain an ORAS method,

$$\boldsymbol{u}^{n+1} = \boldsymbol{u}^n + \left(\sum_{j=1}^{J} \tilde{R}_j^T \tilde{A}_j^{-1} R_j \right) (\boldsymbol{f} - A\boldsymbol{u}^n), \tag{3.4}$$

which produces the same iterates as (3.3). An advantage of the ORAS implementation (3.4) over the optimized Schwarz method (3.3) is that the additional transmission operators $\tilde{B}_{jk}$ are not needed in ORAS, which greatly simplifies the transition from an existing RAS implementation to ORAS. For a simplified proof in the case of two subdomains and a link to the Schur complement system, consult [28].

DEFINITION 3.1 (consistency). *Let R_j, $j = 1, \ldots, J$ be restriction operators covering the entire discrete domain, and let $\boldsymbol{f}_j = R_j \boldsymbol{f}$. The matrix splitting R_j, $\tilde{A}_j$, $\tilde{B}_{jk}$, $j = 1, \ldots, J$ and $k = 1, \ldots, J$, in* (3.3) *is consistent if for all $\boldsymbol{f}$ and associated solution $\boldsymbol{u}$ of* (2.2), *$\boldsymbol{u}_j = R_j \boldsymbol{u}$ satisfy*

$$\tilde{A}_j \boldsymbol{u}_j = \boldsymbol{f}_j + \sum_{k=1}^{J} \tilde{B}_{jk} \boldsymbol{u}_k. \tag{3.5}$$

LEMMA 3.2. *Let A in* (2.2) *have full rank. For a consistent matrix splitting R_j, $\tilde{A}_j$, $\tilde{B}_{jk}$, $j = 1, \ldots, J$ and $k = 1, \ldots, J$, we have the matrix identities*

$$\tilde{A}_j R_j - \sum_{k=1}^{J} \tilde{B}_{jk} R_k = R_j A, \quad j = 1, \ldots, J. \tag{3.6}$$

Proof. For an arbitrary $\boldsymbol{f}$, we apply R_j to (2.2) and obtain, using consistency (3.5),

$$R_j A \boldsymbol{u} = R_j \boldsymbol{f} = \boldsymbol{f}_j = \tilde{A}_j \boldsymbol{u}_j - \sum_{k=1}^{J} \tilde{B}_{jk} \boldsymbol{u}_k.$$

Now using $\boldsymbol{u}_j = R_j \boldsymbol{u}$ and $\boldsymbol{u}_k = R_k \boldsymbol{u}$ on the right-hand side yields

$$\left(\tilde{A}_j R_j - \sum_{k=1}^{J} \tilde{B}_{jk} R_k - R_j A \right) \boldsymbol{u} = 0.$$

Because $\boldsymbol{f}$ was arbitrary and A is invertible, the identity is true for all $\boldsymbol{u}$, and therefore the identity (3.6) is established. ∎

While the definition of consistency is simple, it has important consequences: if the classical submatrices are used, i.e., $\tilde{A}_j = A_j = R_j A R_j^T$, then the restriction operators R_j can be overlapping or nonoverlapping, and with the associated B_{jk}, we obtain a consistent splitting R_j, A_j, B_{jk}, $j = 1, \ldots, J$, $k = 1, \ldots, J$. However, if alternative subdomain matrices $\tilde{A}_j$ are employed, then the restriction operators R_j must be such that the unknowns in $\boldsymbol{u}_j$ affected by the change in $\tilde{A}_j$ are also available in neighboring $\boldsymbol{u}_k$ to compensate via $\tilde{B}_{jk}$ in (3.5). Hence consistency implies for all nonclassical splittings a condition on the overlap in the R_j. The following further restriction on the overlap is necessary for the optimized RAS algorithm.

ASSUMPTION 1. *We assume that the restriction operators R_j and the prolongation operators $\tilde{R}_j^T$ from the ORAS method* (3.4) *and the transmission operators $\tilde{B}_{jk}$ from the optimized parallel Schwarz method* (3.3) *satisfy*

$$\tilde{B}_{jk} R_k \tilde{R}_m^T = 0, \quad m \neq k. \tag{3.7}$$

Remark 1. The conditions (3.7) in Assumption 1 relate the overlap to the operators $\tilde{B}_{jk}$. Classical Schwarz methods only employ interface values from neighboring

subdomains, and thus these conditions are automatically satisfied. The optimized Schwarz operators $\tilde{B}_{jk}$ approximate derivatives, requiring values at the interface and neighboring points. The operators $\tilde{R}_j$ must not overwrite these values, hence the requirement of a small overlap in the ORAS formulation.

LEMMA 3.3. *Let R_j, $j = 1, \dots, J$, be restriction operators covering the entire discrete domain, and let $\tilde{R}_j$ be the corresponding RAS versions of these operators. If Assumption* 1 *holds, then $\tilde{B}_{jk} R_k \tilde{R}_k^T = \tilde{B}_{jk}$ for all $j = 1, \dots, J$, $k = 1, \dots, J$.*

Proof. We first note that by the nonoverlapping definition of $\tilde{R}_j$, $j = 1, \dots, J$, the identity matrix I can be written as

$$I = \sum_{j=1}^{J} \tilde{R}_j^T \tilde{R}_j = \sum_{j=1}^{J} \tilde{R}_j^T R_j. \tag{3.8}$$

Now, multiplying for $m \neq k$ the identity $\tilde{B}_{jk} R_k \tilde{R}_m^T = 0$ on the right by R_m and substituting the term $\tilde{R}_m^T R_m$ using (3.8) leads to

$$\tilde{B}_{jk} R_k \left(I - \sum_{l \neq m} \tilde{R}_l^T R_l \right) = 0 \quad \Longrightarrow \quad \tilde{B}_{jk} R_k = \sum_{l \neq m} \tilde{B}_{jk} R_k \tilde{R}_l^T R_l,$$

which, using Assumption 1, gives $\tilde{B}_{jk} R_k = \tilde{B}_{jk} R_k \tilde{R}_k^T R_k$. Hence we obtain $(\tilde{B}_{jk} - \tilde{B}_{jk} R_k \tilde{R}_k^T) R_k = 0$, which completes the proof, because the restriction matrix R_k has full rank. ∎

We are now ready to prove the main result of this subsection.

THEOREM 3.4. *Let R_j, $\tilde{A}_j$, $\tilde{B}_{jk}$, $j = 1, \dots, J$ and $k = 1, \dots, J$, be a consistent matrix splitting, and let $\tilde{R}_j$ be the corresponding RAS versions of R_j. If the initial iterates $\boldsymbol{u}_j^0$, $j = 1, \dots, J$, of the optimized Jacobi–Schwarz method* (3.3) *and the initial iterate $\boldsymbol{u}^0$ of the ORAS method* (3.4) *satisfy*

$$\boldsymbol{u}^0 = \sum_{j=1}^{J} \tilde{R}_j^T \boldsymbol{u}_j^0, \tag{3.9}$$

and if Assumption 1 *holds, then the two methods* (3.3) *and* (3.4) *generate an identical sequence of iterates,*

$$\boldsymbol{u}^n = \sum_{j=1}^{J} \tilde{R}_j^T \boldsymbol{u}_j^n. \tag{3.10}$$

Remark 2. While condition (3.9) is important in proving that the sequence of iterates of the two methods, and thus the two methods, are equivalent, in practice one would not need to compute an initial condition $\boldsymbol{u}^0$ from given initial conditions $\boldsymbol{u}_j^0$ or vice versa, even though this can be achieved directly using the formula (3.9). Note that for given $\boldsymbol{u}^0$, the choice of the $\boldsymbol{u}_j^0$ is not unique: entries in $\boldsymbol{u}_j^0$ erased by $\tilde{R}_j^T$ can be chosen arbitrarily.

Proof. The proof is by induction. For $n = 0$, (3.10) follows by assumption (3.9) on the initial iterates. We now assume that $\boldsymbol{u}^n = \sum_{j=1}^{J} \tilde{R}_j^T \boldsymbol{u}_j^n$ and show that the identity (3.10) holds for $n + 1$. Applying Lemma 3.2 to the jth term of the sum in

(3.4), we obtain

$$
\begin{aligned}
\tilde{R}_j^T \tilde{A}_j^{-1} R_j(\boldsymbol{f} - A\boldsymbol{u}^n) &= \tilde{R}_j^T \tilde{A}_j^{-1}(\boldsymbol{f}_j - R_j A\boldsymbol{u}^n) \\
&= \tilde{R}_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j - \left(\tilde{A}_j R_j - \sum_{k=1}^{J} \tilde{B}_{jk} R_k\right)\boldsymbol{u}^n\right) \\
&= \tilde{R}_j^T \left(\tilde{A}_j^{-1}\boldsymbol{f}_j - R_j\boldsymbol{u}^n + \tilde{A}_j^{-1}\sum_{k=1}^{J} \tilde{B}_{jk} R_k \boldsymbol{u}^n\right).
\end{aligned} \tag{3.11}
$$

Substituting this expression into (3.4) and using the identity (3.8) leads to

$$
\boldsymbol{u}^{n+1} = \sum_{j=1}^{J} \tilde{R}_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j + \sum_{k=1}^{J} \tilde{B}_{jk} R_k \boldsymbol{u}^n\right).
$$

Now using the induction hypothesis to replace $\boldsymbol{u}^n$ by $\sum_{m=1}^{J} \tilde{R}_m^T \boldsymbol{u}_m^n$ on the right-hand side, we obtain

$$
\boldsymbol{u}^{n+1} = \sum_{j=1}^{J} \tilde{R}_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j + \sum_{k=1}^{J}\sum_{m=1}^{J} \tilde{B}_{jk} R_k \tilde{R}_m^T \boldsymbol{u}_m^n\right).
$$

By Assumption 1, the inner sum over m vanishes except for $m = k$, and together with Lemma 3.3, the above relation becomes

$$
\boldsymbol{u}^{n+1} = \sum_{j=1}^{J} \tilde{R}_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j + \sum_{k=1}^{J} \tilde{B}_{jk} R_k \tilde{R}_k^T \boldsymbol{u}_k^n\right) = \sum_{j=1}^{J} \tilde{R}_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j + \sum_{k=1}^{J} \tilde{B}_{jk} \boldsymbol{u}_k^n\right).
$$

Finally, using (3.3), we find

$$
\boldsymbol{u}^{n+1} = \sum_{j=1}^{J} \tilde{R}_j^T \boldsymbol{u}_j^{n+1},
$$

which concludes the proof by induction. ∎

3.3. Optimized multiplicative Schwarz methods. The OMS method is an alternative to ORAS. In contrast to ORAS with an additional condition on the overlap, the consistency of the splitting suffices here. However, OMS needs a coloring of subdomains to remain a parallel method. To implement a parallel optimized Schwarz method without conditions on the overlap, an augmented formulation is required, as shown in subsection 3.4.

The OMS method is based on the MS method (2.5), but uses different subdomain matrices, which come from the discretized optimized alternating Schwarz method

$$
\tilde{A}_j \boldsymbol{u}_j^{n+1} = \boldsymbol{f}_j + \sum_{k=1}^{j-1} \tilde{B}_{jk} \boldsymbol{u}_k^{n+1} + \sum_{k=j+1}^{J} \tilde{B}_{jk} \boldsymbol{u}_k^n, \quad j = 1, \ldots, J. \tag{3.12}
$$

This method differs from (3.3), because subdomain solves are performed in a Gauss–Seidel fashion. The MS method (2.5) always uses the most recently updated values in the iteration by definition. To guarantee the same property for the alternating Schwarz

method (3.12), we need the following assumption which states this in mathematical terms.

ASSUMPTION 2. *We assume that the restriction operators R_j and the transmission operators $\tilde{B}_{jk}$ in the alternating Schwarz method* (3.12) *satisfy*

$$\tilde{B}_{jk} R_k R_m^T = 0$$

for all $j = 1, \ldots, J$ *and*

$$k \neq \begin{cases} j-1 & \text{if } j > 1, \\ J & \text{otherwise,} \end{cases} \qquad m \in \begin{cases} \{1, \ldots, j-1, k+1, \ldots, J\} & \text{if } k > j, \\ \{k+1, \ldots, j-1\} & \text{otherwise.} \end{cases}$$

Remark 3. Assumption 2 appears deceptively similar to the overlap Assumption 1 in the ORAS method, but it is not a constraint on the overlap. It simply states that the most recently updated values must be used by the transmission operators $\tilde{B}_{jk}$ in (3.12), i.e., we need $\tilde{B}_{jk} R_k R_m^T = 0$, if values from subdomain m have been updated more recently than from subdomain k, which with the ordering implied by (3.12) leads to the conditions in Assumption 2.

We now show that by replacing the subdomain matrices A_j, $j = 1, \ldots, J$, in the MS method (2.5) by their optimized variants $\tilde{A}_j$ from (3.12), the new OMS method

$$\boldsymbol{u}^{n+\frac{j}{J}} = \boldsymbol{u}^{n+\frac{j-1}{J}} + R_j^T \tilde{A}_j^{-1} R_j (\boldsymbol{f} - A \boldsymbol{u}^{n+\frac{j-1}{J}}), \quad j = 1, \ldots, J, \tag{3.13}$$

produces the same iterates as (3.12), again without the explicit use of the transmission operators $\tilde{B}_{jk}$. Three lemmas are needed to prove this result.

LEMMA 3.5. *For $j = 1, \ldots, J$, the matrix identity $R_j(I - R_j^T R_j) = 0$ holds.*

Proof. The result follows by multiplying through by R_j:

$$R_j(I - R_j^T R_j) = (R_j - R_j R_j^T R_j) = (I - R_j R_j^T) R_j = 0,$$

because $R_j R_j^T = I$. ∎

LEMMA 3.6. *For overlapping or nonoverlapping restriction operators R_j, $j = 1, \ldots, J$, covering the entire domain, we have*

$$\prod_{j=1}^{J} (I - R_j^T R_j) = 0.$$

Proof. For $A \in \mathbb{R}^{m \times m}$, the rectangular Boolean matrices R_j are of dimensions $n_j \times m$ and have rank n_j. Let S_j be the index set formed by the integers representing columns of R_j containing a 1. Since the restriction operators R_j are covering the entire domain, we have $\cup_{j=1}^{J} S_j = \{1, 2, 3, \ldots, m\} \equiv M$. If for the index set S we denote by I_S the matrix with 1's on the diagonal indicated by the indices in S and zeros everywhere else, we have $I_{S_j^c} = I - R_j^T R_j$, where S_j^c denotes the complement of S_j in M. We now obtain

$$\prod_{j=1}^{J} (I - R_j^T R_j) = \prod_{j=1}^{J} I_{S_j^c} = I_{\cap_{j=1}^{J} S_j^c} = 0,$$

since $\cap_{j=1}^{J} S_j^c = (\cup_{j=1}^{J} S_j)^c = M^c = \emptyset$ by De Morgan's law. ∎

LEMMA 3.7. *For any given set of subdomain vectors* $\boldsymbol{u}_l$, $l = 1, \ldots, J$, *and under Assumption* 2 *we have*

$$\tilde{B}_{jk} R_k \sum_{l=1}^{j-1} \prod_{i=l+1}^{j-1} (I - R_i^T R_i) R_l^T \boldsymbol{u}_l = \begin{cases} \tilde{B}_{jk} \boldsymbol{u}_k & \text{if } k < j, \\ 0 & \text{otherwise,} \end{cases} \tag{3.14}$$

and

$$\tilde{B}_{jk} R_k \prod_{i=1}^{j-1} (I - R_i^T R_i) \left(\sum_{p=1}^{J} \prod_{q=p+1}^{J} (I - R_q^T R_q) R_p^T \boldsymbol{u}_p \right) = \begin{cases} \tilde{B}_{jk} \boldsymbol{u}_k & \text{if } k > j, \\ 0 & \text{otherwise.} \end{cases} \tag{3.15}$$

Proof. We first start by showing (3.14): if $k < j$, we split the left-hand side in (3.14) into three parts:

$$\begin{aligned} \tilde{B}_{jk} R_k \sum_{l=1}^{j-1} \prod_{i=l+1}^{j-1} (I - R_i^T R_i) R_l^T \boldsymbol{u}_l &= \sum_{l=1}^{k-1} \tilde{B}_{jk} R_k \prod_{i=l+1}^{j-1} (I - R_i^T R_i) R_l^T \boldsymbol{u}_l \\ &+ \tilde{B}_{jk} R_k \prod_{i=k+1}^{j-1} (I - R_i^T R_i) R_k^T \boldsymbol{u}_k + \sum_{l=k+1}^{j-1} \tilde{B}_{jk} R_k \prod_{i=l+1}^{j-1} (I - R_i^T R_i) R_l^T \boldsymbol{u}_l. \end{aligned} \tag{3.16}$$

The first sum on the right vanishes, because $k < j$ and the product includes the term $i = k$, and because the product terms commute, each term in the sum contains $R_k(I - R_k^T R_k)$ which is identically zero by Lemma 3.5. In the second term on the right in (3.16), two cases need to be distinguished: if $k = j - 1$, then the product is empty, and because $R_k R_k^T = I$, the term equals $\tilde{B}_{jk} \boldsymbol{u}_k$. On the other hand, if $k < j - 1$, we obtain

$$\tilde{B}_{jk} R_k \prod_{i=k+1}^{j-1} (I - R_i^T R_i) R_k^T \boldsymbol{u}_k = \tilde{B}_{jk} R_k R_k^T \boldsymbol{u}_k = \tilde{B}_{jk} \boldsymbol{u}_k,$$

where the assumption that $\tilde{B}_{jk} R_k R_i^T = 0$ for $k < j - 1$ and $i \in \{k + 1, \ldots, j - 1\}$ was used, leading to $R_k R_k^T = I$. Hence, the second term always equals $\tilde{B}_{jk} \boldsymbol{u}_k$. Now for the last term in (3.16), two cases are again possible: if $k = j - 1$, then the sum is empty and thus the term is zero. If $k < j - 1$, then

$$\sum_{l=k+1}^{j-1} \tilde{B}_{jk} R_k \prod_{i=l+1}^{j-1} (I - R_i^T R_i) R_l^T \boldsymbol{u}_l = \sum_{l=k+1}^{j-1} \tilde{B}_{jk} R_k R_l^T \boldsymbol{u}_l = 0,$$

because again by assumption $\tilde{B}_{jk} R_k R_i^T = 0$ for $k < j - 1$ and $i \in \{k + 1, \ldots, j - 1\}$, and also $\tilde{B}_{jk} R_k R_l^T = 0$ for $k < j - 1$ and $l \in \{k + 1, \ldots, j - 1\}$, which concludes the proof for the first result (3.14) if $k < j$. Now if $k = j$, then the left-hand side of (3.14) is zero because by definition $\tilde{B}_{jj} = 0$. Finally, if $k > j$, zero is obtained for $j = 1$, because the sum is empty, and for $j > 1$

$$\sum_{l=1}^{j-1} \tilde{B}_{jk} R_k \prod_{i=l+1}^{j-1} (I - R_i^T R_i) R_l^T \boldsymbol{u}_l = \sum_{l=1}^{j-1} \tilde{B}_{jk} R_k R_l^T \boldsymbol{u}_l = 0,$$

where the assumption $\tilde{B}_{jk} R_k R_i^T = 0$ for $k > j$ and $i \in \{2, \ldots, j-1\}$ and $\tilde{B}_{jk} R_k R_l^T = 0$ for $k > j$ and $l \in \{1, \ldots, j-1\}$ was again employed. This concludes the proof of (3.14).

To show the second identity (3.15), first note that for $k \le j$,

$$\tilde{B}_{jk} R_k \prod_{i=1}^{j-1} (I - R_i^T R_i) = 0,$$

because for $k = j$, $\tilde{B}_{jk} = 0$, and for $k < j$ the product includes the term $R_k(I - R_k^T R_k)$ which is identically zero by Lemma 3.5. Now if $k > j$, then

$$\tilde{B}_{jk} R_k \prod_{i=1}^{j-1} (I - R_i^T R_i) = \tilde{B}_{jk} R_k,$$

because for $j = 1$ the product is empty, and for $j > 1$ we have by assumption $\tilde{B}_{jk} R_k R_i^T = 0$ for $k > j$ and $i \in \{1, \dots, j-1\}$. The remaining sum is separated into three terms:

(3.17)
$$\begin{aligned} \tilde{B}_{jk} R_k \sum_{p=1}^{J} \prod_{q=p+1}^{J} (I - R_q^T R_q) R_p^T \boldsymbol{u}_p &= \sum_{p=1}^{k-1} \tilde{B}_{jk} R_k \prod_{q=p+1}^{J} (I - R_q^T R_q) R_p^T \boldsymbol{u}_p \\ &+ \tilde{B}_{jk} R_k \prod_{q=k+1}^{J} (I - R_q^T R_q) R_k^T \boldsymbol{u}_k + \sum_{p=k+1}^{J} \tilde{B}_{jk} R_k \prod_{q=p+1}^{J} (I - R_q^T R_q) R_p^T \boldsymbol{u}_p. \end{aligned}$$

The first term on the right vanishes, because the product always contains the term $i = k$, and because the product terms commute, each term in the sum contains $R_k(I - R_k^T R_k)$ which is identically zero by Lemma 3.5. The second term on the right in (3.17) simplifies to

$$\tilde{B}_{jk} R_k \prod_{q=k+1}^{J} (I - R_q^T R_q) R_k^T \boldsymbol{u}_k = \tilde{B}_{jk} R_k R_k^T \boldsymbol{u}_k = \tilde{B}_{jk} \boldsymbol{u}_k,$$

because by assumption for $k > j$ and $k \neq J$ we have $\tilde{B}_{jk} R_k R_q^T = 0$ for $q \in \{k+1, \dots, J\}$, and for $k = J$ the product is empty. Finally the last term in (3.17) becomes

$$\sum_{p=k+1}^{J} \tilde{B}_{jk} R_k \prod_{q=p+1}^{J} (I - R_q^T R_q) R_p^T \boldsymbol{u}_p = \sum_{p=k+1}^{J} \tilde{B}_{jk} R_k R_p^T \boldsymbol{u}_p = 0,$$

because for $k = J$ the sum is empty, and for $j < k < J$, by assumption, $\tilde{B}_{jk} R_k R_q^T = 0$ for $q \in \{k+2, \dots, J\}$, and also $\tilde{B}_{jk} R_k R_p^T = 0$ for $p \in \{k+1, \dots, J\}$, which concludes the proof. ∎

THEOREM 3.8. *Let R_j, $\tilde{A}_j$, $\tilde{B}_{jk}$, $j = 1, \dots, J$, $k = 1, \dots, J$, be a consistent matrix splitting. If the initial iterates $\boldsymbol{u}_j^0$, $j = 1, \dots, J$, of the optimized Schwarz method* (3.12) *and the initial iterate $\boldsymbol{u}^0$ of the OMS method* (3.13) *satisfy*

$$\boldsymbol{u}^0 = \sum_{j=1}^{J} \prod_{i=j+1}^{J} (I - R_i^T R_i) R_j^T \boldsymbol{u}_j^0 \tag{3.18}$$

and Assumption 2 holds, then (3.12) *and* (3.13) *generate an equivalent sequence of iterates,*

$$\boldsymbol{u}^n = \sum_{j=1}^{J} \prod_{i=j+1}^{J} (I - R_i^T R_i) R_j^T \boldsymbol{u}_j^n. \tag{3.19}$$

Proof. The proof has two steps, both shown by induction. We first assume that for a fixed n, relation (3.19) holds and show by induction that this implies the relation

$$\boldsymbol{u}^{n+\frac{j}{J}} = \prod_{i=1}^{j}(I - R_i^T R_i)\boldsymbol{u}^n + \sum_{l=1}^{j}\prod_{i=l+1}^{j}(I - R_i^T R_i)R_l^T \boldsymbol{u}_l^{n+1} \tag{3.20}$$

for $j = 0, 1, \ldots, J$. This relation trivially holds for $j = 0$. Assuming that it holds for $j-1$, we find from (3.13) using the matrix identity (3.6)

$$\begin{aligned}
\boldsymbol{u}^{n+\frac{j}{J}} &= \boldsymbol{u}^{n+\frac{j-1}{J}} + R_j^T \tilde{A}_j^{-1} R_j(\boldsymbol{f} - A\boldsymbol{u}^{n+\frac{j-1}{J}}) \\
&= \boldsymbol{u}^{n+\frac{j-1}{J}} + R_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j - \tilde{A}_j R_j \boldsymbol{u}^{n+\frac{j-1}{J}} + \sum_{k=1}^{J}\tilde{B}_{jk}R_k\boldsymbol{u}^{n+\frac{j-1}{J}}\right) \\
&= (I - R_j^T R_j)\boldsymbol{u}^{n+\frac{j-1}{J}} + R_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j + \sum_{k=1}^{J}\tilde{B}_{jk}R_k\boldsymbol{u}^{n+\frac{j-1}{J}}\right).
\end{aligned}$$

Now, replacing relation (3.20) at $j-1$ in the last sum, together with Lemma 3.7, leads to

$$\begin{aligned}
\sum_{k=1}^{J}\tilde{B}_{jk}R_k\boldsymbol{u}^{n+\frac{j-1}{J}} &= \sum_{k=1}^{J}\tilde{B}_{jk}R_k\left(\prod_{i=1}^{j-1}(I - R_i^T R_i)\boldsymbol{u}^n + \sum_{l=1}^{j-1}\prod_{i=l+1}^{j-1}(I - R_i^T R_i)R_l^T\boldsymbol{u}_l^{n+1}\right) \\
&= \sum_{k=1}^{j-1}\tilde{B}_{jk}\boldsymbol{u}_k^{n+1} + \sum_{k=j+1}^{J}\tilde{B}_{jk}\boldsymbol{u}_k^n.
\end{aligned}$$

Substituting this result back into the expression for $\boldsymbol{u}^{n+\frac{j}{J}}$, we find, using (3.12) and relation (3.20) at $j-1$ again,

$$\begin{aligned}
\boldsymbol{u}^{n+\frac{j}{J}} &= (I - R_j^T R_j)\boldsymbol{u}^{n+\frac{j-1}{J}} + R_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j + \sum_{m=1}^{j-1}\tilde{B}_{jk}\boldsymbol{u}_k^{n+1} + \sum_{m=j+1}^{J}\tilde{B}_{jk}\boldsymbol{u}_k^n\right) \\
&= \prod_{i=1}^{j}(I - R_i^T R_i)\boldsymbol{u}^n + \sum_{l=1}^{j-1}\prod_{i=l+1}^{j}(I - R_i^T R_i)R_l^T\boldsymbol{u}_l^{n+1} + R_j^T\boldsymbol{u}_j^{n+1} \\
&= \prod_{i=1}^{j}(I - R_i^T R_i)\boldsymbol{u}^n + \sum_{l=1}^{j}\prod_{i=l+1}^{j}(I - R_i^T R_i)R_l^T\boldsymbol{u}_l^{n+1},
\end{aligned}$$

which concludes the first proof by induction. The main result (3.19) can now be proved by induction on n. By the assumption on the initial iterate, (3.19) holds for $n = 0$. Thus assuming it holds for n, we obtain from the first part for this n that relation (3.20) holds for $j = 0, 1, \ldots, J$. In particular, for $j = J$, we have

$$\boldsymbol{u}^{n+1} = \prod_{i=1}^{J}(I - R_i^T R_i)\boldsymbol{u}^n + \sum_{l=1}^{J}\prod_{i=l+1}^{J}(I - R_i^T R_i)R_l^T\boldsymbol{u}_l^{n+1},$$

and by Lemma 3.6 the first product vanishes, which completes the proof. ∎

3.4. Optimized additive Schwarz methods for the augmented system. To obtain parallel discrete optimized Schwarz methods, which in contrast to ORAS can be used in a nonoverlapping fashion, we need to introduce an augmented system, where unknowns in the overlap and at the interfaces are stored for each subdomain. Tang [29] called this an *enhanced* system, whereas the term *augmented* system was employed in [33].

At convergence, observe that the discretized optimized Schwarz method (3.3) leads naturally to the augmented system

$$\begin{bmatrix} \tilde{A}_1 & -\tilde{B}_{12} & \cdots & -\tilde{B}_{1,J-1} & -\tilde{B}_{1,J} \\ -\tilde{B}_{21} & \tilde{A}_2 & -\tilde{B}_{23} & \cdots & -\tilde{B}_{2,J} \\ \vdots & & \ddots & & \vdots \\ -\tilde{B}_{J-1,1} & \cdots & -\tilde{B}_{J-1,J-2} & \tilde{A}_{J-1} & -\tilde{B}_{J-1,J} \\ -\tilde{B}_{J,1} & -\tilde{B}_{J,2} & \cdots & -\tilde{B}_{J,J-1} & \tilde{A}_J \end{bmatrix} \begin{bmatrix} \boldsymbol{u}_1 \\ \boldsymbol{u}_2 \\ \vdots \\ \boldsymbol{u}_{J-1} \\ \boldsymbol{u}_J \end{bmatrix} = \begin{bmatrix} \boldsymbol{f}_1 \\ \boldsymbol{f}_2 \\ \vdots \\ \boldsymbol{f}_{J-1} \\ \boldsymbol{f}_J \end{bmatrix},$$

or in matrix notation, specifying augmented quantities by a hat,

$$\hat{A}\hat{\boldsymbol{u}} = \hat{\boldsymbol{f}}. \tag{3.21}$$

Applying a standard AS method with nonoverlapping restriction operators $\hat{R}_j$ to the augmented system (3.21), $\boldsymbol{u}_j = \hat{R}_j\hat{\boldsymbol{u}}$, we obtain the iterative method

$$\hat{\boldsymbol{u}}^{n+1} = \hat{\boldsymbol{u}}^n + \sum_{j=1}^{J} \hat{R}_j^T \tilde{A}_j^{-1} \hat{R}_j(\hat{\boldsymbol{f}} - \hat{A}\hat{\boldsymbol{u}}^n). \tag{3.22}$$

Note that the nonoverlapping restriction operators $\hat{R}_j$ are related to the restriction operators for the consistent splitting R_j, $\tilde{A}_j$, $\tilde{B}_j$, $j = 1, \ldots, J$: their range is the same, only their domain is enlarged to account for the augmented matrix $\hat{A}$.

THEOREM 3.9. *Let R_j, $\tilde{A}_j$, $\tilde{B}_{jk}$, $j = 1, \ldots, J$, $k = 1, \ldots, J$, be a consistent matrix splitting. If the initial iterates $\boldsymbol{u}_j^0$, $j = 1, \ldots, J$, of the optimized Jacobi–Schwarz method* (3.3) *and the initial iterate $\hat{\boldsymbol{u}}^0$ of the AS method applied to the augmented system* (3.22) *satisfy*

$$\hat{\boldsymbol{u}}^0 = \left[(\boldsymbol{u}_1^0)^T,\ (\boldsymbol{u}_2^0)^T, \ldots, (\boldsymbol{u}_J^0)^T\right]^T, \tag{3.23}$$

then (3.3) *and* (3.22) *generate the same sequence of iterates, i.e.,*

$$\hat{\boldsymbol{u}}^n = \left[(\boldsymbol{u}_1^n)^T,\ (\boldsymbol{u}_2^n)^T, \ldots, (\boldsymbol{u}_J^n)^T\right]^T. \tag{3.24}$$

Proof. The proof is again by induction. By assumption, (3.24) holds for $n = 0$. Assuming it holds for n, we obtain from (3.22), using the fact that the restriction operators $\hat{R}_j$, $j = 1, \ldots, J$, are nonoverlapping, Lemma 3.2, and (3.3),

$$\begin{aligned} \hat{\boldsymbol{u}}^{n+1} &= \hat{\boldsymbol{u}}^n + \sum_{j=1}^{J} \hat{R}_j^T \tilde{A}_j^{-1} \hat{R}_j(\hat{\boldsymbol{f}} - \hat{A}\hat{\boldsymbol{u}}^n) = \hat{\boldsymbol{u}}^n + \sum_{j=1}^{J} \hat{R}_j^T \tilde{A}_j^{-1}(\boldsymbol{f}_j - \hat{R}_j\hat{A}\hat{\boldsymbol{u}}^n) \\ &= \hat{\boldsymbol{u}}^n + \sum_{j=1}^{J} \hat{R}_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j - \tilde{A}_j\boldsymbol{u}_j^n + \sum_{l=1}^{J} \tilde{B}_{jl}\boldsymbol{u}_l^n\right) = \sum_{j=1}^{J} \hat{R}_j^T \tilde{A}_j^{-1}\left(\boldsymbol{f}_j + \sum_{l=1}^{J} \tilde{B}_{jl}\boldsymbol{u}_l^n\right) \\ &= \sum_{j=1}^{J} \hat{R}_j^T \boldsymbol{u}_j^{n+1} = \left[(\boldsymbol{u}_1^{n+1})^T,\ (\boldsymbol{u}_2^{n+1})^T, \ldots, (\boldsymbol{u}_J^{n+1})^T\right]^T = \hat{\boldsymbol{u}}^{n+1}, \end{aligned} \tag{3.25}$$

which concludes the proof. ∎

An advantage of this formulation is that nonoverlapping parallel preconditioners can be used, such as the optimized Jacobi–Schwarz method (3.3) and optimized alternating Schwarz method (3.12). A disadvantage is that the operators $\tilde{B}_{jk}$ must be constructed explicitly, because they are needed in the application of $\tilde{A}_j^{-1}$ in (3.22).

4. Application to the positive definite Helmholtz problem. We now apply the results of the previous sections to finite difference and spectral element discretizations of the positive definite Helmholtz problem on the domain Ω,

$$\mathcal{L}u = (\eta - \Delta)u = f \quad \text{in } \Omega, \tag{4.1}$$

where Ω is an open set in two dimensions, and we impose homogeneous Dirichlet conditions to simplify the exposition.

4.1. Finite differences. Discretizing (4.1) using a standard five-point discretization on an equidistant grid on the domain $\Omega = (0,1) \times (0,1)$, as shown in Figure 4.1, and using a lexicographic ordering enumerating the unknowns from bottom to top and left to right leads to the matrix problem

$$A\boldsymbol{u} = \boldsymbol{f}, \quad A = \frac{1}{h^2}\begin{bmatrix} T_\eta & -I & \\ -I & T_\eta & \ddots \\ & \ddots & \ddots \end{bmatrix}, \quad T_\eta = \begin{bmatrix} \eta h^2 + 4 & -1 & \\ -1 & \eta h^2 + 4 & \ddots \\ & \ddots & \ddots \end{bmatrix},$$

where $A \in \mathbb{R}^{m^2 \times m^2}$, $T_\eta \in \mathbb{R}^{m \times m}$, $I \in \mathbb{R}^{m \times m}$ denotes the identity matrix and $h = \frac{1}{m+1}$. Decomposing the domain Ω into the two subdomains $\Omega_1 = (0, \beta) \times (0,1)$ and $\Omega_2 = (\alpha, 1) \times (0,1)$, as indicated in Figure 4.1, we obtain the rectangular restriction matrices $R_1 \in \mathbb{R}^{mb \times m^2}$ and $R_2 \in \mathbb{R}^{m(m-a+1) \times m^2}$ of the form $R_1 = [I\ 0]$ and $R_2 = [0\ I]$, where the 1's in the identity matrices I of appropriate size correspond to the grid points indicated in Figure 4.1 by D_1 and D_2, respectively. The new restriction matrices $\tilde{R}_j$ are of the same size and form as R_j, $j = 1, 2$, but have 1's only on the diagonals for the grid points indicated by the nonoverlapping $\tilde{D}_j$ in Figure 4.1. The classical subdomain matrices associated with this decomposition are by definition $A_j = R_j A R_j^T$, $j = 1, 2$, which implies that $A_1 \in \mathbb{R}^{mb \times mb}$ and $A_2 \in \mathbb{R}^{m(m-a+1) \times m(m-a+1)}$.

To obtain optimized RAS, MS, and AS methods, it suffices according to the results in section 3 to simply replace the classical subdomain matrices A_j by optimized subdomain matrices $\tilde{A}_j$ from optimized Schwarz methods. Since one changes only the transmission conditions to obtain optimized Schwarz methods, it suffices to replace the last diagonal block T_η in A_1, which is an interface block to the second subdomain, and the first diagonal block T_η in A_2, which is an interface block to the first subdomain, by the blocks corresponding to optimized transmission conditions to obtain the optimized subdomain matrices $\tilde{A}_j$. We choose here interface blocks based on the continuous analysis of the underlying PDE and transmission conditions [9], which suggests replacing the two interface blocks T_η by the matrix

$$\tilde{T} = \frac{1}{2}T_\eta + phI + \frac{q}{h}(T_0 - 2I), \quad T_0 = T_\eta|_{\eta=0}, \tag{4.2}$$

which corresponds to a general optimized transmission condition of order 2 with two parameters p and q; see [9]. The optimal choice for the parameters p and q in the

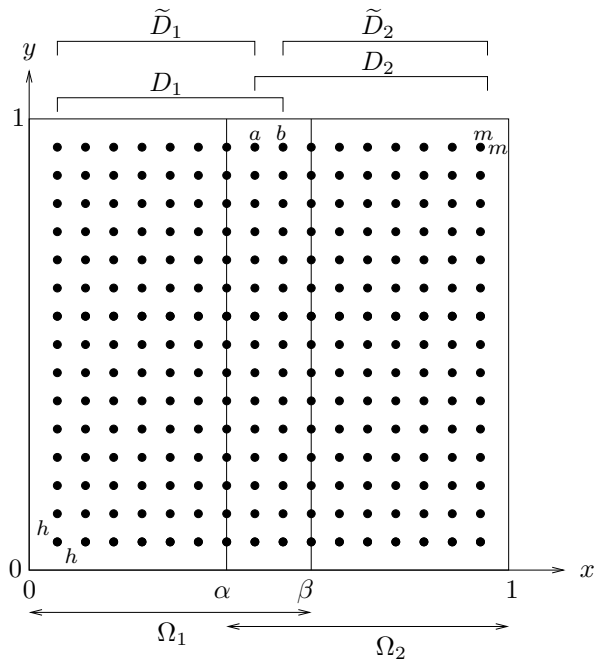

FIG. 4.1. *Finite difference discretization points and a two-subdomain decomposition.*

TABLE 4.1

Hierarchy of choices for the parameters p and q in the new interface blocks $\tilde{T}$ in (4.2). Here, TOj stands for "Taylor of order j," and OOj stands for "optimized of order j."

	p	q

new block $\tilde{T}$ depends on the problem parameter η, the overlap in the method, the mesh parameter h, and the lowest frequency along the interface, $k_{\min}$, which in our case would be $k_{\min}=\pi$, since this is the lowest possible mode at the interfaces fixed at $y=0$ and $y=1$ by a Dirichlet condition. In [9], the hierarchy of choices in Table 4.1 was derived for h small for the PDE (4.1). Figure 4.2 displays the effect of replacing the classical subdomain matrices A_j by the optimized subdomain matrices $\tilde{A}_j$, $j=1,2$, on the convergence of RAS for the model problem (4.1) on the unit square with $\eta=1$ and $h=1/30$. We applied the asymptotic formulas from Table 4.1 for the various choices of the parameters p and q in the new interface blocks $\tilde{T}$ (4.2) of the optimized subdomain matrices $\tilde{A}_j$. Clearly, the convergence of RAS is greatly enhanced with the new subdomain matrices $\tilde{A}_j$, and exchanging the interface blocks T_η by $\tilde{T}$ does not change the number of operations per iteration in any way.

There is an interesting observation concerning the overlap: in the experiment above, we used an overlap at the matrix level of two blocks in the definition of the

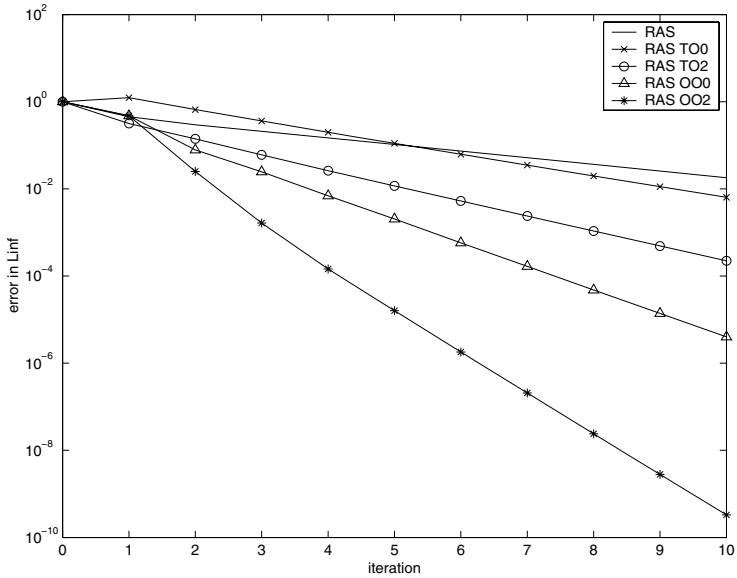

FIG. 4.2. *Convergence curves of classical RAS (top), with overlap* $3h$*, compared to the hierarchy of ORAS methods with overlap* h*.*

restriction operators R_j, $j = 1, 2$, which corresponds to the drawing in Figure 4.1 and is the smallest possible satisfying the overlap condition in Theorem 3.4. This corresponds for the classical RAS method to an overlap of $3h$, because the matrices $B_{12} = B_{21} = h^{-2}I$, which pick up the Dirichlet values from the other subdomains in (2.11), are a distance $3h$ apart in physical space; see the decomposition in Figure 4.1. This distance remains the same in ORAS, but the values picked up by the new $\tilde{B}_{12}$ and $\tilde{B}_{21}$ now include, in addition to those picked up by B_{12} and B_{21}, values in the neighboring row corresponding to the changes in $\tilde{A}_j$, and the values from B_{12} and B_{21} are used for the normal derivatives inside the neighboring domain. This implies that the physical interface has shifted by h on each subdomain, and hence the physical overlap is reduced by $2h$ and is thus only of size h for ORAS. In other words, the new physical interface is now on the grid lines denoted by a and b in Figure 4.1. We therefore used $C = 1$ for overlap h in the formulas in Table 4.1 to determine the parameters p and q. This shows that ORAS cannot be used without physical overlap, because we chose the smallest overlap according to Theorem 3.4, even though optimized Schwarz methods can be used without overlap.

Another interesting equivalence is now apparent: from formula (4.2), we observe that the new interface blocks $\tilde{T}$ and the classical interface blocks T coincide if one chooses

$$p = \frac{2 + \eta h^2}{2h}, \quad q = \frac{h}{2}, \tag{4.3}$$

and thus the ORAS method with parameters (4.3) and overlap h is identical to the classical RAS method with overlap $3h$. The numerical results in Figure 4.2 demonstrate, however, that the reduction in overlap is more than compensated for by a good choice of the parameters p and q.

In Figure 4.3, we illustrate the impact of the new subdomain matrices on the

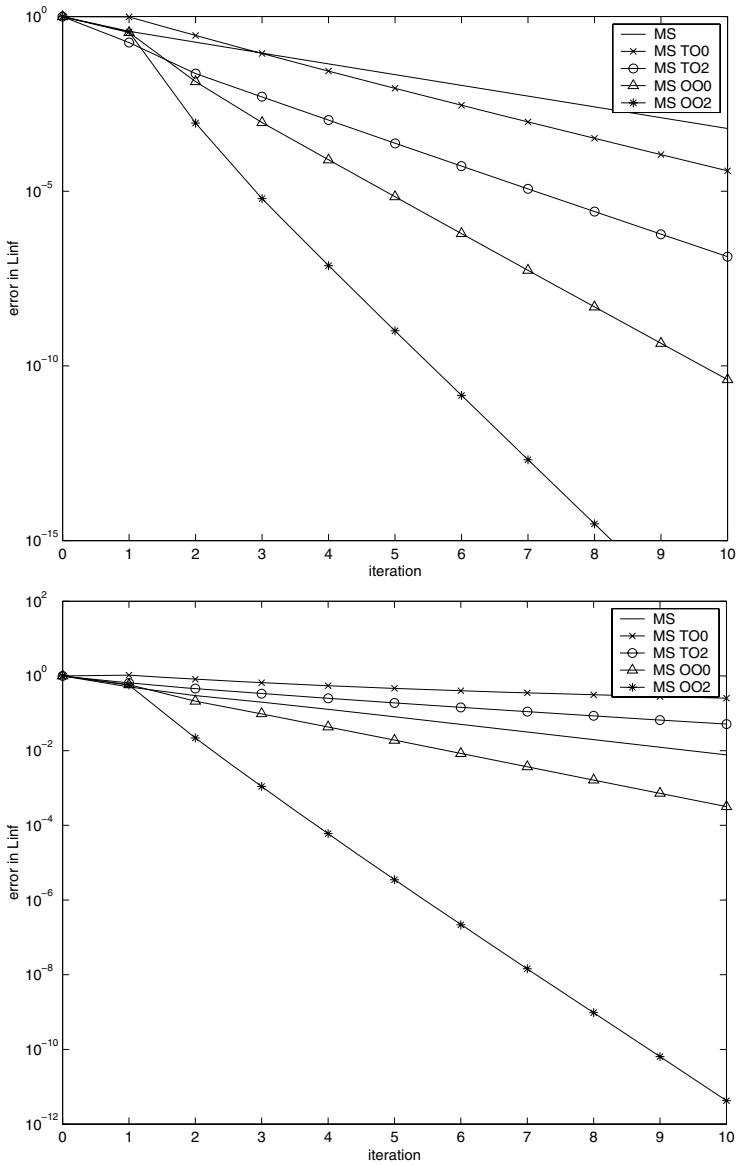

FIG. 4.3. *Convergence curves of classical MS compared to the hierarchy of OMS methods, at the top for overlap h (3h for classical MS), and at the bottom for zero overlap (2h for classical MS).*

convergence of MS. The error is plotted on top for the same configuration as in the previous experiments with RAS. As expected, the convergence is about two times faster than for RAS. At the bottom we show the results obtained for OMS with zero overlap, which corresponds in the classical case to an overlap of $2h$. Here, one can see that the Taylor transmission conditions are not effective enough to compensate for the loss of overlap, even though asymptotically they are comparable to classical MS with overlap $2h$, as shown in [9]. The optimized transmission conditions without overlap again improve upon the classical results with overlap by a large margin.

4.2. Spectral elements. In a nodal spectral element discretization, the computational domain Ω is partitioned into J quadrilateral elements Ω_j in which the dependent and independent variables are approximated by Nth order tensor-product polynomial expansions. A function $u : \mathbb{R}^2 \to \mathbb{R}$ is expanded, on element Ω_j, in terms of the Nth degree Lagrangian interpolants h_i as defined in [21],

$$u^h(\mathbf{x}(r_1^j, r_2^j))|_{\Omega_j} \equiv u_j(\mathbf{x}(r_1^j, r_2^j)) \equiv \sum_{k=0}^{N}\sum_{l=0}^{N} (\mathbf{u}_j)_{kl}\, h_k(r_1^j(\mathbf{x}))\, h_l(r_2^j(\mathbf{x})), \tag{4.4}$$

where $\mathbf{x} \to (r_1^j(\mathbf{x}), r_2^j(\mathbf{x}))$ is an affine transformation from the quadrilateral element Ω_j, on the original domain, to the reference element $[-1,1]\times[-1,1]$, and $(\mathbf{u}_j)_{kl}$ are the nodal basis coefficients defined at the Gauss–Lobatto–Legendre (GLL) quadrature points $\{\xi_i\}_{i=0}^N$. The weak formulation is obtained by integrating the differential equation (4.1) with respect to test functions in $H_0^1(\Omega)$ if Dirichlet conditions are assumed on the physical boundary $\partial\Omega$. By directly evaluating integrals using Gaussian quadrature, the generalized Galerkin problem consists of finding u in $X^N \equiv \mathbb{P}_{N,J}^2 \cap H_0^1(\Omega)$ such that

$$a^h(\phi, u) \equiv \eta(\phi, u)_{GLL} + (\nabla\phi, \nabla u)_{GLL} = (\phi, f)_{GLL} \equiv f^h(\phi) \tag{4.5}$$

for all ϕ in X^N, where the polynomial space $\mathbb{P}_{N,J}^2$ of degree N is defined as in [8]. The integrals are obtained as follows:

$$(f,g)_{GLL} \equiv \sum_{j=1}^{J}\sum_{k,l=0}^{N} f(\mathbf{x}^j(\xi_k,\xi_l))|_{\Omega_k} \cdot g(\mathbf{x}^j(\xi_k,\xi_l))|_{\Omega_j}\ |\mathcal{J}^j(\xi_k,\xi_l)|\rho_k\rho_l, \tag{4.6}$$

where $|\mathcal{J}^j(\xi_k,\xi_l)|$ is the Jacobian of the transformation $\mathbf{x}^j(\mathbf{r})$ and $\{\rho_i\}_{i=0}^N$ are the GLL weights associated with the quadrature points $\{\xi_i\}_{i=0}^N$. In our numerical experiments, the Jacobian is simply $\frac{h^2}{4}$ for all quadrilaterals Ω_j.

In order to construct a nonoverlapping algorithm, the augmented system must be explicitly derived to find an expression for the matrices $\tilde{B}_{ij}$. This can be accomplished in two different ways. The first approach employs the weak formulation directly on each domain. The second is simply to use the consistency relation in Lemma 3.2 and to construct the matrices $\tilde{B}_{jk}$. The latter can be extracted by specifying the form of the operator $\tilde{A}_j$ on each element. The complete derivation can be found in [26] for general curvilinear domains. Assuming that the spectral elements Ω_j coincide with the subdomains and that a general transmission condition between each element is used,

$$\left[\frac{\partial u_j}{\partial \mathbf{n}} + T(u_j,p,q,\tau)\right]_{\Gamma_{ij}}^{n+1} = \left[\frac{\partial u_i}{\partial \mathbf{n}} + T(u_j,p,q,\tau)\right]_{\Gamma_{ij}}^{n},$$

where $T(u_j,p,q,\tau) \equiv pu_j - q\frac{\partial^2 u_j}{\partial\tau^2}$, we now construct the OAS algorithm. At the continuous level, the optimized Schwarz algorithm solves the following problem for u_j^{n+1} on each Ω_j:

$$\begin{array}{rcll} \eta u_j^{n+1} - \Delta u_j^{n+1} & = & f_j(x,y) & \text{in } \Omega_j, \\ T(u_j^{n+1},p,q,\tau) + \frac{\partial u_j^{n+1}}{\partial \mathbf{n}_{jl}} & = & T(u_l^n,p,q,\tau) + \frac{\partial u_l^n}{\partial \mathbf{n}_{jl}} & \text{on } \Gamma_{jl} \equiv \partial\Omega_j \cap \partial\Omega_l, \\ u_j^{n+1} & = & g(x,y) & \text{on } \partial\Omega_j \cap \partial\Omega, \end{array} \tag{4.7}$$

where $l \in \mathcal{N}(\Omega_j)$, which represents the set of integers containing the indices of the elements which are neighbors of Ω_j sharing a complete edge or a vertex, $\mathbf{n}_{jl}$ is a normal vector pointing from element Ω_j to element Ω_l along the boundary Γ_{jl}, and superscript n denotes the iterate of the Schwarz algorithm. After some manipulation, one step of the discrete optimized Schwarz algorithm for the spectral element discretization is to find u_j^{n+1} in $X_j^N \equiv \mathbb{P}_{N,J}^2 \cap H^1(\Omega_j) \cap H_0^1(\Omega)$ such that

$$\begin{aligned} a_j^h(u_j^{n+1}, \phi_j) + \sum_{l \in \mathcal{N}(\Omega_j)} \langle \phi_j, T(u_j^{n+1}, p, q, \tau) \rangle|_{\Gamma_{jl}} &= f_j^h(\phi_j) + \sum_{l \in \mathcal{N}(\Omega_j)} f_l^h(\phi_l|_{\Gamma_{jl}}) \\ - \sum_{l \in \mathcal{N}(\Omega_j)} a_l^h(u_l^n, \phi_l|_{\Gamma_{jl}}) + \sum_{l \in \mathcal{N}(\Omega_j)} \langle \phi_l, T(u_l^n, p, q, \tau) \rangle|_{\Gamma_{jl}} & \end{aligned} \tag{4.8}$$

for all ϕ_j in X_j^N. The bracket $\langle \cdot, \cdot \rangle|_{\Gamma_{jl}}$ is the discrete one-dimensional integral on an edge or vertex Γ_{jl} performed using the GLL quadrature, and $a_j^h(\cdot, \cdot)$ is identical to $a^h(\cdot, \cdot)$ with the exception that the sum is taken for element Ω_j only with the same convention for $f_j^h(\cdot)$. The notation $\phi_l|_{\Gamma_{jl}}$ denotes the trace of the test function on the edge Γ_{jl}, including end points, and $\phi_l|_{\Gamma_{jl}}(x) = \phi_j|_{\Gamma_{jl}}(x)$ since, at convergence, the functions must be in $H_0^1(\Omega)$; see [19], for example.

Remark 4. The vertex integrals are performed in the same way as their edge or surface counterparts except that the test function is nonzero only at the vertex point and zero at all other collocation points. Using the basis described in [8], such a test function for the vertex situated at $-(1,1)$, on the reference element, would be $h_0(r_1^j)h_0(r_2^j)$.

The proposed algorithm (4.8) is a relaxation of the assembly procedure at the heart of any finite element method. The following links to Lemma 3.2 can be established:

$$\underline{\phi}_j^T \tilde{A}_j \hat{R}_j \hat{\mathbf{u}} = a_j^h(\mathbf{u}_j, \underline{\phi}_j) + \sum_{l \in \mathcal{N}(\Omega_j)} \langle \underline{\phi}_j, T(\mathbf{u}_j, p, q, \tau) \rangle|_{\Gamma_{jl}}, \tag{4.9}$$

$$\underline{\phi}_j^T \sum_{l=1}^{J} \tilde{B}_{jl} \hat{R}_l \hat{\mathbf{u}} = - \sum_{l \in \mathcal{N}(\Omega_j)} a_l^h(\mathbf{u}_l, \underline{\phi}_l|_{\Gamma_{jl}}) + \sum_{l \in \mathcal{N}(\Omega_j)} \langle \underline{\phi}_l, T(\mathbf{u}_l, p, q, \tau) \rangle|_{\Gamma_{jl}}, \tag{4.10}$$

$$\underline{\phi}_j^T \hat{R}_j A \hat{\mathbf{u}} = a_j^h(\mathbf{u}_j, \underline{\phi}_j) + \sum_{l \in \mathcal{N}(\Omega_j)} a_l^h(\mathbf{u}_l, \underline{\phi}_l|_{\Gamma_{jl}}), \tag{4.11}$$

$$\underline{\phi}_j^T \hat{R}_j \hat{\mathbf{f}} = f_j^h(\underline{\phi}_j) + \sum_{l \in \mathcal{N}(\Omega_j)} f_l^h(\underline{\phi}_l|_{\Gamma_{jl}}) \tag{4.12}$$

for all $1 \le j \le J$ and vector $\underline{\phi}_j$ such that $\mathbf{u}_j = \hat{R}_j \hat{\mathbf{u}}$. Finally, the preconditioned system can be written as

$$\left(I - \sum_{j=1}^{J} \hat{R}_j^T \tilde{A}_j^{-1} \sum_{l=1}^{J} \tilde{B}_{jl} \hat{R}_l \right) \hat{\mathbf{u}} = \sum_{j=1}^{J} \hat{R}_j^T \tilde{A}_j^{-1} \hat{R}_j \hat{\mathbf{f}}. \tag{4.13}$$

Notice that no Lagrange multipliers were introduced to find the value of the normal derivative at corners as in [15]. Coerciveness must be ensured for each local problem. The coefficient $p = O(\sqrt{\eta})$, in the case of a zeroth-order Taylor approximation, can be too small for spectral elements. For a zeroth-order optimized p, this seems not to be a

problem. This was also observed in the case of locally discontinuous Galerkin approximations where good bounds on the penalty coefficient p are available for triangles of degree up to 8 (see [24], for instance).

In order to test the spectral element optimized Schwarz algorithm, the positive definite Helmholtz problem is solved with the C^∞ right-hand side

$$f(x,y) = (1 + 5\pi^2/4)\sin(\pi x + \pi/4)\sin(\pi y/2 + \pi/4). \tag{4.14}$$

The domain Ω is the rectangle $[0,2] \times [0,4]$. The solution is depicted in the top panel of Figure 4.4. In the case of GMRES, in the most favorable situation, one should expect the number of iterations to be proportional to the square root of the condition number of the preconditioned spectral element matrix $\kappa(M^{-1}A)$. The bottom panel of Figure 4.4 depicts the number of GMRES iterations with respect to the polynomial degree N. In all tests, a starting vector with random entries between $[0,1]$ was employed, which guarantees that all frequencies are contained in the error during the iteration, and is important when verifying asymptotics; see [9]. For a classical Schwarz preconditioner applied to the augmented system, the asymptotic behavior in the number of iterations reveals the expected growth in the condition number, namely, $\kappa(M_{AS}^{-1}A) = O(N^2)$; see, for instance, [31]. For the zeroth-order optimized Robin transmission condition, the convergence rate is $\kappa(M_{OO0}^{-1}A) = O(N)$, which is an order N better than that of the classical Schwarz or a substructuring method. The most dramatic gains are obtained when the second-order tangential derivatives are added to the transmission operator. A very slow growth in the condition number is observed: $\kappa(M_{OO2}^{-1}A) = O(\sqrt{N})$. This result is in agreement with the theory developed in [18]. In addition to the change in the asymptotic behavior, the number of iterations also decreases for a fixed polynomial degree and an increasingly sophisticated transmission operator.

The behavior of the algorithm with respect to the number of spectral elements, which equals the number of subdomains, is considered next. In the top panel of Figure 4.5, if the parameter η is kept fixed, then the number of iterations behaves like $O(H^{3/4})$, which is well within the limits established in [18]. However, if the parameter η is changed following the rule $O(JN^4)$, where J is the number of spectral elements in two dimensions and N is the polynomial degree, then the number of iterations is independent of both H and N (see bottom panel of Figure 4.5). This was observed by Cai in [2] for the classical Schwarz method and by Qin and Xu in [18] for optimized Schwarz methods in the general case.

The method was also tested in an atmospheric general circulation model (GCM). At each semi-implicit Eulerian time step, a positive definite Helmholtz problem must be solved (see [20]). The computational domain is the projection of a cube onto the surface of the sphere where the primitive equations are solved in a thin layer above the surface. Vertical acceleration is ignored due to the hydrostatic assumption. Details of the semi-implicit time discretization with spectral elements can be found in Thomas and Loft [30]. The vertical finite difference discretization results in a set of uncoupled positive definite Helmholtz problems where the parameter η in (4.1) depends on the vertical structure of the atmosphere. It should be noted that the problem stiffness increases with height above the surface due to the increasing linear gravity wave speeds. Here, the test proposed by Held and Suarez [13] is considered where an analytical solution is not available. In the experimental setup, a diabatic heating is prescribed together with a frictional forcing. This gives rise to climate simulations similar to those obtained with more complex physics; see Figure 4.6. The domain is partitioned into 6144 spectral elements, and each one of these elements is considered as

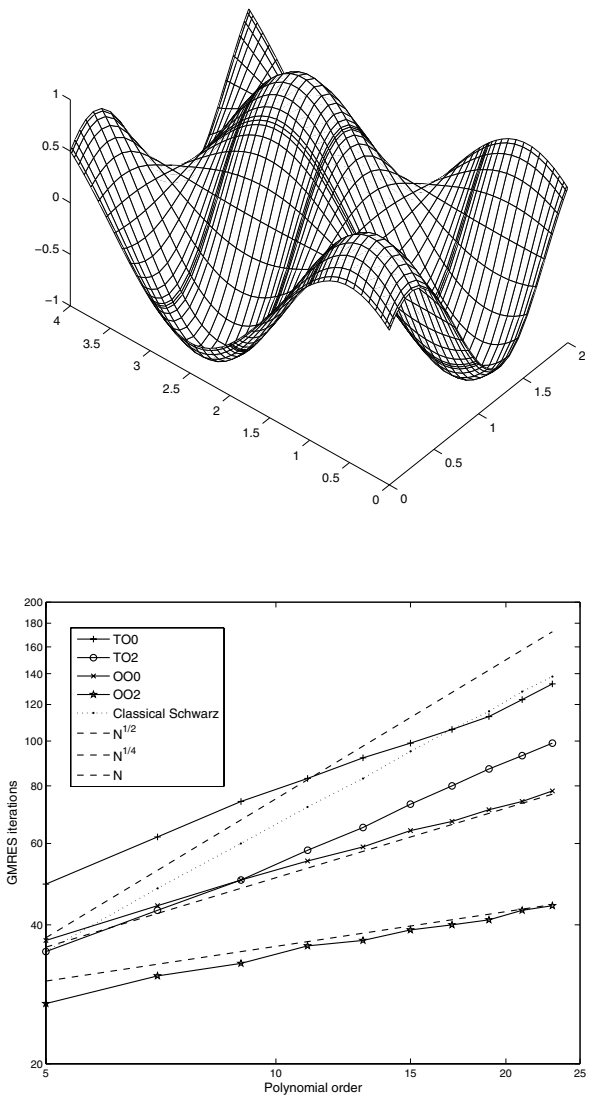

FIG. 4.4. *Top: spectral elements method (SEM) solution to the positive definite Helmholtz problem on a biperiodic domain for a C^∞ right-hand side, polynomial order* 15 *and* 8 *spectral elements. The expected asymptotic behavior of each preconditioner is also displayed.*

a subdomain in the optimized Schwarz algorithm. A fifth-order polynomial expansion is employed on each element. Parallel performance results obtained on the IBM Blue Gene machine are presented in Figure 4.7 and are shown to be competitive with the explicit time-stepping approach in terms of scaling. For integration rates of the model for various computer architectures, see [4] and [26]. The number of operations, or computational cost, in two dimensions, required to perform a preconditioned matrix vector multiplication behaves asymptotically like $O(JN^3)$ as compared to $O(JN^4)$

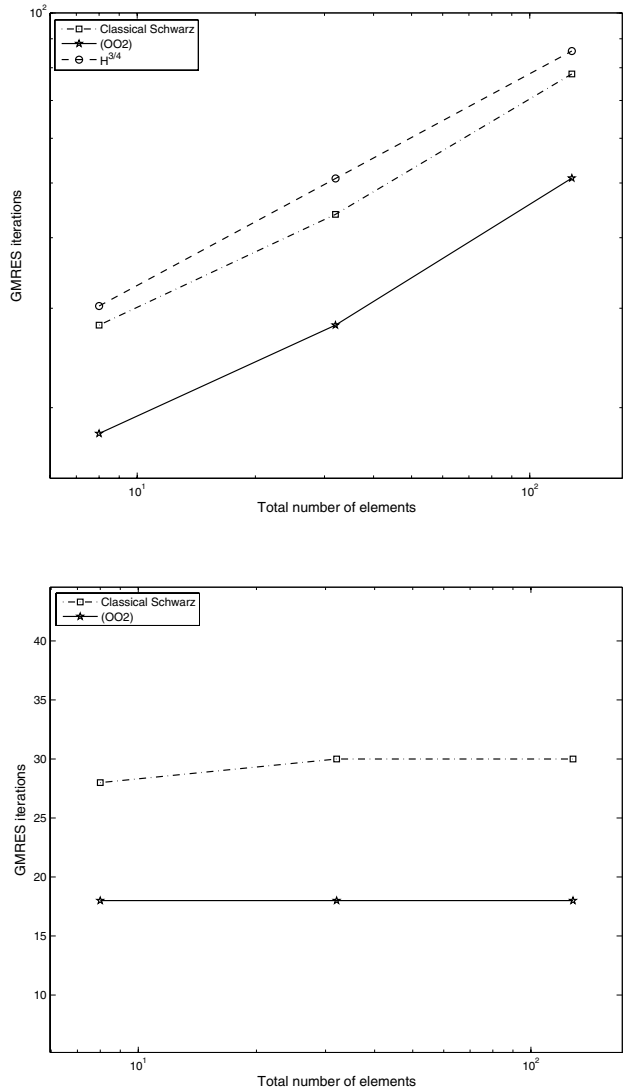

FIG. 4.5. *Top and bottom: number of GMRES iterations for classical Schwarz and optimized Schwarz (OO2) using polynomial degree $N = 5$ and a varying number of elements and no coarse solver. when a fast diagonalization method cannot be employed. The speedup of the explicit time stepping was scaled with respect to the semi-implicit one. For an overview of the machine, its two modes (coprocessor and virtual node), and techniques for optimizing the communication patterns, consult [1]. Note that the augmented system formulation enables one to store only $O(N^3)$ matrix entries per spectral element for application of the inverse instead of the $O(N^4)$ entries required in the case of an LU factorization. Since the L2 cache available on the Blue Gene machine is rather small (2KB), the savings are advantageous. No coarse solver is needed in the GCM.

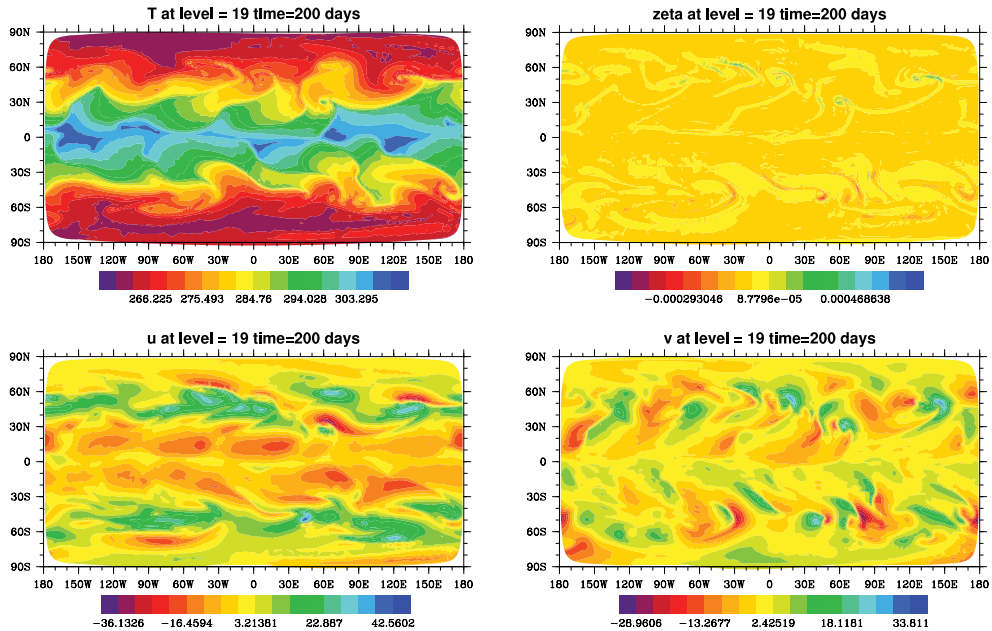

FIG. 4.6. *Held–Suarez test, temperature field, vorticity and velocities (latitudinal and longitudinal) at the surface of the planet after* 200 *days of simulation obtained with the spectral element general circulation model (GCM).*

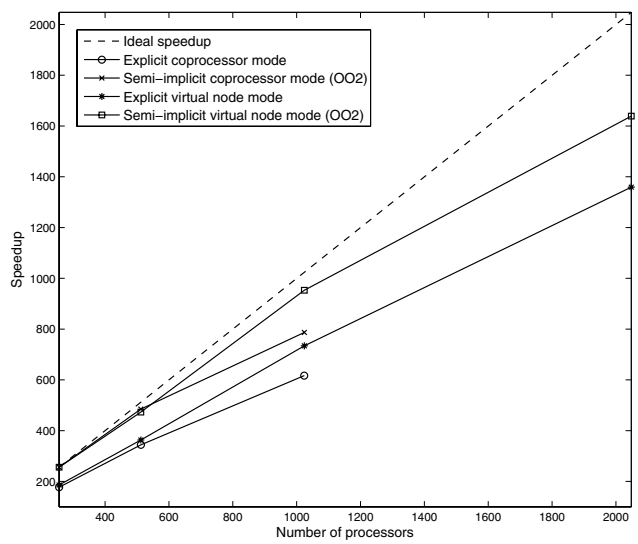

FIG. 4.7. *Speedup for the GCM on a single rack of the IBM Blue Gene machine for* 6144 *spectral elements,* 20 *vertical levels, and polynomial order* 5.

This is a consequence of the semi-implicit time discretization. The model time step is restricted by the advective Courant–Friedrichs–Levy condition which scales the parameter $\eta = \eta(\Delta t)$ as $O(JN^4)$. On massively parallel computers such as the Blue Gene machine, avoiding the coarse solve is of utmost importance. A quantification of how a coarse solver affects parallel performance on such machines can be found in [32].

5. Conclusion. Our presentation showed how the one-level RAS and MS algorithms can be modified to increase their respective convergence rates in the context of multiple domains. For the optimized restricted additive Schwarz algorithm, a condition on the overlap is required to produce optimized iterates. It was also shown how an augmented system can be constructed to generate optimized iterates for domains with nonoverlapping regions. Theoretical results were obtained at the algebraic level and are independent of the underlying spatial discretization. Finite difference and high-order spectral element examples document the simplicity and significant convergence acceleration. The augmented system is appropriate for high-order methods, where the construction of an overlapping grid is cumbersome and technically challenging. For zeroth-order optimized transmission conditions, the condition number of the preconditioned spectral element matrix is asymptotically N times better than the condition number resulting from a classical Schwarz method or a substructuring method with similar computational cost. For a second-order optimized transmission operator, the behavior with respect to the polynomial order confirms the asymptotic results found in [9, 18]. When the stiffness induced by η in the model equation is modified following the Eulerian semi-implicit GCM advective time-step restriction, all block preconditioners are optimal with respect to H refinement, thus alleviating the use of a coarse solver. Regardless, the second-order optimized Schwarz approach yields the smallest number of iterations. Application of the method to a spectral element climate model results in a significant reduction of the computing time, demonstrating the practicality of the theoretical results. It is conjectured that more realistic subgrid scale physical forcing will result in a much broader range of unresolved frequencies, in which case the optimized algorithm will be the method of choice.

ON RESTART AND ERROR ESTIMATION FOR KRYLOV APPROXIMATION OF $w = f(A)v$*

HILLEL TAL-EZER†

Abstract. Krylov algorithms are widely used for the solution of large scale linear systems. A Krylov approach is implemented also for the approximation of the vector w which results from operating with a function of a matrix on a vector v. For example, when solving a set of linear ODEs we have $w = f(A)v$, where $f(z) = \exp(tz)$. The main drawback of the Krylov algorithm lies in the need to store all the vectors spanning the approximation space. When solving linear systems, it is possible to overcome this drawback by restarting. In this paper we show how to apply restarts in the general case of approximating $w = f(A)v$. This new algorithm allows a much more efficient approximation of the exponential operator than the standard Krylov algorithm, and it is especially useful in the case of functions which cannot be factored into a product of functions. Yet another interesting subject is the error estimate. The scheme given here provides error estimates "for free," a trait which enables us to stop the algorithm whenever the desired accuracy is achieved.

1. Introduction.

Let us assume that A is a square matrix of a large dimension N. The need to approximate a vector w which satisfies

$$w = f(A)v \tag{1.1}$$

may be encountered in diverse ways. The solution of ODEs, for example, entails $U = f(A)U^0$, where $f(z) = \exp(zt)$ in the homogeneous case, and where $f(z) = (\exp(zt) - 1)/z$ in the nonhomogeneous case. In the case of a one-way wave equation, for example, we have $U = f(A)U^0$, while $f(z) = \exp(\alpha\sqrt{z})$. Even the basic problem of solving the linear system $Ax = b$ stems from this family, since the solution vector is $x = f(A)b$, whereas $f(z) = z^{-1}$. Extensive research has been carried out in this field. There are two main approaches:

1. Algorithms based on a polynomial approximation of $f(z)$ in domain D of the complex plane, which includes all the eigenvalues of A [1], [8], [9], [21], [22];

2. Algorithms based on the projection of the problem onto the Krylov space: $Kr = \mathrm{Span}\{v, Av, \ldots, A^{m-1}v\}$ [3], [7], [14], [25].

Each of these two approaches has both advantages and disadvantages. In fact, one may even say that the advantage of one is the disadvantage of the other. The main benefits of the Krylov algorithm are as follows: It does not require knowledge on the domain of eigenvalues, and the algorithm is capable of adjusting itself to the information contained in the vector v. These two qualities combine to make the algorithm highly efficient and robust. On the other hand, its main drawback lies in the need to store all the vectors spanning the Krylov space. When dealing with a large domain of eigenvalues and/or when $f(z)$ is characterized by large gradients, the Krylov space will be of considerable size as well, so that we might not have sufficient memory

to store the basis vectors. Yet another drawback typical of a large Krylov space lies in the fact that the number of scalar products is proportional to m^2, where m is the dimension of this particular space. In the case of a large m, the CPU time needed to compute the scalar products might be significant. When applying the Krylov algorithm to linear systems $Ax = b$, it is still possible to implement Krylov space of small dimension through the use of restarts. The application of a Krylov algorithm of dimension m leads to the approximated solution vector x_m. If the solution does not meet the required accuracy, we may employ yet another Krylov algorithm, solving $A(x - x_m) = b - b_m$. Using restart for the approximation of $w = f(A)$ is not as straightforward a process as in the case of linear systems. This general problem is dealt with in this paper through the development of a restarted Krylov algorithm.

Another important issue relates to the need to find a good and yet relatively cheap error estimate, which will enable us to stop the algorithm when the desired accuracy is reached. This issue will be addressed too.

The paper is organized as follows. Section 2 provides a short description of the Krylov algorithm. In [14] it is shown that the Krylov approach can be regarded as an interpolating polynomial approach, whereby the interpolating points are eigenvalues of a small matrix H_m, resulting from the restriction of A on the Krylov space. Based on this observation, section 3 includes an algorithm for the approximation of $w = f(A)v$ through the use of restarts. Section 4 provides a simple expression of the error estimate. A byproduct of the research described in this paper is a modified algorithm applicable to the standard, nonrestarted algorithm. In [14] there is a corrected scheme which enlarges the approximation subspace by using the vector v_{m+1} (produced by the Krylov algorithm). Unlike the standard case, it allows the solution in the Krylov space of dimension $m + 1$, rather than of m, without necessitating any additional matrix-vector multiplication. It is shown that the resulting w_{m+1} satisfies $w_{m+1} = P_m(A)v$, where $P_m(z)$ interpolates $\exp(z)$ at $\{\lambda_1, \ldots, \lambda_m, 0\}$ while $\lambda_1, \ldots, \lambda_m$ are the eigenvalues of H_m. This method is in turn generalized to allow the development of a modified algorithm which results in $w_{m+1} = P_m(A)v$, where $P_m(z)$ interpolates $f(z)$ at $\{\lambda_1, \ldots, \lambda_m, \lambda\}$ and λ is subsequently chosen optimally. The modified algorithm is described in section 5. We conclude the paper with the numerical results given in section 6.

The restarted algorithm presented in this paper is based on the Arnoldi approach. As in the case of linear systems, one can also develop an algorithm based on the Lanczos approach. The main advantage of the Lanczos approach lies in the fact that there is absolutely no need to restart. On the other hand, in this case one has to be aware of the hazard of losing orthogonality. Yet another disadvantage stems from the need to operate with the transpose of the operator unless some modifications are done as in the transpose-free algorithms. These issues will be addressed in a future paper.

2. Krylov algorithm. We want to approximate w, where

$$w = f(A)v. \tag{2.1}$$

First we build an orthonormal basis of the Krylov space

$$K_m = \mathrm{Span}\{v, Av, \ldots, A^{m-1}v\} \tag{2.2}$$

by applying modified Gram–Schmidt orthogonalization (Arnoldi).

ARNOLDI ALGORITHM.

$\beta = ||v||_2,\ v_1 = \frac{1}{\beta}v.$
for $j = 1 : m$
  $v_{j+1} = Av_j$
  for $i = 1 : j$
    $h_{i,j} = v_i^H v_{j+1}$
    $v_{j+1} = v_{j+1} - h_{i,j}v_i$
  end
  $h_{j+1,j} = ||v_{j+1}||_2$
  if $h_{j+1,j} == 0$
    $m = j$ break
  end
  $v_{j+1} = \frac{1}{h_{j+1,j}}v_{j+1}$
end

If V is an $N \times m$ matrix whose columns are $v_1, \ldots, v_m$ (the orthonormal basis vectors of K_m), we have

$$AV = VH_m + h_{m+1,m}v_{m+1}e_m^H. \tag{2.3}$$

Hence

$$H_m = V^H AV. \tag{2.4}$$

H_m is actually the matrix restriction of A on K_m. Using a Krylov method means that we project the original problem onto the subspace K_m and solve it exactly there. Since $v = \beta V e_1$, we have

$$V^H w = V^H f(A)v = \beta V^H f(A)Ve_1 \approx \beta f(H_m)e_1. \tag{2.5}$$

Defining w_m as

$$w_m = \beta V f(H_m)e_1, \tag{2.6}$$

we get that

$$w_m \approx VV^H w, \tag{2.7}$$

where $VV^H w$ is the projection of w on K_m.

Since m is much smaller than N (the dimension of A), the CPU time needed to compute $f(H_m)e_1$ is negligible. A possible stable algorithm for computing $y = f(H_m)e_1$ can be based on the identity $f(H_m) = P_{m-1}(H_m)$, where the polynomial

$$P_{m-1}(z) = a_1 + a_2(z - \lambda_1) + \cdots + a_m(z - \lambda_1)\cdots(z - \lambda_{m-1}) \tag{2.8}$$

interpolates $f(z)$ at $\lambda_1, \ldots, \lambda_m$, the eigenvalues of H_m. Using Horner's scheme, we get

$y = a_m e_1$
for $i = m - 1 : -1 : 1$
  $y = a_i + (H_m - \lambda_i I)\, y$
end

(If m is large, it is recommended that one stabilize the algorithm by using Leja ordering of the interpolating points [13].)

Here is the Krylov algorithm for approximating $w = f(A)v$ in a space of dimension m.

KRYLOV ALGORITHM.

$\beta = ||v||_2,\ v_1 = \frac{1}{\beta}v.$
for $j = 1 : m$
  $v_{j+1} = Av_j$
  for $i = 1 : j$
    $h_{i,j} = v_i^H v_{j+1}$
    $v_{j+1} = v_{j+1} - h_{i,j}v_i$
  end
  $h_{j+1,j} = ||v_{j+1}||_2$
  if $h_{j+1,j} == 0$
    $m = j$ break
  end
  $v_{j+1} = \frac{1}{h_{j+1,j}}v_{j+1}$
end
$H_m = h(1 : m, 1 : m),\ y = \beta f(H_m)e_1$
$w_m = V(:, 1 : m)y$

Saad has proved in [14] (for $f(z) = \exp(z)$) that w_m satisfies

$$w_m = P_{m-1}(A)v, \tag{2.9}$$

where $P_{m-1}(z)$ is the unique polynomial of degree $m-1$ which interpolates $f(z)$ at the eigenvalues of H_m (if an eigenvalue λ has multiplicity k, then $P_{m-1}^{(i)}(\lambda) = f^{(i)}(\lambda),\ \ i = 0, \ldots, k-1$). The theorem and proof hold for any function $f(z)$ analytic in an open set which contains the spectrum of A and H_m. Based on the equivalence of Krylov and polynomial algorithms, we have developed a restarted algorithm as well as an easily computed error estimate, both of which are described in sections 3 and 4, respectively.

3. Restart. As mentioned above, when the domain of eigenvalues is large and/or whenever $f(z)$ has large gradients, the size of the Krylov space required for a good approximation will also be considerable, so that at times we might not have enough memory to store the basis vectors. In addition, the number of scalar products which is proportional to the square of the dimension of the Krylov domain can result in significant CPU times. We shall now describe a restarted algorithm, which allows a cyclical application of the basic Krylov algorithm. Each cycle (restart) uses a Krylov space of dimension m.

Let us assume that $p_{m-1}(z)$ is the polynomial which interpolates $f(z)$ at $z_1, \ldots, z_m$. The use of Newton representation leads to the following expression of the error:

$$E(z) = f(z) - p_{m-1}(z) = f[z_1, \ldots, z_m, z]r_m(z), \tag{3.1}$$

where $f[z_1, \ldots, z_m, z]$ is the divided differences whose recursive definition is

$f[z_1, z] = \frac{f(z)-f(z_1)}{z-z_1}$
for $k = 1 : m - 1$
  $f[z_1, \ldots, z_{k+1}, z] = \frac{f[z_1,\ldots,z_k,z]-f[z_1,\ldots,z_{k+1}]}{z-z_{k+1}}$
end

and $r_m(z) = \prod_{i=1}^{m}(z - z_i)$.

Hence, approximating w by w_m results in

$$e_m = w - w_m = f(A)v - p_{m-1}(A)v = g(A)r, \tag{3.2}$$

where

$$g(z) = f[z_1, \ldots, z_m, z] \tag{3.3}$$

and

$$r = r_m(A)v = \prod_{i=1}^{m}(A - z_i I)\, v. \tag{3.4}$$

In the appendix we prove that in the case of an analytic function $f(z)$, $g(z)$ is analytic too. When the interpolation points are the eigenvalues of H_m, it is known (see, for example, Exercise 6.8 on p. 216 of [16]) that the vector r given above is parallel to v_{m+1} and satisfies

$$r = \alpha v_{m+1}, \tag{3.5}$$

where

$$\alpha = ||v||_2 h_{m+1,m} q_m \tag{3.6}$$

and q_m is the last element of the first column of $r_m(H_m)$. Hence, (3.2) means that

$$w = w_m + g(A)r, \tag{3.7}$$

where

$$g(z) = f[\lambda_1, \ldots, \lambda_m, z] \tag{3.8}$$

and

$$r = \alpha v_{m+1}. \tag{3.9}$$

Restarted Krylov is based on the concept that if the result is not accurate enough (approximating the accuracy is described in the next section), we continue by applying the Krylov algorithm to allow the approximation of $g(A)r$. Restarting the Krylov algorithm with a Krylov space of dimension m means that each restart is marked by a different function $g(z)$. The functions can be defined recursively as

$$g_1(z) = f(z), \tag{3.10}$$

$$g_{k+1}(z) = g_k[\lambda_1^k, \ldots, \lambda_m^k, z], \qquad k \geq 1, \tag{3.11}$$

where $f(z)$ is the original function and $\lambda_1^k, \ldots, \lambda_m^k$ are the eigenvalues of H_m^k (the matrix restriction of A on the Krylov space at the kth restart). Based on Lemma 3 given in the appendix, $g_k(z)$ is an analytic function.

Below is a recursive MATLAB routine which computes $y = g_k(z)$. Here zp is a two dimensional matrix whose kth column holds the m eigenvalues of H_m at the

$(k-1)$th restart. Similarly, wp is a two dimensional matrix whose kth column holds the values of g_k at the kth column of zp.

```
function y = g(z, k)
global zp, wp
if k == 0
    y = f(z)
    return
end
zp_0 = zp(:, k)
wp_0 = wp(:, k)
m = length(zp_0)
zp_0(m + 1) = z
wp_0(m + 1) = g(z, k − 1)
for j = m : −1 : 1
    wp_0(j, 1) = (wp_0(j + 1) − wp_0(j))/(zp_0(m + 1) − zp_0(j))
end
y = wp_0(1)
```

Observe that, computing $g_k(z)$, we do one computation of $g_{k-1}(z)$ and m divisions. Hence, by induction on k, we get that computing the value of $g_k(z)$ at one interpolating point involves one computation of $f(z)$ and $k \times m$ divisions. Thus, for practical problems where $m \ll N$, the CPU time devoted to this part of the computation is insignificant.

For a given tolerance (tol), maximal Krylov dimension (m), and maximal number of restarts (maxrstrt), the formal restarted algorithm for approximating $w = f(A)v$ is the following.

RESTARTED KRYLOV ALGORITHM.

```
r_1 = v, w = 0, g_0 = f
for k = 1 : maxrstrt
    [u_{k+1}, r_{k+1}, flag] = Krylov (r_k, m, g_{k−1}, tol)
    w = w + u_{k+1}
    if flag == 1
        break
    end
    tol = tol||w||_2
    g_k(z) =def g_{k−1}[λ_1^{k−1}, ..., λ_m^{k−1}, z]
end
```

where r_{k+1} computed by the Krylov algorithm satisfies

$$r_{k+1} = ||r_k||_2 h^k_{m+1,m} q^k_m v^k_{m+1} \tag{3.12}$$

and $flag$ is a parameter which accepts the value 1 when the Krylov algorithm has achieved the desired accuracy. (A Krylov algorithm with error estimate is described in the next section.)

The formal solution of linear system $Ax = b$ is $x = f(A)b$, where $f(z) = z^{-1}$. It can be shown that the application of the restarted Krylov algorithm described above to this function is equivalent to the FOM (full orthogonal method) algorithm [15]. It is well known that restarted FOM, similar to restarted GMRES [17], can exhibit slow

convergence or complete stagnation. This problem (mainly for the GMRES case) was addressed by many researchers in an attempt to provide theoretical explanations and to come up with valid modifications which would allow this hurdle to be overcome. Morgan [11] suggested modifying the restarted algorithm through the deflation of small eigenvalues, using the thick restarting technique developed by Wu and Simon [27]. In another paper [10] Morgan suggests retaining information during the move from one restart to another, by using the implicit Arnoldi methodology developed by Sorensen [20]. Embree [5] provides detailed analysis of the stagnation phenomenon and disproves the common belief that a larger Krylov space leads to faster convergence. This, in turn, gives rise to a very important issue, namely, what is the optimal size of a Krylov space. Zhang and Nodera address this subject in [28]. The source of the stagnation phenomenon can be traced to the singularity of the function $f(z) = z^{-1}$ at $z = 0$. If, for small $\varepsilon > 0$, the ε-pseudospectrum [2] of A contains the singular point, then stagnation is quite probable. Consequently, similar difficulties might arise following the application of the new algorithm to functions having singularities. The concepts discussed in the above-mentioned papers might be useful in these cases. On the other hand, when $f(z)$ is an analytic function, we would not face stagnation.

A widely known example of using the polynomial approximation of a function of a matrix is the numerical solution of a system of ODEs,

$$U_t = GU, \qquad U(t=0) = U^0. \tag{3.13}$$

The formal solution at $t = T$ is

$$U(T) = f(G)U^0, \tag{3.14}$$

where $f(z) = e^{zT}$. The implementation of a Krylov approach for the purpose of approximating the matrix exponential is described and analyzed in many papers, e.g., [6], [7], [14], [19], [23], [24]. In this case $f(z)$ is an analytic function. The approximation of $U(T)$ for large T through a Krylov algorithm which is marked by a restricted size m means that we have to split the time domain into time steps of size Δt. We get

$$U(t + \Delta t) = f(G)U(t), \tag{3.15}$$

where $f(z) = e^{z\Delta t}$. By choosing a Δt which is small enough, the domain of eigenvalues of the matrix $\Delta t G$ remains small, and the Krylov algorithm which utilizes space of small size m can be accurate. The parameters m and Δt control this accuracy. Usually, m is dictated by memory limitations, and Δt is chosen in accordance with the accuracy requirements.

When using the algorithm described in this paper for the approximation of the matrix exponential operation, we do not split the time domain into time steps. The following lemma shows that the implementation of the new algorithm is equivalent to the approximation of the evolution operator by one large degree polynomial which interpolates the exponential function at the union of points produced by the algorithm.

LEMMA 1. *Interpolating $f(z)$ at $z_1^{(1)}, \ldots, z_m^{(1)}$, we have*

$$f(z) = p_{m-1}^{(1)}(z) + g_1(z)(z - z_1^{(1)}) \ldots (z - z_m^{(1)}), \tag{3.16}$$

where

$$g_1(z) = f[z_1^{(1)}, \ldots z_m^{(1)}, z]. \tag{3.17}$$

Interpolating $g_1(z)$ *at* $z_1^{(2)}, \ldots, z_k^{(2)}$, *we have*

$$g_1(z) = p_{k-1}^{(2)}(z) + g_2(z)(z - z_1^{(2)}) \ldots (z - z_k^{(2),}), \tag{3.18}$$

where

$$g_2(z) = g_1[z_1^{(2)}, \ldots z_k^{(2)}, z]. \tag{3.19}$$

Let $w = f(A)v$. *Approximating* w *by* $w_m^{(1)} + w_k^{(2)}$, *where*

$$w_m^{(1)} = p_{m-1}^{(1)}(A)v, \qquad w_k^{(2)} = p_{k-1}^{(2)}(A)r_1 \tag{3.20}$$

while

$$r_1 = (A - z_1^{(1)} I) \ldots (A - z_m^{(1)} I)v, \tag{3.21}$$

is identical to approximating w *by*

$$w_{m+k} = p_{m+k-1}(A)v, \tag{3.22}$$

where the polynomial $p_{m+k-1}(z)$ *interpolates* $f(z)$ *at* $z_1^{(1)}, \ldots z_m^{(1)}, z_1^{(2)}, \ldots, z_k^{(2)}$.

Proof. We have

$$w_m^{(1)} + w_k^{(2)} = p_{m-1}^{(1)}(A)v + p_{k-1}^{(2)}(A)r_1. \tag{3.23}$$

Since $r_1 = (A - z_1^{(1)} I) \ldots (A - z_m^{(1)} I)v$ we get

$$w_m^{(1)} + w_k^{(2)} = p_{m+k-1}(A)v, \tag{3.24}$$

where $p_{m+k-1}(z) = p_{m-1}^{(1)}(z) + p_{k-1}^{(2)}(z)(z - z_1^{(1)}) \ldots (z - z_m^{(1)})$. Hence

$$p_{m+k-1}(z_i^{(1)}) = p_{m-1}^{(1)}(z_i^{(1)}) = f(z_i^{(1)}), \qquad i = 1, \ldots, m. \tag{3.25}$$

It is left to show that

$$p_{m+k-1}(z_i^{(2)}) = f(z_i^{(2)}), \qquad i = 1, \ldots, k. \tag{3.26}$$

Using (3.16), we have

$$g_1(z) = \frac{f(z) - p_{m-1}^{(1)}(z)}{(z - z_1^{(1)}) \ldots (z - z_m^{(1)})}. \tag{3.27}$$

Since $p_{k-1}^{(2)}(z)$ interpolates $g_1(z)$ at $z_1^{(2)}, \ldots, z_k^{(2)}$ we get

$$p_{k-1}^{(2)}(z_i^{(2)}) = \frac{f(z_i^{(2)}) - p_{m-1}^{(1)}(z_i^{(2)})}{(z_i^{(2)} - z_1^{(1)}) \ldots (z_i^{(2)} - z_m^{(1)})}, \qquad i = 1, \ldots, k, \tag{3.28}$$

which results in

$$p_{m-1}^{(1)}(z_i^{(2)}) + p_{k-1}^{(2)}(z_i^{(2)})(z_i^{(2)} - z_1^{(1)}) \ldots (z_i^{(2)} - z_m^{(1)}) = f(z_i^{(2)}), \tag{3.29}$$

$$i = 1, \ldots, k.$$

Hence

$$p_{m+k-1}(z_i^{(2)}) = f(z_i^{(2)}), \qquad i = 1, \ldots, k, \tag{3.30}$$

and the proof is concluded.

The above lemma shows the main difference between the restarted Krylov and the standard marching algorithm (an algorithm where the time domain is cut into time intervals and at each interval we use the Krylov algorithm to compute the solution at the next time step). At each step of the restarted Krylov the interpolating points are considered optimal (in the Arnoldi sense) with regard to the error vector. Hence, the union of points will be distributed across the domain at each step, as obligated by the Arnoldi optimization. On the other hand, when applying the Krylov algorithm at each step of the standard marching algorithm, the interpolating points are considered optimal with respect to the converged solution vector. In this case, the union of points will be more localized. Let us assume now that for each algorithm we have computed an approximation to $\exp(TA)v$ by making M matrix-vector multiplications. The application of a restarted Krylov routine means that we have approximated the evolution operator by $P_M(A)v$, where $P_M(z)$ interpolates $\exp(Tz)$ at a set of points distributed all over the domain. The use of k steps in the marching algorithm, while each time applying a polynomial of degree m, means that$P_M(z) = \Pi_{i=1}^{k} P_m^{(i)}(z)$. In this case, $P_M(z)$ interpolates $\exp(Tz)$ at a localized set of points. In general, the set of points inherent in the restarted Krylov will result in a much more accurate interpolating polynomial. Alternatively, for a given tolerance we will need a lesser number of matrix-vector multiplications. The numerical results presented in section 5 demonstrate the high efficiency of the new algorithm within the overall approximation of the exponential operator.

The approximation of the evolution operator by cutting the time domain into time steps is based on the property of the exponential function

$$\exp(Tz) = (\exp(\Delta t z))^n \qquad (T = n\Delta t). \tag{3.31}$$

However, not every function features this useful property. When the domain of eigenvalues is large and/or when $f(z)$ has large gradients, using a standard Krylov algorithm requires a Krylov space of large dimensions, which may result in an exceedingly large demand on memory. Moreover, since the number of inner products is proportional to the square of the Krylov dimension, it can lead to huge computational demands. The algorithm described in this paper is particularly useful for these kind of functions.

4. Accuracy. Approximating $w = f(A)v$ by $w_m = p_{m-1}(A)v$, we have (3.2),

$$e_m = w - w_m = g(A)r, \tag{4.1}$$

where $g(z) = f[z_1, \ldots, z_m, z]$. Since $r = ||v||_2 h_{m+1,m} q_m v_{m+1}$ we get (for normal matrix A) that the relative error satisfies

$$\frac{||w - w_m||_2}{||w_m||_2} \leq \frac{||v||_2}{||w_m||_2} h_{m+1,m} |q_m| \max_{z \in D} |g(z)|, \tag{4.2}$$

where D is the domain of eigenvalues. Since, in general, the domain D is not known, we will approximate $\max_{z \in D} |g(z)|$ by $\max_{z \in Z} |g(z)|$, where Z is a large set of points distributed across D. Let us describe now a possible way to create the set Z. When

using the Krylov algorithm we create the matrices $\{H_j\}_{j=1}^m$ which are the restrictions of the matrix A on the subspaces $V_j = \text{Span}\{v, Av, \ldots, A^{j-1}v\}$. The eigenvalues of H_j are known as Ritz values [12]. We can take Z as the union of these sets of eigenvalues.

Below is the Krylov algorithm with error estimate applied.

KRYLOV ALGORITHM + ERROR ESTIMATE.

$\beta = ||v||_2,\ v_1 = \frac{1}{\beta}v,\ Z = \{\},$ given tol, maxit
for $j = 1 : \text{maxit}$
  $v_{j+1} = Av_j$
  for $i = 1 : j$
    $h_{i,j} = v_i^H v_{j+1}$
    $v_{j+1} = v_{j+1} - h_{i,j}v_i$
  end
  $h_{j+1,j} = ||v_{j+1}||_2$
  $v_{j+1} = v_{j+1}/h_{j+1,j}$
  $H = h(1 : j, 1 : j)$
  $[U, \lambda] = \text{eig}(H)$
  $Z = Z \cup \text{diag}(\lambda)$
  $y = g_j(H)e_1$ (g_j are defined in (3.11))
  $q = (r_j(H))_{j1}$, $\bar{g} = \max_{z \in Z} |g_j(z)|$
  $e = \beta h_{j+1,j}|q|\bar{g}/||y||_2$
  if $e \leq$ tol
    $w = \beta V(:, 1 : j)y$
    break
  end
end

In the algorithm above we have to compute the vector $y = g_j(H)e_1$ and the scalar $q = r_j(H)_{j1}$. y can be computed by a Horner scheme applied to the interpolating polynomial (2.8), and for the scalar q we can do the following:

$u = [1, 0, \ldots, 0]^H$
for $i = 1 : j - 1$
  $u = Hu - \lambda_{ii}u$
end
$q = u(j)$

In the case of a large degree polynomial r_j, it might be a good idea to stabilize the algorithm described above by implementing Leja ordering [13] on the set of λ_{ii}. The error estimate given above is based on the assumption that the matrix is normal. When the matrix is close to normal, one can account for the nonnormality by changing the expression for e to

$$e = \beta h_{j+1,j}|q|\bar{g}||U||_2||U^{-1}||_2/||y||_2. \tag{4.3}$$

This error estimate is not valid for highly nonnormal matrices.

5. Modified algorithm. As a byproduct of the research on the restarted algorithm, we have developed a modified algorithm which is applicable in the nonrestarted case.

Interpolating $f(z)$ at $\lambda_1, \ldots, \lambda_m$ results in

$$f(z) = P_{m-1}(z) + f[\lambda_1, \ldots, \lambda_m, z] \prod_{j=1}^{m} (z - \lambda_j)\,. \tag{5.1}$$

Adding another interpolating point λ, we have

$$f(z) = P_{m-1}(z) + f[\lambda_1, \ldots, \lambda_m, \lambda] \prod_{j=1}^{m} (z - \lambda_j) \tag{5.2}$$

$$+ f[\lambda_1, \ldots, \lambda_m, \lambda, z]\,(z - \lambda) \prod_{j=1}^{m} (z - \lambda_j)\,.$$

Since

$$w = f(A)v, \qquad w_m = P_{m-1}(A)v, \qquad r = \prod_{j=1}^{m} (A - \lambda_j I)\, v, \tag{5.3}$$

we get

$$w = w_m + f[\lambda_1, \ldots, \lambda_m, \lambda]r + f[\lambda_1, \ldots, \lambda_m, \lambda, A]\,(A - \lambda I)\, r. \tag{5.4}$$

Hence, using (3.9), we can get an improved approximation without any additional matrix-vector operation:

$$w_{m+1} = w_m + \gamma v_{m+1}, \tag{5.5}$$

where

$$\gamma = ||v||_2 h_{m+1,m} q_m f[\lambda_1, \ldots, \lambda_m, \lambda]. \tag{5.6}$$

The idea is to choose λ in some optimal way. In the numerical examples presented in the next section we took

$$\lambda = \min_{z \in Z} \mid f[\lambda_1, \ldots, \lambda_m, z] \mid, \tag{5.7}$$

where Z is the union all the eigenvalues of the matrices $\{H_j\}_{j=1}^{m}$ created in the Krylov algorithm.

The modification described here is applicable only to a restart-free Krylov algorithm, since in the case of the restarted algorithm we employ the vector r. The gain is particularly significant when the Krylov space is of low dimension. As for the error, when estimating it through the last term in (5.4) we have to carry out yet another matrix-vector operation, and there will be no subsequent gain in the modification. Thus we have to settle for the nonmodified estimate (4.2). In general it will be a pessimistic one.

6. Numerical results.

6.1. Restart. In the first example we used the new restarted algorithm to approximate $w = f(A)v$, where $f(z) = \sin(\cos(2z))$, $v = [1, \ldots, 1]^H$, and A is a 500×500 Toeplitz matrix whose elements are

$$A_{ij} = \begin{cases} -1, & j = i - 1, \\ 1, & 0 \le j - i \le 5. \end{cases}$$

The dimension of the Krylov space was 10. The results obtained following each restart are given in Table 1, where

$$\text{Err} = \frac{||w - w_m||_2}{||w||_2} \tag{6.1}$$

and w_m is the approximated solution.

Since we have used Krylov space of dimension 10, a total number of 40 matrix-vector multiplications was needed in order to achieve relative accuracy of $3.4623e-010$. The following example demonstrates the efficiency of the restarted algorithm when applied to the evolution operator. Approximating $w = \exp(tA)v$ by a standard Krylov algorithm, as described in [14] for example, means that we have to split the time domain into time steps. The size of the time step is dictated by the number of Krylov vectors which may be stored in memory. We selected the ORANI678 example given in Expokit [18]. In this example we solve for $U = \exp(tA)U^0$, where A is a nonsymmetric matrix of size 2529×2529 taken from an economic model of Australia. We took $U^0 = [1, 1, \ldots, 1]^H$ and $t = 5$. The results are given in Table 2, where m is the size of the Krylov space and the two columns give the total number of matrix-vector multiplications. The desired accuracy was $5.E-8$.

Observe that the total number of matrix-vector multiplications, in the restarted case, remains almost the same when we change the size of the Krylov space. This means that in each case, the union of Ritz values has a similar quality as a set of interpolating points.

6.2. Error estimate.
Example 2. Let $w = f(A)v$, where $f(z) = \exp(z)\sin(z)$, $v = [1, \ldots, 1]^H$, and

$$A_{i,j} = \begin{cases} -2, & i = j, \\ 1, & |i-j| = 1, \\ 0, & \text{else.} \end{cases}$$

Let $N = 300$ be the dimension of A and m the dimension of the Krylov space. Results for different m are given in Table 3, where

$$\text{Exact} = \frac{||w - w_m||_2}{||w_m||_2}, \qquad \text{Estim} = \frac{||v||_2}{||w_m||_2} \max_{z \in Z} |g(z)| h_{m+1,m} |q_m|, \tag{6.2}$$

Z is the set of Ritz values, and $g(z) = f[\lambda_1, \ldots, \lambda_m, z]$. The next experiment is the same as the previous one except for the matrix. We have created a random normal matrix whose eigenvalues are randomly spread in the square $0 \le \mathrm{Re}(z) \le 1$, $0 \le \mathrm{Im}(z) \le 1$. The results are given in Table 4.

These two examples clearly demonstrate that, for normal matrices, the error estimate is close to the true error.

6.3. Modified algorithm. Once again we took a random normal matrix with $N = 300$. The function is $f(z) = \sin(2z)$, and the initial data $v = [1, \ldots, 1]^H$. In Table 5 we present the relative error for the original and modified schemes for different values of m (the dimension of the Krylov space).

Conclusions. In this paper we have presented a new algorithm for the polynomial approximation of a vector w which satisfies $w = f(A)v$, where $f(z)$ is an analytic function in a domain D, A is a linear operator, and v is a given vector. This problem is typical of various fields of applied mathematics. The new algorithm utilizes a restart technique similar to the one which constitutes a basic ingredient in many iterative algorithms used for solving linear systems. The numerical results presented

in the paper demonstrate the high efficiency of the algorithm in terms of CPU time and memory.

Appendix.

LEMMA 3. *Let $f(z)$ be an analytic function in D. Let $g(z)$ be the divided differences function*

$$g(z) = f[z_1, \ldots, z_n, z], \qquad z_k \in D; \tag{A.1}$$

then $g(z)$ is analytic in D.

Proof. Define

$$g^i(z) = f[z^i, z], \tag{A.2}$$

where z^i is any subset of i points from $z_1, \ldots, z_n$. We will prove the lemma by induction on i. Let us show first that $g^1(z)$ is analytic. Without loss of generality we assume that $z^1 = z_1$.

Hence

$$g^1(z) = \begin{cases} \frac{f(z)-f(z_1)}{z-z_1}, & z \neq z_1, \\ f'(z_1), & z = z_1. \end{cases}$$

Since $f(z)$ is analytic, we have

$$f(z) = \sum_{j=0}^{\infty} \frac{f^{(j)}(z_1)}{j!}(z - z_1)^j. \tag{A.3}$$

Thus

$$g^1(z) = \sum_{j=0}^{\infty} \frac{f^{(j+1)}(z_1)}{(j+1)!}(z - z_1)^j \tag{A.4}$$

and therefore it is analytic.

Now, let us show by induction that $g^{i+1}(z) = f[z_1, \ldots, z_{i+1}, z]$ is analytic. If $z_k = z_j$ for all k and j, then

$$g^{i+1}(z) = \sum_{j=0}^{\infty} \frac{f^{(i+j+1)}(z_1)}{(i+j+1)!}(z - z_1)^j, \tag{A.5}$$

which is analytic. If not, there are two points, let us say z_k and z_j, such that $z_k \neq z_j$. Upon defining

$$\begin{aligned} g_k^i(z) &= f[z_1, \ldots, z_{k-1}, z_{k+1}, \ldots, z_{i+1}, z], \\ g_j^i(z) &= f[z_1, \ldots, z_{j-1}, z_{j+1}, \ldots, z_{i+1}, z], \end{aligned} \tag{A.6}$$

we get

$$g^{i+1}(z) = \frac{g_k^i(z) - g_j^i(z)}{z_j - z_k}. \tag{A.7}$$

Hence, by induction, we get that $g^{i+1}(z)$ is an analytic function.

Acknowledgment. The author would like to thank the referees for their many helpful comments.

Note added in proof. While this manuscript was in the refereeing process, the paper [4] was published. The two papers, ours and [4], are very close and deal with the same problem. The main difference between the two is in the approaches used to construct the approximating algorithm. While the present paper makes use of Newton interpolation, the algorithm described in [4] is based on enlarging the dimension of the Arnoldi subspace while storing a fixed number of basis vectors.

A NUMERICAL BIFURCATION ANALYSIS OF THE ORNSTEIN–ZERNIKE EQUATION WITH HYPERNETTED CHAIN CLOSURE*

R. E. BEARDMORE†, A. T. PEPLOW†, AND F. BRESME‡

Abstract. We study the codimension-one and -two bifurcations of the Ornstein–Zernike equation with hypernetted chain (HNC) closure with Lennard–Jones intermolecular interaction potential. The main purpose of the paper is to present the results of a numerical study undertaken using a suite of algorithms implemented in MATLAB and based on pseudo arc-length continuation for the codimension-one case and a Newton-GMRES method for the codimension-two case. Through careful consideration of the results of our computations, an argument is formulated which shows that *spinodal* isothermal solution branches arising in this model cannot be reproduced numerically. Furthermore, we show that the existence of an upper bound on the density that can be realized on a vapor isothermal solution branch, which must be present at a spinodal, causes the existence of at least one fold bifurcation along that *vapor* branch when density is used as the bifurcation parameter. This provides an explanation for previous inconclusive attempts to compute solutions using Newton–Picard methods that are popular in the physical chemistry literature.

Key words. Ornstein–Zernike equation, spinodal, liquid phase, vapor phase

Invitation. We invite the interested reader to email author R. E. Beardmore in order to obtain a copy of the MATLAB codes developed for this study.

1. Introduction.

The subject of this paper is the Ornstein–Zernike (OZ) equation that was presented almost a century ago to model the molecular structure of a fluid at varying densities [18]:

$$h(\|\mathbf{x}\|) = c(\|\mathbf{x}\|) + \rho \int_{\mathbb{R}^3} h(\|\mathbf{x}-\mathbf{y}\|)c(\|\mathbf{y}\|)d\mathbf{y}. \tag{1.1}$$

Here, $\mathbf{x}, \mathbf{y} \in \mathbb{R}^3$ are spatial coordinates and due to the assumed isotropy of the fluid we need only the radial coordinate $r = \|\mathbf{x}\|$, where $\|\cdot\|$ is the Euclidean distance function. The parameter ρ is the mean particle density of the fluid at temperature T, where $\beta = 1/(k_B T)$ will be used to denote the Boltzmann factor and $u(r)$ the intermolecular potential, a typical example of which is given below. The total (h) and direct (c) correlation functions yield the indirect correlation function of the fluid, $\gamma = h - c$, and the radial distribution function $g(r) = 1 + h(r)$ is the pair correlation function of molecules in the fluid.

The last two years or so have seen an increased use of continuation algorithms in liquid state theory. This can be seen both in [10, 9] in the context of density functional theory and in a study of the OZ equation [15]. The authors of [10, 9] make the express comment that continuation algorithms are needed to track phase transitions, and the

purpose of this paper is to analyze the correspondence between the solutions of the OZ equation and its discretization using continuation algorithms. In particular, we show that for the OZ equation with *hypernetted chain closure*, a term that is defined below, there is no finite-dimensional projection of the equations and hence no algorithm that can approximate physically meaningful solutions when seeking a *spinodal*, a precursor to a phase transition.

1.1. Closures. In order to form a well-posed mathematical system of equations from (1.1) that can be solved, at least in principle, we impose a closure relationship. This is an algebraic equation or pointwise constraint that augments (1.1) and which is deemed to hold throughout the fluid.

Some closures are structured so that the total correlation function is a perturbation of the *Mayer f-function* that is defined by $f(r) = -1 + e^{-\beta u(r)}$. These closures are obtained beginning with the observation that there is a function $B(r)$ such that

$$h = -1 + e^{-\beta u + h - c + B} \tag{1.2}$$

holds throughout the fluid; B is called the Bridge function [6].

Due to the fact that the potential u will have singularities that may prevent $-\beta u + h - c$ from being well defined, let us rewrite (1.2) in the form $h = -1 + e^{-\beta u} + e^{-\beta u}\left(-1 + e^{h-c+B}\right)$. The hypernetted chain (HNC) closure that interests us dates from the late 1950's (see [23]) and is obtained by setting $B(r)$ to zero, something that is not possible to justify on physical grounds in any generality. Thus, the OZ equation with HNC closure (OZ-HNC) is (1.1) coupled to

$$h = f + e^{-\beta u} \cdot (-1 + e^{h-c}). \tag{1.3}$$

Such an approximation suffers from *thermodynamic inconsistency*, the property that different routes to computing thermodynamic quantities such as compressibility and pressure yield different results. This is often seen as a fundamental flaw of theories based on closures like HNC.

Another often-studied problem in the physical chemistry literature (again see [6] for background and further references) is the OZ equation with Percus–Yevick (PY) closure [19]. This also dates from the 1950's and is obtained by setting $B = \ln(\gamma + 1) - \ln \gamma$, leading to the PY closure

$$h = f + e^{-\beta u} \cdot (h - c). \tag{1.4}$$

We do not study this particular thermodynamically inconsistent form here. These and other closures have been in use for around thirty years, as explained in the review [6], and combinations of different closures have also been proposed, some of which are reviewed in the latter reference, but we have chosen to concentrate on OZ-HNC.

The HNC and PY closures can be written in a general form involving the potential, temperature, and the indirect correlation function through a nonlinearity G, say, as follows:

$$h = f + e^{-\beta u} G(h - c), \qquad G(0) = 0. \tag{1.5}$$

The suite of algorithms we have developed are able to solve (1.1) and (1.5) for any function G with β and ρ as bifurcation parameters. Moreover, solution branches obtained by varying ρ but holding β fixed are called *isotherms*; those obtained by fixing ρ but varying β are *isochores*.

1.2. Local existence. Note that the OZ equation with closure of the form (1.5) can be written as a single integral equation

$$\gamma = \rho(f + e^{-\beta u}G(\gamma)) * (f + e^{-\beta u}G(\gamma) - \gamma), \tag{1.6}$$

and in the remainder we shall use $N_\beta(\gamma)$ to denote the operator formed by the right-hand side of (1.6), so that this integral equation can be written $\gamma = \rho N_\beta(\gamma)$ for brevity.

The following basic existence theorem for (1.6) can be easily proven using the implicit function theorem, but we state it here without proof.

THEOREM 1. *If* $G(\gamma) = -1 + e^\gamma, \beta > 0$, *and* $f \in L^1(\mathbb{R}^3), \cap L^\infty(\mathbb{R}^3)$, *then there is a* $\rho' > 0$ *such that* (1.6) *has a solution* $\gamma \in L^1(\mathbb{R}^3) \cap L^\infty(\mathbb{R}^3)$ *for each* $0 \le \rho < \rho'$.

As a result, one generally requires the short-range condition that f is integrable and bounded over $\mathbb{R}^3$ for $\beta > 0$, a property that follows from the assumption that $\int_1^\infty r^2 u(r)dr < \infty$ such that u is measurable on $(0, \infty)$ and continuous on a half-neighborhood of zero and $\lim_{r\to 0_+} u(r) = +\infty$.

Our algorithms are implemented with the assumption that u is smooth on $(0, \infty)$; we do not perform any computations where the potential is nonsmooth, although it is common in the literature to do so [6, 13, 16]. Indeed, all computations presented here use the Lennard–Jones (LJ) 6-12 potential,

$$u_{LJ}(r) = 4\epsilon\left(\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right),$$

where σ is particle diameter and ϵ controls the well-depth. In accordance with [12], we shall express thermodynamic quantities such as density and temperature in reduced units, $\rho^* = \rho\sigma^3$, $T^* = k_B T/\epsilon = 1/(\epsilon\beta)$, although $\sigma = \epsilon = 1$ hold throughout the paper so that $\rho = \rho^*$ and $T^* = 1/\beta$.

1.3. Spinodals. Let us define the *inverse isothermal compressibility* of a fluid

$$\chi^{-1}(c, \rho) := 1 - \rho \int_{\mathbb{R}^3} c(\|\mathbf{x}\|)d\mathbf{x}. \tag{1.7}$$

This quantity plays a fundamental role in the solution of (1.1) and (1.5) for the following reason.

DEFINITION 1. *Let* $\beta > 0$ *be fixed. A spinodal is said to occur in the OZ-HNC equation* (1.1) *and* (1.5) *at* $\rho = \rho_{sp}$ *if there is a sequence* (h_n, c_n, ρ_n) *of solutions such that* $\rho_n \to \rho_{sp}$ *as* $n \to \infty$ *and* $\chi^{-1}(c_n, \rho_n) \to 0$.

As the temperature is reduced the separation of two phases in the fluid, one liquid and one vapor, begins with the creation of two spinodals at a critical value of temperature and density, T_c and ρ_c. Thus the search for two thermodynamic phases begins with the search for a codimension-two point at which a single critical solution can be found, with $T = T_c$ and $\rho = \rho_c$, say, at which inverse isothermal compressibility is zero.

One consequence of the existence of two spinodals that lie on vapor and liquid isotherms is a region of densities between the two where no solution of (1.6) exists; this region is sometimes called a *no-solution region*. Several analyses based on numerical solutions of the discretized OZ equations appear to have established that a *no-solution region* exists [24, 3, 2, 17, 22], and the purpose of this paper is to investigate these claims further, noting that *none* of the cited references use bifurcation algorithms in their studies. Note in particular [20, Fig. 4] whereby a conjectured series of solution

branches have been drawn; we shall demonstrate that this figure is essentially correct but that there may well be more fold bifurcations present than are shown in [20].

Although we shall show that we are not strictly able to locate phase transitions by applying continuation algorithms to (1.6), we shall use the following suggestive terminology. Isotherms that contain the low-density base solution of (1.6) given by $h = f, c = f$, and $\rho = 0$ will be called *vapor* branches throughout. If there are two isothermal solution branches, the one associated with higher densities will be called the *liquid* branch. We shall also use the prefix *discrete* to denote that these terms apply to solution branches of a discretization of (1.6).

1.3.1. Fold bifurcations and pseudospinodals. Let us consider for a moment the following definition of fold bifurcation, noting that it also incorporates solution branches that intersect in pitchfork or transcritical bifurcations.

DEFINITION 2 (fold bifurcation). *Let X be a Banach space. The nonlinear equation $F(\gamma, \rho) = 0$, where $F : X \times \mathbb{R} \to X$, is said to possess a fold bifurcation at ρ_{FB} if there is a $\gamma_{FB} \in X$ and at least two distinct sequences $(\gamma_n) \in X$ and $(\overline{\gamma}_n) \in X$ such that for some sequence $(\rho_n) \subset \mathbb{R}$*

(i) *$F(\gamma_n, \rho_n) = 0$ and $F(\overline{\gamma}_n, \rho_n) = 0$ for all n,*
(ii) *$\rho_n < \rho_{FB}$ for all n, and*
(iii) *$\lim_{n\to\infty}(\gamma_n, \rho_n) = \lim_{n\to\infty}(\overline{\gamma}_n, \rho_n) = (\gamma_{FB}, \rho_{FB}) \in X \times \mathbb{R}$.*

The reason for introducing this definition is that while phase transitions begin with a search for spinodals, it was noted as long ago as 1968 for the PY closure [1] (see [1, Fig. 1] in particular) that fold bifurcations could occur where one might anticipate the existence of spinodals. As a result, fold bifurcations in the context of (1.6) are often called *pseudospinodals*, although *square-root branch points* [2] are also used. Let us again remark that Definition 2 encompasses a greater class of solution curves than simply those with the typical folded structure at a bifurcation point, but the theorems later in the paper are only able to demonstrate the existence of a fold bifurcation in the sense of Definition 2.

Using a standard codimension-one formulation of (1.6), we shall compute curves that illustrate how fold bifurcations of (1.6) vary as a function of temperature and density, and these rather resemble *phase diagrams* and may be thought of as *an approximation* of the boundary of the region of liquid-vapor coexistence.

The basic Newton method has been seen as the most appropriate algorithm for studying (1.6), which is why continuation algorithms were not used to study the OZ equation until very recently [15]. Moreover, the various codimension-two problems associated with OZ have yet to be tackled directly in the physical chemistry literature; hence this paper addresses these issues. This is perhaps a little surprising given the debate that took place in [11, 5, 4, 7] regarding the errors committed when employing inappropriate numerical techniques. Moreover, the study of the correspondence between analytical and numerical solutions of the OZ equation with PY closure performed in [7] shows surprising discrepancies that, to the best of the authors' knowledge, have not received adequate attention in the literature.

Typical behavior: Unphysical isotherms part I. In anticipation of the results to follow, in Figure 1.1 we have plotted a locus of fold bifurcations for (1.6) that has been computed for an LJ fluid using a codimension-one formulation of the OZ-HNC equation; note its resemblance to a phase diagram. (The meaning of the parameter $R = 10\sigma$ that appears in the caption of this figure is explained later in the paper.)

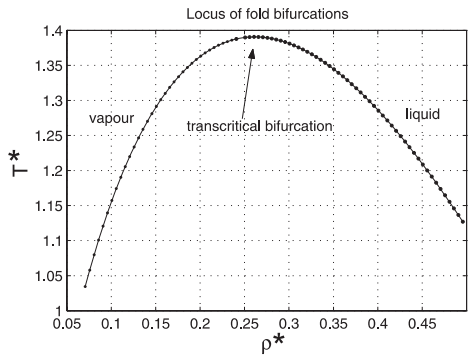

FIG. 1.1. *(LJ potential, HNC closure, $R = 10\sigma$ with $2^{12} + 1$ mesh points.) A locus of fold bifurcations showing liquid and vapor branches created at a transcritical bifurcation. Below the parabolic curve there are regions where no solution exists bounded by two fold bifurcations that occur as ρ is varied and β is fixed; one occurs on the liquid branch and one occurs on the vapor branch (see Figure* 1.2*).*

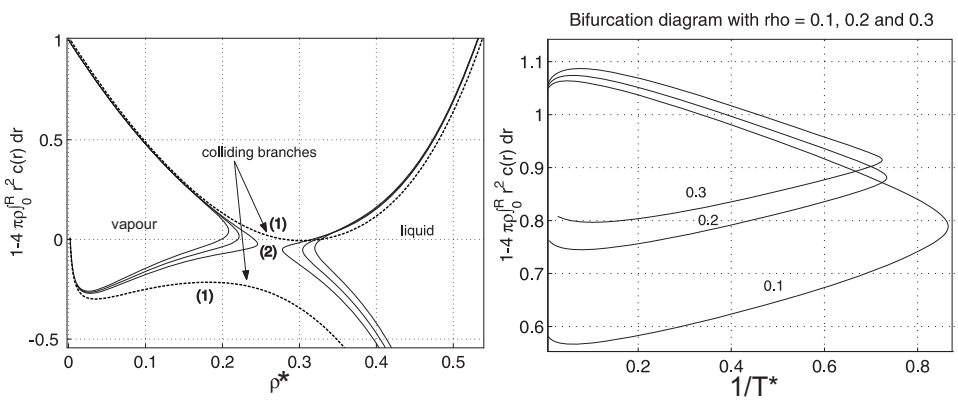

FIG. 1.2. *(LJ potential, HNC closure, $R = 10\sigma$, $2^{12} + 1$ mesh points.) (Left) Two supercritical branches (at* (1)*) touch (near* (2)*) and exchange singularities: Inverse compressibility plotted against density with label* (1) $\beta = 0.696$*, label* (2) $\beta = 0.72$*; two more liquid-vapor isothermal pairs are shown with lower temperatures at* $\beta = 0.725$ *and* 0.73*. (Right) Three isochores showing fold bifurcations at low temperatures; density is fixed at* $\rho = 0.1, 0.2, 0.3$*.*

In Figure 1.2 (left) we have computed a set of isothermal solution branches that show density plotted on the horizontal axis against inverse isothermal compressibility on the vertical axis; to produce each curve, temperature is lowered and a pair of computations is performed, and the resulting figure is an *unfolding* of the apex from Figure 1.1. Label (2) in Figure 1.2 (left) sees the creation of two fold bifurcations or *pseudospinodals* that arise due to a collision of two solution branches, one of which is a vapor branch with positive compressibility, but the other has negative compressibility and is therefore not a branch of physically meaningful solutions.

1.4. Notation. Given a nonlinear mapping $N(\gamma)$ on a Banach space X that contains elements γ and h, $dN(\gamma)[h]$ denotes the Fréchet derivative and $BL(X)$ is the space of bounded, linear mappings from X to itself. We shall write $N_\beta(\gamma)$ to emphasize the dependence of N on a parameter β, but we shall suppress the subscript otherwise. The dual space of all bounded linear functionals on X is written X^*.

Numerical objects that correspond to infinite-dimensional objects will be written using a bold font, so that $\boldsymbol{\gamma}$ will be a vector that corresponds to a correlation function γ projected onto a finite-dimensional subspace of X. The set $\{\mathbf{e}_j\}_{j=0}^n$ is used to denote the standard basis vectors of $\mathbb{R}^{n+1}$. We shall write $B_R(\mathbf{0}) = \{\mathbf{x} \in \mathbb{R}^3 : \|\mathbf{x}\| < R\}$ for a ball in $\mathbb{R}^3$, and $\langle \mathbf{u}, \mathbf{v} \rangle$ is the standard Euclidean inner product of vectors $\mathbf{u}, \mathbf{v} \in \mathbb{R}^{n+1}$.

We depart a little from convention by using $L^p(\mathbb{R}^3)$ to denote the space $\{u : \mathbb{R}^3 \to \mathbb{R} : \int_{\mathbb{R}^3} |u(\mathbf{x})|^p d\mathbf{x} < \infty\}$, where $p \geq 1$, and $C^0(\mathbb{R}^3)$, $C_0^\infty(\mathbb{R}^3)$, and $L^\infty(\mathbb{R}^3)$ are defined analogously (the point is that the range of functions in these spaces is always $\mathbb{R}$). By $C^{\mathrm{Lip}}(\Omega)$ for a domain $\Omega \subset \mathbb{R}^3$ we understand the space $\{u \in C^0(\overline{\Omega}) : \exists K > 0 \text{ s.t. } |u(\mathbf{x}) - u(\mathbf{y})| \leq K\|\mathbf{x} - \mathbf{y}\|\}$ endowed with a standard norm.

We will use a majuscule to represent the Fourier transform of a minuscule, as in

$$\mathcal{F}(c)(\mathbf{s}) := C(\mathbf{s}) = \int_{\mathbb{R}^3} c(\mathbf{x}) e^{i\mathbf{x}\cdot\mathbf{s}} d\mathbf{x}.$$

The convolution of radially symmetric functions can be written using the convolution theorem and the Hankel transform $\mathcal{H}$, the Fourier transform of radially symmetric functions that is given by

$$\mathcal{H}(a)(s) = 4\pi \int_0^\infty \operatorname{sinc}(rs) r^2 a(r) dr$$

so that $\mathcal{H}^{-1}(a)(s) = \frac{1}{2\pi^2} \int_0^\infty \operatorname{sinc}(rs) r^2 a(r) dr$. Thus we may define a convolution operator by $a * b = \mathcal{H}^{-1}((\mathcal{H}a) \cdot (\mathcal{H}b))$, where $a, b : [0, \infty) \to \mathbb{R}$ are given functions.

2. Observations on the OZ-HNC equation. Throughout the remainder of the paper let us consider (1.6) with the HNC closure $G(\gamma) = -1 + e^\gamma$:

$$\gamma = \rho(f + e^{-\beta u(r)}(-1 + e^\gamma)) * (f + e^{-\beta u(r)}(-1 + e^\gamma) - \gamma). \tag{2.1}$$

Formulation (2.1) is advantageous from a theoretical point of view because G can be regarded as a function that maps $L^1(\mathbb{R}^3) \cap L^\infty(\mathbb{R}^3)$ to itself, a property that is not shared by either of the functions $\gamma \mapsto e^\gamma$ or $\gamma \mapsto \gamma - 1$. As this paper is written from a computational perspective, (2.1) will be rewritten in the more common form

$$\gamma = \rho(-1 + e^{-\beta u(r)} e^\gamma) * (-1 + e^{-\beta u(r)} e^\gamma - \gamma).$$

2.1. Spinodals: Bifurcations at infinity in $L^1(\mathbb{R}^3)$. Applying the Fourier transform to (1.1), we obtain the quadratic algebraic equation that holds almost everywhere,

$$H(s)(1 - \rho C(s)) = C(s), \tag{2.2}$$

where $s \in \mathbb{R}$ is the wave number and H and C are the Fourier transforms of h and c, respectively.

LEMMA 2.1. *There is no pair* $(h, c) \in L^1(\mathbb{R}^3) \times L^1(\mathbb{R}^3)$ *that satisfies* (1.1) *and* $\chi^{-1}(c, \rho) = 0$.

Proof. Suppose that a solution (h, c) of (1.1) exists at a given ρ and that $\chi^{-1}(c, \rho) = 0$. Then $1 = \rho C(0) = \rho \int_{\mathbb{R}^3} c d\mathbf{x}$ but (2.2) yields (on allowing $s \to 0$)

$$H(0) \cdot (1 - \rho C(0)) = C(0) \Longrightarrow \int_{\mathbb{R}^3} h d\mathbf{x} \cdot \chi^{-1}(c, \rho) = \int_{\mathbb{R}^3} c d\mathbf{x} = 0,$$

which is a contradiction. ∎

Suppose that an isothermal solution branch of (1.1) and (1.5) exists (call it $\mathcal{C}$) and suppose that it lies in $L^1(\mathbb{R}^3) \times L^1(\mathbb{R}^3) \times \mathbb{R}$. Suppose also that there is a sequence of low-density solutions in $\mathcal{C}$, so that $\mathcal{C}$ connects to the vapor base solution where $\rho = 0$ and therefore $\chi^{-1}(c, \rho)$ is positive along the low-density part of $\mathcal{C}$.

Now suppose that $\mathcal{C}$ contains a *spinodal* in the sense that there is a sequence $(h_n, c_n, \rho_n) \in \mathcal{C}$ such that $\rho_n \to \rho_{sp} > 0$ and $\lim_{n\to\infty} \chi^{-1}(c_n, \rho_n) = 0$. From (2.2) upon setting $s = 0$ we find

$$\int_{\mathbb{R}^3} h_n d\mathbf{x} \cdot \chi^{-1}(c_n, \rho_n) = \int_{\mathbb{R}^3} c_n d\mathbf{x} \to 1/\rho_{sp},$$

and we must conclude that $\int_{\mathbb{R}^3} h_n(\|\mathbf{x}\|)d\mathbf{x} \to \infty$ as $n \to \infty$. Thus, a spinodal is associated with a bifurcation from infinity in $L^1(\mathbb{R}^3)$. Let us record this in a lemma.

LEMMA 2.2. *Suppose that* $(h_n, c_n, \rho) \subset L^1(\mathbb{R}^3) \times L^1(\mathbb{R}^3) \times \mathbb{R}$ *is a spinodal sequence that accumulates at a nonzero density* $\rho = \rho_{sp}$*; then* $\|h_n\|_{L^1(\mathbb{R}^3)} \to \infty$ *as* $n \to \infty$.

Thus, the fact that a spinodal sequence is a bifurcation at infinity in an $L^1(\mathbb{R}^3)$-norm is a property of the OZ equation alone; whether or not a spinodal is actually present depends essentially on the nature of the closure relationship used in (1.5). For example, the following simple lemma shows that the HNC closure leads to the boundedness of h in the $L^2(\mathbb{R}^3)$-norm at a spinodal, provided that the direct correlation function c in (1.1) is well behaved.

LEMMA 2.3. *Suppose that* $u \in L^1(\mathbb{R}^3 \backslash B_\epsilon(\mathbf{0}))$ *for some* $\epsilon > 0$ *and* (h, c) *solves* (1.1) *and* (1.3) *such that* $\|h\|_{L^\infty} \le M$ *and* $\|c\|_{L^1} + \|c\|_\infty \le M$*. Then there is a* $K_M > 0$ *such that*

$$\int_{\mathbb{R}^3} h(\|\mathbf{x}\|)^2 d\mathbf{x} \le \frac{4\pi\epsilon^2 M^2}{3} + \frac{1}{K_M} \int_{\|\mathbf{x}\|\ge\epsilon} (\beta u + c(\|\mathbf{x}\|))d\mathbf{x}. \tag{2.3}$$

Hence $h \in L^p(\mathbb{R}^3)$ *for all* $2 \le p \le \infty$.

Proof. If we define the function $F(x) = \ln(x + 1) - x$ for all $x > -1$, then $F(0) = 0, F'(0) = 0$, and $F''(x) = -1/(x + 1)^2 < 0$ so that F is concave. Clearly, for each $M > 0$ fixed, there is a $K_M > 0$ such that $F(x) \le -K_M x^2$ for all x such that $-1 < x \le M$. Now, if (h, c) solves (1.1) and (1.3), then from (1.3) we deduce

$$K_M \int_{\|\mathbf{x}\|\ge\epsilon} h^2 d\mathbf{x} \le -\int_{\|\mathbf{x}\|\ge\epsilon} F(h)d\mathbf{x} = \int_{\|\mathbf{x}\|\ge\epsilon} (\beta u + c)d\mathbf{x}$$

because $h(\|\mathbf{x}\|) > -1$ if $\|\mathbf{x}\| > \epsilon$ from the HNC closure. Hence,

$$\begin{aligned}\int_{\mathbb{R}^3} h^2 d\mathbf{x} &\le \int_{\|\mathbf{x}\|\le\epsilon} h^2 d\mathbf{x} + \frac{1}{K_M} \int_{\|\mathbf{x}\|\ge\epsilon} (\beta u + c)d\mathbf{x} \\ &\le M^2 \text{meas}\{\mathbf{x} : \|\mathbf{x}\| \le \epsilon\} + \frac{1}{K_M} \int_{\|\mathbf{x}\|\ge\epsilon} (\beta u + c)d\mathbf{x},\end{aligned}$$

and the result follows. ∎

We can now use the bound from Lemma 2.3 to obtain the following result which states that if a spinodal sequence exists and the correlation functions stay uniformly bounded, and the direct correlation function that is known to be integrable is in fact absolutely integrable, then there are functions $h_0 \in L^2(\mathbb{R}^3) \backslash L^1(\mathbb{R}^3)$ and c_0 that

together satisfy the OZ equation. Any function $h_0 \in L^\infty(\mathbb{R}^3)$ that satisfies an almost-everywhere bound of the form

$$\frac{C}{r^3} < |h_0(\mathbf{x})| < \frac{C'}{r^{(3+\delta)/2}} \qquad \text{(a.a. } \mathrm{r} \geq \mathrm{R})$$

for constants C, C', and R, where $\delta \in (0,3)$ is arbitrary and $r = \|\mathbf{x}\|_2$, the Euclidean length of $\mathbf{x}$, satisfies $h_0 \in L^2(\mathbb{R}^3) \backslash L^1(\mathbb{R}^3)$, and this may give us some clue as to how the total correlation function behaves at a spinodal.

LEMMA 2.4. *Suppose that ρ_{sp} is a density associated with a spinodal sequence $(h_n, c_n, \rho_n) \in L^1(\mathbb{R}^3) \times L^1(\mathbb{R}^3) \times \mathbb{R}$ for $n \geq 1$ and there is an $M > 0$ such that $\|h_n\|_{L^\infty} \leq M$ and $\|c_n\|_{L^1} + \|c_n\|_{L^\infty} \leq M$. Then there are functions $h_0 \in L^2(\mathbb{R}^3) \backslash L^1(\mathbb{R}^3)$ and $c_0 \in L^2(\mathbb{R}^3) \cap L^\infty(\mathbb{R}^3)$ such that*

$$h_0 = c_0 + \rho_{sp}(h_0 * c_0) \quad \text{and} \quad \chi^{-1}(c_0, \rho_{sp}) = 0.$$

Proof. (In this proof, although all functions are defined on $\mathbb{R}^3$, we assume them to be radially symmetric.) The result follows from the continuity of the convolution operator $*$ with respect to weak convergence. For if (h_n, c_n, ρ_n) has the stated properties, then, although $\|h_n\|_{L^1(\mathbb{R}^3)} \to \infty$ as $n \to \infty$, there are bounds of the form

$$\|h_n\|_{L^\infty} \leq M \quad \text{and} \quad \|c_n\|_{L^1} + \|c_n\|_{L^\infty} \leq M$$

that come from the definition of an admissible spinodal sequence. From Lemma 2.3 we may assume that $\|h_n\|_{L^2} \leq M$. We can now apply the Banach–Alaoglu theorem to extract weak and weak* convergent subsequences to find an $h_0 \in L^2$ and a $c_0 \in L^\infty \cap L^2$ such that

$$h_n \rightharpoonup h_0 \text{ in } L^2, c_n \rightharpoonup c_0 \text{ in } L^2, \text{ and } c_n \overset{*}{\rightharpoonup} c_0 \text{ in } L^\infty$$

as $n \to \infty$, using $(L^1)^* \cong L^\infty$ and the fact that $(c_n) \subset (L^1)^*$, which is a bounded sequence.

Now suppose that $\phi \in C_0^\infty(\mathbb{R}^3)$ has support on some closed ball Ω and let $\epsilon > 0$. From the symmetry properties of convolution there is an N_0 such that

$$\begin{aligned} |\langle \phi, h * c\rangle - \langle \phi, h_n * c_n\rangle| &= |\langle h * \phi, c - c_n\rangle - \langle (h_n - h) * \phi, c_n\rangle| \\ &= |\langle h * \phi, c - c_n\rangle - \langle (h_n - h) * \phi, c_n - c\rangle - \langle (h_n - h) * \phi, c\rangle| \\ &\leq \epsilon + |\langle (h_n - h) * \phi, c_n - c\rangle| + \epsilon \end{aligned}$$

for all $n \geq N_0$.

Suppose now that $u_n := h_n - h_0 \rightharpoonup 0$ in L^2 and $v_n := c_n - c_0 \rightharpoonup 0$ in L^2 as $n \to \infty$; then $u_n * \phi$ has support in $2 \cdot \Omega$, where $2 \cdot \Omega = \{2\mathbf{x} : \mathbf{x} \in \Omega\}$. Moreover, from the Cauchy–Schwarz inequality

$$\operatorname{ess\,sup}_{\mathbf{x} \in 2\cdot\Omega} |(u_n * \phi)(\mathbf{x})| \leq \|u_n\|_{L^2} \|\phi\|_{L^2} < \infty$$

and

$$|(u_n * \phi)(\mathbf{x}_1) - (u_n * \phi)(\mathbf{x}_2)| \leq \operatorname{meas}(2 \cdot \Omega)^{1/2} \|\phi\|_{C^1} \|\mathbf{x}_1 - \mathbf{x}_2\| \|u_n\|_{L^2},$$

and we may assume that $u_n * \phi$ is continuous and uniformly bounded. Clearly the Lipschitz norm $\|u_n * \phi\|_{C^{\mathrm{Lip}}(2\cdot\Omega)}$ is bounded and because the embedding $C^{\mathrm{Lip}}(2 \cdot \Omega) \subset$

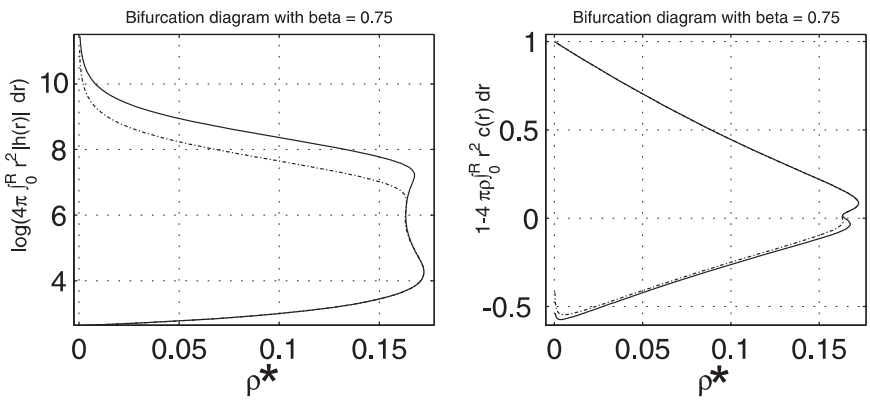

FIG. 2.1. *(LJ potential, HNC closure,* $2^{12}+1$ *mesh points, and* $\beta = 0.75$*.) Two computations with different cut-off parameters* $R = 50\sigma$ *(dashed line) and* 80σ *(full line). Spinodal-like behavior is clearly visible, and note the presence of multiple fold bifurcations.*

$C^0(2\cdot\Omega)$ is compact and $u_n \rightharpoonup 0$ in L^2, it follows that $u_n * \phi \rightharpoonup 0$ in L^2, and so we may assume that $u_n * \phi \to 0$ uniformly on $2\cdot\Omega$.

Hence $|\langle u_n * \phi, v_n\rangle| \le \|u_n * \phi\|_{C^0(2\cdot\Omega)}\|v_n\|_{L^2}$ and on setting $u_n := h_n - h_0$, $v_n := c_n - c_0$ we have shown that $h_n * v_n \rightharpoonup h_0 * v_0$ in L^2 because $C_0^\infty(\mathbb{R}^3)$ is dense in $L^2(\mathbb{R}^3)$. Since $-h_n + c_n + \rho_n h_n * v_n = 0$ for all n we find that the pair (h_0, c_0) satisfies the OZ equation.

To obtain the zero inverse compressibility of this pair, because $\chi^{-1}(c_n, \rho_n) = 1 - \rho_n \int_{\mathbb{R}^3} c_n(\|\mathbf{x}\|)d\mathbf{x} \to 0$ it suffices to show that $\int_{\mathbb{R}^3} c_n d\mathbf{x} \to \int_{\mathbb{R}^3} c_0 d\mathbf{x}$, which itself follows if $\int_{\mathbb{R}^3} c_n\phi d\mathbf{x} \to \int_{\mathbb{R}^3} c_0\phi d\mathbf{x}$ for all $\phi \in L^\infty$. Now, $c_n \in L^1(\mathbb{R}^3)$ can be viewed as a continuous linear functional in $(L^\infty)^*$ acting via integration, as in $c_n(\psi) = \int_{\mathbb{R}^3} c_n\psi d\mathbf{x}$ and $\|c_n\|_{(L^\infty)^*} \le \|c_n\|_{L^1}$. The result now follows by applying the Banach–Alaoglu theorem and choosing $\phi = 1$. □

One might call the functions h_0 and c_0 spinodal *semisolutions* because, although they satisfy the OZ equation (1.1), they may well not satisfy the constraint (1.3). Establishing the existence of the a priori bounds needed for Lemma 2.4 depends on the closure (1.5) and is not a straightforward task. However, given that (1.1) is a description of the fluid that holds under any thermodynamic conditions, it is essential that conditions exist such that (1.1) continues to hold whether or not the fluid is at a spinodal.

Computing spinodals: Unphysical isotherms part II. The property of Lemma 2.3 of having a sequence of total correlation functions (h_n) that are $L^2(\mathbb{R}^3)$-bounded but divergent in $L^1(\mathbb{R}^3)$ will cause difficulties for any numerical discretization of (1.1) and (1.5). Indeed, it will force such a discretization to possess uniform a priori bounds because of the equivalence of different norms on finite-dimensional spaces.

This simple observation ensures that admissible spinodal sequences cannot be reproduced easily with a computational procedure, and this may go some way to explaining the claims made in [2, 20] that apparent spinodals in numerically computed solutions are not true spinodals. Moreover, if Lemma 2.3 does provide a description of the fluid through a spinodal, the resulting computations must behave in a manner that produces nonphysical results.

We have illustrated this problem in Figure 2.1 containing two plots. The left-hand figure shows the $L^1(\mathbb{R}^3)$-norm of h plotted on a log scale against density where a very rapid change in this norm takes place over a very small density interval. This is clear

numerical evidence of the existence of a spinodal, and the right-hand plot shows the numerically obtained inverse compressibility χ^{-1} against density, with this variable passing through zero, which seems to confirm this observation. However, yet again we find that there are physically meaningless solutions with negative compressibility.

Clearly, the values of χ^{-1} are very close to zero along the *vertical* part of the branch in the left-hand plot of Figure 2.1. However, a number of fold bifurcations can be seen (three in this plot) and there is a final fold after which the density monotonically decreases before finally heading toward zero as the norm grows further; this is also physically meaningless behavior. We shall give a tentative explanation of this behavior later in the paper and prove that the existence of a spinodal along a vapor branch in a discretization of (1.1) with the HNC closure must yield the existence of a fold bifurcation.

Remark 1. The existence of an apparent solution whereby $\chi^{-1}(c,\rho)=0$ is troublesome in light of Lemma 2.1 and is an artifact of the discretization used to solve (2.1). However, the discretization procedure used to produce Figure 2.1 is standard in the physical chemistry literature: as described in the following section, the fluid is truncated to a ball of radius R, called the cut-off parameter, and (2.1) is solved as an integral equation on the resulting finite domain. In Figure 2.1 we have used two different values for R—one of $R=50\sigma$ and one of $R=80\sigma$, where σ is the particle diameter, here taken to be 1.

3. Computational procedures.

3.1. The cut-off parameter *R*. In all of the liquid-state physics literature that we have cited (see [24, 3, 17, 2, 15], for example), one solves (1.1) numerically by first truncating the region of integration to a finite region, and so we also adopt this procedure. So, rather than solving (1.1), one seeks solutions of a *windowed* integral equation,

$$h(r)=c(r)+\int_{\mathbb{R}^3}[X_{_R}h](\|\mathbf{x}-\mathbf{y}\|)[X_{_R}c](\|\mathbf{y}\|)d\mathbf{y}\qquad(0\le r\le R),\tag{3.1}$$

where $X_{_R}$ is the windowing operator:

$$(X_{_R}v)(\mathbf{x})=\begin{cases} v(\mathbf{x}) & : \quad \|\mathbf{x}\|\le R,\\ 0 & : \quad \text{otherwise.}\end{cases}$$

The region of integration in (3.1) is therefore finite, which permits a straightforward method of discretization to be applied to (3.1) in tandem with the HNC constraint.

Clearly, $X_{_R}$ is a projection operator in the sense that $X_{_R}(X_{_R}(u))=X_{_R}(u)$ for all $u\in L^1(\mathbb{R}^3)$, and so if we set $h_R=X_{_R}h$ and $c_R=X_{_R}c$, (3.1) is equivalent to

$$h_R=c_R+\rho X_{_R}(h_R*c_R),\tag{3.2}$$

so that when we take the Fourier transform of (3.2) we obtain a relationship involving convolution with the transform of the windowing operator applied to the constant function that is identically one, here denoted 1,

$$H_R=C_R+\rho\widehat{X_{_R}(1)}*(H_R\cdot C_R),\tag{3.3}$$

where $\widehat{X_{_R}(1)}(s)=(2R)^{-1/2}s^{-3/2}J_{3/2}(Rs)$ is a certain Bessel function.

The point of this is the Fourier transform of the windowed OZ equation does not lead to an algebraic equation but rather to a convolution equation with a fixed

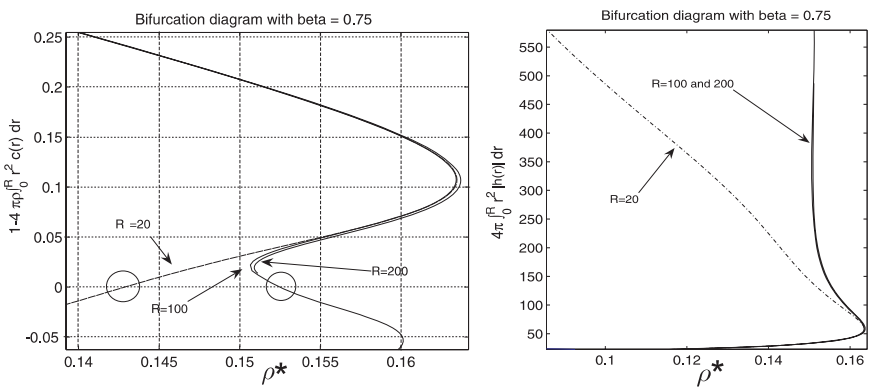

FIG. 3.1. *(LJ potential, HNC closure, $R = 20\sigma, 100\sigma, 200\sigma, \beta = 0.75$, and $2^{13} + 1$ mesh points.) An illustration of the high sensitivity of the bifurcation diagram to changes in the windowing parameter R near an apparent spinodal (marked by circles). (Left) Inverse compressibility against ρ^*. (Right) $L^1(\mathbb{R}^3)$-norm of h against ρ^*.*

kernel, and this makes it difficult to define a *compressibility* functional of the windowed problem (3.1) with the correct qualitative properties. For example, the argument of Lemma 2.1 breaks down when the cut-off procedure is applied, and so the relationship between spinodals and bifurcations from infinity is no longer apparent.

Moreover, if one still defines inverse compressibility in the sense of (1.7), then it may well be possible to realize $L^1(\mathbb{R}^3)$ solutions of the windowed OZ equation (3.1) with zero inverse compressibility. This is illustrated in Figure 3.1 (left), where two regions have been circled that indeed appear to contain numerically computed solutions with zero inverse compressibility.

Based on Figure 3.1 a further comment can be made in terms of the order of convergence of approximate solutions of (3.1) and (1.5) in a suitable norm as $R \to \infty$. One needs estimates of $\|h - X_R h\|_Z$ in some space Z, and, bearing in mind the $L^1(\mathbb{R}^3)$-divergence at a spinodal, the bounds

$$\|h - X_R h\|_Z \leq \begin{cases} 1/(4\pi R^2)\|h - X_R h\|_{L^1(\mathbb{R}^3)} = o(R^{-2}), \\ 1/(4\pi R)^{1/2}\|h - X_R h\|_{L^2(\mathbb{R}^3)} = o(R^{-1/2}) \end{cases}$$

apply with $Z = L^1(0, \infty)$ if $h \in L^1(\mathbb{R}^3) \cap L^2(\mathbb{R}^3)$.

One *may* subsequently anticipate a degradation of the convergence of approximate solutions with respect to R as one nears a spinodal. Indeed, the relatively poor convergence of the bifurcation picture with respect to R is illustrated in Figure 3.1, where a computation is made along an apparent near-spinodal solution branch. Three choices are used, $R = 20\sigma$, 100σ, and 200σ, recalling that the particle diameter σ is 1, where only the larger two of the values resolve a number of bifurcations that seem to be missed when the smaller value is used for R.

3.2. Numerical implementation of OZ-HNC. Suppose that $v : [0, \infty) \to \mathbb{R}$ is a given function, and define the windowed Hankel transforms

$$\mathcal{H}_R v = X_R \mathcal{H}(X_R v) \text{ and } \mathcal{H}_R^{-1} v = X_R \mathcal{H}^{-1}(X_R v);$$

we then finally arrive at the equation that is to be solved as part of our computational study:

$$\gamma = \rho \mathcal{H}_R^{-1}[\mathcal{H}_R(f + e^{-\beta u} G(\gamma)) \cdot \mathcal{H}_R(f + e^{-\beta u} G(\gamma) - \gamma)], \tag{3.4}$$

which is the windowed analogue of (1.6). Now let us briefly explain our discretization of (3.4). First recall that our computations are performed using only the HNC form for G given by $G(\gamma) = -1 + e^{\gamma}$, and note that in the following description, we shall use a subscript applied to a vector in $\mathbb{R}^{n+1}$ to denote a coordinate from that vector.

So, begin by choosing a set of basis functions $\{\phi_i(r)\}_{i=0}^n$ centered on nodes (r_i) of a uniform mesh, taking mesh points $r_i = iR/n$ for $0 \le i \le n$. We seek an approximate solution of (3.4) of the form $\gamma = \sum_{i=0}^n \gamma_i \phi_i(r)$, and the resulting system is projected onto ϕ_j for all $j = 0, \dots, n$. For any such set of basis functions, this procedure yields a finite-dimensional system of equations of dimension $n+1$ and, writing

$$e^{-\beta \mathbf{U}} = (e^{-\beta u(r_i)})_{i=0}^n \text{ such that } (e^{-\beta \mathbf{U}})_0 = 0,$$

$\mathbf{h} = (h_i)_{i=0}^n$, and $\mathbf{c} = (c_i)_{i=0}^n$, the HNC closure yields

$$h_0 = -1,\ h_i = -1 + e^{-\beta u(r_i)} \exp(\gamma_i), \text{ and } c_i = h_i - \gamma_i \qquad (i = 1, \dots, n), \tag{3.5}$$

and we obtain the following system of equations for $\mathbf{h}$ and $\mathbf{c}$:

$$\mathbf{h} = \mathbf{c} + \rho B(\mathbf{h}, \mathbf{c}), \tag{3.6}$$

$$\mathbf{h} = \mathbf{f} + e^{-\beta \mathbf{U}}(-\mathbf{1} + \exp(\mathbf{h} - \mathbf{c})). \tag{3.7}$$

Here $\mathbf{1} = (1, 1, \dots, 1)$ and $B : \mathbb{R}^{n+1} \times \mathbb{R}^{n+1} \to \mathbb{R}^{n+1}$ is a bilinear form that represents a discrete convolution operator and we shall also write, here and throughout,

$$\mathbf{f} = -\mathbf{1} + e^{-\beta \mathbf{U}}$$

for the so-called discrete Mayer f-function.

The convolution operator from (1.1) is the only part of the problem that is discretized in a nontrivial way to give (3.6); the algebraic constraint given by the HNC closure (1.3) simply yields the elementwise constraint (3.7). This means that the bilinear form B in (3.6) is central to any analysis, and we shall assume that B is nonzero and satisfies properties B1–B2 defined as follows:

B1. $B(\mathbf{u}_1 + \mathbf{u}_2, \mathbf{v}) = B(\mathbf{u}_1, \mathbf{v}) + B(\mathbf{u}_2, \mathbf{v})$ and $B(\lambda \mathbf{u}, \mathbf{v}) = \lambda B(\mathbf{u}, \mathbf{v})$,

B2. $B(\mathbf{u}, \mathbf{v}) = B(\mathbf{v}, \mathbf{u})$,

B3. $B(\mathbf{u}, \mathbf{u}) = 0 \Longrightarrow \mathbf{u} = 0$, and

B4. $\langle \mathbf{u}, B(\mathbf{u_1}, \mathbf{u_2}) \rangle = \langle \mathbf{u}_1, B(\mathbf{u}, \mathbf{u_2}) \rangle$

for all $\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}, \mathbf{v} \in \mathbb{R}^{n+1}$, and $\lambda \in \mathbb{R}$.

Properties B1 and B2 are the bilinearity and symmetry properties of convolution, whereas B3 reflects the property of convolution over $\mathbb{R}^d$ whereby if the autocorrelation function is identically zero, that is, if $v * v = 0$, then v is zero almost everywhere. It turns out that B3 is not satisfied by the Hankel transform implemented here and by Kelley and Montgomery–Pettitt [15] for (3.6)–(3.7) because it is based on the sine transform, and a weaker property akin to B3 does hold, but only on a codimension-two subspace of $\mathbb{R}^{n+1}$. Property B4 holds whenever $B(\mathbf{u}, \mathbf{v}) = \varphi F^T(F\mathbf{u} \otimes F\mathbf{v})$ for some constant φ and some linear mapping F, and then B3 holds for such a B if F is invertible, where here and below we use $\otimes$ to denote the elementwise product of two vectors.

The finite-dimensional analogy of (3.4) under the HNC closure is a single equation for $\boldsymbol{\gamma} = (\gamma_i)_{i=0}^n$:

$$\boldsymbol{\gamma} = \rho B(\mathbf{f} + e^{-\beta \mathbf{U}} G(\gamma)), \mathbf{f} + e^{-\beta \mathbf{U}} G(\boldsymbol{\gamma} - \boldsymbol{\gamma}), \tag{3.8}$$

where $G(\boldsymbol{\gamma}) = -1 + \exp(\boldsymbol{\gamma})$. We shall use $\mathbf{N}_\beta(\boldsymbol{\gamma})$ to denote the operator that appears in the right-hand side of (3.8).

For the particular case of piecewise-constant basis functions used to locate approximate solutions of (3.4), we obtain the convolution operator B_n given by

$$B_n(\mathbf{u}, \mathbf{v}) = H^*((H\mathbf{u}) \otimes (H\mathbf{v})) \tag{3.9}$$

and H is a discrete Hankel transform that is defined elementwise by

$$(H\mathbf{u})_j = \left(\frac{R}{n}\right)^3 \frac{4n}{j^2} \sum_{i=1}^{n-1} \left[ij \sin\left(\frac{\pi ij}{n}\right) u_i\right] \qquad (\text{for } 1 \le j \le n-1)$$

and where $(H\mathbf{u})_0 = 2(H\mathbf{u})_1 - (H\mathbf{u})_2$ and $(H\mathbf{u})_n = 2(H\mathbf{u})_{n-1} - (H\mathbf{u})_{n-2}$. Similarly, H^* is the transform defined by

$$(H^*\mathbf{u})_j = \frac{n}{2R^2 j^2} \sum_{i=1}^{n-1} \left[ij \sin\left(\frac{\pi ij}{n}\right) u_i\right] \qquad (\text{for } 1 \le j \le n-1),$$

and this is also extended to the zeroth and nth coordinates by extrapolation. Of course, by the nature of the Hankel transform one can scale H to satisfy $H^2 = I$, but we have not done this; it is, however, clear that there is a constant φ depending on R and n such that $H^* = \varphi H = \varphi H^T$.

3.2.1. Localized vectors. The practical evaluation of the convolution of two vectors via the form B_n can be evaluated using three FFT-sine transforms, and note that the resulting convolution satisfies Properties B1–B2 above: B1 comes from the linearity of H, and B2 is true by definition. However, B3 is *not* satisfied for the following reason:

$$B_n(\mathbf{u}, \mathbf{u}) = \mathbf{0} \Longrightarrow H^*((H\mathbf{u})^2) = \mathbf{0} \Longrightarrow (H\mathbf{u})^2 \in \ker(H^*) = \operatorname{span}\{\mathbf{e}_0, \mathbf{e}_n\},$$

because both H and H^*, when acting on either of the vectors $\mathbf{e}_0 = (1, 0, \ldots, 0)$ or $\mathbf{e}_n = (0, \ldots, 0, 1)$, yield the zero vector.

As a result, $B_n(\mathbf{u}, \mathbf{u}) = \mathbf{0}$ for all $\mathbf{u} \in \operatorname{span}\{\mathbf{e}_0, \mathbf{e}_n\}$, and so we shall call any element of span $\{\mathbf{e}_0, \mathbf{e}_n\}$ a *localized* vector. Note that H is only a pseudoinverse of H^* in the sense that they are mutual inverses only on the space $\{0\} \times \mathbb{R}^{n-1} \times \{0\}$, the orthogonal complement of the space of localized vectors.

3.3. Algorithm implementation. Any smooth system of equations of the form (1.6), (3.4), or (3.8) is amenable to a Picard iteration algorithm for small values of ρ, and so we use this approach to locate a base solution on a solution branch. In the vicinity of a bifurcation, both Picard- and Newton-based iteration methods will fail to converge and one must modify the system to be solved in order to account for this instability. We have therefore adopted the well-known pseudo arc-length (PAL) strategy due to Keller [14] and others: view a solution branch $\mathcal{B}$ as a one-dimensional manifold that can be parameterized by an arc-length parameter s and augment (1.6) with a constraint in order to obtain a well-posed system of equations.

The system we solve in practice, again with a Newton method, is $F(\boldsymbol{\gamma}, \rho, s) = (0, 0)$, where

$$\mathbf{F}(\boldsymbol{\gamma}, \rho, s) \equiv (\boldsymbol{\gamma} - \rho \mathbf{N}_\beta(\boldsymbol{\gamma}), \mathbf{g}(\boldsymbol{\gamma}, \rho, s)), \tag{3.10}$$

and $\mathbf{g}$ is an additional arc-length constraint. In principle, there are many possible choices for the function $\mathbf{g}$, but the constraint used in [14] is

$$\mathbf{g}(\boldsymbol{\gamma}, \rho, s) = \langle \mathbf{s}_0, \boldsymbol{\gamma} - \boldsymbol{\gamma}_0 \rangle + \sigma_0(\rho - \rho_0) - (s - s_0),$$

where $(\mathbf{s}_0, \sigma_0)$ is the unit tangent vector at a given point $(\gamma_0, \rho_0, s_0) \in \mathcal{B}$, so that $\mathbf{F}(\boldsymbol{\gamma}_0, \rho_0, s_0) = 0$.

The difference $ds := s - s_0$ is a fixed and typically small quantity but it is sometimes necessary to reduce ds if $\mathcal{B}$ nears an apparent spinodal as there can be many fold bifurcations over a small interval of densities. We do this by monitoring the number of Newton iterations required to reduce the residual to a prescribed tolerance and reduce ds by a constant factor if this number is four or greater.

The Newton step of the PAL algorithm requires a linear solver, and we use an unpreconditioned, restarted GMRES(20) algorithm. As discussed in [15], this is appropriate for integral equations posed on a finite domain as the nonlinear convolution operator in the right-hand side of (1.6) can be formulated as a compact mapping in a suitable function space, and this leads to robust convergence properties for GMRES without preconditioning.

3.3.1. Computing loci of fold bifurcations. Since the problem (1.1) and (1.5) contains the parameters ρ and β, the location of a fold bifurcation may be considered to vary as a function of either ρ or β. We have therefore implemented an algorithm to compute the locus of bifurcation points as they change with respect to changes in temperature (or, rather, changes in β) by applying a Newton method to a discretization of the following augmented or codimension-two formulation:

$$\boldsymbol{\gamma} = \rho\, \boldsymbol{N}_\beta(\boldsymbol{\gamma}), \tag{3.11}$$

$$\boldsymbol{k} = \rho\, d_{\boldsymbol{\gamma}} \boldsymbol{N}_\beta(\boldsymbol{\gamma})[\boldsymbol{k}], \tag{3.12}$$

$$1 = \frac{1}{n} \sum_{j=0}^{n} \langle \boldsymbol{k}, \mathbf{e}_j \rangle\,. \tag{3.13}$$

Applying a Newton iteration to (3.11)–(3.12) allows us to locate a locus of fold points parameterized by ρ, noting that (3.11)–(3.12) ask that $\boldsymbol{\gamma}$ solve (3.8), but also that the linearization of the system not be invertible due to the existence of a nonzero null vector, $\boldsymbol{k}$, that appears in (3.12). The integral constraint in (3.13) is present only to ensure that $\boldsymbol{k}$ is nonzero.

Again, we used GMRES(20) as the linear solver for the Newton iteration method applied to (3.11)–(3.13). Moreover, because we were able to locate $(\boldsymbol{\gamma}, \boldsymbol{k}, \beta)$ for each candidate ρ in practice, a property that can be seen in Figure 1.1, we had no need to implement the PAL algorithm on (3.11)–(3.13).

3.4. Other details.

3.4.1. A fourth-order convolution operator. In order to increase the order of approximation of the finite-dimensional convolution operator $B_n(\mathbf{u}, \mathbf{v})$ with respect to the mesh parameter n, we utilized a simple Richardson extrapolation scheme that provides a fourth-order convolution form denoted $B_n^4(\mathbf{u}, \mathbf{v})$ that utilizes six FFT-sine operations and a single cubic interpolation.

Analytic derivatives were used for the discretization of (3.10), but these were calculated numerically using B_n rather than B_n^4, although the map $\mathbf{N}_\beta(\boldsymbol{\gamma})$ itself was

calculated using B_n^4. To form the numerical derivative operators of (3.11)–(3.13) we again used a difference formula based on the convolution operator B_n, rather than its fourth-order extension B_n^4. However, to evaluate (3.11)–(3.13) as a nonlinear operator acting on $(\boldsymbol{\gamma}, \boldsymbol{k}, \rho)$, we did use the fourth-order discrete convolution operator B_n^4. Irrespective of the parameter values, we used a high tolerance of 10^{-3} for GMRES, controlling the arc-length *ds* in such a way that three Newton iterations (or four for some computations) were needed for a nonlinear residual of 10^{-11}.

4. The fundamental property of discrete vapor spinodals. Let us begin this section with a definition.

DEFINITION 3. *A solution branch* $\boldsymbol{\mathcal{C}}$ *of the discrete OZ equation* (3.8) *(with any closure function* G *and any bilinear form* B*) is said to possess a* discrete vapor spinodal *if* $(\rho, \boldsymbol{\gamma}) = (0, \mathbf{0}) \in \boldsymbol{\mathcal{C}}$ *and* $\sup\{\rho : (\rho, \boldsymbol{\gamma}) \in \boldsymbol{\mathcal{C}}\} < \infty$.

Let us now assume a structure on the function G in (3.8) that is chosen to mimic the behavior of the floating-point realization of the exponential function $-1 + e^{\gamma}$:

G1. $G(\gamma) \geq -1$ and there exists an $m > 0$ such that $G(\gamma) = -1$ for all $\gamma \leq -m$,

G2. G is continuous and monotonic increasing, and it is C^1 smooth on $(-m, +\infty)$, and

G3. G is superlinear in the sense that $\lim_{\gamma \to +\infty} G(\gamma)/\gamma = +\infty$.

Assumption G1 effectively states that e^{-m} is indistinguishable from zero if m is sufficiently large and so is not actually satisfied by the choice $G(\gamma) = -1 + e^{\gamma}$ that yields the HNC closure. However, by taking m to be as large as we like, one can find functions G that satisfy G1–G3 and which are as close as we like to the HNC choice. Given the approximate nature of the integral equation theories considered in this paper, perhaps this is not the unreasonable assumption it first appears to be.

Throughout the remainder of the paper, we shall write $\mathtt{g}$ for the inverse of $1 + G$ on the domain $[-m, \infty)$ so that the domain of $\mathtt{g}$ is $[0, \infty)$ with range $[-m, \infty)$ and $\lim_{x \to \infty} \mathtt{g}(x)/x = 0$ by G3.

The following proposition shows that the finite-dimensionality of (3.8) ensures that one cannot observe a divergent-in-norm total correlation function independently of the direct correlation function, quite unlike the continuous case.

PROPOSITION 1. *For fixed* $\beta > 0$ *and any discrete convolution form* B *that satisfies* B1 *and* B2*, there is a connected set* $\mathcal{C} \subset \mathbb{R}^{n+1}$ *of solutions of* (3.8) *such that* $(\boldsymbol{\gamma}, \rho) = (0, 0) \in \mathcal{C}$ *and* $\mathcal{C}$ *is unbounded in the following sense: for each* $M > 0$*, a solution pair* $(\boldsymbol{\gamma}, \rho) \in \mathcal{C}$ *can be found such that* $\|\boldsymbol{\gamma}\| + \rho = M$ *with* $\rho > 0$*. As a result, if* $\mathcal{C}$ *possesses a discrete vapor spinodal, then there is a sequence* $(\boldsymbol{\gamma}_k, \rho_k)$ *and a* $\rho_{\rm sp} \geq 0$ *such that* $\|\boldsymbol{\gamma}_k\| \to \infty$ *and* $\rho_k \to \rho_{\rm sp}$ *as* $k \to \infty$*.*

The discrete total and direct correlation functions $\mathbf{h}_k$ *and* $\mathbf{c}_k$ *corresponding to* $\boldsymbol{\gamma}_k$ *satisfy*

$$\mathbf{h} = \mathbf{c} + \rho_k B(\mathbf{h}, \mathbf{c}), \tag{4.1}$$

$$\mathbf{h} = \mathbf{f} + e^{-\beta \mathbf{U}} G(\mathbf{h} - \mathbf{c}). \tag{4.2}$$

If $\|\boldsymbol{h}_k\| \to \infty$*, then* $\|\boldsymbol{c}_k\| \to \infty$ *and* $\|\boldsymbol{c}_k\|_\infty \sim \|\boldsymbol{h}_k\|_\infty + o(1)$ *as* $k \to \infty$*.*

Finally, suppose B *also satisfies* B4 *and has the property that* $B(\mathbf{e}_0, \mathbf{e}_0) = \mathbf{0}$*. Under these additional assumptions if* $\|\boldsymbol{c}_k\| \to \infty$*, then* $\|\boldsymbol{h}_k\| \to \infty$*.*

Proof. The existence of $\mathcal{C}$ with the stated properties follows immediately from the implicit function theorem and the Leray–Schauder continuation principle (see [25] for example).

Now suppose that $\mathcal{C}$ is a discrete vapor spinodal; then the only solution of (3.8) with $\rho = 0$ is the base solution $\boldsymbol{\gamma} = \mathbf{0}$, and it follows immediately that any solution pair $(\boldsymbol{\gamma}, \rho) \in \mathcal{C}$ with $\boldsymbol{\gamma} \neq \mathbf{0}$ must satisfy $0 < \rho \leq \rho_{\max}$, where $\rho_{\max} := \sup\{\rho \geq 0 : (\boldsymbol{\gamma}, \rho) \in \mathcal{C}\}$. Hence it follows from the unboundedness of $\mathcal{C}$ in the sense stated that the norm of $\boldsymbol{\gamma}$ must diverge along $\mathcal{C}$.

From (4.2) and G1 it follows that $\mathbf{h} \geq -\mathbf{1}$ and that the zeroth component of $\mathbf{h}$ is $\mathbf{h}_0 = -1$ so that (4.2) can be written

$$\mathsf{g}(e^{\beta \mathbf{U}}(\mathbf{h} + \mathbf{1})) = \mathbf{h} - \mathbf{c}, \tag{4.3}$$

ignoring the undefined zeroth component of $e^{\beta \mathbf{U}}(\mathbf{h}+\mathbf{1})$ *for the moment.* Hence, considering the vectors $\mathbf{h}$ and $\mathbf{c}$ and supposing that the ith entry in $\mathbf{h}$ is nonzero, assuming $i \geq 1$, we obtain

$$c_i = h_i - \mathsf{g}(e^{\beta u(r_i)}(h_i + 1)) = h_i \left(1 - \frac{\mathsf{g}(e^{\beta u(r_i)}(h_i + 1))}{h_i}\right),$$

and therefore, if $h_j = \langle \mathbf{e}_j, \mathbf{h} \rangle = \|\mathbf{h}\|_\infty > 1$ and so $j \geq 1$ by the lower uniform bound $\mathbf{h} \geq -\mathbf{1}$, then

$$c_j = \|\mathbf{h}\|_\infty \left(1 - \frac{\mathsf{g}(e^{\beta u(r_j)}(\|\mathbf{h}\|_\infty + 1))}{\|\mathbf{h}\|_\infty}\right),$$

where $\|\cdot\|_\infty$ is the usual maximum norm of a vector. Hence, we may assume by choosing a subsequence if necessary that if $\mathcal{C}$ has a discrete vapor spinodal, then for some fixed, nonzero $j \in \{1, 2, \ldots, n\}$ there results

$$\frac{\|\mathbf{c}\|_\infty}{\|\mathbf{h}\|_\infty} \geq \frac{|c_j|}{\|\mathbf{h}\|_\infty} = \left|1 - \frac{\mathsf{g}(e^{\beta u(r_j)}(\|\mathbf{h}\|_\infty + 1))}{\|\mathbf{h}\|_\infty}\right|,$$

again provided $\|\mathbf{h}\|_\infty > 1$.

Thus, if $(\mathbf{h}_k, \mathbf{c}_k)$ is a sequence of solutions of (4.1)–(4.2) and $\|\mathbf{h}_k\| \to \infty$ as $k \to \infty$ in any norm, then $\|\mathbf{h}_k\|_\infty \to \infty$ as all finite-dimensional norms are equivalent. Since $\lim_{x\to\infty} \mathsf{g}(x)/x = 0$ it is clear that $\|\mathbf{c}_k\|_\infty / \|\mathbf{h}_k\|_\infty \to 1$ as $k \to \infty$ as claimed.

For the last part, suppose, without loss of any generality, that there is an $M > 0$ such that $\|\mathbf{h}_k\|_\infty \leq M$; then (4.3) shows that the jth component of $\mathbf{c}_k$, $|\langle \mathbf{e}_j, \mathbf{c}_k \rangle|$ for $j \geq 1$, is bounded above by

$$|\langle \mathbf{e}_j, \mathbf{c}_k \rangle| \leq M + \max_{-1 \leq x \leq M} g((x+1)e^{\beta \max_{j\geq 1}(u(r_j))}) < \infty, \tag{4.4}$$

which is potentially very large in practice but finite nevertheless.

Thus, the only way in which $\|\mathbf{c}_k\|$ can diverge is if $c_k := \langle \mathbf{e}_0, \mathbf{c}_k \rangle$ diverges as $k \to \infty$. From (4.1) there results

$$\langle \mathbf{e}_0, \mathbf{h}_k \rangle = c_k + \rho_k \langle \mathbf{e}_0, B(\mathbf{h}_k, \mathbf{c}_k) \rangle$$

so that

$$|c_k| \leq |\langle \mathbf{e}_0, \mathbf{h}_k \rangle| + \rho_{\max} |\langle \mathbf{e}_0, B(\mathbf{h}_k, \mathbf{c}_k) \rangle| \leq |-1| + \rho_{\max} |\langle \mathbf{h}_k, B(\mathbf{c}_k, \mathbf{e}_0) \rangle|.$$

Writing $\mathbf{c}_k = c_k \mathbf{e}_0 + \mathbf{c}_k^\perp$, where $\langle \mathbf{e}_0, \mathbf{c}_k^\perp \rangle \equiv 0$, we obtain

$$|c_k| \leq 1 + \rho_{\max} |\langle \mathbf{h}_k, B(c_k \mathbf{e}_0 + \mathbf{c}_k^\perp, \mathbf{e}_0) \rangle| \leq 1 + \rho_{\max} |\langle \mathbf{h}_k, B(\mathbf{c}_k^\perp, \mathbf{e}_0) \rangle|.$$

As a result, we finally obtain a bound on $|c_k|$ because of the existence of the pointwise upper bound (4.4) on $\mathbf{c}_k^\perp$, and so the final claim holds. ∎

We can now prove the following.

THEOREM 2. *Suppose that* G1–G3 *are satisfied by* G, *that* $B = B_n$, *and that the resulting equation* (3.8) *has a solution branch* $\mathcal{C}$ *with a discrete vapor spinodal. Take any sequence of solutions* $(\mathbf{h}_k, \boldsymbol{c}_k)$ *of* (4.1)–(4.2) *with density values* ρ_k *corresponding to solutions from* $\mathcal{C}$ *such that* $\|\mathbf{h}_k\| \to \infty$ *and* $(\mathbf{h}_k)$ *does not* localize at the cut-off *in the sense that*

$$\liminf_{k\to\infty} \frac{|\langle \mathbf{e}_j, \mathbf{h}_k\rangle|}{\|\mathbf{h}_k\|} > 0 \qquad \text{for some } j \in \{1,\dots,n-1\}.$$

Assuming also that $\langle \mathbf{e}_0, \mathbf{c}_k\rangle$ *is a bounded sequence, if* $\rho_k \to \rho_{\rm sp}$ *as* $k \to \infty$, *then* $\rho_{\rm sp} = 0$.

Proof. Let us begin by reformulating (4.1)–(4.2) by writing $\mathbf{c} = c_0\mathbf{e}_0 + \mathbf{c}^\perp$ and $\mathbf{h} = h_0\mathbf{e}_0 + \mathbf{h}^\perp$, where $\mathbf{c}^\perp, \mathbf{h}^\perp \in \text{span}\{\mathbf{e}_0\}^\perp$. Then (4.1) becomes

$$c_0\mathbf{e}_0 + \mathbf{c}^\perp = h_0\mathbf{e}_0 + \mathbf{h}^\perp + \rho B(c_0\mathbf{e}_0 + \mathbf{c}^\perp, h_0\mathbf{e}_0 + \mathbf{h}^\perp),$$

and projecting this onto $\text{span}\{\mathbf{e}_0\}$ gives

$$\begin{aligned} c_0 &= h_0 - \rho\left\langle \mathbf{e}_0, B(c_0\mathbf{e}_0 + \mathbf{c}^\perp, h_0\mathbf{e}_0 + \mathbf{h}^\perp)\right\rangle \\ &= h_0 - \rho\left\langle B(\mathbf{e}_0, c_0\mathbf{e}_0 + \mathbf{c}^\perp), h_0\mathbf{e}_0 + \mathbf{h}^\perp\right\rangle \quad \text{(using B1 and B4)} \\ &= h_0 - \rho\left\langle B(\mathbf{e}_0, \mathbf{c}^\perp), h_0\mathbf{e}_0 + \mathbf{h}^\perp\right\rangle \\ &= h_0 - \rho\left\langle \mathbf{c}^\perp, B(\mathbf{e}_0, h_0\mathbf{e}_0 + \mathbf{h}^\perp)\right\rangle \quad (\text{since } B_n(\mathbf{e}_0, \mathbf{e}_0) = \mathbf{0}) \\ &= h_0 - \rho\left\langle \mathbf{c}^\perp, B(\mathbf{e}_0, \mathbf{h}^\perp)\right\rangle = h_0 - \rho\left\langle \mathbf{e}_0, B(\mathbf{c}^\perp, \mathbf{h}^\perp)\right\rangle. \end{aligned}$$

However, from (4.2), $h_0 = -1$ as $(e^{-\beta\mathbf{U}})_0$ is interpreted as zero, whence

$$c_0 = -1 - \rho\left\langle \mathbf{e}_0, B(\mathbf{c}^\perp, \mathbf{h}^\perp)\right\rangle,$$

which defines a bilinear functional of $\mathbf{c}^\perp$ and $\mathbf{h}^\perp$ that depends affinely on ρ.

Now (4.1) can be projected onto $\text{span}\{\mathbf{e}_0\}^\perp$ with projector Π to yield

$$\mathbf{h}^\perp = \mathbf{c}^\perp + \rho\Pi B(c_0(\rho, \mathbf{c}^\perp, \mathbf{h}^\perp)\mathbf{e}_0 + \mathbf{c}^\perp, -\mathbf{e}_0 + \mathbf{h}^\perp), \tag{4.5}$$

$$\mathbf{h}^\perp = -\mathbf{1}^\perp + e^{-\beta\mathbf{U}^\perp} G(\mathbf{h}^\perp - \mathbf{c}^\perp), \tag{4.6}$$

where the advantage of this formulation is that $e^{-\beta\mathbf{U}^\perp}$ is strictly positive for any intermolecular potential, thus removing the problematic singularity at $r = 0$. Here, we are using a superscript $\perp$, as in $\mathbf{v}^\perp$, to denote the projection $\Pi(\mathbf{v})$. As a result, the singularity in (4.6) has been removed and (4.6) is now equivalent to

$$\mathbf{c}^\perp = \mathbf{h}^\perp - \mathbf{g}(e^{\beta\mathbf{U}^\perp}(\mathbf{h}^\perp + \mathbf{1}^\perp)). \tag{4.7}$$

Returning to the sequence of solutions from $\mathcal{C}$, define new sequences

$$P_k := \mathbf{h}_k^\perp/\|\mathbf{h}_k\| \quad \text{and} \quad Q_k := \mathbf{c}_k^\perp/\|\mathbf{h}_k\|,$$

as defined in the statement of the theorem; then

$$\frac{P_k - Q_k}{\|\mathbf{h}_k\|} = \rho_k \Pi B \left(\frac{\langle \mathbf{e}_0, \mathbf{c}_k \rangle \mathbf{e}_0}{\|\mathbf{h_k}\|} + Q_k, -\frac{\mathbf{e}_0}{\|\mathbf{h}_k\|} + P_k \right),$$

and

$$Q_k = P_k - \frac{\mathbf{g}(e^{\beta \mathbf{U}^\perp}(\mathbf{h}_k^\perp + \mathbf{1}^\perp))}{\|\mathbf{h}_k\|}. \tag{4.8}$$

Using standard compactness properties, one can find P' of unit norm such that $P_k \to P'$, and therefore $Q_k \to P'$ by (4.8) using the sublinearity of $\mathbf{g}$. As a result, we find that

$$\rho_k \Pi B \left(\frac{\langle \mathbf{e}_0, \mathbf{c}_k \rangle}{\|\mathbf{h_k}\|} + P', P' \right) \to 0$$

as $k \to \infty$.

By hypothesis we can find a $\rho_{\text{sp}} \geq 0$ such that by extracting a further subsequence if necessary $\rho_{\text{sp}} \Pi B\,(P', P') = \mathbf{0}$. If $\rho_{\text{sp}} > 0$ then $\Pi B\,(P', P') = \mathbf{0}$ follows and so $B\,(P', P') = \alpha \mathbf{e}_0$. Recalling that $B = B_n$ in the statement of the theorem, $H^*(HP')^2 = \alpha \mathbf{e}_0$ whence $\alpha = 0$ by the fact that $H\mathbf{e}_0 = \mathbf{0}$. Hence $(HP')^2 = \alpha \mathbf{e}_0$ for some $\alpha \in \mathbb{R}$, so that $HP' = \sqrt{\alpha}\mathbf{e}_0$ giving $\alpha = 0$ as H is self-adjoint, so that finally $P' \in \text{span}\{\mathbf{e}_0, \mathbf{e}_n\}$. By construction of the sequence (P_k), it follows that $P' \in \text{span}\{\mathbf{e}_n\}$ which states that $\mathbf{h}_k$ localizes at the cut-off, contradicting an assumption of the theorem. □

From Theorem 2 we have the following trichotomy in terms of discrete vapor spinodals when using the convolution form $B = B_n$ in (4.1)–(4.2). If $\boldsymbol{\mathcal{C}}$ is that discrete vapor spinodal, at least one of the following applies along a sequence $(\mathbf{h}_k, \mathbf{c}_k, \rho_k) \in \boldsymbol{\mathcal{C}}$:

T1. Density ρ_k heads to zero,

T2. $\langle \mathbf{e}_0, \mathbf{c}_k \rangle$ is unbounded, or

T3. $\mathbf{h}_k / \|\mathbf{h}_k\|$ (up to a subsequence) tends toward the localized vector $\mathbf{e}_n$.

Note that each of T1, T2, and T3 represents a different, nonphysical possibility, and both T1 and T3 have been observed in practice when G takes the HNC form, even though G1 does not apply in that context. On the other hand, we have not observed T2 in practice. It is an immediate corollary of T1 that (4.1)–(4.2) has a fold bifurcation in the sense of Definition 2 at some value of the density parameter, and so one should expect to observe a folded geometry of isothermal vapor solution branches at subcritical temperatures.

4.1. Qualitatively correct convolution forms. The T1–T3 trichotomy again raises the central question of the choice of convolution form B in (3.8). There are advantages in defining B by

$$B(\mathbf{u}, \mathbf{v}) = F^T(F\mathbf{u} \otimes F\mathbf{v}) \quad \text{such that } FF^T = I \tag{4.9}$$

for some linear transformation F for the following reason. Such a choice for B allows one to introduce a *qualitatively correct* discrete compressibility functional, χ_d^{-1}, say, for (4.1)–(4.2) (with any nonlinearity G) by setting

$$\chi_d^{-1} = 1 - \rho \langle \mathbf{e}_0, F\mathbf{c} \rangle .$$

By the term *qualitatively correct*, we mean that unlike (4.1)–(4.2) which is realized on setting $B = B_n$, using instead the convolution form B which is based on such

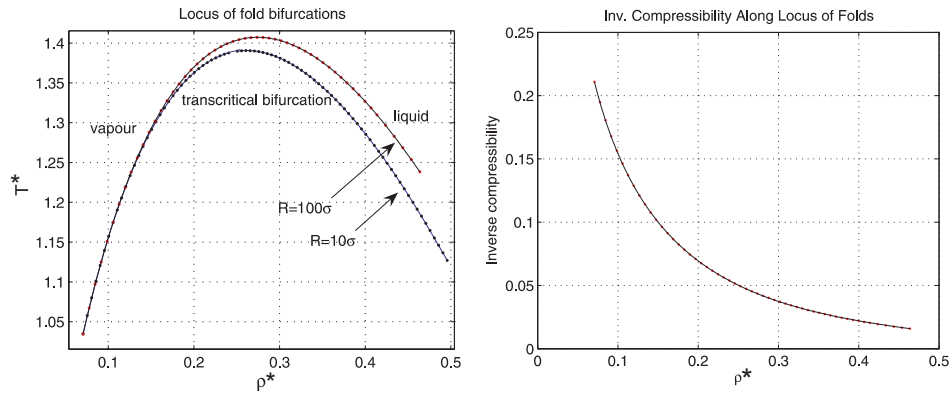

FIG. 5.1. *(Left) A comparison of two computed bifurcation loci for two values of R, namely,* 10σ *and* 100σ*. (Right) For the* $R = 100\sigma$ *case, inverse compressibility is evaluated along the liquid and vapor branches; note that this is never zero.*

a transformation F in (4.9) ensures that there is no solution of (4.1)–(4.2) that has zero inverse compressibility. This means that there is a version of Lemma 2.1 that holds when the convolution form B is based on (4.9), but Lemma 2.1 fails to hold when B_n is the chosen convolution form. We shall report the results of an analysis that results from the implemenation of a qualitatively correct convolution form in a separate publication.

5. Computations.

5.1. The LJ 6-12 potential. Throughout this section we use the Lennard–Jones potential and set $\sigma = 1, \epsilon = 1$, with the cut-off R chosen to be 100σ unless stated otherwise, and we have used a numerical mesh of $2^{13} + 1$ points.

1. Figure 5.1 (left) is a comparison of two codimension-two bifurcation loci in the (ρ, T)-plane that shows a significant discrepancy between the use of two choices of cut-off parameter R. The right-hand figure shows the values of inverse compressibility obtained along the loci from the left-hand curve for the $R = 100\sigma$ case. For *true spinodals*, which we gleaned from our previous analysis should not occur in the computations, this curve should be identically zero; clearly it is not.

One may notice that the curve in Figure 5.1 (left) lies slightly above that reported by others, such as [17, p. 833] and Figure 3 of [3]. The reasons for this are that the cut-off parameter R in the stated references is different from ours, and we have generally used a different number of points for our discretization than the cited articles. Our data may be slightly different also because we have computed the location of bifurcation points, rather than relying on the extrapolation of a numerical algorithm in order to estimate their location.

2. Figure 5.2 shows a computed unfolding of the transcritical bifurcation from the apex of Figure 5.1 (left), where nine different temperature values have been used to compute three subcritical isothermal solution branch pairs and six supercritical vapor isotherms. The appearance of several fold bifurcations can be seen on both liquid (high-density) and vapor (low-density) branches, and note the apparent existence of a locus of solutions of (3.6)–(3.7) with zero inverse compressibility.

3. Shown in Figure 5.3 (left) are the results of a computation undertaken with a *high* temperature at $\beta = 1$ and with $R = 120\sigma$; note the large number of fold bifurcations that seem to accumulate in the vicinity where inverse compressibility is

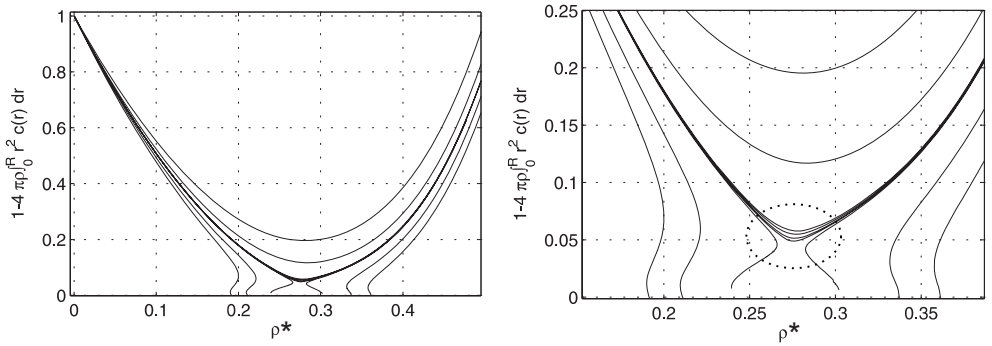

FIG. 5.2. *(Left) Inverse compressibility against density. (Right) Zoom of left-hand plot showing positive values of inverse compressibility at the fold points. Solutions with zero inverse compressibility are clearly seen but not* at *the fold bifurcations.*

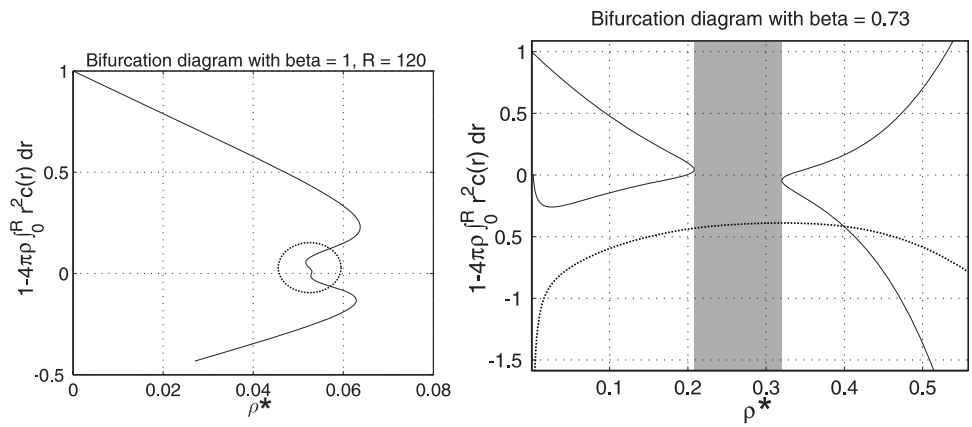

FIG. 5.3. *(Left) A solution branch with several bifurcations showing inverse compressibility against density with* $R = 120$ *and* $(1/T^* =)\beta = 1$. *(Right) Three solution branches and bifurcations with inverse compressibility plotted against density at* $R = 120$ *and* $\beta = 0.73$. *An apparent region (the shaded region) that contains no solutions is filled by a solution branch with negative compressibility.*

zero. In the right-hand figure we have located a branch of solutions at $\beta = 0.73$ that spans a shaded region where no solution is believed to exist, although this particular branch contains only solutions that have negative compressibility. Other branches of solutions have been found before within this region [21], but they were complex-valued and their presence was a simple consequence of the existence of fold bifurcations. We have not been able to locate any *real* solutions in this region with positive compressibility; that is not to say that none are there, but, unlike vapor isotherms, we have no systematic method for locating solutions in this region.

5.2. Comparison with the double Yukawa potential. For all of the following computations we used a numerical mesh with $2^{12} + 1$ points with the following double Yukawa (DY) intermolecular potential for various values of the cut-off R:

$$u_{DY}(r) = \frac{\epsilon}{r}\left(A_1 e^{-z_1(r-\sigma)} - A_2 e^{-z_2(r-\sigma)}\right),$$

where σ is particle diameter, and $A_1 = 1.6438\sigma$, $z_1 = 14.7\sigma^{-1}$, $A_2 = 2.03\sigma$, and $z_2 = 2.69\sigma^{-1}$ are the parameter values used in [8, 20]. This intermolecular potential

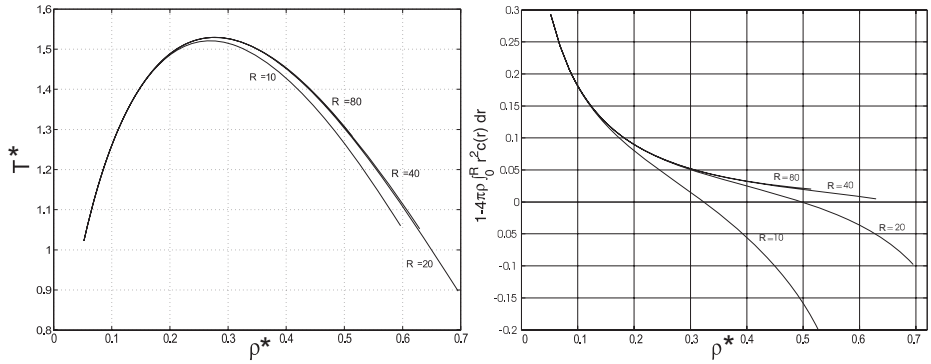

FIG. 5.4. *(Left) Locus of fold bifurcations for the DY potential with varied cut-offs and* 4096 *mesh points. (Right) Values of inverse compressibility along the locus for* $R = 10\sigma, \ldots, 80\sigma$.

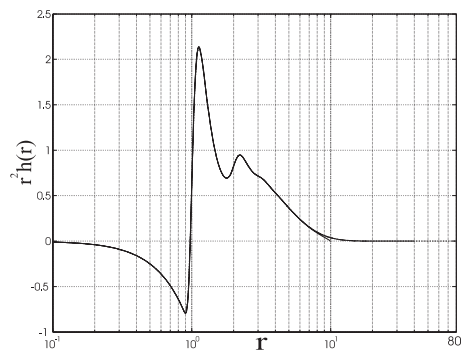

FIG. 5.5. *(Left) A plot of the low-density correlation function* $r^2h(r)$ *along the bifurcation locus from Figure* 5.4 *(left) at* $(\rho^*, T^*) = (0.085, 1.2)$ *for cut-off values* $R = 10\sigma, 20\sigma, 40\sigma$, *and* $R = 80\sigma$. *(Right) The high-density correlation function* $r^2h(r)$ *along the same bifurcation locus at* $(\rho^*, T^*) = (0.597, 1.06)$ *with* $R = 80\sigma$.

is commonly used as it has more rapid decay than LJ, with a repulsive soft core and attractive tail, which, it is believed, should lead to greater stability in computations. However, the property associated with the HNC closure of having L^1-divergence of the total correlation with L^2-boundedness at a spinodal is totally unaffected by the choice of potential and the decay rate of its tail.

1. Figure 5.4 is a repetition of Figure 5.1 for the DY potential for varying cut-offs: $R = 10\sigma, 20\sigma, 40\sigma$, and 80σ. The critical points at the apex of the locus in Figure 5.4 (left) are all close to $\rho_c = 0.27$ at $T_c = 1.52$. The curves corresponding to different cut-off points are in good agreement up to the apex but differ slightly beyond it; however, the values of inverse compressibility do vary somewhat with respect to the cut-off as shown in Figure 5.4 (right).

2. Figure 5.5 (left) illustrates a computed thermodynamic state with large compressibility that is located in the relatively low-density vapor Figure 5.4 (left), specifically at $(\rho^*, T^*) = (0.085, 1.2)$. Solutions have been computed with $R = 10\sigma, 20\sigma, 40\sigma$, and 80σ, and note that solutions at cut-offs higher than $R = 10\sigma$ are visually indistinguishable. A thermodynamic state from the high-density liquid region of Figure 5.4 (left) is shown in Figure 5.5 (right) for comparison.

FAST COMPUTATION OF FOURIER INTEGRAL OPERATORS*

EMMANUEL CANDÈS†, LAURENT DEMANET‡, AND LEXING YING§

Abstract. We introduce a general purpose algorithm for rapidly computing certain types of oscillatory integrals which frequently arise in problems connected to wave propagation, general hyperbolic equations, and curvilinear tomography. The problem is to numerically evaluate a so-called Fourier integral operator (FIO) of the form $\int e^{2\pi i\Phi(x,\xi)}a(x,\xi)\,\hat{f}(\xi)\mathrm{d}\xi$ at points given on a Cartesian grid. Here, ξ is a frequency variable, $\hat{f}(\xi)$ is the Fourier transform of the input f, $a(x,\xi)$ is an amplitude, and $\Phi(x,\xi)$ is a phase function, which is typically as large as $|\xi|$; hence the integral is highly oscillatory. Because a FIO is a dense matrix, a naive matrix vector product with an input given on a Cartesian grid of size N by N would require $O(N^4)$ operations. This paper develops a new numerical algorithm which requires $O(N^{2.5}\log N)$ operations and as low as $O(\sqrt{N})$ in storage space (the constants in front of these estimates are small). It operates by localizing the integral over polar wedges with small angular aperture in the frequency plane. On each wedge, the algorithm factorizes the kernel $e^{2\pi i\Phi(x,\xi)}a(x,\xi)$ into two components: (1) a diffeomorphism which is handled by means of a nonuniform FFT and (2) a residual factor which is handled by numerical separation of the spatial and frequency variables. The key to the complexity and accuracy estimates is the fact that the separation rank of the residual kernel is *provably independent of the problem size*. Several numerical examples demonstrate the numerical accuracy and low computational complexity of the proposed methodology. We also discuss the potential of our ideas for various applications such as reflection seismology.

1. Introduction.

This paper introduces a general purpose algorithm to compute the action of linear operators which are frequently encountered in analysis and scientific computing. These operators take the form

$$(Lf)(x) = \int_{\mathbb{R}^d} a(x,\xi)e^{2\pi i\Phi(x,\xi)}\hat{f}(\xi)\,\mathrm{d}\xi, \tag{1.1}$$

where $\Phi(x,\xi)$ is a phase function that is smooth in (x,ξ) for $\xi \neq 0$ and obeys the homogeneity relation $\Phi(x,\lambda\xi) = \lambda\Phi(x,\xi)$ for λ positive, and $a(x,\xi)$ is a smooth amplitude term. As is standard, $\hat{f}$ is the Fourier transform of f defined by

$$\hat{f}(\xi) = \int_{\mathbb{R}^d} f(x)e^{-2\pi ix\xi}\,\mathrm{d}x. \tag{1.2}$$

With the proper regularity assumptions on the amplitude and the phase,[1] (1.1) defines a class of oscillatory integrals known as Fourier integral operators (FIOs). FIOs are the subject of considerable study for many of the operators encountered in physics and other fields. For instance, most differential and pseudodifferential operators are FIOs. Convolutions and multiplications by smooth functions are FIOs. Some "principal value" integrals are FIOs. And the list goes on.

An especially important example of a FIO is the solution operator to the free-space wave equation in $\mathbb{R}^d$, $d > 1$,

$$\frac{\partial^2 u}{\partial t^2}(x,t) = c^2 \Delta u(x,t), \tag{1.3}$$

with initial conditions $u(x,0) = u_0(x)$ and $\frac{\partial u}{\partial t}(x,0) = 0$, say. Everyone knows that for constant speeds, the Fourier transform decouples the different frequency components of u. Each Fourier component obeys an ordinary differential equation which can be solved explicitly. The solution $u(x,t)$ is the superposition of these Fourier modes and is given by

$$u(x,t) = \frac{1}{2}\left(\int e^{2\pi i(x\cdot\xi + c|\xi|t)} \hat{u_0}(\xi) \mathrm{d}\xi + \int e^{2\pi i(x\cdot\xi - c|\xi|t)} \hat{u_0}(\xi) \mathrm{d}\xi \right). \tag{1.4}$$

The connection is now clear: the solution operator is the sum of two FIOs with phase functions

$$\Phi_{\pm}(x,\xi) = x\cdot\xi \pm c|\xi|t.$$

For variable but reasonably smooth sound speeds $c(x)$, the solution operator is for small times a sum of two FIOs with more complicated phases and amplitudes. In particular, the phase can be constructed from the optical traveltime in a medium with index of refraction $1/c(x)$; see [11] for details.

An important property of FIOs is that they *displace* wavefront sets and singular supports (where the solution is singular), which is the favored mathematical way of formulating propagation of singularities along characteristic manifolds for hyperbolic equations [20]. For this reason, the solution operators for heat equations or Schrödinger equations are not FIOs, because these equations *diffuse* or *disperse* wavefronts. More precisely, their solution operators could potentially be put in the form (1.1), but the homogeneity relation $\Phi(x,\lambda\xi) = \lambda\Phi(x,\xi)$ would be lost.

In short, it is useful to think of FIOs as proxies for the solution operator to large classes of hyperbolic differential equations.

1.1. FIO computations. Numerical simulation of free wave propagation with constant sound speed is straightforward. As long as the solution $u(x,t)$ is sufficiently well localized both in space and frequency, it can be computed accurately and rapidly by applying the sequence of steps below.

1. Compute the fast Fourier transform (FFT) of u_0.
2. Multiply the result by $e^{\pm 2\pi i c|\xi|t}$, and sum as in (1.4).

[1]The amplitude should be C^∞ and obey (2.3). The phase should be C^∞ except at $\xi = 0$. In general, we do *not* require the nondegeneracy condition $\det(\frac{\partial^2 \Phi}{\partial x_i \partial \xi_j}) \neq 0$ if the only goal is to apply the FIO (note that such a FIO may not be invertible). With this being said, we can handle only canonical relations that are locally the graph of a function; i.e., we do not deal with multivalued phases.

3. Compute the inverse FFT.

Of course, this works only in the very special case where the amplitude a is independent of x, and where the phase is of the form $x \cdot \xi$ plus a function of ξ alone. Expressed differently, this works when the FIO is shift-invariant so that it is diagonal in the Fourier basis. Note that there is in general no formula for the eigenfunctions when Φ or a depend on x. Computing these eigenfunctions on the fly is out of the question when the objective is merely to compute the action of the operator. (Note that even if the spectral decomposition of the operator were available, it is not clear how one would use it to speed up computations.)

The object of this paper is to find an algorithm that is considerably faster than evaluating (1.1) by direct quadratures and is yet suited to handle large classes of phases and amplitudes. Most of the existing fast summation techniques rely on either the nonoscillatory behavior (such as wavelet-based techniques [8]) or the existence of a low rank approximation (fast multipole methods [26], hierarchical matrices [27], pseudodifferential separation [4]). The difficulty here is that the kernel $e^{2\pi i\Phi(x,\xi)}$ is highly oscillatory and does not have a low rank separated approximation. Therefore, all the modern techniques are not directly applicable.

The main claim of this paper, however, is that there is a way to decompose the operator into a sum of components for which the oscillations are well understood and low rank representations are available. In addition, the number of such components is reasonably small, which paves the way to faster algorithms. Before expanding on this idea, we first explain the discretization of the operator (1.1).

1.2. Discretization. For simplicity, we restrict our attention in this paper to the two-dimensional case $d = 2$. The main ideas apply readily to the higher dimensions, though the analysis and implementation would be more involved.

Just as the discrete Fourier transform is the digital analogue of the continuous Fourier transform, one can also introduce discrete FIOs. Given a function f defined on a Cartesian grid $X = \{x = (\frac{n_1}{N}, \frac{n_2}{N}), 0 \le n_1, n_2 < N, \text{ and } n_1, n_2 \in \mathbb{Z}\}$, we simply define the discrete FIO by

$$(Lf)(x) := \frac{1}{N} \sum_{\xi \in \Omega} a(x,\xi) e^{2\pi i \Phi(x,\xi)} \hat{f}(\xi) \tag{1.5}$$

for every $x \in X$. (We are sorry for overloading the symbol L to denote both the discrete and continuous objects but there will be no confusion in what follows.) The summation above is taken over all $\Omega = \{\xi = (n_1, n_2), -\frac{N}{2} \le n_1, n_2 < \frac{N}{2}, \text{ and } n_1, n_2 \in \mathbb{Z}\}$, and throughout this paper, we will assume that N is an even integer. Here and below, $\hat{f}$ is the discrete Fourier transform (DFT) of f and is defined as

$$\hat{f}(\xi) = \frac{1}{N} \sum_{x \in X} e^{-2\pi i x \cdot \xi} f(x). \tag{1.6}$$

The normalizing constant $\frac{1}{N}$ in (1.5) (resp., (1.6)) ensures that L (resp., the DFT) is a discrete isometry in the case where $\Phi(x,\xi) = x \cdot \xi$.

The formula (1.5) turns out to be an accurate discretization of (1.1) as soon as f obeys standard localization estimates both in space and frequency. A justification of this fact, however, would go beyond the scope of this paper and is omitted. In the remainder of the paper, we will take (1.5) as the quantity we wish to compute once we are given a phase and an amplitude function.

The parameter N measures the size and difficulty of the computational problem. In a nutshell, it corresponds to the number of points which are needed in each direction to accurately sample the continuous object $f(x)$. This is the reason why N will be a central quantity throughout the rest of paper.

As mentioned earlier, the straightforward method for computing (1.5) simply evaluates the summation independently for each x. Since each sum takes $O(N^2)$ operations and there are N^2 grid points in X, this strategy requires $O(N^4)$ operations. When N is moderately large, this can be prohibitive. This paper describes a novel algorithm which computes all the values of $Lf(x)$ for $x \in X$ with high accuracy in $O(N^{2.5} \log N)$ operations. The only requirement is that the amplitude and the phase obey mild smoothness conditions, which are in fact standard. As a matter of fact, our algorithm can be applied even to the cases where the nondegeneracy condition $\det\left(\frac{\partial^2 \Phi}{\partial x_i \partial \xi_j}\right) \neq 0$ does not hold.

1.3. Separation within angular wedges. This section outlines the main idea of the paper. Let $\arg \xi$ be the angle between ξ and the horizontal vector $(1, 0)$, and partition the frequency domain into a family of angular wedges $\{W_\ell\}$ defined by

$$W_\ell = \{\xi : (2\ell - 1)\pi/\sqrt{N} \leq \arg \xi < (2\ell + 1)\pi/\sqrt{N}\}$$

for $0 \leq \ell < \sqrt{N}$ (assume $\sqrt{N}$ is an integer). An important property of these wedges is that each W_ℓ satisfies the parabolic relationship

$$\textit{length} \simeq \textit{width}^2, \tag{1.7}$$

up to multiplicative constants independent of N. There are $O(\sqrt{N})$ such wedges, as illustrated in Figure 1.

For each wedge W_ℓ, we let χ_ℓ be the indicator function of W_ℓ. Similarly, we denote by $\hat{\xi}_\ell$ the unit vector pointing to the center direction of W_ℓ

$$\hat{\xi}_\ell = \left(\cos \frac{2\ell\pi}{\sqrt{N}}, \sin \frac{2\ell\pi}{\sqrt{N}}\right).$$

It follows from the identify $\sum_\ell \chi_\ell(\xi) = 1$ that one can decompose the operator L as $\sum_\ell L_\ell$, where

$$(L_\ell f)(x) = \frac{1}{N} \sum_\xi a(x, \xi) e^{2\pi i \Phi(x,\xi)} \chi_\ell(\xi) \hat{f}(\xi).$$

Within each wedge W_ℓ, we can perform a Taylor expansion of $\Phi(x, \xi)$ in the second variable, around the point $\hat{\xi}_\ell |\xi|$. There is a point $\xi^\star$ which belongs to the line segment $[\hat{\xi}_\ell |\xi|, \xi]$ such that

$$\Phi(x, \xi) = \Phi(x, \hat{\xi}_\ell |\xi|) + \nabla_\xi \Phi(x, \hat{\xi}_\ell |\xi|) \cdot (\xi - \hat{\xi}_\ell |\xi|) + \frac{1}{2} (\xi - \hat{\xi}_\ell |\xi|)^T \nabla_{\xi\xi} \Phi(x, \xi^\star)(\xi - \hat{\xi}_\ell |\xi|).$$

By homogeneity of the phase ($\Phi(x, \lambda\xi) = \lambda \Phi(x, \xi)$ for $\lambda > 0$), it holds that $\Phi(x, \xi) = \xi \cdot \nabla_\xi \Phi(x, \xi)$ and $\nabla_\xi \Phi(x, \xi) = \nabla_\xi \Phi(x, \hat{\xi})$. The first and third terms in the above expression cancel, and thus

$$\Phi(x, \xi) = \nabla_\xi \Phi(x, \hat{\xi}_\ell) \cdot \xi + \frac{1}{2} (\xi - \hat{\xi}_\ell |\xi|)^T \nabla_{\xi\xi} \Phi(x, \xi^\star)(\xi - \hat{\xi}_\ell |\xi|).$$

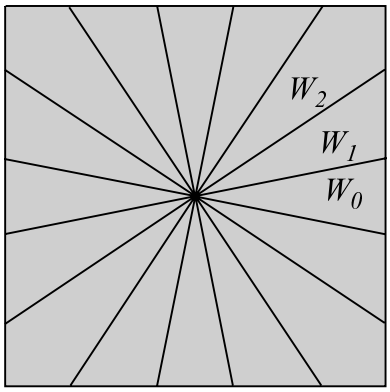

FIG. 1. *The frequency domain is partitioned into* $\sqrt{N}$ *equiangular wedges.*

The first term $\nabla_\xi \Phi(x, \hat{\xi}_\ell) \cdot \xi$, which is linear in ξ, is called *the linearized phase* and poses no problem as we will see later on. The rest, denoted as $\Phi_\ell(x, \xi) = \Phi(x, \xi) - \nabla_\xi \Phi(x, \hat{\xi}_\ell) \cdot \xi$ and called *the residual phase*, is of order $O(1)$ for $\xi \in W_\ell$, independently of N. This follows from

$$\nabla_{\xi\xi} \Phi(x, \xi^\star) = O(|\xi^\star|^{-1}) = O(|\xi|^{-1}),$$

since $\Phi(x, \xi)$ is homogeneous of degree 1 in ξ, together with

$$|\xi - \hat{\xi}_\ell |\xi||^2 = O(|\xi|^2/N) = O(|\xi|)$$

for all $|\xi| \leq N$, which uses the fact that the shape of W_ℓ obeys the parabolic relationship (1.7).

Because the residual phase $\Phi_\ell(x, \xi)$ is of order $O(1)$ independently of N, we say that the function $e^{2\pi i \Phi_\ell(x,\xi)}$ is *nonoscillatory*. Under mild assumptions, this observation guarantees the existence of a low rank separated representation which decouples the variables x and ξ and approximates the complex exponential very well. Define the ϵ-separation rank of a function $f(x, y)$ of two variables as the smallest integer r_ϵ for which there exist $c_n(x)$, $d_n(y)$ such that

$$\left| f(x, y) - \sum_{n=0}^{r_\epsilon - 1} c_n(x) d_n(y) \right| \leq \epsilon.$$

Then we prove the following theorem in section 2.

THEOREM. *For all* $0 < \epsilon \leq 1$, *there exist* $N^* > 0$ *and* $C > 0$ *such that for all* $N \geq N^*$, *the* ϵ*-separation rank of* $e^{2\pi i \Phi_\ell(x,\xi)}$ *for* $x \in [0, 1]^2$ *and* $\xi \in W_\ell$ *obeys*

$$r_\epsilon \leq \log_2(C\epsilon^{-1}). \tag{1.8}$$

In section 2 we make explicit the values of the constants N^* and C by relating them, among other things, to the smoothness of Φ and the angular span of W_ℓ. We will also provide results in the case where $N \leq N^*$ and explain why the separation rank for the amplitude is also under control.

The point of the theorem is that the bound on the ϵ-rank does not grow as a function of N—in fact, the threshold condition on N indicates that the ϵ-rank *decays*

as N grows. The logarithmic dependence on ϵ is the signature of what is usually called spectral accuracy.

Note that the decomposition into frequency wedges obeying the parabolic scaling has a long history in mathematics. A multiscale version of this partitioning, the second dyadic decomposition, was introduced by Fefferman in 1973 for the study of Bochner–Riesz multipliers [22] and used by Seeger, Sogge, and Stein in 1991 to prove a sharp L^p-boundedness result for FIOs [36]. More recently, it also served as the basis for the construction of curvelets, with applications to sparsity of FIOs and related results for wave equations [37, 10, 11].

1.4. Outline of the algorithm. The low rank separated representation provided by the theorem above offers us a way to compute (1.5) efficiently with high accuracy. Each term in the decomposition $Lf = \sum_\ell L_\ell f$ can be further simplified as follows:

$$\begin{aligned}
(L_\ell f)(x) &= \frac{1}{N} \sum_\xi a(x,\xi) e^{2\pi i \Phi(x,\xi)} \chi_\ell(\xi) \hat{f}(\xi) \\
&= \frac{1}{N} \sum_\xi e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi}\ a(x,\xi) e^{2\pi i \Phi_\ell(x,\xi)}\ \chi_\ell(\xi) \hat{f}(\xi) \\
&= \frac{1}{N} \sum_\xi e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi}\ \sum_{t=1}^{\infty} \gamma_{\ell t}^x(x) \gamma_{\ell t}^\xi(\xi)\ \chi_\ell(\xi) \hat{f}(\xi) \\
&= \frac{1}{N} \sum_{t=1}^{\infty} \gamma_{\ell t}^x(x) \sum_\xi e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi} \left[\gamma_{\ell t}^\xi(\xi) \chi_\ell(\xi) \hat{f}(\xi) \right]. \qquad (1.9)
\end{aligned}$$

Our analysis guarantees that the sum over t can be truncated to a fixed, hopefully small number of terms without significant loss of precision.

In order to carry out the final summation over t, we first need to construct the functions $\gamma_{\ell t}^x(x)$ and $\gamma_{\ell t}^\xi(\xi)$. Sections 3.1 and 3.2 discuss two different methods of finding these functions. In section 3.1 we present an elementary deterministic approach, while in section 3.2 we present a randomized approach that offers better efficiency both timewise and storagewise. Assuming that $\gamma_{\ell t}^x(x)$ and $\gamma_{\ell t}^\xi(\xi)$ are available for all values of ℓ and t, the computation of (Lf) for a given f consists of the following four steps:

1. Fourier transform f by means of the FFT to get $\hat{f}$.
2. Choose a bound q greater than the ε-rank r_ε. For each ℓ and $t \le q$, form $\hat{f}_{\ell t}(\xi) := \gamma_{\ell t}^\xi(\xi) \chi_\ell(\xi) \hat{f}(\xi)$.
3. For each ℓ and $t \le q$, compute $g_{\ell t}(x) := \sum_\xi e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi} \hat{f}_{\ell t}(\xi)$ by means of a nonuniform FFT algorithm.
4. Compute $(Lf)(x) \approx \frac{1}{N} \sum_\ell \sum_{t=1}^q \gamma_{\ell t}^x(x) g_{\ell t}(x)$.

The only step that requires further discussion is the computation of $g_{\ell,t}$. We defer the details to section 3.4.

It is instructive to understand why linearizing the phase is so important. If we disregard the error introduced by the discretization in ξ, we observe that $g_{\ell,t}(x)$ is simply

$$g_{\ell,t}(x) = f_{\ell,t}(\nabla_\xi \Phi(x, \hat{\xi}_\ell)).$$

The interpretation of an oscillatory integral in the Fourier domain as a diffeomorphism is possible only when the phase is linear in ξ. For each ℓ and t, the computation of $g_{\ell,t}$, which is an interpolation problem, is therefore a much simpler problem than applying the original operator. Admittedly, diffeomorphisms do not provide accurate approximations to FIOs over angular wedges, but the content of our analysis in section 2 shows that the computational budget to make up for the residual is safely under control.

1.5. Significance. Applying nontrivial FIOs repeatedly has proved to be the computational bottleneck in various inverse problems. There is serious scientific as well as industrial interest in speeding up FIO computations, and accordingly many resources have been invested over the past decades in engineering better codes.

We believe that the ideas introduced in this paper provide new directions. To explain and illustrate this contrast, let us consider an important example from the field of reflection seismology: Kirchhoff migration. The problem is to produce an image of the discontinuities in the Earth's upper crust from seismograms, i.e., wave measurements $f_s(t, x_r)$ parameterized by time t, receiver coordinate x_r, and source coordinate x_s. The core of Kirchhoff migration is a generalized Radon transform (GRT) which, (in its shot-gather version) consists in integrating several different functions $f_s(t, x_r)$ indexed by s over a fixed set of curves, determined as the level lines of a traveltime function $\tau(x, x_r) + \tau(x, x_s)$, and modulated by an amplitude $a(t, x_r, x_s)$:

$$g_s(x) = \int \delta(t - \tau(x, x_r) - \tau(x, x_s)) a(t, x_r, x_s) f_s(t, x_r)\, \mathrm{d}t\, \mathrm{d}x_r. \tag{1.10}$$

The functions $g_s(x)$ determine the model. A stack operation over the s index then allows us to recover the adequate physical parameters of the Earth, like the speed of sound. When x_r is one-dimensional, it is useful to think of the traveltime level curves as distorted hyperbolas in the (t, x_r) plane. A standard notation for Kirchhoff migration is $g_s(x) = (F^* f_s)(x)$, where F^* is called the imaging operator.

Equation (1.10) is in fact a backprojection strategy for approximately inverting a forward GRT—F in the above notation—which in turn comes from a linearization for the physical parameters about small perturbations, combined with a leading-order high-frequency approximation of the wave equation's Green's function. This view of migration as a GRT is now authoritative in the field of seismic imaging and was pioneered in work by Beylkin and also Miller, Tarantola, Lailly, and Rakesh. The original papers by Beylkin and collaborators are [6, 7, 33]. For more references, see the review article [39] and references therein.

A GRT like (1.10), with a proper cutoff amplitude, can be put in a FIO form suitable for our algorithm. For convenience, the appendix explains why integration along ellipses—a simple GRT—is a sum of two FIOs.

The standard algorithm for applying the imaging operator as in (1.10) is a simple quadrature of $f(t, x_r)$, interpolated and integrated along each curve $t = \tau(x, x_r) + \tau(x, x_s)$ (parameterized by x). Assume again that x_r is one-dimensional for simplicity. If the data $f(t, x_r)$ oscillates at a wavelength comparable to the grid spacing $1/N$, then an accurate quadrature on a smooth curve requires $O(N)$ points. Since x takes on $O(N^2)$ values, the curve integration results in a total complexity of $O(N^3)$ for applying the imaging operator (which is of course better than the $O(N^4)$ complexity of the naive summation).

The first claim of this paper is that a potentially more attractive computational strategy for computing (1.10) is to transform it into FIOs, by considering the data

$f_s(t, x_r)$ in the frequency domain (in both variables t and x_r). The asymptotic complexity is then reduced to $O(N^{2.5} \log N)$ for the algorithm presented in this paper.

The second claim is that since our algorithm is based on FIOs and not just GRTs, it can potentially handle more general migration and imaging operators. For instance, the true imaging operator F^* is almost never a GRT like (1.10). If more terms are kept in the geometric optics approximation leading to (1.10), then the resulting migration operator is no longer a GRT, although it is still a FIO under some very general assumptions; see [38] for a detailed exposition. This observation is akin to the fact that the retarded propagator of the wave equation in two dimensions is not a distribution strictly supported on the boundary of the light cone—only its singular support coincides with the boundary of the cone.

The advantages of the proposed algorithm should now be clear: quite general FIOs can be handled with an asymptotic computational complexity which is lower than that required for GRT summation, i.e., $O(N^{2.5} \log N)$ versus $O(N^3)$, and this without making any curvilinear approximation. In addition, we will show that the storage overhead (on top of storing the phase and amplitude) is negligible and scales like $O(\sqrt{N})$.

We have discussed only applications to reflection seismology, but there are many other areas where nontrivial FIOs are computed routinely, e.g., as part of solving an inverse problem. Examples in radar imaging, ultrasound imaging, and electron microscopy all come to mind. Some Hough transforms for feature detection in image processing can also be formulated as FIOs. In short, the ideas presented in this paper may enable the speedup of fundamental computations in a variety of problem areas.

1.6. Related work. In the case where $\Phi(x, \xi) = x \cdot \xi$, the operator is said to be pseudodifferential. In this simpler setting, it is known that separated variable expansions of the symbol $a(x, \xi)$ are good strategies for reducing complexity. For instance, Bao and Symes [4] propose an $O(N^2 \log N)$ numerical method based on a Fourier series expansion of the symbol in the angular variable $\arg \xi$, and a polyhomogeneous expansion in $|\xi|$, which is a particularly effective example of separation of variables.

Another popular approach for compressing operators is to decompose them in a well-chosen, possibly adaptive basis of L^2. Once a sparse representation is achieved, evaluation simply consists of applying a sparse matrix in the transformed domain. In the case of one-dimensional oscillatory integrals, this program was advocated and carried out by Bradie, Coifman, and Grossman [9] and Averbuch et al. [3]. In spite of these successes, the generalization to multiple dimensions has so far remained an open problem. We will come back to this question in section 5 and in particular will discuss the relationship with modern multiscale transformations such as curvelets [10, 11] and wave atoms [15, 16].

We would also like to acknowledge the line of research related to Filon-type quadratures for oscillatory integrals [29]. When the integrand is of the form $g(x)e^{ikx}$ with g smooth and k large, it is not always necessary to sample the integrand at the Nyquist rate. For instance, integration of a polynomial interpolant of g (Filon quadrature) provides an accurate approximation to $\int g(x)e^{ikx}\,\mathrm{d}x$ using fewer and fewer evaluations of the function g as $k \to \infty$. While these ideas are important, they are not directly applicable in the case of FIOs. The reasons are threefold. First, we make no notable assumption on the support of the function to which the operator is applied, meaning that the oscillations of $\hat{f}(\xi)$ may be on the same scale as those of the exponential $e^{2\pi i \Phi(x,\xi)}$. Second, the phase does not in general have a simple formula that would lend itself to precomputations. And third, Filon-type quadratures do not

address the problem of simplifying computations of *several* such oscillatory integrals at once (i.e., computing a family of integrals indexed by x in the case of FIOs).

Finally, we remark that FIOs are also interesting when the canonical relation is nontrivial—that is, multivalued phase—because they allow us to study propagation of singularities of hyperbolic equations in regimes of multipathing and caustics [28, 20]. To mathematicians taking this specialized viewpoint, the focus of the present paper may appear restrictive. Our outlook and ambition are different. We find FIOs to be interesting mathematical objects even when the canonical relation is a graph and degenerates to the gradient of a phase. Our concern is to understand their structure from an operational standpoint and exploit it to design efficient numerical algorithms. In fact, we expect this paper to be the first of a projected series which will eventually deal with more complex setups.

1.7. Contents. The rest of the paper is organized as follows. Section 2 proves all the analytical estimates which support our methodology. In section 3, we describe algorithms for constructing the low rank separated approximation, evaluating $(Lf)(x)$, as well as for evaluating its adjoint, namely, computing $(L^*f)(x)$. Numerical examples in section 4 illustrate the properties of our algorithms. Finally, section 5 discusses some related work and potential alternatives.

2. Analytical estimates. In this section, we return to a description of the problem in continuous variables x and ξ to prove estimates on the separation rank of $e^{2\pi i\Phi_\ell(x,\xi)}$, where $\Phi_\ell(x,\xi)$ is the residual phase after linearization about $\hat{\xi}_\ell$.

2.1. Background. We begin with a lemma which concerns the separation of the exponential function and whose variations play a central role in modern numerical analysis.

LEMMA 1. *Consider the domain defined by $x \in [-A, A]$ for some $A > 0$, and $y \in [-1, 1]$. For all $\epsilon > 0$ the ϵ-rank r_ϵ of e^{ixy} on $[-A, A] \times [-1, 1]$ obeys the bound $r_\epsilon \le r_\epsilon^*$, where*

$$r_\epsilon^* = 1 + \max\{2eA\ ,\ \log_2(2\epsilon^{-1})\}. \tag{2.1}$$

Furthermore, if $A \le \frac{1}{2e}$, then the stronger bound

$$r_\epsilon^* = 1 + \frac{\log(2\epsilon^{-1})}{\log \frac{1}{eA}} \tag{2.2}$$

holds as well. In both cases, the corresponding separated representation is the expansion

$$\left| e^{ixy} - \sum_{n=0}^{r_\epsilon^*-1} \frac{i^n}{n!} x^n y^n \right| \le \epsilon.$$

Proof. The proof is very simple. We start with

$$\left| e^{ixy} - \sum_{n=0}^{r-1} \frac{(ixy)^n}{n!} \right| \le \sum_{n\ge r} \frac{A^n}{n!} \le \sum_{n\ge r} \left(\frac{eA}{n}\right)^n \le \sum_{n\ge r} \left(\frac{eA}{r}\right)^n = \left(\frac{eA}{r}\right)^r \frac{1}{1-\frac{eA}{r}}.$$

If $eA \le 1/2$, then a fortiori $eA/r \le 1/2$, and the condition $r \ge \log(2\epsilon^{-1})/\log\frac{1}{eA}$ allows us to bound

$$\left(\frac{eA}{r}\right)^r \frac{1}{1-\frac{eA}{r}} \le 2 \cdot (eA)^r \le \epsilon.$$

On the other hand, if $eA \geq 1/2$, then we have to impose $eA/r \leq 1/2$ by hand, as one of the alternatives of the max in (2.1). Then the extra condition $r \geq \log_2(2\epsilon^{-1})$ allows us to bound

$$\left(\frac{eA}{r}\right)^r \frac{1}{1-\frac{eA}{r}} \leq 2 \cdot 2^{-r} \leq \epsilon.$$

Since the ϵ-rank r_ϵ is integer-valued, the estimate on r may need to be rounded up to the next integer—hence the precaution of incrementing the bounds in (2.1) and (2.2) by one. □

In the next section we will make use of Lemma 1 to prove that the nonoscillatory factor $e^{2\pi i \Phi_\ell(x,\xi)}$ has a separation rank which is independent of N. The other factor in the kernel $a(x,\xi)e^{2\pi i \Phi_\ell(x,\xi)}$, namely, the amplitude $a(x,\xi)$, is in general a simpler object to study. The standard assumption in the literature, and also in applications, is to assume that $a(x,\xi)$ is a smooth symbol of order zero and type $(1,0)$, meaning that for each pair of integers (α,β), there is a positive constant $C_{\alpha\beta}$ obeying

$$|\partial_\xi^\alpha \partial_x^\beta a(x,\xi)| \leq C_{\alpha\beta}(1+|\xi|^2)^{-|\alpha|/2}. \tag{2.3}$$

For simplicity, we will also assume that $a(x,\xi)$ is compactly supported in x.[2] The nice separation properties of a are simple consequences of its assumed smoothness.

LEMMA 2. *Assume $a(x,\xi)$ is a symbol of order zero. Then for all $M > 0$ there exists $C_M > 0$ such that for all $\epsilon > 0$, the ϵ-rank for the separation of x and ξ in $a(x,\xi)$ obeys*

$$r_\epsilon \leq C_M\, \epsilon^{-1/M}.$$

Proof. Perform a Fourier transform of the C^∞, compactly supported function $a(\cdot,\xi)$. It suffices to keep $O(\epsilon^{-1/M})$ Fourier modes to approximate $a(\cdot,\xi)$ to accuracy ϵ on its compact support. Each Fourier mode is of the form $\hat{a}(\omega,\xi)e^{i\omega x}$ and is hence separated. □

It goes without saying that the ϵ-rank of the product $a(x,\xi)e^{2\pi i\Phi_\ell(x,\xi)}$ is bounded by a constant times the product of the individual ϵ-ranks, and we now focus on the real object of interest, the factor $e^{2\pi i\Phi_\ell}$.

2.2. Large N asymptotics. In this section we assume that the phase $\Phi(x,\xi)$ is C^3 in ξ, measurable only in x, and we define

$$C_k = 2\pi \sup_{x\in[0,1]^2} \sup_{\xi:|\xi|=1} |\partial_\theta^k \Phi(x,\xi)| \qquad \text{for } 0 \leq k \leq 3,$$

where $\theta = \arg\xi$. These constants will enter our estimates only through the following combinations:

$$D_2 = C_0 + C_2 \qquad \text{and} \qquad D_3 = C_1 + C_3.$$

As before, we also require homogeneity of order one in ξ. Finally, we let the general angular opening of the cone W_ℓ be $\frac{2\alpha}{\sqrt{N}}$ radians for some constant α (the introduction section proposed $\alpha = \pi$).

[2]This assumption is equivalent to assuming that functions in the range of L are themselves compactly supported in situations of interest, which ought to be the case for accurate numerical computations.

The result below is a more precise version of the theorem we introduced in section 1.

THEOREM 1. *For all* $0 < \epsilon \le 1$ *and* $N \ge \frac{\alpha^6 D_3^2}{18\epsilon^2}$, *the* ϵ*-separation rank of* $e^{2\pi i \Phi_\ell(x,\xi)}$ *for* $x \in [0,1]^2$ *and* $\xi \in W_\ell$ *obeys*

$$r_\epsilon \le 1 + \max\left\{ \frac{e\sqrt{2}}{2}\alpha^2 D_2 \, , \, \log_2(4\epsilon^{-1}) \right\}. \tag{2.4}$$

Furthermore, if α *is admissible in the sense that* $\alpha \le \sqrt{\frac{\sqrt{2}}{eD_2}}$, *then*

$$r_\epsilon \le 1 + \frac{\log(4\epsilon^{-1})}{\log \frac{2\sqrt{2}}{e\alpha^2 D_2}}. \tag{2.5}$$

Proof. Put $r = |\xi|$ and θ as the angle measured from the vector ξ_ℓ. The phase Φ can be rewritten as $\Phi(x,\xi) = r\phi(x,\theta)$. Let ξ_1 be the frequency coordinate along ξ_ℓ and ξ_2 orthogonal to ξ_1, so that we can switch between polar and Cartesian coordinates using

$$\frac{\partial \Phi}{\partial \xi_1}(x,\xi_\ell) = \phi(x,0) \qquad \text{and} \qquad \frac{\partial \Phi}{\partial \xi_2}(x,\xi_\ell) = \phi'(x,0),$$

where the derivative of ϕ is taken in θ. The residual phase is

$$\begin{aligned} \Phi_\ell(x,\xi) &= \Phi(x,\xi) - \nabla_\xi \Phi(x,\xi_\ell)\cdot\xi \\ &= r\,\left(\phi(x,\theta) - \cos\theta\phi(x,0) - \sin\theta\phi'(x,0)\right). \end{aligned}$$

We can now expand $\phi(x,\theta)$, $\cos\theta$, and $\sin\theta$ in a Maclaurin series (around $\theta = 0$) to obtain

$$\Phi_\ell(x,\xi) = \frac{r\theta^2}{2}\left(\phi(x,0) + \phi''(x,0)\right) + \frac{r\theta^3}{6}\left[\phi'''(x,\overline{\theta}) - \cos(\tilde{\theta})\phi'(x,0)\right] \tag{2.6}$$

for some $\tilde{\theta}$ and $\overline{\theta}$ between 0 and θ (with $\overline{\theta}$ depending on x.)

The x and ξ variables are separated in the first term of (2.6), and so we write

$$f(x)g(\xi) \equiv 2\pi\left(\phi(x,0) + \phi''(x,0)\right)\frac{r\theta^2}{2}.$$

The term with square brackets is the remainder, and we write

$$R(x,\xi) = 2\pi\frac{r\theta^3}{6}\left[\phi'''(x,\overline{\theta}) - \cos(\tilde{\theta})\phi'(x,0)\right].$$

Our strategy will be to choose N large enough so that $R(x,\xi)$ becomes negligible; hence only the exponential of the first term needs to be separated.

Recall that in two dimensions the frequency domain is the square $[-\frac{N}{2}, \frac{N}{2} - 1]^2$. Since $|\theta| \le \frac{\alpha}{\sqrt{N}}$ in the wedge W_ℓ, and $r \le \frac{\sqrt{2}}{2}N$, we have the following bounds for the two terms in (2.6):

$$|f(x)g(\xi)| \le \frac{\sqrt{2}}{4}\alpha^2 D_2, \qquad |R(x,\xi)| \le \frac{\sqrt{2}}{12}\frac{\alpha^3}{\sqrt{N}}D_3.$$

It is instructive to notice that the bound on $|fg|$ is independent of N. That is the reason why we chose the angular opening of the cone W_ℓ proportional to $N^{-1/2}$ (parabolic scaling).

The first contribution to the separation remainder is given by

$$|e^{i(fg+R)} - e^{ifg}| = |e^{iR} - 1|$$

$$\leq |R| \leq \frac{\sqrt{2}}{12}\frac{\alpha^3}{\sqrt{N}} D_3.$$

The condition on N ensures precisely that this remainder be dominated by $\epsilon/2$.

The second contribution to the total error is due to the separation of e^{ifg} itself and needs to be made smaller than $\epsilon/2$ as well. We invoke Lemma 1 with $f(x) \times \sup|g(\xi)|$ in place of x, $g(\xi)/\sup|g(\xi)|$ in place of y, and $\epsilon/2$ in place of ϵ. With these choices, A becomes $\frac{\sqrt{2}}{4}\alpha^2 D_2$, and we obtain the desired result. □

2.3. Small ϵ asymptotics. Theorem 1 is a special asymptotic result in the case of large N (problem size)—or alternatively small α (cone's angular opening). This regime may not be attained in practice, and so we need another result, without restrictions on N and informative for arbitrarily small ϵ.

To this effect, we need stronger (yet still realistic) smoothness assumptions on the phase Φ: for each x, we require that $\Phi(x,\xi)$ be a real-analytic function of ξ. This condition implies the bound

$$2\pi \sup_{|\xi|=1} |\partial_\theta^k \Phi(x,\xi)| \leq Q\, k!\, R^{-k}$$

for some constants Q and R. For example, R can be taken as any number smaller than the uniform radius of convergence in θ, in which case Q will in general depend on R. Let us term such phases, or functions, (Q,R)-*analytic*. As before, we also require homogeneity in ξ.

THEOREM 2. *Assume $\Phi_\ell(x,\xi)$ is measurable in x and (Q,R)-analytic in ξ for some constants Q and R. Assume that α is admissible in the sense that*

$$\alpha < \min\left\{ \frac{R\sqrt{N}}{2}, \frac{R}{\sqrt{\sqrt{2}Q}} \right\}.$$

Then for all $0 < \epsilon \leq 1$, the ϵ-separation rank of $e^{2\pi i \Phi_\ell(x,\xi)}$ for $x \in [0,1]^2$ and $\xi \in W_\ell$ obeys

$$r_\varepsilon \leq C_p\, \epsilon^{-p} \quad \forall p : p > \frac{2}{\log_2\left(\frac{R\sqrt{N}}{\alpha}\right)}.$$

Proof. Throughout the proof, $x \in [0,1]^2$ and $\xi \in W_\ell$. Using the smoothness assumption on Φ_ℓ, we can repeat the reasoning of the proof of Theorem 1 and obtain the convergent series

$$2\pi\Phi_\ell(x,\xi) = \sum_{k=0}^{\infty} f_k(x) g_k(\xi),$$

where $f_k(x) = 2\pi\phi^{(k)}(x,0)$ (the differentiations are in θ) and

$$g_0(\xi) = r(1-\cos\theta), \qquad g_1(\xi) = r(\theta - \sin\theta), \qquad g_k(\xi) = \frac{r\theta^k}{k!}.$$

We denote the bound $|f_k(x)g_k(\xi)| \le A_k$ with

$$A_0 = \frac{\sqrt{2}}{4} Q\alpha^2, \qquad A_1 = \frac{\sqrt{2}}{12} Q \frac{\alpha^3}{R\sqrt{N}}, \qquad A_k = \frac{\sqrt{2}}{2} QN \left(\frac{\alpha}{R\sqrt{N}}\right)^k \quad \text{for } k > 2.$$

Our strategy will be to call upon Lemma 1 for the first few factors $e^{if_k g_k}$ in order to obtain a separation rank r_k and an error ϵ_k for each of them:

$$\left| e^{if_k g_k} - \sum_{n=0}^{r_k - 1} \frac{i^n}{n!} f_k^n(x) g_k^n(\xi) \right| \le \epsilon_k. \tag{2.7}$$

We will perform this operation for each $k < K$, with K large enough, to be determined. Once the separation of each factor is available, we can write

$$e^{i\sum_{k=0}^{K-1} f_k g_k} = \prod_{k=0}^{K-1} e^{if_k g_k}$$

and obtain the bound on the overall separation rank as the *product* $\prod_{k=0}^{K-1} r_k$.

There are two sources of errors we must contend with:

- *Truncation in k.* The factors $e^{if_k g_k}$ for $k \ge K$ will be deemed negligible if their combined contribution results in an overall error smaller than $\epsilon/2$, meaning

  $$|e^{2\pi i \Phi_\ell} - e^{i\sum_{k=0}^{K-1} f_k g_k}| \le \frac{\epsilon}{2}. \tag{2.8}$$

  The left-hand side is bounded by $|\sum_K^\infty f_k g_k|$. Using the bound we stated earlier on A_k and the admissibility condition on α, a bit of algebra shows that (2.8) is satisfied for

  $$K = \left\lceil \frac{\log\left(2\sqrt{2} QN \epsilon^{-1}\right)}{\log\left(\frac{R\sqrt{N}}{\alpha}\right)} \right\rceil \tag{2.9}$$

  (meaning the smallest integer greater than the quotient inside the brackets). This quantity in turn obeys $K \le \log_2(16\epsilon^{-1})$.
- *Truncation in n.* The truncation errors from (2.7) must be made sufficiently small so that their combined contribution also results in an overall error smaller than $\epsilon/2$, meaning

  $$\left| \prod_{k=0}^{K-1} e^{if_k g_k} - \prod_{k=0}^{K-1} \sum_{n=0}^{r_k - 1} \frac{i^n}{n!} f_k^n(x) g_k^n(\xi) \right| \le \frac{\epsilon}{2}. \tag{2.10}$$

  Easy manipulations[3] show that (2.10) follows from the bound

[3] To justify this step, put $E_k(x,\xi) = e^{if_k(x)g_k(\xi)}$ and start from the identity

$$\prod_{k=0}^{K-1} (E_k + \epsilon_k) - \prod_{k=0}^{K-1} E_k = \sum_j \epsilon_j \prod_{k \ne j} (E_k + \tau_{jk}\epsilon_k)$$

$$= \sum_j \epsilon_j E_j^{-1} \prod_{k=0}^{K-1} (E_k + \tau_{jk}\epsilon_k),$$

where $\tau_{jk} = 0$ if $j \le k$, and $\tau_{jk} = 1$ if $j > k$. Then make use of the bound $(1 + \frac{\epsilon}{3K})^K < e^{\epsilon/3} \le e^{1/3} < 3/2$.

$$\epsilon_k = \frac{\epsilon}{3K}.$$

(Recall that K is comparable to $\log(C\epsilon^{-1})$.)
Such a bound holds if, in turn, we take r_k large enough. The admissibility condition on α ensures, among others, that we can invoke the strong version of Lemma 1, namely, (2.2), and obtain

$$r_k \le 1 + \frac{\log(2\epsilon_k^{-1})}{\log \frac{1}{eA_k}}. \tag{2.11}$$

It now remains to estimate $\prod_{k=0}^{K-1} r_k$, where r_k is given by (2.11) and K by (2.9). We treat the first two factors independently. It follows from the bounds on A_0, A_1, and K and the fact that α and Q are constant in ϵ and N that

$$r_0 \le 1 + \frac{\log(6K\epsilon^{-1})}{\log \frac{4}{e\sqrt{2}Q\alpha^2}} \le C\log(6K\epsilon^{-1})$$

$$\le C\log(3\log(16\epsilon^{-1})) + C\log(2\epsilon^{-1}) \le C\log(2\epsilon^{-1})$$

(the constant C changes from expression to expression), and similarly

$$r_1 \le C\log(2\epsilon^{-1}).$$

The same logarithmic bound holds for r_k in the case $k \ge 2$ but will not suffice for our purpose. Instead, we write

$$r_k \le 1 + \frac{\log(6K\epsilon^{-1})}{\log\left[\frac{\sqrt{2}}{QN}\left(\frac{R\sqrt{N}}{\alpha}\right)^k\right]}$$

$$\le \frac{\log(C\epsilon^{-1}\log(2\epsilon^{-1})) + k\log\left(\frac{R\sqrt{N}}{\alpha}\right)}{\log(C) + k\log\left(\frac{R\sqrt{N}}{\alpha}\right)}$$

$$\equiv \frac{A+k}{B+k} \qquad (k \ge 2).$$

We simplified notations only in the last line. Notice that $A > B$ and that $B + k \ge 1$ when $k \ge 2$. We will assume without loss of generality that A and B are integers. The value of the product $\prod r_k$ can increase only if we replace the initial bound $0 \le k < K$ by the condition that the bound on r_k be greater than 2. So we certainly have

$$r_\epsilon \le \prod_{k\ge 2 : r_k \ge 2} r_k \le \frac{A+2}{B+2}\,\frac{A+3}{B+3}\,\cdots\,\frac{A+A}{B+A}$$

$$= \frac{(2A)!/(A+1)!}{(B+A)!/(B+1)!}.$$

We can now make use of the two-sided Stirling bound

$$\sqrt{2\pi}\, n^{n+1/2} e^{-n+\frac{12}{n+1}} \le n! \le \sqrt{2\pi}\, n^{n+1/2} e^{-n+\frac{12}{n}}$$

to obtain

$$\begin{aligned} r_\epsilon &\le C\,\frac{(2A)^{2A}(A+1)^{-(A+1)}}{(A+B)^{A+B}(B+1)^{-(B+1)}} \\ &\le C\,2^{2A}\,\frac{A^{2A}}{(A+1)^{(A+1)}(A+B)^{A-1}}\,\frac{(B+1)^{(B+1)}}{(A+B)^{B+1}} \\ &\le C\,2^{2A}. \end{aligned}$$

In turn,

$$2^{2A} \le \left(C\epsilon^{-1}\log(2\epsilon^{-1})\right)^{\frac{2}{\log_2\left(\frac{R\sqrt{N}}{\alpha}\right)}},$$

which concludes the proof. □

The lower the fractional exponent of ϵ^{-1} the faster the convergence of separated expansions. Theorem 2 shows exactly which factors can make this exponent arbitrarily small:

- large grid size N, or
- small angular opening constant α, or
- large radius of analyticity R of the phase in arg ξ (uniformly in x).

Observe that the rank bound *decreases* as N increases.

Theorem 2 assumes that the residual phase function $\Phi_\ell(x,\xi)$ is (Q,R)-analytic in ξ. The variation below follows the same path of reasoning and is useful when $\Phi_\ell(x,\xi)$ is only C^∞ in ξ for $\xi \neq 0$.

THEOREM 3. *Assume $\Phi_\ell(x,\xi)$ is C^∞ in ξ for $\xi \neq 0$. For any $p > 0$, there exist two constants C_p and C'_p such that for any N, the ϵ-separation rank with $\varepsilon = C_p\,N^{-p}$ is bounded by $C'_p\,\log N$.*

Proof. The structure of the proof is similar to that of Theorem 2. One needs only to keep the first $2p+2$ term of the series

$$2\pi\Phi_\ell(x,\xi) = \sum_{k=0}^{\infty} f_k(x)g_k(\xi)$$

in order to have $\varepsilon = C_p\,N^{-p}$ for some constant C_p which depends only on p and Φ_ℓ. The product $\prod_{k=0}^{2p+1} r_k$ upper bounds the overall separation rank and is less than $C'_p\,\log N$ for some constant C'_p which depends only on p. □

In many computational problems, the mesh size N^{-1} is linked directly to the desired accuracy ε, usually in the form of a power law, e.g., $\varepsilon = O(N^{-p})$ for some constant p. Therefore, Theorem 3 is interesting for practical reasons.

3. Algorithm. For notational convenience, we assume in this section that the amplitude is identically equal to one; that is, we focus on the so-called (discretized) Egorov operator

$$(Lf)(x) = \frac{1}{N}\sum_{\xi\in\Omega} e^{2\pi i\Phi(x,\xi)}\hat{f}(\xi). \tag{3.1}$$

Both in practice (section 4) and in theory (section 2), one can easily take care of general amplitude terms.

The algorithm for computing (3.1) has two main components:

- *Preprocessing step.* Given the residual phase $\Phi_\ell(x,\xi) \equiv \Phi(x,\xi) - \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi$, this step constructs, for each wedge W_ℓ, a low rank separated approximation

$$\left| e^{2\pi i \Phi_\ell(x,\xi)} - \sum_{t=1}^{q} \gamma_{\ell t}^x(x)\gamma_{\ell t}^\xi(\xi) \right| \le \varepsilon.$$

  The functions $\{\gamma_{\ell t}^x(x)\}$ and $\{\gamma_{\ell t}^\xi(\xi)\}$, or their compressed versions, are then stored for use in the next step.
- *Evaluation step.* Given a function f, this step computes $(Lf)(x)$ approximately by

$$(Lf)(x) \approx \frac{1}{N} \sum_\ell \sum_t \gamma_{\ell t}^x(x) \sum_\xi e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi} \left[\gamma_{\ell t}^\xi(\xi)\chi_\ell(\xi)\hat{f}(\xi) \right].$$

The preprocessing step is performed only once for a fixed phase function $\Phi(x,\xi)$. The family of functions $\{\gamma_{\ell t}^x(x)\}$ and $\{\gamma_{\ell t}^\xi(\xi)\}$ should of course be used again and again to compute $(Lf)(x)$ for different inputs f.

In sections 3.1 and 3.2, we propose two different approaches for constructing the families $\{\gamma_{\ell t}^x(x)\}$ and $\{\gamma_{\ell t}^\xi(\xi)\}$. Section 3.4 describes the details of the evaluation step. Finally, section 3.5 outlines the algorithm for rapidly applying the adjoint operator. In this section, we calculate time and storage complexity under the assumption of large grids, i.e., that of Theorem 2. For other kinds of asymptotics, one may need to adjust these estimates with a multiplicative $\log N$ factor, which is typically negligible.

3.1. Preprocessing step: Deterministic approach. We first describe a deterministic approach for constructing the low rank separated expansion, based on a Taylor expansion, exactly as in the proof of Lemma 1. For each wedge W_ℓ, the strategy consists of the following sequence of steps:

- First, construct a low rank separated approximation of $\Phi_\ell(x,\xi)$. This is done by truncating the polar coordinates Taylor expansion to the $(2p+1)$st term

$$\Phi_\ell(x,\xi) \approx |\xi| \sum_{k=1}^{2p+1} c_{\ell k}(x)(\theta - \theta_\ell)^k.$$

  Here p is a constant that determines the level of accuracy.
- Second, for each k construct a separated expansion of $e^{2\pi i c_{\ell k}(x)\,|\xi|(\theta-\theta_\ell)^k}$. This is done by truncating the Taylor expansion to the first $d_{\ell k}$ terms

$$e^{2\pi i c_{\ell k}(x)\,|\xi|(\theta-\theta_\ell)^k} \approx \sum_{m=0}^{d_{\ell k}-1} \beta_{\ell k m}^x(x)\beta_{\ell k m}^\xi(\xi).$$

  The value of each $d_{\ell k}$ is also chosen to obtain a good accuracy.
- Third, combine the separated expansions for $k = 1, \ldots, 2p+1$ into one separated representation for $e^{2\pi i \Phi_\ell(x,\xi)}$. Simply expanding the product of the expansions obtained in the previous step would be sufficient for proving a theorem like those presented in section 2, but in practice, though, the number of terms in the expansion is too large and far from optimal. We thus combine the product of separated expansions two-by-two with the compression procedure to be described next and repeat the process until there is only one separated expansion left. The final expansion provides us with the required functions $\{\gamma_{\ell t}^x(x)\}$ and $\{\gamma_{\ell t}^\xi(\xi)\}$.

The compression procedure used to combine the product of two separated expansions is quite standard. Suppose we have only two expansions (the subscript ℓ is implicit) and write their product as

$$\left(\sum_{m_1=0}^{d_1-1} \beta^x_{1m_1}(x)\beta^\xi_{1m_1}(\xi)\right)\left(\sum_{m_2=0}^{d_2-1} \beta^x_{2m_2}(x)\beta^\xi_{2m_2}(\xi)\right)$$
$$= \sum_{m_1,m_2} \left(\beta^x_{1m_1}(x)\beta^x_{2m_2}(x)\right)\left(\beta^\xi_{1m_1}(\xi)\beta^\xi_{2m_2}(\xi)\right) := \sum_m c^x_m(x)c^\xi_m(\xi).$$

We adopt the matrix notation and introduce

$$(A)_{x,m} = c^x_m(x), \quad (B^*)_{m,\xi} = c^\xi_m(\xi).$$

The problem is to find two matrices $\tilde{A}$ and $\tilde{B}$ which have far fewer columns than A and B yet obey $\tilde{A}\tilde{B}^* \approx AB^*$. This may be achieved by means of the QR factorization and the SVD:

1. Construct QR factorizations $A = Q_A R_A$ and $B = Q_B R_B$.
2. Compute the SVD of $R_A R_B^*$ and truncate the singular values below a threshold ε together with their associated left and right singular vectors, i.e., $R_A R_B^* \approx U_M S_M V_M^*$, where S_M is a truncated diagonal matrix of singular values.
3. Set $\tilde{A} = Q_A U_M S_M$ and $\tilde{B} = Q_B V_M$.

Suppose A is $m \times q$ and B is $n \times q$ with both m and n much larger than q. The computational complexity of the compression procedure is $O((m+n)q^2)$. In our setup, $m = |X| = N^2$, $n = |W_\ell| = O(N^{1.5})$, and q, the rank bound, is uniformly bounded in N (Theorem 2 shows that q is bounded by a small fractional power of ε, independently of N). Therefore, the complexity of a single compression procedure is $O(N^2)$. Since this needs to be carried out $2p-1$ times for each of the $\sqrt{N}$ wedges, the overall complexity of the deterministic preprocessing is $O(\sqrt{N} \times N^2) = O(N^{2.5})$, where the constant is directly related to the rank bounds of section 2.

Next, let us consider the storage requirement. For each wedge, the size of the final separated expansion is $O(N^2)$. Since there are $\sqrt{N}$ wedges, the total storage requirement is $O(N^{2.5})$, which can be costly when N is large. For example, in a typical problem with $N = 1024$ and $q = 20$, the total storage would be about 10 GB assuming double precision is used. Our second approach to solving the preprocessing step addresses this issue and requires dramatically less storage space.

3.2. Preprocessing step: Randomized approach. This section describes a randomized approach for computing the functions $\{\gamma^x_{\ell t}(x)\}$ and $\{\gamma^\xi_{\ell t}(\xi)\}$ for a fixed ℓ. The method is based on the work presented in Kapur and Long [30]. We use matrix notation and set A to be the matrix defined by

$$A_{x,\xi} := e^{2\pi i \Phi_\ell(x,\xi)}, \quad x \in X,\ \xi \in W_\ell. \tag{3.2}$$

The matrix A is m by n with $m = N^2$ and $n = O(N^{1.5})$. Assume the prescribed error ε is fixed. Theorem 2 tells us that there exists a low rank factorization of A with rank $r_\varepsilon = O(1)$ (again, by this we mean that r_ε is bounded by a constant independent of N, although not independent of ϵ). Using this knowledge, the following randomized method finds an approximate factorization

$$A \approx UT,$$

where U is of size $m \times q$, T is $q \times n$, and $q = O(1)$ in N.

- Select a set C of r columns taken from A uniformly at random, and define $A_{[C]}$ to be the submatrix formed by these columns. In practice, a safe choice is to take r about three times larger than the (unknown) r_ε.
- Compute the SVD $A_{[C]} \approx USV^*$, where the diagonal of S contains only the singular values greater than the threshold ε. Since A has a separation rank $r_\varepsilon = O(1)$, we expect U to be of size $m \times q$, where q is about r_ϵ.
- Select a set R of r rows taken from A uniformly at random, and define $A_{[R]}$ to be the submatrix formed by these rows. Similarly, let $U_{[R]}$ be the submatrix of U containing the same rows.
- Set $T = U^+_{[R]} A_{[R]}$, where $U^+_{[R]}$ is the pseudoinverse of $U_{[R]}$.
- The matrices U and T provide an approximate factorization, i.e., $A \approx UT$. We identify the columns of U with the family $\{\gamma^x_{\ell t}(x)\}$ and the rows of T with $\{\gamma^\xi_{\ell t}(\xi)\}$.

This randomized approach works well in practice, although we are not able to offer a rigorous proof of its accuracy and expect one to be nontrivial. We merely argue that the validity of this methodology hinges on the following observations:

- First, the columns of A are highly correlated. Following the arguments in section 2, it is not difficult to show that a pair of columns with nearby values of the frequency index $\xi \in W_\ell$ has a large inner product. Therefore, as we sample uniformly at random, we get good coverage of the set W_ℓ (leaving no large hole), and as a result, the sampled columns nearly span the space generated by the columns of A. Note that one could also use a deterministic regular sampling strategy; for instance, we could take a Cartesian subgrid as a subset of W_ℓ. We observed that, in practice, the probabilistic approach provides slightly better approximations.
- As the SVD routine is numerically stable, it allows us to extract an orthobasis of the column space of $A_{[C]}$ in a robust way.
- By construction, the columns of U are orthonormal. Results from random projection and the geometry of high-dimensional spaces imply that, as long as U does not correlate with the canonical orthobasis, the columns of $U_{[R]}$ are almost orthogonal as well. This allows us to recover the matrix T in a stable and robust fashion.

The computational complexity of this randomized approach is quite low. The SVD step has a complexity of $O(mr^2) = O(N^2)$, while the matrix product $T = U^+_{[R]} A_{[R]}$ takes $O(nrq) = O(N^{1.5})$ operations. Therefore, for each ℓ, the complexity of the randomized approach is $O(N^2)$. Since the same procedure needs to be carried out for all the $\sqrt{N}$ wedges, the overall complexity is $O(N^{2.5})$.

Often we do not know the exact value of r_ε. Instead of setting r conservatively to be an unnecessarily large number, this difficulty is addressed as follows: we begin with a small r, and check whether q is significantly smaller than r. If this is the case, we accept the factorization. Otherwise, we double r and restart the process. Geometrical increase guarantees that the work wasted (due to unsuccessful attempts) is bounded by the work of the final successful attempt. In practice, we accept the result when $q \leq r/3$, and this criterion seems to work well in our numerical experiments. A more conservative test certainly improves the reliability of the factorization but increases the running time.

We finally examine the storage requirement. A naive approach is to store the matrices U and T for each wedge W_ℓ. As T is much smaller than U in size, the storage requirement for each wedge is roughly the size of U, which is $N^2 q = O(N^2)$.

TABLE 1
Comparison of the deterministic and randomized approaches.

	Time	Storage
Randomized	$O(N^{2.5})$ (small constant)	$O(\sqrt{N})$
Deterministic	$O(N^{2.5})$ (large constant)	$O(N^{2.5})$

Multiplying this by the number of wedges gives a total storage requirement of $O(N^{2.5})$, which can be quite costly for large N, as already mentioned in the last section. We propose to store the matrices VS^{-1} and $U^+_{[R]}$ instead. Both matrices require only storage of size $O(rq) = O(1)$. Whenever we need U and T, we form the products $U = A_{[C]}VS^{-1}$ and $T = U^+_{[R]}A_{[R]}$. Note that the elements of the matrices $A_{[C]}$ and $A_{[R]}$ are given explicitly by the formula (3.2), and there is of course no need to store them at all. Putting it differently, we rewrite the computed factorization as

$$A \approx A_{[C]}\, VS^{-1} U^+_{[R]}\, A_{[R]} \tag{3.3}$$

and store only the matrices VS^{-1} and $U^+_{[R]}$.

We would like to point out that such a scheme is not likely to work for the deterministic approach. The main reason is that the deterministic approach involves multiple compression procedures which make use of QR factorizations and SVD decompositions. These numerical linear algebra routines are quite complicated, and therefore, it would be difficult to relate the resulting low rank factorization with the elements of the matrix A, which have the simple form (3.2).

3.3. Comparison. Table 1 compares the deterministic and the randomized approaches in view of the computational complexity and storage requirement. The deterministic approach has the advantage of guaranteeing an accurate low rank separation. However, the constant in the time complexity can be quite large, as for each wedge, it requires $2p$ compression procedures to combine multiple separated expansions into a single one. Moreover, since the compression step uses QR factorizations and SVDs, we are forced to store the final expansion, which can be quite costly for large N. In practice, the randomized approach constructs a near-optimal low rank expansion with very high probability, requires very low storage space, and enjoys a significantly lower constant in time complexity since it does not utilize repeated QR factorizations or SVDs.

3.4. Evaluation step. Once the families $\{\gamma^x_{\ell t}(x)\}$ and $\{\gamma^\xi_{\ell t}(\xi)\}$ are available, we use the approximation

$$(Lf)(x) \approx \frac{1}{N} \sum_\ell \sum_t \gamma^x_{\ell t}(x) \sum_\xi e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi} \left[\gamma^\xi_{\ell t}(\xi) \chi_\ell(\xi) \hat{f}(\xi) \right]$$

to evaluate $Lf(x)$. The algorithm simply carries out the evaluation step by step:

1. Compute $\hat{f}$, the Fourier transform of f.
2. For each ℓ and t, form $\hat{f}_{\ell t}(\xi) := \gamma^\xi_{\ell t}(\xi)\chi_\ell(\xi)\hat{f}(\xi)$.
3. For each ℓ and t, compute $g_{\ell t}(x) := \sum_\xi e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi} \hat{f}_{\ell t}(\xi)$.
4. Compute $(Lf)(x) \approx \frac{1}{N}\sum_\ell \sum_t \gamma^x_{\ell t}(x) g_{\ell t}(x)$.

The only step that requires attention is the third: it asks to evaluate the Fourier series $\sum_\xi e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi} \hat{f}_{\ell t}(\xi)$ at the N^2 points $\{\nabla_\xi \Phi(x,\hat{\xi}_\ell) : x \in X\}$. Even though X is a Cartesian grid, the warped grid $\{\nabla_\xi \Phi(x,\hat{\xi}_\ell) : x \in X\}$ is no longer so. In

fact, the formula for $g_{\ell t}$ is a nonuniform Fourier transform of the second kind, a subject of considerable attention [2, 5, 25, 34, 35] since the seminal paper of Dutt and Rokhlin [21]. We adopt the approach introduced in the latter paper and, following their notation, set

- $m = 4$, $q = 8$, and $b = 0.425$ for 6 digits of accuracy,
- $m = 4$, $q = 16$, and $b = 0.785$ for 11 digits of accuracy.

We specify these parameter values because they impact the numerical accuracies we will report in the next section, and because it will help anyone interested in reproducing our results.

The algorithm in [21] generally assumes that the Fourier coefficients are supported on the full grid Ω which is symmetric with respect to the origin. For each ℓ, the support of $\hat{f}_{\ell t}(\xi)$ is W_ℓ, which is to say that most of the values of the input on the grid Ω are zero. To speed up the nonuniform FFT, each wedge W_ℓ, which is close to either one of the diagonals, is sheared by 45 degrees so that it becomes approximately horizontal or vertical. Notice that 45 degree shearing of $\hat{f}_{\ell t}(\xi)$ is a simple relabeling of the array. In addition, all wedges are then translated so that their support fits in a rectangle of smaller volume centered around the origin. As the nonuniform FFT [21] asks to compute the FFT of the input data (and then finds a way of interpolating the result on an unstructured grid), we gain efficiency since the input array is now of smaller size. Mathematically, the shearing operation takes the form

$$\xi' = M\xi - \xi_c,$$

where M is either the identity or a 45-degree shear matrix and ξ_c is a translation parameter. Thus, we organize the computations as in

$$\begin{aligned}\sum_{\xi} e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot\xi} \hat{f}_{\ell t}(\xi) &= \sum_{\xi'} e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot M^{-1}(\xi'+\xi_c)} \hat{f}_{\ell t}(M^{-1}(\xi'+\xi_c)) \\ &= e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot M^{-1}\xi_c} \sum_{\xi'} e^{2\pi i \nabla_\xi \Phi(x,\hat{\xi}_\ell)\cdot M^{-1}\xi'} \hat{f}_{\ell t}(M^{-1}(\xi'+\xi_c)),\end{aligned}$$

where the final summation is a nonuniform Fourier transform at the set of points $(M^*)^{-1}\nabla_\xi \Phi(x,\hat{\xi}_\ell)$. In condensed form, the oscillatory modes of the function we wish to evaluate are centered around a center frequency; we factor out this frequency, interpolate the residual, and add the factor back in; for the same accuracy, interpolating the smoother residual requires a smaller computational effort.

A two-dimensional nonuniform FFT takes $O(N^2 \log N)$ operations. This operation needs to be repeated $q = O(1)$ times for each one of the $\sqrt{N}$ wedges. Therefore, the overall complexity is $O(N^{2.5} \log N)$.

3.5. Evaluating the adjoint operator. We conclude this section by presenting how to rapidly apply the adjoint FIO. Begin by expanding the Fourier transform in (1.1) and write

$$(Lf)(x) = \int \left(\int e^{2\pi i(\Phi(x,\xi) - y\cdot\xi)} \mathrm{d}\xi \right) f(y) \mathrm{d}y$$

for $x, y, \xi \in \mathbb{R}^2$. The adjoint operator is then given by

$$\begin{aligned}(L^* f)(x) &= \int \left(\int e^{-2\pi i(\Phi(y,\xi) - x\cdot\xi)} \mathrm{d}\xi \right) f(y) \mathrm{d}y \\ &= \int \left(\int e^{-2\pi i \Phi(y,\xi)} f(y) \mathrm{d}y \right) e^{2\pi i x\cdot\xi} \mathrm{d}\xi\end{aligned}$$

or equivalently as

$$\widehat{(L^*f)}(\xi) = \int e^{-2\pi i\Phi(y,\xi)} f(y)\mathrm{d}y$$

in the Fourier domain. Similarly, one readily checks that the adjoint of the discrete-time FIO is given by the formula

$$\widehat{(L^*f)}(\xi) = \frac{1}{N}\sum_y e^{-2\pi i\Phi(y,\xi)} f(y),$$

where $\xi \in \Omega$ and $y \in X$.

Now follow the same set of ideas as in section 3.4, and decompose L^* as

$$\begin{aligned}
\widehat{(L^*f)}(\xi) &= \frac{1}{N}\sum_\ell \chi_\ell(\xi)\sum_y e^{-2\pi i\Phi(y,\xi)} f(y) \\
&= \frac{1}{N}\sum_\ell \chi_\ell(\xi)\sum_y e^{-2\pi i\Phi_\xi(y,\hat{\xi}_\ell)\cdot\xi} e^{-2\pi i\Phi_\ell(y,\xi)} f(y) \\
&= \frac{1}{N}\sum_\ell \chi_\ell(\xi)\sum_y e^{-2\pi i\Phi_\xi(y,\hat{\xi}_\ell)\cdot\xi}\sum_t \overline{\gamma_{\ell t}^x(y)\gamma_{\ell t}^\xi(\xi)} f(y) \\
&= \frac{1}{N}\sum_\ell \sum_t \chi_\ell(\xi)\overline{\gamma_{\ell t}^\xi(\xi)}\sum_y e^{-2\pi i\Phi_\xi(y,\hat{\xi}_\ell)\cdot\xi}\left(\overline{\gamma_{\ell t}^x(y)} f(y)\right).
\end{aligned}$$

The right-hand side of the last equation provides the key steps of the algorithm.

1. For each ℓ and $t \le q$, compute $f_{\ell t}(y) := \overline{\gamma_{\ell t}^x(y)} f(y)$.
2. For each ℓ and $t \le q$, compute $g_{\ell t}(\xi) := \sum_y e^{-2\pi i\Phi_\xi(y,\hat{\xi}_\ell)\cdot\xi} f_{\ell t}(y)$ using the nonuniform FFT of the first kind; see [21, 25] for details.
3. Compute $\widehat{(L^*f)}(\xi) \approx \frac{1}{N}\sum_\ell \sum_t \chi_\ell(\xi)\overline{\gamma_{\ell t}^\xi(\xi)} g_{\ell t}(\xi)$.
4. Finally, take an inverse two-dimensional FFT to get $(L^*f)(x)$.

Clearly, all the results and discussions concerning the matrix vector product Lf apply here as well.

4. Numerical results. This section presents several numerical examples to demonstrate the effectiveness of the algorithms introduced in section 3. Our implementation is in MATLAB and all the computational results we are about to report were obtained on a desktop computer with a 2.6 GHz CPU and 3 GB of memory. We have implemented both the deterministic and randomized approaches for the preprocessing step. We choose to report the timing and accuracy results of the randomized approach only since it requires less time and storage, as shown in section 3.2.

We first study the error of the separated approximation generated by the randomized preprocessing step. For $x = (x_1, x_2)$ and $\xi = (\xi_1, \xi_2)$, set the phase function to be

$$\Phi_\pm(x,\xi) = x\cdot\xi \pm \sqrt{r_1^2(x)\xi_1^2 + r_2^2(x)\xi_2^2}. \tag{4.1}$$

We show in the appendix that the transformation, which for each x integrates f along an ellipse centered at x and with axes of length $r_1(x)$ and $r_2(x)$, can be cast as a sum $L_+ + L_-$ of two FIOs given by

$$(L_\pm f)(x) = \int a_\pm(x,\xi) e^{2\pi i\Phi_\pm(x,\xi)}\hat{f}(\xi)\mathrm{d}\xi, \tag{4.2}$$

TABLE 2
Relative errors of the low rank separated representation constructed using the randomized approach.

	$\varepsilon =$ 1e-3	$\varepsilon =$ 1e-4	$\varepsilon =$ 1e-5	$\varepsilon =$ 1e-6
$N = 64$	3.57e-04	4.93e-05	3.21e-06	5.17e-07
$N = 128$	3.11e-04	2.28e-05	4.19e-06	5.81e-07
$N = 256$	2.85e-04	2.83e-05	2.94e-06	4.13e-07
$N = 512$	1.66e-04	2.82e-05	4.38e-06	6.80e-07

and with phases obeying (4.1).

In our numerical example, we consider the phase Φ_+ and choose

$$r_1(x) = \frac{1}{9}(2 + \sin(4\pi x_1))(2 + \sin(4\pi x_2)),$$

$$r_2(x) = \frac{1}{9}(2 + \cos(4\pi x_1))(2 + \cos(4\pi x_2)).$$

In each wedge W_ℓ, the phase is then linearized and a low rank separated approximation UT of the matrix

$$A = \left(e^{2\pi i \Phi_\ell(x,\xi)}\right)_{x \in X, \xi \in W_\ell}$$

is computed. To estimate the approximation error, we randomly select two sets Γ and Δ of s rows and s columns. Put $A_{\Gamma\Delta}$ to be the s by s submatrix of A with these rows and columns. The separated rank approximation to $A_{\Gamma\Delta}$ is then obtained by multiplying U_Γ and T_Δ, where U_Γ is the submatrix of U with rows in Γ and T_Δ is that of T with columns in Δ. The error is then estimated via

$$\frac{\|A_{\Gamma\Delta} - U_\Gamma T_\Delta\|_F}{\|A_{\Gamma\Delta}\|_F},$$

where $\|\cdot\|_F$ stands for the Frobenius norm. In our numerical test, we set s to be 200, and Table 2 displays approximation errors for different combinations of problem size N and accuracy ε. The results show that the randomized approach works quite well and that the estimated error is controlled well below the threshold ε.

Next, consider the relationship between the separation rank and the threshold ε. Theorem 3 shows that ε scales like N^{-p} for a fixed constant p provided that the separation rank grows gently like $p \log N$. In this experiment, we use the same phase function $\Phi(x, \xi)$ in (4.1) and show the separation rank for different values of N and p in Table 3. These results suggest that the separation rank is roughly proportional to both p and the logarithm of N, which is compatible with the theoretical estimate. Moreover, when N is fixed, the rank seems to grow linearly with respect to p, which possibly implies that the constant $C(p)$ in Theorem 3 in fact grows linearly with respect to p.

We would like to point out that the number of wedges affects the complexity of our algorithm in two ways. On the one hand, it is obvious from section 3.4 that the complexity grows with the number of wedges in a linear fashion. On the other hand, if we lower the number of wedges, the angular aperture of each wedge has to increase. This implies an increase in the separation rank, which results in a growing computational complexity. In our experiments (Tables 2 and 3), we set the number of wedges to be $\lceil \sqrt{2N} \rceil$, which, in practice, balances these two competing factors.

TABLE 3

Ranks of the separated representation generated by the randomized approach for different values of N and p. The prescribed error is equal to N^{-p}.

	$p=1$	$p=1.5$	$p=2$	$p=2.5$	$p=3$
$N=64$	7	10	14	18	22
$N=128$	9	12	17	21	24
$N=256$	9	12	17	21	25
$N=512$	10	15	19	24	27

TABLE 4

Numerical evaluation of $Lf(x)$ with f a two-dimensional white-noise array. The second and third columns give the number of seconds spent in the preprocessing and evaluation steps, respectively. The fourth column shows the speedup factor over the naive algorithm for computing $(Lf)(x)$ using the direct summation (4.3). The fifth column is the estimated relative error, and the last gives the amount of memory used in terms of megabytes.

(N,ε)	Preprocessing	Evaluation	Speedup	Error	Storage
(64,2.44e-03)	2.06e+00s	3.89e+00s	2.05e+00	2.08e-03	0.76M
(128,6.10e-04)	1.09e+01s	2.45e+01s	6.58e+00	8.02e-04	1.26M
(256,1.53e-04)	8.10e+01s	1.65e+02s	1.67e+01	1.00e-04	2.01M
(512,3.81e-05)	4.67e+02s	9.88e+02s	4.46e+01	4.22e-05	3.06M

We now turn to the numerical evaluation of $(Lf)(x)$,

$$(Lf)(x) = \frac{1}{N}\sum_{\xi} e^{2\pi i\Phi(x,\xi)}\hat{f}(\xi), \tag{4.3}$$

where the phase function Φ is the same as in (4.1). In this example, f is an array of independently and identically mean-zero normal random variables (Gaussian white noise), which in some ways is the most challenging input. The threshold ε is set to be $10\,N^{-2}$ (i.e., $p=2$). To estimate the error, we first pick s points $\{x_i : i=1,\dots,s\}$ from X and put $\{\widetilde{(Lf)}(x_i)\}$ for the output of our algorithm (section 3.4). We then compare the values of $\widetilde{(Lf)}(x_i)$ at these points with those of $\{(Lf)(x_i)\}$ obtained by evaluating (4.3) directly. Finally, we estimate the relative error with

$$\sqrt{\frac{\sum_i |(Lf)(x_i) - \widetilde{(Lf)}(x_i)|^2}{\sum_i |(Lf)(x_i)|^2}}.$$

Here, we choose $s=100$, and Table 4 summarizes our findings for various values of N. The results show that our algorithm performs well. The error is controlled well below threshold and the speedup over the naive algorithm is significant for large values of N.

We have considered only the evaluation of FIOs in "Egorov" form thus far (constant amplitude), but the algorithm described in section 3 can be easily extended to operate with general amplitudes provided that the term $a(x,\xi)$ also admits a low rank separated representation in the variables x and ξ.

To study the performance of our algorithm in the more general setup of variable amplitudes, we continue with the example where f is integrated along ellipses (4.2) (recall the phase (4.1)). The appendix shows that a possible choice for the amplitudes $a_\pm(x,\xi)$ and phases $\Phi_\pm(x,\xi)$ is

$$a_\pm(x,\xi) = \frac{1}{4\pi}(J_0(2\pi\rho(x,\xi)) \pm iY_0(2\pi\rho(x,\xi)))e^{\mp 2\pi i\rho(x,\xi)}, \tag{4.4}$$

$$\Phi_\pm(x,\xi) = x\cdot\xi \pm \rho(x,\xi) \tag{4.5}$$

TABLE 5
Numerical evaluation of $Lf(x)$ with f a two-dimensional white-noise array.

(N, ε)	Preprocessing	Evaluation	Speedup	Error	Storage
(64,2.44e-03)	2.18e+01s	3.67e+01s	4.54e+00	7.30e-04	0.37M
(128,6.10e-04)	1.09e+02s	1.65e+02s	1.49e+01	4.00e-04	0.59M
(256,1.53e-04)	6.62e+02s	8.46e+02s	4.49e+01	1.39e-04	0.89M
(512,3.81e-05)	3.42e+03s	4.43e+03s	1.62e+02	3.69e-05	1.38M

with

$$\rho(x,\xi) = \sqrt{r_1^2(x)\xi_1^2 + r_2^2(x)\xi_2^2}.$$

Here, J_0 and Y_0 are Bessel functions of the first and second kinds, respectively; see the appendix for details.

For the axes lengths, set

$$r_1(x) = r_2(x) \equiv r(x) = \frac{1}{16}(3 + \sin(4\pi x_1))(3 + \sin(4\pi x_2)) \tag{4.6}$$

(which means that our ellipses are circles). We compute $(L_+ f)(x)$ for different values of N and ε and provide the results in Table 5. The computational analysis shows that our algorithm performs equally well in the variable amplitude case. For $N = 512$, the speedup factor over the naive evaluation is about 162. It is clear from section 3.4 that the dominant part of the evaluation step is the $O(q\sqrt{N})$ calls to the nonuniform FFT. An improved implementation of the nonuniform FFT would certainly result in greater speedup factors.

An extremely important property of Fourier integral operators is that, under the nondegeneracy condition

$$\det\left(\frac{\partial^2 \Phi}{\partial x_i \partial \xi_j}\right) \neq 0,$$

the composition of a FIO with its adjoint preserves the singularities of the input function. Mathematically speaking, if $WF(f)$ is the wave front set of f [20, 39], then

$$WF(L^* L f) = WF(f).$$

This property serves as the foundation for most of the current imaging techniques in reflection seismology [39]. In the final example of this section, we verify this phenomenon numerically. We choose the phase function to be

$$\Phi(x,\xi) = x \cdot \xi + r(x)|\xi|,$$

where $r(x)$ is given by (4.6), and compute $(L^* L f)$ using the algorithm discussed in sections 3.4 and 3.5. Figure 2 displays results for three input functions with different kinds of singularities. Looking at the picture, we see that the "singularities" of Lf are of course different than those of f, but we also see that the "singularities" of $L^* L f$ coincide with those of f.

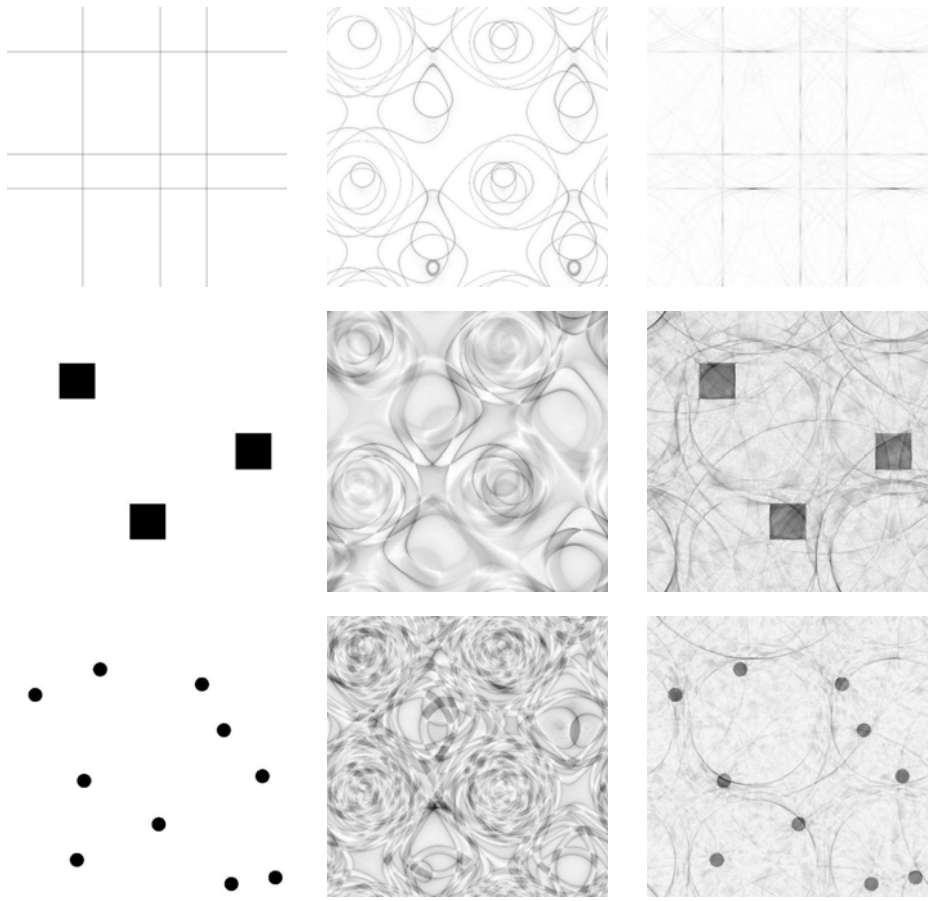

FIG. 2. *Numerical verification of the fact* $WF(L^*Lf) = WF(f)$. *Each row, from left to right, shows the magnitudes of* $f(x)$, $(Lf)(x)$, *and* $(L^*Lf)(x)$. *Notice that the wave front set of* $f(x)$ *and* $(L^*Lf)(x)$ *are numerically close.* Remark*: The images in the left column and in the right column are not supposed to be the same; only their "singularities" coincide. In other words, the adjoint* L^* *is not the inverse of* L. *The artifacts appear because the data to which we apply the FIO is not bandlimited.*

5. Discussion.

5.1. About randomized algorithms. The method used in the randomized preprocessing step was first introduced by Kapur and Long [30]. Lately, there has been a lot of research devoted to the development of randomized algorithms for generating low rank factorizations, and we would like to discuss some of this work.

Drineas, Kannan, and Mahoney [19] describe a randomized algorithm for computing a low rank approximation to a fixed matrix. The main idea is to form a submatrix by selecting columns with a probability proportional to their norm. Since this work is about unstructured general matrices, it does not guarantee a small approximation error. As an example, suppose all the columns of the matrix have the same norm and one of them is orthogonal to the span of the other columns. Unless this column is selected, the orthogonal component is lost and the resulting approximation is poor.

Our situation is different. Since each entry of our matrix

$$A = \left(e^{2\pi i \Phi_\ell(x,\xi)}\right)_{x\in X, \xi\in W_\ell}$$

has unitary magnitude, the uniform probability used in our algorithm is actually the same as that proposed above [19]. In some ways, then, our approach is a special case of that of Drineas, Kannan, and Mahoney. But the point is that our matrix has a special structure. As we argued earlier, the columns of A are often highly correlated, and we believe that this is the reason why the randomized subsampling performs well.

A recent article by Martinsson, Rokhlin, and Tygert [32] presents a new randomized solution to the same problem. The only inconvenience of this algorithm, probably inevitable for general matrices, is that one needs to visit all the entries of the matrix multiple times. This can be quite costly in our setup since there are $O(N^4)$ entries. This is why we adopt the method by Kapur and Long.

5.2. Storage compression. We would like to comment on the storage compression strategy discussed at the end of section 3.2. In fact, what we described there can be viewed as a way of compressing low rank matrices.

In a general context, the entries of a matrix can be viewed as interaction coefficients between a set of objects indexed by the rows and another set indexed by the columns. In our case, the first set contains the grid points x in X, while the second set consists of the frequencies ξ in W_ℓ. Call these two sets I and J, and the interaction matrix $A_{I,J}$. The standard practice for compressing $A_{I,J}$ is to find two sets I' and J' of smaller sizes and form an approximation

$$A_{I,J} \approx M_{I,I'} M_{I',J'} M_{J',J}.$$

Here I' is either a subset of I or a set which is close by in some sense, and likewise for J' and J. For example, in the fast multipole method of Greengard and Rokhlin [26], J' is the multipole representation at the center of the box containing J, while I' is the local representation at the center of the box containing I. The matrices $M_{I,I'}$, $M_{I',J'}$, and $M_{J',J}$ are implemented as the multipole-to-multipole, multipole-to-local, and local-to-local translations. This becomes even more obvious when one considers the newly proposed kernel independent fast multipole method by Ying, Biros, and Zorin [40]. There, I' and J' are the equivalent densities supported on the boxes containing I and J, while $M_{I,I'}$, $M_{I',J'}$, and $M_{J',J}$ can be computed directly from interaction matrices and their inverses. In both cases, we are fortunate in the sense that prior knowledge offers us efficient ways to multiply $M_{I,I'}$, $M_{I',J'}$, and $M_{J',J}$ with arbitrary vectors. Whenever this is not true, one might be forced to store these matrices, which could be quite costly.

What we have presented in (3.3) is a different factorization:

$$A_{IJ} \approx A_{IJ'} R_{J'I'} A_{I'J}.$$

This factorization can be viewed as a variant of the pseudoskeleton approximation proposed in [23, 24], which came to our attention after we had released the initial version of this paper. Notice that since $A_{IJ'}$ and $A_{I'J}$ are interaction matrices themselves, there is no need to store them as long as we can compute the interaction coefficients easily. The only thing we need to keep in storage is the matrix $R_{J'I'}$. However, as long as the interaction is low rank, I' and J' have far fewer objects than I and J, so that $R_{J'I'}$ uses only very little storage. Finally, we would like to point out

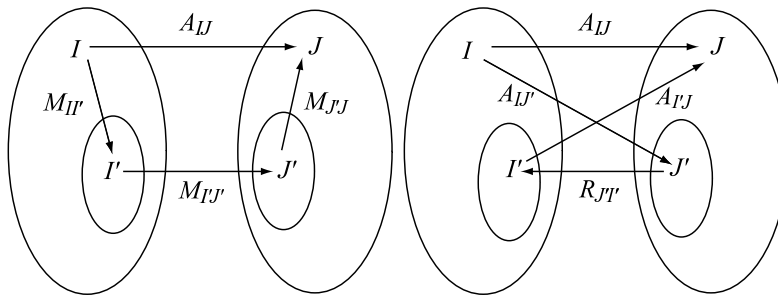

FIG. 3. *Factorization of interaction between A and B.* (a) *The standard scheme.* (b) *The scheme abstracted from the storage compression method used in* (3.3).

that, instead of representing the interaction from J' (a subset of J) to I' (a subset of I), $R_{J'I'}$ is a reverse interaction. Figure 3 shows conceptually how the current factorization differs from the standard one.

5.3. Curvelets, wave atoms, and beamlets. There might be other ways of evaluating FIOs, and we would like to discuss their relationships to the approach taken in this paper.

Curvelets, proposed by Candès and Donoho [12], are two-dimensional waveforms which are highly anisotropic in the fine scales. Each curvelet is identified with three numbers to indicate its scale, orientation, and position, and the set of all curvelets forms a tight frame. Recently, Candès and Demanet [10, 11] have shown that the curvelet representation of the FIOs is optimally sparse. More precisely, a FIO has only $O(N^2)$ nonnegligible entries in the curvelet domain. The wave atom frame, which was recently introduced by Demanet and Ying [16], has the same property. If we were able to find such a representation efficiently, we would hold an $O(N^2 \log N)$ algorithm for evaluating a FIO which would operate as follows:

1. Apply the forward curvelet transform to the input and get curvelet coefficients.
2. Apply the sparse FIO to the curvelet coefficient sequence.
3. Apply the inverse curvelet transform.

Both steps 1 and 3 require at most $O(N^2 \log N)$ operations [13].

Constructing the curvelet representation of a FIO from the phase function $\Phi(x, \xi)$ efficiently has, however, proved to be nontrivial. At the moment, we are able only to construct an approximation which is asymptotically accurate by studying the canonical relation embedded inside the phase function $\Phi(x, \xi)$. Such a construction would be adequate if we were interested in applying a FIO to input functions with only high frequency modes. However, one often wants a representation which is accurate for all frequency modes, and we are currently not aware of any efficient method for constructing such a representation.

Beamlets [17] were introduced by Donoho and Huo at roughly the same time as curvelets. Beamlets are small segments at different positions, scales, and orientations. As pointed out in section 4, curvilinear integrals make up an important subclass of FIOs, and beamlets may offer ways to efficiently compute such simpler integrals. One might think of something like this:

1. Compute the beamlet coefficient sequence of the input.
2. For each $x \in X$, figure out the integration curve and approximate it with a chain of beamlet segments. Sum up the beamlet coefficients along the chain.

Assuming the integration curves are twice differentiable, we would need about $\sqrt{N}$ beamlet segments to approximate each curve. Thus, the overall complexity of this algorithm might scale like $O(N^{2.5})$, which is the same scaling as that of our algorithm. The problem is that it is unclear how one would efficiently approximate the integration curve with beamlet segments without sacrificing accuracy. Situations in which the input function f is highly oscillatory or in which the integration curves have parts with a high curvature seem very problematic.

Our algorithms decompose the FIO in the frequency domain, whereas the beamlet based approach processes data in the spatial domain. Sandwiched right in the middle, curvelets and wave atoms operate in the phase-space—the product of the frequency and of the spatial domains. We believe that operating in phase-space by exploiting the microlocal properties of FIOs would be important in bringing down the complexity to the optimal value of about N^2 operations.

Appendix. Integration along ellipses. The material in this section is probably not new, but we expand on it for the convenience of the nonspecialist. Consider the generalization Radon transform that consists in integrating $f(x)$ along ellipses of axes lengths $r_1(x)$ and $r_2(x)$, and centered around x:

$$Gf(x) = \int f\left(x + \begin{pmatrix} r_1(x)\cos\theta \\ r_2(x)\sin\theta \end{pmatrix}\right) d\theta.$$

We want to recast it as a sum of FIOs. Let us start by writing

$$Gf(x) = \int K(x,\xi)\hat{f}(\xi)\, d\xi$$

with

$$K(x,\xi) = e^{2\pi i x\cdot\xi} \int \exp\left[2\pi i \begin{pmatrix} r_1(x)\cos\theta \\ r_2(x)\sin\theta \end{pmatrix} \cdot \xi\right] d\theta.$$

Put $\rho(x,\xi) = \sqrt{r_1^2(x)\xi_1^2 + r_2^2(x)\xi_2^2}$ and rewrite

$$K(x,\xi) = e^{2\pi i x\cdot\xi} \int \exp\left[2\pi i \rho(x,\xi) \begin{pmatrix} \cos\theta \\ \sin\theta \end{pmatrix} \cdot \begin{pmatrix} \alpha(x,\xi) \\ \beta(x,\xi) \end{pmatrix}\right] d\theta.$$

Here $\alpha^2 + \beta^2 = 1$, and both α and β depend on x and ξ, but the value of the integral is independent of their particular value. This is because any change of variables $\theta \to \theta + \phi(x,\xi)$, effectively corresponding to a rotation of the unit vector (α,β), keeps the integral invariant. So we may as well take $\alpha = 1$, $\beta = 0$ and obtain

$$K(x,\xi) = e^{2\pi i x\cdot\xi} \int e^{2\pi i \rho(x,\xi)\cos\theta}\, d\theta = \frac{e^{2\pi i x\cdot\xi}}{2\pi} J_0(2\pi\rho(x,\xi)).$$

Of course the Bessel function J_0 oscillates, and we need to extract the phase from its asymptotic behavior

$$J_0(2\pi\rho(x,\xi)) \sim \sqrt{\frac{1}{\pi^2\rho(x,\xi)}} \cos\left(2\pi\rho(x,\xi) - \frac{\pi}{4}\right).$$

The idea is now to express $J_0(2\pi\rho(x,\xi))$ as a sum of two terms, each of which is the product between a smooth amplitude (a demodulated version of J_0 or the envelope of

J_0 if you will) and the oscillatory exponential $e^{\pm 2\pi i \rho(x,\xi)}$. In effect, K is decomposed as a sum of two FIOs:

$$K(x,\xi) = a_+(x,\xi)e^{2\pi i \Phi_+(x,\xi)} + a_-(x,\xi)e^{2\pi i \Phi_-(x,\xi)}$$

with

$$\Phi_\pm(x,\xi) = x \cdot \xi \pm \rho(x,\xi).$$

There are different ways to choose the amplitudes. One way is to let Y_0 be the Bessel function of the second kind of order zero [1] and exploit the identity $2J_0 = (J_0 + iY_0) + (J_0 - iY_0)$, which allows us to write

$$a_\pm(x,\xi) = \frac{1}{4\pi}(J_0(2\pi\rho(x,\xi)) \pm iY_0(2\pi\rho(x,\xi)))e^{\mp 2\pi i \rho(x,\xi)}.$$

Both amplitudes behave asymptotically like $\sqrt{1/\pi^2\rho(x,\xi)}$ as $x \to \infty$, which incidentally shows that the order of the FIO is $-1/2$. The logarithmic singularity of Y_0 near the origin in ξ is mild and easily regularized with no loss of accuracy.

Acknowledgments. We are thankful to William Symes for stimulating discussions about Kirchhoff migration and related topics, to Mark Tygert for pointing our attention to the pseudoskeleton approximation, and to the referees for their scrutiny.

NUMERICAL SOLUTION TO THE SINE-GORDON EQUATION DEFINED ON THE WHOLE REAL AXIS*

CHUNXIONG ZHENG†

Abstract. Numerical simulation of the solution to the sine-Gordon equation on the whole real axis is considered in this paper. Based on nonlinear spectral analysis, exact nonreflecting boundary conditions are derived at two artificially introduced boundary points. Then a numerical scheme of second order is proposed to approximate the solution. In the end, some numerical examples are provided to demonstrate the effectiveness of the proposed scheme.

Key words. sine-Gordon equation, unbounded domains, nonreflecting boundary conditions, inverse scattering

1. Introduction.

In this paper, we consider the numerical simulation of the solution to the sine-Gordon equation

$$q_{tt} - q_{xx} + \sin q = 0,\ x \in \mathbf{R},\ 0 < t \le T, \tag{1}$$

$$q(x,0) = q_0(x),\ q_t(x,0) = q_1(x),\ x \in \mathbf{R}. \tag{2}$$

The sine-Gordon equation has applications in various research areas, such as differential geometry and relativistic field theory, and it also appears in a number of other physical applications, including the propagation of fluxons in Josephson junctions, the motion of rigid pendula attached to a stretched wire, and dislocations in crystals [4, 5].

When numerically solving problems formulated on unbounded domains, such as the considered problem (1)–(2), the unboundedness of definition domains usually presents a great numerical difficulty. This is simply because most of the well-developed methods, such as finite element and finite difference, are domain-based and capable only of handling problems with finite domains. Thus, a natural resolution for these problems is to limit the computational domains by introducing artificial boundaries where suitable artificial boundary conditions (ABCs) can be imposed. As repeatedly shown by different authors both theoretically and experimentally, the overall accuracy and performance of numerical schemes strongly depend on the choice of ABCs. For more details, the readers are referred to the review papers by Givoli [8], Hagstrom [10, 11], and Tsynkov [18].

The ideal ABCs, which are usually referred to as the exact nonreflecting boundary conditions (NRBCs) for wave-like equations in the literature, make the solution to the "truncated" problem exactly the same as that of the untruncated one restricted to the computational domain. For some linear time-dependent problems, these ABCs

*Received by the editors September 19, 2005; accepted for publication (in revised form) April 12, 2007; published electronically October 17, 2007. can be derived with the tool of Laplace transformation or by other means; see [1, 3, 9, 13, 16, 17]. But for genuinely nonlinear time-dependent problems, this is by no means a trivial matter. Compared with the large number of papers on linear problems, there are only a few concerned with the nonlinear ones. For at least two special types of nonlinear problems, it is possible to derive the exact ABCs. The first one includes those nonlinear equations which can be transformed into linear equations by the Cole–Hopf transformation, such as the viscous Burgers' equation [12] and the deterministic Kardar–Parisi–Zhang equation [19], and the second one includes some integrable nonlinear evolution equations, such as the one-dimensional cubic nonlinear Schrödinger equation, the sine-Gordon equation, and the modified KdV equation [7]. Apart from these two types, how to derive the exact ABCs is still an open and complicated issue.

Instead of deriving the exact ABCs, some authors turn to the highly accurate approximate ABCs for nonlinear problems. Using pseudodifferential operator theory, Antoine, Besse, and Descombes [2] designed a series of NRBCs for the one-dimensional cubic nonlinear Schrödinger equation and proved their stability. With the tool of pseudodifferential and paradifferential calculus, Szeftel [14] constructed two families of NRBCs for the more general one-dimensional nonlinear Schrödinger equations. Some of these NRBCs were shown to present well-posed initial boundary value problems. Additionally, Szeftel also extended his method to the nonlinear scalar partial differential equations [15].

In [6, 7], Fokas derived a kind of exact generalized Dirichlet-to-Neumann (DtN) mapping for some integrable evolution equations by inverse scattering theory, which unfortunately cannot be used directly for the numerical treatment from the computational point of view. Based on his excellent work, Zheng derived new forms of these generalized DtN mappings for the Schrödinger equation [20] and the modified KdV equation [21] and designed numerical schemes for these two equations.

In this paper, we will derive a new generalized DtN mapping for the sine-Gordon equation following the main procedure of deduction in [7]. A function transformation will be made to avoid the singularity of tangent function involved in the generalized DtN mapping given in [7]. Following the idea involved in [20], a numerical scheme based on the five-point difference stencil will be proposed. In the end, some numerical tests will be presented to demonstrate the performance of this numerical scheme.

2. Exact nonreflecting boundary conditions. Assume there exists a finite interval $\Omega = (a, b)$, such that $q_0(x) = 2\pi m_1$ when $x > b$ and $q_0(x) = 2\pi m_2$ when $x < a$, and $q_1(x)$ is compactly supported in Ω. Here, m_1 and m_2 are two integers. We also assume that the solution of problem (1)–(2) is smooth, and that the functions q_x, q_t, $\sin q$, and $\cos q - 1$ decay to zero sufficiently fast when x goes to infinity. To seek the numerical solution in Ω, two boundary conditions are needed at two artificial boundary points $\{a, b\}$.

Let σ_j denote the usual Pauli matrices

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \ \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \ \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

and let $\hat{\sigma}_3$ be the corresponding matrix commutator of σ_3, i.e.,

$$\hat{\sigma}_3 A \stackrel{def}{=} [\sigma_3, A] = \sigma_3 A - A\sigma_3.$$

Here, A is any 2-by-2 matrix. It is straightforward to verify that

$$e^{\hat{\sigma}_3} A = e^{\sigma_3} A e^{-\sigma_3}. \tag{3}$$

The sine-Gordon equation (1) admits a Lax pair in the form

$$\mu_x + if_1(k)\hat{\sigma}_3\mu = Q(x,t,k)\mu, \tag{4}$$

$$\mu_t + if_2(k)\hat{\sigma}_3\mu = \tilde{Q}(x,t,k)\mu,\ \ k \in \mathcal{C}, \tag{5}$$

where $\mathcal{C}$ is the complex field, $\mu = \mu(x,t,k)$ is a 2-by-2 matrix-valued function, and

$$f_1(k) = \frac{1}{4}\left(k - \frac{1}{k}\right),\ \ f_2(k) = \frac{1}{4}\left(k + \frac{1}{k}\right), \tag{6}$$

$$Q(x,t,k) = -\frac{i}{4}(q_x + q_t)\sigma_1 - \frac{i}{4k}(\sin q)\sigma_2 + \frac{i}{4k}(\cos q - 1)\sigma_3, \tag{7}$$

$$\tilde{Q}(x,t,k) = Q(x,t,-k). \tag{8}$$

The existence of a Lax pair in the form of (4)–(5) means that, if and only if function $q = q(x,t)$ satisfies the sine-Gordon equation (1), then system (4)–(5) is compatible and thus solvable. In this case, we have

$$d\left(e^{i(f_1(k)x + f_2(k)t)\hat{\sigma}_3}\mu\right) = e^{i(f_1(k)x + f_2(k)t)\hat{\sigma}_3}(Q\mu dx + \tilde{Q}\mu dt), \tag{9}$$

which implies the right-hand side of (9) is the exact differential 1-form of function $e^{i(f_1(k)x + f_2(k)t)\hat{\sigma}_3}\mu$.

Now we determine $e^{i(f_1(k)x + f_2(k)t)\hat{\sigma}_3}\mu$, and thus μ, by specifying its value at point $(+\infty, t^*)$ as the identity matrix $I = \mathrm{diag}(1,1)$. Here, $t^* \in [0,T]$ is a fixed time point. That is to say, we let μ be determined by

$$e^{i(f_1(k)x + f_2(k)t)\hat{\sigma}_3}\mu = I + \int_{(+\infty,t^*)}^{(x,t)} e^{i(f_1(k)\xi + f_2(k)\tau)\hat{\sigma}_3}(Q\mu d\xi + \tilde{Q}\mu d\tau). \tag{10}$$

The integration is performed on a smooth curve of the $\{x,t\}$-plane which connects $(+\infty, t^*)$ to (x,t). Several remarks should be made here. First, since the right-hand side of (9) is an exact differential 1-form, function μ is independent of the choice of integrating path. Second, the definition of μ is also independent of the choice of t^*. This is because the functions Q and $\tilde{Q}$ decay to zero sufficiently fast thanks to our assumption on the solution q. Third, function μ might not be well defined for some $k \in \mathcal{C}$, since an improper integral gets involved in (10).

We let the integrating path go straight from $(+\infty, t)$ to (x,t), and we rewrite the integral equation (10) as

$$e^{if_1(k)x\hat{\sigma}_3}\mu(x,t,k) = I - \int_x^{+\infty} e^{if_1(k)\xi\hat{\sigma}_3}Q(\xi,t,k)\mu(\xi,t,k)d\xi$$

or, equivalently,

$$\mu(x,t,k) = I - \int_x^{+\infty} e^{if_1(k)(\xi - x)\hat{\sigma}_3}Q(\xi,t,k)\mu(\xi,t,k)d\xi.$$

Since

$$e^{\alpha\hat{\sigma}_3}\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} = \begin{pmatrix} a_{11} & a_{12}e^{2\alpha} \\ a_{21}e^{-2\alpha} & a_{22} \end{pmatrix},$$

the second column of μ, denoted by μ_2, satisfies an integral equation with exponential $e^{2if_1(k)(\xi - x)}$ involved. Since $\xi - x \geq 0$, μ_2 is at least well defined on the complex

domain with $\Im f_1(k) \geq 0$, i.e., $\Im k \geq 0$ except $|k| = 0$. Also, one can show that μ_2 is bounded and continuous and behaves like $(0,1)^T + O(1/k)$ as $k \to \infty$ on this domain. μ_2 is also analytic on the upper-half complex domain. On the other hand, μ_1, the first column of μ, is at least well defined, bounded, and continuous on the complex domain with $\Im k \leq 0$ except $|k| = 0$. It is also analytic on the lower-half complex plane, behaving like $(1,0)^T + O(1/k)$ as $k \to \infty$. More detailed results can be found in [7].

We next study $\mu(b,t,k)$, the value of $\mu(x,t,k)$ on the line $x = b$. We let the integrating path go straight from $(+\infty, 0)$ to $(b,0)$ first, and then straight to (b,t). Since $Q(x,0,k) = \tilde{Q}(x,0,k) = 0$, we have $\mu(x,0,k) = I$ from integral equation (10). Thus, $\mu(b,t,k)$ satisfies the integral equation

$$e^{if_2(k)t\hat{\sigma}_3}\mu(b,t,k) = I + \int_0^t e^{if_2(k)\tau\hat{\sigma}_3}\tilde{Q}(b,\tau,k)\mu(b,\tau,k)d\tau.$$

Setting $\Psi(t,k) = \mu(b,t,k)e^{-if_2(k)t\sigma_3}$ and recalling the identity (3), one knows that Ψ satisfies

$$e^{if_2(k)t\sigma_3}\Psi(t,k) = I + \int_0^t e^{if_2(k)\tau\sigma_3}\tilde{Q}(b,\tau,k)\Psi(\tau,k)d\tau$$

or, equivalently,

$$\Psi_t(t,k) + if_2(k)\sigma_3\Psi(t,k) = \tilde{Q}(b,t,k)\Psi(t,k),\ \Psi(0,k) = I.$$

Setting $g_0(t) = q(b,t)$ and $g_1(t) = q_x(b,t)$, from the definition (8) of $\tilde{Q}$, one has

$$\tilde{Q}(b,t,k) = -\frac{i}{4}(\dot{g}_0 + g_1)\sigma_1 + \frac{i}{4k}(\sin g_0)\sigma_2 - \frac{i}{4k}(\cos g_0 - 1)\sigma_3.$$

It can be verified directly that the second column of function $\Psi(t,k)$, denoted by $\Phi(t,k)$, can be expressed as

$$\Phi(t,k) = \begin{pmatrix} 0 \\ e^{if_2 t} \end{pmatrix} + \int_{-t}^{t} \begin{pmatrix} iL_1(t,s) - \frac{1}{2k}\left[\cos\left[\frac{g_0(t)}{2}\right]M_1(t,s) + \sin\left[\frac{g_0(t)}{2}\right]M_2(t,s)\right] \\ iL_2(t,s) + \frac{i}{2k}\left[-\cos\left[\frac{g_0(t)}{2}\right]M_2(t,s) + \sin\left[\frac{g_0(t)}{2}\right]M_1(t,s)\right] \end{pmatrix} e^{if_2 s}ds \tag{11}$$

with $\{L_j, M_j\}_{j=1,2}$ defined by the following equations:

$$L_1(t,t) = -\frac{g_1(t) + \dot{g}_0(t)}{8},\ M_1(t,t) = -\frac{1}{2}\sin\left[\frac{g_0(t)}{2}\right], \tag{12}$$

$$L_2(t,-t) = M_2(t,-t) = 0,$$

$$L_{1_t} - L_{1_s} = -\frac{g_1(t) + \dot{g}_0(t)}{4}L_2 + \frac{1}{4}\sin\left[\frac{g_0(t)}{2}\right]M_2, \tag{13}$$

$$L_{2_t} + L_{2_s} = \frac{g_1(t) + \dot{g}_0(t)}{4}L_1 - \frac{1}{4}\sin\left[\frac{g_0(t)}{2}\right]M_1, \tag{14}$$

$$M_{1_t} - M_{1_s} = -\sin\left[\frac{g_0(t)}{2}\right]L_2 + \frac{g_1(t) - \dot{g}_0(t)}{4}M_2, \tag{15}$$

$$M_{2_t} + M_{2_s} = \sin\left[\frac{g_0(t)}{2}\right]L_1 - \frac{g_1(t) - \dot{g}_0(t)}{4}M_1. \tag{16}$$

Since $\Psi(t,k)=\mu(b,t,k)e^{-if_2(k)t\sigma_3}$, and μ_2 and Φ are the second column of μ and Ψ, respectively, one has

$$e^{if_2(k)t}\Phi = e^{2if_2(k)t}\mu_2. \tag{17}$$

Let D denote the upper-half complex plane with oriented boundary ∂D, which originates from $-\infty$ to -1 on the real axis, then to 1 on the upper-half unit circle, and finally to $+\infty$ on the real axis. Multiplying (17) by $\left(1-\frac{1}{k^2}\right)e^{-2if_2(k)t'}$ with $0<t'<t$ and performing integration along ∂D, the first element of the right-hand side vanishes owing to Jordan's lemma. Thus,

$$\int_{\partial D}\left(1-\frac{1}{k^2}\right)e^{-2if_2(k)t'}e^{if_2(k)t}\Phi_1 dk = 0. \tag{18}$$

Here, Φ_1 is the first element of vector Φ. From the expression of Φ (11), one has

$$\begin{aligned}\Phi_1 &= \int_{-t}^{t}\left(iL_1(t,s)-\frac{1}{2k}\left[\cos\left[\frac{g_0(t)}{2}\right]M_1(t,s)+\sin\left[\frac{g_0(t)}{2}\right]M_2(t,s)\right]\right)e^{if_2(k)s}ds\\ &= 2\int_0^t\left(iL_1(t,2\tau-t)-\frac{1}{2k}\left[\cos\left[\frac{g_0(t)}{2}\right]M_1(t,2\tau-t)\right.\right.\\ &\qquad\left.\left.+\sin\left[\frac{g_0(t)}{2}\right]M_2(t,2\tau-t)\right]\right)e^{if_2(k)(2\tau-t)}d\tau.\end{aligned}$$

Substituting the above expression of Φ_1 into (18), using the identity

$$\int_{\partial D}\left(1-\frac{1}{k^2}\right)\left[\int_0^t e^{2if_2(\tau-t')}K(\tau,t)d\tau\right]dk = 4\pi K(t',t),$$

taking the limit $t'\to t$, and finally using boundary condition (12), one derives

$$\begin{aligned}g_1(t) &= -\dot g_0(t)-\frac{1}{i\pi}\int_{\partial D}\frac{1}{k}\left(1-\frac{1}{k^2}\right)\\ &\left[\int_0^t e^{-\frac{i}{2}\left(k+\frac{1}{k}\right)(t-\tau)}\left(\cos\left[\frac{g_0(t)}{2}\right]M_1(t,2\tau-t)+\sin\left[\frac{g_0(t)}{2}\right]M_2(t,2\tau-t)\right)d\tau\right]dk.\end{aligned}$$

Exchanging the integrating order of the double integral gives

$$\begin{aligned}g_1(t) = -\dot g_0(t)-\int_0^t \mathcal{Z}(t-\tau)&\left(\cos\left[\frac{g_0(t)}{2}\right]M_1(t,2\tau-t)\right.\\ &\left.+\sin\left[\frac{g_0(t)}{2}\right]M_2(t,2\tau-t)\right)d\tau,\end{aligned} \tag{19}$$

with

$$\begin{aligned}\mathcal{Z}(t) &\overset{def}{=} \frac{1}{i\pi}\int_{\partial D}\frac{1}{k}\left(1-\frac{1}{k^2}\right)e^{-\frac{i}{2}\left(k+\frac{1}{k}\right)t}dk\\ &= -\frac{4}{\pi}\int_1^{+\infty}(x-\sqrt{x^2-1})\sin(xt)dx-\frac{2J_1(t)}{t}+\frac{4}{\pi}\frac{t\cos t-\sin t}{t^2}.\end{aligned}$$

At any fixed time point t, $\mathcal{Z}(t)$ can be evaluated by a numerical quadrature scheme. We depict this function in Figure 1.

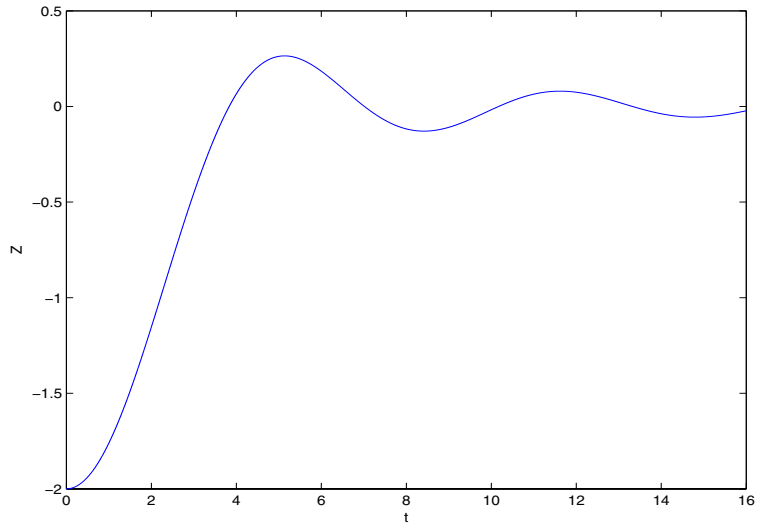

FIG. 1. *Plot of function* $\mathcal{Z}(t)$.

Given $g_0(t)$ and $g_1(t)$, $\{L_j, M_j\}_{j=1,2}$ can be determined from (12)–(16). Thus, the right-hand side of (19) defines a mapping from $g_0(t)$ and $g_1(t)$. We designate this mapping as $\mathcal{K}$ and rewrite (19) as

$$g_1(t) = \mathcal{K}(t; g_0(\cdot), g_1(\cdot)). \tag{20}$$

This equation reveals clearly how the Dirichlet datum $g_0(t)$ and the Neumann datum $g_1(t)$ are related to each other: given $g_0(t)$, $g_1(t)$ is just the fixed point function of mapping $\mathcal{K}$. In this sense, (19) or (20) can be taken as a generalized DtN mapping. We remark that this mapping is different from that given in [7]. A function transformation has been made to avoid the singularity of tangent function $\tan(\cdot)$, which appears in the generalized DtN mapping given in [7, pp. 649–650].

Now imposing the mapping (20) at $x = b$ as a boundary condition, and similarly at $x = a$, we can derive a new "truncated" problem, which is defined only on the finite interval $\Omega = (a, b)$:

$$q_{tt} - q_{xx} + \sin q = 0,\ x \in \Omega,\ t > 0, \tag{21}$$

$$q_\nu(a,t) = \mathcal{K}(t; q(a,\cdot), q_\nu(a,\cdot)),\ q_\nu(b,t) = \mathcal{K}(t; q(b,\cdot), q_\nu(b,\cdot)),\ t > 0, \tag{22}$$

$$q(x,0) = q_0(x),\ q_t(x,0) = q_1(x),\ x \in \Omega. \tag{23}$$

Here, ν denotes the outer normal direction. Based on our analysis, the solution to this problem is exactly the same as that of problem (1)–(2) restricted to Ω.

3. Numerical scheme. Let Δt be the time step size, and let $h = (b-a)/M$ be the spatial step size with M being the number of the grid points. Let

$$t_n = n\Delta t,\ x_j = a + jh,\ q_j^n \sim q(x_j, t_n).$$

We note that owing to the requirement of numerical stability, Δt must be less than h.

We start with numerically approximating the generalized DtN mapping $\mathcal{K}$ in (20) if $g_0(t)$ and $g_1(t)$ are prescribed at discrete time points t_n. We take two steps: seek the

numerical solutions of $\{L_j, M_j\}_{j=1,2}$, and then approximate the integral in (19) by a numerical quadrature scheme. The idea used is a direct adaptation of that involved in [20] for the generalized DtN mapping of the cubic nonlinear Schrödinger equation.

For any function $A(\cdot,\cdot)$ defined in $\{(t,s) : -t \le s \le t,\ 0 \le t \le N\Delta t = T\}$, we let $A_j^n \sim A(t_n, -t_n + 2j\Delta t)$, $j = 0, 1, \ldots, n$. Additionally, we let $g_0^n \sim g_0(t_n)$ and $g_1^n \sim g_1(t_n)$. For the simplicity of notation, we would like to rewrite (12)–(16) in a vector form. Setting $V_1 = (L_1, M_1)^T$ and $V_2 = (L_2, M_2)^T$, we have

$$V_1(t,t) = \left(-\frac{g_1(t) + \dot{g}_0(t)}{8}, -\frac{1}{2}\sin\left[\frac{g_0(t)}{2}\right]\right)^T,\ V_2(t,-t) = (0,0)^T, \tag{24}$$

$$V_{1_t} - V_{1_s} = R(t)V_2,\ V_{2_t} + V_{2_s} = -R(t)V_1, \tag{25}$$

with

$$R(t) = \begin{pmatrix} -\frac{g_1(t)+\dot{g}_0(t)}{4} & \frac{1}{4}\sin\left[\frac{g_0(t)}{2}\right] \\ -\sin\left[\frac{g_0(t)}{2}\right] & \frac{g_1(t)-\dot{g}_0(t)}{4} \end{pmatrix}.$$

By boundary conditions (24), we naturally set

$$V_{1,n}^n = \left(-\frac{1}{8}\left(\frac{g_0^{n+1} - g_0^{n-1}}{2\Delta t} + g_1^n\right), -\frac{1}{2}\sin\left[\frac{g_0^n}{2}\right]\right)^T,\ V_{2,0}^n = (0,0)^T. \tag{26}$$

Since $\frac{1}{\sqrt{2}}(A_t + A_s) = (\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}) \cdot \nabla A$ is the directional derivative of A with angle $\frac{\pi}{4}$, while $\frac{1}{\sqrt{2}}(A_t - A_s) = (\frac{1}{\sqrt{2}}, -\frac{1}{\sqrt{2}}) \cdot \nabla A$ is that with angle $-\frac{\pi}{4}$, we can discretize the directional derivative with the central difference scheme in (25),

$$\frac{V_{1,j}^n - V_{1,j}^{n-1}}{\Delta t} = R_c\frac{V_{2,j}^n + V_{2,j}^{n-1}}{2},\ \frac{V_{2,j}^n - V_{2,j-1}^{n-1}}{\Delta t} = -R_c\frac{V_{1,j}^n + V_{1,j-1}^{n-1}}{2}, \tag{27}$$

with

$$R_c = \begin{pmatrix} -\frac{1}{4}\left[\frac{g_0^n - g_0^{n-1}}{\Delta t} + \frac{g_1^n + g_1^{n-1}}{2}\right] & \frac{1}{4}\sin\left[\frac{g_0^n + g_0^{n-1}}{4}\right] \\ -\sin\left[\frac{g_0^n + g_0^{n-1}}{4}\right] & -\frac{1}{4}\left[\frac{g_0^n - g_0^{n-1}}{\Delta t} - \frac{g_1^n + g_1^{n-1}}{2}\right] \end{pmatrix}.$$

Equation (27) is a linear system with $4(n-1)$ degrees of freedom, and solving this system turns costly when the number of time steps is large. For example, a direct solver needs $O(n^3)$ operations. Instead of the trapezoidal scheme, we can employ the modified Euler scheme, a technique similar to that used in [20]. That is to say, we first use the Euler scheme to derive the first-order approximations $\{V_{1,j,*}^n, V_{2,j,*}^n\}$ through

$$\frac{V_{1,j,*}^n - V_{1,j}^{n-1}}{\Delta t} = R_c V_{2,j}^{n-1},\ \frac{V_{2,j,*}^n - V_{2,j-1}^{n-1}}{\Delta t} = -R_c V_{1,j-1}^{n-1}, \tag{28}$$

and then we compute $\{V_{1,j}^n, V_{2,j}^n\}$ through

$$\frac{V_{1,j}^n - V_{1,j}^{n-1}}{\Delta t} = R_c\frac{V_{2,j,*}^n + V_{2,j}^{n-1}}{2},\ \frac{V_{2,j}^n - V_{2,j-1}^{n-1}}{\Delta t} = -R_c\frac{V_{1,j,*}^n + V_{1,j-1}^{n-1}}{2}. \tag{29}$$

The final scheme is still of second order, but needs only $O(n)$ operations, which is a significant improvement compared with any direct solver.

Next, we consider the approximation of the relation (20). This can be easily handled by a proper interpolation method. If the piecewise linear interpolation is used, and the integration is approximated with the midpoint scheme, one derives the relation

$$g_1^n = -\frac{g_0^{n+1} - g_0^{n-1}}{2\Delta t} - \frac{\Delta t}{4}\sum_{j=0}^{n-1}(\mathcal{Z}(t_{n-j}) + \mathcal{Z}(t_{n-j-1}))(f_{j+1}^n + f_j^n) \tag{30}$$

with

$$f_j^n \stackrel{def}{=} \cos\left[\frac{g_0^n}{2}\right] M_{1,j}^n + \sin\left[\frac{g_0^n}{2}\right] M_{2,j}^n.$$

Now we can see that if g_0^{n+1} and g_1^n are given, $\{V_{1,j}^n, V_{2,j}^n\}$, and thus $\{M_{1,j}^n, M_{2,j}^n\}$, can be computed through (26), (28), and (29). Then, the right-hand side of (30) defines a mapping. Designating this mapping as $\mathcal{K}_{\Delta t}$, (30) can be abbreviated to

$$g_1^n = \mathcal{K}_{\Delta t}(n; g_0^{n+1}, g_1^n). \tag{31}$$

This is a discrete analogy of the continuous generalized DtN mapping (20), and g_1^n can be determined by g_0^{n+1}.

Now we consider the discretization of the sine-Gordon equation in Ω. There are many choices which can serve this purpose. Here, we employ the standard five-point difference scheme. Discretizing the equation at the nth time step and utilizing the five-point stencil of second order, we obtain for $n \geq 1$ and $j = 0, 1, \ldots, M$

$$\frac{q_j^{n+1} - 2q_j^n + q_j^{n-1}}{\Delta t^2} - \frac{q_{j+1}^n - 2q_j^n + q_{j-1}^n}{h^2} + \sin q_j^n = 0, \tag{32}$$

$$\frac{q_{-1}^n - q_1^n}{2h} = \partial_\nu q_0^n, \ \frac{q_{M+1}^n - q_{M-1}^n}{2h} = \partial_\nu q_M^n, \tag{33}$$

$$q_j^0 = q_0(x_j), \ q_j^1 = q_j^0 + \Delta t q_1(x_j) + \frac{\Delta t^2}{2}\left(\frac{q_{j+1}^0 - 2q_j^0 + q_{j-1}^0}{h^2} - \sin q_j^0\right), \tag{34}$$

where $\partial_\nu q_0^n$ and $\partial_\nu q_M^n$ are determined by

$$\partial_\nu q_0^n = \mathcal{K}_{\Delta t}(n; q_0^{n+1}, \partial_\nu q_0^n), \ \partial_\nu q_M^n = \mathcal{K}_{\Delta t}(n; q_M^{n+1}, \partial_\nu q_M^n). \tag{35}$$

On the nth time step, $\{q_1^n, \ldots, q_{M-1}^n\}$ can be determined directly through (32). From (32) and (33), we have

$$q_0^{n+1} = 2q_0^n - q_0^{n-1} + \Delta t^2\left(\frac{2q_1^n - 2q_0^n + 2h\partial_\nu q_0^n}{h^2} - \sin q_0^n\right), \tag{36}$$

$$q_M^{n+1} = 2q_M^n - q_M^{n-1} + \Delta t^2\left(\frac{2q_{M-1}^n - 2q_M^n + 2h\partial_\nu q_M^n}{h^2} - \sin q_M^n\right). \tag{37}$$

Defining

$$\mathcal{L}_{\Delta t,h}(u, v, w, q) = 2u - v + \Delta t^2\left(\frac{2w - 2u + 2hq}{h^2} - \sin u\right),$$

we get

$$q_0^{n+1} = \mathcal{L}_{\Delta t,h}(q_0^n, q_0^{n-1}, q_1^n, \partial_\nu q_0^n), \ q_M^{n+1} = \mathcal{L}_{\Delta t,h}(q_M^n, q_M^{n-1}, q_{M-1}^n, \partial_\nu q_M^n).$$

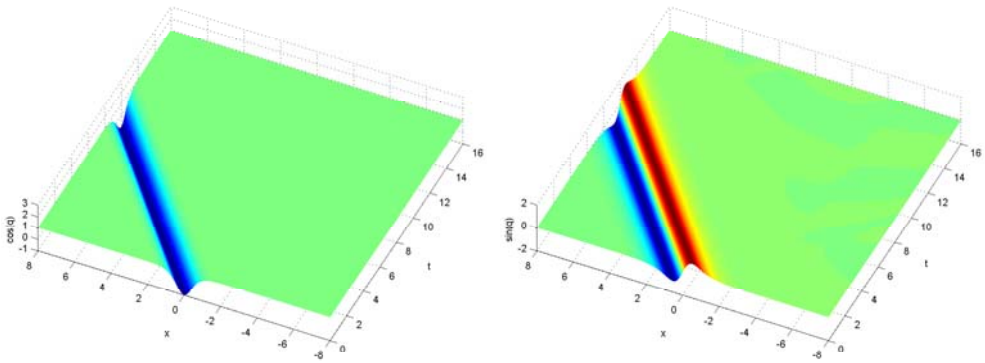

FIG. 2. *Evolution of the kink solution.* $\Delta t = \frac{1}{256}$. *Left:* $\cos q$. *Right:* $\sin q$.

Substituting the above formula into (35) gives

$$\partial_\nu q_0^n = \mathcal{K}_{\Delta t}(n; \mathcal{L}_{\Delta t,h}(q_0^n, q_0^{n-1}, q_1^n, \partial_\nu q_0^n), \partial_\nu q_0^n), \tag{38}$$

$$\partial_\nu q_M^n = \mathcal{K}_{\Delta t}(n; \mathcal{L}_{\Delta t,h}(q_M^n, q_M^{n-1}, q_{M-1}^n, \partial_\nu q_M^n), \partial_\nu q_M^n). \tag{39}$$

We can solve $\partial_\nu q_0^n$ and $\partial_\nu q_M^n$ with fixed point iterations. Once this is done, q_0^n and q_M^n are then obtained through (36)–(37).

4. Numerical tests. The sine-Gordon equation admits some traveling soliton solutions: the kink solution

$$q_{kink} = 4 \arctan \exp \frac{x - at}{\sqrt{1 - a^2}}$$

and the antikink solution

$$q_{antikink} = 4 \arctan \exp - \frac{x - at}{\sqrt{1 - a^2}},$$

with $a \in (0, 1)$ being the moving velocity. When $t = 0$, these solutions tend to some constants exponentially fast as x tends to infinity. For example, $q_{kink} \to 2\pi$ as $x \to +\infty$, and $q_{kink} \to 0$ as $x \to -\infty$. Thus we can take them as reference solutions to test the performance of our numerical scheme. In all computations, we let $h = 2\Delta t$. To evaluate the quality of the numerical solution, we define an error function as

$$E(t) = \frac{||q_{num}(\cdot, t) - q_{exa}(\cdot, t)||_{0,\Omega}}{||q_{exa}(\cdot, t)||_{0,\Omega}}.$$

First, we test the accuracy of our numerical scheme. Let $a = 0.8$, $T = 10$, and $(a, b) = (-8, 8)$, and take $q_0 = q_{kink}(x, 0)$ and $q_1 = \frac{\partial}{\partial t} q_{kink}(x, 0)$ as the initial data. Figure 2 shows the numerical solution with $\Delta t = \frac{1}{256}$ and $h = \frac{1}{128}$. No reflection can be observed. Figure 3 shows the evolution of the relative errors for different time step sizes, and Table 1 lists the errors and the convergence orders. It can be seen that our numerical scheme is of second order, just as we anticipated.

Next, we use our scheme to study the interaction of two solitons. The sine-Gordon equation admits the kink-antikink solution

$$q_{kink\text{-}antikink} = 4 \arctan \left(\frac{p \sinh(\sqrt{p^2 - 1}t)}{\sqrt{p^2 - 1} \cosh(px)} \right)$$

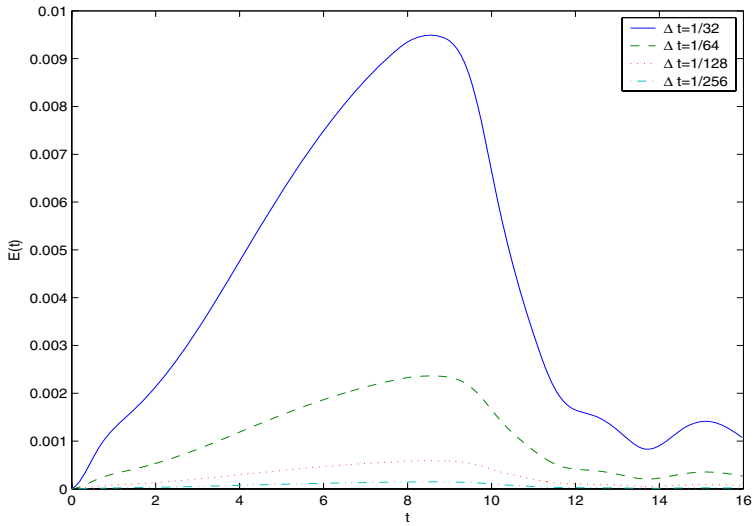

FIG. 3. *Evolution of E for different time step sizes.* $h = 2\Delta t$.

TABLE 1
Computation of $E(10)$ *and the convergence order.* $h = 2\Delta t$.

Time step size Δt	$\frac{1}{32}$	$\frac{1}{64}$	$\frac{1}{128}$	$\frac{1}{256}$
$E(10)$	6.659E-3	1.656E-3	4.134E-4	1.030E-4
Convergence order	-	2.008	2.002	2.005

and the kink-kink solution

$$q_{kink\text{-}kink} = 4\arctan\left(\frac{\sqrt{p^2-1}\sinh(px)}{p\cosh(\sqrt{p^2-1}t)}\right).$$

These two solitons move with the same speed $\sqrt{p^2-1}/p$ but different direction. In these two cases, we let $p = 2$, $\Omega = (-8, 8)$, and

$$q_0(x) = q_{exa}(x, -4),\ q_1(x) = \frac{\partial}{\partial t} q_{exa}(x, -4),$$

with q_{exa} being either $q_{kink\text{-}antikink}$ or $q_{kink\text{-}kink}$. Figures 4 and 5 show the evolution of numerical solutions. Again, no reflections can be observed.

We then consider a more complicated setting. The initial data are set to be four well-separated kink solitons. More precisely, we set

$$q_0(x) = q_{kink\text{-}kink}(x, -6) + q_{kink\text{-}kink}(x, -2),$$
$$q_1(x) = \frac{\partial}{\partial t}\left(q_{kink\text{-}kink}(x, -6) + q_{kink\text{-}kink}(x, -2)\right).$$

The exact solution for this setup is approximately

$$q_{exa} \approx q_{kink\text{-}kink}(x, t-6) + q_{kink\text{-}kink}(x, t-2),$$

which represents the interaction of four kink solitons. At $T = 20$, all solitons will move out of the computational domain $\Omega = (-8, 8)$. We depict the numerical solution in

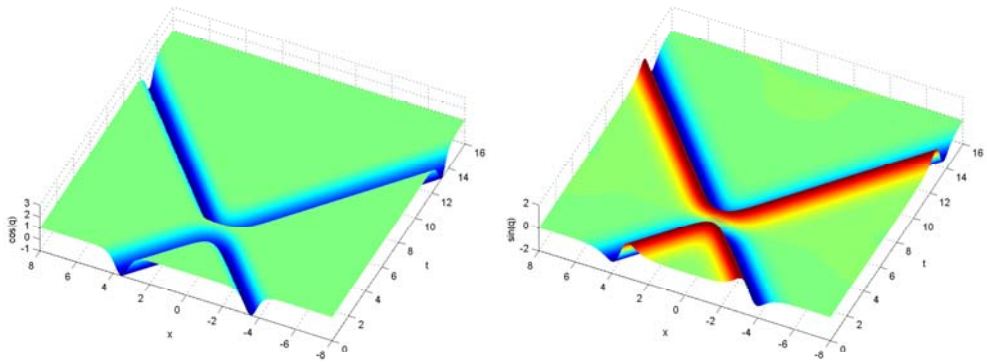

FIG. 4. *Interaction of a kink and an antikink with opposite direction.* $\Delta t = \frac{1}{256}$. *Left:* $\cos q$. *Right:* $\sin q$.

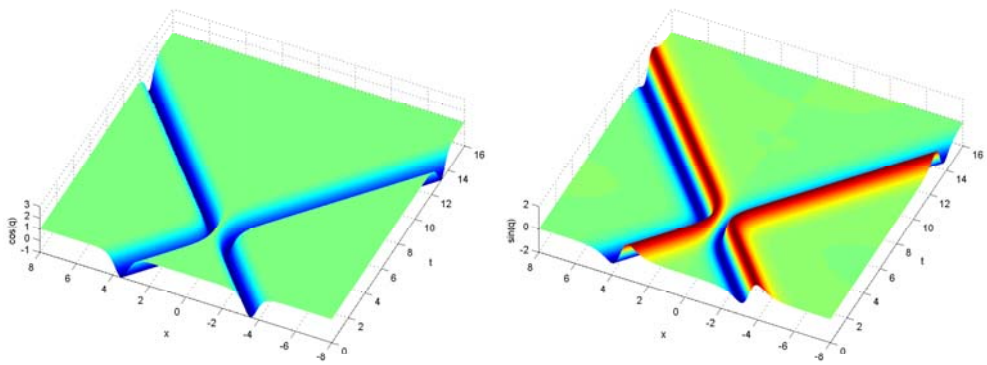

FIG. 5. *Interaction of two kinks with opposite direction.* $\Delta t = \frac{1}{256}$. *Left:* $\cos q$. *Right:* $\sin q$.

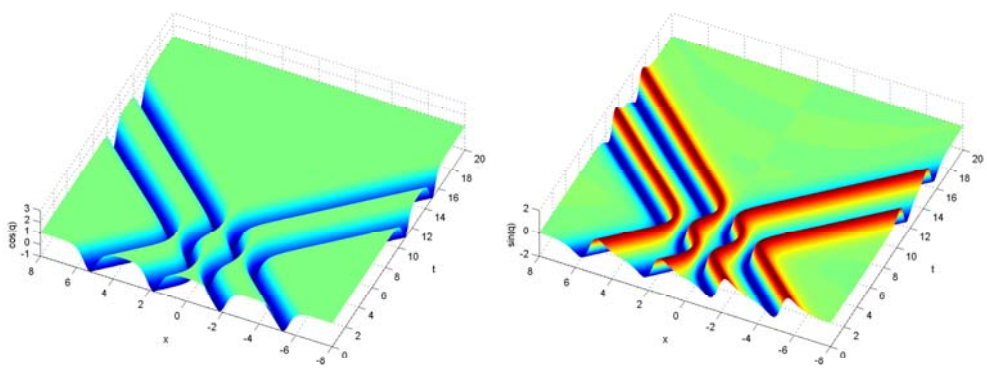

FIG. 6. *Interaction of four kinks.* $\Delta t = \frac{1}{256}$. *Left:* $\cos q$. *Right:* $\sin q$.

Figure 6. It is shown that the interaction of solitons is elastic and our boundary conditions work very well.

Finally, we consider the evolution of a Gaussian wave packet. The initial data are set to be

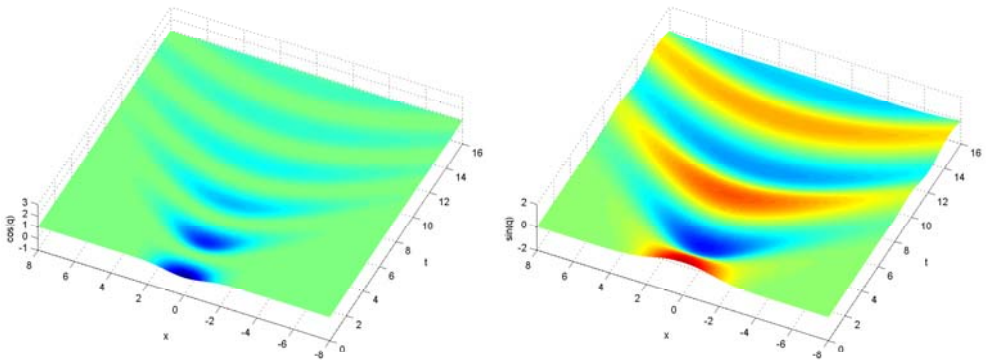

FIG. 7. *Evolution of a Gaussian wave packet.* $\Delta t = \frac{1}{256}$. *Left:* $\cos q$. *Right:* $\sin q$.

TABLE 2
Some statistics in the computation.

Time step size Δt	$\frac{1}{32}$	$\frac{1}{64}$	$\frac{1}{128}$	$\frac{1}{256}$
Max iterations	15	14	13	12
Average iterations	13.12	12.11	11.13	10.13
Time	2.2	7.52	27.25	99.33

$$q_0(x) = e^{-x^2/4},\ q_1(x) = 0.$$

From Figure 7, we see that soliton-like humps are generated successively and move away from the center of this wave packet. In Table 2, we list some numerical statistics. Remember that on the nth time step, we need to solve nonlinear equations (38)–(39) with fixed point iterations, and each iteration needs $O(n)$ operations. Iterations are terminated when the difference of two successive approximations is less than a threshold value, which is set to be 10^{-6} in all our computations. The second row of Table 2 lists the maximal number of iterations $\max_{n=1}^{N} i_n$ for different time step sizes. Here, i_n denotes the number of iterations on the nth time step. Since on different time steps, each iteration requires different operations, we define the average number of iterations as $\sum_{n=1}^{N} i_n n \,/\, \sum_{n=1}^{N} n$, listed in the third row of Table 2. We see that both the maximal and the average iteration numbers decrease with the time step size. The last row of Table 2 lists the time of computation. It increases nearly quadratically with the number of time steps. This statement will cease to hold when the number of time steps becomes much larger. In that case, the evaluation of discrete convolution involved in (30) becomes much more expensive, and the overall cost of computation would increase nearly cubically with the total number of time steps. That means that for long time computation, fast evaluation of convolution must be considered. This discussion is beyond the scope of this paper, and we leave it open here.

We should remark that no instability has been observed in any of our computations.

Acknowledgment. The author would like to thank the anonymous reviewers for their valuable suggestions, which have greatly improved the quality of this paper.

IMPLEMENTING GENERATING SET SEARCH METHODS FOR LINEARLY CONSTRAINED MINIMIZATION*

ROBERT MICHAEL LEWIS†, ANNE SHEPHERD‡, AND VIRGINIA TORCZON‡

Abstract. We discuss an implementation of a derivative-free generating set search method for linearly constrained minimization with no assumption of nondegeneracy placed on the constraints. The convergence guarantees for generating set search methods require that the set of search directions possesses certain geometrical properties that allow it to approximate the feasible region near the current iterate. In the hard case, the calculation of the search directions corresponds to finding the extreme rays of a cone with a degenerate vertex at the origin, a difficult problem. We discuss here how state-of-the-art computational geometry methods make it tractable to solve this problem in connection with generating set search. We also discuss a number of other practical issues of implementation, such as the careful treatment of equality constraints and the desirability of augmenting the set of search directions beyond the theoretically minimal set. We illustrate the behavior of the implementation on several problems from the CUTEr test suite. We have found it to be successful on problems with several hundred variables and linear constraints.

1. Introduction.

We consider ways to implement direct search methods for solving linearly constrained nonlinear optimization problems of the form

$$\begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to} && \ell \le Ax \le u. \end{aligned} \tag{1.1}$$

The objective function is $f : \mathbb{R}^n \to \mathbb{R}$, with decision variables $x \in \mathbb{R}^n$. The constraint matrix is $A \in \mathbb{R}^{m \times n}$. If some constraints are unbounded below or above, the components of ℓ and u are allowed to take on the values $-\infty$ and $+\infty$, respectively. Our approach handles both equality and inequality constraints.

A key step in generating set search (GSS) algorithms [16] is the computation of the requisite search directions. Generating set search methods for linearly constrained problems achieve convergence without explicit recourse to the gradient or the directional derivative of the objective. They also do not attempt to estimate Lagrange multipliers. Instead, when the search is close to the boundary of the feasible region, the set of search directions must include directions that conform to the ge-

ometry of the nearby boundary. For linearly constrained minimization, this requires identifying a working set of nearly binding constraints at each iteration. The search directions then are computed as the generators of the polar of the cone generated by the outward-pointing normals to the constraints in the working set [23, 29, 20, 21, 17]. When the working set defines a cone with a nondegenerate vertex at the origin, the case is straightforward; computational approaches for handling this case have been known for some time [23, 29, 20].

The hard case arises if the working set defines a cone with a degenerate vertex at the origin. Analysis of algorithms that allow degenerate working sets is well-established [20, 21]. On the other hand, the resulting calculation of the search directions quickly becomes too difficult for a naive approach. As noted in [20], sophisticated and efficient computational geometry algorithms are required.

In this paper we show that, by using state-of-the-art algorithms from computational geometry, the hard case can be dealt with in a computationally effective way and that the naive bounds on the combinatorial complexity involved in managing the hard case are unduly pessimistic. For example, in section 9 we illustrate a problem for which the estimate on the number of possible vectors to be considered is more than 2×10^{17} when, in fact, only 5 vectors are needed—and those vectors are correctly identified in less than one-fifth of a second on a standard desktop computer.

Our specific implementation makes use of the analysis of generating set search found in [17], which synthesizes the analytical results found in [20, 21]. A new feature of the algorithms presented in [17] is the way in which the working set of constraints is chosen, which we show here to be effective in practice.

We use Ω to denote the feasible region for problem (1.1):

$$\Omega = \{\, x \in \mathbb{R}^n \,:\, \ell \leq Ax \leq u \,\}.$$

The algorithm we present here, like all of the approaches referenced previously, is a *feasible iterates* method for solving (1.1): The initial iterate x_0 must be feasible, and all subsequent iterates x_k must satisfy $x_k \in \Omega$. We assume that f is continuously differentiable on Ω but that gradient information is not computationally available; i.e., no procedure exists for computing the gradient of the objective function, and it cannot be approximated accurately. We do not assume that the constraints are nondegenerate.

We discuss several topics regarding our implementation, though computing a sufficient set of search directions is the primary focus of this paper. Our goal is to dynamically identify a set of search directions sufficient to guarantee desirable convergence properties. The general idea is that the set must contain search directions that comprise all the generators for a particular cone of feasible directions, hence the name generating set search. An important question to be addressed in any implementation of this approach is what is meant by "close to the boundary"—i.e., which constraints belong in the current working set—since the current working set determines the requirements on the set of search directions needed for the iteration.

Once the current working set has been identified, the next question becomes how to obtain the desired set of search directions. If the current working set is not degenerate, then straightforward procedures are outlined in [23, 20]. In the presence of degeneracy, the situation becomes considerably more complex—a key issue we discuss here. Equalities in the working set were not treated explicitly in previous work, so here we elaborate on this case. We also discuss how augmenting the set of search directions can accelerate progress toward a solution.

Once a set of search directions has been identified, a step of appropriate length along each of the search directions must be found. The analysis makes this straightforward through the use of a scalar step-length control parameter Δ_k. In our implementation the choice of the working set is tied to Δ_k as proposed in [17].

Finally, there are the usual implementation details of optimization algorithms to consider. These include step acceptance criteria, stopping criteria, scaling of the variables, and data caching.

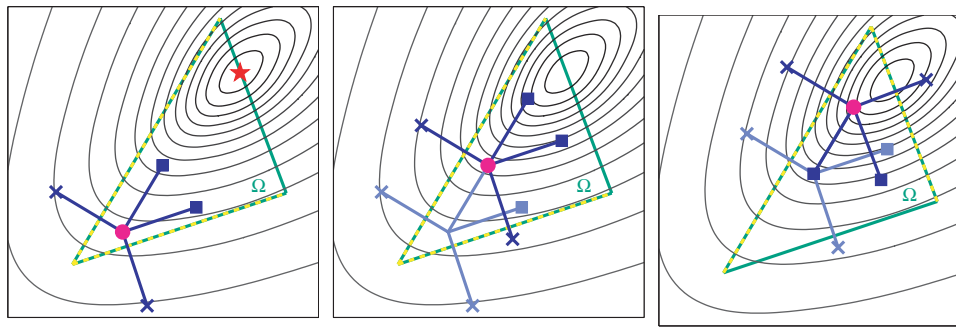
We begin in section 2 with an example and then give some preliminary definitions and notation in section 3. Section 4 discusses how to identify the working set of constraints, while section 5 discusses how to generate the core set of search directions once the working set has been identified. Section 6 discusses why it may be advantageous to augment the core set of search directions. Section 7 discusses how we determine the lengths of the steps to be taken. In section 8 we state the algorithm and discuss other details such as initial feasible iterates (section 8.1), step-acceptance criteria (section 8.2), stopping conditions (section 8.3), scaling (section 8.4), and caching data (section 8.5). Section 9 contains some illustrative numerical results. Concluding remarks are given in section 10.

2. An illustrative example. Figure 2.1 illustrates a few iterations of a greatly simplified linearly constrained GSS method applied to the two-dimensional modified Broyden tridiagonal function [4, 25], to which we have added three linear inequality constraints. Level curves of f are shown in the background. The three constraints form a triangle. In each figure, a dot denotes the current iterate x_k, which is the "best" point—the feasible point with the lowest value of f found so far.

We partition the indices of the iterations into two sets: $\mathcal{S}$ and $\mathcal{U}$. The set $\mathcal{S}$ corresponds to all *successful* iterations—those for which $x_k \neq x_{k+1}$ (i.e., at iteration k the search identified a feasible point with a lower value of the objective, and that point will become the next iterate). The set $\mathcal{U}$ corresponds to all *unsuccessful* iterations—those for which $x_{k+1} = x_k$ since the search was unable to identify a feasible point with a lower value of the objective.

Each of the six subfigures in Figure 2.1 represents one iteration of a linearly constrained GSS method. Taking a step of length Δ_k along each of the four search directions yields the four trial points. The squares represent the trial points under consideration (points at which the objective function is evaluated) at that particular iteration. The crosses represent the trial points that are not considered (points at which the objective function is not evaluated) at that particular iteration because they are infeasible. In subfigures (b)–(f), the trial points from the previous iteration are shown in the background for comparison. In subfigure (a), the solution to the problem is marked with a star.

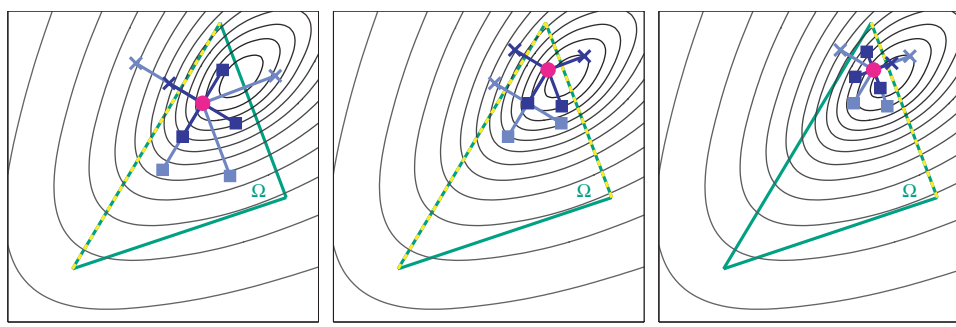
In subfigure (a), the initial iterate x_0 is near two constraints, which are highlighted using dashed lines. (The mechanism by which we identify nearby constraints and its connection to the value of Δ_k are discussed in more detail in section 4.) Two of the initial search directions are chosen so that they are parallel to these two nearby constraints. The other two search directions are the normals to the nearby constraints, translated to x_0. In this instance, there are two feasible descent directions; i.e., moving along two of the four search directions would allow the search to realize descent on the value of f at x_0 while remaining feasible. Either of the two trial points produced by these two feasible descent directions is acceptable; here we choose the one that gives the larger decrease in the value of the objective f to become x_1. Since the step of length Δ_0 from x_0 to x_1 was sufficient to produce decrease, we set Δ_1 to Δ_0.



(a) $k = 0$. The initial set of search directions. Move Northeast; $k \in \mathcal{S}$.

(b) $k = 1$. Keep the set of search directions. Move Northeast; $k \in \mathcal{S}$.

(c) $k = 2$. Change the set of search directions. Contract; $k \in \mathcal{U}$.



(d) $k = 3$. Change the set of search directions. Move Northeast; $k \in \mathcal{S}$.

(e) $k = 4$. Change the set of search directions. Contract; $k \in \mathcal{U}$.

(f) $k = 5$. Change the set of search directions. Move Southeast; $k \in \mathcal{S}$.

FIG. 2.1. *A version of linearly constrained GSS applied to the modified Broyden tridiagonal function augmented with three linear inequality constraints.*

In subfigure (b), the same two constraints remain nearby, so we leave the set of search directions unchanged. Again, there are two feasible descent directions, each of which leads to a trial point that decreases the value of f at the current iterate. We accept the trial point that yields the larger decrease as x_2 and set Δ_2 to Δ_1.

In subfigure (c), the set of nearby constraints changes. We drop one of the constraints that had existed in our working set of nearby constraints in favor of a newly identified constraint that yields a different working set. The set of search directions that results is shown. We do have one descent direction, but now the difficulty is that currently the step along that direction takes the search outside the feasible region. Thus, the best iterate is unchanged, so we set x_3 to x_2. We then *contract* by setting Δ_3 to half the value of Δ_2, which has the effect of halving the length of the steps taken at the next iteration.

The consequences of the contraction are illustrated in subfigure (d). In addition to reducing the length of the step allowed, the contraction reduced the working set to one constraint. Given both the new set of search directions along with the reduction in the length of the steps allowed, we now have a feasible trial point that gives a decrease in the value of the objective, which we make x_4, and set Δ_4 to Δ_3.

In subfigure (e) the search moves to the new iterate. Once again the search is near the same two constraints seen in subfigure (c), so we have the same working set and the same set of search directions, though now we search with a reduced step length (i.e., $\Delta_4 = \frac{1}{2}\Delta_2$). Again, the length of the steps along the two descent directions is too long. So we set x_5 to x_4 and Δ_5 to $\frac{1}{2}\Delta_4$.

The result of halving Δ is illustrated in subfigure (f). In addition to reducing the length of the steps allowed, we have changed the set of working constraints; once again, we have reduced the set to only one working constraint. A new feasible trial point that gives a decrease in the value of f is identified (to the Southeast), and at the next iteration the search will proceed from there.

This example illustrates the essential features the implementation must address: how to identify the nearby constraints, how to obtain a suitable set of feasible search directions, how to find a step of an appropriate length, and how to categorize the iteration as either successful ($k \in \mathcal{S}$) or unsuccessful ($k \in \mathcal{U}$).

3. Notation and definitions. Norms and inner products are assumed to be the Euclidean norm and inner product.

A *cone* K is a set that is closed under nonnegative scalar multiplication: K is a cone if $x \in K$ implies $ax \in K$ for all $a \geq 0$. A cone is *finitely generated* if there exists a (finite) set of vectors $v_1, \ldots, v_r$ such that

$$K = \{\ \lambda_1 v_1 + \cdots + \lambda_r v_r \ \mid\ \lambda_1, \ldots, \lambda_r \geq 0\ \}.$$

The vectors $v_1, \ldots, v_r$ are *generators* of K. Conversely, the cone generated by a set of vectors $v_1, \ldots, v_r$ is the set of all nonnegative combinations of these vectors.

The maximal linear subspace contained in a cone K is its *lineality space* [12]. The *polar* of a cone K, denoted by K°, is the set

$$K^\circ = \left\{\ v \ \mid\ w^T v \leq 0 \text{ for all } w \in K\ \right\}.$$

The polar K° is a convex cone, and if K is finitely generated, then so is K°.

Let K be a convex cone. Given a vector v, let v_K and v_{K° denote the projections of v onto K and its polar K°, respectively. The polar decomposition [24, 31] says that any vector v can be written as the sum of its projections onto K and K° and that the projections are orthogonal: $v = v_K + v_{K^\circ}$, and $v_K^T v_{K^\circ} = 0$. This means that $\mathbb{R}^n$ is positively spanned by a set of generators of K together with a set of generators of K°, a generalization of the direct sum decomposition given by a subspace and its orthogonal complement.

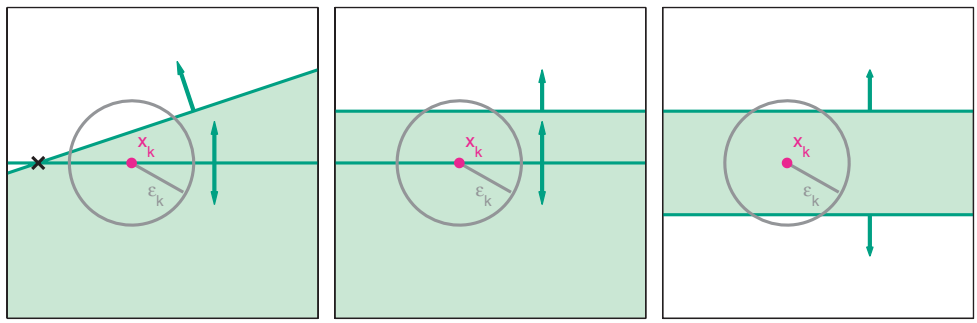
We borrow the following definition from [17]. For any finite set of vectors $\mathcal{G}$,

$$\kappa(\mathcal{G}) = \inf_{\substack{v \in \mathbb{R}^n \\ v_K \neq 0}} \max_{d \in \mathcal{G}} \frac{v^T d}{\| v_K \| \, \| d \|}, \quad \text{where } K \text{ is the cone generated by } \mathcal{G}. \tag{3.1}$$

The value $\kappa(\mathcal{G})$ is a property of the set $\mathcal{G}$, not of the cone K. The measure $\kappa(\mathcal{G})$ plays a critical role when choosing the set of search directions, as discussed further in section 5. Given (3.1), we then have the following.

PROPOSITION 3.1 (proposition 10.3 of [20]). *If $\mathcal{G} \neq \{\mathbf{0}\}$, then $\kappa(\mathcal{G}) > 0$.*

If K is a vector space, then a set of generators for K is called a *positive spanning set* [7]. A positive spanning set is like a linear spanning set but with the additional requirement that all of the coefficients be nonnegative.



(a) The inequality constraint is not included in the working set since its intersection with the equality constraint lies outside the ε_k-ball.

(b) The inequality constraint is redundant given the equality constraint.

(c) Both the upper and lower bounds are in the working set.

FIG. 4.1. *Special cases for linear equality constraints.*

4. Constructing the working set of constraints. We next discuss how we determine the working set of constraints that is used to compute the minimal set of necessary search directions. Let a_i^T denote the rows of A, indexed by i. We partition the constraints into the equalities and inequalities:

$$\mathcal{E} = \{\ i\ \mid\ \ell_i = u_i\ \} \quad \text{and} \quad \mathcal{I} = \{\ i\ \mid\ \ell_i < u_i\ \}.$$

We denote by $\mathcal{C}_{\ell,i}$ and $\mathcal{C}_{u,i}$ the sets where the bounds on constraint i are binding:

$$\mathcal{C}_{\ell,i} = \left\{\ y\ \mid\ a_i^T y = \ell_i\ \right\} \quad \text{and} \quad \mathcal{C}_{u,i} = \left\{\ y\ \mid\ a_i^T y = u_i\ \right\}.$$

These sets are faces of the feasible polyhedron. Of interest to us are the outward-pointing normals to the faces within a prescribed distance of x.

The presence of equality constraints slightly complicates the identification of inequality constraints near a given iterate. Figure 4.1(a) illustrates the desirability of measuring the distances to nearly binding inequality constraints only along directions that are feasible with respect to equality constraints. The horizontal line in Figure 4.1(a) represents an equality constraint, while the line at an oblique angle represents an inequality constraint. The shaded region represents the set of points feasible with respect to the inequality constraint. The inequality constraint is in close proximity to the equality constraint near x but only at points that are infeasible with respect to the equality constraint (a cross indicates where both constraints are active).

We compute the distance to nearby binding inequality constraints along directions that are feasible with respect to equality constraints as follows. Let $\mathcal{N}$ denote the nullspace of the equality constraints (i.e., the matrix whose rows are a_i^T for $i \in \mathcal{E}$), and let Z be an $n \times r$ orthogonal matrix whose columns are a basis for $\mathcal{N}$. Given $a \in \mathbb{R}^n$ and $b \in \mathbb{R}$, let $S = \left\{\ y\ \mid\ a^T y = b\ \right\}$. We then define

$$\operatorname{dist}_{\mathcal{N}}(x, S) = \begin{cases} |\, a^T x - b\,| / \| \, Z^T a \, \| & \text{if } Z^T a \neq 0, \\ 0 & \text{if } Z^T a = 0 \text{ and } a^T x = b, \\ \infty & \text{if } Z^T a = 0 \text{ and } a^T x \neq b. \end{cases}$$

This is the distance from x to S inside the nullspace $\mathcal{N}$. If S is parallel to $\mathcal{N}$, as is the case for the inequality constraint in Figure 4.1(b), we set this distance to be ∞, unless $x \in S$, in which case the distance is 0, as is true for the equality constraint in Figure 4.1(b).

Using this specialized notion of distance, we define the sets of inequalities at their bounds that are within distance ε of x:

$$\mathcal{I}_\ell(x,\varepsilon) = \{\ i \in \mathcal{I}\ \mid\ \mathrm{dist}_{\mathcal{N}}(x, \mathcal{C}_{\ell,i}) \le \varepsilon\ \},$$
$$\mathcal{I}_u(x,\varepsilon) = \{\ i \in \mathcal{I}\ \mid\ \mathrm{dist}_{\mathcal{N}}(x, \mathcal{C}_{u,i}) \le \varepsilon\ \}.$$

Let $\mathcal{I}_E(x,\varepsilon) = \mathcal{I}_\ell(x,\varepsilon) \cap \mathcal{I}_u(x,\varepsilon)$.

We now define the working set of constraints. Given a feasible x and an $\varepsilon > 0$, the corresponding working set $\mathcal{W}(x,\varepsilon)$ is made up of two pieces, the first consisting of vectors we treat as defining equalities and the second consisting of vectors we treat as defining inequalities. The first piece is

$$\mathcal{W}_E(x,\varepsilon) = \{\ a_i\ \mid\ i \in \mathcal{E}\ \} \cup \{\ a_i\ \mid\ i \in \mathcal{I}_E(x,\varepsilon)\ \},$$

which corresponds to the equality constraints together with every inequality for which the faces for both its lower and upper bounds are within distance ε of x, as in Figure 4.1(c). The second piece is

$$\mathcal{W}_I(x,\varepsilon) = \{\ -a_i\ \mid\ i \in \mathcal{I}_\ell(x,\varepsilon) \setminus \mathcal{I}_E(x,\varepsilon)\ \} \cup \{\ a_i\ \mid\ i \in \mathcal{I}_u(x,\varepsilon) \setminus \mathcal{I}_E(x,\varepsilon)\ \},$$

which is the set of outward-pointing normals to the inequalities for which the faces of exactly one of their lower or upper bounds is within distance ε of x. Note that, for the three examples illustrated in Figure 4.1, $\mathcal{W}_I(x,\varepsilon) = \emptyset$. The distinction between $\mathcal{W}_E$, which consists of constraints that are treated as equalities, and $\mathcal{W}_I$, which consists of constraints that are treated as inequalities, figures in the computation of the requisite search directions. We return to this point in section 5.

Given $x \in \Omega$, the *ε-normal cone*, denoted $N(x,\varepsilon)$, is the cone generated by the linear span of the vectors in $\mathcal{W}_E(x,\varepsilon)$ together with the nonnegative span of the vectors in $\mathcal{W}_I(x,\varepsilon)$:

$$N(x,\varepsilon) = \left\{ \sum_{a_i \in \mathcal{W}_E(x,\varepsilon)} u_i a_i + \sum_{a_i \in \mathcal{W}_I(x,\varepsilon)} \xi_i a_i\ \mid\ \xi_i \ge 0 \right\}. \tag{4.1}$$

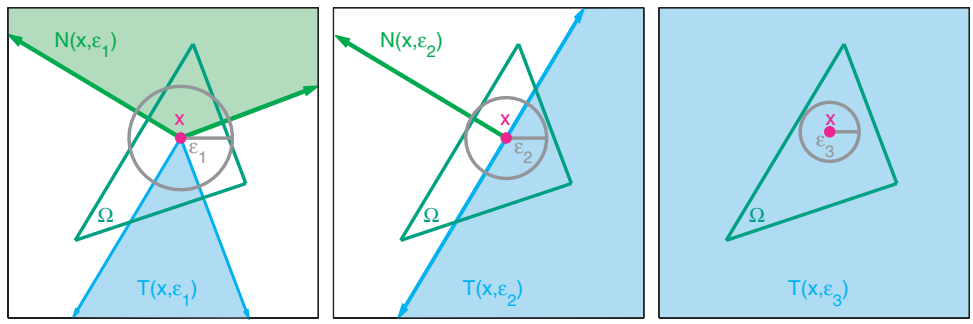
If both of the latter sets are empty, then $N(x,\varepsilon) = \{\mathbf{0}\}$. The *$\varepsilon$-tangent cone*, denoted by $T(x,\varepsilon)$, is the polar of $N(x,\varepsilon)$:

$$T(x,\varepsilon) = \left\{\ v\ \mid\ w^T v \le 0 \text{ for all } w \in N(x,\varepsilon)\ \right\}.$$

If $N(x,\varepsilon) = \{\mathbf{0}\}$, then $T(x,\varepsilon) = \mathbb{R}^n$. In addition to the examples illustrated in Figure 4.1, three examples involving only inequality constraints with three different values of ε are illustrated in Figure 4.2.

The set $x + T(x,\varepsilon)$ approximates the feasible region near x, where "near" is in terms of ε as measured using $\mathrm{dist}_{\mathcal{N}}(x,S)$. The cone $T(x,\varepsilon)$ is important because if $T(x,\varepsilon) \ne \{\mathbf{0}\}$, then one can proceed from x along all directions in $T(x,\varepsilon)$ for a distance of at least ε and still remain inside the feasible region [20, 17]. The examples in Figures 4.1–4.2 illustrate this point.

In the algorithm, we allow different values of ε_k at every iteration k. There is a lot of flexibility in determining the choice of ε_k, as discussed in [17]. We have chosen to yoke ε_k to Δ_k, for the reasons given in [17].



(a) Cones for ε_1. (b) Cones for ε_2. (c) Cones for ε_3.

FIG. 4.2. *The cones $N(x,\varepsilon)$ and $T(x,\varepsilon)$ for three values of ε. Note that for this example, as ε varies from ε_1 to 0, there are only the three distinct pairs of cones ($N(x,\varepsilon_3) = \{\mathbf{0}\}$).*

5. Generating the core set of search directions. Once the nearby constraints for a given iteration have been identified, we select the search directions. To ensure that the convergence results in [17] hold, we make the search conform to the local geometry of Ω in the sense that, at each iteration k, there is at least one direction in $\mathcal{D}_k$, the set of search directions at iteration k, along which the search can take an acceptably long step and still remain feasible.

We decompose $\mathcal{D}_k$ into $\mathcal{G}_k$ and $\mathcal{H}_k$, where $\mathcal{G}_k$ is made up of the directions necessary to ensure desirable convergence properties and $\mathcal{H}_k$ contains any additional directions. We sometimes refer to $\mathcal{G}_k$ as the *core set* of search directions. Several options for choosing $\mathcal{G}_k$ have been proposed:

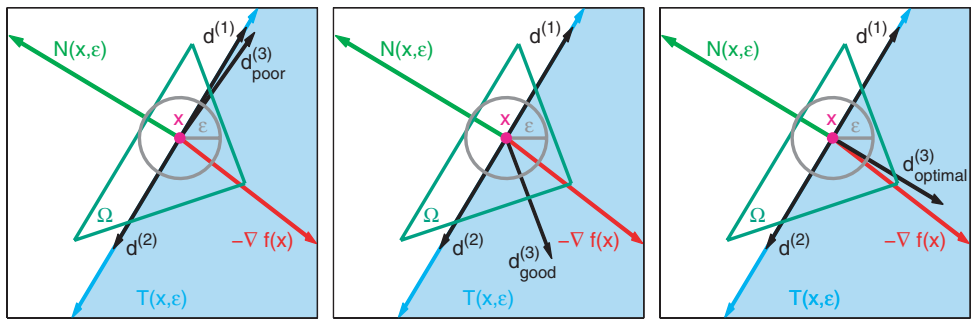
1. $\mathcal{G}_k$ contains generators for all of the cones $T(x_k,\varepsilon)$ for all $\varepsilon \in [0,\varepsilon_*]$, where $\varepsilon_* > 0$ is independent of k [23, 20].
2. $\mathcal{G}_k$ is exactly the set of generators for the cone $T(x_k,\varepsilon_k)$, where $\varepsilon_k \to 0$ is updated according to whether acceptable steps are found, and $\mathcal{H}_k = \emptyset$ [21].
3. $\mathcal{G}_k$ contains generators for the cone $T(x_k,\varepsilon_k)$, where $\varepsilon_k = \Delta_k \beta_{\max}$, and $\beta_{\max}$ is described in [17].

Here we use the third option, with its explicit link between ε_k and Δ_k, and choose $\beta_{\max} = 1$. As discussed further in section 6, the third option allows us to use a nonempty set $\mathcal{H}_k$ of additional directions chosen so as to accelerate the overall progress of the search. For any of the three options, the following is required of $\mathcal{G}_k$ [20, 17]:

> CONDITION 1. There exists a constant $\kappa_{\min} > 0$, independent of k, such that, for every k for which $T(x_k,\varepsilon_k) \neq \{\mathbf{0}\}$, the set $\mathcal{G}_k$ generates $T(x_k,\varepsilon_k)$ and satisfies $\kappa(\mathcal{G}_k) \geq \kappa_{\min}$.

Observe that the number of distinct ε-normal cones (and consequently the number of distinct ε-tangent cones) is finite.

The following simple technique, outlined in [17], ensures Condition 1 is satisfied. Let $k_2 > k_1$. If $\mathcal{W}_E(x_{k_2},\varepsilon_{k_2}) = \mathcal{W}_E(x_{k_1},\varepsilon_{k_1})$ and $\mathcal{W}_I(x_{k_2},\varepsilon_{k_2}) = \mathcal{W}_I(x_{k_1},\varepsilon_{k_1})$, then use the same generators for $T(x_{k_2},\varepsilon_{k_2})$ as were used for $T(x_{k_1},\varepsilon_{k_1})$. There are at most 2^m distinct sets $\mathcal{G}$ if the same set of generators is always used to generate a particular ε-tangent cone. Recall that m is the number of linear constraints. Since by Proposition 3.1 each $\mathcal{G}_k \neq \{\mathbf{0}\}$ has a strictly positive value for $\kappa(\mathcal{G}_k)$, and since this



(a) Poor choice (b) Reasonable choice (c) "Optimal" choice (w.r.t. $\kappa(\mathcal{G}_k)$)

FIG. 5.1. *Condition* 1 *is needed to avoid a poor choice when choosing* $\mathcal{G}_k$.

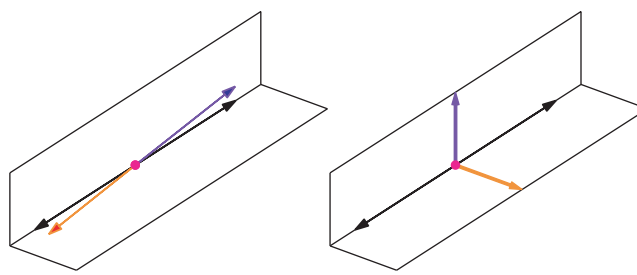


FIG. 5.2. *On the right, a set of generators for the cone (which includes a lineality space along the fold) that satisfies Condition* 1 *with a relatively large value of* $\kappa_{\min}$. *On the left, a different set of generators for which* $\kappa_{\min}$ *is much closer to zero.*

technique ensures there are only finitely many $\mathcal{G}_k$'s, we can set $\kappa_{\min} = \min\{\kappa(\mathcal{G}_k) : T(x_k, \varepsilon_k) \neq \{\mathbf{0}\}\}$. Thus, Condition 1 is satisfied.

The need for Condition 1 arises when there is a lineality space present in $T(x_k, \varepsilon_k)$. In this case the directions of the generators $\mathcal{G}_k$ are not uniquely determined. Figure 5.1 depicts the situation where $T(x_k, \varepsilon_k)$ contains a halfspace. Condition 1 enforces a lower bound on $\kappa(\mathcal{G}_k)$ to avoid the situation illustrated in Figure 5.1(a), in which the search directions can be almost orthogonal to the direction of steepest descent. Figure 5.1(c), which uses a minimal number of vectors but ensures as large a value for $\kappa(\mathcal{G}_k)$ as possible, represents an optimal choice in the absence of explicit knowledge of the gradient.

In $\mathbb{R}^2$ the presence of a lineality space in $T(x, \varepsilon)$ means that $T(x, \varepsilon)$ is either a halfspace, as illustrated in Figures 4.2(b) and 5.1, or $\mathbb{R}^2$, as illustrated in Figure 4.2(c). In more than two dimensions there are other geometrical possibilities that cause the directions of the generators of $T(x, \varepsilon)$ not to be uniquely determined, as illustrated in Figure 5.2.

As discussed in [17], we need to enforce lower and upper bounds on the lengths of the search directions. Here we accomplish this by simply normalizing all of the search directions.

The necessary conditions on the set of search directions all involve the calculation of generators for the polars of cones determined by the current working set. We treat

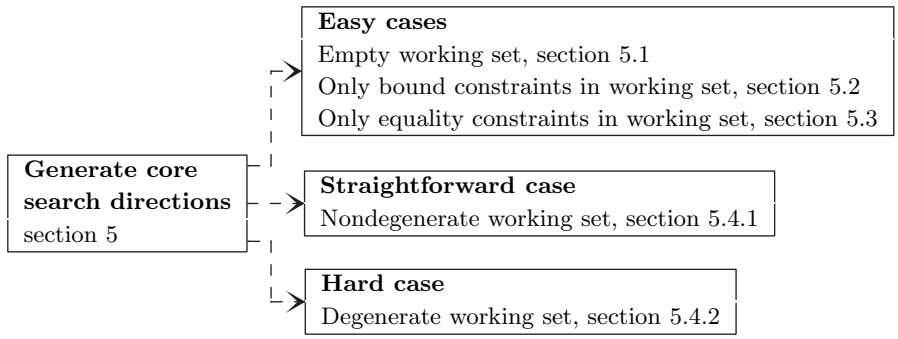

FIG. 5.3. *The components involved in the generation of the search directions.*

the determination of the search directions in increasing order of difficulty. Figure 5.3 shows the various cases to consider.

5.1. When the working set is empty. If the working set is empty, then $N(x_k, \varepsilon_k) = \{\mathbf{0}\}$ and $T(x_k, \varepsilon_k) = \mathbb{R}^n$, and any positive spanning set of $\mathbb{R}^n$ suffices as $\mathcal{G}_k$ [30, 18]. We use the unit coordinate vectors $\pm e_i$, $i = 1, \ldots, n$, to form $\mathcal{G}_k$ both because they are apt for many applications and because the orthonormality of the vectors ensures a reasonable value for $\kappa_{\min}$ in Condition 1. In our testing we have found that the coordinate directions are a consistently effective set of search directions for scientific and engineering problems. The coordinate directions have physical meaning for such applications; thus using them to form the core set of search directions $\mathcal{G}_k$ both guarantees a positive basis and seems to lead to better overall performance.

5.2. When the working set contains only bound constraints. A similar situation holds if only bound constraints are present. This case is also simple since we know a priori that the generators for the ε-normal and ε-tangent cones can be drawn from the set of coordinate directions [19]. Thus we include in $\mathcal{G}_k$ the unit coordinate vectors $\pm e_i$, $i = 1, \ldots, n$. As noted in [20, section 8.3], if not all of the variables are bounded, then one can make a choice of $\mathcal{G}_k$ that is more parsimonious in the number of directions, but we did not choose to do so in our implementation.

5.3. When the working set consists only of equality constraints. If the working set consists only of equality constraints, then the generators of $T(x_k, \varepsilon_k)$ correspond to a positive spanning set for the nullspace of the vectors in $\mathcal{W}_E(x_k, \varepsilon_k)$. In this situation by default we compute an orthonormal basis Z for this nullspace and take as our generators the "coordinatelike" set consisting of the elements of Z and their negatives.

5.4. When the working set contains general linear constraints. Once the nearby constraints have been identified using x_k and ε_k, their outward-pointing normals are extracted from the rows of the constraint matrix A to form the working set of constraints. So, for instance, in the case shown in Figure 5.4 the outward-pointing normals a_1 and a_2 constitute the working set $\mathcal{W}_I(x_k, \varepsilon_k) = \{a_1, a_2\}$ (there are no equality constraints in this example). There are then two cases to consider: when the working set is known to be nondegenerate and when the working set may be degenerate.

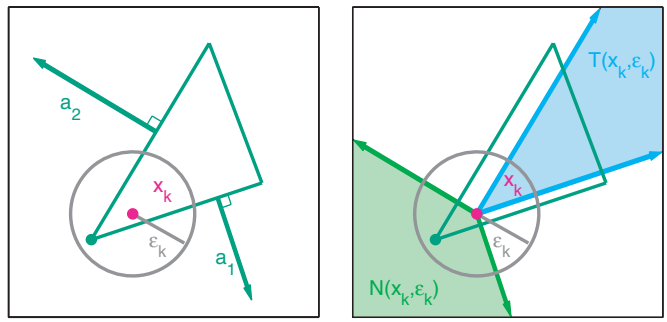

FIG. 5.4. *The outward-pointing normals a_1 and a_2 of the nearby constraints are translated to x_k to form the ε-normal cone $N(x_k, \varepsilon_k)$ and thus define its polar the ε-tangent cone $T(x_k, \varepsilon_k)$. The normalized generators for $N(x_k, \varepsilon_k)$ and $T(x_k, \varepsilon_k)$ form the set of search directions.*

5.4.1. When the working set is known to be nondegenerate. Figure 5.4 depicts the computationally straightforward case.

We begin with two general propositions concerning the polar of a finitely generated cone K. Proposition 5.1 is an elaboration of the construction given in [20, section 8.2] and shows how one can construct generators for K° if the generators of K are linearly independent. In particular, this means that K cannot contain a linear subspace. In those situations where K does contain a linear subspace, for instance, as illustrated in Figures 5.1–5.2, Proposition 5.2 enables us to reduce the situation to one where we can apply Proposition 5.1.

PROPOSITION 5.1. *Suppose K is generated by the positive span of the columns of the matrix $Q = [q_1 \dots q_r]$. Let N be a matrix whose columns are a positive spanning set for the nullspace of Q^T. Finally, suppose Q^T has a right inverse R.*

Then K° is the positive span of the columns of $-R$ together with the linear span of the columns of N:

$$K^\circ = \{\, w \mid w = -Ru + N\xi, \quad u \geq 0 \,\}.$$

Proof. Let $C = \{\, w \mid w = -Ru + N\xi, \quad u \geq 0 \,\}$. We first show that $C \subset K^\circ$. Suppose $d \in C$. To show that $d \in K^\circ$, we must show that $q_i^T d \leq 0$ for all $i = 1, \dots, r$, i.e., $Q^T d \leq 0$. Since $Q^T R = I$ and $Q^T N = 0$,

$$Q^T d = Q^T(-Ru + N\xi) = -u \leq 0.$$

Therefore $d \in K^\circ$, so $C \subset K^\circ$.

We next show that $C^\circ \subset K$, whence $K^\circ \subset C$, and so $K^\circ = C$. If $d \in C^\circ$, then $d^T(-Ru + N\xi) \leq 0$ for $u \geq 0$ and for all ξ. In particular, $d^T N\xi = 0$ for all ξ, so d is orthogonal to the positive span of the columns of N, which is the nullspace of Q^T. The latter means that d lies in the range of Q, so $d = Qs$ for some s. At the same time, we know that $-d^T Ru \geq 0$ for all $u \geq 0$, whence $-s^T Q^T Ru = -s^T u \leq 0$ for all $u \geq 0$, so $s \geq 0$. Thus $d = Qs$ for $s \geq 0$, meaning $d \in K$ and $C^\circ \subset K$. ∎

Proposition 5.2 says that if the cone K contains a linear subspace L, then computing K° is a matter of looking at the polar of $K \cap L^\perp$.

PROPOSITION 5.2. *Suppose that the cone K can be written as the linear span of the vectors $v_1, \dots, v_q$ together with the nonnegative span of the vectors $p_1, \dots, p_r$:*

$$K = \{\, v \mid v = \alpha_1 v_1 + \cdots + \alpha_q v_q + \lambda_1 p_1 + \cdots + \lambda_r p_r, \ \lambda_i \geq 0 \text{ for } i = 1, \dots, r \,\}.$$

Step 1. Let L be the linear subspace spanned by the vectors in $\mathcal{W}_E(x_k, \varepsilon_k)$. Compute a basis Z for $L^\perp$.

Step 2. Check whether the set of vectors $\{ Z^T p \mid p \in \mathcal{W}_I(x_k, \varepsilon_k) \}$ is linearly independent. If so, proceed to Step 3. If not, proceed to the more complicated construction described in section 5.4.2.

Step 3. Let Q be the matrix whose columns are the vectors $Z^T p$ for $p \in \mathcal{W}_I(x_k, \varepsilon_k)$. Compute a right inverse R for Q^T and a matrix N whose columns are a positive spanning set for the nullspace of Q^T.

Step 4. $\mathcal{G}_k$ is then the columns of $-ZR$ together the columns of ZN.

FIG. 5.5. *The process for attempting the straightforward construction of* $\mathcal{G}_k$.

Let L be the linear subspace spanned by $v_1, \ldots, v_q$. Then

$$K^\circ = \{ w \in L^\perp \mid w^T p_i \le 0 \text{ for all } i = 1, \ldots, r \}.$$

Proof. Let $P = \{ w \in L^\perp \mid w^T p_i \le 0 \text{ for all } i = 1, \ldots, r \}$. Clearly, $P \subset K^\circ$. Conversely, if $w \in K^\circ$, then we have $w^T p_i \le 0$ for all $i = 1, \ldots, r$. In addition, since L is contained in K we have $v_i \in K$ and $-v_i \in K$ for all $i = 1, \ldots, q$. Thus we have $w^T v_i \le 0$ and $-w^T v_i \le 0$, so $w^T v_i = 0$ and $w \in L^\perp$, whence $K^\circ \subset P$. ∎

We use Propositions 5.1 and 5.2 to compute generators for $T(x_k, \varepsilon_k) = N(x_k, \varepsilon_k)^\circ$ as follows. Recall the definition of $N(x_k, \varepsilon_k)$ in (4.1). Let L denote the linear span of the vectors in $\mathcal{W}_E(x_k, \varepsilon_k)$. Let Z denote a matrix whose columns span $L^\perp$. Applying Proposition 5.2 with $K = N(x_k, \varepsilon_k)$ then says

$$\begin{aligned} T(x_k, \varepsilon_k) &= \{ w \in L^\perp \mid w^T p \le 0 \text{ for all } p \in \mathcal{W}_I(x_k, \varepsilon_k) \} \\ &= \{ Zc \mid c^T Z^T p \le 0 \text{ for all } p \in \mathcal{W}_I(x_k, \varepsilon_k) \}. \end{aligned}$$

The latter condition says that the set of c of interest to us is actually the polar of the cone $\tilde{K}$ generated by the vectors $Z^T p$ for all $p \in \mathcal{W}_I(x_k, \varepsilon_k)$. If this latter set of vectors is linearly independent, we can apply Proposition 5.1 to obtain generators for $\tilde{K}^\circ$ and then map them back to the original space under the action of Z. If they are not linearly independent, we must use the more sophisticated approach discussed in section 5.4.2. The procedure is summarized in Figure 5.5.

In our implementation we compute an orthonormal basis Z in Step 1. In Step 3 we use the pseudoinverse of Q^T as the right inverse. This choice is attractive because the columns of the pseudoinverse are orthogonal to the lineality space of $T(x_k, \varepsilon_k)$ (as in the examples on the right in Figures 5.1–5.2), which helps improve the conditioning of the resulting set of search directions (Condition 1).

Also in Step 3 our implementation computes the positive spanning set N by computing an orthonormal basis B for the nullspace of Q^T and setting $N = [B \ -B]$. This corresponds to a coordinatelike search in the nullspace of Q^T.

5.4.2. When the working set may be degenerate. If the construction described in Figure 5.5 cannot be applied, because linear dependence of the set of vectors $\{ Z^T p \mid p \in \mathcal{W}_I(x_k, \varepsilon_k) \}$ is detected, the computation of the search directions

is more complicated. In this case $N(x_k, \varepsilon_k)$ is a cone with a degenerate vertex at the origin, so we refer to this situation as the degenerate case. (The easiest example to envision is the apex defined by the four triangular faces of a pyramid.)

The problem of finding a set of generators for $T(x_k, \varepsilon_k)$ is a special case of the problem of finding the vertices and extreme rays of a polyhedron (the V-representation of the polyhedron) given the description of the polyhedron as an intersection of halfspaces (the H-representation). This is a well-studied problem in computational geometry (see [2] for a survey) for which practical algorithms have been developed.

The two main classes of algorithms for solving this type of problem are pivoting algorithms and insertion algorithms. Pivoting algorithms move from vertex to vertex along the edges of the polyhedron by generating feasible bases, as in the simplex method. The reverse search algorithm [1, 3] is an example of such a method.

Insertion algorithms compute the V-description by working with the intersection of an increasing number of halfspaces. Typically, for a polyhedral cone these algorithms start with a maximal linearly independent set of normals defining the halfspaces and construct an initial set of extreme rays as in Figure 5.5. Additional halfspaces are then introduced, and the extreme rays are recomputed as positive combinations of existing extreme rays; this process continues until the entire set of halfspaces has been introduced. The double description method [26] is an example of an insertion algorithm. A discussion of the double description method, along with a description of the techniques used in a practical implementation, can be found in [9].

As observed in [2], pivoting algorithms can be inefficient if they encounter a highly degenerate vertex. For this reason we chose the double description method. We use Fukuda's `cddlib` package [11], which is based on an efficient implementation of the double description algorithm that directly addresses known—and serious—pitfalls of a naive implementation of the double description method and that has been shown to be effective in dealing with highly degenerate vertices [9]. We conducted our own comparison of Avis's `lrs` reverse search code [3] and Fukuda's `cdd` double description code [11] on problems we knew to be highly degenerate. Our experience confirmed the observation made in [10]: `cdd` tends to be efficient for highly degenerate inputs, while `lrs` tends to be efficient for nondegenerate or slightly degenerate problems.

Another observation made in [10] that bears repeating is that the number of inequalities defining the polyhedron does not by itself indicate the degree of difficulty of a vertex/ray enumeration problem. It is noted in [10] that `cdd` can handle a highly degenerate problem with 711 inequalities in 19 dimensions quite easily, while a problem with 729 inequalities in 8 dimensions is extremely difficult to solve. Our own experience confirms this, as discussed further in section 9.

During our testing with `cdd`, one useful lesson we learned is that it is more efficient to retain equalities in the problem rather than to eliminate the equalities by reparameterizing the problem in terms of a basis for the nullspace of the equality constraints. We initially thought that using the equalities to eliminate variables and reduce the dimension of the problem would be an advantage. But this did not prove to be the case. In several instances, elimination of equalities led to a significant deterioration in the performance of `cdd`. This is due to the fact that the arrays of constraint coefficients went from being sparse—and frequently integral—to being dense real arrays, which greatly hindered the progress of the double description method.

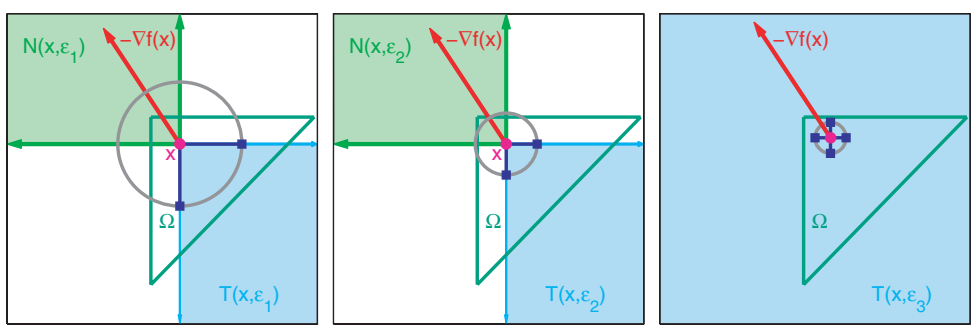
We close by noting that only a subset of the generators for $T(x_k, \varepsilon_k)$ may suffice at some iterations. For example, if an iteration is successful, the iteration can be terminated as soon as at least one of the search directions yields a trial point that

satisfies the acceptance criterion. Thus, the generators could be computed on an "as needed" basis (though, for an unsuccessful iteration, ultimately a complete set of generators for $T(x_k, \varepsilon_k)$ will be required). Such an approach would be akin to that used by the pivoting algorithms. But, as already noted, the pivoting algorithms can be inefficient if they encounter a highly degenerate vertex. Since `cdd` has proven efficient on all but one of the problems we have tested, we currently compute all of the generators for $T(x_k, \varepsilon_k)$ at each iteration for which the working set changes.

6. Augmenting the core set of search directions. While generators of $T(x_k, \varepsilon_k)$ are theoretically sufficient for the convergence analysis, in practice there can be appreciable benefits to including additional search directions. The situation illustrated in Figure 6.1 shows the desirability of additional directions, since the generators for $T(x_k, \varepsilon_k)$ necessarily point into the relative interior of the feasible region, while it may be preferable to move toward the boundary.

At the very least, we would like the total set of search directions to be a positive basis for $\mathbb{R}^n$ or, if equality constraints are present, a positive basis for the nullspace of the equality constraints. If $\mathcal{W}_E(x_k, \varepsilon_k)$ is empty, one simple way to accomplish this is to include in $\mathcal{H}_k$ the set $\mathcal{W}_I(x_k, \varepsilon_k)$, the outward-pointing normals to the working set of constraints. Since these vectors generate $N(x_k, \varepsilon_k)$, and since $T(x_k, \varepsilon_k)$ is polar to $N(x_k, \varepsilon_k)$, by the polar decomposition, $\mathbb{R}^n = N(x_k, \varepsilon_k) \oplus T(x_k, \varepsilon_k)$. Thus, including the vectors that generate $N(x_k, \varepsilon_k)$ in $\mathcal{H}_k$ means that $\mathcal{D}_k$ constitutes a positive spanning set for $\mathbb{R}^n$, as illustrated in Figure 6.2. See section 9 for a computational illustration of the advantage of including these directions.

The preceding discussion needs to be modified if equality constraints are present. Typically, in this case the outward-pointing normals a_i to constraints in the working set are infeasible directions—they do not lie in the nullspace of the equality constraints. Thus, a step along a direction a_i will lead to violation of the equality constraints. In this situation we replace the outward-pointing normals by their projection into the nullspace of the equality constraints.

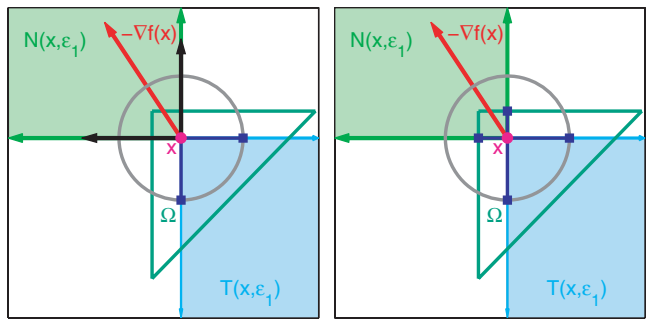


(a) First iteration is unsuccessful and so Δ_1 is halved for the next iteration.

(b) The second iteration is also unsuccessful and so Δ_2 is halved again.

(c) Now, locally, the problem looks unconstrained and a successful step toward the boundary is possible.

FIG. 6.1. *Minimizing the number of function evaluations at a single iteration might require more total function evaluations since in this instance it will take at least five function evaluations to find decrease.*



(a) Both generators of $N(x, \varepsilon_1)$ are descent directions.

(b) Limiting the steps along the generators of $N(x, \varepsilon_1)$ ensures feasible steps.

FIG. 6.2. *Why including the generators for the ε-normal cone $N(x, \varepsilon_1)$ might be a good idea since decrease may be found after as few as one function evaluation.*

7. Determining the lengths of the steps. The *step-length control parameter* Δ_k determines the length of a step along each direction for a given set of search directions. In the presence of constraints, we must consider the possibility that some of the trial points $x_k + \Delta_k d_k^{(i)}$, $d_k^{(i)} \in \mathcal{D}_k$, may be infeasible. With this in mind, we choose the maximum $\tilde{\Delta}_k^{(i)} \in [0, \Delta_k]$ such that $x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)} \in \Omega$, thereby ensuring that a full step will be taken, if feasible.

It is possible to choose $\tilde{\Delta}_k^{(i)} = \Delta_k$ if the result will be feasible and $\tilde{\Delta}_k^{(i)} = 0$ otherwise, thereby rejecting infeasible points. This simple strategy was illustrated in the initial example given in Figure 2.1. We have found it much more efficient, however, to allow steps that stop at the boundary, as suggested in [22, 21]. The latter strategy is illustrated in Figure 6.2(b).

For the search directions in $\mathcal{H}_k$ we actually choose $\tilde{\Delta}_k^{(i)}$ to be the maximum value in $[\sigma_{\text{tol}} \Delta_k, \Delta_k]$ satisfying $x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)} \in \Omega$, where $\sigma_{\text{tol}} \geq 0$. The factor σ_{tol} prevents excessively short steps to the boundary, relative to the current value of Δ_k. Our experience has been that such steps typically yield little improvement and have the overall effect of retarding decrease in Δ_k.

8. Linearly constrained GSS. The variant of GSS that we have implemented for problems with linear constraints is outlined in Figure 8.1. See [17] for discussions of some of the many other possible variations on the specification of GSS algorithms for linearly constrained optimization. The remainder of this section is devoted to further explanation of the algorithm given in Figure 8.1.

8.1. Finding an initial feasible iterate. GSS methods for linearly constrained problems are feasible iterates methods—all iterates x_k, $k = 0, 1, 2, \ldots$, satisfy $x_k \in \Omega$. If an infeasible initial iterate is given, then we compute its Euclidean projection onto the feasible polyhedron; this is a quadratic program. For some of the test problems discussed in section 9 the starting value provided is infeasible, and for these we used this projection strategy. Alternatively, one could use phase one of the simplex method to obtain a starting point at a vertex of the feasible region.

ALGORITHM 8.1 (LINEARLY CONSTRAINED GSS USING A SUFFICIENT DECREASE GLOBALIZATION STRATEGY)

INITIALIZATION.

Let $f : \mathbb{R}^n \to \mathbb{R}$ be given. Let Ω be the feasible region.

Let $x_0 \in \Omega$ be the initial guess.

Let $\Delta_{\text{tol}} > 0$ be the step-length convergence tolerance.

Let $\Delta_0 > \Delta_{\text{tol}}$ be the initial value of the step-length control parameter.

Let $\sigma_{\text{tol}} \geq 0$ control the lower bound on the length of successful steps.

Let $\varepsilon_{\max} > \Delta_{\text{tol}}$ be the maximum distance used to identify nearby constraints ($\varepsilon_{\max} = +\infty$ is permissible).

Let $\rho(\Delta) = \alpha\Delta^2$ be the forcing function, with $\alpha > 0$.

ALGORITHM. For each iteration $k = 0, 1, 2, \ldots$

Step 1. Let $\varepsilon_k = \min\{\varepsilon_{\max}, \Delta_k\}$. Choose a set of normalized search directions $\mathcal{D}_k = \mathcal{G}_k \cup \mathcal{H}_k$ satisfying Condition 1.

Step 2. If there exists $d_k^{(i)} \in \mathcal{D}_k$, together with the maximum $\tilde{\Delta}_k^{(i)} \in [\sigma_{\text{tol}}\Delta_k, \Delta_k]$ such that $x_k + \tilde{\Delta}_k d_k \in \Omega$, which satisfy

$$f\left(x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)}\right) < f(x_k) - \rho(\Delta_k),$$

then:

- Set $x_{k+1} = x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)}$ (a successful step).
- Set $\Delta_{k+1} = \Delta_k$.

Step 3. Otherwise, for every $d \in \mathcal{G}_k$,

$$f(x_k + \Delta_k d) \geq f(x_k) - \rho(\Delta_k).$$

In this case:

- Set $x_{k+1} = x_k$ (an unsuccessful step).
- Set $\Delta_{k+1} = \frac{1}{2}\Delta_k$.

If $\Delta_{k+1} < \Delta_{\text{tol}}$, then terminate.

FIG. 8.1. *Linearly constrained GSS using a sufficient decrease globalization strategy.*

8.2. Accepting steps. We opted to impose the sufficient decrease condition

$$f(x_k + \tilde{\Delta}_k d_k) < f(x_k) - \rho(\Delta_k),$$

with $\rho(\Delta) = \alpha\Delta^2$. For any given problem the value of α should be chosen to reflect the relative magnitude of f and Δ. Our primary reason for using a sufficient decrease condition was that, as discussed in section 7 (and illustrated in Figure 6.2(b)), it allows

us to choose $\tilde{\Delta}_k^{(i)}$ to be the maximum value in $[\sigma_{\text{tol}}\Delta_k, \Delta_k]$ satisfying $x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)} \in \Omega$. Furthermore, as shown in [17, section 6], this particular choice of $\rho(\Delta)$ ensures the useful estimate (8.1), which we discuss in the next section.

For the results reported here we used the classical update for Δ_k. If $k \in \mathcal{S}$, then $\Delta_{k+1} = \phi_k \Delta_k$, with $\phi_k = 1$ for all k; otherwise, $\Delta_{k+1} = \theta_k \Delta_k$, with $\theta_k = \frac{1}{2}$ for all k.

8.3. Stopping criteria. We stop the algorithm once the step-length parameter Δ_k falls below a specified tolerance Δ_{tol}. This stopping criterion is motivated by the relationship between Δ_k and $\chi(x_k)$, a particular measure of progress toward a Karush–Kuhn–Tucker (KKT) point of (1.1). For $x \in \Omega$, let

$$\chi(x) \equiv \max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} -\nabla f(x)^T w.$$

Of interest to us here are the following properties [6, 5]: (1) $\chi(x)$ is continuous on Ω, (2) $\chi(x) \geq 0$, and (3) $\chi(x) = 0$ if and only if x is a KKT point for (1.1). We therefore wish to see $\chi(x_k)$ tend to zero.

In [17, Theorem 6.4] it is shown that once Δ_k is small enough, so that $\varepsilon_k = \Delta_k$, then

$$\chi(x_k) = O(\Delta_k) \text{ for } k \in \mathcal{U}. \tag{8.1}$$

Theorem 6.4 is most simply stated under the assumptions that the set $\mathcal{F} = \{ x \in \Omega \mid f(x) \leq f(x_0) \}$ is bounded and that the gradient of f is Lipschitz continuous with constant M on $\mathcal{F}$. Relaxations of these assumptions, along with a full statement and proof of the theorem, are found in [17].

The big-O relationship between $\chi(x_k)$ and Δ_k means that as Δ_k is reduced, which happens only at unsuccessful iterations, the upper bound on the value of the measure of stationarity is also reduced. Relationship (8.1) is analogous to the unconstrained minimization result (see [8, section 3] or [16, section 3.6]):

$$\| \nabla f(x_k) \| = O(\Delta_k) \text{ for } k \in \mathcal{U}. \tag{8.2}$$

Results (8.1) and (8.2) support using the magnitude of Δ_k as a test for termination.

Obviously, one can also stop after a specified number of objective evaluations, an option we exercise in our testing in section 9.

8.4. Scaling. The relative scaling of variables can have a profound effect on the efficiency of optimization algorithms. We allow as an option the common technique of shifting and rescaling the variables so that they have a similar range and size. We work in a computational space whose variables w are related to the original variables x via $x = Dw + c$, where D is a diagonal matrix with positive diagonal entries and c is a constant vector, both provided by the user. We solve the transformed problem

$$\begin{aligned} &\text{minimize} && f(Dw + c) \\ &\text{subject to} && \ell - Ac \;\leq\; ADw \;\leq\; u - Ac. \end{aligned}$$

The scaling scheme we use in the numerical tests presented in section 9 is based on that described in [13, section 7.5.1]. The latter scaling is based on the range of the variables and transforms the variables to lie between -1 and 1.

One advantage of scaling is that it makes it easier to define a reasonable default value for Δ_0. For the results reported in section 9, whenever scaling is applied to a problem, the default value for Δ_0 is 2 since the longest possible feasible step along a unit coordinate direction is 2 (the variables in the rescaled problem lie between -1 and 1).

8.5. Caching data. The potentially regular pattern to the steps the search takes means that the search may revisit points. This is particularly true for unconstrained and bound constrained problems. To avoid reevaluating known values of f, we store values of x at which we evaluate the objective and the corresponding objective values. Before evaluating f at a trial point w_t in the rescaled space, we examine the data cache to see whether we have already evaluated f at a point within some relative distance of w_t. We do not evaluate f at w_t if we have already evaluated f at a point $\bar{w}$ for which $\| w_t - \bar{w} \| < r_{\text{tol}} \| w_t \|$. By default, $r_{\text{tol}} = 10^{-8}$. This strategy allows us to take advantage of the vectorization within Matlab when searching the cache. For an alternative strategy based on splay trees, see [15].

Caching yields only minor improvements in efficiency if general linear inequality constraints are present. If there are a considerable number of general linear constraints (i.e., constraints other than bounds) in the working set, then there is only a small chance of reevaluating f near a previous iterate. Still, if each evaluation of the objective function is expensive, then it is worth avoiding reevaluations.

9. Some numerical illustrations. We present some illustrations of the behavior of our implementation of the algorithm given in Figure 8.1 using five test problems from the CUTEr test suite [14], listed in Table 9.1. All five problems have nonlinear objectives. We chose these specific problems for illustration since the algorithm must deal repeatedly with highly degenerate instances of the search direction calculation discussed in section 5.4.2. As the results in section 9.2 show, the solution of such problems is usually quite tractable given a good implementation of the double description algorithm.

9.1. Starting values and tolerances for the results reported here. We started with the value of x_0 specified by CUTEr, though we often had to project into the feasible region, as discussed in section 8.1.

We terminated the program either when the value of Δ_k fell below $\Delta_{\text{tol}} = \Delta_0/2^{20}$ or when the number of evaluations of the objective reached that which would have been needed for 20 centered difference evaluations of the gradient if one had used the equality constraints to eliminate variables. See Table 9.2 for the maximum number of evaluations allowed for each problem.

When the problem was scaled (as it was for all but LOADBAL), we used $\Delta_0 = 2$, as discussed in section 8.4. We used the default value $\sigma_{\text{tol}} = 10^{-3}$. We set $\varepsilon_{\max} = 2^5\Delta_0$ so that it played no role in the results reported here. We set $\alpha = 10^{-4}$ in the forcing function $\rho(\Delta) = \alpha\Delta^2$.

The core set of search directions $\mathcal{G}_k$ consisted of generators for the ε-tangent cone $T(x_k, \varepsilon_k)$. With one exception (for the purposes of illustrating the potential advantage of allowing a nonempty set $\mathcal{H}_k$) $\mathcal{H}_k$ consisted of generators for the ε-normal cone $N(x_k, \varepsilon_k)$ (projected into the nullspace of any equality constraints in the working set, as described in section 6). Recall that, by definition, $\mathcal{D}_k = \mathcal{G}_k \cup \mathcal{H}_k$.

TABLE 9.1
Problems used from the CUTEr test problem set.

		# of linear			# of bounds

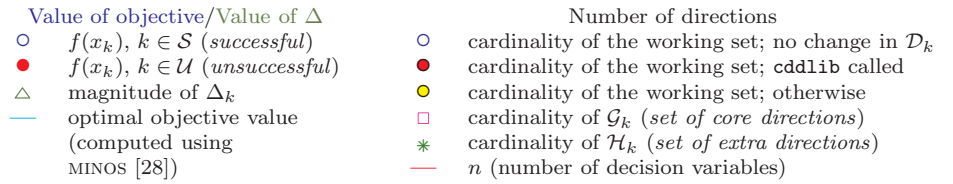

FIG. 9.1. *Legends for the remaining figures.*

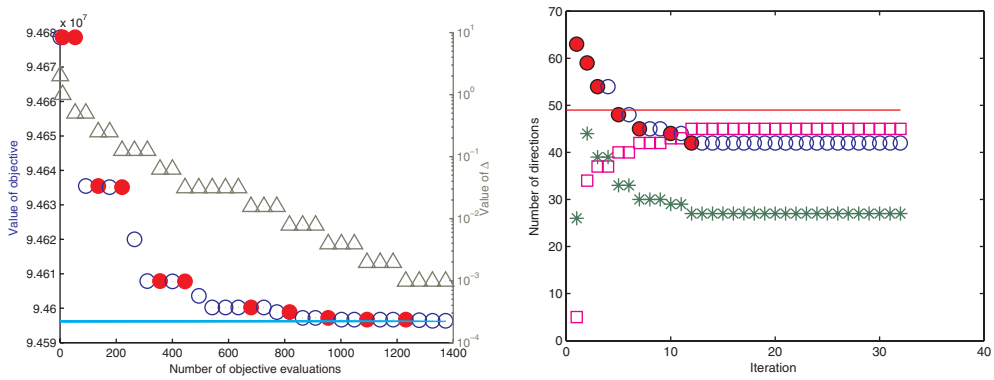

FIG. 9.2. *Results for the* AVION2 *test problem. Legends are given in Figure* 9.1.

The tests were run on a 1 processor, 3 GHz Pentium 4 workstation with 2 GB memory running Linux and using Matlab R2006b.

9.2. The results. Below we include a summary, along with illustrations, of the the iteration history for each problem. See Figure 9.1 for a legend.

The first problem is AVION2, an aeronautical design problem. In this case the equality constraints have rank 15, leaving 34 degrees of freedom in the problem. The plot on the left in Figure 9.2 gives the iteration history for the value of the objective and the value of Δ, both plotted against the number of evaluations of the objective. Solid circles indicate where unsuccessful iterations were encountered. The plot on the right in Figure 9.2 shows the size of the working set at each iteration, the number of vectors in $\mathcal{G}_k$, and the number of vectors in $\mathcal{H}_k$. Solid circles in this plot indicate iterations where the simple polar construction in section 5.4.1 was not applicable and consequently `cddlib` was called, as described in section 5.4.2. Open circles indicate iterations where the working set was unchanged from the previous iteration so no new calculation of the search directions was needed. The set $\mathcal{H}_k$ has fewer vectors than the working set because we do not include outward-pointing normals for equality constraints in the working set. The solid line indicates the number of decision variables in the problem; when the size of the working set is above this line, the algorithm must deal with the degeneracy discussed in section 5.4.2. Observe that degeneracy is also encountered when the size of the working set is smaller than the number of decision variables; this occurs because of redundant constraints.

The next test problem is SPANHYD, a model of a hydroelectric system. This problem includes 33 network equality constraints of rank 32 and 16 fixed variables, leaving 49 degrees of freedom in the problem. We modify the scaling scheme slightly by not scaling variables whose original range is narrow; specifically, we scale only the variables that vary over a range of more than 0.1. The plot on the left in Figure 9.3

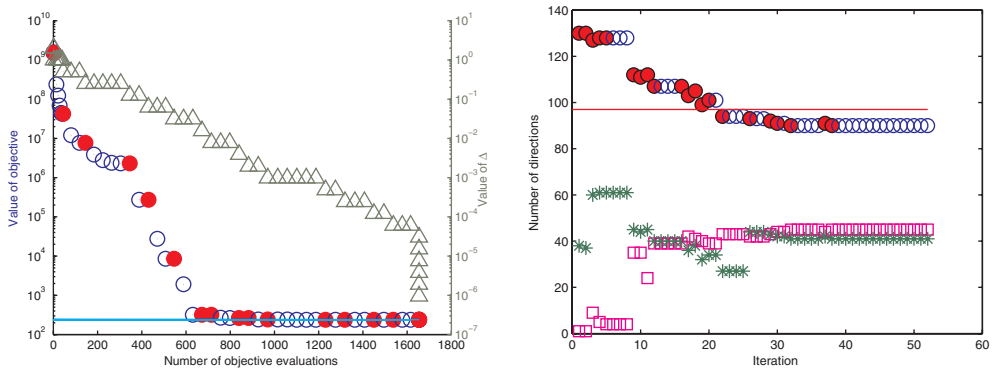

FIG. 9.3. *Results for the* SPANHYD *test problem. Legends are given in Figure* 9.1.

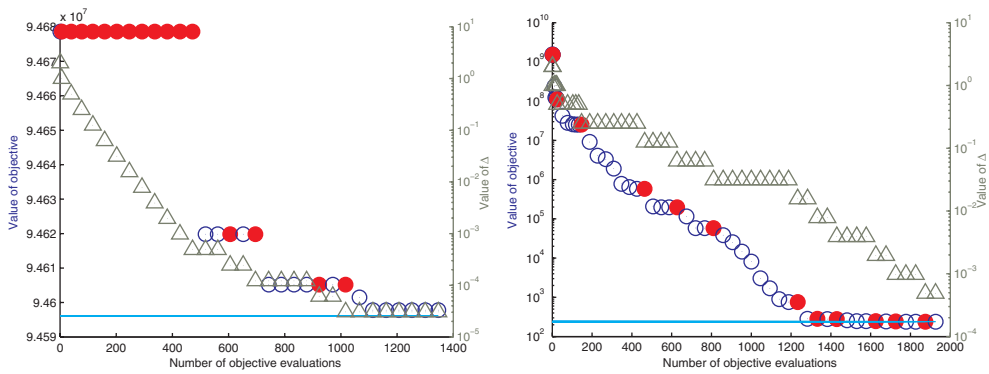

FIG. 9.4. *Progress versus cost history for the* AVION2 *(left) and* SPANHYD *(right) test problems if only the theoretically minimal set of search directions $\mathcal{D}_k = \mathcal{G}_k$ is used at each iteration k. Legend is given in Figure* 9.1.

shows that the algorithm makes good progress toward the optimal objective value. For this problem the test terminated because $\Delta_k \leq \Delta_{\text{tol}}$.

More interesting is the plot on the right, which shows that the degenerate case arises multiple times. Moreover, the plot on the right in Figure 9.3 reveals how badly one can be fooled by the naive bound on the potential number of search directions. For instance, at iteration 4 there are 128 constraints in the working set. Of these, 67 are equality constraints, with rank 66. Eliminating these degrees of freedom from the 97 variables still leaves brute force enumeration of

$$\begin{pmatrix} 128 - 67 \\ 97 - 66 \end{pmatrix} = \frac{61!}{31!\ 30!} \approx 2.33 \times 10^{17}$$

possible generators for $T(x_k, \varepsilon_k)$. There are, in fact, only 5 generators, which `cddlib` finds in less than 0.17 seconds.

Figure 9.4 illustrates the point made in section 6 about the desirability of using more than the theoretically minimal set of search directions. In this test we used only the generators of $T(x_k, \varepsilon_k)$ (the core set of search directions), setting $\mathcal{H}_k = \emptyset$. Comparisons with Figures 9.2 and 9.3 show that using the smaller set of search directions can appreciably retard the progress of the search.

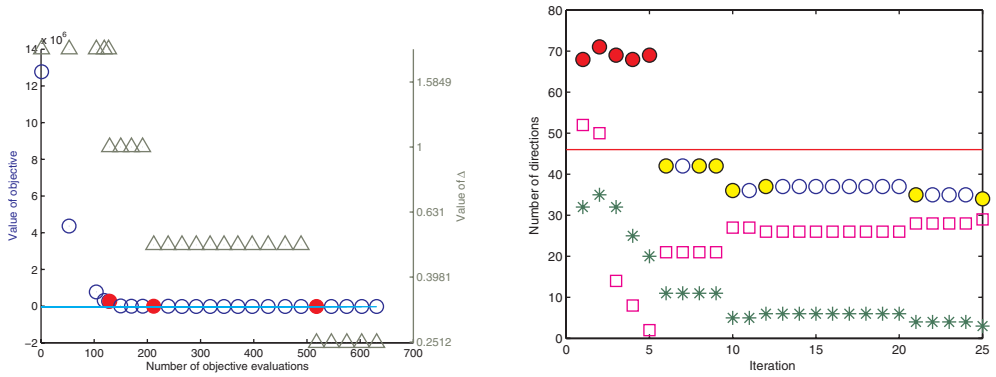

FIG. 9.5. *Results for the* DALLASS *test problem. Legends are given in Figure* 9.1.

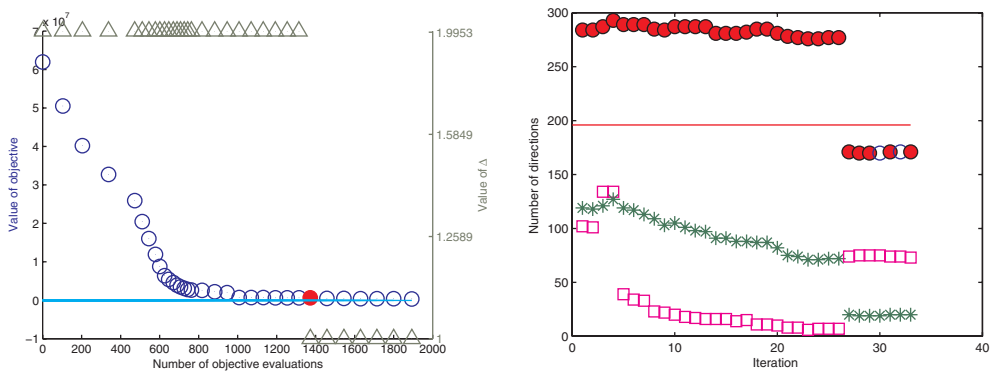

FIG. 9.6. *Results for the* DALLASM *test problem. Legends are given in Figure* 9.1.

Figure 9.5 gives results for the DALLASS test problem, a small model of the Dallas water system. The plot on the left shows that the problem is solved quickly. In the plot on the right, lighter solid circles indicate iterations where the simpler construction of the search directions given in section 5.4.1 was used. The degenerate case occurs only in the first five iterations.

In Figure 9.6 we give the results for the DALLASM test problem, a medium size model of the Dallas water system. While the algorithm makes progress towards the solution, reducing the value of the objective by a factor of 160, it does not solve the problem within the budget of objective evaluations allowed. The plot on the right shows that in the first 26 iterations there is considerable degeneracy in the working set. In the most extreme case, at iteration 4 there are 293 constraints in the working set, of which 151 are equalities with rank 150. Eliminating these degrees of freedom from the 197 variables leaves

$$\begin{pmatrix} 293 - 151 \\ 197 - 150 \end{pmatrix} = \frac{142!}{47!\ 95!} \approx 1.01 \times 10^{38}$$

possible generators for $T(x_k, \varepsilon_k)$. There are actually only 134 generators, which `cddlib` finds in about 4.3 seconds.

Figure 9.7 gives results for the LOADBAL problem, a load-balancing problem from computer science. Absent upper bounds on all of the variables, and with no prior

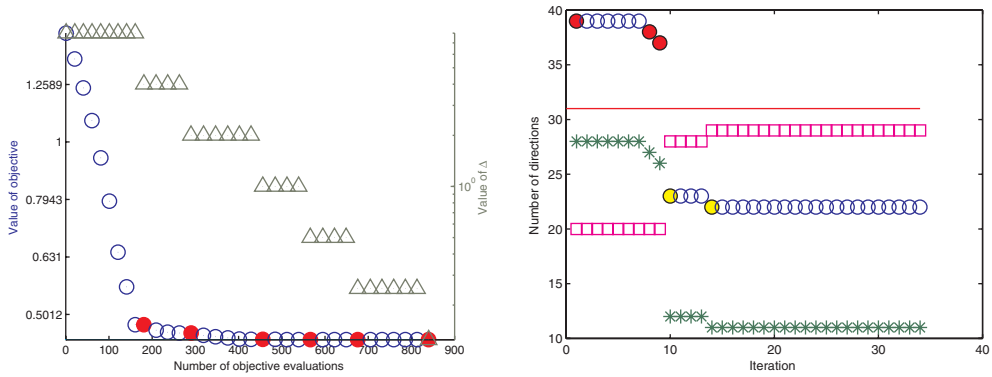

FIG. 9.7. *Results for the* LOADBAL *test problem. Legends are given in Figure* 9.1.

TABLE 9.2
Summary of test results.

CUTEr problem	Degrees of freedom	Stopping conditions		Total time (seconds)	
		Max evals.	Reason	Elapsed	In `cddlib`
AVION2	34	1380	Max evals.	2.47	0.15
DALLASM	47	1900	Max evals.	92.91	75.86
DALLASS	16	660	Max evals.	1.32	0.09
LOADBAL	21	860	Max evals.	1.56	0.02
SPANHYD	49	1980	$\Delta < \Delta_{\text{tol}}$	6.68	2.43

knowledge of reasonable ranges for the variables, we do not scale. We choose $\Delta_0 = 8$ based on the magnitude of the starting point. There is rapid progress toward the solution.

We summarize the test results in Table 9.2. In evaluating the timings, one should bear in mind that the cost of an objective evaluation was insignificant since the objectives are explicitly defined functions. In more realistic settings the cost of an objective evaluation would likely be much higher, so the relative cost of treating degenerate working sets should be appreciably less.

We tested our implementation on other problems from the CUTEr test set (e.g., HIMMELBI) and for most of them saw results comparable to the ones reported above. Two exceptions were QPCBOEI1 and QPCBOEI2. In both cases we encountered highly degenerate cases of the working set that exercised `cddlib`. For instance, in QPCBOEI1, a 384 variable problem, we encountered working sets with over 700 constraints for which `cddlib` took about 40 seconds to compute the core search directions. In QPCBOEI2, a 143 variable problem, we encountered a working set consisting of 30 equalities and 189 inequalities for which `cddlib` did not find a set of core search directions in an acceptable amount of time; we terminated the job after allowing `cddlib` to work for 12 hours.

10. Concluding remarks. Our numerical results illustrate the value of the condition defining the working set for generating set search introduced in [17]. This condition reduces the number of core search directions required in [20] while allowing the flexibility of introducing extra search directions. As the discussion in section 6 would suggest, we have found that augmenting the set of search directions beyond the theoretically minimal set typically leads to greater overall efficiency of the algorithm. We also have shown that state-of-the-art computational geometry methods make the

calculation of the search directions needed by generating set search tractable even in the degenerate case. In addition, the presentation here addresses the various details that arise when handling linear equality constraints. Finally, the introduction of linear constraints has allowed us to solve larger dimensional problems than is usually possible for the unconstrained case.

Our implementation gives us a basis for implementing a generating set search version of the augmented Lagrangian algorithm in [6]. In this approach, linear constraints are treated explicitly rather than being included in the augmented Lagrangian. The ability to treat degeneracy explicitly, as we do here, is important because the combination of general linear constraints and simple bounds frequently leads to degeneracy, and treatment of degeneracy by an augmented Lagrangian approach can be slow.

Future work includes using information collected during the progress of the algorithm to estimate the set of constraints binding at a solution as well as developing strategies for moving more quickly to solutions on the boundary.

Acknowledgments. Komei Fukuda has made his `cdd` package publicly available and graciously answered our questions about `cddlib`. Conversations with Rakesh Kumar about his experience implementing and testing the algorithm in [20] for the MathWorks Genetic Algorithm and Direct Search Toolbox [28] provided many useful insights when we tackled degenerate constraints. Josh Griffin read an early version of the paper and reported back numerous bugs and inconsistencies that we had overlooked. Tammy Kolda, Associate Editor, and two anonymous referees carefully read the paper and responded with numerous suggestions that appreciably improved the presentation. Stephen Nash also sent along several helpful observations concerning the first version of the paper. We extend our sincere thanks to all of these people.

A DUAL OPTIMIZATION APPROACH TO INVERSE QUADRATIC EIGENVALUE PROBLEMS WITH PARTIAL EIGENSTRUCTURE*

ZHENG-JIAN BAI†, DELIN CHU‡, AND DEFENG SUN‡

Abstract. The inverse quadratic eigenvalue problem (IQEP) arises in the field of structural dynamics. It aims to find three symmetric matrices, known as the mass, the damping, and the stiffness matrices, such that they are closest to the given analytical matrices and satisfy the measured data. The difficulty of this problem lies in the fact that in applications the mass matrix should be positive definite and the stiffness matrix positive semidefinite. Based on an equivalent dual optimization version of the IQEP, we present a quadratically convergent Newton-type method. Our numerical experiments confirm the high efficiency of the proposed method.

Key words. nonlinear optimization, quadratic eigenvalue problem, inverse eigenvalue problem, partial eigenstructure

1. Introduction.

Throughout this paper the following notation will be used:

- $A \succeq 0$ ($A \succ 0$, respectively) means that the $n \times n$ real matrix A is symmetric and positive semidefinite (symmetric and positive definite, respectively).
- A^T, $\sigma(A)$, and $\|A\|$ denote the transpose, the spectrum, and the Frobenius norm of $A \in \mathbb{R}^{n\times n}$, respectively.
- I denotes the identity matrix of an appropriate dimension.
- $\mathcal{S}^n$ and $\mathcal{S}^n_+$ denote the set of all real $n \times n$ symmetric matrices and the cone of positive semidefinite matrices in this set, respectively. Let

$$\Omega_0 := \mathcal{S}^n \times \mathcal{S}^n \times \mathcal{S}^n \quad \text{and} \quad \Omega := \mathcal{S}^n_+ \times \mathcal{S}^n \times \mathcal{S}^n_+.$$

For given matrices $M, C, K \in \mathbb{R}^{n\times n}$, let

$$Q(\lambda) := \lambda^2 M + \lambda C + K.$$

Then the quadratic eigenvalue problem (QEP) is to find scalars $\lambda \in \mathbb{C}$ and nonzero vectors x such that

$$Q(\lambda)x = 0, \tag{1.1}$$

where λ and x are called the eigenvalue and the eigenvector, respectively. For various applications, mathematical properties, and numerical solution techniques of the QEP,

we refer the reader to the survey paper [48]. In many practical applications, the matrices M, C, and K are required to be symmetric. In particular, in one of the most popular numerical models, the finite element model (FEM) [19, 48]

$$M\ddot{x}(t) + C\dot{x}(t) + Kx(t) = 0, \tag{1.2}$$

the mass matrix M, the damping matrix C, and the stiffness matrix K are required to be symmetric with M and K being positive definite and positive semidefinite, respectively. It is shown in [48] that the general solution to the homogeneous equation (1.2) is given in terms of the solution of the QEP (1.1). Unfortunately, the natural frequencies and model shapes (eigenvalues and eigenvectors) predicted by the FEM often disagree with the physical experimental results. The FEM updating aims to improve the numerical model (1.2) by the measured data. Various model updating methods have been presented in the literature [19, 27, 29, 33]. Mathematically, the model updating problem is an inverse quadratic eigenvalue problem (IQEP) which aims to find matrices M, C, and K such that they are closest to the given estimated analytical matrices and satisfy the partially measured eigendata. The general IQEP can be defined as follows: Given a measured partial eigenpair $(\Lambda, X) \in \mathbb{R}^{k\times k} \times \mathbb{R}^{n\times k}$ with

$$1 \le k \le n, \quad \mathrm{rank}(X) = k, \quad \text{and} \quad \Lambda = \mathrm{diag}\{\Lambda_1, \ldots, \Lambda_\mu, \Lambda_{\mu+1}, \ldots, \Lambda_\nu\}, \tag{1.3}$$

where

$$\Lambda_i = \mathrm{diag}\{\overbrace{\lambda_i^{[2]}, \ldots, \lambda_i^{[2]}}^{s_i}\} \quad \text{for} \quad 1 \le i \le \mu \quad \text{and} \quad \Lambda_i = \lambda_i I_{s_i} \quad \text{for} \quad \mu+1 \le i \le \nu,$$

$$\lambda_i^{[2]} = \begin{bmatrix} \alpha_i & \beta_i \\ -\beta_i & \alpha_i \end{bmatrix} \in \mathbb{R}^{2\times 2}, \quad \beta_i \ne 0, \quad \sigma(\Lambda_i) \cap \sigma(\Lambda_j) = \emptyset, \quad \forall\, 1 \le i \ne j \le \mu,$$

$$\lambda_i \in \mathbb{R}, \quad \lambda_i \ne \lambda_j, \quad \forall\, \mu+1 \le i \ne j \le \nu,$$

$$k = \sum_{i=1}^{\mu} 2s_i + \sum_{i=\mu+1}^{\nu} s_i,$$

find $M, C, K \in \mathcal{S}^n$ with $M \succ 0$ and $K \succeq 0$ such that

$$MX\Lambda^2 + CX\Lambda + KX = 0. \tag{1.4}$$

The model updating problem for given $M_a, C_a, K_a \in \mathcal{S}^n$, which are called the estimated analytic mass, damping, and stiffness matrices, respectively, in the FEM updating [19], is then to find $M, C, K \in \mathcal{S}^n$ such that (M, C, K) is a solution to the following optimization problem:

$$\begin{array}{ll} \inf & \dfrac{c_1}{2}\|M - M_a\|^2 + \dfrac{c_2}{2}\|C - C_a\|^2 + \dfrac{1}{2}\|K - K_a\|^2 \\ \text{subject to (s.t.)} & MX\Lambda^2 + CX\Lambda + KX = 0, \\ & M \succ 0, \quad C = C^T, \quad K \succeq 0, \end{array}$$

where c_1 and c_2 are two positive weighting parameters. It is noted that in numerical computation it is better to replace the condition $M \succ 0$ by $M \succeq 0$. This consideration leads us to focus on the following optimization problem:

$$\begin{array}{ll} \min & \dfrac{c_1}{2}\|M - M_a\|^2 + \dfrac{c_2}{2}\|C - C_a\|^2 + \dfrac{1}{2}\|K - K_a\|^2 \\ \text{s.t.} & MX\Lambda^2 + CX\Lambda + KX = 0, \\ & M \succeq 0, \quad C = C^T, \quad K \succeq 0. \end{array} \tag{1.5}$$

To avoid confusion, we refer to the optimization problem (1.5) as the IQEP.

As in [25], let the QR factorization of X be given by

$$X = Q \begin{bmatrix} R \\ 0 \end{bmatrix},$$

where $Q \in \mathbb{R}^{n\times n}$ is orthogonal and $R \in \mathbb{R}^{k\times k}$ is nonsingular and upper triangular. By renaming $M := \sqrt{c_1}Q^T M Q$, $C := \sqrt{c_2}Q^T C Q$, $K := Q^T K Q$, $M_a := \sqrt{c_1}Q^T M_a Q$, $C_a := \sqrt{c_2}Q^T C_a Q$, and $K_a := Q^T K_a Q$, without loss of generality, we may assume from now on that problem (1.5) takes the following form:

$$\begin{aligned} \min \quad & \frac{1}{2}\|M - M_a\|^2 + \frac{1}{2}\|C - C_a\|^2 + \frac{1}{2}\|K - K_a\|^2 \\ \text{s.t.} \quad & \frac{1}{\sqrt{c_1}} M \begin{bmatrix} R \\ 0 \end{bmatrix} \Lambda^2 + \frac{1}{\sqrt{c_2}} C \begin{bmatrix} R \\ 0 \end{bmatrix} \Lambda + K \begin{bmatrix} R \\ 0 \end{bmatrix} = 0, \\ & M \succeq 0, \quad C = C^T, \quad K \succeq 0. \end{aligned} \tag{1.6}$$

THEOREM 1.1. *Problem* (1.6) *admits a strictly feasible solution if and only if* Λ *is nonsingular.*

Proof. First we show the *necessity* by contradiction. Assume that Λ is singular. Then there exists a nonzero vector y such that

$$\Lambda y = 0.$$

As a result, for any feasible solution (M, C, K) to problem (1.6), we have

$$\left(\frac{1}{\sqrt{c_1}} M \begin{bmatrix} R \\ 0 \end{bmatrix} \Lambda^2 + \frac{1}{\sqrt{c_2}} C \begin{bmatrix} R \\ 0 \end{bmatrix} \Lambda + K \begin{bmatrix} R \\ 0 \end{bmatrix} \right) y = 0; \quad \text{i.e.,} \quad K \begin{bmatrix} Ry \\ 0 \end{bmatrix} = 0.$$

Note that R is nonsingular, which yields that $Ry \neq 0$. Hence K must be singular. This is a contradiction to the existence of a strictly feasible solution to problem (1.6). Therefore, problem (1.6) can admit a strictly feasible solution only if Λ is nonsingular.

Next we show the *sufficiency*. Following the idea of [12], we can obtain a special feasible solution to (1.6) as follows:

$$\begin{cases} \widehat{M} = \sqrt{c_1} \begin{bmatrix} (RR^T)^{-1} & 0 \\ 0 & I \end{bmatrix}, \\ \widehat{C} = \sqrt{c_2} \begin{bmatrix} -R^{-T}(\Lambda + \Lambda^T)R^{-1} & 0 \\ 0 & 0 \end{bmatrix}, \\ \widehat{K} = \begin{bmatrix} R^{-T}\Lambda^T \Lambda R^{-1} & 0 \\ 0 & I \end{bmatrix}. \end{cases} \tag{1.7}$$

Since both R and Λ are nonsingular, $\widehat{M}$ and $\widehat{K}$ are symmetric and positive definite. This implies that $(\widehat{M}, \widehat{C}, \widehat{K})$ above is a strictly feasible solution to problem (1.6). ∎

Because of Theorem 1.1 and the generalized Slater condition (2.4) (see section 2) used in our dual approach, in the following development we make a blanket assumption, unless stated otherwise, that the following condition holds.

Assumption 1.2. Λ is nonsingular.

Remark 1.3. Problem (1.6) fails to possess a strictly feasible solution if Λ is singular. As a remedy, we can reduce problem (1.6) equivalently to a similar problem which admits a strictly feasible solution. See Appendix B for discussions on this.

Due to complicated structures of the IQEP and a lack of tools for dealing with it, many authors considered various simplified versions of the IQEP by dropping or relaxing the requirement on the positive semidefiniteness of the matrices M and K [3, 4, 5, 6, 14, 18, 19, 26, 51, 52, 53]. As observed in the literature on structural dynamics [18, 19], however, these approaches may fail to guarantee the positive semidefiniteness of M and K, which is vital in applications.

In this paper, we deal directly with the IQEP with the required positive semidefiniteness condition on the matrices M and K. We shall introduce a generalized Newton method to the dual of problem (1.6), whose objective function is continuously differentiable but not twice differentiable. This approach is motivated by two recent papers due to Chu, Kuo, and Lin [12] and Qi and Sun [37]. In [12], Chu, Kuo, and Lin made an important step by showing for the first time that the general IQEP admits a nontrivial solution; i.e., there exist symmetric matrices M, C, and K with $M \succ 0$ and $K \succeq 0$ satisfying (1.4). In [37], based on recent developments in strongly semismooth matrix-valued functions [47], Qi and Sun presented a highly efficient quadratically convergent Newton method for solving the nearest correlation matrix problem proposed by Higham in [22] (see Boyd and Xiao [10], Malick [30], and Toh, Tütüncü, and Todd [50] for more discussions on this problem and its extensions). Theoretically, the Newton method introduced in [37] can be used to solve a much broader class of problems that includes the IQEP. However, there exist several practical difficulties in applying the approach by Qi and Sun [37] to the IQEP. In particular, for the IQEP we must first circumvent the incomputability of an element in Clarke's generalized Jacobian of the gradient mapping of the dual function needed in the approach by Qi and Sun [37]. We shall address this important issue under a more general setting in this paper by introducing a modified version of Clarke's generalized Jacobian. Consequently, the convergence analysis must be modified, too. Note that the IQEP is a special constrained least-squares problem, which can be solved by applying conventional approaches such as first order methods or a quasi-Newton method (e.g., Malick [30] suggested using the BFGS update) to its dual problem. Here, we show that a generalized Newton method can be applied to the dual of the IQEP with guaranteed quadratic convergence and high efficiency.

The organization of this paper is as follows. In section 2, we discuss some basic convex optimization theory used in this paper and present some results regarding Clarke's generalized Jacobian of certain locally Lipschitz functions. In section 3, we present the dual forms of the IQEP. In section 4, we give the details of our generalized Newton method and its convergence analysis. We report our numerical results in section 5 and make some final conclusions in section 6.

2. Preliminaries. Let $\mathcal{X}$ and $\mathcal{Y}$ be two finite dimensional real vector spaces, each equipped with a scalar inner product $\langle \cdot, \cdot \rangle$ and its induced norm $\| \cdot \|$. Let $\mathcal{A} : \mathcal{X} \to \mathcal{Y}$ be a linear operator and $\mathcal{A}^* : \mathcal{Y} \to \mathcal{X}$ be the adjoint of $\mathcal{A}$. Let x^0 be a given vector in $\mathcal{X}$. Consider the following constrained least-squares problem:

$$\begin{array}{ll} \min & \dfrac{1}{2}\langle x - x^0, x - x^0 \rangle \\ \text{s.t.} & \mathcal{A}x = b, \\ & x \in \mathcal{Q}, \end{array} \tag{2.1}$$

where $b \in \mathcal{Y}$ and $\mathcal{Q}$ is a closed convex cone in $\mathcal{X}$. In the literature, problem (2.1) is also known as the best approximation problem in Hilbert space. For a survey on the latter, see [36]. Let $\mathcal{D} \subseteq \mathcal{X}$ be a closed convex set. For any $x \in \mathcal{X}$, let $\Pi_{\mathcal{D}}(x)$ denote

the metric projection of x onto $\mathcal{D}$; i.e., $\Pi_{\mathcal{D}}(x)$ is the unique optimal solution to the following convex programming problem:

$$\begin{array}{ll} \min & \dfrac{1}{2}\langle z-x, z-x\rangle \\ \text{s.t.} & z \in \mathcal{D}. \end{array}$$

Then, the dual of problem (2.1) (cf. Rockafellar and Wets [44]) has the following form:

$$\begin{array}{ll} \max & -\theta(y) \\ \text{s.t.} & y \in \mathcal{Y}, \end{array} \tag{2.2}$$

where $\theta : \mathcal{Y} \to \mathbb{R}$ is given by

$$\theta(y) := \frac{1}{2}\|x^0 + \mathcal{A}^* y\|^2 - \frac{1}{2}\|x^0 + \mathcal{A}^* y - \Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y)\|^2 - \langle b, y\rangle - \frac{1}{2}\|x^0\|^2. \tag{2.3}$$

Recall that the generalized Slater condition is said to hold for the convex optimization problem (2.1) if

$$\begin{cases} \mathcal{A} : \mathcal{X} \to \mathcal{Y} \text{ is onto,} \\ \exists\ \bar{x} \in \mathcal{X} \text{ such that } \mathcal{A}\bar{x} = b,\ \bar{x} \in \operatorname{int}(\mathcal{Q}), \end{cases} \tag{2.4}$$

where "int" denotes the topological interior of a given set. The following result is well known in the classical duality theory for convex programming [43, Theorems 17 and 18].

PROPOSITION 2.1. *Under the generalized Slater condition* (2.4)*, the following hold:*

(i) *There exists at least one $\bar{y} \in \mathcal{Y}$ that solves the dual problem* (2.2)*. The unique solution to the original problem* (2.1) *is given by*

$$\bar{x} = \Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* \bar{y}). \tag{2.5}$$

(ii) *For every real number τ, the level set $\{y \in \mathcal{Y} : \theta(y) \le \tau\}$ is closed, bounded, and convex.*

For more recent discussions about the above duality theory for the constrained least-squares problem (2.1) and its extensions, see [10, 30, 37].

Since $\mathcal{Q}$ is assumed to be a closed convex cone, by [54], we know that the function θ defined by (2.3) takes the following form:

$$\theta(y) = \frac{1}{2}\|\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y)\|^2 - \langle b, y\rangle - \frac{1}{2}\|x^0\|^2, \quad y \in \mathcal{Y}. \tag{2.6}$$

From [54] we also know that θ is a continuously differentiable convex function and that its gradient at $y \in \mathcal{Y}$ is given by

$$\nabla\theta(y) = \mathcal{A}\,\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y) - b.$$

Furthermore, since $\Pi_{\mathcal{Q}}(\cdot)$ is globally Lipschitz continuous with modulus 1, $\nabla\theta(\cdot)$ is globally Lipschitz continuous. Therefore, if the Slater condition (2.4) holds, then one may use any gradient-based method, such as the steepest descent method or quasi-Newton methods (e.g., the BFGS method suggested by Malick [30]), to find an optimal solution y^* to the dual problem (2.2) first and then use (2.5) to get an optimal

solution to problem (2.1). This is exactly the dual approach outlined by Rockafellar in [43, page 4] for general convex optimization problems and tailored to the constrained least-squares problem (2.1). Since in general $\Pi_{\mathcal{Q}}(\cdot)$ is not continuously differentiable, $\theta(\cdot)$ is not twice differentiable. So we cannot directly use the Newton method to solve (2.2); i.e.,

$$\begin{array}{ll} \min & \theta(y) \\ \text{s.t.} & y \in \mathcal{Y}. \end{array} \tag{2.7}$$

Fortunately, we may apply Clarke's Jacobian-based Newton method developed in the last two decades for solving locally Lipschitz equations [24, 39]. The success of using Clarke's Jacobian-based Newton method to solve the nearest correlation matrix problem in Qi and Sun [37] inspires us to explore this idea further.

Let $\mathcal{Z}$ be an arbitrary finite dimensional real vector space. Let $\mathcal{O}$ be an open set in $\mathcal{Y}$ and let $\Xi : \mathcal{O} \subseteq \mathcal{Y} \to \mathcal{Z}$ be a locally Lipschitz continuous function on the open set $\mathcal{O}$. Rademacher's theorem [44, Chapter 9.J] says that Ξ is almost everywhere Fréchet differentiable in $\mathcal{O}$. We denote by $\mathcal{O}_\Xi$ the set of points in $\mathcal{O}$ where Ξ is Fréchet differentiable. Let $\Xi'(y)$ denote the Jacobian of Ξ at $y \in \mathcal{O}_\Xi$. Then Clarke's generalized Jacobian of Ξ at $y \in \mathcal{O}$ is defined by [13]

$$\partial \Xi(y) := \mathrm{conv}\{\partial_B \Xi(y)\},$$

where "conv" denotes the convex hull and the Bouligand subdifferential $\partial_B \Xi(y)$ is defined by Qi in [38] as

$$\partial_B \Xi(y) := \left\{ V \,:\, V = \lim_{j \to \infty} \Xi'(y^j),\, y^j \to y,\, y^j \in \mathcal{O}_\Xi \right\}.$$

Suppose that $F : \mathcal{O} \subseteq \mathcal{Y} \to \mathcal{Y}$ is a locally Lipschitz continuous function on the open set $\mathcal{O}$. Let y^0 be an arbitrary point in $\mathcal{O}$. Then Clarke's Jacobian-based Newton method for solving the locally Lipschitz equation $F(y) = 0$ can be described by

$$y^{j+1} = y^j - V_j^{-1} F(y^j), \qquad V_j \in \partial F(y^j), \quad j = 0, 1, 2, \ldots. \tag{2.8}$$

In general, the above iterative method does not converge even if $\{\|V_j^{-1}\|\}$ is uniformly bounded and y^0 is arbitrarily close to a given solution of $F(y) = 0$ (see [24]). Kummer in [24] proposed a general condition guaranteeing the superlinear convergence of (2.8), which generalized Kojima and Shindo's condition for superlinear (quadratic) convergence of the Newton method for piecewise smooth equations [23]. Kummer's result was largely unnoticed until Qi and Sun in [39] published their now well-known work by showing that the iteration sequence generated by (2.8) can converge superlinearly if F is a *semismooth function*.

The concept of semismoothness was introduced by Mifflin [32] for functionals. In order to study the convergence of the iterative method (2.8), Qi and Sun [39] extended the definition of semismoothness to vector-valued functions. The following definition of semismoothness is convenient to use.

DEFINITION 2.2. *Let $\Xi : \mathcal{O} \subseteq \mathcal{Y} \to \mathcal{Z}$ be a locally Lipschitz continuous function on the open set $\mathcal{O}$. We say that Ξ is semismooth at a point $y \in \mathcal{O}$ if*

(i) *Ξ is directionally differentiable at y, and*

(ii) *for any $x \to y$ and $V \in \partial \Xi(x)$,*

$$\Xi(x) - \Xi(y) - V(x - y) = o(\|x - y\|). \tag{2.9}$$

The function $\Xi : \mathcal{O} \subseteq \mathcal{Y} \to \mathcal{Z}$ is said to be strongly semismooth at a point $y \in \mathcal{O}$ if F is semismooth at y, and for any $x \to y$ and $V \in \partial\Xi(x)$,

$$\Xi(x) - \Xi(y) - V(x-y) = O(\|x-y\|^2). \tag{2.10}$$

The following convergence result is established in [39, Theorem 3.2], while the result on superlinear convergence can also be found in [24, Proposition 3].

PROPOSITION 2.3. *Let $F : \mathcal{O} \subseteq \mathcal{Y} \to \mathcal{Y}$ be a locally Lipschitz continuous function on the open set $\mathcal{O}$. Let $\bar{y} \in \mathcal{O}$ be such that $F(\bar{y}) = 0$. Assume that F is semismooth at $\bar{y}$ and that every element in $\partial F(\bar{y})$ is nonsingular. Then every sequence generated by (2.8) converges to $\bar{y}$ superlinearly provided that the starting point y^0 is sufficiently close to $\bar{y}$. Moreover, if F is strongly semismooth at $\bar{y}$, the rate of convergence is quadratic.*

Now, we consider the following equation:

$$F(y) := \nabla\theta(y) = \mathcal{A}\,\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y) - b = 0, \quad y \in \mathcal{Y}. \tag{2.11}$$

We have already shown that F is a globally Lipschitz continuous mapping, and thus $\partial F(y)$ is well defined everywhere in $\mathcal{Y}$. In order to apply Clarke's Jacobian-based Newton method (2.8) to find a solution of (2.11), we need to assume that the two conditions imposed in Proposition 2.3 are valid. Certainly, the (strong) semismoothness of F at $\bar{y}$ follows easily if the metric projector $\Pi_{\mathcal{Q}}(\cdot)$ is (strongly) semismooth at $x^0 + \mathcal{A}^*\bar{y}$. This means that if one knows in advance that $\Pi_{\mathcal{Q}}(\cdot)$ is (strongly) semismooth everywhere in $\mathcal{Y}$ (as is the case for the IQEP discussed in this paper), then there is no need to be concerned about the semismoothness assumption on F. However, the second condition, i.e., the nonsingularity assumption on the generalized Jacobian $\partial F(\bar{y})$, needs more elaboration. We shall discuss this issue in the remaining part of this section.

Let $F : \mathcal{Y} \to \mathcal{Y}$ be defined by (2.11). The next proposition on Clarke's Jacobian of F follows easily from [13, page 75].

PROPOSITION 2.4. *Let $\bar{y} \in \mathcal{Y}$ and $\bar{x} := x^0 + \mathcal{A}^*\bar{y}$. Then, for any $d \in \mathcal{Y}$, it holds that*

$$\partial F(\bar{y})d \subseteq \mathcal{A}\,\partial\Pi_{\mathcal{Q}}(\bar{x})\mathcal{A}^* d. \tag{2.12}$$

Proposition 2.4 relates the Jacobian of F to the Jacobian of the metric projector $\Pi_{\mathcal{Q}}(\cdot)$. Note, however, that (2.12) does not mean that $\partial F(\bar{y}) \subseteq \mathcal{A}\,\partial\Pi_{\mathcal{Q}}(\bar{x})\mathcal{A}^*$. For the metric projector, we have the following result from [31, Proposition 1].

LEMMA 2.5. *Let $\mathcal{D} \subseteq \mathcal{X}$ be a closed convex set. Then, for any $x \in \mathcal{X}$ and $V \in \partial\Pi_{\mathcal{D}}(x)$,*

(i) *V is self-adjoint,*
(ii) *$\langle d, Vd\rangle \geq 0$ for all $d \in \mathcal{X}$,*
(iii) *$\langle Vd, d - Vd\rangle \geq 0$ for all $d \in \mathcal{X}$.*

Let $\mathcal{D} \subseteq \mathcal{X}$ be a closed convex set. For any $x \in \mathcal{X}$, denote

$$\mathrm{dist}(x, \mathcal{D}) := \inf\{\|x - d\| \,:\, d \in \mathcal{D}\}.$$

The *tangent cone* of $\mathcal{D}$ at a point $x \in \mathcal{D}$, which we denote by $\mathcal{T}_{\mathcal{D}}(x)$, consisting of all tangent vectors of $\mathcal{D}$ at x, is defined by (cf. [9, section 2.2.4])

$$\mathcal{T}_{\mathcal{D}}(x) := \{d \in \mathcal{X} \,:\, \mathrm{dist}(x + td, \mathcal{D}) = o(t),\ t \geq 0\}. \tag{2.13}$$

For any $x \in \mathcal{D}$, we denote by $\operatorname{lin}(\mathcal{T}_{\mathcal{D}}(x))$ the lineality space of $\mathcal{T}_{\mathcal{D}}(x)$, i.e., the largest linear space in $\mathcal{T}_{\mathcal{D}}(x)$.

The following definition of constraint nondegeneracy is adapted from the works of Robinson, who defined it for general optimization problems and variational inequalities [40, 41, 42].

DEFINITION 2.6. *We say that a feasible point x to problem* (2.1) *is constraint nondegenerate if*

$$\begin{pmatrix} \mathcal{A} \\ I \end{pmatrix} \mathcal{X} + \begin{pmatrix} 0 \\ \operatorname{lin}(\mathcal{T}_{\mathcal{Q}}(x)) \end{pmatrix} = \begin{pmatrix} \mathcal{Y} \\ \mathcal{X} \end{pmatrix} \tag{2.14}$$

or, equivalently, if

$$\mathcal{A} \operatorname{lin}(\mathcal{T}_{\mathcal{Q}}(x)) = \mathcal{Y}. \tag{2.15}$$

The constraint nondegenerate condition (2.14) in its general form is extensively used by Bonnans and Shapiro in [9] for perturbation analysis of optimization problems. In the context of semidefinite programming, condition (2.14) reduces to the primal nondegenerate condition proposed by Alizadeh, Haeberly, and Overton [1]. For the conventional nonlinear programming problem with finitely many equality and inequality constraints, the constraint nondegenerate condition is equivalent to the well-known linear independence constraint qualification [40, 46].

DEFINITION 2.7. *Let $\mathcal{D} \subseteq \mathcal{X}$ be a closed convex set. We say that the metric projector $\Pi_{\mathcal{D}}(\cdot)$ is Jacobian amicable at $x \in \mathcal{X}$ if, for any $V \in \partial\Pi_{\mathcal{D}}(x)$ and $d \in \mathcal{X}$ such that $Vd = 0$, it holds that*

$$d \in \left(\operatorname{lin}\left(\mathcal{T}_{\mathcal{D}}(x_+)\right)\right)^{\perp},$$

where $x_+ := \Pi_{\mathcal{D}}(x)$ and $\left(\operatorname{lin}\left(\mathcal{T}_{\mathcal{D}}(x_+)\right)\right)^{\perp}$ is defined by

$$\left(\operatorname{lin}\left(\mathcal{T}_{\mathcal{D}}(x_+)\right)\right)^{\perp} := \{d \in \mathcal{X} \,:\, \langle d, h\rangle = 0 \quad \forall\, h \in \operatorname{lin}\left(\mathcal{T}_{\mathcal{D}}(x_+)\right)\}.$$

We say that $\Pi_{\mathcal{D}}(\cdot)$ is Jacobian amicable if it is Jacobian amicable at every point in $\mathcal{X}$.

Now, we are ready to state our result on the nonsingularity of Clarke's Jacobian of the mapping F defined by (2.11).

PROPOSITION 2.8. *Let $\bar{y} \in \mathcal{Y}$ be such that $F(\bar{y}) = 0$. Let $\bar{x} := x^0 + \mathcal{A}^*\bar{y}$ and $\bar{x}_+ := \Pi_{\mathcal{Q}}(\bar{x})$. Assume that the constraint nondegenerate condition* (2.15) *holds at $\bar{x}_+$ and that $\Pi_{\mathcal{Q}}(\cdot)$ is Jacobian amicable at $\bar{x}$. Then every element in $\mathcal{A}\partial\Pi_{\mathcal{Q}}(\bar{x})\mathcal{A}^*$ is self-adjoint and positive definite.*

Proof. Let V be an arbitrary element in $\mathcal{A}\partial\Pi_{\mathcal{Q}}(\bar{x})\mathcal{A}^*$. Then, there exists an element $W \in \partial\Pi_{\mathcal{Q}}(\bar{x})$ such that

$$V = \mathcal{A}W\mathcal{A}^*.$$

Since, by Lemma 2.5, W is self-adjoint and positive semidefinite, we know that V is also self-adjoint and positive semidefinite.

Next, we show the positive definiteness of V. Let $d \in \mathcal{Y}$ be such that $Vd = 0$. Then, by (iii) of Lemma 2.5, we obtain that

$$0 = \langle d, Vd\rangle = \langle d, \mathcal{A}W\mathcal{A}^*d\rangle = \langle \mathcal{A}^*d, W\mathcal{A}^*d\rangle \geq \langle W\mathcal{A}^*d, W\mathcal{A}^*d\rangle,$$

which implies

$$W\mathcal{A}^*d = 0.$$

Therefore, by the assumption that $\Pi_{\mathcal{Q}}(\cdot)$ is Jacobian amicable at $\bar{x}$, we know that

$$\mathcal{A}^* d \in (\mathrm{lin}\,(\mathcal{T}_{\mathcal{Q}}(\bar{x}_+)))^{\perp}.$$

Since the constraint nondegenerate condition (2.15) holds at $\bar{x}_+$, there exists a vector $h \in \mathrm{lin}\,(\mathcal{T}_{\mathcal{Q}}(\bar{x}_+))$ such that $\mathcal{A}h = d$. Hence, since $\mathcal{A}^* d \in (\mathrm{lin}\,(\mathcal{T}_{\mathcal{Q}}(\bar{x}_+)))^{\perp}$ and $h \in \mathrm{lin}\,(\mathcal{T}_{\mathcal{Q}}(\bar{x}_+))$, it holds that

$$\langle d, d\rangle = \langle d, \mathcal{A}h\rangle = \langle \mathcal{A}^* d, h\rangle = 0.$$

Thus $d = 0$. This, together with the fact that V is self-adjoint and positive semidefinite, shows that V is self-adjoint and positive definite. □

Proposition 2.8 motivates us to define the following modified version of the Jacobian-based Newton method (2.8) to solve (2.11):

$$y^{j+1} = y^j - V_j^{-1} F(y^j), \quad V_j := \mathcal{A} W_j \mathcal{A}^*, \quad W_j \in \partial \Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y^j), \quad j = 0, 1, 2, \ldots, \tag{2.16}$$

where $y^0 \in \mathcal{Y}$ is an initial point.

By Proposition 2.8, we can obtain the following convergence results for the iterative method (2.16) in a way similar to that of Proposition 2.3. We include a brief proof for the sake of completeness.

PROPOSITION 2.9. *Let $\bar{y} \in \mathcal{Y}$ be such that $F(\bar{y}) = 0$. Let $\bar{x} := x^0 + \mathcal{A}^* \bar{y}$ and $\bar{x}_+ := \Pi_{\mathcal{Q}}(\bar{x})$. Assume that the constraint nondegenerate condition* (2.15) *holds at $\bar{x}_+$, $\Pi_{\mathcal{Q}}(\cdot)$ is semismooth at $\bar{x}$, and $\Pi_{\mathcal{Q}}(\cdot)$ is Jacobian amicable at $\bar{x}$. Then every sequence generated by* (2.16) *converges to $\bar{y}$ superlinearly provided that the starting point y^0 is sufficiently close to $\bar{y}$. Moreover, if $\Pi_{\mathcal{Q}}(\cdot)$ is strongly semismooth at $\bar{x}$, the rate of convergence is quadratic.*

Proof. Since, by Proposition 2.8, every element in $\mathcal{A}\partial\Pi_{\mathcal{Q}}(\bar{x})\mathcal{A}^*$ is positive definite, we know from the basic properties of $\partial\Pi_{\mathcal{Q}}(\cdot)$ (cf. [13, Proposition 2.6.2]) that there exist a constant $c > 0$ and an open neighborhood $\mathcal{N}$ of $\bar{y}$ such that for any $y \in \mathcal{N}$ and $W \in \partial\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y)$, $\mathcal{A}W\mathcal{A}^*$ is positive definite and satisfies

$$\| (\mathcal{A} W \mathcal{A}^*)^{-1} \| \le c. \tag{2.17}$$

By using (2.9) in Definition 2.2, we obtain for any $y \in \mathcal{N}$ and $W \in \partial\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y)$ with $y \to \bar{y}$ that

$$\|\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y) - \Pi_{\mathcal{Q}}(\bar{x}) - W(\mathcal{A}^* y - \mathcal{A}^* \bar{y})\| = o(\|\mathcal{A}^*(y - \bar{y})\|) = o(\|(y - \bar{y})\|), \tag{2.18}$$

which implies that for any $y \in \mathcal{N}$ (shrinking $\mathcal{N}$ if necessary) and $W \in \partial\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y)$ we have

$$\|\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y) - \Pi_{\mathcal{Q}}(\bar{x}) - W(\mathcal{A}^* y - \mathcal{A}^* \bar{y})\| \le (2c\|\mathcal{A}\|)^{-1} \|y - \bar{y}\|. \tag{2.19}$$

Then from (2.16), (2.17), and (2.19), we know that for any $y^j \in \mathcal{N}$, $W_j \in \partial\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y^j)$, and $V_j = \mathcal{A} W_j \mathcal{A}^*$,

$$\begin{aligned}
\|y^{j+1} - \bar{y}\| &= \|y^j - \bar{y} - V_j^{-1} F(y^j)\| \\
&= \|V_j^{-1}[V_j(y^j - \bar{y}) - F(y^j) + F(\bar{y})]\| \\
&\le c\|F(y^j) - F(\bar{y}) - V_j(y^j - \bar{y})\| \\
&\le c\|\mathcal{A}\|\|\Pi_{\mathcal{Q}}(x^0 + \mathcal{A}^* y^j) - \Pi_{\mathcal{Q}}(\bar{x}) - W_j(\mathcal{A}^* y^j - \mathcal{A}^* \bar{y})\| \\
&\le \frac{1}{2}\|y^j - \bar{y}\|.
\end{aligned} \tag{2.20}$$

This shows that once $y^0 \in \mathcal{N}$, the whole iteration sequence $\{y^j\}$ converges to $\bar{y}$ linearly. The superlinear convergence of $\{y^j\}$ follows from (2.18) and the second inequality in (2.20).

If $\Pi_{\mathcal{Q}}(\cdot)$ is strongly semismooth at $\bar{x}$, then by repeating the above process and using (2.10) in Definition 2.2 we can easily prove the quadratic convergence of $\{y^j\}$. □

In Proposition 2.9, besides the well-studied constraint nondegenerate condition (2.15) at $\bar{x}_+$ in the literature, we also assume that $\Pi_{\mathcal{Q}}(\cdot)$ is Jacobian amicable at $\bar{x}$, which may hold for many interesting closed convex cones. Here we discuss the Jacobian amicability of $\Pi_{\mathcal{Q}}(\cdot)$ only for the case that $\mathcal{Q} = \mathcal{S}^n_+$, the cone of symmetric and positive semidefinite matrices in $\mathcal{S}^n$.

Let $A \in \mathcal{S}^n$. Then A admits the following spectral decomposition:

$$A = P\Sigma P^T, \tag{2.21}$$

where

$$\Sigma = \begin{bmatrix} \sigma_1 & & & & & & & & \\ & \ddots & & & & & & & \\ & & \sigma_{k_1} & & & & & & \\ & & & 0 & & & & & \\ & & & & \ddots & & & & \\ & & & & & 0 & & & \\ & & & & & & \sigma_{k_1+k_2+1} & & \\ & & & & & & & \ddots & \\ & & & & & & & & \sigma_n \end{bmatrix}$$

with $\sigma_i > 0$ $(i = 1, \ldots, k_1)$ and $\sigma_i < 0$ $(i = k_1 + k_2 + 1, \ldots, n)$ is the diagonal matrix of eigenvalues of A, and

$$P = \begin{bmatrix} P_1 & P_2 & P_3 \end{bmatrix}$$

with $P_1 \in \mathbb{R}^{n\times k_1}$, $P_2 \in \mathbb{R}^{n\times k_2}$, and $P_3 \in \mathbb{R}^{n\times(n-k_1-k_2)}$ is a corresponding orthogonal matrix of orthonormal eigenvectors. Under the Frobenius inner product, the projection $A_+ := \Pi_{\mathcal{S}^n_+}(A)$ of a matrix $A \in \mathcal{S}^n$ onto the cone $\mathcal{S}^n_+$ has an analytic formula [21, 49]

$$A_+ = P \begin{bmatrix} \sigma_1 & & & & & \\ & \ddots & & & & \\ & & \sigma_{k_1} & & & \\ & & & 0 & & \\ & & & & \ddots & \\ & & & & & 0 \end{bmatrix} P^T.$$

Define the matrix $U \in \mathbb{R}^{k_1\times(n-k_1-k_2)}$ with entries

$$U_{ij} := \frac{\max\{\sigma_i, 0\} + \max\{\sigma_{k_1+k_2+j}, 0\}}{|\sigma_i| + |\sigma_{k_1+k_2+j}|}, \quad i = 1, \ldots, k_1, \quad j = 1, \ldots, n - k_1 - k_2.$$

Bonnans, Cominetti, and Shapiro [8] showed that $\Pi_{\mathcal{S}^n_+}(\cdot)$ is directionally differentiable everywhere in $\mathcal{S}^n$. For any $H \in \mathcal{S}^n$, D. Sun and J. Sun [47] gave the following explicit

formula for $\Pi'_{\mathcal{S}^n_+}(A;H)$:

$$\Pi'_{\mathcal{S}^n_+}(A;H) = P \begin{bmatrix} P_1^T H P_1 & P_1^T H P_2 & U \circ P_1^T H P_3 \\ P_2^T H P_1 & \Pi_{\mathcal{S}^{k_2}_+}\left(P_2^T H P_2\right) & 0 \\ P_3^T H P_1 \circ U^T & 0 & 0 \end{bmatrix} P^T, \tag{2.22}$$

where $\circ$ denotes the Hadamard product. More importantly, Sun and Sun proved that $\Pi_{\mathcal{S}^n_+}$ is a strongly semismooth matrix-valued function [47]. When A is nonsingular, i.e., $k_2 = 0$, $\Pi_{\mathcal{S}^n_+}(\cdot)$ is continuously differentiable around A, and the formula (2.22) reduces to the classical result of Löwner [28]. See Donoghue [16] and Bhatia [7] for detailed discussions on the latter and Chen, Qi, and Tseng [11] for a generalization.

From (2.13) and (2.22), one can obtain Arnold's well-known characterization of the tangent cone of $\mathcal{S}^n_+$ at A_+ [2],

$$\begin{aligned} \mathcal{T}_{\mathcal{S}^n_+}(A_+) &= \{B \in \mathcal{S}^n \,:\, B = \Pi'_{\mathcal{S}^n_+}(A_+;B)\} \\ &= \left\{B \in \mathcal{S}^n \,:\, \begin{bmatrix} P_2 & P_3 \end{bmatrix}^T B \begin{bmatrix} P_2 & P_3 \end{bmatrix} \succeq 0\right\}, \end{aligned}$$

and its lineality space,

$$\operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(A_+)\right) = \left\{B \in \mathcal{S}^n \,:\, \begin{bmatrix} P_2 & P_3 \end{bmatrix}^T B \begin{bmatrix} P_2 & P_3 \end{bmatrix} = 0\right\}. \tag{2.23}$$

Let $\Phi(\cdot) := \Pi'_{\mathcal{S}^n_+}(A;\cdot)$. It is proved in [35, Lemma 11] that

$$\partial_B \Pi_{\mathcal{S}^n_+}(A) = \partial_B \Phi(0) \tag{2.24}$$

and that the operator $W : \mathcal{S}^n \to \mathcal{S}^n$ defined by

$$W(H) = P \begin{bmatrix} P_1^T H P_1 & P_1^T H P_2 & U \circ P_1^T H P_3 \\ P_2^T H P_1 & 0 & 0 \\ P_3^T H P_1 \circ U^T & 0 & 0 \end{bmatrix} P^T \quad \forall\, H \in \mathcal{S}^n \tag{2.25}$$

is an element in $\partial_B \Pi_{\mathcal{S}^n_+}(A)$.

The next proposition shows that $\Pi_{\mathcal{S}^n_+}(\cdot)$ is Jacobian amicable at A.

PROPOSITION 2.10. *The projection operator $\Pi_{\mathcal{S}^n_+}(\cdot)$ is Jacobian amicable everywhere in $\mathcal{S}^n$.*

Proof. Let $A \in \mathcal{S}^n$ admit the spectral decomposition (2.21). Let $W \in \partial\Pi_{\mathcal{S}^n_+}(A)$ and $H \in \mathcal{S}^n$ be such that $W(H) = 0$. Then from (2.22), (2.24), and the definition of the matrix U, we obtain

$$P_1^T H P_1 = 0, \quad P_1^T H P_2 = 0, \quad \text{and} \quad P_1^T H P_3 = 0,$$

which, together with (2.23), implies

$$H \in \left(\operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(A_+)\right)\right)^{\perp}.$$

Since A is chosen arbitrarily, we know from the definition that $\Pi_{\mathcal{S}^n_+}(\cdot)$ is Jacobian amicable everywhere in $\mathcal{S}^n$. ∎

3. Dual reformulations. In this section, we will consider the dual problem of the IQEP, i.e., problem (1.6). As mentioned in section 1, we need only focus on the IQEP under Assumption 1.2, i.e., Λ is nonsingular. Denote

$$M := \begin{bmatrix} M_1 & M_2 \\ M_2^T & M_4 \end{bmatrix}, \quad C := \begin{bmatrix} C_1 & C_2 \\ C_2^T & C_4 \end{bmatrix}, \quad K := \begin{bmatrix} K_1 & K_2 \\ K_2^T & K_4 \end{bmatrix},$$

where $M_1, C_1, K_1 \in \mathcal{S}^k$, $M_2, C_2, K_2 \in \mathbb{R}^{k\times(n-k)}$, and $M_4, C_4, K_4 \in \mathcal{S}^{(n-k)}$. Let $S := R\Lambda R^{-1}$. Then problem (1.6) can be written equivalently as

$$\begin{array}{ll} \min & \frac{1}{2}\|M - M_a\|^2 + \frac{1}{2}\|C - C_a\|^2 + \frac{1}{2}\|K - K_a\|^2 \\ \text{s.t.} & \frac{1}{\sqrt{c_1}}(\Lambda^2)^T(R^T M_1 R) + \frac{1}{\sqrt{c_2}}\Lambda^T(R^T C_1 R) + (R^T K_1 R) = 0, \\ & \frac{1}{\sqrt{c_1}}(S^2)^T M_2 + \frac{1}{\sqrt{c_2}}S^T C_2 + K_2 = 0, \\ & (M, C, K) \in \Omega. \end{array} \tag{3.1}$$

Let Ω_0 be equipped with the natural inner product

$$\left\langle (M, C, K), (\widetilde{M}, \widetilde{C}, \widetilde{K}) \right\rangle := \langle M, \widetilde{M}\rangle + \langle C, \widetilde{C}\rangle + \langle K, \widetilde{K}\rangle, \quad (M, C, K), (\widetilde{M}, \widetilde{C}, \widetilde{K}) \in \Omega_0,$$

and its induced norm $\|\cdot\|$. Define

$$\begin{aligned} &\mathcal{H}(M, C, K) \\ &:= \frac{1}{\sqrt{c_1}}(\Lambda^2)^T\left(R^T M_1 R\right) + \frac{1}{\sqrt{c_2}}\Lambda^T\left(R^T C_1 R\right) + \left(R^T K_1 R\right), \quad (M, C, K) \in \Omega_0, \end{aligned} \tag{3.2}$$

$$\mathcal{G}(M, C, K) := \frac{1}{\sqrt{c_1}}(S^2)^T M_2 + \frac{1}{\sqrt{c_2}}S^T C_2 + K_2, \quad (M, C, K) \in \Omega_0, \tag{3.3}$$

and

$$\mathcal{A}(M, C, K) := (\mathcal{H}(M, C, K), \mathcal{G}(M, C, K)), \quad (M, C, K) \in \Omega_0. \tag{3.4}$$

Then, problem (3.1), which is a special case of problem (2.1), becomes

$$\begin{array}{ll} \min & \frac{1}{2}\|(M, C, K) - (M_a, C_a, K_a)\|^2 \\ \text{s.t.} & \mathcal{A}(M, C, K) = 0, \\ & (M, C, K) \in \Omega. \end{array} \tag{3.5}$$

Let

$$\mathcal{R}(\mathcal{H}) := \{\mathcal{H}(M, C, K) \,:\, (M, C, K) \in \Omega_0\}. \tag{3.6}$$

Obviously, the linear operator $\mathcal{H} : \Omega_0 \to \mathcal{R}(\mathcal{H})$ defined in (3.2) is surjective. The adjoint $\mathcal{H}^* : \mathcal{R}(\mathcal{H}) \to \Omega_0$ of $\mathcal{H}$ is given by

$$\mathcal{H}^*(Y) := (\mathcal{H}_1^*(Y), \mathcal{H}_2^*(Y), \mathcal{H}_3^*(Y)), \quad Y \in \mathcal{R}(\mathcal{H}), \tag{3.7}$$

where for each $Y \in \mathcal{R}(\mathcal{H})$,

$$\mathcal{H}_1^*(Y) = \frac{1}{2\sqrt{c_1}} \begin{bmatrix} R\Lambda^2 Y R^T + (R\Lambda^2 Y R^T)^T & 0 \\ 0 & 0 \end{bmatrix},$$
$$\mathcal{H}_2^*(Y) = \frac{1}{2\sqrt{c_2}} \begin{bmatrix} R\Lambda Y R^T + (R\Lambda Y R^T)^T & 0 \\ 0 & 0 \end{bmatrix},$$
$$\mathcal{H}_3^*(Y) = \frac{1}{2} \begin{bmatrix} RYR^T + (RYR^T)^T & 0 \\ 0 & 0 \end{bmatrix}.$$

Similarly, $\mathcal{G} : \Omega_0 \to \mathbb{R}^{k\times(n-k)}$ defined in (3.3) is also surjective, and its adjoint $\mathcal{G}^* : \mathbb{R}^{k\times(n-k)} \to \Omega_0$ is given by

$$\mathcal{G}^*(Z) := (\mathcal{G}_1^*(Z), \mathcal{G}_2^*(Z), \mathcal{G}_3^*(Z)), \tag{3.8}$$

where for each $Z \in \mathbb{R}^{k\times(n-k)}$,

$$\mathcal{G}_1^*(Z) = \frac{1}{2\sqrt{c_1}} \begin{bmatrix} 0 & S^2 Z \\ (S^2 Z)^T & 0 \end{bmatrix},$$
$$\mathcal{G}_2^*(Z) = \frac{1}{2\sqrt{c_2}} \begin{bmatrix} 0 & SZ \\ (SZ)^T & 0 \end{bmatrix},$$
$$\mathcal{G}_3^*(Z) = \frac{1}{2} \begin{bmatrix} 0 & Z \\ Z^T & 0 \end{bmatrix}.$$

Since both $\mathcal{H} : \Omega_0 \to \mathcal{R}(\mathcal{H})$ and $\mathcal{G} : \Omega_0 \to \mathbb{R}^{k\times(n-k)}$ are surjective, the linear operator $\mathcal{A} : \Omega_0 \to \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$ defined by (3.4) is also surjective. The adjoint $\mathcal{A}^* : \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)} \to \Omega_0$ of $\mathcal{A}$ takes the following form:

$$\begin{aligned} \mathcal{A}^*(Y,Z) &:= (\mathcal{A}_1^*(Y,Z), \mathcal{A}_2^*(Y,Z), \mathcal{A}_3^*(Y,Z)) \\ &= \mathcal{H}^*(Y) + \mathcal{G}^*(Z), \quad (Y,Z) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}, \end{aligned} \tag{3.9}$$

where for each $(Y,Z) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$, $\mathcal{H}^*(Y)$ and $\mathcal{G}^*(Z)$ are defined by (3.7) and (3.8), respectively. Define $\theta : \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)} \to \mathbb{R}$ by

$$\theta(Y,Z) := \frac{1}{2}\|\Pi_\Omega((M_a, C_a, K_a) + \mathcal{A}^*(Y,Z))\|^2 - \frac{1}{2}\|(M_a, C_a, K_a)\|^2. \tag{3.10}$$

By (2.6) and (2.7), the dual of problem (3.5) is

$$\begin{aligned} &\min \quad \theta(Y,Z) \\ &\text{s.t.} \quad (Y,Z) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}. \end{aligned} \tag{3.11}$$

Since Λ is nonsingular, by Theorem 1.1, problem (1.6), or, equivalently, problem (3.5), admits a strictly feasible solution; i.e., there exists a triplet $(\widehat{M}, \widehat{C}, \widehat{K}) \in \Omega_0$ such that $\mathcal{A}(\widehat{M}, \widehat{C}, \widehat{K}) = 0$ and $(\widehat{M}, \widehat{C}, \widehat{K}) \in \operatorname{int}(\Omega)$. Moreover, the linear operator $\mathcal{A} : \Omega_0 \to \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$ defined by problem (3.5) is surjective. Thus, for the convex optimization problem (3.5), the generalized Slater condition (2.4) is satisfied. Consequently, the following result follows directly from Proposition 2.1.

PROPOSITION 3.1. *There exists at least one pair* $(\overline{Y}, \overline{Z}) \in \mathbb{R}^{k\times k} \times \mathbb{R}^{k\times(n-k)}$ *that solves the dual problem* (3.11). *The unique solution to the original problem* (1.6) *is given by*

$$(\overline{M}, \overline{C}, \overline{K}) = \Pi_\Omega\left((M_a, C_a, K_a) + \mathcal{A}^*(\overline{Y}, \overline{Z})\right).$$

Furthermore, for every real number τ, the level set

$$\{(Y,Z)\in\mathbb{R}^{k\times k}\times\mathbb{R}^{k\times(n-k)}:\ \theta(Y,Z)\le\tau\}$$

is closed, bounded, and convex.

It is clear from Proposition 3.1 that we need only find a solution of the dual problem (3.11) in order to obtain the unique solution of the original problem (1.6).

Remark 3.2. The operator $\mathcal{H}$ defined above is not necessarily surjective from Ω_0 to $\mathbb{R}^{k\times k}$. To see this, we refer the reader to Proposition A.1 in Appendix A.

Next, we discuss the following simplified version of the IQEP:

$$\begin{aligned}\min\quad & \frac{1}{2}\|(M,C,K)-(M_a,C_a,K_a)\|^2\\ \text{s.t.}\quad & \mathcal{A}(M,C,K)=0,\\ & (M,C,K)\in\Omega_0,\end{aligned}\tag{3.12}$$

which admits an explicit optimal solution and has been considered by many authors; for example, see [14, 19]. The dual of problem (3.12) is

$$\begin{aligned}\min\quad & \theta_0(Y,Z)\\ \text{s.t.}\quad & (Y,Z)\in\mathcal{R}(\mathcal{H})\times\mathbb{R}^{k\times(n-k)},\end{aligned}\tag{3.13}$$

where $\theta_0:\mathcal{R}(\mathcal{H})\times\mathbb{R}^{k\times(n-k)}\to\mathbb{R}$ is defined by

$$\theta_0(Y,Z):=\frac{1}{2}\|\Pi_{\Omega_0}((M_a,C_a,K_a)+\mathcal{A}^*(Y,Z))\|^2-\frac{1}{2}\|(M_a,C_a,K_a)\|^2.$$

Let $(Y^0,Z^0)\in\mathcal{R}(\mathcal{H})\times\mathbb{R}^{k\times(n-k)}$ be a solution to the dual problem (3.13). By section 2, the solution (M^0,C^0,K^0) to problem (3.12) is given by

$$(M^0,C^0,K^0)=\Pi_{\Omega_0}((M_a,C_a,K_a)+\mathcal{A}^*(Y^0,Z^0))=(M_a,C_a,K_a)+\mathcal{A}^*(Y^0,Z^0).\tag{3.14}$$

Although (Y^0,Z^0) may not be a solution to the dual problem (3.11) as M^0 and K^0 above may fail to be positive semidefinite, it may be a good guess at the solution of problem (3.11). Hence, we will use it as the starting point to our Newton method to be proposed in the next section.

Now we discuss the computation of (Y^0,Z^0) based on (3.13). Since $(Y^0,Z^0)\in\mathcal{R}(\mathcal{H})\times\mathbb{R}^{k\times(n-k)}$ satisfies

$$\nabla\theta_0(Y^0,Z^0)=\mathcal{A}\left((M_a,C_a,K_a)+\mathcal{A}^*(Y^0,Z^0)\right)=0,$$

thus, by (3.4), $(Y^0,Z^0)\in\mathcal{R}(\mathcal{H})\times\mathbb{R}^{k\times(n-k)}$ is a solution of

$$\left(\mathcal{H}\left((M_a,C_a,K_a)+\mathcal{A}^*(Y,Z)\right),\mathcal{G}\left((M_a,C_a,K_a)+\mathcal{A}^*(Y,Z)\right)\right)=0.\tag{3.15}$$

Therefore, we can obtain (Y^0,Z^0) by solving (3.15). Since the linear operator $\mathcal{A}:\Omega_0\to\mathcal{R}(\mathcal{H})\times\mathbb{R}^{k\times(n-k)}$ defined by (3.4) is surjective, $\mathcal{A}\mathcal{A}^*$ is self-adjoint and positive definite. This implies that (Y^0,Z^0) is the unique solution to (3.15).

By (3.7), (3.8), and (3.9), we obtain that for any $(Y,Z)\in\mathcal{R}(\mathcal{H})\times\mathbb{R}^{k\times(n-k)}$,

$$\begin{aligned}&\mathcal{H}((M_a,C_a,K_a)+\mathcal{A}^*(Y,Z))=\mathcal{H}(M_a,C_a,K_a)+\mathcal{H}(\mathcal{H}^*(Y))\\ &\quad=\mathcal{H}(M_a,C_a,K_a)+U_1YR^TR\\ &\qquad+\frac{1}{2}\left(\frac{1}{c_1}(\Lambda^2)^TR^TRY^T(\Lambda^2)^TR^TR+\frac{1}{c_2}\Lambda^TR^TRY^T\Lambda^TR^TR+R^TRY^TR^TR\right)\end{aligned}$$

and

$$\mathcal{G}((M_a, C_a, K_a) + \mathcal{A}^*(Y, Z)) = \mathcal{G}(M_a, C_a, K_a) + \mathcal{G}(\mathcal{G}^*(Z)) = \mathcal{G}(M_a, C_a, K_a) + U_2 Z,$$

where

$$U_1 := \frac{1}{2}\left(\frac{1}{c_1}(\Lambda^2)^T R^T R \Lambda^2 + \frac{1}{c_2}\Lambda^T R^T R \Lambda + R^T R\right) \tag{3.16}$$

and

$$U_2 := \frac{1}{2}\left(\frac{1}{c_1}(S^2)^T S^2 + \frac{1}{c_2} S^T S + I\right). \tag{3.17}$$

Since the linear operator $\mathcal{H} : \Omega_0 \to \mathcal{R}(\mathcal{H})$ defined by (3.2) is surjective, $\mathcal{H}\mathcal{H}^*$ is self-adjoint and positive definite. So we may use the conjugate gradient (CG) method[1] [20, Algorithm 10.2.1] to solve the first equation of (3.15), i.e.,

(3.18)
$$-\mathcal{H}(M_a, C_a, K_a) = \mathcal{H}(\mathcal{H}^*(Y))$$
$$= U_1 Y R^T R + \frac{1}{2}\left(\frac{1}{c_1}(\Lambda^2)^T R^T R Y^T (\Lambda^2)^T R^T R + \frac{1}{c_2}\Lambda^T R^T R Y^T \Lambda^T R^T R + R^T R Y^T R^T R\right),$$

to get $Y^0 \in \mathcal{R}(\mathcal{H})$. The required total computational cost of computing Y^0 is $O(k^5)$ flops (the CG method needs at most k^2 steps with each step costing $O(k^3)$ flops). The solution to the second equation of (3.15), i.e,

$$-\mathcal{G}(M_a, C_a, K_a) = \mathcal{G}(\mathcal{G}^*(Z)) = U_2 Z,$$

is given explicitly by

$$Z^0 = -U_2^{-1}\mathcal{G}(M_a, C_a, K_a).$$

We need $O(nk^2)$ flops to compute Z^0. The optimal solution to problem (3.12) can then be obtained via (3.14).

Remark 3.3. The above arguments imply that if we drop the positive semidefiniteness requirement on M and K, we can obtain the solution to problem (3.12) with a total cost of $O(nk^2 + k^5)$. This cost amount is small as in practice $k \ll n$. It is noted that in our approach the presence of the weighting parameters c_1 and c_2 presents no difficulty at all.

4. Algorithm and convergence analysis. In this section, we shall first present a globalized version of Clarke's Jacobian-based Newton method (2.16) for solving the dual problem (3.11) with $\theta : \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)} \to \mathbb{R}$ being defined by (3.10).

Let $F : \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)} \to \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$ be defined by

$$F(Y, Z) = \nabla\theta(Y, Z) = \mathcal{A}\,\Pi_\Omega\left((M_a, C_a, K_a) + \mathcal{A}^*(Y, Z)\right), \quad (Y, Z) \in \mathcal{R}(\mathcal{H})\times\mathbb{R}^{k\times(n-k)},$$

where $\mathcal{A} : \Omega_0 \to \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$ is defined by (3.4) and $\mathcal{A}^*$ is the adjoint of $\mathcal{A}$.

[1]Strictly speaking, we should apply the CG method to the equivalent equation form $Ax = b$ of (3.18), where $A \in \mathcal{S}^m$ is positive definite, $b \in \mathbb{R}^m$, and m is the dimension of $\mathcal{R}(\mathcal{H})$. In the implementation of CG methods there is no need to form A and b explicitly. One may also consider the preconditioned CG method to solve (3.18). However, caution should be taken as the preconditioned CG method may not guarantee that the generated matrices Y stay in $\mathcal{R}(\mathcal{H})$.

ALGORITHM 4.1 (Newton method).

Step 0. Given $(Y^0, Z^0) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$, $\eta \in (0,1)$, $\rho, \delta \in (0, 1/2)$. $j := 0$.

Step 1. Select an element $W_j \in \partial\Pi_\Omega\left((M_a, C_a, K_a) + \mathcal{A}^*(Y^j, Z^j)\right)$ and let $V_j := \mathcal{A}W_j\mathcal{A}^*$. Apply the conjugate gradient method [20, Algorithm 10.2.1] to find an approximate solution $(\Delta Y^j, \Delta Z^j) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$ to

$$F(Y^j, Z^j) + V_j(\Delta Y, \Delta Z) = 0 \tag{4.1}$$

such that

$$\|F(Y^j, Z^j) + V_j(\Delta Y^j, \Delta Z^j)\| \le \eta_j \|F(Y^j, Z^j)\| \tag{4.2}$$

and

$$\left\langle F(Y^j, Z^j), (\Delta Y^j, \Delta Z^j)\right\rangle \le -\eta_j \left\langle (\Delta Y^j, \Delta Z^j), (\Delta Y^j, \Delta Z^j)\right\rangle, \tag{4.3}$$

where $\eta_j := \min\{\eta, \|F(Y^j, Z^j)\|\}$. If (4.2) and (4.3) are not achievable, let

$$(\Delta Y^j, \Delta Z^j) := -F(Y^j, Z^j) = -\mathcal{A}\,\Pi_\Omega\left((M_a, C_a, K_a) + \mathcal{A}^*(Y^j, Z^j)\right).$$

Step 2. Let m_j be the smallest nonnegative integer m such that

$$\theta\left((Y^j, Z^j) + \rho^m(\Delta Y^j, \Delta Z^j)\right) - \theta(Y^j, Z^j) \le \delta\rho^m \left\langle F(Y^j, Z^j), (\Delta Y^j, \Delta Z^j)\right\rangle.$$

Set

$$(Y^{j+1}, Z^{j+1}) := (Y^j, Z^j) + \rho^{m_j}(\Delta Y^j, \Delta Z^j).$$

Step 3. Replace j by $j+1$ and go to Step 1.

Next we make several comments on the above algorithm before we present our convergence analysis.

- *The starting point.* One may choose an arbitrary starting point (Y^0, Z^0) as long as $(Y^0, Z^0) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$. In numerical computation, we recommend choosing the solution to (3.15) as (Y^0, Z^0).
- *The generalized Jacobian.* In Step 1 of Algorithm 4.1, we need to select an element

$$W_j \in \partial\Pi_\Omega\left((M_a, C_a, K_a) + \mathcal{A}^*(Y^j, Z^j)\right)$$

at the jth iteration. This can be computed according to (2.25) once the spectral decompositions of $M_a + \mathcal{A}_1^*(Y^j, Z^j)$ and $K_a + \mathcal{A}_3^*(Y^j, Z^j)$ are available.
- *The conjugate gradient method.* In Step 1 of Algorithm 4.1, if we apply the CG method [20, Algorithm 10.2.1] to (4.1), we can always keep $(\Delta Y^j, \Delta Z^j) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$ when the initial guess is in $\mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$. One may also consider the preconditioned CG method to solve (3.18) as long as the preconditioned CG method can guarantee that $(\Delta Y^j, \Delta Z^j) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$.

The next theorem is our global convergence result.

THEOREM 4.2. *For any $(Y^0, Z^0) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$, Algorithm 4.1 generates an infinite sequence $\{(Y^j, Z^j)\}$ with the properties that for each $j \ge 0$, $(Y^j, Z^j) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$, $\{(Y^j, Z^j)\}$ is bounded, and any accumulation point of $\{(Y^j, Z^j)\}$ is a solution to problem (3.11).*

Proof. Since, by Step 1 of Algorithm 4.1, for any $j \geq 0$, $(\Delta Y^j, \Delta Z^j)$ is always a descent direction of $\theta(\cdot)$ at (Y^j, Z^j) and $(\Delta Y^j, \Delta Z^j) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$, Algorithm 4.1 is well defined. Then an infinite sequence $\{(Y^j, Z^j)\}$ is generated and for each $j \geq 0$, $(Y^j, Z^j) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$.

From Theorem 1.1 we know that problem (3.1) has a strictly feasible solution. This, together with the surjectivity of $\mathcal{A} : \Omega_0 \to \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$, implies that the generalized Slater condition (2.4) holds for problem (3.1). Thus, by Proposition 3.1, the level set

$$\{(Y, Z) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)} \,:\, \theta(Y, Z) \leq \theta(Y^0, Z^0)\}$$

is bounded. Therefore, the sequence $\{(Y^j, Z^j)\}$ is bounded. Furthermore, by employing standard convergence analysis of optimization methods (cf. [15, Theorem 6.3.3]), we can conclude that

$$\lim_{j\to\infty} \nabla\theta(Y^j, Z^j) = 0,$$

which, together with the convexity of $\theta(\cdot)$ and the boundedness of $\{(Y^j, Z^j)\}$, implies that any accumulation point of $\{(Y^j, Z^j)\}$ is a solution to (3.11). ∎

Theorem 4.2 shows that our algorithm converges globally. For discussions on the rate of convergence, we need the constraint nondegenerate condition (2.15) at the solution $(\overline{M}, \overline{C}, \overline{K})$ of problem (1.6). In our case, this condition can be written as

$$\mathcal{A}\left(\operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{M})\right), \mathcal{S}^n, \operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{K})\right)\right) = \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}. \tag{4.4}$$

PROPOSITION 4.3. *Condition* (4.4) *holds if the solution* $(\overline{M}, \overline{C}, \overline{K}) \in \Omega_0$ *to problem* (1.6) *satisfies* $\overline{K} \succ 0$ *or* $\overline{M} \succ 0$.

Proof. Since

$$\operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{K})\right) = \mathcal{S}^n \qquad \text{if } \overline{K} \succ 0,$$
$$\operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{M})\right) = \mathcal{S}^n \qquad \text{if } \overline{M} \succ 0,$$

the proof of Proposition A.1 in Appendix A gives that

$$\mathcal{H}\left(\operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{M})\right), \mathcal{S}^n, \mathcal{S}^n\right) = \mathcal{R}(\mathcal{H})$$

and

$$\mathcal{G}\left(\operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{M})\right), \mathcal{S}^n, \mathcal{S}^n\right) = \mathbb{R}^{k\times(n-k)},$$

and a similar discussion also yields that

$$\mathcal{H}\left(\mathcal{S}^n, \mathcal{S}^n, \operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{K})\right)\right) = \mathcal{R}(\mathcal{H})$$

and

$$\mathcal{G}\left(\mathcal{S}^n, \mathcal{S}^n, \operatorname{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{M})\right)\right) = \mathbb{R}^{k\times(n-k)},$$

Proposition 4.3 follows readily. ∎

Another interesting special case that guarantees condition (4.4) is $\Lambda = \tau I$ for some $\tau \neq 0$. This can be seen easily because in this case, for the solution $(\overline{M}, \overline{C}, \overline{K})$ to problem (1.6), we have

$$\mathcal{H}\left(\mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{M})\right), \mathcal{S}^n, \mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{K})\right)\right) = \mathcal{S}^k = \mathcal{R}(\mathcal{H})$$

and

$$\mathcal{G}\left(\mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{M})\right), \mathcal{S}^n, \mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{K})\right)\right) = \mathbb{R}^{k\times(n-k)} = \mathcal{R}(\mathcal{G}),$$

where $\mathcal{R}(\mathcal{G})$ denotes the range of the linear operator $\mathcal{G} : \Omega_0 \to \mathbb{R}^{k\times(n-k)}$ defined by (3.3).

We are now ready to show the quadratic convergence of Algorithm 4.1.

THEOREM 4.4. *Let $(\overline{Y}, \overline{Z})$ be an accumulation point of the infinite sequence $\{(Y^j, Z^j)\}$ generated by Algorithm* 4.1 *for solving the dual problem* (3.11). *Then let $(\overline{M}, \overline{C}, \overline{K})$ be the solution to problem* (1.6). *Assume that the constraint nondegenerate condition* (4.4) *holds at $(\overline{M}, \overline{C}, \overline{K})$. Then the whole sequence $\{(Y^j, Z^j)\}$ converges to $(\overline{Y}, \overline{Z})$ quadratically.*

Proof. By Proposition 3.1, we know

$$(\overline{M}, \overline{C}, \overline{K}) := \Pi_\Omega\left((M_a, C_a, K_a) + \mathcal{A}^*(\overline{Y}, \overline{Z})\right).$$

By Theorem 4.2, the whole sequence $\{(Y^j, Z^j)\}$ is bounded and $(\overline{Y}, \overline{Z})$ is a solution of the dual problem (3.11) such that

$$F(\overline{Y}, \overline{Z}) = \nabla\theta(\overline{Y}, \overline{Z}) = 0.$$

From the constraint nondegenerate condition (4.4) and Propositions 2.8 and 2.10, we know that any element $V := \mathcal{A}W\mathcal{A}^*$ with $W \in \partial\Pi_\Omega(\overline{M}, \overline{C}, \overline{K}))$ is self-adjoint and positive definite. Then, by Proposition 2.4, any element in $\partial F(\overline{Y}, \overline{Z})$ is also positive definite. This, together with the convexity of θ, implies that $(\overline{Y}, \overline{Z})$ is the unique solution of (3.11). Consequently, by Theorem 4.2, the whole sequence $\{(Y^j, Z^j)\}$ converges to $(\overline{Y}, \overline{Z})$. Thus, for all j sufficiently large, V_j is positive definite and $\{\|V_j^{-1}\|\}$ is uniformly bounded. Hence, for all j sufficiently large, the CG method can find $(\Delta Y^j, \Delta Z^j) \in \mathcal{R}(\mathcal{H}) \times \mathbb{R}^{k\times(n-k)}$ such that both (4.2) and (4.3) are satisfied. Then, by Propositions 2.9 and 2.10, for all j sufficiently large,

(4.5)
$$\begin{aligned}\|(Y^j, Z^j) + (\Delta Y^j, \Delta Z^j) - (\overline{Y}, \overline{Z})\| &\le O(\|(Y^j, Z^j) - (\overline{Y}, \overline{Z})\|^2) + \eta_j\|V_j^{-1}\|\|F(Y^j, Z^j)\| \\ &= O(\|(Y^j, Z^j) - (\overline{Y}, \overline{Z})\|^2) + O(\|F(Y^j, Z^j)\|^2) \\ &= O(\|(Y^j, Z^j) - (\overline{Y}, \overline{Z})\|^2),\end{aligned}$$

where in the last inequality the global Lipschitz continuity of F was used. By using (4.5) and the fact that $\{(Y^j, Z^j)\}$ converges to $(\overline{Y}, \overline{Z})$, we have for all j sufficiently large that

$$(Y^j, Z^j) - (\overline{Y}, \overline{Z}) = -(\Delta Y^j, \Delta Z^j) + O(\|(\Delta Y^j, \Delta Z^j)\|^2) \text{ and } (\Delta Y^j, \Delta Z^j) \to 0. \tag{4.6}$$

For each $j \ge 0$, let

$$r_j := F(Y^j, Z^j) + V_j(\Delta Y^j, \Delta Z^j).$$

Then for all j sufficiently large,

$$
\begin{aligned}
&-\left\langle F(Y^j,Z^j),(\Delta Y^j,\Delta Z^j)\right\rangle\\
&=\left\langle(\Delta Y^j,\Delta Z^j),V_j(\Delta Y^j,\Delta Z^j)\right\rangle-\left\langle(\Delta Y^j,\Delta Z^j),r_j\right\rangle\\
&\geq\left\langle(\Delta Y^j,\Delta Z^j),V_j(\Delta Y^j,\Delta Z^j)\right\rangle-\|(\Delta Y^j,\Delta Z^j)\|\|r_j\|\\
&\geq\left\langle(\Delta Y^j,\Delta Z^j),V_j(\Delta Y^j,\Delta Z^j)\right\rangle-\eta_j\|(\Delta Y^j,\Delta Z^j)\|\|F(Y^j,Z^j)\|\\
&\geq\left\langle(\Delta Y^j,\Delta Z^j),V_j(\Delta Y^j,\Delta Z^j)\right\rangle-\|(\Delta Y^j,\Delta Z^j)\|\|F(Y^j,Z^j)\|^2\\
&=\left\langle(\Delta Y^j,\Delta Z^j),V_j(\Delta Y^j,\Delta Z^j)\right\rangle-\|(\Delta Y^j,\Delta Z^j)\|\|F(Y^j,Z^j)-F(\overline{Y},\overline{Z})\|^2\\
&\geq\left\langle(\Delta Y^j,\Delta Z^j),V_j(\Delta Y^j,\Delta Z^j)\right\rangle-\|(\Delta Y^j,\Delta Z^j)\|\|\mathcal{A}\|^2\|\mathcal{A}^*\|^2\|(Y^j,Z^j)-(\overline{Y},\overline{Z})\|^2,
\end{aligned}
$$

which, together with (4.6) and the uniform positive definiteness of V_j, implies that there exists a positive constant $\hat{\rho}>0$ such that for all j sufficiently large we have

$$-\left\langle F(Y^j,Z^j),(\Delta Y^j,\Delta Z^j)\right\rangle\geq\hat{\rho}\|(\Delta Y^j,\Delta Z^j)\|^2.$$

Then, since F is strongly semismooth at $(\overline{Y},\overline{Z})$ as $\Pi_{\mathcal{S}^n_+}(\cdot)$ is strongly semismooth [47], we know from [17, Theorem 3.3 and Remark 3.4] that for all j sufficiently large,

$$\theta\left((Y^j,Z^j)+(\Delta Y^j,\Delta Z^j)\right)-\theta(Y^j,Z^j)\leq\delta\left\langle F(Y^j,Z^j),(\Delta Y^j,\Delta Z^j)\right\rangle,$$

which implies that for all j sufficiently large,

$$(Y^{j+1},Z^{j+1})=(Y^j,Z^j)+(\Delta Y^j,\Delta Z^j).$$

This, together with (4.5), completes the proof. □

Theorems 4.2 and 4.4 present global and local convergence analysis of Algorithm 4.1 for solving the IQEP under Assumption 1.2. In fact, our algorithm can also be used to solve the IQEP of general matrix weights even if Assumption 1.2 fails to hold. Without giving details, we briefly outline the way of doing so in Appendix B.

5. Numerical experiments. In this section, we report our numerical experiments of Algorithm 4.1 for solving the IQEP (1.6) carried out in `MATLAB 7.0.1` running on a PC Intel Pentium IV of 2.40 GHz CPU. In both of the following two numerical examples, we randomly generate $\Lambda\in\mathbb{R}^{k\times k}$ by using the built-in function `randn` in `MATLAB 7.0.1`. The total number of complex-valued eigenvalues is chosen to be around $k/2$. The matrix $R\in\mathbb{R}^{k\times k}$ is obtained by applying the QR factorization to a random generated $n\times k$ matrix X by using `randn`.

Example 5.1. Let $\widehat{M}$, $\widehat{C}$, and $\widehat{K}$ be given by (1.7). Set

$$M_a:=\widehat{M}+\tau R_M,\quad C_a:=\widehat{C}+\tau R_C,\quad K_a:=\widehat{K}+\tau R_K,$$

where R_M, R_C, and R_K are $n\times n$ symmetric matrices with random entries uniformly distributed between -1.0 and 1.0, and $\tau\in\mathbb{R}$ is a perturbed parameter. We report our numerical results for (a) $k=30$, $n=100,200,500,1000,1500,2000$, and $\tau=0.1,1.0$ and (b) $k\approx n/3$, $n=100,200,300,400,450$, and $\tau=0.1,1.0$.

Example 5.2. The matrices G_M and G_K are random $n\times n$ correlation matrices generated by `MATLAB 7.0.1`'s `gallery ('randcorr',n)`, and the matrix G_C is a random $n\times n$ symmetric matrix with entries $(G_C)_{ij}\in[-1,1]$ and $(G_C)_{ii}=1.0$ for $i,j=1,2,\ldots,n$. Then M_a, C_a, and K_a are, respectively, obtained via perturbing $\sqrt{c_1}G_M$, $\sqrt{c_2}G_C$, and G_K by a random $n\times n$ symmetric matrix with entries in $[-\tau,\tau]$, where $\tau=0.1,1.0$. We report our numerical results for (a) $k=30$,

$n = 100, 200, 500, 1000, 1500, 2000$, and $\tau = 0.1, 1.0$ and (b) $k \approx n/3$, $n = 100, 200, 300, 400, 450$, and $\tau = 0.1, 1.0$.

In our numerical experiments, the initial point (Y^0, Z^0) is chosen to be the solution to (3.15), and the stopping criterion is

$$\texttt{Tol.} := \frac{\|\nabla\theta(Y_k, Z_k)\|}{\max\left\{1, \left\|\left(\frac{1}{\sqrt{c_1}}M_a, \frac{1}{\sqrt{c_2}}C_a, K_a\right)\right\|\right\}} \le 10^{-7}.$$

We set other parameters used in our algorithm as $\eta = 10^{-6}$, $\rho = 0.5$, and $\delta = 10^{-4}$. Our numerical results are given in Tables 1–4, where `It.`, `Func.`, `Res0.`, and `Res*.` stand for the number of iterations, the number of function evaluations, and the residuals $\|\nabla\theta(\cdot)\|$ at the starting point (Y^0, Z^0) and at the final iterate of our algorithm (the largest number of iterations in CG is set to be $\max(5000, nk)$), respectively. In Algorithm 4.1, the major cost at the jth iteration is solving the linear system (4.1), i.e.,

$$\begin{pmatrix} \mathcal{H}\left(\Pi_\Omega((M_a, C_a, K_a) + \mathcal{A}^*(Y^j, Z^j)) + W_j\mathcal{A}^*(\Delta Y^j, \Delta Z^j)\right) \\ \mathcal{G}\left(\Pi_\Omega((M_a, C_a, K_a) + \mathcal{A}^*(Y^j, Z^j)) + W_j\mathcal{A}^*(\Delta Y^j, \Delta Z^j)\right) \end{pmatrix} = 0,$$

where $W_j \in \partial\Pi_\Omega\left((M_a, C_a, K_a) + \mathcal{A}^*(Y^j, Z^j)\right)$. For better numerical performance, instead of solving the above linear system directly, we apply the CG method to the following preconditioned linear system [45, Chapter 9]:

TABLE 2
Numerical results of Example 5.1(b).

$$\begin{pmatrix} U_1^{-1}\mathcal{H}\left(\Pi_\Omega((M_a, C_a, K_a) + \mathcal{A}^*(Y^j, Z^j)) + W_j\mathcal{A}^*(\Delta Y^j, \Delta Z^j)\right)(R^T R)^{-1} \\ U_2^{-1}\mathcal{G}\left(\Pi_\Omega((M_a, C_a, K_a) + \mathcal{A}^*(Y^j, Z^j)) + W_j\mathcal{A}^*(\Delta Y^j, \Delta Z^j)\right) \end{pmatrix} = 0,$$

where U_1 and U_2 are given by (3.16) and (3.17), respectively. That is, we apply a preconditioned CG method to the linear system (4.1).

Based on our numerical experiments, we make the following observations.

- Our algorithm converges to the required accuracy at a relatively small number of iterations for all but one case ($n = 2,000$, $k = 30$, $c_1 = 10$, $c_2 = 0.1$, $\tau = 1$) in Table 3. Here, Failed means that the CG method fails to converge within the required maximum number of iterations. Therefore, it is not contradictive with the global convergence result as in Theorem 4.2. Quadratic convergence was observed for all convergent cases. This confirms our theoretical result on quadratic convergence.
- The largest numerical examples that we tested in this paper are (i) $n = 2{,}000$ and $k = 30$ and (ii) $n = 450$ and $k = 150$. For case (i), there are roughly 6,000,000 unknowns in the primal problem and 60,000 unknowns in the dual problem, while for case (ii), these numbers are roughly 300,000 and 67,000, respectively. In consideration of the scales of problems solved, our algorithm is very effective.
- We also tested the cases where $k \approx n/4$, which have better numerical performance than the cases where $k \approx n/3$. Generally speaking, the smaller the ratio $\frac{k}{n}$ is, the better our algorithm performs. This is no surprise as a smaller ratio $\frac{k}{n}$ implies that the constraint nondegenerate condition (4.4) is more likely to hold.
- Finally, note that the numbers of iterations for some small cases (see, for instance, $n = 100, 200$, $\tau = 0.1$, $c_1 = c_2 = 1$ in Table 1 and $n = 300$, $\tau = 0.1$,

	100	34.6 s	135	271	3.7×10^{-5}
	150	01 m 20 s	134	269	4.1×10^{-5}
	200	02 m 29 s	135	270	4.4×10^{-5}

$c_1 = c_2 = 1$ in Table 2) are larger than those of some large-scale cases. This is normal, as these problems are randomly generated so that the resulting linear system (4.1) may have different condition numbers and the total number of iterations may be different.

To further illustrate the effectiveness of our method, we compared the performance of our method with that of the well-known BFGS method with the Wolfe line search, which was described in detail in [34, Chapter 8] and was suggested by Malick [30] to solve some semidefinite least-squares problems.

In our experiments for the comparison, the starting point is the solution of (3.15), and the stopping tolerance is

$$\|\nabla\theta(Y^j, Z^j)\| \le 5.0 \times 10^{-5}.$$

The reason that we did not choose a higher accuracy is because the BFGS method may run into difficulties for an accuracy greater than 5.0×10^{-5}. In Tables 5–8, we report the numerical results of Examples 5.1 and 5.2 for the following two cases: (I) $k = 10$, $n = 50, 100, 150, 200$, and $\tau = 0.1$ and (II) $k \approx n/3$, $n = 50, 75, 100$, and $\tau = 0.1$. Table 9 includes the numerical results of Example 5.2 for the fixed $n = 100$ and $k = 10$ with the varying τ: $\tau = 0.01, 0.1, 1.0$. Here, `Res*.` stands for the residuals $\|\nabla\theta(\cdot)\|$ at the final iterate of an algorithm (the maximal number of iterations is set to be 5,000), while `It.` and `Func.` still denote the number of iterations and the number of function evaluations, respectively. LS failed means that the line search failed (i.e., the step length is too small to proceed) during the computation.

We see from the numerical performances that our method needs fewer than 15 iterations for all the problems to obtain the required accuracy, while the BFGS method needs more iterations. In terms of the cputime, our method also performs much better than the BFGS method.

6. Conclusions. In this paper, we considered the inverse quadratic eigenvalue problem (IQEP) with the positive semidefiniteness condition on matrices M and K.

We expressed the IQEP as a semidefinite constraint nonlinear optimization problem and introduced a quadratically convergent Newton method for solving the problem. Our numerical experiments show that our method is very efficient. We also observed that the BFGS method converges much more slowly than the Newton method and, moreover, that the Newton method is capable of solving problems of large scales. Since the vast majority of our computer cputime is spent on the preconditioned conjugate gradient method for solving the linear equation (4.1), we would save much computing time by finding a better preconditioner for (4.1). We leave this as our future research topic. Another interesting topic would be to study the IQEP with M, C, and K being of various special structures.

Appendix A. In this appendix, we study the linear space $\mathcal{R}(\mathcal{H})$ defined by (3.6), which varies according to the distribution of the prescribed eigenvalues. For the sake

of convenience, we define a new linear operator $\mathcal{J} : \mathcal{S}^k \times \mathcal{S}^k \times \mathcal{S}^k \to \mathbb{R}^{k\times k}$ by

$$\mathcal{J}(B, D, E) := \frac{1}{\sqrt{c_1}}(\Lambda^2)^T B + \frac{1}{\sqrt{c_2}}\Lambda^T D + E, \quad (B, D, E) \in \mathcal{S}^k \times \mathcal{S}^k \times \mathcal{S}^k,$$

where Λ is defined by (1.3).

Denote

$$\mathcal{R}(\mathcal{J}) := \{\mathcal{J}(B, D, E) \,:\, (B, D, E) \in \mathcal{S}^k \times \mathcal{S}^k \times \mathcal{S}^k\}.$$

By the definitions of $\mathcal{R}(\mathcal{H})$ and $\mathcal{R}(\mathcal{J})$, we can see that $\mathcal{R}(\mathcal{H}) = \mathcal{R}(\mathcal{J})$. The following result gives the exact number of $\mathrm{Dim}\,(\mathcal{R}(\mathcal{H}))$, the dimension of $\mathcal{R}(\mathcal{H})$.

PROPOSITION A.1. *Suppose that the prescribed eigenmatrix* Λ *is defined by* (1.3). *Then we have*

$$\mathrm{Dim}\,(\mathcal{R}(\mathcal{H})) = \mathrm{Dim}\,(\mathcal{R}(\mathcal{J})) = k^2 - \sum_{i=1}^{\mu} s_i(s_i - 1) - \frac{1}{2}\sum_{i=\mu+1}^{\nu} s_i(s_i - 1).$$

In particular, if $s_1 = \cdots = s_\mu = s_{\mu+1} = \cdots = s_\nu = 1$, $\mathrm{Dim}\,(\mathcal{R}(\mathcal{H})) = \mathrm{Dim}\,(\mathcal{R}(\mathcal{J})) = k^2$.

Proof. For any $\widetilde{D} \in \mathcal{S}^k$ and $Y \in \mathbb{R}^{k\times k}$, denote

$$\widetilde{D} = \begin{bmatrix} \widetilde{D}_{1,1} & \cdots & \widetilde{D}_{1,\mu} & \widetilde{D}_{1,\mu+1} & \cdots & \widetilde{D}_{1,\nu} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ \widetilde{D}_{1,\mu}^T & \cdots & \widetilde{D}_{\mu,\mu} & \widetilde{D}_{\mu,\mu+1} & \cdots & \widetilde{D}_{\mu,\nu} \\ \widetilde{D}_{1,\mu+1}^T & \cdots & \widetilde{D}_{\mu,\mu+1}^T & \widetilde{D}_{\mu+1,\mu+1} & \cdots & \widetilde{D}_{\mu+1,\nu} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ \widetilde{D}_{1,\nu}^T & \cdots & \widetilde{D}_{\mu,\nu}^T & \widetilde{D}_{\mu+1,\nu}^T & \cdots & \widetilde{D}_{\nu,\nu} \end{bmatrix}$$

and

$$Y = \begin{bmatrix} Y_{1,1} & \cdots & Y_{1,\mu} & Y_{1,\mu+1} & \cdots & Y_{1,\nu} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ Y_{\mu,1} & \cdots & Y_{\mu,\mu} & Y_{\mu,\mu+1} & \cdots & Y_{\mu,\nu} \\ Y_{\mu+1,1} & \cdots & Y_{\mu+1,\mu} & Y_{\mu+1,\mu+1} & \cdots & Y_{\mu+1,\nu} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ Y_{\nu,1} & \cdots & Y_{\nu,\mu} & Y_{\nu,\mu+1} & \cdots & Y_{\nu,\nu} \end{bmatrix}, \tag{A.1}$$

where $\widetilde{D}_{i,j}, Y_{i,j} \in \mathbb{R}^{s_i\times s_j}$ and $Y_{j,i} \in \mathbb{R}^{s_j\times s_i}$ with $1 \le i \le j \le \nu$.

First, we note that for any $Y \in \mathbb{R}^{k\times k}$,

(A.2)

$$\begin{aligned}
& Y \in \mathcal{R}(\mathcal{J}) \\
\Leftrightarrow\ & \tfrac{1}{\sqrt{c_1}}(\Lambda^2)^T B + \tfrac{1}{\sqrt{c_2}}\Lambda^T D + E = Y && \text{for some } (B,D,E) \in \mathcal{S}^k\times\mathcal{S}^k\times\mathcal{S}^k \\
\Leftrightarrow\ & E = Y - (\Lambda^2)^T\left(\tfrac{1}{\sqrt{c_1}}B\right) - \Lambda^T\left(\tfrac{1}{\sqrt{c_2}}D\right) && \text{for some } (B,D,E) \in \mathcal{S}^k\times\mathcal{S}^k\times\mathcal{S}^k \\
\Leftrightarrow\ & Y - (\Lambda^2)^T\left(\tfrac{1}{\sqrt{c_1}}B\right) - \Lambda^T\left(\tfrac{1}{\sqrt{c_2}}D\right) = E = E^T \\
& \quad = Y^T - \left(\tfrac{1}{\sqrt{c_1}}B\right)\Lambda^2 - \left(\tfrac{1}{\sqrt{c_2}}D\right)\Lambda && \text{for some } (B,D,E) \in \mathcal{S}^k\times\mathcal{S}^k\times\mathcal{S}^k \\
\Leftrightarrow\ & \left(\tfrac{1}{\sqrt{c_2}}D\right)\Lambda - \Lambda^T\left(\tfrac{1}{\sqrt{c_2}}D\right) \\
& \quad = Y^T - Y + (\Lambda^2)^T\left(\tfrac{1}{\sqrt{c_1}}B\right) - \left(\tfrac{1}{\sqrt{c_1}}B\right)\Lambda^2 && \text{for some } (B,D) \in \mathcal{S}^k\times\mathcal{S}^k \\
\Leftrightarrow\ & \widetilde{D}\Lambda - \Lambda^T\widetilde{D} = Y^T - Y && \text{for some } \widetilde{D} \in \mathcal{S}^k,
\end{aligned}$$

where $\widetilde{D} = \frac{1}{\sqrt{c_2}}D + (\frac{1}{\sqrt{c_1}}B)\Lambda + \Lambda^T(\frac{1}{\sqrt{c_1}}B)$. Then it is easy to verify that the last equation in (A.2) holds for some $\widetilde{D} \in \mathcal{S}^k$ if and only if

$$\widetilde{D}_{i,i}\Lambda_i - \Lambda_i^T\widetilde{D}_{i,i} = Y_{i,i}^T - Y_{i,i}, \quad i = 1,\ldots,\nu, \tag{A.3}$$

$$\widetilde{D}_{i,j}\Lambda_j - \Lambda_i^T\widetilde{D}_{i,j} = Y_{j,i}^T - Y_{i,j}, \quad 1 \le i < j \le \nu. \tag{A.4}$$

- Since $\sigma(\Lambda_i) \cap \sigma(\Lambda_j) = \emptyset$, for any $Y_{i,j} \in \mathbb{R}^{s_i\times s_j}$, there always exists a unique $\widetilde{D}_{i,j} \in \mathbb{R}^{s_i\times s_j}$ such that (A.4) holds.
- For $\mu+1 \le i \le \nu$, since $\Lambda_i = \lambda_i I_{s_i}$, (A.3) holds if and only if

$$Y_{i,i}^T = Y_{i,i}. \tag{A.5}$$

- For $1 \le i \le \mu$,

$$\Lambda_i = \alpha_i I + \beta_i J, \quad J = \operatorname{diag}(\overbrace{J_2, \ldots, J_2}^{s_i}), \quad J_2 = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}.$$

Thus, (A.3) holds if and only if

(A.6)
$$(Y_{i,i}(2q+1:2q+2, 2p+1:2p+2))^T - Y_{i,i}(2p+1:2p+2, 2q+1:2q+2) \in \left\{ \begin{bmatrix} y_1 & y_2 \\ -y_2 & y_1 \end{bmatrix} : y_1, y_2 \in \mathbb{R} \right\},$$

where $0 \le p < q \le s_i - 1$ and $Y_{i,i}(u_1 : u_2,\ v_1 : v_2)$ denotes the submatrix obtained by extracting rows u_1 through u_2 and columns v_1 through v_2 from a matrix $Y_{i,i}$.

Hence, we have obtained that $Y \in \mathcal{R}(\mathcal{J})$ if and only if Y is of form (A.1) satisfying (A.5) and (A.6). Therefore,

$$\operatorname{Dim}(\mathcal{R}(\mathcal{H}))\operatorname{Dim}(\mathcal{R}(\mathcal{J})) = k^2 - \sum_{i=1}^{\mu} s_i(s_i-1) - \frac{1}{2}\sum_{i=\mu+1}^{\nu} s_i(s_i-1),$$

which implies that if $s_1 = \cdots = s_\mu = s_{\mu+1} = \cdots = s_\nu = 1$, $\operatorname{Dim}(\mathcal{R}(\mathcal{H})) = \operatorname{Dim}(\mathcal{R}(\mathcal{J})) = k^2$. □

Remark A.2. From the proof of Proposition A.1 on the dimension of $\mathcal{R}(\mathcal{J})$ (and also $\mathcal{R}(\mathcal{H})$), we actually get the general solution of $\mathcal{J}(B, D, E) = 0$ for any fixed $B \in \mathcal{S}^k$, and thus the general solution of $\mathcal{A}(M, C, K) = 0$ for any fixed $M \in \mathcal{S}^n$. This generalizes a corresponding result of [25] for Λ with simple eigenvalues only.

Appendix B. Let $\Phi_M, \Phi_C, \Phi_K \in \mathcal{S}^n$ be three positive definite matrices. The IQEP of matrix weights can be defined as

(B.1)
$$\begin{aligned} \min \quad & \tfrac{1}{2}\|\Phi_M^{-1}(M - M_a)\Phi_M^{-1}\|^2 + \tfrac{1}{2}\|\Phi_C^{-1}(C - C_a)\Phi_C^{-1}\|^2 + \tfrac{1}{2}\|\Phi_K^{-1}(K - K_a)\Phi_K^{-1}\|^2 \\ \text{s.t.} \quad & M \begin{bmatrix} R \\ 0 \end{bmatrix} \Lambda^2 + C \begin{bmatrix} R \\ 0 \end{bmatrix} \Lambda + K \begin{bmatrix} R \\ 0 \end{bmatrix} = 0, \\ & (M, C, K) \in \Omega. \end{aligned}$$

By renaming $M := \Phi_M^{-1} M \Phi_M^{-1}$, $C := \Phi_C^{-1} C \Phi_C^{-1}$, $K := \Phi_K^{-1} K \Phi_K^{-1}$, $M_a := \phi_M^{-1} M_a \Phi_M^{-1}$, $C_a := \Phi_C^{-1} C_a \Phi_C^{-1}$, and $K_a := \Phi_K^{-1} K_a \Phi_K^{-1}$, we can write problem (B.1) equivalently as

(B.2)
$$\begin{aligned} \min \quad & \tfrac{1}{2}\|M - M_a\|^2 + \tfrac{1}{2}\|C - C_a\|^2 + \tfrac{1}{2}\|K - K_a\|^2 \\ \text{s.t.} \quad & (\Phi_M M \Phi_M) \begin{bmatrix} R \\ 0 \end{bmatrix} \Lambda^2 + (\Phi_C C \Phi_C) \begin{bmatrix} R \\ 0 \end{bmatrix} \Lambda + (\Phi_K K \Phi_K) \begin{bmatrix} R \\ 0 \end{bmatrix} = 0, \\ & (M, C, K) \in \Omega. \end{aligned}$$

Then, from the proof of Theorem 1.1, we can see that problem (B.2) admits a strictly feasible solution if and only if Λ is nonsingular.

Next, we shall show how problem (B.1) can be reduced to a similar problem which has a strictly feasible solution if Λ is singular. Without loss of generality, we assume that

$$\Lambda = \mathrm{diag}\{O_t, \Gamma\},$$

where $O_t = \mathrm{diag}\{\overbrace{0, \ldots, 0}^{t}\}$ and Γ is nonsingular and has the same structure as Λ defined in (1.3). Partition M, C, K, and $\left[\begin{smallmatrix} R \\ 0 \end{smallmatrix}\right]$ by

$$M = \begin{bmatrix} M_1 & M_2 \\ M_2^T & M_4 \end{bmatrix}, \quad C = \begin{bmatrix} C_1 & C_2 \\ C_2^T & C_4 \end{bmatrix}, \quad K = \begin{bmatrix} K_1 & K_2 \\ K_2^T & K_4 \end{bmatrix},$$

$$\text{and} \quad \begin{bmatrix} R \\ 0 \end{bmatrix} = \begin{bmatrix} R_1 & R_2 \\ 0 & R_3 \end{bmatrix},$$

where $M_1, C_1, K_1 \in \mathcal{S}^t$, $M_2, K_2, C_2, \in \mathbb{R}^{t\times(n-t)}$, $M_4, C_4, K_4 \in \mathcal{S}^{(n-t)}$, and $R_1 \in \mathbb{R}^{t\times t}$, $R_2 \in \mathbb{R}^{t\times(k-t)}$, $R_3 \in \mathbb{R}^{(n-t)\times(k-t)}$. The matrix R_3 can be further written as $R_3 = \left[\begin{smallmatrix} R_4 \\ 0 \end{smallmatrix}\right]$, where $R_4 \in \mathbb{R}^{(k-t)\times(k-t)}$ is an invertible upper triangular matrix. Then the first equation in problem (B.1) takes the following form:

$$\text{(B.3)} \qquad \begin{cases} K_1R_1 = 0, \quad K_2^TR_1 = 0, \\ (M_1R_2\Gamma^2 + C_1R_2\Gamma) + (M_2R_3\Gamma^2 + C_2R_3\Gamma) + (K_1R_2 + K_2R_3) = 0, \\ (M_2^TR_2\Gamma^2 + C_2^TR_2\Gamma) + (M_4R_3\Gamma^2 + C_4R_3\Gamma + K_4R_3) + K_2^TR_2 = 0. \end{cases}$$

Since R_1 is invertible, we have

$$K_1 = 0 \quad \text{and} \quad K_2 = 0.$$

Let

$$\widehat{\mathcal{A}}(M, C, K_4) := \begin{pmatrix} (M_1R_2\Gamma^2 + C_1R_2\Gamma) + (M_2R_3\Gamma^2 + C_2R_3\Gamma) \\ (M_2^TR_2\Gamma^2 + C_2^TR_2\Gamma) + (M_4R_3\Gamma^2 + C_4R_3\Gamma + K_4R_3) \end{pmatrix}.$$

Then the last two equations in (B.3) reduce to $\widehat{\mathcal{A}}(M, C, K_4) = 0$. Partition K_a by

$$K_a = \begin{bmatrix} (K_a)_1 & (K_a)_2 \\ (K_a)_2^T & (K_a)_4 \end{bmatrix}$$

with $(K_a)_1 \in \mathcal{S}^t$, $(K_a)_2 \in \mathbb{R}^{t\times(n-t)}$, and $(K_a)_4 \in \mathcal{S}^{(n-t)}$. Let

$$\Psi := \Phi_K^{-1} = \begin{bmatrix} L_1 & L_2 \\ L_2^T & L_4 \end{bmatrix} \quad \text{and} \quad \Psi K_a \Psi := \begin{bmatrix} (H_a)_1 & (H_a)_2 \\ (H_a)_2^T & (H_a)_4 \end{bmatrix},$$

where $L_1, (H_a)_1 \in \mathcal{S}^t$, $L_2, (H_a)_2 \in \mathbb{R}^{t\times(n-t)}$, and $L_4, (H_a)_4 \in \mathcal{S}^{(n-t)}$. By using the fact that

$$\begin{aligned} \|\Psi(K - K_a)\Psi\|^2 &= \left\| \begin{bmatrix} L_2K_4L_2^T - (H_a)_1 & L_2K_4L_4 - (H_a)_2 \\ L_4K_4L_2^T - (H_a)_2^T & L_4K_4L_4 - (H_a)_4 \end{bmatrix} \right\|^2 \\ &= \left\|\Psi_K^{-1}(K_4 - \Upsilon_a)\Psi_K^{-1}\right\|^2 + \kappa, \end{aligned}$$

where

$$\begin{aligned}\Psi_K &= (L_2^T L_2 + L_4^2)^{-\frac{1}{2}},\\ \Upsilon_a &= \Psi_K^2\left[(L_2^T(H_a)_1 L_2 + 2L_2^T(H_a)_2 L_4 + L_4(H_a)_4 L_4\right]\Psi_K^2,\\ \kappa &= -\|\Psi_K^{-1}\Upsilon_a\Psi_K^{-1}\|^2 + \|\Psi K_a \Psi\|^2,\end{aligned}$$

we can see that problem (B.1) is equivalent to

(B.4)
$$\begin{aligned}\min\quad & \tfrac{1}{2}\|\Phi_M^{-1}(M-M_a)\Phi_M^{-1}\|^2 + \tfrac{1}{2}\|\Phi_C^{-1}(C-C_a)\Phi_C^{-1}\|^2 + \tfrac{1}{2}\|\Psi_K^{-1}(K_4-\Upsilon_a)\Psi_K^{-1}\|^2\\ \text{s.t.}\quad & \widehat{\mathcal{A}}(M,C,K_4)=0,\\ & M\succeq 0,\quad C^T=C,\quad K_4\succeq 0.\end{aligned}$$

By renaming $M := \Phi_M^{-1}M\Phi_M^{-1}$, $C := \Phi_C^{-1}C\Phi_C^{-1}$, $K_4 := \Psi_K^{-1}K_4\Psi_K^{-1}$, $M_a := \Phi_M^{-1}M_a\Phi_M^{-1}$, $C_a := \Phi_C^{-1}C_a\Phi_C^{-1}$, and $\Upsilon_a := \Psi_K^{-1}\Upsilon_a\Psi_K^{-1}$, we see that problem (B.4) takes the following form:

(B.5)
$$\begin{aligned}\min\quad & \tfrac{1}{2}\|M-M_a\|^2 + \tfrac{1}{2}\|C-C_a\|^2 + \tfrac{1}{2}\|K_4-\Upsilon_a\|^2\\ \text{s.t.}\quad & \widehat{\mathcal{A}}\left(\Phi_M M\Phi_M, \Phi_C C\Phi_C, \Psi_K K_4\Psi_K\right)=0,\\ & M\succeq 0,\quad C^T=C,\quad K_4\succeq 0.\end{aligned}$$

Let $\widehat{M}$, $\widehat{C}$, and $\widehat{K}_4$ be defined by

$$\widehat{M} := \begin{bmatrix}\widehat{M}_1 & \widehat{M}_2\\ \widehat{M}_2^T & \widehat{M}_4\end{bmatrix},\quad \widehat{C} := \begin{bmatrix}\widehat{C}_1 & \widehat{C}_2\\ \widehat{C}_2^T & \widehat{C}_4\end{bmatrix},\quad \text{and}\quad \widehat{K}_4 := \begin{bmatrix}R_4^{-T}\Gamma^T\Gamma R_4^{-1} & 0\\ 0 & I\end{bmatrix},$$

where

$$\widehat{M}_1 = R_1^{-T}R_1^{-1},\quad \widehat{M}_2 = -\begin{bmatrix}R_1^{-T}R_1^{-1}R_2R_4^{-1} & 0\end{bmatrix},\quad \widehat{C}_1=0,\quad \widehat{C}_2=0,$$

and

$$\widehat{M}_4 = \begin{bmatrix}R_4^{-T}R_2^TR_1^{-T}R_1^{-1}R_2R_4^{-1} + R_4^{-T}R_4^{-1} & 0\\ 0 & I\end{bmatrix},$$

$$\widehat{C}_4 = -\begin{bmatrix}R_4^{-T}(\Gamma+\Gamma^T)R_4^{-1} & 0\\ 0 & 0\end{bmatrix}.$$

Clearly,

$$\left(\Phi_M^{-1}\widehat{M}\Phi_M^{-1}, \Phi_C^{-1}\widehat{C}\Phi_C^{-1}, \Psi_K^{-1}\widehat{K}_4\Psi_K^{-1}\right)$$

is a strictly feasible solution to problem (B.5). Therefore, we can apply Algorithm 4.1 to the dual of problem (B.5).

Acknowledgments. The authors would like to thank the associate editor and the referees for their valuable comments.

INEXACT UNIFORMIZATION METHOD FOR COMPUTING TRANSIENT DISTRIBUTIONS OF MARKOV CHAINS*

ROGER B. SIDJE†, KEVIN BURRAGE†, AND SHEV MACNAMARA†

Abstract. The uniformization method (also known as randomization) is a numerically stable algorithm for computing transient distributions of a continuous time Markov chain. When the solution is needed after a long run or when the convergence is slow, the uniformization method involves a large number of matrix-vector products. Despite this, the method remains very popular due to its ease of implementation and its reliability in many practical circumstances. Because calculating the matrix-vector product is the most time-consuming part of the method, overall efficiency in solving large-scale problems can be significantly enhanced if the matrix-vector product is made more economical. In this paper, we incorporate a new relaxation strategy into the uniformization method to compute the matrix-vector products only approximately. We analyze the error introduced by these inexact matrix-vector products and discuss strategies for refining the accuracy of the relaxation while reducing the execution cost. Numerical experiments drawn from computer systems and biological systems are given to show that significant computational savings are achieved in practical applications.

Key words. Markov chains, uniformization, inexact methods, relaxed matrix-vector

1. Introduction.

Computing transient probabilities is an important problem in Markov chain modeling. Numerical techniques are based on solving the Chapman–Kolmogorov system of differential equations:

$$\begin{cases} \dfrac{d\boldsymbol{w}(t)}{dt} = \boldsymbol{A}\boldsymbol{w}(t), & t \in [0,\ T], \\ \boldsymbol{w}(0) = \boldsymbol{v}, & \text{an initial probability distribution.} \end{cases} \tag{1}$$

The coefficient matrix $\boldsymbol{A}$ is an *infinitesimal generator* of order n, where n is the number of states in the Markov chain. Thus $\boldsymbol{A} \in \mathbb{R}^{n\times n}$, with elements $a_{ij} \geq 0$ when $i \neq j$, and $a_{jj} = -\sum_{i=1, i\neq j}^{n} a_{ij}$, which means that $\boldsymbol{A}$ is a minus Z-matrix [2] with zero column sum (our notation uses column vectors and transposes the transition matrix; see, e.g., [18, section 8.5.2]). Of interest is the *transient solution*, $\boldsymbol{w}(t)$, which is given by the solution of (1) and is known to be

$$\boldsymbol{w}(t) = e^{t\boldsymbol{A}}\boldsymbol{v}. \tag{2}$$

Since the matrix exponential can be full even when the original matrix is sparse, the practical computation of $e^{t\boldsymbol{A}}$ in full remains possible only when $\boldsymbol{A}$ is relatively small, i.e., when the number of states in the Markov chain does not exceed a few hundreds. Examples of such methods can be found in Moler and Van Loan [11]. In general, aspects such as size, stiffness, and accuracy are the main concerns when solving

Markov chains numerically. Solution techniques for large-scale problems include general ODE solvers and Krylov-based methods [13, 14, 18]. However, Markovian analysts have traditionally used the uniformization method, which still remains very popular. Evidence suggests that it can work very well, especially on nonstiff problems [15], and this is one of the reasons why it remains one of the most widely used methods for computing transient solutions.

Because the matrix-vector product is the most time-consuming part of the uniformization method, the overall efficiency of the method in solving large-scale problems can be significantly enhanced if the matrix-vector product is made more economical. In this paper, we incorporate a new relaxation strategy into the method so as to perform matrix-vector products only approximately. We analyze the error introduced by these inexact matrix-vector products, and discuss strategies for refining the accuracy of the relaxation while reducing the execution cost. Numerical experiments drawn from computer systems and biological systems show that significant computational savings are achieved in practical applications.

The paper is structured as follows. Section 2 provides a brief overview of the uniformization method. Section 3 describes our proposed variant of the method based on matrix-vector products that are inexact. An analysis of the error is given, and strategies to refine the accuracy while reducing the execution cost are discussed. Section 4 presents some numerical results. Section 5 provides some concluding remarks.

2. The uniformization method. The uniformization (or randomization) algorithm is based on the evaluation of the ℓth partial Taylor series expansion of the matrix exponential [6, 7]. The length ℓ is determined so that the prescribed tolerance on the approximation is fulfilled. Since $\boldsymbol{A}$ is a minus Z-matrix (i.e., the diagonal elements of $\boldsymbol{A}$ are negative and the off-diagonal elements are nonnegative), a naive use of the expression

$$\boldsymbol{w}(t) = e^{t\boldsymbol{A}}v \approx \boldsymbol{v} + \frac{t\boldsymbol{A}}{1!}\boldsymbol{v} + \cdots + \frac{(t\boldsymbol{A})^{\ell}}{\ell!}\boldsymbol{v} + \cdots$$

is subject to severe roundoff errors due to terms of alternating signs. Thus the uniformization technique instead uses the modified formulation

$$\boldsymbol{w}(t) = e^{\alpha t(\boldsymbol{P}-\boldsymbol{I})}\boldsymbol{v} = e^{-\alpha t}e^{\alpha t\boldsymbol{P}}\boldsymbol{v}, \quad \boldsymbol{P} = \boldsymbol{I} + \frac{1}{\alpha}\boldsymbol{A}, \quad \alpha = \max_i |a_{ii}|,$$

where $0 \le \boldsymbol{P} \le 1$ componentwise and $\|\boldsymbol{P}\|_1 = 1$. The resulting truncated approximation

$$\overline{\boldsymbol{w}}(t) = \sum_{k=0}^{\ell} e^{-\alpha t}\frac{(\alpha t)^k}{k!}\boldsymbol{P}^k\boldsymbol{v} \tag{3}$$

involves only nonnegative terms and becomes numerically stable. If ε_{tol} denotes the prescribed error tolerance, the condition

$$\|\boldsymbol{w}(t) - \overline{\boldsymbol{w}}(t)\|_1 \le \varepsilon_{\text{tol}}$$

leads to a choice of ℓ such that

$$\sum_{k=0}^{\ell} e^{-\alpha t}\frac{(\alpha t)^k}{k!} \ge 1 - \varepsilon_{\text{tol}}. \tag{4}$$

The length ℓ may therefore be determined simply by adding up the above series until the inequality is met. In fact, practical implementations will subdivide the integration domain to prevent overflow issues. Specifically, choose θ in advance (say, $\theta = 100$), and set

$$m = \left\lceil \frac{\alpha t}{\theta} \right\rceil, \quad \bar{t} = \frac{t}{m};$$

then we have

$$\overline{\boldsymbol{w}}(t) = \left(e^{-\alpha \bar{t}} e^{\alpha \bar{t} \boldsymbol{P}} \right)^m \boldsymbol{v} = e^{-\alpha \bar{t}} e^{\alpha \bar{t} \boldsymbol{P}} \cdots e^{-\alpha \bar{t}} e^{\alpha \bar{t} \boldsymbol{P}} \boldsymbol{v}, \tag{5}$$

which is evaluated from left to right, and each step amounts essentially to our earlier discussion with different $\boldsymbol{v}$'s and a reduced $\bar{t}$ such that $\alpha \bar{t} \leq \theta$. The overall scheme is summarized in the pseudocode below.

ALGORITHM 1: Uniformization$(t, A, v, \varepsilon_{\text{tol}})$.
{Compute $\boldsymbol{w} \approx \exp(t\boldsymbol{A})\boldsymbol{v}$}
1. $\alpha = \max_i |a_{ii}|$; $\boldsymbol{P} := \boldsymbol{I} + \boldsymbol{A}/\alpha$;
2. $\theta := 100$; $m := \lceil \alpha t/\theta \rceil$; $t := t/m$;
3. $s := \alpha t$; $r := e^{-s}$;
4. Choose ℓ to satisfy (4) ;
5. $\boldsymbol{w} := \boldsymbol{v}$;
6. **for** $i := 1 : m$ **do**
7. $\quad \boldsymbol{f} := \boldsymbol{w}$;
8. $\quad$ **for** $k := 1 : \ell$ **do**
9. $\quad\quad \boldsymbol{f} := \frac{s}{k} \boldsymbol{P} \boldsymbol{f}$;
10. $\quad\quad \boldsymbol{w} := \boldsymbol{w} + \boldsymbol{f}$;
11. $\quad$ **end**
12. $\quad \boldsymbol{w} := r\boldsymbol{w}$;
13. **end**

The popularity of uniformization is related to three main facts. First, its simplicity and malleability facilitate its implementation—only a matrix-vector product is needed per Horner-like iteration, with absolutely minimal extra storage (the matrix $\boldsymbol{P}$ need not be formed explicitly). Second, it works surprisingly well in a great variety of circumstances. Third, and perhaps most significantly, the transformation from $\boldsymbol{A}$ to $\boldsymbol{P}$ has a concrete interpretation. The matrix $\boldsymbol{P}$ is stochastic and is the transition matrix of a discrete time Markov chain (DTMC) that emulates the behavior of the continuous time Markov chain (CTMC), whose infinitesimal generator is $\boldsymbol{A}$. As described in Gross and Miller [7], this probabilistic interpretation allows deriving other parameters of interest. A shortcoming of uniformization is that ℓ is likely to be large, and thus (3) involves many matrix-vector multiplications, for large values of αt. Therefore, making the matrix-vector product economical, as we are proposing, can substantially decrease the execution time.

3. Inexact uniformization. Over recent years, there has been a growing interest in using inexact (or relaxed) matrix-products that are computed only to sufficient accuracy as needed [3, 16, 19]. Such interest has been motivated by applications where the matrix is not known exactly or is too expensive to apply. Most of the studies have focused, however, on Krylov subspace methods because by construction they are matrix-free and heavily dependent on matrix-vector products. The results obtained there have so far been quite promising [4, 10].

3.1. The inexact uniformization algorithm. Based on this evidence, we are interested in developing an inexact uniformization, where the matrix in statement 9 of Algorithm 1 is allowed to be $\boldsymbol{P} + \boldsymbol{E}_k$, where $\boldsymbol{E}_k$ is an error matrix at the kth step, and can change at each iteration. Thus, at each step, rather than computing $\boldsymbol{f}_k = \frac{\alpha t}{k}\boldsymbol{P}\boldsymbol{f}_{k-1}$, we compute an approximation $\tilde{\boldsymbol{f}}_k = \frac{\alpha t}{k}(\boldsymbol{P}+\boldsymbol{E}_k)\tilde{\boldsymbol{f}}_{k-1}$. Directly doing such a substitution is, however, fraught with the risk of corrupting the computations. To understand why, observe that if we are to compute $\tilde{\boldsymbol{f}}_k = \frac{\alpha t}{k}(\boldsymbol{P} + \boldsymbol{E}_k)\tilde{\boldsymbol{f}}_{k-1}$, the sequence of $\|\tilde{\boldsymbol{f}}_k\|$ grows before it decays, amplifying any error introduced and/or making it difficult to monitor the error. In general, this illustrates a possible pitfall when converting an existing method to using an inexact matrix-vector product. Thus we draw the attention of the reader to the fact that it may sometimes be necessary to recast an algorithm for it to fully benefit from the inexact matrix-vector idea.

In our present case, a small yet vital change is needed to make the approach successful. In this formulation, we split the computations using

$$\gamma_k = \frac{(\alpha t)^k}{k!}$$

and

$$\widetilde{\boldsymbol{f}}_k = (\boldsymbol{P} + \boldsymbol{E}_k)\widetilde{\boldsymbol{f}}_{k-1},$$

where $\boldsymbol{E}_k$ is the error matrix at step k. The updated algorithm is given below, showing the change (statement 11 of Algorithm 2).

ALGORITHM 2: InexactUniformization$(t, A, v, \varepsilon_{\text{tol}})$.

{Compute $\boldsymbol{w} \approx \exp(t\boldsymbol{A})\boldsymbol{v}$}

```
 1.  α = max_i |a_ii| ;   P := I + A/α ;
 2.  θ := 100 ;   m := ⌈αt/θ⌉ ;   t := t/m ;
 3.  s := αt ;   r := e^{-s} ;
 4.  Choose ℓ to satisfy (4) ;
 5.  w := v ;
 6.  for i := 1 : m do
 7.      γ := 1 ;
 8.      f := w ;
 9.      for k := 1 : ℓ do
10.          γ := γ s/k ;
11.          f :≈ Pf ;
12.          w := w + γf ;
13.      end
14.      w := rw ;
15.  end
```

If we were using *exact* arithmetic with $\boldsymbol{E}_k = 0$, we would generate the sequence of vectors $\boldsymbol{f}_k = \boldsymbol{P}\boldsymbol{f}_{k-1}$, which themselves would remain probability vectors, but with our relaxation approach, we compute

$$e^{\alpha t}\widetilde{\boldsymbol{w}} = \boldsymbol{v} + \sum_{k=1}^{\ell} \frac{(\alpha t)^k}{k!}(\boldsymbol{P} + \boldsymbol{E}_k)\cdots(\boldsymbol{P} + \boldsymbol{E}_1)\boldsymbol{v}$$

$$= \boldsymbol{v} + \sum_{k=1}^{\ell} \frac{(\alpha t)^k}{k!}(\boldsymbol{P}^k + \boldsymbol{\mathcal{E}}_k)\boldsymbol{v},$$

where

$$\boldsymbol{\mathcal{E}}_k = (\boldsymbol{P} + \boldsymbol{E}_k) \cdots (\boldsymbol{P} + \boldsymbol{E}_1) - \boldsymbol{P}^k.$$

Therefore the global error due to the inexact matrix-vector products is

$$\overline{\boldsymbol{w}} - \widetilde{\boldsymbol{w}} = -\sum_{k=1}^{\ell} e^{-\alpha t} \frac{(\alpha t)^k}{k!} \boldsymbol{\mathcal{E}}_k \boldsymbol{v}, \tag{6}$$

and the total error is

$$\|\boldsymbol{w} - \widetilde{\boldsymbol{w}}\|_1 = \|(\boldsymbol{w} - \overline{\boldsymbol{w}}) + (\overline{\boldsymbol{w}} - \widetilde{\boldsymbol{w}})\|_1 \le \varepsilon_{\text{tol}} + \|\overline{\boldsymbol{w}} - \widetilde{\boldsymbol{w}}\|_1. \tag{7}$$

In order to show that our inexact scheme is a viable approach, we have to show that the gap between the true solution and the computed solution, $\|\overline{\boldsymbol{w}} - \widetilde{\boldsymbol{w}}\|_1$, can be bounded in a practically useful way. This correlates with [16, 19], where a bound is established for the gap between the true residual and the computed residual in the context of linear systems. To obtain a meaningful bound in our context, it is helpful to consider the relationship between the global error and the local errors. This relationship is derived in the following result.

THEOREM 3.1. *Let $\widetilde{\boldsymbol{f}}_0 \equiv \boldsymbol{v}$ be the given starting vector, and for $k = 1, \ldots, \ell$ let $\widetilde{\boldsymbol{f}}_k$ be the approximate vector computed by the inexact matrix-vector product at step k, and let $\boldsymbol{\varepsilon}_k$ be the corresponding local error, that is,*

$$\boldsymbol{P}\widetilde{\boldsymbol{f}}_{k-1} = \widetilde{\boldsymbol{f}}_k + \boldsymbol{\varepsilon}_k, \quad k = 1, \ldots, \ell.$$

Then the global error of the inexact uniformization method satisfies

$$\overline{\boldsymbol{w}} - \widetilde{\boldsymbol{w}} = \sum_{k=1}^{\ell} e^{-\alpha t} \frac{(\alpha t)^k}{k!} \sum_{j=1}^{k} \boldsymbol{P}^{k-j} \boldsymbol{\varepsilon}_j \tag{8}$$

and therefore

$$\|\overline{\boldsymbol{w}} - \widetilde{\boldsymbol{w}}\|_1 \le \sum_{k=1}^{\ell} \|\boldsymbol{\varepsilon}_k\|_1. \tag{9}$$

Proof. We have

$$\begin{aligned} e^{\alpha t}\widetilde{\boldsymbol{w}} &= \widetilde{\boldsymbol{f}}_0 + \sum_{k=1}^{\ell} \frac{(\alpha t)^k}{k!} \widetilde{\boldsymbol{f}}_k \\ &= \boldsymbol{v} + \sum_{k=1}^{\ell} \frac{(\alpha t)^k}{k!} (\boldsymbol{P}\widetilde{\boldsymbol{f}}_{k-1} - \boldsymbol{\varepsilon}_k) \\ &= \boldsymbol{v} + \sum_{k=1}^{\ell} \frac{(\alpha t)^k}{k!} (\boldsymbol{P}^k \boldsymbol{v} - \boldsymbol{P}^{k-1}\boldsymbol{\varepsilon}_1 - \boldsymbol{P}^{k-2}\boldsymbol{\varepsilon}_2 - \cdots - \boldsymbol{\varepsilon}_k). \end{aligned}$$

Hence (8) follows immediately. And, using the fact that $\|\boldsymbol{P}\|_1 = 1$, we obtain

$$\|\overline{\boldsymbol{w}} - \widetilde{\boldsymbol{w}}\|_1 \le \sum_{k=1}^{\ell} e^{-\alpha t} \frac{(\alpha t)^k}{k!} \sum_{j=1}^{k} \|\boldsymbol{\varepsilon}_j\|_1 \le \left(\sum_{k=1}^{\ell} e^{-\alpha t} \frac{(\alpha t)^k}{k!} \right) \sum_{k=1}^{\ell} \|\boldsymbol{\varepsilon}_k\|_1 \le \sum_{k=1}^{\ell} \|\boldsymbol{\varepsilon}_k\|_1. \qquad \square$$

COROLLARY 3.2. *With the same notation as in Theoreom* 3.1, *the accumulated error due to the inexact matrix-vector products satisfies*

$$\boldsymbol{f}_k - \widetilde{\boldsymbol{f}}_k = -\boldsymbol{\mathcal{E}}_k \boldsymbol{v} = -\sum_{j=1}^{k} \boldsymbol{P}^{k-j} \boldsymbol{\varepsilon}_j$$

and therefore

$$\|\boldsymbol{f}_k - \widetilde{\boldsymbol{f}}_k\|_1 = \|\boldsymbol{\mathcal{E}}_k \boldsymbol{v}\|_1 \leq \sum_{j=1}^{k} \|\boldsymbol{\varepsilon}_j\|_1.$$

Proof. The result can be inferred from (6) and (8) and the uniqueness of the Taylor expansion. Another way is to expand $\boldsymbol{f}_k - \widetilde{\boldsymbol{f}}_k = \boldsymbol{P}(\boldsymbol{f}_{k-1} - \widetilde{\boldsymbol{f}}_{k-1}) - \boldsymbol{\varepsilon}_k$. ∎

The above analysis shows that the local errors in the matrix-vector products provide a useful mechanism for estimating the accumulated errors. And more significantly, (9) shows that the global error grows only linearly with the local errors, which implies that the algorithm is robust. When the domain is split as shown in (5), we do not have $\widetilde{\boldsymbol{f}}_0 = \boldsymbol{v}$ anymore, but the analysis can be easily extended to this case by setting $\widetilde{\boldsymbol{f}}_0 = \boldsymbol{v} + \boldsymbol{\varepsilon}_0$, with $\boldsymbol{v}$ understood as the current operand and $\boldsymbol{\varepsilon}_0$ as the error so far. We now discuss some ways of relaxing the matrix-vector product while controlling the local error.

3.2. Monitoring the inexact matrix-vector product. For very large problems, the probability sum condition $\|\boldsymbol{f}\|_1 = \mathbb{1}^T \boldsymbol{f} = 1$ implies that some of the components of $\boldsymbol{f}$ must necessarily be zero or at least very small. In other words, the most significant part of the support of the distribution at a given time is limited to a few components corresponding to the subset of most likely reachable states at that time. This subset changes over time, and hence the most significant part of the support changes over time too, but the size of the current subset remains small compared to the size of the full state space. While this may not always be the case, for example, if the distribution is uniform, there is a large class of important problems that exhibit this property, reflecting the fact that not all states are reached instantaneously. This observation is the cornerstone of our strategy for reducing the cost of the matrix-vector product. Let

$$\mathrm{Supp}(\boldsymbol{f}) = \{1 \leq j \leq n \mid f_j > 0\};$$

we can write the matrix-vector product in a column-oriented manner as

$$\boldsymbol{P}\boldsymbol{f} = \Big(\boldsymbol{I} + \frac{1}{\alpha}\boldsymbol{A}\Big)\boldsymbol{f} = \boldsymbol{f} + \frac{1}{\alpha}\begin{bmatrix}\boldsymbol{a}_1 & \boldsymbol{a}_2 & \dots & \boldsymbol{a}_n\end{bmatrix}\begin{bmatrix} f_1 \\ f_2 \\ \vdots \\ f_n \end{bmatrix} = \boldsymbol{f} + \sum_{j \in \mathrm{Supp}(\boldsymbol{f})} \frac{f_j}{\alpha}\boldsymbol{a}_j.$$

The key to efficiency resides therefore in tracking only a suitable approximation of this support. To this end, define the ε-support of $\boldsymbol{f}$ as

$$\mathrm{Supp}_\varepsilon(\boldsymbol{f}) = \{1 \leq j \leq n \mid f_j > \varepsilon\},$$

and let $\mathrm{Supp}_\varepsilon^C(\boldsymbol{f})$ be its complement, that is,

$$\mathrm{Supp}(\boldsymbol{f}) = \mathrm{Supp}_\varepsilon(\boldsymbol{f}) \cup \mathrm{Supp}_\varepsilon^C(\boldsymbol{f}).$$

We now use

$$\boldsymbol{P}\boldsymbol{f} \approx \boldsymbol{f} + \sum_{j \in \operatorname{Supp}_\varepsilon(\boldsymbol{f})} \frac{f_j}{\alpha} \boldsymbol{a}_j.$$

Since the essential part of the support is captured in this way, the inexact matrix-vector product may be quite a good approximation. Furthermore, the larger the problem size, the fewer (comparatively) the number of components of significance in the support, making the approach even more effective. The corresponding local error vector is therefore

$$\boldsymbol{\varepsilon} = \sum_{j \notin \operatorname{Supp}_\varepsilon(\boldsymbol{f})} \frac{f_j}{\alpha} \boldsymbol{a}_j = \sum_{j \in \operatorname{Supp}_\varepsilon^C(\boldsymbol{f})} \frac{f_j}{\alpha} \boldsymbol{a}_j.$$

Noting that $\|\boldsymbol{a}_j\|_1 = 2|a_{jj}|$ and $\|\boldsymbol{a}_j\|_\infty = |a_{jj}|$ since $a_{jj} = -\sum_{i=1, i\neq j}^n a_{ij}$, we have

$$\|\boldsymbol{\varepsilon}\|_1 \leq \sum_{j \in \operatorname{Supp}_\varepsilon^C(\boldsymbol{f})} \frac{2\varepsilon}{\alpha} |a_{jj}|, \qquad \|\boldsymbol{\varepsilon}\|_\infty \leq \sum_{j \in \operatorname{Supp}_\varepsilon^C(\boldsymbol{f})} \frac{\varepsilon}{\alpha} |a_{jj}|,$$

and since $\alpha \geq |a_{jj}|$, we get

$$\|\boldsymbol{\varepsilon}\|_1 \leq 2\varepsilon(|\operatorname{Supp}(\boldsymbol{f})| - |\operatorname{Supp}_\varepsilon(\boldsymbol{f})|), \qquad \|\boldsymbol{\varepsilon}\|_\infty \leq \varepsilon(|\operatorname{Supp}(\boldsymbol{f})| - |\operatorname{Supp}_\varepsilon(\boldsymbol{f})|),$$

where $|S|$ denotes the cardinality of the set S. Note that $|\operatorname{Supp}(\boldsymbol{f})| - |\operatorname{Supp}_\varepsilon(\boldsymbol{f})|$ is anticipated to be less than n, although we shall later use n as an upper bound for simplicity. Combining this analysis with Theorem 3.1, we obtain the following result.

THEOREM 3.3. *For $k = 1, \ldots, \ell$ let $\widetilde{\boldsymbol{f}}_k$ be the approximate vector computed by the inexact matrix-vector product at step k using the ε-support criteria. Then the global error of the inexact uniformization method satisfies*

$$\|\overline{\boldsymbol{w}} - \widetilde{\boldsymbol{w}}\|_1 \leq 2\varepsilon \sum_{k=1}^{\ell} (|\operatorname{Supp}(\widetilde{\boldsymbol{f}}_k)| - |\operatorname{Supp}_\varepsilon(\widetilde{\boldsymbol{f}}_k)|) \leq 2\varepsilon \sum_{k=1}^{\ell} (n - |\operatorname{Supp}_\varepsilon(\widetilde{\boldsymbol{f}}_k)|) \leq 2n\ell\varepsilon.$$

Remark 3.4. Our description has focused on applying a threshold on the support of a probability vector $\boldsymbol{f}$. It has the severity of not weighting the components with the actual matrix. Indeed since $|a_{jj}|/\alpha \leq 1$, it is possible to have an $f_j > \varepsilon$, and yet $f_j|a_{jj}|/\alpha \leq \varepsilon$, in which case we may ignore the column $\boldsymbol{a}_j$ as well. Thus we can trade the conciseness of the earlier formulation for a little extra saving in the matrix-vector product. In fact, in our experiments, our column-oriented matrix-vector product $\boldsymbol{A}\boldsymbol{f}/\alpha$ accumulates columns only where $f_j|a_{jj}|/\alpha > \varepsilon$. Thus our inexact matrix-vector product is effectively

$$\boldsymbol{P}\boldsymbol{f} \approx \boldsymbol{f} + \sum_{j \text{ s.t. } f_j \frac{|a_{jj}|}{\alpha} > \varepsilon} \frac{f_j}{\alpha} \boldsymbol{a}_j, \tag{10}$$

for which the corresponding local error vector is

$$\boldsymbol{\varepsilon} = \sum_{j \text{ s.t. } f_j \frac{|a_{jj}|}{\alpha} \leq \varepsilon} \frac{f_j}{\alpha} \boldsymbol{a}_j \leq \varepsilon \left| \left\{ j \text{ s.t. } f_j \frac{|a_{jj}|}{\alpha} \leq \varepsilon \right\} \right|.$$

We shall refer to this scheme as the *scaled* ε-support.

Remark 3.5. Another way to identify the most relevant part of the support is to determine the components of $\boldsymbol{f}$ that quickly sum to one, by, for example, sorting $\boldsymbol{f}$ in decreasing order and selecting the first few probabilities that quickly sum to one. However, for large problems, the sort, in $O(n \log n)$ operations, is potentially more expensive than the matrix-vector product, in $O(nz)$ operations, where nz is the number of nonzero entries of the matrix. A partial, heuristic sort is possible, but this is more involved.

Remark 3.6. Sparse matrices are usually stored using compact storage formats, of which a great variety exist [1]. Since our approach is column-oriented, it is crucial to use a format that fits the approach; otherwise the overhead of looking up and accessing the relevant columns of the matrix can outweigh any benefit of the relaxation algorithm. We recommend therefore the compressed column storage (CCS) format (cf. [1]), as it is ideally suited to our approach. Unfortunately, if the algorithm is implemented in MATLAB, which has its native sparse data type [5], referencing the relevant columns at each matrix-vector product hampers the vectorization and introduces a severe overhead. We observed that when performing the matrix-vector product $\boldsymbol{f} \leftarrow \boldsymbol{f} + \boldsymbol{A}\boldsymbol{f}/\alpha$, with $\boldsymbol{A}$ stored as a native sparse matrix in MATLAB, it is actually more efficient to zero the nonrelevant components of $\boldsymbol{f}$ than to index the corresponding columns of $\boldsymbol{A}$. That is, letting `diagA = abs(diag(A))`, it is more efficient in MATLAB to execute

```
support = find(diagA.*f > alpha*tol);
g(1:n) = 0;  g(support) = (1/alpha)*f(support);
f = f + A*g;
```

rather than

```
support = find(diagA.*f > alpha*tol);
f = f + A(:,support)*((1/alpha)*f(support));
```

Thus the advantage of the inexact matrix-vector product is lost in this environment. The ideal is of course to completely avoid arithmetic operations involving zeros or the negligible part of the support. The reader wishing to experiment with our approach in MATLAB should bear in mind these issues. Our numerical experiments were conducted using the CCS format in FORTRAN, which offers a finer granularity on controlling the operations without an excessive tradeoff. We anticipate that such a procedural language is the most appropriate for very large problems.

3.3. Detecting the stationary probability distribution. A particular feature of a Markov chain is that its transition matrix $\boldsymbol{A}$ has 0 as a simple eigenvalue, and for any other nonzero eigenvalue λ of $\boldsymbol{A}$, $\Re e(\lambda) < 0$. Hence the differential system (1) is stable and has a steady-state solution. It follows from this property that if $\tilde{\boldsymbol{w}}$ denotes the eigenvector associated with the eigenvalue 0, that is, $\boldsymbol{A}\tilde{\boldsymbol{w}} = 0$, then we have

$$\lim_{t \to \infty} e^{t\boldsymbol{A}} \boldsymbol{v} = \tilde{\boldsymbol{w}}.$$

The vector $\tilde{\boldsymbol{w}}$ is known as the *stationary* probability vector. When integrating therefore over a very long time t, it is possible for the uniformization method to tend to $\tilde{\boldsymbol{w}}$. However, implementations often shy away from attempting to detect this situation not only because it is not obvious how to do so cheaply and reliably, but also because of the unwarranted overhead of testing for an event that is more often than not unlikely to happen. However, we observed that when the stationary distribution

is reached (to within the error tolerance), a vast amount of computation is wasted unnecessarily. We can afford to check this in our approach. Indeed if in the course of our algorithm the stationary probability distribution is reached, then (10) implies that

$$\boldsymbol{P}\boldsymbol{f} \approx \boldsymbol{f}.$$

Detecting this situation enables further computational savings by avoiding the addition of unnecessary terms in the series. We implemented this check only in between the steps of (5). In other words, there are at most $m-1$ checkpoints in Algorithm 2, with the steady solution assumed if $\|\boldsymbol{P}\boldsymbol{f} - \boldsymbol{f}\|_\infty \leq \varepsilon_{\text{tol}}$, where $\boldsymbol{P}\boldsymbol{f}$ is itself approximated with the inexact scheme.

4. Numerical experiments. Experiments were undertaken at the National Facility of the Australian Partnership for Advanced Computing (APAC). We used its SGI Altix supercomputer infrastructure, but in a single node execution (Intel Itanium2 with 1.6 GHz). We implemented the code in FORTRAN using double precision (machine precision $= 0.2\,10^{-15}$), and used the Intel FORTRAN compiler (ifort) with a compilation switch to request its highest level of optimization (`-O3`). For comparison, we include the exact uniformization where we added the provision of detecting the steady solution as described in section 3.3. We also include the Krylov code (DGEXPV) from the EXPOKIT package [14], which implements Arnoldi's full orthogonalization method (FOM), where we set 30 as the dimension of the Krylov basis everywhere. This is labeled as Krylov(30) in the tables. The same ε_{tol} is used for the error control criteria. Refer to [14] for more details.

We compute the transient probability vector, $\boldsymbol{w}(t) = \exp(t\boldsymbol{A})\boldsymbol{v}$, for $t = 1,\ 10,\ 100$ over nine different data sets with $\boldsymbol{v} = (1, 0, \ldots, 0)^T$ of appropriate length. The choice of e_1 as the starting vector may seem too special, but it reflects the fact that we order the state space by reachability and that the Markov chain starts in the first state before evolving into other states. We repeated some of the calculations with a random starting vector. In general the computation time for the inexact uniformization increased from the case where e_1 is the starting vector, but it was still notably faster than the exact uniformization, although the differences in performance were less marked the more stringent the error tolerance became.

Recall from (7) that, in order to achieve a desired accuracy on the final result, we should set a comparable (or higher) accuracy for the inexact matrix-vector product, leading evidently to the exact uniformization if the matrix-vector product is computed to full accuracy. In the experiments, we set the same ε_{tol} value to control the inexact matrix-vector product (10). We run the experiments with the accuracy tolerance parameter ranging from $\varepsilon_{\text{tol}} = 10^{-5}$ to $\varepsilon_{\text{tol}} = 10^{-10}$. Note that the graphical charts use a logarithmic scale.

4.1. Mutual exclusion (MUTEX) problem. Mutual exclusion is a situation commonly encountered in computer systems. In this model, N distinguishable processes compete for a shared resource. Each of these processes alternates between a *sleeping* state and a resource *using* state. However, the number of processes that may concurrently use the resource is limited to P, where $1 \leq P \leq N$, so that when a process wishing to move from the sleeping state to the resource using state finds P processes already using the resource, that process fails to access the resource and returns to the sleeping state. Notice that when $P = 1$ this model reduces to the usual mutual exclusion problem. When $P = N$ all of the processes are independent. Let

$\lambda^{(i)}$ be the rate at which process i awakes from the sleeping state wishing to access the resource, and let $\mu^{(i)}$ be the rate at which this same process releases the resource when it has possession of it. In the experiments, we set the pair (N, P) to be $(16, 4)$, $(20, 8)$, and $(20, 16)$, with the rates chosen as $\lambda^{(i)} = 1/i$ and $\mu^{(i)} = i$, for $i = 1, \ldots, N$. The largest matrix in this series is of order $n = 1,047,225$ with $nz = 21,972,345$ nonzero elements, and $\|A\|_\infty = 232.65$. A modified version of the MARCA Markov chain modeling package [17] was used for the generation.

4.2. Nearly completely decomposable (NCD) queueing network. This model represents a multiuser interactive computer environment in which the system architecture is a time-shared, multiprogrammed, paged, virtual memory computer. The system consists of a set of N terminals, from which N users generate commands; a central processing unit (CPU); a secondary memory device (SM); and a filing device (FD). A queue of requests is associated with each device, and the scheduling is assumed to be FCFS (first come first served). When a command is generated, the user at the terminal remains inactive until the system responds. Symbolically, a user having generated a command enters the CPU queue. The behavior of the process in the system is characterized by a compute time followed either by a page fault, after which the process enters the SM queue, or an input/output (file request), in which case the process enters the FD queue. Processes that terminate their service at the SM or FD queue return to the CPU queue. Symbolically, completion of a command is represented by a departure of the process from the CPU to the terminals. This model has been often used in previous studies (see [12]). The matrices that are obtained are NCD, a factor that makes computation of stationary distribution by certain methods rather difficult. Our interest is in seeing how it affects methods for obtaining transient solutions. Parameter values were chosen to generate three matrices, the largest of which is of order $n = 91,881$ with $nz = 623,241$ nonzero elements (see Table 1).

4.3. Mitogen-activated protein kinase (MAPK) cascade. The mitogen-activated protein kinase (MAPK) cascade is implicated in a variety of signaling processes governing transitions in a cell's phenotype [9]. The MAPK cascade consists of 22 chemical species and 30 chemical reaction channels. A schematic of the cascade and the reactions, with their associated rate constants, is given in Figure 1. By simulating the dynamics of the MAPK cascade using the chemical master equation (CME), we obtain a Markov chain of very large dimension [4]. This example shows that it is possible to solve the CME for the MAPK cascade, at least for small numbers of molecules.

TABLE 1

Problem characteristics. The table shows n, the order of the transition rate matrix; its number of nonzero entries, $nz(\boldsymbol{A})$; the minimum and maximum number of nonzero entries on its columns, $\min nz(\boldsymbol{a}_j)$ and $\max nz(\boldsymbol{a}_j)$; and its L-$\infty$ norm (maximum row sum) $\|\boldsymbol{A}\|_\infty = \max_i \sum_{j=1}^{n} |a_{ij}|$. The MAPK and MUTEX problems are described in sections 4.3 *and* 4.1*, respectively, while the NCD problems are described in* 4.2.

Reactions and their rate constants

FIG. 1. *Schematic and detailed reactions in a mitogen-activated protein kinase (MAPK) cascade consisting of* 10 *coupled Michaelis–Menten enzyme kinetic models (adapted from* [9]*).*

In the largest experiment here, there can be anywhere from 0 to 5 molecules of each of the 22 species, so that an upper bound on the dimension of the full state space is 6^{22}. This reflects the so-called *curse of dimensionality*, which motivates the need for efficient solution techniques in systems biology. Since not all of these states are reachable in one step, the matrix is sparse and is generated based on the reachability from seven key species: the MAPK, MAPK kinase, MAPK kinase-kinase (KKK), and enzymes denoted E1, E2, MAPK phosphatase, and MAPKK phosphatase.

4.4. Discussion. The results of our extensive simulations are presented in the appendix. These detailed tables show how the results are affected by varying the choice of ε_{tol} (which determines the ε-support) from $\varepsilon_{\text{tol}} = 10^{-5}$ to $\varepsilon_{\text{tol}} = 10^{-10}$. The reported computation times (in seconds) over such a range give an indication of the extra work required per decimal place of accuracy. For each test problem, we present $w_1(t)$ and $w_n(t)$, the first and last components of $\boldsymbol{w}(t)$, as computed by the three different

methods. The results show that the inexact method produces results accurate to the specified tolerance.

In order to encapsulate the simulation results given in the appendix we present a number of figures. Figure 2 shows how the probability vector and the support evolve over time for each of the three classes of problems. Clearly the three problems have very different characteristics.

In Figure 3, we present timing results for the three classes of problems with $\varepsilon_{\text{tol}} = 10^{-7}$ and $\varepsilon_{\text{tol}} = 10^{-10}$. We see that the inexact uniformization (inexactUnif) outperforms the exact uniformization (exactUnif) in nearly all cases (except one where the exactUnif detects equilibrium early). Furthermore, for integration intervals that are not too large, the inexactUnif is very competitive with the Krylov approach. However, as the integration interval increases, the inexactUnif becomes less competitive. One of the reasons for this is that the Krylov method is very efficient in detecting equilibrium.

In Figure 4, we compare the numbers of uMATVEC between the three methods.

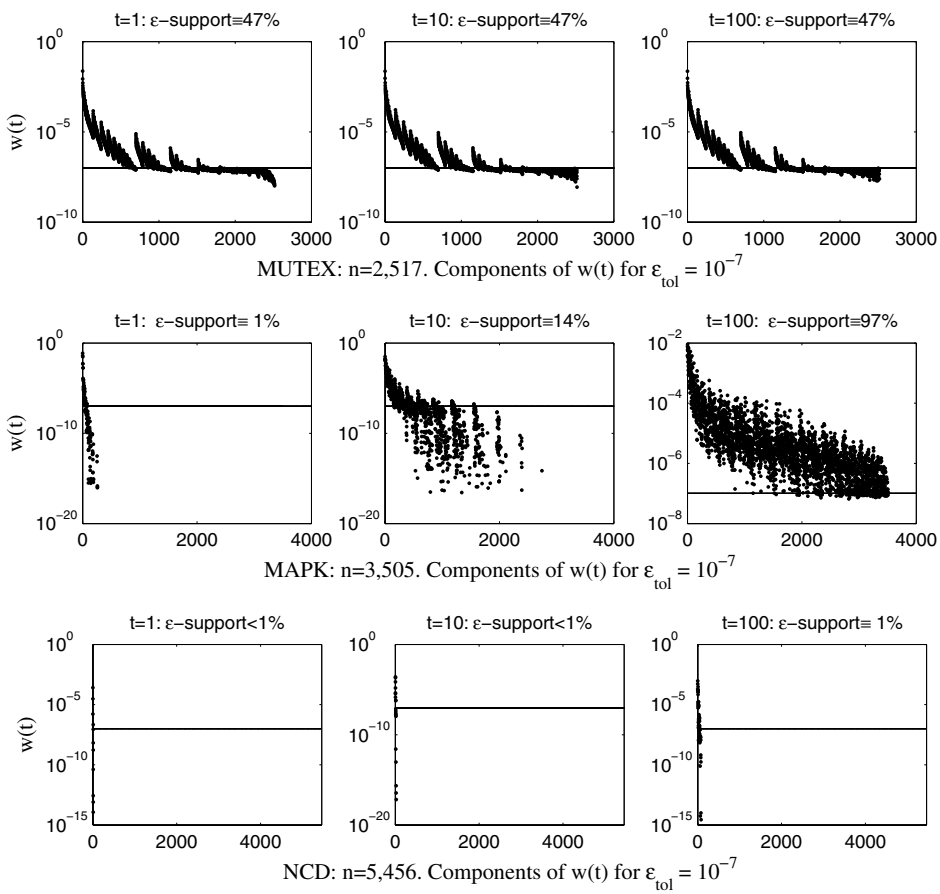

FIG. 2. *Evolution of the probability vector over time. The figure shows the* scaled *components as explained in Remark* 3.4. *Components above the straight line are those in the scaled ε-support, and thus they are those involved in the inexact matrix-vector product. The reported percentage is their proportion with respect to the number of components. It is seen that the ε-support changes over time, and various situations can happen depending on the matrix.*

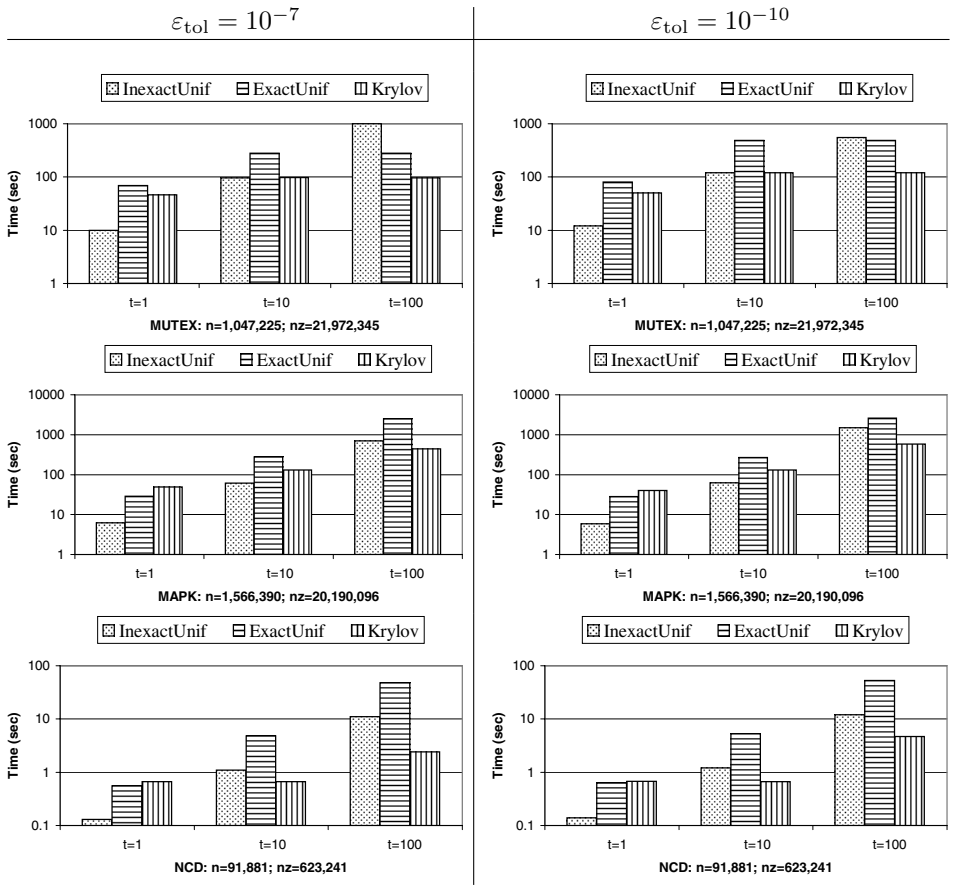

FIG. 3. *Timings for the largest matrices in the series when* $\varepsilon_{\text{tol}} = 10^{-7}$ *and* $\varepsilon_{\text{tol}} = 10^{-10}$. *At short integration intervals,* $t = 1$ *and* $t = 10$, *the times are all small in the NCD plots, but on the other problems it is seen that the inexactUnif is effective. Note in the MUTEX plots that the steady state occurs early at* $t = 10$. *The Krylov method is able to detect this almost immediately (due to an invariant subspace in its Arnoldi loop) and keeps a constant execution time as soon as* $t \geq 10$. *The exactUnif detects equilibrium later than the Krylov method but sooner than the inexact method.*

uMATVEC measures one unit of a matrix-vector product. This amounts to the standard matrix-vector product for the normal matrix-free methods, exactUnif and Krylov. However, in the case of inexactUnif, since not all columns participate in its matrix-vector operation, the number of uMATVEC is obtained by counting the number of participating columns over the entire run and dividing this by the order n.

In all cases, we see that there are substantially fewer uMATVEC operations with the inexactUnif technique. However, in this case, a single uMATVEC becomes increasingly more expensive as more and more conditional checks need to be processed. Indeed, this is one of the reasons why the inexactUnif becomes less competitive with the Krylov technique as the integration domain increases. It should be recalled that inexactUnif still uses almost the same number of iterations as exactUnif. Thus uMATVEC is a simple metric that gives a unified way of contrasting the methods in terms of matrix-vector products while giving a sense of the number of columns discarded by inexactUnif. Since it does not capture the fact that we still have to loop over the entire matrix using conditional checks to decide whether to skip over columns

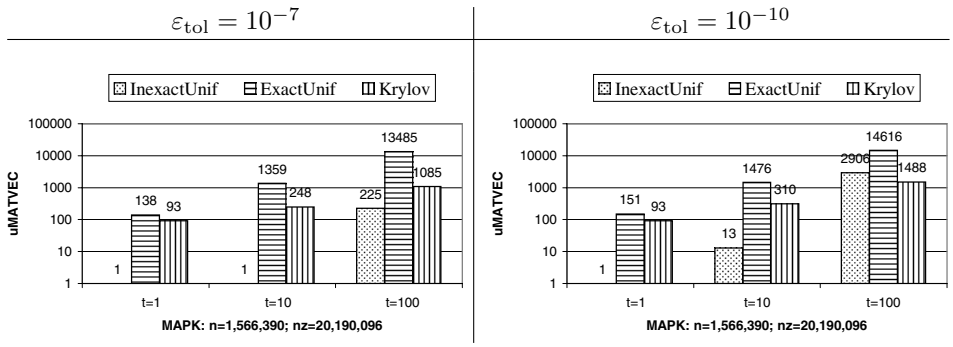

FIG. 4. *Numbers of uMATVEC operations for the largest MAPK matrix when* $\varepsilon_{\text{tol}} = 10^{-7}$ *and* $\varepsilon_{\text{tol}} = 10^{-10}$. *uMATVEC measures one unit of a matrix-vector product. This amounts to the standard matrix-vector product for the normal matrix-free methods, exactUnif and Krylov. However, in the case of inexactUnif, since not all columns participate in the matrix-vector operation, the reported number of uMATVEC operations is obtained by summing the number of participating columns over the entire run and dividing this by the order* n.

TABLE 2

*Distribution of the numbers of nonzeros in the columns. For example, the MAPK*1 *matrix has one column with two nonzero elements,* 11 *columns with three nonzero elements, and so forth. The location of the nonzero elements in these columns is not relevant.*

(together with scaling the components as indicated before), the reader should look at the value of inexactUnif in conjunction with that of exactUnif, keeping in mind the increasing number of conditional checks for matrices of large dimension over thousands of steps. This explains why the execution time of inexactUnif, seen in Figure 3, is not directly proportionate to its number of uMATVEC operations. Rather, the pay-off of the inexact matrix-vector routine is worthwhile if the discarded columns have sufficient nonzero elements so that the savings in floating point operations exceeds the conditional checks. Refer to Table 2 for the distribution of the numbers of nonzeros in the columns.

We can draw some other conclusions based on our extensive numerical tests.

- The inexactUnif is a worthy challenger not only to the exactUnif but also to the Krylov method in a number of cases. In general the inexactUnif method brings about a 10-fold improvement over the uniformization method on problems of significant dimension and a wide range of the accuracy tolerance parameter ε_{tol}, to the point of even becoming faster than the Krylov method at short integration domains, $t = 1$ and $t = 10$.
- Only when $t = 100$ does the Krylov method become the fastest due to its inherent higher convergence rate [8]. This comes at the price of the extra storage for the Krylov basis (which may not be possible on all computer systems for problems this large).
- For the MUTEX problems the steady state occurs early at $t = 10$. Since the Krylov method is able to detect this almost immediately (due to an invariant subspace in its Arnoldi loop), this explains why its uMATVEC and execution time are constant as soon as $t \geq 10$. The exactUnif detects equilibrium later than the Krylov method, but sooner than the inexact method. Hence the inexactness tends to delay the detection of the steady state. This can be clearly seen on the MUTEX plots in Figure 3. The inexact method took many more iterations, while the other methods finished early, thus keeping their constant execution time.
- The inexact method is able to track the ε-support and exclude impressive numbers of columns, making the method worthwhile and very efficient on problems with a large number of nonzero elements per column. Understandably, it is disadvantaged on problems with very few nonzero elements per column (such as a bidiagonal or tridiagonal matrix, for example). Determining whether to avoid a column may not be worth the effort on a nearly empty column (and testing this for all columns of a large matrix over thousands of steps would incur a substantial overhead too).

5. Conclusion. We have presented a new approach to substantially reducing the cost of the uniformization method. Our new algorithm consists of relaxing the matrix-vector products so as to perform them only to sufficient accuracy. Our approach is of practical value as it tells precisely how this relaxation can be performed, with the added benefit of retaining the minimalism and malleability that make the method so popular with Markovian analysts. We characterized the ensuing global error and showed that it grows at most linearly with the local errors introduced by the inexact matrix-vector products. We discussed strategies for refining the accuracy while reducing the execution cost. It has been observed that using our technique in an environment such as MATLAB does not reap the full benefits because of the overhead of operating on its native sparse data structure from the scripting level. However, using the appropriate sparse storage format in FORTRAN, numerical experiments showed that significant computational savings can be achieved in practical applications without a marked deterioration of accuracy.

Appendix A. MAPK results. Detailed results with the accuracy tolerance parameter ranging from $\varepsilon_{\text{tol}} = 10^{-5}$ to $\varepsilon_{\text{tol}} = 10^{-10}$, and the first and last components of $\boldsymbol{w}(t)$ as computed by the different methods at various times. See section 4.4 for how to interpret the results.

A HIGH-ORDER SOLVER FOR THE HEAT EQUATION IN 1D DOMAINS WITH MOVING BOUNDARIES*

SHRAVAN K. VEERAPANENI† AND GEORGE BIROS‡

Abstract. We describe a fast high-order accurate method for the solution of the heat equation in domains with moving Dirichlet or Neumann boundaries and distributed forces. We assume that the motion of the boundary is prescribed. Our method extends the work of Greengard and Strain [*Comm. Pure Appl. Math.*, XLIII (1990), pp. 949–963]. Our scheme is based on a time-space Chebyshev pseudo-spectral collocation discretization, which is combined with a recursive product quadrature rule to accurately and efficiently approximate convolutions with Green's function for the heat equation. We present numerical results that exhibit up to eighth-order convergence rates. Assuming N time steps and M spatial discretization points, the evaluation of the solution of the heat equation at the same number of points in space-time requires $\mathcal{O}(NM \log M)$ work. Thus, our scheme can be characterized as "fast"; that is, it is work-optimal up to a logarithmic factor.

Key words. integral equations, spectral methods, Chebyshev polynomials, moving boundaries, heat equation, quadratures, Nyström's method, collocation methods, potential theory

DOI. 10.1137/060677896

1. Introduction.

We present a fast and high-order method for the solution of the one-dimensional (1D) heat equation in domains with moving boundaries. We assume that the boundary motion is prescribed. Given smooth functions f, g, and w we seek to compute $u(x,t)$ such that

$$\begin{aligned} \frac{\partial u}{\partial t} &= \triangle u(x,t) + f(x,t) \quad \text{in} \quad \omega(t), \qquad t > 0, \\ u(x,0) = w(x) \quad \text{in} \quad \omega(0), &\quad u(x,t) = g(x,t) \quad \text{on} \quad \gamma(t). \end{aligned} \tag{1.1}$$

All of our algorithmic choices can be extended to 2D and 3D. The details, however, become quite involved, and additional algorithmic components are necessary. For clarity and due to space limitations, we present the core ideas of our method for the one-dimensional case. We will report the extensions to higher dimensions in a future article.

Formulation. The proposed algorithm is based on potential theory [13]. Without loss of generality, let $\omega(t)$ be contained in the unit box $\Omega = [0,1]$. Let Γ denote the boundary of the unit box. By linearity, we decompose the problem (1.1) into the initial condition component u_i, the distributed force component u_f, and the boundary contribution u_b:

$$\frac{\partial u_i}{\partial t} = \triangle u_i \quad \text{in} \quad \Omega, \quad u_i(x,0) = w(x), \quad u_i(\Gamma,t) = 0, \quad t > 0, \tag{1.2}$$

‡Department of Mechanical Engineering and Applied Mechanics and Department of Computer and Information Science, University of Pennsylvania, Philadelphia, PA 19104 (biros@seas.upenn.edu.)

$$\frac{\partial u_f}{\partial t} = \triangle u_f + f \quad \text{in} \quad \Omega, \quad u_f(x,0) = 0, \quad u_f(\Gamma,t) = 0, \quad t > 0, \tag{1.3}$$

$$\frac{\partial u_b}{\partial t} = \triangle u_b \quad \text{in} \quad \omega(t), \quad u_b(x,0) = 0, \quad u_b(\gamma(t),t) = g - u_i - u_f, \quad t > 0. \tag{1.4}$$

We solve (1.2), (1.3), and (1.4) using an integral equation formulation; we compute u_i and u_f by

$$\begin{aligned} u_i(x,t) &= \mathcal{V}_0[w](x,t) = \int_\Omega G(x,t;y)w(y)dy, \\ u_f(x,t) &= \mathcal{V}[f](x,t) = \int_0^t \int_\Omega G(x,t;y,\tau)f(y,\tau)dy\,d\tau, \end{aligned} \tag{1.5}$$

where $G(x,t;y,\tau)$ is Green's function for the unit box Ω with periodic boundary conditions.[1] The solution of (1.4) is obtained by the solution of a double layer indirect integral equation formulation, which is given by

$$u_b(x,t) = \mathcal{D}[\phi](x,t) = \int_0^t \int_{\gamma(\tau)} \frac{\partial G(x,t;y,\tau)}{\partial n(y,\tau)} \phi(y,\tau) ds(y) d\tau, \ x \in \omega \times (0,T]. \tag{1.6}$$

Here n is the outward normal to γ. The double layer potential denoted by $\mathcal{D}[\phi]$ is the solution for problem (1.4) provided the boundary density ϕ solves the following Fredholm second-kind integral equation for $t > 0$:

$$-\frac{1}{2}\phi(x,t) + \mathcal{D}[\phi](x,t) = u_b(x,t) \quad \forall x \in \gamma(t). \tag{1.7}$$

Computational complexity. The solution of (1.1) through potential theory requires evaluation of double layer and volume potentials. A direct evaluation of $\mathcal{V}[f]$ using $M \times N$ quadrature points at $M \times N$ locations in space and time requires $\mathcal{O}(M^2N^2)$ work. The history dependence of this convolution can be overcome by using the fast algorithm of Greengard and Strain [6]. The key idea is to use two equivalent expansions for the kernel $G(x,t)$: one that converges fast at distant times and the other that converges fast locally. The volume potential $\mathcal{V}$ is split into a local or near part $\mathcal{V}_L$ and a far part $\mathcal{V}_F$. For the evaluation of the local part, a method-of-images expansion of G is used; for the far part, a Fourier expansion is used. A recurrence relation to update the Fourier coefficients in the far part eliminates the need to integrate over the entire history. As pointed out in [22], discrete sums of the form $\sum_{n=1}^{p} C_n \sin(n\pi x)$ and $\sum_{k=1}^{M} \sin(n\pi y_k) f_k$ that arise in the computation of $\mathcal{V}_F$ can be computed in optimal time by using the nonuniform FFT (NUFFT) [4]. The local part can be computed optimally using the fast Gauss transform [7]. Using these methods the overall complexity of computing the volume potential can be reduced to $\mathcal{O}(MN \log M)$; the overall scheme is second-order accurate.

Synopsis of the new method. Here we extend the Greengard and Strain algorithm to a high-order accurate scheme. We develop special product integration rules to compute the local and far parts of the heat potentials. The basic idea is to approximate the boundary density using Chebyshev polynomials and then compute the resulting moments exactly. To achieve optimal complexity, we propose a scheme

[1] Here we describe the decomposition into three subproblems for the case of a Dirichlet boundary condition. The extension to the Neumann case is analogous.

that makes use of fast summation methods [4, 6, 7]. We then build a solver for (1.1) based on a fast and high-order accurate evaluation of volume and layer potentials.

Following Greengard and Strain, this is the outline of our method:

- We use a double layer integral equation formulation for (1.1), which results in a well-conditioned linear system;
- we discretize using a pseudo-spectral collocation method using Chebyshev polynomials;
- we develop high-order quadratures for the heat (and other sharply peaked) kernels using recurrences;
- we derive a high-order scheme for the heat equation in domains with moving boundaries (with prescribed motion) and distributed forces.

The main contributions of this work are the high-order time-marching scheme and the extension to problems with moving boundaries and distributed sources.

Related work. Much of the research on solving the heat equation on moving boundaries has been concentrated on Stefan's problem for which the motion of the boundary is unknown. In this paper, we consider only problems in which the motion of the boundary is *prescribed.*[2] Fast algorithms introduced recently dramatically improved the computational complexity of solving integral equation formulations for parabolic PDEs. The fast Gauss transform [7] can be used to accelerate the solution of the free-space initial value problem for the heat equation. The Greengard and Strain algorithm [6] can be used for the efficient evaluation of single and double layer heat potentials in bounded domains. Fast algorithms for unbounded domains are discussed in [5, 14]. The work of [2, 20] is one of the first attempts to design fast methods for the heat equation. A direct formulation was used in [10, 28] for the 1D Stefan problem. In the case of prescribed Dirichlet data, a direct integral equation formulation leads to a Volterra system of equations that is ill-conditioned.[3] Ill-conditioning can be avoided by using an indirect double layer formulation, which we describe in detail in section 5. Recently, epitaxial step flow growth in 1D was simulated in [9] using layer potentials. Despite these remarkable advances, however, none of the existing methods achieves both high accuracy and optimal complexity.

Indeed, fast summation algorithms and high-order schemes are necessary to build work-efficient solvers for (1.1). The time integrals in all variants of the heat potentials have kernels that are sharply peaked. A generic quadrature rule can be used, but it will not achieve its order of convergence for reasonable discretization sizes. Uniform second-order convergence in computing the single layer was achieved in [6, 20] using asymptotic expansions. To obtain high-order convergence through asymptotic expansions, one needs high-order derivatives of the boundary density ϕ, something that can be computationally expensive. In [22, 23] a uniform second-order convergence was achieved by using a piecewise linear approximation for the boundary density and computing the convolution with the heat kernel exactly.

An alternative is the design of special quadrature rules: Given $I(\alpha) = \int_{-1}^{1} K(\alpha, \theta)\, \phi(\theta) d\theta$, with K being a singular, sharply peaked, or oscillatory kernel, the goal is to design high-order accurate integration schemes. There exists a substantial body

[2]There is a large (and significant) body of work regarding local stencil-based discretizations of (1.1); we do not attempt to review this literature. We believe that, for certain problems, there are significant advantages in using integral equations. Since this work is in 1D, we postpone the discussion to a future paper.

[3]In 1D ill-conditioning has little impact in practical computations. The argument is important for problems in higher dimensions.

of work on quadrature rules for such problems. The main challenge is to ensure optimal algorithmic complexity and compatibility with fast summation methods. In Kapur and Rokhlin [12] and Rokhlin [19], corrections to the trapezoidal rule have been suggested for integrating singular functions. In Ma and Wandzura [11] and in Yarvin and Rokhlin [26], numerical tools to obtain generalized Gaussian quadratures have been devised. In Alpert [1] hybrid Gauss-trapezoidal rules for regular functions and singular kernels were developed. These approaches, however, are not directly applicable to the heat kernel due to the spatial and temporal components of the kernel. Although it may be the case that they can be extended to the heat kernel, we have opted for an alternative approach based on recurrence relationships.

Such recurrences have been established by Piessens and Branders [15] for a wide variety of kernels. In Hasegawa and Torii [8], Cauchy principal value integrals were evaluated using quadrature rules combined with Chebyshev-polynomial approximations. Here we concentrate on heat potentials, but this strategy can be applied to solving other PDEs via integral equations. For example, in Piessens [16] integral equations like the Abel integral equation were solved. The main difference between this method and quadrature rules is that we discretize the density but not the integral operator. Given a density $\phi(\theta)$ and a kernel $K(\alpha,\theta)$ we write:

(1.8)
$$\phi(\theta)=\sum_{k=0}^{q-1}\phi(k)T_k(\theta)\ \Rightarrow I(\alpha)=\sum_{k=0}^{q}\phi(k)I_k(\alpha),\quad \text{where } I_k(\alpha)=\int_{-1}^{1}K(\alpha,\theta)T_k(\theta)d\theta,$$

based on the Chebyshev-polynomial expansion of ϕ. The integrals $I_k(\alpha)$ are computed to machine accuracy using recurrence relations (section 2). Using the FFT, the Chebyshev coefficients $\{\phi(n)\}_{n=0}^{q}$ can be computed in $\mathcal{O}(q\log q)$ work, and all $I_k(\alpha)$ can be computed using recurrence relations in $\mathcal{O}(q)$ work. Hence the overall complexity of computing the integral $I(\alpha)$ is $\mathcal{O}(q\log q)$. Using this method we compute heat potentials by approximating the potential density function using piecewise $(q-1)$th-order Chebyshev polynomials and thus obtain a qth-order accurate method.

Contents. In section 2, we discuss algorithms for the fast evaluation of heat potentials. In section 3, we derive recurrence relations for computing the moments $I_k(\alpha)$ defined in (1.8) for heat kernels. The details of implementing the boundary integral solver for (1.1) with static boundaries are given in section 4. The case of boundaries with prescribed motion is discussed in section 5. We report numerical results that verify the efficiency and accuracy of our scheme in section 6.

2. Fast summation. The direct evaluation of u_b by (1.6) at M spatial locations and N time levels requires $\mathcal{O}(N^2M)$ work in 1D. The Greengard–Strain algorithm reduces this work to $\mathcal{O}(NM)$. The key idea is to use two different representations of Green's function (for a square box with periodic boundary conditions) in different time intervals: one for the history part that represents the influence of the sources located temporally away from the current evaluation time and one for the local part that represents the influence of the sources located at times closer to the current evaluation time.

Green's function for the unit box is the solution to the adjoint problem with homogeneous boundary conditions:

$$\frac{\partial G}{\partial \tau}+\triangle_y G=\delta(x-y,t-\tau)\quad \text{in } \Omega\quad \text{such that (s.t.) } G(\Gamma,t)=0. \tag{2.1}$$

The solution of this problem by Fourier series and by Kelvin's method of images give

us two equivalent expansions:

$$G(x,y;t,\tau) = \sum_{n=1}^{\infty} e^{-n^2\pi^2(t-\tau)} 2\sin(n\pi x)\sin(n\pi y) \tag{2.2}$$

$$= \sum_{n=-\infty}^{\infty} \left(\frac{e^{-(x-y-2n)^2/4(t-\tau)}}{\sqrt{4\pi(t-\tau)}} - \frac{e^{-(x+y-2n)^2/4(t-\tau)}}{\sqrt{4\pi(t-\tau)}} \right). \tag{2.3}$$

These expansions converge with different rates in different time intervals. The Fourier representation converges faster at distant times (from the current evaluation time), whereas the method of images representation converges faster at closer times. This motivates splitting of heat potentials into two parts:

$$\mathcal{V}[f] = \mathcal{V}_F[f] + \mathcal{V}_L[f] = \int_0^{t-\delta} \int_\Omega Gf + \int_{t-\delta}^{t} \int_\Omega Gf. \tag{2.4}$$

Here δ is a parameter that determines the error in truncating both of the series in (2.3). The operator $\mathcal{V}_F$ will be termed as the far part, and $\mathcal{V}_L$ will be termed as the local part. The exact same decomposition is also valid for single and double layer potentials, with f being replaced by the boundary density ϕ.

2.1. Truncating the series. In 1D the boundary γ of the domain ω corresponds to two points b_1 and b_2. Then the far part of the double layer potential simplifies to

$$\mathcal{D}_F[\phi] = \sum_{n=1}^{\infty} \sum_{k=1}^{2} (-1)^k 2n\pi \sin(n\pi x) \int_0^{t-\delta} \cos(n\pi b_k) e^{-n^2\pi^2(t-\tau)} \phi(b_k,\tau) d\tau. \tag{2.5}$$

The error in truncating the series (2.5) after p terms can be bounded from above as follows:

$$\begin{aligned}
\mathcal{E}_F(p) &= \left| \mathcal{D}_F[\phi] - \sum_{n=1}^{p} \sum_{k=1}^{2} (-1)^k 2n\pi \sin(n\pi x) \int_0^{t-\delta} \cos(n\pi b_k) e^{-n^2\pi^2(t-\tau)} \phi(b_k,\tau) d\tau \right| \\
&= \left| \sum_{n=p+1}^{\infty} \sum_{k=1}^{2} (-1)^k 2n\pi \sin(n\pi x) \int_0^{t-\delta} \cos(n\pi b_k) e^{-n^2\pi^2(t-\tau)} \phi(b_k,\tau) d\tau \right| \\
&\le 4|\phi|_\infty \sum_{n=p+1}^{\infty} \left| \int_0^{t-\delta} n\pi e^{-n^2\pi^2(t-\tau)} d\tau \right| = 4|\phi|_\infty \sum_{n=p+1}^{\infty} \left| \frac{e^{-n^2\pi^2\delta} - e^{-n^2\pi^2 t}}{n\pi} \right| \\
&\le \frac{4|\phi|_\infty}{\pi(p+1)} \sum_{n=p+1}^{\infty} e^{-n^2\pi^2\delta} \le \frac{4|\phi|_\infty}{\pi(p+1)} e^{-(p+1)^2\pi^2\delta} \int_0^{\infty} e^{-\pi^2 x^2 \delta} dx \\
&= \frac{2|\phi|_\infty}{\pi\sqrt{\pi\delta}(p+1)} e^{-(p+1)^2\pi^2\delta}.
\end{aligned}$$

The local part expansion represents the influence of Gaussian pulses initiated at $t = 0$ and located at $\{x - 2n, 2n - x\}_{n=-\infty}^{\infty}$. The value of a Gaussian pulse evaluated at a distance $2r\sqrt{t}$ from its center would be of the order $\frac{e^{-r^2}}{\sqrt{t}}$. Hence, if the boundary γ is a distance d away from the boundary of the unit box Γ, then the error in approximating Green's function by just the first term ($n = 0$) is of the order $\frac{e^{-d^2/\delta}}{\sqrt{\delta}}$.

Then the local part of the double layer is

$$\mathcal{D}_L[\phi] = \int_{t-\delta}^{t} \int_{\gamma(\tau)} \frac{x-y}{4[\pi(t-\tau)]^{3/2}} e^{-\frac{(x-y)^2}{4(t-\tau)}} \phi(y,\tau) d\tau + \mathcal{O}\left(\frac{e^{-d^2/\delta}}{\delta^{3/2}}\right). \tag{2.6}$$

2.2. Fast evaluation of the far part. A direct evaluation of $\mathcal{D}_F[\phi]$ at $M \times N$ points in space and time requires $\mathcal{O}(N^2 M p)$ computations. Optimal complexity of $\mathcal{O}((M+p)N)$ can be achieved by using the fast algorithms in [4, 6]. We briefly summarize these algorithms here. Let

$$\hat{\phi}_n(\tau) = \int_{\gamma(\tau)} \frac{\partial \sin(n\pi y)}{\partial n(y)} \phi(y,\tau) ds(y) = n\pi \left(\cos(n\pi b_2)\phi(b_2,\tau) - \cos(n\pi b_1)\phi(b_1,\tau)\right), \tag{2.7}$$

$$C_n(t,\delta) = 2\int_0^{t-\delta} e^{-n^2\pi^2(t-\tau)} \hat{\phi}_n(\tau)\, d\tau. \tag{2.8}$$

Then

$$\mathcal{D}_F[\phi](x,t) = \sum_{n=1}^{p} C_n(t,\delta)\sin(n\pi x). \tag{2.9}$$

The Fourier coefficients can be updated with constant work per time step using the following recurrence:

$$C_n(t+\triangle t,\delta) = e^{-n^2\pi^2\triangle t} C_n(t,\delta) + 2\int_{t-\delta}^{t+\triangle t-\delta} e^{-n^2\pi^2(t+\triangle t-\tau)} \hat{\phi}_n(\tau) d\tau. \tag{2.10}$$

This recurrence is the key step that eliminates the history dependence of the far part. Once we have computed the C_n coefficients, we can evaluate (2.9) using the inverse NUFFT.

2.3. Optimal splitting of the heat potentials. In this section we briefly comment on the selection[4] of the parameters associated with the splitting of the heat potentials to a far and local part. If we retain p terms in the far part expansion and if $\delta = l\triangle t$, the overall complexity of computing $\mathcal{D}[\phi]$ is $W = \mathcal{O}(N(M+p)\log p + MNl)$. For each target point, the local part computation involves integrating over l time steps, hence the local part evaluation contributes $\mathcal{O}(MNl)$ to W. For fixed constants (c_1, c_2), we set $p = c_1\sqrt{M}$ and $l = \left\lceil \frac{c_2 \log M}{N\triangle t} \right\rceil$ to obtain $W = \mathcal{O}(MN\log M)$, which is off from being optimal only by a logarithmic factor. For this choice of parameters (assuming exact evaluation of the far and near integrals) the error estimates due to the splitting are given by

$$\begin{aligned} \mathcal{E}_F(M,N) &= \mathcal{O}\left(\left(\frac{N}{M\log M}\right)^{1/2} e^{-\frac{\pi^2 c_1^2 c_2 M \log M}{N}}\right), \\ \mathcal{E}_L(M,N) &= \mathcal{O}\left(\left(\frac{N}{\log M}\right)^{3/2} e^{-\frac{d^2 N}{c_2 \log M}}\right). \end{aligned} \tag{2.11}$$

[4]The discussion here is important only in the asymptotic limit, i.e., when the size of the time step is small. But for significantly large time-step discretizations, we can just fix the parameters p, δ such that $\delta < \triangle t$ and such that the truncation errors are within the required accuracy. This would suffice to obtain optimal complexity.

Therefore, both errors are exponentially converging as M and N are increased. For instance, if $N = M = 256$, by choosing $c_1 = 2.5, c_2 = 0.1$, both $\mathcal{E}_F, \mathcal{E}_L$ are less than 10^{-15}, and for this choice we get $p = 40, \delta \approx 0.0022$.

Next we describe our construction of recursive product integration rules for the local and far parts.

3. Quadratures. In this section, we compute the moments $I_k(\alpha)$ as defined by (1.8) for the kernels: $e^{-\alpha\theta}$, $\frac{e^{-\frac{\alpha}{\theta}}}{\sqrt{\theta}}$, $\frac{e^{-\frac{\alpha}{\theta}}}{\sqrt{\theta^3}}$ and then show how they can be used to compute the time integrals in $\mathcal{D}_L$ and $\mathcal{D}_F$. First, we review some basic properties of Chebyshev polynomials. For $x \in [-1, 1]$, the closed-form expression for the nth-order Chebyshev polynomial $T_n(x)$ is given by:

$$T_n(x) = \cos(n \cos^{-1} x). \tag{3.1}$$

The Chebyshev polynomials $T_n(x)$ are orthogonal w.r.t. the inner product defined by:

$$\langle f(x), g(x) \rangle = \int_{-1}^{1} \frac{f(x)g(x)}{\sqrt{1-x^2}} dx. \tag{3.2}$$

The nth-order Chebyshev coefficient of $f(x)$ denoted by $f(n)$ can be computed by taking the inner product with $T_n(x)$:

(3.3)
$$f(n) = \int_{-1}^{1} \frac{f(x)T_n(x)}{\sqrt{1-x^2}}\, dx = \frac{c_n}{\pi} \int_0^{\pi} f(\cos\theta) \cos n\theta \, d\theta = \frac{c_n}{2\pi} \int_0^{2\pi} f(\cos\theta) \cos n\theta \, d\theta,$$

$$\text{where} \quad c_0 = 1 \quad \text{and} \quad c_k = 2 \quad \text{for} \quad k \geq 1. \tag{3.4}$$

Now as the function $f(\cos\theta)$ is 2π-periodic, we can use FFT or the fast cosine transform to compute $\{f(n)\}_{n=0}^{q-1}$ in $\mathcal{O}(q \log q)$ time. Also, we will use the following properties of Chebyshev polynomials:

$$T_n(x) = 2xT_{n-1}(x) - T_{n-2}(x), \quad \text{and} \quad \int T_n = \frac{1}{2}\left(\frac{T_{n+1}}{n+1} - \frac{T_{n-1}}{n-1}\right) + C.$$

For more details on the properties of Chebyshev polynomials, we refer to [18]; a review on spectral methods for solving PDEs using the Chebyshev polynomials can be found in [24].

3.1. Recurrence relations. The idea of computing the integrals through the approximation of the integrand by Chebyshev polynomials and then computing the moments of smooth functions by recurrences was first used by Clenshaw and Curtis [3]. Consider integrating a smooth function $f(x)$ in the interval $(0, 1)$:

$$I = \int_0^1 f(x)dx = \sum_{n=0}^{q-1} f(n) \int_0^1 T_n(2x-1)dx = \sum_{n=0}^{q-1} f(n) I_n,$$

$$\text{where} \quad I_n = \int_0^1 T_n(2x-1)dx = \left[\frac{T_{n+1}(2x-1)}{n+1} - \frac{T_{n-1}(2x-1)}{n-1}\right]_0^1.$$

One can easily show that evaluation of this will yield:

$$I_n = \begin{cases} 0 & \text{if } n \text{ is odd,} \\ -\frac{1}{n^2-1} & \text{otherwise.} \end{cases} \tag{3.5}$$

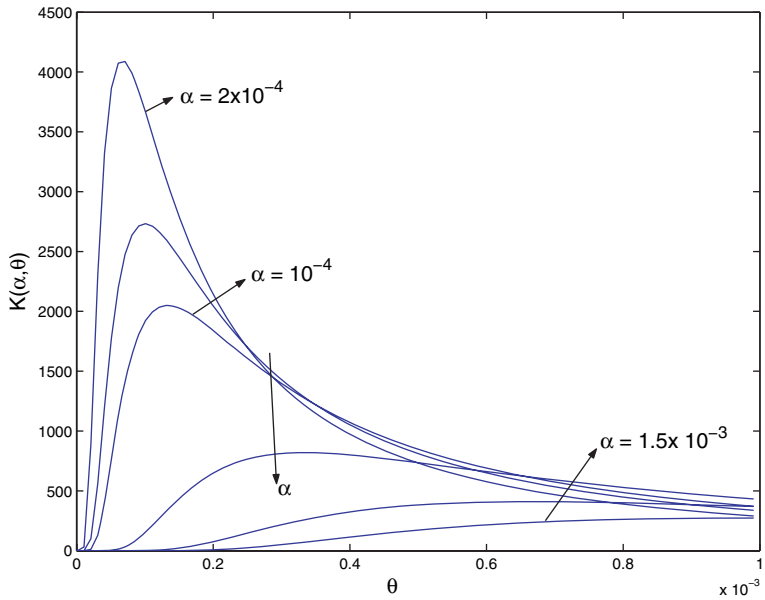

FIG. 3.1. *Kernel* $K(\alpha,\theta) = \frac{\sqrt{\alpha}}{\sqrt{\theta^3}} e^{-\frac{\alpha}{\theta}}$ *for different values of* α. *The kernel becomes sharply peaked as* α *decreases, so an accurate evaluation of* (3.6) *by generic quadratures requires an excessive number of points.*

Similarly we can derive the recurrences for computing the moments $I_k(\alpha) = \int_0^1 K(\alpha,\theta)$ $T_k(\theta)$ for a variety of kernels K. In Appendix A we give recurrences for the singular kernels $\theta^{-\gamma}$ for $\gamma \in (-\infty, 1)$ and $\log\theta$. As the approximation of $f(\theta)$ by Chebyshev polynomials is superalgebraically convergent, the error in the computation of the integral $I(\alpha)$ is approaching zero exponentially (numerical examples can be found in section 6). Now we discuss the computation of integral operators that will arise while evaluating the heat potentials. Let us consider

$$I(\alpha) = \int_0^1 \frac{\sqrt{\alpha}}{\sqrt{\theta^3}} e^{-\frac{\alpha}{\theta}} f(\theta)\, d\theta, \quad \text{and} \quad J(\alpha) = \int_0^1 \frac{1}{\sqrt{\theta}} e^{-\frac{\alpha}{\theta}} f(\theta)\, d\theta. \tag{3.6}$$

In the limit any generic quadrature rule will converge to the correct value of I and J with its optimal convergence rate. The quality of the approximation, however, will be nonuniform in the value of α. In fact, the constants deteriorate dramatically with small α. As a result, I and J become very difficult to compute accurately; a generic rule will require thousands of points—even for a few digits of accuracy. This is because the kernel becomes sharply peaked for smaller values of α; see Figure 3.1.

This poses a challenge for Nyström-type methods as one would need to develop specialized quadratures for different values of α. Instead, we are using a Chebyshev approximation of f and derive recurrence relations to compute the moments I_n. In this way, given α, we can compute all I_n with $\mathcal{O}(q)$ work.

First we compute the base condition for the recurrence:

$$I_0(\alpha) = \int_0^1 \frac{\sqrt{\alpha}}{\sqrt{\theta^3}} e^{-\frac{\alpha}{\theta}}\, d\theta = 2\int_{\sqrt{\alpha}}^{\infty} e^{-z^2} dz = \sqrt{\pi}\mathrm{erfc}(\sqrt{\alpha}).$$

Then we compute higher moments by

$$I_n(\alpha) = \int_0^1 \frac{\sqrt{\alpha}}{\sqrt{\theta^3}} e^{-\frac{\alpha}{\theta}} T_n \, d\theta = \int_0^1 \frac{\sqrt{\alpha}}{\sqrt{\theta^3}} e^{-\frac{\alpha}{\theta}} \left[2(\lambda\theta+\eta)T_{n-1} - T_{n-2}\right] d\theta,$$

$$\Rightarrow I_n(\alpha) = 2\lambda\sqrt{\alpha} J_{n-1} + \eta I_{n-1} - I_{n-2}, \tag{3.7}$$

$$\text{where} \quad J_{n-1}(\alpha) = \int_0^1 \frac{1}{\sqrt{\theta}} e^{-\frac{\alpha}{\theta}} T_{n-1} \, d\theta = 2\lambda \int_0^1 \sqrt{\theta} e^{-\frac{\alpha}{\theta}} T_{n-2} \, d\theta + 2\eta J_{n-2} - J_{n-3}.$$

Integrating by parts, we get:

$$2\lambda \int_0^1 \sqrt{\theta} e^{-\frac{\alpha}{\theta}} T_{n-2} \, d\theta = C_n - \int_0^1 \left(\frac{1}{2\sqrt{\theta}} + \frac{\alpha}{\sqrt{\theta^3}}\right) e^{-\frac{\alpha}{\theta}} \left(\frac{T_{n-1}}{n-1} - \frac{T_{n-3}}{n-3}\right) d\theta.$$

Substituting this back in the expression for J_{n-1}, we obtain the following recurrence:

$$J_{n-1}(\alpha) = \frac{2n-2}{2n-1}\left(C_n - \frac{2n-7}{2n-6} J_{n-3} + 2\eta J_{n-2} - \sqrt{\alpha}\left(\frac{I_{n-1}}{n-1} - \frac{I_{n-3}}{n-3}\right)\right), \tag{3.8}$$

$$\text{where} \quad C_n = e^{-\alpha}\left(\frac{T_{n-1}(\lambda+\eta)}{n-1} - \frac{T_{n-3}(\lambda+\eta)}{n-3}\right). \tag{3.9}$$

Using (3.8) we can compute $J_{n-1}(\alpha)$, from which $I_n(\alpha)$ can be computed using (3.7). Now we establish the recurrences for the kernel $e^{-\alpha\theta}$:

$$I_n = \int_0^1 e^{-\alpha x} T_n(\lambda x + \eta) \, dx,$$

$$= \left[\frac{e^{-\alpha x}}{2\lambda}\left(\frac{T_{n+1}}{n+1} - \frac{T_{n-1}}{n-1}\right)\right]_0^1 + \int_0^1 \left[\frac{e^{-\alpha x}}{2\lambda}\left(\frac{T_{n+1}}{n+1} - \frac{T_{n-1}}{n-1}\right)\right],$$

$$\Rightarrow I_{n+1} = c_{n+1} + (n+1)\left(\frac{2\lambda}{\alpha} I_n + \frac{I_{n-1}}{n-1}\right),$$

$$\text{where } c_{n+1} = \frac{n+1}{\alpha}\left[e^{-\alpha x}\left(\frac{T_{n+1}}{n+1} - \frac{T_{n-1}}{n-1}\right)\right]_0^1. \tag{3.10}$$

The recurrences (3.8) and (3.10) are numerically unstable[5] in the forward direction. More specifically, we get a dominant solution rather than a minimal[6] solution for these recurrences, which prohibits us from computing higher-order moments (see [17]

[5]There are algorithms that can be used for stabilizing these recurrences; see, for example, [25]. The length of the domain ω (which is less than 1) sets an upper bound on the parameter α in the recurrences (3.7), (3.8). Based on this upper bound, we have obtained a global eighth-order accurate method without resorting to any such recurrence-stabilizing algorithms. In general, it is possible to get *arbitrary* order of accuracy by stabilizing the recurrences.

[6]If we take two linearly independent solutions f_n and g_n of a three term recurrence $y_{n+1} + a_n y_n + b_n y_{n-1} = 0$, then f_n is called a minimal solution if $f_n/g_n \to 0$ as $n \to \infty$; g_n is then termed as the dominant solution. Adding any multiple of f_n to g_n would give us another dominant solution, but the minimal solution is always unique.

for more details). Since we use a qth-order piecewise polynomial approximation of $\mu(\theta)$ we need to ensure that the recurrences are stable up to $n = q$.

Remark. The more sharply peaked the integration kernel is, the more stable the recurrences are and thus the higher the order of moments that we can compute accurately. For example, the kernel $e^{-\alpha\theta}$ is sharply peaked for higher values of α.

For $\alpha \ll 1$, instead of using the recurrence (3.10), we use $e^{-\alpha x} = \sum_{k=0}^{p}(-1)^k \frac{(\alpha x)^k}{k!}$ and the recurrences given in Appendix A to compute

$$I_n = \int_0^1 e^{-\alpha x} T_n \, dx = \sum_{k=0}^{p} \frac{(-\alpha)^k}{k!} M_{nk}, \quad \text{where } M_{nk} = \int_0^1 x^k T_n \, dx; \tag{3.11}$$

here p is chosen such that $\frac{\alpha^p}{p!} < \epsilon$, the required accuracy.

The numerical instability is a property of the recurrence relation; different recurrences such as (3.5) and the ones given in Appendix A for the kernels $\frac{1}{\theta^\gamma}$ for $\gamma \in (-\infty, 1)$ and $\log\theta$ are unconditionally stable.

3.2. Heat kernels. Using the recurrences derived here, we now develop product integration rules for the time integrals of far and near parts of the double layer.

(a) *Far part.* To compute $C_n(t + \triangle t, \delta)$ using the recurrence (2.10), we have to compute

$$U_n[\hat{\phi}] = \int_{t-\delta}^{t+\triangle t-\delta} e^{-n^2\pi^2(t+\triangle t-\tau)} \hat{\phi}_n(\tau) \, d\tau. \tag{3.12}$$

As n increases, the kernel becomes sharply peaked, prohibiting the use of smooth quadrature rules to compute (3.12). Instead, we use the recurrences. We compute the Chebyshev coefficients of $\hat{\phi}_n(\tau)$ in the interval[7] $(t - \delta, t + \triangle t - \delta)$, then we have $\hat{\phi}_n(\tau) = \sum_{k=0}^{q-1} \hat{\phi}_n(k) T_k(\frac{2}{\triangle t}(\tau - t + \delta) - 1)$. By setting $\tau = t + \triangle t - \theta\triangle t - \delta$ we obtain

$$U_n[\hat{\phi}] = \triangle t e^{-n^2\pi^2\delta} \sum_{k=0}^{q-1} \hat{\phi}_n(k) \int_0^1 e^{-(n^2\pi^2\triangle t)\theta} T_k(-2\theta + 1) \, d\theta = \sum_{k=0}^{q-1} \hat{\phi}_n(k) E_{nk}. \tag{3.13}$$

For a fixed step size $\triangle t$ we can precompute

$$E_{nk} = \triangle t e^{-n^2\pi^2\delta} \int_0^1 e^{-(n^2\pi^2\triangle t)\theta} T_k(-2\theta + 1), \quad n = 1, \ldots, p, \; k = 1, \ldots, q. \tag{3.14}$$

This precomputation is done in an optimal $\mathcal{O}(pq)$ time using the recurrence (3.10) with $\alpha = n^2\pi^2\triangle t$ and the scaling parameters $\lambda = -2, \eta = 1$.

(b) *Local part.* The local part approximation of the double layer potential is given by

$$\mathcal{D}_L[\phi] = \sum_{k=1}^{2}(-1)^k \int_{t-\delta}^{t} \frac{x - b_k}{4[\pi(t-\tau)]^{3/2}} e^{-\frac{(x-b_k)^2}{4(t-\tau)}} \phi(b_k, \tau) d\tau. \tag{3.15}$$

[7]Here we assume $\delta = l\triangle t$. We have the Chebyshev coefficients of $\hat{\phi}_n(\tau)$ at each time interval Δt (see section 4). If $\delta < \triangle t$, we use the recurrence (3.10) with modified scaling factors (λ, η) instead of computing the Chebyshev coefficients in the interval $(t - \delta, t + \triangle t - \delta)$.

Let

$$\mathcal{D}_{L_{b_k}}[\phi] = (-1)^k \int_{t-\delta}^{t} \frac{x-b_k}{4[\pi(t-\tau)]^{3/2}} e^{-\frac{(x-b_k)^2}{4(t-\tau)}} \phi(b_k,\tau) d\tau. \tag{3.16}$$

Then

$$\mathcal{D}_L[\phi] = \mathcal{D}_{L_{b_1}}[\phi] + \mathcal{D}_{L_{b_2}}[\phi]. \tag{3.17}$$

Setting $\theta = \frac{t-\tau}{\delta}$ and substituting $\alpha = \frac{(x-b_k)^2}{4\delta}$ we get

$$\mathcal{D}_{L_{b_k}}[\phi] = \frac{1}{2\sqrt{\pi}} \int_0^1 \frac{\sqrt{\alpha}}{\sqrt{\theta^3}} e^{-\frac{\alpha}{\theta}} \phi(b_k, t-\delta\theta)\, d\theta. \tag{3.18}$$

Similarly to the far part case, we compute the Chebyshev coefficients[8] of $\phi(b_k,\tau)$ for $\tau \in (t-\delta, t)$. Then we use the recurrence relations (3.7) together with (3.8) to compute (3.18).

4. The overall algorithm for a stationary boundary. So far we have presented (1) an integral equation formulation for (1.1); (2) a near-far decomposition in time of the volume and layer potentials; and (3) quadratures for convolutions of functions (defined in terms of Chebyshev polynomials) for singular or nearly singular kernels and in particular heat kernels. Next we describe how we can combine these techniques to efficiently solve (1.1) on stationary boundaries. In a nutshell, we compute the volume potentials $u_i(x,t)$ and $u_f(x,t)$ using the formulas (1.5), solve the integral equation (1.7) for the double layer density $\phi(\gamma,t)$, and use (1.6) to compute $u_b(x,t)$.

4.1. Evaluation of the volume potentials. We will need two additional algorithms.

Computing Fourier coefficients for the far part. We need a fast algorithm for computing the sine transforms $\hat{w}$ and $\hat{f}(\tau)$ used in $\mathcal{V}_{0,F}[w]$ and $\mathcal{V}_F[f]$:

$$\hat{w}_n = \int_\Omega w(y)\sin(n\pi y)\, dy; \quad \hat{f}_n(\tau) = \int_\Omega f(y,\tau)\sin(n\pi y)\, dy, \quad n = 1,\dots,p. \tag{4.1}$$

We assume that both f and w are given in regular grid points in space time. If f and w are periodic, then (4.1) can be computed using FFTs. Otherwise, we use the high-order hybrid Gauss trapezoidal rules developed in [1]. The advantage of using those rules is that, except for a few Gaussian nodes, all of the other quadrature nodes are on a regular grid. Then if n_g is the number of Gaussian nodes and M is the number of trapezoidal nodes, the complexity of computing the discretization of (4.1) can be reduced from $\mathcal{O}((M+n_g)p)$ to $\mathcal{O}((M+p)\log M + pn_g)$ using the FFT.

Fast Gauss transform. We need an accurate and fast evaluation of the Gauss transform defined by

$$G_\sigma[\mu](x) = \frac{1}{\sqrt{\pi\sigma}} \int_\Omega e^{-\frac{(x-y)^2}{\sigma}} \mu(y)\, dy. \tag{4.2}$$

[8] If $\delta = l\triangle t$, we need to loop through the l time intervals, each of which has a Chebyshev polynomial representation of $\phi(b_k,\tau)$. On the other hand, if $\delta < \triangle t$, we compute (3.18) from the polynomial representation of $\phi(b_k,\tau)$ in the interval $(t-\triangle t, t)$.

Using quadrature rules to discretize (4.2) and applying the fast Gauss transform (FGT) [7] on the resulting discrete sum, the complexity of computing G_σ at M points in space using M quadrature points is reduced from $\mathcal{O}(M^2)$ to $\mathcal{O}(M)$. But through this approach, uniform high-order convergence would not be possible for smaller values of σ, since the Gaussian becomes sharply peaked. So, to get the expected convergence with optimal complexity, we proceed as follows:

- We divide Ω into M/q_s uniform cells, each of size l_C; q_s is defined below.
- In each cell we use a fixed number of quadrature nodes q_s. One way to choose q_s is to ensure that a Gaussian of support equal to the size of cell can be resolved using q_s points.
- An approximate support of a Gaussian is given by $2r\sqrt{\sigma}$, where r is such that $e^{-r^2} < \epsilon$ and ϵ is the desired accuracy. If $2r\sqrt{\sigma} > l_C$, we use the FGT to compute G_σ at the M target points. Since there are M sources the complexity is $\mathcal{O}(M)$.
- If $2r\sqrt{\sigma} < l_C$ we compute G_σ directly: We truncate the domain of integration from Ω to the support $(x - r\sqrt{\sigma}, x + r\sqrt{\sigma})$ and use q_s quadrature points to discretize the integral. The forcing term at these points is computed using an appropriate high-order interpolation. The complexity is $\mathcal{O}(M)$.

4.1.1. Initial condition volume potential. The kernel $G(x, y, t)$ is approximated by the truncated Fourier series expansion if $t > \delta$ and by the Kelvin expansion otherwise. Hence,

$$u_i(x,t) = \begin{cases} G_{2t}[w](x), & \text{if } t \le \delta, \\ \sum_{n=1}^{p} (2e^{-n^2\pi^2 t}\hat{w}_n)\sin(n\pi x), & \text{otherwise.} \end{cases} \tag{4.3}$$

The transform $G_{2t}[w]$ is evaluated using the aforementioned strategy with a quadrature rule of order q. The inverse NUFFT is used to compute the discrete sum in (4.3) for $t > \delta$.

4.1.2. Distributed forcing volume potential. The evaluation of (1.5) is split into a far part $(0, t-\delta)$ and a local part $(t-\delta, t)$. At time interval $(t, t+\triangle t)$ the evaluation of the far part $\mathcal{V}_F[f]$ involves the following steps:

- Computation of the Chebyshev coefficients for each of $\{\hat{f}_n(\tau)\}_{n=1}^p$ by evaluating (4.1) (using quadrature rules in space) at the Chebyshev nodes belonging to $(t-\delta, t+\triangle t-\delta)$.
- For $n = 1, \ldots, p$, computation of the update $U_n[\hat{f}]$ as defined in (3.12) using Chebyshev recurrences developed in section 3.
- Update of $\{C_n\}_{n=1}^p$ using $C_n(t+\triangle t, \delta) = C_n(t, \delta) + 2U_n[\hat{f}]$.
- Evaluation of the discrete sum $\mathcal{V}_F[f](x, t+\triangle t) = \sum_{n=1}^{p} C_n(t+\triangle t, \delta)\sin(n\pi x)$ at the target points using the inverse NUFFT.

The local part of $u_f(x,t)$ denoted by $\mathcal{V}_L[f]$ is given by

$$\mathcal{V}_L[f](x,t) = \int_{t-\delta}^{t}\int_{\Omega} \frac{e^{-\frac{(x-y)^2}{4(t-\tau)}}}{\sqrt{4\pi(t-\tau)}} f(y,\tau)dy\,d\tau. \tag{4.4}$$

Setting $\sigma^2 = t-\tau$ and noting that, outside the interval $(x-2r\sigma, x+2r\sigma)$, the Gaussian decays exponentially fast to zero, we obtain

$$\mathcal{V}_L[f](x,t) \approx \int_0^{\sqrt{\delta}} g(\sigma)\,d\sigma, \quad \text{where } g(\sigma) = \frac{1}{\sqrt{\pi}}\int_{x-2r\sigma}^{x+2r\sigma} e^{-\frac{(x-y)^2}{4\sigma^2}} f(y, t-\sigma^2)dy. \tag{4.5}$$

By substituting $y = x + 2\xi\sigma$, we get $g(\sigma) = \frac{2\sigma}{\sqrt{\pi}} \int_{-r}^{r} e^{-\xi^2} f(x + 2\xi\sigma, t - \sigma^2) d\xi$; the integrand is smooth, and hence, $g(\sigma)$ is a smooth function in σ. Then, we use a high-order quadrature rule of order q to integrate $g(\sigma)$, i.e., $\mathcal{V}_L[f](x,t)] = \sum_{k=1}^{q} w_k g(\sigma_k)$, where w_k, σ_k are the quadrature weights and nodes, respectively. Notice that $g(\sigma_k) = 2\sigma_k G_{2\sigma_k}[f](t - \sigma_k^2)$ at each σ_k. Hence, the optimal strategy for computing the Gauss transform discussed previously can be used for the accurate computation of $g(\sigma_k)$.

4.2. Computation and evaluation of the boundary double layer potential. To evaluate $u_b(x,t)$, we first need to compute the density $\phi(\gamma, t)$ by solving (1.7). At each time step, we incrementally solve (1.7) for the Chebyshev coefficients of $\phi(b_1, t)$ and $\phi(b_2, t)$. Let $\phi(b_1, n), \phi(b_2, n)$ denote the corresponding nth-order Chebyshev coefficients. Then, for any $\tau \in [t, t + \triangle t]$, we have

$$\phi(b_k, \tau) = \sum_{n=0}^{q-1} \phi(b_k, n) T_n \left(\frac{2}{\triangle t}(\tau - t) - 1 \right), \quad k = 1, 2.$$

Since we require q Chebyshev coefficients at each point on the boundary, we need to solve (1.7) at q collocation nodes $\{t + t_i\}_{i=1}^{q}$. The natural choice of the collocation nodes are the zeros of qth-order Chebyshev polynomial defined in the interval $[t, t + \triangle t]$. Then the transformation between physical and spectral space can be performed using the FFT. In addition, interpolation at the Chebyshev nodes gives rise to a stable approximation of the interpolated function.

The Chebyshev nodes are given by

$$t_i = \frac{\triangle t}{2} \left(1 + \cos \frac{\pi(i-1)}{q} \right), \qquad i = 1, \ldots, q. \tag{4.6}$$

The integral equation (1.7) can be rewritten as

$$\begin{aligned} &-\frac{1}{2}\phi(x, t + t_i) + \int_t^{t+t_i} \int_\gamma \frac{\partial G(x, t + t_i; y, \tau)}{\partial n(y)} \phi(y, \tau) ds(y) d\tau \\ &= u_b(x, t + t_i) - \int_0^t \int_\gamma \frac{\partial G(x, t + t_i; y, \tau)}{\partial n(y)} \phi(y, \tau) ds(y)\, d\tau \quad \forall x \in \gamma. \end{aligned} \tag{4.7}$$

The resulting finite-dimensional linear equation is $K\phi_h = r$, where

$$\phi_h = [\phi(b_1, 0), \ldots, \phi(b_1, q-1),\ \phi(b_2, 0), \ldots, \phi(b_2, q-1)]^T. \tag{4.8}$$

Assuming $\delta \geq \triangle t$, the entries of K are given by $K = \begin{bmatrix} A & B \\ B & A \end{bmatrix}$,

$$\text{where} \quad A_{ij} = -\frac{1}{2} T_{j-1} \left(\frac{2}{\triangle t} t_i - 1 \right), \quad i, j = 1, \ldots, q, \tag{4.9}$$

$$B_{ij} = \int_t^{t+t_i} \frac{b_2 - b_1}{4[\pi(t-\tau)]^{3/2}} e^{-\frac{(b_2 - b_1)^2}{4(t-\tau)}} T_{j-1} \left(\frac{2}{\triangle t}(\tau - t) - 1 \right) d\tau. \tag{4.10}$$

The entries of B can be computed using recurrences on $I_n(\alpha) = \int_0^1 \frac{\sqrt{\alpha}}{\sqrt{\theta^3}} e^{-\frac{\alpha}{\theta}} T_n(\lambda\theta + \eta) d\theta$. The operator K is well-conditioned and can by "inverted" using a matrix-free GMRES.[9] The integration of the history part of double layer on the right-hand side

[9] Given a fixed time step $\triangle t$, we can precompute the inverse K^{-1} once and subsequently solve for ϕ_h by just one matrix vector multiplication $K^{-1}r$. This is can be done efficiently only in 1D and for static boundaries.

of (4.7), denoted by $\mathcal{D}_h$, is split into $(0, t+t_i-\delta)$ and $(t+t_i-\delta, t)$. The first interval integral is

$$\sum_{n=1}^{p} \left(e^{-n^2\pi^2 t_i} C_n(t,\delta) + 2\int_{t-\delta}^{t+t_i-\delta} e^{-n^2\pi^2(t+t_i-\tau)} \hat{\phi}(\tau)\, d\tau \right) \sin(n\pi x). \tag{4.11}$$

We use the local part expansion of the kernel for the second interval. The time integration in both intervals is performed using the product integration rules discussed in section 3. Since the coefficients C_n are updated at each time step, r can be computed with constant work per time step. Then $u_b(x,t)$ can be evaluated at the target M spatial locations using (1.6) and the fast summation method for the double layer described in section 2.

4.3. Summary of the overall scheme for stationary boundaries. The overall algorithm is summarized in Algorithm 1. The output of the algorithm is $u(x,t)$ at the target points. The inputs are

- **parameters:** A fixed time step Δt and an error tolerance ϵ.
- **boundary conditions:** In each time interval $(t, t+\triangle t)$, the boundary data at the collocation nodes $g(b_k, t+t_i), i = 1, \ldots, q$.
- **distributed force:** The forcing f at points belonging to a regular grid of size $M \times N$ imposed on $\Omega \times [0,T]$.
- **initial condition:** w at M regular points on Ω.

Since we use special quadrature points to compute the volume integrals (4.1), f and w are evaluated using high-order interpolation schemes; for example, FFT combined with B-splines can be used [27].

The overall complexity of the algorithm is $\mathcal{O}(MN \log M)$. Below, we discuss the different sources for errors in the final solution.

- Truncating the series expansion for Green's function in the near and far parts. These have been shown to be exponentially convergent with increasing M, N.
- The order of the Chebyshev polynomials used for approximating the density ϕ in each time interval.
- The quadrature rule used for the computing the spatial integrals (4.1) and time integral (4.5).

By approximating ϕ with $(q-1)$th-order Chebyshev polynomials and picking a quadrature rule of order q to perform the space and time integration for the volume potentials, we get a qth-order method. In section 6, we present results that validate our scheme.

5. Moving boundary. Now we will describe the methodology for solving (1.1) for boundaries with a prescribed motion. By linearity, we decompose the solution into three parts: $u = u_i + u_f + u_b$. The three parts correspond to the solutions of an initial-value problem (1.2), an inhomogeneous problem with homogeneous boundary conditions (1.3), and a homogeneous problem with inhomogeneous boundary conditions (1.4). The motion of the boundary $\omega(t)$ is assumed to be contained within the unit box Ω; hence, the solutions $u_i(x,t)$ and $u_f(x,t)$ are given by (1.5). At any point x inside the domain $\omega(t)$ we assume that $u_b(x,t) = \mathcal{D}[\phi](x,t)$. As $G(x,t;y,\tau)$ satisfies the adjoint equation (2.1) and the potential u_b satisfies the heat equation, the initial condition $u_b(x,0) = 0$ is satisfied by construction. To satisfy the prescribed boundary conditions on $\gamma(t)$, we need to compute the jumps in the double layer as $x \to \gamma(t)$. The conditions have been derived before; for example, see [21, 9]. We have included their derivation for completeness. We first discuss the computation of the double layer potential at a point away from the boundary, and then we give the jump conditions.

Algorithm 1. Overall algorithm for stationary boundaries.

INITIALIZATION
Choose p and l using (2.11)
Compute E (3.14) using (3.10)
Compute $\hat{w}_n$ and set $C_n = 2e^{-n^2\pi^2(l-1)\triangle t}\hat{w}_n$, $n = 1 \dots p$ $\mathcal{O}((M+p)\log M)$
Compute t_i using (4.6)
Compute K^{-1} $\mathcal{O}(q^3)$

TIME MARCHING
for $j = 1 : N$ do

    end for $\mathcal{O}(pq + p)$
    $u(x_k, j\triangle t) += \sum_{n=1}^{p} C_n \sin(n\pi x_k)$, $k = 1 \dots M$ $\mathcal{O}((M+p)\log M)$
  end if
end for

To evaluate the double layer, we split it into a local and a far part: $\mathcal{D}[\phi] = \mathcal{D}_L[\phi] + \mathcal{D}_F[\phi]$. We first discuss the local part computation. We rewrite the local part as $\mathcal{D}_L[\phi] = \mathcal{D}_{L_{b_1}}[\phi] + \mathcal{D}_{L_{b_2}}[\phi]$, with each term being defined as in (3.16) but using the time-dependent boundaries. Let's look at computing $D_{L_{b_2}}[\phi](x,t)$ defined by

$$\mathcal{D}_{L_{b_2}}[\phi] = \int_{t-\delta}^{t} \frac{x - b_2(\tau)}{4[\pi(t-\tau)]^{3/2}} e^{-\frac{(x-b_2(\tau))^2}{4(t-\tau)}} \phi(b_2(\tau), \tau) d\tau. \tag{5.1}$$

Setting $\tau = t - \delta\theta$, $\frac{x - b_2(\tau)}{2\sqrt{\delta}} = \beta(\theta)$, and $\phi(b_2, t - \delta\theta) = \psi(\theta)$ we get

$$\mathcal{D}_{L_{b_2}}[\phi] = \frac{1}{2\sqrt{\pi}} \int_0^1 \frac{\beta(\theta)}{\sqrt{\theta^3}} e^{-\frac{\beta^2(\theta)}{\theta}} \psi(\theta)\, d\theta. \tag{5.2}$$

Unlike the static boundary case, we cannot directly use the recurrences (3.7), (3.8) to compute (5.2) as β is not a constant. Instead, we rewrite (5.2) as

$$\mathcal{D}_{L_{b2}} = \frac{1}{2\sqrt{\pi}} \int_0^1 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta^3}} \left\{\beta(\theta) E_\beta(\theta) \psi(\theta)\right\} d\theta, \quad \text{where } E_\beta(\theta) = e^{-\frac{\beta^2 - \beta_0^2}{\theta}}, \tag{5.3}$$

and $\beta_0 = \beta(0)$. The kernel in this expression is similar to the static boundaries case (3.18). Therefore, we first compute the Chebyshev coefficients of the function $\beta E_\beta \psi$ and then use the recurrences (3.7), (3.8) with $\alpha = \beta_0^2$ to compute (5.3).

Remark. Assuming $\beta(\theta)$ is sufficiently smooth, it is easy to see that E_β is also smooth: By expanding $\beta(\theta)$ about $\theta = 0$ using Taylor's series as $\beta(\theta) = \sum_{k=0}^{\infty} \beta_k \theta^k$, we can see that $E_\beta(\theta)$ is of the form $e^{-\sum_{k=0}^{\infty} c_k \theta^k}$.

Similarly, the single layer potential is calculated by rewriting it as

$$\mathcal{S}_{L_{b_2}}[\phi] = \frac{1}{2\sqrt{\pi}} \int_0^1 \frac{e^{-\frac{\beta^2(\theta)}{\theta}}}{\sqrt{\theta}} \psi(\theta)\, d\theta = \frac{1}{2\sqrt{\pi}} \int_0^1 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta}} \left\{E_\beta \psi(\theta)\right\} d\theta \tag{5.4}$$

and using the recurrence (3.8). Now let us examine the limit as the evaluation point x approaches the boundary. As $x \to b_2(t)$, the constant term in Taylor's expansion of $\beta(\theta)$ given by $\beta_0 = \frac{x - b_2(t)}{2\sqrt{\delta}}$ approaches zero.

PROPOSITION 5.1. *We define the single layer potential as* $\mathcal{S}_L[f](\beta_0) = \int_0^1 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta}} f(\theta)\, d\theta$ *and the double layer potential as* $\mathcal{D}_L[f](\beta_0) = \int_0^1 \beta_0 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta^3}} f(\theta)\, d\theta$. *Then* $\mathcal{S}_L[f]$ *is continuous as* $\beta_0 \to 0$, *whereas* $\mathcal{D}_L[f]$ *sustains a jump equal to* $f(0)$.

$$\lim_{\beta_0 \to 0^-} \mathcal{S}_L[f] = \lim_{\beta_0 \to 0^+} \mathcal{S}_L[f] = \int_0^1 \frac{f(\theta)}{\sqrt{\theta}}\, d\theta, \tag{5.5}$$

$$\lim_{\beta_0 \to 0^-} \mathcal{D}_L[f] = -\frac{1}{2} f(0), \quad \lim_{\beta_0 \to 0^+} \mathcal{D}_L[f] = \frac{1}{2} f(0). \tag{5.6}$$

We give a proof of this proposition in Appendix B. In the case of static boundaries, using this proposition, we arrived at the Volterra system (1.7). For moving boundaries, clearly the proposition cannot be applied directly, since β is not constant. Here we write the double layer potential defined in (5.2) as follows:

$$\mathcal{D}_{L_{b_2}} = \frac{1}{2\sqrt{\pi}} \int_0^1 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta}} \left\{ \left(\frac{\beta(\theta) - \beta_0}{\theta} \right) E_\beta \psi(\theta) \right\} d\theta + \frac{1}{2\sqrt{\pi}} \int_0^1 \frac{\beta_0 e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta^3}} \left\{E_\beta \psi(\theta)\right\} d\theta. \tag{5.7}$$

Let us define $F_\beta(\theta) = \frac{\beta(\theta) - \beta_0}{\theta}$. Using Taylor's series (and assuming sufficient smoothness), we have $F_\beta(\theta) = \sum_{k=1}^{\infty} \beta_k \theta^{k-1}$. Therefore, $F_\beta(\theta)$ is smooth and independent of β_0 and $\lim_{\theta \to 0} F_\beta(\theta) = \beta_1$, where $\beta_1 = -\frac{\dot{b}(t)}{2\sqrt{\delta}}$. We denote the first integral in (5.7) by $\tilde{\mathcal{S}}_{L_{b_1}}$; it is a single layer potential with constant β_0, and hence it is continuous as $\beta_0 \to 0$. By Proposition 5.1, the second integral approaches $-\frac{1}{2} E_\beta(0) \psi(0)$

as $\beta \to 0^-$. We can show that $\lim_{\theta \to 0_{\beta_0 \to 0}} E_\beta(\theta) = 1$. The Volterra system that we obtain for moving boundaries is given by

$$-\frac{1}{2}\phi(x,t) + \int_0^t \int_{\gamma(\tau)} \frac{\partial G(x,t;y,\tau)}{\partial n(y)} \phi(y,\tau)\, ds(y)\, d\tau = u_b(x,t)\, \forall x \in \gamma(\tau). \tag{5.8}$$

In the case of static boundaries, the Volterra equation (1.7) at the boundary point b_1 at time t can be written as

$$\left(-\frac{1}{2}I + \mathcal{D}_{F_{b_1}} + \mathcal{D}_{b_2}\right)[\phi](b_1,t) = u_b(b_1,t), \tag{5.9}$$

since the local part of the double layer $D_{L_{b_1}}[\phi](b_1,t) \to -\frac{1}{2}\phi(b_1,t)$. The far part does not contribute to the jump in the double layer. From (5.7), we can show that the Volterra equation in the case of moving boundaries at $(b_1(t),t)$ is given by

$$\left(-\frac{1}{2}I + \mathcal{D}_{F_{b_1}} + \tilde{\mathcal{S}}_{L_{b_1}} + \mathcal{D}_{b_2}\right)[\phi](b_1(t),t) = u_b(b_1(t),t). \tag{5.10}$$

We can verify that, as the boundary motion becomes negligible, (5.10) leads to (5.9): $\beta(\theta) \to \beta_0$ and $\lim_{\beta(\theta)\to\beta_0} \tilde{\mathcal{S}}_{L_b}[\phi](b(t),t) = 0$ as the function $F_\beta(\theta) \to 0$ since $\beta_k \to 0$ for all $\{\beta_k\}_{k=1}^\infty$.

We now summarize the changes in the algorithm described in section 4, which are necessary for moving boundary problems. At each time step, we solve (5.8) for the Chebyshev coefficients of $\phi(b_1(t),t)$ and $\phi(b_2(t),t)$ using GMRES. Assuming $\phi(b_2,t)$ is given, our aim is to solve the resulting algebraic system after discretizing the operator equation (5.10) by collocation at nodes t_i. Starting with an initial guess $\{\phi_n(b_1)\}_{n=0}^{q-1}$, we first compute $\phi_0(b_1,t_i)$ at the collocation nodes in time t_i by inverse FFT. Computing the left-hand side of (5.10) involves computing three operators at (b_1,t_i) : the far part $\mathcal{D}_{F_{b_1}}[\phi]$, the local part of the single layer $\tilde{\mathcal{S}}_{L_{b_1}}[\phi]$, and the double layer $\mathcal{D}_{b_2}[\phi]$.

- As with the static case, the far part $\mathcal{D}_{F_{b_1}}[\phi](b_1,t)$ is computed by storing and updating $\{C_n(t,\delta)\}_{n=1}^p$ and evaluating (2.9). The only difference is that the boundaries are time-dependent in the definition of $\hat{\phi}_n(\tau)$.
- To compute $\tilde{\mathcal{S}}_{L_{b_1}}[\phi](b_1,t_i)$, we need to evaluate the function $F_\beta(\theta)E_\beta(\theta)\psi(\theta)$ in (5.7). Let

$$\phi_{\tilde{\mathcal{S}}}(t,\tau) = \frac{b_1(t) - b_1(\tau)}{2(t-\tau)} e^{-\frac{(b_1(t)-b_1(\tau))^2}{4(t-\tau)}} \phi(b_1(\tau),\tau), \tag{5.11}$$

and then

$$\begin{aligned}\tilde{\mathcal{S}}_{L_{b_1}}[\phi](b_1(t_i),t_i) &= \int_{t_i-\delta}^{t_i} G\left(b_1(t_i), b_1(t_i); t_i, \tau\right) \phi_{\tilde{\mathcal{S}}}(t_i,\tau)\, d\tau \\ &= \int_{t_i-\delta}^{t_i} \frac{\phi_{\tilde{\mathcal{S}}}(t_i,\tau)}{\sqrt{4\pi(t_i-\tau)}}\, d\tau.\end{aligned}$$

To compute the Chebyshev coefficients $\{\phi_{\tilde{\mathcal{S}}}(t_i,n)\}_{n=0}^{q-1}$, we evaluate $\phi_{\tilde{\mathcal{S}}}(t_i,\tau)$ at the collocation nodes $\{t_j\}_{j=1}^q$ (which also are the Chebyshev nodes). Note that, when $\tau \to t$, we have $\lim_{\tau\to t} \phi_{\tilde{\mathcal{S}}}(t,\tau) = -\dot{b}_1(t)$. Then we evaluate $\tilde{\mathcal{S}}_{L_{b_1}}[\phi](b_1(t_i),t_i)$ using the recurrence (3.8) with appropriate scaling factors and $\alpha = 0$.

- To compute $\mathcal{D}_{b_2}[\phi]$, we split it into a far and a local part. The local part is computed by rewriting it as in (5.3) with $\beta_0 = \frac{b_1(t_i)-b_2(t_i)}{2\sqrt{\delta}}$.

Once we solve for the Chebyshev coefficients of $\phi(b_1, t)$ and $\phi(b_2, t)$ the potential u_b is evaluated at all target locations using (1.6). The asymptotic complexity and accuracy of the algorithm are the same with the stationary case.

6. Numerical results. In this section we illustrate the accuracy of the quadrature scheme described in section 3 for different kernels. Then we present numerical results for solving the heat equation (1.1).

6.1. Quadratures. We compare the hybrid quadratures of Alpert [1] with the Chebyshev spectral method. First we compute the following integral:

$$\int_0^1 \cos(200x)s(x) + \cos(200x + 0.5)\ dx \tag{6.1}$$

for the functions $s(x) = 0, s(x) = \frac{1}{\sqrt{x}}, s(x) = \log x$. The recurrence relations for computing the moments $I_k = \int_0^1 s(x)T_k(2x-1)dx$ are given in Appendix A. We report relative errors for both the Chebyshev method and the quadrature methods in [1] for convergence orders 4, 8, and 16. See Figure 6.1.

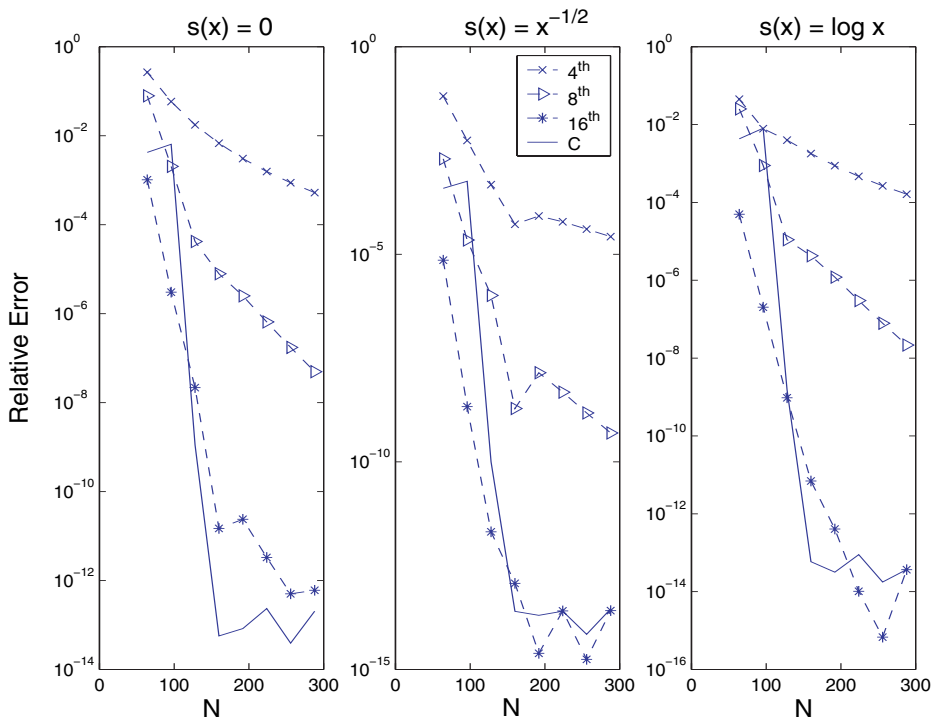

FIG. 6.1. *Plot of the relative errors given in Tables* 6.1, 6.2, *and* 6.3 *w.r.t. p, the number of Chebyshev modes used. As the number of quadrature points is increased, we observe that the quadrature error gets reduced by a constant multiple, whereas in the case of the Chebyshev approximation, the error decays exponentially.*

We now present numerical results for evaluating the following integral for two different functions $f(x)$:

$$J(\alpha) = \int_0^1 \frac{e^{-\frac{\alpha}{x}}}{\sqrt{x}} f(x)\, dx. \tag{6.2}$$

The relative errors in computing (6.2) using two different methods are presented in Tables 6.4 and 6.5. One is to use *Nyström's method* with the quadrature nodes and weights of the singular kernel $x^{-1/2}$, and the other is to approximate the function $f(x)$ using Chebyshev polynomials and then using the recurrence relations (3.8). In Table 6.4, we can see that the relative error is high in the case of Nyström's method even if we take as many as 512 points. This can be expected as the behavior of the heat kernels is different from $x^{-1/2}$. So we need to develop separate quadrature rules. Developing such quadratures for each value α is not practical. Instead, we can compute $\{I_n(\alpha)\}_{n=1}^{p}$ for each α in $\mathcal{O}(p)$ work using the recurrence relations (3.8). For

TABLE 6.4

Relative errors in computing the double layer heat potential with density $f_1(x) = 1 + x^{10}$ and $\alpha = 2 \times 10^{-4}$. Here N indicates the number of quadrature nodes or the order of Chebyshev polynomials used to approximate the function $f(x)$; q denotes the order of singular quadrature rule used. Observe that the error in the case of quadrature doesn't reduce as $\mathcal{O}(N^{-q})$, whereas in the second case the error reaches machine precision for $N > 10$. Recall that the smaller the α, the more difficult the computation of the heat kernel becomes.

the same functions $f_1(x)$ and $f_2(x)$, we evaluate the integrals

$$I(\alpha) = \int_0^1 \frac{\sqrt{\alpha} e^{-\frac{\alpha}{x}}}{\sqrt{x^3}} f(x)\, dx. \tag{6.3}$$

See Table 6.6. In Figure 6.2, we plot the relative errors in computing aforementioned integral operators by the Chebsyshev method.

6.2. The heat equation: Stationary boundaries. In this section we report results for the diffusion problems in domains with static boundaries. In all of the examples, the domain ω is taken to be $[0.4, 0.6]$, $\delta = 10^{-3}$, and the total time $T = 0.1$; N indicates the number of time steps and q the number of Chebyshev polynomials used to approximate the functions in the boundary integrals at each time step. We report the l_∞ error evaluated at M spatial points and N time levels in Tables 6.7 and 6.8 for two different analytic solutions.

6.3. The heat equation on domains with moving boundaries. Here we present numerical results for the solution of the heat equation on domains with prescribed boundary motion. The boundary position, as a function of time, is given by

TABLE 6.8

In this table we report l_∞-norm errors for the heat equation (1.1) problem with an analytic solution given by $u(x,t) = \cos(100x)\cos(200t)$ and a corresponding nonzero distributed force. We consider Dirichlet boundary conditions and an indirect double layer formulation. We use eight quadrature points in computing the volume integrals in (4.1). See Table 6.9 for running times.

Example 1 (prescribed Neumann conditions). We solve the homogeneous heat equation with Neumann boundary conditions given by $\frac{\partial u}{\partial x}(b_k, t) = 2e^{-4t}\cos(2b_k(t))$ and an initial condition given by $u(x, 0) = \sin(2x)$. For this problem the exact solution is given by $u(x, t) = e^{-4t}\sin(2x)$. We report l_∞-norm errors of our numerical approximation scheme in Tables 6.11, 6.13, and 6.14. We have used a direct formulation that results in a well-conditioned integral equation. We solve this problem for the three cases of boundary motion. At each time step, we sample the numerical and exact solution at a uniformly spaced spatial grid. We report the maximum of the absolute error values over all time steps and spatial points. We observe optimal convergence rates for all three cases.

Example 2 (prescribed Dirichlet data). In this second example we solve a heat equation problem with distributed forces and prescribed Dirichlet boundary condi-

tions:

$$\frac{\partial u}{\partial t} = \triangle u + 4\cos(2x)\cos(100t) - 100\cos(2x)\sin(100t) \quad \text{in } \omega(t), \tag{6.4}$$

$$\text{and} \quad u(x,0) = \cos(2x),\ u(b_k(t),t) = \cos(2b_k(t))\cos(100t). \tag{6.5}$$

The exact solution for this problem is given by $u(x,t) = \cos(2x)\cos(100t)$. We report l_∞ errors, computed as in the case of the other examples, in Tables 6.15, 6.16, and 6.17. Again, we observe optimal convergence rates.

7. Conclusions. We have presented an extension of the Greengard and Strain algorithm [6] for the fast solution of the heat equation with moving boundaries. Our main contribution is the introduction of the product integration quadrature and a

scheme for moving boundaries. Our approach results in a high-order scheme in both space and time. We presented results for the Neumann and Dirichlet problems with distributed forces. In all cases the accuracy and efficiency of the proposed scheme is verified—even in the case of highly oscillatory boundary motions. Optimal complexity has been achieved by using the fast Gauss transform and nonuniform FFT. Also, our method can be extended to variable-coefficient and nonlinear problems by introducing a volume density for which we have to solve.

A shortcoming of our method is that it has a complex implementation. A second, more important drawback is that high-order accuracy can be achieved for sufficiently smooth data only (forces, boundary conditions, and boundary motion). For certain applications, in particular industrial ones, this can be a quite restrictive assumption. For general nonsmooth data the high-order properties of our scheme will be lost.

We are currently working on extending this work to higher dimensions. As we mentioned in the introduction, all algorithmic choices extend to higher dimensions: the product quadrature rules, the Chebyshev approximation (using adaptive, tensor products), the kernel splitting for the local and far parts, and the approximations in the case of prescribed boundaries. The most significant complication is the fact that the boundary of the target domain becomes an infinite-dimensional manifold. Boundary convolution with the heat kernel requires additional algorithmic machinery. Although one can outline the extensions of the method in higher dimensions, such a task is difficult when one wants to preserve work optimality and high accuracy. Finally, the assumption that f and w are defined everywhere is restrictive; in most practical applications the data will be defined only on a regular grid or at random points. Smooth extensions and design of special quadrature rules for such data are not trivial. We are currently working on addressing some of these issues, and we will report our work in a future paper.

Appendix A. Here we give recurrence relations to compute $I_k = \int_0^1 \sigma(\theta) T_k(2\theta - 1) d\theta$ for the singular kernels $\sigma_1(\theta) = \theta^{-\gamma}$ for any $\gamma \in (-\infty, 1)$ and $\sigma_2(\theta) = \log(\theta)$. These recurrences are unconditionally stable.

$$I_n = -\frac{n}{n+1-\gamma}\left(\frac{2}{n(n-2)} + 2I_{n-1} + \frac{n-3+\gamma}{n-2} I_{n-2}\right) \quad n > 2 \quad \text{for } \sigma_1(\theta). \tag{A.1}$$

$$I_n = \frac{n}{n+1}\left(C_n - 2I_{n-1} - \frac{n-3}{n-2} I_{n-2}\right) \quad n > 2 \quad \text{for } \sigma_2(\theta), \tag{A.2}$$

$$\text{where} \quad C_n = \begin{cases} 0 & n \text{ is odd,} \\ -\frac{6}{n^4 - 4n^3 + n^2 + 6n} & \text{otherwise.} \end{cases}$$

Appendix B.

Proof of the direct formulation. The Leibniz rule for differentiating the volume integral, also called Reynold's transport theorem, states that, for any function $q(x,t)$ defined in $\Omega(t)$,

$$\frac{d}{dt}\int_{\Omega(t)} q d\Omega = \int_{\Omega(t)} \frac{\partial q}{\partial t} d\Omega + \int_{\gamma(t)} q(v.n) d\gamma,$$

where v is the velocity of the boundary. Substituting $q = Gu$, we get

$$\begin{aligned}\frac{d}{dt}\int_{\Omega(t)} Gu d\Omega &= \int_{\Omega(t)} \frac{\partial G}{\partial t}u + G\frac{\partial u}{\partial t} + \int_{\gamma(t)} Gu(v\cdot n)d\gamma \\ &= \int_{\Omega(t)} \frac{\partial G}{\partial t}u + G(\triangle u + b) + \int_{\gamma(t)} Gu(v\cdot n) \\ &= \int_{\Omega(t)} \left(\frac{\partial G}{\partial t} + \triangle G\right)u + Gb + \int_{\gamma(t)} \left(G\frac{\partial u}{\partial n} - u\frac{\partial G}{\partial n}\right) + Gu(v\cdot n).\end{aligned}$$

Integrating both sides from 0 to t and using $G(x,y,t,t) = 0$ for any t, we get

$$-\int_{\Omega_0} Gw = \int_0^t \int_{\Omega(\tau)} [-\delta(x,t)u + Gb] + \int_0^t \int_{\gamma(\tau)} \left(G\frac{\partial u}{\partial n} - u\frac{\partial G}{\partial n}\right) + Gu(v\cdot n),$$

$$\Rightarrow u(x,t) = \int_{\Omega_0} Gw + \int_0^t \int_{\Omega(\tau)} Gb \; + \int_0^t \int_{\gamma(\tau)} \left(G\frac{\partial u}{\partial n} - u\frac{\partial G}{\partial n}\right) + Gu(v\cdot n). \tag{B.1}$$

Jump conditions: (a) Defining $I(\beta_0) = \int_0^1 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta}} f(\theta)\, d\theta$, we have to prove:

$$\lim_{\beta_0\to 0^-} I(\beta_0) = \lim_{\beta_0\to 0^+} I(\beta_0) = \int_0^1 \frac{1}{\sqrt{\theta}} f(\theta)\, d\theta. \tag{B.2}$$

Proof. Consider the sequence of functions g_n defined as $g_n = e^{-\frac{\beta_n^2}{\theta}}$ with the sequence β_n chosen such that $\lim_{n\to\infty} \beta_n = 0$. Clearly $|g_n| \le 1$ and $g_n \to 1$ pointwise almost everywhere. The result follows by Lebesgue's dominated convergence theorem.

(b) Assuming that $f(\theta)$ is uniformly continuous in $\theta \in (0,1)$, we need to prove:

$$\begin{gathered}\lim_{\beta_0\to 0^+} I(\beta_0) = \frac{1}{2}f(0); \\ \lim_{\beta_0\to 0^-} I(\beta_0) = -\frac{1}{2}f(0), \quad \text{where } I(\beta_0) = \frac{\beta_0}{2\sqrt{\pi}}\int_0^1 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta^3}} f(\theta)\, d\theta. \qquad \square\end{gathered} \tag{B.3}$$

Proof. We split the integral into two parts: $I(\beta_0) = I_1(\beta_0) + I_2(\beta_0)$. The integrals I_1 and I_2 are defined as follows:

$$I_1 = \frac{\beta_0 f(0)}{2\sqrt{\pi}} \int_0^1 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta^3}}\, d\theta = \frac{\beta_0}{2\,|\beta_0|}\mathrm{Erfc}(\beta_0) f(0). \tag{B.4}$$

$$\therefore \lim_{\beta_0\to 0^-} I_1(\beta_0) = -\frac{1}{2}f(0) \quad \text{and} \quad \lim_{\beta_0\to 0^+} I(\beta_0) = \frac{1}{2}f(0). \tag{B.5}$$

$$I_2 = \frac{1}{2\sqrt{\pi}} \int_0^1 \frac{e^{-\frac{\beta_0^2}{\theta}}}{\sqrt{\theta^3}} \left(f(\theta) - f(0)\right) d\theta = \frac{1}{\sqrt{\pi}} \int_{\beta_0}^\infty e^{-\sigma^2} \left(f\left(\frac{\beta_0^2}{\sigma^2}\right) - f(0)\right), \tag{B.6}$$

by the change of variables $\sigma = \frac{\beta_0}{\sqrt{\theta}}$. Now breaking the interval of integration into two parts $\left(\beta_0, \sqrt{\beta_0}\right)$ and $\left(\sqrt{\beta_0}, \infty\right)$, we see that as $\beta_0 \to 0$ the integral of the first interval vanishes. The integral of the second interval $\sigma \ge \sqrt{\beta_0} \Rightarrow |\frac{\beta_0^2}{\sigma^2}| \le |\beta_0|$. Since $f(\theta)$ is uniformly continuous, we can choose δ such that $|f(\frac{\beta_0^2}{\sigma^2}) - f(0)| < \epsilon$ whenever $|\beta_0| < \delta$. Thus,

$$\lim_{\beta_0\to 0} |I_2(\beta_0)| < \lim_{\epsilon\to 0} \frac{\epsilon}{2\sqrt{\pi}} \int_{\sqrt{\beta_0}}^\infty e^{-\sigma^2}\, d\sigma = 0. \qquad \square \tag{B.7}$$

IMPLICIT SCHEME FOR HYPERBOLIC CONSERVATION LAWS USING NONOSCILLATORY RECONSTRUCTION IN SPACE AND TIME*

KARTHIKEYAN DURAISAMY† AND JAMES D. BAEDER‡

Abstract. The efficiency of high order accurate schemes for the solution of unsteady hyperbolic conservation laws is adversely affected by time-step restrictions that arise from monotonicity requirements. When applied to the solution of problems involving discontinuities, these restrictions render conventional high order implicit time integration schemes impractical. In the present study, a new single step second order implicit scheme that uses nonoscillatory reconstruction in space and time is presented. Both the spatial and temporal limiters are dependent on the evolving solution, and this nonlinearity allows for a circumvention of total variation diminishing bounds. Numerical results on model scalar and vector hyperbolic equations suggest that the scheme holds promise in achieving accurate and unconditionally nonoscillatory solutions.

Key words. high resolution schemes, implicit schemes, time limiting

DOI. 10.1137/070683271

1. Introduction.

The present study is concerned with the solution of hyperbolic conservation equations using high order accurate implicit schemes. Hyperbolic conservation laws allow for discontinuities, and hence a good numerical solution scheme should be able to accurately represent such features without generating spurious oscillations. Over the past few decades, much research has focused on designing high order accurate nonoscillatory numerical schemes. Spatial discretizations like the uniformly accurate (UNO) schemes [1], the essentially nonoscillatory (ENO) and weighted ENO (WENO) [2] schemes, and the monotonicity preserving (MP) [3] schemes have been successfully used with high order explicit Runge–Kutta methods (for time integration) in the solution of a variety of hyperbolic conservation laws.

The stability of explicit schemes is governed by the CFL condition, placing a restriction on the allowable time-step size. Hence these methods could become inefficient when the hyperbolic system is highly stiff or when the spatial mesh is largely nonuniform. In such cases, it is desirable to use implicit schemes for which the time step is usually limited by accuracy and not stability. Implicit schemes will also be beneficial for unsteady flows in which the dominant time scales are much larger than the characteristic-based time scales (an example is the flow around a pitching airfoil). Also, implicit time integration may be preferred in practical computations when the time-step size required to achieve the desired accuracy may be several times larger than the explicit limit. However, ensuring nonoscillatory behavior of linear implicit high order time integration schemes imposes severe time-step restrictions (see Gottlieb, Shu, and Tadmor [4]). These restrictions are a result of nonlinear stability constraints, a well-known measure of which is the total variation diminishing con-

[1]Imp. BDF2: Implicit second order backwards difference; SDIRK-2: Singly diagonally implicit Runge–Kutta method (two stages) [6].

dition (TVD) [5]. For a given spatial discretization, Table 1 shows the ratio of the maximum allowable time step (from a TVD viewpoint) of a few implicit schemes to that of explicit schemes (specifically, the explicit Euler method). It is evident that linear high order implicit schemes become impractical in the solution of flow fields with discontinuities since the allowable time steps are only slightly higher than that of explicit schemes.

In an attempt to overcome this time-step barrier, Duraisamy, Baeder, and Liu [7] proposed a class of nonlinear implicit time integration schemes in a method-of-lines framework. In this method, a convex combination of a first and a second order implicit scheme is used, and the coefficients of this combination are changed such that the time accuracy locally drops to first order near discontinuities. Forth [8] presented a scheme for scalar equations that switches between the implicit Euler and second order backwards difference methods in different parts of the domain. Both of the aforementioned approaches yielded nominally nonoscillatory schemes but turned out to be highly diffusive at large CFL numbers. In this work, an implicit scheme that is accurate and nonoscillatory at large time steps is presented.

2. Formulation. Consider a scalar conservation law of the form

$$\frac{\partial u(x,t)}{\partial t} + \frac{\partial f(u(x,t))}{\partial x} = 0 \tag{1}$$

with suitable initial and boundary conditions. To discretize this equation, space is divided into cells $[x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}}]$, and time is divided into intervals $[t^n, t^{n+1}]$ as depicted in Figure 1. The integral form of (1) in the control volume $[x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}}] \times [t^n, t^{n+1}]$ is given by

$$\int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} [u(x,t^{n+1}) - u(x,t^n)]dx = -\int_{t^n}^{t^{n+1}} [f(u(x_{j+\frac{1}{2}},t)) - f(u(x_{j-\frac{1}{2}},t))]dt.$$

This can then be written in the *conservation form*

$$\bar{u}_j^{n+1} = \bar{u}_j^n - \tau(\hat{f}_{j+\frac{1}{2}} - \hat{f}_{j-\frac{1}{2}}), \tag{2}$$

where

$$\bar{u}_j^n = \frac{1}{\Delta x}\int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} u(x,t^n)dx \quad \text{and} \quad \hat{f}_{j+\frac{1}{2}} = \frac{1}{\Delta t}\int_{t^n}^{t^{n+1}} f(u(x_{j+\frac{1}{2}},t))dt \tag{3}$$

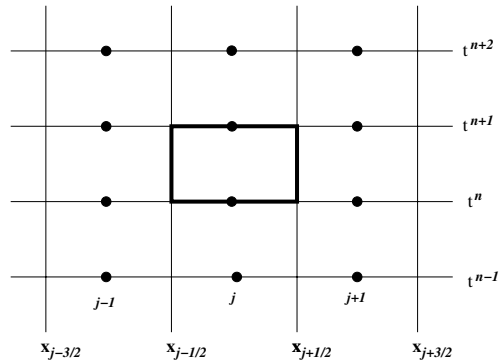

FIG. 1. *Schematic of discretization in time and space.*

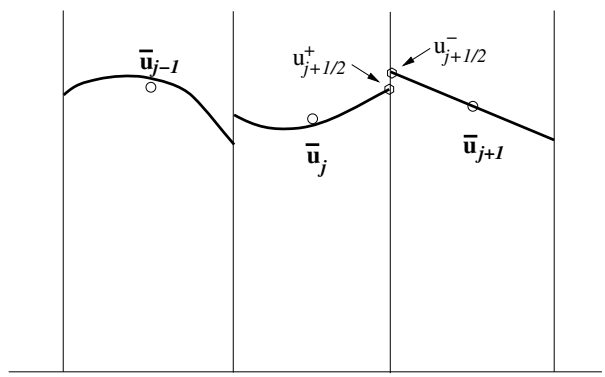

FIG. 2. *Spatial reconstruction.*

with $\Delta x = x_{j+\frac{1}{2}} - x_{j-\frac{1}{2}}$, $\Delta t = t^{n+1} - t^n$, and $\tau = \frac{\Delta t}{\Delta x}$. By defining a suitable approximation to the flux integral (3), numerical schemes can be constructed to an arbitrary order of accuracy. Higher order accurate schemes can be constructed using multiple stages or multiple steps or by increasing the stencil size. In this work, we are concerned with Godunov-type MUSCL methods [9]. In this method, the flux $f(u(x_{j+\frac{1}{2}}))$ at a cell interface is evaluated by the following:

(1) Defining *reconstructed* values of the solution to the left (+) and right (−) of the interface (Figure 2): These values are usually computed using monotone interpolation of the cell-average values.

(2) Using an appropriate upwind solver treating the left and right states as defining a Riemann problem: For instance, the Roe upwind solver would yield $f(u(x_{j+\frac{1}{2}})) = \frac{1}{2}(f(u^-_{j+\frac{1}{2}}) + f(u^+_{j+\frac{1}{2}})) - \frac{1}{2}|a|(u^-_{j+\frac{1}{2}} - u^+_{j+\frac{1}{2}})$, where a is an approximation to the interface flux Jacobian.

For the new scheme, $\hat{f}_{j+\frac{1}{2}}$ is approximated by

$$\begin{aligned}\hat{f}_{j+\frac{1}{2}} &= \frac{1}{\Delta t}\int_{t^n}^{t^{n+1}} f(u(x_{j+\frac{1}{2}}, t))dt \\ &= f(u(x_{j+\frac{1}{2}}, t^{n+\frac{1}{2}})) + O(\Delta t^2).\end{aligned}$$

Second order accuracy is achieved by considering the midpoint in time. To define the

interface values, a Taylor series approximation is used:

$$u(x,t) = \bar{u}(x_j, t^{n+1}) + \frac{\partial u}{\partial x}(x_j, t^{n+1})(x - x_j) + \frac{\partial u}{\partial t}(x_j, t^{n+1})(t - t^{n+1}) + O(\Delta x^2, \Delta t^2).$$

Since the Taylor series is centered about the new time-level t^{n+1}, the resulting numerical scheme would be implicit in time. Similar approaches with series centered at time-level t^n abound in the literature (see, for instance, [10]). The usual practice is to approximate the time derivative using the governing equation. For instance,

$$\frac{\partial u}{\partial t}(x_j, t^n) = -\frac{\partial f}{\partial u}(x_j, t^n)\frac{\partial u}{\partial x}(x_j, t^n).$$

High order accurate schemes can be constructed by using higher order terms in the Taylor series and replacing the time derivative terms by equivalent spatial derivatives. The present scheme differs in the sense that it is implicit and the time derivative is not approximated by spatial derivatives. This allows a definition of the reconstructed value in terms of spatial and temporal differences. The interface value (to the left of the interface) would then be defined as

$$u^{+}{}_{j+\frac{1}{2}}^{n+\frac{1}{2}} = \bar{u}_j^{n+1} + \frac{(\Delta_x)_{j+1/2}^{n+1}}{2} - \frac{(\Delta_t)_j^{n+1/2}}{2}, \tag{4}$$

where $(\Delta_x)_{j+1/2}^{n+1} = \bar{u}_{j+1}^{n+1} - \bar{u}_j^{n+1}$ and $(\Delta_t)_j^{n+1/2} = \bar{u}_j^{n+1} - \bar{u}_j^n$.

Figure 3 shows results for the new method as applied to the linear convection equation $u_t + u_x = 0$ with $u(x,0) = \sin^4(x/2)$ and periodic boundary conditions. A CFL number $\sigma = \Delta t/\Delta x = 3.5$ is used. The shaded profile is the exact evolution of the solution at the half–time step. It is evident that the addition of the time reconstruction greatly improves the final solution when compared to an implicit Euler method which can be viewed as using a purely spatial reconstruction.

It has to be mentioned that the current scheme gives an exact solution to the linear advection equation at $\sigma = 1.0$ *and* $\sigma = 2.0$. This is especially interesting because implicit time integration (in a method-of-lines framework) is typically characterized by large diffusive errors at modest CFL numbers.

3. Monotonicity constraints. The reconstruction defined in (4) is not guaranteed to be monotone in the presence of discontinuities, and hence limiters are introduced as follows:

$$u^{+}{}_{j+\frac{1}{2}}^{n+\frac{1}{2}} = \bar{u}_j^{n+1} + \phi_j \frac{(\Delta_x)_{j+1/2}^{n+1}}{2} - \psi_j \frac{(\Delta_t)_j^{n+1/2}}{2}.$$

The design of the spatial ($\phi_j(r_j)$) and temporal ($\psi_j(s_j)$) limiters will be guided by the TVD condition, and these limiters are functions of $r_j = \frac{(\Delta_x)_{j-1/2}^{n+1}}{(\Delta_x)_{j+1/2}^{n+1}}$ and $s_j = \frac{(\Delta_t)_{j+1}^{n+1/2}}{(\Delta_t)_j^{n+1/2}}$, respectively.

Consider the linear advection equation $u_t + au_x = 0$, with $a > 0$. From this point forward, the overbar for cell-averaged quantities and superscripts for the spatial $(n+1)$ and temporal $(n+1/2)$ differences are dropped for clarity. For the new scheme,

$$\hat{f}_{j+\frac{1}{2}} = a\left[u_j^{n+1} + \phi_j \frac{(\Delta_x)_{j+1/2}}{2} - \psi_j \frac{(\Delta_t)_j}{2}\right]. \tag{5}$$

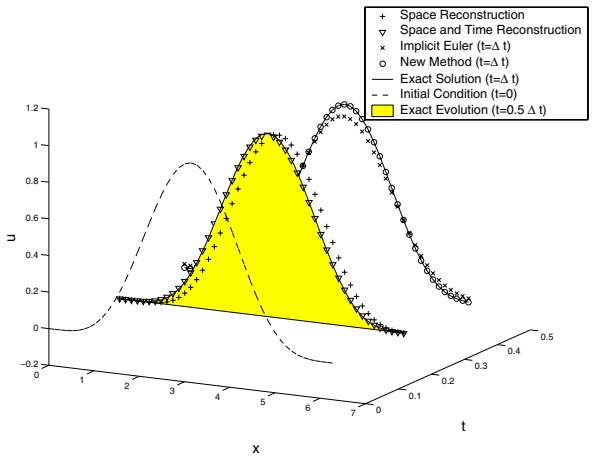

FIG. 3. *Linear advection equation with* $\sigma = 3.5$.

Therefore,

$$\begin{aligned} u_j^{n+1} &= u_j^n - \tau(\hat{f}_{j+\frac{1}{2}} - \hat{f}_{j-\frac{1}{2}}) \\ &= u_j^n - \sigma\Bigg[(u_j^{n+1} - u_{j-1}^{n+1}) \\ &\quad + \frac{1}{2}\left(\frac{\phi_j}{r_j} - \phi_{j-1}\right)(\Delta_x)_{j-1/2} - \frac{1}{2}\left(\psi_j - \frac{\psi_{j-1}}{s_{j-1}}\right)(\Delta_t)_j\Bigg], \end{aligned}$$

where $\sigma = a\frac{\Delta t}{\Delta x}$. Rearranging terms,

$$\left[1 + \frac{\sigma}{2}\left(\frac{\psi_{j-1}}{s_{j-1}} - \psi_j\right)\right](u_j^{n+1} - u_j^n) = -\sigma\left[1 + \frac{1}{2}\left(\frac{\phi_j}{r_j} - \phi_{j-1}\right)\right](\Delta_x)_{j-1/2}.$$

Finally, this gives

$$u_j^{n+1} + \sigma\left[\frac{1 + \frac{1}{2}(\frac{\phi_j}{r_j} - \phi_{j-1})}{1 + \frac{\sigma}{2}(\frac{\psi_{j-1}}{s_{j-1}} - \psi_j)}\right](\Delta_x)_{j-1/2} = u_j^n. \tag{6}$$

Casting the scheme in this form, the above scheme is TVD (see appendix) if

$$\infty > \frac{1 + \frac{1}{2}(\frac{\phi_j}{r_j} - \phi_{j-1})}{1 + \frac{\sigma}{2}(\frac{\psi_{j-1}}{s_{j-1}} - \psi_j)} \geq 0. \tag{7}$$

For $a < 0$, a similar expression involving $j+1$ is obtained. For the nonlinear case $u_t + f(u)_x = 0$, a similar condition involving a local CFL-like number is obtained. Both these expressions and the corresponding TVD conditions are provided in the appendix.

Notice that the numerator and denominator represent spatial and temporal reconstruction, respectively, and hence both should be individually positive. For the spatial part, any standard limiter can be used, but in this work, the following is used:

$$\phi(r) = \begin{cases} r & \text{if } |r| \leq 1, \\ 1 & \text{if } |r| > 1. \end{cases} \tag{8}$$

This is equivalent to second order accurate ENO reconstruction. The ENO method is spatially second order accurate *and* strictly TVD when used with the implicit Euler time integration. In other words, the numerator is nonnegative for any value of r. It is apparent that the temporal terms (denominator) are similar to the spatial terms except for the scaling by the CFL number; hence, in order to satisfy the TVD conditions (nonnegativity of the denominator), the time limiter can be defined as

$$\psi(s) = \begin{cases} s/\sigma & \text{if} \quad |s| \leq 1 \quad \text{and} \quad \sigma > 1, \\ 1/\sigma & \text{if} \quad |s| > 1 \quad \text{and} \quad \sigma > 1, \\ s & \text{if} \quad |s| \leq 1 \quad \text{and} \quad \sigma \leq 1, \\ 1 & \text{if} \quad |s| > 1 \quad \text{and} \quad \sigma \leq 1. \end{cases} \tag{9}$$

Equations (8) and (9) are sufficient to guarantee an *unconditionally TVD scheme*. However, from (9) it is seen that for (local) $\sigma > 1$, the TVD region has shrunk because of the scaling, and this results in a local drop in temporal accuracy even when the solution is smooth in space and time ($s \approx 1$). This can be overcome by taking advantage of the implicitness of the scheme. The denominator of (7) is positive (and the numerator divided by the denominator is bounded) if

$$\psi_j < \frac{2}{\sigma} + \frac{\psi_{j-1}}{s_{j-1}}.$$

In implicit schemes, the system of equations is solved in an approximate linearized form at each time step, but to restore time accuracy, Newton *subiterations* have to be performed. Refer to [12] for a review of the approach. In the current method, the first subiteration is performed assuming $\psi_j = 0$ throughout the domain. After this, for any subiteration $p+1$, ψ can be set using information from p:

$$\psi_j^{p+1} = \min\left[1, \max\left[\frac{2}{\sigma} + \frac{\psi_{j-1}^p}{s_{j-1}^p} - \epsilon, 0\right]\right], \tag{10}$$

where $\epsilon > 0$ is a small number (to ensure that the denominator does not equal zero). This restores accuracy (see Figure 4) when the solution is smooth. To an extent, this also ensures smooth variation of the time limiter between grid points. In practice, this marginally degrades the convergence of subiterations.

Equations (8) and (10) define the limiters that will be used in this work for space and time reconstruction.

4. Numerical results. Numerical results are presented for the one-dimensional inviscid Burgers equation and the Euler equations. For each of the above cases, Newton-type subiterations [12] are used to solve the implicit set of equations at each time step. Typically, about five subiterations are required for convergence within one time step. The new scheme is termed the *implicit second order* space-time reconstruction (STR). For comparative purposes, all linear time integration schemes are used with the second order ENO spatial discretization. For this spatial scheme, explicit time integration schemes will be nonoscillatory up to a maximum CFL number $\sigma = \max_j\{\sigma_j\} = 0.5$.

4.1. The Burgers equation. The first test case is the inviscid Burgers equation $u_t + (\frac{u^2}{2})_x = 0$, with periodic boundary conditions and a domain $[0, 2\pi]$ of 100 equally spaced points. The initial condition is composed of an expansion wave and a

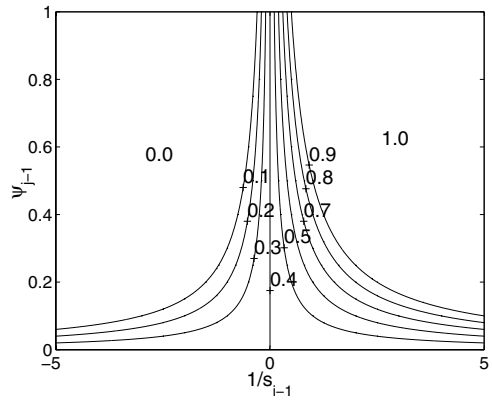

FIG. 4. *ψ_j as a function of ψ_{j-1} and s_{j-1} for $\sigma = 5$. For higher σ, there is more limiting in the left half-plane.*

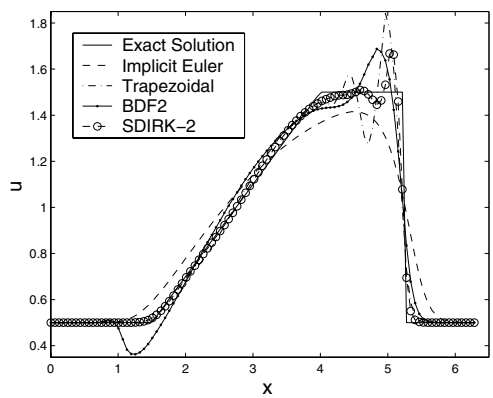

FIG. 5. *The Burgers equation with $\sigma = 4.0$, $N = 100$, and $T_{final} = 2.0$.*

compression wave. This profile is convected to a time $t = 2.0$, before which the compression wave becomes a shock. The Roe–Riemann solver is used for the interfacial flux.

For a time step corresponding to a CFL number $\sigma = \max_j\{u_j \frac{\Delta t}{\Delta x}\} = 4.0$, Figure 5 shows that the implicit Euler method shows high dissipation and the linear second order time integration schemes develop oscillations in the vicinity of the shock. The trapezoidal (Crank–Nicolson) method performs particularly poorly since it provides very little damping for high frequency dispersive errors. It is seen that the new scheme (Figure 6) is nonoscillatory. As expected, limiter-1 (9) is very dissipative and is only marginally better than the implicit Euler method. Limiter-2 (10) is seen to resolve the shock and the expansion wave well and will be used in the rest of the paper. Figures 7 and 8 assess the performance of the scheme up to $\sigma = 10.0$. It is evident that the new method remains nonoscillatory and reasonably accurate for the entire range of time-step sizes.

4.2. One-dimensional Euler equations. The one-dimensional Euler equations of gas dynamics are given by

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} = 0,$$

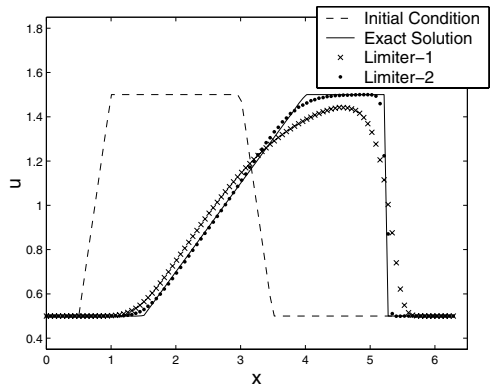

FIG. 6. *The Burgers equation with* $\sigma = 4.0$, $N = 100$, *and* $T_{final} = 2.0$.

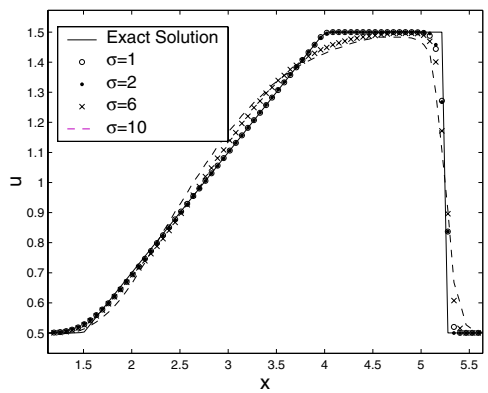

FIG. 7. *Performance of second order STR for various CFL numbers for the Burgers equation.* $N = 100$ *and* $T_{final} = 2.0$.

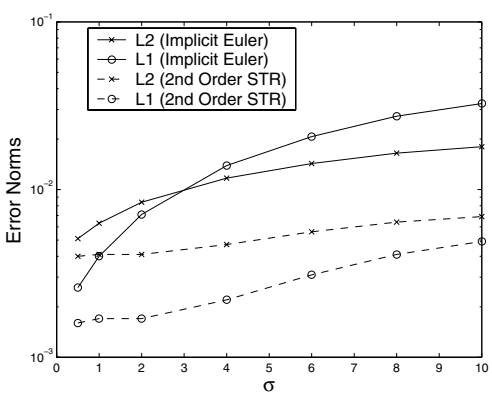

FIG. 8. L_1 *and* L_2 *norms for the Burgers equation.* $N = 100$ *and* $T_{final} = 2.0$.

where $\mathbf{U}$, the vector of conserved variables, and $\mathbf{F}$, the flux vector, are defined by

$$\mathbf{U} = \left\{ \begin{array}{l} \rho \\ \rho u \\ e \end{array} \right\}, \quad \mathbf{F} = \left\{ \begin{array}{l} \rho u \\ p + \rho u^2 \\ (e + p)u \end{array} \right\},$$

where ρ, u, and p are density, velocity, and pressure, respectively. e is the total energy per unit volume given by

$$e = \frac{p}{\gamma - 1} + \frac{\rho u^2}{2}.$$

Space and time limiters can be applied to each scalar equation $i = 1, \ldots, 3$ at each point $j = 1, \ldots, j\max$ in the domain. The reconstruction may be based on primitive, conservative, or characteristic variables. However, if primitive or conservative variables are used, the time limiter is somewhat arbitrary, and σ_j will have to be based on the maximum eigenvalue $\max\{|\lambda_i|)\}_j$. Based on numerical computations, this approach still seems to work if the time limiter (ψ_i) for a given cell is restricted to the minimum of the three computed limiters, resulting in increased dissipation. If characteristic variables are used for reconstruction, $(\sigma_i)_j$ can be based on $(|\lambda_i|)_j$, and hence different ψ_i can be used. Computations prove that this is indeed much more accurate, especially in treating contact discontinuities, which being linear, are more susceptible to smearing. It is also known [10], [3] that in many cases (including Lax's problem), even high order explicit schemes operating at very small CFL numbers require characteristic variables for nonoscillatory reconstruction. Hence, this approach will be used to obtain the following numerical results. Once the reconstruction is accomplished, Roe's approximate Riemann solver [13] is used to calculate the interfacial fluxes.

Sod's problem. Sod's problem for an infinite length constant area duct is defined by the initial left and right states given by $\{p_L, \rho_L, u_L\} = \{1.0,\ 1.0,\ 0.0\}$ and $\{p_R, \rho_R, u_R\} = \{0.1,\ 0.125,\ 0.0\}$. Figures 9–11 confirm that the scheme is less diffusive than the first order method and stable compared to the second order methods.

Lax's problem. Lax's problem is defined by $\{p_L, \rho_L, u_L\} = \{3.528,\ 0.445,0.698\}$ and $\{p_R, \rho_R, u_R\} = \{0.571,\ 0.5,\ 0.0\}$. This problem is slightly more difficult than Sod's problem in that the density is not monotone decreasing, and hence the contact discontinuity and the shock are more difficult to capture without spurious oscillations. As mentioned earlier, reconstructions based on primitive and conserved variables yield a fair amount of noise at high CFL numbers. Figures 12 and 13 outline some results for this problem.

5. Perspectives. For second order accurate schemes with symmetric spatial differencing, the determination of the interface value $u_{j+\frac{1}{2}}^{n+\frac{1}{2}}$ essentially comes from the set of four values $\{u_j^n, u_{j+1}^n, u_j^{n+1}, u_{j+1}^{n+1}\}$. Therefore, a family of schemes can be constructed, and many well-known methods can be defined based on particular combinations of these values. For instance, the calculation of the interface value in the unlimited STR-2 reduces to just a diagonal average as shown in Figure 14, and a few other schemes are shown in Table 2 (for a linear advection equation with a positive wave speed). Definition of better limiters can take advantage of the solution geometry as suggested in [14], [3]. In general, adopting less stringent monotonicity criteria than the TVD condition can improve solution accuracy, especially near extrema.

6. Conclusions. A new single step second order accurate implicit scheme that uses *reconstruction in space and time* has been developed. Conventionally, to achieve high order accuracy in single step methods, temporal derivatives are replaced by equivalent spatial derivatives. In the present approach, the temporal derivative is retained and approximated by a difference in time. The resulting STR is made nonoscillatory by the introduction of limiters that satisfy TVD conditions. Numerical experiments on model problems show accurate nonoscillatory solutions over a large range of time steps. Future work can involve increasing the order of accuracy by possibly having more quadrature points in the time interval.

7. Appendix.

7.1. Proof of TVD property. Lemma 3.1 in [11] states that if a numerical scheme for a conservation law can be written as $L.v^{n+1} = v^n$, then the scheme is TVD if the finite difference operator L is total variation increasing (TVI). Further, Lemma 3.2 in [11] states that if L can be represented in the form $(L.v)_j = v_j - C^-_{j-\frac{1}{2}}(\Delta_x)_{j-\frac{1}{2}}$, then L is TVI if $-\infty < C^-_{j-\frac{1}{2}} \leq 0$. Therefore, the TVD condition for the numerical scheme (6) is

$$-\infty < -\frac{1+\frac{1}{2}(\frac{\phi_j}{r_j}-\phi_{j-1})}{1+\frac{\sigma}{2}(\frac{\psi_{j-1}}{s_{j-1}}-\psi_j)} \leq 0 \tag{11}$$

or

$$\infty > \frac{1+\frac{1}{2}(\frac{\phi_j}{r_j}-\phi_{j-1})}{1+\frac{\sigma}{2}(\frac{\psi_{j-1}}{s_{j-1}}-\psi_j)} \geq 0. \tag{12}$$

7.2. Limiter in a general framework. For the linear convection case $u_t + au_x = 0$ with $a < 0$, the TVD condition is

$$\frac{1+\frac{1}{2}(-\frac{\phi_{j+1}}{r_{j+1}}+\phi_j)}{1+\frac{|\sigma|}{2}(\frac{\psi_{j+1}}{s^-_{j+1}}-\psi_j)} \geq 0,$$

where $s^-_{j+1} = \frac{(\Delta_t)_j}{(\Delta_t)_{j+1}}$.

For a nonlinear case $u_t + f(u)_x = 0$, with $\frac{\partial f}{\partial u}$ being positive or negative, we get similar conditions except for the fact that σ is replaced by $\sigma_j = \frac{\Delta t}{\Delta x}\frac{(f_j^{n+1}-f_j^n)}{(u_j^{n+1}-u_j^n)}$. Hence the time limiter (10) for a general case would be

$$\psi_j^{p+1} = \max\left[0, \min\left[\frac{2}{|\sigma_j|}+\frac{\psi^p_{j-1}}{s^p_{j-1}}, \frac{2}{|\sigma_j|}+\frac{\psi^p_{j+1}}{(t^-_{j+1})^p}, 1\right]\right].$$

7.3. Linear stability of the unlimited scheme. A conventional Fourier stability analysis of the unlimited scheme as applied to the linear convection equation ($a > 0$) results in the amplification function G as a function of the spatial wave number β and the CFL number σ given by

$$G(\beta,\sigma) = \frac{1-\frac{\sigma}{2}(1-e^{-i\beta})}{1-\frac{\sigma}{2}(1-e^{i\beta})}.$$

It is seen that $|G| = 1$ for all possible β and σ. This implies unconditional linear stability, and the scheme performs well for smooth solutions. However, for discontinuous solutions, accumulation of dispersion errors will result in spurious oscillations.

THE EFFECT OF PROBLEM PERTURBATIONS ON NONLINEAR DYNAMICAL SYSTEMS AND THEIR REDUCED-ORDER MODELS*

RADU SERBAN†, CHRIS HOMESCU‡, AND LINDA R. PETZOLD‡

Abstract. Reduced-order models are used extensively in many areas of science and engineering for simulation, design, and control. Reduction techniques for nonlinear dynamical systems produce models that depend strongly on the nominal set of parameters for which the reduction is carried out. In this paper we address the following two questions: "What is the effect of perturbations in the problem parameters on the output functional of a nonlinear dynamical system?" and "to what extent does the reduced-order model capture this effect?"

Key words. model reduction, small-sample statistical condition estimation, adjoint method, valid parameter range, singular value analysis

1. Introduction.

In this paper we consider nonlinear dynamical systems of the generic form

$$\mathcal{M}(t, y', y, p) = 0, \quad y(t_0) = y^0(p), \tag{1.1}$$

where y are the model states, y^0 are the initial conditions, and p are model parameters. The system may be an ordinary differential equation (ODE), a semidiscretized partial differential equation (PDE), or a differential-algebraic equation (DAE). An important problem which arises in a wide variety of engineering and scientific applications is to find the amount of change which can be expected in a model response functional $h(t, y(t), p)$ at a later time t, as a function of changes in the parameters p. The direction in the parameter space of the perturbation that produces the maximum change in the output may also be needed. For example, in weather prediction one wishes to find those perturbations in the initial conditions that can produce the greatest change in the accuracy of the forecast, because they identify the locations where the acquisition of additional data can be most effective [7, 16].

For large-scale dynamical systems, such decisions making use of the sensitivity of the system to perturbations in the problem parameters may necessarily be based on the corresponding sensitivities of a reduced-order model (ROM). A ROM corresponding to (1.1) is a system of the form

$$\widetilde{\mathcal{M}}(t, \tilde{y}', \tilde{y}, p) = 0, \quad \tilde{y}(t_0) = \tilde{y}^0(p), \tag{1.2}$$

such that its solution $\tilde{y}$ is an approximation to the solution y of (1.1). The ROM must be computationally less expensive than the full model. Depending on the particular model reduction technique employed, this can be achieved either through a

reduction in the dimension of the state space, through a reduction in the complexity of the forcing term, or both. Nonlinear ROMs have been obtained through proper orthogonal decomposition (POD) [14, 20], reduction of complexity [19, 22], balanced truncation [9], principal component analysis [12], and many other techniques [1]. An important property of nonlinear ROMs is that they are (necessarily) based on a nominal set of parameters or a limited range of operating conditions. Thus the question naturally arises: To what extent does a given nonlinear ROM capture the changes in the output functional of the full system that result from perturbations in the problem parameters?

We present in section 2 an efficient method for the estimation of perturbation-induced errors in the solution of a dynamical system. The method is based on a combination of adjoint sensitivity analysis [4] and the small-sample statistical condition estimate (SCE) method [13, 8]. We show how to apply these ideas to systems described by ODEs, semiexplicit index-1 DAEs, and Hessenberg index-2 DAEs [10, 3]. This algorithm is closely related to our earlier work on estimating errors for POD-based ROM applied to ODE systems [11] but extends those techniques to DAEs and to more general nonlinear reduced-order models.

Using this methodology, in section 3 we show how the direction in parameter space of maximum error growth in the output functional can be computed with very few solutions of the adjoint model. This is related to singular vector (SV) analysis in the weather prediction literature, e.g., [5]. By interpreting the initial perturbation as the error (or uncertainty) at the initial time, it was found in [5] that the maximum possible error growth is the largest singular value of the operator obtained from the linearization of the differential system. In section 4 we tackle the issue of estimating the extent to which a given ROM preserves the value of the maximum perturbation-induced error and/or the direction of the perturbations that induce it. We introduce two types of similarity index which measure this property. The problem of estimating the error which combines the effects of both model reduction and perturbations in parameters is addressed in section 5.

Numerical results are given in section 6. Models described by both ODEs and DAEs and corresponding ROMs generated by several different methods are presented. An example is given for which the ROM is quite accurate for the nominal values of the parameters but fails to capture the behavior of the full model when the parameters are slightly perturbed. We demonstrate that the similarity index can be very effective in detecting this type of situation.

Before proceeding, we would like to state that studying the errors induced by change in parameter values via a linearized equation is not new, and sensitivity analysis has been used extensively as a model analysis tool. However, the two usual sensitivity analysis methods based on solving continuous sensitivity equations, the forward and adjoint sensitivity analysis methods, respectively, are limited (from computational effort considerations) in the number of parameters that are allowed to vary or in the number of model responses that are monitored. As a consequence, methods based on a forward sensitivity approach are feasible only for problems with relatively few parameters, while methods based directly on an adjoint sensitivity approach allow the inclusion in the analysis of only a few model responses.

The new aspect of this work is in using aproximate schemes (namely, the SCE approach) which, combined with adjoint methods, allow the effective estimation of the "many parameters-many responses" case, e.g., estimating the influence of perturbations in all initial conditions on the entire state vector at some final time. Using the methodology described in the following, this capability enables a more robust

assessment of the quality of ROMs under perturbations by capturing in the analysis the influence of perturbations in any of the (potentially) many problem parameters on (potentially) the entire model state.

Finally, we note that rigurous error bounds for the various approximations used in the proposed approach are difficult, if not impossible, to get within the scope of the current scheme. Indeed approximations due to the SCE (see section 2.1) would defeat any attempt at deriving such error bounds. However, as demonstrated by the examples presented in section 6, the methodology proposed proves to be a very effective indicator of potential shortcomings of any given ROM under perturbations of problem parameters away from their nominal values (the parameter values used in constructing the ROM).

2. Estimation of perturbation-induced errors. In this section we present a method for the estimation of errors induced by perturbations in the initial conditions of a dynamical system. This approach, based on adjoint sensitivity analysis and small-sample SCE, will be used throughout this paper.

For dynamical systems of the form (1.1), we wish to find an estimate of the error $e(t) = Y(t) - y(t)$ at some time $t > t_0$, where $Y(t)$ is the solution of the perturbed system

$$\mathcal{M}(t, Y', Y, p + \delta p) = 0, \quad Y(t_0) = y^0(p + \delta p). \tag{2.1}$$

Subtracting (1.1) from (2.1) yields the following equation for the error $e(t)$:

$$\mathcal{M}_{y'}(t)e' + \mathcal{M}_y(t)e + \mathcal{M}_p(t)\delta p + \mathcal{O}(\|e\|^2) = 0,$$

where $\mathcal{M}_{y'}$, $\mathcal{M}_y$, and $\mathcal{M}_p$ are the Jacobians of $\mathcal{M}$ with respect to y', y, and p, respectively, evaluated at $(t, y'(t), y(t), p)$. Thus, to a first-order approximation, the error satisfies

$$\mathcal{M}_{y'}(t)e' + \mathcal{M}_y(t)e + \mathcal{M}_p(t)\delta p = 0, \quad e(t_0) = y_p^0(p)\,\delta p. \tag{2.2}$$

Note that the problem of estimating the error for perturbations in the initial conditions is a particular case of the problem of estimating the error for perturbations in the parameters, for which $p = y^0$. For any given perturbation δp, one can solve the forward sensitivity equation (2.2) to obtain the time evolution of the error $e(t)$ at any time $t > t_0$. However, this forward approach to error estimation can become expensive if one wishes to estimate the error over a range of perturbations, because (2.2) must be solved for *each* perturbation of interest.

We can, with the SCE technique described below, obtain an estimate of the norm of the error at some arbitrary but fixed time $t > t_0$, i.e., $\|e(t)\|$, as long as scalar products of the form $z^T e(t)$ are available, for any given unit vector z. This estimate takes the form

$$\|e(t)\| \approx \frac{W_q}{W_n} \left(\sum_{j=1}^{q} \left| z_j^T e(t) \right|^2 \right)^{1/2},$$

where $\{z_j\}_{j=1\ldots q}$ are q orthogonal vectors, uniformly and randomly selected from the unit sphere $\mathbb{S}_{n-1}$, where n is the dimension of y.

In the remainder of this section, after a short introduction to the SCE technique, we present an adjoint-based method for efficiently computing the scalar products

$z^T e(t)$. First, we consider dynamical systems that can be written as ODEs, and then we present the derivation for DAE systems. We base our SCE estimates on the solution of adjoint systems that are *independent* of δp and can thus be used for the estimation of errors induced by *any* perturbation.

2.1. Small-sample statistical method for condition estimation. The small-sample SCE method, originally proposed in [13], offers an efficient means for condition estimation for general nonlinear functions, at the cost of allowing moderate relative errors in the estimate. The basic idea is described below (for complete details, see [13, 8]).

For any vector $v \in \mathbb{R}^n$, if u is selected uniformly and randomly from the unit sphere $\mathbb{S}_{n-1}$, the expected value of $u^T v$ is proportional to the norm of v:

$$E(|u^T v|) = W_n \|v\|.$$

The proportionality factor, called the *Wallis factor*, depends only on n. It is defined as $W_1 = 1$ and

$$W_n = \begin{cases} \dfrac{1 \cdot 3 \ldots (n-2)}{2 \cdot 4 \ldots (n-1)} & \text{for } n \text{ odd}, \\ \dfrac{2}{\pi} \dfrac{2 \cdot 4 \ldots (n-2)}{1 \cdot 3 \ldots (n-1)} & \text{for } n \text{ even} \end{cases}$$

and can be approximated by $W_n \approx \sqrt{\frac{2}{\pi(n-\frac{1}{2})}}$.

Thus the expression $\xi = \frac{|u^T v|}{W_n}$ is used to estimate the norm $\|v\|$. This estimate is first order in the sense that the probability of a relative error in the estimate is inversely proportional to the size of the error. That is, for $\gamma > 1$, we have

$$\Pr\left(\frac{\|v\|}{\gamma} \le \xi \le \gamma \|v\| \right) \ge 1 - \frac{2}{\pi\gamma} + O\left(\frac{1}{\gamma^2} \right).$$

Additional function evaluations can improve the accuracy of the estimate.

Suppose that we obtain estimates $\xi_1, \xi_2, \ldots, \xi_q$ corresponding to orthogonal vectors $u_1, u_2, \ldots, u_q$ selected uniformly and randomly from the unit sphere $\mathbb{S}_{n-1}$. The expected value of the norm of the projection of v onto the span $\mathcal{U}$ generated by $u_1, u_2, \ldots, u_q$ is

$$E\left(\sqrt{|u_1^T v|^2 + |u_2^T v|^2 + \cdots + |u_q^T v|^2} \right) = \frac{W_n}{W_q} \|v\|.$$

The estimate $\nu(q) = \frac{W_q}{W_n} \sqrt{|u_1^T v|^2 + |u_2^T v|^2 + \cdots + |u_q^T v|^2}$ is qth order accuracy; i.e., a relative error of size γ in the estimate occurs with probability proportional to γ^{-q} [13]:

$$\begin{aligned} \Pr\left(\frac{\|v\|}{\gamma} \le \nu(2) \le \gamma \|v\| \right) &\approx 1 - \frac{\pi}{4\gamma^2}, \\ \Pr\left(\frac{\|v\|}{\gamma} \le \nu(3) \le \gamma \|v\| \right) &\approx 1 - \frac{32}{3\pi^2\gamma^3}, \\ \Pr\left(\frac{\|v\|}{\gamma} \le \nu(4) \le \gamma \|v\| \right) &\approx 1 - \frac{81\pi^2}{512\gamma^4}. \end{aligned}$$

Usually at most four random vectors are required in practice.

2.2. Ordinary differential equation systems. Consider the following system:

$$f(t, y', y, p) = 0, \quad y(t_0) = y^0(p), \tag{2.3}$$

for $t \in [t_0, t_f]$, y, $y^0 \in \mathbb{R}^n$, and $f : \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^n$. The partial derivative matrix $f_{y'}$ is nonsingular. The linearized error equation in this case is

$$M(t)e' + A(t)e = -f_p(t)\delta p, \quad e(t_0) = y_p^0(p)\delta p, \tag{2.4}$$

where the matrices of partial derivatives $M(t) = f_{y'}$, $A(t) = f_y$, and f_p are evaluated at $(t, y'(t), y(t), p)$. For the remainder of this section, for the sake of readability, we will drop the time argument for these matrices, except where absolutely necessary.

We begin by noting that the solution of (2.4) can be written as

$$e(t) = \Phi(t) \left(y_p^0 - \int_{t_0}^{t} \Phi^{-1}(\tau) M^{-1} f_p \, d\tau \right) \delta p,$$

where $\Phi(t) \in \mathbb{R}^{n \times n}$ is the fundamental matrix corresponding to (2.4), i.e.,

$$M\Phi' + A\Phi = 0, \quad \Phi(t_0) = I. \tag{2.5}$$

It is straightforward to verify that the solution λ of the adjoint system

$$(M^T\lambda)' - A^T\lambda = 0, \tag{2.6}$$

with final condition $\lambda(t) = z$, satisfies

$$\begin{aligned} &\lambda^T(\tau) = z^T\Phi(t)\Phi^{-1}(\tau)M^{-1}(\tau) \quad \forall \tau \in [t_0, t], \\ &\lambda^T(t_0)M(t_0) = z^T\Phi(t), \end{aligned} \tag{2.7}$$

and therefore,

$$z^T e(t) = \left(\lambda^T(t_0)M(t_0)y_p^0 - \int_{t_0}^{t} \lambda^T(\tau) f_p \, d\tau \right) \delta p. \tag{2.8}$$

The case of perturbations in initial conditions is obtained by setting $f_p(t) = 0$ for all t and $y_p^0 = I$, while the case of perturbations in the right-hand side corresponds only to $y_p^0 = 0$.

If we consider q orthogonal vectors $z_j, 1 \le j \le q$, uniformly and randomly selected from the unit sphere $\mathbb{S}_{n-1}$, we obtain the SCE estimate

$$\begin{aligned} \|e(t)\| &\approx \frac{W_q}{W_n} \left(\sum_{j=1}^{q} \left| z_j^T e(t) \right|^2 \right)^{1/2} \\ &= \frac{W_q}{W_n} \left(\sum_{j=1}^{q} \left| \left(\lambda_j^T(t_0)M(t_0)y_p^0 - \int_{t_0}^{t} \lambda_j^T(\tau) f_p(\tau) \, d\tau \right) \delta p \right|^2 \right)^{1/2}, \end{aligned} \tag{2.9}$$

where λ_j are solutions of the adjoint systems (2.6) with final conditions based on z_j.

An important property of this error estimate is that the adjoint system (2.6) on which it is based is *independent* of the perturbation δp. Thus the same adjoint solutions λ_j can be used to estimate the error induced by any perturbation. Finally,

we note that very few (less than four) unit vectors z_j (and hence adjoint system solutions) are usually sufficient for acceptable SCE estimates.

In preparation for using the above estimate in comparing two different models, let us consider the perturbation-induced error in a model response functional $h(t, y(t), p)$. We seek the norm of this error, namely, $\epsilon(t) := h(t, Y(t), p + \delta p) - h(t, y(t), p)$ (see Figure 5.1). A linearization around $\delta p = 0$ yields

$$\epsilon(t) = h_y e(t) + h_p \delta p.$$

Thus

$$\begin{aligned}\|\epsilon(t)\| &\approx \frac{W_q}{W_{n_h}} \left(\sum_{j=1}^{q} \left| z_j^T h_y e(t) + z_j^T h_p \delta p \right|^2 \right)^{1/2} \\ &= \frac{W_q}{W_{n_h}} \left(\sum_{j=1}^{q} \left| \left(\lambda_j^T(t_0) M(t_0) y_p^0 - \int_{t_0}^{t} \lambda_j^T(\tau) f_p(\tau)\, d\tau + z_j^T h_p \right) \delta p \right|^2 \right)^{1/2},\end{aligned}$$

where λ_j is the solution of the adjoint system (2.6) with the final condition $\lambda_j(t) = h_y^T(t) z_j$. We select the q vectors z_j uniformly and randomly from the unit sphere $\mathbb{S}_{n_h - 1}$, where n_h is the dimension of h.

2.3. Semiexplicit index-1 differential-algebraic equation systems. A semiexplicit index-1 DAE takes the form

$$\begin{aligned} & f(t, y', y, x, p) = 0, \\ & g(t, y, x, p) = 0, \\ & y(t_0) = y^0(p),\ x(t_0) = x^0(p), \end{aligned} \tag{2.10}$$

where y are the differential variables, x are the algebraic variables, and p are model parameters. The Jacobian matrices $f_{y'}$ and g_x are nonsingular. Note that the initial conditions y^0, x^0 are assumed to be consistent with the algebraic constraints; that is, $g(t_0, y^0, x^0, p) = 0$.

We are interested in estimating the norm of the error $e(t)$ between the solution $(Y(t), X(t))$ of the system with perturbed parameters and the solution $(y(t), x(t))$ of the unperturbed system. We decompose $e(t)$ into the differential and algebraic components: $e_d(t) = Y(t) - y(t)$ and $e_a(t) = X(t) - x(t)$. As in the ODE case, a linearization along the solution of the unperturbed DAE leads to

$$\begin{aligned} & M(t) e_y' + A(t) e_d + B(t) e_a = -f_p(t) \delta p, \\ & C(t) e_d + D(t) e_a = -g_p(t) \delta p, \\ & e_d(0) = y_p^0 \delta p\,,\ e_a(t_0) = x_p^0 \delta p, \end{aligned} \tag{2.11}$$

where the matrices of partial derivatives $M(t) = f_{y'}$, $A(t) = f_y$, $B(t) = f_x$, $C(t) = g_y$, $D(t) = g_x$, f_p, and g_p are all evaluated at $(t, y(t), x(t), p)$. Consistency of the initial conditions for the above DAE is equivalent to the requirement that the perturbation δp satisfies

$$(C(t_0) y_p^0 + D(t_0) x_p^0 + g_p(t_0)) \delta p = 0. \tag{2.12}$$

We reduce the analysis to the ODE case by using the essential underlying ODE (EUODE) [2]:

$$Me_y' + (A - BD^{-1}C)e_d = -(f_p - BD^{-1}g_p)\delta p, \quad e_d(t_0) = y_p^0 \delta p. \tag{2.13}$$

The corresponding fundamental matrix Φ_1 satisfies

$$M\Phi_1' + (A - BD^{-1}C)\Phi_1 = 0, \quad \Phi_1(t_0) = I, \tag{2.14}$$

and therefore

$$\begin{aligned} e_d(t) &= \Phi_1(t)\left(y_p^0 - \int_{t_0}^{t} \Phi_1^{-1}(\tau)M^{-1}(f_p - BD^{-1}g_p)\,d\tau\right)\delta p, \\ e_a(t) &= -D^{-1}\left(Ce_d(t) + g_p\delta p\right). \end{aligned}$$

The SCE norm estimate of the error vector $[e_d^T(t);\, e_a^T(t)]^T$ is based on scalar products of the form

$$z_d^T e_d(t) + z_a^T e_a(t) = \left(z_d^T - z_a^T D^{-1}C\right)e_d(t) - z_a^T D^{-1}g_p\delta p,$$

for some vector $z = [z_d^T;\, z_a^T]^T \in \mathbb{S}_{n-1}$. It can be easily verified that the differential component λ of the solution of the adjoint system

$$\begin{aligned} &(M^T\lambda)' - A^T\lambda - C^T\mu = 0, \\ &-B^T\lambda - D^T\mu = 0, \\ &\lambda(t) = z_d - C^T D^{-T} z_a, \end{aligned} \tag{2.15}$$

satisfies $\lambda(\tau) = M^{-T}(\tau)\Phi_1^{-T}(\tau)\Phi_1^T(t)\lambda(t)$. As a consequence,

$$\begin{aligned} \left(\lambda^T(t_0)M(t_0)y_p^0 - \int_{t_0}^{t}\lambda^T(f_p - BD^{-1}g_p)\,d\tau\right)\delta p &= \left(z_d - C^T D^{-T} z_a\right)^T \\ &\times \left(\Phi_1(t)\Phi_1^{-1}(t_0)y_p^0 - \int_{t_0}^{t}\Phi_1(t)\Phi_1^{-1}(\tau)M^{-1}(f_p - BD^{-1}g_p)\,d\tau\right)\delta p. \end{aligned}$$

Thus

$$z_d^T e_d(t) + z_a^T e_a(t) = \left(\lambda^T(t_0)M(t_0)y_p^0 - \int_{t_0}^{t}\lambda^T(f_p - BD^{-1}g_p)\,d\tau - z_a^T D^{-1}g_p\right)\delta p,$$

or, using $\mu^T = -\lambda^T BD^{-1}$,

$$z_d^T e_d(t) + z_a^T e_a(t) = \left(\lambda^T(t_0)M(t_0)y_p^0 - \int_{t_0}^{t}\left(\lambda^T f_p + \mu^T g_p\right)\,d\tau - z_a^T D^{-1}g_p\right)\delta p. \tag{2.16}$$

Following the same argument as in section 2.2, an SCE norm estimate for the perturbation-induced error $\epsilon(t)$ in a model response $h(t, y(t), x(t), p)$ can be obtained by replacing the final condition on λ with

$$\lambda(t) = (h_y - h_x D^{-1}C)^T z, \quad z \in \mathbb{S}_{n_h - 1},$$

and using

$$z^T\epsilon(t) = \left(\lambda^T(t_0)M(t_0)y_p^0 - \int_{t_0}^{t}\left(\lambda^T f_p + \mu^T g_p\right)\,d\tau - z^T h_x D^{-1}g_p + z^T h_p\right)\delta p.$$

If we consider only perturbations in the initial conditions ($f_p = g_p = y_p^0 = 0$, implying $x_p^0 = I$) and if we are interested in the norm of the entire error vector $e(t)$, the following refinement of the above procedure, which takes advantage of the geometry of the problem, results in more accurate SCE estimates. We begin by observing that, since $e_d(t)$ and $e_a(t)$ must be consistent with the algebraic constraints, we need only consider unit vectors z that satisfy the linearized constraint $C(t)z_d + D(t)z_a = 0$. Let $n_y = \dim(y)$ be the number of degrees of freedom of the system (2.10). We start by selecting q vectors z_d uniformly and randomly from $\mathbb{S}_{n_y-1}$ and, for each one of them, construct the vector $z_a = -D^{-1}(t)C(t)z_d$. We then orthonormalize the set of q vectors $z = [z_d^T; z_a^T]^T$ and thus obtain q orthogonal unit vectors in $\mathbb{R}^n$ which are uniformly and randomly distributed over the sphere $\mathbb{S}_{n_y-1}$ embedded on the linear subspace of $\mathbb{R}^n$ of codimension $n - n_y$.

2.4. Hessenberg index-2 differential-algebraic equation systems. Consider next a dynamical system expressed in Hessenberg index-2 DAE form:

$$\begin{aligned} &f(t, y', y, x, p) = 0, \\ &g(t, y, p) = 0, \\ &y(t_0) = y^0(p),\ x(t_0) = x^0(p), \end{aligned} \tag{2.17}$$

where y are the differential variables, x are the algebraic variables, and p are model parameters. The matrices $f_{y'}$ and $g_y f_{y'}^{-1} f_x$ are nonsingular, and the initial conditions are assumed to be consistent, i.e., $g(t_0, y^0, p) = 0$ and $\frac{d}{dt} g(t_0, y^0, p) = 0$.

Let $A(t) = f_y$, $B(t) = f_x$, $C(t) = g_y$, and $M(t) = f_{y'}$. To keep the derivation as simple as possible, we start by assuming that $M(t) = I$. Results for a general mass matrix will be given at the end of this section. With $M(t) = I$, the linearized error equation becomes

$$\begin{aligned} &e_y' + A(t)e_d + B(t)e_a = -f_p(t)\delta p, \\ &C(t)e_d = -g_p(t)\delta p, \\ &e_d(t_0) = y_p^0 \delta p,\ e_a(t_0) = x_p^0 \delta p \end{aligned} \tag{2.18}$$

for the errors $e_d(t) = Y(t) - y(t)$ and $e_a(t) = X(t) - x(t)$, where $Y(t)$, $X(t)$ is the solution of (2.17) with perturbed parameters. Consistency of the initial conditions in (2.18) requires

$$\begin{aligned} &C y_p^0 \delta p = -g_p \delta p, \\ &-(C' - CA) y_p^0 \delta p + CB x_p^0 \delta p = (g_p' - C f_p)\delta p \end{aligned} \tag{2.19}$$

at $t = t_0$.

For the Hessenberg index-2 DAE (2.18), the EUODE is derived as follows [2]. If B is sufficiently smooth, there exists a smooth bounded matrix function $R(t) \in \mathbb{R}^{(n_y - n_x) \times n_y}$ whose linearly independent, normalized rows form a basis for the nullspace of B^T. Thus, $RB = 0$, and $\begin{bmatrix} R \\ C \end{bmatrix}$ is invertible.

With the change of variables $u(t) = R(t)e_d(t)$, e_d is obtained as

$$e_d = \begin{bmatrix} R \\ C \end{bmatrix}^{-1} \begin{bmatrix} u \\ -g_p \delta p \end{bmatrix} = Su - F g_p \delta p,$$

where $S(t) \in \mathbb{R}^{n_y \times (n_y - n_x)}$ satisfies $R(t)S(t) = I$, and $C(t)S(t) = 0$ and $F = B(CB)^{-1}$. The EUODE is obtained as $u' = (R' - RA)Su - (R' - RA)F g_p \delta p - R f_p \delta p$.

Before proceeding further, we note that

$$F = B(CB)^{-1},$$
$$SR = I - B(CB)^{-1}C,$$

and thus the EUODE can be written as

$$u' = (R' - RA)Su + R\left((B' + AB)(CB)^{-1}g_p - f_p\right)\delta p, \quad u(t_0) = u_0, \tag{2.20}$$

where we have used $R'F = R'B(CB)^{-1} = -RB'(CB)^{-1}$. Note that, to satisfy the first condition in (2.19), a perturbation δp must be such that

$$y_p^0 \delta p = S(t_0)u_0 - B(t_0)(C(t_0)B(t_0))^{-1}g_p(t_0)\delta p, \tag{2.21}$$

for an arbitrary u_0.

If Φ_2 is the fundamental matrix corresponding to (2.20), that is,

$$\Phi_2' = (R' - RA)S\Phi_2, \quad \Phi_2(t_0) = I,$$

then

$$u(t) = \Phi_2(t)\left(u_0 + \int_{t_0}^{t} \Phi_2^{-1}(\tau)R\left((B' + AB)(CB)^{-1}g_p - f_p\right)\delta p\, d\tau\right),$$
$$e_d(t) = Su(t) - Fg_p\delta p = Su(t) - B(CB)^{-1}g_p\delta p,$$
$$e_a(t) = (CB)^{-1}\Big((C' - CA)e_d(t) + (g_p' - Cf_p)\delta p\Big).$$

Consider next the adjoint system

$$\begin{aligned} \lambda' - A^T\lambda - C^T\mu &= 0, \\ -B^T\lambda &= 0, \end{aligned} \tag{2.22}$$

whose EUODE can be obtained with the change of variables $v = S^T\lambda$ (implying $\lambda = R^T v$) as

$$v' = \left(S'^T + S^T A^T\right)R^T v = -S^T(R' - RA)^T v, \quad v(t) = \nu.$$

Since the EUODE of the adjoint is the adjoint of the EUODE (2.20), we get

$$\lambda(\tau) = R^T(\tau)v(\tau) = R^T(\tau)\Phi_2^{-T}(\tau)\Phi_2^T(t)\nu. \tag{2.23}$$

The scalar products required by the SCE procedure in this case are of the form

$$z_d^T e_d(t) + z_a^T e_a(t) = z_d^T e_d(t) + z_a^T(CB)^{-1}(C' - CA)e_d(t) + z_a^T(CB)^{-1}(g_p' - Cf_p)\delta p$$
$$= \left(z_d^T + z_a^T(CB)^{-1}(C' - CA)\right)\left(Su(t) - B(CB)^{-1}g_p\right)\delta p + z_a^T(CB)^{-1}(g_p' - Cf_p)\delta p.$$

Using (2.23) and (2.21) we get

$$\left(\lambda^T(t_0)y_p^0 + \int_{t_0}^{t} \lambda^T\left((B' + AB)(CB)^{-1}g_p - f_p\right)\, d\tau\right)\delta p$$
$$= \nu\Phi_2(t)\left(u_0 + \int_{t_0}^{t} \Phi_2^{-1}(\tau)R\left((B' + AB)(CB)^{-1}g_p - f_p\right)\delta p\, d\tau\right),$$

where we have used $R(t_0)S(t_0) = I$ and $R(t_0)B(t_0) = 0$. Taking into account $\mu^T = -\lambda^T(B' + AB)(CB)^{-1}$ and selecting the final condition for (2.22) to be

$$\lambda(t) = \left(I - B(CB)^{-1}C\right)^T \left(z_d + (C' - CA)^T(CB)^{-T}z_a\right),$$

we get

$$z_d^T e_d(t) + z_a^T e_a(t) = \Bigg(\lambda^T(t_0)y_p^0 - \int_{t_0}^{t} \left(\lambda^T f_p + \mu^T g_p\right)\, d\tau \\ - z_d^T B(CB)^{-1}g_p + z_a^T(CB)^{-1}\left(g_p' - (C' - CA)B(CB)^{-1}g_p - Cf_p\right)\Bigg)\delta p.$$

If the final condition for λ is replaced with

$$\lambda(t) = \left(I - B(CB)^{-1}C\right)^T \left(h_y^T + (C' - CA)^T(CB)^{-T}h_x^T\right) z,$$

for some $z \in \mathbb{R}^{n_h}$, the resulting adjoint variable can be used in evaluating the scalar product $z^T\epsilon(t)$, which is necessary in an SCE estimate of the norm of the perturbation-induced error in the model response $h(t, y(t), x(t), p)$, as

$$z^T\epsilon(t) = \Bigg(\lambda^T(t_0)y_p^0 - \int_{t_0}^{t} \left(\lambda^T f_p + \mu^T g_p\right)\, d\tau - z^T h_y B(CB)^{-1}g_p \\ + z^T h_x(CB)^{-1}\left(g_p' - (C' - CA)B(CB)^{-1}g_p - Cf_p\right) + z^T h_p\Bigg)\delta p.$$

Finally, for a general mass matrix $M(t)$, we note that the matrix $CM^{-1}B$ must always be nonsingular. Then the scalar product $z_d^T e_d(t) + z_a^T e_a(t)$ can be obtained, using the solution $\{\lambda, \nu\}$ of the following adjoint system:

$$\begin{aligned} (M^T\lambda)' - A^T\lambda - C^T\mu &= 0, \\ -B^T\lambda &= 0, \\ M^T(t)\lambda(t) = \left(I - M^{-1}B(CM^{-1}B)^{-1}C\right)^T &\left(z_d + (C' - CM^{-1}A)^T(CM^{-1}B)^{-T}z_a\right), \end{aligned} \tag{2.24}$$

as

$$\begin{aligned} z_d^T e_d(t) + z_a^T e_a(t) = \Bigg(&\lambda^T(t_0)M(t_0)y_p^0 - \int_{t_0}^{t} \left(\lambda^T f_p + \mu^T g_p\right)\, d\tau \\ &-z_d^T M^{-1}B(CM^{-1}B)^{-1}g_p \\ &+z_a^T(CM^{-1}B)^{-1}\left(g_p' - (C' - CM^{-1}A)M^{-1}B(CM^{-1}B)^{-1}g_p - CM^{-1}f_p\right)\Bigg)\delta p. \end{aligned} \tag{2.25}$$

3. Singular vector analysis. SV analysis, introduced by Lorenz in the 1960s [18], is employed to compute the largest error growth and to help estimate model predictability. Finding the direction of maximal error growth implies solving a generalized eigenvalue problem for a matrix involving the product $\Phi^T\Phi$, where Φ is the fundamental matrix of the differential system.[1] Solving the resulting eigenvalue problem is quite computationally expensive. It is typically accomplished using Lanczos-type

[1] In the meteorological and weather prediction literature this matrix is often called the *propagator*.

algorithms which require only the evaluation of matrix-vector products. However, every such product involves a forward integration of a linearized model followed by a backward in time solution of the corresponding adjoint model. Based on the combination of SCE estimate and adjoint models, we describe below a method for finding an approximation to the leading SV (representing the direction of maximal error growth) that requires only very few solutions of the adjoint model (equal to the number of unit vectors considered in the SCE estimate).

Consider again the error $\epsilon(t) := h(t, Y(t), p + \delta p) - h(t, y(t), p)$ in some model response functional $h(t, y, p)$. We wish to find the direction of perturbations in the parameters p that gives rise to the maximum error $\|\epsilon(t)\|$ at some time $t \geq t_0$. In other words, we seek

$$\mathcal{E} := \sup_{\substack{\|u\| = 1 \\ u \in \mathbb{R}^{n_u}}} \|\epsilon(t, u)\|, \tag{3.1}$$

where ϵ is the response error induced by a perturbation $\delta p = \delta p(u)$ in the parameters p. The directions u over which we search for the maximum error norm growth are constrained to belong to a search space $\mathbb{R}^{N_u}$ such that the resulting perturbations $\delta p(u)$ are admissible. The dimension N_u is model- and problem-dependent and will be defined below for each of the dynamical systems discussed in section 2.

Using an SCE estimate for the error norm in (3.1) we get

$$\mathcal{E}^2 = \left(\frac{W_q}{W_{n_h}}\right)^2 \sup_{\substack{\|u\| = 1 \\ u \in \mathbb{R}^{n_u}}} \sum_{j=1}^{q} |z_j^T \epsilon(t, u)|^2,$$

where, for the dynamical systems considered in this paper, the scalar products $z_j^T \epsilon(t, u)$ were derived in sections 2.2–2.4. The essence of these formulas is that, in all cases,

$$z_j^T \epsilon(t, u) = \alpha_j^T \delta p,$$

with α_j defined in terms of the solution λ_j of an appropriate adjoint system. Therefore

$$\mathcal{E}^2 = \left(\frac{W_q}{W_{n_h}}\right)^2 \sup_{\substack{\|u\| = 1 \\ u \in \mathbb{R}^{n_u}}} \sum_{j=1}^{q} |\alpha_j^T \delta p(u)|^2 = \left(\frac{W_q}{W_{n_h}}\right)^2 \sup_{\substack{\|u\| = 1 \\ u \in \mathbb{R}^{n_u}}} \delta p^T(u) \left(\sum_{j=1}^{q} \alpha_j \alpha_j^T\right) \delta p(u)$$

$$= \left(\frac{W_q}{W_{n_h}}\right)^2 \sup_{\substack{\|u\| = 1 \\ u \in \mathbb{R}^{n_u}}} u^T P^T \left(\sum_{j=1}^{q} \alpha_j \alpha_j^T\right) P u,$$

where we have assumed that the admissible perturbations can be written as $\delta p(u) = Pu$, for some matrix P. Let $\Psi := P^T(\sum_{j=1}^{q} \alpha_j \alpha_j^T)P$. The matrix Ψ is symmetric and has $\operatorname{rank}(\Psi) \leq q$. Thus its singular value decomposition (SVD) is $\Psi = U^T \Sigma U = \sum_{j=1}^{q} \sigma_j u_j u_j^T$, and $u^T \Psi u = \sum_{j=1}^{q} \left(\sqrt{\sigma_j} u^T u_j\right)^2$. If the singular values of Ψ are numbered in decreasing order, it is easy to see that

$$\sup_{\substack{\|u\| = 1 \\ u \in \mathbb{R}^{n_u}}} u^T \Psi u = \sigma_1,$$

which is attained for $u^* = u_1$. Thus

$$\mathcal{E} = \frac{W_q}{W_{n_h}}\sqrt{\sigma_1}, \tag{3.2}$$

and the direction of perturbations along which the error is maximized is $\delta p^* = Pu_1$.[2]

Next we establish the dimension n_u in (3.1) and the corresponding matrix P (defining the allowable parameter perturbations $\delta p(u) = Pu$) for the dynamical systems discussed in the previous section.

1. For an ODE system, any perturbation δp is admissible. Thus $n_u = n_p \equiv \dim(p)$ and $P = I_{n_p}$.
2. For a semiexplicit index-1 DAE, requiring the initial condition for (2.12) to be consistent is equivalent to requiring that δp be in the nullspace of the matrix $Q_1 = C(t_0)y_p^0 + D(t_0)x_p^0 + g_p(t_0)$. Then $P = \mathcal{N}(Q_1)$ and $n_u = \dim(\mathcal{N}(Q_1))$, where $\mathcal{N}(Q_1)$ is a basis for the nullspace of Q_1. In the particular case of perturbations in initial conditions $e_d(t_0) = \delta p$ and $e_a(t_0) = -D^{-1}(t_0)C(t_0)\delta p$. Therefore $\mathcal{U} \equiv \mathbb{R}^{n_y}$ and $P = I_{n_y}$.
3. For a Hessenberg index-2 DAE, similarly to the index-1 DAE case, the conditions (2.19), modified here to account for a general mass matrix, are equivalent to the requirement that δp be in the nullspace of

$$Q_2 = \begin{bmatrix} Cy_p^0 + g_p \\ -(C' - CM^{-1}A)y_p^0 + CM^{-1}Bx_p^0 - g_p' + CM^{-1}f_p \end{bmatrix}$$

at $t = t_0$. Thus $P = \mathcal{N}(Q_2)$ and $n_u = \dim(\mathcal{N}(Q_2))$. In the case of perturbations in the initial conditions, $e_d(t_0) = \delta p$ and $e_a(t_0) = (C(t_0)B(t_0))^{-1}(C'(t_0) - C(t_0)A(t_0))\delta p$. Consistent perturbations must then satisfy $\delta p = S(t_0)u$, with $u \in \mathbb{R}^{n_y - n_x}$. Note that $n_y - n_x$ represents the number of degrees of freedom of the system (2.18).

Finally, if the parameter perturbations δp are to be further restricted to the range of some matrix Π, then $P = \Pi$ in the ODE case, and $P = \Pi\mathcal{N}(Q\Pi)$, where $Q = Q_1$ for index-1 DAEs or $Q = Q_2$ for index-2 DAEs.

4. Quality measures for reduced-order models. The quality of a given ROM can be judged by the extent to which it preserves the value of the maximum possible error and/or the direction of perturbations that induce it. We begin by constructing a matrix whose entries

$$m_{ij} = \langle u_i, \tilde{u}_j \rangle^2$$

are the squared scalar products of the ith SV of the full model and the jth SV of the reduced model. These entries represent the amount of energy[3] of the ith full model SV that can be explained by the jth reduced model SV. The SV analysis must be based on a model response that is common to both the full and reduced-order models.

[2] As indicated by one of the reviewers of this paper, if considering only perturbations in initial conditions, such an error estimate is equivalent to an approximation to the dominant local (i.e., finite-time) Lyapunov exponent of the system. For a discussion on the connection between singular vectors and Lyapunov vectors, see, for example, [21]. See also [6] for methods for the computation of Lyapunov exponents based on orthogonal decompositions of the system Jacobian.

[3] The energy depends on the particular inner product used. Here we use the usual Euclidean inner product.

Based on the matrix m_{ij}, a similarity index can be defined [17] as

$$\mathcal{S}_1 = \frac{1}{q} \sum_{i,j=1}^{q} m_{ij}. \tag{4.1}$$

Although the proposed method (based on SCE norm estimation) provides only an approximation to $\mathcal{S}_1$, since the evaluation of $\mathcal{S}_1$ requires several singular vectors, it is more computationally attractive than the alternative offered by Lanczos-type algorithms, not to mention the option of computing the entire fundamental matrix Φ.

A second measure of similarity can be defined in terms of the ratio between the norms of the errors induced in the full model and in the reduced-order model by a perturbation of the unit norm along the dominant SV of the full model

$$\mathcal{S}_2 = \min\left(\frac{\|\tilde{\epsilon}(t,u_1)\|}{\|\epsilon(t,u_1)\|}, \frac{\|\epsilon(t,u_1)\|}{\|\tilde{\epsilon}(t,u_1)\|}\right). \tag{4.2}$$

Since both similarity indexes are related to the assessment of ROM quality, one may ask when one index is more relevant than the other. Each similarity index evaluates different aspects of the ROM quality. The first index $\mathcal{S}_1$ quantifies the similarity between subspaces spanned by the first q SVs for the full model and, respectively, for the reduced model. Thus it provides an overall picture of ROM approximation of the phenomena described by the full model. The second index $\mathcal{S}_2$ gives a more localized result, by estimating the extent to which the ROM preserves the error due to perturbations along the direction of maximal error growth, given by the dominant SV of the full model.

Finally, we note that both indexes take values between 0 and 1 and that, for identical models, they will equal unity. The index $\mathcal{S}_2$ is a more stringent ROM quality test, in the sense that, typically, $\mathcal{S}_2 < \mathcal{S}_1$.

5. ROM error under perturbations. Consider next the problem of estimating the error $\|\Theta(t)\|$, which combines the effects of both model reduction and perturbations in parameters (see Figure 5.1). For an arbitrary, but fixed, time $t > t_0$, let[4]

$$\begin{aligned}\Theta(t) &= h(Y) - \tilde{h}(\tilde{Y}) = \big(h(y) - \tilde{h}(\tilde{y})\big) + \big(h(Y) - h(y)\big) - \big(\tilde{h}(\tilde{Y}) - \tilde{h}(\tilde{y})\big)\\ &= \theta(t) + \epsilon(t) - \tilde{\epsilon}(t)\\ &\approx \theta(t) + h_y e(t) - \tilde{h}_{\tilde{y}}\tilde{e}(t) + \big(h_p - \tilde{h}_p\big)\delta p,\end{aligned} \tag{5.1}$$

where $\theta(t) = h(t, y(t), p) - \tilde{h}(t, \tilde{y}(t), p)$ is the error in the model response due solely to model reduction, $e(t) = Y(t) - y(t)$ is the error introduced by the perturbation in the original system, and $\tilde{e}(t) = \tilde{Y}(t) - \tilde{y}(t)$ is the error introduced by the perturbation in the reduced system. We distinguish two cases. In both, the projections $z_j^T h_y e(t)$ and $z_j^T \tilde{h}_{\tilde{y}} \tilde{e}(t)$ are based on the solution of adjoint problems corresponding to the full and reduced models, respectively, using the procedure of section 2.

[4]For the sake of clarity, only the relevant function arguments were kept.

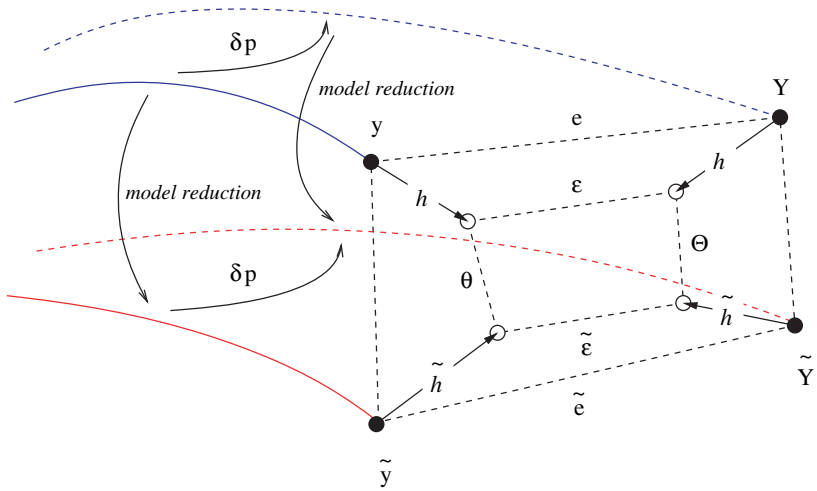

FIG. 5.1. *Graphical representation of model reduction and perturbation-induced errors. Solid-line trajectories and quantities in lowercase $(y, \tilde{y}, \theta)$ correspond to unperturbed systems, while dashed-line trajectories and states in uppercase $(Y, \tilde{Y}, \Theta)$ correspond to the perturbed systems. Quantities with a tilde correspond to reduced-order models.*

1. If the components of the error $\theta(t)$ are known, we can directly use an SCE estimate for the norm $\|\Theta(t)\|$:

$$\|\Theta(t)\| = \|\theta(t) + h_y e(t) - \tilde{h}_{\tilde{y}}\tilde{e}(t)\|$$
$$\approx \frac{W_q}{W_{n_h}} \left[\sum_{j=1}^{q} \left| z_j^T \theta(t) + z_j^T \left(h_p - \tilde{h}_p\right)\delta p + z_j^T h_y e(t) - z_j^T \tilde{h}_{\tilde{y}} \tilde{e}(t) \right|^2 \right]^{1/2}.$$

2. If only the norm $\|\theta(t)\|$ is available, we use the bounds

$$\left| \|\theta(t) + \left(h_p - \tilde{h}_p\right)\delta p\| - \|h_y e(t) - \tilde{h}_{\tilde{y}}\tilde{e}(t)\| \right| \le \|E(t)\|$$
$$\le \|e(t) + \left(h_p - \tilde{h}_p\right)\delta p\| + \|h_y e(t) - \tilde{h}_{\tilde{y}}\tilde{e}(t)\|$$

and the following SCE estimate:

$$\|h_y e(t) - \tilde{h}_{\tilde{y}}\tilde{e}(t)\| \approx \frac{W_q}{W_{n_h}} \left[\sum_{j=1}^{q} \left| z_j^T h_y e(t) - z_j^T \tilde{h}_{\tilde{y}} \tilde{e}(t) \right|^2 \right]^{1/2}.$$

6. Numerical results. We have implemented our methodology to problems representative of the dynamical systems considered in this paper. We consider models described by systems of ODEs—the two-dimensional Brusselator (modeling autocatalytic, oscillating chemical reactions) and the Gas Research Institute (GRI) combustion model (from chemical kinetics)—and by DAEs (the heat shock model in biology).

6.1. 2D Brusselator. The following 2D time-dependent PDE models a chemically reacting system:

$$u_t = \epsilon_1 \Delta u + A + u^2 v - (B+1)u,$$
$$v_t = \epsilon_2 \Delta v + Bu - u^2 v,$$

where the diffusion coefficients are $\epsilon_1 = \epsilon_2 = 2 \cdot 10^{-3}$ and the chemical parameters are given by $A = 1$ and $B = 3.4$. The PDE is defined over the square $\Omega = [0,1] \times [0,1]$, for $t \in [0,1]$. Homogeneous Neumann conditions are imposed at the boundary of the domain, while the initial conditions are

$$u(x,y,0) = 1 - 0.5 \cdot \cos(\pi y), \quad v(x,y,0) = 3.5 - 2.5 \cdot \cos(\pi x). \tag{6.1}$$

Using the method of lines, we convert this PDE to an ODE initial value problem using central finite differences to approximate the spatial derivatives on a grid of $N_x \times N_y = 16 \times 16$ interior points, with the boundary conditions explicitly used to define the necessary ghost boundary points. The resulting system, of the form (2.3), has dimension $n = 512$.

Proper orthogonal decomposition (POD) provides a method for finding the best approximating affine subspace to a given set of data. When using POD for model reduction of dynamical systems, the data are time snapshots of the solution obtained via numerical simulations or from experiments. Consider next the solutions of (1.1) at m time points, collected in the $n \times m$ matrix $\mathcal{Y} = [y(t_1) - \overline{\mathbf{y}}, y(t_2) - \overline{\mathbf{y}}, \ldots y(t_m) - \overline{\mathbf{y}}]$, where $\overline{\mathbf{y}}$ is the mean of these observations. POD seeks a subspace $S \in \mathbb{R}^n$ and the corresponding projection matrix $P = \rho\rho^T$ so that the total square distance

$$\|\mathcal{Y} - P\mathcal{Y}\|^2 = \sum_{i=1}^{m} \| \left(y(t_i) - \overline{\mathbf{y}}\right) - P\left(y(t_i) - \overline{\mathbf{y}}\right) \|^2$$

is minimized. The solution to the above minimization problem can be easily obtained by considering the SVD of the correlation matrix $R = \mathcal{Y}\mathcal{Y}^T$ (see [20, 11] for details). A POD-based reduced model that approximates the original problem can then be constructed by projecting onto S the model (1.1):

$$\rho^T \mathcal{M}(t, \rho\tilde{y} + \overline{\mathbf{y}}, \rho\tilde{y}') = 0, \quad \tilde{y}(t_0) = \rho^T(y_0 - \overline{\mathbf{y}}).$$

Returning to the Brusselator model, a POD-based ROM is constructed using 100 equally spaced snapshots from the trajectory corresponding to the initial conditions (6.1) and retaining 12 modes. We note that the resulting ROM retains 99.52% of the "energy" of the full system. Moreover, comparing the solutions of the full and reduced models at the final time, we find that

$$\frac{\|y(t) - \tilde{y}(t)\|}{\|y(t)\|} \cdot 100.0 = 0.3661\%. \tag{6.2}$$

We are therefore led to believe that this ROM (of dimension only 12) can very accurately represent the solution of full model. However, using the analysis of the preceding sections, it turns out that this ROM does not perform well under perturbations in the initial conditions.

We have applied the approach presented in section 3 to estimate the leading singular vectors for both the full model and the ROM, using $q = 12$ and $q = 4$ unit vectors for the SCE, respectively. The results are summarized in Table 6.1. Next, applying the approach presented in section 4 and using the first four leading singular vectors, (4.1) gives a similarity index of only $\mathcal{S}_1 = 0.03287$, while (4.2) gives $\mathcal{S}_2 = 0.02328$. The reason for this poor agreement is that the direction of maximum error growth for the full system is almost orthogonal to the POD subspace in which the ROM is bound to evolve. Indeed, if u_1 is the leading singular vector for the full system, we have that $\|(I - \rho * \rho^T)u_1\| = 0.95266$, while

TABLE 6.1

Brusselator example: SV analysis results. For both the full and reduced models the following quantities are given: the estimated maximum perturbation-induced error norm given by (3.2) *at the final time* $t = 1.0$*, the actual norm of the error in the estimated direction of maximum error growth, and the norms of errors induced by several random perturbations.*

Full model		Reduced-order model	
$\mathcal{E}$	6.70690e+01	$\tilde{\mathcal{E}}$	6.50318e+00
$\|e(t,u_1)\|$	5.18372e+01	$\|\tilde{e}(t,\tilde{u}_1)\|$	5.85795e+00
$\|e(t,u_{rnd})\|$	2.82639e+00	$\|\tilde{e}(t,\tilde{u}_{rnd})\|$	2.54461e+00
	5.18880e+00		2.58347e+00
	3.79540e+00		3.32946e+00
	5.81685e+00		1.59148e+00
	4.14449e+00		1.65752e+00

$\|\rho^T u_1\| = 0.30404$, where ρ is the POD projection matrix. Moreover, the leading singular vector $\tilde{u}_1$ of the ROM fails to approximate well even the projection of u_1 on the POD subspace: the angle $\measuredangle(\tilde{u}_1, \rho^T u_1) = 150.87°$ (an angle of 0° or 180° indicates perfect agreement). The discrepancies between the leading singular vector of the full model and that of the ROM can also be seen in Figure 6.1 in which the singular vectors are color coded and superimposed over the unperturbed initial conditions.

As a final verification, introducing a perturbation along u_1 of magnitude of only $1/100 \cdot \|y_0\|$, the quantity (6.2) becomes

$$\frac{\|Y(t) - \tilde{Y}(t)\|}{\|Y(t)\|} \cdot 100.0 = 16.268\%,$$

which is in perfect agreement with the similarity index $\mathcal{S}_2$ (indeed, $0.02328 = \mathcal{S}_2 \approx 0.3661/16.268 = 0.0225$).

6.2. GRI combustion model. Given n_s chemical species with mass fractions y_i and m reactions, the constant-volume batch reactor is modeled by the ODE system

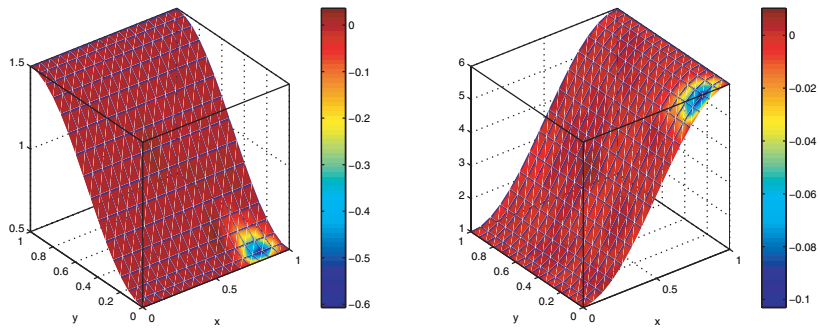
$$y' = S(y)F(y), \quad y(t_0) = y_0, \tag{6.3}$$

where $S \in \mathbb{R}^{n_s \times m}$ includes the stoichiometric matrix and the thermodynamic equations. $F \in \mathbb{R}^m$ is the vector of nonlinear responses corresponding to elementary reactions, with $F_i(y)$ denoting the reaction rate of the ith physical elementary reaction.

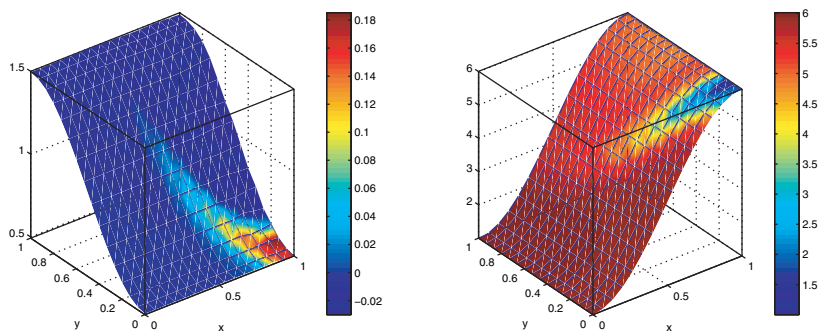
A ROM can be constructed by choosing some (small) subset of the reactions to use in the mechanism so that the behavior of the reduced system is as close as possible to that of the original system, given a range of operating conditions. Often this is done by a chemist based on physical knowledge and intuition. A numerical method for the construction of such reduced models is given by [19]. In that approach, one seeks a ROM in the form

$$\tilde{y}' = S(\tilde{y})DF(\tilde{y}), \quad \tilde{y}(t_0) = y_0, \tag{6.4}$$

such that the norm of the error $e = y - \tilde{y}$ is minimized over a given interval $[t_0, t]$. In (6.4), $D \in \mathbb{R}^{m \times m}$ is a diagonal matrix whose diagonal elements d_i are either 1 or 0 (depending on whether or not the reaction i is selected for the reduced mechanism).



(a) Leading singular vector for the full model.



(b) Leading singular vector for the reduced-order model.

FIG. 6.1. *Brusselator example: Singular vectors color coded and superimposed over the initial conditions (u component on the left, v component on the right).*

The problem of finding the reduced mechanism is written as a discrete constrained optimization where the minimum is over $d_1, d_2, \ldots, d_m$, with $d_i \in \{0, 1\}$, and $\sum d_i = k \ll m$ is prescribed.

The GRI combustion model is a set of $m = 177$ reactions describing the combustion of natural gas and involves $n_s = 32$ chemical species. For more details on this model, see [19, 22]. The resulting ODE system has dimension $n = n_s + 1 = 33$, the last differential equation describing the evolution of the temperature; i.e., $y = [c, T/T_0]$, where c are the species concentrations and T is the temperature, scaled by its initial value T_0.

We consider two different ROMs, corresponding to $k = 32$ and $k = 78$ reactions selected in the reduced mechanism and denoted by ROM_{32} and ROM_{78}, respectively. The time evolution of O_2, CH_4, and CO_2, as well as T/T_0 are shown in Figure 6.2. The full system solution is depicted with a thin solid line, while the ROM solutions are depicted with thick lines (solid for ROM_{32} and dashed for ROM_{78}).

For each ROM the similarity indexes $\mathcal{S}_1$ and $\mathcal{S}_2$ were calculated using $q = 5$ SCE unit vectors. The model parameters were defined to be scaling factors, with nominal values of 1.0, for the $m = 177$ reaction rates in the full model. The model response was taken to be the set of all species concentrations; i.e., $h(t, y, p) = c(t)$. Table 6.2 provides the similarity indexes at two different times $t_1 = 5$ and $t_2 = 10$, before and after ignition, respectively.

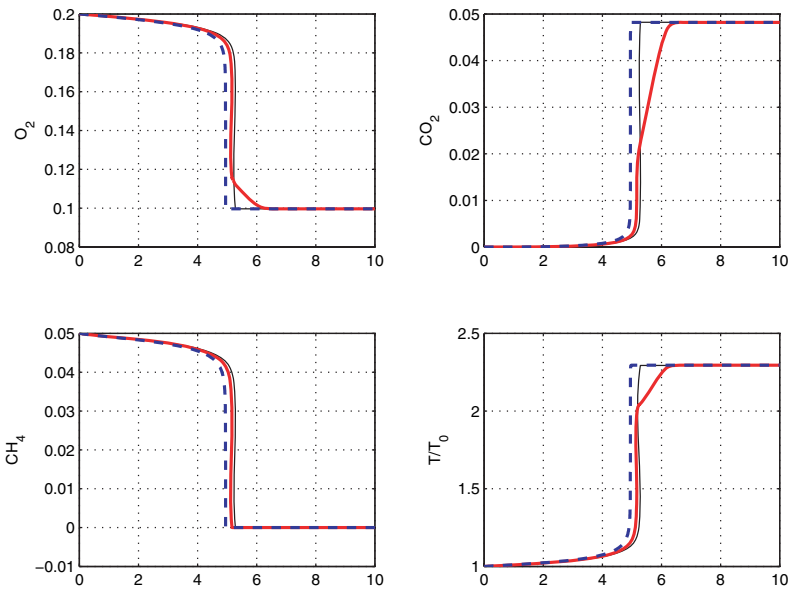


FIG. 6.2. *GRI combustion example: Full system (thin line) and ROM solutions (*ROM_{32}*: thick solid line,* ROM_{78}*: thick dashed line).*

TABLE 6.2
GRI combustion example: Similarity indexes.

	ROM_{32}			ROM_{78}	
	$t_1 = 5$	$t_2 = 10$		$t_1 = 5$	$t_2 = 10$
$\mathcal{S}_1$	0.8991	0.6076	$\mathcal{S}_1$	0.3656	0.6306
$\mathcal{S}_2$	0.4992	$9.366 \cdot 10^{-3}$	$\mathcal{S}_2$	$1.870 \cdot 10^{-2}$	$7.206 \cdot 10^{-2}$

As these results show, ROM_{78} is more robust than ROM_{32} based on the similarity indexes at $t_2 = 10$ but much less robust at the time before ignition $t_1 = 5$. To explain this (apparently) surprising result, note first that the selection of reactions kept in the reduced-order models was based on minimizing the norm $\|e\|_{L_2} = \|y - \tilde{y}\|_{L_2}$ over the time interval $[t_0, t_2]$. For ROM_{78} we have $\|e^*_{78}\| = 1.3736 \cdot 10^{-2}$, while for ROM_{32}, $\|e^*_{32}\| = 3.0349 \cdot 10^{-1}$. In this global measure, ROM_{78} is a better reduced-order model, but, as can be seen in Figure 6.2, at the price of predicting an earlier ignition. Second, note that a parameter perturbation along the direction of largest error growth at $t_1 = 5$ for the full model also leads to an earlier ignition time. As a consequence, ROM_{32} is better at predicting a perturbation-induced hastening of the ignition. This can also be seen in Figure 6.3, which depicts the time evolution up to $t_1 = 5$ of the temperature for the perturbed and unperturbed, full and reduced-order models.

6.3. Heat shock model. The previous reduced models were obtained via automatic procedures that are not specifically designed with the objective of robustness of the reduced model to perturbations in the problem parameters. Those reduced models did not perform well in that situation. The following reduced model was obtained using physics-based methods. It turns out to yield a robust reduced model. It is a DAE system, but this fact is not so important in the interpretation of the results.

This problem models the production of heat shock proteins in *Escherichia coli* cells as a response to extreme heat. These special proteins refold other cell proteins,

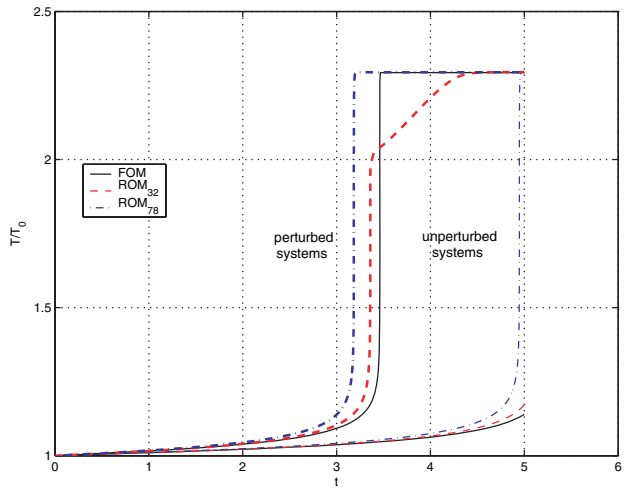

FIG. 6.3. *GRI combustion example: Evolution of the temperature over the time interval* $[t_0, t_1]$ *for the full model (solid line),* ROM_{32} *(dashed line), and* ROM_{78} *(dotted-dashed line). Both unperturbed solutions (thin lines) and perturbed solutions (thick lines) are represented. The perturbation is in the direction of maximum error growth in the norm of the concentrations at time* $t_1 = 5$ *for the full model.*

essential to cell survival, that have become unfolded due to excessive heat. The optimization problem is to find a balance between the effect of the protective proteins and the cost of their production. The mathematical model of the heat shock response is reported in [15]. The model employs first-order kinetics (law of mass action) to describe the various components of the heat shock system, namely, the synthesis of heat shock proteins and their regulator σ_{32}, in addition to protein folding and the association/dissociation activity of molecules. Reactions involving association/dissociation of molecules are often faster than synthesis and degradation of new molecules. Therefore the model exhibits a wide range of time scales and is subject to numerical stiffness. The differential equations that describe the fast states were transformed into algebraic constraints by means of a partial equilibrium approximation, yielding an index-1 DAE system. This system describes the evolution of 11 differential variables, coupled to the evolution of 20 algebraic variables, and includes 31 parameters:

$$\begin{aligned} &y' = F(t, y, x, p^{[1]}, p^{[2]}) = 0, \\ &G(t, y, x, p^{[2]}) = 0, \\ &y(0) = y_0, \;\; x(0) = x_0, \end{aligned}$$

where we have split the model parameters $p \in \mathbb{R}^{31}$ into two subsets, with the parameters $p^{[1]} \in \mathbb{R}^{11}$ appearing only in the differential equations. The integration time interval was taken such that the heat shock response occurs exactly at the middle of the time interval.

The reduced model is obtained in two steps. During the first step we reduce the number of differential variables from 11 to 5 by using an approximation which relates 6 variables (through a proportionality constant) to 2 other variables. The second step reduces further the number of variables by 15, taking advantage of the fact that the reduced variables can be well approximated by constants before and after the heat shock response. In the heat shock response region their behavior is highly nonlinear,

TABLE 6.3

δ in:	$p^{[1]}$	$p^{[1]}$ and $p^{[2]}$	δ in:	$p^{[1]}$	$p^{[1]}$ and $p^{[2]}$
$\mathcal{E}$	$8.2541 \cdot 10^4$	$5.6598 \cdot 10^4$	$\tilde{\mathcal{E}}$	$5.2887 \cdot 10^3$	$7.4958 \cdot 10^3$
$\|e(t,u_1)\|$	$6.0817 \cdot 10^4$	$6.7626 \cdot 10^4$	$\|\tilde{e}(t,\tilde{u}_1)\|$	$6.6292 \cdot 10^3$	$6.6292 \cdot 10^3$
$\|e(t,u_{rnd})\|$	$1.7648 \cdot 10^4$	$4.2042 \cdot 10^3$	$\|\tilde{e}(t,\tilde{u}_{rnd})\|$	$1.8461 \cdot 10^3$	$4.7902 \cdot 10^2$
	$1.9156 \cdot 10^4$	$2.2488 \cdot 10^4$		$1.3622 \cdot 10^3$	$1.3374 \cdot 10^3$
	$1.8371 \cdot 10^4$	$7.3998 \cdot 10^3$		$2.2759 \cdot 10^3$	$1.1942 \cdot 10^4$
	$1.9269 \cdot 10^3$	$9.5864 \cdot 10^3$		$1.4381 \cdot 10^3$	$1.2135 \cdot 10^3$

but the length of this region is much smaller than the length of any neighboring region, allowing us to make the approximation.

We analyze the full and reduced-order models under perturbations in the model parameters. The following two cases are considered:

(a) Perturbation only in the subset $p^{[1]}$ of model parameters representing those parameters that do *not* appear in the algebraic equations.

(b) Perturbation in all model parameters $p^{[1]}$ and $p^{[2]}$.

For both the full and reduced-order models, the direction of maximum error growth was estimated with the method described in section 3 using 4 adjoint systems, i.e., 4 unit vectors in the SCE estimates. We considered perturbations either in only the subset $p^{[1]}$ of model parameters or in all of the model parameters. In both cases, all of the states of the corresponding model were included in the perturbation-induced errors. Table 6.3 provides the estimated value $\mathcal{E}$ compared against the norm of the error along the estimated direction of maximum error growth computed by integrating the forward error equation $\|e(t,u_1)\|$. We also provide the norms of errors due to perturbations along a few random directions $\|e(t,u_{rnd})\|$ to emphasize the fact that it is very unlikely to get close to the "worst-case" scenario by only using random perturbations. All perturbations were $0.01 \cdot u$ (with u either $u^* = u_1$ or some random unit vector).

Next, we computed the similarity indexes of section 4 for this example. If we base the errors on all states of the ROM, the two indexes are as follows:

	Perturbation in $p^{[1]}$	Perturbation in $p^{[1]}$ and $p^{[2]}$
$\mathcal{S}_1$	0.9788	0.4844
$\mathcal{S}_2$	0.1089	0.0882

Considering only the differential variables in the ROM in the error estimates, the reduced-order model is found to be closer (in the sense of these similarity indexes) to the full model:

	Perturbation in $p^{[1]}$	Perturbation in $p^{[1]}$ and $p^{[2]}$
$\mathcal{S}_1$	0.9998	0.7340
$\mathcal{S}_2$	0.1499	0.1213

Table 6.4 summarizes the analysis of the effect of parameter perturbations on the ROM through the estimation of the norm of the cumulative error due to model reduction and perturbations in parameters. The same information (in a slightly dif-

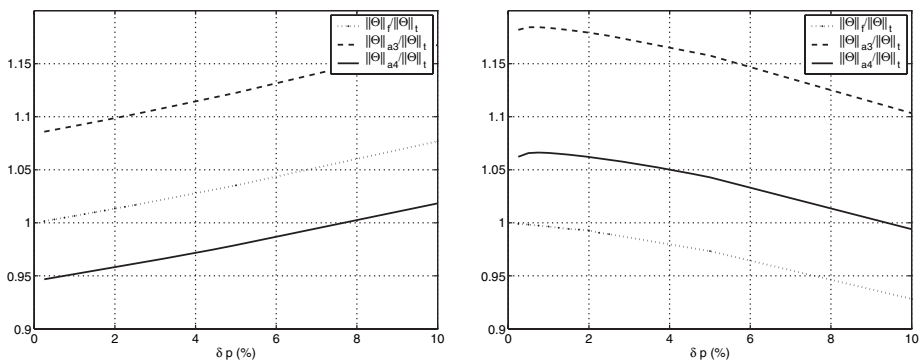
10.00	$2.791 \cdot 10^4$	$3.005 \cdot 10^4$	$2.842 \cdot 10^4$	$3.774 \cdot 10^3$	$3.503 \cdot 10^3$	$3.751 \cdot 10^3$



(a) Only those parameters *not* affecting the algebraic equations were perturbed.

(b) All model parameters were perturbed.

FIG. 6.4. *Heat shock example: Cumulative error due to model reduction and perturbations in parameters. The plots show the ratio of the estimated norm of the cumulative error and the norm of the true (nonlinear) cumulative error for different magnitudes of parameter perturbations along some random direction.*

ferent form) is shown in Figure 6.4. The norms of the following quantities were computed: the true (nonlinear) error ($\|\Theta\|_{true}$), the estimation using integration of the forward error equation ($\|\Theta\|_{fwd}$), and the SCE estimate based on $q = 4$ unit vectors ($\|\Theta\|_{SCE}$). All of the ROM variables (which are a subset of the full model variables) were considered in these errors. The calculations were done for different perturbation magnitudes, given as a percentage of the norm of the perturbed parameters. The perturbation itself was along some random direction.

7. Conclusions. Our research extends the work presented in [11], focusing on estimating validity concepts for general nonlinear ROMs of dynamical models, with application to systems described by ODEs and DAEs. Our estimates, based on a combination of adjoint sensitivity analysis and the small-sample SCE, quantify how well a given ROM captures the changes in the output functional of the full system that result from perturbations in the problem parameters. We measure the extent to

which the ROM preserves the value of maximum perturbation-induced error (and/or the direction of the perturbations that induce it) by considering two types of similarity indexes. The direction in parameter space of maximum error growth in the output functional is efficiently computed within the framework of singular vector analysis, using the SCE estimate for the error norm.

Numerical examples (for both ODE and DAE systems) validate our approach. They also show that the similarity index concept is very effective for detecting situations where the ROM fails to capture the behavior of the full model when the parameters are slightly perturbed. Our numerical experiments indicate that it is quite possible, particularly when the reduced model is constructed via automatic procedures, to generate reduced models that agree well with the original data but are not robust to even small perturbations in the system parameters. This is perhaps not surprising, given that such automatic procedures are in general not specifically constructed with this kind of robustness in mind. We plan to address the construction of reduced models that are robust to perturbations in the problem data in future work.

NUMERICAL METHODS FOR TWO-PARAMETER LOCAL BIFURCATION ANALYSIS OF MAPS*

W. GOVAERTS†, R. KHOSHSIAR GHAZIANI‡, YU. A. KUZNETSOV§, AND H. G. E. MEIJER¶

Abstract. We discuss new and improved algorithms for the bifurcation analysis of fixed points and periodic orbits (cycles) of maps and their implementation in MATCONT, a MATLAB toolbox for continuation and bifurcation analysis of dynamical systems. This includes the numerical continuation of fixed points of iterates of the map with one control parameter, detecting and locating their bifurcation points (i.e., limit point, period-doubling, and Neimark–Sacker) and their continuation in two control parameters, as well as detection and location of all codimension 2 bifurcation points on the corresponding curves. For all bifurcations of codim 1 and 2, the critical normal form coefficients are computed, both numerically with finite directional differences and using symbolic derivatives of the original map. Using a parameter-dependent center manifold reduction, explicit asymptotics are derived for bifurcation curves of double and quadruple period cycles rooted at codim 2 points of cycles with arbitrary period. These asymptotics are implemented into the software and allow one to switch at codim 2 points to the continuation of the double and quadruple period bifurcations. We provide two examples illustrating the developed techniques: a generalized Hénon map and a juvenile/adult competition model from mathematical biology.

1. Introduction.

Discrete-time dynamical systems generated by iterated maps appear in many scientific areas, such as economics, engineering, and ecology. The usual method for getting an insight into their behavior is to compute many orbits, starting from various initial points (i.e., *simulation*). Another tool for gaining a better understanding of these systems is *bifurcation analysis*. It provides theoretic results on the classification of possible modes of behavior, which may explain results of the simulations at different values of control parameters. The application of such theoretical results requires robust numerical computational tools, as a purely symbolic approach is often futile. In the present paper we describe how CL_MATCONT, which supports only ODEs [7, 8], has been complemented by the addition of the new package CL_MATCONTM, which supports local bifurcation analysis of generic finite-dimensional smooth maps. The software and a manual are freely available at http://www.matcont.ugent.be/. Before discussing and comparing existing computer tools for maps, we fix some notation and discuss some events which any standard

software should be able to handle.

Consider a map

$$x \mapsto f(x, \alpha), \tag{1.1}$$

where $x \in \mathbb{R}^n$ is a state variable vector and $\alpha \in \mathbb{R}^p$ is a parameter vector. We assume that f is sufficiently smooth so that all partial derivatives below are well defined. Write the Kth iterate of (1.1) at some parameter value as

$$x \mapsto f^{(K)}(x, \alpha), \quad f^{(K)} : \mathbb{R}^n \times \mathbb{R}^p \to \mathbb{R}^n, \tag{1.2}$$

where

$$g(x, \alpha) := f^{(K)}(x, \alpha) = \underbrace{f(f(f(\cdots f}_{K \text{ times}}(x, \alpha), \alpha), \alpha), \alpha). \tag{1.3}$$

The bifurcation analysis of (1.1) usually starts with fixed points. Numerically we continue fixed points of this map, i.e., solutions to the equation

$$F(x, \alpha) \equiv f(x, \alpha) - x = 0, \tag{1.4}$$

with one control parameter.

While varying one parameter, one may encounter codim 1 bifurcations of fixed points, i.e., critical parameter values where the stability of the fixed point changes. The eigenvalues of the Jacobian matrix of f are called multipliers. The fixed point is asymptotically stable if $|\lambda| < 1$ for every multiplier λ. If there exists a multiplier λ with $|\lambda| > 1$, then the fixed point is unstable. While following a curve of fixed points, three codim 1 singularities related to stability changes can generically occur, namely a *limit point* (*fold*, LP), a *period-doubling* (*flip*, PD), and a *Neimark–Sacker* (NS) point; see section 2 for details. Encountering such a bifurcation, one may use the formulas for the normal form coefficients derived via the center manifold reduction (see, e.g., [18, section 5.4]) to analyze the bifurcation. A nongeneric situation occurs at a branch point (BP) where the Jacobian matrix $[F_x(x, \alpha), F_\alpha(x, \alpha)]$ of (1.4) is rank deficient. Here the implicit function theorem cannot be applied to ensure the existence of a unique smooth branch of solutions. However, it is encountered often in practical problems that exhibit some form of symmetry (equivariance).

When two control parameters are allowed to vary, eleven codim 2 bifurcations can be met in generic families of maps (1.1), where curves of codim 1 bifurcations intersect or meet tangentially. The critical normal form coefficients for all generic codim 2 bifurcation points have been derived earlier in [19, 20] using a combined reduction-normalization technique. Note that the full verification of the genericity of a codim 2 bifurcation requires not only establishing its nondegeneracy at the critical parameter values but also a careful analysis of how the system depends on parameters. This "transversality" issue, which includes the expression of the canonical unfolding parameters of the normal form in terms of the original map parameters, has received little attention in the literature to date. When available, this information could be used to approximate codim 1 bifurcation curves that emanate from the codim 2 points.

There are several standard software packages supporting bifurcation analysis of iterated maps. Orbits of maps and one-dimensional invariant manifolds of saddle fixed points can be computed and visualized using DYNAMICS [24] and DsTool [3]. Location and continuation of fixed-point bifurcations is implemented in AUTO [9]

and the LBFP-version of LOCBIF [15]. The latter program computes the critical normal form coefficient at LP points and locates some codim 2 bifurcations along branches of codim 1 fixed points and cycles. CONTENT [17] was the first software that computed the critical normal form coefficients for all three codim 1 bifurcations of fixed points and cycles and allowed one to continue these bifurcations in two parameters and to detect all eleven codim 2 singularities along them. Branch switching at PD and BP points is also implemented in AUTO, LOCBIF, and CONTENT. However, only trivial branch switching is possible at codim 2 points and only for two (cusp and 1:1 resonance) of eleven codim 2 bifurcations are the critical normal form coefficients computed by the current version of CONTENT. No software supports switching at codim 2 points to the continuation of the double- and quadruple-period bifurcation curves. In the present paper we describe how CL_MATCONTM continues fixed points of an iterate of a map and handles the above-mentioned bifurcations.

The paper is organized as follows. In section 2, we first discuss continuation of fixed points of the iterated map (1.2) and detection of fold, flip, and NS bifurcations and branch points. After a short discussion of all generic codim 1 bifurcations of period-K orbits, we present the continuation of fold, flip, and NS curves of a cycle and detection of codim 2 points along these curves. The algorithms used here are similar to those implemented in CONTENT [12]. In section 3, we provide a (parameter-dependent) normal form for each codim 2 bifurcation point of period-K orbits in the minimal possible phase dimension. Then we consider the branch switching at codim 2 points, where we use parameter-dependent center-manifold reduction. In section 4 we present some algorithmic and numerical details, including the computation of partial derivatives of (1.2) up to and including order 5, using both symbolic partial derivatives of (1.1) and finite differences. In section 5 we demonstrate the use of the algorithms and implementation. Finally, in section 6 we draw some conclusions and mention a few problems for future work.

2. Continuation and detection for codim 1 bifurcations of fixed points and cycles.

2.1. Defining the system and singularities for cycles. Assume that for some $\alpha = \alpha_0$ and $K \geq 1$ the map g has a fixed point $x = x_0$, which is not a fixed point of $f^{(J)}(\cdot, \alpha_0)$ for $1 \leq J < K$ when $K > 1$. In other words, x_0 is a fixed point or a cycle with minimal period K of $f(\cdot, \alpha_0)$.

Each point x of the cycle of period K then satisfies the fixed point equation for the Kth iterate

$$g(x, \alpha) - x = 0. \tag{2.1}$$

As in CONTENT, branches of period-K cycles are computed in CL_MATCONTM by a variant of the Gauss–Newton continuation algorithm [1] applied to (2.1); see [7, 8].

If the Jacobian matrix $A = g_x(x_0, \alpha_0)$ has no eigenvalue λ with $|\lambda| = 1$, i.e., for a hyperbolic fixed point, the dynamics near the origin is topologically equivalent to that of the linear map $x \mapsto Ax$ by the Grobman–Hartman theorem. If eigenvalues with $|\lambda| = 1$ are present, the center manifold theorem guarantees the existence of local stable, unstable, and center invariant manifolds near the fixed point for parameter values close to α_0. Exact formulations of these theorems, together with references to the original papers, can be found in any standard book on dynamical systems, e.g., [2]. On the stable and unstable manifolds, the local dynamics is still determined by the linear part of the map. In contrast, the dynamics in the center manifolds depends on

both linear and nonlinear terms. Not all nonlinear terms are equally important, since some of them can be eliminated by an appropriate smooth coordinate transformation that depends smoothly on parameters and that puts the map restricted to the center manifold into a normal form, at least up to some order. Nonhyperbolic fixed points bifurcate; i.e., the dynamics near such points changes topologically under parameter variations. The birth of extra invariant objects, such as cycles or tori, is described by a parameter-dependent normal form of the restriction of g to a center manifold. Even though neither the center manifold nor the normal form on it is unique, the qualitative conclusions do not depend on the choices that are made [2, p. 266].

For the computations of the center manifold we write the Taylor expansion of g about (x_0, α_0):

$$\begin{aligned} g(x_0+x,\alpha_0+\alpha) = x_0 &+ Ax + \frac{1}{2}B(x,x) + \frac{1}{6}C(x,x,x) \\ &+ \frac{1}{24}D(x,x,x,x) + \frac{1}{120}E(x,x,x,x,x) \\ &+ J_1\alpha + \frac{1}{2}J_2(\alpha,\alpha) \\ &+ A_1(x,\alpha) + \frac{1}{2}B_1(x,x,\alpha) + \frac{1}{6}C_1(x,x,x,\alpha) + \frac{1}{24}D_1(x,x,x,x,\alpha) \\ &+ \frac{1}{2}A_2(x,\alpha,\alpha) + \frac{1}{4}B_2(x,x,\alpha,\alpha) + \frac{1}{12}C_2(x,x,x,\alpha,\alpha) \\ &+ \cdots, \end{aligned} \tag{2.2}$$

where all functions are multilinear forms of their arguments and the dots denote higher order terms in x and α. In particular, $A = g_x(x_0, \alpha)$, and the components of the multilinear functions B and C are given by

$$B_i(u,v) = \sum_{j,k=1}^{n} \frac{\partial^2 g_i(x_0,\alpha_0)}{\partial x_j \partial x_k} u_j v_k, \quad C_i(u,v,w) = \sum_{j,k,l=1}^{n} \frac{\partial^3 g_i(x_0,\alpha_0)}{\partial x_j \partial x_k \partial x_l} u_j v_k w_l, \tag{2.3}$$

for $i = 1, 2, \ldots, n$. From now on, I_n is the unit $n \times n$ matrix and $\|x\| = \sqrt{\langle x, x\rangle}$, where $\langle u, v\rangle = \bar{u}^T v$ is the standard scalar product in $\mathbb{C}^n$ (or $\mathbb{R}^n$).

Generically, the following events happen in the state space near a bifurcation (see, for example, [18]). When the control parameter crosses the critical value corresponding to a fold (LP) bifurcation, two fixed points of g collide and disappear, provided that $a_1 \neq 0$. This implies the collision of two period-K cycles of the original map f. When the control parameter crosses the critical value corresponding to a flip (PD) bifurcation and $b_1 \neq 0$, a cycle of period 2 for g bifurcates from the fixed point, which is a cycle of period $2K$ for map f. Finally, provided that $c_1 = \Re(d_1) \neq 0$, a unique closed invariant curve for g around the fixed point appears on the center manifold, when the control parameter crosses the critical value corresponding to the Neimark–Sacker (NS) bifurcation. For the original map, this means the appearance of K disjoint curves, cyclically shifted by f.

To detect the aforementioned bifurcations, as well as branch points of (2.1), we use in CL_MATCONTM the standard test functions listed in Table 2.1, where t is the tangent vector to the curve (2.1) in the X-space for $X = (x, \alpha)^T$, $F(X) = g(x, \alpha) - x$, $A = g_x$ is the Jacobian matrix of $g = f^{(K)}$, and $\odot$ is the *bialternate matrix product*; see, e.g., [13, section 4.4.4]. We notice that $\det(A \odot A - I_m)$, where $m = \frac{1}{2}\, n(n-1)$,

TABLE 2.1
Detection of codim 1 *bifurcations of cycles.*

Bifurcation	Test function(s)
LP	$t_{n+1} = 0, \begin{pmatrix} F_X \\ t^T \end{pmatrix} \neq 0$
PD	$\det(A + I_n) = 0$
NS	$\det(A \odot A - I_m) = 0$
BP	$\det \begin{pmatrix} F_X \\ t^T \end{pmatrix} = 0$

also vanishes at neutral saddles. We distinguish true NS bifurcations from neutral saddles when processing the NS points.

2.2. Defining systems and singularities for codim 1 bifurcations of cycles. In CL_MATCONTM, LP, PD, and NS curves for period-K cycles are computed by the mentioned Gauss–Newton continuation algorithm applied to *minimally extended defining systems*; cf. [13]. These systems were first implemented, together with the *standard extended defining systems*, in CONTENT [12]. We have adopted in CL_MATCONTM the most robust and efficient methods tested there. For completeness we include a brief description of the defining systems, as we will refer to them in section 4 and use some of the auxiliary variables for the detection of singularities.

The *limit point curve* and *period-doubling curve* are both defined by the following system:

$$\begin{cases} g(x,\alpha) - x &= 0, \\ s(x,\alpha) &= 0, \end{cases} \tag{2.4}$$

where $(x,\alpha) \in \mathbb{R}^{n+2}$, g is given by (1.3), while s is obtained by solving one of the algebraic systems

$$\begin{pmatrix} g_x(x,\alpha) \mp I_n & w_{bor} \\ v_{bor}^T & 0 \end{pmatrix} \begin{pmatrix} v \\ s \end{pmatrix} = \begin{pmatrix} 0_n \\ 1 \end{pmatrix}, \tag{2.5}$$

where $w_{bor}, v_{bor} \in \mathbb{R}^n$ are chosen such that the matrix in (2.5) is nonsingular. One should take the "$-$" sign in (2.5) for the LP-curve and the "$+$" sign for the PD-curve. The derivatives of s can be obtained easily from the derivatives of $g_x(x,\alpha)$:

$$s_z = -w^T (g_x)_z v, \tag{2.6}$$

where z is a state variable or an active parameter and w is obtained by solving

$$\begin{pmatrix} g_x^T(x,\alpha) \mp I_n & v_{bor} \\ w_{bor}^T & 0 \end{pmatrix} \begin{pmatrix} w \\ s \end{pmatrix} = \begin{pmatrix} 0_n \\ 1 \end{pmatrix}. \tag{2.7}$$

We note that the quantities called s in (2.5) and (2.7) are the same since they are both equal to the bottom-right element of the inverse of the square matrix in (2.5).

The *NS* and *neutral-saddle curves* are defined by the following system:

$$\begin{cases} g(x,\alpha) - x = 0, \\ s_{i_1 j_1}(x,\alpha,\kappa) = 0, \\ s_{i_2 j_2}(x,\alpha,\kappa) = 0, \end{cases} \tag{2.8}$$

TABLE 2.3
Smooth normal forms for generic codim 1 bifurcations of fixed points on center manifolds.

	Eigenvectors	Normal form	Critical coefficients
LP	$Aq = q$ $A^T p = p$	$w \mapsto \beta + w + a_1 w^2$ $+O(w^3), \quad w \in \mathbb{R}$	$a_1 = \frac{1}{2}\langle p, B(q,q)\rangle$
PD	$Aq = -q$ $A^T p = -p$	$w \mapsto -(1+\beta)w + b_1 w^3$ $+O(w^4), \quad w \in \mathbb{R}$	$b_1 = \frac{1}{6}\langle p, C(q,q,q) + 3B(q, h_{200})\rangle$ $h_{200} = (I_n - A)^{-1} B(q,q)$
NS	$Aq = \mathrm{e}^{i\theta_0} q$ $A^T p = \mathrm{e}^{-i\theta_0} p$ $\mathrm{e}^{i\nu\theta_0} \neq 1$ $\nu = 1, 2, 3, 4.$	$w \mapsto w e^{i\theta}\left(1 + \beta + d_1 \lvert w\rvert^2\right)$ $+ O(\lvert w\rvert^4), \quad w \in \mathbb{C}$	$d_1 = \frac{1}{2} e^{-i\theta_0}\langle p, C(q,q,\bar{q})$ $+ 2B(q, h_{1100})$ $+ B(\bar{q}, h_{2000})\rangle$ $h_{1100} = (I_n - A)^{-1} B(q,\bar{q})$ $h_{2000} = (e^{2i\theta_0} I_n - A)^{-1} B(q,q)$

i.e. by $n + 2$ equations for the $(n + 3)$ unknowns $x \in \mathbb{R}^n$, $\alpha \in \mathbb{R}^2$, $\kappa \in \mathbb{R}$. Here $(i_1, j_1, i_2, j_2) \in \{1, 2\}$ and $s_{i,j}$ are the components of S,

$$S = \begin{pmatrix} s_{11} & s_{12} \\ s_{21} & s_{22} \end{pmatrix},$$

which is obtained by solving

$$\begin{pmatrix} (g_x)^2(x,\alpha) - 2\kappa g_x + I_n & W_{bor} \\ V_{bor}^T & O \end{pmatrix} \begin{pmatrix} V \\ S \end{pmatrix} = \begin{pmatrix} 0_{n,2} \\ I_2 \end{pmatrix}, \tag{2.9}$$

where $V_{bor}, W_{bor} \in \mathbb{R}^{n\times 2}$ are chosen (and can be adapted) so that the matrix in (2.9) is nonsingular. Along the NS curve, κ is the real part of the critical multipliers $\mathrm{e}^{\pm i\theta}$. The derivatives of s_{ij} can be obtained easily from the derivatives of $g_x(x,\alpha)$ as before.

Table 2.2 specifies test functions used in CL_MATCONTM to detect and locate relevant codim 2 singularities along the codim 1 bifurcation curves. Here a_1 and b_1 are the critical normal form coefficients given in Table 2.3, where q and p should be replaced by the vectors v and w, respectively, computed in (2.5) and (2.7). The test function c_1 is given by the *Lyapunov coefficient* $c_1 = \Re(d_1)$, where d_1 is also specified in Table 2.3. Matrix A_1 is defined as $A_1 = A|_{N^\perp}$, where $A = g_x$ and $N^\perp$ is the orthogonal complement in $\mathbb{R}^n$ of the two-dimensional eigenspace associated with the pair of multipliers with unit product of A^T; $m_1 = \frac{1}{2}(n-2)(n-3)$.

It is possible and sometimes necessary to adapt the defining system while continuing a bifurcation curve, i.e., to update the auxiliary variables used in the defining

system of the computed branch. The bordering vectors v_{bor} and w_{bor} may require updating since they must ensure that the matrices in (2.5) and (2.7) are nonsingular. Updating is done in CL_MATCONTM by replacing v_{bor} and w_{bor} with the normalized vectors v, w computed in (2.5), (2.7), respectively. Updating of V and W in (2.9) is done similarly, while (i_1, j_1, i_2, j_2) are updated in such a way that the linearized system of (2.8) is as well-conditioned as possible.

3. Numerical analysis of codim 2 bifurcations.

3.1. Codim 2 cases. While, as mentioned in the introduction, methods to study codim 1 bifurcations are implemented in several packages [12], the numerical analysis of codim 2 bifurcations has remained a laborious task. We implemented in CL_MATCONTM the formulas for the critical center manifold reduction from [19, 20] for all eleven codim 2 bifurcations. Below we give normal forms to which the restriction of a generic map $g(x, \alpha) = f^{(K)}(x, \alpha)$ to the parameter-dependent center manifold can be transformed near the corresponding bifurcation by smooth invertible coordinate and parameter transformations. When CL_MATCONTM detects a codim 2 bifurcation, the critical coefficients of these normal forms are automatically computed and reported to the user, so that nondegeneracy is now easily checked. We stress that they can also be used to predict certain behavior of the system. In 6 out of 11 cases, branches of local codim 1 bifurcations are rooted at codim 2 bifurcations, and for these cases we also incorporate the parameter-dependent part of the normal form and provide asymptotic expressions for the new curves. In section 3.2 we specify how we switch the continuation to those branches.

The $\mathcal{O}$-symbol denotes higher order terms in phase-variables, the coefficients of which may also depend on parameters. But the qualitative picture is determined by the lowest order terms listed below. We refer to [18, Chapter 9] and [19, 20] for more details, including explicit expressions for all critical normal form coefficients which are not repeated in the present paper. If a complex critical eigenvalue λ is involved, it is always assumed that $\lambda^\nu \neq 1$ for $\nu = 1, 2, 3, 4$. In some cases, we combine two real unfolding parameters (β_1, β_2) into one complex parameter $\beta = \beta_1 + i\beta_2 \in \mathbb{C}$.

3.1.1. CP. The critical smooth normal form on the center manifold at a *cusp bifurcation* is

$$w \mapsto w + a_2 w^3 + \mathcal{O}(|w|^4), \quad w \in \mathbb{R}, \tag{3.1}$$

where, generically, $a_2 \neq 0$. Under this condition, a generic two-parameter unfolding of this singularity has two fold curves in the parameter plane which form a cuspidal wedge. For nearby parameter values, the map g has up to three fixed points that pairwise collide along the fold curves. In the direct product of the state and the parameter spaces, there is one smooth fold curve, so no branch switching is needed. CL_MATCONTM reports the value of a_2 at the bifurcation.

3.1.2. GPD. Near a *generalized flip* bifurcation the restriction of the map g to the parameter-dependent center manifold is smoothly equivalent to the normal form

$$w \mapsto -(1 + \beta_1)w + \beta_2 w^3 + b_2(\beta) w^5 + \mathcal{O}(|w|^6), \quad w \in \mathbb{R}, \tag{3.2}$$

where, generically, the coefficient $b_2(0) \neq 0$, while the components of $\beta = (\beta_1, \beta_2)$ are smooth functions of α, which can serve as new unfolding parameters. The value of $b_2(0)$ is reported by the software. The fixed point $w = 0$ of the map (3.2) exhibits a flip bifurcation for $\beta_1 = 0$. It is well known that from the point $\beta = 0$, corresponding

to the degenerate flip bifurcation, a fold curve of double-period cycles emanates. The asymptotic expression for this curve in (3.2) is given by

$$(w, \beta_1, \beta_2) = (\varepsilon, -b_2\varepsilon^4 + \mathcal{O}(\varepsilon^5), -2b_2\varepsilon^2 + \mathcal{O}(\varepsilon^3)). \tag{3.3}$$

3.1.3. CH. If $e^{i\nu\theta_0} \neq 1$ for $\nu = 1, 2, \ldots, 6$, the critical smooth normal form on the center manifold at the *Chenciner bifurcation* can be written as

$$z \mapsto ze^{i\theta_0}(1 + d_1|z|^2 + d_2|z|^4 + \mathcal{O}(|z|^6)), \quad z \in \mathbb{C}, \tag{3.4}$$

where $c_1 = \Re(d_1) = 0$ but, generically, $c_2 = \Re(d_2) + \frac{1}{2}\Im(d_1)^2 \neq 0$ and is reported to the user. A generic two-parameter unfolding of this singularity has a complicated bifurcation set due to the "collision" and destruction of two closed invariant curves of different stability born via the sub- and supercritical NS bifurcations, respectively. There are no cycle bifurcation curves rooted at this bifurcation.

3.1.4. R1. The restriction of the map at a 1:1 *resonance* to the corresponding center manifold can be written in the form

$$\begin{pmatrix} w_1 \\ w_2 \end{pmatrix} \mapsto \begin{pmatrix} w_1 + w_2 \\ w_2 + a_1 w_1^2 + b_1 w_1 w_2 \end{pmatrix} + \mathcal{O}(\|w\|^3), \quad w \in \mathbb{R}^2. \tag{3.5}$$

Generically, an NS bifurcation curve of the fixed point meets the fold bifurcation curve tangentially. CL_MATCONTM reports the sign of $a_1(b_1 - 2a_1)$, giving the first Lyapunov coefficient along the NS curve near the bifurcation. The local branch switching problem is trivial here, since both curves correspond to fixed points of g. The full bifurcation diagram near the codim 2 point is complicated and involves global bifurcations, e.g., tangencies of stable and unstable invariant manifolds of saddle fixed points of g and destruction of a closed invariant curve born via the NS bifurcation.

3.1.5. R2. Near a 1:2 resonance the restriction of the map g to the parameter-dependent center manifold is smoothly equivalent to the normal form

$$\begin{aligned} \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} \mapsto & \begin{pmatrix} -w_1 + w_2 \\ \beta_1 w_1 + (-1 + \beta_2) w_2 + C_1(\beta) w_1^3 + D_1(\beta) w_1^2 w_2 \end{pmatrix} \\ & + \mathcal{O}(\|w\|^4), \quad w \in \mathbb{R}^2, \end{aligned} \tag{3.6}$$

which depends on two unfolding parameters (β_1, β_2). If $C_1(0) < 0$, then there is an NS curve of fixed points of g with double period that emanates from the flip bifurcation curve $\beta_2 = 0$ of fixed points. It has the following asymptotic expression:

$$(w_1^2, w_2, \beta_1, \beta_2) = \left(-\frac{1}{C_1}, 0, 1, \left(2 + \frac{D_1}{C_1}\right)\right)\varepsilon + \mathcal{O}(\varepsilon^2). \tag{3.7}$$

There are also global bifurcations associated with the destruction of closed invariant curves. CL_MATCONTM reports the values of $4C_1(0)$ and $-2D_1(0) - 6C_1(0)$ (relevant for the flow approximation) to the user.

3.1.6. R3. At a 1:3 resonance the restriction of the map g to the parameter-dependent center manifold is smoothly equivalent to the normal form

$$z \mapsto (e^{2i\pi/3} + \beta)z + B_1(\beta)\bar{z}^2 + C_1(\beta)z|z|^2 + \mathcal{O}(|z|^4), \quad z \in \mathbb{C}, \tag{3.8}$$

where $\beta = \beta_1 + i\beta_2 \in \mathbb{C}$. A generic unfolding of this singularity has a period-3 saddle cycle that does not bifurcate for nearby parameter values, although it merges with the primary fixed point as the parameters approach R3. Only global bifurcations related to the destruction of a closed invariant curve born via the primary NS bifurcation occur in a neighborhood of this codim 2 point.

Note that the period-3 cycle becomes neutral near this bifurcation. Recall that a saddle cycle is called *neutral* if the corresponding fixed point has a pair of real eigenvalues with product 1. This singularity is important in analyzing global bifurcations of invariant manifolds of cycles. Moreover, the curve of neutral period-3 saddle cycles may turn into a true NS bifurcation at R1 or R2. Therefore, we give here an asymptotic of this curve.

First we need a vector field for which the time-1 flow approximates the third iterate of the map, i.e.,

$$\widetilde{g}(\eta, \widetilde{\beta}) = \widetilde{\beta}\eta + \bar{\eta}^2 + C_0(\beta)\eta^2\bar{\eta} + \mathcal{O}(|\eta|^4), \tag{3.9}$$

where

$$\widetilde{\beta} = 3\mathrm{e}^{-2i\pi/3}\beta, \quad z = \frac{1}{|B_1(\beta)|}\mathrm{e}^{i\arg(B_1(\beta))/3}\eta, \quad C_0(\beta) = \frac{1}{3}\left(\frac{C_1(\beta)}{|B_1(\beta)|^2}\mathrm{e}^{-2i\pi/3} - 1\right).$$

We write $C_0 = a + ib$, where a is reported upon detection, so that for $\eta = \rho\mathrm{e}^{i\phi}$ the neutral saddle curve has the following asymptotic expression:

$$(\rho, \phi, \beta_1, \beta_2) = \left(\varepsilon, s(\pi/6 - a\varepsilon/3), -2a\varepsilon^2, s\varepsilon - b\varepsilon^2\right) + \mathcal{O}(\varepsilon^3), \tag{3.10}$$

where $s = \pm 1$.

3.1.7. R4. Near a 1:4 resonance the restriction of the map g to the parameter-dependent center manifold is smoothly equivalent to the normal form

$$z \mapsto (i + \beta)z + C_1(\beta)z^2\bar{z} + D_1(\beta)\bar{z}^3 + \mathcal{O}(|z|^4), \quad z \in \mathbb{C}, \tag{3.11}$$

where $\beta = \beta_1 + i\beta_2 \in \mathbb{C}$. For this bifurcation we need not only this parameter-dependent normal form, but also an approximation of its fourth iterate by a unit-time shift along orbits of a vector field

$$\widetilde{g}(\eta, \widetilde{\beta}) = \widetilde{\beta}\eta + A_0(\beta)\eta^2\bar{\eta} + \bar{\eta}^3 + \mathcal{O}(|\eta|^4), \tag{3.12}$$

where $\eta \in \mathbb{C}$ and $\widetilde{\beta} = \tilde{\beta}_1 + i\tilde{\beta}_2$, $\tilde{\beta}_i \in \mathbb{R}$. Here we use

$$z = \frac{1}{\sqrt{|D_1(\beta)|}}\mathrm{e}^{i\arg(D_1(\beta))/4}\eta, \qquad A_0(\beta) = -i\frac{C_1(\beta)}{|D_1(\beta)|}.$$

Moreover, we have

$$\begin{pmatrix}\widetilde{\beta}_1\\ \widetilde{\beta}_2\end{pmatrix} = \begin{pmatrix}0 & 4\\ -4 & 0\end{pmatrix}\begin{pmatrix}\beta_1\\ \beta_2\end{pmatrix}. \tag{3.13}$$

There are three possible branch switches for this bifurcation. Denote the reported values by $a = \Re(A_0(0))$ and $b = \Im(A_0(0))$. If $\Delta \equiv a^2 + b^2 - 1 > 0$, then there are two half-lines $l_{1,2}$ of a limit-point curve of cycles with four times the original period. If

$$|b| > \frac{(1 + a^2)}{\sqrt{1 - a^2}},$$

then there is a curve n_1 along which a cycle of four times the primary period exhibits an NS bifurcation. Using $\eta = re^{i\phi}$, we have the following approximations:

$$l_{1,2} : (r^2, \phi, \widetilde{\beta}_1, \widetilde{\beta}_2) = \left(\varepsilon, \frac{1}{4}\arctan\left(\frac{ab \pm \sqrt{\Delta}}{b^2-1}\right) + \mathcal{O}(\varepsilon),\right.$$

$$\left.\frac{-a\Delta \mp b\sqrt{\Delta}}{a^2+b^2}\varepsilon, \frac{-b\Delta \pm a\sqrt{\Delta}}{a^2+b^2}\varepsilon\right) + \mathcal{O}(\varepsilon^2), \tag{3.14}$$

$$n_1 : (r^2, \phi, \widetilde{\beta}_1, \widetilde{\beta}_2) = \Big(\varepsilon + \mathcal{O}(\varepsilon^2), \operatorname{sign}(b)\arccos(a)/4 + \mathcal{O}(\varepsilon),$$

$$-2a\varepsilon + \mathcal{O}(\varepsilon^2), -(b - \operatorname{sign}(b)\sqrt{1-a^2})\varepsilon + \mathcal{O}(\varepsilon^2)\Big).$$

Taking into account (3.13), we obtain expressions for the unfolding parameters β_1 and β_2. If, in the formula for n_1, we replace $\operatorname{sign}(b)$ by $-\operatorname{sign}(b)$, then this gives the asymptotic for a neutral saddle singularity of the period-4 cycle.

Generically, there are also global bifurcations near `R4`.

3.1.8. LPPD. Near a *fold-flip* bifurcation, the restriction of the map g to the parameter-dependent center manifold is smoothly equivalent to the normal form

$$\begin{pmatrix} w_1 \\ w_2 \end{pmatrix} \mapsto \begin{pmatrix} \beta_1 + (1+\beta_2)w_1 + a(\beta)w_1^2 + b(\beta)w_2^2 + c_1(\beta)w_1^3 + c_2(\beta)w_1w_2^2 \\ -w_2 + e(\beta)w_1w_2 + c_3(\beta)w_1^2w_2 + c_4(\beta)w_2^3 \end{pmatrix} + \mathcal{O}(\|w\|^4), \quad w \in \mathbb{R}^2. \tag{3.15}$$

A new branch predicted by (3.15) for a generic map g is an NS bifurcation of double period that exists if $be > 0$ and has the asymptotic expression

$$(x, y^2, \beta_1, \beta_2) = \left(-\frac{c_4}{e}, 1, -b, -\frac{2b + ec_2 - 2(a+e)c_4}{e}\right)\varepsilon + \mathcal{O}(\varepsilon^2). \tag{3.16}$$

CL_MATCONTM reports the coefficients $\frac{a}{e}$ and be and the sign of the Lyapunov coefficient if applicable. As for the majority of the considered cases, there are also global bifurcations near this codim 2 point.

3.1.9. LPNS. For a *fold-NS* bifurcation, the critical normal form on the center manifold is given by

$$\begin{pmatrix} w \\ z \end{pmatrix} \mapsto \begin{pmatrix} w + sz\bar{z} + w^2 + cx^3 \\ e^{i\theta_0}z + awz + bzw^2 \end{pmatrix} + \mathcal{O}(\|(w,z)\|^4), \quad (w,z) \in \mathbb{R}\times\mathbb{C}. \tag{3.17}$$

The critical coefficients s, a, b, c are reported. Depending on their values, several bifurcation scenarios are possible in parameter-dependent unfoldings, which all involve global phenomena.

3.1.10. PDNS. Near a *flip-NS* bifurcation, the restriction of the map g to the parameter-dependent center manifold is smoothly equivalent to the parameter-dependent normal form

$$\begin{pmatrix} w \\ z \end{pmatrix} \mapsto \begin{pmatrix} -w(1 + \beta_1 + c_1(\beta)w^2 + c_2(\beta)|z|^2) \\ ze^{i\theta(\beta)}(1 + \beta_2 + c_3(\beta)w^2 + c_4(\beta)|z|^2) \end{pmatrix} + \mathcal{O}(\|(w,z)\|^4), \quad (w,z) \in \mathbb{R}\times\mathbb{C}, \tag{3.18}$$

where $\Re(c_i(0))$ are reported and $\theta(0) = \theta_0$. Besides global bifurcations, an NS bifurcation curve of double period for g is rooted at $\beta = 0$; it is always present. The asymptotic expression of this curve is given by

$$(w^2, z, \beta_1, \beta_2) = (1, 0, -c_1, -\text{sign}(c_1)\Re(c_3))\,\varepsilon + \mathcal{O}(\varepsilon^2). \tag{3.19}$$

3.1.11. NSNS. For a *double NS bifurcation*, provided that $l\theta_0 \neq j\theta_1$ for integer l and j with $l + j \leq 4$, the critical normal form on the center manifold is

$$\begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \mapsto \begin{pmatrix} z_1(e^{i\theta_0} + c_1|z_1|^2 + c_2|z_2|^2) \\ z_2(e^{i\theta_1} + c_3|z_1|^2 + c_4|z_2|^2) \end{pmatrix} + \mathcal{O}(\|z\|^4), \quad z \in \mathbb{C}^2. \tag{3.20}$$

Depending on the values of $\Re(c_i)$, which are reported, several bifurcation scenarios are possible in parameter-dependent unfoldings, which all involve global phenomena. To analyze some of them, one has to take into account fourth- and fifth-order terms.

3.2. Branch switching from codim 2 bifurcations. Here we address the problem of branch switching at codim 2 bifurcation points of maps, when the emanating curve corresponds to a local bifurcation. This involves the degenerate flip, 1:2 resonance, 1:4 resonance, fold-flip, and flip-NS bifurcations only. To obtain appropriate initial continuation data for the original map, we combine parameter-dependent center-manifold reduction with asymptotic expressions for the new curves given in section 3.1.

Although we know that in several cases global bifurcations are also involved, we will not try to switch to those branches, as the continuation of these global bifurcations is not supported by the current version of CL_MATCONTM.

3.2.1. Parameter-dependent center-manifold reduction. In all our cases, the map $g(x, \alpha) : \mathbb{R}^n \times \mathbb{R}^2 \to \mathbb{R}^n$, where g is defined by (1.3), satisfies $g(x_0, \alpha_0) = x_0$, and its Jacobian matrix $A = g_x(x_0, \alpha_0)$ has at most three multipliers on the unit circle. Furthermore we know a parameter-dependent smooth normal form $G(w, \beta)$ for the corresponding bifurcation; see section 3.1. Then we assume a relation

$$\alpha - \alpha_0 = V(\beta) = v_{10}\beta_1 + v_{01}\beta_2 + \mathcal{O}(\|\beta\|^2) \tag{3.21}$$

between the original and the unfolding parameters. Note that V incorporates linear scalings. Occasionally, we interpret $\beta_1 = \bar{\beta}_2$ as one parameter $\beta \in \mathbb{C}$; in such cases, $v_{01} = \bar{v}_{10} \in \mathbb{C}^2$.

To find a parameter-dependent center manifold as the graph of $x = x_0 + H(w, \beta)$ we make a Taylor expansion of the *homological equation*

$$g(x_0 + H(w, \beta), \alpha_0 + V(\beta)) = H(G(w, \beta), \beta) \tag{3.22}$$

in w and β at $(w, \beta) = (0, 0)$, where we expand g as in (2.2) and write

$$H(w, \beta) = \sum_{|\mu|+|\nu|\geq 1} h_{\mu,\nu} w^\mu \beta^\nu, \tag{3.23}$$

and μ, ν are multi-indices. All coefficients must vanish, and this leads to a solution for H and V. Below we will focus only on the parameter-dependent computations and assume full knowledge of the critical center manifold and the critical normal form coefficients; see [18, 19, 20]. The solvability conditions imposed coincide with the transversality of the original family to the bifurcation manifold. A similar technique

was introduced in [5, section 11] to switch at codim 2 bifurcations of equilibria in ODEs.

Initial data for the new curve is now provided by substituting for w and β the asymptotic expression in ε of section 3.1 into H and V up to a certain order in ε, usually 2. In CL_MATCONTM the user can specify ε to obtain a starting point near the emanating curve for which the continuation code converges to a point on the new curve.

It will be convenient to introduce some notation. Let p denote an eigenvector of A^T corresponding to the eigenvalue -1 of A. We will then write $\Gamma : \mathbb{R}^{n+2} \to \mathbb{R}^n$ for $\Gamma(q,v) = \langle p, A_1(q,v) + B(q,(I_n - A)^{-1}J_1 v)\rangle$ and $\gamma_i = \Gamma(q,e_i)$ for the evaluation of Γ on the standard basis vectors in $\mathbb{R}^2$. If $\gamma_i \neq 0$ for $i = 1,2$, then $s_1 = \frac{1}{(\gamma_1^2+\gamma_2^2)}(\gamma_1,\gamma_2)^T$ and $s_2 = (-\gamma_2,\gamma_1)^T$ compose a new orthogonal basis in $\mathbb{R}^2$.

3.2.2. Degenerate flip. The homological equation (3.22) provides the following systems to be solved:

$$(A - I_n)[h_{010},\ h_{001}] = -J_1[v_{10},\ v_{01}], \tag{3.24}$$

$$(A + I_n)[h_{110},\ h_{101}] = -[q,\ 0] - A_1(q,[v_{10},\ v_{01}]) - B(q,[h_{010},\ h_{001}]), \tag{3.25}$$

where $[a,\ b]$ is an $n \times 2$-matrix with columns $a, b \in \mathbb{R}^n$. The higher orders give

$$\begin{aligned}(A - I_n)h_{210} = 2h_{200} - [&B_1(q,q,v_{10}) + B(h_{200},h_{010}) + A_1(h_{200},v_{10}) \\ &+ 2B(q,h_{110}) + C(q,q,h_{010})]\,,\end{aligned} \tag{3.26}$$

$$\begin{aligned}(A - I_n)h_{201} = -[&B_1(q,q,v_{01}) + B(h_{200},h_{001}) + A_1(h_{200},v_{01}) \\ &+ 2B(q,h_{101}) + C(q,q,h_{001})]\,,\end{aligned} \tag{3.27}$$

$$\begin{aligned}(A + I_n)h_{310} = -3h_{300} - [&D(q,q,q,h_{010}) + 3C(q,q,h_{110}) + C_1(q,q,q,v_{10}) \\ &+ 3B(h_{110},h_{200}) + B(h_{300},h_{010}) + 3B_1(h_{200},q,v_{10}) \\ &+ A_1(h_{300},v_{10}) + 3C(h_{200},q,h_{010}) + 3B(h_{210},q)]\,,\end{aligned} \tag{3.28}$$

$$\begin{aligned}(A + I_n)h_{301} = 6q - [&D(q,q,q,h_{001}) + 3C(q,q,h_{101}) + C_1(q,q,q,v_{01}) \\ &+ 3B(h_{101},h_{200}) + B(h_{300},h_{001}) + 3B_1(h_{200},q,v_{01}) \\ &+ A_1(h_{300},v_{01}) + 3C(h_{200},q,h_{001}) + 3B(h_{201},q)]\,.\end{aligned} \tag{3.29}$$

The linear part of V involves four unknowns to be found from equations with singular left-hand sides, i.e., (3.25), (3.28), (3.29). For the solution we start with substitution of $[h_{010},\ h_{001}] = (I_n - A)^{-1}J_1[v_{10},\ v_{01}]$ from (3.24) into (3.25). As the left-hand side of (3.25) is singular, the right-hand side must be orthogonal to the adjoint eigenvector p. Application of the Fredholm alternative leads to

$$\begin{aligned}&\langle p, (A + I_n)[h_{110},\ h_{101}]\rangle \\ &\quad = -\langle p, [q,\ 0] + A_1(q,[v_{10},\ v_{01}]) + B(q,(I_n - A)^{-1}J_1[v_{10},v_{01}])\rangle.\end{aligned}$$

We see that the operator $\Gamma(q,v)$ appears naturally and rewrite it as

$$[\gamma_1,\ \gamma_2][v_{10},\ v_{01}] = [-1,\ 0].$$

The general solution is given by

$$v_{10} = -s_1 + \delta_1 s_2, \quad v_{01} = \delta_2 s_2, \quad \delta_1, \delta_2 \in \mathbb{R}.$$

Since v_{10}, v_{01} appear linearly in these equations (via the multilinear functions), application of the Fredholm alternative to (3.28), (3.29) results in a linear system for the constants δ_1, δ_2.

3.2.3. 1:2 resonance. As before, we first list the necessary equations obtained from the homological equation

$$(A - I_n)[h_{0010},\ h_{0001}] = -J_1[v_{10},\ v_{01}], \tag{3.30}$$

$$(A + I_n)[h_{1010},\ h_{1001}] = [q_1,\ 0] - A_1(q_0, [v_{10},\ v_{01}]) - B(q_0, [h_{0010},\ h_{0001}]), \tag{3.31}$$

$$\begin{aligned}(A + I_n)[h_{0110},\ h_{0101}] = {} & [h_{1010},\ q_1 + h_{1001}] - A_1(q_1, [v_{10},\ v_{01}]) \\ & - B(q_1, [h_{0010},\ h_{0001}]).\end{aligned} \tag{3.32}$$

As for the degenerate flip, we substitute $[h_{0010},\ h_{0001}] = (I_n - A)^{-1} J_1[v_{10},\ v_{01}]$ into (3.31). As (3.31) is similar to (3.25), the solution for v_{10} and v_{01} is now

$$v_{10} = s_1 + \delta_1 s_2, \quad v_{01} = \delta_2 s_2, \quad \delta_1, \delta_2 \in \mathbb{R}.$$

We substitute the s_i into (3.32) and write

$$Q_1 = \langle p_1, A_1(q_0, s_1) + B(q_0, (A - I_n)^{-1} J_1 s_1) \rangle, \qquad Q_2 = \Gamma(q_1, s_1),$$

$$Q_3 = \langle p_1, A_1(q_0, s_2) + B(q_0, (A - I_n)^{-1} J_1 s_2) \rangle, \qquad Q_4 = \Gamma(q_1, s_2).$$

A little algebra shows that

$$\delta_1 = -\left(\frac{Q_1 + Q_2}{Q_3 + Q_4}\right), \quad \delta_2 = \frac{1}{Q_3 + Q_4}.$$

3.2.4. 1:3 resonance. We follow a slightly different procedure here. We want to find $V(\beta) = v\beta + \bar{v}\bar{\beta}$, where $\beta = \beta_1 + i\beta_2$. Then we treat β and $\bar{\beta}$ as independent variables, which makes it slightly easier to find the solutions. As the final $V(\beta)$ should be real, it follows that $v = v_{10} = \bar{v}_{01}$.

Let $\lambda = \mathrm{e}^{2i\pi/3}$, and introduce $Aq = \lambda q,\ A^T p = \bar{\lambda} p,\ \langle p, q \rangle = 1$. As before, the first linear systems resulting from (3.22) are given by

$$(A - I_n)[h_{0010},\ h_{0001}] = -J_1[v_{10},\ v_{01}],$$

$$(A - \lambda I_n)[h_{1010},\ h_{1001}] = [q,\ 0] - A_1(q, [v_{10},\ v_{01}]) - B(q, [h_{0010},\ h_{0001}]),$$

and two complex conjugated systems for h_{0101} and h_{0110}. With the same approach we will now find complex γ_i, and rewriting the system for $v = v_{10} = \bar{v}_{01}$, we have $(\gamma_1, \gamma_2)v = 1, (\gamma_1, \gamma_2)\bar{v} = 0$, with $v = (\bar{\gamma}_2, -\bar{\gamma}_1)/(\gamma_1\bar{\gamma}_2 - \gamma_2\bar{\gamma}_1)$ as solution.

3.2.5. 1:4 resonance. Replacing $\lambda = i$, we can repeat the procedure for the case of 1:3 resonance.

3.2.6. Fold-flip. Let $Aq_{1,2} = \pm q_{1,2},\ A^T p_{1,2} = \pm p_{1,2},\ \langle p_1, q_1\rangle = \langle p_2, q_2\rangle = 1$. The necessary systems to solve from the homological equation (3.22) are

$$(A - I_n)[h_{0010},\ h_{0001}] = [q_1,\ 0] - J_1[v_{10},\ v_{01}], \tag{3.33}$$

$$\begin{aligned}(A - I_n)[h_{1010},\ h_{1001}] = {}& [h_{2000},\ q_1] - A_1(q_1, [v_{10},\ v_{01}]) \\ & - B(q_1, [h_{0010},\ h_{0001}]),\end{aligned} \tag{3.34}$$

$$\begin{aligned}(A + I_n)[h_{0110},\ h_{0101}] = {}& [h_{1100},\ 0] - A_1(q_2, [v_{10},\ v_{01}]) \\ & - B(q_2, [h_{0010},\ h_{0001}]).\end{aligned} \tag{3.35}$$

First note that all matrices in the left-hand sides are singular. If we take $(\gamma_1, \gamma_2) = p_1^T J_1$, we can define the orthogonal vectors s_1 and s_2 as before, and then $v_{10} = s_1 + \delta_1 s_2$ and $v_{01} = \delta_2 s_2$ solve system (3.33) for arbitrary δ_1, δ_2. Bordering the singular matrix $(A - I_n)$, one can solve for h_{0010} and h_{0001}. Any multiple of q_1 can be added to h_{0010} and h_{0001}, so we use $h_{0010} = (A - I_n)^{INV}(q_1 - J_1 v_{10}) + \delta_3 q_1$ and $h_{0010} = -(A - I_n)^{INV}(J_1 v_{01}) + \delta_4 q_1$. We will use this freedom to solve (3.34) and (3.35) simultaneously for all δ's. Note that h_{2000} and h_{1100} are also found using bordered systems chosen, but such that $\langle p_1, h_{2000}\rangle = \langle p_2, h_{1100}\rangle = 0$.

Then we obtain the following four-dimensional system:

$$\begin{pmatrix} L & 0_{2\times 2} \\ 0_{2\times 2} & L \end{pmatrix} \begin{pmatrix} \delta_1 \\ \delta_3 \\ \delta_2 \\ \delta_4 \end{pmatrix} = \begin{pmatrix} -\langle p_1, A_1(q_1, s_1) + B(q_1, (A - I_n)^{INV}(q_1 - J_1 s_1))\rangle \\ -\langle p_2, A_1(q_2, s_1) + B(q_2, (A - I_n)^{INV}(q_1 - J_1 s_1))\rangle \\ 1 \\ 0 \end{pmatrix}, \tag{3.36}$$

where L is defined by

$$L = \begin{pmatrix} \langle p_1, A_1(q_1, s_2) + B(q_1, (I_n - A)^{INV} J_1 s_2)\rangle & \langle p_1, B(q_1, q_1)\rangle \\ \langle p_2, A_1(q_2, s_2) + B(q_2, (I_n - A)^{INV} J_1 s_2)\rangle & \langle p_2, B(q_1, q_2)\rangle \end{pmatrix}. \tag{3.37}$$

Notice that $2a(0) = \langle p_1, B(q_1, q_1)\rangle$ and that q_1 can be chosen such that $e(0) = \langle p_2, B(q_1, q_2)\rangle = 1$. The condition $\gamma_1\gamma_2 \det(L) \neq 0$ is equivalent with the transversality to the bifurcation manifold of the family $g(x, \alpha)$.

3.2.7. Flip-NS. Introduce $Aq_1 = q_1,\ A^T p_1 = p_1,\ \langle p_1, q_1\rangle = 1$ and $Aq_2 = e^{i\theta_0} q_2,\ A^T p_2 = e^{-i\theta_0} p_2,\ \langle p_2, q_2\rangle = 1$. The linear systems obtained from the homological equation (3.22) are

$$(A - I_n)[h_{00010},\ h_{00001}] = -J_1[v_{10},\ v_{01}],$$

$$(A + I_n)[h_{10010},\ h_{10001}] = [-q_1,\ 0] - A_1(q_1, [v_{10},\ v_{01}]) - B(q_1, [h_{00010},\ h_{00001}]),$$

$$(A - e^{i\theta_0} I_n)[h_{01010},\ h_{01001}] = [0,\ q_2 e^{i\theta_0}] - A_1(q_2, [v_{10},\ v_{01}]) - B(q_2, [h_{00010},\ h_{00001}]).$$

The same approach as for the degenerate flip and 1:2-resonance cases is to substitute the formal solution of the first equation into the second, and we write

$$v_{10} = -s_1 + \delta_1 s_2, \quad v_{01} = \delta_2 s_2,$$

where the constants δ_i are to be found from the last equation. We compute

$$Q_i = \langle p_2, A_1(q_2, s_i) + B(q_2, (I_n - A)^{-1} J_1 s_i)\rangle$$

for $i = 1, 2$. To obtain the derivative of the modulus and not the argument of the complex multiplier, we proceed as in [26, Appendix] but adapt to the case of maps. Then we find the following real solutions:

$$\delta_1 = \frac{\Re(e^{-i\theta_0}Q_1)}{\Re(e^{-i\theta_0}Q_2)}, \qquad \delta_2 = -\frac{1}{\Re(e^{-i\theta_0}Q_2)}. \tag{3.38}$$

4. Algorithmic and numerical details. In this section we consider the computation of the derivatives and tensor-vector products, which are necessary not only for the continuation, but also for the computation of the critical normal form coefficients at codim 1 and 2 bifurcation points.

4.1. Recursive formulas for derivatives of iterates of maps.

4.1.1. Derivatives with respect to phase variables. The iteration of (1.1) gives rise to a sequence of points

$$\{x^1, x^2, x^3, \dots, x^{K+1}\},$$

where $x^{J+1} = f^{(J)}(x^1, \alpha)$ for $J = 1, 2, \dots, K$. Suppose that symbolic derivatives of f up to order 5 can be computed at each point. We write

$$A(x^J)_{i,j} = \frac{\partial f_i}{\partial x_j}(x^J), \quad B(x^J)_{i,j,k} = \frac{\partial^2 f_i}{\partial x_j \partial x_k}(x^J), \quad C(x^J)_{i,j,k,l} = \frac{\partial^3 f_i}{\partial x_j \partial x_k \partial x_l}(x^J),$$

and similarly for $D(x^J)$ and $E(x^J)$.

We want to find recursive formulas for the derivatives of the composition (1.2), i.e., the coefficients of the multilinear functions in (2.2) that we now denote by $A^{(J)}, B^{(J)}$, and $C^{(J)}$ to indicate the iterate explicitly:

$$(A^{(J)})_{i,j} = \frac{\partial (f^{(J)}(x^1))_i}{\partial x_j}, \quad (B^{(J)})_{i,j,k} = \frac{\partial^2 (f^{(J)}(x^1))_i}{\partial x_j \partial x_k}, \quad (C^{(J)})_{i,j,k,l} = \frac{\partial^3 (f^{(J)}(x^1))_i}{\partial x_j \partial x_k \partial x_l},$$

and $D^{(J)}$ and $E^{(J)}$ are analogously defined. What follows is a straightforward application of the chain rule.

For $J = 1$ we have $A^{(1)} = A(x^1), B^{(1)} = B(x^1)$, and $C^{(1)} = C(x^1)$, and these are known. Now, as

$$A^{(J)}_{i,j} = \sum_k \frac{\partial f_i}{\partial x_k}(f^{(J-1)}(x^1)) \frac{\partial (f^{(J-1)}(x^1))_k}{\partial x_j} = \sum_l A(x^J)_{i,k} A^{(J-1)}_{k,j}, \tag{4.1}$$

we see that

$$(F(x,\alpha))_x = A(x^K)A(x^{K-1}) \cdots A(x^1) - I_n, \tag{4.2}$$

where $F(x, \alpha) = f^{(K)}(x, \alpha) - x$.

For the second-order derivatives we first write $B^{(J)}$ once in coordinates

$$\begin{aligned} B^{(J)}_{i,j,k} &= \frac{\partial}{\partial x_j}\frac{\partial}{\partial x_k} f_i(f^{(J-1)}(x)) \\ &= \sum_{l,m} \frac{\partial^2 f_i}{\partial x_l \partial x_m}(x^J) \frac{\partial (f^{(J-1)})_m}{\partial x_j} \frac{\partial (f^{(J-1)})_l}{\partial x_k} + \sum_l \frac{\partial f_i}{\partial x_l}(x^J) \frac{\partial^2 (f^{(J-1)})_l}{\partial x_j \partial x_k}. \end{aligned}$$

For any two vectors q_1 and q_2, we can multiply the previous expression by $(q_1)_j(q_2)_k$ and sum over (j,k) to obtain

$$B^{(J)}(q_1,q_2) = B(x^J)(A^{(J-1)}q_1, A^{(J-1)}q_2) + A(x^J)B^{(J-1)}(q_1,q_2). \tag{4.3}$$

As $A(x^J)$ and $B(x^J)$ are known, (4.3) allows us to compute the multilinear form $B^{(J)}(q_1,q_2)$ recursively.

Let $q_i,\ i = 1,2,3,4,5$, be given vectors. Multilinear forms with higher order derivatives can be computed with

$$\begin{aligned} C^{(J)}(q_1,q_2,q_3) &= C(x^J)(A^{(J-1)}q_1, A^{(J-1)}q_2, A^{(J-1)}q_3) \\ &\quad + B(x^J)(B^{(J-1)}(q_1,q_2), A^{(J-1)}q_3)^* \\ &\quad + A(x^J)(C^{(J-1)}(q_1,q_2,q_3)), \end{aligned} \tag{4.4}$$

where * means that all combinatorially different terms have to be included, i.e.,

$$\begin{aligned} B(x^J)(B^{(J-1)}(q_1,q_2), A^{(J-1)}q_3)^* &= B(x^J)(B^{(J-1)}(q_1,q_2), A^{(J-1)}q_3) \\ &\quad + B(x^J)(B^{(J-1)}(q_1,q_3), A^{(J-1)}q_2) \\ &\quad + B(x^J)(B^{(J-1)}(q_2,q_3), A^{(J-1)}q_1). \end{aligned}$$

For $D^{(J)}$ we get

$$\begin{aligned} D^{(J)}(q_1,q_2,q_3,q_4) &= D(x^J)(A^{(J-1)}q_1, A^{(J-1)}q_2, A^{(J-1)}q_3, A^{(J-1)}q_4) \\ &\quad + C(x^J)(B^{(J-1)}(q_1,q_2), A^{(J-1)}q_3, A^{(J-1)}q_4)^* \\ &\quad + B(x^J)(B^{(J-1)}(q_1,q_2), B^{(J-1)}(q_3,q_4))^* \\ &\quad + B(x^J)(C^{(J-1)}(q_1,q_2,q_3), A^{(J-1)}q_4)^* \\ &\quad + A(x^J)D^{(J-1)}(q_1,q_2,q_3,q_4). \end{aligned} \tag{4.5}$$

Finally, for $E^{(J)}$ the following holds:

$$\begin{aligned} E^{(J)}(q_1,q_2,q_3,q_4,q_5) &= E(x^J)(A^{(J-1)}q_1, A^{(J-1)}q_2, A^{(J-1)}q_3, A^{(J-1)}q_4, A^{(J-1)}q_5) \\ &\quad + D(x^J)(B^{(J-1)}(q_1,q_2), A^{(J-1)}q_3, A^{(J-1)}q_4, A^{(J-1)}q_5)^* \\ &\quad + C(x^J)(B^{(J-1)}(q_1,q_2), B^{(J-1)}(q_3,q_4), A^{(J-1)}q_5)^* \\ &\quad + C(x^J)(C^{(J-1)}(q_1,q_2,q_3), A^{(J-1)}q_4, A^{(J-1)}q_5)^* \\ &\quad + B(x^J)(C^{(J-1)}(q_1,q_2,q_3), B^{(J-1)}(q_4,q_5))^* \\ &\quad + B(x^J)(D^{(J-1)}(q_1,q_2,q_3,q_4))(A^{(J-1)}q_5)^* \\ &\quad + A(x^J)(E^{(J-1)}(q_1,q_2,q_3,q_4,q_5)). \end{aligned} \tag{4.6}$$

The multilinear forms $A^{(K)}(q_1)$, $B^{(K)}(q_1,q_2)$, $C^{(K)}(q_1,q_2,q_3)$, $D^{(K)}(q_1,q_2,q_3,q_4)$, and $E^{(K)}(q_1,q_2,q_3,q_4,q_5)$ are then used in the computations of the normal form coefficients for codim 1 and codim 2 bifurcations of period-K cycles and also in branch switching.

4.1.2. Derivatives with respect to parameters. If enough symbolic derivatives of f are available, then MATCONT computes the expressions involving J_1 and A_1 in (2.2) symbolically. The idea is as follows. Taking the derivative of (1.3) with respect to α_k gives

$$\frac{\partial(f^{(J)}(x^1,\alpha))}{\partial\alpha_k} = \frac{\partial f}{\partial\alpha_k}(x^J,\alpha) + \frac{\partial f}{\partial x}(x^J,\alpha)\frac{\partial(f^{(J-1)}(x^1,\alpha))}{\partial\alpha_k}, \tag{4.7}$$

which is recursively computable. Also mixed derivatives, which are necessary for continuation and branch switching, can be found recursively:

$$\frac{\partial^2(f^{(J)}(x^1,\alpha))}{\partial\alpha_k\partial x} = \frac{\partial^2 f}{\partial\alpha_k\partial x}(x^J,\alpha) + \frac{\partial^2 f}{\partial x^2}(x^J,\alpha)\frac{\partial(f^{(J-1)}(x^1,\alpha))}{\partial\alpha_k}. \tag{4.8}$$

In fact, the recursion is not applied to (4.8) itself, but to its product with a fixed vector.

This is sufficient for all continuations of fixed points and their codim 1 bifurcations. It is also sufficient for all cases of branch switching from codim 2 points, except for the case of degenerate flip. For this case, we fall back to a finite difference approximation. Since it is used only in the prediction step for which high accuracy is not needed, this seems acceptable.

4.2. Recursive formulas for derivatives of the defining systems for continuation. For the continuation of fixed points and cycles we need the derivatives of (1.3), which can be computed from (4.2) and (4.7).

Now, we consider the derivatives of s (as defined in (2.4)) with respect to z, a state variable or parameter. The flip and NS cases can be handled in a similar way. Let M be the matrix in (2.5). By taking derivatives of (2.5) with respect to z, we obtain

$$M\begin{bmatrix} v_z \\ s_z \end{bmatrix} + \begin{bmatrix} A_z^{(K)} & 0 \\ 0 & 0 \end{bmatrix}\begin{bmatrix} v \\ s \end{bmatrix} = 0. \tag{4.9}$$

Using (2.7), we obtain

$$s_z = -w^T(A^{(K)})_z v. \tag{4.10}$$

If z represents one of the state variables, then $s_{x_i} = -\langle w, B^{(K)}(e_i, v)\rangle$, as computed in section 4.1. When z is a parameter α_k we can write

$$s_{\alpha_k} = \sum_{J=1}^{K} C_J, \tag{4.11}$$

where

$$C_J = -w^T f_x(x^K)\ \cdots\ (f_x(x^J))_{\alpha_k} f_x(x^{J-1})\ \cdots\ f_x(x^1)v, \tag{4.12}$$

where $J = 1,\dots,K$. In this expression

$$(f_x(x^J))_{\alpha_k} = [f_x(f^{(J)}(x^1,\alpha))]_{\alpha_k} = f_{x\alpha}(x^J,\alpha) + B(x^J)T_J, \tag{4.13}$$

where T_J is a vector that can be recursively defined by

$$T_J = f_{\alpha_k}(x^{J-1},\alpha) + A(x^{J-1})T_{J-1}, \quad T_1 = 0. \tag{4.14}$$

Summarizing, for the computation of s_α we need to compute $f_x, f_{\alpha_k}, f_{xx}, f_{x\alpha_k}$ in all iteration points $x^1,\dots,x^K$, and given these, compute T_J and C_J for $J = 1,\dots,K$.

4.3. Numerical computation of the directional derivatives. If symbolic derivatives of the original map are not available, then finite differences have to be used. However, the full tensors are not needed, but rather the multilinear forms evaluated on vectors, which can be computed with directional derivatives and central finite differences. This is an option of last resort and is not reliable for very high iterates. For a general discussion of directional derivatives, we refer to [18]. Similar to the analysis in [14, Appendix D], it can be shown that to compute a derivative of order k the choice $h_k = (\epsilon_m)^{1/(k+2)}$ for the stepsize minimizes the truncation and roundoff error under modest assumptions. Here ϵ_m denotes machine precision. In CL_MATCONTM, the *Increment* ($= h_1$) can be adjusted by the user. The increments of the higher order derivatives are then adapted according to $h_k = (h_1)^{3/(k+2)}$.

5. Examples. Here we give two examples illustrating the developed techniques and their implementation in CL_MATCONTM.

5.1. Generalized Hénon map. Consider the map

$$F : \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \mapsto \begin{pmatrix} x_2 \\ \alpha - \beta x_1 - x_2^2 + r x_1 x_2 \end{pmatrix}, \tag{5.1}$$

where r is in principle not too large. This map appears in numerous theoretical studies of degenerate homoclinic bifurcations. A bifurcation analysis of this map can be found in [23] for $r = 0$ and in [11] for general r. This map exhibits all planar codim 2 bifurcations with branch switching as in section 3.2. Let us start with the 1:2 resonance and the fold-flip. For these cases we can apply the algorithms analytically, i.e., with r as a parameter. We note that $q = (1, -1)^T$ in both cases is an eigenvector of the Jacobian matrix corresponding to eigenvalue -1.

For the 1:2 resonance we have the critical values $x_1 = x_2 = \frac{\beta-1}{r}$ and $(\alpha_0, \beta_0) = (\frac{4(3-r)}{(2-r)^2}, \frac{2+r}{2-r})$. For the coefficients of (3.6) the critical center manifold reduction yields (see [11])

$$C_1 = -\frac{1+r}{2}, \quad D_1 = \frac{1}{4}(6 + 5r + r^2). \tag{5.2}$$

Applying the algorithm from section 3.2.3, we find the prediction for the NS bifurcation curve of the period-2 cycle:

$$(x, y) = \left(\frac{2}{2-r}, \frac{2}{2-r}\right) + \sqrt{\frac{2\varepsilon}{1+r}}\, q,$$

$$(\alpha, \beta) = \left(\frac{4(3-r)}{(2-r)^2}, \frac{2+r}{2-r}\right) + \left(\frac{2(4+3r^2-r^3)}{(1+r)(2-r)^2}, \frac{2r^2}{(1+r)(2-r)}\right)\varepsilon.$$

The fold-flip bifurcation occurs for $(x_1, x_2) = (0, 0)$ at $(\alpha_0, \beta_0) = (0, -1)$. The critical center manifold reduction yields

$$a = \frac{1}{2}(1-r), \quad b = \frac{1}{2}(1+r), \quad c_2 = -\frac{1}{4}(1-r), \quad c_4 = \frac{1}{4}(1+r)^2. \tag{5.3}$$

Then applying the algorithm from section 3.2.6, we find the prediction for the NS bifurcation curve of the period-2 cycle emanating here:

$$(x, y) = (0, 0) + \sqrt{\frac{2\varepsilon}{1+r}}\, q, \qquad (\alpha, \beta) = (0, -1) + \left(2, \frac{-2r^2}{(1+r)(2-r)}\right)\varepsilon.$$

Let us compare the predictions with the exact expressions for these curves. Consider the following set:

$$\alpha = \frac{(1+\beta)(\beta - 1 - r + r^2)}{r^2}, \tag{5.4}$$

$$x_{1,2} = \frac{r(\beta+1) \pm \sqrt{(r-2)(\beta+1)(2+r-\beta(2-r))}}{2r}, \tag{5.5}$$

when

$$\frac{1}{4}(3-r)(\beta+1)^2 \le \alpha \le \frac{5+4r+r^2+2\beta(3+r)+\beta^2(5+2r-r^2)}{2(2+2r+r^2)}.$$

It consists of two different pieces, where an NS bifurcation of a cycle of period 2 occurs. If we take $0 \le \varepsilon \ll 1$ and consider the linear approximations of (5.4) near $\beta = -1 - \frac{r^2}{2-r}\tilde{\varepsilon}$ and $\beta = (\frac{2+r}{2-r}) + \frac{r^2}{2-r}\tilde{\varepsilon}$, we find for the 1:2 resonance

$$(\alpha,\beta) = \left(\frac{4(3-r)}{(2-r)^2}, \frac{2+r}{2-r}\right) + \left(\frac{4+3r^2-r^3}{(2-r)^2}, \frac{r^2}{2-r}\right)\tilde{\varepsilon} + \mathcal{O}(\tilde{\varepsilon}^2),$$

$$(x,y) = \left(\frac{2}{2-r}, \frac{2}{2-r}\right) + \sqrt{\tilde{\varepsilon}}q + \mathcal{O}(\tilde{\varepsilon}),$$

and for the fold-flip bifurcation

$$(\alpha,\beta) = (0,-1) + \left(1+r, \frac{-r^2}{2-r}\right)\tilde{\varepsilon} + \mathcal{O}(\tilde{\varepsilon}^2),$$

$$(x,y) = (0,0) - \sqrt{\tilde{\varepsilon}}q + \mathcal{O}(\tilde{\varepsilon}).$$

So up to a positive factor our results coincide up to first order in ε.

For the other three cases a numerical approach is more illuminating. We now fix $r = -0.1$ and show in Figure 5.1(a) a (partial) bifurcation diagram in the parameters α, β computed with CL_MATCONTM. We pay closer attention to three specific regions, where we can switch branches: a spring area near $(\alpha,\beta) = (3,-1)$ with fold and PD curves with degeneracies, and two domains close to strong resonances near $\beta = 1$. In the parameter space our predictions are linear, and for small initial amplitude the initialization routines worked well.

In Figure 5.1(b), there is a PD curve of period-4 cycles along which there are two degenerate flips near $(\alpha,\beta) = (3,-1)$, where we found a fold curve and a PD curve of cycles of period 4. Then we produced the approximations to the fold curves of the eighth iterates in the degenerate flip points and from these easily continued the fold curves of cycles of period 8. The bifurcation structure of Figure 5.1(b) is rather universal; see [6]. In Figure 5.1(c) we show a neighborhood of the 1:3 resonance. For $r = -0.1$ the 1:4 resonance involves all of the mentioned local branches (see Figure 5.1(d)). In all subfigures we show the continuation results and also the approximate curves.

5.2. Leslie–Gower competition model. The origin of this example is in [21, 22, 10]. It has been found in biological experiments that two species of flour beetles can coexist under strong competition for the same food. This was rather unexpected at the time, and several models were built to explain this phenomenon. One of the

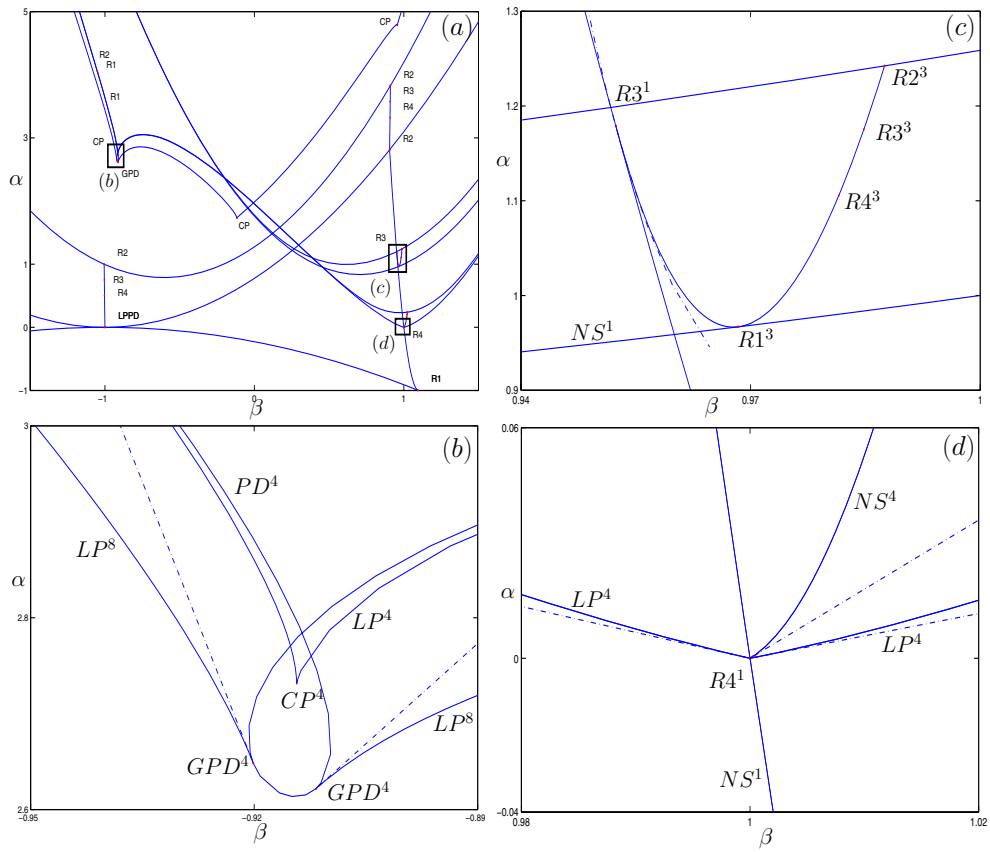

FIG. 5.1. *Bifurcation diagram for the generalized Hénon map* (a). *The close-ups near a spring area of period* 4 (b), 1:3 *resonance of period* 1 (c), 1:4 *resonance of period* 1 (d). *The solid lines are computed with* CL_MATCONTM*; the dashed lines are the predictions from the switching algorithms.*

ideas proposed in [10] and [25] was to use an age-structured population model. We consider the four-dimensional map model with 14 parameters in [25]:

$$M_{LG}: \begin{pmatrix} j \\ a \\ y \\ z \end{pmatrix} \mapsto \begin{pmatrix} j' \\ a' \\ y' \\ z' \end{pmatrix} = \begin{pmatrix} \dfrac{b_1 a}{(1 + c_{jj} j + c_{ja} a + c_{jy} y + c_{jz} z)} \\ (1-\mu_j) j + (1-\mu_a) a \\ \dfrac{b_2 z}{(1 + c_{yj} j + c_{ya} a + c_{yy} y + c_{yz} z)} \\ (1-\mu_y) y + (1-\mu_z) z \end{pmatrix}. \tag{5.6}$$

This is the Leslie–Gower competition model for the interaction between the juveniles (j) and adults (a) of one species of the flour beetle *Tribolium* and the juveniles (y) and adults (z) of another species. Each species has its own juvenile recruitment rate $b_1 > 0$, $b_2 > 0$, juvenile death rates μ_j and μ_y, and adult death rates μ_a and μ_z. For biological reasons we have $0 < \mu_j, \mu_a, \mu_y, \mu_z < 1$.

The other coefficients $c_{jj}, c_{ja}, c_{jy}, c_{jz}$ and $c_{yj}, c_{ya}, c_{yy}, c_{yz}$ describe the competition. They are all strictly positive. By assumption, the competition does not affect the adults of either species. As in [25], we will study the influence of the coefficients

TABLE 5.1
Parameter values for the Leslie–Gower model.

$b_1 = 20$	$c_{jj} = 0.36$	$b_2 = 18$	$c_{ja} = 0.55$	$c_{jz} = 0.23$	$\mu_j = 0.23$
$\mu_a = 0.72$	$c_{ya} = 0.08$	$c_{yy} = 0.18$	$c_{yz} = 0.26$	$\mu_y = 0.29$	$\mu_z = 0.98$

c_{yj} and c_{jy} on the behavior of M_{LG} in a case where all other parameters are fixed. In other words, we study the role of the competition between juveniles alone.

The origin $(0, 0, 0, 0)$ is a fixed point of (5.6) but is of little interest. The model also has "horizontal" fixed points of the form $(j^*, a^*, 0, 0)$, where $j^*, a^* > 0$ (i.e., biologically meaningful) when $b_1(1 - \mu_j) > \mu_a$. Similarly, there are unique "vertical" fixed points of the form $(0, 0, y^*, z^*)$. These are biologically meaningful if $y^*, z^* > 0$, i.e., when $b_2(1 - \mu_y) > \mu_z$.

Furthermore there exists a unique coexistence fixed point (j^*, a^*, y^*, z^*), provided

$$H \equiv \delta\gamma - \epsilon\eta \neq 0, \tag{5.7}$$

where

$$\alpha = \frac{1 - \mu_j}{\mu_a}, \qquad \beta = \frac{1 - \mu_y}{\mu_z},$$

$\epsilon = c_{jj} + c_{ja}\alpha$, $\gamma = c_{jy} + c_{jz}\beta$, $\delta = c_{yj} + c_{ya}\alpha$, and $\eta = c_{yy} + c_{yz}\beta$. The equation $H = 0$ defines a hyperbola in (c_{yj}, c_{jy}) space. We will study the overall dynamics of the model for the parameter values specified in Table 5.1. The parameters c_{jy} and c_{yj} will vary. First we consider the horizontal and the vertical fixed points and their stability. For the given model parameters, the horizontal fixed point is stable if $c_{yj} > c_{yj0}$, where $c_{yj0} = 0.474477674$. It is biologically plausible that the horizontal fixed point is stable only if the juveniles of the first species suppress the juveniles of the second species to a sufficient degree. The vertical fixed point is stable if $c_{jy} > c_{jy0}$, where $c_{jy0} = 0.4571312026$.

Now we consider the coexistence fixed point (j^*, a^*, y^*, z^*), starting the continuation from the point where $c_{yj} = c_{jy} = 0$. This fixed point bifurcates into vertical and horizontal fixed points, respectively, when one of c_{jy} and c_{yj} is varied and the other variable is fixed at 0. In the model this means that one species drives another to extinction. Continuation of the coexistence fixed point, where c_{jy} is the free parameter, leads to BP and PD bifurcations at $c_{jy} = c_{yj0}$ and $c_{jy} = 0.170849$, respectively. The coexistence fixed point is stable before the BP and unstable afterwards. If we continue the coexistence fixed points with the free parameter c_{yj}, the points bifurcate into the horizontal fixed point at another BP. The coexistence fixed point is stable before this BP and unstable afterwards.

The solutions to the equation $H = 0$, where H is given by (5.7), are the parameter values for which the existence and uniqueness of the coexistence fixed point is not guaranteed. In the present context, where only c_{yj} and c_{jy} vary, this leads to the condition

$$c_{yj}c_{jy} + ac_{yj} + bc_{jy} - c = 0, \tag{5.8}$$

where $a = 0.1666326531$, $b = 0.0855555552$, and $c = 0.3350275226$, which indeed defines a hyperbola in (c_{yj}, c_{jy}) space. It is not hard to prove that the point (c_{yj0}, c_{jy0}) lies on the hyperbola.

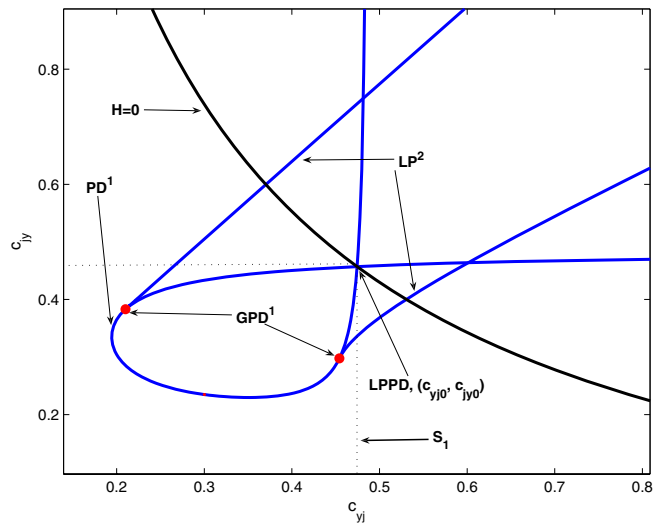

FIG. 5.2. *The flip curve PD^1, the fold curve of the second iterate LP^2, hyperbola $H = 0$, and the rectangle S_1 in the (c_{yj}, c_{jy})-plane.*

Now we return to the stability of the coexistence fixed points. The coexistence fixed point is unstable outside the rectangle

$$S_1 = \{(c_{yj}, c_{jy}) : 0 \le c_{yj} \le c_{yj0}, \quad 0 \le c_{jy} \le c_{jy0}\}.$$

Figure 5.2 shows the hyperbola $H = 0$ and the rectangle S_1.

By numerical continuation we find that there is an interior region inside of S_1 in which the coexistence fixed points are unstable. This region is bounded by the PD curve, where the stability changes. The projection of the PD curve on the (c_{yj}, c_{jy})-plane goes twice through the point (c_{yj0}, c_{jy0}). Indeed, the PD curve has two fold-flip points, where $(c_{yj}, c_{jy}) = (c_{yj0}, c_{jy0})$. Moreover, there are two degenerate PD points `GPD` on the PD curve: $(c_{yj}, c_{jy}) = (0.210138, 0.383143)$ and $(c_{yj}, c_{jy}) = (0.454279, 0.297779)$. The branches of fold curves of the second iterate can be computed by switching at the `GPD` points. These curves emanate tangentially to the PD curve.

The region where there are stable fixed points of the second iterate is bounded by the two fold curves of the second iterate and the lower left part of the PD curve. From the applications point of view, this is the most interesting region because it shows that indeed the two species can coexist even when the competition is strong. If both c_{yj} and c_{jy} are larger than 0.5, then the horizontal fixed points, the vertical fixed points, and the fixed points of the second iterate are all stable. The PD curve and the fold curves of the second iterate are given in Figure 5.2.

6. Conclusions. We have described the implementation of continuation and normal form analysis of fixed points and cycles in MATCONT. Codim 1 bifurcation analysis is standard by now, while the analysis of codim 2 bifurcations, both quantitative and qualitative, on which this paper focuses, is new. Our implementation uses all aspects of the center-manifold reduction. First, the critical normal form coefficients are calculated automatically, which determines the type of the unfolding. Second,

when nondegeneracy and transversality are checked, predictions about new codim 1 branches are made.

We use the iterates of maps to continue cycles. When dealing with strongly expanding/contracting systems and small basins of attraction, a BVP-like approach using extended systems for the fixed point, i.e., $f(x^1) - x^2 = 0, \ldots, f(x^n) - x^1 = 0$, might be more efficient.

Version 2.1 of CL_MATCONTM for maps uses automatic differentiation as an alternative to symbolic derivatives. One reason is that symbolic derivatives may not always be available. The second is that the computation of normal form coefficients for high iterates is faster when automatic differentiation is used.

Finally, we mention that we did not discuss global bifurcations. As a first step, it is well worth the effort to incorporate into our package some of the existing algorithms to compute (un)stable manifolds, e.g., [16]. If a transverse intersection is present, then using the defining systems as in [4], approximations of homoclinic orbits and their tangencies may be computed.

STRUCTURED QUADRATIC INVERSE EIGENVALUE PROBLEM, I. SERIALLY LINKED SYSTEMS*

MOODY T. CHU†, NICOLETTA DEL BUONO‡, AND BO YU§

Abstract. Quadratic pencils arising from applications are often inherently structured. Factors contributing to the structure include the connectivity of elements within the underlying physical system and the mandatory nonnegativity of physical parameters. For physical feasibility, structural constraints must be respected. Consequently, they impose additional challenges on the inverse eigenvalue problems which intend to construct a structured quadratic pencil from prescribed eigeninformation. Knowledge of whether a structured quadratic inverse eigenvalue problem is solvable is interesting in both theory and applications. However, the issue of solvability is problem dependent and has to be addressed structure by structure. This paper considers one particular structure where the elements of the physical system, if modeled as a mass-spring system, are serially linked. The discussion recasts both undamped and damped problems in a framework of inequality systems that can be adapted for numerical computation. Some open questions are described.

Key words. quadratic pencil, inverse eigenvalue problem, linear oscillator, inner-connectivity, nonnegativity, linear system of inequalities

1. Introduction.

The time-invariant second order differential system

$$M\ddot{\mathbf{x}} + C\dot{\mathbf{x}} + K\mathbf{x} = f(t), \tag{1.1}$$

where $\mathbf{x} \in \mathbb{R}^n$ and M, C, $K \in \mathbb{R}^{n\times n}$, arises in many important applications, including applied mechanics, electrical oscillation, vibro-acoustics, fluid mechanics, signal processing, and finite element discretization of PDEs. In most cases, parameters characterizing the underlying physical system are embedded in the matrix coefficients M, C, and K. It is well known that if

$$\mathbf{x}(t) = \mathbf{v}e^{\lambda t}$$

represents a fundamental solution to (1.1), then the scalar λ and the vector $\mathbf{v}$ must solve the *quadratic eigenvalue problem* (QEP)

$$(\lambda^2 M + \lambda C + K)\mathbf{v} = 0. \tag{1.2}$$

That is, the dynamical bearing of the differential system (1.1) usually can be interpreted via the eigenvalues and eigenvectors of the algebraic system (1.2). Because of this connection, considerable efforts have been devoted to the QEP in the literature. Readers are referred to the treatise by Tisseur and Meerbergen [28] for a good survey

of many applications, mathematical properties, and a variety of numerical techniques for the QEP.

The eigenvalue problem associated with the model (1.1) can be considered from two different viewpoints. From a priori known physical parameters such as mass, length, elasticity, inductance, capacitance, and so on, the process of analyzing and deriving the spectral information so as to induce the dynamical behavior of a system is referred to as a *direct* problem. The *inverse* problem, in contrast, is to validate, determine, or estimate the parameters of the system according to its observed or expected behavior. The concern in the direct problem is to express the behavior in terms of the parameters, whereas in the inverse problem the concern is to express the parameters in terms of the behavior. Both problems are important in applications. This paper concerns the inverse problem.

The inverse eigenvalue problem is a diverse area full of research interests and activities. See the newly revised book by Gladwell [20] for mechanics applications, the review article [7] for linear problems, the recently completed monograph by Chu and Golub [8] for general theory, algorithms, and applications, and the many references collected therein from various disciplines. Among current developments, the quadratic inverse eigenvalue problem (QIEP) is particularly more important and challenging, with many unanswered questions [5, 9, 13]. This paper concentrates only on the issue of solvability for one specially structured QIEP.

We have to stress that depending on the applications, the term QIEP has been used in the literature to mean a rather wide variety of formulations. For instance, the QIEP studied by Ram and Elhay in [25] involves only symmetric tridiagonal matrix coefficients where *two* sets of eigenvalues are given. The QIEP studied by Starek and Inman in [27] is associated with nonproportional underdamped systems. Lancaster and Prells [23] considered the QIEP with symmetric and positive semidefinite damping C where *complete* information on eigenvalues and eigenvectors is given and all eigenvalues are simple and nonreal. There are also works which utilize notions of feedback control to reassign the eigenstructure [11, 12, 24]. The list goes on and can hardly be exhaustive. The QIEP considered in this article deals with yet another scenario which is quite common in practice—construct the quadratic pencil with only *a few* eigenvalues and their corresponding eigenvectors.

In vibration industries, including aerospace, automobile, and manufacturing, through vibration tests where the excitation and the response of the structure at selected points are measured experimentally, there are identification techniques to extract a portion of eigenpair information from the measurements. However, the size of the physical system can be so large and complicated that it is not always possible to attain knowledge of the entire spectrum. While there is no reasonable analytical tool available to evaluate all of the spectral information, it is simply unwise to use experimental values of high natural frequencies to reconstruct a model. Additionally, it is often demanded, especially in structural design, that certain eigenvectors should also satisfy some specific conditions [3, 30]. A finite element generated model therefore needs to be updated using only a few measured eigenvalues and eigenvectors [1, 14, 17, 18, 21]. Furthermore, quantities related to high frequency terms in a *finite model* generally are susceptible to measurement errors due to the finite bandwidth of measuring devices. Spectral information, therefore, should not be used at its full extent. For these reasons, it might be more sensible to consider an inverse eigenvalue problem where only a *portion* of eigenvalues and eigenvectors is available. The QIEP that is of interest to us therefore can be formulated as follows:

QIEP. Construct a nontrivial quadratic pencil $Q(\lambda) = \lambda^2 M + \lambda C + K$ so that its matrix coefficients (M, C, K) are of a specified structure and $Q(\lambda)$ has a specified set $\{(\lambda_i, \mathbf{v}_i)\}_{i=1}^k$ as its eigenpairs.

Since we are interested only in real matrices, it is natural to expect that the prescribed eigenpairs are closed under complex-conjugation. Without loss of generality, we shall denote the prescribed eigenpairs in the matrix form (Λ, X), where $\Lambda \in \mathbb{R}^{k\times k}$ is block diagonal with at most 2×2 blocks along the diagonal wherever a complex-conjugate pair of eigenvalues appears in the prescribed spectrum, and $X \in \mathbb{R}^{n\times k}$ represents the "eigenvector matrix" in the sense that each pair of column vectors associated with a 2×2 block in Λ retains the real and the imaginary parts, respectively, of the original complex eigenvector. In this way, we may identify the given eigenpairs (Λ, X) as an element in $\mathbb{R}^k \times \mathbb{R}^{n\times k}$. The QIEP therefore amounts to solving the algebraic equation

$$MX\Lambda^2 + CX\Lambda + KX = 0. \tag{1.3}$$

At first glance, the relationship (1.3) is only a homogeneous linear system of nk algebraic equations. If there are no other constraints, the triplet (M, C, K) constitutes $3n^2$ unknowns. Since k is bounded above by $2n$, the system is well under-determined. It is intuitively true that the system should be solvable in general. The real challenge is to characterize the solution in terms of the given (Λ, X), when the matrix coefficients in the pencil are required to satisfy some structural constraints.

The particular constraints that will be studied in this paper are twofold—the connectivity constraint inherent to the serially linked physical structure and the nonnegative constraint required by the physical parameters. Despite the fact that some general results have been obtained for the QIEPs [22, 23, 25], we have not seen the above-mentioned constraints being taken into account. Our contribution is innovative in that the structured QIEP is cast as a system of inequalities whose solvability can then be checked numerically.

2. Issue of connectivity. An inverse eigenvalue problem without a structure is often trivial and meaningless [8]. This is particularly true for QIEPs arising from applications. The structure imposed on a QIEP depends inherently on the *connectivity* of the underlying physical system. For practical reasons, the physical feasibility must be respected. It is therefore necessary that the reconstructed pencil in the inverse problem satisfies the inherent connectivity structure. In other words, there is more to just solving the algebraic equation (1.3) for a QIEP. The matrices in the solution (M, C, K) must carry a certain specified structure. We give two examples to illustrate how the connectivity affects the structure.

Example 1. Assuming that the springs respond according to Hook's law and that the damping is negatively proportional to the velocity, the coefficient matrices corresponding to the four-degree-of-freedom mass-spring system depicted in Figure 2.1 should be structured as follows:

$$M = \begin{bmatrix} m_1 & 0 & 0 & 0 \\ 0 & m_2 & 0 & 0 \\ 0 & 0 & m_3 & 0 \\ 0 & 0 & 0 & m_4 \end{bmatrix}, \; C = \begin{bmatrix} c_1 + c_2 & 0 & -c_2 & 0 \\ 0 & 0 & 0 & 0 \\ -c_2 & 0 & c_2 + c_3 & -c_3 \\ 0 & 0 & -c_3 & c_3 \end{bmatrix},$$

$$K = \begin{bmatrix} k_1 + k_2 + k_3 & -k_2 & -k_5 & 0 \\ -k_2 & k_2 + k_3 & -k_3 & 0 \\ -k_5 & -k_3 & k_3 + k_4 + k_5 & -k_4 \\ 0 & 0 & -k_4 & k_4 \end{bmatrix}.$$

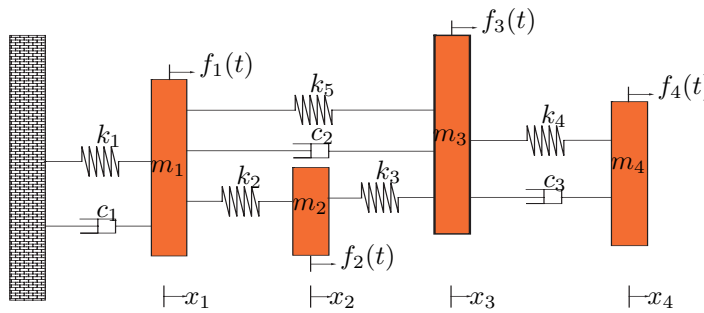

FIG. 2.1. *A four-degree-of-freedom mass-spring system.*

A typical way in the literature to describe the structure of a general mass-spring system is that the mass matrix M is diagonal, both the damping matrix C and the stiffness matrix K are symmetric and banded, M is positive definite, and K is positive semidefinite. But now we see that such a characterization indeed is not fine enough for physical feasibility. One must be specific in that the internal connectivity of the masses and springs defines how the diagonal entries of C and K are related to their off-diagonal entries. A different configuration of the connectivity in the system will lead to a different structure. It is extremely important to point out an additional inherent constraint; that is, all physical parameters are expected to be nonnegative.

Example 2. Assuming Ohm's law and Kirchoff's law in the circuit, the matrix coefficients for the governing equation of the current in the RLC network depicted in Figure 2.2 should have the following structure:

$$M = \begin{bmatrix} -L_2 & L_2 & 0 & 0 \\ L_2 & -L_2 & 0 & 0 \\ 0 & 0 & L_3 & 0 \\ 0 & 0 & 0 & L_4 \end{bmatrix}, \; C = \begin{bmatrix} 0 & R_2 & -R_2 & 0 \\ R_1 + R_4 & 0 & 0 & -R_4 \\ 0 & -R_2 & R_2 + R_3 & 0 \\ -R_4 & 0 & 0 & R_4 \end{bmatrix},$$

$$K = \begin{bmatrix} 0 & \frac{1}{C_2} & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{1}{C_3} & -\frac{1}{C_3} \\ 0 & 0 & -\frac{1}{C_3} & \frac{1}{C_3} + \frac{1}{C_4} \end{bmatrix}.$$

In contrast to the structure associated with a mass-spring system, note that the structure associated with an electronic circuit generally may not be definite or even symmetric.

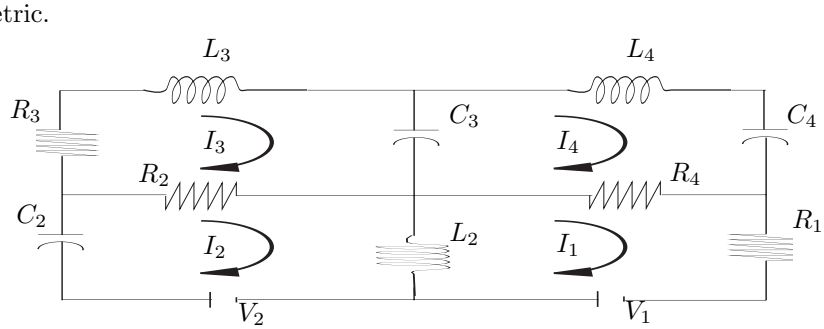

FIG. 2.2. *An RLC electronic network.*

Since structured problems often result in special interrelationships within their eigenstructures, the observed measurement which in many cases is contaminated with random noise may not be consistent with that innate structure. The structural constraint therefore severely limits whether a QIEP is solvable. It would be desirable to have a general theory by which one can obtain an affirmative answer on whether a specifically configured system could be built or not and, if yes, how the parameters should be valued. To our knowledge, such a theory does not exist. Most of the current QIEP techniques consider only the algebraic solvability, that is, solving the QIEP without taking into account the nonnegativity of the solution. The main thrust of this paper is to discuss the (physical) solvability of one particular structure. This is only one step forward with the hope of stimulating further studies toward solving the general structured QIEPs.

3. Symmetric structure. One of the simplest structural constraints in many applications is symmetry. If all matrix coefficients involved in a pencil are symmetric, we say that we have a *self-adjoint* pencil. The theory of solvability for self-adjoint QIEPs has been established recently by Chu et al. in [6]. To make this note more self-contained, it might be informative to summarize some of the results in this section without repeating the details. Define

$$k_{max} = \begin{cases} 3\ell + 1 & \text{if } n = 2\ell, \\ 3\ell + 2 & \text{if } n = 2\ell + 1. \end{cases} \tag{3.1}$$

The following theorem characterizes the general solvability [6].

THEOREM 3.1. *Given any positive integer $k \le k_{max}$, let (Λ, X) represent k arbitrarily prescribed eigenpairs which are closed under complex-conjugation. Then the following hold:*

1. *The self-adjoint QIEP associated with (Λ, X) is always solvable.*
2. *For almost all k prescribed eigenpairs (Λ, X), the solutions to the corresponding self-adjoint QIEP form a subspace of dimensionality $\frac{3n(n+1)}{2} - nk$.*

Elaborating a little further upon the solvability indicated in the above theorem might provide some additional insight. In the event that $k \ge n$, partition the eigenvalues and eigenvectors as

$$\Lambda = \text{diag}\{\Upsilon_1, \Upsilon_2\},$$

$$X = [Z_1, Z_2],$$

with $Z_1 \in \mathbb{R}^{n\times n}$, $Z_2 \in \mathbb{R}^{n\times(k-n)}$, $\Upsilon_1 \in \mathbb{R}^{n\times n}$, and $\Upsilon_2 \in \mathbb{R}^{(k-n)\times(k-n)}$, respectively. Define

$$\Xi := Z_1^{-1} Z_2. \tag{3.2}$$

Then there exists a nontrivial self-adjoint quadratic pencil $Q(\lambda)$ with partial eigenstructure (Λ, X) if and only if the system of matrix equations [8]

$$\begin{cases} \Upsilon_1^\top B - B\Upsilon_1 &= A\Upsilon_1^2 - \Upsilon_1^{2\top} A, \\ \Upsilon_1^\top B\Xi - B\Xi\Upsilon_2 &= A\Xi\Upsilon_2^2 - \Upsilon_1^{2\top} A\Xi, \\ A &= A^\top, \\ B &= B^\top \end{cases} \tag{3.3}$$

has a nontrivial solution (A, B) in $\mathbb{R}^{n\times n} \times \mathbb{R}^{n\times n}$. In that case, the solution to the QIEP is given by

$$\begin{aligned} M &= Z_1^{-\top} A Z_1^{-1}, \\ C &= Z_1^{-\top} B Z_1^{-1}, \\ K &= Z_1^{-\top}(-\Upsilon_1^{\top} B - \Upsilon_1^{2\top} A) Z_1^{-1}. \end{aligned}$$

To better grasp the linear system (3.3), let $\mathbf{vec}(A)$ represent the matrix A by stacking the columns of A into one long vector. Let $\mathcal{K} \in \mathbb{R}^{\frac{n(n-1)}{2}\times n^2}$ denote the matrix representation of the projection of a square matrix onto the subspace of skew-symmetric matrices. Then (3.3) can be expressed as

$$\underbrace{\begin{bmatrix} \Upsilon_1^{2\top} \otimes I_n - I_n \otimes \Upsilon_1^{2\top} & \Upsilon_1^{\top} \otimes I_n - I_n \otimes \Upsilon_1^{\top} \\ (\Xi\Upsilon_2^2)^{\top} \otimes I_n - \Xi^{\top} \otimes \Upsilon_1^{2\top} & (\Xi\Upsilon_2)^{\top} \otimes I_n - \Xi^{\top} \otimes \Upsilon_1^{\top} \\ \mathcal{K} & O_{\frac{n(n-1)}{2}\times n^2} \\ O_{\frac{n(n-1)}{2}\times n^2} & \mathcal{K} \end{bmatrix}}_{\mathcal{T}} \begin{bmatrix} \mathbf{vec}(A) \\ \mathbf{vec}(B) \end{bmatrix} = 0. \tag{3.4}$$

In other words, in order to have nontrivial solution (A, B) for (3.3), the prescribed eigenpairs (Λ, X) must be such that the $n(n + k - 1) \times 2n^2$ coefficient matrix $\mathcal{T}$ has column rank less than $2n^2$.

COROLLARY 3.2. *Given $k \geq n$ arbitrarily prescribed eigenpairs (Λ, X) which are closed under complex-conjugation, define the matrix $\mathcal{T}$ as in* (3.4).

1. *If $n \leq k \leq k_{max}$, then the null space of $\mathcal{T}$ has dimensionality at least $\frac{3n(n+1)}{2} - nk$ and is generically of that dimensionality.*
2. *If $k > k_{max}$, then the matrix $\mathcal{T}$ is generically of full column rank. The collection of (Λ, X) for which* (1.3) *has a nontrivial self-adjoint solution has measure zero in the space $\mathbb{R}^n \times \mathbb{R}^{n\times k}$.*

In the event that $k < n$, we still can solve the QIEP by embedding this eigeninformation in a larger set of n eigenpairs. In particular, we expand $X \in \mathbb{R}^{n\times k}$ to

$$\widehat{X} := [X, \widetilde{X}] \in \mathbb{R}^{n\times n}, \tag{3.5}$$

where $\widetilde{X} \in \mathbb{R}^{n\times(n-k)}$ is arbitrary while making $\hat{X}$ nonsingular and expand $\Lambda \in \mathbb{R}^{k\times k}$ to

$$\widehat{\Lambda} := \operatorname{diag}\{\Lambda, \widetilde{\Lambda}\}, \tag{3.6}$$

where $\widehat{\Lambda}$ is a diagonal matrix with distinct eigenvalues. Taking into account the freedom of this expansion, it is not difficult to prove that the solutions to the QIEP with $k < n$ form a subspace of dimensionality $\frac{n(n+3)}{2} + n(n - k)$.

Example 3. Suppose n distinct eigenvalues Λ and n linearly independent eigenvectors X, both of which are closed under conjugation, are given. Let $A \in \mathbb{R}^{n\times n}$ be an *arbitrary* symmetric matrix. The system (3.3) is reduced to the equation

$$\Lambda^{\top} B - B\Lambda = A\Lambda^2 - \Lambda^{2\top} A \tag{3.7}$$

for the unknown symmetric matrix B. From the block diagonal structure of Λ, it follows that B is determined up to n free parameters. Using A and B as parameters,

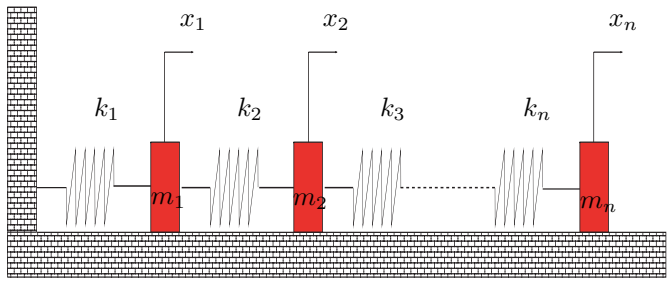

FIG. 4.1. *An undamped mass-spring system.*

the general solution to the self-adjoint QIEP with the prescribed pair (X, Λ) as part of its eigenstructure is given by

$$M = X^{-\top} A X^{-1}, \tag{3.8}$$

$$C = X^{-\top} B X^{-1}, \tag{3.9}$$

$$K = -X^{-\top} \Lambda^{\top} (B + \Lambda^{\top} A) X^{-1}. \tag{3.10}$$

In all cases, so long as the self-adjoint QIEP is solvable, we do have a way to obtain a parametric representation of the solution (M, C, K) of (1.3). Despite the fact that we know how to solve a self-adjoint QIEP algebraically, it must be stressed that algebraic solvability does not necessarily imply physical feasibility. Physical feasibility means, for example, that the special matrix structure resulting from the underlying connectivity must hold and that the physical parameters must be nonnegative. These added conditions make the QIEP much more interesting but harder. We are not aware of many research results in this regard. In what follows, we consider a special structure resulting from serially linked mass-spring systems.

4. Serially linked structure without damping. Our experience seems to indicate that whether a structured QIEP is solvable is probably problem dependent. The issue of solvability needs to be analyzed structure by structure. One special setting, the serially linked, undamped, mass-spring system depicted in Figure 4.1, is considered in this section. Such a setting can be used to model many other physical systems, including a vibrating beam, a composite pendulum, or a string with beads [20].

Matrices corresponding to the quadratic pencil $\lambda^2 M + K$ for the system in Figure 4.1 have the structure

$$M = \begin{bmatrix} m_1 & 0 & \dots & 0 \\ 0 & m_2 & & \\ \vdots & & \ddots & \\ 0 & & & m_n \end{bmatrix}, \quad K = \begin{bmatrix} k_1 + k_2 & -k_2 & 0 & \dots & 0 & 0 \\ -k_2 & k_2 + k_3 & -k_3 & & & 0 \\ 0 & -k_3 & k_3 + k_4 & & & \\ \vdots & & & \ddots & & \vdots \\ 0 & & & & k_{n-1} + k_n & -k_n \\ 0 & & & & -k_n & k_n \end{bmatrix}. \tag{4.1}$$

It is natural to assume that the masses and spring constants are all positive. In this case, eigenvalues associated with this kind of system are necessarily purely imaginary. The inverse eigenvalue problem means to find positive values for the masses $m_1, \dots, m_n$ and spring constants $k_1, \dots, k_n$ from prescribed eigeninformation.

4.1. Sign condition. A typical approach in the literature for this type of inverse problem has been to recast the quadratic pencil as a linear pencil $\mu I + J$ with a Jacobi matrix $J = M^{-1/2}KM^{-1/2}$. A classical theory has been that *two sets of eigenvalues* can uniquely solve the corresponding Jacobi inverse eigenvalue problem [8, section 4.2], but that result does not guarantee the nonnegativity of M and K. Furthermore, what can be said if the system is to be reconstructed from eigenpairs?

A total of $2n$ physical parameters are to be determined in (4.1). Each given eigenpair provides n equations. Imposing two eigenpairs generally will lead to the trivial algebraic solution for such a system, unless the prescribed eigenpairs satisfy some additional internal relationship. So it is reasonable to ask a more fundamental question of constructing the system with *one* prescribed eigenpair $(i\beta, \mathbf{x})$, where $i = \sqrt{-1}$, $\beta \in \mathbb{R}$, and $\mathbf{x} \in \mathbb{R}^n$.

Denote $\mathbf{x} = [x_1, \ldots, x_n]^\top$ and $x_0 = 0$. It is not difficult to see from (1.3) under the structure (4.1) that the recursive relationship

$$k_n = \frac{\beta^2 m_n x_n}{x_n - x_{n-1}}, \tag{4.2}$$

$$k_i = \frac{\beta^2 m_i x_i + k_{i+1}(x_{i+1} - x_i)}{x_i - x_{i-1}}, \quad i = n-1, \ldots, 1, \tag{4.3}$$

must hold. Our goal is to choose a positive value for m_i so as to define a positive value for k_i. In order to achieve this goal, the entries of the eigenvector $\mathbf{x}$ must satisfy some sign properties. More specifically, we observe the following fact directly from (4.2) and (4.3).

THEOREM 4.1. *The necessary condition for a given vector* $\mathbf{x} = [x_1, \ldots, x_n]^\top \in \mathbb{R}^n$ *with distinct entries to be an eigenvector of a quadratic pencil* $\lambda^2 M + K$ *with structure as is specified in* (4.1) *where masses* m_i *and spring constants are positive is that* $x_n(x_n - x_{n-1}) > 0$ *and the signs of the triplets* $(x_{i+1} - x_i, x_i, x_i - x_{i-1})$ *for* $i = 2, \ldots, n-1$ *are neither* $(+,+,-)$ *nor* $(-,-,+)$.

4.2. Numerical algorithm. In the event that the given vector $\mathbf{x}$ does satisfy the necessary condition in Theorem 4.1, there are infinitely many ways to choose positive values for m_i which are then used to define k_i. The following is a *make-or-break* algorithm for the construction where we specify only one particular way of selecting m_i.

ALGORITHM 4.1. *Given an arbitrary eigenpair* $(i\beta, \mathbf{x})$, $\beta \neq 0$ *and* $\mathbf{x} \neq 0$, *assume the normalization* $x_n = 1$ *and* $m_n = 1$. *The following steps either construct the masses* $m_1, \ldots, m_{n-1}$ *and spring constants* $k_1, \ldots, k_n$, *all positive, for the pencil* $\lambda^2 M + K$, *or determine that such a system with the prescribed eigenpair does not exist.*

1. *initialization:*

end
(c) $\eta = \eta + \beta^2 m_1 x_1$;
(d) $k_1 = \frac{\eta}{x_1}$; *(use formula (4.3))*

The working of the algorithm, based on Theorem 4.1, appears naive enough in just checking a few signs. It is precisely this simplicity of the necessary and sufficient conditions on the given eigenvector for ensuring a *positive* solution that we think is gratifying and elegant.

Note that in the above construction no restriction on the magnitude of β is imposed. This is quite curious in that the physical system can have one arbitrary natural frequency. One might thus ask, after the pencil $\lambda^2 M + K$ is determined, what the remaining eigenstructure should look like. To explore this important question, it is

interesting to recall the classical Courant nodal line theorem [31]. Roughly speaking, it has been known that critical information about a vibration system can be recovered from the places where *nothing happens*. These places are referred to as the *nodal lines*. In our discrete model, the incident of "nothing happens" means that the natural mode crosses the zero equilibrium. Courant's theorem gives an exact count of the numbers of nodal lines. We shall not elaborate on the particulars here, but refer readers to the treatises [10, 31] for more detailed discussion. Its simplest form related to our application can be stated as follows.

THEOREM 4.2. *If the given eigenvector* $\mathbf{x}$ *is feasible and if there are* τ *changes of signs in the sequence when going through* x_1 *to* x_n*, then* $\mathbf{x}$ *is the* $(\tau+1)$*th eigenvector (in the series where the corresponding frequencies are arranged in the ascending order) of the pencil regardless how the masses* m_i *are defined.*

In other words, from the changes of signs in the prescribed eigenvector $\mathbf{x}$, we know precisely how many other natural frequencies are above β and how many are below, although the values of these other frequencies can be quite arbitrary. The normalization $m_n = 1$ is immaterial. It indicates only the unit of mass used relative to m_n. It is the choice of values for other m_i's, which in turn determines values for other k_i's, that affects the total spectrum. How to select values for m_i when there are multiple alternatives so as to satisfy some additional spectral information is a very different but important question. At present, we have no knowledge about how this problem should be tackled. For other types of connectivity including damped systems or RLC configurations, the resulting pencil matrix structure will be different. We are not aware of any similar nodal line theorem. It is very likely that the condition of solvability will also vary. Again, this is a widely open area for further research.

5. Serially linked structure with damping. When damping is present in the mass-spring system in the way depicted in Figure 5.1, the QIEP becomes much more complicated. The associated matrices in the pencil $\lambda^2 M + \lambda C + K$ have the same structure of M and K as in (4.1) and, additionally, that of

$$C = \begin{bmatrix} c_1+c_2 & -c_2 & 0 & \cdots & 0 & 0 \\ -c_2 & c_2+c_3 & -c_3 & & & 0 \\ 0 & -c_3 & c_3+c_4 & & & \\ \vdots & & & \ddots & & \vdots \\ 0 & & & & c_{n-1}+c_n & -c_n \\ 0 & & & & -c_n & c_n \end{bmatrix}. \tag{5.1}$$

There are a total of $3n$ physical parameters to be determined, all of which need to be positive real numbers. It is clear that specifying more than three eigenpairs will make the QIEP over-determined. In the same spirit as before, we shall consider that two pairs of eigenpairs are given, and we want to determine $c_1, \ldots, c_n$ and $k_1, \ldots, k_n$ in terms of $m_1, \ldots, m_n$. Depending upon whether the specified eigenvalues are complex or not, we divide our discussion into two cases.

5.1. Complex eigenpairs. Assume that the given eigenpairs are complex-conjugate to each other. This eigeninformation is given through the matrices

$$\Lambda = \begin{bmatrix} \alpha & \beta \\ -\beta & \alpha \end{bmatrix}, \quad X = \begin{bmatrix} x_1 & x_2 & \cdots & x_n \\ y_1 & y_2 & \cdots & y_n \end{bmatrix}^\top, \tag{5.2}$$

where the 2×2 matrix Λ represents the complex-conjugate eigenvalues $\alpha \pm i\beta$, and the first and the second columns of X represent the real and the imaginary parts of the corresponding eigenvector, respectively.

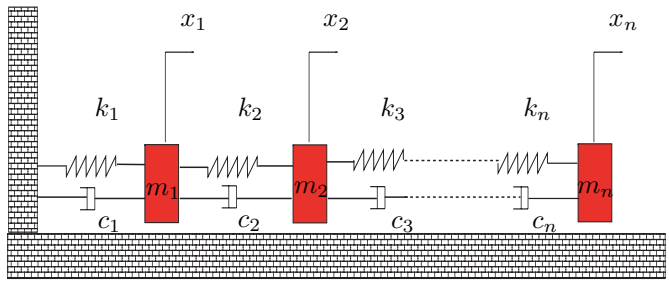

FIG. 5.1. *A damped mass-spring system.*

For $i = 1, \ldots, n$, denote the differences

$$X_i := x_i - x_{i-1}, \tag{5.3}$$

$$Y_i := y_i - y_{i-1} \tag{5.4}$$

with the notation $x_0 = y_0 = 0$. The algebraic system (1.3) characterizing the QIEP can be expressed as a system of n pairs of equations:

$$\begin{cases} \left((\alpha^2 - \beta^2)x_n - 2\alpha\beta y_n\right) m_n + (\alpha X_n - \beta Y_n)c_n + X_n k_n &= 0, \\ \left(2\alpha\beta x_n + (\alpha^2 - \beta^2)y_n\right) m_n + (\alpha Y_n + \beta X_n)c_n + Y_n k_n &= 0 \end{cases} \tag{5.5}$$

and

$$\begin{cases} \left((\alpha^2 - \beta^2)x_i - 2\alpha\beta y_i\right) m_i + (\alpha X_i - \beta Y_i)c_i - (\alpha X_{i+1} - \beta Y_{i+1})c_{i+1} \\ \qquad + X_i k_i - X_{i+1}k_{i+1} = 0, \\ \left(2\alpha\beta x_i + (\alpha^2 - \beta^2)y_i\right) m_i + (\alpha Y_i + \beta X_i)c_i - (\alpha Y_{i+1} + \beta X_{i+1})c_{i+1} \\ \qquad + Y_i k_i - Y_{i+1}k_{i+1} = 0 \end{cases} \tag{5.6}$$

for $i = n-1, \ldots, 1$. Our goal is to seek *positive* solutions $c_1, \ldots, c_n$ and $k_1, \ldots, k_n$ in terms of *positive* values of $m_1, \ldots, m_n$. Toward that end, we find it convenient to rewrite the above equations in matrix form. Define

$$\Gamma := -\begin{bmatrix} \alpha^2 - \beta^2 & -2\alpha\beta \\ 2\alpha\beta & \alpha^2 - \beta^2 \end{bmatrix} = -\Lambda^{2\top} \tag{5.7}$$

and

$$\Theta_i := \begin{bmatrix} \alpha X_i - \beta Y_i & X_i \\ \beta X_i + \alpha Y_i & Y_i \end{bmatrix}, \tag{5.8}$$

$$\mathbf{z}_i := \begin{bmatrix} x_i \\ y_i \end{bmatrix} \tag{5.9}$$

for $i = 1, \ldots, n$. It is readily seen that (5.5) and (5.6) can be conveniently expressed in the compact form

$$\Theta_n \begin{bmatrix} c_n \\ k_n \end{bmatrix} = m_n \Gamma \mathbf{z}_n, \tag{5.10}$$

$$\Theta_i \begin{bmatrix} c_i \\ k_i \end{bmatrix} = \Theta_{i+1} \begin{bmatrix} c_{i+1} \\ k_{i+1} \end{bmatrix} + m_i \Gamma \mathbf{z}_i, \quad i = n-1, \ldots, 1. \tag{5.11}$$

Clearly, $\det(\Theta_i) = -\beta(X_i^2 + Y_i^2)$. By assuming the generic condition that no two consecutive entries of the given eigenvectors are the same, all matrices Θ_i are invertible. We thus obtain the following recursive relationship:

$$\begin{bmatrix} c_n \\ k_n \end{bmatrix} = m_n \Theta_n^{-1} \Gamma \mathbf{z}_n, \tag{5.12}$$

$$\begin{bmatrix} c_i \\ k_i \end{bmatrix} = \Theta_i^{-1} \Gamma \left[m_n \mathbf{z}_n + m_{n-1} \mathbf{z}_{n-1} + \cdots + m_i \mathbf{z}_i \right], \qquad i = n-1, \ldots, 1, \tag{5.13}$$

where we can express Θ_i^{-1} explicitly as

$$\Theta_i^{-1} = \frac{1}{\beta(X_i^2 + Y_i^2)} \begin{bmatrix} -Y_i & X_i \\ \beta X_i + \alpha Y_i & -\alpha X_i + \beta Y_i \end{bmatrix}.$$

It remains to analyze conditions under which the physical parameters are positive.

Observe that all entries in Γ, Θ_i^{-1}, and $\mathbf{z}_i$, $i = 1, \ldots, n$, are known and fixed from the prescribed eigenpairs. For each $i = 1, \ldots, n$ and $j = i, \ldots, n$, write

$$\Theta_i^{-1} \Gamma \mathbf{z}_j = \begin{bmatrix} a_{ij} \\ b_{ij} \end{bmatrix}. \tag{5.14}$$

Assemble these entries into upper triangular matrices

$$A := \begin{bmatrix} a_{11} & a_{12} & \ldots & a_{1n} \\ 0 & a_{22} & \ldots & a_{2n} \\ \vdots & & & \vdots \\ 0 & 0 & \ldots & a_{nn} \end{bmatrix}, \quad B := \begin{bmatrix} b_{11} & b_{12} & \ldots & b_{1n} \\ 0 & b_{22} & \ldots & b_{2n} \\ \vdots & & & \vdots \\ 0 & 0 & \ldots & b_{nn} \end{bmatrix},$$

respectively. From (5.12) and (5.13), we now recast the QIEP as a system of inequalities.

THEOREM 5.1. *Solving for positive physical parameters c_i and k_i in terms of positive masses m_i, $i = 1, \ldots, n$, for the QIEP amounts to showing that the system of inequalities*

$$\begin{bmatrix} A \\ B \end{bmatrix} \mathbf{m} > 0 \tag{5.15}$$

is consistent *for some* $\mathbf{m} = [m_1, \ldots, m_n]^\top > 0$.

5.2. Real eigenpairs. Assume that the given pair of eigenvalues are real and distinct. We denote the prescribed eigenpairs via the matrices

$$\Lambda = \begin{bmatrix} \alpha & 0 \\ 0 & \gamma \end{bmatrix}, \qquad X = \begin{bmatrix} x_1 & x_2 & \ldots & x_n \\ y_1 & y_2 & \ldots & y_n \end{bmatrix}^\top, \tag{5.16}$$

where the two columns of X are the two eigenvectors associated with eigenvalues α and γ, respectively. The corresponding algebraic equation (1.3) can be formulated as the following n pairs of equations:

$$\begin{cases} \alpha^2 m_n x_n + \alpha X_n c_n + X_n k_n &= 0, \\ \gamma^2 m_n y_n + \gamma Y_n c_n + Y_n k_n &= 0 \end{cases} \tag{5.17}$$

and

$$\left\{ \begin{array}{rcl} \alpha^2 m_i x_i + \alpha X_i c_i - \alpha X_{i+1} c_{i+1} + X_i k_i - X_{i+1} k_{i+1} &=& 0, \\ \gamma^2 m_i y_i + \gamma Y_i c_i - \gamma Y_{i+1} c_{i+1} + Y_i k_i - Y_{i+1} k_{i+1} &=& 0 \end{array} \right. \tag{5.18}$$

for $i = 1, \ldots, n-1$. Defining the 2×2 matrices

$$\Pi_i := -\begin{bmatrix} \alpha X_i & X_i \\ \gamma Y_i & Y_i \end{bmatrix}, \qquad i = 1, \ldots, n, \tag{5.19}$$

we obtain equivalent equations in compact form:

$$\Pi_n \begin{bmatrix} c_n \\ k_n \end{bmatrix} = m_n \Lambda^2 \mathbf{z}_n, \tag{5.20}$$

$$\Pi_i \begin{bmatrix} c_i \\ k_i \end{bmatrix} = \Pi_{i+1} \begin{bmatrix} c_{i+1} \\ k_{i+1} \end{bmatrix} + m_i \Lambda^2 \mathbf{z}_i, \qquad i = n-1, \ldots, 1. \tag{5.21}$$

Assuming that all matrices Π_i are nonsingular, again we obtain a recursive relationship,

$$\begin{bmatrix} c_n \\ k_n \end{bmatrix} = m_n \Pi_n^{-1} \Lambda^2 \mathbf{z}_n, \tag{5.22}$$

$$\begin{bmatrix} c_i \\ k_i \end{bmatrix} = \Pi_i^{-1} \Lambda^2 \left[m_n \mathbf{z}_n + m_{n-1} \mathbf{z}_{n-1} + \cdots + m_i \mathbf{z}_i \right], \qquad i = n-1, \ldots, 1, \tag{5.23}$$

which is in the same format as that in (5.12) and (5.13). If we write

$$\Pi_i^{-1} \Lambda^2 \mathbf{z}_j = \begin{bmatrix} a_{ij} \\ b_{ij} \end{bmatrix}, \tag{5.24}$$

then determining positive c_i and k_i in terms of positive m_i would result in a system of inequalities similar to (5.15).

5.3. Numerical algorithm. We have shown above that solving a QIEP with damping from two given eigenpairs, both of which are either real-valued or complex-conjugate, is equivalent to solving a linear (strict) inequality system of the form (5.15). Without causing any ambiguity, we shall use the same notation A and B to represent the coefficient matrices involved in the inequality systems for both cases. Specifically, recall that both A and B are upper triangular matrices whose entries are defined by either (5.14) or (5.24). The question now is to determine the conditions on the prescribed eigenpairs under which the QIEP is solvable. In contrast to the QIEP with no damping in the preceding section, we are not aware of any analytic way to characterize the solvability of the QIEP with damping. To check the feasibility, we will have to resort to some numerical procedures.

Solving inequality systems of convex functions is a classical problem that has been discussed extensively in the literature, including the Farkas lemma [16], the von Neumann theorem [29, pp. 138–143], and the Ky Fan theorem [15, Theorem 1]. As an example, we state without proof the strong alternative theorem [4, pp. 260–262] as follows.

THEOREM 5.2. *The system of strictly linear inequalities* $\mathcal{A}\mathbf{x} < \mathbf{b}$ *is infeasible if and only if there exists a vector* $\boldsymbol{\omega} \geq 0$, $\boldsymbol{\omega} \neq \mathbf{0}$, *such that* $\mathcal{A}^\top \boldsymbol{\omega} = \mathbf{0}$ *and* $\mathbf{b}^\top \boldsymbol{\omega} \leq 0$.

For our application, we embed the need of $\mathbf{m} > 0$ in the inequalities and consider the augmented system $\mathcal{A}\mathbf{m} > 0$ with

$$\mathcal{A} = \begin{bmatrix} A \\ B \\ I \end{bmatrix}.$$

By Theorem 5.2, we see that $\mathcal{A}\mathbf{m} > 0$ is infeasible, and, hence, our (serially linked with damping) structured QIEP is not solvable if and only if there exist nonnegative vectors $\boldsymbol{\omega}_1, \boldsymbol{\omega}_2$, and $\boldsymbol{\omega}_3$, not all zero, such that $A^\top \boldsymbol{\omega}_1 + B^\top \boldsymbol{\omega}_2 + \boldsymbol{\omega}_3 = \mathbf{0}$. This is equivalent to the statement that $A^\top \boldsymbol{\omega}_1 + B^\top \boldsymbol{\omega}_2 \leq \mathbf{0}$ for some nonnegative, but not both zero, vectors $\boldsymbol{\omega}_1$ and $\boldsymbol{\omega}_2$. Such a result of duality, though interesting in theory, might not be easy to realize in computation [2]. Instead, we propose a much simpler numerical approach.

Observe that the inequality system (5.15) is solvable for some $\mathbf{m} > 0$ if and only if it is solvable for $c\mathbf{m}$ with any $c > 0$. By scaling the variable $\mathbf{m}$ if necessary, we can recast our problem of solving an inequality system into the problem of finding a minimax solution of a multivariable function [19]. More specifically, we consider the problem

$$\max_{0 \leq \mathbf{m} \leq 1} \min \{A\mathbf{m}, B\mathbf{m}\}, \tag{5.25}$$

where for each given $\mathbf{m} \in \mathbb{R}^n$ the minimum is taken over the $2n$ entries of the vectors $A\mathbf{m}$ and $B\mathbf{m}$. It is not difficult to observe the following fact.

THEOREM 5.3. *If the inequality system* (5.15) *is consistent, then the maximal objective value in* (5.25) *is positive. Conversely, if* (5.15) *is inconsistent, then the optimal objective value to* (5.25) *is necessarily zero with* $\mathbf{m} = 0$.

Note that the function $\min\{A\mathbf{m}, B\mathbf{m}\}$ is concave in $\mathbf{m}$. Thus its maximal value over the convex domain $\{\mathbf{m} \in \mathbb{R}^n | 0 \leq m_i \leq 1,\ i = 1, \ldots, n\}$ is unique. We can easily convert (5.25) into a convex programming problem and there are readily available routines to solve (5.25). For example, the MATLAB routine fminimax implements a sequential quadratic programming method and seems capable of handling our problem reasonably well. With the equivalence of (5.15) and (5.25) in mind, we propose the following algorithm.

ALGORITHM 5.1. *Given two arbitrary complex-conjugate (or real-valued) eigenpairs, the following steps generally will either construct the masses* $m_1, \ldots, m_n$, *the damping constants* $c_1, \ldots, c_n$, *and the spring constants* $k_1, \ldots, k_n$, *all positive and* $m_i \leq 1$, *for the pencil* $\lambda^2 M + \lambda C + K$ *with the prescribed eigenpairs, where* M, C, *and* K *are of the structure specified in* (4.1) *and* (5.1), *or determine that such a system does not exist. In the rare case where the algorithm is terminated prematurely, the prescribed eigenpairs are not generic enough in the sense that one of the matrices* Θ_i *defined in* (5.8) *(or* Π_i *defined in* (5.19)*) is singular for some* $i = 1, \ldots, n$.

1. *Let* (Λ, X) *represent the given eigenpairs in the sense of* (5.2) *(or* (5.16)*).*
   (a) *For* $i = 1, \ldots, n$, *form vectors* $\mathbf{z}_i$ *according to* (5.9), *and compute the differences* X_i *and* Y_i *according to* (5.3) *and* (5.4), *respectively.*
   (b) *Check to see that* Θ_i *(or* Π_i*) is nonsingular for all* $i = 1, \ldots, n$. *Otherwise, report that the given spectral information is not generic and stop.*
2. *Form the upper triangular matrices* A *and* B *according to* (5.14) *(or* (5.24)*).*
3. *Solve the minimax problem* (5.25).
   (a) *If a solution* $\mathbf{m} > 0$ *exists, define* $\mathbf{c} = A\mathbf{m}$ *and* $\mathbf{k} = B\mathbf{m}$.
   (b) *If a solution* $\mathbf{m} > 0$ *does not exist, the given eigenpairs are not feasible.*

6. Numerical experiment. In this section we demonstrate the above ideas by some numerical examples.

Example 4. We first randomly generate the data

$$\mathbf{m} = [1.0660, 0.2593, 0.6809, 0.5453, 1.0000]^\top,$$

$$\mathbf{k} = [7.6210, 4.5647, 0.1850, 8.2141, 4.4470]^\top$$

and create an undamped pencil $\lambda^2 M + K$ in the form (4.1). The resulting system has natural frequencies

$$5.7620, 4.9207, 2.5971, 2.3485, 0.2768,$$

with columns in the matrix

$$\begin{bmatrix} -0.0080 & -0.5440 & -0.1126 & 0.7932 & 0.0153 \\ 0.0405 & 1.6238 & -0.1232 & 1.0958 & 0.0405 \\ -0.6480 & -0.0019 & 0.7796 & 0.0902 & 0.6579 \\ 1.1197 & -0.0347 & 0.3641 & 0.0263 & 0.6677 \\ -0.1732 & 0.0078 & -0.7046 & -0.1095 & 0.6794 \end{bmatrix},$$

as the corresponding natural modes. We point out earlier that the order of frequencies corresponds precisely to the number of sign changes in the eigenvector. Suppose now that we use the third eigenpair as the given eigenpair and apply Algorithm 4.1 to reconstruct the quadratic pencil. To illustrate the working of Algorithm 4.1, we allow the mass increasing factor s_p to vary from 1.001 to 10^5. The resulting allowable masses and the corresponding frequencies are plotted in the top and bottom graphs of Figure 6.1, respectively. Clearly, the solution to the QIEP is not unique. Note that in this particular example, only the second and the third masses are changed by our algorithm, whereas in all cases the third frequency stays invariant. The experiment also suggests an interesting observation that an increase on the second and the third masses, while maintaining the third eigenpair, has more effect on the first eigenvalue than on the fourth or the fifth eigenvalue.

Example 5. We randomly generate the data

$$\mathbf{m} = [3.4915, 4.4928, 5.2297, 4.1880, 1.0000]^\top,$$

$$\mathbf{c} = [0.0579, 0.3529, 0.8132, 0.0099, 0.1389]^\top,$$

$$\mathbf{k} = [4.0571, 9.3547, 9.1690, 4.1027, 8.9365]^\top$$

and create a pencil $\lambda^2 M + \lambda C + K$ in the form (5.1). The resulting system has 5 pairs of complex-conjugate eigenvalues,

$$-0.0863 \pm 3.3596i, -0.1792 \pm 2.6044i, -0.0792 \pm 1.7918i,$$

$$-0.0079 \pm 1.0365i, -0.0019 \pm 0.3736i,$$

not necessarily in any particular order, and the corresponding eigenvectors

$$\begin{bmatrix} 0.0005 \mp 0.0005i & 0.0696 \mp 0.2457i & -0.2044 \pm 0.3474i & -0.2495 \pm 0.3822i & -0.3451 \pm 0.1371i \\ -0.0012 \pm 0.0015i & -0.1084 \pm 0.2648i & -0.0325 \pm 0.0894i & -0.2572 \pm 0.3949i & -0.4763 \pm 0.1907i \\ 0.0019 \mp 0.0056i & 0.0566 \mp 0.1061i & 0.1583 \mp 0.3303i & -0.1457 \pm 0.1913i & -0.5767 \pm 0.2341i \\ -0.0176 \pm 0.0597i & -0.0018 \pm 0.0095i & -0.0335 \pm 0.0987i & 0.3470 \mp 0.5006i & -0.7014 \pm 0.2830i \\ 0.0676 \mp 0.2260i & -0.0181 \pm 0.0339i & -0.0575 \pm 0.1522i & 0.3943 \mp 0.5691i & -0.7125 \pm 0.2875i \end{bmatrix}.$$

Suppose we use the first complex-conjugate eigenpairs as the given eigenpairs and apply Algorithm 5.1 to reconstruct the quadratic pencil. We solve the minimax

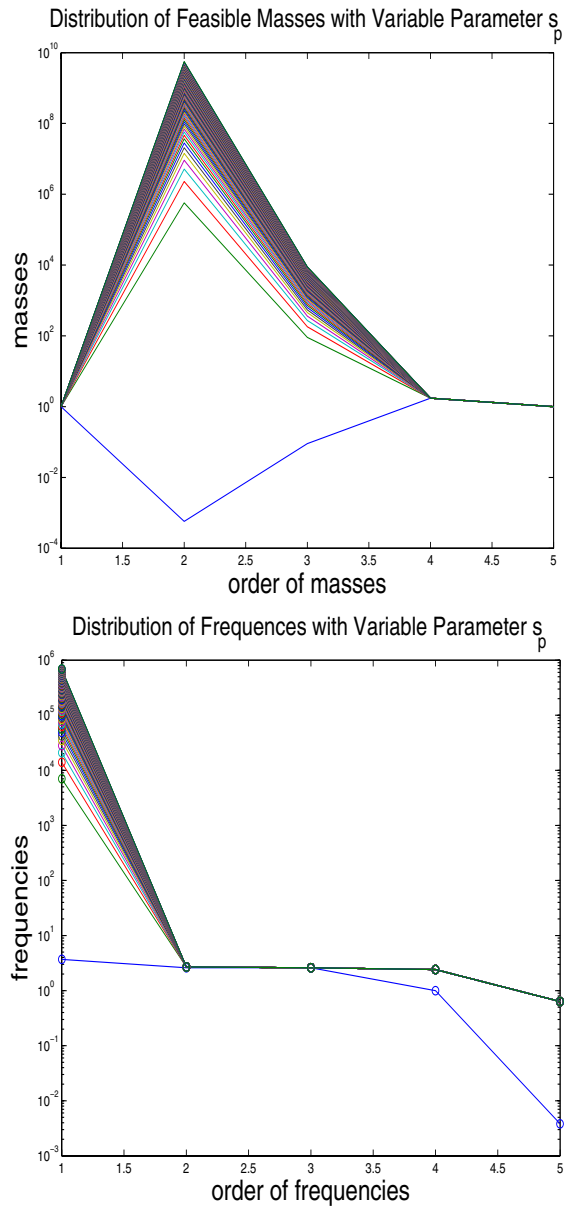

FIG. 6.1. *Allowable masses and frequency responses for the undamped system.*

problem (5.25) by employing the MATLAB code fminimax with tolerance TolFun = TolCon $= 10^{-8}$. We obtain a solution to the QIEP at

$$\mathbf{m} = [0.0512, 0.2413, 0.5096, 0.1653, 0.0326]^\top,$$

$$\mathbf{c} = [0.0045, 0.0045, 0.0588, 0.0045, 0.0045]^\top,$$

$$\mathbf{k} = [0.0045, 0.1520, 0.6021, 0.4316, 0.2912]^\top.$$

Note that $\mathbf{m}$ is limited to the range $[0, 1]$, whereas we could have normalized m_5 to unit mass without affecting the spectrum. An examination of the remaining eigenvalues does not seem to suggest that there is anything analogous to the Courant nodal line theorem for the damped case.

7. Conclusion. We have studied the QIEP arising from dynamical systems whose vibratory properties can be modeled after a serially linked mass-spring oscillator. The resulting QIEP must oblige a special matrix structure. In particular, the physical parameters must be positive. These constraints severely limit the solvability of the QIEP.

We show that for the undamped problem, the order of frequencies corresponds precisely to the number of sign changes in the eigenvectors. A make-or-break algorithm is proposed in this work. For the damped problem, we show that the solvability of the QIEP is equivalent to the consistency of a certain system of inequalities which can be solved via a minimax algorithm.

Thus far, the permissible eigenpair information is rather limited. For the undamped problem only one eigenpair is allowed, while for the damped problem only two eigenpairs are allowed. In either case, the masses $\mathbf{m}$ are used as the free parameters to express the other two physical parameters $\mathbf{c}$ and $\mathbf{k}$. In certain applications, it is desirable to express $\mathbf{m}$ and $\mathbf{c}$ in terms of $\mathbf{k}$. However, such a task is much harder to analyze, and we have not obtained significant results yet.

If the QIEP is solvable, usually there are multiple solutions. Although we are able to match the prescribed eigenpair information in our construction, our technique thus far cannot control the remaining eigenvalues or eigenvectors. It remains an open question whether additional eigenvalue information, not eigenvector information, can help to further restrict the number of solutions or control the remaining eigenstructure.

PRESSURE SCHUR COMPLEMENT PRECONDITIONERS FOR THE DISCRETE OSEEN PROBLEM*

MAXIM A. OLSHANSKII† AND YURI V. VASSILEVSKI‡

Abstract. We consider several preconditioners for the pressure Schur complement of the discrete steady Oseen problem. Two of the preconditioners are well known from the literature and the other is new. Supplemented with an appropriate approximate solve for an auxiliary velocity subproblem, these approaches give rise to a family of the block preconditioners for the matrix of the discrete Oseen system. In the paper we critically review possible advantages and difficulties of using various Schur complement preconditioners. We recall existing eigenvalue bounds for the preconditioned Schur complement and prove such for the newly proposed preconditioner. These bounds hold both for LBB stable and stabilized finite elements. Results of numerical experiments for several model two-dimensional and three-dimensional problems are presented. In the experiments we use LBB stable finite element methods on uniform triangular and tetrahedral meshes. One particular conclusion is that in spite of essential improvement in comparison with "simple" scaled mass-matrix preconditioners in certain cases, none of the considered approaches provides satisfactory convergence rates in the case of small viscosity coefficients and a sufficiently complex (e.g., circulating) advection vector field.

Key words. Navier–Stokes equations, Oseen equations, finite element, iterative methods, preconditioning, pressure Schur complement

1. Introduction.

We consider the numerical solution of the steady Oseen problem: Given a divergence free advection velocity $\mathbf{w} : \Omega \to \mathbb{R}^d$, force field $\mathbf{f} : \Omega \to \mathbb{R}^d$, and boundary data $\mathbf{g} : \partial\Omega \to \mathbb{R}^d$, find a velocity $\mathbf{u} : \Omega \to \mathbb{R}^d$ and a pressure $p : \Omega \to \mathbb{R}$ such that

$$-\nu\Delta\mathbf{u} + (\mathbf{w}\cdot\nabla)\,\mathbf{u} + \nabla p = \mathbf{f} \quad \text{in } \Omega, \tag{1.1}$$

$$\operatorname{div}\mathbf{u} = 0 \quad \text{in } \Omega, \tag{1.2}$$

$$\mathbf{u} = \mathbf{g} \quad \text{on } \partial\Omega, \tag{1.3}$$

where $\Omega \subset \mathbb{R}^d$ $(d = 2, 3)$ is a bounded, connected domain with a piecewise smooth Lipschitz boundary $\partial\Omega$. The coefficient $\nu > 0$ is a given kinematic viscosity. For the sake of uniqueness of p one may impose some additional condition, such as $\int_\Omega p\,dx = 0$.

A necessity of solving Oseen equations numerically is commonly related to using Picard-type iterative methods to find a solution to steady Navier–Stokes problems. In this case $\mathbf{w}$ is an approximation of the velocity from previous iterative steps, so it is updated on every nonlinear iteration. Among another applications we mention Uzawa-type algorithms for the augmented variational inequality approach to the modeling of

Bingham fluids; see, e.g., [24]. Again one may need to solve discrete Oseen systems many times with different $\mathbf{w}$ and $\mathbf{f}$. Thus there is a demand for efficient iterative solvers for the discrete Oseen problem. We note that besides (1.3) other boundary conditions may be imposed in various models. Furthermore we remark that when using different boundary conditions special attention may be required.

In this paper we consider a finite element method to discretize (1.1)–(1.3). However, the linear algebraic solvers discussed here can be applied in a finite difference or finite volume context in the same manner. We assume that the finite element velocity (not necessarily conforming) and pressure spaces $\mathbb{V}_h$ and $\mathbb{Q}_h$ approximate $\mathbf{H}_0^1(\Omega)$ and $L_2^0(\Omega) := \{q \in L_2(\Omega) : (q,1) = 0\}$, respectively. Consider the following finite element problem: Find $\mathbf{u}_h \in \mathbb{V}_h$ and $p_h \in \mathbb{Q}_h$ satisfying

$$a_h(\mathbf{u}_h, \mathbf{v}_h) - (p_h, \operatorname{div} \mathbf{v}_h) + (q_h, \operatorname{div} \mathbf{u}_h) + c_h(p_h, q_h) = (\mathbf{f}_h, \mathbf{v}_h) + (g_h, q_h) \quad \forall\ \mathbf{v}_h \in \mathbb{V}_h,\ q_h \in \mathbb{Q}_h. \tag{1.4}$$

The bilinear form $a_h(\cdot,\cdot)$ may include some stabilizing terms for the advection dominated case. The nonnegative bilinear form $c_h(\cdot,\cdot)$ may be included in the finite element formulation if $\mathbb{V}_h$ and $\mathbb{Q}_h$ form an LBB unstable pair [21]; otherwise, $c_h(\cdot,\cdot) \equiv 0$. Denote by $(\cdot,\cdot)_{\mathbb{V}}$ the energy scalar product on $\mathbb{V}_h$ satisfying $(\psi,\phi)_{\mathbb{V}} = (\nabla\psi, \nabla\phi)$ for $\psi, \phi \in \mathbb{V}_h \cap \mathbf{H}_0^1$. For the bilinear forms a_h and c_h we assume ellipticity, continuity, and stability conditions

$$\alpha_1 \|\mathbf{v}_h\|_{\mathbb{V}}^2 \le a_h(\mathbf{v}_h, \mathbf{v}_h), \qquad a_h(\mathbf{v}_h, \mathbf{u}_h) \le \alpha_2 \|\mathbf{v}_h\|_{\mathbb{V}} \|\mathbf{u}_h\|_{\mathbb{V}} \quad \forall\ \mathbf{v}_h, \mathbf{u}_h \in \mathbb{V}_h, \tag{1.5}$$

$$\gamma_1^2 \|q_h\|^2 \le \sup_{\mathbf{v}_h \in \mathbb{V}_h} \frac{(q_h, \operatorname{div} \mathbf{v}_h)^2}{\|\mathbf{v}_h\|_{\mathbb{V}}^2} + c_h(q_h, q_h) \quad \forall\ q_h \in \mathbb{Q}_h, \tag{1.6}$$

$$c_h(q_h, p_h) \le \gamma_2 \|q_h\| \|p_h\|, \quad (q_h, \operatorname{div} \mathbf{v}_h) \le \gamma_3 \|q_h\| \|\mathbf{v}_h\|_{\mathbb{V}} \quad \forall\ q_h, p_h \in \mathbb{Q}_h,\ \mathbf{v}_h \in \mathbb{V}_h, \tag{1.7}$$

with positive mesh-independent constants α_1, α_2, γ_1, γ_2, and γ_3. We note that conditions (1.6) and (1.7) are common for the pressure stabilized finite element methods; see, e.g., the recent studies in [8]. For the LBB stable pairs (1.6) and (1.7) trivially hold.

Let $\{\phi_i\}_{1 \le i \le n}$ and $\{\psi_j\}_{1 \le j \le m}$ be bases of $\mathbb{V}_h$ and $\mathbb{Q}_h$, respectively. Define the following matrices:

$$A_{i,j} = a_h(\phi_j, \phi_i), \quad B_{i,j} = -(\operatorname{div} \phi_j, \psi_i), \quad C_{i,j} = c_h(\psi_j, \psi_i).$$

The linear algebraic system corresponding to (1.4) (*the discrete Oseen system*) takes the form

$$\begin{pmatrix} A & B^T \\ B & -C \end{pmatrix} \begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}. \tag{1.8}$$

We are interested in solving (1.8) by a preconditioned iterative method. Following the conventional approach [21, 29, 12] we consider the block triangular preconditioner for the system (1.8):

$$\mathcal{P} = \begin{pmatrix} \hat{A} & B^T \\ O & -\hat{S} \end{pmatrix}. \tag{1.9}$$

The matrix $\hat{A}$ is a preconditioner for the matrix A, such that $\hat{A}^{-1}$ may be considered as an inexact solver for linear systems involving A. The matrix $\hat{S}$ is a preconditioner for the pressure Schur complement of (1.8) $S = BA^{-1}B^T + C$. In an iterative algorithm one needs the actions of $\hat{A}^{-1}$ and $\hat{S}^{-1}$ on subvectors, rather than the matrices $\hat{A}$, $\hat{S}$ explicitly. Once good preconditioners for A and S are given, an appropriate Krylov subspace iterative method for (1.8) with the block preconditioner (1.9) is an efficient solver. In the literature one can find geometric or algebraic multigrid (see, e.g., [21] and references therein) or domain decomposition [23, 35] iterative algorithms which provide effective preconditioners $\hat{A}$ for a wide range of ν and various meshes. However, despite considerable recent effort and progress, building a preconditioner for S, which is robust for a wide range of parameters (especially viscosity), discretizations, and meshes, is still a challenge.

In this paper we recall two recent approaches to construct a preconditioner for S. One is due to Kay, Loghin, and Wathen [28], and another is from Elman and coauthors [16, 18]. Furthermore, in attempting to overcome some difficulties associated with these approaches we consider a new preconditioner for S. We give motivation for different choices of $\hat{S}^{-1}$, prove eigenvalue bounds, and present results of several numerical experiments.

As already mentioned, a good preconditioner $\hat{S}$ is necessary for building the block triangular preconditioner (1.9). Furthermore, there exist other numerical methods for the incompressible Navier–Stokes equations, where finding a proper approximation to S is vital. These methods are based on the Uzawa method and its variants [22, 40, 10], Arrow–Hurwicz [22, 1], SOR [14], and special factorizations [3, 5] for the linearized problems. Moreover, the performance of the widely used splitting algorithms like SIMPLE, projection, or pressure correction methods for the time integration of unsteady problem is also closely related with the issue of the Schur complement preconditioning [34, 38, 37].

There are also iterative methods for solving (1.8) which do not require consideration of the Schur complement S or its preconditioner, at least explicitly. Among these are coupled multigrid methods of Vanka type [27, 38], methods based on Hermitian splitting [4], augmented Lagrangian based preconditioning [6], and implicit-factorization preconditioning [15, 13]; see also the review article [5]. It is not the intention of this paper to discuss or compare these methods. We note only that implementing some of them in a purely algebraic manner may involve serious difficulties [41]. Thus the pressure Schur complement based block solvers remain attractive for treating "real-life" engineering problems and have potential for developing black-box algorithms.

The remainder of the paper is organized as follows. In section 2 we consider two well-known preconditioners for S and present a new approach. In section 3 we prove eigenvalue bounds. For the new preconditioner the h-independent bounds both for the LBB stable and the pressure stabilized discretizations are shown. In section 4 results of numerical experiments with different preconditioners are given for two-dimensional (2D) and three-dimensional (3D) problems discretized on simplicial meshes.

2. Schur complement preconditioners. In this paper all variants of preconditioner $\hat{S}$ are defined through their inverses. Before proceeding to the preconditioners we define the pressure mass, velocity mass, and Laplacian matrices:

$$(M_p)_{i,j} = (\psi_j, \psi_i), \quad (M_u)_{i,j} = (\phi_j, \phi_i), \quad L_{i,j} = (\phi_j, \phi_i)_{\mathbb{V}}.$$

2.1. Pressure convection-diffusion. We first consider the *pressure convection-diffusion* (PCD) preconditioner, proposed by Kay, Loghin, and Wathen [28] and studied by these and other authors (see [21]):

$$\hat{S}^{-1} := \hat{M}_p^{-1} A_p L_p^{-1}. \tag{2.1}$$

Here $\hat{M}_p^{-1}$ denotes an approximate solve with the pressure mass matrix. Matrices A_p and L_p are approximations to convection-diffusion and Laplacian operators in $\mathbb{Q}_h$, respectively. Note that both A_p and L_p need some boundary conditions to be prescribed.

In discretizations of (1.1)–(1.3) with continuous pressure approximations, one can use the conforming discretization of the pressure Poisson problem with Neumann boundary conditions. The corresponding finite element formulation for the case of the Neumann conditions is standard: Find $p_h \in \mathbb{Q}_h$ such that

$$(\nabla p_h, \nabla q_h) = (f, q_h) \qquad \forall\ q_h \in \mathbb{Q}_h \subset \mathrm{H}^1(\Omega).$$

Neumann boundary conditions are conventionally set for the convection-diffusion problem on $\mathbb{Q}_h$.

An alternative way to define L_p is to set $L_p = (B\hat{M}_u^{-1}B^T)$, where $\hat{M}_u$ is a diagonal approximation to the velocity mass matrix. Although a diagonal matrix might be a poor approximation to M_u in the case of anisotropic grids, this operator can be seen as a mixed discretization of the pressure Poisson problem with Neumann boundary conditions. Using $(B\hat{M}_u^{-1}B^T)$ is convenient in the case of discontinuous pressures. It is not straightforward to define A_p for the case of discontinuous pressures; see section 4 for a definition of A_p in the case of isoP_2-P_0 elements.

Analysis of the PCD preconditioner and numerical results found in the literature (see also section 4) recover several specific features of the method. In particular, the advantages of using this preconditioner are the following:

1. The PCD preconditioner provides mesh-independent convergence rates for moderate values of ν.
2. Dependence of the convergence rates on ν^{-1} is significantly improved in comparison to a scaled pressure mass matrix.
3. Numerical results [42, 30] suggest that the preconditioner is not very sensitive to grid anisotropy, at least for some discretizations. Thus in [42] the PCD preconditioning was used to solve the Oseen problem on every step of Picard iterations for the 3D driven cavity problem discretized with Q_2-Q_1 finite elements on a regular grid. The number of iterations was essentially independent of the aspect ratio of elements. In [30] the preconditioner was successfully used to compute a flow around an obstacle in a 3D cube, using isoP_2-P_1 elements on unstructured grid and allowing elements with high aspect ratios.
4. Some theoretical analysis of the preconditioner is available in [20], where the authors prove eigenvalue estimates for the preconditioned system. We recall these results in section 3.
5. The preconditioner can be used both for LBB stable and pressure stabilized discretizations.

There are also some open questions associated with using this method:

1. Degradation of the convergence rates as $\nu \to 0$ is easily seen even for the simplest constant flow: $\mathbf{w} = (1, 0)$ or $\mathbf{w} = (1, 0, 0)$.

2. The issue of proper boundary conditions in L_p and A_p is not very well understood. We address this question below in more detail.
3. The A_p matrix does not naturally arise in the original problem. Some effort may be needed to build it, especially for discontinuous pressure approximations.
4. The preconditioner is specifically oriented to the Oseen problem. Its extension to similar problems, like Newton linearization, quasi-Newtonian fluids, the Navier–Stokes system coupled with other equations, or general problems having the same 2×2 structure as (1.8), is not clear.

The choice of boundary conditions for the definition of A_p and L_p depends on boundary conditions in the Oseen problem. In [21] it is recommended that Neumann boundary conditions should be prescribed on those parts of $\partial\Omega$ where in the original formulation of the Oseen problem one has Dirichlet boundary conditions for $\mathbf{u}$, and Dirichlet boundary conditions in A_p and L_p should be used on those parts of $\partial\Omega$ where in the original formulation one has outflow boundary conditions for the stress tensor. A motivation for these recommendations comes from the symmetric case of the unsteady Stokes problem, where this choice proved to work well for the Cahouet–Chabard preconditioner [11, 32]. Our experiments and analysis suggest that for the case of dominating convection ($\nu \to 0$) this choice is not optimal. Below we give arguments that on the inflow boundary for small ν one may prefer using a Dirichlet homogeneous fictitious boundary for constructing A_p. Experimentally we observed that the change of boundary conditions on the outflow part of the boundary is not crucial. On the characteristic parts of $\partial\Omega$ and outflow parts with conditions on the stress tensor (the so-called do-nothing boundary conditions), Neumann boundary conditions in A_p and L_p are more appropriate.

We consider the continuous counterpart of the pressure Schur complement operator: $S := -\operatorname{div}(-\nu\Delta + (\mathbf{w}\cdot\nabla))_0^{-1}\nabla$, where $(-\nu\Delta + (\mathbf{w}\cdot\nabla))_0^{-1}$ is the solution operator for the vector convection-diffusion problem with Dirichlet boundary conditions. The operator S defines a mapping of L_0^2 onto L_0^2. For a given function $p \in L_0^2$ denote $\mathbf{v} = (-\nu\Delta + (\mathbf{w}\cdot\nabla))_0^{-1}\nabla p$, $\mathbf{v} \in \mathbf{H}_0^1(\Omega)$; then one can rewrite the relation $q = S\,p$ in the form

$$-\nu\Delta\mathbf{v} + (\mathbf{w}\cdot\nabla)\,\mathbf{v} - \nabla p = \mathbf{0}, \qquad -\operatorname{div}\mathbf{v} = q \quad \text{in } \Omega, \tag{2.2}$$

$$\mathbf{v}|_{\partial\Omega} = \mathbf{0}. \tag{2.3}$$

Let $\nu = 0$ and prescribe boundary condition (2.3) only on the inflow part Γ_{in} of $\partial\Omega$, i.e., $\Gamma_{in} = \{\mathbf{x} \in \partial\Omega \,:\, \mathbf{w}(\mathbf{x})\cdot\mathbf{n} < 0\}$. For the sake of simplicity we assume the following: the plain patch Γ_{in} is orthogonal to the x-axis, and $\mathbf{w}$ is sufficiently smooth, orthogonal to Γ_{in} at each point, and stays parallel to the x-axis in some neighborhood $\mathcal{O} \subset \Omega$ of Γ_{in}. For simplicity, we consider the 2D case (the 3D case is considered similarly). Integrating the first equation in (2.2) along characteristics in $\mathcal{O}$, using condition $\mathbf{v}|_{\Gamma_{in}} = 0$ and assumptions $\nu = 0$ and $\mathbf{w} = (1, 0)$ in $\mathcal{O}$ one gets the equality

$$\mathbf{v}(x, y) = \int_0^x \nabla p\,(s, y)\; d\,s \quad \text{in } \mathcal{O}. \tag{2.4}$$

Now we compute $\operatorname{div}\mathbf{v}$ in $\mathcal{O}$. If p is sufficiently smooth, the equality (2.4) yields

$$\operatorname{div}\mathbf{v} = \frac{\partial}{\partial x}\int_0^x \frac{\partial}{\partial s} p\,(s, y)\; d\,s + \frac{\partial}{\partial y}\int_0^x \frac{\partial}{\partial y} p\,(s, y)\; d\,s = \frac{\partial p}{\partial x} + \int_0^x \frac{\partial^2 p}{\partial y^2}\; d\,s \quad \text{in } \mathcal{O}.$$

The second equation in (2.2) implies $q = -\partial p/\partial x - \int_0^x \partial^2 p/\partial y^2 \, d\,s$ in $\mathcal{O}$. Therefore, we have in the sense of traces

$$q = -\frac{\partial p}{\partial x} \quad \text{on} \quad \Gamma_{in}. \tag{2.5}$$

On the other hand, the PCD approach suggests approximating $p = S^{-1}q$ by

$$p = -(\mathbf{w} \cdot \nabla)\Delta^{-1} q, \tag{2.6}$$

where Δ^{-1} is a solution operator to the Poisson problem with *some* boundary conditions. We want to define these conditions on Γ_{in} in a way consistent with (2.5). To this end we rewrite (2.6) in $\mathcal{O}$:

$$p = -\frac{\partial r}{\partial x}, \qquad \frac{\partial^2 r}{\partial x^2} + \frac{\partial^2 r}{\partial y^2} = q. \tag{2.7}$$

Relations (2.5) and (2.7) lead to $\partial^2 r/\partial y^2 = 0$ on Γ_{in}. The corresponding homogeneous boundary condition in the definition of Δ^{-1} is $r = 0$ on Γ_{in}. Therefore, for the practically important case when the flow $\mathbf{w}$ is orthogonal to Γ_{in} and ν is small, the reasonable boundary conditions for the PCD preconditioner on the *inflow* are *homogeneous Dirichlet boundary conditions*.

Although the above analysis studies the limit case of $h \to 0$ and $\nu \to 0$ (continuous inviscid problem), we believe it to be useful for understanding the issue of proper boundary conditions in the discrete preconditioner (2.1). In particular, it suggests that the choice of the optimal boundary conditions in $\hat{S}^{-1}$ depends not only on the type of conditions in (1.3), but also on ν and $\mathbf{w}$ (it may be different for inflow, outflow, and characteristic parts of $\partial\Omega$). From the practical standpoint there are still open questions. Thus in the continuous counterpart of the preconditioner ($\hat{S}^{-1} = (\nu\Delta - \mathbf{w}\cdot\nabla)\Delta^{-1}$) one has to prescribe boundary conditions *only* for the Poisson problem solution operator Δ^{-1}, while in the discrete case some boundary conditions are involved in the definition of *both* matrices A_p and L_p. The guess that conditions in A_p and L_p should be the same for optimal performance is not fully confirmed by our numerical experiments. In particular, the best convergence rates were observed with Neumann boundary conditions in L_p and different boundary conditions in A_p depending on ν and $\mathbf{w}$. We do not have a clear explanation of this phenomenon. Furthermore, from the implementation standpoint, Dirichlet boundary conditions for A_p may not be imposed on the nodes at Γ_{in} since these nodes have to contribute to the set of pressure degrees of freedom. For this reason one introduces outside Ω a fictitious one-cell layer attached to Γ_{in}. Dirichlet boundary conditions are assigned at layer nodes not belonging to Γ_{in}. Technical details can be found in section 4.

Results of numerical experiments suggest that the choice of boundary conditions on $\Gamma_{out} = \{\mathbf{x} \in \partial\Omega \,:\, \mathbf{w}(\mathbf{x})\cdot\mathbf{n} > 0\}$ in the preconditioner does not affect its performance in any substantial way. If in the Oseen problem (1.1)–(1.3) instead of Dirichlet conditions one sets the normal component of the stress tensor equal to zero on the outflow,

$$-\nu(\nabla\mathbf{u} + (\nabla\mathbf{u})^T)\cdot\mathbf{n} + 2p\,\mathbf{n} = 0 \quad \text{on} \quad \Gamma_{out}, \tag{2.8}$$

then for $\nu \to 0$ one gets $p = 0$ on Γ_{out}. Now relation (2.6) immediately gives $(\mathbf{w}\cdot\nabla)r = 0$ on Γ_{out}. For the case when $\mathbf{w}$ is orthogonal to Γ_{out} this results in the *homogeneous Neumann boundary conditions* for the matrices in the PCD preconditioner.

Using similar arguments one can show that Neumann boundary conditions "inside" $\hat{S}$ are appropriate for the characteristic part of $\partial\Omega$.

2.2. BFBt. Next we consider the BFBt preconditioner, proposed by Elman [16] and further developed by Elman and coauthors in [18]. The best available modification from [18] is

$$\hat{S}^{-1} := (B\hat{M}_u^{-1}B^T)^{-1}B\hat{M}_u^{-1}A\hat{M}_u^{-1}B^T(B\hat{M}_u^{-1}B^T)^{-1}, \tag{2.9}$$

where $\hat{M}_u$ is a diagonal approximation of M_u. In the case of continuous pressure elements the BFBt preconditioner may be reformulated as

$$\hat{S}^{-1} := L_p^{-1}B\hat{M}_u^{-1}A\hat{M}_u^{-1}B^TL_p^{-1}.$$

Below some observations on the BFBt preconditioner are listed. On the positive side one has the following:

1. In contrast to the PCD method, the preconditioner (2.9) is built from the matrices readily available. Indeed, matrices A and B are already in the system (1.8), and $\hat{M}_u$ is fairly easy to construct from M_u by the lumping procedure.
2. The preconditioner can be defined for general problems like (1.8), although in the general case one may need to find some other scaling matrices instead of the velocity mass matrix.
3. We found the BFBt preconditioner to be robust with respect to ν for the simplest parallel constant wind, $\mathbf{w} = (1, 0)$, and continuous pressure elements.
4. The issue of proper pressure boundary conditions does not arise explicitly.

On the other hand, one has the following:

1. The dependence on ν^{-1} is still observed for more complicated flows, like circulating flows.
2. h-independence of the convergence rate is observed for the special case of small ν, parallel constant wind with isoP_2-P_1 elements. Otherwise the BFBt method shows some h-dependence.
3. Two pressure Poisson problems should be solved instead of one, as for the PCD preconditioner.

We have no clear explanation of why, for certain discretizations, the mesh-dependent convergence rates occur for the BFBt preconditioner (see some arguments in section 2.3). In [16] and [17] Elman observed some h-dependence in the convergence rate of the GMRES method using the BFBt preconditioner for the finite difference (MAC) and finite element Q_2-Q_1 discretizations. Some h-dependence was also observed by Vainikko and Graham in [39] with Q_2-P_{-1} elements and by Hemmingsson and Wathen in [26] with a finite difference method. In all these papers the variant of the preconditioner with identity matrices instead of $\hat{M}_u$ in (2.9) was used. In the recent paper [18] it was noted that introducing $\hat{M}_u$ in (2.9) improves the situation significantly in the case of Q_2-Q_1 finite element discretizations, leading to virtually no h-dependence. The explanation of this phenomenon was partially heuristic. Furthermore, if one considers a uniform grid and applies finite differences or finite elements with piecewise linear velocity, then $\hat{M}_u$ is a scaled identity matrix (at least for the case of Dirichlet boundary conditions in (1.3)). Thus in this case the matrix $\hat{M}_u$ in (2.9) has no effect on the preconditioner. We note that a possible deterioration of convergence rates is consistent with available eigenvalue estimates for this preconditioner (see (3.2)) which also show the h-dependence.

An attempt to extend the preconditioner for the pressure-stabilized elements was recently made by Elman and coauthors [19]. It leads to a somewhat more complicated definition of $\hat{S}^{-1}$.

We have not found results in the literature about the performance of the BFBt preconditioner in the case of stretched grids.

2.3. More preconditioners. Our motivation is to build a preconditioner based on available matrices (blocks) in the spirit of BFBt with similar "robustness" properties with respect to ν, but without possible convergence failures for small h. To this end, let us consider the preconditioner (2.9) once again. If one ignores the velocity stabilization terms in A, the continuous counterpart of the BFBt preconditioner can be written as

$$\Delta_N^{-1}\mathrm{div}\,(-\nu\Delta+\mathbf{w}\cdot\nabla)\,\nabla\,\Delta_N^{-1}, \tag{2.10}$$

where Δ_N^{-1} is the solution operator for the Poisson problem with Neumann boundary conditions. Consider the operator (2.10) acting on some $p\in L_2(\Omega)$. Trouble might be caused by the lack of a proper tangential boundary condition for $\mathbf{v}=\nabla\,\Delta_N^{-1}p$. Indeed, for the normal component of $\mathbf{v}$ we have $\mathbf{v}\cdot\mathbf{n}=0$ on $\partial\Omega$, but the tangential component does not necessarily vanish on $\partial\Omega$. At the same time the computing of $(\nu\Delta+\mathbf{w}\cdot\nabla)\mathbf{v}$ requires $\mathbf{v}=0$ on $\partial\Omega$, since the discrete counterpart of $(\nu\Delta+\mathbf{w}\cdot\nabla)$—matrix A—was built assuming homogeneous Dirichlet boundary conditions for velocity. Similarly, for the vector function $\mathbf{u}=(\nu\Delta+\mathbf{w}\cdot\nabla)\mathbf{v}$ the normal condition $\mathbf{u}\cdot\mathbf{n}=0$ is not ensured, although this condition was used to define the matrix B—a discrete counterpart of div. Another relevant question is whether the operator in (2.10) is well defined in a bounded domain as an operator from L_0^2 to L_0^2. It can be shown that this requires the H^2-regularity assumption for the Poisson problem and proper homogeneous boundary conditions for the intermediate function $\mathbf{u}$ as discussed above.

It is necessary to point out that such regularity and boundary condition issues formally do not arise on the discrete level. However, the failure of the discrete operator to approximate a well-posed continuous counterpart as $h\to 0$ may be a reason for the h-dependence of the BFBt preconditioner for some discretizations.

The suggested remedy is to commute ∇ and div with Δ_N^{-1} in (2.10). We obtain

$$\mathrm{div}\,\Delta_0^{-1}(-\nu\Delta+\mathbf{w}\cdot\nabla)\,\Delta_0^{-1}\nabla, \tag{2.11}$$

where Δ_0^{-1} is a solution operator for the velocity vector Poisson problem with Dirichlet boundary conditions. Note that instead of the pressure Poisson problem like in the PCD and BFBt preconditioners the new approach involves the velocity Poisson problem. This allows one to avoid issues of pressure boundary conditions and regularity. The commutation property which we used holds only with special boundary conditions, e.g., periodic; this property is even more questionable for discrete operators. However, variants of such commutation arguments are often used in the literature to deduce PCD and BFBt preconditioners. The discrete operator corresponding to (2.11) is

$$\hat{S}^{-1}:=\hat{M}_p^{-1}BL^{-1}AL^{-1}B^T\hat{M}_p^{-1}. \tag{2.12}$$

Here L^{-1} is an approximate solve for the discrete velocity vector Poisson problem.

Our observations about this preconditioner are the following. On the positive side one has the following:

1. The preconditioner (2.12) is built from the matrices already available: matrix L is the diffusion part of matrix A.
2. The action of L^{-1} may be performed using the same technology as that of $\hat{A}^{-1}$ (MG, AMG, etc.).

3. Since the preconditioner does not use a discrete pressure Poisson solver, the issue of appropriate boundary conditions does not arise.
4. Preconditioner (2.12) can be easily extended for more general linearized Navier–Stokes-type problems.
5. In our experiments preconditioner (2.12) shows h-independent convergence results in a wider set of cases: both FE choices, various convection fields, up to $\nu = 10^{-3}$. This is supported by the h-independent eigenvalue estimates, which we prove in the next section.

On the other hand, one has the following:

1. Dependence on ν^{-1} is observed for more complicated flows, like circulating flows.
2. For the diffusion dominated case the condition number of the preconditioned matrix $\hat{S}^{-1}S$ is squared compared to the optimal mass matrix preconditioner. Indeed, if $\mathbf{w} = 0, \nu = 1$, and L^{-1} is the exact inverse, we have $A = L$ and
$$\hat{S}^{-1}S = \hat{M}_p^{-1}BL^{-1}AL^{-1}B^T\hat{M}_p^{-1}S = (\hat{M}_p^{-1}S)^2.$$
This results in nearly doubling the iteration numbers for the diffusion dominated case.
3. Compared to the PCD and BFBt preconditioners, the matrix L in (2.12) has a larger dimension than L_p or $(B\hat{M}_u^{-1}B^T)$.

Remark 2.1. Similar to BFBt, the new preconditioner (2.12) cannot be immediately used for the LBB unstable finite elements. However, for this case it admits a simple modification:
$$S^{-1} := \hat{M}_p^{-1}(BL^{-1}AL^{-1}B^T + C)\hat{M}_p^{-1}.$$
It is easy to show that for the symmetric case this modification ensures h-independent convergence. For the nonsymmetric case h-independent eigenvalue bounds will be proved in the next section.

Let us also mention a method from [9] for constructing a preconditioner $\hat{S}$. The approach is quite different from the techniques considered above. It is based on a hierarchical matrix technique for building approximate inverses for matrices. However, the numerical experiments in [9] show a large setup time in this approach, which makes it rather expensive in practice. Finally, we remark that effective pressure Schur complement preconditioners can be built for the linearized Navier–Stokes equations with nonlinear terms written in the rotation form [33, 31].

3. Eigenvalues estimates. It is well known that characterizing the rate of convergence of nonsymmetric preconditioned iterations can be a difficult task. In particular, eigenvalue information alone may not be sufficient to give meaningful estimates of the convergence rate of a method like preconditioned GMRES [25]. The situation is even more complicated for a method like BiCGStab, for which virtually no convergence theory exists. Nevertheless, experience shows that for many linear systems arising in practice, a well-clustered spectrum (away from zero) usually results in rapid convergence of the preconditioned iteration. Therefore, in this section we recall some known estimates for the eigenvalues of the preconditioned Schur complement with the PCD (2.1) and BFBt (2.9) preconditioners for LBB stable elements. Bounds for the PCD preconditioning will be extended to the pressure stabilized case. Also we prove analogous estimates for the new preconditioning (2.12).

Below we use the following notation: $\|\cdot\|$, $\langle\cdot,\cdot\rangle$ denotes the Euclidean norm and scalar product. We also define the norm $\|q\|_* := \langle M_p^{-1}q, q\rangle^{\frac{1}{2}}$. Note that for a matrix

$D \in \mathbb{R}^{m\times m}$ and corresponding matrix norms it holds that $\|D\|_* = \|M_p^{-\frac{1}{2}} D M_p^{\frac{1}{2}}\|$. Furthermore, the PCD preconditioner from (2.1) we denote by S_1, the BFBt preconditioner from (2.9) we denote by S_2, and S_3 will be the new preconditioner from (2.12).

Assume a quasi-uniform discretization (partition into triangles or quadrilaterals) of Ω. Let h denote a maximum diameter of elements. Assume that finite element spaces $\mathbb{V}_h$ and $\mathbb{Q}_h$ satisfy standard approximation properties and inverse inequalities. For the LBB stable case in [20] the following bounds for the eigenvalues of the preconditioned Schur complement were proved:

$$c_1 \le |\lambda(S{S_1}^{-1})| \le C_1, \tag{3.1}$$

$$c_2 \le |\lambda(S{S_2}^{-1})| \le C_2 h^{-2} \tag{3.2}$$

with positive constants c_1, c_2, C_1, C_2 independent of the meshsize h. For the pressure stabilized case ($C \neq 0$) we do not find in the literature any eigenvalue estimates with the PCD preconditioner S_1. Hence we give the proof of such bounds below in Theorem 3.2. As we already mentioned, using the BFBt preconditioner S_2 in the pressure stabilized case is not straightforward and requires some modifications [19]; this modified preconditioner is not considered in the paper. Also no eigenvalue estimates are known for the modified preconditioning.

Remark 3.1. The constants in (3.1), (3.2) may depend on other parameters; in particular, they depend on viscosity ν. It is hard to find this dependence in an optimal way. At the same time, one-dimensional analysis from [16] suggests that the upper bound in (3.2) may be tight with respect to h at least for some discretizations.

The following theorem extends results in (3.1) for the LBB unstable case and provides h-independent bounds for preconditioner (2.12). For the sake of brevity we prove the theorem assuming the exact inverses M_p^{-1} and L^{-1}. More practical choices involving the use of spectrally equivalent preconditioners do not change the result.

THEOREM 3.2. *For a quasi-uniform discretization of Ω assume that finite element spaces $\mathbb{V}_h$ and $\mathbb{Q}_h$, forming a* not *necessarily LBB stable pair, satisfy standard approximation and inverse inequalities. Assume conditions* (1.5)–(1.7) *for the bilinear forms of the discrete Oseen problem. The following estimates hold:*

$$c_1 \le |\lambda(S{S_1}^{-1})| \le C_1, \tag{3.3}$$

$$c_3 \le |\lambda(S{S_3}^{-1})| \le C_3 \tag{3.4}$$

with positive constants c_1, C_1, c_3, C_3 independent of the meshsize h.

To prove the theorem we will need several auxiliary estimates, which we put together in the following lemma.

LEMMA 3.3. *The ellipticity, continuity, and stability assumptions* (1.5)–(1.7)

yield the following estimates involving matrices A, L, B, C, and M_p:

$$\alpha_1\alpha_2^{-2}\|z\|^2 \le \langle A^{-1}L^{\frac12}z, L^{\frac12}z\rangle \qquad \forall\, z\in\mathbb{R}^n, \tag{3.5}$$

$$\|L^{\frac12}A^{-1}L^{\frac12}\| \le \alpha_1^{-1}, \tag{3.6}$$

$$\|L^{-\frac12}AL^{-\frac12}\| \le \alpha_2, \tag{3.7}$$

$$\|M_p^{-\frac12}BL^{-\frac12}\| = \|L^{-\frac12}B^TM_p^{-\frac12}\| \le \gamma_3, \tag{3.8}$$

$$\|M_p^{-\frac12}CM_p^{-\frac12}\| \le \gamma_2, \tag{3.9}$$

$$\langle (BL^{-1}B^T + C)q, q\rangle \ge \gamma_1^2\langle M_pq, q\rangle \qquad \forall\, q\in\mathbb{R}^m. \tag{3.10}$$

Proof. Note that the continuity and ellipticity estimates from (1.5) can be rewritten in the matrix-vector notation

$$\langle Au, v\rangle \le \alpha_2\|L^{\frac12}u\|\|L^{\frac12}v\| \qquad \forall\, u, v\in\mathbb{R}^n, \tag{3.11}$$

$$\alpha_1\|L^{\frac12}u\|^2 \le \langle Au, u\rangle \qquad \forall\, u\in\mathbb{R}^n. \tag{3.12}$$

For arbitrary $z\in\mathbb{R}^n$ consider $u = A^{-1}z$ and $v = L^{-1}z$. Due to (3.11) and (3.12) one gets

$$\begin{aligned}\langle L^{-1}z, z\rangle = \langle v, z\rangle = \langle v, Au\rangle &\le \alpha_2\|L^{\frac12}u\|\|L^{\frac12}v\| = \alpha_2\|L^{\frac12}u\|\langle L^{-1}z, z\rangle^{\frac12}\\ &\le \alpha_1^{-\frac12}\alpha_2\langle Au, u\rangle^{\frac12}\langle L^{-1}z, z\rangle^{\frac12} = \alpha_1^{-\frac12}\alpha_2\langle A^{-1}z, z\rangle^{\frac12}\langle L^{-1}z, z\rangle^{\frac12}.\end{aligned}$$

This yields $\langle L^{-1}z, z\rangle \le \alpha_1^{-1}\alpha_2^2\langle A^{-1}z, z\rangle$ for any $z\in\mathbb{R}^n$ which is equivalent to (3.5). Furthermore, consider the following relations:

$$\begin{aligned}\langle A^{-1}z, z\rangle = \langle u, z\rangle = \langle u, Lv\rangle &\le \|L^{\frac12}u\|\|L^{\frac12}v\| \le \alpha_1^{-\frac12}\langle Au, u\rangle^{\frac12}\|L^{\frac12}v\|\\ &= \alpha_1^{-\frac12}\langle A^{-1}z, z\rangle^{\frac12}\langle L^{-1}z, z\rangle^{\frac12}.\end{aligned}$$

Thus we obtain

$$\alpha_1\langle A^{-1}z, z\rangle \le \langle L^{-1}z, z\rangle \qquad \forall\, z\in\mathbb{R}^n.$$

We use this inequality and (3.12) to check

$$\langle A^{-1}z, y\rangle \le \alpha_1^{-1}\langle L^{-1}z, z\rangle^{\frac12}\langle L^{-1}y, y\rangle^{\frac12} \qquad \forall\, y, z\in\mathbb{R}^n. \tag{3.13}$$

Indeed, denoting $u = A^{-1}z$ and $v = L^{-1}y$, we have

$$\begin{aligned}\langle A^{-1}z, y\rangle = \langle u, y\rangle = \langle u, Lv\rangle &\le \|L^{\frac12}u\|\|L^{\frac12}v\| \le \alpha_1^{-\frac12}\langle Au, u\rangle^{\frac12}\langle L^{-1}y, y\rangle^{\frac12}\\ &= \alpha_1^{-\frac12}\langle A^{-1}z, z\rangle^{\frac12}\langle L^{-1}y, y\rangle^{\frac12} \le \alpha_1^{-1}\langle L^{-1}z, z\rangle^{\frac12}\langle L^{-1}y, y\rangle^{\frac12}.\end{aligned}$$

Now (3.6) follows from (3.13) through

$$\|L^{\frac12}A^{-1}L^{\frac12}\| = \sup_{x\ne0}\sup_{y\ne0}\frac{\langle L^{\frac12}A^{-1}L^{\frac12}x, y\rangle}{\|x\|\|y\|} = \sup_{x\ne0}\sup_{y\ne0}\frac{\langle A^{-1}x, y\rangle}{\|L^{-\frac12}x\|\|L^{-\frac12}y\|} \le \alpha_1^{-1}.$$

In the same way (3.7) follows from (3.11):

$$\|L^{-\frac{1}{2}}AL^{-\frac{1}{2}}\| = \sup_{u\neq 0}\sup_{v\neq 0}\frac{\langle L^{-\frac{1}{2}}AL^{-\frac{1}{2}}u,v\rangle}{\|u\|\|v\|} = \sup_{u\neq 0}\sup_{v\neq 0}\frac{\langle Au,v\rangle}{\|L^{\frac{1}{2}}u\|\|L^{\frac{1}{2}}v\|} \leq \alpha_2.$$

Finally, thanks to (1.7) we get

$$\|L^{-\frac{1}{2}}B^TM_p^{-\frac{1}{2}}\|$$

$$= \sup_{q\neq 0}\frac{\|L^{-\frac{1}{2}}B^Tq\|}{\|M_p^{\frac{1}{2}}q\|} = \sup_{q\neq 0}\sup_{v\neq 0}\frac{\langle L^{-\frac{1}{2}}B^Tq,v\rangle^{\frac{1}{2}}}{\|M_p^{\frac{1}{2}}q\|\|v\|} = \sup_{q\neq 0}\sup_{v\neq 0}\frac{\langle q,Bv\rangle^{\frac{1}{2}}}{\|M_p^{\frac{1}{2}}q\|\|L^{\frac{1}{2}}v\|} \leq \gamma_3$$

and $\|M_p^{-\frac{1}{2}}BL^{-\frac{1}{2}}\| = \|(L^{-\frac{1}{2}}B^TM_p^{-\frac{1}{2}})^T\| \leq \gamma_3$.

Inequalities (3.9) and (3.10) easily follow from the conditions (1.7) and (1.6), respectively. □

Now we are in position to prove Theorem 3.2.

Proof. The proof uses the technique of norm equivalence developed in [20]. In particular, we will show that

$$c_5\|M_pq\|_* \leq \|Sq\|_* \leq C_5\|M_pq\|_* \qquad \forall\ q\in\mathbb{Q}_h \tag{3.14}$$

and prove the estimates for S_k:

$$c_4\|M_pq\|_* \leq \|S_kq\|_* \leq C_4\|M_pq\|_*, \quad k=1,3, \qquad \forall\ q\in\mathbb{Q}_h. \tag{3.15}$$

From (3.15) and (3.14) one obtains the norm equivalence

$$c\|S_kq\|_* \leq \|Sq\|_* \leq C\|S_kq\|_*, \quad k=1,3, \qquad \forall\ q\in\mathbb{Q}_h \tag{3.16}$$

with mesh-independent positive constants c and C. To complete the proof one may consider the obvious inequalities

$$\|S_kS^{-1}\|_*^{-1} \leq |\lambda(SS_k^{-1})| \leq \|SS_k^{-1}\|_*. \tag{3.17}$$

As a consequence of (3.16) and (3.17) the estimate (3.4) follows from the eigenvalues of $S_k^{-1}S$ with some constants c_k, C_k independent of the meshsize h.

Therefore, we can focus on checking (3.14) and (3.15). First we prove (3.14). The upper bound in (3.14) follows from

$$\|SM_p^{-1}\|_* = \|M_p^{-\frac{1}{2}}(BA^{-1}B^T+C)M_p^{-\frac{1}{2}}\|$$

$$\leq \|M_p^{-\frac{1}{2}}BL^{-\frac{1}{2}}\|\|L^{\frac{1}{2}}A^{-1}L^{\frac{1}{2}}\|\|L^{-\frac{1}{2}}B^TM_p^{-\frac{1}{2}}\| + \|M_p^{-\frac{1}{2}}CM_p^{-\frac{1}{2}}\| \leq \gamma_3\alpha_1^{-1}+\gamma_2;$$

here we used estimates (3.6), (3.8), and (3.9). Next we find a lower bound for $\frac{\|SM_p^{-1}q\|_*}{\|q\|_*}$:

$$\inf_{q\neq 0}\frac{\|SM_p^{-1}q\|_*}{\|q\|_*} = \inf_{q\neq 0}\frac{\|M_p^{-\frac{1}{2}}SM_p^{-\frac{1}{2}}q\|}{\|q\|} \geq \inf_{q\neq 0}\frac{\langle M_p^{-\frac{1}{2}}SM_p^{-\frac{1}{2}}q,q\rangle}{\|q\|^2} \tag{3.18}$$

$$= \inf_{q\neq 0}\frac{\langle A^{-1}B^TM_p^{-\frac{1}{2}}q,B^TM_p^{-\frac{1}{2}}q\rangle + \langle CM_p^{-\frac{1}{2}}q,M_p^{-\frac{1}{2}}q\rangle}{\|q\|^2}$$

with use of the Cauchy–Schwarz inequality. Denoting $u = B^T M_p^{-\frac{1}{2}} q$ and applying (3.5) and (3.10), we continue with (3.18):

$$\inf_{q\neq 0} \frac{\|SM_p^{-1}q\|_*}{\|q\|_*} \geq \inf_{q\neq 0} \frac{\alpha_1\alpha_2^{-2}\langle L^{-1}B^T M_p^{-\frac{1}{2}} q, B^T M_p^{-\frac{1}{2}} q\rangle + \langle CM_p^{-\frac{1}{2}} q, M_p^{-\frac{1}{2}} q\rangle}{\|q\|^2}$$

$$= \inf_{q\neq 0} \frac{\langle (\alpha_1\alpha_2^{-2} BL^{-1}B^T + C)q, q\rangle}{\|M_p^{\frac{1}{2}} q\|^2} \geq \min\{\alpha_1\alpha_2^{-2}, 1\}\gamma_1^2.$$

Thus the lower bound in (3.14) is proved with the h-independent constant $c_5 = \min\{\alpha_1\alpha_2^{-2}, 1\}\gamma_1^2$.

For $k = 1$ inequalities (3.15) were proved in [20]. The proof in [20] does not use the LBB stability assumption. Thus we can use this result and conclude that eigenvalue bounds (3.3) hold with h-independent constants c_1, C_1.

To show (3.15) for $k = 3$ we first prove an upper bound on $\|M_p S_3^{-1}\|_*$. Thanks to (3.7), (3.8), and (3.9), one gets

$$\|M_p S_3^{-1}\|_* = \|M_p^{-\frac{1}{2}}(BL^{-1}AL^{-1}B^T + C)M_p^{-\frac{1}{2}}\|$$

$$\leq \|M_p^{-\frac{1}{2}} BL^{-\frac{1}{2}}\|\|L^{-\frac{1}{2}} AL^{-\frac{1}{2}}\|\|L^{-\frac{1}{2}} B^T M_p^{-\frac{1}{2}}\| + \|M_p^{-\frac{1}{2}} CM_p^{-\frac{1}{2}}\| \leq \gamma_3\alpha_2 + \gamma_2.$$

Hence the low bound in (3.15) holds with the h-independent constant $c_4 = \frac{1}{(\gamma_3\alpha_2+\gamma_2)}$.

Finally, we find an upper bound for $\|S_3 M_p^{-1}\|_*$:

$$\|S_3 M_p^{-1}\|_*^{-1} = \|M_p^{-\frac{1}{2}} S_3 M_p^{-\frac{1}{2}}\|^{-1} \tag{3.19}$$

$$= \inf_{q\neq 0}\sup_{p\neq 0} \frac{\langle M_p^{\frac{1}{2}} S_3^{-1} M_p^{\frac{1}{2}} q, p\rangle}{\|q\|\|p\|} \geq \inf_{q\neq 0} \frac{\langle M_p^{\frac{1}{2}} S_3^{-1} M_p^{\frac{1}{2}} q, q\rangle}{\|q\|^2}$$

$$= \inf_{q\neq 0} \frac{\langle AL^{-1}B^T M_p^{-\frac{1}{2}} q, L^{-1}B^T M_p^{-\frac{1}{2}} q\rangle + \langle CM_p^{-\frac{1}{2}} q, M_p^{-\frac{1}{2}} q\rangle}{\|q\|^2}.$$

Denote $u = L^{-\frac{1}{2}} B^T M_p^{-\frac{1}{2}} q$. The condition (3.12) yields $\langle AL^{-\frac{1}{2}} u, L^{-\frac{1}{2}} u\rangle \geq \alpha_1\|u\|^2$. Therefore, we continue with (3.19):

$$\|S_3 M_p^{-1}\|_*^{-1} \geq \inf_{q\neq 0} \frac{\alpha_1\langle L^{-\frac{1}{2}} B^T M_p^{-\frac{1}{2}} q, L^{-\frac{1}{2}} B^T M_p^{-\frac{1}{2}} q\rangle + \langle CM_p^{-\frac{1}{2}} q, M_p^{-\frac{1}{2}} q\rangle}{\|q\|^2}$$

$$= \inf_{q\neq 0} \frac{\langle (\alpha_1 BL^{-1}B^T + C)q, q\rangle}{\|M_p^{\frac{1}{2}} q\|^2} \geq \min\{\alpha_1, 1\}\gamma_1^2.$$

Thus the upper bound in (3.15) is proved with the h-independent constant $C_4 = (1 + \alpha_1^{-1})\gamma_1^{-2}$. ∎

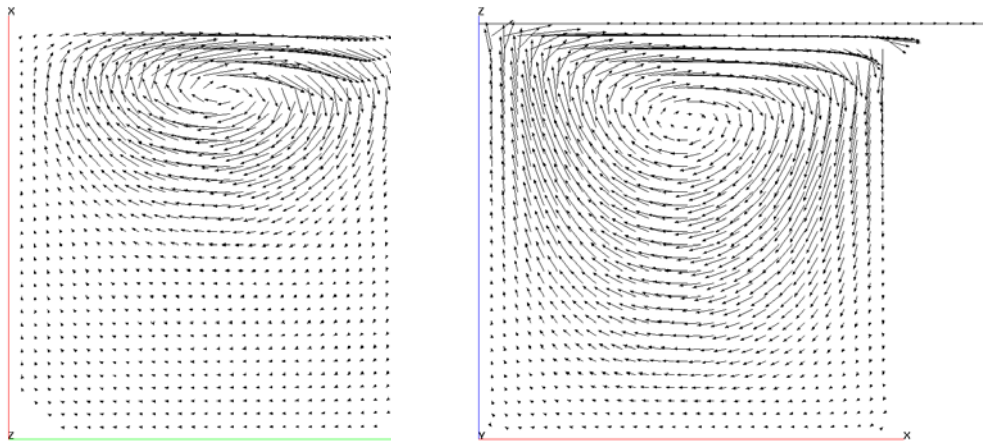

FIG. 4.1. *Left picture: The 2D velocity field* (4.2). *Right picture: The central cross-section by the OXZ-plane of the 3D velocity field.*

4. Numerical experiments. In this section we present numerical results for two model problems in $[0,1]^d$ for $d = 2, 3$. In the first problem the wind is parallel to the x-axis and constant:

$$\mathbf{w} = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad \text{or} \quad \mathbf{w} = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}. \tag{4.1}$$

The second problem is the linearized "driven cavity" problem. In the 2D case the velocity function is suggested in [7]:

$$\mathbf{w} = \begin{pmatrix} \frac{r_2}{2\pi}\frac{e^{r_2 y}}{(e^{r_2}-1)}\sin\left(\frac{2\pi(e^{r_2 y}-1)}{e^{r_2}-1}\right)\left(1-\cos\left(\frac{2\pi(e^{r_1 x}-1)}{e^{r_1}-1}\right)\right) \\ -\frac{r_1}{2\pi}\frac{e^{r_1 x}}{(e^{r_1}-1)}\sin\left(\frac{2\pi(e^{r_1 x}-1)}{e^{r_1}-1}\right)\left(1-\cos\left(\frac{2\pi(e^{r_2 y}-1)}{e^{r_2}-1}\right)\right) \end{pmatrix}, \tag{4.2}$$

where $r_1 = 4$, $r_2 = 0.1$. This type of convection simulates a rotating vortex, whose center has coordinates (x_0, y_0), $x_0 \approxeq 0.831$, $y_0 \approxeq 0.512$, and $\max_\Omega |\mathbf{w}| \approxeq 1$ (Figure 4.1, left). In the 3D case the convection velocity field $\mathbf{w}$ is the solution of the "driven cavity" Stokes problem (Figure 4.1, right).

For the discretization method we use isoP_2-P_0 and isoP_2-P_1 finite elements defined on uniform triangulation (tetrahedrization) of a square (cubic) mesh in $[0,1]^d$. The velocity triangulation is built by connecting the midpoints on the edges of triangles or tetrahedra. In all the cases the convection term is stabilized by using the SUPG stabilization [36]. In the tables below h denotes the size for the pressure triangulations.

We use the block triangular matrix (1.9) as a right preconditioner in the Krylov subspace method for solving system (1.8). Some details of experiments may differ in the 2D and 3D cases (cf. below), since we used two different FE software packages to treat 2D and 3D problems, respectively. In the 2D experiments we used the BiCGStab and for 3D ones the full GMRES method was applied as an outer iterative solver. Note that the expense of one BiCGStab iteration approaches the cost of two GMRES iterations. The stopping criterion is the 10^{-6} decrease of the Euclidean norm of the residual. The approximate inverses involved in the application of the

preconditioner (1.9) were computed as follows. The application of $\hat{A}^{-1}$ to a vector is achieved via 3 multigrid W(1,1)-cycles with the alternating Gauss–Seidel method as a smoother. In the 2D case a W-cycle of geometric multigrid was used, whereas in the 3D case a V-cycle of algebraic multigrid was adopted. Both choices give a fairly good approximation to A^{-1} for all values of h and ν under consideration. Application of $(B\hat{M}_u^{-1}B^T)^{-1}$ and L_p^{-1} was evaluated using 10 V(4,4)-cycles in the 2D case and exact sparse factorization in the 3D case. We note that although the latter method is applicable to general meshes, it is asymptotically not optimal. If N is the number of the pressure degrees of freedom, then the method needs about $O(N^{2.2})$ flops for the computation of $O(N^{1.5})$ nonzero entries in triangular factors. This limits the size of L_p to several tens of thousands for the PC we used for running numerical tests. At the same time, in the case of isoP_2-P_1 elements, N is less than the size of matrix A by a factor of 24, and the practical limit for N is not very restrictive. L^{-1} was evaluated using interior iterations to provide a very good approximation of the inversion. Thus all the inverses involved in all Schur complement preconditioners were evaluated with pretty high accuracy.

In the first experiment we illustrate the effect of different boundary conditions in A_p on the performance of the PCD preconditioner. Recall that our analysis in section 2.1 suggests that for the problem with **w** from (4.1) one should implement Dirichlet conditions at the inflow boundaries, while for the problem with **w** from (4.2) one should use Neumann conditions on the entire boundary. In Table 4.1 we compare iteration counts for the PCD preconditioner with different boundary conditions in A_p in two and three dimensions and for two types of convection flow **w**. For the case of **w** from (4.1) we test two variants of boundary conditions in A_p: one consists in setting Neumann boundary conditions on the whole boundary; alternatively, we set Dirichlet boundary conditions on the inflow and Neumann conditions on the rest of the boundary. For the case of **w** from (4.2) the problem has only characteristic boundaries; thus we test setting either Dirichlet or Neumann conditions in A_p on the whole boundary. It was mentioned in section 2.1 that Dirichlet boundary conditions may not be imposed on the boundary nodes, since these nodes contribute to the set of pressure degrees of freedom. The Dirichlet condition is imposed on fictitious boundary nodes of an h-extension of the original mesh. Therefore, the actual boundary nodes are considered as interior in the extended mesh. This may be implemented in two ways. For a rectangular mesh we simply copy matrix entries for interior nodes to

TABLE 4.2
Number of preconditioned iterations for isoP_2-P_1 FE. PCD/BFBt/preconditioner (2.12).

Meshsize h	Viscosity ν			
	0.1	0.01	10^{-3}	10^{-4}
w is 2D constant wind, #BiCGStab				
1/32	13 / 8 / 22	21 / 6 / 35	28 / 8 / 39	48 / 10 / 46
1/64	13 / 12 / 27	24 / 8 / 34	33 / 7 / 34	51 / 12 / 40
1/128	13 / 17 / 23	24 / 16 / 30	41 / 6 / 37	62 / 9 / 37
w is 2D cavity vortex, #BiCGStab				
1/32	12 / 9 / 27	24 / 14 / 29	56 / 30 / 70	248 / 120 / 242
1/64	12 / 13 / 27	22 / 20 / 31	64 / 45 / 76	619 / 211 / 314
1/128	13 / 17 / 29	25 / 26 / 33	77 / 61 / 69	1053 / 349 / 446
w is 3D cavity vortex, #GMRES				
1/8	35 / 71 / 129	46 / 104 / 178	112 / 233 / 512	243 / 437 / 787
1/16	38 / 82 / 143	50 / 102 / 167	114 / 415 / 781	462 / 1402 / >2000

matrix entries for actual boundary nodes. However, for a general mesh one has to generate the fictitious mesh layer by reflecting the close-to-boundary layer of cells with respect to the actual boundary.

In L_p we use Neumann conditions only. We found that changing boundary conditions in L_p does not improve convergence rates. Results of the experiments in Table 4.1 are consistent with the analysis in section 2.1. In particular, better results with Neumann conditions for the cavity vortex test confirm that this is the right choice on characteristic boundaries, for the constant wind Dirichlet boundary conditions on the inflow show an advantage for small enough ν. This behavior is also expected, since the analysis in section 2.1, predicting this choice, was done for the limit case of $\nu = 0$. The same phenomenon was observed in numerical experiments for discretizations with isoP_2-P_0 finite elements. Thus, further in the experiments we will always define A_p with Neumann conditions for rotating **w** and Dirichlet conditions at the "inflow" for **w** from (4.1).

In Table 4.2 we compare convergence results for all three preconditioners tested for the isoP_2-P_1 discretization of the Oseen problem with **w** from (4.1) and (4.2), the latter case being examined in both two and three dimensions. All preconditioners demonstrate almost h-independent results except for the case of small ν. In general, rotating flow with small viscosity turns out to be a hard problem for all preconditioners.

The difficulty in treating the case of small ν may be related to the fact that Navier–Stokes flows become less stable in this case. For example, in [2] it was found that the first point of bifurcation for the 2D driven cavity problem occurs around $Re = 8.018$. Therefore, for the case of small viscosity solving unsteady, rather then steady, Navier–Stokes equations can be more appropriate sometimes. After linearization the unsteady problem would lead to a slightly modified Oseen problem (1.1)–(1.3) with an additional positive-definite reaction term in the momentum equations. This additional term, when also included in a Schur complement preconditioner, may improve the performance of the preconditioned iterations for small values of ν [21].

Next we proceed to approximations with the isoP_2-P_0 finite element method. For this discretization with discontinuous pressure approximation the BFBt preconditioner shows a strong h-dependence result even for the simplest constant parallel flow. This is illustrated in Table 4.3.

In Table 4.4 we examine PCD and (2.12) preconditioners which demonstrate h-

TABLE 4.3
Number of preconditioned BiCGStab iterations for the BFBt preconditioner with isoP$_2$-P$_0$ FE.

Meshsize h	Viscosity ν			
	0.1	0.01	10^{-3}	10^{-4}
w is 2D constant wind				
1/32	39	35	52	71
1/64	80	65	93	147
1/128	174	141	154	219

TABLE 4.4
Number of preconditioned BiCGStab iterations for PCD/(2.12) preconditioner with isoP$_2$-P$_0$ FE.

Meshsize h	Viscosity ν			
	0.1	0.01	10^{-3}	10^{-4}
w is 2D constant wind				
1/32	9 / 17	11 / 24	21 / 36	68 / 58
1/64	9 / 13	12 / 23	21 / 32	57 / 66
1/128	9 / 11	14 / 23	25 / 31	50 / 59
w is 2D cavity vortex				
1/32	10 / 18	18 / 22	66 / 60	>2000 / 191
1/64	9 / 21	19 / 23	74 / 63	>2000 / 306
1/128	9 / 21	19 / 23	78 / 58	>2000 / 453

independent convergence rates at least for the simplest case (4.1). We note that in the PCD preconditioner we now use mixed approximation for the pressure Poisson problem: $L_p = (B\hat{M}_u^{-1}B^T)$. To define A_p, we set $F_p := r_{u\to p}\, A_x r_{p\to u}$, where A_x is the x-subblock of A (maybe with different boundary conditions), $r_{u\to p}$ and $r_{p\to u}$ are suitable mappings from $\mathbb{Q}_h$ to $\mathbb{V}_h$, and vice versa. The type of boundary conditions in A_p was taken the same as for isoP_2-P_1 discretizations. We observe that up to $\nu = 10^{-3}$ both methods exhibit feasible convergence rates, and for $\nu = 10^{-4}$ the PCD method fails to converge.

Finally, we remark that although Theorem 3.2 guarantees that all eigenvalues of preconditioned matrices lie in the right half of the complex plane and are bounded independent of h (at least for the PCD and (2.12) preconditioners), iteration counts in Tables 4.2 and 4.4 have some increase with $h \to 0$ in the case of small ν. A most likely explanation of this phenomenon is that the implicit dependence of the constants from bounds (3.3) and (3.4) on ν makes them not useful when $\nu \to 0$.

5. Conclusions. This paper studies a preconditioning technique for finite element discretizations of the Oseen problem arising from Picard linearizations of the steady Navier–Stokes equations. The preconditioner is block triangular and requires an approximation to the inverse of the pressure Schur complement matrix. We focus on several approaches for building the pressure Schur complement preconditioner. Two of them are well known from the literature and one is new. The preconditioners differ in implementation and performance for various discretizations and flow patterns. The paper gives an account of their properties and available theoretical results. We prove missing eigenvalue estimates and discuss some open implementation problems, such as the choice of an appropriate pressure boundary condition in the method of Kay, Loghin, and Wathen. Numerical experiments show that all the methods work satisfactorily (with mild dependence on ν) in the range of small and modest Reynolds numbers; however, they may experience serious loss of efficiency when the Reynolds

number is larger.
