A MULTIRESOLUTION APPROACH TO THE ELECTRIC FIELD INTEGRAL EQUATION IN ANTENNA PROBLEMS*

F. P. ANDRIULLI†, A. TABACCO†, AND G. VECCHI†

Abstract. This paper deals with a multiresolution approach to the finite-element solution of the electric field integral equation (EFIE) formulation of the boundary value problem for Maxwell equations. After defining a multiresolution set of discretized spaces, each of them is first separated into solenoidal and nonsolenoidal complementary spaces. The possibility of obtaining these two spaces with a scalar-to-vector space mapping is used to consider first two separate scalar wavelet decompositions, and then to transform them properly into the two desired vector finite-element sets, finally joined to obtain the complete multiresolution basis. Numerical results, obtained for real life antennas, are presented to verify the actual sparsity of the system matrix and to show the fast convergence behavior of iterative solvers.

Key words. multiresolution analysis, wavelets, integral equations, method of moments, triangular meshes, antennas

1. Introduction.

The problem of finding the electromagnetic field radiated by an antenna and its network parameters (impedance, scattering matrix) is of key importance in applied electromagnetics, and the related numerical simulation tools are part of all practical antenna design. The typical antenna structure is constituted of metal conductors (typically assumed ideal) and of dielectric bodies that are piecewise homogeneous; the related analysis thus amounts to the solution of Maxwell equations with boundary conditions to be enforced on the surface of material discontinuity. It is to be noted that a fully three-dimensional electromagnetic problem is intrinsically vector-valued and in general cannot be transformed in a straightforward manner to multiple scalar problems. Various numerical methods have been devised and applied to antenna analysis over the past decades, either based on the differential formulation of the boundary-value problem or on its transformation into an integral equation; for a review, one can, e.g., refer to [13].

In the following, we will explicitly consider antennas made of metal structures embedded in a homogeneous medium (air, vacuum, etc.) called "free space"; the metals will be considered perfect electric conductors (PECs). Although not directly addressed in the presented results, the method proposed here is directly applicable to the case of conductors embedded in a layered dielectric medium that can be considered infinite in two directions (as is commonly assumed in the analysis of "printed" antennas and circuits). We will consider the integral-equation formulation of the boundary-value problem for time-harmonic dependence, which is very well suited for this class of structures.

In our setting, we will consider antennas that can be modelled by a two-dimensional surface Γ that need not be close. The electric field integral equation (EFIE) for the boundary-value problem is obtained (see, e.g., [13]) by invoking the equivalence theorem ("Huygens' principle") to substitute the PEC surface with unknown equivalent surface currents $\boldsymbol{J}$ that radiate in free space; the total electric field $\boldsymbol{E}$ is then separated into a "primary" (or "incident") field $\boldsymbol{E}_{in}$ produced in free space by the independent sources, and a secondary (or "scattered") field $\boldsymbol{E}_{sc}$ produced by the equivalent currents, $\boldsymbol{E} = \boldsymbol{E}_{in} + \boldsymbol{E}_{sc}$. The boundary conditions on the conductor surface require that the total tangent field be zero, whose enforcement leads to the integral equation for the unknown current $\boldsymbol{J}$:

$$
\begin{aligned}
-i\omega\mu \iint_{\Gamma} \frac{e^{ik|\boldsymbol{r}-\boldsymbol{r}'|}}{4\pi\,|\boldsymbol{r}-\boldsymbol{r}'|}\ \boldsymbol{J}(\boldsymbol{r}')\ \mathrm{d}S(\boldsymbol{r}') + \\
+\frac{1}{\epsilon}\nabla_s \iint_{\Gamma} \frac{e^{ik|\boldsymbol{r}-\boldsymbol{r}'|}}{4\pi\,|\boldsymbol{r}-\boldsymbol{r}'|}\nabla_s\cdot\boldsymbol{J}(\boldsymbol{r}')\ \mathrm{d}S(\boldsymbol{r}') - \boldsymbol{E}_{in}^{tan}(\boldsymbol{r}) = 0,
\end{aligned}
\tag{1.1}
$$

where a time dependence $\exp(-i\omega t)$ has been assumed and suppressed, ϵ and μ denote the permeability and the permittivity of the free space, $k = \omega\sqrt{\epsilon\mu}$ is the wave-number, and ∇_s indicates the surface divergence. The operator setting of the EFIE (1.1) and the solution spaces are discussed in [8, 4]. The discussion of the above issues is, however, outside the scope of the present paper, as will be explained later.

The parameters of practical interest (radiated field, impedance, etc.) are obtained from operations on the surface current $\boldsymbol{J}$. In scattering problems, the source term $\boldsymbol{E}_{in}$ is typically an incident plane (or spherical) wave radiated by a distant source; the connection between the source term and the physical problem is more involved for antennas, where the feeding region is part of the problem. The typical choice is to relate the primary field $\boldsymbol{E}_{in}$ to the so-called voltage-gap between the antenna (circuit) terminals (e.g., [13]). A more satisfactory model involves magnetic-current sources [2, 5, 10], and it can be shown that in this case the impedance is a stationary (variational) functional of the current $\boldsymbol{J}$; however, implementation of this source modelling is clumsier than the widespread voltage-gap approximation.

The numerical solution of the problem is customarily obtained via finite-element approximation of the unknown $\boldsymbol{J}$ and weighted-residual (weak) enforcement of the EFIE (1.1). Summarizing the basic steps of the procedure, one begins with choosing an approximating space X of finite dimension d, spanned by a suitable basis x_i, $i = 1 \dots d$, yet to be discussed, and accordingly expressing the approximate sought-for solution via

$$
\boldsymbol{J} = \boldsymbol{J}_X + \boldsymbol{e}, \qquad \boldsymbol{J}_X = \sum_i I_i\, \boldsymbol{x}_i,
\tag{1.2}
$$

where $\boldsymbol{J}_X$ is the approximate solution, obtained by projection onto X, and $\boldsymbol{e}$ is the approximation error; when (1.2) is inserted into (1.1), the approximation error gives rise to a residual term. The equation (1.1) is then weakly enforced by requiring that the residual term be zero upon projection onto a specified finite-dimensional test space T; the most common choice is the Galerkin choice, in which $T = X$. This gives rise to the finite-dimensional linear system

$$
\left[Z^A + Z^{\phi}\right][I] = [V],
\tag{1.3}
$$

where

$$\left[Z^A\right]_{p,q} = i\omega\mu \int_\Gamma \boldsymbol{x}_p(\boldsymbol{r}) \cdot \int_\Gamma \frac{e^{ik|\ -\ '|}}{4\pi\,|\boldsymbol{r}-\boldsymbol{r'}|} \boldsymbol{x}_q(\boldsymbol{r'})\ \mathrm{d}S(\boldsymbol{r'})\,\mathrm{d}S(\boldsymbol{r}), \tag{1.4}$$

$$\left[Z^\phi\right]_{p,q} = -\frac{i}{\omega\epsilon} \int_\Gamma \nabla_s \cdot \boldsymbol{x}_p(\boldsymbol{r}) \cdot \int_\Gamma \frac{e^{ik|\ -\ '|}}{4\pi\,|\boldsymbol{r}-\boldsymbol{r'}|} \nabla_s \cdot \boldsymbol{x}_q(\boldsymbol{r'})\ \mathrm{d}S(\boldsymbol{r'})\,\mathrm{d}S(\boldsymbol{r}), \tag{1.5}$$

$$[V]_i = -\int_\Gamma \boldsymbol{x}_i(\boldsymbol{r}) \cdot E_i^{tan}(\boldsymbol{r})\ \mathrm{d}S(\boldsymbol{r}), \tag{1.6}$$

$$[I]_i = I_i. \tag{1.7}$$

The overall approach is a boundary-element method, but in computational electromagnetics the above approach is widely known with the name "method of moments" (MoM). For a general shape conductor, the construction of the approximation space X has two steps: (a) the construction of a mesh on the surface Γ, or surface discretization, and (b) the construction of an appropriate finite-element basis over the cells of the mesh. In the following, we will assume the most employed such basis, constructed upon a triangular-facet approximation of the actual geometry; the basis was first introduced in computational electromagnetics by Rao, Wilton, and Glisson in [15], and since then the basis functions have been called RWG; for a discussion on the history of this basis see [13]. The RWG functions are edge-defined (e.g., there is one RWG function per inner edge of the mesh) and are linear-tangential continuous-normal (LTCN) with respect to the defining edge; they are also div-conforming (refer to section 2 for the formal definition). The system matrix $[Z] = \left[Z^A\right] + \left[Z^\phi\right]$ is fully populated, with poor conditioning and poor convergence performance of iterative solvers for practical large problems. Furthermore, the condition number of the problem and the speed of convergence degrade with increasing density of the mesh (e.g., [23]).

Among the several attempts to overcome the difficulties of the standard approach, the properties of multiresolution representations have attracted researchers of computational electromagnetics. Chief among these is the property of having, under certain conditions, vanishing moments; this is usually considered the key to the sparsification of the MoM matrix, i.e., the clipping of entries below a given threshold. The earlier works (e.g., [18, 7]), and many of those that use more structured wavelets, are confined to the analysis of two-dimensional (i.e., scalar) problems, or to wire-type problems in which the current direction is one-dimensional. For the sake of brevity we will not attempt to list them here, since this work specifically concentrates on the issue of vector electromagnetic problems for surfaces. Due to the difficulties of extending wavelets to this latter class of problems, applications in this sense are more recent; in [1, 16, 9] the analysis of planar circuits on rectangular meshes is addressed, taking advantage of the separability of the current into two Cartesian components. A wavelet-related approach has been applied to scattering from plates in [19], again employing the separability of the problem, and to triangular grids in [20] separating the current directions into local Cartesian and diagonal components. In [12], Coifman intervallic wavelets are applied to scattering problems from closed smooth bodies, for which the surface current can be conveniently decomposed along two locally orthogonal directions (azimuth and elevation components on spheres and spheroids).

In our approach, we want to keep the geometric flexibility of the RWG approach, yet construct a multiresolution (MR) basis for X; our procedure will generate a hierarchical sequence of successively refined meshes over which the MR functions will be

defined, but in the end we will be able to express all of our MR basis as a linear combination of the RWG basis for the finest mesh. This has the important consequence that the present method allows the reuse of existing MoM codes for the RWG basis.

Another relevant feature of our approach is the use of the MR basis as a preconditioner; i.e., in addition to the more usual emphasis on the sparsifying potential of the MR bases, we will also focus on the effect of the MR transformation on the spectrum of the system matrix, as it results from the improved convergence properties of iterative solvers.

In our approach, we employ first a mapping between the approximate current $\boldsymbol{J}_X$ and two isotropically scalar quantities [22] that can be viewed as projection of the Helmholtz decomposition onto the RWG space X. This allows the use of scalar MR functions on triangular grids, and this issue has already been addressed in the literature [21]. The vector-to-scalar transformation will be done with a proper operator mapping, which ensures the preservation of the necessary wavelet properties. The employed mapping to scalars is based on the separation of the current $\boldsymbol{J}_X$ into a solenoidal component and a quasi-irrotational remainder. The side benefit of this decomposition is that it prevents the low-frequency problem of the EFIE, i.e., the instability that appears when the cell size is much smaller than the wavelength, as often happens when the size of the mesh cells is dictated by frequency-independent fine geometrical details and not by the operating wavelength.

The present approach follows the strategy outlined in [14] and applied there to planar and quasi-planar antennas and circuits on rectangular grids. Here, we extend that approach to a triangular grid; the present paper has to be considered a companion to [25]. The emphasis of the present paper is on the mathematical properties of the developed MR vector-valued basis; conversely, a detailed account of the algorithmic issues and their application is given in [25, 24].

The paper is organized as follows: In section 2 we describe the MR analysis setting. All the computation and justification are postponed to the appendices in order to avoid technicalities at a first reading. Finally, in section 3 we present our numerical results and we compare them with the previous approaches.

2. Multiresolution analysis. We start defining projection spaces X_j that will be used in the following. In doing this we need a triangular mesh on Γ. For sake of simplicity we will assume that Γ is a faceted structure; i.e., the triangularization can be obtained using planar triangles (examples can be found in Figures 3.1, 3.2, and 3.3). If this is not verified, a continuous bijection is needed in addition to the following construction [26]. In antenna problems, a widely used finite-element space is the one introduced in [11] and applied to computational electromagnetics in [15], spanned by the so called [illegible] (RWG) functions. These are defined on the inner edges of the mesh, and, referring to Figure 2.1, their expression in local coordinates is

$$\boldsymbol{f}_p = \begin{cases} \dfrac{l_n}{2A_p^+}\rho_p^+, & \boldsymbol{r} \in T_p^+, \\ \dfrac{l_n}{2A_p^-}\rho_p^-, & \boldsymbol{r} \in T_p^-, \\ 0 & \text{otherwise.} \end{cases} \tag{2.1}$$

Let us define

$$X_j^{\mathrm{RWG}} = \operatorname{span}\left\{\boldsymbol{f}_1, \ldots, \boldsymbol{f}_{n_{ed}^j}\right\},$$

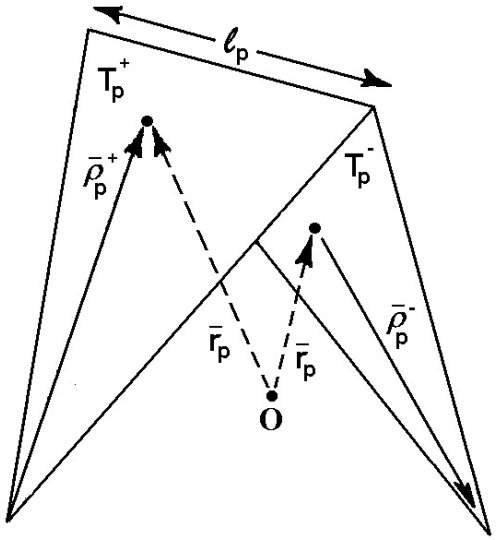

FIG. 2.1. *Rao–Wilton–Glisson function.*

where j labels a particular mesh and n_{ed}^j is the number of inner edges relative to the mesh j.

Considering the antenna surface Γ and a mesh at level j defined on it, we can obtain a finer mesh bisecting each edge (refer to Figure 2.2). The obtained mesh will be labelled $j+1$. Thus on each mesh one can define an RWG space, obtaining spaces X_j^{RWG}, X_{j+1}^{RWG}, $X_{j+2}^{\mathrm{RWG}}, \ldots$ which satisfy the inclusion relationship

$$X_j^{\mathrm{RWG}} \subset X_{j+1}^{\mathrm{RWG}} \tag{2.2}$$

(see Appendix B).

The relationship (2.2) makes spaces X_j^{RWG} eligible for a wavelet construction, according to the formal setting described in Appendix A.1. The coarsest mesh will be labelled $j = 0$. Referring to notation introduced in Appendix A.1, it is a natural choice to set $V_j = X_j^{\mathrm{RWG}}$. Now we look for spaces W_j^{RWG} that satisfy the decomposition relationship

$$X_{j+1}^{\mathrm{RWG}} = X_j^{\mathrm{RWG}} \oplus W_j^{\mathrm{RWG}}$$

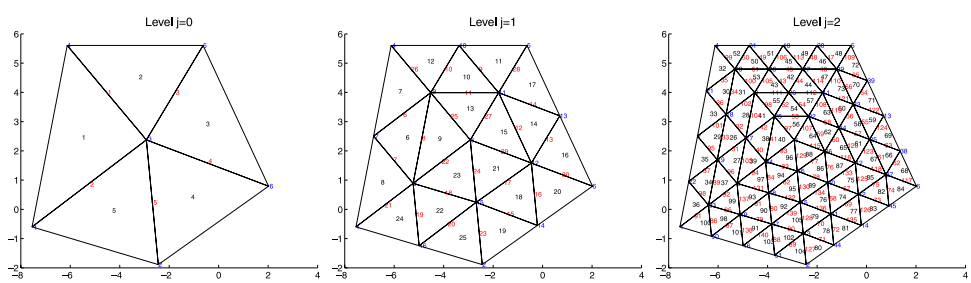

FIG. 2.2. *Different level meshes.*

or, equivalently,

$$X_l^{\mathrm{RWG}} = X_0^{\mathrm{RWG}} \oplus \bigoplus_{j=0}^{l} W_j^{\mathrm{RWG}}, \tag{2.3}$$

where X_0^{RWG} is the space spanned by the RWG functions defined on the coarsest level mesh.

The space W_j^{RWG} will be decomposed into two parts denoted W_j^T and W_j^B, respectively. The space W_j^T is obtained working separately on each cell. More precisely,

$$W_j^T = \bigoplus_{i=1}^{n_{cell}^0} W_{j,i}^T, \tag{2.4}$$

where the spaces $W_{j,i}^T$ are suitable detail spaces of functions with domains included in each of the single coarsest level cells i. The space W_j^B is instead a connection space in the sense that

$$W_j^{\mathrm{RWG}} = W_j^T \oplus W_j^B \tag{2.5}$$

and it takes into account functions with domain between two cells of the coarsest level.

In choosing the basis functions, it is convenient to separate the basis element belonging to the kernel of operator $\nabla_s \cdot$, the so-called [illegible] (see [22]). For this reason the spaces $W_{j,i}^T$ will be obtained by maintaining this separation; in other words,

$$W_{j,i}^T = W_{j,i}^{TE} \oplus W_{j,i}^{qTM} \tag{2.6}$$

with

$$(\nabla_s \cdot)\left(W_{j,i}^{TE}\right) = 0. \tag{2.7}$$

2.1. The solenoidal spaces $\boldsymbol{W}^{\boldsymbol{E}}$. We recall that when i is fixed, we are looking for a decomposition starting from a single triangular cell. The space spanned by RWG functions defined on the mesh obtained by bisecting j times the triangular cell i will be called $T_{j,i}^{\mathrm{RWG}}$, and clearly $T_{j,i}^{\mathrm{RWG}} \subset X_j^{\mathrm{RWG}}$. A basis for the kernel of $\nabla_s \cdot$ acting on $T_{j,i}^{\mathrm{RWG}}$ (with fixed j) can be found by considering the loop functions (as introduced in [22]):

$$\boldsymbol{l}_n^j(\boldsymbol{r}) = \nabla_s \times \hat{n}\Lambda_n^j(\boldsymbol{r}), \quad n = 1, \ldots, n_{nodes}, \tag{2.8}$$

where $\hat{n}$ is the direction normal to the antenna surface, Λ_n^j is the scalar linear Lagrange nodal interpolating function defined on inner node n (equal to one at the node and linearly going to zero on all neighboring nodes), and n_{nodes}^j is the number of inner nodes of the mesh j (refer to Figure 2.3).

Observe that the elements of the space $\nabla_s \cdot (T_{j,i}^{\mathrm{RWG}})$ are the functions piecewise constant on each cell at level j with zero mean value. Indeed, referring to notation used in Figure 2.1,

$$\nabla_s \cdot \boldsymbol{f}_p = \begin{cases} l/A_p^+ & \text{when } \boldsymbol{r} \in T_p^+, \\ -l/A_p^+ & \text{when } \boldsymbol{r} \in T_p^-, \\ 0 & \text{elsewhere.} \end{cases} \tag{2.9}$$

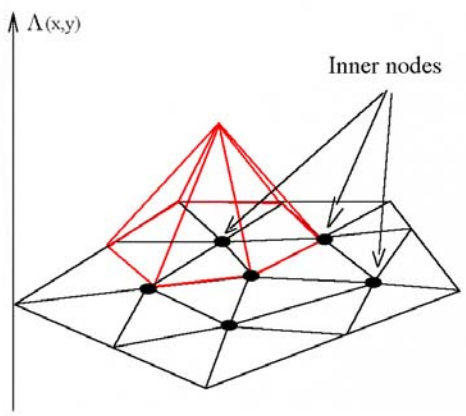

FIG. 2.3. Λ *function defined on an inner node.*

Moreover, the dimension of $\nabla_s \cdot (T_{j,i}^{\mathrm{RWG}})$ is equal to $n_{cell}^j - 1$, where n_{cell}^j is the number of cells at level j. In fact, from the Euler theorem

$$n_{cell}^j + n_{nodes}^j = n_{ed}^j + 1;$$

thus

$$\dim \ker(\nabla_s \cdot|_{T_{j,i}^{\mathrm{RWG}}}) = \dim T_j^{\mathrm{RWG}} - \dim \nabla_s \cdot \left(T_j^{\mathrm{RWG}}\right) = n_{ed}^j - n_{cell}^j + 1 = n_{nodes}^j.$$

Therefore, the functions $\boldsymbol{l}_n^j(\boldsymbol{r})$ belong to the kernel and are linearly independent.

Calling $V_{j,i}^{\Lambda}$ the space obtained by the span of Lagrange functions Λ_n^j on inner nodes

$$\ker(\nabla_s \cdot)|_{T_{j,i}^{\mathrm{RWG}}} = \nabla_s \times \hat{n}\left(V_{j,i}^{\Lambda}\right),$$

it is possible to obtain a wavelet construction for the spaces $V_{j,i}^{\Lambda}$ (refer, for example, to [26]). A basis of $V_{j+1,i}^{\Lambda}$ is obtained by adding to a basis of $V_{j,i}^{\Lambda}$ the functions Λ_n^{j+1}, where $n \in N_{j+1,i}^{new}$, the set of nodes of level $j+1$. In other words, we define

$$W_{j,i}^{\Lambda} = \mathrm{span}\left\{\Lambda_n^{j+1},\, n \in N_{j+1,i}^{new}\right\}$$

so that

$$V_{j+1,i}^{\Lambda} = V_{j,i}^{\Lambda} \oplus W_{j,i}^{\Lambda}.$$

According to the construction presented in section A.2 relative to the operator $\mathcal{A} = \nabla_s \times$, we obtain

$$W_{j,i}^{TE} = \mathrm{span}\left\{\boldsymbol{l}_n^{j+1},\, n \in N_{j+1,i}^{new}\right\} \tag{2.10}$$

and

$$\ker(\nabla_s \cdot|_{T_{j,i}^{\mathrm{RWG}}}) = \bigoplus_{y=0}^{j} W_{y,i}^{TE}. \tag{2.11}$$

2.2. The complementary spaces $\boldsymbol{W}_{\ }^{\ \boldsymbol{M}}$. We recall that $W_{j,i}^{qTM}$ is a space so that

$$T_{j+1,i}^{\mathrm{RWG}} = T_{j,i}^{\mathrm{RWG}} \oplus W_{j,i}^{TE} \oplus W_{j,i}^{qTM}. \tag{2.12}$$

Since we are working with finite dimension spaces, it is ensured that the decomposition

$$T_{j,i}^{\mathrm{RWG}} = \ker(\nabla_s \cdot|_{T_{j,i}^{\mathrm{RWG}}}) \oplus \ker(\nabla_s \cdot|_{T_{j,i}^{\mathrm{RWG}}})^c \tag{2.13}$$

holds. Taking into account the relationship (2.11), the equality (2.12) would be satisfied if

$$\ker(\nabla_s \cdot|_{T_{j,i}^{\mathrm{RWG}}})^c = \bigoplus_{y=0}^{j} W_{y,i}^{qTM};$$

in other words, it is sufficient to find a decomposition for $\ker(\nabla_s \cdot|_{T_{j,i}^{\mathrm{RWG}}})^c$ to satisfy (2.12). We will use again the approach explained in Appendix A.2 starting first from a scalar construction. The space $\nabla_s \cdot (T_{j,i}^{\mathrm{RWG}})$ considered before can be decomposed using a generalized Haar basis [26]. This is obtained, referring to Figure 2.4, by considering in each cell of level j the three functions

$$\psi_{1,k}^{j+1,i}(\boldsymbol{r}) = \begin{cases} 1, & \boldsymbol{r} \in T_4, \\ -1, & \boldsymbol{r} \in T_1, \\ 0 & \text{otherwise}, \end{cases} \tag{2.14}$$

$$\psi_{2,k}^{j+1,i}(\boldsymbol{r}) = \begin{cases} 1, & \boldsymbol{r} \in T_4, \\ -1, & \boldsymbol{r} \in T_2, \\ 0 & \text{otherwise}, \end{cases} \tag{2.15}$$

$$\psi_{3,k}^{j+1,i}(\boldsymbol{r}) = \begin{cases} 1, & \boldsymbol{r} \in T_4, \\ -1, & \boldsymbol{r} \in T_3, \\ 0 & \text{otherwise}. \end{cases} \tag{2.16}$$

In this way, letting $n_{cell}^{j,i}$ be the number of cells at level j obtained by bisecting j times edges of coarsest level cell i and defining the space

$$W_{j,i}^{H} = \operatorname{span}\left\{ \psi_{q,k}^{j+1,i},\ k = 1 \ldots, n_{cell}^{j,i},\ q = 1,2,3 \right\},$$

we have

$$\nabla_s \cdot \left(T_{j,i}^{\mathrm{RWG}}\right) = \bigoplus_{y=0}^{j} W_{y,i}^{H}. \tag{2.17}$$

We observe that the divergence operator can be inverted if restricted to the space $\ker(\nabla_s \cdot|_{T^{\mathrm{RWG}}})^c$ that excludes the div-free functions. Therefore, we consider the operator

$$\mathcal{A} = \left(\nabla_s \cdot|_{\ker(\nabla_s \cdot|_{T_{j,i}^{\mathrm{RWG}}})^c} \right)^{-1} \tag{2.18}$$

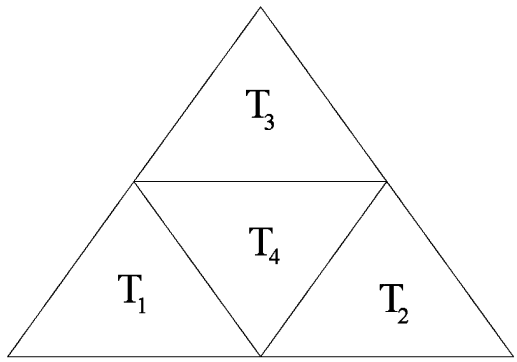

FIG. 2.4. *Cell conventions.*

and observe that

$$\mathcal{A}:\ \nabla_s\cdot\left(T_{j,i}^{\mathrm{RWG}}\right)\quad\mapsto\quad\ker(\nabla_s\cdot|_{T_{j,i}^{\mathrm{RWG}}})^c.$$

Using relationships (A.11), (2.17), and (2.18), we obtain

$$W_{j,i}^{qTM}=\mathrm{span}\left\{\mathcal{A}\left(\psi_{q,k}^{j+1,i}\right),\ k=1\ldots,n_{cell}^{j},\ q=1,2,3\right\}.$$

The interested reader can find a general approach to discretize the operator $\mathcal{A}$ in [22] (by setting to zero the solenoidal component of equation (22)); this allows one to find the RWG coefficients of image of any charge distribution, i.e., for any divergence of RWG functions. However, a generic implementation of $\mathcal{A}(\psi_{q,k}^{j+1,i})$ may result in spreading the support of the charge functions $\psi_{q,k}^{j+1,i}$ to significant portions of the structure, Γ. In this case, due to the simplicity of a single triangle domain (which is without loops), this is avoided by restricting the divergence operator to the complementary kernel with the mapping that leaves unchanged the function domains. In other words, the restriction is such that $\mathcal{A}\left(\psi_{q}^{k,j+1}\right)$ is simply the RWG with the same domain of the starting function $\psi_{q}^{k,j+1}$. A further modification of the mapping is necessary in order to obtain better moment properties for the basis: on each cell k of level j, we will consider the three functions

$$\begin{pmatrix}\boldsymbol{g}_{1,k}^{j+1,i}(\boldsymbol{r})\\ \boldsymbol{g}_{2,k}^{j+1,i}(\boldsymbol{r})\\ \boldsymbol{g}_{3,k}^{j+1,i}(\boldsymbol{r})\end{pmatrix}=\begin{pmatrix}-1&-1&1\\1&-1&-1\\1&1&1\end{pmatrix}\begin{pmatrix}\mathcal{A}\left(\psi_{1}^{k,j+1}\right)\\ \mathcal{A}\left(\psi_{2}^{k,j+1}\right)\\ \mathcal{A}\left(\psi_{3}^{k,j+1}\right)\end{pmatrix}$$

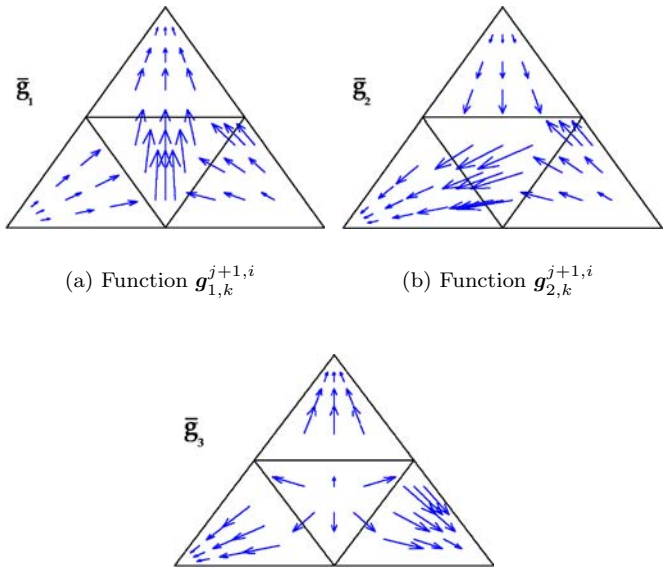
that are represented in Figures 2.5(a), 2.5(b), and 2.5(c).

Finally,

$$W_{j,i}^{qTM}=\mathrm{span}\left\{\boldsymbol{g}_{q}^{k,j+1},\ k=1\ldots,n_{cell}^{j},\ q=1,2,3\right\}\tag{2.19}$$

and

$$\ker(\nabla_s\cdot|_{T_{j,i}^{\mathrm{RWG}}})^c=\bigoplus_{y=0}^{j}W_{y,i}^{qTM}.\tag{2.20}$$



(a) Function $\boldsymbol{g}_{1,k}^{j+1,i}$ (b) Function $\boldsymbol{g}_{2,k}^{j+1,i}$

(c) Function $\boldsymbol{g}_{3,k}^{j+1,i}$

FIG. 2.5. *Basis functions for the* $W_{j,i}^{qTM}$ *space.*

2.3. The connection spaces W^B. Since spaces $T_{j,i}^{\mathrm{RWG}}$ are spanned by the RWG of level j completely included in the coarsest level cell i, it is clear that the spaces

$$T_j^{\mathrm{RWG}} = \bigoplus_{i=1}^{n_{cell}^0} T_{j,i}^{\mathrm{RWG}}$$

are spanned by RWG functions of level j completely included in one of the coarsest level cells. Moreover, from relationships (2.20), (2.11), (2.13), (2.6), (2.4), (2.5), and (2.3), we obtain

$$X_j^{\mathrm{RWG}} = T_j^{\mathrm{RWG}} \oplus X_0^{\mathrm{RWG}} \oplus \bigoplus_{y=0}^{j} W_y^B;$$

in other words, $X_0^{\mathrm{RWG}} \oplus \bigoplus_{y=0}^{j} W_y^B$ is the space of RWG of level j defined between two cells of coarsest level. Referring to the notation introduced in Appendix A.2, starting from X_0^{RWG} each RWG between two cells of a level j have to be substituted, at level $j+1$, by the two corresponding RWGs labelled I and II (refer to Figure B.1). For the relationship shown between the RWG function and the eight sub-RWGs in its domain, instead of taking the two $j+1$ level RWGs it is possible to maintain the RWG of level j and add a linear combination of the two $j+1$ level functions I and II. The most symmetric choice is to take the loop spanned by functions I, III, IV, II, VII, and VI. The linear independence of the chosen element is ensured by the fact that the two functions I and II have to be taken in the same direction to span the

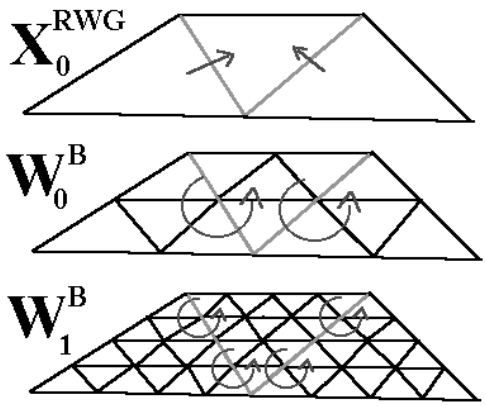


FIG. 2.6. *Spaces* W^B.

whole RWG and in opposite directions to span the loop. From these considerations it follows that

$$W_j^B = \text{span}\left\{\boldsymbol{l}_n^{j+1},\, n \in N_{j+1,edg}^{new}\right\}, \tag{2.21}$$

where $N_{j+1,edg}^{new}$ is the set of new nodes of level $j+1$. This is exemplified in Figure 2.6. With this last space, the decomposition of X_j^{RWG} is complete. We recall here that the completeness property of the decomposition is ensured, according to (2.3), (2.5), and (2.6), since we have proved the relationships (2.11), (2.20), and (2.21). Summarizing, the combination of the basis sets (2.10), (2.19) for each cell i and (2.21) represent an alternative basis for the space X_j^{RWG} that now will be used instead of RWG functions in (1.4), (1.5), and (1.6).

3. Numerical results. The surfaces Γ that will be considered represent some antenna structures that are actually usable in applications. The first structure is a wide band dipole known as a bowtie antenna. In Figure 3.1 the structure is presented with a mesh that is relative to the coarsest level $j = 0$. Two levels ($j = 0, 1, 2$) of the wavelets presented in this work have been used for this structure, so each edge of the coarsest level presented in Figure 3.1 has been bisected twice. The second structure is a sub-array of four printed patches (Figure 3.2, coarse level), a frequent configuration in the microstrip technology. Also for this structure the figure represents the coarsest level mesh, and two level of wavelets have been used. The last structure is a so-called log-periodic antenna (Figure 3.3, coarse level), which is a well-known wide band antenna; for this structure one level of wavelets ($j = 0, 1$) has been used. In the following, we will compare the performances of the MR basis with that of the conventional RWG basis. We remark here that the final spaces spanned by the RWG and by the wavelet basis are the same; in other words, the comparison is made by keeping constant the error on the discretization. The number of MR levels depends on the (average) cell dimension of the coarsest ($j = 0$) and finest meshes; the size of the coarsest mesh is essentially dictated by geometry, and the number of levels is then related to the desired level of RWG mesh fineness. It can be observed that the larger the number of levels, the better, but this obviously entails a larger number of unknowns. The numbers of levels adopted in the examples derive from a preliminary convergence study (with respect to finest mesh size) that is essentially the same as one

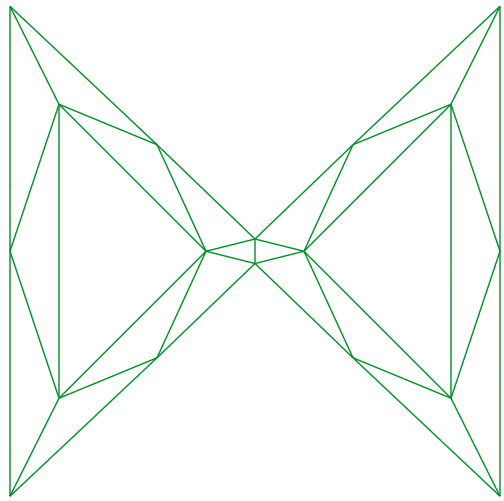

FIG. 3.1. Γ: *Bowtie.*

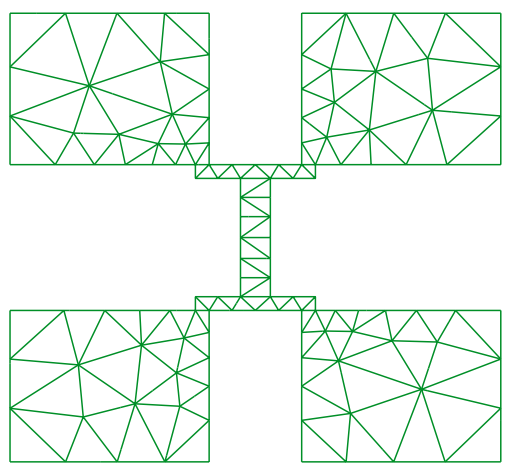

FIG. 3.2. Γ: *Patch array.*

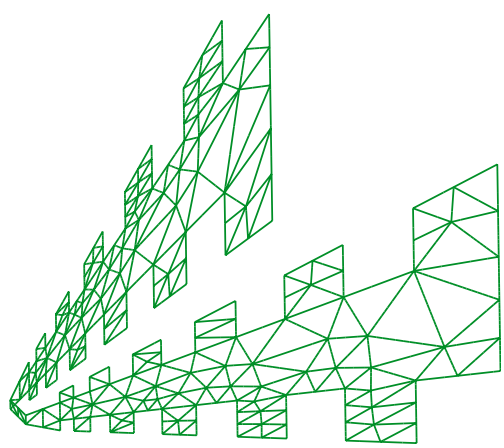

FIG. 3.3. Γ: *Log-periodic.*

would need to assess the smallest problem size versus accuracy using the usual RWG basis. On the other hand, the adopted numbers of levels appear sufficient to achieve the benefits of the multiscale nature of the basis, as will emerge from the results.

Prior to the solution, a [illegible] preconditioning is always effected, which is an integral constituent of the method (i.e., the basis allows a diagonal preconditioner to actually condition the system).

To solve the linear system (1.3) obtained by the numerical method, the modified Laczos conjugate gradient presented in [17] has been used. Before solving the system, the abovementioned diagonal preconditioning is used, and the functions of level $j = 0$ are made orthogonal using the singular value decomposition [25]. The performances of the new basis will be tested considering the number of iterations needed by the conjugate gradient (CG) to obtain a fixed relative residual on the solution; we have considered a rather restrictive threshold, 10^{-6}, to make sure that no convergence stagnation could be hidden by termination. The number of iterations of the modified conjugate gradient needed to solve the system obtained with the usual RWG basis is compared with the number of iterations needed with the basis presented in this work. This comparison is made for several frequencies $f = \frac{\omega}{2\pi}$, where ω is the constant which appears in (1.1). It is well known that the actual CG solution error is related to the residual and the matrix condition number. The results below, and those more extensively reported in [25], show that the condition number of the matrix obtained with MR is significantly lower than with RWG; therefore, comparing iterations counts for a fixed residual is indeed a conservative estimate of the MR performance with respect to RWG (the RWG solution error will be larger than with MR).

In Figure 3.4, we present the results for the bowtie antenna; the same analysis is performed for the other two structures, and the results are presented in Figures 3.5 and 3.6.

In order to put into better perspective the preconditioning performances of the proposed MR method, we have compared them with those achievable with the well-known incomplete LU (ILU) preconditioner. Other preconditioners have been developed for specific problems, including similar endeavors (e.g., [27]), but comparison with ILU can be considered a benchmarking. The test has been performed on the bowtie structure (Figure 3.7), and the parameter of the preconditioner at each frequency is set so that the preconditioner sparsity is always equal to $\frac{1}{3}$. This makes the

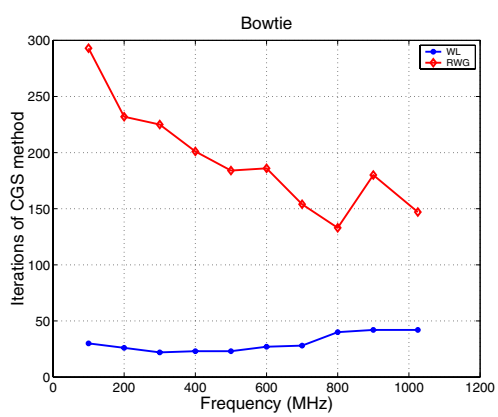

FIG. 3.4. *Bowtie: number of CG iterations of* RWG *basis versus wavelet basis.*

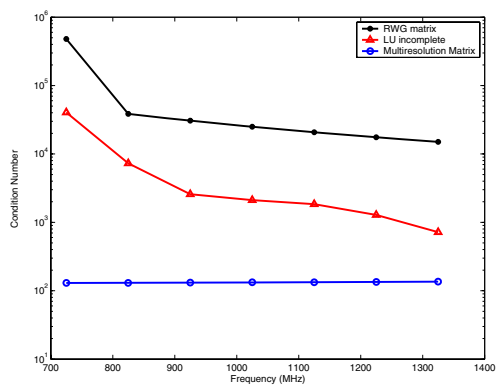

FIG. 3.7. *Condition number comparison for the* RWG *basis,* RWG *preconditioned with incomplete LU basis, and wavelet basis.*

cost of the LU preconditioning operation scale as $O(\frac{N}{3}^3)$, a choice that we consider impractical and clearly conservative. It can be observed that the MR always outper-

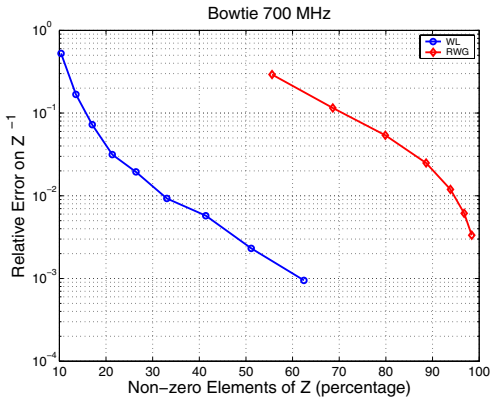

FIG. 3.8. *Bowtie:* RWG *basis versus wavelet basis sparsification properties.*

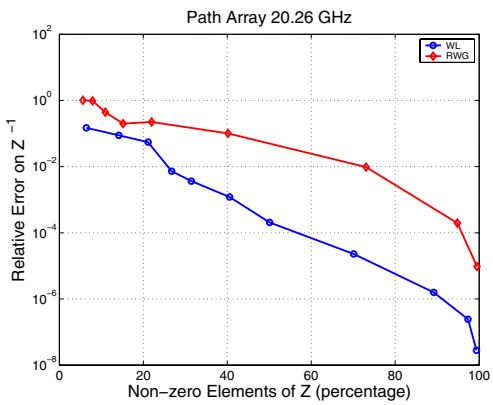

FIG. 3.9. *Patch array:* RWG *basis versus wavelet basis sparsification properties.*

forms the ILU in terms of condition number, even with the present parameter setting that makes the ILU preconditioning cost not comparable to that of MR.

As already stated in the introduction, a good condition number is not the only benefit that can be obtained using an MR basis; in fact, attention to conditioning properties is rather uncommon in wavelet applications in this field. The more usual achievement of a wavelet basis is that the matrix of the system can be sparsified with a low error on the solution by a thresholding operation, i.e., the setting to zero of all matrix entries below (in absolute value) a properly chosen threshold. We remark that the results discussed above refer to the convergence history of the matrix without any sparsification. Turning to sparsification, for the bowtie antenna this property is tested in Figure 3.8, where increasing sparsification percentages (number of zero elements over the total number of elements), due to the increasing threshold levels, are plotted versus the obtained relative error on the system solution. The test is performed with $f = 800$ MHz since this is a resonance frequency for the structure considered. With the same criterion, sparsification performances are tested for the other two structures in Figures 3.9 and 3.10, respectively. We finally observe that the condition number and iteration count do not change when the MR matrix is sparsified (not shown).

Appendix A. Multilevel decompositions. We will recall how to define a multilevel decomposition of a separable Banach space V, with norm denoted by $\|\cdot\|$. For more details and proofs we refer to, among others, [3, 6].

A.1. Abstract setting. Let $\{V_j\}_{j\in\mathbb{N}}$ be a family of closed subspaces of V such that $V_j \subset V_{j+1}$ for all $j \in \mathbb{N}$. For all $j \in \mathbb{N}$, let $P_j : V \to V_j$ be a continuous linear operator satisfying the following properties:

$$\|P_j\|_{\mathcal{L}(V,V_j)} \le C \qquad (\text{independent of } \cdot), \tag{A.1}$$

$$P_j v = v \qquad \forall v \in V_j, \tag{A.2}$$

$$P_j \circ P_{j+1} = P_j. \tag{A.3}$$

Observe that (A.1) and (A.2) imply

$$\|v - P_j v\| \le C \inf_{u\in V_j} \|v - u\| \qquad \forall v \in V,$$

where C is a constant independent of j. Through P_j, we define another set of operators $Q_j : V \to V_{j+1}$ by

$$Q_j v = P_{j+1} v - P_j v \qquad \forall v \in V,\ \forall j \in \mathbb{N},$$

and the detail spaces

$$W_j := \operatorname{Im} Q_j \qquad \forall j \in \mathbb{N},$$

where $\operatorname{Im} Q_j$ is the range of Q_j. Thanks to the assumptions (A.1)–(A.3), every Q_j is a continuous linear projection on W_j, the sequence $\{Q_j\}_{j\in\mathbb{N}}$ is uniformly bounded in $\mathcal{L}(V, V_{j+1})$, and each space W_j is a complement space of V_j in V_{j+1}, i.e.,

$$V_{j+1} = V_j \oplus W_j. \tag{A.4}$$

By iterating the decomposition (A.4), we get for any integer j_n,

$$V_{j_n} = V_0 \oplus \bigoplus_{j=0}^{j_n-1} W_j, \tag{A.5}$$

so that every element in V_{j_n} can be viewed as a rough approximation of itself on a coarse level plus a sum of refinement details. For each $j \in \mathbb{N}$, let us fix a basis for the subspaces V_j,

$$\Phi_j = \{\varphi_{jk} \,:\, k \in \breve{\mathcal{K}}_j\}, \tag{A.6}$$

and for the subspaces W_j,

$$\Psi_j = \{\psi_{jk} \,:\, k \in \hat{\mathcal{K}}_j\}, \tag{A.7}$$

with $\breve{\mathcal{K}}_j$ and $\hat{\mathcal{K}}_j$ suitable sets of indices.

We can represent the operators P_j and Q_j in the form

$$P_j v = \sum_{k \in \breve{\mathcal{K}}_j} \breve{v}_{jk} \varphi_{jk}, \qquad Q_j v = \sum_{k \in \hat{\mathcal{K}}_j} \hat{v}_{jk} \psi_{jk} \quad \forall v \in V. \tag{A.8}$$

Functions φ_{jk} are often referred to as [illegible] while ψ_{jk} are referred to as [illegible].

A.2. Decomposition with a linear operator. We start with a wavelet decomposition of a space V as described earlier. We consider a linear, bounded, surjective operator

$$A : V \longmapsto X$$

mapping V onto a linear space X. Starting from a decomposition in V we will find, through A, a decomposition in X. Assume first that A is invertible. Defining the subspaces $X_j = A\,(V_j)$, we immediately obtain the inclusion relationship

$$X_{j+1} \subset X_j. \tag{A.9}$$

Moreover, defining

$$P_j^X = A P_j A^{-1}, \tag{A.10}$$

it is not difficult to show that P_j^X satisfy conditions (A.1)–(A.3).

Similarly, the operators

$$Q_j^X = A Q_j A^{-1} = P_{j+1}^X - P_{j+1}^X$$

allow us to define the subspaces W_j^X as

$$W_j^X = \operatorname{Im} Q_j.$$

Since A is invertible, it maps linearly independent vectors into linearly independent ones; in other words, starting from bases of V_j and W_j, we obtain bases of V_j^X and W_j^X through the relations

$$\varphi_{jk}^X = A\varphi_{jk} \quad \text{and} \qquad \psi_{jk}^X = A\psi_{jk}. \tag{A.11}$$

We can now extend the construction to a noninvertible operator A. We may assume a decomposition of V of the form

$$V = \ker A \oplus (\ker A)^c\,,$$

where $(\ker A)^c$ is a complementary space to the kernel. The existence of at least one of these spaces $(\ker A)^c$ is ensured when V is a Hilbert space; in fact, since A is bounded, the decomposition

$$V = \ker A \oplus (\ker A)^{\perp}$$

exists. Thus

$$\dim (\ker A)^c = \dim (\ker A)^{\perp} = \dim (\operatorname{Im} A)\,;$$

it follows that A restricted to $(\ker A)^c$ is invertible. In other words, we can apply the previous construction to the operator

$$A' = A|_{(\ker A)^c}.$$

Appendix B. Inclusion relationship between spaces $\boldsymbol{X^{\mathrm{RWG}}}$. We will make explicit the coefficients that allow us to express an RWG function of a given level j as a linear combination of RWG functions of level $j+1$. Referring to Figure B.1, the following conventions are used: RWG functions are identified by the edge on which they are defined, and the positive sign on a cell indicates that it is a T^+ cell (according to conventions used in Figure B.1) for each of the RWG functions on it and, similarly, the minus sign on a cell indicates that it is of the kind T^-. We shall use the following conventions. The Greek letter α will indicate coefficients of linear combinations, and their index will indicate a particular edge; similarly, the letter l corresponds to the length of an edge, $\mathcal{A}$ to the area of a cell. Vertices are labelled with capital letters and are thought of as vectors; an independent vector variable is denoted by $\boldsymbol{x}$. We will proceed considering a single cell at a time. We start from cell number 1. On this cell we have to enforce, according to (2.1),

$$\alpha_{\mathrm{I}}\, l_{\mathrm{I}}\, \frac{\boldsymbol{x}-D}{2\mathcal{A}_1} + \alpha_{\mathrm{III}} l_{\mathrm{III}} \frac{\boldsymbol{x}-A}{2\mathcal{A}_1} = l_{Tot} \frac{\boldsymbol{x}-F}{2\mathcal{A}^+_{Tot}}, \qquad \boldsymbol{x} \in 1,$$

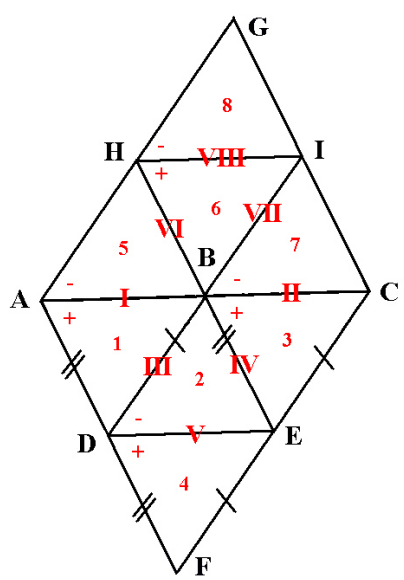

FIG. B.1. *Conventions used for functions.*

where $\mathcal{A}^+_{Tot} = \mathcal{A}_1 + \mathcal{A}_2 + \mathcal{A}_3 + \mathcal{A}_4$ and $l_{Tot} = l_{\rm I} + l_{\rm II}$. This is equivalent to the two conditions

$$\begin{cases} \alpha_{\rm I}\dfrac{l_{\rm I}}{\mathcal{A}_1} + \alpha_{\rm III}\dfrac{l_{\rm III}}{\mathcal{A}_1} &= \dfrac{l_{Tot}}{\mathcal{A}^+_{Tot}}, \\ \alpha_{\rm I}\dfrac{l_{\rm I}}{\mathcal{A}_1} D + \alpha_{\rm III}\dfrac{l_{\rm III}}{\mathcal{A}_1} A &= \dfrac{l_{Tot}}{\mathcal{A}^+_{Tot}} F; \end{cases} \tag{B.1}$$

thus

$$\alpha_{\rm I}\frac{l_{\rm I}}{\mathcal{A}_1}(D-A) = \frac{l_{Tot}}{\mathcal{A}^+_{Tot}}(F-A).$$

Since the two vectors $(A-D)$ and $(F-D)$ have the same direction (refer to Figure B.1), this is actually a scalar condition, obtained taking the vectors' magnitude

$$\alpha_{\rm I}\frac{l_{\rm I}}{\mathcal{A}_1}\,|A-D| = \frac{l_{Tot}}{\mathcal{A}^+_{Tot}}\,|A-F|\,. \tag{B.2}$$

Combining with B.1, we get

$$\alpha_{\rm I} = \frac{l_{Tot}}{l_{\rm I}}\frac{\mathcal{A}_1}{\mathcal{A}^+_{Tot}}\frac{|A-F|}{|A-D|}, \tag{B.3}$$

$$\alpha_{\rm III} = \frac{l_{Tot}}{l_{\rm III}}\frac{\mathcal{A}_1}{\mathcal{A}^+_{Tot}}\left(1-\frac{|A-F|}{|A-D|}\right). \tag{B.4}$$

For symmetry reasons,

$$\alpha_{\rm II} = \frac{l_{Tot}}{l_{\rm II}}\frac{\mathcal{A}_3}{\mathcal{A}^+_{Tot}}\frac{|C-F|}{|C-E|}, \tag{B.5}$$

$$\alpha_{\rm IV} = \frac{l_{Tot}}{l_{\rm IV}}\frac{\mathcal{A}_3}{\mathcal{A}^+_{Tot}}\left(1-\frac{|C-F|}{|C-E|}\right). \tag{B.6}$$

Consider now cell number 4; we have

$$\alpha_{\rm V}(\boldsymbol{x}-F)\frac{l_{\rm V}}{2\mathcal{A}_4} = (\boldsymbol{x}-F)\frac{l_{Tot}}{2\mathcal{A}_{Tot}}, \qquad \boldsymbol{x}\in 4,$$

so that

$$\alpha_{\rm V} = \frac{\mathcal{A}_4}{\mathcal{A}^+_{Tot}}\frac{l_{Tot}}{l_V}. \tag{B.7}$$

Now we have to verify that everything is coherent also on cell number 2. We get

$$\alpha_{\rm III}\frac{l_{\rm III}}{\mathcal{A}_2}(E-\boldsymbol{x}) + \alpha_{\rm IV}\frac{l_{\rm IV}}{\mathcal{A}_2}(D-\boldsymbol{x}) + \alpha_{\rm V}\frac{l_{\rm V}}{\mathcal{A}_2}(B-\boldsymbol{x}) = \frac{l_{Tot}}{\mathcal{A}_{Tot}}(\boldsymbol{x}-F),$$

which is equivalent to

$$\begin{cases} \alpha_{\rm III}\dfrac{l_{\rm III}}{\mathcal{A}_2} + \alpha_{\rm IV}\dfrac{l_{\rm IV}}{\mathcal{A}_2} + \alpha_{\rm V}\dfrac{l_{\rm V}}{\mathcal{A}_2} &= -\dfrac{l_{Tot}}{\mathcal{A}_{Tot}}, \\ \alpha_{\rm III}\dfrac{l_{\rm III}}{\mathcal{A}_2} E + \alpha_{\rm IV}\dfrac{l_{\rm IV}}{\mathcal{A}_2} D + \alpha_{\rm V}\dfrac{l_{\rm V}}{\mathcal{A}_2} B &= -\dfrac{l_{Tot}}{\mathcal{A}^+_{Tot}} F. \end{cases} \tag{B.8}$$

Substituting (B.4), (B.6), and (B.7) in (B.8), we get from the first equation the constraint

$$\mathcal{A}_{Tot} = \mathcal{A}_1 \frac{|A-F|}{|A-D|} + \mathcal{A}_3 \frac{|C-F|}{|C-E|}. \tag{B.9}$$

This relation is verified when the triangle edges are bisected, as in our case. In fact, $\frac{|A-F|}{|A-D|} = 2$ and $\mathcal{A}_{Tot} = 2\mathcal{A}_1 + 2\mathcal{A}_3$ holds since $\mathcal{A}_1$ and $\mathcal{A}_3$ are both equal to $\mathcal{A}_{Tot}/4$. From the second equation we get

$$\mathcal{A}_1 \left(1 - \frac{|A-F|}{|A-D|}\right) E + \mathcal{A}_3 \left(1 - \frac{|C-F|}{|C-E|}\right) D + \mathcal{A}_4 B = -F \mathcal{A}_2. \tag{B.10}$$

Again this holds in our case since the $\mathcal{A}_i$ are all equal and $\frac{|A-F|}{|A-D|} = \frac{|C-F|}{|C-E|} = 2$, so that

$$B - D = E - F.$$

In regard to the remaining coefficients, they are easily obtained by symmetry considerations in the following way:

$$\alpha_{\mathrm{I}}^{-} = \frac{l_{Tot}}{l_{\mathrm{I}}} \frac{\mathcal{A}_5}{\mathcal{A}_{Tot}^{-}} \frac{|A-G|}{|A-H|}, \tag{B.11}$$

$$\alpha_{\mathrm{II}}^{-} = \frac{l_{Tot}}{l_{\mathrm{II}}} \frac{\mathcal{A}_7}{\mathcal{A}_{Tot}^{-}} \frac{|C-G|}{|C-I|}, \tag{B.12}$$

$$\alpha_{\mathrm{VI}} = \frac{l_{Tot}}{l_{\mathrm{VI}}} \frac{\mathcal{A}_5}{\mathcal{A}_{Tot}^{-}} \left(1 - \frac{|A-G|}{|A-H|}\right), \tag{B.13}$$

$$\alpha_{\mathrm{VII}} = \frac{l_{Tot}}{l_{\mathrm{VII}}} \frac{\mathcal{A}_7}{\mathcal{A}_{Tot}^{-}} \left(1 - \frac{|C-G|}{|C-I|}\right), \tag{B.14}$$

$$\alpha_{\mathrm{VIII}} = \frac{\mathcal{A}_8}{\mathcal{A}_{Tot}^{-}} \frac{l_{Tot}}{l_{\mathrm{VIII}}}. \tag{B.15}$$

Moreover, $\alpha_{\mathrm{I}}^{-} = \alpha_{\mathrm{I}}$ and $\alpha_{\mathrm{II}}^{-} = \alpha_{\mathrm{II}}$ since the sides are bisected.

Acknowledgments. The authors would like to thank C. Canuto for useful comments at different stages of the work, and F. Vipiana and P. Pirinoli, who contributed with the background finite-element code and the first MR codes.

NUMERICAL SENSITIVITY ANALYSIS FOR THE QUANTITY OF INTEREST IN PDE-CONSTRAINED OPTIMIZATION*

ROLAND GRIESSE† AND BORIS VEXLER†

Abstract. In this paper, we consider the efficient computation of derivatives of a functional (the quantity of interest) which depends on the solution of a PDE-constrained optimization problem with inequality constraints and which may be different from the cost functional. The optimization problem is subject to perturbations in the data. We derive conditions under with the quantity of interest possesses first and second order derivatives with respect to the perturbation parameters. An algorithm for the efficient evaluation of these derivatives is developed, with considerable savings over a direct approach, especially in the case of high-dimensional parameter spaces. The computational cost is shown to be small compared to that of the overall optimization algorithm. Numerical experiments involving a parameter identification problem for Navier–Stokes flow and an optimal control problem for a reaction-diffusion system are presented which demonstrate the efficiency of the method.

DOI. 10.1137/050637273

1. Introduction.

In this paper we consider PDE-constrained optimization problems with inequality constraints. The optimization problems are formulated in a general setting including optimal control as well as parameter identification problems. The problems are subject to perturbation in the data. We suppose we are given a quantity of interest (output functional), which depends on both the state and the control variables and which may be different from the cost functional used during the optimization.

The quantity of interest is shown to possess first and, under tighter assumptions, second order derivatives with respect to the perturbation parameters. In the presence of control constraints, strict complementarity and compactness of certain derivatives of the state equation are assumed; for second order derivatives, stability of the active set is required in addition. The precise conditions are given in section 3. The main contribution of this paper is to devise an efficient algorithm to evaluate these sensitivity derivatives which offers considerable savings over a direct approach, especially in the case of high-dimensional parameter spaces. We show that the derivatives of the quantity of interest can be computed with little additional numerical effort in comparison to the corresponding derivatives of the cost functional. Moreover, the computational cost for the evaluation of the gradient of the quantity of interest is independent of the dimension of the parameter space and low compared to that of the overall optimization algorithm. The cost to evaluate the Hessian grows linearly with the dimension of the parameter space. We refer to Table 3.1 for details.

The parametric derivatives of the quantity of interest offer a significant amount of additional information on top of an optimal solution. The derivative information can be used to assess the stability of an optimal solution, or to compute a Taylor

†Johann Radon Institute for Computational and Applied Mathematics (RICAM), Austrian Academy of Sciences, Linz, Austria (roland.griesse@oeaw.ac.at, boris.vexler@oeaw.ac.at).

expansion which allows the fast prediction of the perturbed value of the quantity of interest in a neighborhood of a reference parameter.

We note that a quantity of interest different from the cost functional is often natural. For instance, an optimization problem in fluid flow may aim at minimizing the drag of a given body, e.g., by adjusting the boundary conditions. The quantity of interest, however, may be the lift coefficient of the optimal configuration. We also mention the applicability of our results to bilevel optimization problems where the outer variable is the "perturbation" parameter and the outer objective is the output functional, whose derivatives are needed to employ efficient optimization algorithms.

The necessity to compute higher order derivatives may impose possible limitations to the applicability of the methods presented in this paper. Second order derivatives of the cost functional and the PDE constraint are required to evaluate the gradient of the quantity of interest, and third order derivatives are required to evaluate the Hessian.

Let us put our work into perspective. The existence of first and second order sensitivity derivatives of the [illegible] (cost functional) in optimal control of PDEs with control constraints has been proved in [7, 18]. Moreover, [8] addresses the numerical computation of these derivatives. Recently, the computation of the gradient of the quantity of interest in the [illegible] has been discussed in [3].

Problem setting. We consider the PDE-constrained optimization problem in the following abstract form: The state variable u in an appropriate Hilbert space $\mathcal{V}$ with scalar product $(\cdot,\cdot)_{\mathcal{V}}$ is determined by a PDE ([illegible]) in weak form:

$$a(u,q,p)(\phi) = f(\phi) \quad \forall \phi \in \mathcal{V}, \tag{1.1}$$

where q denotes the control, or, more generally, design variable, in the Hilbert space $\mathcal{Q} = L^2(\omega)$ with the standard scalar product $(\cdot,\cdot)$. Typically, ω is a subset of the computational domain Ω or a subset of its boundary $\partial\Omega$. In case of finite-dimensional controls we set $\mathcal{Q} = \mathbb{R}^n$ and identify this space with $L^2(\omega)$, where $\omega = \{1, 2, \dots, n\}$ to keep the notation consistent. The parameter p from a normed linear space $\mathcal{P}$ describes the perturbations of the data.

For fixed $p \in \mathcal{P}$, the semilinear form $a(\cdot,\cdot,p)(\cdot)$ is defined on the Hilbert space $\mathcal{V} \times \mathcal{Q} \times \mathcal{V}$. Semilinear forms are written with two parentheses; the first one refers to the nonlinear arguments, whereas the second one embraces all linear arguments. The partial derivatives of the semilinear form $a(\cdot,\cdot,p)(\cdot)$ are denoted by $a'_u(\cdot,\cdot,p)(\cdot,\cdot)$, $a'_q(\cdot,\cdot,p)(\cdot,\cdot)$, etc. The linear functional $f \in \mathcal{V}'$ represents the right-hand side of the state equation, where $\mathcal{V}'$ denotes the dual space of $\mathcal{V}$. For the cost functional (objective functional) we assume the form

$$J(u,p) + \frac{\alpha}{2}\|q - \overline{q}\|^2_{\mathcal{Q}}, \tag{1.2}$$

which is typical in PDE-constrained optimization problems. Here, $\alpha > 0$ is a regularization parameter and $\overline{q} \in \mathcal{Q}$ is a reference control. The functional $J : \mathcal{V} \times \mathcal{P} \to \mathbb{R}$ is also subject to perturbation. It is possible to extend our analysis to more general cost functionals than (1.2). In particular, only notational changes are necessary if J contains linear terms in q, and if α and $\overline{q}$ also depend on the perturbation parameter. However, full generality of the cost functional comes at the expense of additional assumptions which would unnecessarily complicate the discussion.

In order to cover additional control constraints we introduce a nonempty closed convex subset $\mathcal{Q}_{ad} \subset \mathcal{Q}$ by

$$\mathcal{Q}_{ad} = \{q \in \mathcal{Q} \mid b_-(x) \le q(x) \le b_+(x) \text{ a.e. on } \omega\},$$

with bounds $b_- \le b_+ \in \mathcal{Q}$. In the case of finite-dimensional controls the inequality $b_- \le q \le b_+$ is meant to hold componentwise.

The problem under consideration is to

$$(\mathbf{OP}(p)) \qquad \begin{aligned} &\text{minimize (1.2) over } \mathcal{Q}_{ad} \times \mathcal{V} \\ &\text{subject to the state equation (1.1)} \end{aligned}$$

for fixed $p \in \mathcal{P}$. We assume that in a neighborhood of a reference parameter p_0, there exist functions $u = U(p)$ and $q = Q(p)$, which map the perturbation parameter p to a local solution (u, q) of the problem $(\mathbf{OP}(p))$. In section 3, we give sufficient conditions ensuring the existence and differentiability of these functions. Our results complement previous findings in [7, 10, 18].

The quantity of interest is denoted by a functional

$$I : \mathcal{V} \times \mathcal{Q} \times \mathcal{P} \to \mathbb{R}. \tag{1.3}$$

This gives rise to the definition of the reduced quantity of interest $i : \mathcal{P} \to \mathbb{R}$,

$$i(p) = I(U(p), Q(p), p). \tag{1.4}$$

Likewise, we denote by $j : \mathcal{P} \to \mathbb{R}$ the reduced cost functional

$$j(p) = J(U(p), p) + \frac{\alpha}{2}\|Q(p) - \overline{q}\|^2_{\mathcal{Q}}. \tag{1.5}$$

As stated above, the main contribution of this paper is to devise an efficient algorithm to evaluate the first and second derivatives of the reduced quantity of interest $i(p)$.

The outline of the paper is as follows: In the next section we specify the first order necessary optimality conditions for the problem under consideration. We recall a primal-dual active set method for its solution. The core step of this method is described in some detail since it is also used for the problems arising during the sensitivity computation. In section 3 we use duality arguments for the efficient evaluation of the first and second order sensitivities of the quantity of interest with respect to perturbation parameters. Throughout, we compare the standard sensitivity analysis for the reduced cost functional $j(p)$ with our analysis for the reduced quantity of interest $i(p)$. In the last section we discuss two numerical examples illustrating our approach. The first example deals with a parameter identification problem for a channel flow described by the incompressible Navier–Stokes equations. In the second example we consider the optimal control of time-dependent three-species reaction-diffusion equations under control constraints.

2. Optimization algorithm. In this section we recall the first order necessary conditions for the problem $(\mathbf{OP}(p))$ and describe the optimization algorithm with active set strategy which we use in our numerical examples. In particular, we specify the Newton step taking into account the active sets since the sensitivity problems arising in section 3 are solved by the same technique.

Throughout the paper we make the following assumption.

ASSUMPTION 2.1.

1. $a(\cdot,\cdot,\cdot)(\cdot)$ [illegible] (u,q,p)
2. $J(\cdot,\cdot)$ [illegible] (u,p)
3. $I(\cdot,\cdot,\cdot)$ [illegible] (u,q,p)

In order to establish the optimality system, we introduce the Lagrangian $\mathcal{L} : \mathcal{V} \times \mathcal{Q} \times \mathcal{V} \times \mathcal{P} \to \mathbb{R}$ as follows:

$$\mathcal{L}(u,q,z,p) = J(u,p) + \frac{\alpha}{2}\|q-\overline{q}\|^2_{\mathcal{Q}} + f(z) - a(u,q,p)(z), \tag{2.1}$$

where $z \in \mathcal{V}$ denotes the adjoint state. The first order necessary conditions for the problem $(\mathbf{OP}(p))$ read

$$\mathcal{L}'_u(u,q,z,p)(\delta u) = 0 \quad \forall \delta u \in \mathcal{V}, \tag{2.2}$$

$$\mathcal{L}'_q(u,q,z,p)(\delta q - q) \geq 0 \quad \forall \delta q \in \mathcal{Q}_{ad}, \tag{2.3}$$

$$\mathcal{L}'_z(u,q,z,p)(\delta z) = 0 \quad \forall \delta z \in \mathcal{V}. \tag{2.4}$$

They can be explicitly rewritten as follows:

$$J'_u(u,p)(\delta u) - a'_u(u,q,p)(\delta u, z) = 0 \quad \forall \delta u \in \mathcal{V}, \tag{2.5}$$

$$\alpha(q-\overline{q}, \delta q - q) - a'_q(u,q,p)(\delta q - q, z) \geq 0 \quad \forall \delta q \in \mathcal{Q}_{ad}, \tag{2.6}$$

$$f(\delta z) - a(u,q,p)(\delta z) = 0 \quad \forall \delta z \in \mathcal{V}. \tag{2.7}$$

For given u, q, z, p, we introduce an additional Lagrange multiplier $\mu \in L^2(\omega)$ by the following identification:

$$\begin{aligned}(\mu, \delta q) &:= -\mathcal{L}'_q(u,q,z,p)(\delta q) \\ &= -\alpha(q-\overline{q}, \delta q) + a'_q(u,q,p)(\delta q, z) \quad \forall \delta q \in L^2(\omega).\end{aligned}$$

The variational inequality (2.6) is known to be equivalent to the following pointwise conditions a.e. on ω:

$$q(x) = b_-(x) \Rightarrow \mu \leq 0, \tag{2.8}$$

$$q(x) = b_+(x) \Rightarrow \mu \geq 0, \tag{2.9}$$

$$b_-(x) < q(x) < b_+(x) \Rightarrow \mu = 0. \tag{2.10}$$

In addition to the necessary conditions above, in the following lemma we recall second order sufficient optimality conditions.

LEMMA 2.2 (sufficient optimality conditions). [illegible] $x = (u,q,z)$ [illegible] (2.2)–(2.4) [illegible] $(\mathbf{OP}(p))$ [illegible] $a'_u(u,q,p) \colon \mathcal{V} \to \mathcal{V}'$ [illegible] $\rho > 0$ [illegible]

$$\begin{pmatrix}\delta u & \delta q\end{pmatrix} \begin{bmatrix}\mathcal{L}''_{uu}(x,p) & \mathcal{L}''_{uq}(x,p) \\ \mathcal{L}''_{qu}(x,p) & \mathcal{L}''_{qq}(x,p)\end{bmatrix} \begin{pmatrix}\delta u \\ \delta q\end{pmatrix} \geq \rho \left(\|\delta u\|^2_{\mathcal{V}} + \|\delta q\|^2_{\mathcal{Q}}\right)$$

[illegible] $(\delta u, \delta q)$ [illegible]

$$a'_u(u,q,p)(\delta u, \varphi) + a'_q(u,q,p)(\delta q, \varphi) = 0 \quad \forall \varphi \in \mathcal{V},$$

[illegible] (u,q) [illegible] $(\mathbf{OP}(p))$

For the proof we refer the reader to [19].

For the solution of the first order necessary conditions (2.5)–(2.7) for fixed $p \in \mathcal{P}$, we employ a nonlinear primal-dual active set strategy; see [4, 12, 15, 16]. In the following we sketch the corresponding algorithm on the continuous level:

Nonlinear primal-dual active set strategy

1. Choose initial guess u^0, q^0, z^0, μ^0 and $c > 0$ and set $n = 1$
2. While not converged
3. Determine the active sets $\mathcal{A}_+^n$ and $\mathcal{A}_-^n$

$$\mathcal{A}_-^n = \{x \in \omega \mid q^{n-1} + \mu^{n-1}/c - b_- \leq 0\},$$
$$\mathcal{A}_+^n = \{x \in \omega \mid q^{n-1} + \mu^{n-1}/c - b_+ \geq 0\}$$

4. Solve the equality-constrained optimization problem

$$\text{Minimize} \quad J(u^n, p) + \frac{\alpha}{2}\|q^n - \overline{q}\|_{\mathcal{Q}}^2 \text{ over } \mathcal{V} \times \mathcal{Q}$$

subject to (1.1) and to

$$q^n(x) = b_-(x) \text{ on } \mathcal{A}_-^n, \qquad q^n(x) = b_+(x) \text{ on } \mathcal{A}_+^n$$

with adjoint variable z^n

5. Set $\mu^n = -\alpha(q^n - \overline{q}) + a_q'(u^n, q^n, p)(\cdot, z^n)$
6. Set $n = n + 1$ and go to 2.

. . .. 2.3.

1. The initial guess for the Lagrange multiplier μ^0 can be taken according to step 5. Another possibility is choosing $\mu^0 = 0$ and $q^0 \in \mathcal{Q}_{ad}$, which leads to solving the optimization problem (step 4) without control constraints in the first iteration.
2. The convergence in step 2 can be determined conveniently from agreement of the active sets in two consecutive iterations. The problem is then solved only on the inactive set $\mathcal{I}^n = \omega \setminus (A_-^n \cup A_+^n)$, e.g., by applying Newton's method to the corresponding first order necessary conditions.

Later on, the above algorithm is applied on the discrete level. The concrete discretization schemes are described in section 4 for each individual example.

Clearly, the main step in the primal-dual algorithm is the solution of the equality-constrained nonlinear optimization problem in step 4. We shall describe the Lagrange Newton SQP method for its solution in some detail since exactly the same procedure may be used to solve the sensitivity problems in section 3, which are the main focus of our paper.

For given active and inactive sets $\mathcal{A} = \mathcal{A}_+ \cup \mathcal{A}_-$ and $\mathcal{I} = \omega \setminus \mathcal{A}$, let us define the

"restriction" operator $R_{\mathcal{I}} : L^2(\omega) \to L^2(\omega)$ by

$$R_{\mathcal{I}}(q) = q \cdot \chi_{\mathcal{I}},$$

where $\chi_{\mathcal{I}}$ is a characteristic function of the set $\mathcal{I}$. Similarly, the operators $R_{\mathcal{A}}$, $R_{\mathcal{A}_+}$, and $R_{\mathcal{A}_-}$ are defined. Note that $R_{\mathcal{I}}$, etc., are obviously self-adjoint.

The first order necessary conditions for the purely equality-constrained problem in step 4 are (compare (2.2)–(2.4), respectively, (2.5)–(2.7)):

$$\mathcal{L}'_u(u,q,z,p)(\delta u) = 0 \quad \forall \delta u \in \mathcal{V}, \tag{2.11}$$

$$\mathcal{L}'_q(u,q,z,p)(\delta q) = 0 \quad \forall \delta q \in L^2(\mathcal{I}^n), \tag{2.12}$$

$$q - b_- = 0 \quad \text{on } A^n_-, \tag{2.13}$$

$$q - b_+ = 0 \quad \text{on } A^n_+, \tag{2.14}$$

$$\mathcal{L}'_z(u,q,z,p)(\delta z) = 0 \quad \forall \delta z \in \mathcal{V}, \tag{2.15}$$

with the inactive set $\mathcal{I}^n = \omega \backslash (\mathcal{A}^n_- \cup \mathcal{A}^n_+)$. Using the restriction operators, (2.12)–(2.14) can be reformulated as

$$\mathcal{L}'_q(u,q,z,p)(R_{\mathcal{I}^n}\delta q) + (q - b_-, R_{\mathcal{A}^n_-}\delta q) + (q - b_+, R_{\mathcal{A}^n_+}\delta q) = 0 \quad \forall \delta q \in \mathcal{Q}.$$

The Lagrange Newton SQP method is defined as Newton's method, applied to (2.11)–(2.15). To this end, we define B as the Hessian operator of the Lagrangian $\mathcal{L}$, i.e.,

$$B(x,p) = \begin{bmatrix} \mathcal{L}''_{uu}(x,p)(\cdot,\cdot) & \mathcal{L}''_{uq}(x,p)(\cdot,\cdot) & \mathcal{L}''_{uz}(x,p)(\cdot,\cdot) \\ \mathcal{L}''_{qu}(x,p)(\cdot,\cdot) & \mathcal{L}''_{qq}(x,p)(\cdot,\cdot) & \mathcal{L}''_{qz}(x,p)(\cdot,\cdot) \\ \mathcal{L}''_{zu}(x,p)(\cdot,\cdot) & \mathcal{L}''_{zq}(x,p)(\cdot,\cdot) & 0 \end{bmatrix}. \tag{2.16}$$

To shorten the notation, we abbreviate $x = (u,q,z)$ and $\mathcal{X} = \mathcal{V} \times \mathcal{Q} \times \mathcal{V}$. Note that $B(x,p)$ is a bilinear operator on the space $\mathcal{X}$. By "multiplication" of B with an element $\delta x \in \mathcal{X}$ from the left, we mean the insertion of the components of δx into the first argument. Similarly we define the "multiplication" of B with an element $\delta x \in \mathcal{X}$ from the right as insertion of the components of δx into the second argument. When only one element is inserted, B is interpreted as a linear operator $B : \mathcal{X} \to \mathcal{X}'$. In what follows, we shall omit the $(\cdot,\cdot)$ notation if no ambiguity arises.

In the absence of control constraints, the Newton update $(\Delta u, \Delta q, \Delta z)$ for (2.11)–(2.15) at the current iterate (u_k, q_k, z_k) is given by the solution of

$$B(x_k,p)\begin{pmatrix} \Delta u \\ \Delta q \\ \Delta z \end{pmatrix} = -\begin{pmatrix} \mathcal{L}'_u(x_k,p) \\ \mathcal{L}'_q(x_k,p) \\ \mathcal{L}'_z(x_k,p) \end{pmatrix}. \tag{2.17}$$

With nonempty active sets $\mathcal{A}^n_-$ and $\mathcal{A}^n_+$, however, (2.17) is replaced by

$$\widetilde{B}(x_k,p)\begin{pmatrix} \Delta u \\ \Delta q \\ \Delta z \end{pmatrix} = -\begin{pmatrix} \mathcal{L}'_u(x_k,p) \\ R_{\mathcal{I}^n}\mathcal{L}'_q(x_k,p) + R_{\mathcal{A}^n_-}(q_k - b_-) + R_{\mathcal{A}^n_+}(q_k - b_+) \\ \mathcal{L}'_z(x_k,p) \end{pmatrix}, \tag{2.18}$$

where

$$\widetilde{B}(x_k,p) = \begin{pmatrix} id & & \\ & R_{\mathcal{I}^n} & \\ & & id \end{pmatrix} B(x_k,p) \begin{pmatrix} id & & \\ & R_{\mathcal{I}^n} & \\ & & id \end{pmatrix} + \begin{pmatrix} 0 & & \\ & R_{\mathcal{A}^n} & \\ & & 0 \end{pmatrix}. \tag{2.19}$$

In other words, $\widetilde{B}$ is obtained from B by replacing those components in the derivatives with respect to the control q by the identity which belongs to the active set. In our practical realization, we reduce the system (2.18) to the control space $L^2(\omega)$ using Schur complement techniques; see, e.g., [17]. The reduced system is solved iteratively using the conjugate gradient method, where each step requires the evaluation of a matrix-vector product for the reduced Hessian, which in turn requires the solution of one tangent and one dual problem; see, e.g., [13] or [2] for a detailed description of this procedure in the context of space-time finite element discretization of the problem. In fact, the reduced system needs to be solved only on the currently inactive part $L^2(\mathcal{I}^n)$ of the control space since on the active sets, the update Δq satisfies the trivial relation $R_{\mathcal{A}_\pm^n}(\Delta q) = R_{\mathcal{A}_\pm^n}(b_\pm - q_{k-1})$.

The Newton step is completed by applying the update

$$(u_{k+1}, q_{k+1}, z_{k+1}) = (u_k, q_k, z_k) + (\Delta u, \Delta q, \Delta z).$$

3. Sensitivity analysis. In this section we analyze the behavior of local optimal solutions for (**OP**(p)) under perturbations of the parameter p. We derive formulas for the first and second order derivatives of the reduced quantity of interest and develop an efficient method for their evaluation.

To set the stage, we outline the main ideas in section 3.1 by means of a finite-dimensional optimization problem, without partitioning the optimization variables into states and controls, and in the absence of control constraints. To facilitate the discussion of the infinite-dimensional case, we treat the case of no control constraints in section 3.2 and turn to problems with these constraints in section 3.3. Throughout, we compare the standard sensitivity analysis for the reduced cost functional $j(p)$ (1.5) with our analysis for the reduced quantity of interest $i(p)$ (1.4). The main results can be found in Theorem 3.6 for the unconstrained case and in Theorems 3.18 and 3.21 for the case with control constraints. An algorithm at the end of section 3 summarizes the necessary steps to evaluate the various sensitivity quantities.

3.1. Outline of ideas. Let us consider the nonlinear finite-dimensional equality-constrained optimization problem

$$\text{Minimize } J(x,p) \text{ s.t. } g(x,p) = 0, \tag{3.1}$$

where $x \in \mathbb{R}^n$ denotes the optimization variable, $p \in \mathbb{R}^d$ is the perturbation parameter, and $g : \mathbb{R}^n \times \mathbb{R}^d \to \mathbb{R}^m$ collects a number of equality constraints. The Lagrangian of (3.1) is $\mathcal{L}(x,p) = J(x,p) - z^\top g(x,p)$, and under standard constraint qualifications, a local minimizer x_0 of (3.1) at the reference parameter p_0 has an associated Lagrange multiplier $z_0 \in \mathbb{R}^m$ such that

$$\begin{aligned} &\mathcal{L}'_x(x_0, z_0, p_0) = J'_x(x_0, p_0) - z_0^\top g'_x(x_0, p_0) = 0, \\ &\mathcal{L}'_z(x_0, z_0, p_0) = g(x_0, p_0) = 0 \end{aligned} \tag{3.2}$$

hold. If we assume second order sufficient conditions to hold in addition, then the implicit function theorem yields the local existence of functions $X(p)$ and $Z(p)$ which satisfy (3.2) with p instead of p_0, and $X(p_0) = x_0$ and $Z(p_0) = z_0$ hold. Moreover, (3.2) can be differentiated totally with respect to the parameter and we obtain

$$\begin{pmatrix} \mathcal{L}''_{xx}(x_0, z_0, p_0) & g'_x(x_0, p_0)^\top \\ g'_x(x_0, p_0) & 0 \end{pmatrix} \begin{pmatrix} X'(p_0)\,\delta p \\ Z'(p_0)\,\delta p \end{pmatrix} = - \begin{pmatrix} \mathcal{L}''_{xp}(x_0, z_0, p_0)\,\delta p \\ g'_p(x_0, p_0)\,\delta p \end{pmatrix}. \tag{3.3}$$

The solution of (3.3) is a directional derivative of $X(p)$ (and $Z(p)$) at $p = p_0$, and we note that it is equivalent to the solution of a linear-quadratic optimization problem. Hence the evaluation of the full Jacobian $X'(p_0)$ requires $d = \dim \mathcal{P}$ solves of (3.3) with different δp. In our context of large-scale problems, iterative solvers need to be used and the numerical effort to evaluate the full Jacobian scales linearly with the number of right-hand sides, i.e., with the dimension of the parameter space $d = \dim \mathcal{P}$.

We adapt the definition of the reduced cost functional and the reduced quantity of interest to our current setting, $j(p) = J(X(p), p)$ and $i(p) = I(X(p), p)$. Since we wish to compare the effort to compute the first and second order derivatives of both, we begin by recalling the following result.

LEMMA 3.1.

$$
\begin{aligned}
j'(p_0)\,\delta p &= \mathcal{L}'_p(x_0, z_0, p_0)\,\delta p,\\
\delta p^\top j''(p_0)\,\widehat{\delta p} &= \delta p^\top \big[\mathcal{L}''_{px}(x_0, z_0, p_0)X'(p_0)\,\widehat{\delta p} + \mathcal{L}''_{pz}(x_0, z_0, p_0)Z'(p_0)\,\widehat{\delta p}\\
&\qquad + \mathcal{L}''_{pp}(x_0, z_0, p_0)\,\widehat{\delta p}\big].
\end{aligned}
$$

. We have $j(p) = \mathcal{L}(X(p), Z(p), p)$ and hence by the chain rule $j'(p_0) = \mathcal{L}'_x(x_0, z_0, p_0)X'(p_0) + \mathcal{L}'_z(x_0, z_0, p_0)Z'(p_0) + \mathcal{L}'_p(x_0, z_0, p_0)$, where the first two terms vanish in view of (3.2). Differentiating again totally with respect to p yields the expression for the second derivative. ∎

Lemma 3.1 shows that the evaluation of the gradient of $j(\cdot)$ does not require any linear solves of the sensitivity system (3.3), while the evaluation of the Hessian requires $d = \dim \mathcal{P}$ such solves. The corresponding results for the infinite-dimensional case can be found below in Propositions 3.5 and 3.16 for the unconstrained and control constrained cases.

We will show now that the derivatives of the reduced quantity of interest $i(\cdot)$ can be evaluated efficiently, requiring just one additional system solve. This is a significant improvement over a direct approach; see Table 3.1.

From a first look at

$$
i'(p_0)\,\delta p = I'_x(x_0, p_0)X'(p_0)\,\delta p + I'_p(x_0, p_0)\,\delta p
$$

it seems that the evaluation of the gradient $i'(p_0)$ requires $d = \dim \mathcal{P}$ solves of the system (3.3). This is referred to as the direct approach in Table 3.1. However, using (3.3), we may rewrite this as

$$
i'(p_0)\,\delta p = \big[-\big(I'_x(x_0, p_0), 0\big)\,B_0^{-1}\big] \begin{pmatrix} \mathcal{L}''_{xp}(x_0, z_0, p_0)\,\delta p \\ g'_p(x_0, p_0)\,\delta p \end{pmatrix} + I'_p(x_0, p_0)\,\delta p,
$$

where B_0 is the matrix on the left-hand side of (3.3). Realizing that $I'_x(x_0, p_0)$ has just one row, evaluating the term in square brackets amounts to only one linear system solve. We define the dual quantities (v, y) by

$$
B_0^\top \begin{pmatrix} v \\ y \end{pmatrix} = - \begin{pmatrix} I'_x(x_0, p_0) \\ 0 \end{pmatrix}
$$

and finally obtain

$$
i'(p_0)\,\delta p = v^\top \mathcal{L}''_{xp}(x_0, z_0, p_0)\,\delta p + y^\top \mathcal{L}''_{zp}(x_0, z_0, p_0)\,\delta p + I'_p(x_0, p_0)\,\delta p. \tag{3.4}
$$

We refer to this as a dual approach. In our context, B_0 is symmetric and hence the computation of the dual quantities requires just one solve of (3.3) with a modified right-hand side; see again Table 3.1.

For the second derivative, we differentiate (3.4) totally with respect to p. From the chain rule we infer that the sensitivities $X'(p_0)$ and $Z'(p_0)$ now come into play. In addition, v and y need to be differentiated with respect to p, but again a duality technique can be used in order to avoid computing these extra terms. Hence the extra computational cost to evaluate the Hessian of $i(\cdot)$ amounts to $d = \dim \mathcal{P}$ solves for the evaluation of the sensitivity matrices $X'(p_0)$ and $Z'(p_0)$; see Table 3.1. Details can be found in the proofs of Theorem 3.6 for the unconstrained case and Theorems 3.18 and 3.21 for the case with control constraints.

3.2. The case of no control constraints. Throughout this and the following section, we denote by $p_0 \in \mathcal{P}$ a given reference parameter and by $x_0 = (u_0, q_0, z_0)$ a solution to the corresponding first order optimality system (2.11)–(2.15). Moreover, we make the following regularity assumption which we require throughout.

ASSUMPTION 3.2. $a'_u(u_0, q_0, p_0) : \mathcal{V} \to \mathcal{V}'$

In the case of no control constraints, i.e., $\mathcal{Q}_{ad} = \mathcal{Q}$, the first order necessary conditions (2.11)–(2.15) simplify to

$$\mathcal{L}'_u(u, q, z, p)(\delta u) = 0 \quad \forall \delta u \in \mathcal{V}, \tag{3.5}$$

$$\mathcal{L}'_q(u, q, z, p)(\delta q) = 0 \quad \forall \delta q \in \mathcal{Q}, \tag{3.6}$$

$$\mathcal{L}'_z(u, q, z, p)(\delta z) = 0 \quad \forall \delta z \in \mathcal{V}. \tag{3.7}$$

The analysis in this subsection is based on the classical implicit function theorem. We denote by $B_0 = B(x_0, p_0)$ the previously defined Hessian operator at the given reference solution. For the results in this section we require that B_0 is boundedly invertible. This property follows from the second order sufficient conditions; see, for instance, [14].

LEMMA 3.3. 2.2 x_0 **OP**(p_0) B_0

The following lemma is a direct application of the implicit function theorem (see [5]) to the first order optimality system (3.5)–(3.7).

LEMMA 3.4. B_0 $\mathcal{N}(p_0) \subset \mathcal{P}$ p_0 $\mathcal{N}(x_0) \subset \mathcal{X}$ x_0 $(U, Q, Z) : \mathcal{N}(p_0) \to \mathcal{N}(x_0)$

(a) $p \in \mathcal{N}(p_0)$ $(U(p), Q(p), Z(p))$ (3.5)–(3.7) $\mathcal{N}(x_0)$

(b) $(U(p_0), Q(p_0), Z(p_0)) = (u_0, q_0, z_0)$

(c) (U, Q, Z) p_0 $\delta p \in \mathcal{P}$

$$B_0 \begin{pmatrix} U'(p_0)(\delta p) \\ Q'(p_0)(\delta p) \\ Z'(p_0)(\delta p) \end{pmatrix} = - \begin{pmatrix} \mathcal{L}''_{up}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{qp}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{zp}(x_0, p_0)(\cdot, \delta p) \end{pmatrix}. \tag{3.8}$$

In the following proposition we recall the first and second order sensitivity derivatives of the $j(p)$; compare this to [18].

PROPOSITION 3.5. B_0 $j(p) = J(U(p), p) + \frac{\alpha}{2}\|Q(p) - \overline{q}\|^2_{\mathcal{Q}}$ $\mathcal{N}(p_0)$

p_0 $\delta p \in \mathcal{P}$

$$j'(p_0)(\delta p) = \mathcal{L}'_p(x_0, p_0)(\delta p). \tag{3.9}$$

δp $\widehat{\delta p}$

$$\begin{aligned} j''(p_0)(\delta p, \widehat{\delta p}) &= \mathcal{L}''_{up}(x_0, p_0)(U'(p)(\delta p), \widehat{\delta p}) + \mathcal{L}''_{qp}(x_0, p_0)(Q'(p)(\delta p), \widehat{\delta p}) \\ &\quad + \mathcal{L}''_{zp}(x_0, p_0)(Z'(p)(\delta p), \widehat{\delta p}) + \mathcal{L}''_{pp}(x_0, p_0)(\delta p, \widehat{\delta p}). \end{aligned} \tag{3.10}$$

Since $(U(p), Q(p))$ satisfies the state equation, we have

$$j(p) = \mathcal{L}(U(p), Q(p), Z(p), p)$$

for all $p \in \mathcal{N}(p_0)$. By the chain rule, the derivative of $j(p)$ reads

$$\begin{aligned} j'(p_0)(\delta p) = \mathcal{L}'_u(x_0, p_0)(U'(p_0)(\delta p)) + \mathcal{L}'_q(x_0, p_0)(Q'(p_0)(\delta p)) + \mathcal{L}'_z(x_0, p_0)(Z'(p_0)(\delta p)) \\ + \mathcal{L}'_p(x_0, p_0)(\delta p). \end{aligned}$$

The three terms in the first line vanish in view of the optimality system (3.5)–(3.7). Differentiating (3.9) again totally with respect to p in the direction of $\widehat{\delta p}$ yields (3.10), which completes the proof. ∎

The previous proposition allows us to evaluate the first order derivative of the reduced cost functional computing the sensitivity derivatives of the state, control, and adjoint variables. That is, the effort to evaluate $j'(p_0)$ is negligible compared to the effort required to solve the optimization problem. In order to obtain second order derivative $j''(p_0)$, however, the sensitivity derivatives have to be computed according to formula (3.8). This corresponds to the solution of one additional linear-quadratic optimization problem per perturbation direction δp, whose optimality system is given by (3.8).

We now turn to our main result in the absence of control constraints. In the following theorem, we show that the first and second order derivatives of the can be evaluated at practically the same effort as those of the cost functional. To this end, we use a duality technique (see section 3.1) and formulate the following dual problem for the dual variables $v \in \mathcal{V}$, $r \in \mathcal{Q}$, and $y \in \mathcal{V}$:

$$B_0 \begin{pmatrix} v \\ r \\ y \end{pmatrix} = - \begin{pmatrix} I'_u(q_0, u_0, p_0) \\ I'_q(q_0, u_0, p_0) \\ 0 \end{pmatrix}. \tag{3.11}$$

We remark that this dual problem involves the same operator matrix B_0 as the sensitivity problem (3.8) since B_0 is self-adjoint.

THEOREM 3.6. B_0 $i(p)$ (1.4) $\mathcal{N}(p_0)$ p_0 $\delta p \in \mathcal{P}$

$$\begin{aligned} i'(p_0)(\delta p) = \mathcal{L}''_{up}(x_0, p_0)(v, \delta p) + \mathcal{L}''_{qp}(x_0, p_0)(r, \delta p) + \mathcal{L}''_{zp}(x_0, p_0)(y, \delta p) \\ + I'_p(u_0, q_0, p_0)(\delta p). \end{aligned} \tag{3.12}$$

δp $\widehat{\delta p}$

$$\begin{aligned} i''(p_0)(\delta p, \widehat{\delta p}) &= \langle v, \eta \rangle_{\mathcal{V} \times \mathcal{V}'} + \langle r, \kappa \rangle_{\mathcal{Q} \times \mathcal{Q}'} + \langle y, \sigma \rangle_{\mathcal{V} \times \mathcal{V}'} \\ &+ \begin{pmatrix} U'(p_0)(\delta p) \\ Q'(p_0)(\delta p) \\ \delta p \end{pmatrix}^\top \begin{pmatrix} I''_{uu}(q_0, u_0, p_0) & I''_{uq}(q_0, u_0, p_0) & I''_{up}(q_0, u_0, p_0) \\ I''_{qu}(q_0, u_0, p_0) & I''_{qq}(q_0, u_0, p_0) & I''_{qp}(q_0, u_0, p_0) \\ I''_{pu}(q_0, u_0, p_0) & I''_{pq}(q_0, u_0, p_0) & I''_{pp}(q_0, u_0, p_0) \end{pmatrix} \begin{pmatrix} U'(p_0)(\widehat{\delta p}) \\ Q'(p_0)(\widehat{\delta p}) \\ \widehat{\delta p} \end{pmatrix}. \end{aligned} \tag{3.13}$$

. $(\eta, \kappa, \sigma) \in \mathcal{V}' \times \mathcal{Q}' \times \mathcal{V}'$, , , .

$$
\begin{aligned}
\begin{pmatrix} \eta \\ \kappa \\ \sigma \end{pmatrix} &= \begin{pmatrix} \mathcal{L}'''_{upp}()(\cdot, \delta p, \widehat{\delta p}) \\ \mathcal{L}'''_{qpp}()(\cdot, \delta p, \widehat{\delta p}) \\ \mathcal{L}'''_{zpp}()(\cdot, \delta p, \widehat{\delta p}) \end{pmatrix} \\
&+ \begin{pmatrix} \mathcal{L}'''_{upu}()(\cdot, \delta p, U'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{upq}()(\cdot, \delta p, Q'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{upz}()(\cdot, \delta p, Z'(p_0)(\widehat{\delta p})) \\ \mathcal{L}'''_{qpu}()(\cdot, \delta p, U'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{qpq}()(\cdot, \delta p, Q'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{qpz}()(\cdot, \delta p, Z'(p_0)(\widehat{\delta p})) \\ \mathcal{L}'''_{zpu}()(\cdot, \delta p, U'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{zpq}()(\cdot, \delta p, Q'(p_0)(\widehat{\delta p})) \end{pmatrix} \\
&+ \Big(B'_u()(U'(p_0)(\widehat{\delta p})) + B'_q()(Q'(p_0)(\widehat{\delta p})) + B'_z()(Z'(p_0)(\widehat{\delta p})) + B'_p()(\widehat{\delta p}) \Big) \begin{pmatrix} U'(p_0)(\delta p) \\ Q'(p_0)(\delta p) \\ Z'(p_0)(\delta p) \end{pmatrix}.
\end{aligned}
$$

. . . . 3.7.

(a) In the definition of (η, κ, σ) we have abbreviated the evaluation at the point (x_0, p_0) by $()$.
(b) The bracket $\langle \cdot, \cdot \rangle_{\mathcal{V} \times \mathcal{V}'}$ in (3.13) denotes the duality pairing between $\mathcal{V}$ and its dual space $\mathcal{V}'$. For instance, the evaluation of $\langle v, \eta \rangle_{\mathcal{V} \times \mathcal{V}'}$ amounts to plugging in v instead of $\cdot$ in the definition of η. A similar notation is used for the control space $\mathcal{Q}$.
(c) It is tedious but straightforward to check that (3.13) coincides with (3.10) if the quantity of interest is chosen equal to the cost functional. In this case, it follows from (3.11) that the dual quantities v and r vanish and $y = z_0$ holds.

. . . . . 3.6. From the definition of the reduced quantity of interest (1.4), we infer that

$$
\begin{aligned}
i'(p_0)(\delta p) &= I'_u(u_0, q_0, p_0)(U'(p_0)(\delta p)) \\
&\quad + I'_q(u_0, q_0, p_0)(Q'(p_0)(\delta p)) + I'_p(u_0, q_0, p_0)(\delta p)
\end{aligned} \tag{3.14}
$$

holds. In virtue of (3.8) and (3.11), the sum of the first two terms equals

$$
- \begin{pmatrix} I'_u(u_0, q_0, p_0) \\ I'_q(u_0, q_0, p_0) \\ 0 \end{pmatrix}^\top B_0^{-1} \begin{pmatrix} \mathcal{L}''_{up}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{qp}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{zp}(x_0, p_0)(\cdot, \delta p) \end{pmatrix} = \begin{pmatrix} v \\ r \\ y \end{pmatrix}^\top \begin{pmatrix} \mathcal{L}''_{up}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{qp}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{zp}(x_0, p_0)(\cdot, \delta p) \end{pmatrix},
$$

which implies (3.12). In order to obtain the second derivative, we differentiate (3.14) totally with respect to p in the direction of $\widehat{\delta p}$. This yields

$$
\begin{aligned}
&i''(p_0)(\delta p, \widehat{\delta p}) \\
&= \begin{pmatrix} U'(p_0)(\delta p) \\ Q'(p_0)(\delta p) \\ \delta p \end{pmatrix}^\top \begin{pmatrix} I''_{uu}(q_0, u_0, p_0) & I''_{uq}(q_0, u_0, p_0) & I''_{up}(q_0, u_0, p_0) \\ I''_{qu}(q_0, u_0, p_0) & I''_{qq}(q_0, u_0, p_0) & I''_{qp}(q_0, u_0, p_0) \\ I''_{pu}(q_0, u_0, p_0) & I''_{pq}(q_0, u_0, p_0) & I''_{pp}(q_0, u_0, p_0) \end{pmatrix} \begin{pmatrix} U'(p_0)(\widehat{\delta p}) \\ Q'(p_0)(\widehat{\delta p}) \\ \widehat{\delta p} \end{pmatrix} \\
&\qquad + \begin{pmatrix} I'_u(u_0, q_0, p_0) \\ I'_q(u_0, q_0, p_0) \\ 0 \end{pmatrix}^\top \begin{pmatrix} U''(p_0)(\delta p, \widehat{\delta p}) \\ Q''(p_0)(\delta p, \widehat{\delta p}) \\ Z''(p_0)(\delta p, \widehat{\delta p}) \end{pmatrix}.
\end{aligned} \tag{3.15}
$$

From differentiating (3.8) totally with respect to p in the direction of $\widehat{\delta p}$, we obtain

$$B_0 \begin{pmatrix} U''(p_0)(\delta p, \widehat{\delta p}) \\ Q''(p_0)(\delta p, \widehat{\delta p}) \\ Z''(p_0)(\delta p, \widehat{\delta p}) \end{pmatrix} = - \begin{pmatrix} \eta \\ \kappa \\ \sigma \end{pmatrix}. \tag{3.16}$$

From here, (3.13) follows. □

The main statement of the previous theorem is that the first and second order derivatives of the reduced quantity of interest can be evaluated at the additional expense of just one dual problem (3.11), compared to the evaluation of the reduced cost functional's derivatives. More precisely, computing the gradient of $i(p)$ at p_0 requires only the solution of (3.11). In addition, in order to compute the Hessian of $i(p)$ at p_0, the sensitivity quantities $U'(p_0)$, $Q'(p_0)$, and $Z'(p_0)$ need to be evaluated in the directions of a collection of basis vectors of the parameter space $\mathcal{P}$. That is, $\dim \mathcal{P}$ sensitivity problems (3.8) need to be solved. These are exactly the same problems which have to be solved for the computation of the Hessian of the [illegible]; see Table 3.1. Note that in the combined effort $1 + \dim \mathcal{P}$, "1" refers to the same dual problem (3.11) that has already been solved during the computation of the gradient of $i(p)$. In case that the space $\mathcal{P}$ is infinite-dimensional, it needs to be discretized first. Finally, in order to evaluate the second order Taylor expansion for a given direction δp,

$$i(p_0 + \delta p) \approx i(p_0) + i'(p_0)(\delta p) + \frac{1}{2} i''(p_0)(\delta p, \delta p),$$

the same dual problem (3.11) and one sensitivity problem (3.8) in the direction of δp are needed; see Table 3.1.

TABLE 3.1
Number of linear-quadratic problems to be solved to evaluate the derivatives of $j(p)$ and $i(p)$.

	Reduced cost functional $j(p)$	Reduced quantity of interest $i(p)$	
		Dual approach	Direct approach
Gradient	0	1	$\dim \mathcal{P}$
Hessian	$\dim \mathcal{P}$	$1 + \dim \mathcal{P}$	$(\dim \mathcal{P})\ (\dim \mathcal{P} + 1)/2$

Note that the sensitivity and dual problems (3.8) and (3.11), respectively, are solved by the technique described in section 2. The solution of such problems amounts to the computation of one additional QP step (2.17), with a different right-hand side. Therefore, the numerical effort to compute, e.g., the second order Taylor expansion for a given direction is typically low compared to the solution of the nonlinear optimization problem $\mathbf{OP}(p_0)$.

3.3. The control-constrained case. The analysis is based on the notion of strong regularity for the problem $\mathbf{OP}(p)$. Strong regularity extends the previous assumption of bounded invertibility of B_0 used throughout section 3.2.

Below, we make use of $\mu_0 \in \mathcal{Q}$ given by the following identification:

$$(\mu_0, \delta q) = -\mathcal{L}_q'(x_0, p_0)(\delta q) \quad \forall \delta q \in \mathcal{Q}. \tag{3.17}$$

This quantity acts as a Lagrange multiplier for the control constraint $q \in \mathcal{Q}_{ad}$. For the definition of strong regularity we introduce the following linearized optimality system

which depends on $\varepsilon = (\varepsilon^u, \varepsilon^q, \varepsilon^z) \in \mathcal{V} \times \mathcal{Q} \times \mathcal{V}$:

(**LOS**(ε))

$$\begin{aligned} &\mathcal{L}''_{uu}(x_0,p_0)(\delta u, u-u_0) + \mathcal{L}''_{uq}(x_0,p_0)(\delta u, q-q_0) \\ &\quad + \mathcal{L}''_{uz}(x_0,p_0)(\delta u, z-z_0) + \mathcal{L}'_{u}(x_0,p_0)(\delta u) \\ &\quad + (\varepsilon^u, \delta u)_{\mathcal{V}} = 0 \quad \forall \delta u \in \mathcal{V}, \end{aligned} \tag{3.18}$$

$$\begin{aligned} &\mathcal{L}''_{uq}(x_0,p_0)(u-u_0, \delta q - q) + \mathcal{L}''_{qq}(x_0,p_0)(\delta q - q, q-q_0) \\ &\quad + \mathcal{L}''_{qz}(x_0,p_0)(\delta q - q, z-z_0) \\ &\quad + \mathcal{L}'_{q}(x_0,p_0)(\delta q - q) + (\varepsilon^q, \delta q - q) \geq 0 \quad \forall \delta q \in \mathcal{Q}_{ad}, \end{aligned} \tag{3.19}$$

$$\begin{aligned} &\mathcal{L}''_{zu}(x_0,p_0)(\delta z, u-u_0) + \mathcal{L}''_{zq}(x_0,p_0)(\delta z, q-q_0) \\ &\quad + \mathcal{L}'_{z}(x_0,p_0)(\delta z) + (\varepsilon^z, \delta z)_{\mathcal{V}} = 0 \quad \forall \delta z \in \mathcal{V}. \end{aligned} \tag{3.20}$$

In what follows, we refer to (3.18)–(3.20) as (**LOS**(ε)).

DEFINITION 3.8 (strong regularity). $p_0 \in \mathcal{P}$ $x_0 = (u_0, q_0, z_0)$ (2.5)–(2.7) $\mathcal{N}(0) \subset \mathcal{X} = \mathcal{V} \times \mathcal{Q} \times \mathcal{V}$ 0 $\mathcal{N}(x_0) \subset \mathcal{X}$ x_0

(a) $\varepsilon \in \mathcal{N}(0)$ $(u^\varepsilon, q^\varepsilon, z^\varepsilon)$ (3.18)–(3.20)

(b) $(u^\varepsilon, q^\varepsilon, z^\varepsilon)$ (3.18)–(3.20) $\mathcal{N}(x_0)$

(c) $(u^\varepsilon, q^\varepsilon, z^\varepsilon)$ ε $L > 0$

$$\|u^{\varepsilon_1} - u^{\varepsilon_2}\|_{\mathcal{V}} + \|q^{\varepsilon_1} - q^{\varepsilon_2}\|_{\mathcal{Q}} + \|z^{\varepsilon_1} - z^{\varepsilon_2}\|_{\mathcal{V}} \leq L \, \|\varepsilon_1 - \varepsilon_2\|_{\mathcal{X}} \tag{3.21}$$

$\varepsilon_1, \varepsilon_2 \in \mathcal{N}(0)$

(2.5)–(2.7) strongly regular x_0

Note that (u_0, q_0, z_0) solves (3.18)–(3.20) for $\varepsilon = 0$. It is not difficult to see that in the case of no control constraints, i.e., $\mathcal{Q} = \mathcal{Q}_{ad}$, strong regularity is nothing else than bounded invertibility of B_0 which we had to assume in section 3.2. In the following lemma we show that strong regularity holds under suitable second order sufficient optimality conditions, in analogy to Lemma 3.3. The proof can be carried out using the techniques presented in [21].

LEMMA 3.9. 2.2 x_0 **OP**(p_0) $\varepsilon \in \mathcal{X}$ (3.18)–(3.20) $(u^\varepsilon, q^\varepsilon, z^\varepsilon)$

$$\mathcal{X} \ni \varepsilon \mapsto (u^\varepsilon, q^\varepsilon, z^\varepsilon) \in \mathcal{X} \tag{3.22}$$

x_0

In the next step, we proceed to prove that the solution $(u^\varepsilon, q^\varepsilon, z^\varepsilon)$ of the linearized optimality system (3.18)–(3.20) is directionally differentiable with respect to the perturbation ε. To this end, we need the following assumption.

ASSUMPTION 3.10. (u_0, q_0, z_0)

1. $\mathcal{V} \ni u \mapsto a''_{qu}(u_0, q_0, p_0)(\cdot, u, z_0) \in \mathcal{Q}'$
2. $\mathcal{Q} \ni q \mapsto a''_{qq}(u_0, q_0, p_0)(\cdot, q, z_0) \in \mathcal{Q}'$
3. $\mathcal{V} \ni z \mapsto a'_{q}(u_0, q_0, p_0)(\cdot, z) \in \mathcal{Q}'$

3.11. The previous assumption is satisfied for the following important classes of PDE-constrained optimization problems on bounded domains $\Omega \subset \mathbb{R}^d$, $d \in \{1, 2, 3\}$:

(a) If (**OP**(p)) is a distributed optimal control problem for a semilinear elliptic PDE, e.g.,

$$-\Delta u = f(u) + q \text{ on } \Omega$$

with $\mathcal{V} = H_0^1(\Omega)$ and $\mathcal{Q} = L^2(\Omega)$, then $a''_{qu} = a''_{qq} = 0$ and a'_q is the compact injection of $\mathcal{V}$ into $\mathcal{Q}$.

(b) In the case of Neumann boundary control on $\partial\Omega$, e.g.,

$$-\Delta u = f(u) \text{ on } \Omega \quad \text{and} \quad \frac{\partial}{\partial n} u = q \text{ on } \partial\Omega,$$

we have $\mathcal{V} = H^1(\Omega)$ and $\mathcal{Q} = L^2(\partial\Omega)$. Again, $a''_{qu} = a''_{qq} = 0$ and a'_q is the compact Dirichlet trace operator from $\mathcal{V}$ to $\mathcal{Q}$.

(c) For bilinear control problems, e.g.,

$$-\Delta u = qu + f \text{ on } \Omega$$

with $\mathcal{V} = H_0^1(\Omega)$, $\mathcal{Q} = L^2(\Omega)$, and an appropriate admissible set $\mathcal{Q}_{ad}$, we have $a''_{qq} = 0$. Moreover, the operators $u \mapsto a''_{qu}(u_0, q_0, p_0)(\cdot, u, z_0) = (uz_0, \cdot)$ and $z \mapsto a'_q(u_0, q_0, z_0) = (u_0 z, \cdot)$ are compact from $\mathcal{V}$ to $\mathcal{Q}'$ since the pointwise product of two functions in $\mathcal{V}$ embeds compactly into $\mathcal{Q}$.

(d) For parabolic equations such as

$$u_t = \Delta u + f(u) + q$$

with solutions in $\mathcal{V} = \{u \in L^2(0, T; H_0^1(\Omega)) : u_t \in L^2(0, T; H^{-1}(\Omega))\}$ we have $a''_{qu} = a''_{qq} = 0$ and a'_q is the compact injection of $\mathcal{V}$ into $\mathcal{Q} = L^2(\Omega \times (0, T))$.

(e) Finally, Assumption 3.10 is always satisfied if the space $\mathcal{Q}$ is finite-dimensional. This includes all cases of parameter identification problems without any additional restrictions on the coupling between the parameters q and the state variable u. For instance, the Arrhenius law leads to reaction-diffusion equations of the form

$$-\Delta u = f(u) + e^{qu} \text{ on } \Omega$$

with unknown Arrhenius parameter $q \in \mathbb{R}$.

For the following theorem, we introduce the admissible set $\widehat{\mathcal{Q}}_{ad}$, defined as

$$\widehat{\mathcal{Q}}_{ad} = \{\hat{q} \in \mathcal{Q} : \widehat{b}_-(x) \le \hat{q}(x) \le \widehat{b}_+(x) \text{ a.e. on } \omega\}$$

with bounds

$$\widehat{b}_-(x) = \begin{cases} 0 & \text{if } \mu_0(x) \neq 0 \text{ or } q_0(x) = b_-(x), \\ -\infty & \text{else,} \end{cases}$$

$$\widehat{b}_+(x) = \begin{cases} 0 & \text{if } \mu_0(x) \neq 0 \text{ or } q_0(x) = b_+(x), \\ +\infty & \text{else.} \end{cases}$$

THEOREM 3.12. [illegible] 2.2 [illegible] x_0 [illegible] **OP**(p_0) [illegible] 3.10 [illegible]

(3.22) [illegible] $\varepsilon = 0$ [illegible] $\delta\varepsilon = (\delta\varepsilon^u, \delta\varepsilon^q, \delta\varepsilon^z) \in \mathcal{X}$ [illegible] $(\hat{u}, \hat{q})$ [illegible] $\hat{z}$ [illegible] $\mathbf{DQP}(\delta\varepsilon)$

($\mathbf{DQP}(\delta\varepsilon)$)

$$\text{[illegible]} \quad \frac{1}{2}\begin{pmatrix}\hat{u} & \hat{q}\end{pmatrix}\begin{pmatrix}\mathcal{L}''_{uu}(x_0,p_0) & \mathcal{L}''_{uq}(x_0,p_0)\\ \mathcal{L}''_{qu}(x_0,p_0) & \mathcal{L}''_{qq}(x_0,p_0)\end{pmatrix}\begin{pmatrix}\hat{u}\\ \hat{q}\end{pmatrix} + (\hat{u}, \delta\varepsilon^u)_{\mathcal{V}} + (\hat{q}, \delta\varepsilon^q)$$

[illegible] $\hat{q} \in \widehat{\mathcal{Q}}_{ad}$ [illegible]

$$a'_u(u_0,q_0,p_0)(\hat{u},\phi) + a'_q(u_0,q_0,p_0)(\hat{q},\phi) + (\delta\varepsilon^z,\phi) = 0 \quad \forall \phi \in \mathcal{V}.$$

[illegible]

$$\mathcal{L}''_{uu}(x_0,p_0)(\delta u,\hat{u}) + \mathcal{L}''_{uq}(x_0,p_0)(\delta u,\hat{q}) + \mathcal{L}''_{uz}(x_0,p_0)(\delta u,\hat{z}) + (\delta\varepsilon^u,\delta u) = 0 \quad \forall \delta u \in \mathcal{V}, \tag{3.23}$$

$$\mathcal{L}''_{uq}(x_0,p_0)(\hat{u},\delta q-\hat{q}) + \mathcal{L}''_{qq}(x_0,p_0)(\delta q-\hat{q},\hat{q}) + \mathcal{L}''_{qz}(x_0,p_0)(\delta q-\hat{q},\hat{z}) + (\delta\varepsilon^q,\delta q-\hat{q}) \geq 0 \quad \forall \delta q \in \hat{\mathcal{Q}}_{ad}, \tag{3.24}$$

$$\mathcal{L}''_{zu}(x_0,p_0)(\delta z,\hat{u}) + \mathcal{L}''_{zq}(x_0,p_0)(\delta z,\hat{q}) + (\delta\varepsilon^z,\delta z) = 0 \quad \forall \delta z \in \mathcal{V}. \tag{3.25}$$

[illegible]. Let $\delta\varepsilon = (\delta\varepsilon^u, \delta\varepsilon^q, \delta\varepsilon^z) \in \mathcal{X}$ be given and let $\{\tau_n\} \subset \mathbb{R}^+$ denote a sequence converging to zero. We denote by $(u_n, q_n, z_n) \in \mathcal{X}$ the unique solution of $\mathbf{LOS}(\varepsilon_n)$, where $\varepsilon_n = \tau_n \delta\varepsilon$. Note that (u_0, q_0, z_0) is the unique solution of $\mathbf{LOS}(0)$ and that $(u_n, q_n, z_n) \to (u_0, q_0, z_0)$ strongly in $\mathcal{X}$. From Lemma 3.9 we infer that

$$\left\|\frac{u_n-u_0}{\tau_n}\right\|_{\mathcal{V}} + \left\|\frac{q_n-q_0}{\tau_n}\right\|_{\mathcal{Q}} + \left\|\frac{z_n-z_0}{\tau_n}\right\|_{\mathcal{V}} \leq L\,\|\delta\varepsilon\|_{\mathcal{X}}.$$

This implies that a subsequence (still denoted by index n) of the difference quotients converges weakly to some limit element $(\hat{u}, \hat{q}, \hat{z}) \in \mathcal{X}$. The proof proceeds with the construction of the [illegible] limit $\widetilde{q}$ of $(q_n - q_0)/\tau_n$, which is later shown to coincide with $\hat{q}$. It is well known that the variational inequality (3.19) in $\mathbf{LOS}(\varepsilon_n)$ can be equivalently rewritten as

$$q_n(x) = \Pi_{[b_-(x),b_+(x)]}\big(d_n(x)\big) \text{ a.e. on } \omega, \tag{3.26}$$

where $\Pi_{[b_-(x),b_+(x)]}$ is the projection onto the interval $[b_-(x), b_+(x)]$ and

$$d_n = \bar{q} + \frac{1}{\alpha}\Big(a''_{qu}(u_0,q_0,p_0)(\cdot,u_n-u_0,z_0) + a''_{qq}(u_0,q_0,p_0)(\cdot,q_n-q_0,z_0) + a'_q(u_0,q_0,p_0)(\cdot,z_n) - \varepsilon^q_n\Big) \in \mathcal{Q}. \tag{3.27}$$

The linear operators in (3.27) are understood as their Riesz representations in $\mathcal{Q}$. Similarly, we have $q_0(x) = \Pi_{[b_-(x),b_+(x)]}\big(d_0(x)\big)$ a.e. on ω, where

$$d_0 = \bar{q} + \frac{1}{\alpha}a'_q(u_0,q_0,p_0)(\cdot,z_0) \in \mathcal{Q}. \tag{3.28}$$

Note that $d_n \to d_0$ strongly in $\mathcal{Q}$ since the Fréchet derivatives in (3.27) are bounded linear operators. From the compactness properties in Assumption 3.10 we infer that

$$\frac{d_n - d_0}{\tau_n} \to \hat{d} \text{ strongly in } \mathcal{Q}, \quad \text{where}$$

$$\hat{d} = \frac{1}{\alpha}\Big(a''_{qu}(u_0,q_0,p_0)(\cdot,\hat{u},z_0) + a''_{qq}(u_0,q_0,p_0)(\cdot,\hat{q},z_0) + a'_q(u_0,q_0,p_0)(\cdot,\hat{z}) - \delta\varepsilon^q\Big).$$

By taking another subsequence, we obtain that $d_n \to d_0$ and $(d_n - d_0)/\tau_n \to \hat{d}$ hold also pointwise a.e. on ω. The construction of the pointwise limit

$$\widetilde{q}(x) = \lim_{n\to\infty} \frac{q_n(x) - q_0(x)}{\tau_n}$$

uses the following partition of ω into five disjoint subsets:

$$\omega = \omega^I \cup \omega_0^+ \cup (\omega^+ \setminus \omega_0^+) \cup \omega_0^- \cup (\omega^- \setminus \omega_0^-), \tag{3.29}$$

where

$$\omega^I = \{x \in \omega : b_-(x) < q_0(x) < b_+(x)\} \quad \text{(inactive)}, \tag{3.30a}$$

$$\omega_0^+ = \{x \in \omega : \mu_0(x) > 0\} \quad \text{(upper strongly active)}, \tag{3.30b}$$

$$\omega^+ = \{x \in \omega : q_0(x) = b_+(x)\} \quad \text{(upper active)}, \tag{3.30c}$$

$$\omega_0^- = \{x \in \omega : \mu_0(x) < 0\} \quad \text{(lower strongly active)}, \tag{3.30d}$$

$$\omega^- = \{x \in \omega : q_0(x) = b_-(x)\} \quad \text{(lower active)}. \tag{3.30e}$$

The Lagrange multiplier μ_0 belonging to the constraint $q_0 \in \mathcal{Q}_{ad}$ defined in (3.17) allows the following representation:

$$\mu_0 = \alpha(d_0 - q_0). \tag{3.31}$$

Note that the five sets in (3.29) are guaranteed to be disjoint if $b_-(x) < b_+(x)$ holds a.e. on ω. However, one can easily check that $\widetilde{q}$ is well defined also in the case that the bounds coincide on all or part of ω. We now distinguish five cases according to the sets in (3.29).

1. For almost every x in the inactive subset ω^I, we have $q_0(x) = d_0(x)$ and $q_n(x) = d_n(x)$ for all sufficiently large n. Therefore,

$$\widetilde{q}(x) = \lim_{n\to\infty} \frac{q_n(x) - q_0(x)}{\tau_n} = \hat{d}(x).$$

2. For almost every $x \in \omega_0^+$, $\mu_0(x) > 0$ implies $d_0(x) > q_0(x)$ by (3.31). Therefore, $q_0(x) = b_+(x)$ and $d_n(x) > q_0(x)$ for sufficiently large n. Hence $q_n = b_+(x)$ for these n and

$$\widetilde{q}(x) = \lim_{n\to\infty} \frac{q_n(x) - q_0(x)}{\tau_n} = 0.$$

3. For almost every $x \in \omega^+ \setminus \omega_0^+$, we have $q_0(x) = b_+(x) = d_0(x)$.

(a) If $\hat{d}(x) > 0$, then $d_n(x) > b_+(x)$ for sufficiently large n. Therefore, $q_n(x) = b_+(x)$ for these n and hence $\widetilde{q}(x) = 0$.

(b) If $\hat{d}(x) = 0$, then $(q_n(x) - q_0(x))/\tau_n = \min\{0, d_n(x) - b_+(x)\}/\tau^n$ for sufficiently large n; hence $\widetilde{q}(x) = 0$.

(c) If $\hat{d}(x) < 0$, then $d_n(x) < b_+(x)$ and hence $q_n(x) = d_n(x)$ for sufficiently large n. Therefore, $\widetilde{q}(x) = \hat{d}(x)$ holds.

Case 3 can be summarized as

$$\widetilde{q}(x) = \lim_{n\to\infty} \frac{q_n(x) - q_0(x)}{\tau_n} = \min\{0, \hat{d}(x)\}.$$

4. For almost every $x \in \omega_0^-$, we obtain, similarly to Case 2,

$$\widetilde{q}(x) = \lim_{n\to\infty} \frac{q_n(x) - q_0(x)}{\tau_n} = 0.$$

5. For almost every $x \in \omega^- \setminus \omega_0^-$, we obtain, similarly to Case 3,

$$\widetilde{q}(x) = \lim_{n\to\infty} \frac{q_n(x) - q_0(x)}{\tau_n} = \max\{0, \hat{d}(x)\}.$$

Summarizing all previous cases, we have shown that

$$\widetilde{q}(x) = \Pi_{[\hat{b}_-(x), \hat{b}_+(x)]}(\hat{d}(x)). \tag{3.32}$$

We proceed by showing that

$$\frac{q_n - q_0}{\tau_n} \to \widetilde{q} \text{ strongly in } \mathcal{Q} = L^2(\omega). \tag{3.33}$$

From the Lipschitz continuity of the projection Π, it follows that

$$\begin{aligned}\left\| \frac{q_n - q_0}{\tau_n} - \widetilde{q} \right\|_{\mathcal{Q}} &= \left\| \frac{1}{\tau_n} \left(\Pi_{\mathcal{Q}_{ad}}(d_n) - \Pi_{\mathcal{Q}_{ad}}(d_0)\right) - \Pi_{\widehat{\mathcal{Q}}_{ad}}(\hat{d}) \right\|_{\mathcal{Q}} \\ &\le \left\| \frac{d_n - d_0}{\tau_n} \right\|_{\mathcal{Q}} + \|\hat{d}\|_{\mathcal{Q}} \to 2\|\hat{d}\|_{\mathcal{Q}}.\end{aligned}$$

From Lebesgue's dominated convergence theorem, (3.33) follows. Consequently, we have $\widetilde{q} = \hat{q}$. The projection formula (3.32) is equivalent to the variational inequality (3.24). Using (3.18) and (3.20) for (u_n, q_n, z_n) and for (u_0, q_0, z_0), we infer that the weak limit $(\hat{u}, \hat{q}, \hat{z})$ satisfies (3.23) and (3.25). It is readily checked that (3.23)–(3.25) are the first order necessary conditions for (**DQP**$(\delta\varepsilon)$). In view of the second order sufficient optimality conditions (Lemma 2.2), (**DQP**$(\delta\varepsilon)$) is strictly convex and thus it has a unique solution. In view of Assumption 3.2 and (3.25), we obtain

$$\left\| \frac{u_n - u_0}{\tau_n} - \hat{u} \right\|_{\mathcal{V}} \le C \left\| \frac{q_n - q_0}{\tau_n} - \hat{q} \right\|_{\mathcal{Q}},$$

where C is independent of n. Hence $\hat{u}$ is also the strong limit of the difference quotient in $\mathcal{V}$. The same argument holds for $\hat{z}$. Our whole argument remains valid if in the beginning, we start with an arbitrary subsequence of $\{\tau_n\}$. Since the limit $(\hat{u}, \hat{q}, \hat{z})$ is always the same, the convergence extends to the whole sequence. ∎

From the previous theorem we derive the following important corollary. The proof follows from a direct application of the implicit function theorem for generalized equations; see [6, Theorem 2.4].

COROLLARY 3.13.
$\mathcal{N}(p_0) \subset \mathcal{P}$ p_0 $\mathcal{N}(x_0) \subset \mathcal{X}$ x_0
$(U, Q, Z) : \mathcal{N}(p_0) \to \mathcal{N}(x_0)$
(a) $p \in \mathcal{N}(p_0)$ $(U(p), Q(p), Z(p))$
(2.5)–(2.7) $\mathcal{N}(x_0)$
(b) $(U(p_0), Q(p_0), Z(p_0)) = (u_0, q_0, z_0)$

(c) [illegible] (U, Q, Z) [illegible] p_0 [illegible] $\delta p \in \mathcal{P}$ [illegible] $\varepsilon \mapsto (u^\varepsilon, q^\varepsilon, z^\varepsilon)$ [illegible] $\varepsilon = 0$ [illegible]

$$\delta\varepsilon = \begin{pmatrix} \mathcal{L}''_{up}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{qp}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{zp}(x_0, p_0)(\cdot, \delta p) \end{pmatrix}, \tag{3.34}$$

[illegible] $(\hat{u}, \hat{q}, \hat{z})$ [illegible] **DQP**$(\delta\varepsilon)$

We remark that computing the sensitivity derivative of (U, Q, Z) for a given direction δp amounts to solving the linear-quadratic optimal control problem **DQP**$(\delta\varepsilon)$ for $\delta\varepsilon$ given by (3.34). Note that this problem, like the original one **OP**(p_0), is subject to pointwise inequality constraints for the control variable. Due to the structure of the admissible set $\widehat{\mathcal{Q}}_{ad}$, the directional derivative of (U, Q, Z) is in general not a linear function of the direction δp, but only positively homogeneous. Note, however, that if the admissible set $\widehat{\mathcal{Q}}_{ad}$ is a linear space (which follows from a condition known as strict complementarity; see below), then the directional derivative becomes a linear function of the direction (i.e., it is the Gateaux differential).

Definition 3.14 (strict complementarity). [illegible] (x_0, p_0)

$$\Big\{ x \in \omega \,:\, q_0(x) \in \{b_-(x), b_+(x)\} \quad \mu_0(x) = 0 \Big\}$$

[illegible]

A consequence of the strict complementarity condition is that the sensitivity derivatives are characterized by a linear system of equations set forth in the following lemma. We recall that $\widetilde{B}$ was defined in (2.19) and that R_I denotes the multiplication of a function in $L^2(\omega)$ with the characteristic function of the inactive set $\omega^I = \{x \in \omega : b_-(x) < q_0(x) < b_+(x)\}$; see section 2.

Lemma 3.15. [illegible] 3.12 [illegible] (x_0, p_0) [illegible] (U, Q, Z) [illegible] linear [illegible]

$$\widetilde{B}(x_0, p_0) \begin{pmatrix} U'(p_0)(\delta p) \\ Q'(p_0)(\delta p) \\ Z'(p_0)(\delta p) \end{pmatrix} = - \begin{pmatrix} \mathcal{L}''_{up}(x_0, p_0)(\cdot, \delta p) \\ R_I \mathcal{L}''_{qp}(x_0, p_0)(\cdot, \delta p) \\ \mathcal{L}''_{zp}(x_0, p_0)(\cdot, \delta p) \end{pmatrix}. \tag{3.35}$$

[illegible] $\widetilde{B}(x_0, p_0) : \mathcal{X} \to \mathcal{X}'$ [illegible]. By virtue of the strict complementarity property, the admissible set $\widehat{\mathcal{Q}}_{ad}$ defined in Theorem 3.12 becomes

$$\widehat{\mathcal{Q}}_{ad} = \Big\{ \hat{q} \in \mathcal{Q} \,:\, \hat{q}(x) = 0, \text{ where } q_0(x) \in \{b_-(x), b_+(x)\} \Big\}.$$

Consequently, the variational inequality (3.24) simplifies to the following equation for $Q'(p_0)(\delta p) \in \widehat{\mathcal{Q}}_{ad}$:

$$\begin{aligned} &\mathcal{L}''_{qu}(x_0, p_0)(\delta q, U'(p_0)(\delta p)) + \mathcal{L}''_{qq}(x_0, p_0)(\delta q, Q'(p_0)(\delta p)) \\ &\qquad + \mathcal{L}''_{qz}(x_0, p_0)(\delta q, Z'(p_0)(\delta p)) = -\mathcal{L}''_{qp}(x_0, p_0)(\delta q, \delta p) \quad \forall \delta q \in \widehat{\mathcal{Q}}_{ad}, \end{aligned}$$

which is equivalent to the middle equation in (3.35). The first and third equation in (3.35) coincide with (3.23) and (3.25), which proves the first claim. From Theorem 3.12 we conclude that $\widetilde{B}(x_0, p_0)$ is bijective. Since it a continuous linear operator from $\mathcal{X} \to \mathcal{X}'$, so is its inverse. ∎

We are now in the position to recall the first and second order sensitivity derivatives of the reduced cost functional $j(p)$; see again [18]. Note that we do not make use of strict complementarity in the following proposition.

PROPOSITION 3.16. [illegible] 3.12 [illegible]

$$j(p) = J(U(p), p) + \frac{\alpha}{2}\|Q(p) - \overline{q}\|_{\mathcal{Q}}^2$$

[illegible] $\mathcal{N}(p_0)$ [illegible] p_0 [illegible] $\delta p \in \mathcal{P}$ [illegible]

$$j'(p)(\delta p) = \mathcal{L}_p'(x_0, p_0)(\delta p). \tag{3.36}$$

[illegible] j [illegible]

$$\begin{aligned} j''(p_0)(\delta p, \widehat{\delta p}) = {} & \mathcal{L}_{up}''(x_0, p_0)(U'(p_0)(\delta p), \widehat{\delta p}) + \mathcal{L}_{qp}''(x_0, p_0)(Q'(p_0)(\delta p), \widehat{\delta p}) \\ & + \mathcal{L}_{zp}''(x_0, p_0)(Z'(p_0)(\delta p), \widehat{\delta p}) + \mathcal{L}_{pp}''(x_0, p_0)(\delta p, \widehat{\delta p}). \end{aligned} \tag{3.37}$$

[illegible]. As in the unconstrained case there holds

$$\begin{aligned} j'(p_0)(\delta p) = {} & \mathcal{L}_u'(x_0, p_0)(U'(p_0)(\delta p)) + \mathcal{L}_q'(x_0, p_0)(Q'(p_0)(\delta p)) \\ & + \mathcal{L}_z'(x_0, p_0)(Z'(p_0)(\delta p)) + \mathcal{L}_p'(x_0, p_0)(\delta p), \end{aligned}$$

and the terms $\mathcal{L}_u'$ and $\mathcal{L}_z'$ vanish. Moreover,

$$\mathcal{L}_q'(x_0, p_0)(Q'(p_0)(\delta p)) = -(\mu_0, Q'(p_0)(\delta p)) = 0$$

since $Q'(p_0)(\delta p)$ is zero on the strongly active set and μ_0 vanishes on its complement. The formula for the second order derivative follows as in Proposition 3.5 by total directional differentiation of the first order formula. ∎

[illegible] 3.17. We note that the expressions for the first and second order derivatives in Proposition 3.16 are the same as in the unconstrained case; see Proposition 3.5.

We now turn to our main result in the control-constrained case, concerning the differentiability and efficient evaluation of the sensitivity derivatives for the reduced quantity of interest (1.4). We recall that in the unconstrained case, we have made use of a duality argument for the efficient computation of the first and second order derivatives; see section 3.2. However, in the presence of control constraints, this technique seems to be applicable only in the case of strict complementarity since otherwise, the derivatives $(U'(p_0)(\delta p), \xi'(p_0)(\delta p), Z'(p_0)(\delta p))$ do not depend linearly on the direction δp. In analogy to (3.11) and (3.35), we define the dual quantities $(\widetilde{v}, \widetilde{r}, \widetilde{y}) \in \mathcal{X}$ by

$$\widetilde{B}(x_0, p_0) \begin{pmatrix} \widetilde{v} \\ \widetilde{r} \\ \widetilde{y} \end{pmatrix} = - \begin{pmatrix} I_u'(q_0, u_0, p_0) \\ R_I I_q'(q_0, u_0, p_0) \\ 0 \end{pmatrix}. \tag{3.38}$$

THEOREM 3.18. [illegible] 3.12 [illegible] $i(p)$ [illegible] p_0 [illegible] (x_0, p_0) [illegible]

p_0 $\delta p \in \mathcal{P}$

$$i'(p_0)(\delta p) = \mathcal{L}''_{up}(x_0,p_0)(\widetilde{v},\delta p) + \mathcal{L}''_{qp}(x_0,p_0)(R_I\widetilde{r},\delta p) + \mathcal{L}''_{zp}(x_0,p_0)(\widetilde{y},\delta p) + I'_p(u_0,q_0,p_0)(\delta p). \tag{3.39}$$

The proof is carried out similarly to the proof of Theorem 3.6 using Lemma 3.15. □

Our next goal is to consider second order derivatives of the reduced quantity of interest. In order to apply the approach used in the unconstrained case, we rely on the existence of second order directional derivatives of (U, Q, Z) at p_0. However, these second order derivatives do not exist without further assumptions, as seen from the following simple consideration: Suppose that near a given reference parameter $p_0 = 0$, the local optimal control is given by $Q(p)(x) = \max\{0, x + p\} \in L^2(\omega)$ for $x \in \omega = (-1, 1)$ and $p \in \mathbb{R}$. (An appropriate optimal control problem (**OP**(p)) can be easily constructed.) Then $Q'(p)(x) = H(x+p)$ (the Heaviside function), which is not directionally differentiable with respect to p and values in $L^2(\omega)$. Note that the point $x = -p$ of discontinuity marks the boundary between the active and inactive sets of (**OP**(p)). Hence we conclude that the reason for the nonexistence of the second order directional derivatives of Q lies in the change of the active set with p.

The preceding argument leads to the following assumption.

ASSUMPTION 3.19. $\mathcal{N}(p_0) \subset \mathcal{P}$ p_0 $p \in \mathcal{N}(p_0)$ $(U(p), Q(p), Z(p))$ (u_0, q_0, z_0)

3.20. The previous assumption seems difficult to satisfy in the general case. However, if the control variable is finite-dimensional and strict complementarity is assumed at the reference solution (u_0, q_0, z_0), then Assumption 3.19 is satisfied since the Lagrange multiplier $\mu(p) = -\mathcal{L}'_q(U(p), Q(p), Z(p), p)$ is continuous with respect to p and has values in $\mathbb{R}^n$.

We now proceed to our main result concerning second order derivatives of the reduced quantity of interest. In the theorem below, we use again () to denote evaluation at the point (x_0, p_0).

THEOREM 3.21. 3.12 3.19 $i(p)$ p_0 δp $\widehat{\delta p}$

$$i''(p_0)(\delta p, \widehat{\delta p}) = \langle \widetilde{v}, \eta\rangle_{\mathcal{V}\times\mathcal{V}'} + \langle \widetilde{r}, \kappa\rangle_{\mathcal{Q}\times\mathcal{Q}'} + \langle \widetilde{y}, \sigma\rangle_{\mathcal{V}\times\mathcal{V}'} + \begin{pmatrix} U'(p_0)(\delta p) \\ Q'(p_0)(\delta p) \\ \delta p \end{pmatrix}^\top \begin{pmatrix} I''_{uu}(q_0,u_0,p_0) & I''_{uq}(q_0,u_0,p_0) & I''_{up}(q_0,u_0,p_0) \\ I''_{qu}(q_0,u_0,p_0) & I''_{qq}(q_0,u_0,p_0) & I''_{qp}(q_0,u_0,p_0) \\ I''_{pu}(q_0,u_0,p_0) & I''_{pq}(q_0,u_0,p_0) & I''_{pp}(q_0,u_0,p_0) \end{pmatrix} \begin{pmatrix} U'(p_0)(\widehat{\delta p}) \\ Q'(p_0)(\widehat{\delta p}) \\ \widehat{\delta p} \end{pmatrix}. \tag{3.40}$$

$(\eta, \kappa, \sigma) \in \mathcal{V}' \times \mathcal{Q}' \times \mathcal{V}'$

$$\begin{pmatrix} \eta \\ \kappa \\ \sigma \end{pmatrix} = \begin{pmatrix} \mathcal{L}'''_{upp}()(\cdot, \delta p, \widehat{\delta p}) \\ \mathcal{L}'''_{qpp}()(\cdot, \delta p, \widehat{\delta p}) \\ \mathcal{L}'''_{zpp}()(\cdot, \delta p, \widehat{\delta p}) \end{pmatrix} \tag{3.41}$$

Evaluation of sensitivity derivatives

1. Evaluate $j'(p_0)\,\delta p$ according to (3.36)
2. Compute the sensitivities $U'(p_0)\,\delta p$, $Q'(p_0)\,\delta p$, and $Z'(p_0)\,\delta p$ from (3.35)
3. Evaluate $j''(p_0)(\delta p, \widehat{\delta p})$ according to (3.37)
4. Compute the dual quantities $(\widetilde{v}, \widetilde{r}, \widetilde{y})$ from (3.38)
5. Evaluate $i'(p_0)\,\delta p$ according to (3.39)
6. Compute the sensitivities $U'(p_0)\,\widehat{\delta p}$, $Q'(p_0)\,\widehat{\delta p}$, and $Z'(p_0)\,\widehat{\delta p}$ from (3.35)
7. Compute the auxiliary quantities (η, κ, σ) from (**??**)
8. Evaluate $i''(p_0)(\delta p, \widehat{\delta p})$ according to (3.40).

ALGORITHM 3.1. *Evaluating the first and second order derivatives of the reduced cost function j and the reduced quantity of interest i.*

$$+\begin{pmatrix} \mathcal{L}'''_{upu}()(\cdot,\delta p, U'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{upq}()(\cdot,\delta p, Q'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{upz}()(\cdot,\delta p, Z'(p_0)(\widehat{\delta p})) \\ \mathcal{L}'''_{qpu}()(\cdot,\delta p, U'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{qpq}()(\cdot,\delta p, Q'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{qpz}()(\cdot,\delta p, Z'(p_0)(\widehat{\delta p})) \\ \mathcal{L}'''_{zpu}()(\cdot,\delta p, U'(p_0)(\widehat{\delta p})) + \mathcal{L}'''_{zpq}()(\cdot,\delta p, Q'(p_0)(\widehat{\delta p})) \end{pmatrix}$$

$$+\left(\widetilde{B}'_u()(U'(p_0)(\widehat{\delta p})) + \widetilde{B}'_q()(Q'(p_0)(\widehat{\delta p})) + \widetilde{B}'_z()(Z'(p_0)(\widehat{\delta p})) + \widetilde{B}'_p()(\widehat{\delta p})\right)\begin{pmatrix} U'(p_0)(\delta p) \\ Q'(p_0)(\delta p) \\ Z'(p_0)(\delta p) \end{pmatrix}.$$

. The proof uses the same argument as the proof of Theorem 3.6. Note that in view of Assumption 3.19, $\widetilde{B}(U(p), Q(p), Z(p), p)$ is totally directionally differentiable with respect to p at p_0. In the direction $\widehat{\delta p}$, the derivative is

$$\widetilde{B}'_u()(U'(p_0)(\widehat{\delta p})) + \widetilde{B}'_q()(Q'(p_0)(\widehat{\delta p})) + \widetilde{B}'_z()(Z'(p_0)(\widehat{\delta p})) + \widetilde{B}'_p()(\widehat{\delta p}).$$

Due to the constant active sets, these partial derivatives have the following form:

$$\widetilde{B}'_u() = \begin{pmatrix} id & & \\ & R_I & \\ & & id \end{pmatrix} B'_u(x_0, p_0) \begin{pmatrix} id & & \\ & R_I & \\ & & id \end{pmatrix}.$$

In view of the bounded invertibility of $\widetilde{B}(x_0, p_0)$ (see Lemma 3.15), the second order partial derivatives of (U, Q, Z) at p_0 exist by the implicit function theorem. They satisfy the analogue of (3.16). ∎

We conclude this section by stating Algorithm 3.1 which collects the necessary steps to evaluate the first and second order sensitivity derivatives $j'(p_0)\,\delta p$ and $j''(p_0)(\delta p, \widehat{\delta p})$ as well as $i'(p_0)\,\delta p$ and $i''(p_0)(\delta p, \widehat{\delta p})$ for given $\delta p, \widehat{\delta p} \in \mathcal{P}$. We suppose that the original optimization problem (**OP**(p)) has been solved, e.g., by the primal-dual active set approach in section 2, for the nominal parameter p_0. We denote by

$\mathcal{A}_\pm$ and $\mathcal{I}$ the active and inactive sets belonging to the nominal solution (u_0, q_0) and adjoint state z_0. For the definition of $\widetilde{B}(x_0, p_0)$ appearing in (3.35) and (3.38), we refer the reader to (2.19).

4. Numerical examples. In this section we illustrate our approach using two examples from different areas. The first example is concerned with a parameter identification problem for the stationary Navier–Stokes system. No inequality constraints are present in this problem, and first and second order derivatives of the quantity of interest are obtained. In the second example, we consider a control-constrained optimal control problem for an instationary reaction-diffusion system subject to an infinite-dimensional parameter, which demonstrates the full potential of our approach.

4.1. Example 1. In this section we illustrate our approach using as an example a parameter identification flow problem without inequality constraints. We consider the configuration sketched in Figure 4.1.

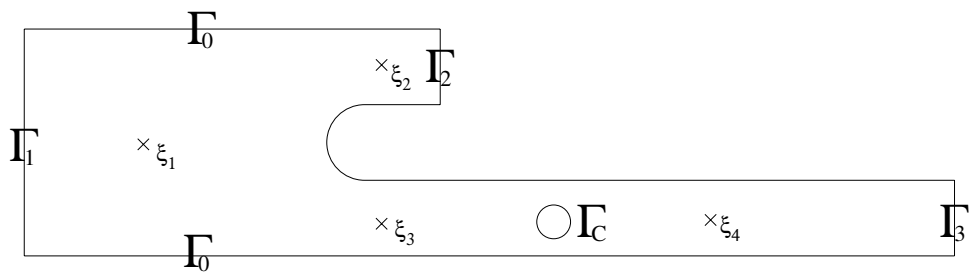

FIG. 4.1. *Configuration of the system of pipes with measurement points.*

The (stationary) flow in this system of pipes around the cylinder Γ_C is described by incompressible Navier–Stokes equations, with unknown viscosity q:

$$
\begin{aligned}
-q\Delta v + v\cdot\nabla v + \nabla p &= f && \text{in} && \Omega,\\
\nabla\cdot v &= 0 && \text{in} && \Omega,\\
v &= 0 && \text{on} && \Gamma_0\cup\Gamma_C,\\
v &= v_{in} && \text{on} && \Gamma_1,\\
q\tfrac{\partial v}{\partial n} - pn &= \pi n && \text{on} && \Gamma_2,\\
q\tfrac{\partial v}{\partial n} - pn &= 0 && \text{on} && \Gamma_3.
\end{aligned}
\tag{4.1}
$$

Here, the state variable $u = (v, p)$ consists of the velocity $v = (v^1, v^2) \in H^1(\Omega)^2$ and the pressure $p \in L^2(\Omega)$. The inflow Dirichlet boundary condition on Γ_1 is given by a parabolic inflow v_{in}. The outflow boundary conditions of the Neumann type are prescribed on Γ_2 and Γ_3 involving the perturbation parameter $\pi \in P = \mathbb{R}$. (Unlike in previous sections, we denote the perturbation parameter by π to avoid the confusion with the pressure p.) Physically, the perturbation parameter π describes the pressure difference between Γ_2 and Γ_3; see [11] for a detailed discussion of this type of outflow boundary condition. The reference parameter chosen is $\pi_0 = 0.029$.

The aim is to estimate the unknown viscosity $q \in Q = \mathbb{R}$ using the measurements of the velocity in four given points; see Figure 4.1. By the least squares approach, this results in the following parameter identification problem:

$$
\text{Minimize } \sum_{i=1}^{4}\sum_{j=1}^{2}(v^j(\xi_i) - \bar{v}_i^j)^2 + \alpha q^2, \quad \text{subject to (4.1).}
$$

Here, $\bar{v}_i^j$ are the measured values of the components of the velocity at the point ξ_i and α is a regularization parameter. For a priori error analysis for finite element discretization of parameter identification problems with pointwise measurements we refer the reader to [20].

The sensitivity analysis of previous sections allows us to study the dependence on the perturbation parameter π. To illustrate this, we define two functionals describing the possible quantities of interest:

$$I_1(u,q) = q, \qquad I_2(u,q) = c_d(u),$$

where $c_d(u)$ is the drag coefficient on the cylinder Γ_C defined as

$$c_d(u) = c_0 \int_{\Gamma_C} n \cdot \sigma \cdot d \, ds, \tag{4.2}$$

with a chosen direction $d = (1,0)$, a given constant c_0, and the stress tensor σ given by

$$\sigma = \frac{\nu}{2}(\nabla v + (\nabla v)^T) - pI.$$

For the discretization of the state equation we use conforming finite elements on a shape-regular quadrilateral mesh $\mathcal{T}_h$. The trial and test spaces consist of cellwise bilinear shape-functions for both pressure and velocities. We add further terms to the finite element formulation in order to obtain a stable formulation with respect to both the pressure-velocity coupling and convection dominated flow. This type of stabilization technique is based on local projections of the pressure first introduced in [1]. The resulting parameter identification problem is solved by Newton's method on the parameter space as described in [3] which is known to be mesh-independent. The nonlinear state equation is likewise solved by Newton's method, whereas the linear subproblems are computed using a standard multigrid algorithm. With these ingredients, the total numerical cost for the solution of this parameter identification problem on a given mesh behaves like $\mathcal{O}(N)$, where N is the number of degrees of freedom (dofs) for the state equation.

For the reduced quantities of interest $i_1(\pi)$ and $i_2(\pi)$ we compute the first and second derivatives using the representations from Theorem 3.6. In Tables 4.1 and 4.2 we collect the values of these derivatives for a sequence of uniformly refined meshes.

In order to verify the computed sensitivity derivatives, we make a comparison with the derivatives computed by the second order difference quotients. To this end we choose $\varepsilon = 10^{-4}$ and compute

$$di_l = \frac{i_l(\pi_0+\varepsilon) - i_l(\pi_0-\varepsilon)}{2\,\varepsilon}, \quad ddi_l = \frac{i_l(\pi_0+\varepsilon) - 2i_l(\pi_0) + i_l(\pi_0-\varepsilon)}{\varepsilon^2}$$

by solving the optimization problem additionally for $\pi = \pi_0 - \varepsilon$ and $\pi = \pi_0 + \varepsilon$. The results are shown in Table 4.3.

Example 4.1. The relative errors in Table 4.3 are of the order of the estimated finite difference truncation error. We therefore consider the correctness of our method to have been verified to within the accuracy of this test. The same holds for Example 2 and Table 4.4 below.

TABLE 4.1
The values of $i_1(\pi)$ and its derivatives on a sequence of uniformly refined meshes.

4.2. Example 2. The second example concerns a control-constrained optimal control problem for an instationary reaction-diffusion model in three spatial dimensions. As the problem setup was described in detail in [9], we will be brief here. The reaction-diffusion state equation is given by

$$(c_1)_t = D_1 \Delta c_1 - k_1 c_1 c_2 \quad \text{in } \Omega \times (0, T), \tag{4.3a}$$

$$(c_2)_t = D_2 \Delta c_2 - k_2 c_1 c_2 \quad \text{in } \Omega \times (0, T), \tag{4.3b}$$

where c_i denotes the concentration of the ith substance, and hence $u = (c_1, c_2)$ is the state variable. Ω is a domain in $\mathbb{R}^3$, in this case an annular cylinder (Figure 4.2), and T is the given final time. The control q enters through the inhomogeneous boundary conditions

$$D_1 \frac{\partial c_1}{\partial n} = 0 \quad \text{in } \partial\Omega \times (0, T), \tag{4.4a}$$

$$D_2 \frac{\partial c_2}{\partial n} = q(t)\, \alpha(t, x) \quad \text{in } \partial\Omega_c \times (0, T), \tag{4.4b}$$

$$D_2 \frac{\partial c_2}{\partial n} = 0 \quad \text{in } (\partial\Omega \setminus \partial\Omega_c) \times (0, T), \tag{4.4c}$$

and α is a given shape function on the boundary, modeling a revolving nozzle on the control surface $\partial\Omega_c$, the upper annulus. Initial conditions

$$c_1(0, x) = c_{10}(x) \quad \text{in } \Omega, \tag{4.5a}$$

$$c_2(0, x) = c_{20}(x) \quad \text{in } \Omega \tag{4.5b}$$

are also given. The objective to be minimized is

$$J(c_1, c_2, q) = \frac{1}{2} \int_\Omega \alpha_1 \, |c_1(T, \cdot) - c_{1T}|^2 + \alpha_2 \, |c_2(T, \cdot) - c_{2T}|^2 \, \mathrm{d}x + \frac{\gamma}{2} \int_0^T |q - q_d|^2 \, \mathrm{d}t$$
$$+ \frac{1}{\varepsilon} \max \left\{ 0, \int_0^T q(t) \, \mathrm{d}t - q_c \right\}^3 ;$$

i.e., it contains contributions from deviation of the concentrations at the given terminal time T from the desired ones c_{iT}, plus control cost and a term stemming from a penalization of excessive total control action. We consider here the particular setup described in [9, Example 1], where substance c_1 is to be driven to zero at time T (i.e., we have $\alpha_1 = 1$ and $\alpha_2 = 0$) from given uniform initial state $c_{10} \equiv 1$. This problem features a number of parameters, and differentiability of optimal solutions with respect to these parameters was proved in [10]; hence, we may apply the results of section 3. The nominal as well as the sensitivity and dual problems were solved using a primal-dual active set strategy; see [9, 15]. The nominal control is depicted in Figure 4.2. One clearly sees that the upper and lower bounds with values 5 and 1, respectively, are active in the beginning and end of the time interval. All computations were carried out using piecewise linear finite elements on a tetrahedral grid with roughly 3300 vertices, 13200 tetrahedra, and 100 time steps.

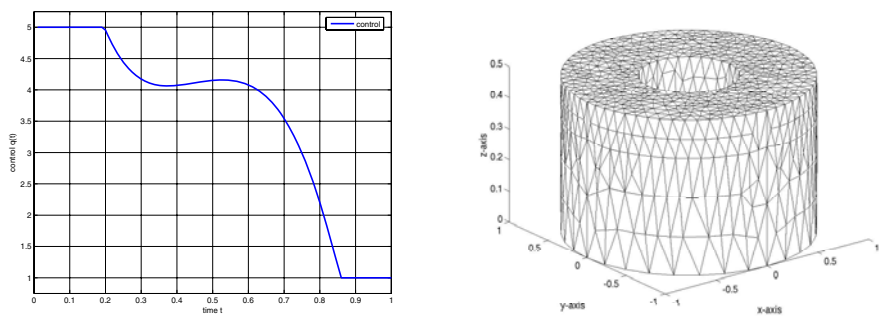

FIG. 4.2. *Optimal (unperturbed) control q (left) and computational domain (right).*

Since the control variable is infinite-dimensional and control constraints are active in the solution, the active sets will in general change even under arbitrarily small perturbations; hence second order derivatives of the reduced quantity of interest $i(p)$ may not exist (see the discussion before Asumption 3.19).

We choose as quantity of interest the total amount of control action

$$I(u, q) = \int_0^T q(t) \, \mathrm{d}t.$$

In contrast to the previous example, we consider now an infinite-dimensional parameter $p = c_{10}$, the initial value of the first substance. After discretization on the given spatial grid, the parameter space has a dimension $\dim P \approx 3300$. A look at Table 3.1 now reveals the potential of our method: The direct evaluation of the derivative $i'(p_0)$ would have required the solution of 3300 auxiliary linear-quadratic problems, an unbearable effort. By our dual approach, however, we need to solve only one additional such problem (3.38) for the dual quantities. The derivative $i'(p_0)$ is shown

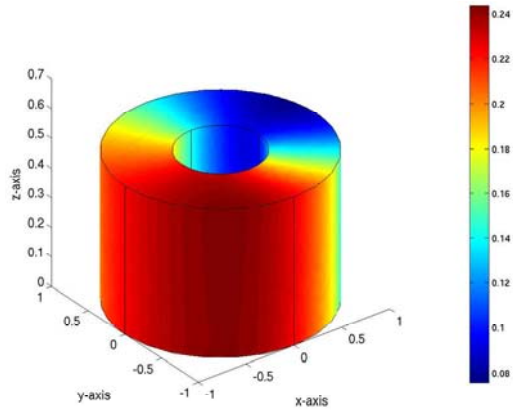

FIG. 4.3. *Gradient of the quantity of interest.*

in Figure 4.3 as a distributed function on Ω. In the unperturbed setup, the desired terminal state $c_1(T)$ is everywhere above the desired state $c_{1T} \equiv 0$. By increasing the value of the initial state c_{10}, the desired terminal state is even more difficult to reach, which leads to an increased control effort and thus an increased value of the quantity of interest. This is reflected by the sign of the function in Figure 4.3, which is everywhere positive. Moreover, one can identify the region of Ω where perturbations in the initial state have the greatest impact on the value of the quantity of interest.

In order to check the derivative, we use again a comparison with a difference quotient in the given direction of $\delta p \equiv 1$. Table 4.4 shows the analogue of Table 4.3 with $\varepsilon = 10^{-2}$ for this example.

5. Conclusion. In this paper, we considered PDE-constrained optimization problems with inequality constraints, which depend on a perturbation parameter p. The differentiability of optimal solutions with respect to this parameter is shown in Theorem 3.12. This result complements previous findings in [7, 18] and makes precise the compactness assumptions needed for the proof.

We obtained sensitivity results for a quantity of interest which depends on the optimal solution and is different from the cost functional. The main contribution of this paper is to devise an efficient algorithm to evaluate these sensitivity derivatives. Using a duality technique, we showed that the numerical cost of evaluating the gradient or the Hessian of the quantity of interest is only marginally higher than the evaluation of the gradient or the Hessian of the cost functional. The small additional effort is spent for the solution of one additional linear-quadratic optimization problem for a suitable dual quantity. A comparison with a direct approach for the evaluation of the gradient and the Hessian revealed the tremendous savings of the dual approach especially in the case of a high-dimenensional parameter space. Two numerical examples confirmed the correctness of our derivative formulae and illustrated the applicability

of our results.

HIERARCHICAL NONLINEAR APPROXIMATION FOR EXPERIMENTAL DESIGN AND STATISTICAL DATA FITTING*

DANIEL BUSBY†, CHRIS L. FARMER‡, AND ARMIN ISKE§

Abstract. This paper proposes a hierarchical nonlinear approximation scheme for scalar-valued multivariate functions, where the main objective is to obtain an accurate approximation with using only very few function evaluations. To this end, our iterative method combines at any refinement step the selection of suitable evaluation points with kriging, a standard method for statistical data analysis. Particular improvements over previous nonhierarchical methods are mainly concerning the construction of new evaluation points at run time. In this construction process, referred to as experimental design, a flexible two-stage method is employed, where adaptive domain refinement is combined with sequential experimental design. The hierarchical method is applied to statistical data analysis, where the data is generated by a very complex and computationally expensive computer model, called a simulator. In this application, a fast and accurate statistical approximation, called an emulator, is required as a cheap surrogate of the expensive simulator. The construction of the emulator relies on computer experiments using a very small set of carefully selected input configurations for the simulator runs. The hierarchical method proposed in this paper is, for various analyzed models from reservoir forecasting, more efficient than existing standard methods. This is supported by numerical results, which show that our hierarchical method is, at comparable computational costs, up to ten times more accurate than traditional nonhierarchical methods, as utilized in commercial software relying on the response surface methodology (RSM).

1. Introduction.

Approximation of scalar-valued multivariate functions from scattered data is of primary importance in many applications from computational science and engineering. To describe the mathematical problem, let $f : \Omega \to \mathbb{R}$, for some domain $\Omega \subset \mathbb{R}^d$, denote an unknown multivariate function, whose scalar function values in $f\big|_X = (f(\mathbf{x}_1), \ldots, f(\mathbf{x}_n))^T \in \mathbb{R}^n$, taken at a scattered set $X = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\} \subset \Omega$ of pairwise distinct points, are given. Scattered data approximation requires the construction of a suitable function $s : \mathbb{R}^d \to \mathbb{R}$, which is [illegible] to f in a sense to be described. Usually, the quality of the approximation s is, for a fixed normed linear space $\mathcal{V}$ containing f and s, i.e., $f, s \in \mathcal{V}$, measured by the approximation error

$$\eta_{\mathcal{V}}(f, s) = \|f - s\|_{\mathcal{V}}.$$

The construction of an approximation to f is usually accomplished by first specifying a suitable finite-dimensional approximation space $\mathcal{S} \subset \mathcal{V}$, before a $s^* \in \mathcal{S}$ to f is computed by minimizing the distance between f and $\mathcal{S}$, so that s^* satisfies

$$\min_{s \in \mathcal{S}} \|f - s\|_{\mathcal{V}} = \|f - s^*\|_{\mathcal{V}}.$$

In the above-mentioned approximation problem, the beforehand construction of a approximation space $\mathcal{S}$ usually depends on X, and so the resulting approximation scheme is . In such a setting, the sample points in X and the function values $f|_X$ are required to be .

We remark that there are only a few powerful approximation methods available for solving such linear scattered data approximation problems for multivariate data, where radial basis function methods are among the most popular tools. For a comprehensive treatment of scattered data approximation and radial basis function methods, we refer the reader to the textbooks [1, 10, 30], where in particular relevant aspects concerning numerical stability, approximation orders for suitable (native) functions spaces, $\mathcal{V}$, and the construction of best approximations are explained in great detail.

In this paper we wish to propose a approximation scheme for data fitting, where the nonlinearity is due to the variation of the sample points in X. The goal of our resulting computational method is to obtain a sufficiently accurate approximation to f by using as few as possible sample points in X; i.e., n is required to be very small. Moreover, we assume that the dimension of the input variables is very large, i.e., $d \gg 1$, and the input data are assumed to be . The latter essentially requires suitable methods for data fitting, i.e., statistical approximation schemes which are relying on suitable statistical models.

To this end, we prefer to work with , a well-established statistical method first introduced by Krige in the 1950's, then formalized as a fundamental geostatistical technique by Matheron [16] in 1963, and later utilized by Sacks, Welch, Mitchell, and Wynn [24] in computer experiments. We remark that kriging is under specific conditions equivalent to Bayesian methods (see [6] for details), and also to radial basis function interpolation (as recently shown in [8, 31]).

By combining kriging with adaptive domain decomposition, the proposed method of this paper results in a hierarchical nonlinear approximation scheme, where the nonlinearity is due to the adaptive selection of suitable sample points X at the algorithm's run time.

The motivation for this work is mainly given by specific applications from experimental design and statistical data fitting in computer experiments. In the general setting of this wide application field, many scientific phenomena are investigated by using complex computer models or codes. In oil reservoir forecasting, for instance, are used to model the evolution of time-dependent physical quantities in a hydrocarbon reservoir production scenario, where long time scales are common; see [11].

The simulation codes are often computationally expensive to run, which requires cheaper predictors, , as surrogates for the too expensive simulators. The construction of an emulator relies on a sequence of computer experiments, involving a number of costly simulator runs with various different input configurations, where the overall aim is to obtain a sufficiently accurate emulator at an as small as possible number of simulator runs. This requires a careful selection of input configurations for the simulator runs.

In such and similar application scenarios for computer experiments, the simulator output is [illegible]; i.e., rerunning the code with the same inputs gives identical observations, but major computational difficulties are often due to [illegible] and [illegible] input data. This requires customized methods for the construction of a sufficiently accurate emulator, in particular as experimenters are interested in [illegible] of the simulation output, [illegible] of the simulator by using external data from the physical system, such as in [illegible], and the optimization of adjustable input parameters.

In the mathematical formulation of this problem, the simulator is viewed as a multivariate target function $f : \mathbb{R}^d \to \mathbb{R}$, the emulator is an approximation $s : \mathbb{R}^d \to \mathbb{R}$ to f, and the selected input configurations, often referred to as [illegible], are the sample points in X.

In general, the construction of an efficient emulator involves the following steps.

1. [illegible]. The goal is to determine configurations of input parameters for running the simulator to build a sufficiently accurate emulator with an as small as possible number of simulator runs.
2. [illegible]. The aim is to reduce the dimensionality of the problem under investigation. This is usually done in a preprocessing step by performing a sensitivity analysis with the available data, in order to discard irrelevant parameters which were initially included in the model. Therefore, screening can also be viewed as an a priori model selection problem, where the [illegible] and [illegible] input parameters are determined.
3. [illegible]. Model parameters are tuned for the selection of an (optimal) emulator which is used to make accurate predictions on the response at untried inputs. This is usually done by optimizing a functional of the response. A common approach for analyzing statistical data is [illegible], as explained in section 3.

The proposed hierarchical approximation scheme aims at the efficient construction of an accurate emulator. This is accomplished by an iterative refinement strategy where the available data collected so far is used to apply at each iteration step an adaptive two-stage process for the experimental design, followed by a statistical data analysis to optimize the parameters of the emulator. Following standard concepts [18] concerning screening, we refrained from including screening in this hierarchical refinement process, although this may be an option in situations where the dimension d of the input data is extremely high, so that further eliminations of input variables are inevitably needed to reduce the required computational costs. A formal description of the proposed hierarchical approximation scheme is given by Algorithm 1.

Our nonlinear approximation scheme results in a multiresolution representation of the emulator, from coarse to fine. That is, with increasing accuracy at each iteration, to obtain a sufficiently accurate emulator at the finest level after merely a few iterations. In this way, the utilized refinement strategy allows control of the gradually increasing computational costs for building the hierarchical emulator sequence, and their increasing accuracy.

We remark that the proposed approach in this paper uses ideas from previous work [5, 6, 7, 13, 24, 26, 27, 29] concerning experimental (sequential) design, sensitivity analysis, and interpolation schemes in nonhierarchical methods.

Our approach aims at two important objectives in experimental design, that is, (1) reducing the uncertainty predicted by the model and (2) improving the model reliability. The first objective is addressed by entropy minimization, in combination

with a customized adaptive gridding algorithm. The second objective is achieved by adaptive cross validation, with acquiring further observations from input configurations where the model prediction is bad ( ). Although both kinds of adaptivity look similar at first sight, these two approaches are fundamentally different from a mathematical and conceptual point of view.

The outline of the paper is as follows. In section 2, the basic ideas of the hierarchical nonlinear approximation scheme are explained, before the kriging method is discussed in section 3. In section 4, the construction of an initial design is explained and some selected aspects concerning screening are briefly addressed. Sections 5 and 6 are devoted to details concerning adaptivity in experimental design, which works with a two-stage process. In section 5, we explain the global approach of adaptive gridding, before turning to local optimal design in section 6. A schematic description of the final algorithm is given in section 7. Finally, section 8 presents numerical results obtained by applying our method to a given function, being regarded as a simulator, and to two different reservoir forecasting problems. It is shown that our hierarchical scheme is for the analyzed reservoir models more efficient than existing methodologies. Indeed, our approximation method is, at comparable computational costs, up to ten times more accurate than the quadratic method in reservoir uncertainty analysis software, such as COUGAR [4], which relies on the response surface methodology (RSM).

2. Hierarchical nonlinear approximation. The proposed hierarchical approximation scheme constructs a sequence $s_1, s_2, \ldots, s_L$ of approximations to an unknown function $f : \mathbb{R}^d \to \mathbb{R}$ from samples of f taken at scattered locations $X = \{x_1, \ldots, x_m\}$. The construction of the approximation relies on a data hierarchy

$$X_1 \subset X_2 \subset \cdots \subset X_L \subset X \tag{2.1}$$

of nested subsets of X, where L denotes the number of levels. Then, the functions s_ℓ approximate f at the subsets X_ℓ of the level ℓ, $1 \le \ell \le L$, according to some specific approximation scheme. Examples for recent approximation schemes are discussed in [10]. Note that the sequence $s_1, s_2, \ldots, s_L$ of approximations to f is from coarse to fine. Indeed, the coarsest approximation s_1 is computed on the basis of the initial design X_1, which includes only very few data. In contrast, the approximations s_ℓ at finer levels ℓ contain gradually more information from their corresponding designs X_ℓ.

The approach taken in this paper is ; that is, the construction of the data hierarchy in (2.1) is done at run time in the approximation process, rather than in a preprocessing step. This adaptive approach, dating back to [12], allows control of both the cumulative computational cost and the accuracy of the current approximation s_ℓ at any level ℓ.

Recall that in the setting and language of this paper, the sets X_ℓ in (2.1) are constructed, one after the other, by an adaptive experimental design strategy. Moreover, any approximation s_ℓ is viewed as an emulator of the simulator f. Each emulator is computed by statistical data fitting at level ℓ, $1 \le \ell \le L$.

The following algorithm schema outlines our hierarchical approximation method, described in detail in sections 3–6.

ALGORITHM 1 (hierarchical nonlinear approximation).

INPUT: $f : \mathbb{R}^d \to \mathbb{R}$

(1) X_1 f X_1 $\{f(\mathbf{x}) : \mathbf{x} \in X_1\}$

(2)

(3) [illegible] s_1 [illegible]
(4) FOR $\ell = 2, 3, \ldots$ DO
(4a) [illegible] X_ℓ (2.1) [illegible]
(4b) [illegible] f [illegible] $X_\ell \setminus X_{\ell-1}$ [illegible] $\{f(\mathbf{x}) : \mathbf{x} \in X_\ell \setminus X_{\ell-1}\}$
(4c) [illegible] $\{f(\mathbf{x}) : \mathbf{x} \in X_\ell\}$ [illegible] s_ℓ [illegible] ℓ
OUTPUT: [illegible] $s_1, s_2, \ldots, s_L$ [illegible]

Note that the iterative approximation scheme performs a sequential refinement of the (emulator) model. In the following sections, we explain steps (1)–(3), (4a), and (4c) of Algorithm 1 in detail. The construction of the initial design X_1 in step (1) is done by using [illegible] (LHC), as discussed in section 4, where also screening, as required in step (2), is briefly addressed. The two-stage experimental design of step (4a) is explained in sections 5 and 6. The construction of the emulators s_ℓ in steps (3) and (4c) relies on kriging, a standard statistical approach, which for the reader's convenience is reviewed in the following section.

3. Kriging. The approximation process at each level of Algorithm 1 can be divided into two main steps: In the first step, a statistical model $S(\mathbf{x})$ for the given data (obtained from the simulator) is derived. In the second step, a deterministic predictor for the statistical model—the emulator—is computed. Therefore, the emulator can be viewed as a statistical approximation, and so the proposed method, Algorithm 1, provides a suitable tool for statistical data fitting.

The construction of the individual emulators s_ℓ, $\ell = 1, \ldots, L$, in Algorithm 1 uses [illegible]. Kriging, due to Matheron [16], is a statistical method for scattered data interpolation which can be used for prediction in computer experiments [24, 29]. To explain kriging, denote, at any fixed level $1 \le \ell \le L$, the emulator by $s \equiv s_\ell$ and let $X \equiv X_\ell$ be the corresponding design at level ℓ.

In the underlying statistical model of kriging, the deterministic response, say, $f(\mathbf{x}) : \mathbb{R}^d \to \mathbb{R}$, is considered as a realization of a random function. Therefore, the simulator f is treated as a realization of a stochastic process, whose form is assumed as

$$S(\mathbf{x}) = \sum_{j=1}^{k} \beta_j h_j(\mathbf{x}) + Z(\mathbf{x}). \tag{3.1}$$

The regression part in this stochastic model (3.1) is a linear combination of preselected real-valued functions $h_1, \ldots, h_k$, with coefficients $\beta = (\beta_1, \ldots, \beta_k)^T \in \mathbb{R}^k$, where h_1 is a constant. Moreover, Z in (3.1) is assumed to be a Gaussian random process with mean zero and covariance

$$\operatorname{cov}[\mathbf{x}, \mathbf{y}] = \mathrm{E}[Z(\mathbf{x})Z(\mathbf{y})] = \sigma^2 R(\mathbf{x}, \mathbf{y}) \tag{3.2}$$

between $Z(\mathbf{x})$ and $Z(\mathbf{y})$, where σ^2 denotes the process variance, $R(\mathbf{x}, \mathbf{y})$ is a specific correlation function, and the symbol E denotes the usual statistical expectation. The choice of σ and R is discussed later in this section.

In a Bayesian approach, the random process $S(\mathbf{x})$ is regarded as a [illegible] model and the response values $\{f(\mathbf{x}) : \mathbf{x} \in X\}$ are viewed as observations. It remains to determine a suitable [illegible] predictor—the emulator—from the given set of observations.

In kriging, for given design $X = \{\mathbf{x}_1, \ldots, \mathbf{x}_m\} \subset \mathbb{R}^d$ and for given responses $\mathbf{f}_X = (f(\mathbf{x}_1), \ldots, f(\mathbf{x}_m))^T \in \mathbb{R}^m$, a linear predictor

$$\hat{S}(\mathbf{x}) = \mathbf{a}^T(\mathbf{x})\mathbf{f}_X$$

of $f(\mathbf{x}) \in \mathbb{R}$ at an untried $\mathbf{x} \in \mathbb{R}^d$ is assumed (being the required statistical model for the emulator $s(\mathbf{x}) \equiv \hat{S}(\mathbf{x})$), where the entries in the coefficient vector $\mathbf{a}(\mathbf{x}) = (a_1(\mathbf{x}), \ldots, a_m(\mathbf{x}))^T \in \mathbb{R}^d$ are unknown. The [illegible] for the deterministic response $f(\mathbf{x})$ is then obtained by minimizing the [illegible]

$$\mathrm{MSE}[\hat{S}(\mathbf{x})] = \mathrm{E}[\mathbf{a}^T(\mathbf{x})\mathbf{f}_X - S(\mathbf{x})]^2 \tag{3.3}$$

under variation of $\mathbf{a}(\mathbf{x})$ and subject to the [illegible]

$$\mathrm{E}[\mathbf{a}^T(\mathbf{x})\mathbf{f}_X] = \mathrm{E}[S(\mathbf{x})]. \tag{3.4}$$

Recall that $\mathbf{f}_X$ is regarded as a realization of $S(\mathbf{x})$. Thus, using (3.4), the mean square error in (3.3) can be rewritten as

$$\sigma^2 \left[\mathbf{a}^T(\mathbf{x})\mathbf{R}\mathbf{a}(\mathbf{x}) - 2\mathbf{a}(\mathbf{x})^T\mathbf{r}(\mathbf{x}) + 1\right],$$

and the linear constraints in (3.4) can be rewritten as

$$\mathbf{H}^T\mathbf{a}(\mathbf{x}) = \mathbf{h}(\mathbf{x}),$$

where

$$\begin{aligned}
\mathbf{h}(\mathbf{x}) &= (h_1, h_2(\mathbf{x}), \ldots, h_k(\mathbf{x}))^T \in \mathbb{R}^k, \\
\mathbf{H} &= (h_j(\mathbf{x}_k))_{1\le k\le m; 1\le j\le k} \in \mathbb{R}^{m\times k}, \\
\mathbf{R} &= (R(\mathbf{x}_i, \mathbf{x}_j))_{1\le i,j\le m} \in \mathbb{R}^{m\times m}, \\
\mathbf{r}(\mathbf{x}) &= (R(\mathbf{x}_1, \mathbf{x}), \ldots, R(\mathbf{x}_m, \mathbf{x}))^T \in \mathbb{R}^m.
\end{aligned}$$

Here, $\mathbf{H}$ is the [illegible], $\mathbf{R}$ is the [illegible] between the values of Z at the design sites X, and $\mathbf{r}(\mathbf{x})$ is the correlation vector between Z at the sites X and an untried input $\mathbf{x}$.

Therefore, minimizing (3.3) subject to (3.4) amounts to solving the linear system

$$\begin{bmatrix} \mathbf{R} & \mathbf{H} \\ \mathbf{H}^T & 0 \end{bmatrix} \begin{bmatrix} \mathbf{a}(\mathbf{x}) \\ \mathbf{b}(\mathbf{x}) \end{bmatrix} = \begin{bmatrix} \mathbf{r}(\mathbf{x}) \\ \mathbf{h}(\mathbf{x}) \end{bmatrix}, \tag{3.5}$$

where $\mathbf{b}(\mathbf{x}) = (b_1(\mathbf{x}), \ldots, b_k(\mathbf{x}))^T \in \mathbb{R}^k$ are the Lagrange multipliers for the linear constraints of the quadratic optimization problem.

By solving the linear system (3.5), the best linear unbiased prediction $\hat{S}(\mathbf{x})$ can be written as

$$\hat{S}(\mathbf{x}) = \mathbf{h}^T(\mathbf{x})\hat{\beta} + \mathbf{r}^T(\mathbf{x})\mathbf{R}^{-1}(\mathbf{f}_X - \mathbf{H}\hat{\beta}),$$

where

$$\hat{\beta} = (\mathbf{H}^T\mathbf{R}^{-1}\mathbf{H})^{-1}\mathbf{H}^T\mathbf{R}^{-1}\mathbf{f}_X \tag{3.6}$$

is the usual generalized least squares estimate of coefficients $\beta \in \mathbb{R}^k$ in (3.1).

Note that the kriging method not only gives an estimate of the posterior mean $\hat{S}(\mathbf{x})$ of the stochastic process $S(\mathbf{x})$, but it also provides by

$$\mathrm{MSE}[S(\mathbf{x})] = \sigma^2 \left[1 - [\mathbf{r}^T(\mathbf{x}), \mathbf{h}^T(\mathbf{x})] \begin{bmatrix} \mathbf{R} & \mathbf{H} \\ \mathbf{H}^T & 0 \end{bmatrix}^{-1} \begin{bmatrix} \mathbf{r}(\mathbf{x}) \\ \mathbf{h}(\mathbf{x}) \end{bmatrix} \right]$$

an estimate of the posterior variance of the random process [24]. For further details, see Matheron [16] or the more recent papers [24, 31]. A different formulation based on a maximum probability interpolant can be found in [8].

Now let us finally turn to the model selection problem, where we need to determine the unknown functions and parameters in (3.1). The selection of the functions $h_2, \ldots, h_k$ of the regression part in the stochastic model (3.1) relies on prior knowledge concerning the model response. For instance, linear or quadratic terms are preferred in situations where there is strong evidence to suggest weakly nonlinear trends in the response, or whenever the number of affordable simulations is particularly small.

When using kriging, in combination with hierarchical adaptive design, it is often sufficient to merely include the constant term h_1 in the polynomial regression (3.1) in order to obtain emulators s_ℓ, each of whose performance (in terms of their prediction quality) is at least as good or even superior to that of comparable one-level emulators. This is supported by our numerical results in section 8.

The selection of the correlation function, R, also requires prior knowledge concerning the stochastic process. To this end, we follow the common approach in [5, 6, 13, 24, 29], where it is suggested to use a correlation function of the form

$$R(\mathbf{x}, \mathbf{y}) = r(\mathbf{x} - \mathbf{y}) = \exp\left(- \sum_{j=1}^{d} \theta_j |x_j - y_j|^p \right) \tag{3.7}$$

with $\theta_j > 0$, $1 \le j \le d$, and $0 < p \le 2$.

Moreover, by following the recommendations in [29], the unknown coefficients $\theta = (\theta_1, \ldots, \theta_d) \in \mathbb{R}^d$ and p in (3.7) are determined by [illegible] (MLE). Likewise, the parameter σ for the process variance in (3.2) and $\beta \in \mathbb{R}^k$ are determined by MLE; see [29] for details. In this case, the log-likelihood for the Gaussian process $S(\mathbf{x})$ is given by

$$\ell(\beta, \sigma, \theta, p) \sim -1/2 \left(m \ln \sigma^2 + \ln \det(\mathbf{R}) + (\mathbf{f}_X - \mathbf{H}\beta)^T \mathbf{R}^{-1} (\mathbf{f}_X - \mathbf{H}\beta)/\sigma^2 \right). \tag{3.8}$$

In order to reduce the required computational complexity, it is reasonable to work with the following simplification. Note that with assuming the parameters θ_j, $1 \le j \le d$, and p as fixed, the MLE for $\beta \in \mathbb{R}^k$ is given by the generalized least squares estimate $\hat{\beta} \in \mathbb{R}^k$ in (3.6). Moreover, the MLE estimate for the process variance σ^2 in (3.2) is given by

$$\hat{\sigma}^2 = \frac{1}{m} (\mathbf{f}_X - \mathbf{H}\hat{\beta})^T \mathbf{R}^{-1} (\mathbf{f}_X - \mathbf{H}\hat{\beta}).$$

Using these estimates $\hat{\beta}$ and $\hat{\sigma}^2$ in the log-likelihood (3.8), the coefficients θ_j, $1 \le j \le d$, and p are then determined by maximizing the simpler expression

$$\ell(\theta, p) \sim -1/2 \left(m \ln \sigma^2 + \ln \det(\mathbf{R}) \right). \tag{3.9}$$

Maximizing the expression (3.9) requires global optimization, which can be computationally too expensive. However, as pointed out in [25], MLE is in practice regarded as sufficiently reliable. But in situations where several regression terms $h_1, \ldots, h_n$ are included in the model (3.1), a [illegible] (REML) is recommended [25]. In this case, parameter estimation by REML is accomplished by maximizing the likelihood for transformed data

$$W = \mathbf{C}\mathbf{f}_X \sim \mathrm{N}[\mathbf{C}\mathbf{H}\beta = 0, \sigma^2 \mathbf{C}\mathbf{R}(\theta)\mathbf{C}^T],$$

with a transformation matrix $\mathbf{C} \in \mathbb{R}^{(m-k)\times m}$ satisfying $\mathbf{C}\mathbf{H} = 0$, and where $\mathrm{N}(\mu, \sigma^2\mathbf{R})$ denotes the usual statistical normal distribution with mean μ and covariance $\sigma^2\mathbf{R}$. Further details on MLE and REML are immaterial for the purposes of this paper, and so we prefer to refer the interested reader to the textbook [25]. We finally remark that within our hierarchical approximation, Algorithm 1, the computational costs required for the performance of MLE and REML are negligible.

4. Initial design and screening. This section first explains in subsection 4.1 the construction of the utilized initial design, before some relevant aspects concerning screening are briefly addressed in subsection 4.2.

4.1. Initial design. To determine the initial design X_1 in Algorithm 1, we prefer to work with LHCs [17]. This standard technique is easy to use and has mainly two advantages. First, with using LHC most regions of the input domain are well covered by a well-balanced distribution of the design sites. Second, if some of the input variables are found inactive, then the initial design can [illegible] be projected onto the restricted space of the remaining active variables. Commonly used alternative designs, such as fractional factorial designs (FFDs) [7], as they are used in RSM [7, 18], usually lack these two important properties, even though they are usually better suited for sensitivity analysis.

LHCs were first introduced by McKay, Beckman, and Conover [17] in computer experiments. Later on, their utility in numerical integration of real-valued functions of many variables were discussed in several papers by Owen [19]. As shown in [19], LHC is closely related to quasi–Monte Carlo methods [3].

For the numerical experiments of section 8, a simplified version of LHC is utilized. To explain this simplified LHC, assume that the range of any input variable is the interval $I = [-1, 1]$. On a preselected number m of input configurations, each of the m input sites in the initial design $X_1 = \{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$ is assumed to have coordinates from

$$I_m = \{-1 + 2i/(m-1) : 0 \le i \le m-1\},$$

where for every input parameter x_i, $1 \le i \le d$, the m corresponding components $\mathbf{x}_1^{(i)}, \ldots, \mathbf{x}_m^{(i)}$ of the sites in X_1 are required to be pairwise distinct. To this end, according to the construction of LHC, the m components $\mathbf{x}_1^{(i)}, \ldots, \mathbf{x}_m^{(i)}$ are chosen from I_m in random order; i.e., for each $1 \le i \le d$, the components $\mathbf{x}_1^{(i)}, \ldots, \mathbf{x}_m^{(i)}$ are a permutation of the m numbers in I_m.

Note that in our formulation of LHC the input coordinates are randomly selected from a [illegible] set, I_m, rather than from a [illegible] parameter interval. The reason for doing so is mainly for the sake of stability. To be more precise, we are aiming at the construction of well-separated design sites. This serves to stabilize the required maximization of matrix determinants by MLE in the subsequent local optimal design. Details on this are explained in section 6.

Moreover, note that our construction guarantees that the data points in the design X_1 are uniquely projectable to low-dimensional point sets; see the second remark at the outset of this section. This is particularly useful for dimension reduction, especially in situations where we expect only a small set of variables from the tried responses. In this case, we want to discard the remaining variables. Using LHC, this can, unlike in FFD, be done unambiguously and without any modeling conflicts by just removing the components of the inactive variables from the design X_1.

As suggested in [29], LHC does also support efficient estimation of the correlation lengths $\lambda_j = 1/\theta_j > 0$ in (3.7). This will be very important in the subsequent steps of our method. As further explained in [29], the correlation lengths λ_j should be used in the screening process. In fact, a very large correlation length λ_j indicates that the response output is not very sensitive to the variation of the input parameter x_j, $1 \le j \le d$.

4.2. Screening. Screening usually works with a linear polynomial model, where a specific statistical test, called the , is applied. The Student test relies on least squares estimates for the coefficients in the linear model, in order to evaluate their contribution to the response variability. These estimates are used in order to recursively eliminate inactive terms from the model. More details on this standard statistical technique can be found in [18] or in the COUGAR [4] user manual.

As supported by our numerical experiments, a screening criterion should be preferred to avoid premature discarding of input variables, as they may become significant at a later stage of the hierarchical approximation algorithm. In our implementation, this is accomplished by combining several independent screening criteria, in which case an input variable will only be discarded if it satisfies screening criteria involved, rather than just . For a more detailed discussion on the related sensitivity analysis from a Bayesian perspective, we refer the reader to the recent work of Oakley and O'Hagan [14].

5. Adaptive gridding. In comparison to the rather easy task of initial design, as described in subsection 4.1, is a much more challenging task, requiring rather sophisticated optimization techniques. Global sequential optimal designs, as suggested in previous papers [5, 6, 24], are commonly used iterative methods for optimal design in computer experiments. In these methods, a sequence of design sites is constructed for the computational domain Ω, which usually involves very expensive computations to determine an design point in each step of the iteration. Due to their large computational costs, the applicability of such methods is rather limited. Moreover, in these global strategies for optimal design, design points often cluster in some region of Ω, whereas they are sparse in other regions of Ω [24]. In fact, sequential optimal designs are often not too efficient, due to a too heterogeneous distribution of the design sites. This section proposes a more efficient approach for hierarchical optimal design, called , as utilized in the design step (4a) of Algorithm 1.

Adaptive gridding is a domain decomposition strategy which splits the computational domain Ω into smaller subdomains, , according to a suitable splitting criterion [12]. In our method, Ω is adaptively partitioned into anisotropic cells of equal size, where the splitting criterion is according to the correlation of the response $f(\mathbf{x})$. By using (3.7), this correlation is chosen as a function $R(\mathbf{x}, \mathbf{y})$ which is rapidly decaying at growing distance between the points $\mathbf{x}$ and $\mathbf{y}$.

Our approach combines global adaptive gridding with local optimal design. To this end, the construction of the design sites is done locally, by applying a local sequential optimal design to the (highly correlated) cells which are output by global adaptive gridding. The correlation is measured by the correlation lengths $\lambda_i = 1/\theta_i$ of the corresponding input parameters x_i, $1 \le i \le d$.

We shall be more precise on this two-stage procedure in this and in the following section. But let us first make a few more general remarks concerning computational aspects. Note that adaptive gridding, in combination with local optimal design, allows us to distribute the required computations to different processors. Therefore, at any design level ℓ, several computations for new design sites and corresponding simulations may be run, one for each cell, at the same time. In relevant applications, such as in oil reservoir forecasting or climate modeling, where each simulation run may take several hours or even several days, parallelization is in fact essential in order to reduce the required computational time.

Now the basic idea of adaptive gridding is to construct a partitioning of Ω into cells of equal size, where the cell edges have different lengths depending on their spatial direction. Moreover, each cell edge is aligned with one coordinate axis x_i, corresponding to one specific input parameter. The aim of adaptive gridding is to perform the splitting, such that the edge lengths are proportional to the [illegible] λ_i of the corresponding input parameter x_i, $1 \le i \le d$.

We further explain adaptive gridding in subsection 5.1, before we turn to the construction of a customized error indicator in subsection 5.2, which allows us to evaluate the prediction quality at each of the individual cells. The latter will establish an important link between global adaptive gridding and local optimal design.

5.1. Adaptive gridding algorithm. To define adaptive gridding, suppose that the domain Ω is a hypercuboid in $\mathbb{R}^d$,

$$\Omega = [x_\ell^{(1)}, x_r^{(1)}] \times \cdots \times [x_\ell^{(d)}, x_r^{(d)}] \subset \mathbb{R}^d,$$

and so Ω is defined by its lower left corner point $\mathbf{x}_\ell = (x_\ell^{(1)}, \ldots, x_\ell^{(d)}) \in \mathbb{R}^d$ and its upper right corner point $\mathbf{x}_r = (x_r^{(1)}, \ldots, x_r^{(d)}) \in \mathbb{R}^d$.

We intend to decompose Ω into a collection $\mathcal{L} = \{\omega\}_{\omega \in \mathcal{L}}$ of smaller hypercuboidal subdomains, [illegible], of equal sizes and with pairwise disjoint interior, so that

$$\Omega = \bigcup_{\omega \in \mathcal{L}} \omega$$

yields a partitioning of Ω.

The decomposition of Ω is computed by splitting the $d \times 2^{d-1}$ edges of Ω. Note that each edge e is aligned with one coordinate axis x_i, $1 \le i \le d$. That is, any edge e in Ω corresponds to one variable x_i, $1 \le i \le d$, and therefore e may be viewed as an interval I_i on coordinate axis x_i. In adaptive gridding, each interval I_i, corresponding to one edge e (and thus to one variable x_i), is uniformly split into n_i pairwise disjoint intervals $I_i^{(1)}, \ldots, I_i^{(n_i)}$, $1 \le i \le d$, of equal length, so that

$$I_i = \bigcup_{j=1}^{n_i} I_i^{(j)}, \qquad \text{with } |I_i^{(j)}| \equiv |I_i|/n_i \quad \text{for } 1 \le j \le n_i,\ 1 \le i \le d.$$

Now the basic idea of adaptive gridding is to perform the splitting of each interval I_i, such that the resulting constant length of the n_i subintervals $|I_i^{(j)}| \equiv |I_i|/n_i$,

$1 \le j \le n_i$, is of the order of the correlation length λ_i of variable x_i; i.e., $\lambda_i \sim |I_i|/n_i$, or $n_i \sim |I_i|/\lambda_i$ for $1 \le i \le d$, so that $\prod_{i=1}^d n_i \sim \prod_{i=1}^d |I_i|/\lambda_i$ is the number of cells.

In this way, each of the resulting cells $\omega \in \mathcal{L}$ has long edges along coordinate directions where the variation of the response f is small, whereas short edges of ω correspond to variables with stronger fluctuation of the response. Therefore, adaptive gridding captures preferred directions of the response f quite effectively. This in turn leads to an adaptive distribution of the design points, according to the global behavior of f.

The adaptive gridding algorithm outputs a uniform partitioning $\mathcal{L} = \{\omega\}_{\omega \in \mathcal{L}}$ of Ω into $\prod_{i=1}^d n_i$ smaller cells of equal size, where each cell $\omega \in \Omega$ is a hypercuboid in $\mathbb{R}^d$. For the illustration, we refer the reader to Figure 8.2 of subsection 8.1, where examples for partitionings of a planar domain $\Omega \subset \mathbb{R}^2$ are shown.

Recall that the adaptive gridding algorithm is performed at each level $\ell \ge 2$ in step (4a) of Algorithm 1. In particular, the correlation lengths $\lambda_i \equiv \lambda_i^{(\ell)}$ are reevaluated at each level $\ell \ge 2$, and so the partitioning $\mathcal{L} = \{\omega\}_{\omega \in \mathcal{L}}$ is updated accordingly.

5.2. Cell prediction errors. Having applied adaptive gridding to obtain a partitioning $\mathcal{L} = \{\omega\}_{\omega \in \mathcal{L}}$ of the domain Ω into smaller cells ω, further design points are to be added to the cells $\omega \in \mathcal{L}$. This is done by following ideas from our previous work [9], where again adaptivity plays an important role.

To this end, we first assign for the current design X_ℓ a prediction error η_ω to each cell ω, by cross validation. More precisely, let $X_\omega = X_\ell \cap \omega$ denote the set of current design sites lying in cell ω, so that by

$$X_\ell = \bigcup_{\omega \in \mathcal{L}} X_\omega$$

this yields a partitioning of X_ℓ.

Note that the set X_ω of design sites contained in a cell ω may be empty, in which case we let $\eta_\omega = \eta_{\max}$ for the prediction error of cell ω, where $\eta_{\max}$ is a (very high) preselected value. Otherwise, if ω is not empty, we work with a cell prediction error of the form

$$\eta_\omega = \max_{\mathbf{x}_\omega \in X_\omega} |f(\mathbf{x}_\omega) - s_{X_\ell \setminus \mathbf{x}_\omega}(\mathbf{x}_\omega)|, \tag{5.1}$$

where $s_{X_\ell \setminus \mathbf{x}_\omega}$ is the kriging emulator (see section 3), whose construction uses [illegible] design sites from X_ℓ except $\mathbf{x}_\omega$. This way, the cell prediction error (5.1) reflects the [illegible] approximation behavior, i.e., the quality of the emulator's local prediction at the cell ω.

Indeed, if η_ω is small, then the response f is usually smooth on ω and the emulator makes good predictions, whereas for large η_ω the response is usually subject to strong variation in ω (e.g., for nonlinear behavior of f), in which case further design points should be added to ω in order to improve the prediction of the emulator.

The cell prediction error is used in combination with a preselected [illegible], $\eta^* \le \eta_{\max}$, where further points are to be added to every cell ω satisfying $\eta_\omega \ge \eta^*$. We call any cell ω, where (by $\eta_\omega \ge \eta^*$) the emulator's prediction is rather poor, a [illegible] cell; otherwise (if $\eta_\omega < \eta^*$) the cell ω is called a [illegible] cell. Moreover, an empty cell is said to be a bad cell, unless the prediction error η_ω of [illegible] nonempty cell ω lies below the global threshold η^*. In this case, there are no bad cells in the partitioning $\mathcal{L} = \{\omega\}_{\omega \in \mathcal{L}}$.

Now the insertion of new design points is done by applying a local optimal design (as explained in section 6) to each bad cell ω, where we add—primarily for the sake of computational efficiency—only [illegible] point per (bad) cell ω. Note that the chosen refinement strategy allows one to combine the construction of new design sites with parallel computing, and so to further reduce the computational time required for the experimental design.

The utilized refinement strategy makes up an important link between global adaptive splitting and local optimal design through this two-stage construction of new design sites. Indeed, our construction reduces the likelihood that some unexplored areas of the computational domain Ω are classified as [illegible] at a too early refinement level by a too optimistic prediction indicator.

Finally let us remark that the target η^* should ideally reflect the desired accuracy threshold of the computer experiment. However, one should note that η^* can only be a rough estimate of the emulator's global prediction error. Nevertheless, as supported by our numerical experiments, the accuracy η^* can in fact be regarded as a suitable estimate for the emulator accuracy. Moreover, the estimate turns out to be useful for subsequent optimization and postprocessing calibration.

In practice, however, the stopping criterion is usually dominated by the maximum number of affordable simulations rather than by the desired problem accuracy. Therefore, any beforehand selection of the target accuracy η^* should not only depend on the required problem accuracy, but also on the available computational power and hardware capacity. Note that by the iterative construction in our hierarchical approximation scheme, the pay-off in terms of number of simulations versus accuracy can be monitored quite effectively during the performance of Algorithm 1.

6. Local optimal design. This section explains how the local optimal design is performed. Recall that this step concerns construction of new design sites, to be added to the current set $X \equiv X_\ell$ in step (4a) of Algorithm 1.

The local design is performed on a cell ω, which is constructed by adaptive gridding, as explained in section 5. The local optimal design is, for any cell ω, done by using an [illegible]. In this approach, dating back to Lindley [15], a design is determined by minimizing the posterior Shannon's entropy [22].

As later shown by Shewry and Wynn [23], this approach is equivalent to maximizing the prior entropy. For the special case of a Gaussian prior, this in turn is equivalent to maximizing the determinant of the covariance matrix $\sigma^2\mathbf{R}$. For a more detailed discussion on this, we refer to [6, 23]. As a result, regarding β as fixed and considering the variance σ^2 as stationary, this amounts to maximizing the determinant $\det(\mathbf{R}_X)$ of the correlation matrix

$$\mathbf{R}_X = (R(\mathbf{x}_i, \mathbf{x}_j))_{1\le i,j\le m} \in \mathbb{R}^{m\times m}$$

under variation of design sites $X = \{\mathbf{x}_1, \dots, \mathbf{x}_m\}$; see [6].

Therefore, we wish to insert one point $\mathbf{x} = \mathbf{x}^*$ into ω, which maximizes the determinant $\det(\mathbf{R}_{X\cup\mathbf{x}})$ of the resulting correlation matrix $\mathbf{R}_{X\cup\mathbf{x}}$ among all points in ω. To determine $\mathbf{x}^* \in \omega$, the search for a maximum of $\det(\mathbf{R}_{X\cup\mathbf{x}})$ on ω is done by varying the position of the point $\mathbf{x} = \mathbf{x}_\omega$ in the cell ω, while keeping the design sites in X fixed. The required numerical optimization relies on the algorithm [illegible], a constrained version of the quasi-Newton method, due to Byrd et al. [2]. In this local optimization algorithm, we apply the L-BFGS-B algorithm with different choices for the initial point $\mathbf{x}_0 \in \omega$, namely, with the center of ω and with a small number $n \ll 2^d$ of randomly chosen points from the 2^d corners of ω. We then take a point

$\mathbf{x}^* \in \omega$, where the maximum of the determinant $\det(\mathbf{R}_{X\cup\mathbf{x}})$ among these $n+1$ points is attained.

In our local optimal design, the points in X are, for each cell $\omega \in \mathcal{L}$, given by the union of the points in X_ω and a [illegible] set of neighbors around ω. Therefore, the size of the matrix $\mathbf{R}_X$ is [illegible]. In our numerical experiments, we considered using a number of n_ω [illegible] neighbors of the center $\mathbf{c}_\omega$, where n_ω is between 15 and 20. In order to determine these nearest neighbors for $\mathbf{c}_\omega \in \omega$, we considered working with the [illegible]

$$\mathbf{d}(\mathbf{x},\mathbf{y}) = \sqrt{\sum_{j=1}^{n}\left(\frac{x_j - y_j}{\lambda_j}\right)^2} \qquad \text{for } \mathbf{x} = (x_1,\dots,x_d),\ \mathbf{y} = (y_1,\dots,y_d),$$

for measuring the distance between two points. This is in order to take different statistical variations for the different input parameters better into account.

Note that this procedure can recursively be applied to any cell ω, just in case one wants to add more than one new design point into ω. This then complies with the ideas of (local) sequential optimal design.

7. Formulation of the hierarchical approximation algorithm. Now that each step of Algorithm 1 has been explained in detail we provide a more precise schematic description in the following algorithm.

ALGORITHM 2 (hierarchical nonlinear approximation).

INPUT: [illegible] $f : \mathbb{R}^d \to \mathbb{R}$

(1) [illegible] X_1

(2) [illegible] θ_j, p [illegible] (3.7) [illegible]

(3) [illegible] f [illegible] X_1 [illegible]
$\mathbf{f}_{X_1} = \{f(\mathbf{x}) : \mathbf{x} \in X_1\}$

(4) [illegible] $\theta_j \sim 0$ [illegible] $1 \le j \le d$ [illegible]

(5) [illegible] s_1 [illegible] X_1 [illegible] $\mathbf{f}_{X_1}$ [illegible]

(6) FOR $\ell = 2, 3, \dots$ DO

(6a) [illegible] θ_j, p [illegible] (3.7) [illegible]

(6b) [illegible] ω [illegible]

(6c) [illegible] η_ω [illegible] ω [illegible]
[illegible] $\eta_\omega \ge \eta^*$

(6d) [illegible] ω [illegible] ω [illegible]
[illegible] ω [illegible] $D_\ell = X_\ell \setminus X_{\ell-1}$

(6e) [illegible] f [illegible] D_ℓ [illegible]
$\mathbf{f}_{D_\ell} = \{f(\mathbf{x}) : \mathbf{x} \in D_\ell\}$

(6f) [illegible] s_ℓ [illegible] X_ℓ [illegible] $\mathbf{f}_{X_\ell}$ [illegible]

OUTPUT: [illegible] $s_1, s_2, \dots, s_L$ [illegible]

8. Numerical results. We have implemented the proposed hierarchical approximation scheme, Algorithm 2, for arbitrary space dimension d by using the programming language R [20]. This section investigates the performance of our algorithm. To this end, we work with three different model problems, one involving an analytical function (subsection 8.1), and two model problems from reservoir forecasting (subsection 8.2), called [illegible] and the [illegible] model. In the two examples concerning reservoir forecasting, the method is compared with the standard RSM (see [7, 18]) which is utilized in reservoir uncertainty analysis software, such as COUGAR [4].

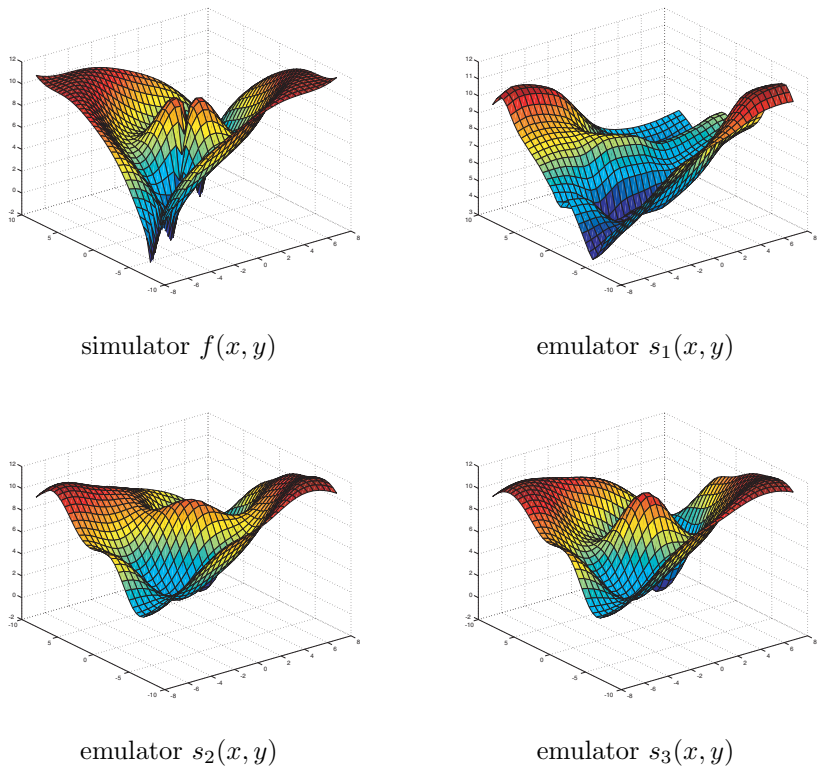

FIG. 8.1. *Hierarchical approximation. Graphs of the simulator f and emulators s_1, s_2, s_3.*

In each numerical comparison, the required number of simulations is fixed, and the quality of the resulting emulators is compared by their prediction accuracy. Note that the required number of simulations reflects the required computational costs, since each simulator run takes much more time than the computational time required for building the emulator, no matter which method is employed.

8.1. Analytical test example. In this first test case, consider the trivariate function

$$f(x, y, z) = 7\,\frac{\sin(\sqrt{x^2 + y^2}) + \epsilon}{\sqrt{x^2 + y^2}} + 3|x - y|^{1/2} + 0.01z,$$

where $\epsilon = 10^{-7}$, which is regarded as the "simulator." Note that f is linear in variable z, but nonlinear in x and y. In fact, the two variables x and y are identified as [illegible] variables, whereas z is classified as [illegible]. This conclusion was reached in the preprocessing screening, where it was found that $\lambda_3 \gg \max(\lambda_1, \lambda_2)$. This allows us to view $f \equiv f_z(x, y)$ for fixed z as a bivariate surface, where $z \equiv 0$ after screening. The graph of the "true response surface" f is shown in Figure 8.1 (top left).

The correlation lengths λ_1 and λ_2 belonging to the remaining two active variables, x and y, are shown, along with the parameter p in (3.7), in Table 8.1 for three levels $\ell = 1, 2, 3$. For the construction of the initial design X_1, we apply an LHC to generate 18 points, and so the size of the initial point set X_1 is $|X_1| = 18$.

Then, the surface $f : \Omega \to \mathbb{R}$ is approximated on the computational domain

TABLE 8.1

X_1 X_2 X_3

FIG. 8.2. *Hierarchical approximation. Adaptive grids and designs X_1, X_2, X_3.*

$\Omega = [-8, 8] \times [-8, 8]$ by an emulator, whose construction is done by using our hierarchical approximation scheme. In this method, we apply kriging without including a regression part in the stochastic model (3.1).

Figure 8.1 shows the graphs of the three resulting emulators, s_1, s_2, s_3, from coarse to fine, and Figure 8.2 shows the corresponding sequence X_1, X_2, X_3 of three design sets.

Note from the visual appearance of the surface graphs in Figure 8.1 that the prediction quality of emulators s_1, s_2, s_3 is gradually improved. This is confirmed by our numerical results, which are shown in Table 8.1. Table 8.1 displays for each level $\ell = 1, 2, 3$ the number of points $|X_\ell|$ in the design set X_ℓ, the resulting

(8.1) $$\eta_1 = \|f - s_\ell\|_1/|G| = \frac{1}{|G|}\sum_{\mathbf{x}\in G} |f(\mathbf{x}) - s_\ell(\mathbf{x})|,$$

(8.2) $$\eta_2 = \left(\|f - s_\ell\|_2^2/|G|\right)^{1/2} = \sqrt{\frac{1}{|G|}\sum_{\mathbf{x}\in G} |f(\mathbf{x}) - s_\ell(\mathbf{x})|^2},$$

and

(8.3) $$\eta_\infty = \|f - s_\ell\|_\infty = \max_{\mathbf{x}\in G} |f(\mathbf{x}) - s_\ell(\mathbf{x})|,$$

where G denotes a fine uniform grid contained in Ω.

Note that by our adaptive design, that is, by the efficient distribution of the sites in X_1, X_2, X_3, the features of f are captured remarkably well, especially in regions where f has large derivatives.

8.2. Test cases from reservoir forecasting.

8.2.1. The PUNQS reservoir test case. In this second example, we analyze the case of a reservoir simulator containing seven uncertain scalar input variables and one scalar output. The example is generated by using the PUNQS [7] reservoir model in combination with Schlumberger's multiphase flow simulator ECLIPSE [21]. The input variables and their range of variation were suggested by reservoir engineers. In this model problem, the utilized input variables are corresponding to the aquifer strength, the residual gas oil saturation, the residual water oil saturation, and the vertical and horizontal permeability multipliers of the low and of the high quality sands. We have analyzed several outputs of the ECLIPSE simulator. The numerical results, presented in this subsection, were obtained by regarding the seven input variables, and the output oil production rate at 13 years of a given production well (called PRO-15 in the model [7]).

An LHC is used to generate the initial design X_1 comprising 50 different configurations, i.e., $|X_1| = 50$. In the screening preprocess, the input parameter x_4 is classified as inactive. In fact, the corresponding correlation length $\lambda_4 \gg 1000$, as predicted by MLE, is much larger than the initial correlation lengths of the other six input variables. Therefore, x_4 is discarded, the correlation lengths of the other six variables are for each level $\ell = 1, \ldots, 5$ shown in Table 8.2.

Recall that by the LHC, the projection of the initial seven-dimensional design to the active six-dimensional design is injective, and so it does not produce coincident data points.

The construction of the emulators s_ℓ is done by using our hierarchical approximation scheme, Algorithm 2. In this method, we apply kriging with using a quadratic regression part in the stochastic model (3.1) at each level ℓ, where the regression terms $x_1, x_2, x_3, x_5, x_6, x_1x_5, x_1^2$ were found to be dominant by the utilized statistical data analysis.

In order to analyze the accuracy of the emulators s_ℓ, we compare the emulators' function values $s_\ell(\mathbf{x})$ with the response output $f(\mathbf{x})$ of the simulator at 200 randomly selected configurations of input parameters $\mathbf{x}$, which are not contained in the design sites X_ℓ. We let $\eta^* = 3$ for the target accuracy. Our numerical results are shown in Table 8.3.

The numerical results in Table 8.3 document significant gain in performance between consecutive levels, in terms of the emulators' accuracy; see the different errors in Table 8.3. At final level $\ell = 5$, the target accuracy, $\eta^* = 3$, is approximated sufficiently well, as the mean absolute error drops from $\eta_1 = 4.62$ (at initial level $\ell = 1$) to $\eta_1 = 2.88$ (at $\ell = 5$), and so we obtain $\eta_1 \leq \eta^*$ at final level $\ell = 5$.

In order to further evaluate the performance of our hierarchical design, we have performed another test run based on a LHC with 258 points, matching

TABLE 8.3

the number of points $|X_5| = 258$ in the hierarchical design at the final level $\ell = 5$. The numerical results are shown in the sixth row (**LHC**) of Table 8.3. Note that our hierarchical approximation method is superior to this plain LHC in terms of the emulator accuracy. Indeed, while the mean absolute error η_1 of the emulator s_5 and that of the one-level LHC emulator, say, s_{LHC}, are about equal, the emulator s_5 reduces the root mean square error η_2 of s_{LHC} by about 10%, and the maximum error η_∞ of s_{LHC} is reduced by even about 20%.

We can explain the significant gain concerning the reduction of the maximum error η_∞ as follows. Due to the hierarchical design, the design sites are adaptively inserted, such that at each refinement step new points are inserted in regions (by local optimal design) where the current maximum error is likely to be highest. This interactive prediction cannot be achieved by a plain one-level LHC, where ,, design sites are selected beforehand in a preprocessing step.

We have also compared our hierarchical approximation method with a polynomial regression model, as usually used in the standard RSM [7, 18]. Two experiments were made; the first uses 79 simulations selected from a central composite face centered design, and the second uses 258 design sites generated from a one-level LHC.

In the first experiment the regression terms were selected by using the step by step fit used in COUGAR [4] based on sensitivity analysis arguments similar to the ones described in section 4 for the screening process. The results, displayed in the penultimate row of Table 8.3, are about comparable to the ones obtained by our emulator s_2, at a slightly smaller maximum error though. The difference in maximum error is mainly due to small overshoots of the kriging emulator in local areas of the domain, where the simulator f is subject to strong variation. The emulator s_{RSM} manages to somewhat reduce these undesired local overshoots.

However, in the second experiment, displayed in the last row (**RSM**) of Table 8.3, our emulator s_5 is clearly superior to the comparable one-level method RSM. Indeed, the emulator s_5 of our hierarchical method reduces the mean absolute error η_1 obtained by RSM (i.e., by emulator s_{RSM}), by more than 25%, and the root mean square error η_2 of s_{RSM} is reduced by about 15%. The resulting maximum error η_∞ of s_5, however, is again slightly larger than that of the emulator s_{RSM}.

Our numerical results also show that the emulator s_{RSM} does not significantly improve its accuracy at the insertion of more design points; see the last two rows in Table 8.3. In contrast, our hierarchical emulator gradually reduces the prediction errors η_1 and η_2 at increasing refinement level.

TABLE 8.4
*IC Fault model. Results obtained from our hierarchical approximation method; comparison with RSM using FFD (***RSM***), and kriging using LHC (***KRG***). Note the definitions of η_1, η_2, and η_∞ in* (8.1), (8.2), *and* (8.3).

ℓ	$\lvert X_\ell \rvert$	η_1	η_2	η_∞
1	22	3.6	5.4	28.7
2	49	1.4	3.2	25.2
3	72	1.1	1.8	12.5

RSM	146	7.2	8.4	22.9
KRG	146	1.0	1.5	11.7

We finally remark that the variation of the response surface of the PUNQS model is rather small. More complicated test case scenarios from relevant applications are dealing with discontinuous response surfaces of strong variation. One example is the challenging IC Fault model treated in the following subsection.

8.2.2. The IC Fault model. In this final example, we apply our hierarchical approximation method to a more difficult test case from Imperial College, called the [illegible] model, which has previously been used for parameter identification by history matching. The IC Fault model incorporates a rather complicated discontinuous response surface. Therefore, the IC Fault model is regarded as a very challenging test example, where standard methods for history matching often fail [28]. For a detailed description on the IC Fault model, see [28].

Let us first discuss only some of the relevant features of the IC Fault model. The simplified reservoir of the IC Fault model has three uncertain input parameters, corresponding to the fault throw and the good and the poor sand permeability multipliers. The analyzed output from the response surface is in this test case the oil production rate at 10 years. The three input parameters are referred to as x_1, x_2, and x_3. According to [28], the input configurations are uniformly distributed in the computational domain $\Omega = [0, 50] \times [100, 200] \times [0, 50]$.

Having rescaled each of the variables' range to the interval $[-1, 1]$, the reservoir simulator ECLIPSE is run on an LHC consisting of $|X_1| = 22$ different configurations for the initial design X_1. We then apply our hierarchical approximation method to the IC Fault model, using Algorithm 2, where we let $\eta^* = 0.5$ for the target accuracy. This results in a hierarchical approximation with six design levels, that is, $L = 6$.

The construction of the emulators s_ℓ is done by using our hierarchical approximation scheme, Algorithm 2. In this method, we apply kriging with using a quadratic regression part in the stochastic model (3.1) at each level ℓ, where the regression terms x_2, x_3, x_3^2 were found to be dominant by the utilized statistical data analysis.

In order to evaluate the prediction accuracy of emulator s_ℓ at each design level ℓ, $1 \le \ell \le 6$, the simulator was run at an additional set X comprising 200 points, where the points in X are generated by another LHC, being different from the one used to generate the initial design X_1 in our hierarchical approximation method.

We have recorded the mean absolute error η_1, the root mean square error η_2, as well as the maximum error η_∞ for our emulator s_ℓ at each level. The numerical results are shown in Table 8.4. Note that the mean absolute error η_1 is at the final level $\ell = 6$ very close to the target accuracy $\eta^* = 0.5$, after only 146 simulations.

TABLE 8.5
IC Fault model. Correlation parameters at different levels.

ℓ	$\lvert X_\ell \rvert$	λ_1	λ_2	λ_3	p
1	22	16.40	1.70	0.40	2.00
2	49	24.00	42.20	0.13	1.80
3	72	22.90	89.90	0.40	1.20
4	102	34.00	98.80	0.12	1.40
5	124	16.10	37.40	0.10	1.50
6	146	10.40	37.70	0.30	1.00

For the purpose of comparison, we consider two alternative (one-level) methods to compare their numerical results with those of our emulator. The first emulator, s_{RSM}, is obtained by RSM in combination with an FFD. For the emulator s_{RSM} a quadratic regression polynomial was used. The second emulator, s_{KRG}, is obtained by using kriging in combination with an LHC. Table 8.4 shows the numerical results obtained by using these two emulators, s_{RSM} and s_{KRG}.

Note that the final emulator s_6 of our hierarchical approximation method (see Table 8.4) is superior to both the kriging emulator s_{KRG} (see Table 8.4, last row) and the emulator s_{RSM} (see Table 8.4, second last row). Indeed, the mean absolute error η_1 and the maximum error η_∞ obtained by s_6 is about half of the corresponding error obtained by s_{KRG}, whereas the root mean square error η_2 of s_{KRG} is reduced by a third. Note that a comparable prediction accuracy of s_{KRG} is obtained by s_3 after only three steps of our hierarchical approximation method, with using only $|X_3| = 72$ simulator runs rather than $|X_6| = 146$ runs.

As for the comparison between our emulator and that of RSM, s_{RSM}, the performance of our hierarchical emulator is much better than that of s_{RSM}. Indeed, note that the accuracy of our final emulator s_6 is for the mean absolute error η_1 more than ten times smaller than that of the emulator s_{RSM}, when using $|X_6| = 146$ design points, whereas its root mean square error η_2 is about eight times smaller than that of s_{RSM}, and the maximum error η_∞ of s_6 is only about one quarter of the maximum error of s_{RSM}.

Note that the accuracy of our initial emulator, s_1, is superior to the accuracy of the emulator s_{RSM}, when using only $|X_1| = 22$ design points. Indeed, while the maximum error η_∞ of s_1 is comparable to that of s_{RSM}, the mean absolute error η_1 of s_1 is less than half of the corresponding mean absolute error of s_{RSM}. Moreover, the root mean square error η_2 of s_1 is about half the corresponding mean square error of s_{RSM}; see Table 8.4, first row, and Table 8.4, third to last row. That s_1 outperforms s_{RSM} is not too surprising, since s_1 is the best linear unbiased predictor for the deterministic response $\mathbf{f}_{X_1}$; see the discussion in section 3.

Finally, Table 8.5 shows the correlation lengths λ_i, $1 \le i \le 3$, of the correlation parameters for the three different input parameters, at the six different design levels. Note that input parameter x_3 has, in comparison with x_1 and x_2, a rather short correlation length λ_3. This behavior is well treated by the adaption strategy (i.e., global adaptive gridding in combination with local optimal design) of our hierarchical approximation method, which prefers to insert further design points (at run time of Algorithm 2) in the direction of coordinate axis x_3. This enhanced flexibility gives our hierarchical approximation method another advantage over commonly used nonhierarchical methods which are not designed to determine potentially dominant input parameters.

9. Conclusion and future work. We have proposed a hierarchical nonlinear approximation scheme for scalar-valued multivariate functions. The main objective of the utilized iterative refinement is to obtain a sufficiently accurate approximation at very few function evaluations. The hierarchical approximation method has been applied to relevant applications from experimental design and statistical data analysis in computer experiments. Our hierarchical method combines different important requirements for efficient designs in computer experiments, such as screening, entropy minimization, statistical data fitting, and parallelization. This results in a flexible and efficient iterative method, whose main components are adaptive gridding, local optimal design, and kriging, in combination with MLE. As supported by numerical examples, including two real-world model problems from reservoir forecasting, the performance of our hierarchical approximation method is in terms of the resulting emulators' prediction accuracy superior to that of traditional nonhierarchical methods, such as the widely used RSM. Further important aspects of this research are uncertainty reduction and calibration, which we will treat in a forthcoming paper.

Acknowledgments. We wish to thank Jonathan Rougier for many useful suggestions and fruitful discussions. Moreover, we received much technical help and advice from our colleagues at Schlumberger. Last but not least, we thank the anonymous referees for their useful comments and constructive suggestions, which helped improve a previous version of the paper.

EFFICIENT ALGORITHMS FOR PROBLEMS WITH FRICTION*

S. HÜEBER†, A. MATEI‡, AND B. I. WOHLMUTH†

Abstract. In this paper, a nonconforming discretization method for the frictional contact between two bodies subjected to antiplane shear deformation is considered. The method is based on a mixed variational formulation where dual basis functions are used for the discretization of the Lagrange multiplier. Under some regularity assumptions on the solution, an optimal a priori error estimate is obtained. To solve the discrete nonlinear problem an inexact primal-dual active set strategy is introduced. Finally, numerical examples confirming the theoretical result for the a priori error estimate and illustrating the performance of the algorithm are presented. The results can easily be generalized to the case of Coulomb friction. For this case a numerical example is given.

Key words. antiplane shear deformation, frictional contact, mixed formulation, dual Lagrange multipliers, nonconforming meshes, optimal a priori error estimates, inexact primal-dual active set strategy

1. Introduction.

In this paper, we study the antiplane shear deformation of two elastic bodies in frictional contact on their common boundary. For a cylindrical body subject to antiplane shear, the displacement is parallel to the generators of the cylinder and is independent of the axial coordinate. The displacement field is described by a scalar function, and therefore the governing equations and boundary conditions are quite simple. The antiplane shear (or longitudinal shear, generalized shear) may be viewed as complementary to [illegible] and represents the mode III fracture mode for crack problems. This model was considered by many authors; see, for instance, [BHP02, HMM02, Hor95, HS01, HS04, Kno76, Kno77, MMS01]. An excellent reference concerning antiplane shear deformation in solid mechanics is the review article [Hor95], where modern developments for the antiplane shear model and its applications are described for both linear and nonlinear solid mechanics. Note that in [HMM02, MMS01] quasi-static antiplane contact problems were considered, and the study was made within the framework of variational inequalities. For the basics in the theory of variational inequalities, we refer to [GLT81, Glo84].

To model the friction, we use Tresca's law; a description of this law can be found in [DL76, Pan85] and more recently in [HS02, SST04]. Our study is based on a mixed variational formulation with dual Lagrange multipliers, the well-posedness of this weak formulation being guaranteed by arguments in the saddle point theory; details on the saddle point theory and its applications can be found, e.g., in

[Bra97, BF91, ET76, Hcc96]. To discretize our frictional problem, we use a mortar technique on nonconforming meshes. For mortar techniques with standard Lagrange multipliers, we refer to [BR03, BHL99, CHLS01, Hil00, HL02]. Mortar techniques with dual Lagrange multipliers were recently used in [HW05b, HW05a] within the framework of frictionless unilateral multibody contact problems. Due to the use of dual basis functions for the Lagrange multiplier, we can apply a primal-dual active set strategy based on [Sta04] to solve the resulting nonlinear algebraic form of the discrete problem. Furthermore, the dual Lagrange multiplier allows us in the multibody case to easily apply a basis transformation of the finite element basis such that the problem in the new basis for the multibody case has exactly the same structure as for the one body case. In contrast, to standard Lagrange multiplier basis functions, this transformation is obtained by a local scaling of the coupling matrix. As a consequence, the constraints can be verified pointwise for each node on the slave side. This is not the case for the standard Lagrange multiplier. The considered primal-dual active set strategy can be interpreted as a semi-smooth quasi-Newton method. A further advantage of the approach is that the nonlinear friction conditions are applied as Dirichlet or Neumann boundary conditions on the interface. This makes the implementation extremly simple, and an existing finite element code can be easily adapted to this solution strategy. Since there is no need for a penalty parameter in the primal-dual active set strategy, the condition number of the stiffness matrix is the same as in a linear setting. Therefore, we combine the considered method with an optimal multigrid solver (see [Woh05]), yielding an inexact method. This approach results in an efficient nonlinear multigrid method for the contact problem with a negligible additional effort compared to solving a linear problem.

The structure of the rest of the paper is as follows. In section 2, we describe the frictional antiplane contact problem involving two elastic bodies, and we provide a weak formulation. In section 3, we propose a nonconforming discretization method based on dual Lagrange multipliers; see [Woh00]. We obtain an optimal a priori error estimate of order $h^{1/2}+\nu$, $0<\nu\leq\frac{1}{2}$, for the solution and for the Lagrange multiplier if the solution is regular enough. In section 4, the inexact primal-dual active set algorithm is presented. Finally, numerical examples confirming our theoretical results and illustrating the performance of our algorithm are given in section 5. Section 6 describes the generalization of our algorithm to the case of Coulomb friction.

We mention that the idea of a primal-dual active set strategy for frictional problems can also be generalized to the three-dimensional case. Here the use of a more general nonlinear complementarity function involving the direction is necessary (see also [HSW06]).

2. An antiplane frictional contact problem. Let us consider two deformable solids, $\mathcal{B}^m$, $\mathcal{B}^s\subset\mathbb{R}^3$, that are cylinders, with the generators parallel to the x_3-axis of a rectangular Cartesian coordinate system $Ox_1x_2x_3$. The subscripts m and s are motivated by the presence of the mortar setting in the numerical analysis of our model. Everywhere below, we will use a superscript k to indicate that a quantity is related to the cylinder $\mathcal{B}^k$, $k=m,s$. We assume that the bodies are homogeneous, isotropic and elastic media; more precisely, we will use the constitutive law:

$$\boldsymbol{\sigma}^k=\lambda^k\mathrm{tr}(\boldsymbol{\varepsilon}(\boldsymbol{u}^k))\,\mathrm{Id}+2\mu^k\boldsymbol{\varepsilon}(\boldsymbol{u}^k)\quad\text{in}\quad\mathcal{B}^k, \tag{2.1}$$

where $\boldsymbol{\sigma}^k=(\boldsymbol{\sigma}^k_{ij})$ denotes the stress field, $\boldsymbol{\varepsilon}(\boldsymbol{u}^k)=(\varepsilon_{ij}(\boldsymbol{u}^k))$ the linearized strain tensor, $\lambda^k>0$ and $\mu^k>0$ are the Lamé coefficients, $\mathrm{tr}(\boldsymbol{\varepsilon}(\boldsymbol{u}^k))=\sum_{i=1}^3\varepsilon_{ii}(\boldsymbol{u}^k)$, and Id is the unit tensor in $\mathbb{R}^3$. Moreover, we assume that the generators are sufficiently

long so that end effects in the axial direction are negligible. Let us denote by Ω^k a cross-section, which is a domain in $\mathbb{R}^2$. Thus, $\mathcal{B}^k = \Omega^k \times (-\infty, +\infty)$. For each domain Ω^k, we assume that its boundary Γ^k is Lipschitz continuous and is divided into three disjoint measurable parts Γ_1^k, Γ_2^k and Γ_3^k, with meas $(\Gamma_1^k) > 0$. We assume that the bodies are clamped on Γ_1^k, body forces of density $\boldsymbol{f}_0^k$ act on Ω^k, and surface traction of density $\boldsymbol{f}_2^k$ act on Γ_2^k. Moreover, we assume that the bodies in the initial configuration are in contact on their common boundary part $\Gamma_3 = \Gamma_3^1 = \Gamma_3^2$ and that $\overline{\Gamma}_3$ is a compact subset of $\partial\Omega^k \backslash \overline{\Gamma}_1^k$, $k = m$, s. We load the solid in a special way as follows:

$$\boldsymbol{f}_0^k = (0, 0, f_0^k), \quad f_0^k = f_0^k(x_1, x_2) : \Omega^k \to \mathbb{R}, \tag{2.2}$$

$$\boldsymbol{f}_2^k = (0, 0, f_2^k), \quad f_2^k = f_2^k(x_1, x_2) : \Gamma_2^k \to \mathbb{R}. \tag{2.3}$$

The unit outward normal on $\Gamma^k \times (-\infty, +\infty)$ is denoted by $\boldsymbol{n}^k$, $\boldsymbol{n}^k = (n_1^k, n_2^k, 0)$ and is defined a.e.. We note that on Γ_3,

$$\boldsymbol{n} := \boldsymbol{n}^s = -\boldsymbol{n}^m, \quad \boldsymbol{\sigma}^s\, \boldsymbol{n}^s = -\boldsymbol{\sigma}^m\, \boldsymbol{n}^m, \quad \boldsymbol{\sigma}_\tau := \boldsymbol{\sigma}_\tau^s = -\boldsymbol{\sigma}_\tau^m.$$

For a vector $\boldsymbol{v}^k$, we denote by v_n^k and $\boldsymbol{v}_\tau^k$ its [illegible] and [illegible] parts on the boundary, given by $v_n^k := \boldsymbol{v}^k \cdot \boldsymbol{n}^k$ and $\boldsymbol{v}_\tau^k := \boldsymbol{v}^k - v_n^k \boldsymbol{n}^k$, respectively. Furthermore, for a given stress field $\boldsymbol{\sigma}^k$, we denote by σ_n^k and $\boldsymbol{\sigma}_\tau^k$ the [illegible] and the [illegible] parts on the boundary, that is $\sigma_n^k := (\boldsymbol{\sigma}^k \boldsymbol{n}^k) \cdot \boldsymbol{n}^k$ and $\boldsymbol{\sigma}_\tau^k := \boldsymbol{\sigma}^k \boldsymbol{n}^k - \sigma_n^k \boldsymbol{n}^k$, respectively.

The body forces (2.2) and the surface traction (2.3) would be expected to give rise to a deformation of the elastic cylinder $\mathcal{B}^k$, such that the displacement $\boldsymbol{u}^k$ is of the form

$$\boldsymbol{u}^k = (0, 0, u^k), \quad u^k = u^k(x_1, x_2) : \Omega^k \to \mathbb{R}. \tag{2.4}$$

Consequently, keeping in mind (2.1), the traction vector on $\Gamma^k \times (-\infty, +\infty)$ is given by

$$\boldsymbol{\sigma}^k \boldsymbol{n}^k = (0, 0, \mu^k \partial_n u^k),$$

where, as usual, $\partial_n u^k := \nabla \boldsymbol{u}^k \cdot \boldsymbol{n}^k$. Moreover, we note that

$$\text{Div}\, \boldsymbol{\sigma}^k = (0, 0, \mu^k\, \Delta u^k). \tag{2.5}$$

According to the physical setting, we have

$$\text{Div}\, \boldsymbol{\sigma}^k + \boldsymbol{f}_0^k = \boldsymbol{0} \qquad \text{in} \qquad \mathcal{B}^k, \tag{2.6}$$

$$\boldsymbol{u}^k = \boldsymbol{0} \qquad \text{on} \qquad \Gamma_1^k \times (-\infty, +\infty), \tag{2.7}$$

$$\boldsymbol{\sigma}^k \boldsymbol{n}^k = \boldsymbol{f}_2^k \qquad \text{on} \qquad \Gamma_2^k \times (-\infty, +\infty). \tag{2.8}$$

Finally, we have to describe the frictional contact condition on $\Gamma_3 \times (-\infty, +\infty)$. Everywhere in what follows, we will use $|\cdot|$ to denote the Euclidean norm on $\mathbb{R}^d$, $d = 1$ or 3. Since $u_n^s = u_n^m = 0$, on $\Gamma_3 \times (-\infty, +\infty)$ the contact is bilateral. Let us model the friction using Tresca's law,

$$\left\{ \begin{array}{l} |\boldsymbol{\sigma}_\tau| \le g, \\ |\boldsymbol{\sigma}_\tau| < g \;\Rightarrow\; \boldsymbol{u}_\tau^s - \boldsymbol{u}_\tau^m = 0, \\ |\boldsymbol{\sigma}_\tau| = g \;\Rightarrow\; \boldsymbol{\sigma}_\tau = -\beta(\boldsymbol{u}_\tau^s - \boldsymbol{u}_\tau^m), \quad \beta > 0, \end{array} \right. \qquad \text{on} \quad \Gamma_3 \times (-\infty, +\infty), \tag{2.9}$$

where g is a given function, called the [illegible]. We note that $\boldsymbol{u}_\tau^k = (0, 0, u^k)$ and $\boldsymbol{\sigma}_\tau^k = (0, 0, \sigma_\tau^k)$ with $\sigma_\tau^k = \mu^k \, \partial_n u^k$. In addition, we have

$$\partial_n u := \mu^s \partial_n u^s = -\mu^m \partial_n u^m \quad \text{on} \quad \Gamma_3. \tag{2.10}$$

Using (2.6)–(2.9) and keeping in mind (2.4)–(2.5), the study of our three-dimensional mechanical model reduces to the study of the following mathematical problem.

PROBLEM 2.1. [illegible] $u^k : \Omega \to \mathbb{R}$, $k = m, s$, [illegible]

$$\mu^k \Delta u^k + f_0^k = 0 \qquad \text{[illegible]} \qquad \Omega^k, \tag{2.11}$$

$$u^k = 0 \qquad \text{[illegible]} \qquad \Gamma_1^k, \tag{2.12}$$

$$\mu^k \partial_n u^k = f_2^k \qquad \text{[illegible]} \qquad \Gamma_2^k, \tag{2.13}$$

[illegible]

$$\left\{ \begin{array}{l} |\partial_n u| \le g, \\ |\partial_n u| < g \Rightarrow u^s - u^m = 0, \\ |\partial_n u| = g \Rightarrow \partial_n u = -\beta(u^s - u^m), \quad \beta > 0, \end{array} \right. \qquad \text{[illegible]} \quad \Gamma_3 \tag{2.14}$$

[illegible]

In the study of Problem 2.1, we assume that

$$f_0^k \in L^2(\Omega^k), \quad f_2^k \in L^2(\Gamma_2^k), \tag{2.15}$$

$$g \in L^2(\Gamma_3), \qquad g \ge 0 \ \text{ a.e. on } \Gamma_3. \tag{2.16}$$

In order to obtain a weak formulation for Problem 2.1, we introduce the Hilbert space

$$V^k := \left\{ v^k \in H^1(\Omega^k) \,|\, v^k = 0 \quad \text{on} \quad \Gamma_1^k \right\}$$

endowed with the inner product given by

$$(u^k, v^k)_{V^k} := \int_{\Omega^k} \nabla u^k \cdot \nabla v^k \, dx, \qquad u^k, v^k \in V^k,$$

and the associated norm,

$$\|v^k\|_{V^k} := \|\nabla v^k\|_{L^2(\Omega^k)^2}, \qquad v^k \in V^k,$$

which is equivalent to $\|\cdot\|_{1,\Omega^k}$. Let us consider the product space $V := V^m \times V^s$ and let $a : V \times V \to \mathbb{R}$ be the bilinear form

$$a(u, v) := \sum_{k=1}^{2} \mu^k (u^k, v^k)_{V^k}.$$

Clearly, this form is continuous with the continuity constant $M_a = \mu^m + \mu^s$, and V-elliptic with the V-ellipticity constant $m_a = \min\{\mu^m, \mu^s\}$. Defining $f \in V$ such that

$$(f, v)_V = \sum_{k=m,s} \left(\int_{\Omega^k} f_0^k \, v^k \, dx + \int_{\Gamma_2^k} f_2^k \, v^k \, ds \right),$$

due to Green's formula, for regular functions u^m and u^s satisfying (2.11)–(2.13), we get

$$a(u,\, v) = (f, v)_V + \int_{\Gamma_3} (\mu^m \partial_n u^m\, v^m + \mu^s \partial_n u^s\, v^s)\, ds, \qquad v = (v^m, v^s) \in V. \tag{2.17}$$

Keeping in mind (2.10), we define a Lagrange multiplier λ in $M := (H^{1/2}(\Gamma_3))'$ by

$$\langle \lambda, w\rangle_{\Gamma_3} := -\int_{\Gamma_3} \partial_n u\, w\, ds, \qquad w \in H^{1/2}(\Gamma_3), \tag{2.18}$$

where $\langle\cdot,\cdot\rangle_{\Gamma_3}$ denotes the duality pairing. Furthermore, we introduce a nonempty closed convex set,

$$\Lambda := \left\{ \zeta \in M \,:\, \langle \zeta,\, w\rangle_{\Gamma_3} \le \int_{\Gamma_3} g\,|w|\, ds, \quad w \in H^{1/2}(\Gamma_3) \right\}. \tag{2.19}$$

Clearly, $\lambda \in \Lambda$ and we can rewrite (2.17) as

$$a(u,\, v) = (f, v)_V \,-\, \langle \lambda, [v]\rangle_{\Gamma_3}, \qquad v \in V, \tag{2.20}$$

where $[v]$ denotes the [illegible] defined on Γ_3 by

$$[v] := v^s - v^m, \qquad v = (v^m, v^s) \in V.$$

Let us denote by $b : V \times M \to \mathbb{R}$ the bilinear and continuous form

$$b(v,\, \zeta) := \langle \zeta, [v]\rangle_{\Gamma_3}. \tag{2.21}$$

Keeping in mind the properties of the trace operator, it can be shown that the form $b(\cdot,\cdot)$ satisfies the [illegible]: there exists a constant $\alpha > 0$ such that

$$\inf_{0\neq\mu\in M} \sup_{0\neq v\in V} \frac{b(v,\zeta)}{\|v\|_V \|\zeta\|_M} \ge \alpha,$$

where $\|\cdot\|_M$ denotes the natural norm of $(H^{1/2}(\Gamma_3))'$. The friction law (2.14) leads to the identity

$$\int_{\Gamma_3} \partial_n u\, [u]\, ds = -\int_{\Gamma_3} g|[u]|\, ds.$$

Taking into account the definition of λ, (2.18), the definition of $b(\cdot,\cdot)$, (2.21), and the definition of Λ, (2.19), we can write

$$b(u,\lambda) = \int_{\Gamma_3} g|[u]|\, ds \quad \text{and} \quad b(u,\zeta) \le \int_{\Gamma_3} g|[u]|\, ds, \qquad \zeta \in \Lambda.$$

Consequently, we get the inequality

$$b(u, \zeta - \lambda) \le 0, \qquad \zeta \in \Lambda.$$

Combining this, (2.20), and (2.21), we obtain the following weak formulation of Problem 2.1.

PROBLEM 2.2. [illegible] $u \in V$ [illegible] $\lambda \in \Lambda$ [illegible]

$$\begin{aligned} a(u, v) + b(v, \lambda) &= (f, v)_V, \quad v \in V, \\ b(u, \zeta - \lambda) &\leq 0, \qquad \zeta \in \Lambda. \end{aligned}$$

The well-posedness of Problem 2.2 is given by the following theorem.

THEOREM 2.1. [illegible] (2.15) [illegible] (2.16) [illegible] $(u, \lambda) \in V \times \Lambda$ [illegible] 2.2 [illegible] f_1, f_2 [illegible] V [illegible] $(f_0, f_2)_1, (f_0, f_2)_2$, [illegible]

$$\|u_1 - u_2\|_V + \|\lambda_1 - \lambda_2\|_M \leq \frac{\alpha + m_a + M_a}{\alpha\, m_a} \|f_1 - f_2\|_V, \tag{2.22}$$

[illegible] (u_1, λ_1), (u_2, λ_2) [illegible] 2.2 [illegible] $f_1, f_2 \in V$, [illegible]

In order to prove the existence and the uniqueness of the solution of Problem 2.2, we can use Theorem 3.11 in [Hcc96]. The stability result can be obtained by standard techniques and by using the inf-sup property of the bilinear form $b(\cdot, \cdot)$.

3. Nonconforming discretization and optimal a priori error estimates. In this section we give the discretization of Problem 2.2, and we derive an optimal a priori error estimate for the discretization error. To do so, we introduce a suitable basis transformation of our nodal finite element basis. Let us assume that the bodies Ω^k, $k = m, s$, are polygonal domains. To approximate V, we use linear finite elements on simplicial triangulations and bilinear finite elements on quadrilateral triangulations. The finite element space associated with the shape regular triangulation $\mathcal{T}_{h,\Omega^k}$ is denoted by $S_1(\Omega^k, \mathcal{T}_{h,\Omega^k})$. The mesh size h is defined by the maximal diameter of the elements in $\mathcal{T}_{h,\Omega^m}$ and $\mathcal{T}_{h,\Omega^s}$. For simplicity we assume that Γ_1^k, $k = m, s$, and that Γ_3 can be written as the union of edges, Γ_3 both from the triangulation $\mathcal{T}_{h,\Omega^s}$ of the slave side and from the triangulation $\mathcal{T}_{h,\Omega^m}$ of the master side. Before introducing the discrete spaces, we decompose the set of all vertices into three disjoint sets $\mathcal{S}$, $\mathcal{M}$, and $\mathcal{N}$. By the first subset $\mathcal{S}$ we denote all vertices on $\overline{\Gamma}_3$ of the triangulation $\mathcal{T}_{h,\Omega^s}$ on the slave side, and by $\mathcal{M}$ we denote all vertices on $\overline{\Gamma}_3$ of the triangulation $\mathcal{T}_{h,\Omega^m}$ on the master side. The set $\mathcal{N}$ contains all remaining ones. Then we have for the discrete spaces V_h^k

$$V_h^k := \left\{ v_h^k \in S_1\left(\Omega^k,\, \mathcal{T}_{h,\Omega^k}\right) \,:\, v_h^k = 0 \quad \text{on} \quad \Gamma_1^k \right\} \subset V^k,$$

and we define $V_h := V_h^m \times V_h^s$. For the discretization of the Lagrange multiplier space we use dual shape functions, introduced in [Woh00]. In the case of linear or bilinear finite elements in two dimensions, the dual basis functions are associated with the vertices. We use discontinuous piecewise linear functions having value two at the associated vertex and value minus one at the two neighboring vertices as basis functions. We denote this discrete Lagrange multiplier space by $M_h = \operatorname{span}\{\psi_p,\ p \in \mathcal{S}\}$, where ψ_p denotes the basis function associated with the vertex p. Then the biorthogonality of the basis functions yields

$$\langle \psi_p, \phi_q \rangle_{\Gamma_3} \,=\, \delta_{pq} \int_{\Gamma_3} \phi_q \, ds, \qquad p, q \in \mathcal{S}, \tag{3.1}$$

where ϕ_q are the standard nodal basis functions of $S_1(\Omega^s, \mathcal{T}_{h,\Omega^s})$ associated with the vertex q. The finite element space V_h can be written in terms of the standard finite element basis $\boldsymbol{\phi}$ as $V_h = \operatorname{span}\{\phi_p,\ p \in \mathcal{S} \cup \mathcal{M} \cup \mathcal{N}\}$. In addition to the basis $\boldsymbol{\phi}$, we introduce the constrained finite element basis $\hat{\boldsymbol{\phi}}$ (see [WK03]). To introduce these basis functions, we define the entries of the coupling matrices D and M between the finite element basis functions ϕ_p and the basis functions for the Lagrange multiplier space ψ_p by

$$\begin{aligned} D[p,q] &:= \langle \psi_p, \phi_q \rangle_{\Gamma_3}, \quad p,\, q \in \mathcal{S}, \\ M[p,q] &:= \langle \psi_p, \phi_q \rangle_{\Gamma_3}, \quad p \in \mathcal{S},\, q \in \mathcal{M}. \end{aligned}$$

Due to the biorthogonality (3.1), the matrix D is diagonal. Defining $\hat{M} := D^{-1}M$, we obtain the constrained basis $\hat{\boldsymbol{\phi}}$ of V_h from the nodal basis $\boldsymbol{\phi}$ of V_h by the transformation

$$\hat{\boldsymbol{\phi}} := \begin{pmatrix} \hat{\phi}_{\mathcal{N}} \\ \hat{\phi}_{\mathcal{M}} \\ \hat{\phi}_{\mathcal{S}} \end{pmatrix} := \begin{pmatrix} \mathrm{Id} & 0 & 0 \\ 0 & \mathrm{Id} & \hat{M}^\top \\ 0 & 0 & \mathrm{Id} \end{pmatrix} \begin{pmatrix} \phi_{\mathcal{N}} \\ \phi_{\mathcal{M}} \\ \phi_{\mathcal{S}} \end{pmatrix} =: Q\boldsymbol{\phi}. \tag{3.2}$$

We note that only basis functions associated with a node $p \in \mathcal{M}$ are changed and that by definition

$$b(\hat{\phi}_q, \psi_p) = 0, \quad p \in \mathcal{S},\, q \in \mathcal{M}.$$

For simplicity of notation, we use the same symbol for a function in V_h and M_h as for its algebraic representation with respect to the nodal basis. Let v_h be the algebraic representation of an element $v_h \in V_h$ with respect to the basis $\boldsymbol{\phi}$ and let $\hat{v}_h$ be the corresponding algebraic representation with respect to the constrained basis $\hat{\boldsymbol{\phi}}$. Then we have the relation $v_h = Q^\top \hat{v}_h$. Now, after an easy computation and taking into account the biorthogonality (3.1), we get

$$b(v_h, \mu_h) = \langle \mu_h, \sum_{p\in\mathcal{S}} v_p\phi_p - \sum_{q\in\mathcal{M}} v_q\phi_q \rangle_{\Gamma_3} = \langle \mu_h, \sum_{p\in\mathcal{S}} \hat{v}_p\hat{\phi}_p \rangle_{\Gamma_3} = \langle \mu_h, \sum_{p\in\mathcal{S}} \hat{v}_p\phi_p \rangle_{\Gamma_3}.$$

Before introducing the discrete set Λ_h for the admissible Lagrange multipliers, we define for $v_h \in V_h$ the restriction to the slave side of the interface Γ_3 by

$$v_{h,\mathcal{S}} := \sum_{p\in\mathcal{S}} v_p\phi_p.$$

Now we define the discrete convex set Λ_h by

$$\Lambda_h := \Big\{ \mu_h \in M_h \,:\, \langle \mu_h, v_{h,\mathcal{S}} \rangle_{\Gamma_3} \le \int_{\Gamma_3} g|v_{h,\mathcal{S}}|_h \, ds, \quad v_h \in V_h \Big\}, \tag{3.3}$$

where the mesh dependent absolute value $|v_{h,\mathcal{S}}|_h$ of the function $v_{h,\mathcal{S}}$ is given by

$$|v_{h,\mathcal{S}}|_h := \sum_{p\in\mathcal{S}} |v_p|\phi_p.$$

We remark that in general $|v_{h,\mathcal{S}}|_h \neq |v_{h,\mathcal{S}}|$. Henceforth in this section, we assume that g is a strictly positive constant. In this case, the convex set Λ_h can be written equivalently as

$$\Lambda_h := \Big\{ \mu_h \in M_h \,:\, \mu_h = \sum_{p\in\mathcal{S}} \gamma_p\psi_p, \quad |\gamma_p| \le g, \quad p \in \mathcal{S} \Big\}. \tag{3.4}$$

The discrete formulation of Problem 2.2 is as follows.

PROBLEM 3.1. [illegible] $u_h \in V_h$ [illegible] $\lambda_h \in \Lambda_h$ [illegible]

$$\begin{aligned} a(u_h, v_h) + b(v_h, \lambda_h) &= (f, v_h)_V, \qquad && v_h \in V_h, \\ b(u_h, \zeta_h - \lambda_h) &\leq 0, && \zeta_h \in \Lambda_h. \end{aligned}$$

Using the discrete inf-sup property for the spaces M_h and V_h (see, e.g., [Woh00]), we get the existence and the uniqueness of the solution. In order to obtain an optimal a priori error estimate, several lemmas will be proved. We note that $\Lambda_h \not\subset \Lambda$.

Before presenting the first lemma, we have to consider for a function $v_h \in V_h$ the discrete jump $\hat{v}_{h,\mathcal{S}}$ on the interface Γ_3 in the constrained basis and its mesh dependent absolute value by

$$\hat{v}_{h,\mathcal{S}} = \sum_{p \in \mathcal{S}} \hat{v}_p \phi_p, \quad |\hat{v}_{h,\mathcal{S}}|_h = \sum_{p \in \mathcal{S}} |\hat{v}_p| \phi_p,$$

respectively. Now we can prove the following lemma.

LEMMA 3.1. [illegible] (u, λ) [illegible] 2.2 [illegible] (u_h, λ_h) [illegible] 3.1 [illegible]

$$b(u, \lambda) = \int_{\Gamma_3} g|[u]|\, ds, \qquad b(u_h, \lambda_h) = \int_{\Gamma_3} g|\hat{u}_{h,\mathcal{S}}|_h\, ds.$$

[illegible]. In order to prove the first equality, we define $\mu \in M$ by

$$\langle \mu, v \rangle_{\Gamma_3} := \int_{\Gamma_3} g\ \mathrm{sgn}([u])\, v\, ds, \quad v \in H^{1/2}(\Gamma_3).$$

Thus, we have $\mu \in \Lambda$. Using the definition of Λ and taking into account that

$$b(u, \mu - \lambda) \leq 0, \qquad \mu \in \Lambda,$$

we can write

$$\int_{\Gamma_3} g\,|[u]|\, ds \geq \langle \lambda, [u] \rangle_{\Gamma_3} \geq \langle \mu, [u] \rangle_{\Gamma_3} = \int_{\Gamma_3} g\ \mathrm{sgn}([u])\,[u]\, ds = \int_{\Gamma_3} g\,|[u]|\, ds.$$

Keeping in mind (2.21), we have the first relation.

In order to prove the second equality, we consider $\zeta_h = \sum_{p \in \mathcal{S}} g\ \mathrm{sgn}(\hat{u}_p)\, \psi_p$. Obviously, we have $\zeta_h \in \Lambda_h$. Due to the relation

$$b(u_h, \zeta_h - \lambda_h) \leq 0, \quad \zeta_h \in \Lambda_h,$$

we deduce that

$$b(u_h, \lambda_h) \geq \langle \sum_{p \in \mathcal{S}} g\ \mathrm{sgn}(\hat{u}_p) \psi_p, \hat{u}_{h,\mathcal{S}} \rangle_{\Gamma_3}.$$

Using the biorthogonality relation of the basis function (3.1), we get

$$\begin{aligned} \left\langle \sum_{p \in \mathcal{S}} g\ \mathrm{sgn}(\hat{u}_p)\, \psi_p, \hat{u}_{h,\mathcal{S}} \right\rangle_{\Gamma_3} &= \sum_{p \in \mathcal{S}} g\ \mathrm{sgn}(\hat{u}_p)\, \hat{u}_p \int_{\Gamma_3} \phi_p\, ds = \sum_{p \in \mathcal{S}} g\,|\hat{u}_p| \int_{\Gamma_3} \phi_p\, ds \\ &= \int_{\Gamma_3} g\,|\hat{u}_{h,\mathcal{S}}|_h\, ds. \end{aligned}$$

From this, we obtain

$$b(u_h, \lambda_h) = \langle \lambda_h, \hat{u}_{h,\mathcal{S}} \rangle_{\Gamma_3} \geq \int_{\Gamma_3} g\, |\hat{u}_{h,\mathcal{S}}|_h \, ds.$$

Taking into account (2.21) and the definition of Λ_h, we have

$$b(u_h, \lambda_h) \leq \int_{\Gamma_3} g |\hat{u}_{h,\mathcal{S}}|_h \, ds.$$

Combining the last inequalities, we deduce the second relation. □

Furthermore, the following result holds.

LEMMA 3.2. [illegible] $(u, \lambda) \in V \times \Lambda$ [illegible] 2.2 [illegible] $(u_h, \lambda_h) \in V_h \times \Lambda_h$ [illegible] 3.1 [illegible] C [illegible] h, [illegible] $v_h \in V_h$, $\mu_h \in M_h$,

$$\|u - u_h\|_V^2 + \|\lambda - \lambda_h\|_M^2 \leq C \left\{ \|u - v_h\|_V^2 + \|\lambda - \mu_h\|_M^2 \right\} + b(u, \lambda_h - \lambda).$$

[illegible]. The proof follows directly from the arguments given in [HL02]. For the convenience of the reader, we adapt the proof to our situation and take into account the different definitions of Λ and Λ_h. Evaluating $a(u - u_h, u - u_h)$, we find for $v_h \in V_h$ the relation

$$\begin{aligned} a(u - u_h, u - u_h) &= a(u - u_h, u - v_h) + a(u - u_h, v_h - u_h) \\ &= a(u - u_h, u - v_h) - b(v_h - u_h, \lambda) + b(v_h - u_h, \lambda_h) \\ &= a(u - u_h, u - v_h) - b(v_h - u, \lambda - \lambda_h) - b(u - u_h, \lambda - \lambda_h). \end{aligned}$$

Due to the V-ellipticity of $a(\cdot, \cdot)$ and continuity of $a(\cdot, \cdot)$ and $b(\cdot, \cdot)$, we deduce from this expression, using a trace theorem, the inequality

$$\|u - u_h\|_V^2 \leq C \left(\|u - u_h\|_V + \|\lambda - \lambda_h\|_M \right) \|u - v_h\|_V - b(u - u_h, \lambda - \lambda_h). \tag{3.5}$$

Here and below, we denote by C a positive constant independent of the mesh size, whose value may change from place to place. Using Lemma 3.1, we can write for the last term on the previous estimate

$$-b(u - u_h, \lambda - \lambda_h) = b(u, \lambda_h - \lambda) + b(u_h, \lambda) - \int_{\Gamma_3} g |\hat{u}_{h,\mathcal{S}}|_h \, ds,$$

and from this, since $b(u_h, \lambda) \leq \int_{\Gamma_3} g |\hat{u}_{h,\mathcal{S}}| \, ds$ and $|\hat{u}_{h,\mathcal{S}}| \leq |\hat{u}_{h,\mathcal{S}}|_h$, we deduce that

$$-b(u - u_h, \lambda - \lambda_h) \leq b(u, \lambda_h - \lambda). \tag{3.6}$$

On the other hand, taking into account the inf-sup property of the form $b(\cdot, \cdot)$, we find that

$$\begin{aligned} \|\mu_h - \lambda_h\|_M &\leq \alpha \sup_{0 \neq w_h \in V_h} \frac{b(w_h, \mu_h - \lambda_h)}{\|w_h\|_V} \\ &= \alpha \sup_{0 \neq w_h \in V_h} \frac{b(w_h, \mu_h - \lambda) + a(u_h - u, w_h)}{\|w_h\|_V} \\ &\leq C(\|\mu_h - \lambda\|_M + \|u_h - u\|_V), \end{aligned}$$

and, using the triangle inequality, we can write

$$\|\lambda - \lambda_h\|_M \le C(\|\mu_h - \lambda\|_M + \|u_h - u\|_V). \tag{3.7}$$

We conclude our proof using (3.5), (3.6), and (3.7). □

To estimate the first two terms on the right side of the inequality of Lemma 3.2, we use the approximation properties of the spaces V_h and M_h. In addition, we have to estimate the residual term $b(u, \lambda_h - \lambda)$. To this end, we define $\overline{\gamma_{sl}} := \text{supp}\,[u] \subset \Gamma_3$, $\gamma_{st} := \Gamma_3 \backslash \gamma_{sl}$, and we introduce the sets

$$\mathcal{W}^* := \overline{\mathring{\gamma}_{st}} \cap \overline{\gamma_{sl}},$$
$$\mathcal{W}^0 := \Big\{ w \in \Gamma_3 \,:\, [u](w) = 0 \text{ and } \exists\, r > 0 \,:\, [u](w-\varepsilon)\,[u](w+\varepsilon) < 0, \quad 0 < \epsilon < r \Big\},$$
$$\mathcal{W} := \mathcal{W}^* \cup \mathcal{W}^0.$$

Everywhere below we will use the following assumption.

3.1. The number of points in $\mathcal{W}$ is finite.

The minimum distance between elements in $\mathcal{W}$ is denoted by a, i.e.,

$$a := \inf\{|w_j - w_k| \,:\, 1 \le j \ne k \le N_w\},$$

where N_w denotes the number of points in $\mathcal{W}$. By Assumption 3.1, $N_w < \infty$ and thus $a > 0$. For $h < \frac{a}{2} =: h_0$, we find between two neighboring points in $\mathcal{W}$ at [illegible] in $\mathcal{S}$. Then the following lemma holds.

LEMMA 3.3. [illegible] $(u, \lambda) \in V \times \Lambda$ [illegible] 2.2 [illegible] $(u_h, \lambda_h) \in V_h \times \Lambda_h$ [illegible] 3.1 [illegible] 3.1 [illegible] $u^k \in H^{\frac{3}{2}+\nu}(\Omega^k)$ $0 < \nu \le \frac{1}{2}$ $k = m, s,$ [illegible]

$$b(u, \lambda_h - \lambda) \le C h^{\frac{1}{2}+\nu} \|\lambda - \lambda_h\|_M \sum_{k=m,s} |u^k|_{\frac{3}{2}+\nu,\Omega^k}$$

[illegible] C [illegible] $h < h_0$

[illegible]. For each element $w \in \mathcal{W}$, we can choose an element in $\mathcal{S}$ denoted by $p_{j(w)}$, such that

$$|p_{j(w)} - w| = \min_{p \in \mathcal{S},\, [u](p) \ne 0} |w - p| \quad \text{if} \quad w \in \mathcal{W} \backslash \mathcal{S},$$
$$p_{j(w)} = w \qquad\qquad\qquad\qquad \text{if} \quad w \in \mathcal{S}.$$

Let us consider the set $\tilde{\mathcal{S}}$, defined by

$$\tilde{\mathcal{S}} := \Big\{ p \in \mathcal{S} \,:\, \exists\, w \in \mathcal{W} \text{ s.t. } p = p_{j(w)} \Big\}.$$

For this set, we consider the disjoint decomposition

$$\tilde{\mathcal{S}} = \mathcal{S}^* \cup \mathcal{S}^l \cup \mathcal{S}^r,$$

where

$$\mathcal{S}^* := \Big\{ p \in \mathcal{S} \,:\, \exists\, w \in \mathcal{W}^* \text{ s.t. } p = p_{j(w)} \Big\},$$
$$\mathcal{S}^l := \Big\{ p \in \mathcal{S} \,:\, \exists\, w \in \mathcal{W}^0 \text{ s.t. } p = p_{j(w)} \text{ and } p_{j(w)} \text{ is on the left side of } w \Big\},$$
$$\mathcal{S}^r := \Big\{ p \in \mathcal{S} \,:\, \exists\, w \in \mathcal{W}^0 \text{ s.t. } p = p_{j(w)} \text{ and } p_{j(w)} \text{ is on the right side of } w \Big\};$$

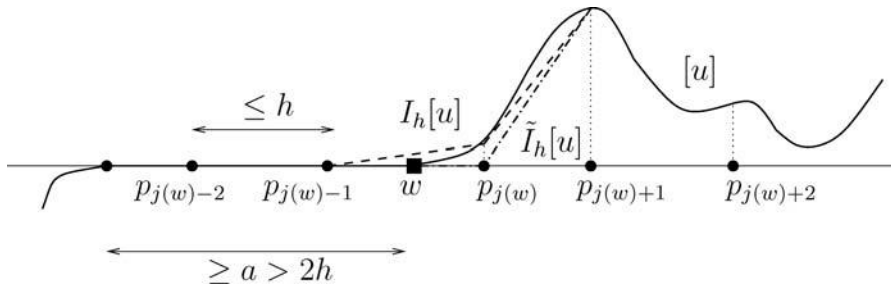

FIG. 3.1. $w \in \mathcal{W}^*$, $p_{j(w)} \in \mathcal{S}^*$, $[u]$, $I_h[u]$, $\tilde{I}_h[u]$.

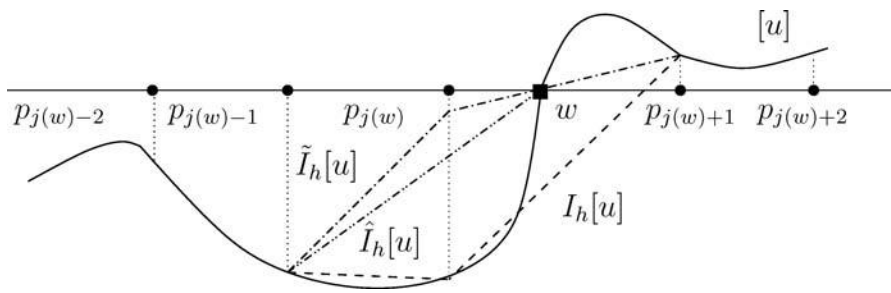

FIG. 3.2. $w \in \mathcal{W}^0$, $p_{j(w)} \in \mathcal{S}^l$, $[u]$, $I_h[u]$, $\tilde{I}_h[u]$, $\hat{I}_h[u]$.

see Figure 3.1 for an example of an element in $\mathcal{S}^*$ and Figure 3.2 for an example of an element in $\mathcal{S}^l$. Let I_h be the standard interpolation operator; that is, on Γ_3

$$I_h[u] = \sum_{p \in \mathcal{S}} [u](p)\phi_p.$$

Let $\tilde{I}_h$ be a modified interpolation operator such that

$$(\tilde{I}_h[u])(p) = \begin{cases} [u](p) & \text{if} \quad p \in \mathcal{S} \backslash \tilde{\mathcal{S}}, \\ [u](p_{j(w)+1})\frac{s^l}{s^l-1} & \text{if} \quad p = p_{j(w)} \in \mathcal{S}^l, \ s^l := \frac{|w-p_{j(w)}|}{|p_{j(w)+1}-p_{j(w)}|}, \\ [u](p_{j(w)-1})\frac{s^r}{s^r-1} & \text{if} \quad p = p_{j(w)} \in \mathcal{S}^r, \ s^r := \frac{|p_{j(w)}-w|}{|p_{j(w)}-p_{j(w)-1}|}, \\ 0 & \text{if} \quad p = p_{j(w)} \in \mathcal{S}^*; \end{cases}$$

see, e.g., Figures 3.1 and 3.2. In the construction of $\tilde{I}_h$ the value of I_h at the point $p_{j(w)}$ is modified such that $(\tilde{I}_h[u])(w) = 0$ holds. In order to simplify the writing, everywhere below we will use the notation $p_{j\pm l}$ instead of $p_{j(w)\pm l}$ for $l \in \{0, 1, 2\}$. We note that $0 < s^l, s^r \leq \frac{1}{2}$. Moreover, the identity

$$[u]\ \tilde{I}_h[u] \geq 0 \tag{3.8}$$

holds on Γ_3. Finally, we introduce the Lagrange interpolation operator $\hat{I}_h$ with respect to the nodes $(\mathcal{S} \backslash (\mathcal{S}^l \cup \mathcal{S}^r)) \cup \mathcal{W}^0$. Due to the shape regularity of the grid given by the nodes in $\mathcal{S}$, and because of $0 < s^l, s^r \leq \frac{1}{2}$, the new grid is also shape regular.

Let us evaluate $b(u, \lambda_h - \lambda)$ using the interpolation operators introduced above. First, using I_h and $\tilde{I}_h$, we can write

$$b(u, \lambda_h - \lambda) \leq \langle \lambda_h - \lambda, [u] - I_h[u] \rangle_{\Gamma_3} + \langle \lambda_h - \lambda, I_h[u] - \tilde{I}_h[u] \rangle_{\Gamma_3} + \langle \lambda_h - \lambda, \tilde{I}_h[u] \rangle_{\Gamma_3}. \tag{3.9}$$

For the first term in the right side of the previous inequality, we get

$$\langle \lambda_h - \lambda, [u] - I_h[u] \rangle_{\Gamma_3} \leq \|\lambda_h - \lambda\|_M \|[u] - I_h[u]\|_{\frac{1}{2},\Gamma_3},$$

and from this, we obtain

$$\langle \lambda_h - \lambda, [u] - I_h[u] \rangle_{\Gamma_3} \leq C\|\lambda_h - \lambda\|_M h^{1/2+\nu} \sum_{k=m,s} |u^k|_{\frac{3}{2}+\nu,\Omega^k}. \tag{3.10}$$

In order to evaluate the second term, we use the inverse inequality to write

$$\|I_h[u] - \tilde{I}_h[u]\|^2_{\frac{1}{2},\Gamma_3} \leq \frac{C}{h}\|I_h[u] - \tilde{I}_h[u]\|^2_{0,\Gamma_3},$$

and from this, we find that

$$\|I_h[u] - \tilde{I}_h[u]\|^2_{\frac{1}{2},\Gamma_3} \leq \frac{C}{h} \sum_{p_j \in \mathcal{S}^l \cup \mathcal{S}^r} \|I_h[u] - \tilde{I}_h[u]\|^2_{0,[p_{j-1},p_{j+1}]} + C \sum_{p_j \in \mathcal{S}^*} \Big([u](p_j)\Big)^2. \tag{3.11}$$

We note that for each $p_j \in \mathcal{S}^*$ we have

$$0 = (\tilde{I}_h[u])(p_j) \neq (I_h[u])(p_j) = [u](p_j).$$

Let p_j be an element in $\mathcal{S}^l$ and let us evaluate $\|I_h[u] - \tilde{I}_h[u]\|^2_{0,[p_{j-1},p_{j+1}]}$. First, we note that

$$\|I_h[u] - \tilde{I}_h[u]\|^2_{0,[p_{j-1},p_{j+1}]} \leq Ch\Big((I_h[u] - \tilde{I}_h[u])(p_j)\Big)^2.$$

Furthermore we have

$$(I_h[u] - \tilde{I}_h[u])(p_j) = \frac{1}{1-s^l}\Big((1-s^l)[u](p_j) + s^l[u](p_{j+1})\Big),$$

and from this, we obtain the identity

$$(I_h[u] - \tilde{I}_h[u])(p_j) = \frac{1}{1-s^l}(I_h[u])(w). \tag{3.12}$$

Since $0 < s^l \leq \frac{1}{2}$, we get, using also (3.12),

$$\|I_h[u] - \tilde{I}_h[u]\|^2_{0,[p_{j-1},p_{j+1}]} \leq Ch\Big((I_h[u] - \hat{I}_h[u])(w)\Big)^2.$$

Now we deduce that

$$\|I_h[u] - \tilde{I}_h[u]\|^2_{0,[p_{j-1},p_{j+1}]} \leq C\|I_h[u] - \hat{I}_h[u]\|^2_{0,[p_{j-1},p_{j+1}]}.$$

Using the triangle inequality and the interpolation error for Lagrange interpolation operators, we find that

$$\|I_h[u] - \tilde{I}_h[u]\|^2_{0,[p_{j-1},p_{j+1}]} \leq Ch\Big(h^{1/2+\nu}|[u]|_{1+\nu,[p_{j-1},p_{j+1}]}\Big)^2. \tag{3.13}$$

In a similar way, for each p_j in $\mathcal{S}^r$, we can also find the estimate (3.13). In order to estimate the last term in (3.11), let us introduce the notation

$$\mathcal{S}^{*l} := \big\{p_j \in \mathcal{S}^* \,:\, [u](p_{j+1}) = 0\big\}, \qquad \mathcal{S}^{*r} := \big\{p_j \in \mathcal{S}^* \,:\, [u](p_{j-1}) = 0\big\}. \tag{3.14}$$

We note that for each $p_j \in \mathcal{S}^{*l}$, $[u] \neq 0$ on $[p_j, w]$ and $[u] = 0$ on $(w, p_{j+2}]$. In addition, for each $p_j \in \mathcal{S}^{*r}$, $[u] \neq 0$ on $[w, p_j]$ and $[u] = 0$ on $[p_{j-2}, w)$. The regularity assumption on u yields $[u] \in H^{1+\nu}(\Gamma_3)$, and following [HW05a], for each point $p_j \in \mathcal{S}^{*l}$,

$$\Big([u](p_j)\Big)^2 \leq Ch^{1+2\nu}|[u]|^2_{1+\nu,[p_j,\,p_{j+2}]},$$

and for each point $p_j \in \mathcal{S}^{*r}$,

$$\Big([u](p_j)\Big)^2 \leq Ch^{1+2\nu}\,|[u]|^2_{1+\nu,[p_{j-2},\,p_j]}.$$

Using these last estimates for each $p_j \in \mathcal{S}^*$ and (3.13) for each $p_j \in \mathcal{S}^r \cup \mathcal{S}^l$, by summing and using a trace theorem we get

$$\|I_h[u] - \tilde{I}_h[u]\|_{\frac{1}{2},\Gamma_3} \leq C\,h^{\frac{1}{2}+\nu} \sum_{k=m,s} |u^k|_{\frac{3}{2}+\nu,\Omega^k}. \tag{3.15}$$

In the final step, we show that

$$\langle \lambda_h - \lambda, \tilde{I}_h[u]\rangle_{\Gamma_3} \leq 0. \tag{3.16}$$

First, we can find a constant $\delta > 0$ such that

$$\operatorname{sgn}[u] = \operatorname{sgn}\Big([u] - \delta(\tilde{I}_h[u])\Big) \quad \text{on} \quad \Gamma_3.$$

Using (3.8) we can write, on Γ_3,

$$|[u]| = |\delta(\tilde{I}_h[u])| + |[u] - \delta(\tilde{I}_h[u])|.$$

Taking into account Lemma 3.1, we get

$$\langle \lambda, [u]\rangle_{\Gamma_3} = \int_{\Gamma_3} g\,|\delta(\tilde{I}_h[u])|\,ds + \int_{\Gamma_3} g\,|[u] - \delta(\tilde{I}_h[u])|\,ds. \tag{3.17}$$

On the other hand, we have

$$\langle \lambda, [u]\rangle_{\Gamma_3} = \langle \lambda, \delta(\tilde{I}_h[u])\rangle_{\Gamma_3} + \langle \lambda, [u] - \delta(\tilde{I}_h[u])\rangle_{\Gamma_3}, \tag{3.18}$$

and due to the definition of Λ, we obtain

$$\langle \lambda, \delta(\tilde{I}_h[u])\rangle_{\Gamma_3} \leq \int_{\Gamma_3} g\,|\delta(\tilde{I}_h[u])|\,ds, \tag{3.19}$$

$$\langle \lambda, [u] - \delta(\tilde{I}_h[u])\rangle_{\Gamma_3} \leq \int_{\Gamma_3} g\,|[u] - \delta(\tilde{I}_h[u])|\,ds. \tag{3.20}$$

Using (3.17)–(3.20), we deduce that in (3.19) and (3.20) we can write identities. Since $\delta > 0$ we get

$$\langle \lambda, \tilde{I}_h[u]\rangle_{\Gamma_3} = \int_{\Gamma_3} g\,|\tilde{I}_h[u]|\,ds. \tag{3.21}$$

Now, let us write λ_h as a linear combination of the dual basis functions ψ_p and $\tilde{I}_h[u]$ as a linear combination of the standard basis functions ϕ_p; that is,

$$\lambda_h = \sum_{p\in\mathcal{S}} \gamma_p \psi_p, \quad \tilde{I}_h[u] = \sum_{p\in\mathcal{S}} \alpha_p \phi_p, \text{ where } \alpha_p = \tilde{I}_h[u](p).$$

Keeping in mind (3.1) and (3.21), we obtain

$$\langle \lambda_h - \lambda, \tilde{I}_h[u]\rangle_{\Gamma_3} = \int_{\Gamma_3} \left(\sum_{p\in(\mathcal{S}\setminus\mathcal{S}^*)} \gamma_p\alpha_p\phi_p - g\Big| \sum_{p\in(\mathcal{S}\setminus\mathcal{S}^*)} \alpha_p\phi_p\Big| \right) ds. \tag{3.22}$$

If we consider the subsets of Γ_3 defined by

$$\Gamma_3^+ := \Big\{ \boldsymbol{x} \in \Gamma_3 \,:\, [u](\boldsymbol{x}) > 0 \Big\} \quad \text{and} \quad \Gamma_3^- := \Big\{ \boldsymbol{x} \in \Gamma_3 \,:\, [u](\boldsymbol{x}) < 0 \Big\},$$

then, taking into account (3.8), we deduce that

$$\begin{aligned} &\tilde{I}_h[u](p) > 0, \qquad p \in \Gamma_3^+ \cap (\mathcal{S}\setminus\mathcal{S}^*), \\ &\tilde{I}_h[u](p) < 0, \qquad p \in \Gamma_3^- \cap (\mathcal{S}\setminus\mathcal{S}^*), \\ &\operatorname{supp} \tilde{I}_h[u] \subset \operatorname{supp}[u]. \end{aligned} \tag{3.23}$$

From this, using (3.22), we can write

$$\langle \lambda_h - \lambda, \tilde{I}_h[u]\rangle_{\Gamma_3} = \int_{\Gamma_3^+} \sum_{p\in(\mathcal{S}\setminus\mathcal{S}^*)} (\gamma_p - g)\alpha_p\phi_p \, ds + \int_{\Gamma_3^-} \sum_{p\in(\mathcal{S}\setminus\mathcal{S}^*)} (\gamma_p + g)\alpha_p\phi_p \, ds.$$

Keeping in mind (3.4) and (3.23), we get (3.16); i.e., the last term in the right side of the inequality (3.9) is negative. Taking into account (3.9)–(3.16) we conclude the proof of Lemma 3.3. □

Based on the results obtained in Lemmas 3.2 and 3.3 and using the well-known approximation properties for the spaces V_h and M_h, by applying Young's inequality, the following theorem holds.

THEOREM 3.4. [illegible] $(u,\lambda) \in V\times\Lambda$ [illegible] 2.2 [illegible] $(u_h,\lambda_h) \in V_h \times \Lambda_h$ [illegible] 3.1 [illegible] 3.1 [illegible] $u^k \in H^{\frac{3}{2}+\nu}(\Omega^k)$ $0 < \nu \le \frac{1}{2}$ $k = m, s,$ [illegible]

$$\|u - u_h\|_V + \|\lambda - \lambda_h\|_M \le C h^{\frac{1}{2}+\nu} \sum_{k=m,s} |u^k|_{\frac{3}{2}+\nu,\Omega^k}$$

[illegible] C [illegible] $h < h_0$.

4. Inexact primal-dual active set strategy. In this section, we present our algorithm to solve the discrete nonlinear Problem 3.1. We use an inexact primal-dual active set strategy. Primal-dual active set strategies for problems with friction were also considered in [Sta04]. In contrast to [Sta04], we do not use a penalty parameter and use a different nonlinear complementarity function. In [Sta04] the method can be interpreted as a semismooth Newton method. The nonlinear complementarity function used in the present approach can only be interpreted as a semismooth quasi-Newton method. Let $u_h \in V_h$ and $\lambda_h \in \Lambda_h$ be the solution of the discrete Problem

3.1. For the discrete solution (u_h, λ_h) of Problem 3.1, we get due to $\lambda_h \in \Lambda_h$ and from the definition (3.3) of the space Λ_h the condition

$$|\lambda_{p,s}| \leq g_p := \int_{\Gamma_3} g\phi_p \, ds, \qquad p \in \mathcal{S}, \tag{4.1}$$

where the scaled value $\lambda_{p,s}$ of λ_p is given by $\lambda_{p,s} := \lambda_p D[p,p]$. In terms of Lemma 3.1, the inequality condition of Problem 3.1 results for $g > 0$ in the algebraic system

$$\lambda_{p,s}\hat{u}_p = g_p|\hat{u}_p|, \qquad p \in \mathcal{S}. \tag{4.2}$$

We decompose $\mathcal{S}$ into two disjoint sets $\mathcal{A}$ and $\mathcal{I}$ such that

$$|\lambda_{p,s}| = g_p \ \text{ for } \ p \in \mathcal{A}, \qquad \hat{u}_p = 0 \ \text{ for } \ p \in \mathcal{I}, \tag{4.3}$$

and we refer to $\mathcal{A}$ and $\mathcal{I}$ as active and inactive sets, respectively. We observe that the nonlinear constraints (4.1) and (4.2) are the discrete constraints of (2.14). The constraints (4.1) and (4.2) can at each point with $\lambda_p \neq 0$ equivalently be written as

$$|\lambda_{p,s}| \leq g_p, \qquad \big(\lambda_p\hat{u}_p\big)\big(|\lambda_{p,s}| - g_p\big) = 0, \qquad \lambda_p\hat{u}_p \geq 0, \qquad p \in \mathcal{S}. \tag{4.4}$$

We introduce a nonlinear complementarity function $C(\hat{u}_p,\, \lambda_p)$ defined by

$$C(\hat{u}_p,\, \lambda_p) := \hat{u}_p\lambda_p - \max\big\{0,\, \hat{u}_p\lambda_p + c\,(|\lambda_{p,s}| - g_p)\big\}, \qquad c > 0. \tag{4.5}$$

The equivalence between the constraints (4.4) to the condition $C(\hat{u}_p,\, \lambda_p) = 0$ can be easily shown by a straightforward computation. We remark that in the nonlinear complementarity function we use the nodal value λ_p and the scaled nodal value $\lambda_{p,s}$. To guarantee equivalence between $C(\hat{u}_p,\, \lambda_p) = 0$, $p \in \mathcal{S}$, to (4.1) and (4.2), our algorithm has to make sure that if $C(\hat{u}_p,\, \lambda_p) = 0$ and $\lambda_p = 0$ we also have $\hat{u}_p = 0$. This point will be discussed after introducing the algorithm. To determine the sets $\mathcal{A}$ and $\mathcal{I}$ we use an iterative scheme based on the nonlinear complementarity function (4.5). Let k be the corresponding iteration index. The sign of $\lambda^k_{p,s}$ for $p \in \mathcal{A}_k$ is defined by the previous step. With the decomposition of the vertices introduced in section 3, we set the solution vector $u_h = (u_\mathcal{N},\, u_\mathcal{M},\, u_\mathcal{S})^\top$ and for the Lagrange multiplier we set $\lambda_h = \lambda_\mathcal{S}$. For the first line of Problem 3.1, the algebraic system in the standard basis $\boldsymbol{\phi}$ reads $A_h u_h + B_h\lambda_h = f_h$ with $B = (0,\, -M^\top,\, D)^\top$. The transformation of this algebraic system to the constrained basis $\hat{\boldsymbol{\phi}}$, introduced in (3.2), leads to the system $\hat{A}_h\hat{u}_h + \hat{B}_h\lambda_h = \hat{f}_h$, where we have the relations $\hat{A}_h = QA_hQ^\top$ and $\hat{f}_h = Qf_h$. The coupling matrix $\hat{B}_h$ in the constrained basis $\hat{\boldsymbol{\phi}}$ has the form $\hat{B}_h = (0,\, 0,\, D)^\top$. Combining this system with (4.3) and eliminating the Lagrange multiplier leads to

$$\begin{pmatrix} \hat{A}_{\mathcal{N}\mathcal{N}} & \hat{A}_{\mathcal{N}\mathcal{M}} & \hat{A}_{\mathcal{N}\mathcal{A}} & \hat{A}_{\mathcal{N}\mathcal{I}} \\ \hat{A}_{\mathcal{M}\mathcal{N}} & \hat{A}_{\mathcal{M}\mathcal{M}} & \hat{A}_{\mathcal{M}\mathcal{A}} & \hat{A}_{\mathcal{M}\mathcal{I}} \\ \hat{A}_{\mathcal{A}\mathcal{N}} & \hat{A}_{\mathcal{A}\mathcal{M}} & \hat{A}_{\mathcal{A}\mathcal{A}} & \hat{A}_{\mathcal{A}\mathcal{I}} \\ 0 & 0 & 0 & \mathrm{Id}_{\mathcal{I}\mathcal{I}} \end{pmatrix} \begin{pmatrix} \hat{u}_\mathcal{N} \\ \hat{u}_\mathcal{M} \\ \hat{u}_\mathcal{A} \\ \hat{u}_\mathcal{I} \end{pmatrix} = \begin{pmatrix} \hat{f}_\mathcal{N} \\ \hat{f}_\mathcal{M} \\ \hat{f}_\mathcal{A} + g_\mathcal{A} \\ 0 \end{pmatrix}, \tag{4.6}$$

where $\hat{A}_{k,l}$, $k,l \in \{\mathcal{N}, \mathcal{M}, \mathcal{A}, \mathcal{I}\}$, are the block stiffness matrices of $\hat{A}_h$ associated with the corresponding basis functions. The entries of the vectors $g_\mathcal{A}$ are the values $\pm g_p$ with $p \in \mathcal{A}$. We remark that the sign of the entry g_p of $g_\mathcal{A}$ at the point $p \in \mathcal{A}$ will be specified by the sign of λ_p in the previous iteration step. The Lagrange multiplier can be computed by the residual, i.e.,

$$\lambda_h = D^{-1}\big(\hat{f}_\mathcal{S} - \hat{A}_{\mathcal{S}\mathcal{N}}\hat{u}_\mathcal{N} - \hat{A}_{\mathcal{S}\mathcal{M}}\hat{u}_\mathcal{M} - \hat{A}_{\mathcal{S}\mathcal{S}}\hat{u}_\mathcal{S}\big). \tag{4.7}$$

To solve this linear problem, we use an optimal multigrid method. We use a $\mathcal{W}$-cycle with symmetric Gauß–Seidel iteration as smoother. We apply three pre-smoothing and three post-smoothing steps. Due to the use of a multigrid method as an iterative solver, we can formulate the inexact primal-dual active set algorithm. Based on the condition $C(\hat{u}_p, \lambda_p) = 0$, we introduce the primal-dual active set strategy as an iterative scheme. We note that primal-dual active set methods in combination with exact solvers can be analyzed as a Newton method; see, e.g., [HIK03, Sta04]. In combination with a multigrid method it can be interpreted as a nonlinear multigrid method.

ALGORITHM 1: Inexact primal-dual active set strategy

(0) Set $k = 1$, choose $c > 0$ and $m \in \mathbb{N}$.
Set $\mathcal{A}_1 = \emptyset$ and $\mathcal{I}_1 = \mathcal{S}$.
Initialize $\hat{u}_h^{1,0}$ as an initial solution for the multigrid method.

(1) For $i = 1, \ldots, m$, compute

$$\hat{u}_h^{k,i} = MG(\hat{u}_h^{k,i-1}, \mathcal{A}_k, \mathcal{I}_k).$$

(2) If $\|\hat{u}_h^{k,0} - \hat{u}_h^{k,m}\| / \|\hat{u}_h^{k,m}\|$ small enough, then stop.

(3) Set $\mathcal{A}_{k+1}$ and $\mathcal{I}_{k+1}$ to

$$\begin{aligned} \mathcal{A}_{k+1} &:= \left\{ p \in \mathcal{S} \,:\, \hat{u}_p^{k,m}\lambda_p^{k,m} + c(|\lambda_{p,s}^{k,m}| - g_p) > 0 \right\}, \\ \mathcal{I}_{k+1} &:= \left\{ p \in \mathcal{S} \,:\, \hat{u}_p^{k,m}\lambda_p^{k,m} + c(|\lambda_{p,s}^{k,m}| - g_p) \leq 0 \right\}. \end{aligned} \tag{4.8}$$

(4) Set $\hat{u}_h^{k+1,0} = \hat{u}_h^{k,m}$, set

$$(g_{\mathcal{A}})_p = \operatorname{sign}(\lambda_p^{k,m}) g_p \quad \text{for} \quad p \in \mathcal{A}_{k+1},$$

set $k = k + 1$ and go to step (1).

In this algorithm we denote by $\hat{u}_h^{k,i} = MG(\hat{u}_h^{k,i-1}, \mathcal{A}_k, \mathcal{I}_k)$ the iterate after one multigrid step for the linear system (4.6) with $\mathcal{A} = \mathcal{A}_k$ and $\mathcal{I} = \mathcal{I}_k$. The values $\lambda_p^{k,m}$ are computed by (4.7). We remark that for $m = \infty$, we solve the linear system (4.6) exactly, and we have the case of the exact primal-dual active set strategy. To motivate the choice of the active and inactive sets as presented in (4.8), we refer to Table 4.1. This table contains for any primal-dual pair $(\hat{u}_h^k, \lambda_h^k)$ satisfying $\hat{u}_p^k = 0$ for $p \in \mathcal{I}_k$ and $|\lambda_{p,s}^k| = g_p$ for $p \in \mathcal{A}_k$ the choice of the active and inactive sets $\mathcal{A}_{k+1}$ and $\mathcal{I}_{k+1}$. We point out that for each node $p \in \mathcal{A}_{k+1}$ we have $\lambda_p^{k,m} \neq 0$. Thus the vector $g_{\mathcal{A}}$ in (4.6) is always well defined. The choice of $\mathcal{I}_{k+1}$ guarantees that from $\lambda_p^{k,m} = 0$, it follows that $\hat{u}_p^{k+1,m} = 0$.

TABLE 4.1
Choice for the active set $\mathcal{A}_{k+1}$ and the inactive set $\mathcal{I}_{k+1}$ for a primal-dual pair $(\hat{u}_h^k, \lambda_h^k)$ satisfying $\hat{u}_p^k = 0$ for $p \in \mathcal{I}_k$ and $|\lambda_{p,s}^k| = g_p$ for $p \in \mathcal{A}_k$.

		$p \in$	$\hat{u}_p^k\lambda_p^k + c(\lvert\lambda_{p,s}^k\rvert - g_p)$	choice
$\hat{u}_p^k = 0$	$\lvert\lambda_{p,s}^k\rvert \leq g_p$	$\mathcal{I}_k$	≤ 0	$\mathcal{I}_{k+1}$
	$\lvert\lambda_{p,s}^k\rvert > g_p$	$\mathcal{I}_k$	> 0	$\mathcal{A}_{k+1}$
$\lvert\lambda_{p,s}^k\rvert = g_p$	$\hat{u}_p^k\lambda_p^k > 0$	$\mathcal{A}_k$	> 0	$\mathcal{A}_{k+1}$
	$\hat{u}_p^k\lambda_p^k \leq 0$	$\mathcal{A}_k$	$\leqq 0$	$\mathcal{I}_{k+1}$

We mention that the value of the positive constant c has no influence on the choice of the active and inactive sets $\mathcal{A}$ and $\mathcal{I}$ when we solve the linear system exactly. It only influences the choice in the inexact approach. Our algorithm guarantees that for an inadmissible Lagrange multiplier $\lambda_p^{k,m}$ the sign is preserved in the next step, where the node p is active.

5. Numerical examples. In this last section, we confirm our theoretical results for the discretization error and show the performance of our inexact primal-dual active set Algorithm 1. The implementation of this algorithm is based on the finite element toolbox UG; see [BBJ+97]. We use the material constants for granite, so that Young's modulus $E = 106$ and Poisson's ratio $\nu = 0.25$. These are related to the Lamé's parameters λ and μ by $\lambda = \frac{E\nu}{(1+\nu)(1-2\nu)}$ and $\mu = \frac{E}{2(1+\nu)}$. In all examples we assume conditions of plane strain. We focus on the discretization errors of the solution u in the L^2- and the H^1-norm. The error of the Lagrange multiplier is considered in a weighted L^2-norm $\|\cdot\|_{-\frac{1}{2},h,\Gamma_3}$ given by

$$\|\lambda\|^2_{-\frac{1}{2},h,\Gamma_3} := \sum_{e\in\Gamma_3^s} h_e \|\lambda\|^2_{0,e},$$

where we denote by e the edges of the discretization of Γ_3^s and by h_e the length of the edge e. We remark that using an inverse estimate it is also possible to establish a priori error estimates for the Lagrange multiplier in the weighted L^2-norm. Since there is in general no analytical solution available, we use for computing the discretization errors a reference solution u_{ref} and λ_{ref} on a fine mesh satisfying $h_{\text{ref}} \le 1/4\, h$. The use of $h_{\text{ref}} = 1/2\, h$ as reference mesh size does not yield reliable values for the discretization errors.

5.1. First example. In this section, we consider the example shown in Figure 5.1(a). We set the lower rectangle $\Omega^m = [-1, 1] \times [0, 1]$ and the upper as $\Omega^s = [-1, 1] \times [1, 2]$. On Γ_1^m, being the bottom of the lower rectangle Ω^m, we set the Dirichlet values equal to $u^m = 0$. We assign at the top boundary of the upper body Ω^s given Dirichlet values $u^s = 0.22\exp(-60x_1^2)$. On all the remaining boundary segments, we set homogeneous Neumann boundary conditions. For the friction bound we use $g = 0.6$. The contour lines of the numerical solution u_h are presented in Figure 5.1(b), while Figure 5.1(c) shows the Lagrange multiplier λ_h and the jump u_h amplified to the factor 150 at the interface Γ_3. The discretization errors and the convergence rates are presented in Table 5.1. Here we used the finite element solution on level 8 as reference solution u_{ref}. The grid on level 0 is shown in Figure 5.1(a). On

level 8, we have 525 825 nodes on Ω^s and 394 497 on Ω^m. The convergence rates in the L^2-norm are asymptotically 2.0 and, in the H^1-norm, we get 1.0. As also observed in the linear case, we get better convergence rates for the Lagrange multiplier. The best approximation error in the weighted $L^2(\Gamma_3)$-norm is of order $h^{1.5}$.

5.2. Second example. Now we consider the problem depicted in Figure 5.2(a). Here the interface is a curved one. By means of this example, we illustrate the performance and flexibility of our algorithm. To fix the geometry, we set the three points P_1, P_2 and P_3 equal to $P_1 = (0, 1.5)$, $P_2 = (-1, 0)$ and $P_3 = (1, 0)$. The radius r of the upper half disc is set to be $r = 1$, and for the angle ϕ we choose $\phi = \pi/4$. The lower body plays the role of the slave side Ω_s, and the upper one the role of the master side Ω^m. We fix the domain at the bottom of the master side Ω^m. At the top boundary of the upper body Ω^s, we set the Dirichlet value to $u^s = 0.055x_1$. As done in the first example, we set the friction bound equal to $g = 0.6$.

Figure 5.2(c) shows the contour lines of the solution. Figure 5.3 shows the Lagrange multiplier λ_h, the jump $[u_h]$ amplified to the factor 50, and the solution of the master and slave side u_h^m, u_h^s on the interface Γ_3. The discretization errors and the corresponding convergence rates are listed in Table 5.2. Again we use as reference solution the solution on level 8. The grid on level 1 is presented in Figure 5.2(b).

To illustrate the performance of the inexact primal-dual active set Algorithm 1, we use as multigrid solver for the linear problems a $\mathcal{W}$-cycle with 3 pre-smoothing and post-smoothing steps of the symmetric Gauß–Seidel iteration. For the constant c in Algorithm 1, we use $c = 0.01$. We observe that the value of c has to be small enough to get convergence of the active sets. This value depends on the relation between the stresses λ_p and the displacements $\hat{u}_p$ and therefore on the material data. On each level, we start the multigrid iteration with $\hat{u}_h^{1,0} = 0$. We compare the inexact approach ($m = 1$), where we update the active set $\mathcal{A}$ after each multigrid step, with the exact approach ($m = \infty$), where we solve for each choice of the set $\mathcal{A}$ the resulting

linear system. For each of these two approaches, we compare the case where we start on each level from $\mathcal{A}_1 = \emptyset$ to the nested approach. Here we inherit the active set $\mathcal{A}$ from level $l-1$ to l and use the results as $\mathcal{A}_1$.

For the exact strategy, we denote by K_l the step of the active set iteration on level l in which the correct active sets are found. For the inexact approach, M_l denotes the number of the multigrid iterations after which the correct active sets are found and kept. Table 5.3 shows K_l and M_l for the two choices of $\mathcal{A}_1$. Here we denote by $|\mathcal{A}_k|$ the number of active nodes in the k-th. step. For the case $\mathcal{A}_1 = \emptyset$, we observe that almost on each level $K_l = M_l$. As a result, there is no need to solve the resulting linear system exactly. Furthermore we remark that the required number of steps depends linearly on the level. For the nested approach, we observe $K_l \leq M_l$ and the number of necessary steps is bounded independently of the refinement level. For the exact strategy, we get $K_l \leq 2$ and for the inexact strategy $M_l \leq 4$. Although $M_l \geq K_l$, the inexact strategy is much more efficient because each step requires only one multigrid iteration.

To compare the computational cost to solve the nonlinear problem for the four cases we consider the necessary numbers of multigrid iterations. These numbers are shown in Table 5.4. The last column contains the necessary number of multigrid iterations to solve the nonlinear problem with the exact active and inactive sets $\mathcal{A}$ and $\mathcal{I}$ given. Then the nonlinear problem reduces to a linear one. It turns out that the number of necessary multigrid iterations for the inexact approach with the nested strategy is almost the same as that for the linear problem. So, the additional effort solving the nonlinear problem entailed in is negligible. For the exact approach starting

6	42	11	6	6	6
7	49	12	12	7	7
8	54	12	12	7	7

with $\mathcal{A}_1 = \emptyset$ on each level, the number depends linearly on the level. We find that the inexact strategy is cheaper compared to the exact one. In combination with the nested approach, the inexact strategy yields a very efficient iterative solver for our nonlinear problem.

Finally, we mention that our inexact primal-dual active set Algorithm 1 can also handle nonconstant friction bounds g. If we use $g = (x_1^2 - 1) + 1.2$ instead of $g = 0.6$ in the second example, we find the results shown in Figure 5.4.

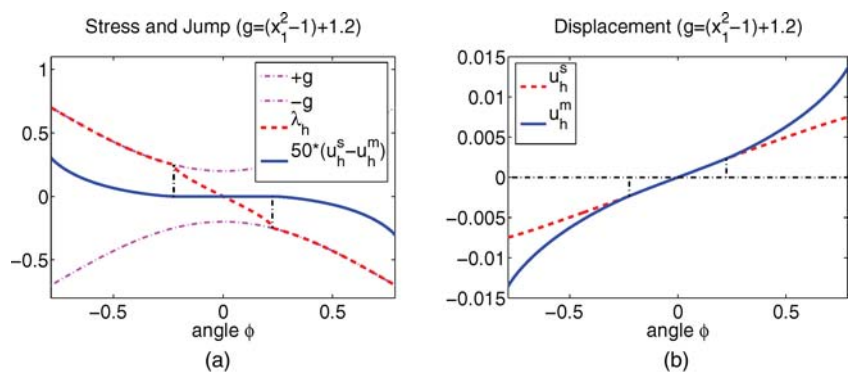

FIG. 5.4. (a) *Lagrange multiplier λ_h and amplified jump $u_h^s - u_h^m$ for $g = (x_1^2 - 1) + 1.2$;* (b) *displacement u_h^s on slave side and u_h^m on master side for $g = (x_1^2 - 1) + 1.2$.*

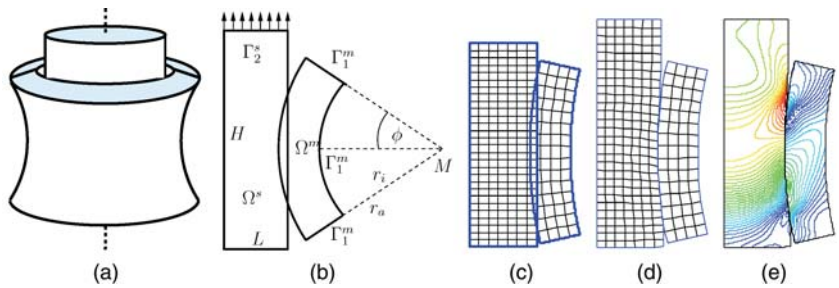

FIG. 6.1. (a) *Problem definition in three dimensions;* (b) *problem definition in two dimensions;* (c) *initial grid on level* 0*;* (d) *distorted grid on level* 0*;* (e) *effective von Mises stress on level* 2.

6. Generalization of Algorithm 1 to Coulomb friction. In this last section, we generalize our algorithm to a multibody contact problem with Coulomb friction. In this case, we replace the constant friction bound g in (2.9) by $\mathfrak{F}|\boldsymbol{\sigma}_n|$, where $\boldsymbol{\sigma}_n := (\boldsymbol{\sigma}\boldsymbol{n}) \cdot \boldsymbol{n}$ and $\mathfrak{F}$ denotes the friction coefficient. The contact condition in the normal direction is that of nonpenetration condition of the two bodies. More details on nonlinear contact conditions can be found, e.g., in [KO88].

Now we have to find two active sets. The active set of nodes on the contact interface are in contact in the normal direction with the second body and the active set for the Lagrange multiplier in the tangential direction. For the first one we use the algorithm given in [HW05b]. For the second one we use Algorithm 1. We remark that here we have to update the values for the friction bound g_p after each step. Combining the inexact versions of these two algorithms leads to an efficient iterative solver for the complex nonlinear problem of Coulomb friction. We mention that after each multigrid step we update both of the two active sets and the solution dependent friction bound.

We consider an example in the three-dimensional case. The geometry is shown in Figure 6.1(a). Due to axisymmetry the problem can be reduced to a two-dimensional setting. The resulting geometry can be seen in Figure 6.1(a). For the geometry we choose $L = 5$, $H = 15$, $r_i = 27$, $r_a = 30$, $M = (34.5, 7.0)^\top$ and $\phi = 13$. For the softer inner body Ω^s, playing the role of the slave side, we use for the material data $\lambda^s = 57.6923$ and $\mu^s = 38.4615$. For the outer body Ω^m, playing the role of the master side, we set $\lambda^m = 576.923$ and $\mu^m = 384.615$. At the top of the inner cylinder, we apply Neumann data $f_2^s = 17.0$. Due to the axisymmetry, we have on the left side of Ω_s, where $r = 0$ holds, homogeneous Dirichlet data in the radial direction. We fix Ω^m at the three segments Γ_1^m, as shown in Figure 6.1(b). For the friction coefficient $\mathfrak{F}$ we choose $\mathfrak{F} = 0.7$. We remark that the two bodies penetrate in the reference configuration.

For the Lamé operator in cylindrical coordinates, we refer to [JL01]. We denote by u_r the displacement in the radial direction, by u_z the displacement in the axial direction and by u_θ the displacement in circumferential direction. Since axisymmetric conditions we have $u_\theta = 0$ and therefore we get the relations $\boldsymbol{\varepsilon}_{r\theta} = \boldsymbol{\varepsilon}_{\theta r} = \boldsymbol{\varepsilon}_{z\theta} = \boldsymbol{\varepsilon}_{\theta z} = 0$. For the other entries of the strain tensor $\boldsymbol{\varepsilon}$ we get

$$\boldsymbol{\varepsilon}_{rr} = \frac{\partial u_r}{\partial r}, \quad \boldsymbol{\varepsilon}_{zz} = \frac{\partial u_z}{\partial z}, \quad \boldsymbol{\varepsilon}_{\theta\theta} = \frac{1}{r}\left(\frac{\partial u_\theta}{\partial \theta} + u_r\right), \quad \boldsymbol{\varepsilon}_{rz} = \boldsymbol{\varepsilon}_{zr} = \frac{1}{2}\left(\frac{\partial u_r}{\partial z} + \frac{\partial u_z}{\partial r}\right).$$

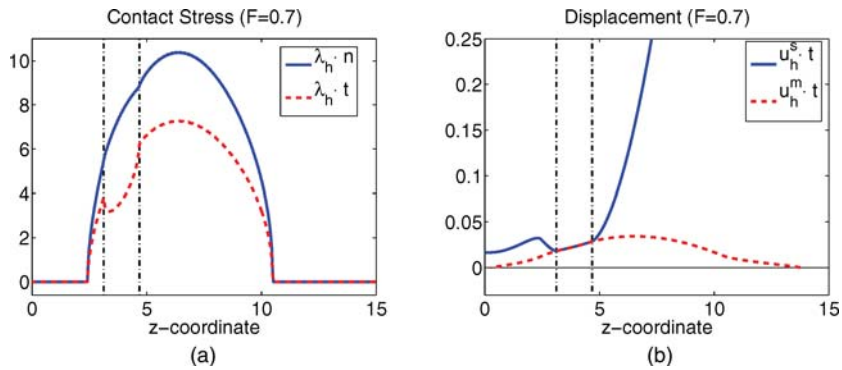

FIG. 6.2. (a) *Normal part* $\lambda_h \cdot n$ *and tangential part* $\lambda_h \cdot t$ *of the Lagrange multiplier* λ_h*;* (b) *tangential part* $u_h^s \cdot t$ *of the displacement on the slave side and tangential part* $u_h^m \cdot t$ *of the displacement on the master side.*

The stress strain relation is now

$$\begin{pmatrix} \boldsymbol{\sigma}_{rr} \\ \boldsymbol{\sigma}_{zz} \\ \boldsymbol{\sigma}_{\theta\theta} \\ \boldsymbol{\sigma}_{rz} \end{pmatrix} = \begin{pmatrix} \lambda + 2\mu & \lambda & \lambda & 0 \\ \lambda & \lambda + 2\mu & \lambda & 0 \\ \lambda & \lambda & \lambda + 2\mu & 0 \\ 0 & 0 & 0 & \mu \end{pmatrix} \begin{pmatrix} \boldsymbol{\varepsilon}_{rr} \\ \boldsymbol{\varepsilon}_{zz} \\ \boldsymbol{\varepsilon}_{\theta\theta} \\ 2\boldsymbol{\varepsilon}_{rz} \end{pmatrix}.$$

Figure 6.2 shows the normal and the tangential parts of the discrete Lagrange multiplier on the contact interface. We remark that the two bodies are in contact where we have $\lambda_h \cdot n \neq 0$. In the tangential direction, we get two active zones where we have $|\lambda_h \cdot t| = \mathfrak{F}|\lambda_h \cdot n|$. Between these two sets the two bodies are glued together in the tangential direction, i.e., $(u_h^s - u_h^m) \cdot t = 0$. The tangential part of the displacements on the slave and the master side is shown in Figure 6.2(b).

ACCURATE EVALUATION OF EUROPEAN AND AMERICAN OPTIONS UNDER THE CGMY PROCESS*

ARIEL ALMENDRAL† AND CORNELIS W. OOSTERLEE†

Abstract. A finite-difference method for integro-differential equations arising from Lévy driven asset processes in finance is discussed. The equations are discretized in space by the collocation method and in time by an explicit backward differentiation formula. The discretization is shown to be second-order accurate for a relevant parameter range determining the degree of the singularity in the Lévy measure. The singularity is dealt with by means of an integration by parts technique. An application of the fast Fourier transform gives the overall amount of work $O(N_t N \log N)$, rendering the method fast.

Key words. partial integro-differential equations, collocation method, option pricing

1. Introduction.

In a seminal paper from 1973, Black and Scholes [8] derived a PDE for option prices, when asset prices behave according to the geometric Brownian motion. The pricing formulas obtained in that paper represented a major breakthrough in understanding financial derivatives, to such an extent that financial institutions and traders immediately adopted the new methodology. Later empirical studies revealed that the normality of the log-returns, as assumed by Black and Scholes, could not capture features like heavy tails and asymmetries observed in market-data log-return densities [12]. The Black–Scholes model assumes in addition constant problem parameters, interest rate, and volatility for the time until the option's expiration (also called maturity). This contradicts the existence of the so-called volatility smile: A numerical inversion of the Black–Scholes formula based on data from different strike prices and fixed maturity resembles a skew or a smile, implying nonconstant volatility. This inconsistency is said to be one of the causes for famous market crashes.

To explain these empirical observations, a number of alternate models have appeared in the financial literature: stochastic volatility [25, 28], deterministic local volatility [17, 20], jump-diffusion [29, 33], and infinite activity Lévy models [7, 15, 21]. Each of these models has its advantages and disadvantages. Jump-diffusion and infinite activity Lévy models are attractive since they can capture the jump patterns exhibited by some stocks and they are more realistic when pricing options close to maturity [18]. Processes with infinite activity, [illegible], represent a family that describes the high activity of the prices, while at the same time they reflect the empirical features desirable in a good model. The pricing equations are, however, numerically more challenging, and the market turns out to be incomplete in the sense that a strategy leading to an instantaneous risk-free portfolio does not exist in general [16, 34].

Due to the close link between the stochastic martingale approach and the PDE approach [24, 30] the field of computational finance has gained a tremendous impulse from well-established numerical techniques for PDEs. For an overview we refer the reader to the introductory books [26, 37]. The development of analogous reliable techniques under Lévy markets is a subject of present research [5, 6, 19] for jump-diffusions and for the infinite activity case [3, 4, 16, 27, 32]. In these papers the numerical solution of a partial integro-differential equation (PIDE) has been addressed as a tool to calculate option prices.

When valuing and risk managing exotic derivatives, practitioners demand fast and accurate prices and sensitivities. Aside from nonstandard exotic derivatives, plain vanilla options in many stock markets are actually of the American (i.e., early exercise) type, for which no analytic solutions exist. As any pricing and risk management system has to be able to calibrate to these plain vanilla options; it is of the utmost importance to be able to value these American options quickly and accurately. This paper deals with a fast, accurate evaluation of options when the underlying process is a Carr–Geman–Madan–Yor (CGMY) Lévy process of infinite activity and finite variation, considered in finance in [13]. In previous work [3, 4], we computed the integral term in the PIDE by the trapezoidal rule, a choice that produced a first-order accurate overall convergence. Our contribution here is to show that second-order convergence may be obtained for a large range of the problem parameters ($0 < \alpha < 1$ in (2) below).

The approach in this paper differs from existing methods in the literature. We use an integration by parts technique to rewrite the integro-differential operator in terms of Volterra operators with a weakly singular kernel. The vast classical numerical literature on this type of operator [10, 11, 31] proves very useful to set up a high-order discretization method. Here we focus on one particular method that has been thoroughly tested in [11], namely, the collocation method for Volterra equations. The integro-differential operator in this new setting is not in the standard form in the literature, so the techniques need to be adapted to this particular example. The computation of integrals is expensive, since the number of operations involved is in general of order $O(N^2)$. With the help of the fast Fourier transform (FFT) algorithm it is possible to speed up computations to gain an almost linear complexity ($O(N \log N)$), provided the grid employed is uniform. The method proposed allows the application of the FFT algorithm. In the context of weakly singular Volterra (integro-differential) equations, this has been implemented in [23].

The paper is organized as follows. Section 2 offers a brief introduction to financial derivatives under exponential Lévy models together with the integro-differential equations of interest. Section 3 contains the core of the paper: the transformation of the equation by integration by parts, the collocation method on the resulting weakly singular Volterra equation, and a time integration method. A series of numerical experiments is presented in section 4, confirming the second-order accuracy of the discretization. One of the advantages of the collocation method is that one can deal with complicated payoffs, e.g., for butterfly options, straddles, etc., without affecting the accuracy. The numerical experiments in section 4 will confirm this statement. Technical details regarding the discretization are placed in appendices. A stability analysis for a model problem is also given in an appendix.

2. The exponential Lévy model in finance. Let us briefly introduce the exponential Lévy model. By a Lévy process $\{L_t\}_{t\geq 0}$ we mean any process starting at the origin, with stationary, independent increments. We restrict ourselves to those

Lévy processes that can be expressed as

$$L_t = (r - q + \zeta)t + \sigma W_t + Z_t, \tag{1}$$

where $r \geq 0$ and $q \geq 0$ denote the risk-free interest rate and the continuous dividend paid by some asset S_t, respectively. The parameter σ denotes the volatility. This process has a drift term controlled by ζ, a Brownian component $\{W_t\}_{t\geq 0}$, and a pure-jump component $\{Z_t\}_{t\geq 0}$. We focus on the case where the Lévy measure associated to Z_t (see [16]) can be written as $d\nu(x) = k(x)dx$, where the weight $k(x)$ is defined as

$$k(x) = \begin{cases} C\dfrac{\exp(-G\,|x|)}{|x|^{1+\alpha}} & \text{if} \quad x < 0, \\ \\ C\dfrac{\exp(-M\,|x|)}{|x|^{1+\alpha}} & \text{if} \quad x > 0 \end{cases} \tag{2}$$

for constants $C > 0$, $G \geq 0$, $M \geq 0$, and $\alpha < 2$. The process $\{Z_t\}_{t\geq 0}$ is known in the literature as the CGMY process [13]; it generalizes a jump-diffusion model by Kou [29] ($\alpha = -1$) and the Variance Gamma (VG) process [15] ($\alpha = 0$). The CGMY process is in turn a particular case of the Kobol process studied in [9], where the constant C is allowed to take on different values on the positive and negative semiaxes. For convenience of notation, we have chosen parameter α instead of the Y in [13].

2.1. Option pricing under the CGMY process. Let a market consist of one risky asset $\{S_t\}_{t\geq 0}$ and a bank account $\{B_t\}_{t\geq 0}$. Assume that the asset process $\{S_t\}_{t\geq 0}$ evolves according to the geometric law

$$S_t = S_0 \exp(L_t), \tag{3}$$

where $\{L_t\}_{t\geq 0}$ is the Lévy process defined in (1), and the bank account follows the law $B_t = \exp(rt)$.

The standard tool to assign prices to options under Lévy processes consists in changing to a convenient probability measure and taking the expectation of the discounted prices. The new probability measure Q is known in the financial literature as the equivalent martingale measure (EMM). It has the same null sets as the market probability, and the discounted process $\{e^{-(r-q)t}S_t\}_{t\geq 0}$ becomes a martingale. The so-called EMM condition $E_Q[S_t] = S_0 e^{t(r-q)}$ together with the formula for the characteristic exponent of L_t [16],

$$E_Q[\exp(L_t)] = \exp\left\{t\left[(r - q + \zeta) + \sigma^2/2 + \int_{\mathbb{R}} (e^x - 1)k(x)dx)\right]\right\}, \tag{4}$$

implies the following "risk-neutral" form for ζ (denoted by ϖ):

$$\varpi + \sigma^2/2 + \int_{\mathbb{R}} (e^x - 1)k(x)dx = 0. \tag{5}$$

Techniques used in Appendix A produce the following expression for ϖ:

$$\varpi = -\frac{\sigma^2}{2} - C\Gamma(-\alpha)\left\{(M-1)^\alpha - M^\alpha + (G+1)^\alpha - G^\alpha\right\} \tag{6}$$

with $\Gamma(\cdot)$ the gamma function. Note that ζ controls the drift of the market process, whereas ϖ is a new parameter controlling the drift in the artificial world described by the new probability measure Q, under which options can be priced straightforwardly. The same notation is kept for the risk-neutral parameters G and M. The other parameters σ, C, and α remain unchanged when passing to the Q measure; see, e.g., [16]. M must be larger than one for ϖ to be well defined.

European vanilla options. Consider a European option on the asset $\{S_t\}_{t\geq 0}$, with maturity time T, and strike price K. Let $\hat{u}(s,t)$ denote its price, with t denoting the time to expiration. It is well known that $\hat{u}$ satisfies a PIDE; see, for example, [16]. In order to write a convenient expression for the PIDE, let $s = \exp(x)$ and consider the log-prices $u(x,t)$. Then in general u solves the Cauchy problem

$$\begin{cases} u_t - \mathcal{L}u = 0, \quad t \in (0,T], \quad x \in \mathbb{R}, \\ \\ u(x,0) = \psi(x), \quad x \in \mathbb{R}, \end{cases} \tag{7}$$

where $\mathcal{L}$ is an integro-differential operator of the form

$$\begin{aligned} \mathcal{L}\varphi := \frac{\sigma^2}{2}\varphi_{xx} + \left(r - q - \frac{\sigma^2}{2}\right)\varphi_x - r\varphi \\ + \int_{\mathbb{R}} \left[\varphi(x+y,t) - \varphi(x,t) - (e^y - 1)\varphi_x(x,t)\right] k(y)dy, \end{aligned} \tag{8}$$

and the so-called payoff function ψ defines the nature of the contract. For example, for a put option $\psi(x) = (K - e^x)^+$, meaning that the holder of the option is entitled to receive the payment $K - S_T$ if the asset value falls below the threshold K; otherwise the option expires worthless.

For the particular case under consideration, namely, $\alpha < 1$, the third term in the integral operator may be computed explicitly (cf. (5)), resulting in the expression

$$\mathcal{L}\varphi := \frac{\sigma^2}{2}\varphi_{xx} + (r - q + \varpi)\varphi_x - r\varphi + \int_{\mathbb{R}} \left[\varphi(x+y,t) - \varphi(x,t)\right] k(y)dy. \tag{9}$$

This operator reduces to the Black–Scholes operator if no jumps are present, i.e., $k \equiv 0$.

American vanilla options. Consider as a matter of example an American put option written on the underlying asset $\{S_t\}_{t\geq 0}$. It is also well known that its price may be found by solving the free-boundary problem [16]

$$\begin{cases} u_t - \mathcal{L}u = 0, \quad t > 0, \quad x > x_f(t), \\ \\ u(x,t) = K - e^x, \quad t > 0, \quad x \leq x_f(t), \\ \\ u(x,t) \geq (K - e^x)^+, \quad t > 0, \quad x \in \mathbb{R}, \\ \\ u_t - \mathcal{L}u \geq 0, \quad t > 0, \quad x \in \mathbb{R}, \\ \\ u(0,x) = (K - e^x)^+, \quad x \in \mathbb{R}, \end{cases} \tag{10}$$

where the operator $\mathcal{L}$ is defined in (8) and the free-boundary is given by

$$x_f(t) = \inf\left\{x \in \mathbb{R} \mid u(x,t) > (K - e^x)^+\right\}, \quad t \in (0,T]. \tag{11}$$

The set $\{x \in \mathbb{R} \mid x \leq x_f(t)\}$ represents the exercise region for the logarithmic prices. Hence, for asset prices $s \leq s_f(t) := \exp(x_f(t))$, the American put should be exercised.

For numerical purposes, a useful reformulation of (10) is the following linear complementarity problem (LCP):

$$\begin{cases} u_t - \mathcal{L}u \geq 0 & \text{in } [0,T] \times \mathbb{R}, \\ u \geq \psi & \text{in } [0,T] \times \mathbb{R}, \\ (u_t - \mathcal{L}u)\,(u - \psi) = 0 & \text{in } [0,T] \times \mathbb{R}, \\ u(x,0) = \psi(x). \end{cases} \tag{12}$$

This formulation does not make use of the free-boundary explicitly, and besides, it does not rely on the form of the continuation region. The free-boundary can be obtained in a postprocessing step by using the relation (11).

3. Discretization of the integral term.

3.1. Integral equation over the positive semiaxis. The core of the numerical method that we propose here lies on a proper discretization of integral expressions of the form

$$f(x) = \int_0^\infty (u(x+y) - u(x)) \frac{e^{-My}}{y^{1+\alpha}} dy \tag{13}$$

that appear in the definition of $\mathcal{L}$ in (9). For ease of notation we have omitted the time variable. We suppose that u is known and we would like to approximate $f(x)$. The reason for not solving with respect to u in the first place is that we will use an explicit time-stepping scheme for solving (7). In the applications, the function $u(x)$ can be continuous but need not be differentiable at certain points.

Integration by parts of (13) yields

$$f(x) = -[u(x+y) - u(x)]\hat{k}(y) \Big|_0^\infty + \int_0^\infty u_y(x+y)\hat{k}(y)dy, \tag{14}$$

where we have introduced the function

$$\hat{k}(w) := \int_w^\infty \frac{e^{-M\zeta}}{\zeta^{1+\alpha}} d\zeta, \qquad w > 0. \tag{15}$$

This new kernel may be written in terms of the upper incomplete gamma function $\Gamma(\cdot,\cdot)$; see (50) in Appendix A for a definition and also [1] for some properties. The following expression holds:

$$\hat{k}(w) = M^\alpha \Gamma(-\alpha, Mw). \tag{16}$$

Under rather general conditions on the function $u(x)$, the first term in (14) vanishes. A possible set of sufficient conditions is

- The function u satisfies the Lipschitz condition; i.e., there is a constant C_0 such that

$$|u(z_1) - u(z_2)| \leq C_0 \,|z_1 - z_2| \qquad \forall z_1, z_2 \in \mathbb{R}. \tag{17}$$

- There exist constants $C_1 \geq 0$ and $0 \leq C_2 < M$ such that

$$|u(z)| \leq C_1 e^{C_2 z}, \qquad z \to +\infty. \tag{18}$$

If these two conditions hold, it is not difficult to show that

$$\lim_{y\to 0}[u(x+y)-u(x)]\hat{k}(y) = \lim_{y\to\infty}[u(x+y)-u(x)]\hat{k}(y) = 0. \tag{19}$$

For commonly used functions in option pricing like $u(x) = (K - e^x)^+$ and $u(x) = (e^x - K)^+$, both conditions above hold.

Changing variable $z = x+y$, integral equation (14) reduces to a Volterra equation of the first kind:

$$f(x) = \int_x^\infty u_z(z)\hat{k}(z-x)dz. \tag{20}$$

This kind of equation has been intensively studied in the last century, both theoretically and numerically; see [10, 11, 31] and the references therein. In this paper we follow very closely the notation in [11].

3.1.1. Collocation method on positive semiaxis. The first observation concerns the order of the singularity of the kernel $\hat{k}$. It is not difficult to realize that $\hat{k}$ behaves like $y^{-\alpha}$, as $y \to 0$. Hence, the integral equation (20) classifies as a weakly singular Volterra equation.

Motivated by the above observations, let us introduce a notation for a new kernel $\widetilde{k}$ and the derivative v of u, i.e.,

$$\widetilde{k}(w) := w^\alpha \hat{k}(w), \qquad v := u_z. \tag{21}$$

From now on we focus on the discretization of the integral equation

$$f(x) = \int_x^\infty (z-x)^{-\alpha} v(z)\widetilde{k}(z-x)dz, \tag{22}$$

following [11] closely. In this form it resembles the well-studied Abel equation [31]. In the examples considered in this paper, the functions u have a rapidly decaying derivative at infinity. Thus, one may truncate this integral to a finite interval $x \in [a, b]$ while having control of the error. An analysis of the size of the truncation domain is given in section 3.1.3 and a numerical test is presented in section 3.1.4.

Let us consider the following (not necessarily uniform) spatial mesh

$$x_0 = a; \qquad x_{n+1} = x_n + h_n, \qquad n = 0, \ldots, N-1; \qquad x_N = b. \tag{23}$$

Equation (22) is discretized by the collocation method. A discretization with two collocation points for each mesh point is considered here. For a more general treatment we refer the reader to [11].

The first step is to choose two numbers c_1 and c_2 such that

$$0 \leq c_1 < c_2 < 1. \tag{24}$$

With these constants the collocation mesh is defined as follows (see Figure 1):

$$x_{n,j} = x_n + c_j h_n, \qquad n = 0, \ldots, N-1; \qquad j = 1, 2. \tag{25}$$

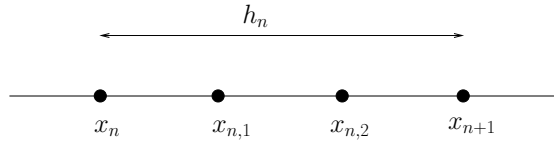

FIG. 1. *Collocation mesh and spatial mesh.*

The polynomial spline collocation method now consists, roughly speaking, in finding a polynomial spline $V(z)$, replacing the function $v(z)$ such that (22) holds exactly at each of the collocation points $x_{n,j}$. The technical details of the treatment of the Volterra equation when the variable of integration runs through the positive semiaxis are presented in Appendix B. For the negative semiaxis the discretization is very similar and is explained in Appendix C. Considering the collocation parameters $0 < c_1 < c_2 \leq 1$, the collocation mesh for the negative semiaxis is defined as in (23); however, these two meshes are typically different. This time $c_1 \neq 0$. In section 3.2 we couple both integrals with the use of a common spatial mesh.

3.1.2. Smoothing the kernel. A simple numerical experiment with (22) reveals that the order of the discretization is only $O(h)$ (cf. Table 1). At first glance it seems that the problem is caused by the nonsmooth payoff. However, the cause of this loss of accuracy is the lack of smoothness of the kernel $\widetilde{k}$. This can be easily remedied by a convenient rewriting of the integral equation. One possible remedy is based on an expansion of the kernel such that the nonsmooth component can be identified. We will add a subscript "+" to the kernel to indicate that we work with the positive of the Lévy measure. A first integration by parts yields

$$\hat{k}(x) = \int_x^\infty \frac{e^{-My}}{y^{1+\alpha}} dy = \frac{e^{-Mx}x^{-\alpha}}{\alpha} - \frac{M}{\alpha}\int_x^\infty e^{-My}y^{-\alpha}dy.$$

A second integration by parts for the integral on the right-hand side gives rise to the identity

$$\int_x^\infty \frac{e^{-My}}{y^{1+\alpha}} dy = \frac{e^{-Mx}x^{-\alpha}}{\alpha} + \frac{Me^{-Mx}x^{1-\alpha}}{\alpha(1-\alpha)} - \frac{M^2}{\alpha(1-\alpha)}\int_x^\infty e^{-My}y^{1-\alpha}dy.$$

So, if we define the constant

$$\theta_+ := \frac{M^2}{\alpha(1-\alpha)}\int_0^\infty e^{-My}y^{1-\alpha}dy,$$

the new kernel

$$k_+(x) := \widetilde{k}(x) + \theta_+ x^\alpha = \frac{e^{-Mx}}{\alpha} + \frac{Me^{-Mx}x}{\alpha(1-\alpha)} - \frac{M^2x^\alpha}{\alpha(1-\alpha)}\int_0^x e^{-My}y^{1-\alpha}dy$$

becomes a differentiable function, in contrast to the original kernel $\widetilde{k}(x)$ in (21) which is only continuous. Moreover, due to the second integration by parts, k_+ is even twice continuously differentiable. Indeed, differentiating twice the relevant term on the right-hand side and neglecting the smooth terms give

$$x^{\alpha-2}\int_0^x e^{-My}y^{1-\alpha}dy,$$

which is continuous, but not differentiable. A final observation is that θ_+ may be written in terms of the gamma function $\Gamma(\cdot)$; i.e.,

$$\theta_+ = \frac{M^\alpha\Gamma(2-\alpha)}{\alpha(1-\alpha)}. \tag{26}$$

The observations lead to the integral equation

$$f(x) = \int_x^\infty (z-x)^{-\alpha}v(z)k_+(z-x)dz - \theta_+\int_x^\infty v(z)dz. \tag{27}$$

Notice that (27) is merely a rewriting of (22), but the kernels present in (27) are smoother. One could continue integrating by parts and extract the smooth components of $\widetilde{k}$. For numerical efficiency this is however not advisable as each additional term means a new integral to be computed numerically, increasing therefore the complexity. In order to avoid truncation errors we treat both terms on the right-hand side in (27) numerically.

3.1.3. Analysis of the truncation error. We sketch an argument that provides an estimate for the truncation error. The details have been omitted for clarity.

It is known that the solution u of (7) admits the stochastic interpretation

$$u(x,t) = e^{-rt}E_Q[\psi(x+L_t)]. \tag{28}$$

Consider the case of a put option, i.e., $\psi(x) = (K-e^x)^+$. Denoting by $\hat{q}(y)$ the probability density function of the variable L_t, we may write

$$u(x,t) = e^{-rt}\int_{-\infty}^{\log K-x}(K-e^{x+y})\hat{q}(y)dy.$$

Differentiating this expression with respect to x yields

$$u_x(x,t) = -e^{-rt+x}\int_{-\infty}^{\log K-x}e^y\hat{q}(y)dy.$$

Since $e^y \le Ke^{-x}$ for $y \le \log(K)-x$, the following estimate holds:

$$|u_x(x,t)| \le Ke^{-rt}. \tag{29}$$

This is a global estimate. A more detailed analysis shows that the derivative of a put decays exponentially, giving a sharper estimate. For our purposes this bound is sufficient. An estimate for the truncation error may be obtained as follows:

$$\begin{aligned}\left|\int_{-\infty}^a u_z(z,t)\hat{k}_-(x-z)dz + \int_b^{+\infty}u_z(z,t)\hat{k}_+(z-x)dz\right| \\ \le Ke^{-rt}\left[\int_{-\infty}^a \hat{k}_-(x-z)dz + \int_b^{+\infty}\hat{k}_+(z-x)dz\right].\end{aligned} \tag{30}$$

Both integrals on the right-hand side have exponential decay as $a \to -\infty$ and $b \to +\infty$. Namely, from (15), a rough estimate is the following:

$$\hat{k}_+(w) \le Ce^{-Mw}. \tag{31}$$

Therefore, the second integral on the right-hand side may be bounded by

$$\frac{C^+}{M} e^{-M(b-x)}.$$

An analogous analysis shows that the first integral is controlled by

$$\frac{C^-}{G} e^{-G(x-a)}.$$

These estimates show that, away from the end points a and b, the error decreases exponentially. Close to the end points the exponential decay of the derivative u_x (for a put option) will play a role in reducing the error by truncation.

3.1.4. First numerical experiments. In this section we first show that the collocation method applied to (27) gives at least a quadratic discretization error. We choose the payoff function for a put option $u(x) = (1 - e^x)^+$ and compare it with the analytic formula for $f(x)$ derived in Appendix A (52). Moreover, we check that indeed the same method applied to (22) gives only a linear order, so that the smoothing of the integrand as explained in section 3.1.2 is necessary for second-order accuracy. The results are displayed in Table 1. The parameters used are $\alpha = 0.8$ and $M = 5$ and the mesh is uniform. The truncation of the domain is in accordance with the analysis in section 3.1.3. In particular, the computational domain in this example is the interval $[-5, 5]$. The truncation does not influence the accuracy negatively.

The same convergence results hold on a nonuniform grid, but we are then not able to apply the FFT algorithm (discussed in section 3.4 and in detail in [3]) to make computations fast. On the other hand, the discretization order depends on the choice of the collocation parameters c_1 and c_2, as Table 1 shows. We actually observe superconvergence at the collocation points with the Radau parameters $c_1 = 0$ and $c_2 = 2/3$. This is in accordance with the results from [11].

In order to obtain superconvergence on the negative semiaxis, the Radau points must be chosen as $c_1 = 1/3$ and $c_2 = 1$.

3.2. Assembling the PIDE. Recall that our main goal is to solve a PIDE of the form (7) with the operator $\mathcal{L}$ given by (9). The interesting case is when $\sigma = 0$, i.e., no smoothing takes place caused by a diffusion component. In case we deal with $\sigma > 0$, the ideas discussed in this paper still apply, but then special care of the diffusion needs

to be taken by means of an implicit-explicit scheme as in [3, 4, 16], where the diffusion part is taken implicitly and early exercise is dealt with by projection methods.

The considerations from previous sections lead us to consider the following rewriting of (7):

$$u_t + ru = C\mathcal{I}_+(u_z) + C\mathcal{I}_-(u_z) + \mu u_x, \tag{32}$$

with the constant (cf. (6))

$$\mu := r - q + \varpi, \tag{33}$$

and the operators

$$\mathcal{I}_+(u_z) := \int_x^{+\infty} (x-z)^{-\alpha} u_z(z) k_+(z-x)dz - \theta_+ \int_x^{+\infty} u_z(z)dz, \tag{34}$$

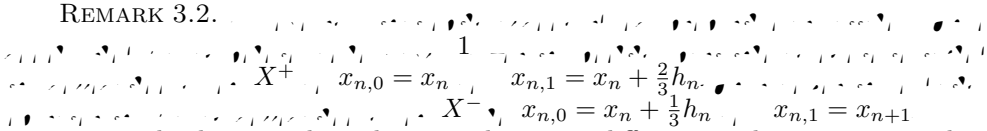
$$\mathcal{I}_-(u_z) := -\int_{-\infty}^{x} (x-z)^{-\alpha} u_z(z) k_-(z-x)dz + \theta_- \int_{-\infty}^{x} u_z(z)dz. \tag{35}$$

Note that these operators involve both the function u and its derivative $v = u_z$. To our knowledge, PIDEs like (32)–(35) have not been considered in the existing literature on Volterra equations.

If one applies a time integration procedure, one faces the problem of finding the numerical derivative of the unknown for a next time step, discussed in section 3.2.1. This is related to the treatment of the term μu_x in a consistent way.

In (32) we make a "superposition" of two operators. The positive operator behaves essentially as a "convection term" in that the solution is "transported" in the negative direction. The negative operator behaves exactly opposite, "transporting" the solution in the positive direction.

REMARK 3.2.



To couple the partial results over these two different meshes we propose here a straightforward interpolation: the evaluation of the integral on the X^+ and X^- meshes is interpolated to the "base mesh" $X^+ \cup X^-$. We use a simple linear interpolation, though a higher-order interpolation is in principle also applicable.

3.2.1. Local differentiation formulas due to the collocation method. There are several choices to discretize the numerical derivative in (34)–(35). The stable one is to apply once more the collocation method to the equation

$$u(x) = -\int_x^b v(s)ds + u(b) \tag{36}$$

for the positive integral. For the negative integral one should instead use the formula

$$u(x) = \int_a^x v(s)ds - u(a). \tag{37}$$

The formulas for the negative operator were derived in [11]. We have derived them for the positive operator. The formulas are summarized below for the sake of completeness. The formulas associated to (36) are called "forward formulas," and the ones

associated to (37) "backward formulas." As remarked in [11], to be able to obtain stable local differentiation formulas, one of the collocation points must coincide with one extreme of the interval, namely, $0 = c_1 < c_2 < 1$. For the backward formulas one must have $0 < c_1 < c_2 = 1$. One picks two arbitrary numbers $\nu_1, \nu_2 \in [0, 1]$, that need not be the same for the forward and backward formulas.

Forward formulas. [illegible] $x_{n,1}$

$$V_{n,1} = \frac{1}{h_n c_2(1-c_2)}[c_2(2\nu_1 - c_2)u(x_n + h_n) + (1-2\nu_1)u(x_n + c_2 h_n) + ((c_2)^2 + 2(1-c_2)\nu_1 - 1)u(x_n)] \tag{38}$$

[illegible] $x_{n,2}$

$$V_{n,2} = \frac{1}{h_n c_2(1-c_2)}[c_2(2\nu_2 - c_2)u(x_n + h_n) + (1-2\nu_2)u(x_n + c_2 h_n) + ((c_2)^2 + 2(1-c_2)\nu_2 - 1)u(x_n)] \tag{39}$$

Backward formulas [11].

$$V_{n,1} = \frac{1}{h_n c_1(1-c_1)}[c_1(2\nu_1 - c_1)u(x_n + h_n) + (1-2\nu_1)u(x_n + c_1 h_n) + ((c_1)^2 + 2(1-c_1)\nu_1 - 1)u(x_n)] \tag{40}$$

$$V_{n,2} = \frac{1}{h_n c_1(1-c_1)}[c_1(2\nu_2 - c_1)u(x_n + h_n) + (1-2\nu_2)u(x_n + c_1 h_n) + ((c_1)^2 + 2(1-c_1)\nu_2 - 1)u(x_n)]. \tag{41}$$

We now explain the treatment of the term μu_x. The consistent way of discretizing this term is by taking into account the transport of information produced by each of the integral operators. We may summarize the criterion as follows.

REMARK 3.3. [illegible] μu_x [illegible] μ [illegible] (38) (39) [illegible] $\mu > 0$ [illegible] (40) (41) [illegible] $\mu < 0$

3.3. Time integration. Let k be the time step size, $t_m = mk$, for $m = 0, \ldots, N_t$. For a European option, the explicit backward differentiation formula (BDF) method reads

$$\frac{3}{2}u^m - 2u^{m-1} + \frac{1}{2}u^{m-2} + kru^m = k[I^+(\bar{v}^m) + I^-(\bar{v}^m) + \mu\bar{v}^m], \tag{42}$$

where $\bar{v}^m = 2v^{m-1} - v^{m-2}$, and I^+, I^- denote the discretizations by collocation of the operators I_+ and I_-, respectively. The addition on the right-hand side needs to be properly defined, as we add quantities that are not defined over the same mesh. To give a meaning to this sum, consider the base mesh $X^+ \cup X^-$, i.e., the mesh where these additions make sense. Let us consider the case of Radau points. Let P_+ denote the prolongation operator from X^+ to $X^+ \cup X^-$. An example of such a prolongation is the following:

$$P_+(w)_{3k} = w_{k,1}, \tag{43}$$

$$P_+(w)_{3k+1} = (w_{k,1} + w_{k,2})/2, \tag{44}$$

$$P_+(w)_{3k+2} = w_{k,2} \tag{45}$$

for $k = 0, \ldots, N-1$. A negative prolongation P_- may be defined likewise. Then, the sum of integrals in (42) is in the sense $P_+(I^+(\bar{v}^m)) + P_-(I^-(\bar{v}^m))$. If the collocation parameters are chosen to be $c_1 = 0, c_2 = 0.5$ for the positive situation and $c_1 = 0.5, c_2 = 1$ for the negative situation, one does not need to interpolate as the meshes coincide, except for boundary points. However, this choice is less accurate as pointed out in section 3.1.4.

Each derivative v^m present in the integrands is evaluated by the local differentiation formulas of section 3.2.1. An iteration of the form

$$u^m = J(v^{m-1}, v^{m-2}) \tag{46}$$

is then found after collecting the prolongation terms. The first input to this iteration is the collocation derivative of the payoff v^0, and the second, v^1, is the result of differentiating one explicit Euler iteration.

For American options the iteration is similar:

$$\begin{cases} u^m \geq J(v^{m-1}, v^{m-2}), \\ u^m \geq \psi, \\ (u^m - J(v^{m-1}, v^{m-2}), u^m - \psi) = 0, \\ u^0 = \psi. \end{cases} \tag{47}$$

Here $(\cdot, \cdot)$ is the standard inner product in $\mathbb{R}^{3N}$, because these iterations are carried out in a mesh of size $3N$ due to the collocation points and the size of the base mesh. The solution of this discrete LCP is simply $u^m = \max(J(v^{m-1}, v^{m-2}), \psi)$.

3.4. The algorithm. We summarize the techniques discussed in an algorithm. The notations v_f and v_b stand for the forward and backward collocation derivative, respectively, as in section 3.2.1. The operator $P_+(u)$ means the prolongation operator by interpolation from collocation mesh X^+ to the base mesh $X^+ \cup X^-$. The operator $P_-(u)$ defines likewise the prolongation from X^-. Finally, the term μu_x is prolongated similarly and added to one of the integrals according to Remark 3.3.

Algorithm

(1) Initialize u^0, and define the starting derivatives v_f^0, v_b^0 according to (38)-(41).
(2) Compute the integral $I_+^0 := I_+(v_f^0)$ from (66) and $I_-^0 := I_-(v_b^0)$ from (79). Make prolongations $P_+(I_+^0)$, $P_-(I_+^0)$ using (44)–(45) and build the right-hand side vector $J(v^0)$ (similar to (46)).
(3) Compute one step Euler u^1; thereafter compute v_f^1 and v_b^1.
(4) Compute $I_+^1 := I_+(v_f^1)$ and $I_-^1 := I_-(v_b^1)$. Make prolongations $P_+(I_+^1)$, $P_-(I_-^1)$ and build the right-hand side vector $J(v^0, v^1)$ as in (46).
(5) Compute a BDF2 step u^2 (cf. (42)), to obtain v_f^2 and v_b^2.
(6) Update $u^1 \to u^0$, $u^2 \to u^1$, $v^1 \to v^0$, $v^2 \to v^1$. Let $m \to m+1$ and repeat steps (4)–(6) until $m = N_t$.

Whenever we compute the integrals I_+ and I_- we apply the FFT algorithm to accelerate the computation of the convolution. This is standard practice so the details are left out. In previous work [3, 4] we made use of this technique to reduce computational time. We only point out that formulas (64) and (82) take on a special form

when the mesh is uniform, representing the multiplication of a Toeplitz matrix by a vector. These matrix-vector multiplications can be efficiently implemented following the explanation in [36].

4. Numerical experiments. The experiments in this section are performed on an AMD Athlon(TM) XP 2700. The first experiment consists in computing European put options with different values of α in order to verify that the order of convergence is quadratic and independent of α; see Table 2. Here, "rate" is defined as the ratio of errors. So, a factor 4 corresponds to second-order accuracy. The numerical values are compared with the Carr–Madan formula [14]. We note that with increasing α, the number of time steps should be increased to obtain a stable solution. The numerical tests for the option pricing problems confirm that in order for the solution to exhibit a stable behavior, a stability condition $k \le C(\alpha)h^{\alpha}$ should be fulfilled. The experiments show also that the stability constant $C(\alpha)$ decreases when α approaches 1, which is in accordance with the stability analysis in Appendix D.

Since the grid convergence rate is also deteriorating with increasing α (Table 2), one does not expect the superconvergence for α close to one. However, $O(h^2)$ accuracy is clearly observed.

A second experiment consists in computing an American put option (Table 3). We again observe at least second-order accuracy of the scheme. An accuracy higher than two seems awkward at first sight with a second-order time integration scheme. Starting with $N = N_t = 20$, however, and doubling both N and N_t, one observes (not shown here) in fact that the explicit BDF2 collocation method is second-order in time. The higher rate observed in Table 3 is basically the effect of having a higher order in space than in time, combined with a special choice of h and k.

The CPU times behave as predicted by the application of the FFT for each time step, with $O(N_t N \log N)$ complexity. Notice that the computations will be significantly more rapid if we need engineering accuracy, i.e., 3 digits accurate. Pictures of the American put option values at $t = 0$ and the time-dependent early exercise boundaries for different values of parameter α are shown in Figure 2. Increasing α means an increase of the intensity of small jumps. Loosely speaking, the prices behave similarly to a volatility increase in the classical Black–Scholes framework.

In a third experiment, European and American butterfly options are considered (Table 4 and Figure 3). A butterfly spread is the result of buying call options with strikes K_1 and K_2, respectively, and selling two call options with strike price $K_3 = (K_1 + K_2)/2$. That is, the payoff is of the form

$$\psi(x) = (e^x - K_1)^+ - 2\left(e^x - \frac{K_1 + K_2}{2}\right)^+ + (e^x - K_2)^+.$$

A European style butterfly is appropriate when the investor thinks large moves in the price of the underlying asset are unlikely. Usually the middle strike K_3 is close to today's spot price S_0, so that it pays off when the underlying asset price stays close to S_0. In Figure 3 we show American style butterflies (in the S coordinate) with different values of α and in Table 4 the second-order convergence of a European style butterfly is shown experimentally. The reason for including a butterfly option example is to show that the method discussed in this paper is rather general and provides accurate numerical results for other kinds of payoffs (nonconvex payoffs, for example), without any further complications.

A final remark is concerning the so-called smooth-fit or smooth-paste principle. This principle essentially states that the derivative of the Black–Scholes American

option price is a continuous function, also at the exercise boundary. It is known that this property does not generally hold true when the underlying follows a Lévy process (for a partial proof see [4] and for a complete characterization for perpetual options see [2]). The butterfly payoff has the feature of combining both the put and the call properties. We observe on the left-hand side of the "hat payoff" in Figure 3 (the call part) that the solution enters the payoff smoothly, whereas, for the right-hand side the smooth-fit is not observable. In this example two free-boundaries appear and despite the continuous dividend yield $q = 0$. This is in contrast to the well-known Black–Scholes situation regarding the call option for which early exercise is not favorable with $q = 0$.

5. Conclusions. In this paper we have proposed a numerical procedure to solve integro-differential scalar equations that arise in finance, when pricing options for which the underlying asset follows a Lévy process. The main idea is to integrate by parts in order to transform the integral operator into a sum of Volterra operators with weakly singular kernels. Known numerical techniques like the collocation method for Volterra equations with weakly singular kernels prove useful to set up a high-order

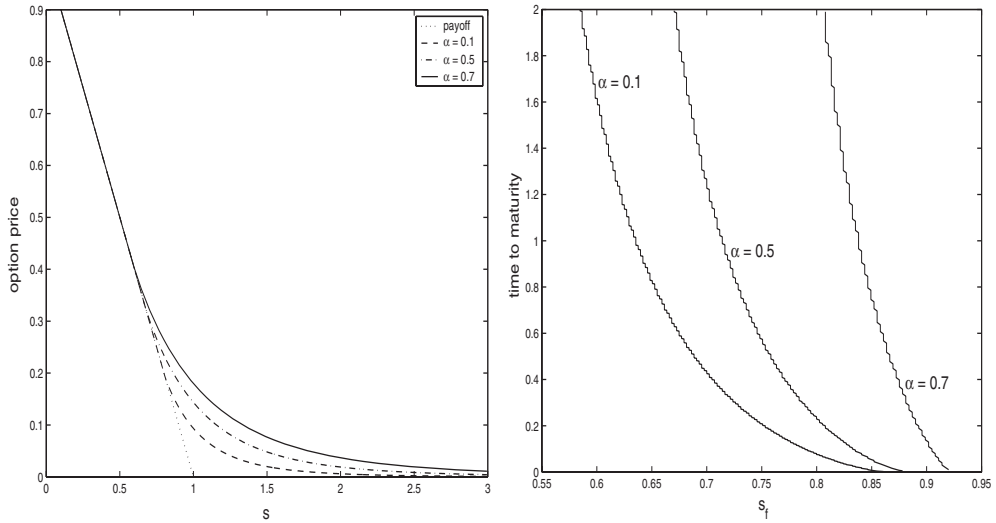

FIG. 2. *American put option prices at $t = 0$ (left) and early exercise boundaries (right) for different values of α. Other parameters: $r = 0.1$, $q = 0$, $K = 1$, $T = 2$, $C = 1$, $G = 5$, $M = 5$.*

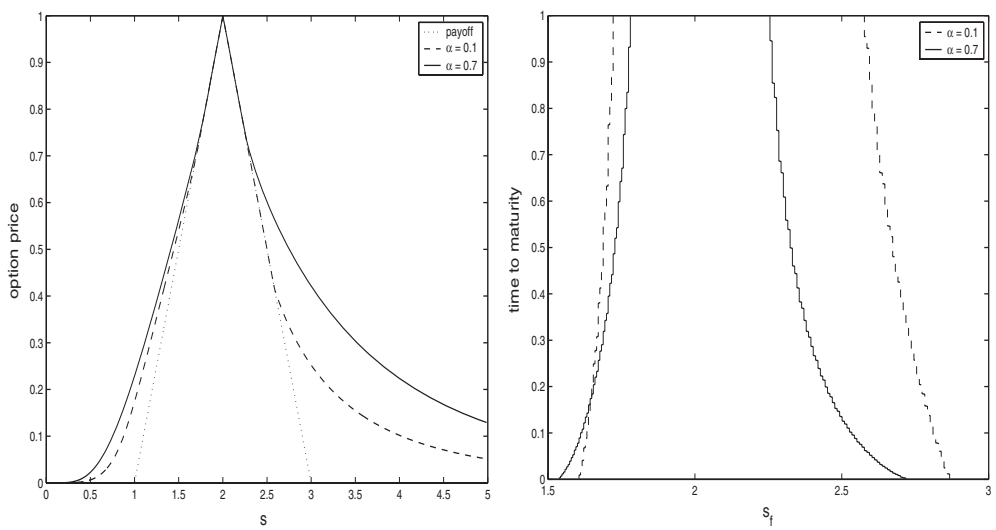

FIG. 3. *American butterfly prices at $t = 0$ (left) and early exercise boundaries for $\alpha = 0.1$ and $\alpha = 0.7$. Other parameters: $r = 0.1$, $q = 0$, $K_1 = 1$, $K_2 = 3$, $T = 1$, $C = 1$, $G = 3$, $M = 5$.*

discretization. Throughout a series of experiments it has been shown that an explicit method is a natural choice for these kinds of problems and for parameter $\alpha \leq 0.7$, as they essentially behave like transport equations. The method proposed can deal with complicated payoffs in a natural way. Due to the FFT algorithm, the complexity of the method is close to linear. With a fast, second-order method at hand, the calibration problem for American options under Lévy processes is now within reach.

Appendix A. Analytic evaluation of integral equation (13). In the numerical experiments in section 3.1.4 we make use of the analytic expression for

$$f(x) = \int_0^\infty (u(x+y) - u(x)) \frac{e^{-My}}{y^{1+\alpha}} dy,$$

where $u(x) = (1 - e^x)^+$. In this paragraph we derive an expression for $f(x)$.

Note that $f(x) = 0$ for $x > 0$. For $x < 0$ we have

$$\begin{aligned} &\int_0^{+\infty} \left[(1 - e^{x+y})^+ - (1 - e^x)^+\right] \frac{e^{-My}}{y^{1+\alpha}} dy \\ &= e^x \int_0^{-x} (1 - e^y) \frac{e^{-My}}{y^{1+\alpha}} dy + (e^x - 1) \int_{-x}^{+\infty} \frac{e^{-My}}{y^{1+\alpha}} dy \\ &= e^x \int_0^{+\infty} (1 - e^y) \frac{e^{-My}}{y^{1+\alpha}} dy + e^x \int_{-x}^{+\infty} \frac{e^{-(M-1)y}}{y^{1+\alpha}} dy - \int_{-x}^{+\infty} \frac{e^{-My}}{y^{1+\alpha}} dy. \end{aligned} \tag{48}$$

To compute the first term, observe that for $\alpha < 0$ the formula

$$\int_0^\infty \frac{e^{-My}}{y^{1+\alpha}} dy = M^\alpha \Gamma(-\alpha)$$

holds. Therefore,

$$\int_0^{+\infty} (1 - e^y) \frac{e^{-My}}{y^{1+\alpha}} dy = \Gamma(-\alpha)[M^\alpha - (M-1)^\alpha]. \tag{49}$$

However, this formula also admits an extension to the complex plane excluding $\alpha \neq 1, 2, \ldots$; see [1]. The second and the third term in (48) can be computed with some quadrature rule, but here we opt for the following approach. These integrals can be written in terms of the so-called upper incomplete gamma function:

$$\Gamma(\beta, y) = \int_y^{+\infty} t^{\beta-1} e^{-t} dt. \tag{50}$$

That is, for instance,

$$\int_{-x}^{+\infty} \frac{e^{-My}}{y^{1+\alpha}} dy = M^\alpha \Gamma(-\alpha, -Mx). \tag{51}$$

An efficient algorithm for computing the incomplete gamma function is discussed in [38].

To summarize, we found that $f(x) = 0$ for $x > 0$ and

$$\begin{aligned} f(x) = e^x \Gamma(-\alpha)[M^\alpha - (M-1)^\alpha] \\ + e^x (M-1)^\alpha \Gamma(-\alpha, -(M-1)x) - M^\alpha \Gamma(-\alpha, -Mx), \quad x < 0. \end{aligned} \tag{52}$$

Appendix B. Collocation method on positive semiaxis. Here, we discretize (22) in the interval $x \in [a, b]$. One looks for a piecewise linear function, defined as V_l on each interval $[x_l, x_{l+1}]$, such that

$$f_{n,j} = \int_{x_{n,j}}^b (z - x_{n,j})^{-\alpha} V(z) \widetilde{k}(z - x_{n,j}) dz. \tag{53}$$

FIG. 4. *Interpolation points.*

The notation $f_{n,j}$ means the values $f(x_{n,j})$.

Splitting the integral term gives the sum

$$f_{n,j} = A_{n,j} + P_{n,j}, \qquad n = 0, \dots, N-1, \qquad j = 1, 2, \tag{54}$$

where the first term is the integral from collocation point $x_{n,j}$ until the next mesh point x_{n+1}:

$$A_{n,j} := \int_{x_{n,j}}^{x_{n+1}} (z - x_{n,j})^{-\alpha} V_n(z) \widetilde{k}(z - x_{n,j}) dz; \qquad j = 1, 2, \tag{55}$$

and the "lag term" $P_{n,j}$ takes into account the intervals $[x_l, x_{l+1}]$:

$$P_{n,j} := \sum_{l=n+1}^{N-1} \int_{x_l}^{x_{l+1}} (z - x_{n,j})^{-\alpha} V_l(z) \widetilde{k}(z - x_{n,j}) dz; \qquad j = 1, 2. \tag{56}$$

With the change of variables $z = x_l + \nu h_l$, both $A_{n,j}$ and $P_{n,j}$ transform, respectively, into

$$A_{n,j} = h_n^{1-\alpha} \int_{c_j}^{1} (\nu - c_j)^{-\alpha} V_n(x_n + \nu h_n) \widetilde{k}(h_n(\nu - c_j)) d\nu, \tag{57}$$

and

$$P_{n,j} = \sum_{l=n+1}^{N-1} h_l^{1-\alpha} \int_0^1 \left[\frac{x_l - x_{n,j}}{h_l} + \nu \right]^{-\alpha} V_l(x_l + \nu h_l) \widetilde{k}(x_l - x_{n,j} + \nu h_l) d\nu. \tag{58}$$

B.1. Product integration formulas on positive semiaxis. Formulas (57) and (58) are not suitable for straightforward evaluation. One would rather prefer some numerical approximation that keeps the order of accuracy. One possibility is to use an interpolatory quadrature rule.

Let us start by fixing two interpolation points belonging to the interval $[c_j, 1)$:

$$c_{j,p} := c_j + (1 - c_j) c_p, \qquad j, p = 1, 2.$$

In other words, the same collocation points c_p are used through a linear mapping of the interval $[0, 1]$ (where they are located) into the interval $[c_j, 1)$; see [11]. Figure 4 illustrates the relative positions of these points. Let $L_{j,p}$ represent the Lagrange interpolation polynomials associated to the points $c_{j,p}$. The product integration rule consists in approximating the integrand (except for the singular part) by a piecewise linear polynomial, i.e., one employs in (57) the following approximation:

$$V_n(x_n + \nu h_n) \widetilde{k}(h_n(\nu - c_j)) \approx \sum_{p=1}^{2} L_{j,p}(\nu) V_n(x_n + c_{j,p} h_n) \widetilde{k}(h_n(c_{j,p} - c_j)) \tag{59}$$

for $\nu \in [c_j, 1]$. This formula requires the values $V_n(x_n + c_{j,p}h_n)$. Let L_q and $V_{n,q}$ denote the Lagrange interpolation polynomials at $x_{n,q}$ for $q = 1, 2$ and the nodal values of V_n at the same collocation points, respectively. It follows that

$$V_n(x_n + c_{j,p}h_n) = \sum_{q=1}^{2} L_q(c_{j,p}) V_{n,q}, \qquad j = 1, 2. \tag{60}$$

The function $V(z)$ need not be continuous. Upon substitution of (60) into (59) and thereafter into (57), one arrives at the formulas suitable for numerical evaluation,

$$\hat{A}_{n,j} = h_n^{1-\alpha} \sum_{p=1}^{2} \sum_{q=1}^{2} \lambda_{j,p} L_q(c_{j,p})\, V_{n,q}\, \widetilde{k}(h_n(1 - c_j)c_p), \tag{61}$$
$$n = 0, \ldots, N-1; \qquad j = 1, 2,$$

where we introduced the (α-dependent) weights

$$\lambda_{j,p} := \int_{c_j}^{1} (\nu - c_j)^{-\alpha} L_{j,p}(\nu) d\nu, \qquad j, p = 1, 2. \tag{62}$$

An analytic expression for these weights will be given in short. For the integrals in the lag term $P_{n,j}$ the analysis goes similarly. There the interpolation nodes are the same as the collocation points c_j, so

$$V_l(x_l + \nu h_l)\widetilde{k}(x_l - x_{n,j} + \nu h_l) \approx \sum_{q=1}^{2} L_q(\nu)\, V_{l,q}\, \widetilde{k}(x_l - x_{n,j} + c_q h_l), \tag{63}$$

which gives the product integration rule for the lag-term

$$\hat{P}_{n,j} = \sum_{l=n+1}^{N-1} h_l^{1-\alpha} \left(\sum_{q=1}^{2} \omega_{l,j,q}\, V_{l,q}\, \widetilde{k}(x_l - x_{n,j} + c_q h_l) \right), \tag{64}$$

and the weights are defined as

$$\omega_{l,j,q} := \int_0^1 \left[\frac{x_l - x_{n,j}}{h_l} + \nu \right]^{-\alpha} L_q(\nu) d\nu, \tag{65}$$
$$j, q = 1, 2; \qquad l = n+1, \ldots, N-1.$$

To conclude, the entries $f_{n,j}$ are approximated as follows:

$$f_{n,j} \approx \hat{P}_{n,j} + \hat{A}_{n,j}, \qquad n = 0, \ldots, N-1, \qquad j = 1, 2. \tag{66}$$

B.2. Weights on positive semiaxis. Formulas for the weights in (62) and (65) are derived next. We start with $\omega_{l,j,q}$ in (65). To simplify the notation let us introduce the numbers

$$d_{l,j} = \frac{x_l - x_{n,j}}{h_l}. \tag{67}$$

This amounts to saying that the following integral is to be evaluated analytically:

$$\int_0^1 (d_{l,j} + \nu)^{-\alpha} L_q(\nu) d\nu. \tag{68}$$

Recall that the Lagrange interpolation polynomials $L_q(\nu)$ are given by the formulas

$$L_1(\nu) = \frac{\nu - c_2}{c_1 - c_2}, \qquad L_2(\nu) = \frac{\nu - c_1}{c_2 - c_1}. \tag{69}$$

We carry out the computation only for L_1, as for L_2 it goes similarly. Adding and subtracting $d_{l,j}$ in the expression $\nu - c_2$ produces two integrals that may be easily evaluated, indeed,

$$\int_0^1 (d_{l,j} + \nu)^{-\alpha}(\nu - c_2)d\nu = \int_0^1 (d_{l,j} + \nu)^{-\alpha+1}d\nu - (d_{l,j} + c_2)\int_0^1 (d_{l,j} + \nu)^{-\alpha}d\nu.$$

Integrating above yields the formulas for the weights

(70)
$$\begin{cases} \omega_{l,j,1} &= \dfrac{(d_{l,j}+1)^{2-\alpha} - (d_{l,j})^{2-\alpha}}{(2-\alpha)(c_1 - c_2)} - (d_{l,j} + c_2)\dfrac{(d_{l,j}+1)^{1-\alpha} - (d_{l,j})^{1-\alpha}}{(1-\alpha)(c_1 - c_2)}, \\ \omega_{l,j,2} &= \dfrac{(d_{l,j}+1)^{2-\alpha} - (d_{l,j})^{2-\alpha}}{(2-\alpha)(c_2 - c_1)} - (d_{l,j} + c_1)\dfrac{(d_{l,j}+1)^{1-\alpha} - (d_{l,j})^{1-\alpha}}{(1-\alpha)(c_2 - c_1)}. \end{cases}$$

To compute $\lambda_{j,p}$, let us change to the variable $\nu = c_j + (1 - c_j)\rho$. This simplifies the Lagrange interpolation polynomials $L_{j,q}(\nu)$ as the following equalities show:

$$L_{j,1}(\nu) = \frac{\nu - c_{j,1}}{c_{j,2} - c_{j,1}} = \frac{v - c_j - (1 - c_j)\rho}{(1 - c_j)(c_2 - c_1)} = \frac{\rho - c_1}{c_2 - c_1} = L_1(\rho).$$

Notice that $c_j \neq 1$ to simplify in this expression. Analogously one finds that $L_{j,2}(\nu) = L_2(\rho)$. Consequently, the expression

$$\lambda_{j,p} = (1 - c_j)^{1-\alpha}\int_0^1 \rho^{-\alpha}L_p(\rho)d\rho$$

gives an alternative way to evaluate these weights. Thus, we may use the previously derived formulas for the ω-weights with $d_{l,j} \equiv 0$ to arrive at the expressions for the λ-weights:

$$\begin{cases} \lambda_{j,1} &= \dfrac{(1 - c_j)^{1-\alpha}}{c_1 - c_2}\left[\dfrac{1}{2-\alpha} - \dfrac{c_2}{1-\alpha}\right], \\ \lambda_{j,2} &= \dfrac{(1 - c_j)^{1-\alpha}}{c_2 - c_1}\left[\dfrac{1}{2-\alpha} - \dfrac{c_1}{1-\alpha}\right]. \end{cases} \tag{71}$$

Appendix C. Integral equation over the negative semiaxis. For the negative semiaxis the discretization is very similar to the one explained in Appendix B. We keep the same notation from the positive situation and summarize the procedure. The integral equation for the negative semiaxis reads

$$g(x) = \int_{-\infty}^0 (u(x + y) - u(x))\frac{e^{-G|y|}}{|y|^{1+\alpha}}dy. \tag{72}$$

This expression reduces, after integration by parts, to

$$g(x) = -\int_{-\infty}^0 v(x + y)\hat{k}(y)dy. \tag{73}$$

Here we have introduced the function

$$\hat{k}(-w) := \int_{-\infty}^{-w} \frac{e^{-G|\zeta|}}{|\zeta|^{1+\alpha}} d\zeta, \qquad w > 0, \tag{74}$$

and v stands for the derivative of u with respect to the space variable. The subscript "-" for the negative kernel is again omitted. An expression in terms of the incomplete gamma function exists, namely, $\hat{k}(-w) = G^{\alpha}\Gamma(-\alpha, Gw)$. The Lipschitz property (17) is now invoked to allow the above integration by parts, along with a growth property for large negative values; i.e.,

- there exist constants $C_3 > 0$ and $0 < C_4 < G$ such that $|u(z)| \leq C_3 e^{C_4|z|}$ for $z \to -\infty$.

Similarly to the situation on the positive semiaxis, one takes into account the singularity of the kernel $\hat{k}$. It is therefore convenient to introduce the kernel

$$\widetilde{k}(w) := w^{\alpha}\hat{k}(-w), \qquad w > 0, \tag{75}$$

and focus on the discretization of the integral equation

$$g(x) = -\int_{-\infty}^{x} (x-z)^{-\alpha} v(z) \widetilde{k}(x-z) dz. \tag{76}$$

Considering the collocation parameters

$$0 < c_1 < c_2 \leq 1, \tag{77}$$

the collocation mesh is defined as in (23). To discretize (76) write

$$g_{n,j} = -\int_{a}^{x_{n,j}} (x_{n,j}-z)^{-\alpha} V(z) \widetilde{k}(x_{n,j}-z) dz. \tag{78}$$

As for the positive semiaxis, one applies the product integration rule with a suitable choice of interpolation points. Summarizing, the quantities $g_{n,j}$ are approximated as follows:

$$g_{n,j} \approx \hat{B}_{n,j} + \hat{Q}_{n,j}, \qquad n = 0, \ldots, N-1, \qquad j = 1, 2. \tag{79}$$

The first component is computed with the formula

$$\hat{B}_{n,j} = -h_n^{1-\alpha} \sum_{p=1}^{2} \sum_{q=1}^{2} \lambda_{j,p} L_q(c_{j,p})\, V_{n,q}\, \widetilde{k}(h_n c_j (1-c_p)), \qquad j = 1, 2, \tag{80}$$

the weights $\lambda_{j,p}$ being

$$\begin{cases} \lambda_{j,1} &= \dfrac{(c_j)^{1-\alpha}}{c_2 - c_1} \left[\dfrac{1}{2-\alpha} - \dfrac{1-c_2}{1-\alpha} \right], \\ \\ \lambda_{j,2} &= \dfrac{(c_j)^{1-\alpha}}{c_1 - c_2} \left[\dfrac{1}{2-\alpha} - \dfrac{1-c_1}{1-\alpha} \right], \end{cases} \tag{81}$$

and $c_{j,p} = c_j c_p$. The second component in this sum corresponds to an approximation of the lag-term,

$$\hat{Q}_{n,j} = -\sum_{l=0}^{n-1} h_l^{1-\alpha} \left[\sum_{q=1}^{2} \omega_{l,j,q}\, V_{l,q}\, \widetilde{k}(x_{n,j} - x_l - c_q h_l) \right], \tag{82}$$

where the weights for the negative semiaxis are

(83)
$$\begin{cases} \omega_{l,j,1} &= -\dfrac{(d_{l,j})^{2-\alpha}-(d_{l,j}-1)^{2-\alpha}}{(2-\alpha)(c_1-c_2)}+(d_{l,j}-c_2)\dfrac{(d_{l,j})^{1-\alpha}-(d_{l,j}-1)^{1-\alpha}}{(1-\alpha)(c_1-c_2)}, \\ \omega_{l,j,2} &= -\dfrac{(d_{l,j})^{2-\alpha}-(d_{l,j}-1)^{2-\alpha}}{(2-\alpha)(c_2-c_1)}+(d_{l,j}-c_1)\dfrac{(d_{l,j})^{1-\alpha}-(d_{l,j}-1)^{1-\alpha}}{(1-\alpha)(c_2-c_1)}. \end{cases}$$

As for the positive integral, a compensation constant is necessary to smooth the kernel. The constant in this situation is

$$\theta_- = \frac{G^\alpha \Gamma(2-\alpha)}{\alpha(1-\alpha)}, \tag{84}$$

so that

$$k_-(x) := \widetilde{k}(x) + \theta_- x^\alpha,$$

and the splitting of the integral equation with respect to the new kernel reads

$$g(x) = -\int_{-\infty}^{x} (x-z)^{-\alpha} v(z) k_-(z-x)dz + \theta_- \int_{-\infty}^{x} v(z)dz. \tag{85}$$

Appendix D. Stability analysis. In order to gain some insight into the stability of the resulting discretization of the PIDE, we perform here a Von Neumann stability analysis; however, we do this for a "model" version of the time-dependent problem under consideration.

Let $\alpha \in (0,1)$ and consider the equation

$$u_t = -\int_0^x (x-z)^{-\alpha} u_z(z,t)dz, \quad x \in [0,1]. \tag{86}$$

To simplify the analysis, we concentrate on a special case of the collocation method, namely, the grid is assumed equidistant, i.e., $h_n = h$, and the collocation parameters are $c_1 = 0.5$ and $c_2 = 1$. These choices give the collocation points $x_{n,1} = (n+1/2)h$ and $x_{n,2} = (n+1)h$.

Let us analyze the Euler scheme for the midpoints $x_{n,1}$ (for the other collocation points the analysis goes similarly). By $u_{n+\frac{1}{2}}$ we denote the value of the solution at the midpoints. With the notation in Appendix C, (80), (81), (82), and (83), we may write the explicit collocation scheme as

$$u^m_{n+\frac{1}{2}} - u^{m-1}_{n+\frac{1}{2}} = -\gamma h \left[\sum_{p=1}^{2} \lambda_{1,p} (L_1(c_{1,p}) V^{m-1}_{n,1} + L_2(c_{1,p}) V^{m-1}_{n,2}) + \sum_{l=0}^{n-1} (\omega_{l,1,1} V^{m-1}_{l,1} + \omega_{l,1,2} V^{m-1}_{l,2}) \right]. \tag{87}$$

Here we have introduced the parameter

$$\gamma := \frac{k}{h^\alpha}. \tag{88}$$

Our objective is to show that by controlling the parameter γ one attains stability of the Euler scheme.

For the collocation parameters under consideration the corresponding collocation derivatives in (87) are

$$V_{n,1}^{m-1} = \frac{u_{n+1}^{m-1} - u_n^{m-1}}{h}, \quad V_{n,2}^{m-1} = \frac{3u_{n+1}^{m-1} - 4u_{n+\frac{1}{2}}^{m-1} + u_n^{m-1}}{h}, \tag{89}$$

and the Lagrange interpolations are

$$L_1(c_{1,1}) = 3/2, \quad L_1(c_{1,2}) = 1, \quad L_2(c_{1,1}) = -1/2, \quad L_2(c_{1,2}) = 0. \tag{90}$$

Substituting (90) and (89) into (87) and collecting terms we arrive at the scheme

$$u_{n+\frac{1}{2}}^{m} = u_{n+\frac{1}{2}}^{m-1} - \gamma \sum_{l=0}^{n} \left[(A_l + 3B_l) u_{l+1}^{m-1} - 4B_l u_{l+\frac{1}{2}}^{m-1} + (B_l - A_l) u_l^{m-1} \right], \tag{91}$$

where $A_n = \frac{3}{2}\lambda_{1,1} + \lambda_{1,2}$, $B_n = -\frac{1}{2}\lambda_{1,1}$, $A_l = \omega_{l,1,1}$, and $B_l = \omega_{l,1,2}$ $(l = 0 \dots n-1)$. The λ-weights are straightforwardly computed using (71), yielding

$$\lambda_{1,1} = \frac{2^\alpha}{2-\alpha}, \quad \lambda_{1,2} = \frac{2^\alpha}{2-\alpha} - \frac{2^{\alpha-1}}{1-\alpha}. \tag{92}$$

The ω-weights are computed using (70) with

$$d_{l,1} = n - l + 1/2, \quad d_{l,2} = n - l + 1. \tag{93}$$

A method to obtain a necessary condition for stability is to substitute the Fourier modes $u_l^m = g^m e^{il\theta}$ into the scheme and thereafter perform the necessary simplifications. This procedure is commonly known as discrete Von Neumann stability analysis. Applied to our case it produces the so-called amplification factor

$$g(\theta) = 1 - \gamma \sum_{l=0}^{n} \left[(A_l + 3B_l) e^{i(l-n+1/2)\theta} - 4B_l e^{i(l-n)\theta} + (B_l - A_l) e^{i(l-n-1/2)\theta} \right]. \tag{94}$$

If the scheme is stable, it is also stable on a particular solution. Hence, the amplification factor must satisfy the requirement

$$|g(\theta)| \leq 1. \tag{95}$$

We refer the reader to [35] for details on the amplification factor in connection with the Von Neumann stability analysis. We are looking for a condition of the form $\gamma \leq C(\alpha)$ such that (95) holds. Instead of deriving this condition for model equation (86), we present in Table 5 some sharp values of $C(\alpha)$ for distinct choices of α, and two representative examples are displayed in Figure 5.

A limiting case is distinguished: For $\alpha \to 0$ one notices that $C(\alpha) \to 1$. This behavior is intuitively correct as for $\alpha = 0$, equation (86) reduces to the ODE $u_t = -u + u(0)$. For $\alpha = 0$ the condition says $k \leq 1$, which is the necessary condition for explicit Euler, since the amplification factor for $u_t = -u + u(0)$ is

$$g(\theta) = 1 - k + ke^{-im\theta}.$$

TABLE 5
Values of $C(\alpha)$ as a function of α.

α	0.05	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	0.95
$C(\alpha)$	0.99	0.97	0.92	0.85	0.76	0.67	0.57	0.46	0.2	0.03	0.007

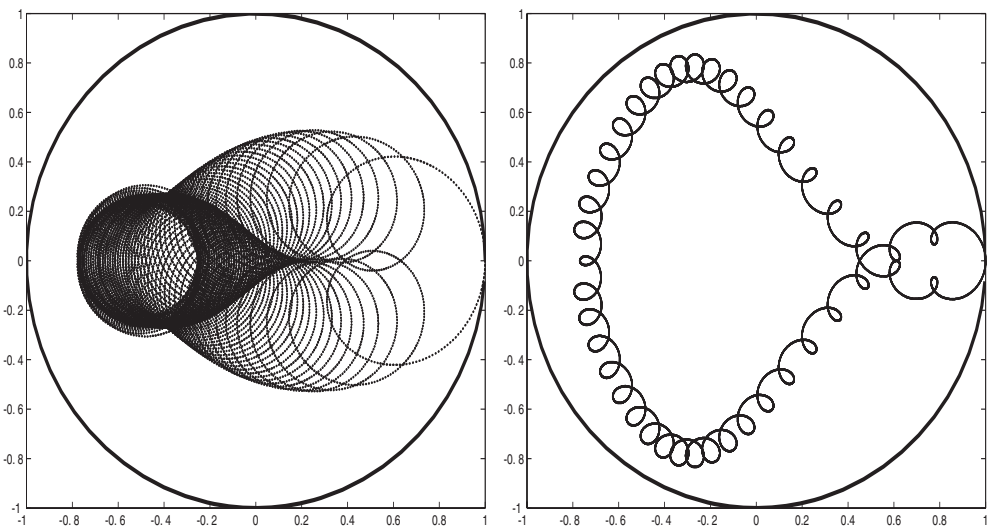

FIG. 5. *Values of $g(\theta)$ inside unit circle, $k = C(\alpha)h^\alpha$. Left: $\alpha = 0.3, N = 50$. Right: $\alpha = 0.7, N = 20$, with $C(0.3) = 0.85$ and $C(0.7) = 0.46$ as in Table 5.*

Then, $|g| \leq 1$ implies $|\operatorname{Re} g| \leq 1$, which in turn implies $k \leq 1$.

The insight gained here from model equation (86) with explicit Euler, i.e., the α-dependent constant $C(\alpha)$ so that (95) holds, is in full agreement with the observations regarding stability for our target discrete PIDE, discretized with explicit BDF2, in the numerical experiments of section 4. We include here a numerical experiment with the test equation (86). Three values of α are chosen to illustrate that the values in Table 5 are sharp; see Table 6. This table shows that

$$k \leq C(\alpha)h^\alpha \tag{96}$$

is in fact a necessary condition for stability. Namely, if (96) is not satisfied, the scheme is not stable. It should be mentioned that $C(\alpha)$ depends weakly on N, and the values in Table 5 are conservative in the sense that they are found with $N = 20$. For larger N, the pictures in Figure 5, for example, tend to shrink.

It can be observed in Table 6 that the number of time steps needed for stability grows with increasing α. For $\alpha \leq 0.7$ the number of time steps remains reasonable, and explicit time-stepping can efficiently be used. For α closer to 1, however, one may need to consider an implicit time discretization. For $\alpha = 0.9$ we see a difference of 200 time steps for a consistency between the stability analysis and the numerical experiment. The reason for this large difference lies in the assumption that a satisfactory stability criterion is $|g| \leq 1$ (95). In fact, a weaker stability criterion that is both necessary and sufficient is given by $|g| \leq 1 + \tilde{C}k$, for $\tilde{C}$ independent of h and k. This typically gives larger circles, so $C(\alpha)$ in the table represents a conservative estimate. The tendency with respect to stability is, however, clear.

TABLE 6
Stability experiments on test equation (86) *with* $T = 1$. *The symbol "v" means "holds" and "X" means "does not hold." The initial condition is taken as* $u(x, 0) = \exp(x)$.

α	N	N_t	Stability	Equation (96)
0.05	100	2	v	v
0.3	100	6	v	v
	100	4	X	X
0.5	100	30	v	v
	100	10	X	X
0.7	100	140	v	v
	100	80	X	v
	100	40	X	X
0.9	20	400	v	v
	20	300	X	v
	20	200	X	X

AN ADAPTIVE MULTILEVEL METHOD FOR TIME-HARMONIC MAXWELL EQUATIONS WITH SINGULARITIES*

ZHIMING CHEN†, LONG WANG†, AND WEIYING ZHENG†

Abstract. We develop an adaptive edge finite element method based on reliable and efficient residual-based a posteriori error estimates for low-frequency time-harmonic Maxwell equations with singularities. The resulting discrete problem is solved by the multigrid preconditioned MINRES (minimum residual) iteration algorithm. We demonstrate the efficiency and robustness of the proposed method by extensive numerical experiments for cavity problems with singular solutions which include, in particular, scattering over screens.

Key words. Maxwell equations, singularities of solutions, adaptive finite element method, multigrid method

1. Introduction.

Let $\Omega \subset \mathbb{R}^3$ be a bounded polygonal domain with two disjoint connected boundaries Γ and Σ. Given a current density $\mathbf{f}$, we seek a time-harmonic electric field $\mathbf{E}$ subject to the perfectly conducting boundary condition on Γ and the impedance boundary condition on Σ:

$$\mathbf{curl}\,(\mu_r^{-1}\,\mathbf{curl}\,\mathbf{E}) - \kappa^2\varepsilon_r\,\mathbf{E} = \mathbf{f} \quad \text{in} \quad \Omega, \tag{1.1}$$

$$\mu_r^{-1}\,\mathbf{curl}\,\mathbf{E} \times \nu - \mathbf{i}\,\kappa\lambda\mathbf{E}_t = \mathbf{g} \quad \text{on} \quad \Sigma, \tag{1.2}$$

$$\mathbf{E} \times \nu = 0 \quad \text{on} \quad \Gamma, \tag{1.3}$$

where $\mathbf{i}$ is the imaginary unit, ν is the unit outer normal of the boundary, $\mathbf{E}_t := (\nu \times \mathbf{E}|_\Sigma) \times \nu$, ε_r is the complex relative dielectric coefficient, $\mu_r > 0$ is the relative magnetic permeability of the material in Ω, $\kappa > 0$ is the wave number, and $\lambda > 0$ is the impedance on Σ. We allow Σ to be empty, in which case (1.1)–(1.3) models electromagnetic wave propagation in a cavity with a perfectly conducting wall. For an absorbing boundary condition approximation of a scatting problem, $\mu_r = \lambda = 1$ on Σ and $\varepsilon_r = \mu_r = 1$ in a neighborhood of Σ, $\mathbf{g}$ can be computed from an incident field $\mathbf{E}_i$ ($\mathbf{g} = \mathbf{curl}\,\mathbf{E}_i \times \nu - \mathbf{i}\,\kappa\mathbf{E}_{i,t}$). In this paper, we focus on low-frequency problems; i.e., κ is not very large.

It is now well known that the solution of time-harmonic Maxwell equations can have much stronger singularities than the corresponding Dirichlet and Neumann singular functions of the Laplace operator when the computational domain is non-convex or the coefficients of the equations are discontinuous. For example, for the domains that have "screen" or "crack" parts as indicated in Figure 1.1, the regularity of the solution is only in $\mathbf{H}^s$ with $s < 1/2$. In this case the $\mathbf{H}^1$-conforming discretization cannot be used directly to solve the time-harmonic cavity problem (1.1)–(1.3). One

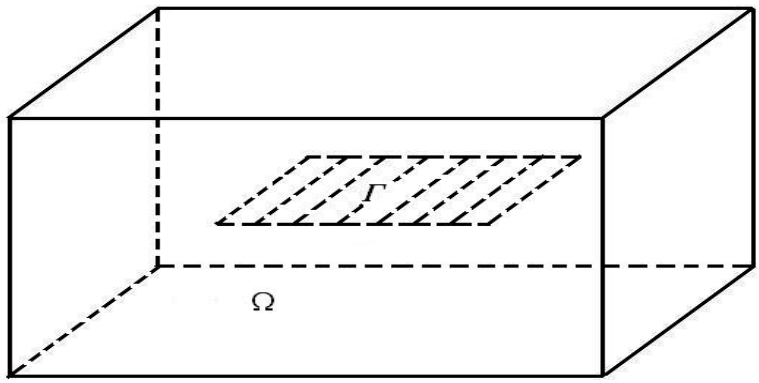

FIG. 1.1. *A domain with screen* Γ.

way to overcome this difficulty is to use the so-called singular field method, which decomposes the solution into a regular part that can be treated by $\mathbf{H}^1$-conforming Lagrangian finite elements and an explicit singular part [2], [10], [18], [19]. For the mathematical analysis of the singularities of the solutions of Maxwell equations, we refer to [8], [9], [16], [17], [18], and the references therein.

The first objective of this paper is to explore the possibility of extending the general framework of adaptive finite element methods based on a posteriori error estimates initiated in [3] to the time-harmonic Maxwell equations. A posteriori error estimates are computable quantities in terms of the discrete solution and known data that measure the actual discrete errors without knowledge of exact solutions. They are essential in designing algorithms for mesh modification which equidistribute the computational effort and optimize the computation. The ability of error control and the asymptotically optimal approximation property (see, e.g., [11] and [27]) make the adaptive finite element methods attractive for complicated physical and industrial processes (cf., e.g., [12], [14], and [15]).

A posteriori error estimates for Nédélec $\mathbf{H}(\mathbf{curl})$-conforming edge elements are obtained in [25] for Maxwell scattering problems and in [6] for eddy current problems. The key ingredient in the analysis is the orthogonal Helmholtz decomposition $\mathbf{v} = \nabla\varphi + \Psi$, where for any $\mathbf{v} \in \mathbf{H}(\mathbf{curl}; \Omega)$, $\varphi \in H^1(\Omega)$ and $\Psi \in \mathbf{H}(\mathbf{curl}; \Omega)$. Since a stable edge element interpolation operator is not available for functions in $\mathbf{H}(\mathbf{curl}; \Omega)$, some kind of regularity result for $\Psi \in \mathbf{H}(\mathbf{curl}; \Omega)$ is required. This regularity result is proved in [25] for domains with smooth boundary and in [6] for convex polyhedral domains. The key observation in our analysis is that if one removes the orthogonality requirement in the Helmholtz decomposition, the regularity $\Psi \in \mathbf{H}^1(\Omega)$ can be proved in the decomposition $\mathbf{v} = \nabla\varphi + \Psi$ for a large class of nonconvex polygonal domains or domains having screens [8], [9]; see also [19]. Our extensive numerical experiments for the lowest order edge element indicate that for the cavity problem (1.1)–(1.3) with very strong singularities $\mathbf{H}^s$ ($s < 1/2$), the adaptive methods based on our a posteriori error estimates have the very desirable quasi-optimality property

$$\|\mathbf{E} - \mathbf{E}_k\|_{\mathbf{H}(\mathbf{curl};\,\Omega)} \leq C\, N_k^{-1/3},$$

where N_k is the number of elements of the kth adaptive mesh $\mathcal{T}_k$, and $\mathbf{E}_k$ is the finite element solution over $\mathcal{T}_k$.

The second objective of this paper concerns the efficient solution of the large linear system of equations resulting from the edge element discretization of (1.1)–(1.3)

which is in general non-Hermitian and indefinite. We propose to use preconditioned MINRES (minimum residual) to solve the linear system of equations where the preconditioner is constructed by the multigrid solver of the stiffness matrix corresponding to the discretization of the following problem:

$$\mathbf{curl}\,(\mu_r^{-1}\,\mathbf{curl}\,\mathbf{u}) + \kappa^2|\varepsilon_r|\,\mathbf{u} = \mathbf{f} \quad \text{in} \quad \Omega, \tag{1.4}$$

$$\mu_r^{-1}\,\mathbf{curl}\,\mathbf{u} \times \nu + \kappa\lambda\mathbf{u}_t = \mathbf{g} \quad \text{on} \quad \Sigma, \tag{1.5}$$

$$\mathbf{u} \times \nu = 0 \quad \text{on} \quad \Gamma. \tag{1.6}$$

Multigrid methods for the edge element discretization of Maxwell equations have been studied in [1], [21], [23], and the references therein. An important discovery in [23] was that for the $\mathbf{H}(\mathbf{curl})$-elliptic problems, multigrid relaxations must be performed on both edges and vertices in order to guarantee the uniform convergence of the multigrid method. We also refer to [5] for the multigrid preconditioned iterative scheme for the Helmholtz equation.

The distinct feature of applying multigrid methods on adaptively refined finite element meshes is that the number of degrees of freedom may not grow exponentially with respect to the number of mesh refinements k. Following the idea of "local" multigrid in [24] for discrete H^1-elliptic problems and [7] for discrete $\mathbf{H}(\mathbf{curl})$-elliptic problems, at each level k of our multigrid algorithm for discrete Maxwell problems, we perform Gauß–Seidel relaxations only on new edges, new vertices, and their immediate neighboring edges and vertices (see (4.3) and Algorithm 4.2 below). Our extensive numerical experiments indicate that our multigrid preconditioned MINRES algorithm has the very desirable property that for low-frequency time-harmonic Maxwell equations with very strong singularity, the number of iterations to reduce the initial residual by a factor of 10^{-8} remains nearly fixed on different levels of adaptively refined meshes. We also test the influence of the frequency to the performance of the preconditioner. It indicates that with the frequency of the problem increasing, the number of preconditioned MINRES iterations increases. But for a fixed frequency, it varies very slightly as the number of degrees of freedom increases. We also refer to [33] for the proof of uniform convergence of the "local" multigrid method for discrete H^1-elliptic problems on adaptively refined meshes.

The rest of the paper is organized as follows. In section 2, we prove Helmholtz-type decompositions of $\mathbf{H}(\mathbf{curl};\,\Omega)$ and introduce conforming finite element approximations to (1.1)–(1.3). In section 3, we derive reliable and efficient residual-based a posteriori error estimates. In section 4, we describe the preconditioned MINRES algorithm. In section 5, we report several numerical experiments to show the competitive performance of the methods proposed in this paper.

2. Hemlholtz-type decompositions and finite element approximations. We start by introducing the definition of a "screen."

DEFINITION 2.1. F [illegible] C^2 [illegible] ∂F [illegible] F [illegible] ∂F

Let Ω be a polyhedral domain in $\mathbb{R}^3$ which satisfies one of the following assumptions.

HYPOTHESIS 2.2.

(i) Ω [illegible] $\Gamma = \partial D$ [illegible] D [illegible] $\bar{D} \cup \Omega$ [illegible] 2.1

(ii) Γ [illegible] $\Omega \cup \Gamma$ [illegible] 1.1

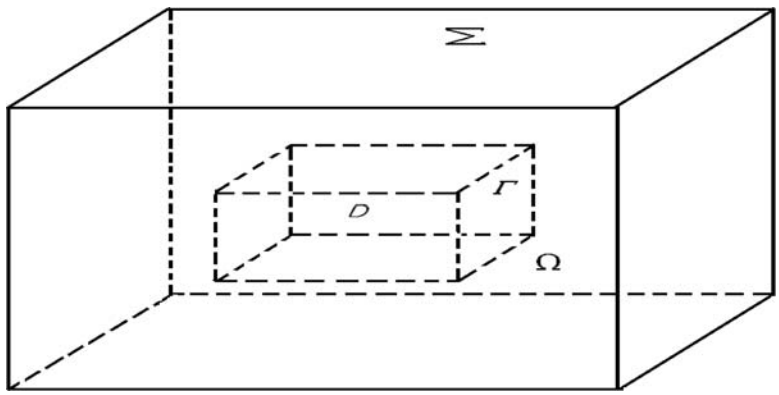

FIG. 2.1. *A domain with an inner scatter D.*

(iii) $\Sigma = \emptyset$ [illegible] $\Gamma = \partial\Omega = \Gamma_{in} \cup \Gamma_{out}$ [illegible] Γ_{in} [illegible] Γ

We remark that in each case Ω need not be simply connected, and the domain in the second case is not even Lipschitz. In the third case, we actually solve a time-harmonic problem with a Dirichlet boundary condition.

We introduce some notations and Sobolev spaces used in this paper. $L^2(\Omega)$ is the usual Hilbert space of square integrable functions equipped with the following inner product and norm:

$$(u,\, v) := \int_\Omega u(\mathbf{x})\, \overline{v(\mathbf{x})}\, d\mathbf{x} \quad \text{and} \quad \|u\|_{0,\Omega} := (u,\, u)^{1/2}.$$

$H^m(\Omega) := \{v \in L^2(\Omega) : D^\xi v \in L^2(\Omega),\ |\xi| \le m\}$ equipped with the norm and seminorm

$$\|u\|_{m,\Omega} := \left(\sum_{|\xi| \le m} \|D^\xi u\|_{0,\Omega}^2 \right)^{1/2} \quad \text{and} \quad |u|_{m,\Omega} := \left(\sum_{|\xi| = m} \|D^\xi u\|_{0,\Omega}^2 \right)^{1/2},$$

where ξ represents a nonnegative triple index. $H^1_\Gamma(\Omega)$ is the subspace of $H^1(\Omega)$ whose functions have zero traces on Γ. We use boldface notation for vectors, such as $\mathbf{L}^2(\Omega) := (L^2(\Omega))^3$ and so on. The following Sobolev spaces are used in the paper:

$$\begin{aligned}
\mathbf{H}(\mathrm{div};\Omega) &:= \{\mathbf{v} \in \mathbf{L}^2(\Omega) \,:\, \mathrm{div}\,\mathbf{v} \in \mathbf{L}^2(\Omega)\},\\
\mathbf{H}(\mathbf{curl};\Omega) &:= \{\mathbf{v} \in \mathbf{L}^2(\Omega) \,:\, \mathbf{curl}\,\mathbf{v} \in \mathbf{L}^2(\Omega)\},\\
\mathbf{H}_\Gamma(\mathbf{curl};\Omega) &:= \{\mathbf{v} \in \mathbf{H}(\mathbf{curl};\,\Omega) \mid \mathbf{v} \times \nu = 0 \ \text{ on } \ \Gamma \ \text{ and } \ \mathbf{v}_t \in \mathbf{L}^2(\Sigma)\}.
\end{aligned}$$

As usual, we denote $H^1_0(\Omega) := H^1_{\partial\Omega}(\Omega)$ and $\mathbf{H}_0(\mathbf{curl};\Omega) := \mathbf{H}_{\partial\Omega}(\mathbf{curl};\Omega)$ for $\Sigma = \emptyset$. $\mathbf{H}(\mathrm{div};\,\Omega)$, $\mathbf{H}(\mathbf{curl};\Omega)$, and $\mathbf{H}_\Gamma(\mathbf{curl};\Omega)$ are equipped, respectively, with the following norms:

$$\begin{aligned}
\|\mathbf{v}\|_{\mathbf{H}(\mathrm{div};\,\Omega)} &:= \left(\|\mathbf{v}\|_{0,\Omega}^2 + \|\mathrm{div}\,\mathbf{v}\|_{0,\Omega}^2\right)^{1/2},\\
\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\Omega)} &:= \left(\|\mathbf{v}\|_{0,\Omega}^2 + \|\mathbf{curl}\,\mathbf{v}\|_{0,\Omega}^2\right)^{1/2},\\
\|\mathbf{v}\|_{\mathbf{H}_\Gamma(\mathbf{curl};\,\Omega)} &:= \left(\|\mathbf{v}\|_{0,\Omega}^2 + \|\mathbf{curl}\,\mathbf{v}\|_{0,\Omega}^2 + \|\mathbf{v}_t\|_{0,\Sigma}^2\right)^{1/2}.
\end{aligned}$$

Let $\mathbf{f} \in \mathbf{L}^2(\Omega)$ and $\mathbf{g} \in \mathbf{L}^2(\Sigma)$ satisfying $\mathbf{g} \cdot \nu = 0$ on Σ. The equivalent weak formulation of (1.1)–(1.3) is to find $\mathbf{E} \in \mathbf{H}_\Gamma(\mathbf{curl}; \Omega)$ such that

$$a(\mathbf{E}, \mathbf{v}) = \int_\Omega \mathbf{f} \cdot \overline{\mathbf{v}} + \int_\Sigma \mathbf{g} \cdot \overline{\mathbf{v}}_t \quad \forall\, \mathbf{v} \in \mathbf{H}_\Gamma(\mathbf{curl}; \Omega), \tag{2.1}$$

where

$$a(\mathbf{E}, \mathbf{v}) := (\mu_r^{-1}\, \mathbf{curl}\, \mathbf{E}, \mathbf{curl}\, \mathbf{v}) - (\kappa^2 \varepsilon_r \mathbf{E}, \mathbf{v}) - \mathbf{i} \int_\Sigma \kappa\, \lambda\, \mathbf{E}_t \cdot \overline{\mathbf{v}}_t\,. \tag{2.2}$$

The existence and uniqueness of the solution of problem (2.1) under various conditions on the domain Ω and the coefficients ε_r, μ_r have been studied in [26]. Here for the sake of simplicity we simply assume that problem (2.1) has a unique solution. Thus there exists a constant $\beta > 0$ depending only on Ω, ε_r, μ_r, λ, and the wave number κ such that [4, Chapter 5]

$$\sup_{0 \neq \mathbf{v} \in \mathbf{H}_\Gamma(\mathbf{curl}; \Omega)} \frac{a(\mathbf{E}, \mathbf{v})}{\|\mathbf{v}\|_{\mathbf{H}_\Gamma(\mathbf{curl}; \Omega)}} \geq \beta \|\mathbf{E}\|_{\mathbf{H}_\Gamma(\mathbf{curl}; \Omega)}. \tag{2.3}$$

Furthermore, it follows from (2.3) that there exists a constant $C > 0$ independent of $\mathbf{E}$, $\mathbf{f}$, and $\mathbf{g}$ such that

$$\|\mathbf{E}\|_{\mathbf{H}_\Gamma(\mathbf{curl}; \Omega)} \leq C(\|\mathbf{f}\|_{0,\Omega} + \|\mathbf{g}\|_{0,\Sigma}). \tag{2.4}$$

The following Helmholtz-type decomposition theorem is applicable to polyhedral domains with Lipschitz screens F.

THEOREM 2.3. $\mathcal{D}$

- $\mathcal{D}$
- $\mathcal{D}$ F $\partial\mathcal{D} = \Gamma \cup F$ $\Gamma \cap F = \emptyset$ $\mathcal{D} \cup F$

1.1

$\mathbf{v} \in \mathbf{H}_0(\mathbf{curl}; \mathcal{D})$ $\psi \in H_0^1(\mathcal{D})$ $\mathbf{v}_s \in \mathbf{H}^1(\mathcal{D}) \cap \mathbf{H}_0(\mathbf{curl}; \mathcal{D})$ $\mathbf{v}_s \in \mathbf{H}_0^1(\mathcal{D})$ $\mathcal{D}$

$$\mathbf{v} = \nabla\psi + \mathbf{v}_s \quad \mathcal{D}, \tag{2.5}$$

$$\|\psi\|_{1,\mathcal{D}} + \|\mathbf{v}_s\|_{1,\mathcal{D}} \leq C\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl}; \mathcal{D})}, \tag{2.6}$$

C $\mathcal{D}$

. The proof for the case when D is a Lipschitz domain is contained in [19, Proposition 5.1]. For completeness we sketch the proof here. The proof below for the case when D has a Lipschitz inner screen F simplifies the argument in [9].

Let $\mathcal{O} := B(0, R)$ be a ball containing D. We extend $\mathbf{v}$ by zero to the exterior of $\mathcal{D}$ and denote the extension by $\tilde{\mathbf{v}}$. Clearly $\tilde{\mathbf{v}} \in \mathbf{H}_0(\mathbf{curl}; \mathcal{O})$. By Theorem 3.4 of [20, p. 45], there exists a $\mathbf{w} \in \mathbf{H}^1(\mathcal{O})$ such that

$$\mathbf{curl}\, \mathbf{w} = \mathbf{curl}\, \tilde{\mathbf{v}}, \quad \mathrm{div}\, \mathbf{w} = 0 \quad \text{in } \mathcal{O}, \tag{2.7}$$

$$\|\mathbf{w}\|_{1,\mathcal{O}} \leq C(\|\mathbf{curl}\, \mathbf{w}\|_{0,\mathcal{O}} + \|\mathrm{div}\, \mathbf{w}\|_{0,\mathcal{O}}) = C\|\mathbf{curl}\, \mathbf{v}\|_{0,\mathcal{D}}. \tag{2.8}$$

Moreover, by (2.7) and Theorem 2.9 of [20, p. 31], there exists a $\varphi \in H^1(\mathcal{O})/\mathbb{R}$ such that

$$\tilde{\mathbf{v}} = \mathbf{w} + \nabla\varphi \quad \text{in } \mathcal{O}, \tag{2.9}$$

$$\|\varphi\|_{1,\mathcal{O}} \leq C|\varphi|_{1,\mathcal{O}} \leq C\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl}; \mathcal{D})}, \tag{2.10}$$

$$|\varphi|_{2,\mathcal{O}\setminus\bar{\mathcal{D}}} \leq \|\mathbf{w}\|_{1,\mathcal{O}} \leq C\|\mathbf{curl}\, \mathbf{v}\|_{0,\mathcal{D}}. \tag{2.11}$$

Since $\mathcal{O}\setminus\bar{\mathcal{D}}$ is a Lipschitz domain, by the extension theorem [22, Theorem 1.4.3.1, p. 25], there exists an extension of $\varphi|_{\mathcal{O}\setminus\bar{\mathcal{D}}}$ denoted by $\tilde{\varphi}\in H^2(\mathbb{R}^3)$ such that

$$\tilde{\varphi}=\varphi \quad \text{in } \mathcal{O}\setminus\bar{\mathcal{D}} \quad \text{and} \quad \|\tilde{\varphi}\|_{2,\mathbb{R}^3}\le C\|\varphi\|_{2,\mathcal{O}\setminus\bar{\mathcal{D}}}\le C\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\mathcal{D})}. \tag{2.12}$$

This completes the proof for the case when D is a Lipschitz domain by setting $\psi=\varphi-\tilde{\varphi}\in H_0^1(D)$ and $\mathbf{v}_s=\mathbf{w}+\nabla\tilde{\varphi}\in\mathbf{H}_0^1(\mathcal{D})$, since $\mathbf{v}_s=\tilde{\mathbf{v}}=\mathbf{0}$ in $\mathcal{O}\setminus\bar{\mathcal{D}}$.

If $\mathcal{D}$ has a Lipschitz screen $\mathcal{F}\subset D$ such that $\partial\mathcal{D}=\Gamma\cup\mathcal{F}$ and $\Gamma\cap\mathcal{F}=\emptyset$, we choose a closed C^2-smooth surface $\mathcal{F}_0\supset\mathcal{F}$ such that $\mathcal{F}_0\cap\partial\bar{\mathcal{D}}=\emptyset$. In view of (2.9), we know that $\nabla_{\mathcal{F}}\varphi=(\nu\times\nabla\varphi)\times\nu=\nu\times(\nu\times\mathbf{w})\in\mathbf{H}^{1/2}(\mathcal{F})$, and thus $\varphi|_{\mathcal{F}}\in H^{3/2}(\mathcal{F})$, where [22, p. 20]

$$H^{m+1/2}(\mathcal{F})=\{v\in L^2(\mathcal{F})\,:\,\|v\|_{m+1/2,\mathcal{F}}<\infty\},\quad m=0,1,$$
$$\|v\|^2_{m+1/2,\mathcal{F}}=\|v\|^2_{m,\mathcal{F}}+\int_{\mathcal{F}}\int_{\mathcal{F}}\frac{|\nabla_{\mathcal{F}}v(x)-\nabla_{\mathcal{F}}v(y)|^2}{|x-y|^3}ds_xds_y,\quad m=0,1.$$

Here $H^{3/2}(\mathcal{F}_0)$ is defined similarly. Since any function in $H^{3/2}(D_1)$ can be continuously extended to be a function in $H^{3/2}(\mathbb{R}^3)$ for any Lipschitz bounded domain $D_1\subset\mathbb{R}^3$ [22, Theorem 1.4.3.1, p. 25], we know that $\varphi|_{\mathcal{F}}$ can be extended continuously to be a function in $H^{3/2}(\mathcal{F}_0)$ by working on the atlas of the C^2-smooth manifold $\mathcal{F}_0$. We denote the extension by $\varphi_{\mathcal{F}}\in H^{3/2}(\mathcal{F}_0)$ which satisfies, by (2.8) and (2.11),

$$\varphi_{\mathcal{F}}=\varphi \quad \text{on } \mathcal{F}, \tag{2.13}$$
$$\|\varphi_{\mathcal{F}}\|_{3/2,\mathcal{F}_0}\le C\|\varphi\|_{3/2,\mathcal{F}}\le C(\|\varphi\|_{1,\mathcal{O}}+\|\mathbf{w}\|_{1,\mathcal{O}})\le C\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\mathcal{D})}. \tag{2.14}$$

Since $\tilde{\varphi}\in H^2(\mathbb{R}^3)$, we have $\tilde{\varphi}\in H^{3/2}(\mathcal{F}_0)$. Thus $\varphi_{\mathcal{F}}-\tilde{\varphi}\in H^{3/2}(\mathcal{F}_0)$, which we may extend to be a function $\varphi_0\in H_0^2(D)$ satisfying

$$\varphi_0=\varphi_{\mathcal{F}}-\tilde{\varphi} \quad \text{on } \mathcal{F} \quad \text{and} \quad \|\varphi_0\|_{2,D}\le C\|\varphi_{\mathcal{F}}-\tilde{\varphi}\|_{3/2,\mathcal{F}_0}\le C\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\mathcal{D})}, \tag{2.15}$$

where we have used (2.12)–(2.14). Define $\psi:=\varphi-\tilde{\varphi}-\varphi_0\in H_0^1(\mathcal{D})$ and $\mathbf{v}_s:=\mathbf{w}+\nabla\tilde{\varphi}+\nabla\varphi_0\in\mathbf{H}^1(\mathcal{D})\cap\mathbf{H}_0(\mathbf{curl};\,\mathcal{D})$. Combining (2.8), (2.12), and (2.15) leads to (2.5) and (2.6). ∎

THEOREM 2.4. Ω … $\partial\Omega=\Sigma\cup\Gamma$ … (i)–(iii) … 2.2 … $\mathbf{v}\in\mathbf{H}(\mathbf{curl};\,\Omega)$ … $\mathbf{v}\times\nu=0$ … Γ … $\mathbf{v}_s\in\mathbf{H}^1(\Omega)$ … $\mathbf{v}_s\times\nu=0$ … Γ … $\varphi\in H^1_\Gamma(\Omega)$ …

$$\mathbf{v}=\nabla\varphi+\mathbf{v}_s \quad \text{in } \Omega, \tag{2.16}$$
$$\|\mathbf{v}_s\|_{1,\Omega}+\|\varphi\|_{1,\Omega}\le C\,\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\Omega)}. \tag{2.17}$$

… For case (iii) in Hypothesis 2.2, Theorem 2.4 follows directly from Theorem 2.3. For case (i), $\Gamma=\partial D$ with D being a bounded Lipschitz domain and $\bar{D}$ embedded in the interior of $\Omega\cup\bar{D}$. Let $\mathcal{O}$ be a ball containing Ω. Extend $\mathbf{v}$ by zero to D such that the extension $\tilde{\mathbf{v}}\in\mathbf{H}(\mathbf{curl};\,\Omega\cup\bar{D})$. By Lemma 2.2 of [13], we may extend $\tilde{\mathbf{v}}$ to the exterior of $\Omega\cup\bar{D}$ such that the extension $E\,\tilde{\mathbf{v}}\in\mathbf{H}_0(\mathbf{curl};\,\mathcal{O})$ and

$$E\,\tilde{\mathbf{v}}=\tilde{\mathbf{v}} \quad \text{in } \Omega\cup\bar{D},$$
$$\|E\,\tilde{\mathbf{v}}\|_{\mathbf{H}(\mathbf{curl};\,\mathcal{O})}\le C\,\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\Omega)},$$

where C depends only on Ω. Since $E\,\tilde{\mathbf{v}}\in\mathbf{H}_0(\mathbf{curl};\,\mathcal{O}\setminus\bar{D})$, by Theorem 2.3, there exist $\varphi\in H_0^1(\mathcal{O}\setminus\bar{D})$ and $\mathbf{v}_s\in\mathbf{H}^1(\mathcal{O}\setminus\bar{D})\cap\mathbf{H}_0(\mathbf{curl};\mathcal{O}\setminus\bar{D})$ such that

$$E\,\tilde{\mathbf{v}}=\nabla\varphi+\mathbf{v}_s \quad \text{in } \mathcal{O}\setminus\bar{D},$$
$$\|\varphi\|_{1,\mathcal{O}\setminus\bar{D}}+\|\mathbf{v}_s\|_{1,\mathcal{O}\setminus\bar{D}}\le C\|E\,\tilde{\mathbf{v}}\|_{\mathbf{H}(\mathbf{curl};\,\mathcal{O}\setminus\bar{D})}\le C\,\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\Omega)},$$

where the constant C depends only on Ω. Clearly, φ and $\mathbf{v}_s$ match all requirements in Theorem 2.4. Case (ii) can be proved similarly using Theorem 2.3. □

REMARK 2.5. The decompositions in Theorems 2.3 and 2.4 extend the so-called Birman–Solomyak decomposition of $H_0(\mathbf{curl};\Omega)$ in [8], [19], and [29].

Let $\mathcal{T}_k$ be a sequence of tetrahedral triangulations of Ω, and let $\mathcal{F}_k$ be the set of faces not lying on Γ, $k \geq 0$. The finite element space $\mathbf{U}_k$ over $\mathcal{T}_k$ is defined by [28]

$$\begin{aligned}\mathbf{U}_k :=\{&\mathbf{u} \in \mathbf{H}(\mathbf{curl};\Omega) \ : \ \mathbf{u}\times\nu|_\Gamma = \mathbf{0} \quad \text{and} \\ &\mathbf{u}|_T = \mathbf{a}_T + \mathbf{b}_T \times \mathbf{x} \quad \text{with} \quad \mathbf{a}_T,\, \mathbf{b}_T \in \mathbb{R}^3 \quad \forall\, T \in \mathcal{T}_k\big\}.\end{aligned}$$

Degrees of freedom on every $T \in \mathcal{T}_k$ are $\int_{E_i} \mathbf{u}\cdot d\,\mathbf{l}$, $i = 1,\ldots,6$, where $E_1,\ldots,E_6$ are six edges of T. For any $T \in \mathcal{T}_k$ and $F \in \mathcal{F}_k$, we denote the diameters of T and F by h_T and h_F, respectively.

The finite element approximation to (2.1) is to find $\mathbf{E}_k \in \mathbf{U}_k$ such that

$$a(\mathbf{E}_k,\,\mathbf{v}) = \int_\Omega \mathbf{f}\cdot\overline{\mathbf{v}} + \int_\Sigma \mathbf{g}\cdot\overline{\mathbf{v}}_t \quad \forall\,\mathbf{v} \in \mathbf{U}_k. \tag{2.18}$$

3. Residual-based a posteriori error estimates. Let $\mathbf{E}$ and $\mathbf{E}_k$ be the solutions of (2.1) and (2.18), respectively. Define the total error function by $\mathbf{e}_k := \mathbf{E} - \mathbf{E}_k$. By (2.3), we know that

$$\|\mathbf{e}_k\|_{\mathbf{H}_\Gamma(\mathbf{curl};\Omega)} \leq \beta^{-1} \sup_{\mathbf{v}\in\mathbf{H}_\Gamma(\mathbf{curl};\Omega)} \frac{a(\mathbf{e}_k,\,\mathbf{v})}{\|\mathbf{v}\|_{\mathbf{H}_\Gamma(\mathbf{curl};\Omega)}}. \tag{3.1}$$

To derive a posteriori error estimates, we introduce the Scott–Zhang operator $\mathcal{I}_k : H^1_\Gamma(\Omega) \to V_k$ [32] and the Beck–Hiptmair–Hoppe–Wohlmuth operator $\Pi_k : \mathbf{H}^1(\Omega) \cap \mathbf{H}_\Gamma(\mathbf{curl};\Omega) \to \mathbf{U}_k$ [6], where V_k is the piecewise linear H^1_Γ-conforming finite element space over $\mathcal{T}_k$ defined by

$$V_k := \big\{v \in H^1_\Gamma(\Omega) \ : \ v|_T = a_T + \mathbf{b}_T\cdot\mathbf{x} \text{ with } a_T \in \mathbb{R}^1 \text{ and } \mathbf{b}_T \in \mathbb{R}^3 \ \forall\, T \in \mathcal{T}_k\big\}. \tag{3.2}$$

$\mathcal{I}_k$ and Π_k satisfy the following approximation and stability properties: For any $T \in \mathcal{T}_k$, $F \in \mathcal{F}_k$,

$$\begin{cases} \mathcal{I}_k\phi_h = \phi_h & \forall\,\phi_h \in V_k, \\ \|\nabla\mathcal{I}_k\phi\|_{0,T} \ \leq \ C\,|\phi|_{1,D_T}, \\ \|\phi - \mathcal{I}_k\phi\|_{0,T} \ \leq \ C\,h_T\,|\phi|_{1,D_T}, \\ \|\phi - \mathcal{I}_k\phi\|_{0,F} \ \leq \ C\,h_F^{1/2}\,|\phi|_{1,D_F} \end{cases} \tag{3.3}$$

and

$$\begin{cases} \Pi_k\mathbf{w}_h = \mathbf{w}_h & \forall\,\mathbf{w}_h \in \mathbf{U}_k, \\ \|\Pi_k\mathbf{w}\|_{\mathbf{H}(\mathbf{curl};T)} \ \leq \ C\,\|\mathbf{w}\|_{1,D_T}, \\ \|\mathbf{w} - \Pi_k\mathbf{w}\|_{0,T} \ \leq \ C\,h_T\,|\mathbf{w}|_{1,D_T}, \\ \|\mathbf{w} - \Pi_k\mathbf{w}\|_{0,F} \ \leq \ C\,h_F^{1/2}\,|\mathbf{w}|_{1,D_F}, \end{cases} \tag{3.4}$$

where D_A is the union of elements in $\mathcal{T}_k$ with nonempty intersection with A, $A = T$ or F. In (3.3) and (3.4), the constant C depends on the ratio of the diameter of T to the diameter of the maximal ball contained in T. In the procedure of mesh refinements used in ALBERT [30], [31], each element is similar to one of a small

number of reference tetrahedra in shape. Thus C in (3.3)–(3.4) is bounded in the refinement procedure.

By Theorem 2.4, for any $\mathbf{v} \in \mathbf{H}_\Gamma(\mathbf{curl};\,\Omega)$ there exist a $\varphi \in H^1_\Gamma(\Omega)$ and a $\mathbf{v}_s \in \mathbf{H}^1(\Omega) \cap \mathbf{H}_\Gamma(\mathbf{curl};\,\Omega)$ such that

$$\mathbf{v} = \nabla\varphi + \mathbf{v}_s, \tag{3.5}$$

$$\|\varphi\|_{1,\Omega} + \|\mathbf{v}_s\|_{1,\Omega} \le C\,\|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\Omega)}, \tag{3.6}$$

where the constant C depends only on Ω. Since $\nabla\mathcal{I}_k\varphi$ and $\Pi_k\mathbf{v}_s$ belong to $\mathbf{U}_k$, by the Galerkin orthogonality, we have

$$a(\mathbf{e}_k,\,\mathbf{v}) = a(\mathbf{e}_k,\,\nabla\varphi - \nabla\mathcal{I}_k\varphi) + a(\mathbf{e}_k,\,\mathbf{v}_s - \Pi_k\mathbf{v}_s) \quad \forall\,\mathbf{v} \in \mathbf{H}_\Gamma(\mathbf{curl};\,\Omega). \tag{3.7}$$

For any face $F \in \mathcal{F}_k$, assuming that $F = T_1 \cap T_2,\ T_1,\ T_2 \in \mathcal{T}_k$, and the unit normal ν points from T_2 to T_1, we denote the jump of a function v across F by $[v]_F := v|_{T_1} - v|_{T_2}$.

LEMMA 3.1. [illegible] $\mathbf{g} \in \mathbf{L}^2(\Sigma)$ [illegible] $\operatorname{div}_\Sigma \mathbf{g} \in L^2(\Sigma)$ [illegible] $\mathbf{g}\cdot\nu = 0$ [illegible] Σ [illegible] [illegible] C_0 [illegible] [illegible] κ [illegible] [illegible] $\mathcal{T}_k$ [illegible]

$$a(\mathbf{e}_k,\,\nabla\varphi - \nabla\mathcal{I}_k\varphi) \le C_0 \left(\sum_{T\in\mathcal{T}_k} \eta_{0,T}^2 + \sum_{F\in\mathcal{F}_k} \eta_{0,F}^2 + \sum_{F\subset\Sigma} \eta_{0,\Sigma,F}^2 \right)^{1/2} \|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\Omega)}, \tag{3.8}$$

[illegible] $\operatorname{div}_\Sigma$ [illegible] Σ [illegible] [illegible] L^2 [illegible] [illegible] $\nabla_\Sigma := -\nu\times(\nu\times\nabla)$ [illegible]

$$\eta_{0,T} := h_T\,\|\operatorname{div}(\kappa^2\varepsilon_r\,\mathbf{E}_k)\|_{0,T},$$

$$\eta_{0,F} := h_F^{1/2}\,\|[\kappa^2\varepsilon_r\,\mathbf{E}_k\cdot\nu]_F\|_{0,F},$$

$$\eta_{0,\Sigma,F} := h_F^{1/2}\|\operatorname{div}_\Sigma(\mathbf{g} + \mathbf{i}\,\kappa\,\lambda\,\mathbf{E}_{k,t})\|_{0,F}.$$

[illegible] Since the tangential field $\mathbf{E}_{k,t}$ is continuous on Σ and piecewise linear, $\mathbf{E}_{k,t} \in \mathbf{H}(\operatorname{div}_\Sigma;\,\Sigma)$. In view of $\mathbf{f}$ being divergence-free, by (2.1) and the formula of integration by parts, we deduce that

$$\begin{aligned}
&a(\mathbf{e}_k,\,\nabla\,\varphi - \nabla\,\mathcal{I}_k\varphi)\\
&\quad= (\mathbf{f} + \kappa^2\varepsilon_r\,\mathbf{E}_k,\,\nabla\,\varphi - \nabla\,\mathcal{I}_k\varphi) + \int_\Sigma (\mathbf{g} + \mathbf{i}\,\kappa\,\lambda\,\mathbf{E}_{k,t})\cdot\nabla_\Sigma\overline{(\varphi - \mathcal{I}_k\varphi)}\\
&\quad= -\sum_{T\in\mathcal{T}_k}\int_T \operatorname{div}(\kappa^2\varepsilon_r\,\mathbf{E}_k)\overline{(\varphi - \mathcal{I}_k\varphi)} + \sum_{F\in\mathcal{F}_k}\int_F [\kappa^2\varepsilon_r\,\mathbf{E}_k\cdot\nu]_F\,\overline{(\varphi - \mathcal{I}_k\varphi)}\\
&\qquad\qquad - \sum_{F\subset\Sigma}\int_F \operatorname{div}_\Sigma(\mathbf{g} + \mathbf{i}\,\kappa\,\lambda\,\mathbf{E}_{k,t})\,\overline{(\varphi - \mathcal{I}_k\varphi)}\\
&\quad\le \sum_{T\in\mathcal{T}_k} \|\operatorname{div}(\kappa^2\varepsilon_r\,\mathbf{E}_k)\|_{0,T}\|\varphi - \mathcal{I}_k\varphi\|_{0,T} + \sum_{F\in\mathcal{F}_k} \|[\kappa^2\varepsilon_r\,\mathbf{E}_k\cdot\nu]_F\|_{0,F}\|\varphi - \mathcal{I}_k\varphi\|_{0,F}\\
&\qquad\qquad + \sum_{F\subset\Sigma} \|\operatorname{div}_\Sigma(\mathbf{g} + \mathbf{i}\,\kappa\,\lambda\,\mathbf{E}_{k,t})\|_{0,F}\|\varphi - \mathcal{I}_k\varphi\|_{0,F}.
\end{aligned}$$

We reach (3.8) by virtue of Schwartz's inequality, (3.3), and (3.6). □

LEMMA 3.2. [illegible] [illegible] C_1 [illegible] [illegible] κ [illegible] [illegible] $\mathcal{T}_k$ [illegible]

$$a(\mathbf{e}_k,\,\mathbf{v}_s - \Pi_k\mathbf{v}_s) \le C_1 \left(\sum_{T\in\mathcal{T}_k} \eta_{1,T}^2 + \sum_{F\in\mathcal{F}_k} \eta_{1,F}^2 + \sum_{F\subset\Sigma} \eta_{1,\Sigma,F}^2 \right)^{1/2} \|\mathbf{v}\|_{\mathbf{H}(\mathbf{curl};\,\Omega)}, \tag{3.9}$$

$$\eta_{1,T} = h_T\|\mathbf{f} + \kappa^2\varepsilon_r\,\mathbf{E}_k - \mathbf{curl}(\mu_r^{-1}\mathbf{curl}\,\mathbf{E}_k)\|_{0,T},$$
$$\eta_{1,F} = h_F^{1/2}\|[\mu_r^{-1}\,\mathbf{curl}\,\mathbf{E}_k \times \nu]_F\|_{0,F},$$
$$\eta_{1,\Sigma,F} = h_F^{1/2}\|\mathbf{g} + \mathbf{i}\,\kappa\,\lambda\,\mathbf{E}_{k,t} + \nu \times \mu_r^{-1}\,\mathbf{curl}\,\mathbf{E}_k\|_{0,F}.$$

. By (2.1) and the formula of integration by parts, we deduce that

$$\begin{aligned}
&a(\mathbf{e}_k,\, \mathbf{v}_s - \Pi_k\mathbf{v}_s)\\
&\quad= \sum_{T\in\mathcal{T}_k}\int_T (\mathbf{f} + \kappa^2\varepsilon_r\,\mathbf{E}_k - \mathbf{curl}\mu_r^{-1}\mathbf{curl}\,\mathbf{E}_k)\cdot\overline{(\mathbf{v}_s - \Pi_k\mathbf{v}_s)}\\
&\qquad+ \sum_{F\in\mathcal{F}_k}\int_F [\nu\times\mu_r^{-1}\,\mathbf{curl}\,\mathbf{E}_k]_F\cdot\overline{(\mathbf{v}_s - \Pi_k\mathbf{v}_s)}\\
&\qquad+ \sum_{F\subset\Sigma}\int_F (\mathbf{g} + \mathbf{i}\,\kappa\,\lambda\,\mathbf{E}_{k,t} + \nu\times\mu_r^{-1}\,\mathbf{curl}\,\mathbf{E}_k)\cdot\overline{(\mathbf{v}_s - \Pi_k\mathbf{v}_s)}\\
&\quad\le \sum_{T\in\mathcal{T}_k}\|\mathbf{f} + \kappa^2\varepsilon_r\,\mathbf{E}_k - \mathbf{curl}\mu_r^{-1}\mathbf{curl}\,\mathbf{E}_k\|_{0,T}\|\mathbf{v}_s - \Pi_k\mathbf{v}_s\|_{0,T}\\
&\qquad+ \sum_{F\in\mathcal{F}_k}\|[\mu_r^{-1}\,\mathbf{curl}\,\mathbf{E}_k\times\nu]_F\|_{0,F}\|\mathbf{v}_s - \Pi_k\mathbf{v}_s\|_{0,F}\\
&\qquad+ \sum_{F\subset\Sigma}\int_F \|\mathbf{g} + \mathbf{i}\,\kappa\,\lambda\,\mathbf{E}_{k,t} + \nu\times\mu_r^{-1}\,\mathbf{curl}\,\mathbf{E}_k\|_{0,F}\,\|\mathbf{v}_s - \Pi_k\mathbf{v}_s\|_{0,F}.
\end{aligned}$$

We reach (3.9) by Schwartz's inequality, (3.4), and (3.6). □

Combining (3.1) and (3.7)–(3.9) leads to the following theorem.

THEOREM 3.3. . $\mathbf{g}\in\mathbf{L}^2(\Sigma)$, $\mathrm{div}_\Sigma\,\mathbf{g}\in L^2(\Sigma)$, $\mathbf{g}\cdot\nu = 0$ Σ .

$$\|\mathbf{e}_k\|^2_{\mathbf{H}_\Gamma(\mathbf{curl};\,\Omega)} \le \frac{2(C_0^2 + C_1^2)}{\beta^2}\sum_{i=0}^{1}\left\{\sum_{T\in\mathcal{T}_k}\eta_{i,T}^2 + \sum_{F\in\mathcal{F}_k}\eta_{i,F}^2 + \sum_{F\subset\Sigma}\eta_{i,\Sigma,F}^2\right\},$$

. β C_0 , C_1 . . , (2.3) (3.8) , (3.9)

Similar to the argument in [6, section 5], we can prove the following lower bound estimates.

THEOREM 3.4. . , μ_r ε_r , λ . , , . C , , μ_r ε_r λ , κ . , , . $\mathcal{T}_k$.

$$\begin{aligned}
(3.10)\qquad &\sum_{T\in\mathcal{T}_k}\left(\eta_{0,T}^2 + \eta_{1,T}^2\right) + \sum_{F\in\mathcal{F}_k}\left(\eta_{0,F}^2 + \eta_{1,F}^2\right) + \sum_{F\subset\Sigma}\left(\eta_{0,\Sigma,F}^2 + \eta_{1,\Sigma,F}^2\right)\\
&\le C\,\|\mathbf{e}_k\|^2_{\mathbf{H}(\mathbf{curl};\,\Omega)} + C\sum_{T\in\mathcal{T}_k}h_T^2\|\mathbf{f} - \mathcal{P}_T\mathbf{f}\|_{0,T}^2 + C\sum_{F\subset\Sigma}h_F\|\mathrm{div}_\Sigma(\mathbf{g} - \mathcal{P}^F_{\mathrm{div}}\,\mathbf{g})\|_{0,F}^2\\

4. Multigrid preconditioned MINRES algorithm. In this section we introduce our preconditioned MINRES (PMINRES) algorithm for solving (2.18). Our preconditioner is a multigrid solver of the stiffness matrix corresponding to the following coercive and Hermitian sesquilinear form on $\mathbf{U}_k$:

$$a_{mg}(\mathbf{u},\,\mathbf{v}) := (\mu_r^{-1}\,\mathbf{curl}\,\mathbf{u},\,\mathbf{curl}\,\mathbf{v}) + (\kappa^2\,|\varepsilon_r|\,\mathbf{u},\,\mathbf{v}) + \int_\Sigma \kappa\,\lambda\,\mathbf{u}_t\cdot\bar{\mathbf{v}}_t\,. \tag{4.1}$$

It is easy to see that $a_{mg}(\cdot,\,\cdot)$ is the sesquilinear form corresponding to the variational formulation of (1.4)–(1.6).

Let $\mathcal{T}_0,\cdots,\mathcal{T}_J$ be a sequence of nested triangulations by repeated adaptive refinements. Let $\mathbf{U}_k$ be the finite element space in (2.18) and V_k be the linear Lagrangian finite element space in (3.2) over $\mathcal{T}_k$. Denote the canonical basis of $\mathbf{U}_k$ by $\left\{\mathbf{w}_1^{(k)},\cdots,\mathbf{w}_{n_k}^{(k)}\right\}$ and the canonical basis of V_k by $\left\{\phi_1^{(k)},\cdots,\phi_{\bar{n}_k}^{(k)}\right\}$, where n_k and $\bar{n}_k$ are, respectively, the numbers of edges and vertices not on Γ.

We now specify the local multigrid algorithm for the solution of the following algebraic system of equations:

$$A_k\,X_k = F_k, \tag{4.2}$$

where $A_k = \left(a_{mg}\big(\mathbf{w}_i^{(k)},\,\mathbf{w}_j^{(k)}\big)\right)_{n_k\times n_k}$. The algorithm is based on the following space decomposition proposed in [7]:

$$\mathbf{U}_J = \mathbf{U}_0 + \sum_{k=1}^{J}\sum_{E\in\mathcal{E}_k^{\rm new}} \mathrm{span}\,\{\mathbf{w}_E\} + \sum_{k=1}^{J}\sum_{a\in\mathcal{V}_k^{\rm new}} \mathrm{span}\,\{\nabla\phi_a\}\,, \tag{4.3}$$

where $\mathcal{E}_k^{\rm new}$ and $\mathcal{V}_k^{\rm new}$ are, respectively, the set of edges and the set of vertices in new elements of $\mathcal{T}_k$. None of the edges and vertices in (4.3) is on Γ. The algorithm of multigrid V-cycle is defined recursively as follows.

ALGORITHM 4.1. Multigrid V-cycle:

MGsolver(A_J, F_J, m)
{
  Given initial guess $\mathcal{X}_0$
  For $l = 0\ :\ m-1$
    $\mathcal{X}_{l+1} \leftarrow$ MG(J, A_J, F_J, $\mathcal{X}_l$)

  return $\mathcal{X}_m$
}
MG(j, A_j, f, x), $j = 0,\cdots,J$ recursively defined by
{
  if ($j = 0$)
    return $A_0^{-1}f$
  else
  {
    $x \leftarrow$ GSsmooth(A_j, f, x) [Pre-smoothing]
    $y \leftarrow$ MG($j-1$, A_{j-1}, $\mathcal{R}_j^{j-1}(f - A_j\,x)$, 0)
    $x \leftarrow x + \mathcal{I}_{j-1}^{j}\,y$
    $x \leftarrow$ GSsmooth(A_j, f, x) [Post-smoothing]
  }
}

In Algorithm 4.1, $\mathcal{I}_{j-1}^{j}$ is an $n_j \times n_{j-1}$ matrix reflecting the identical embedding $\mathbf{U}_{j-1} \hookrightarrow \mathbf{U}_j$ such that

$$\sum_{i=1}^{n_{j-1}} y_i \mathbf{w}_i^{(j-1)} = \sum_{i=1}^{n_j} \left(\mathcal{I}_{j-1}^{j}\, y\right)_i \mathbf{w}_i^{(j)} .$$

We choose the restriction matrix $\mathcal{R}_j^{j-1}$ to be the transpose of $\mathcal{I}_{j-1}^{j}$, that is, $\mathcal{R}_j^{j-1} = \left(\mathcal{I}_{j-1}^{j}\right)^T$. Define $A_{j,\nabla} = \left(a_{mg}(\nabla\phi_m^{(j)}, \nabla\phi_n^{(j)})\right)_{\bar{n}_j \times \bar{n}_j}$ and $\mathcal{I}_V^E$ to be an $n_j \times \bar{n}_j$ matrix reflecting the identical embedding $\nabla V_j \hookrightarrow \mathbf{U}_j$ such that

$$\sum_{i=1}^{\bar{n}_j} y_i \nabla\phi_i^{(j)} = \sum_{i=1}^{n_j} \left(\mathcal{I}_V^E\, y\right)_i \mathbf{w}_i^{(j)} .$$

GSsmooth(A_j, f, x) is the Gauß–Seidel iterations on level j with initial guess x.

ALGORITHM 4.2. Gauß–Seidel sweeping:

GSsmooth(A_j, f, x)
{
  Gauß–Seidel sweep on DOFs of $A_j\, x = f$ related to $\mathcal{E}_j^{\text{new}}$
  $y \leftarrow f - A_j\, x$
  $y_\nabla \leftarrow (\mathcal{I}_V^E)^T\, y$
  $x_\nabla \leftarrow 0$
  Gauß–Seidel sweep on DOFs of $A_{j,\nabla}\, x_\nabla = y_\nabla$ related to $\mathcal{V}_j^{\text{new}}$
  return $x + \mathcal{I}_V^E\, x_\nabla$
}

5. Adaptive algorithm and numerical results. The implementation of our adaptive algorithm is based on the adaptive finite element package ALBERT [30], [31] and is carried out on Origin 3800. We define the local a posteriori error estimator over an element $T \in \mathcal{T}_h$ by

$$\eta_T := \left\{ \eta_{0,T}^2 + \eta_{1,T}^2 + \frac{1}{2} \sum_{F \subset \partial T} (\eta_{0,F}^2 + \eta_{1,F}^2 + \eta_{0,\Sigma,F}^2 + \eta_{1,\Sigma,F}^2) \right\}^{1/2}$$

and define the global a posteriori error estimate and the maximal element error estimate over $\mathcal{T}_h$, respectively, by

$$\eta_h := \left(\sum_{T \in \mathcal{T}_h} \eta_T^2 \right)^{1/2}, \qquad \eta_{\max} = \max_{T \in \mathcal{T}_h} \eta_T. \tag{5.1}$$

Now we describe the adaptive algorithm used in this paper.

ALGORITHM 5.1. Given a tolerance $Tol > 0$ and the initial mesh $\mathcal{T}_0$, set $\mathcal{T}_h = \mathcal{T}_0$.

(I) Solve the discrete problem (2.18) on $\mathcal{T}_0$.

(II) Compute the local error estimator η_T on each $T \in \mathcal{T}_0$, the global error estimate η_h, and the maximal element error estimate $\eta_{\max}$.

(III) While $\eta_h > Tol$ do

- Refine the mesh $\mathcal{T}_h$ according to the following strategy:

  if $\eta_T > \frac{3}{5}\eta_{\max}$, refine the element $T \in \mathcal{T}_h$.

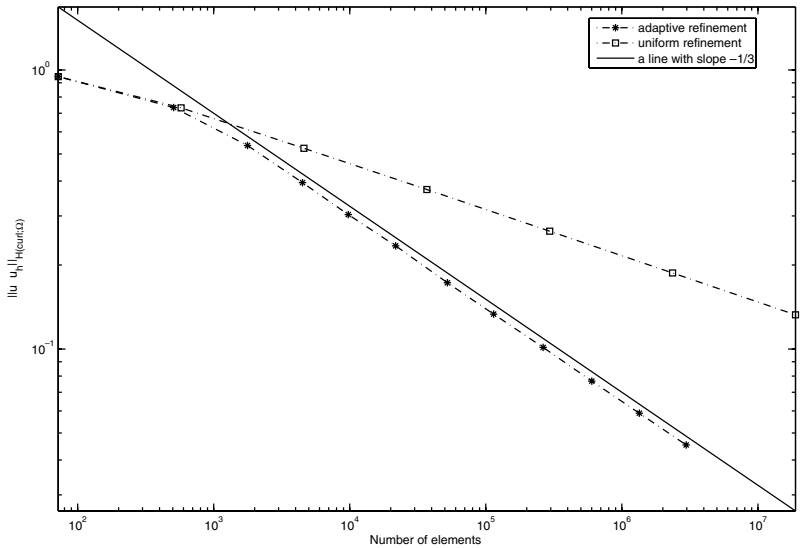

FIG. 5.1. *Quasi optimality of the adaptive mesh refinements of the error* $\|\mathbf{u}-\mathbf{u}_h\|_{\mathbf{H(curl;}\,\Omega)}$ (*Example* 5.1).

- Solve the discrete problem (2.18) on $\mathcal{T}_h$.
- Compute the local error estimator η_T on each $T \in \mathcal{T}_h$, the global error estimate η_h, and the maximal element error estimate $\eta_{\max}$.

end while.

In the following, we report several numerical experiments to demonstrate the competitive behavior of the proposed algorithm. In our PMINRES solver, we use only one step of local multigrid iteration and one Gauß–Seidel sweep for pre- and postsmoothing.

5.1. We consider the Maxwell equation (1.1) on the three-dimensional "L-shaped" domain $\Omega = (-1,\,1)^3 \setminus \{(0,\,1)\times(-1,\,0)\times(-1,\,1)\}$. Let $\mu_r = \kappa^2\varepsilon_r = 1$ and $\Gamma = \partial\Omega$. The nondimensional wavelength is $2\pi/(\kappa \mathrm{diam}(\Omega)) = \pi/\sqrt{3}$, since the diameter of Ω is $2\sqrt{3}$. The Dirichlet boundary condition and the source $\mathbf{f}$ are so chosen that the exact solution is $\mathbf{E} := \nabla\left\{r^{1/2}\sin(\phi/2)\right\}$ in cylindrical coordinates.

Figure 5.1 shows the curves of $\log\|\mathbf{E}-\mathbf{E}_k\|_{\mathbf{H(curl;}\,\Omega)}$ versus $\log N_k$, where N_k is the number of elements and $\mathbf{E}_k$ is the finite element solution of (2.18) over the mesh $\mathcal{T}_k$. Figure 5.2 shows the $\log\eta_k$–$\log N_k$ curves, where η_k is the associated a posteriori error estimate over $\mathcal{T}_k$ defined in Theorem 3.3. They indicate that the adaptive meshes and the associated numerical complexity are quasi-optimal; i.e.,

$$\eta_k = C\,N_k^{-1/3} \qquad \text{and} \tag{5.2}$$

$$\|\mathbf{E}-\mathbf{E}_k\|_{\mathbf{H(curl;}\,\Omega)} = C\,N_k^{-1/3} \tag{5.3}$$

are valid asymptotically. They also clearly show the advantage of the adaptive method compared with the uniform refinements.

Table 5.1 shows the numbers of PMINRES iterations required to reduce the initial residual by a factor of 10^{-8} on different levels. We observe that the PMINRES algorithm converges in very few steps with the number of degrees of freedom varying from 722 to 1,616,983. Figure 5.3 shows the CPU time versus the number of degrees of freedom on different adaptive meshes.

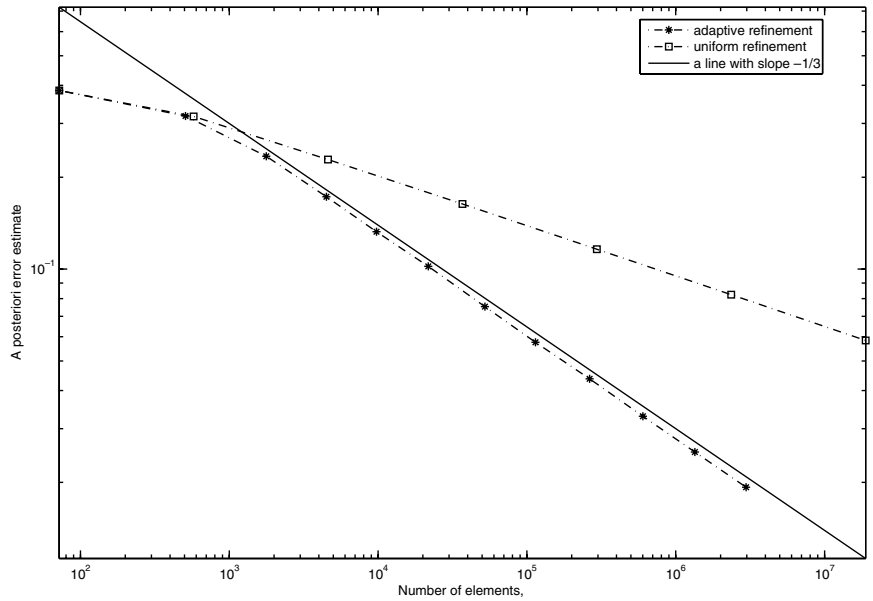

FIG. 5.2. *Quasi optimality of the adaptive mesh refinements of the a posteriori error estimate* (*Example* 5.1).

TABLE 5.1
The number of PMINRES iterations (N_{itrs}) *required to reduce the initial residual by a factor* 10^{-8} (*Example* 5.1).

Level	1	3	5	7	8	9	10
DOFs	722	5668	26810	138667	319360	725217	1616983
N_{itrs}	5	6	6	7	7	8	8

Figure 5.4 shows an adaptive mesh of 18,874,368 elements after 12 adaptive iterations. We observe that the mesh is locally refined near the corner line $x_1 = x_2 = 0$, where the solution is singular.

5.2. We consider a time-harmonic problem containing an inner screen $\Gamma := \{(x, y, z) : -0.5 \le x, z \le 0.5,\ y = 0\}$. We define $\Omega = (-1, 1)^3 \setminus \Gamma$ and $\Sigma = \partial\Omega \setminus \Gamma$. We set $\mu_r = \varepsilon_r = \lambda = 1$ in (1.1) and (1.2) and define

$$\mathbf{f} := \mathbf{0}, \qquad \mathbf{g} := \mathbf{curl}\,\mathbf{E}_i \times \nu - \mathbf{i}\,\kappa\,\mathbf{E}_{i,t},$$

where $\mathbf{E}_i = (e^{\mathbf{i}\,y}, 0, e^{\mathbf{i}\,y})^T/\sqrt{2}$ is perpendicular to the perfect conducting "screen." Thus (1.1)–(1.3) model the scattering by Γ under the incident field $\mathbf{E}_i$. In this case, only $\mathbf{H}^s$-regularity ($s < 1/2$) of the solution is guaranteed.

In this experiment, we test the performance of the a posteriori error estimate and the preconditioned MINRES algorithm under different frequencies, i.e., $\kappa^2 = 1$, 1.5, 10, 20, 36, 64, 100 in (1.1). The nondimensional wavelength here is $\pi/(\sqrt{3}\,\pi)$. Figures 5.5–5.7 show the results for $\kappa = 1$ in (1.1) and (1.2), while Figures 5.8 and 5.9 show the result for $\kappa > 1$.

Figure 5.5 shows the $\log \eta_k$–$\log N_k$ curves and indicates that the adaptive meshes and the associated numerical complexity are quasi-optimal and (5.2) is valid asymptotically. It also clearly shows the advantage of the adaptive method compared with the uniform refinements.

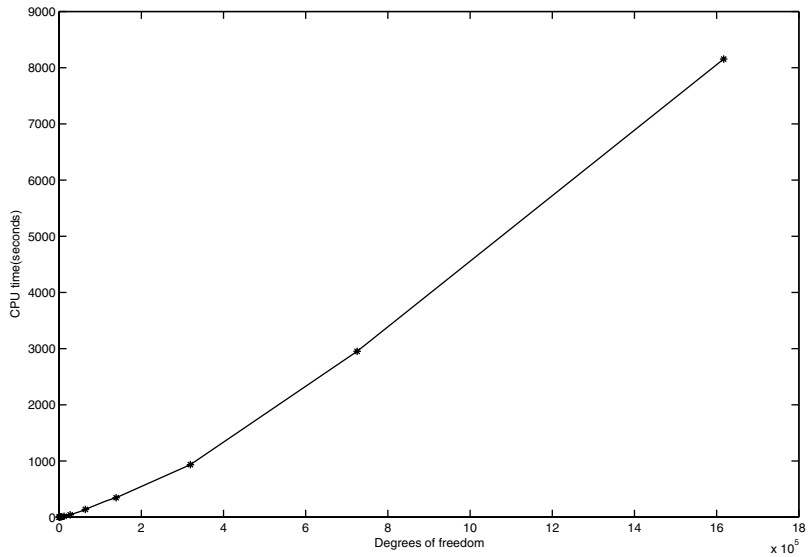

FIG. 5.3. *CPU time for PMINRES iterations on adaptively refined grids* (*Example* 5.1).

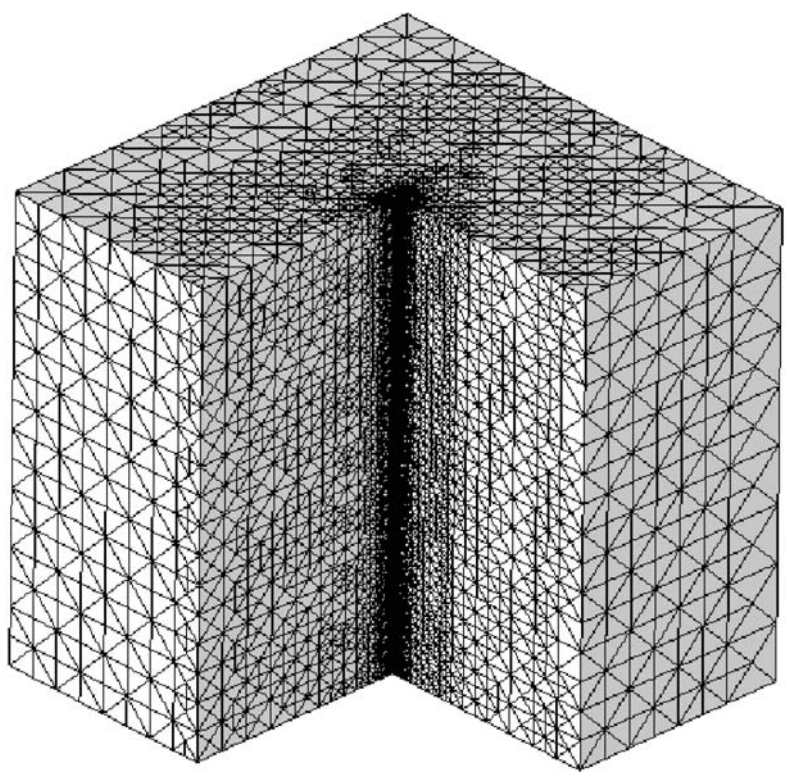

FIG. 5.4. *An adaptively refined mesh of* 18,874,368 *elements after* 12 *adaptive iterations* (*Example* 5.1).

to the number of degrees of freedom. However, when $\kappa^2 \geq 20$, the CPU time increases dramatically compared with the time for small κ.

Table 5.2 shows the numbers of PMINRES iterations required to reduce the initial residual by a factor of 10^{-8} for $\kappa^2 = 1$, 1.5, 10, 20, 36, 64, 100 on different levels. We observe that it remains nearly fixed for $\kappa^2 \leq 10$ with the number of degrees of freedom varying from 1,322 to 1,513,049. When $\kappa^2 \geq 20$, the number of iterations

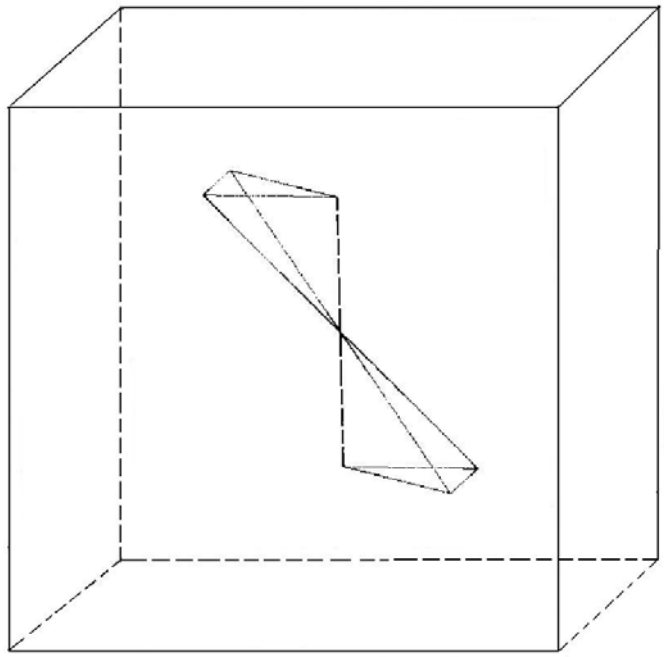

FIG. 5.10. *Two tetrahedral conductors with a common vertex* (*Example* 5.3).

increases rapidly as κ increases, but it varies slightly for all κ with the number of degrees of freedom increasing.

We remark that the frequency of the problem influences the total value of the a posteriori error estimate, but does not influence its reduction rate. These phenomena coincide with Theorems 3.3 and 3.4, where the frequency influences only the constants and the estimates in the theorem, but does not influence the convergence rate. Furthermore, the frequency makes a strong impact on the performance of the preconditioned MINRES algorithm.

5.3. This experiment is to test the robustness of our method for cavity problems on non-Lipschitz domains. The scatter consists of two perfect tetrahedral conductors S_1 and S_2 with vertices

$$\begin{aligned} S_1: &\quad (0,\,0,\,0),\quad (0.5,\,0.5,\,-0.5),\quad (0,\,0.5,\,-0.5),\quad (0,\,0,\,-0.5) \quad \text{and}\\ S_2: &\quad (0,\,0,\,0),\quad (-0.5,\,-0.5,\,0.5),\quad (0,\,-0.5,\,0.5),\quad (0,\,0,\,0.5). \end{aligned}$$

The computational domain is defined by $\Omega = (-1,\ 1)^3 \setminus (S_1 \cup S_2)$ (see Figure 5.10). We set $\mu_r = \epsilon_r = \lambda = \kappa = 1$ in (1.1) and (1.2) and define

$$\mathbf{f} := \mathbf{0}, \quad \mathbf{g} := \mathbf{curl}\,\mathbf{E}_i \times \nu - \mathbf{i}\kappa\,\mathbf{E}_{i,t},$$

where $\mathbf{E}_i = (e^{\mathbf{i}y},\, 0,\, e^{\mathbf{i}y})^T/\sqrt{2}$. The nondimensional wavelength here is $\pi/\sqrt{3}$.

Figure 5.11 shows the $\log \eta_k$–$\log N_k$ curves and indicates that the adaptive meshes and the associated numerical complexity are quasi-optimal and (5.2) is valid asymptotically. It also clearly shows the advantage of adaptive method compared with the uniform refinements.

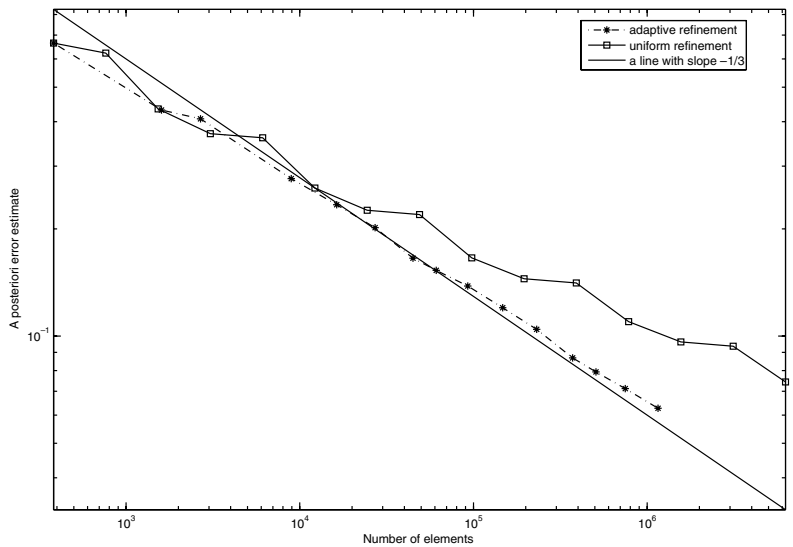

FIG. 5.11. *Quasi optimality of the adaptive mesh refinements of the a posteriori error estimate* (*Example* 5.3).

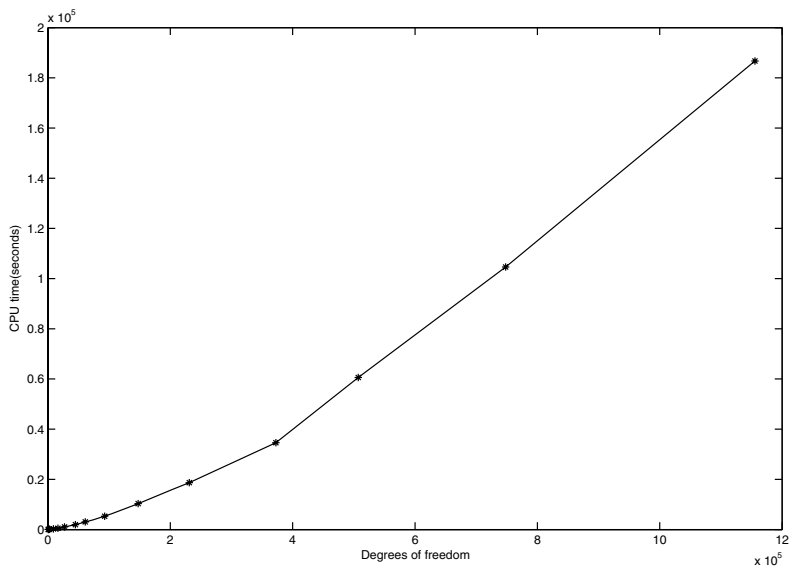

FIG. 5.12. *CPU time for PMINRES iterations on adaptively refined meshes* (*Example* 5.3).

Figure 5.12 shows the CPU time versus the number of degrees of freedom on different adaptive meshes.

Figure 5.13 shows an adaptive mesh of 1,856,117 elements after 15 adaptive iterations. We observe that the mesh is locally refined near the boundary of the scatter.

Table 5.3 shows the number of PMINRES iterations required to reduce the initial residual by a factor of 10^{-8} on different levels. We observe that it remains nearly fixed with the number of degrees of freedom varying from 2,102 to 1,394,075.

USING HIGH-ORDER METHODS ON ADAPTIVELY REFINED BLOCK-STRUCTURED MESHES: DERIVATIVES, INTERPOLATIONS, AND FILTERS*

JAIDEEP RAY†, CHRISTOPHER A. KENNEDY‡, SOPHIA LEFANTZI‡, AND HABIB N. NAJM‡

Abstract. Block-structured adaptive mesh refinement (AMR) is used for efficient resolution of partial differential equations (PDEs) solved on large computational domains by clustering mesh points only where required by large gradients. Previous work has indicated that fourth-order convergence can be achieved on such meshes by using a suitable combination of high-order derivative, interpolation, and filter stencils and can deliver significant computational savings over conventional second-order methods at engineering error tolerances. In this paper, we explore the interactions between the errors introduced by the discretized operators for derivatives, interpolations, and filters. We develop general expressions for high-order derivative, interpolation, and filter stencils applicable in multiple dimensions, using a Fourier approach, to facilitate high-order block-structured AMR implementations. These stencils are derived under the assumption that the fields that they are applied to are smooth. For a given derivative stencil (and thus a given order of accuracy), the necessary interpolation order is found to be dependent on the highest spatial derivative in the PDE being solved. This is demonstrated empirically, using one- and two-dimensional model equations, by observing the increase in delivered accuracy as the order of accuracy of the interpolation stencil is increased. We also examine the empirically observed order of convergence, as the effective resolution of the mesh is increased by successively adding levels of refinement, with different orders of derivative, interpolation, and filter stencils. The procedure devised here is modular and its various pieces, i.e., the derivative, interpolation, and filter stencils, can be extended independently to higher orders and dimensions (in the case of interpolation stencils). The application of these methods often requires nontrivial logic, especially near domain boundaries; this logic, along with the stencils used in this study, are available as a freely downloadable software library.

1. Introduction.

Space-time partial differential equations (PDEs) are routinely solved numerically in scientific and engineering studies. Using the method of lines, and possibly finite-difference techniques applied to the spatial operators, one solves a large system of ordinary differential equations (ODEs). A critical aspect of solving these sometimes enormous problems is the efficiency of the spatial discretization. Ideally, one first establishes an error tolerance requirement for the simulations and then

sets about finding the method that will reliably deliver this tolerance at minimum cost. In general, there are two simple guiding ideas to consider: high-order methods become relatively more efficient as error tolerances are reduced, and grid points should be allocated more generously to less smooth parts of the solution. Combining these two ideas in simple geometries, we will consider high-order spatial discretizations in conjunction with adaptive mesh refinement (AMR) for solution of PDEs having substantial spatial variation in smoothness but lacking spatial discontinuities. In particular, we will use block-structured AMR [4, 5], where a layered hierarchy of rectangular uniform-mesh patches is used to discretize the domain. While this approach resolves a domain efficiently by refining a grid only where required, one would also like to minimize the number of mesh levels, and this is facilitated by high-order methods. Large multiphysics problems are typically solved on distributed memory parallel computers. These require that the domain of the solution be decomposed among processors in a load-balanced manner. If one tries to achieve a given spatial error tolerance by refining repeatedly, one gets localized regions of very high mesh density, distributed within an otherwise coarse mesh. This strongly inhomogeneous grid poses a challenge to domain-decomposition parallel load-balancing algorithms, which frequently fail to achieve a scalable decomposition. Thus, while AMR does allow one to concentrate mesh density in regions of interest, a certain moderation in its use adds tremendously to the ease and speed of computation.

High-order (i.e., > 2) discretizations on adaptively refined meshes are not very common. If one forgoes domains with intricate geometries, one may use block-structured adaptive meshes and exploit the meshs' regularity to consider high-order finite-difference methods. Barad and Colella [3] address the problem of solving the Poisson equation to fourth-order accuracy on block-structured adaptively refined meshes. Starting with a classical Mehrstellen method, the authors develop and test a fourth-order solution methodology for the Poisson equation in two and three dimensions. Tests were done on an adaptive mesh (a coarse base mesh with one extra level of refinement), and fourth-order convergence was predicted theoretically and demonstrated empirically. Interpolations at coarse-fine boundaries were done using a sequence of high-order one-dimensional interpolations, some fourth-order accurate and others sixth-order accurate, depending upon the configuration of patches. Their method requires that the refinement ratio between successive levels be four. Huang and Zhang [15] used fourth-order dispersion relation preserving (DRP) [35, 34] and prefactored compact schemes [2, 13] to solve a coupled set of three linear hyperbolic equations. A "halo" of cells, set up around the fine mesh block, is filled via symmetric one-dimensional interpolations of order 4. Tests showed that a Gaussian pulse propagating across a coarse-fine boundary showed far smaller oscillations when fourth-order interpolants were used; the authors used filters and artificial viscosity in separate tests to remove them. A preference for artificial viscosity was indicated, since it can be controlled in a spatially variable manner. Tests were done in two dimensions with a 3-level block-structured adaptive mesh. Rectangular overset grids may be considered to be block-structured adaptive meshes which are adaptive in space (i.e., have variable resolution in space) but do not change in time. Henshaw [12] studied fourth-order solutions of the Navier–Stokes equations on cylindrical and spherical meshes overset on a Cartesian mesh. Fifth-order one-dimensional interpolations were used between overset grids. Many of the numerical results used in the study were developed in [7], which also contains recommendations for the order of interpolations to be used when an arbitrary PDE is solved to arbitrary order of accuracy on overset grids. A proof for the order of the interpolation was developed for $\partial^{2n}\phi/\partial x^{2n} = F$ for a second-

order discretization only. Alternative approaches to high-order AMR are discussed by Holmström in [14], where wavelets are often central to the AMR procedure.

The use of block-structured AMR to perform PDE-based simulations requires the resolution of a host of issues concerning efficiency, accuracy, and ease of use/implementation of a particular numerical strategy within a block-structured AMR context. In our study, we will follow the approach of [16, 20, 19, 18, 9], where differentiation and interpolations are performed in physical space, as opposed to being done via wavelets. From a computational efficiency point of view, [19] points out that block-structured AMR is preferable to a traditional single grid method only when the higher wavenumber content of the flowfield is relatively nonuniform and resides within smaller regions of the domain. A key element of typical block-structured AMR constructions is that the more accurate solution from the finest grids is periodically interpolated onto the coarser ones, and solutions from the coarse mesh are used at coarse-fine interfaces. The coarse-fine interface takes the form of a "halo" of cells/grid points around fine patches, where the solution is interpolated from the underlying coarse mesh. Since integration variables on each grid are eventually the result of interpolations based on local polynomials, one cannot differentiate this interpolated data indefinitely. Interpolated data based on an order p_I interpolant, which is differentiated k times (differentiation order), result in a field with a maximum differentiation order of $p_I - k + 1$, i.e., C^{p_I-k+1} (see Appendix C). For example, the viscous terms in the Navier–Stokes equations are expressed as second derivatives in space. Consider a point A where a second derivative has to be evaluated. If the evaluation of this derivative requires data to be interpolated in the vicinity of A, prior to being acted on by a (p_D)th-order stencil, one may observe an order reduction in the solution to $p_D - 1$ unless interpolations of the correct order are used. Note, however, that this will be observed only if the viscous terms are of significant magnitude; otherwise the errors in the viscous terms (of order $p_D - 1$) could be swamped by (p_D)th-order derivative errors contributed by other (e.g., convective) terms.

Another important issue in high-order AMR is dealing with the potential for the [illegible] associated with interpolation on uniform grids. A key result of [36] is that for spatial modes of the grid variables, the error in interpolation of modes, $\exp(i\xi x)$, decreases to zero as the grid density tends to infinity if and only if ξ, the wavenumber [32], is small enough to provide six grid points per wavelength. This implies that high-order interpolation will succeed only if there is active control of the spatial wavenumbers that live on the computational grid. Central to this are robust refinement/coarsening criteria combined with careful addition of numerical dissipation for an otherwise low-dissipation numerical method. This robust refinement/coarsening strategy might act to ensure that the energy content of a grid variable above some chosen cut-off wavenumber is essentially zero. This also establishes the requirement that reliable spatial error estimates be available. Wavelets are one of the means for doing this [29]. One could also carry on two simultaneous computations, one on an "actual" grid and another on a "ghost" grid with a factor-of-two coarser resolution. The difference between the two solutions gives an estimate of the spatial discretization error [4]. However, approximate error estimation techniques based on first and second derivatives are more commonly used [30]. To facilitate the interpolations required in both refinement and coarsening, several approaches to high-wavenumber dissipation may be utilized. Filtering of grid variables may be done directly using stand-alone filters. Indirectly, this may be accomplished by using upwinded derivative operators rather than centered-difference approximations in evaluating the RHS, or a hyperviscosity term may be added. A robust refine-

ment/coarsening strategy along with control of numerical dissipation is essential to an efficient high-order AMR method, but one does not appear to fully exist currently.

Several other outstanding issues must be considered when contemplating high-order AMR. One is the proper specification of interpolant boundary closures. It is well known that elaborate boundary closures must be used if one seeks uniformly high-order, finite-difference, first-derivative operators and time-stable integration [6, 26, 27, 31]. Less clear is what, if anything, is required of finite-difference interpolant boundary closures above and beyond satisfying accuracy requirements. Do interpolant boundary closures affect time stability of the overall method? The literature offers no guidance on this matter. Another topic that may affect the efficiency of an AMR procedure is the selection of the Level0 grid spacing. Large initial grid spacings imply more grid levels, more interpolations, but fewer total grid points. A lower grid point count can be advantageous for expensive source terms like chemical reaction rates—more so if the chemical mechanism is stiff. If the refinement/coarsening apparatus is of high quality, interpolations are relatively cheap, and the domain decomposition is good; then a relatively larger Level0 grid spacing seems appropriate. On the other hand, to the degree to which these three items are not met, a smaller Level0 grid spacing seems more prudent. When determining the number of mesh levels, one must also remember that the smallest acceptable grid spacing on any grid level is a function not just of the governing equations but also of the numerical dissipation.

Block-structured AMR algorithms allow variables to be declared at the center of the rectangular or cuboid cells of a Cartesian mesh ("cell-centered" collocation), as well as at the cell corners ("vertex-centered") or at the center of the faces ("face-centered"). One of the major challenges in high-order block-structured AMR is in cell-centered settings, where discrete numerical conservation of the stencils is also demanded. In second-order methods, where a field variable is assumed to vary linearly across a cell, the cell-centered value is also the cell-averaged one. In high-order methods, where the intracell variation is not linear, a distinction has to be made between cell-centered and cell-averaged values, as indicated by Barad and Colella in [3]. They also ensure discrete conservation by imposing continuity of fluxes across coarse-fine interfaces. Their basic approach is the same as the one outlined in [4] (where discrepancies between coarse and fine mesh fluxes are stored in "registers" to "fix up" coarse cells abutting a coarse-fine interface after a timestep), but the fourth-order approach is considerably more involved.

Although AMR with high-order discretizations is appealing and potentially useful, it complicates the time integration strategy. Each mesh level has its own grid spacing, and consequently the stiffness of the convective and diffusive eigenvalues vary inversely and inversely squared with the grid spacing, respectively. If convection and diffusion are treated explicitly in time, then there will be a large range in stepsizes corresponding to the stability limit based upon convection and diffusion on each grid. One may approach this by integrating all grids with a uniform stepsize. In this way, the formal order of traditional ODE integrators is maintained; however, the global timestep is restricted by the stability constraint on the finest grid. Alternatively, a "time-refined" approach can be used, where different timestep sizes are employed for each mesh level [5]. Typically, this is approached with a [illegible] integration on the various mesh levels, starting with the coarsest level (at a timestep determined by the stability constraint of the mesh level itself), followed recursively by the integration of its children mesh levels, which are processed more often but at their (smaller) stability-constrained timesteps. For example, in a viscous CFL dominated problem on a 4-level block-structured AMR mesh, the finest grid takes 2^8 steps for every one on the coarsest. Generally, this approach constitutes what is known as [illegible],

but may also be approached more rigorously using partitioned multirate [10] methods. This approach constitutes partitioning of the RHS at the mesh level. Applying a nonmultirate integrator in a multirate context may often return less than the formal rate of convergence. One may further optimize the integration strategy by treating convection, diffusion, and reaction using different integration methods. A partitioning like this is often referred to as an additive partitioning [23]. Alternatively, A- and L-stable [11] implicit schemes may ignore stability restrictions and select stepsizes based exclusively on accuracy and iteration concerns. Such methods usually result in linear systems which are solved by iterative techniques.

In [24] we demonstrated, using a one-dimensional FitzHugh–Nagumo (FN) equation, that fourth-order convergence could be achieved on block-structured adaptively refined meshes. We motivated the use of high-order AMR by showing, analytically, the savings in mesh resolution (for a given error) and the simplifications in the configuration of the adaptive mesh that could be realized by using high-order discretizations within the context of AMR. This was verified in computational experiments, where actual floating point operations were measured for second- and fourth-order approaches and compared for given error tolerances. For low error tolerances (e.g., 10^{-1}) fourth-order methods were marginally more economical compared to second-order approaches; however, as higher error tolerances were demanded of the computation (e.g., 10^{-4}) the computational saving, as measured in terms of floating point operations, became significant (the fourth-order simulations achieved the same error tolerance as the second-order methods but at a tenth of the floating point operations). These savings in computational work can be directly attributed to the fewer grid points which were needed by the fourth-order simulation, vis-à-vis the second-order simulation, to achieve a given error tolerance. These savings in computational work were also sufficiently large to compensate for the more involved high-order stencils used for the fourth-order simulations. Details of the choice of interpolations and filters, and the interactions between them, were omitted; instead we extended our method to more realistic problems by solving (on 28 processors) a coupled system of 10 reaction-diffusion equations modeling the ignition of H_2 in air.

The goal of this paper is to demonstrate high-order spatial convergence in multidimensions on adaptively refined Cartesian grids by using finite-difference differentiation, interpolation, and dissipation. It is beyond the scope of the paper to address all of the topics relevant to an efficient, high-order spatial scheme; for example, we will not address high-order temporal discretizations or time stable boundary closures for interpolant operators. Instead, we focus on demonstrating methods that give high-order convergence, and begin to address effective strategies for retaining high order but avoiding Runge phenomena. Runge phenomena are avoided by using dealiasing filters. In section 2 we discuss specific numerical and computational issues associated with block-structured AMR constructions and establish the stencil coefficients of the derivatives, interpolants, and filters. In section 3 we use these tools in different problems (the Korteweg–de Vries (KdV) and the Kuramoto–Sivashinsky (KS) equations in one dimension and a FitzHugh–Nagumo (FN) equation in two dimensions) and analyze their efficacy. The KdV and KS equations were solved to gauge the variation in interpolation order as the highest spatial derivative in the equation increased. The two-dimensional FN equation was addressed to study the use of filters to suppress Runge phenomena while preserving the solution order. We draw our conclusions in section 4.

2. Structured AMR. Structured AMR (SAMR; sometimes also referred to as block-structured AMR) [4, 5] is a particularly appealing approach to solving PDEs

within geometrically simple spatial domains. The starting point for the method consists of laying a relatively coarse Cartesian mesh over a rectangular domain. Based on some suitable metric, regions requiring further refinement are identified, and the grid points are flagged and collated into . . . . . children patches on which a denser Cartesian mesh is defined. The refinement factor between parent and child meshes is usually kept constant for a given problem. In this work, it is always specified as 2. The procedure is done recursively, so that one ultimately obtains a hierarchy of patches with different grid densities, with the finest patches overlaying a small part of the domain. This hierarchy will be referred to henceforth as a . . . . . (GH) or the . . ; individual patches will be termed . . . or . . . . Individual patches may be viewed as a wireframe laid over a rectangular domain with the dependent variables of a PDE defined at the intersection of the "wires" (referred to as "vertex-centered grids") or as a division of a domain into small cells, with the variables stored at cell centers ("cell-centered grids"). We will study only . . . . . grids in this paper. Such grids have the property that the finer mesh grid points lie either on top of the coarse mesh grid points or at their geometric midpoints. This may be seen in Figure 2.1, where large circles correspond to the coarse mesh, and fine mesh points are denoted by small triangles, squares, and circles requiring one-, two-, and three-dimensional interpolations, respectively. The solution at these edge-centered (triangles), face-centered (squares), and body-centered (small circle) points, at coarse-fine interfaces/halos, are interpolated from the underlying coarse mesh (the large circles) using a variety of interpolations techniques.

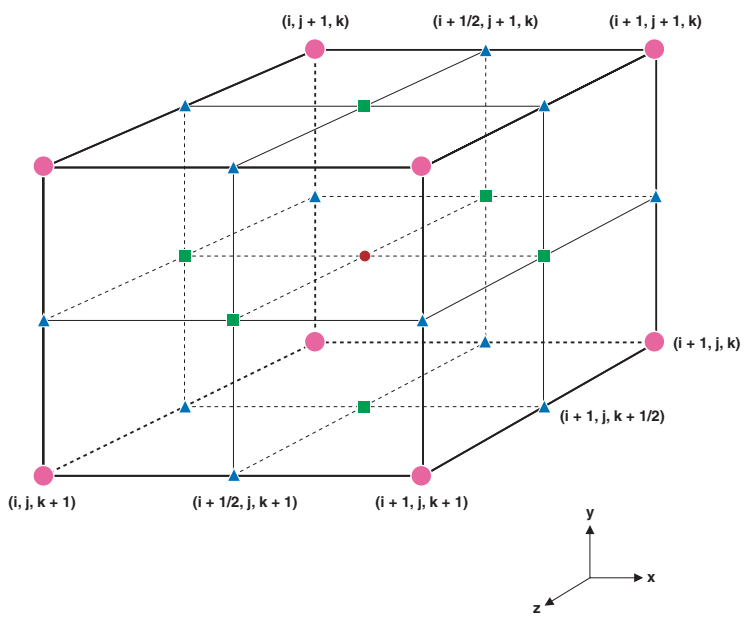

FIG. 2.1. *A vertex-centered grid. The large circles are the coarse mesh, and the fine mesh points at edge centers, face centers, and body centers are represented by triangles, squares, and a (small) circle, respectively.*

If a constant refinement factor is used (e.g., 2), the number of grid points rises rapidly as one refines. When used with time-refined explicit integration, SAMR-based simulations spend almost all their time in the finest levels. Further, in parallel simu-

lations, the requirement of keeping parents and children on the same processor results in poor domain-partitioning by conventional partitioners. Thus, in practice, time-refined simulations usually have shallow hierarchies (e.g., 4 deep) with a fairly dense "coarse" grid. The resulting timestep size (for an explicit integrator) determined by the stability constraints of the fine "coarse" grid is relatively small. To date, second-order spatial discretizations have been typical for SAMR simulations on vertex- and cell-centered grids. Accuracy has been achieved mainly by increasing mesh density, which has exacerbated the problem of a rather fine starting mesh (henceforth called Level0 mesh) or resulted in deep hierarchies. The high-order spatial discretizations employed in the present work will remedy this situation, reducing the requisite resolution requirement on the Level0 mesh.

High-order SAMR has a tremendous potential to reduce resolution requirements to achieve a given level of accuracy. Jameson [17] has attempted to quantify the relative efficiencies of different orders of accuracy in one dimension. Table 1 in [24] contains a listing of the number of grid points needed by centered derivative operators of various orders to resolve a particular wavenumber mode to a given error tolerance; a similar list for high-order interpolants is in Table 2.1. In both cases, we see that a modest increase in order (from second to fourth) reduces the resolution requirements by a factor of 3 at 1% accuracy; at tighter tolerances a factor of 20 is achieved, and at higher orders, one achieves almost 2 orders of magnitude. These savings are magnified as one proceeds to higher spatial dimensions.

TABLE 2.1

Number of grid points per wavelength required to obtain a chosen relative error tolerance ε using explicit, centered-difference, midpoint, interpolant operators of orders 2 *through* 10. *p_I is the order of accuracy of the interpolation operator. See Table* 2.8 *for stencil coefficients.*

ε	$p_I = 2$	$p_I = 4$	$p_I = 6$	$p_I = 8$	$p_I = 10$
$10^{-2.0}$	22.20	7.666	5.381	4.486	4.006
$10^{-2.5}$	39.49	10.29	6.597	5.262	4.577
$10^{-3.0}$	70.24	13.76	8.055	6.144	5.205
$10^{-3.5}$	124.9	18.39	9.810	7.153	5.900
$10^{-4.0}$	222.1	24.55	11.93	8.308	6.671
$10^{-4.5}$	395.0	32.76	14.48	9.635	7.530
$10^{-5.0}$	702.5	43.70	17.57	11.16	8.488

However, the use of high-order discretizations and interpolants is not without its drawbacks. SAMR interpolant operators are evaluated using a linear combination of as many as p_I^d (where p_I is the order of accuracy and d is the dimensionality) values and their respective coefficients. While this renders high-order interpolants more expensive compared to bilinear or biquadratic (trilinear and triquadratic for three dimensions) interpolations on a per-gridpoint basis, results in [24] indicate that the computational savings from the sparser grids may far outweigh the heavier per-gridpoint computational requirement in high-order methods. Nevertheless, high-order derivative and interpolation stencils do lead to certain complications. They may need to be closed to lower order at domain boundaries to preserve time-stability when coupled with explicit time-marching algorithms. Further, they may require smaller timesteps compared to second-order stencils for stability while holding the grid spacing fixed, though this reduction is often not too consequential. In addition, the reduction of timesteps has to be viewed within the context of solutions of PDEs. One usually sets a spatial error tolerance and strives to find a grid spacing and a stencil that delivers it most economically. Since high-order methods can deliver the same accuracy at

far coarser discretization (i.e., Δx) than second-order methods, solutions of PDEs with high-order methods tend to be performed on meshes which are less refined than those required when using second-order methods. These larger Δx's then translate to larger stable timestep sizes (Δt) when using explicit integrators. Thus, in practice, it is frequently possible to use a larger Δt when using high-order discretizations (as opposed to second-order approaches) to solve PDEs.

In this study we examine empirically high-order spatial convergence on a multiple-level SAMR mesh to identify correct derivative-interpolation-dissipation stencil sets. As a first step in that direction, we develop the expression for high-order derivative, interpolant, and filter stencils which will be used in section 3. Adaptive mesh refinement also requires a mesh adaptation criterion, but a discussion of such refinement/derefinement criteria is beyond the scope of this paper. For the purposes of this study, we will not adapt the grid in time. This simplification will allow us to investigate the interaction between various errors (introduced by interpolations and derivative stencils) in the absence of spatial discretization changes introduced by abrupt refinement/derefinement of the grid. In what follows, the Fourier analysis of finite-difference methods is used extensively. The interested reader is referred to the book by Strikwerda [32].

2.1. Derivatives. Finite-difference differentiation operators are constructed for the purposes of providing high-order derivatives as well as, potentially, adding dissipation via upwinding. In the case of arbitrary skewed stencils representing the p_Dth-order accurate approximation to the kth-derivative on a uniform stencil of width Δx, we may write the derivative at grid point i as [21]

$$\begin{aligned}(2.1)\qquad &\cdots + \beta_L f_{i-2}^{(k)} + \alpha_L f_{i-1}^{(k)} + f_i^{(k)} + \alpha_R f_{i+1}^{(k)} + \beta_R f_{i+2}^{(k)} + \cdots \\ &= \cdots + \frac{c_L f_{i-3}}{(\Delta x)^k} + \frac{b_L f_{i-2}}{(\Delta x)^k} + \frac{a_L f_{i-1}}{(\Delta x)^k} + \frac{\Upsilon f_i}{(\Delta x)^k} + \frac{a_R f_{i+1}}{(\Delta x)^k} + \frac{b_R f_{i+2}}{(\Delta x)^k} + \frac{c_R f_{i+3}}{(\Delta x)^k} + \cdots,\end{aligned}$$

where f_i is the value of the function at point i, and $f_i^{(k)}$ is the value of the kth-derivative at that point. The Greek letters α, β, ... are used to denote coefficients of the derivative terms $f_i^{(k)}$ that are one, two, ... grid points on either side of point i, with R and L subscripts denoting the right and left directions on either side of point i, respectively. We use a, b, ... similarly for the coefficients of the function terms f_j for $j = i \pm 1, i \pm 2, \ldots$, and Υ for the coefficient of f_i. The Fourier image of this discrete derivative is given by

$$(2.2)\qquad \Psi = \frac{\left\{\begin{array}{l}[\Upsilon + (a_R + a_L)\cos(\xi) + (b_R + b_L)\cos(2\xi) + (c_R + c_L)\cos(3\xi) + \cdots] \\ \quad + i\,[(a_R - a_L)\sin(\xi) + (b_R - b_L)\sin(2\xi) + (c_R - c_L)\sin(3\xi) + \cdots]\end{array}\right\}}{\left\{\begin{array}{l}[1 + (\alpha_R + \alpha_L)\cos(\xi) + (\beta_R + \beta_L)\cos(2\xi) + \cdots] \\ \quad + i\,[(\alpha_R - \alpha_L)\sin(\xi) + (\beta_R - \beta_L)\sin(2\xi) + \cdots]\end{array}\right\}},$$

where $i = \sqrt{-1}$, or, after expanding the sine and cosine functions as a Taylor series,

$$(2.3)\qquad \Psi = \psi_0 + \psi_1 \xi + \psi_2 \xi^2 + \psi_3 \xi^3 + \cdots + \psi_\infty \xi^\infty,$$

where ξ is the Fourier dual variable, and $\Psi(\xi)$ is the approximation of the derivative in Fourier space [21, 32].

For the kth-derivative, which is p_Dth-order accurate, we must now solve $(p_D + k)$ simultaneous equations; $\psi_k = (i)^k$ and $\psi_l = 0, l = 0, 1, \ldots, (p_D + k - 1), l \neq k$, in

$(p_D + k)$ unknowns; $\{\ldots, \beta_L, \alpha_L, \alpha_R, \beta_R, \ldots, c_L, b_L, a_L, \Upsilon, a_R, b_R, c_R, \ldots\}$. Nonzero values of $\{\ldots, \beta_L, \alpha_L, \alpha_R, \beta_R, \ldots\}$ imply an implicit derivative operator. While implicitness can increase the accuracy of the finite-difference operator, it does this at a significantly higher cost. Throughout this work, we consider only explicit finite-difference derivative, filters, and interpolants, but this is not required for a high-order SAMR method.

2.1.1. Centered-difference explicit derivative operators: Interior. In the interior of a computational domain, one often would like to approximate $\partial^k/\partial x^k$ to some order, p_D, in such a way to preserve the essential character of $\partial^k/\partial x^k$. For k odd, this means a dispersive operator, and for k even, a dissipative operator. To do this, one can choose finite-difference stencils that are either symmetric or antisymmetric about the point where the derivative is being sought. Specific instances of (2.2), where all implicit terms have been set to zero, are listed in Table 2.2 for k odd and Table 2.3 for k even. Orders of accuracy of 2, 4, 6, and 8 are listed, as well as the leading-order truncation error term, $\Psi - (i\xi)^k$. This term is then proportional to ξ^{k+p_D}.

2.1.2. Noncentered explicit first-derivative operators: Interior. In the interest of adding numerical dissipation to a numerical method, it is a common practice to skew a first-derivative, finite-difference operator such that its leading-order error term is dissipative. Stencils like this are referred to as upwind or upwinded stencils. This could be generalized beyond first-derivative operators to those representing $\partial^{2m-1}/\partial x^{2m-1}$; however, we do not attempt this here. Table 2.4 lists various values obtained from solving these equations for $m = 1$, i.e., $\partial/\partial x$ along with their leading-order truncation errors. To obtain order of accuracy p_D for the $k = 1$ derivative operator, at least $p_D + 1$ grid points are needed. One may allocate these points at the grid point where the derivative is sought and to either side of this point. The suffix U is used to denote the most minimal upwind biasing, while UU is for a stronger biasing. It is interesting to inspect these stencils further. On uniform grids, the difference operators may be considered as linear combinations of centered first-derivative differ-

ence operators plus low-order approximations to higher derivatives. Singly upwinded stencils may be readily decomposed as

$$\left({}^{(1)}\Delta^{+}_{(2n-1)}\right)_i = \left({}^{(1)}\Delta^{c}_{(2n)}\right)_i - (-1)^n \frac{(n-1)!n!}{(2n)!}\left({}^{(2n)}\Delta^{c}_{(2)}\right)_i, \tag{2.4}$$

$$\left({}^{(1)}\Delta^{+}_{(2n)}\right)_i = \left({}^{(1)}\Delta^{c}_{(2n)}\right)_i + (-1)^n \frac{(n-1)!n!}{(2n)!}\left({}^{(2n+1)}\Delta^{+}_{(1)}\right)_i, \tag{2.5}$$

where Δ denotes the derivative operator, the northwest superscript is the order of the derivative, the southeast subscript is the order of the accuracy, the northeast superscript denotes centered (c), upwind ($+$), or downwind ($-$), and the subscript outside of the parentheses denotes the grid point at which the difference operator is acting. We illustrate this with an example. Consider stencil 3U in Table 2.4. By (2.4) ($n = 2$), its stencil coefficients can be obtained from those of a fourth-order centered stencil listed in Table 2.2 and by scaling those of a second-order approximation to the fourth derivative (Table 2.3) by $-1/12$. We can verify this by simply reading the stencil coefficients from the tables, performing the scaling, and subtracting similar coefficients. This is done in Table 2.5. The first row contains the fourth-order stencil for the first derivative operator from Table 2.2. The second row contains the second-order approximation for the fourth derivative (Table 2.3), scaled by $-1/12$, as per (2.4) ($n = 2$). The result, in the third row, reproduces the 3U stencil in Table 2.4.

TABLE 2.5

An example of how an upwinded stencil for a derivative (3U from Table 2.4) may be derived from a higher order centered stencil for the same operator ($\partial_x, p_D = 4$ from Table 2.2) augmented by a dissipation operator ∂_{xxxx} discretized to low order (2, in this case). The second-order discretized form of ∂_{xxxx} is scaled by $\frac{-1}{12}$ and added to the fourth-order centered stencil for ∂_x to obtain the third-order upwinded stencil for ∂_x denoted as 3U in Table 2.4.

Stencil	b_L	a_L	Υ	a_R	b_R	Table	Operator, order
$\left({}^{(1)}\Delta^c_{(4)}\right)_i$	$\frac{1}{12}$	$\frac{-8}{12}$	0	$\frac{8}{12}$	$\frac{-1}{12}$	Table 2.2	$\frac{\partial}{\partial x}, p_D = 4$
$\frac{-1}{12}\left({}^{(4)}\Delta^c_{(2)}\right)_i$	$\frac{-1}{12}$	$\frac{-4}{12}$	$\frac{6}{12}$	$\frac{-4}{12}$	$\frac{-1}{12}$	Table 2.3	$\frac{\partial^4}{\partial x^4}, p_D = 2$
$\left({}^{(1)}\Delta^+_{(3)}\right)_i$	0	$\frac{-4}{12}$	$\frac{-6}{12}$	$\frac{12}{12}$	$\frac{-2}{12}$	Table 2.4	$3U$

More elaborate upwinding stencils may be decomposed as

$$\left({}^{(1)}\Delta^{++}_{(4)}\right)_i = \left({}^{(1)}\Delta^c_{(4)}\right)_i + \frac{1}{12}\left({}^{(5)}\Delta^+_{(1)}\right)_i - \frac{1}{4}\left({}^{(5)}\Delta^+_{(1)}\right)_{i+1}, \tag{2.6}$$

$$\left({}^{(1)}\Delta^{++}_{(3)}\right)_i = \left({}^{(1)}\Delta^c_{(6)}\right)_i + \frac{1}{60}\left({}^{(4)}\Delta^c_{(2)}\right)_{i-1} - \frac{1}{12}\left({}^{(4)}\Delta^c_{(2)}\right)_i + \frac{19}{60}\left({}^{(4)}\Delta^c_{(2)}\right)_{i+1}, \tag{2.7}$$

$$\left({}^{(1)}\Delta^{++}_{(5)}\right)_i = \left({}^{(1)}\Delta^c_{(8)}\right)_i - \frac{1}{280}\left({}^{(6)}\Delta^c_{(2)}\right)_{i-1} + \frac{1}{60}\left({}^{(6)}\Delta^c_{(2)}\right)_i - \frac{13}{280}\left({}^{(6)}\Delta^c_{(2)}\right)_{i+1}. \tag{2.8}$$

It may be seen that the even-order, noncentered operators include dispersive components (e.g., (2.6); 4UU in Table 2.4). Other operators have only dissipative components but of both signs (e.g., (2.7); 3UU in Table 2.4) which can amplify errors. It thus seems prudent to consider only odd-order, singly-upwinded derivative operators to add dissipation (i.e., 3U, 5U, 7U, etc.). Note that the reason for the alternating sign in front of the dissipative term is related to the fact that $({}^{(2n)}\Delta^c_{(2)}) \approx (i\xi)^{2n} = (-1)^n\xi^{2n}$. Similarly, for dispersive terms one finds $({}^{(2n+1)}\Delta^c_{(1)}) \approx (i\xi)^{2n+1} = (-1)^n i\xi^{2n+1}$.

2.1.3. Noncentered explicit derivative operators: Boundary. In the absence of periodic boundary conditions, the computational domain must be truncated. Differentiation operators must then be designed to work at all grid points, including those on or adjacent to the boundary. As the centered interior stencils outlined above have widths of $k + p_D$ and $k + p_D - 1$ for odd and even values of k, respectively, there will be a problem obtaining derivatives at the nearest $(k + p_D - 1)/2$ and $(k + p_D)/2$ points to the wall, respectively.

Two important goals in deriving boundary stencils for finite-difference operators are to preserve the order of accuracy of the interior operator and to avoid a temporal instability. In [33], the authors have shown that if one would like to close the boundaries to a $\partial^k/\partial x^k$ operator whose interior operator has order p_D, then the boundary stencils must be at least order $p_D - k$. While it is a simple matter to derive stencils of the appropriate order at these near wall points, this does not necessarily mean that these new boundary stencils will lead to a stable overall numerical method. In the case of first-derivative operators, one can generally no longer take time-stability for granted for boundary closures above third-order accuracy. It may be speculated that this number will decrease as k increases. For first-derivative operators, there is a significant body of literature on constructing time-stable boundary closures [6, 26, 27, 31] but less so for second-derivatives [25] or higher [33].

Given the nontrivial nature of generating high-order, time-stable boundary treatments to all of the derivative operators discussed in this work, lower-order closures are used. While this lowers the formal order of accuracy of the derivative operators, it also likely allows for time-stable integration. No attempt has been made to determine the time-stability characteristics of operators for $\partial^k/\partial x^k$ at $k = 2, 3, 4, 5$. However, since the boundaries must be closed, simple closure stencils are offered. For the stencils listed, each will be given as it would be used at the left boundary. For application to the right boundary, each stencil transforms from its appearance on the left side as

(2.9)
$$f_i^{(k)} = \cdots + \frac{c_L f_{i-3}}{(\Delta x)^k} + \frac{b_L f_{i-2}}{(\Delta x)^k} + \frac{a_L f_{i-1}}{(\Delta x)^k} + \frac{\Upsilon f_i}{(\Delta x)^k} + \frac{a_R f_{i+1}}{(\Delta x)^k} + \frac{b_R f_{i+2}}{(\Delta x)^k} + \frac{c_R f_{i+3}}{(\Delta x)^k} + \cdots$$

into

(2.10)
$$f_i^{(k)} = \cdots - \frac{c_R f_{i-3}}{(\Delta x)^k} - \frac{b_R f_{i-2}}{(\Delta x)^k} - \frac{a_R f_{i-1}}{(\Delta x)^k} - \frac{\Upsilon f_i}{(\Delta x)^k} - \frac{a_L f_{i+1}}{(\Delta x)^k} - \frac{b_L f_{i+2}}{(\Delta x)^k} - \frac{c_L f_{i+3}}{(\Delta x)^k} - \cdots$$

for $\partial^k/\partial x^k$ at $k = 1, 3, 5, \ldots$, and from

(2.11)
$$f_i^{(k)} = \cdots + \frac{c_L f_{i-3}}{(\Delta x)^k} + \frac{b_L f_{i-2}}{(\Delta x)^k} + \frac{a_L f_{i-1}}{(\Delta x)^k} + \frac{\Upsilon f_i}{(\Delta x)^k} + \frac{a_R f_{i+1}}{(\Delta x)^k} + \frac{b_R f_{i+2}}{(\Delta x)^k} + \frac{c_R f_{i+3}}{(\Delta x)^k} + \cdots$$

into

(2.12)
$$f_i^{(k)} = \cdots + \frac{c_R f_{i-3}}{(\Delta x)^k} + \frac{b_R f_{i-2}}{(\Delta x)^k} + \frac{a_R f_{i-1}}{(\Delta x)^k} + \frac{\Upsilon f_i}{(\Delta x)^k} + \frac{a_L f_{i+1}}{(\Delta x)^k} + \frac{b_L f_{i+2}}{(\Delta x)^k} + \frac{c_L f_{i+3}}{(\Delta x)^k} + \cdots$$

for $\partial^k/\partial x^k$ at $k = 2, 4, \ldots$.

To close the boundaries for the first- through fifth-derivative operators when insufficient grid points are available for centered-difference operators, Table 2.6 lists lower-order closures. Expressions for the third and fourth derivatives are used in section 3 to investigate the KdV and KS equations [28]; fifth derivatives could be used to perform a similar investigation for the Kawahara equation [28].

We note that the method developed above to generate centered stencils and their skewed boundary closures is readily generalized to arbitrary orders.

2.2. Filters. Finite-difference filters are a useful adjunct to a numerical method lacking spectral accuracy [21, 22]. In a non-AMR context, they are used simply to remove high-wavenumber spatial information that is not resolvable by the numerical method. However, in an AMR context, they may additionally be used to ensure that the high-order interpolants do not encounter the Runge phenomenon. Several criteria exist for a useful filter. Low-wavenumber information that is resolved should be virtually untouched, while the relatively unresolved high-wavenumber information should be removed. This constitutes dissipation. Dispersion, which is often introduced by the filter boundary closures, is to be avoided if possible. The filter user must estimate which wavenumbers are resolvable by their numerical methods and choose an appropriate filter profile.

$\partial^{14}/\partial x^{14}$	-3432	3003	-2002	1001	-364	91	-14	1	$-\xi^{14} + \frac{7\xi^{16}}{12} + \cdots$

As a filtering function in Fourier space, we seek a function that is equal to 0 at $\xi = \pi$ and is equal to 1 at $\xi = 0$. A simple function to satisfy this is $\left[1 - \sin^{2n}(\xi/2)\right]$. To create this Fourier image using centered explicit finite-difference stencils, one may utilize scaled values of the symmetric $(2n)$th-order derivative for a function f,

$$f_i^{(2n)} = \frac{\Upsilon f_i}{(\Delta x)^{(2n)}} + a\frac{f_{i+1} + f_{i-1}}{(\Delta x)^{(2n)}} + b\frac{f_{i+2} + f_{i-2}}{(\Delta x)^{(2n)}} + c\frac{f_{i+3} + f_{i-3}}{(\Delta x)^{(2n)}} + \cdots, \tag{2.13}$$

where $a = a_L = a_R$, $b = b_L = b_R$, ..., etc. with $\Psi = \Upsilon + 2a\cos(\xi) + 2b\cos(2\xi) + 2c\cos(3\xi) + \cdots$. Solving for the stencil coefficients for the second-order accurate version of this operator, $\partial^{2n} f/\partial x^{2n}$, i.e., $\Psi = (-1)^n \xi^{2n} + O(\xi^{2n+2})$, the Fourier image is given by $\Psi = (-4)^n \sin^{2n}(\xi/2)$. Hence, the forms of Ψ for the desired filters and $f^{(2n)}$ are

$$\Psi_{f^{(2n)}} = (-4)^n \sin^{2n}(\xi/2), \qquad \Psi_{\text{filter}} = 1 - \sin^{2n}(\xi/2), \tag{2.14}$$

and the filter function may then be expressed using the derivative operator as

$$\Psi_{\text{filter}} = 1 + (-1)^{n+1}\left(\frac{1}{2}\right)^{2n} \Psi_{f^{(2n)}}. \tag{2.15}$$

Actual stencil coefficients for the $\partial^{2n}/\partial x^{2n}$ operator, up to fourteenth order, are given in Table 2.7. Alternatively, one could develop these second-order accurate stencils for arbitrary n using Pascal's triangle. Interior stencil coefficients are quickly generated with this small Mathematica code:

```
FiltCoeff = Join[{ups},CharacterRange["a", "z"]];
Do[ Do[ Print[Part[FiltCoeff,(ii-nn+1)]," = ",
  ((-1)^(ii)*(2*nn)!)/((2*nn-ii)!*ii!)]; ,{ii,nn,2*nn}];
Print[""];,{nn,1,26}];
```

The user chooses `nn` as an integer between 1 and 26. It may be determined that the leading-order truncation error is $(n/12)\xi^{2n+2}$. These symmetric stencil coefficients are the interior elements of a dissipation matrix, $\mathbf{D}$, the discretized form of $\partial^{2n}/\partial x^{2n}$ scaled by $(\Delta x)^{2n}$, as applied to the entire solution vector U. If the filters are applied

over periodic domains, no one-sided boundary stencils need to be included in the dissipation matrix. Stencils of order $2n$ give rise to a filter of order $p_F = 2n$. By a slight rescaling of the dissipation matrix, the filtered value of U may be seen to be

$$\hat{U} = (\mathbf{I} + (-1)^{n+1} 2^{-2n} \mathbf{D}) U = \mathbf{F} U, \tag{2.16}$$

where $\hat{U}$ is the filtered vector and $\mathbf{F}$ is the complete finite-difference filter.

One essential ingredient to have in a filter is strictly real eigenvalues of $\mathbf{F}$. Practically, this requires that $\mathbf{F}$ and $\mathbf{D}$ be symmetric. Imaginary eigenvalues will confer a dispersive element to the filter. At the boundaries, where $\partial^{2n}/\partial x^{2n}$ cannot be approximated using symmetric stencils, one must use skewed stencils. To maintain the overall symmetry of $\mathbf{F}$ and $\mathbf{D}$, one may implement stencils representing $\partial^n/\partial x^n$ rather than $\partial^{2n}/\partial x^{2n}$. For any given order filter (the interior operator), $p_F = 2n$, the interior and boundary operators are given by

$$\Psi_{\mathrm{F,Interior}} = (i\xi)^{2n} + O(\xi)^{2n+2} \qquad \Psi_{\mathrm{F,Boundary}} = (i\xi)^n + O(\xi)^{n+1}. \tag{2.17}$$

Boundary blocks are included, if necessary, in the upper-left and lower-right portions of $\mathbf{D}$ with dimension n^2. These boundary blocks reduce the order of the filter at boundary points and can potentially diminish the overall spatial order of the numerical method. Filter boundary coefficients and other details may be found in the literature [21, 22].

A degree of care is required during simulations where filters are applied. For example, in an explicit Runge–Kutta time-integration method, filtering the stage value will destroy the temporal accuracy of the scheme because of the low stage-order of these methods. Therefore, filtering can be applied only to the step value of the solution vector. Further, filtering changes the solution by removing the high-wavenumber spectrum of the solution; thus high-order filters are to be preferred since their effective cut-off wavenumber is high, and small amounts of energy are removed from the variables. If the amount of energy being removed from the solution vector is nontrivial, then users should re-evaluate their numerical method along with the spatial and temporal grids. High-order filters have wide stencils that may pose a practical difficulty in adaptive mesh schemes since this requires the patches to be at least as wide as the filter stencil. In our studies, we impose a "halo" of grid points n wide around each patch. This ensures that all the "valid" grid points on the patch (i.e., the grid points whose refinement is dictated by the requirements of the physics being simulated) are considered "interior" points by the filter matrix. This is not satisfied at the domain boundaries, and fine patches abutting the domain boundary incur filter errors of $O\left((\Delta x)^{n+1}\right)$ at certain points. However, if n is chosen appropriately, this does not adversely affect the desired convergence rate of the overall spatial discretization.

2.3. Hyperviscosity. While not used here, we present the following brief comments on hyperviscosity. Beyond using upwinding to apply high-order dissipation during construction of the RHS of the governing equations or applying stand-alone filters to remove high wavenumbers from the U-vector itself, one can add a hyperviscosity term to the RHS to both dealias the numerical method and to forestall Runge phenomena. The term would appear as $\mu_H(\nabla^2)^n U$ and may be readily constructed using the symmetric dissipation matrices, $\mathbf{D}^{2n}$, used in the filters. To avoid interfering with the order of the overall method, p, it is necessary to use $2n = p_H < p$ in periodic directions and $n < p$ in aperiodic directions.

One may then write $\nabla^{2n}U = (\mathbf{D}_x^{(2)} + \mathbf{D}_y^{(2)} + \mathbf{D}_z^{(2)})^n U$. It is not clear that, for the purposes in mind, this much effort needs to be expended. One could effectively assume that dissipation matrices commute and reduce workload. This would transform

$$\nabla^4 U = \Big(\mathbf{D}_x^{(4)} + \mathbf{D}_y^{(4)} + \mathbf{D}_z^{(4)} + \mathbf{D}_x^{(2)}\mathbf{D}_y^{(2)} + \mathbf{D}_x^{(2)}\mathbf{D}_z^{(2)} + \mathbf{D}_y^{(2)}\mathbf{D}_x^{(2)} + \mathbf{D}_y^{(2)}\mathbf{D}_z^{(2)} + \mathbf{D}_z^{(2)}\mathbf{D}_x^{(2)} + \mathbf{D}_z^{(2)}\mathbf{D}_y^{(2)}\Big)U$$

into

$$\nabla^4 U \approx \left(\mathbf{D}_x^{(4)} + \mathbf{D}_y^{(4)} + \mathbf{D}_z^{(4)} + 2\mathbf{D}_x^{(2)}\mathbf{D}_y^{(2)} + 2\mathbf{D}_y^{(2)}\mathbf{D}_z^{(2)} + 2\mathbf{D}_z^{(2)}\mathbf{D}_x^{(2)}\right) U.$$

To further reduce work, one could ignore cross-terms and simply approximate $\nabla^{2n}U \approx (\mathbf{D}_x^{(2n)} + \mathbf{D}_y^{(2n)} + \mathbf{D}_z^{(2n)})U$. The remaining difficulty is to select an appropriate value for μ_H. It should be remembered that the intent of this construct is to provide a high-order dissipation term to the governing equations. This is why the seemingly inconsistent removal of noncommutativity, cross-terms, and inappropriate boundary closures is immaterial to the purpose at hand.

The use of hyperviscous terms in explicit time-marched schemes can be problematic. Stable integration of the governing equations requires that all eigenvalues from the RHS of the Navier–Stokes equations times the timestep fit with the linear stability envelope of the explicit method. Eigenvalues associated with convection and diffusion scale with the grid spacing as $(\Delta x)^{-1}$ and $(\Delta x)^{-2}$, respectively. If hyperviscosity is included, then new eigenvalues will scale as $(\Delta x)^{-2n}$. This is quite likely to force unacceptably small time steps. While this could be fixed by using an implicit integration method, the procedure would be extremely computationally expensive. Thus, while hyperviscosity appears to be an elegant means of controlling high-wavenumber oscillations, practical considerations make filters more attractive.

2.4. Interpolants. Interpolations, in a vertex-centered AMR context, are used in two instances: (1) to initialize a fine patch (from coarse mesh data) when it is first created, and (2) to fill up the coarse-fine interface or "halo" that is kept around all patches. This "halo" enables the use of symmetric stencils for differentiation and filter operators uniformly on all patches, except near the domain boundaries. As the order of the filters and differentiation operators are increased, the width of the "halo" is increased accordingly. The solution in this halo region is not calculated using the equations being solved; rather they are interpolated from the underlying coarse mesh. Since the halo is additive, i.e., it is added around the "valid" points whose refinement is dictated by resolution requirements, these interpolations are obtained from coarse grid points where the solution is deemed sufficiently resolved.

Interpolation requirements for structured AMR using a vertex-centered grid arrangement include as many as seven distinct finite-difference subinterpolations for up to three Cartesian coordinate directions. All necessary coarse-to-fine interpolations may be accomplished by using one-dimensional interpolants in the x-, y-, and z-directions, two-dimensional interpolants in the xy-, yz-, and zx-directions, and three-dimensional interpolants in the xyz-direction. Two-dimensional simulations require three, say, x-, y-, and xy-interpolations. Three-dimensional simulations require all seven to interpolate the $3^3 - 2^3 = 19$ points inside a unit cube that are unique to the fine mesh. Twelve interpolations require one-dimensional interpolants (the triangles in Figure 2.1), six require two-dimensional interpolants (the squares in Figure 2.1), and one requires a three-dimensional interpolant (the small circle).

TABLE 2.8
Coefficients of one-dimensional, vertex-centered, midpoint interpolants in terms of ξ.

Stencil	2^{nd}-order	4^{th}-order	6^{th}-order	8^{th}-order	10^{th}-order
a	1/2	9/16	150/256	1225/2048	39690/65536

c	0	0	3/256	49/2048	2268/65536
d	0	0	0	−5/2048	−405/65536
e	0	0	0	0	35/65536
$\psi_{p_I}\xi^{p_I}$	$-(1/8)\xi^2$	$-(3/128)\xi^4$	$-(5/1024)\xi^6$	$-(35/32768)\xi^8$	$-(63/262144)\xi^{10}$

Since all $2^3 = 8$ coarse grid points (the large circles in Figure 2.1) are also fine grids points, interpolation from fine-to-coarse is merely an injection and requires no special finite difference stencils. Coarse-to-fine interpolations, however, do need specific stencils. Each of these stencils, whether it be for one, two, or three dimensions, interpolates from the coarse grid data to its geometric midpoint where the fine grid point lies. Although implicitness in finite-difference derivative and interpolant operators provides better high-wavenumber resolution, their added cost makes them ultimately less efficient than explicit methods unless their implicit solves can be made quite economical. Hence, all interpolant operators considered here will be explicit.

Two concerns that should be kept in mind while performing interpolations are, first, what order of accuracy is needed at boundaries to preserve the order of an interior interpolant of order p_I, and second, are there time-stability issues with various interpolant boundary closures. We proceed by closing the boundary points to the same order as the interior and assume that any time-stability issues that may exist with interpolant boundary closures are secondary to more immediate problems.

2.4.1. One dimension: Interior. The stencils in the interior of the domain can symmetrically utilize equal numbers of grid points on either side of the point being interpolated. Hence, the stencil coefficients are identical on each side,

$$f_i^{(0)} = a(f_{i+1/2} + f_{i-1/2}) + b(f_{i+3/2} + f_{i-3/2}) + c(f_{i+5/2} + f_{i-5/2}) + \cdots,$$

and give its Fourier image by

$$\Psi = 2a\cos(\xi/2) + 2b\cos(3\xi/2) + 2c\cos(5\xi/2) + \cdots = \sum_{l=0}^{\infty} \psi_l \xi^l. \tag{2.18}$$

To achieve order p_I, we require $\psi_0 = 1$ and $\psi_l = 0$, with $l = 1, 2, \ldots, (p_I - 1)$. Symmetric interior stencils are listed in Table 2.8 along with their leading-order truncation errors. It will be useful to also cast these stencils in Fourier space as

$$\Psi_I^{2(x)} = \cos\left(\frac{\xi}{2}\right), \tag{2.19}$$

$$\Psi_I^{4(x)} = \frac{-1}{4}\cos\left(\frac{\xi}{2}\right)[-5 + \cos(\xi)], \tag{2.20}$$

$$\Psi_I^{6(x)} = \frac{+1}{64}\cos\left(\frac{\xi}{2}\right)[89 - 28\cos(\xi) + 3\cos(2\xi)], \tag{2.21}$$

$$\Psi_I^{8(x)} = \frac{-1}{512}\cos\left(\frac{\xi}{2}\right)[-762 + 299\cos(\xi) - 54\cos(2\xi) + 5\cos(3\xi)], \tag{2.22}$$

$$\Psi_I^{10(x)} = \frac{+1}{16384}\cos\left(\frac{\xi}{2}\right)[+25609 - 11528\cos(\xi) + 2708\cos(2\xi) - 440\cos(3\xi) + 35\cos(4\xi)], \tag{2.23}$$

for the x-direction. In terms of the original stencil coefficients, the stencil is also expressible as

$$\Psi_I^{2n(x)} = 2\cos(\xi/2)[c_0 + c_1\cos(\xi) + c_2\cos(2\xi) + c_3\cos(3\xi) + c_4\cos(4\xi) + c_5\cos(5\xi) + \cdots], \tag{2.24}$$

where

$$\begin{array}{rcl} c_0 &=& a - b + c - d + e - f + g - \cdots, \\ c_1 &=& 2(b - c + d - e + f - g + \cdots), \\ c_2 &=& 2(c - d + e - f + g - \cdots), \\ c_3 &=& 2(d - e + f - g + \cdots), \\ c_4 &=& 2(e - f + g - \cdots), \\ c_5 &=& 2(f - g + \cdots). \end{array} \tag{2.25}$$

In the y- or z-directions, these expressions are modified by simply replacing ξ with $\eta(y)$ or $\zeta(z)$.

2.4.2. One dimension: Boundaries. As boundaries are approached, interpolant stencils must become asymmetrical if higher order is desired. Stencils are now considered as

$$f_i^{(0)} = \cdots + Cf_{i-5/2} + Bf_{i-3/2} + Af_{i-1/2} + af_{i+1/2} + bf_{i+3/2} + cf_{i+5/2} + \cdots$$

with a Fourier image given by

$$\begin{aligned} \Psi &= \left\{ \begin{array}{c} [(a+A)\ \cos(\xi/2)\ +\ (b+B)\ \cos(3\xi/2)\ +\ (c+C)\ \cos(5\xi/2)\ +\ \cdots] + \\ i\,[(a-A)\ \sin(\xi/2)\ +\ (b-B)\ \sin(3\xi/2)\ +\ (c-C)\ \sin(5\xi/2)\ +\ \cdots] \end{array} \right\} \\ &= \sum_{l=0}^{\infty} \psi_l \xi^l. \end{aligned} \tag{2.26}$$

Again, to achieve order p_I, we require $\psi_0 = 1$ and $\psi_l = 0, l = 1, 2, \ldots, (p_I - 1)$. As the stencils are skewed, we use $\Psi_{\mathsf{a}}^{4(x)}$ to denote the fourth-order interpolant in the x-direction that is shifted one grid point to the right; i.e., the nonzero stencil coefficients are $\{A, a, b, c\}$. Shifting two grid points to the right at sixth order produces $\Psi_{\mathsf{b}}^{6(x)}$ with a stencil determined by $\{A, a, b, c, d, e\}$. To fully close the interpolant boundaries at orders 4, 6, 8, and 10, the stencils as computed from the Mathematica script provided in Appendix A are required. In the y- or z-direction, these expressions are modified by simply replacing ξ with either η or ζ. For stencils shifted to the left rather than the right, the Fourier image expressions should have each occurrence of I replaced with $-I$, and the lowercase letter used to denote the degree of skewness should be replaced with the uppercase version of that letter.

2.4.3. Two dimensions: Interior. Before discussing multidimensional stencils, it will be useful to develop a reasonably clear and compact notation in which to convey both stencils and their coefficients. Let

$$\{\Gamma_\alpha | \alpha = -p_I^*, -p_I^*+1, \ldots, p_I^*-1, p_I^*\} = \{\ldots, C, B, A, a, b, c, \ldots\}$$

be the stencil coefficients associated with grid points $\{\ldots, i-(5/2), i-(3/2), i-(1/2), i+(1/2), i+(3/2), i+(5/2), \ldots\}$. Using this, the stencil coefficient associated with the point $(i-(1/2), j+(1/2))$ would be Aa. With this, the preceding symmetric, one-dimensional stencil may be written as

(2.27)

$$\begin{aligned} f_i^{(0)} &= \sum_{\alpha=-p_I^*}^{p_I^*} \Gamma_\alpha f_{i+\alpha} \\ &= \cdots + C f_{i-5/2} + B f_{i-3/2} + A f_{i-1/2} + a f_{i+1/2} + b f_{i+3/2} + c f_{i+5/2} + \cdots , \end{aligned}$$

where $p_I^* = (p_I - 1)/2$. For a two-dimensional stencil, we have

(2.28)

$$\begin{aligned} f_{i,j}^{(0)} &= \sum_{\alpha=-p_I^*}^{p_I^*} \sum_{\beta=-p_I^*}^{p_I^*} \Gamma_\alpha \Gamma_\beta f_{i+\alpha, j+\beta} \\ &= \cdots + AA\, f_{i-1/2,j-1/2} + Aa\, f_{i-1/2,j+1/2} + aA\, f_{i+1/2,j-1/2} + aa\, f_{i+1/2,j+1/2} + \cdots \end{aligned}$$

and for its Fourier image, we have

$$\Psi = \sum_{\alpha=-p_I^*}^{p_I^*} \sum_{\beta=-p_I^*}^{p_I^*} \Gamma_\alpha \Gamma_\beta \exp(i\alpha\xi) \exp(i\beta\eta) \;=\; \sum_{l=0}^{\infty} \sum_{m=0}^{\infty} \psi_{l,m} \xi^l \eta^m, \tag{2.29}$$

where we require $\psi_{0,0} = 1$ and $\psi_{l,m} = 0$, with $l, m = 1, 2, \ldots, (p_I - 1)$ to achieve order p_I. Symmetry reduces the number of independent stencil coefficients from p_I^2 to $p_I(p_I+2)/8$. For instance, certain off-diagonal stencil coefficients satisfy the relations $ce = cE = Ce = CE = ec = Ec = eC = EC$, while diagonal coefficients satisfy $cc = cC = Cc = CC$. These interior stencils may be cast in Fourier space quite simply as

$$\Psi_I^{p_I(xy)} = \Psi_I^{p_I(x)} \Psi_I^{p_I(y)}, \tag{2.30}$$

where the one-dimensional stencils are given in (2.19)–(2.23). Values for the unique stencil coefficients are listed in Table 2.9 for even orders from 2 to 10.

2.4.4. Two Dimensions: Boundaries. Boundary stencils to two-dimensional interpolants may be constructed in Fourier space by simply multiplying together the proper one-dimensional interpolants. At orders $p_I = \{2, 4, 6, 8, 10\}$, one needs to close the interior method with $\{0, 2, 5, 9, 14\} = p_I(p_I+2)/8 - 1$ unique boundary stencils if one wishes to preserve overall order. At fourth order, when x and y are chosen as the two directions, these are given by

$$\Psi_{I,\mathsf{a}}^{4(xy)} = \Psi_I^{4(x)} \Psi_{\mathsf{a}}^{4(y)}, \qquad \Psi_{\mathsf{a},\mathsf{a}}^{4(xy)} = \Psi_{\mathsf{a}}^{4(x)} \Psi_{\mathsf{a}}^{4(y)}. \tag{2.31}$$

Note that the other stencils, $\Psi_{\mathsf{A},\mathsf{A}}^{4(xy)}$, $\Psi_{\mathsf{a},\mathsf{A}}^{4(xy)}$, and $\Psi_{\mathsf{a},\mathsf{A}}^{4(xy)}$, are simply rotations of $\Psi_{\mathsf{a},\mathsf{a}}^{4(xy)}$, while $\Psi_{\mathsf{a},I}^{4(xy)}$, $\Psi_{\mathsf{A},I}^{4(xy)}$, and $\Psi_{I,\mathsf{A}}^{4(xy)}$ are rotations of $\Psi_{I,\mathsf{a}}^{4(xy)}$. Above fourth order, all needed

stencils may be created in a similar manner by considering all permutations of the relevant one-dimensional stencils, i.e.,

$$\Psi^{2n(xy)}_{\alpha,\beta} = \Psi^{2n(x)}_{\alpha}\Psi^{2n(y)}_{\beta}, \tag{2.32}$$

where α and β each represent one of the following subscripts: I, a, b, c, ... The principal difference at higher order is that there appear additional, different boundary stencils. For instance, at sixth order the unique stencils consist of $\Psi^{6(xy)}_{I,\mathsf{a}}$, $\Psi^{6(xy)}_{I,\mathsf{b}}$, $\Psi^{6(xy)}_{\mathsf{a},\mathsf{a}}$, $\Psi^{6(xy)}_{\mathsf{a},\mathsf{b}}$, and $\Psi^{6(xy)}_{\mathsf{b},\mathsf{b}}$. At eighth order, one must add "c" stencils.

2.4.5. Three dimensions: Interior. Similar to the derivation of two-dimensional stencils, for three dimensions we use

$$f^{(0)}_{i,j,k} = \sum_{\alpha=-p^*_I}^{p^*_I}\sum_{\beta=-p^*_I}^{p^*_I}\sum_{\gamma=-p^*_I}^{p^*_I}\Gamma_\alpha\Gamma_\beta\Gamma_\gamma f_{i+\alpha,j+\beta,k+\gamma}, \tag{2.33}$$

along with its Fourier image,

$$\Psi = \sum_{\alpha=-p^*_I}^{p^*_I}\sum_{\beta=-p^*_I}^{p^*_I}\sum_{\gamma=-p^*_I}^{p^*_I}\Gamma_\alpha\Gamma_\beta\Gamma_\gamma\exp(i\alpha\xi)\exp(i\beta\eta)\exp(i\gamma\zeta) = \sum_{l=0}^{\infty}\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\psi_{l,m,n}\xi^l\eta^m\zeta^n, \tag{2.34}$$

where we require $\psi_{0,0,0} = 1$ and $\psi_{l,m,n} = 0, l, m, n = 1, 2, \ldots, (p_I - 1)$ to achieve order p_I. Stencil coefficients may be computed by either solving for the many conditions placed on $\psi_{l,m,n}$ or by constructing the stencils in Fourier space and then converting the trigonometric functions to exponential functions using

$$\Psi^{p_I(xyz)}_I = \Psi^{p_I(x)}_I\Psi^{p_I(y)}_I\Psi^{p_I(z)}_I. \tag{2.35}$$

The $p_I(p_I+2)(p_I+4)/48$ unique stencil coefficient values are listed in Table B.1 in the appendix for orders $p_I = \{2, 4, 6, 8, 10\}$.

2.4.6. Three dimensions: Boundaries. Boundary stencils to three-dimensional interpolants may be constructed, by a slight extension of the two-dimensional results, by simply multiplying together the proper three one-dimensional interpolants rather than two. At orders $\{2, 4, 6, 8, 10\}$ one needs to close the interior method with $\{0, 3, 9, 19, 34\} = p_I(p_I + 2)(p_I + 4)/48 - 1$ unique boundary stencils if one wishes to preserve overall order, where each stencil has p_I^3 stencil coefficients that may or may not be unique. At fourth order the unique stencils are given by

(2.36)
$$\Psi^{4(xyz)}_{I,I,\mathsf{a}} = \Psi^{4(x)}_{I}\Psi^{4(y)}_{I}\Psi^{4(z)}_{\mathsf{a}}, \quad \Psi^{4(xyz)}_{I,\mathsf{a},\mathsf{a}} = \Psi^{4(x)}_{I}\Psi^{4(y)}_{\mathsf{a}}\Psi^{4(z)}_{\mathsf{a}}, \quad \Psi^{4(xyz)}_{\mathsf{a},\mathsf{a},\mathsf{a}} = \Psi^{4(x)}_{\mathsf{a}}\Psi^{4(x)}_{\mathsf{a}}\Psi^{4(z)}_{\mathsf{a}}.$$

Other combinations using the subscripts I and a are merely rotations of the stencils just listed but with identical stencil coefficients. Similar to two-dimensional boundary stencils, all needed stencils may be created in the same manner by considering all permutations of the relevant one-dimensional stencils, i.e.,

$$\Psi^{2n(xyz)}_{\alpha,\beta,\gamma} = \Psi^{2n(x)}_{\alpha}\Psi^{2n(y)}_{\beta}\Psi^{2n(z)}_{\gamma}, \tag{2.37}$$

where α, β, and γ each represent one of the following subscripts: I, a, b, c, ...

3. Test problems. In this section we will address the following two issues:

1. Given a PDE to solve on a block-structured adaptive mesh, with a derivative stencil of order p_D, what is the order of the interpolations (p_I) that needs to be used for prolongations and restrictions in order to obtain (p_D)th-order spatial convergence?
2. Once an appropriate (p_D, p_I) pair has been identified, which filter order p_F should be used in case Runge phenomenon is observed?

For the purposes of this paper, we will specify a refinement pattern and [illegible] the mesh. The issues regarding the criteria for refining-derefining a mesh point will not be addressed here.

3.1. Appropriate interpolation orders. As described in sections 1 and 2, the solution on any patch in a GH is the result of interpolations from finer patches (restrictions) and/or interpolations from the solution on coarser patches at a coarse-fine boundary (prolongations). In this paper, since we address vertex-centered meshes, restrictions are mere injections and do not involve interpolations; however, prolongations do involve interpolations at coarse-fine boundaries.

The position of the coarse-fine boundary is determined by the refining-derefining criteria. These are usually based on a threshold on the solution error [4, 5] or a threshold on the gradient [30]. Thus, there exists a small but nonzero gradient at a coarse-fine boundary and an interpolation error is incurred there. Ideally the gradient should be small enough that the interpolation error is negligible vis-à-vis the differentiation error regardless of the interpolation chosen, but this is difficult to achieve in practice and still have an efficient grid (we run the risk of refining large areas of the domain and losing the advantage of concentrating resolution only where needed). Since these interpolated values cannot be differentiated indefinitely and still preserve order, it becomes critical to choose an appropriate interpolation order.

In [24], we conducted a study of the appropriate interpolation order p_I given a derivative stencil of order $p_D = 4$. The tests were done with the FN equation in one dimension (where the highest spatial derivative is ∂_{xx}) and we concluded that $p_I \geq (p_D + 2)$ was sufficient. In Appendix C, we present an argument for the requisite

interpolation order p_I for a given order of discretization and arbitrary derivative order. In this analysis, we find that the "correct" interpolation order $p_I = p_I(p_D, H_D)$, where H_D is the highest spatial derivative in the equation. We verify this empirically by using the KdV equation (where highest spatial derivative is ∂_{xxx}) and the KS equation (∂_{xxxx}).

The tests are performed on GHs of different depths. The KdV and KS equations are time-advanced using the classical fourth-order Runge–Kutta method; the FN equation employs a second-order version (Heun's method). Time stepping on a GH, as mentioned in section 1, is done in a time-refined manner; see [4, 24] for a complete description. Briefly, for every timestep on Level0, we take 2 on Level1, 4 on Level2, etc., in a recursive manner, i.e., the sequence is Level0 - Level1 - Level2 - Level2 - Level1 - Level2 - Level2. Each patch has a halo (whose width is dependent on the equation being solved and the stencil used) of points around it so that central difference stencils (for derivatives) may be used. However, at domain boundaries, the width of the halo is restricted to 1, which necessitates the use of skewed, lower-order stencils. Dirichlet boundary conditions are imposed. On each patch, data are stored in a multidimensional FORTRAN77 (F77) array, which is passed into a subroutine, along with a stencil accuracy order, to compute the spatial derivative needed.

The halo of points around a refined (Level1 or higher) patch lies over a valid region of the patch's coarser parent patch and is filled by interpolating (prolonging) the data from the parent. Symmetric interpolation stencils are used, except near domain boundaries where the stencil is skewed; however, the order is preserved. This is practically achieved by passing the parent's data array to an F77 subroutine, along with an index interval (corresponding to the patch's halo) where the interpolation has to be done, along with the order of accuracy desired. The subroutine detects boundaries and skews the stencil accordingly. Further, since the different levels have different Δt, the filling up of "halos" may also involve temporal interpolation of the data of the parent mesh. This temporal interpolation is linear. At the end of a timestep on a given level, its data is restricted down to its coarser parent. Since we use vertex-centered meshes, the coarse and fine mesh points are aligned, and the restriction is a pure injection.

At the end of a Level0 timestep, all the patches on all the levels are processed by a filter (as described in section 2.2). These too are F77 subroutines that accept the multidimensional data array associated with a patch, along with an order of the filter.

These numerical tools, i.e., F77 subroutines for evaluating high-order derivatives, filters, and interpolations, along with a user's guide and code examples, are available online in the form of a software library from [1]. These tools accept multidimensional F77 arrays as inputs and are not tied to any particular data structure; the rest of our adaptive mesh code is in C++. See Appendix D for details regarding the library.

3.1.1. KdV equation. The KdV equation is written as

$$U_t + 6UU_x + U_{xxx} = 0. \tag{3.1}$$

Under the assumption that $U_x \to 0$ as $x \to \pm\infty$, we get a traveling wave solution $U = 2k^2(\cosh\{k(x - x_0 - 4k^2t)\})^{-2}$, where k is a wavenumber and the amplitude and velocity of the traveling wave are $2k^2$ and $4k^2$, respectively.

We solved (3.1) on a 2-level GH (i.e., with a Level0 and Level1 mesh, abbreviated as an $\{L_0, L_1\}$ mesh), with a factor of refinement of 2. The domain was $0 \le x \le 100$ with $x_0 = 50$, i.e., the initial condition was a soliton placed at the center of the

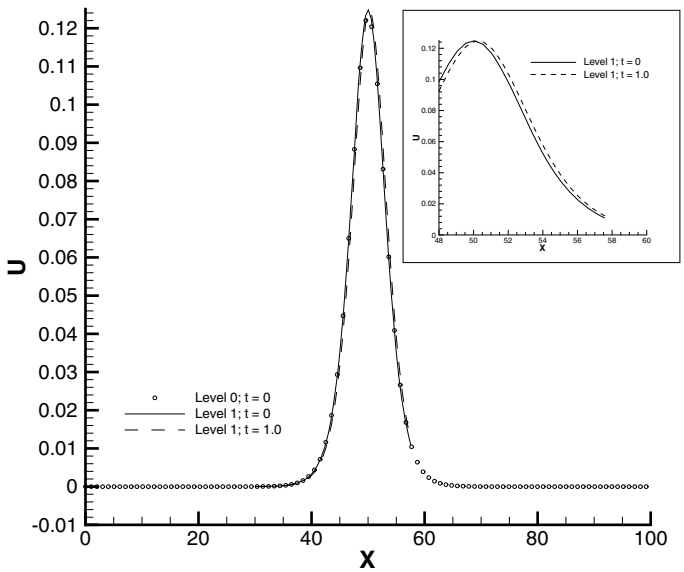

FIG. 3.1. *A soliton solution of* (3.1) *at* $t = 0$ *and* 1. *Symbols are used to plot the solution on* L_0 *and lines on* L_1. *The dashed line shows the solution at* $t = 1.0$. *Inset: A detail of the* L_1 *solution. We see that the movement of the soliton during the simulation is small vis-à-vis its size.*

domain. The region $30 \leq x \leq 56$ was refined to an L_1 mesh. We used $p_D = 4$. Both the first (∂_x) and third (∂_{xxx}) derivative stencils were closed to third order at the two points nearest the domain boundary. We refer to this as the 3-3-4-3-3 discretization strategy. The width of the halo around a fine patch was kept at 6. Runge phenomenon was not observed, and we did not use filters. Figure 3.1 shows the initial condition on L_0 in symbols and the L_1 solution as a solid line. The solution is marched explicitly in a "time-refined" manner using a classic fourth-order explicit Runge–Kutta integrator up to time $t = 1.0$ using a timestep (on the coarse mesh) of $\Delta t_0 = 1.0 \times 10^{-3}$. Such a small timestep was used to keep the temporal content small in the discrepancy between the numerical and exact solutions compared to the spatial content. Figure 3.1 (inset) shows the movement of the profile. We see that there is a nonzero gradient at the coarse-fine boundary. Such a situation might arise in practice if one is not extremely rigorous about the refinement-derefinement criteria. The solution at $t = 1.0$ is also shown.

In Figure 3.2 we show the RMS (root mean square) error in the RHS, i.e., $-(6UU_x + U_{xxx})$ with respect to the analytical solution on L_1. The x-axis is the resolution of the L_0 mesh. The choice of the RHS for convergence analysis is made in order to bring out clearly the effect of interpolation errors, which are best seen in the higher derivatives. We plot solutions obtained with $p_I = 4, 6$, and 8. A uniform mesh solution, i.e., without using interpolations, is also plotted as a guide for an ideal fourth-order convergence slope. We see that with $p_I = 4$ and 6 the slope is shallower than fourth order, while $p_I = 8$ achieves a greater slope. Thus, using $p_I = 8$ should enable (p_D)th-order convergence.

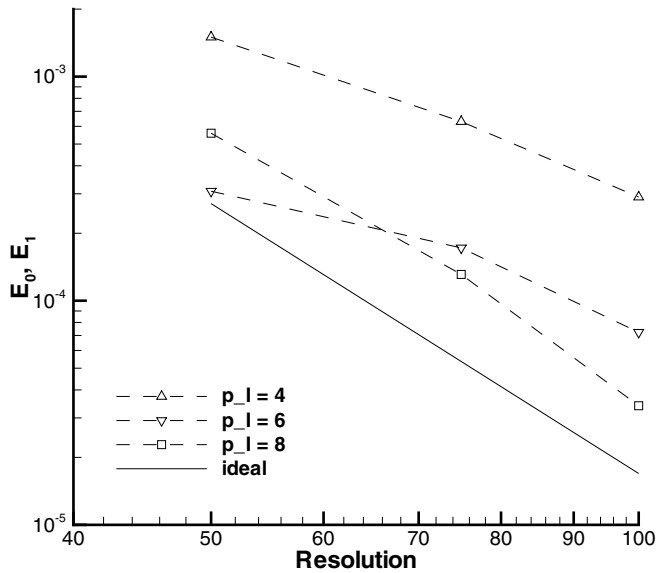

FIG. 3.2. *Convergence of the RHS of the KdV equation on L_1 with $p_D = 4$ and $p_I = 4, 6,$ and 8. The time is $t = 1.0$. A uniform mesh run is plotted as a guide for the convergence slope. $p_I = 8$ shows a convergence steeper than fourth order, while the others do not. Note that the resolution here is L_0 resolution; L_1 is a factor of 2 finer. The uniform mesh run was done on a grid of 100, 150, and 200 grid points. E_1 is the RMS (root mean square) error (with respect to the exact solution) on Level1; E_0 is the error, also of the RHS, for the uniform mesh run.*

Note that an $\{L_0, L_1\}$ mesh has an [illegible] resolution that is twice the L_0 resolution and should be compared with a uniform mesh solution that is equally resolved. This is done in Figure 3.2, where the uniform mesh error plotted against an L_0 resolution of 50 was obtained on a mesh of 100 grid points. Further, the uniform mesh run was uniformly more accurate since the entire domain was well resolved; in the adaptive mesh case, we purposely limited the refinement to $30 \leq x \leq 56$ to see the effect of the interpolants.

3.1.2. Kuramoto–Sivashinsky equation. The KS equation can be written as

$$U_t + UU_x + U_{xx} + U_{xxxx} = 0. \tag{3.2}$$

Under the assumption that $U_x \to 0$ as $x \to \pm\infty$, we get a traveling wave solution

$$\begin{aligned} U &= \frac{15}{19}k(11H^3 - 9H^2 + 2), \qquad k = \sqrt{\frac{11}{19}}, \\ H &= \tanh\left\{\frac{k}{2}\left(x - x_0 - \frac{30}{19}kt\right)\right\}. \end{aligned} \tag{3.3}$$

As in [24], we solved (3.2) on a 2-level GH with a factor of refinement of 2. The domain was $0 \leq x \leq 50$ with $x_0 = 29$. The region $20 \leq x \leq 29$ was refined to an L_1 mesh. A derivative stencil of order $p_D = 4$ was used. The first and second

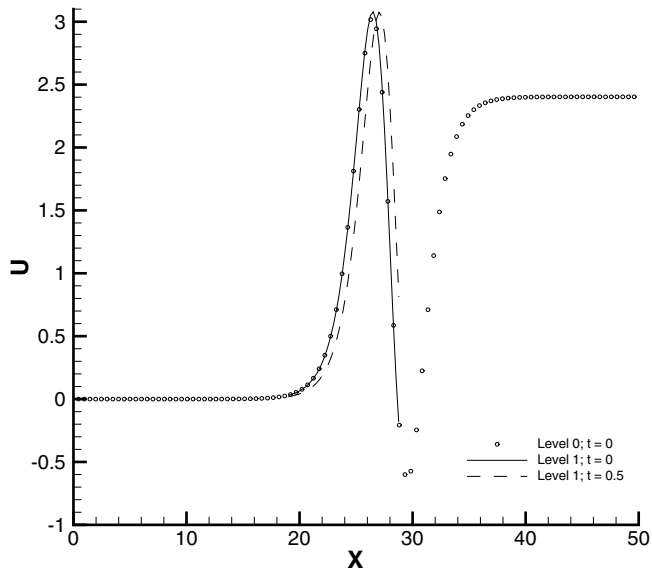

FIG. 3.3. *A traveling wave solution of* (3.2) *at* $t = 0$ *and* 0.5. *Symbols are used to plot the solution on* L_0 *and lines on* L_1. *The dashed line shows the solution at* $t = 0.5$.

derivative stencils were closed in a 3-3-4-3-3 manner, while the fourth derivative stencil was treated in a 3-3-3-4-3-3-3 fashion. The width of the halo was kept at 6. Runge phenomenon was not observed and we did not use filters. Figure 3.3 shows the initial condition on L_0 in symbols and the L_1 solution as a solid line. The solution was marched explicitly using a fourth-order Runge–Kutta integrator to time $t = 0.5$ using a timestep (on the coarse mesh) of $\Delta t_0 = 5.0 \times 10^{-4}$. This solution is also shown in Figure 3.3.

In Figure 3.4 we show the error in the RHS, i.e., $-(UU_x + U_{xx} + U_{xxxx})$ with respect to the analytical solution on L_1. The x-axis is the resolution of the L_0 mesh. We plot solutions obtained with $p_I = 6$ and 8. An ideal fourth-order convergence plot is provided as a guide. We see that with $p_I = 6$ the slope is shallower than fourth order, while $p_I = 8$ and 10 achieve a slope similar to the ideal. Thus, using $p_I = 8$ or 10 should enable (p_D)th-order convergence. However, the choice of interpolant order is also dependent on the position of the coarse-fine boundary. We repeated these runs with a refinement region of $20 \le x \le 38$. In this case, the gradient at the coarse-fine boundaries was small and both $p_I = 6$ and 8 provided fourth-order convergence.

Combining the results obtained above with those in [24], we observe that the results derived in Appendix C hold, i.e., they ensure (p_D)th-order spatial accuracy in block-structured adaptive meshes, even when there exists a substantial gradient at a coarse-fine boundary. This expression is seen to hold true at least for $\partial_{xx}, \partial_{xxx}$ and ∂_{xxxx} using fourth-order discretizations. We will use it to achieve high-order convergence in two dimensions below. A similar study, performed using the Kawahara equation [28], could verify the relationship between p_I, p_D, and H_D for $H_D = 5$.

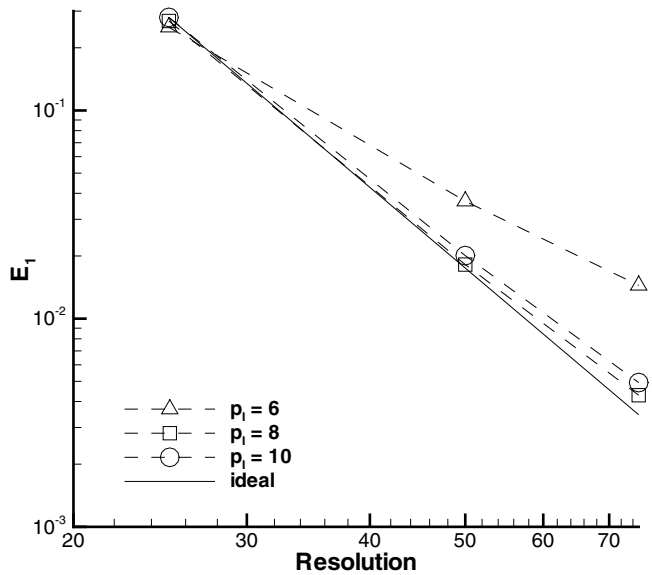

FIG. 3.4. *Convergence of the RHS of the KS equation on L_1 with $p_D = 4$ and $p_I = 6, 8,$ and 10. The time is $t = 0.5$. An ideal fourth-order convergence plot is provided for guidance. Both $p_I = 8$ and 10 show convergence similar to fourth order while the $p_I = 6$ does not. Note that the resolution here is L_0 resolution; L_1 is a factor of 2 finer. E_1 is the RMS error on Level*1.

3.2. Achieving high-order convergence. In this section we combine the tools developed in section 2 to empirically achieve high-order convergence on block-structured adaptive meshes in two dimensions. Tests were carried out in two dimensions using the FN equation. We chose a Level0 resolution that led to Runge phenomenon (because of its coarseness), thus necessitating the use of filters.

The FN equation in two dimensions is

$$U_t = D\nabla^2 U + AU(1-U)(U-\alpha). \tag{3.4}$$

We look for traveling wave solutions to (3.4), similar to the one-dimensional case [8]. We assume that a solution of the form $U = U(\xi + st)$ exists, where $\xi = x + \beta y - c$. We can derive the expression for $\nabla^2 U$ and U_t in terms of U' and U''. Under the assumption that

$$U' = aU(1-U), \tag{3.5}$$

where $U \to 0$ as $\xi \to -\infty$, and $U \to 1$ as $\xi \to \infty$, we get

$$a = \left(\frac{A}{2(1+\beta^2)D}\right)^{1/2}, \qquad s = \left(\frac{AD(1+\beta^2)}{2}\right)^{1/2}(1-2\alpha),$$

and

$$U = \frac{1}{2}\left(1 + \tanh\left(\frac{a\xi}{2}\right)\right) = \frac{1}{2}\left(1 + \tanh\left(\frac{\xi}{2\delta_f}\right)\right). \tag{3.6}$$

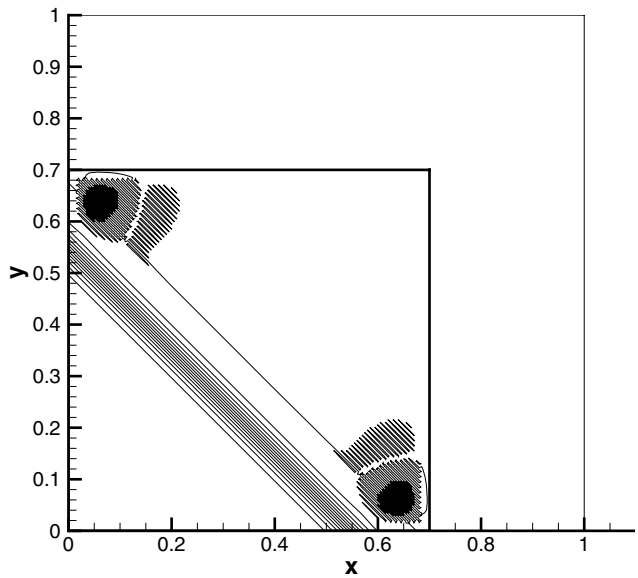

FIG. 3.5. *The Runge phenomenon on a* 2*-level block-structured mesh. The patch outlined in black is the Level*1 *patch. Level*0 *is a* 100×100 *mesh on a unit square. The solution is at* $t = 5 \times 10^{-5}$ *and was computed with* $p_D = 4$ *and* $p_I = 6$*. The correct solution should not contain the structure/oscillations one observes at the southeast and northwest corners of the Level*1 *patch.*

The last expression was obtained by solving (3.5) and completes the solution of (3.4). δ_f, a measure of the front thickness, is defined as $\delta_f = 1/a$.

We solved (3.4) on a unit square. We specified $D = 1, c = 0.5$, and $\beta = 1$. A was set such that $\delta_f = 0.02$. Equation (3.6) evaluated at $t = 0$ provided the initial condition and was also used to specify Dirichlet boundary conditions on the unit square. The analytical solution, (3.6), was also used to evaluate the numerical error (the difference between the exact and the numerical solutions) for convergence tests. The region $0 \leq x \leq 0.7, 0 \leq y \leq 0.7$ was refined (see Figure 3.5). The meshes on successive levels were refined by a factor of 2.

3.2.1. Fourth-order approach. Solving (3.4) with fourth-order derivative stencils ($p_D = 4$) and sixth-order interpolants ($p_I = 6$) led to Runge phenomenon (see Figure 3.5). This was not observed in a one-dimensional context in [24]. The particular choices of $p_D = 4$ and $p_I = 6$ were also obtained from [24]. The solution was filtered after every timestep to remove the Runge phenomenon. The $p_D = 4$ derivative stencils for ∂_{xx} and ∂_{yy} were evaluated in a 3-3-4-3-3 fashion per the nomenclature defined in section 3.1.1.

In order to choose a filter of the correct order p_F, we conducted a series of tests (see Figure 3.6). We fixed a derivative stencil ($p_D = 4$, centered) and experimented with filters of different orders p_F. A (p_F)th-order filter is a (p_F)th-spatial derivative in the interior points of the mesh implemented with a centered stencil that is of second-order accuracy. It is closed at the domain boundaries to first order. The Level0 mesh was kept at 100×100. The solution was advanced to time $t = 4 \times 10^{-4}$ using a

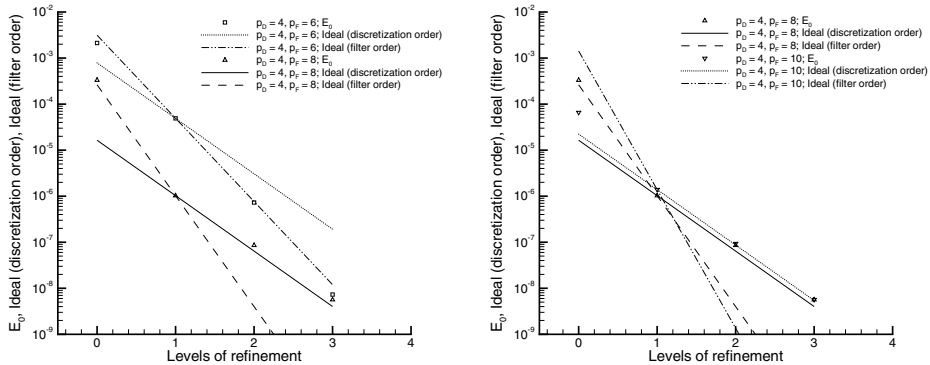

FIG. 3.6. *Numerical errors (calculated using the exact solution) for the FN equations solved using fourth-order discretizations. Numerical solutions computed with $p_F = 6, 8$, and 10 on GHs with up to 3 levels of refinement are plotted with $\square$, $\triangle$, and $\triangledown$, respectively. On the left, we compare results obtained with $p_F = 6$ and 8, while on the right, we compare $p_F = 8$ and 10. (p_D)th-order convergence is denoted by a solid or dotted line, while (p_F)th-order convergence is denoted by a dashed or dash-dotted line. For $p_F \geq 8$, we see fourth-order convergence as errors introduced by filtering are smaller than the derivative stencil's errors. The y-axis has the Level0 RMS error (E_0) and the "ideal" errors plotted as along a (p_D)th- and (p_F)th-order convergence slopes.*

Level0 $\Delta t = 10^{-6}$. The width of the halo was kept at 6. The temporal component in the RMS difference between the numerical and the exact solution was expected to be negligible with respect to the spatial component.

In Figure 3.6, we plot the Level0 RMS error using symbols, though tests were done with zero, one, two, and three levels of refinement (a zero level of refinement is a uniform mesh run). Lines are used to plot the ideal convergence (for the purpose of comparison) at both (p_D)th and (p_F)th order. For $p_F = 6$ (Figure 3.6, left), we see that the RMS errors (square symbols) lie along the dash-dotted line, which has a slope equivalent to sixth-order convergence. We also plot a dotted line, with a slope equivalent to fourth-order convergence (the order of the derivative stencil) as a guide; it is clear that the observed RMS errors do not follow this slope. The RMS errors are also far higher (between one and two orders of magnitude) than a similar run done with a $p_F = 8$ filter (triangles). The errors encountered when using a $p_F = 8$ filter are seen to have a slope close to that denoted by the solid line which is the ideal fourth-order convergence slope. Thus the error convergence is the same as the order of accuracy of the derivative stencil. We also plot a dashed line with a slope equivalent to eighth-order convergence; it is clear that when we have at least one level of refinement, this convergence slope is not observed. The only exception is while going from a uniform mesh to one level of refinement when $p_F = 8$; the two points lie on the dashed line (eighth-order convergence).

In Figure 3.6 (right) we compare the convergence of the RMS error for $p_F = 8$ and 10. The observed results (triangles for $p_F = 8$ and inverted triangles for $p_F = 10$) lie close to each other; further they fall directly on the solid and dotted lines, respectively, which are the ideal fourth-order convergence slopes. The only exceptions are the results when there were no levels of refinement. For the eighth-order filter, the convergence of the RMS error from a uniform mesh to the one-level-of-refinement result follow an eighth-order slope as denoted by the dashed line. For the tenth-order filter, the uniform mesh run shows a behavior that seems to

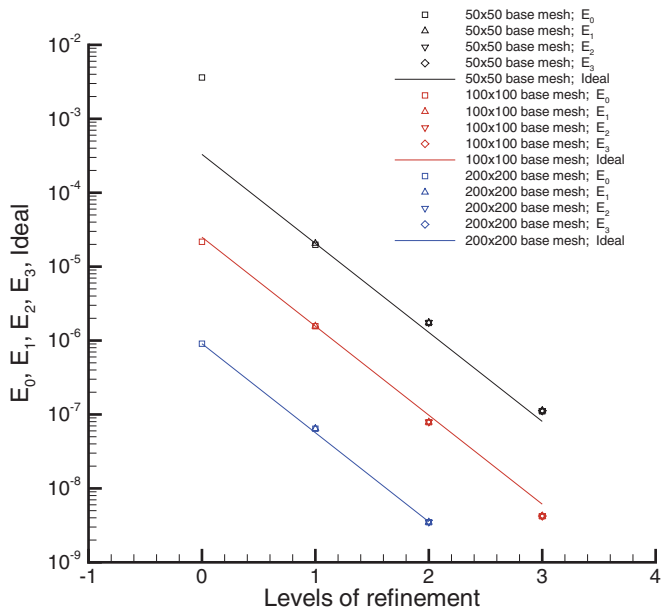

FIG. 3.7. *Numerical (RMS) errors observed when* $p_D = 4, p_F = 8$. *Solutions were done on* 50×50 *(black),* 100×100 *(red), and* 200×200 *(blue) meshes with different levels of refinement. Errors on levels* $0, 1, 2,$ *and* 3 *are plotted with* $\square$, $\triangle$, $\triangledown$, *and* $\diamond$, *respectively. Ideal fourth-order convergence is plotted using solid lines. Apart from the* 50×50 *uniform mesh run, the errors follow the ideal convergence closely.* E_i, $i = 0,\ldots,3$, *refers to the RMS error on level* i.

be intermediate between tenth-order (dash-dotted line) and fourth-order (solid line) convergence. Also, note that once the fourth-order convergence sets it (at one level of refinement), the difference between the $p_F = 8$ and $p_F = 10$ results is very small.

It is clear that using the $p_F = 6$ filter is inappropriate, and the errors introduced by this inappropriate use dominate the derivative stencil error. At higher filter orders, the errors introduced by filtering drop and we recover convergence commensurate with the order of the derivative stencil. That the "correct" filter could depend on the derivative stencil being used is evident in (2.17). In order that the leading-order error due to filters be similar to or smaller than those introduced by the derivative stencil, n (where $2n = p_F$) cannot be chosen at random; a conservative approach is to choose n such that the boundary errors of a filter (caused by the first-order closure of the filter stencil at the boundaries) is smaller than the errors introduced by a derivative stencil in the interior, where it (i.e., the derivative stencil) is full order (as opposed to its own lower-order closure at the boundaries). Further, if the dissipation introduced by the filter is overwhelming, (2.16) indicates that the dissipation will scale as $(\Delta x)^{2n}$.

Based on Figure 3.6 we choose $p_F = 8$ and conduct convergence tests on 50×50, 100×100, and 200×200 Level0 meshes (see Figure 3.7). Numerical errors calculated on each level are plotted, as levels of refinement are allowed. We see that the RMS errors on each of the levels are very similar, as might be expected since the solution is restricted from the finer to the coarser meshes. Further, as more levels of refinement are allowed, fourth-order convergence is observed. The only outlier is the 50×50 uniform mesh run; the grid is too coarse to resolve the traveling front, and the errors

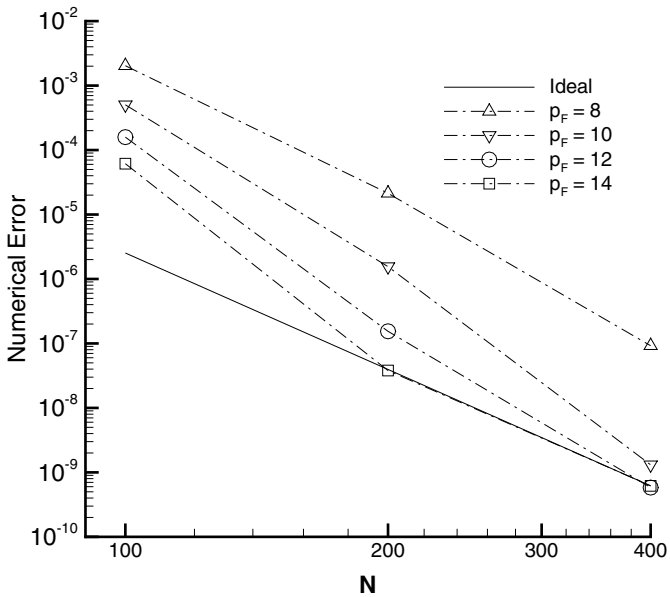

FIG. 3.8. *The RMS difference between numerical and exact solutions for the FN equations solved on an $N \times N$ uniform mesh using $p_D = 6$ with filters of order $p_F = 8, 10, 12,$ and 14. An ideal sixth-order convergence plot is provided for guidance. $\triangle, \triangledown, \bigcirc,$ and $\square$ are used to denote $p_F = 8, 10, 12,$ and 14 results; a solid line is used for runs without filtering.*

are excessive.

3.2.2. Sixth-order approach. In this section, we address the question of using $p_D = 6$ instead of $p_D = 4$ as was done in section 3.2.1. The sixth-order stencils for ∂_{xx} and ∂_{yy} were closed to third order on the two points closest to the domain boundary and to fourth order on one point adjacent to the third-order points, i.e., a 3-3-4-6-4-3-3 discretization strategy was followed. In Figure 3.6, it was seen that (p_D)th-order convergence was observed only with levels of refinement, when errors due to the derivative stencils dominated all other sources of errors (since it is the RMS difference between exact and numerical solutions that we plot). Since sixth-order stencils are expected to be more accurate than fourth-order ones, we first study the interaction between the filters and derivative stencils in a simplified setting, with no interpolations and on a uniform mesh.

In Figure 3.8, we plot the RMS difference between exact solutions and numerical solutions computed with $p_D = 6$ along with filters of order $p_F = 8, 10, 12,$ and 14. An ideal sixth-order convergence is also plotted for comparison. Runs were done on an $N \times N$ grid, where $N = 100, 200,$ and 400 with $\Delta t = 10^{-7}$. The problem was integrated up to time $t = 4 \times 10^{-4}$ as in section 3.2.1. We see that filtering introduces a significant error, and the behavior of the convergence of the errors lies between p_D and p_F. It is only at $N = 200$ that the convergence of the $p_F = 14$ run behaves in a sixth-order manner. Consequently, we will henceforth use the fourteenth-order filter to obtain sixth-order convergence on a GH. Note that the leading-order truncation term at the boundary for a fourteenth-order filter (ξ^8 for $n = 7$; see (2.17)) has the same order of magnitude as the leading-order truncation error term for a sixth-order

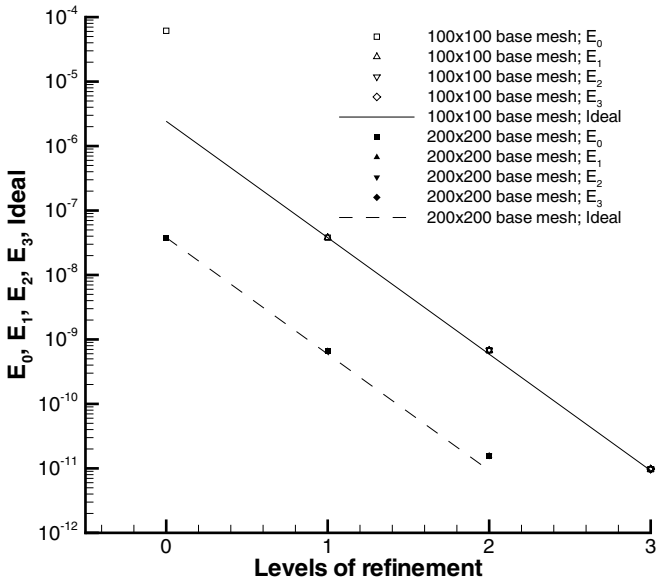

FIG. 3.9. *Numerical (RMS) errors observed when* $p_D = 6, p_I = 8, p_F = 14$ *when solving the FN equation. Solutions were done on a GH with Level*0 *equal to* 100×100 *(open symbols) and* 200×200 *(filled symbols) with different levels of refinement. Errors on levels* $0, 1, 2,$ *and* 3 *are plotted with* $\square$, $\triangle$, $\triangledown$, *and* $\diamond$, *respectively. Ideal sixth-order convergence is plotted using lines. Apart from the* 100×100 *uniform mesh run, the errors follow the ideal convergence closely.* E_i, $i = 0, \ldots, 3$ *refers to the RMS error on level i.*

second derivative stencil (see section 2.1.1).

We performed the analogue of the experiment in section 3.2.1 with $p_D = 6$. A GH with three levels of refinement was used. The interpolation order p_I was kept at 8 along with a halo of 10 cells. In Figure 3.9 we plot the error on each level, as more levels of refinement are enabled in a GH. We performed experiments with Level0 resolutions of 100×100 and 200×200. For the GH with a 200×200 Level0 resolution, we see an ideal sixth-order convergence; for the experiments with a 100×100 Level0, sixth-order convergence sets in only when the effective resolution of the mesh reaches 200×200; i.e., we have a Level1 mesh. This is also consistent with Figure 3.8, where sixth-order convergence sets in only at $N = 200$ with a $p_F = 14$ filter.

4. Conclusions. In this paper we have addressed the problem of the solution of a time-dependent PDE of the form

$$\frac{\partial U}{\partial t} = F\left(U, \frac{\partial U}{\partial x}, \cdots, \frac{\partial^{H_D} U}{\partial x^{H_D}}\right) \tag{4.1}$$

on a block-structured adaptive mesh using an approach that is high-order (> 2) in space. We have developed high-order stencils for derivatives, interpolations, and filters using a Fourier approach, a choice that enables high-order implementations with relative ease. These stencils were tested in one and two dimensions using model equations, and high-order convergence (fourth- and sixth-order) was demonstrated on

"vertex-centered" GHs. Time-instability near the boundaries was not observed, at least not for the fourth- and sixth-order derivative stencils used in this study. The combined use of derivative, interpolation, and filter stencils in these studies required a careful choice of their orders.

The Fourier image of a kth-spatial derivative evaluated using a (p_D)th-order stencil is $\Psi_{\mathrm{D}} = (i\xi)^k + O(\xi^{k+p_D})$, while that of an interpolant of (p_I)th-order accuracy is $\Psi_{\mathrm{I}} = (i\xi)^0 + O(\xi^{p_I})$. In order that the leading-order truncation error introduced by the two discrete operators be similar, one requires that

$$p_I = H_D + p_D, \tag{4.2}$$

where H_D is the highest spatial derivative observed in (4.1). This was verified for $2 \leq H_D \leq 4$ for $p_D = 2, 4$. A Mathematica [37] program that produces the necessary code for all these high-order interpolations is provided in Appendix A.

The use of high-order interpolation stencils to fill "halo" cells can lead to oscillations in situations when the solution is insufficiently resolved on the mesh where the interpolations are being performed. These oscillations (the Runge phenomenon) were observed on Level1 and Level2 and were removed by applying a (p_F)th-order filter to the solution after every timestep. The "correct" filter order p_F can be estimated in a manner similar to that for interpolations. The Fourier image of a filter stencil of order p_F is $\Psi_{\mathrm{F,Interior}} = (i\xi)^{p_F} + O(\xi^{p_F+2})$ in the interior and $\Psi_{\mathrm{F,Boundary}} = (i\xi)^{p_F/2} + O(\xi^{p_F/2+1})$. A conservative estimate of p_F can be obtained by equating the order of magnitudes of the leading-order truncation errors of $\Psi_{\mathrm{F,Boundary}}$ and Ψ_{D} to obtain

$$p_F = 2(p_D + H_D - 1). \tag{4.3}$$

This was shown to hold for $p_D = 4, 6$ for $H_D = 2$.

Combined with [24], this paper presents an alternative approach to the one developed in [3]. Our method, vis-à-vis [3], trades off one complexity versus another. While the high-order one-dimensional interpolations in [3] are far simpler than our multidimensional ones, their application requires bookkeeping, viz., tracking (a) patch configurations and (b) tangential and normal directions to a coarse-fine boundary, whereas we use our interpolations uniformly. Also, unlike [3], we have no requirement, in principle, that the refinement ratio between levels be any particular value, although the practical complexities of deriving and implementing the high-order multidimensional interpolations have led us to use a fixed refinement factor of 2 in the present work. This also ensures that the difference in (resolvable) wavenumber spectra between successive levels of refinement is kept manageable. While this is not much of a problem in vertex-centered grids, where restrictions (interpolating the fine mesh solution to the coarse mesh) are mere injections, cell-centered grids require interpolations to be performed, and care must be taken not to transfer high-wavenumber energies to lower ones while interpolating. This is obviously simpler if the wavenumber spectra are not too different. However, the ramifications of the choice (2 versus 4) of the level-to-level refinement factor, within the context of high-order AMR, need a systematic study. Furthermore, as shown in section 3, our interpolations have consistently provided high-order convergence even when the coarse-fine boundary was placed, on purpose, in a region of high gradient. While such an eventuality is not likely in an AMR simulation, the threshold-based refinement-derefinement criteria do not guarantee against it, and the high-order interpolations serve as a fallback in borderline resolution cases.

High-order methods, coupled with AMR, hold the potential to perform high-accuracy simulations economically. These methods, as presented in this paper, are quite general—stencils for derivatives, filters, and interpolations of any orders, p_D, p_F, and p_I, may be generated using the expressions developed here. There are neither special cases nor assumptions and/or constructions predicated on a specific choice of stencils. Replacements of interpolation, derivative, and filter stencils are affected simply by replacing subroutines. Significant computational savings can be achieved over second-order AMR methods by adopting high-order approaches as documented in [24, 3]. Filtering is used to introduce dissipation to control oscillations, and an inappropriate filter can significantly degrade the accuracy of high-order approaches. In this regard, we have derived and verified the relationship that needs to be preserved between the orders of derivative, filter, and interpolation stencils in order to achieve high-order convergence.

Appendix A. Stencil coefficient computation. Below is a Mathematica [37] program that may be used to generate an F77 file containing all boundary and interior interpolant stencils discussed in this paper. First, write individual stencils as functions.

```
    (* Second-Order *)

121550*Sin[9*a/2]))/32768;
```

Next, set desired parameters. This is the only section of the code that needs to be modified by the user. In the following example, we wish to compute a fourth-order stencil for a point shifted from the center by zero grid points in x, $\Psi_I^{4(x)}$, one in y, $\Psi_{\mathsf{a}}^{4(y)}$, and two in z, $\Psi_{\mathsf{b}}^{4(z)}$, or $\Psi_{I,\mathsf{a},\mathsf{b}}^{4(xyz)}$.

```
(* Specify stencil *)
order = 4;
Psi = Expand[ TrigToExp[ Psi4I[x]*Psi4a[y]*Psi4b[z] ] ];
ix = 0; iy = 1; iz = 2;
```

Alternatively, we could compute the stencil $\Psi_{\mathsf{b},\mathsf{c},\mathsf{d}}^{8(xyz)}$ by writing

---

```
(* Specify stencil *)
order = 8;
Psi = Expand[ TrigToExp[ Psi8b[x]*Psi8c[y]*Psi8d[z] ] ];
ix = 2; iy = 3; iz = 4;
```

Now the actual stencil coefficients are computed and printed to the screen in F77 format.

```
(* Compute stencil *)
leftx=-(order-1)+2*ix;
lefty=-(order-1)+2*iy;
leftz=-(order-1)+2*iz;
psi = Expand[ Factor[ Normal[ Series[ Psi,{x,0,order},{y,0,order},
{z,0,order}]]]];
Print[" psi = ", psi ];
psilistx = CoefficientList[ psi - 1,x] /.  {y -> 0, z -> 0};
psilisty = CoefficientList[ psi - 1,y] /.  {x -> 0, z -> 0};
psilistz = CoefficientList[ psi - 1,z] /.  {x -> 0, y -> 0};
actualorder = Sum[ (psilistx[[i]]+psilisty[[i]]+psilistz[[i]]),
{i,1,order-1}];

Do[
Print["Do loop counter = ", k];
Do[
Do[ bnd[i,j,k] = ExpToTrig[ Expand[
Psi*Exp[-I*(leftx+2*(i-1))*x/2]*Exp[
-I*(lefty+2*(j-1))*y/2]*Exp[-I*(leftz+2*(k-1))*z/2]]]; ,{i,1,order}];
x = 3; y = 17; z = 9973;
Do[ bnd[i,j,k] = Part[ bnd[i,j,k], 1 ];, {i,1,order}];
,{j,1,order}]; ,{k,1,order}];

denominator = Part[ {8,2^(12),2^(24),2^(33),2^(48),2^(58)}, order/2];
letters = {I,a,b,c,d,e,f};
Do[ bnd[i,j,k] = Factor[ denominator*bnd[i,j,k] ];,
{i,1,order},{j,1,order},{k,1,order}];
Do[ Print[" bnd",order,Part[letters,ix+1],Part[letters,iy+1],
Part[letters,iz+1],
"(",i,",",j,",",k,") = ", bnd[i,j,k],".d0/",denominator,".d0" ];,
{i,1,order},{j,1,order},{k,1,order}];
If[ actualorder == 0, Print["Stencil is correct"],
Print["Stencil is wrong"]];
```

Appendix B. Interior stencils for three-dimensional interpolants.

Appendix C. Rules for pairing a derivative and an interpolation stencil.

In this appendix we determine a rule to pair a spatial derivative stencil of order P with an interpolation of order Q given that the highest spatial derivative that needs to be evaluated is R.

Let $\phi^{(R)}$ be the Rth derivative of ϕ in the domain $\mathcal{A}$, the patch G2 in Figure C.1. Let $D_P^{(R)}$ be a discrete operator (a stencil) that, when applied at a point in $\mathcal{A}$, evaluates the derivative with an error proportional to $(\Delta x)^P$. We will analyze only in the x-direction, where points are indexed using i; the results will carry over to a higher-dimensional space.

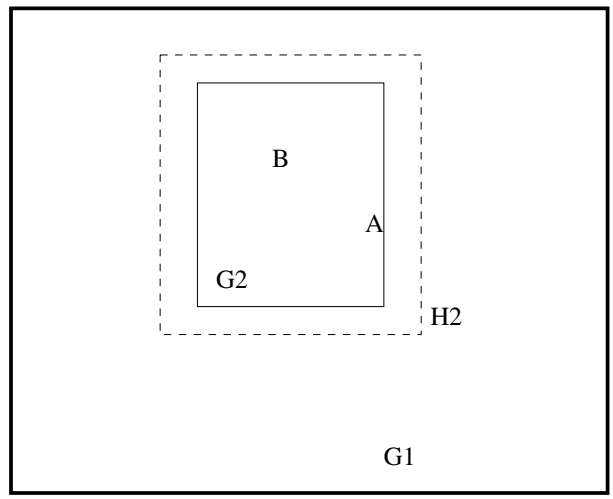

FIG. C.1. *Two overlaid patches* G1 *and* G2. G2 *is finer and has a halo* H2 *around it to facilitate the evaluation of discrete derivatives via stencils. Points* A *and* B *lie on the finer* G2 *patch.*

Applying this at point B in Figure C.1 poses no problems,

$$\begin{aligned}\phi_B^{(R)} &= \frac{D_P^{(R)}(\phi_B)}{(\Delta x)^R} + \varepsilon_1(\Delta x^P) \\ &= \frac{D_P^{(R)}(\ldots, \phi_{i-1}, \phi_i, \phi_{i+1}, \ldots)}{(\Delta x)^R} + \varepsilon_1(\Delta x^P),\end{aligned} \tag{C.1}$$

as long as the stencil has enough points on the left and right. At A, however, the stencil "spills" over into the coarser G1 patch.

Typically, in order to not use skewed stencils, one keeps a halo H2 of points around G2, where data are interpolated from G1 with an interpolant of order Q. Let these interpolated ϕ be called $\tilde{\phi}$, i.e.,

$$\tilde{\phi} = \phi + \varepsilon_2(\Delta x^Q).$$

Thus, we evaluate $\phi_A^{(R)}$ as

$$\begin{aligned}\phi_A^{(R)} &= \frac{D_P^{(R)}(\phi_A)}{(\Delta x)^R} + \varepsilon_1(\Delta x^P) \\ &= \frac{D_P^{(R)}(\ldots, \phi_{i-1}, \phi_i, \tilde{\phi}_{i+1}, \ldots)}{(\Delta x)^R} + \varepsilon_1(\Delta x^P) \\ &= \frac{D_P^{(R)}(\ldots, \phi_{i-1}, \phi_i, \phi_{i+1}, \ldots)}{(\Delta x)^R} + \varepsilon_1(\Delta x^P) + \varepsilon_3(\Delta x^{Q-R}).\end{aligned} \tag{C.2}$$

That $\varepsilon_1(\Delta x^P)$ and $\varepsilon_3(\Delta x^{Q-R})$ be of the same order requires

$$Q = P + R. \tag{C.3}$$

This is sufficient to allow Pth-order convergence of $\phi^{(R)}$. Note that ε_1 exists over $\mathcal{A}$ while ε_3 exists only along $\partial\mathcal{A}$, its boundary, a domain of dimension one less than $\mathcal{A}$.

TABLE C.1

A comparison of the order of interpolation Q for the FN, KdV, and KS equations when solved with fourth- ($P = 4$) and sixth- ($P = 6$) order discretizations as indicated by (C.3) *and* [7]*. The first column also mentions the highest spatial derivative in the equation. The figure in parentheses in the second column indicates the interpolations used in this study—we use only even-order interpolations to avoid dispersive errors.*

Equation	$P = 4$		$P = 6$	
	Eq. (C.3)	[7]	Eq. (C.3)	[7]
FN (∂_{xx})	6	5	8	7
KdV (∂_{xxx})	7 (8)	7	9	10
KS (∂_{xxxx})	8 (8 and 10)	9	10	13

However, the requirement above can be relaxed. Often, errors are measured, integrated, and analyzed in a certain area. This was also the case in this paper. Thus,

$$E = \int_{\mathcal{A}} \varepsilon_1(\Delta x^P) dA + \int_{\partial\mathcal{A}} \varepsilon_3(\Delta x^{Q-R}) ds \\ = E_1(\Delta x^{P-2}) + E_3(\Delta x^{Q-R-1}) \tag{C.4}$$

if $\mathcal{A}$ is two-dimensional. If $\mathcal{A}$ is three-dimensional, the RHS is $E_1(\Delta x^{P-3}) + E_3(\Delta x^{Q-R-2})$. In order that E_1 and E_3 have the same convergence rates,

$$Q = P + R - 1. \tag{C.5}$$

Strictly speaking, (C.5) will ensure Pth-order convergence of $\phi^{(R)}$ in a global sense if $\partial\mathcal{A}$ is one grid point in thickness. For our high-order discretizations, this is not the case; interpolations are done in a thin [illegible] of half the stencil width. Thus, it is unclear whether (C.3) or (C.5) is preferable, but (C.3) should be sufficient.

We contrast this with the recommendation (in [7]) that $Q = \frac{1}{2}PR + 1$. This expression is derived in [7] under the assumption of second-order discretizations ($P = 2$). Empirical studies are performed for $R = 2$ (Laplace and Navier–Stokes equations) for $P = 2$ and 4. In Table C.1 we compare Q as recommended by [7] and (C.3) for the equations used in this study. We find that the recommended values for Q are generally not too far apart.

Appendix D. Description of HODIF: A library of high-order derivatives, interpolations, and filters. In this appendix, we describe HODIF, a library that contains the stencils described in the paper. This library can be downloaded from [1] and comes with a user's manual that explains how this library may be called from FORTRAN or C/C++. Example codes doing so are in the `example/` directory of the distribution.

The library is a collection of F77 subroutines that implement derivative, interpolation, and filter stencils. The subroutines are kept under separate directories `deriv/`, `interp/`, and `filter/`. These subroutines expect double precision (`real*8`) three-dimensional F77 arrays as input, but lower-dimensional arrays may be passed in with the size of the extra dimension set to 1. Multidimensional C/C++ arrays can be used only if the data lie in one contiguous memory segment and are stored in F77 ordering; in such a case, a pointer to this memory segment can be passed in as an argument to the subroutines. The subroutines are called with a set of integers which serve as demarcations of array sections. We explain this further.

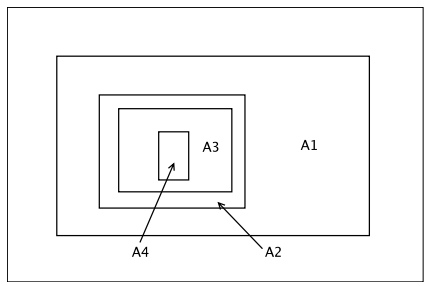

FIG. D.1. *Various array sections and their subsetting.* A1 *is a "distributed" area,* A2 *is a patch, which contains* A3 *which is the valid region/interior points.* A4 *is a "window."*

Our library was developed to be used with frameworks for doing computations on block-structured adaptive meshes, where operations are performed on a patch-by-patch basis. Each patch (A2 in Figure D.1) contains a "valid area"/ "interior points" (A3 in Figure D.1) with a "halo" of points around it. The "halo" is written into during prolongations from the underlying coarse parent patch; alternatively, in parallel computations, they may serve as ghost cells. For the purposes of filter and derivative stencils, the halo is treated as a read-only area of the array, except near domain boundaries, where boundary conditions have to be applied to fill up the halos. However, the data for a patch (interior and halo points) are stored in the same array for ease of access; thus if the data array being passed in is dimensioned `a(fiL:fiR, fjL:fjR)`, the indices `fiL, fiR, fjL, fjR` have to be passed in as arguments. Many parallel software packages provide the notion of a "distributed" array, spread over many processors, with a global indexing convention (A1 in Figure D.1). Each processor owns a section of this global array (in other words, a patch) and accesses are done using the global index. We accommodate this by requiring that indices supplied to the subroutine be either consistently local or global. Inside the subroutine, accesses are done using a local index. We also allow the concept of "windows" (A4 in Figure D.1), the ability to apply an operation to a subsection of the interior points. This is useful during prolongations which only have to be done in a small "window" of a parent patch, encompassing the region around a coarse-fine patch boundary.

By far the most difficult aspect of high-order methods on block-structured adaptive meshes is the application of multidimensional interpolation at corner points. Consider the top left case in Figure D.2. The stencil is symmetric about both the vertical and horizontal axes. For the top right figure, we skew vertically but retain symmetry about the vertical axis. The stencil for the bottom right case is the same as the top right, after a 90° clockwise rotation. The stencil for the bottom right case is completely different. We thus have three unique stencils, applied to four corner points, sometimes with rotation. The task of determining the nature of the points at a corner automatically and identifying the correct skewed stencil, along with the correct rotation, is tedious and error prone; further, as the order of the interpolation stencil increases, the number of corner points increase (as p_I^d, where p_I is the order of interpolation and d is the dimensionality of space). Since we have already gone through this exercise, we are making a validated implementation of this logic available with our library; thus the user calls the library, and the correct stencils are identified and applied without any prompting from the user. It is this enabling algorithm that makes this library far more than a collection of stencils and is integral to the usability of high-order methods.

Another feature of the library is the "piecewise" evaluation of midpoints during

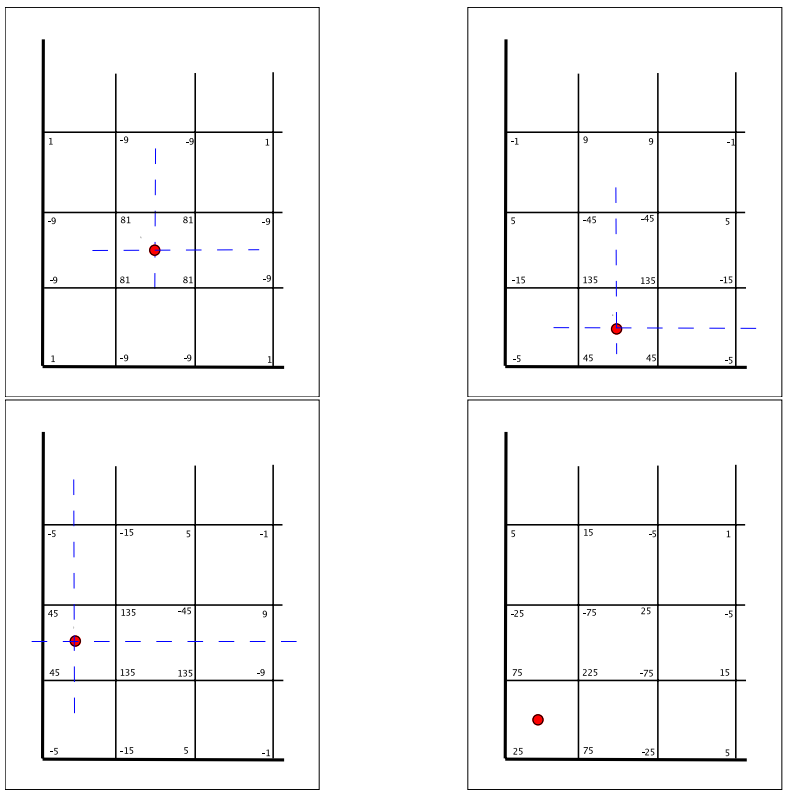

FIG. D.2. *Skewing of stencils near a corner at the domain boundary. At the top left, the value at the circle is obtained by a symmetric interpolation stencil whose coefficients are shown in the figure. For the top right and bottom left cases, the stencils are the same, but differ by a clockwise rotation of* 90°. *The stencil for the bottom right case is completely different but symmetric about the diagonal. All stencil coefficients need to be normalized by* 256.

prolongations. Figure D.3 shows a fine mesh overlayed on a coarse one; the factor of refinement is 2. Data from the large circles have to be interpolated to the small circles and squares. The values at the small circles are obtained by one-dimensional interpolations; further, x- and y-interpolations are performed by different subroutines and have to be called separately. The squares are evaluated by a separate call to a two-dimensional interpolation routine. The interpolated results are stored separately and then inserted by the user into their correct locations on the fine mesh's data array. There are two reasons for not automating the interpolation: (1) The marshaling of the various midpoint values is not difficult, and (2) large temporary arrays, which would be allocated on the stack in F77 subroutines, can lead to overflow. We thus allow the user to reuse any workspace arrays that he/she might have in case large arrays are involved. In adaptive mesh runs, this has not been an issue.

Proficiency in using this library is best achieved by practice. To this effect we have provided examples in F77 and C along with a user's manual. Further, for C/C++ programmers, the interface to the FORTRAN subroutines is in the headers in `include/`; each of the directories `deriv/`, `interp/`, and `filter/` include a C stub that translates the C function into their F77 counterparts. The headers in `include/` are annotated for convenience.

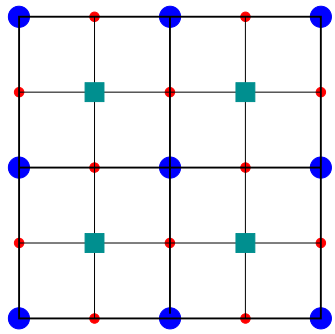

FIG. D.3. *Coarse mesh points (large circles) along with collocation points for the fine child patch (small circles and squares). The values for the small circle points are obtained by one-dimensional interpolations, while for the square points, a two-dimensional interpolation is used.*

We illustrate the general approach to using this library using code snippets from `example/interp_example.f` in the software distribution. The example involves:

1. initializing a field $\sin(2\pi x)\sin(2\pi y)$ on a unit square discretized uniformly by 50 points. This is the coarse mesh.
2. interpolating the field on the coarse mesh onto a fine mesh, twice as fine.
3. taking the root-mean-square difference between the two.

In `MAIN`, we define the array limits and allocate the coarse and fine mesh arrays. We keep the halo width at 2, but this particular aspect does not play a part in this example since the entire fine patch including the halo is filled up during interpolation. The definition and allocation of arrays holding the coarse and fine fields are on lines 48–56 in the example source code.

The coarse mesh is then initialized by a call to a subroutine (`initialize_field`). We next proceed to the process of orchestrating the interpolation. This is done in a separate subroutine called `interp_vc_field`. First, we allocate temporaries that will contain the values interpolated separately at edge-centers in x and y, as well as the values evaluated at cell centers (lines 120–122). We then perform the interpolation in x, i.e., evaluate the field at collocation points that lie at the center of the horizontal edges. In order to do so, we specify the array limits of the incoming (coarse) field, the interior points (which are the same as array limits since we wish to interpolate the entire domain covered by the coarse mesh, including the halo points), and the array limits of the temporary array (which are the same as that of the coarse mesh). Note that all variables `b?L = b?R = 0`, indicating that all points are valid points/interior points. `?` is a wildcard that can stand for `i`, `j`, or `k`. This corresponds to lines 150–189. We make the call to the library on line 203. `iperx, ipery,` and `iperz` are variables that indicate if periodicity exists in any of the directions. `orderi, orderb` indicate which order of interpolation to use for the interior (`i`) and boundary (`b`) and are set to 6. `orderb` is ignored; the library skews the stencil to a lower order by itself. The output is kept in `tempx`.

This is repeated with `tempy` and `tempxy` while calling `y_intp_cf_vc()` and `xy_intp_cf_vc()` for the interpolations in y and the mid-points. Finally, the contents of `tempx, tempy,` and `tempxy` are inserted into their correct places in the "fine" array (lines 238–247).

PRECONDITIONED ITERATIVE SOLVERS FOR INDUCTANCE EXTRACTION OF VLSI CIRCUITS*

HEMANT MAHAWAR† AND VIVEK SARIN†

Abstract. Parasitic extraction techniques are used to estimate signal delay in VLSI circuits. Inductance extraction is a critical component of the parasitic extraction process that involves estimation of on-chip inductive effects with high accuracy. The problem requires the solution of a large, dense, complex linear system of equations, where the unknown current must satisfy the constraint imposed by Kirchoff's current law. In this paper, we describe a solenoidal basis method to transform the constrained linear system into an unconstrained one. The method uses discrete local solenoidal flows to represent the unknown current, and to obtain a reduced linear system. The paper proposes preconditioning techniques that do not require explicit construction of the reduced system. Numerical experiments are presented to illustrate the effectiveness of the preconditioning approach. Comparisons with a well-known inductance extraction package are provided to highlight the advantages of the proposed scheme.

1. Introduction.

Signal integrity and timing analyses of modern VLSI circuits depend on accurate estimates of signal delay in various parts of the circuit. A significant portion of this delay can be attributed to the circuit's , which arises from undesirable resistive, capacitive, and inductive coupling among circuit components. The process of determining the parasitic impedance in a VLSI circuit is known as . It is a common practice to compute signal delay in low-frequency circuits using estimates of the capacitive and resistive parasitics only. At high frequencies, however, the effect of the inductive parasitic cannot be ignored. For instance, the inductive coupling tends to dominate the parasitic impedance for circuits operating at frequencies in the gigahertz (GHz) range. Reducing the resistance of circuit components through the use of low resistive materials and wider interconnect segments also increases the effect of the inductive parasitic. It is widely believed that fast and accurate inductance extraction techniques that are capable of handling large complicated layouts are critical to the design of next-generation VLSI circuits.

In a VLSI circuit, changes in current flow create a varying magnetic field that leads to inductive coupling among different components. This effect is more pronounced when these components are in close physical proximity. Chips designed with submicron VLSI technology are prone to parasitic inductive effects because of tightly packed components. The property of an electrical circuit to resist change in its own current due to the presence of an associated magnetic field is called . Self-inductance of a conductor refers to the resistance offered to current flow by the magnetic field induced by its own current. Mutual inductance between a pair of conductors refers to the resistance in one conductor due to current flow in the other. The

process of estimating the inductive coupling between the components of a layout is called [illegible].

A magneto-quasi-static approach is often used to compute the parasitic inductance for a set of conductors at a particular frequency. The surface of each conductor is discretized by a uniform two-dimensional mesh that represents a network of smaller conductors or filaments, and a linear system of equations is solved to determine the inductive coupling [4]. The linear system is derived from Kirchoff's current and voltage laws that govern the current flow into mesh nodes and the potential drop across mesh edges, respectively. The coefficient matrix is large and complex, with a sparse-dense structure. This matrix consists of a dense submatrix arising from the inductive coupling among filaments and a sparse submatrix arising from the current law. The cost of computing and storing the dense submatrix becomes prohibitive as the problem size grows beyond a few thousand filaments. Matrix-vector products with the dense submatrix are computed approximately via hierarchical multipole-based methods such as the fast multipole method (FMM) [3, 7] and the Barnes–Hut method [1]. These methods do not require construction of a coefficient matrix. Since the dense submatrix is not available explicitly, the linear system must be solved by an iterative solver such as the generalized minimum residual (GMRES) method [10] that relies only on the ability to compute matrix-vector products with the coefficient matrix. In principle, this approach can lead to a matrix-free algorithm that does not require explicit computation of the coefficient matrix. In practice, however, one may be forced to compute "sparse" approximations of the matrix that can then be used to construct preconditioners based on incomplete factorization schemes.

Widely available software for inductance extraction include academic codes such as FastHenry [4], and commercial codes such as Momentum and Columbus. FastHenry uses the approach described earlier to compute accurate estimates of a circuit's parasitic inductance. Although the code is used as a benchmark for accuracy comparison, it has found limited use in the VLSI-CAD (computer-aided design) community due to the high cost of computing sparse approximations and the ineffectiveness of the resulting preconditioners. This paper presents an inductance extraction algorithm that uses a solenoidal basis approach to construct effective preconditioners for the linear systems. Preliminary experiments presented in [5, 6] highlight the performance of the method. This paper analyzes the numerical aspects of the algorithm with particular emphasis on the effectiveness of the preconditioning approach.

The paper is organized as follows. Section 2 presents the mathematical formulation of the inductance extraction problem and the associated linear system of equations. Section 3 outlines the solenoidal basis method that is used to transform the linear system into a reduced system. This is followed by a description of the preconditioning approach in section 4. The inductance extraction algorithm is presented in section 5. This section also includes an overview of the hierarchical multipole-based methods for computing dense matrix-vector products and a comparison with FastHenry. Conclusions are presented in section 6.

2. Mathematical formulation. Inductance extraction of a layout with n_s conductors involves computing an $n_s \times n_s$ impedance matrix $\mathbf{Z}$, where $\mathbf{Z}_{ij}$ represents the inductive coupling between conductors i and j at a given frequency f. To determine the jth column of $\mathbf{Z}$, an alternating current source of unit magnitude and frequency f is applied to the jth conductor. The resulting potential drop across conductor i gives the value of $\mathbf{Z}_{ij}$. The potential drop across all the conductors can be determined simultaneously by solving a linear system of equations with a right-hand side that is

derived from the boundary condition on the jth conductor. One needs to solve n_s instances of the linear system, each with a different right-hand side, to compute the impedance matrix $\mathbf{Z}$.

A number of techniques based on the integral form of Maxwell's equations have been used to model VLSI circuits [2, 8]. Under magneto-quasi-static assumptions, current density $\mathbf{J}(\mathbf{r})$ and potential $\phi(\mathbf{r})$ obey the following equations at steady state:

$$\rho \mathbf{J}(\mathbf{r}) + j\omega \int_V \frac{\mu}{4\pi} \frac{\mathbf{J}(\mathbf{r}')}{\|\mathbf{r} - \mathbf{r}'\|_2} dV' = -\nabla\phi(\mathbf{r}), \tag{2.1}$$

$$\nabla \cdot \mathbf{J}(\mathbf{r}) = 0, \tag{2.2}$$

where $\mathbf{r}$ and $\mathbf{r}'$ denote three-dimensional position vectors, V is the volume of the conductors, dV' is the incremental volume with respect to $\mathbf{r}'$, μ is the magnetic permeability, ρ is the resistivity of the material, ω is the angular frequency that equals $2\pi f$, and $j = \sqrt{-1}$. The magneto-quasi-static assumption ignores the displacement current.

To obtain a numerical solution of (2.1)–(2.2), each conductor surface is discretized by a two-dimensional mesh of filaments that form the edges of the mesh. Within each filament, current density is assumed to be constant. Furthermore, current is assumed to flow along the length of a filament. The vector of unknown filament currents, $\mathbf{I}_f$, is related to the vector of unknown potential differences across filament end-points, $\mathbf{V}_f$, as shown below:

$$[\mathbf{R} + j\omega\mathbf{L}]\,\mathbf{I}_f = \mathbf{V}_f, \tag{2.3}$$

where $\mathbf{R}$ is an $m \times m$ real diagonal matrix of filament resistances for a mesh with m filaments, and $\mathbf{L}$ is an $m \times m$ complex, dense inductance matrix. The kth diagonal element of $\mathbf{R}$ is assigned the value $\rho l_k / a_k$, where l_k and a_k are the length and cross-sectional area, respectively, of the kth filament. The inductance matrix $\mathbf{L}$ is symmetric positive definite with entries:

$$\mathbf{L}_{kl} = \frac{\mu}{4\pi} \frac{1}{a_k a_l} \int_{r_k \in V_k} \int_{r_l \in V_l} \frac{\mathbf{u}_k \cdot \mathbf{u}_l}{\|\mathbf{r}_k - \mathbf{r}_l\|_2} dV_k dV_l,$$

where $\mathbf{u}_k$ denotes the unit vector along the kth filament, and $\mathbf{r}_k$ and $\mathbf{r}_l$ denote position vectors for points in filaments k and l, respectively. The integral is calculated over the volumes of the two filaments. Since $\mathbf{R}$ and $\mathbf{L}$ are symmetric positive definite matrices, the coefficient matrix in (2.3) is nonsingular.

Kirchoff's current law (2.2) imposes an additional set of constraints on the filament current vector:

$$\mathbf{B}^T \mathbf{I}_f = \mathbf{I}_s, \tag{2.4}$$

where $\mathbf{B}^T$ is the branch index matrix and $\mathbf{I}_s$ is the external source current. The branch index matrix for a mesh with n nodes and m filaments is a matrix of size $n \times m$, in which the (k, l) entry has the value -1 if the lth filament originates at node k, 1 if it terminates at k, and 0 otherwise. For example, consider a mesh with an $n_x \times n_y$ array of cells in which the nodes and filaments have a natural ordering starting from the left bottom corner. Horizontal filaments are ordered before vertical filaments. The branch index matrix is the following matrix with $(n_y + 1)$ block rows

and $(2n_y + 1)$ block columns:

$$\mathbf{B}^T = \left[\begin{array}{ccccc|ccccc} T & & & & & I & & & & \\ & T & & & & -I & I & & & \\ & & T & & & & -I & \ddots & & \\ & & & \ddots & & & & \ddots & I & \\ & & & & T & & & & -I & \end{array}\right],$$

where I is the identity matrix of size $(n_x + 1) \times (n_x + 1)$ and T is a matrix of size $(n_x + 1) \times n_x$ given below:

$$T = \begin{bmatrix} 1 & & & \\ -1 & 1 & & \\ & -1 & \ddots & \\ & & \ddots & 1 \\ & & & -1 \end{bmatrix}.$$

The potential difference across the filaments can be expressed in terms of the node potential:

$$\mathbf{V}_f = \mathbf{B}\mathbf{V}_n, \tag{2.5}$$

where $\mathbf{V}_n$ is a vector of node potentials defined with respect to the ground. Equations (2.3), (2.4), and (2.5) give rise to a linear system of equations governing filament currents and node potentials:

$$\begin{bmatrix} \mathbf{R} + j\omega\mathbf{L} & -\mathbf{B} \\ \mathbf{B}^T & 0 \end{bmatrix} \begin{bmatrix} \mathbf{I}_f \\ \mathbf{V}_n \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{I}_s \end{bmatrix}. \tag{2.6}$$

The coefficient matrix of the linear system (2.6) is a sparse-dense matrix of size $(n+m)\times(n+m)$ in which the first diagonal block is dense and the off-diagonal blocks are sparse. Even for a small problem with a few thousand filaments, it is prohibitively expensive to compute and store $\mathbf{L}$. On the other hand, one can use "fast" hierarchical multipole-based methods to compute approximate matrix-vector products with $\mathbf{L}$. When filaments are uniformly distributed, the FMM requires $O(m)$ operations, while multipole-based variants of the Barnes–Hut method [1] require $O(m \log m)$ operations to compute these matrix-vector products. Higher degree multipoles can be used to reduce the approximation error. However, the computational cost grows proportional to d^4, where d is the multipole degree. Due to the unavailability of the coefficient matrix, the linear system (2.6) has to be solved by iterative techniques such as GMRES that rely solely on the ability to compute matrix-vector products with the coefficient matrix. Robust and effective preconditioners are necessary to accelerate the convergence of the solver. Construction of preconditioners in the absence of the coefficient matrix turns out to be a formidable challenge.

3. A solenoidal basis method for inductance extraction. Solenoidal functions are divergence-free functions that satisfy conservation laws such as Kirchoff's current law in electric circuits and the mass conservation law in fluid mechanics. For a uniform mesh, it is easy to construct a solenoidal basis that consists of divergence-free functions in the discrete sense. Figure 3.1 shows several instances of discrete

solenoidal current flows that can be used to construct a solenoidal basis. Each flow consists of a constant amount of current flowing anticlockwise through the four filaments of a cell in the mesh. These flows satisfy Kirchoff's current law since the net flow of current into any node is zero.

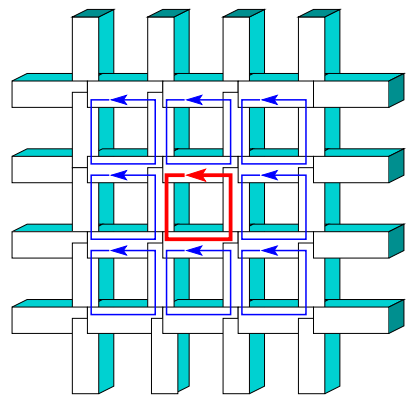

FIG. 3.1. *A set of nine solenoidal current flows in a section of a uniform two-dimensional mesh.*

A basis consisting of such functions can be viewed as a [illegible] in which the basis functions have local support on the mesh. The solenoidal basis matrix $\mathbf{P}$ is an $m \times s$ matrix that is derived from the current flows in mesh cells. Each column corresponds to a cell in the mesh and consists of four nonzero entries that denote the current flow in the cell: 1 indicates a unit current flow along the edge, and -1 indicates a unit current flow opposite the direction of the edge. Construction of the solenoidal basis matrix in this manner ensures that the following condition is satisfied:

$$\mathbf{B}^T\mathbf{P} = 0. \tag{3.1}$$

Again, consider a mesh with an $n_x \times n_y$ array of cells in which the nodes and filaments have a natural ordering starting from the left bottom corner. Horizontal filaments are ordered before vertical filaments. The solenoidal basis matrix is the following matrix with n_y block rows and $(2n_y + 1)$ block columns:

$$\mathbf{P}^T = \left[\begin{array}{cccc|ccc} I & -I & & & W & & \\ & I & -I & & & W & \\ & & \ddots & \ddots & & & \ddots \\ & & & I \quad -I & & & & W \end{array}\right],$$

where I is the identity matrix of size $n_x \times n_x$ and W is a matrix of size $n_x \times (n_x + 1)$ given below:

$$W = \left[\begin{array}{ccccc} 1 & -1 & & & \\ & 1 & -1 & & \\ & & \ddots & \ddots & \\ & & & 1 & -1 \end{array}\right].$$

A local solenoidal basis for a two-dimensional mesh is a complete basis with linearly independent components. The linear independence of the columns of $\mathbf{P}$ is established by observing that the matrix $\mathbf{P}^T\mathbf{P}$ is the standard two-dimensional Laplace

operator matrix. In a uniform two-dimensional mesh consisting of an $n_x \times n_y$ array of cells, the numbers of nodes, edges, and cells are given by $n = (n_x + 1)(n_y + 1)$, $m = 2n - n_x - n_y - 2$, and $s = m - n + 1$, respectively. Since the number of cells equals the dimension of the null space of the discrete divergence matrix $\mathbf{B}^T$, it follows that the local solenoidal basis is complete. It may be noted that $\mathbf{B}$ has a rank-deficiency of 1 to allow the potential to vary by a constant. The rank deficiency can be removed by specifying the value of the potential at a single node.

The linear system (2.6) must be transformed before one can use the solenoidal basis method. The first step is to determine a particular current vector $\mathbf{I}_p$ that satisfies the constraints imposed by the external current source. The vector $\mathbf{I}_p$ represents current flow along an arbitrary path between the nodes, where the external source is connected (see, e.g., Figure 3.2). By splitting the current $\mathbf{I}_f$ into a known component $\mathbf{I}_p$ and an unknown component $\mathbf{I}$, the linear system (2.6) can be transformed into an equivalent system with a different right-hand side:

$$\begin{bmatrix} \mathbf{R} + j\omega\mathbf{L} & -\mathbf{B} \\ \mathbf{B}^T & 0 \end{bmatrix} \begin{bmatrix} \mathbf{I} \\ \mathbf{V}_n \end{bmatrix} = \begin{bmatrix} \mathbf{F} \\ \mathbf{0} \end{bmatrix}, \tag{3.2}$$

where

$$\mathbf{I} = \mathbf{I}_f - \mathbf{I}_p, \qquad \mathbf{F} = -\left[\mathbf{R} + j\omega\mathbf{L}\right]\mathbf{I}_p.$$

The difference between (2.6) and (3.2) is that the first system satisfies current boundary conditions, whereas the second system satisfies voltage boundary conditions.

Note that the linear system in (3.2) includes the constraint $\mathbf{B}^T\mathbf{I} = \mathbf{0}$, which ensures that the net current flowing into every node is zero, as required by Kirchoff's law. Thus, $\mathbf{I} \in Null(\mathbf{B}^T)$. Since $\mathbf{P}$ is a basis for $Null(\mathbf{B}^T)$, the unknown current $\mathbf{I}$ can be represented as a linear combination of the columns of $\mathbf{P}$:

$$\mathbf{I} = \mathbf{P}x,$$

where x is an unknown vector of size s. This is equivalent to representing current as a weighted sum of local solenoidal flows, where the weights are given by x. From (3.1), it follows that $\mathbf{I}$ must satisfy the constraint $\mathbf{B}^T\mathbf{I} = \mathbf{0}$. By restricting the unknown current to the solenoidal subspace in this manner, the linear system (3.2) can be transformed into the following system:

$$\left[\mathbf{R} + j\omega\mathbf{L}\right]\mathbf{P}x - \mathbf{B}\mathbf{V}_n = \mathbf{F}.$$

The vector of unknown node potentials can be eliminated by multiplying the system with $\mathbf{P}^T$ from the left:

$$\mathbf{P}^T\left[\mathbf{R} + j\omega\mathbf{L}\right]\mathbf{P}x = \mathbf{P}^T\mathbf{F}. \tag{3.3}$$

The above system is a linear system of order s that must be solved to determine x.

A physical interpretation of transforming (3.2) into (3.3) can be obtained by noting that $\mathbf{P}$ and $\mathbf{P}^T$ implement discrete curl operators on the conductor surface. The vector x corresponds to magnetic field normal to the surface, whose curl determines the electric field which is proportional to $\mathbf{I}$. The transformation itself can be viewed as a conversion of variables from electric field to magnetic field.

Note that the coefficient matrix in (3.3) is nonsingular because $\mathbf{R}$ and $\mathbf{L}$ are symmetric positive definite matrices and $\mathbf{P}$ is a full rank matrix. Since the coefficient

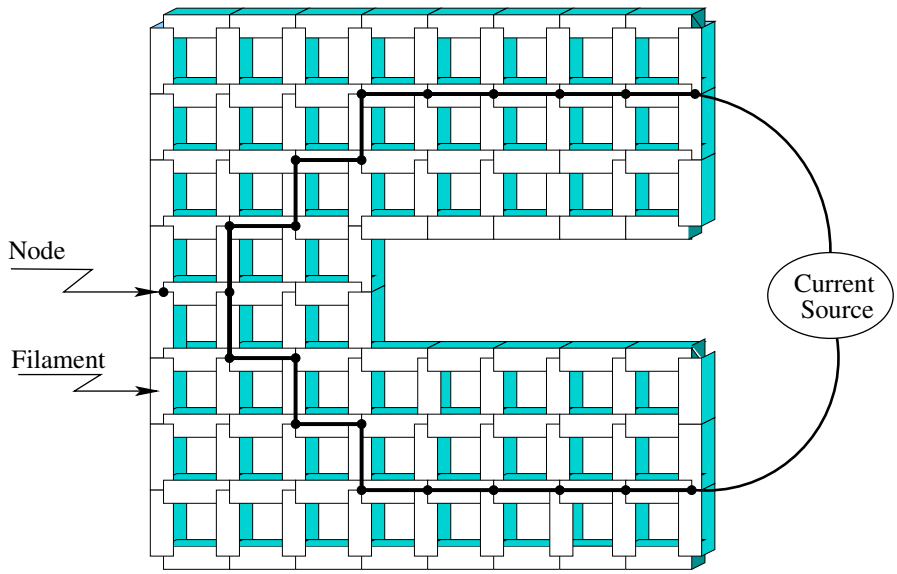

FIG. 3.2. *Current flow along an arbitrary path in the mesh can be used to satisfy the constraints imposed by the external current source.*

TABLE 3.1
The sizes of the original and reduced systems arising in the inductance extraction of a ground plane.

Mesh Size ($n_x \times n_y$)	Nodes (n)	Filaments (m)	Unknowns ($n+m$)	Solenoidal functions (s)
64×64	4225	8320	12545	4096
128×128	16641	33024	49665	16384
256×256	66049	131584	197633	65536
512×512	263169	525312	788481	262144

matrix is never computed explicitly, an iterative method such as GMRES must be used to solve the system. Once x has been computed, the filament current vector, $\mathbf{I}_f$, and the vector of unknown potential differences across the filaments, $\mathbf{V}_f$, can be computed as follows:

$$\mathbf{I}_f = \mathbf{I}_p + \mathbf{P}x, \qquad \mathbf{V}_f = [\mathbf{R} + j\omega\mathbf{L}]\,\mathbf{I}_f.$$

When a unit current is applied by the external source, the impedance between any pair of nodes is equal to the potential difference between the nodes. This potential difference can be calculated by adding the potential differences across the filaments on an arbitrary path between the nodes.

The transformation of the linear system (3.2) into the reduced system (3.3) has several advantages. The number of unknowns reduces considerably whenever two-dimensional discretizations are employed. Table 3.1 shows the number of unknowns in a ground plane problem that involves computing the self-impedance of a square conductor. The use of a local solenoidal basis results in a sparse matrix $\mathbf{P}$ that is amenable to efficient matrix-vector product computations. Matrix-free implementations are also possible since explicit construction of $\mathbf{P}$ is unnecessary. In addition, the sparsity of $\mathbf{P}$ is instrumental in improving the efficiency of parallel implementations.

4. Preconditioning the reduced system. The main challenge in solving the reduced system (3.3) iteratively is posed by the preconditioning step. The ability to precondition the reduced system effectively is critical to the success of the solenoidal basis method. The rate of convergence of the iterative solver depends on the spectral properties of the coefficient matrix. Preconditioning may be considered as a process of transforming a linear system into one that has more favorable spectral properties. For instance, the linear system $\mathbf{A}x = b$ may be preconditioned by postmultiplying $\mathbf{A}$ with a matrix $\mathbf{M}$ as shown below:

$$\mathbf{A}\mathbf{M}y = b, \qquad x = \mathbf{M}y. \tag{4.1}$$

The transformed system is solved by an iterative method. Each iteration now requires an additional preconditioning step that involves a matrix-vector product with $\mathbf{M}$. A preconditioning approach is advantageous only if the overall time to compute the solution is reduced. For this to happen, the preconditioner must be easy to compute, the preconditioning step must be relatively inexpensive, and $\mathbf{M}$ should be an effective preconditioner that reduces the number of iterations considerably. Preconditioning can be done from the left side by premultiplication, from the right side by postmultiplication, or from both sides [9].

A good preconditioner can be characterized in a variety of ways. In general, clustering of eigenvalues of the preconditioned system can lead to rapid convergence. In many cases, a preconditioned system with a small condition number can be solved in a few iterations. A preconditioning approach is considered optimal if the number of iterations required is independent of the discretization parameters.

It is common to use the symbol $\mathbf{M}^{-1}$ instead of $\mathbf{M}$ in (4.1) to indicate that the preconditioner is an approximation of the matrix $\mathbf{A}$ and that the preconditioning step requires the solution of a linear system with the preconditioner as the coefficient matrix. Such approximations are obtained implicitly by computing incomplete factorizations of $\mathbf{A}$. Although the coefficient matrix in the reduced system (3.3) is not available, one can compute a "sparse" approximation by ignoring interactions between distant filament pairs. An incomplete factorization of this sparse matrix yields L and U factors that can be used to define the preconditioner for the reduced system.

FastHenry [4] uses a similar approach in which the matrix is sparsified by several different strategies in order to obtain inexpensive preconditioners. Unfortunately, the sparsification schemes in the package tend to be very expensive from the perspective of computation and memory requirements. This has restricted the use of the code to solving small benchmark problems only.

An effective preconditioning approach can be developed by analyzing the reduced system (3.3) carefully. The use of local solenoidal flows defined on a uniform two-dimensional mesh provides a basis for this analysis. Consider the matrices that form the reduced system: $\mathbf{R}$ is a diagonal matrix with positive entries, $\mathbf{L}$ is a dense symmetric positive definite matrix, and $\mathbf{P}$ is a sparse matrix. The matrices $\mathbf{P}$ and $\mathbf{P}^T$ implement discrete curl operators on the conductor surface, and $\mathbf{P}^T\mathbf{P}$ is a discrete two-dimensional Laplace operator. Table 4.1 provides estimates of the largest and smallest eigenvalues of these matrices for a discretization with filament length h. Discretizations of the conductor surfaces must use filaments with a fixed ratio between length and cross-section area to be consistent with physical laws. As a result, the eigenvalues of $\mathbf{R}$ are independent of h.

At higher frequencies, the reduced system is dominated by the imaginary part, whose condition number is proportional to h^{-1}. The real part dominates at lower

TABLE 4.1
Estimates of the extremal eigenvalues of matrices that form the reduced system.

Matrix	$\lambda_{\min}$	$\lambda_{\max}$
$\mathbf{R}$	c	c

$\mathbf{P}^T\mathbf{R}\mathbf{P}$	$O(h^2)$	$O(1)$
$\mathbf{P}^T\mathbf{L}\mathbf{P}$	$O(h^2)$	$O(h)$
$Re(\mathbf{P}^T[\mathbf{R}+j\omega\mathbf{L}]\mathbf{P})$	$O(h^2)$	$O(1)$
$Im(\mathbf{P}^T[\mathbf{R}+j\omega\mathbf{L}]\mathbf{P})$	$O(\omega h^2)$	$O(\omega h)$

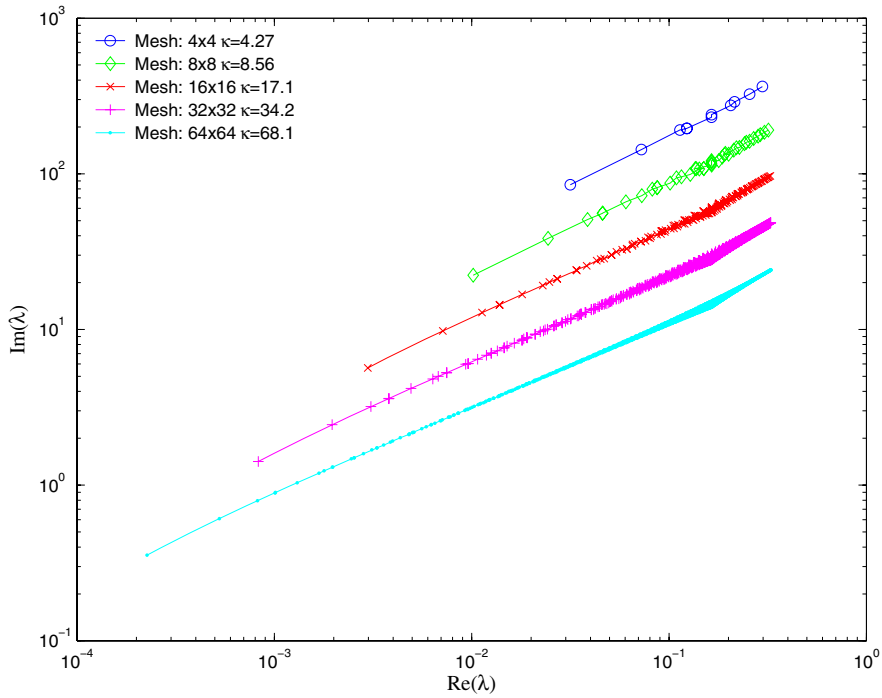

FIG. 4.1. *The spectrum of the reduced system that arises from a uniform discretization of the square ground plane problem ($\omega = 2\pi \times 10$ GHz). The mesh size is $n_x \times n_x$ and the filament length is $h = 1/n_x$. The condition number of the system is denoted by κ.*

frequencies, and the condition number grows proportional to h^{-2}. Figure 4.1 shows the spectrum of the reduced system (3.3) obtained from the ground plane problem with $\omega = 2\pi \times 10$ GHz. A uniform two-dimensional mesh is used to discretize the ground plane of size 1 cm $\times$ 1 cm. The eigenvalues of the matrix lie on a straight line in the complex plane. The condition number of the reduced system doubles every time the mesh is refined.

The entries of $\mathbf{L}$ are derived from Green's function for the three-dimensional Laplace operator. While $\mathbf{P}^T\mathbf{P}$ is a two-dimensional Laplace operator with a condition number proportional to h^{-2}, the matrix $\mathbf{P}^T\mathbf{L}\mathbf{P}$ tends to have a condition number that is proportional to h^{-1} only. Furthermore, as shown in Figure 4.2, the matrix $\mathbf{L}\mathbf{P}$ is a well-conditioned matrix with a condition number that is nearly independent of h. To exploit this fact, we express $\mathbf{L}\mathbf{P}$ as shown below:

$$\mathbf{L}\mathbf{P} = \mathbf{P}\tilde{\mathbf{L}} + \hat{\mathbf{P}}\hat{\mathbf{L}},$$

where $\tilde{\mathbf{L}}$ represents the mutual inductance among hypothetical filaments placed at the center of each mesh cell and oriented in the same direction, $\hat{\mathbf{L}}$ represents the inductive effect of these filaments on the boundary of the conductors, and $\hat{\mathbf{P}}$ updates the boundary filaments. This representation can be viewed as a set of filaments placed at the centers of the mesh cells with an additional set of ghost cells along the boundary. The filaments at the centers of the ghost cells carry no current. Note that $\hat{\mathbf{P}}\hat{\mathbf{L}}$ is a low-rank matrix, whose influence is limited to the boundary. Since it has a marginal effect on the singular values of $\mathbf{LP}$, one can expect $\mathbf{P}\tilde{\mathbf{L}}$ to be a good approximation of $\mathbf{LP}$. Figure 4.2 shows that a large number of singular values of these two matrices are identical. A theoretical estimate of the quality of this approximation remains an open problem.

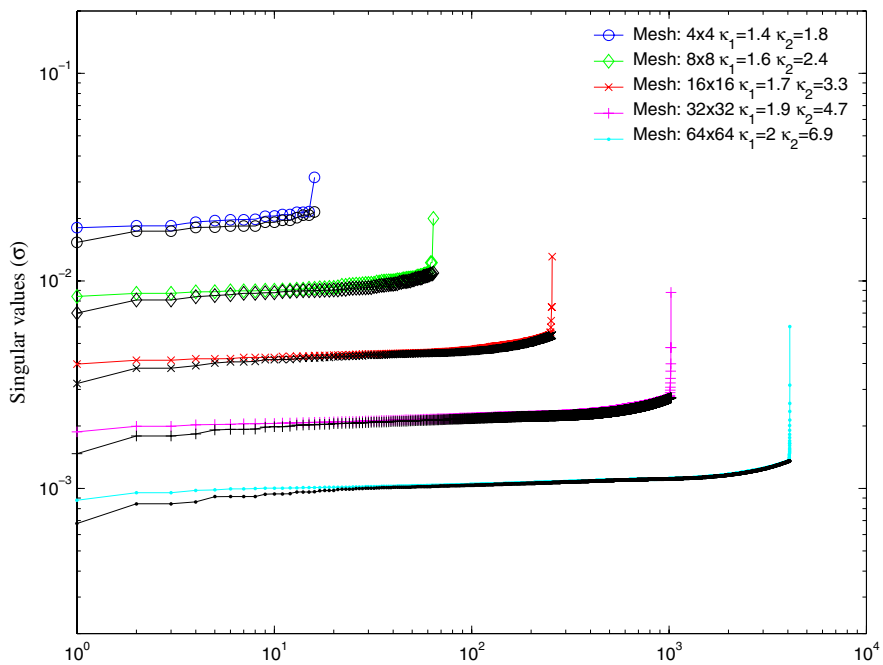

FIG. 4.2. *Singular values of* $\mathbf{LP}$ *(bottom line) and* $\mathbf{P}\tilde{\mathbf{L}}$ *(top line) of the square ground plane problem* ($\omega = 2\pi \times 10$ *GHz) for different meshes. The mesh size is* $n_x \times n_x$ *and the filament length is* $h = 1/n_x$*. The condition numbers of* $\mathbf{LP}$ *and* $\mathbf{P}\tilde{\mathbf{L}}$ *are denoted by* κ_1 *and* κ_2*, respectively.*

The matrix $\tilde{\mathbf{L}}$ is a symmetric positive definite matrix defined as follows:

$$\tilde{\mathbf{L}}_{kl} = \frac{\mu}{4\pi}\frac{1}{a_k a_l}\int_{r_k \in V_k}\int_{r_l \in V_l}\frac{1}{\|\mathbf{r}_k - \mathbf{r}_l\|_2}dV_k dV_l.$$

The matrix element $\tilde{\mathbf{L}}_{kl}$ equals the mutual inductance between a pair of parallel filaments placed at the centers of cells k and l. At high frequencies, when the imaginary part of the reduced system dominates, $\tilde{\mathbf{L}}$ can be used as a preconditioner for the reduced system. Since

$$\mathbf{P}^T\mathbf{LP}\tilde{\mathbf{L}} \approx \mathbf{P}^T\mathbf{L}^T\mathbf{LP},$$

the preconditioner is expected to yield a well-conditioned system. Figure 4.3 shows that the eigenvalues of the preconditioned reduced system are clustered close together,

almost independent of the filament width h. The preconditioned system is solved in a few iterations typically, and the preconditioner appears to be effective for the mid-frequency range as well. For low frequency problems, one should use a two-dimensional Laplace matrix to precondition the real part of the reduced system. It should be noted that accurate inductance extraction may not be needed at low frequencies.

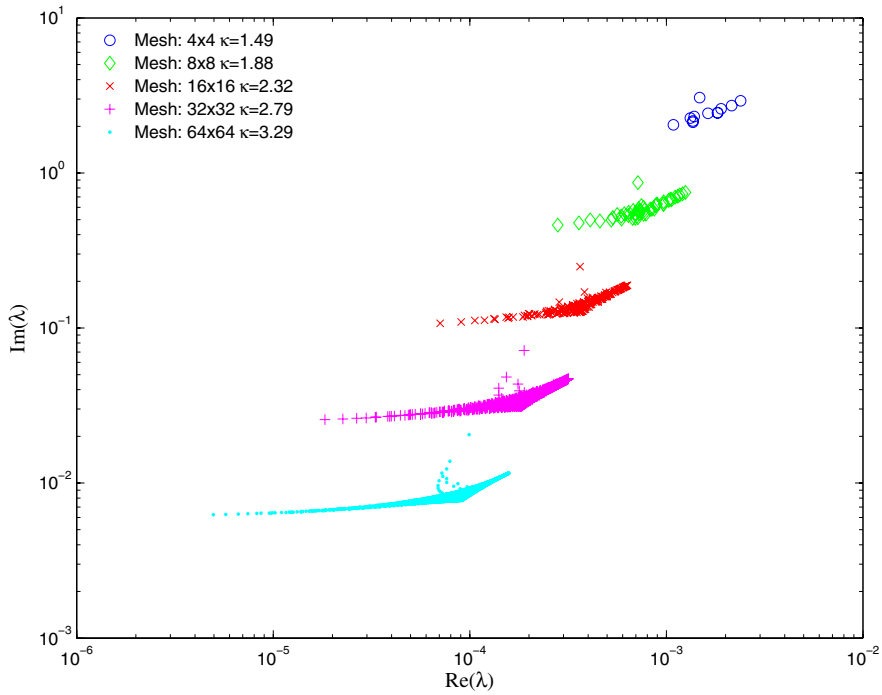

FIG. 4.3. *The spectrum of the preconditioned reduced system for the square ground plane problem ($\omega = 2\pi \times 10$ GHz). The mesh size is $n_x \times n_x$ and the filament length is $h = 1/n_x$. The condition number of the preconditioned system is denoted by κ.*

4.1. Effectiveness of the preconditioning approach. To illustrate the effectiveness of the preconditioning scheme, we consider two benchmark problems. The first problem involves computing the self-inductance of a square ground plane of size 1 cm $\times$ 1 cm. The plane is discretized by a uniform two-dimensional mesh with mesh width h varying from 2^{-5} cm to 2^{-9} cm. The width of each filament is one-third of its length, and the thickness is 2^{-13} cm. A tolerance of 10^{-6} was specified on the relative residual norm. Table 4.2 shows the number of iterations required by the right-preconditioned GMRES method to solve the reduced system. It can be seen that the number of iterations remains nearly constant across a large frequency range. The slow rate of convergence of the GMRES method without any preconditioner can be gauged from the iterations shown in parentheses.

The second benchmark problem is the cross-over problem shown in Figure 4.4. In VLSI circuits, this is a typical layout configuration with interconnect segments crossing each other on different layers. Each conductor is a rectangle of size 2 cm $\times$ 2 mm. The discretization is similar to the first problem. These simulations were con-

TABLE 4.2

ducted for 10 GHz frequency. Table 4.3 reports the number of iterations required by the right-preconditioned GMRES method to reduce the relative residual norm below 10^{-6}. In each case, the range of iterations needed to solve n_s instances of the linear system are reported. The number of iterations grows slowly as the number of conductors in the configuration is increased. Furthermore, the growth in iterations is slow as the mesh is refined. These results illustrate the effectiveness of the preconditioning scheme for typical extraction problems.

5. The inductance extraction algorithm. An outline of the preconditioned solenoidal basis method for computing the impedance matrix $\mathbf{Z}$ is given below.

ALGORITHM 1.

1. Discretize the surfaces of the conductors with two-dimensional uniform meshes.
2. Construct an oct-tree for the filaments in each conductor.
3. Compute the solenoidal basis matrix $\mathbf{P}$.
4. For conductor $l = 1, \ldots, n_s$:
   (a) Compute the particular solution $\mathbf{I}_p^{(l)}$ for a unit current flow through conductor l and the corresponding induced potential difference vector $\mathbf{F}^{(l)}$.
   (b) Solve the preconditioned system

$$\mathbf{P}^T \left[\mathbf{R} + j\omega\mathbf{L}\right] \mathbf{P}\tilde{\mathbf{L}}x = \mathbf{P}^T\mathbf{F}^{(l)}, \qquad x^{(l)} = \tilde{\mathbf{L}}x$$

   to determine $x^{(l)}$, and compute filament current and filament potential difference vectors:

$$\mathbf{I}_f^{(l)} = \mathbf{P}x^{(l)} + \mathbf{I}_p^{(l)}, \qquad \mathbf{V}_f^{(l)} = \left[\mathbf{R} + j\omega\mathbf{L}\right] \mathbf{I}_f^{(l)}.$$

   Use the GMRES method to solve the preconditioned reduced system. Use the FMM to compute matrix-vector products with $\mathbf{L}$ and $\tilde{\mathbf{L}}$ in each iteration.
   (c) For conductor $k = 1, \ldots, n_s$, determine $\mathbf{Z}_{kl}$ by adding the potential difference across all filaments along a path between the two ends of conductor k.

In the above algorithm, a majority of the time is spent in step 4(b). The most time-consuming computations involve matrix-vector products with the reduced system matrix $\mathbf{P}^T \left[\mathbf{R} + j\omega\mathbf{L}\right] \mathbf{P}$ and with the preconditioner matrix $\tilde{\mathbf{L}}$. Products with the reduced system are computed as a sequence of three products:

$$u = \mathbf{P}x, \qquad v = \left[\mathbf{R} + j\omega\mathbf{L}\right] u, \qquad y = \mathbf{P}^T v.$$

The cost of multiplying the dense matrix $\mathbf{L}$ with a vector is significantly larger than the cost of matrix-vector products with $\mathbf{P}$ or $\mathbf{P}^T$. It is worthwhile to use multipole-based hierarchical methods to compute matrix-vector products with $\mathbf{L}$. Furthermore, since the structure of the preconditioner $\tilde{\mathbf{L}}$ is similar to $\mathbf{L}$, these fast methods should be used to compute matrix-vector products in the preconditioning step as well.

The number of operations needed to compute accurate matrix-vector products with an $m \times m$ dense matrix is $O(m^2)$. Approximations to these products can be computed efficiently through hierarchical multipole-based methods that exploit the decaying nature of the $1/r$ kernel in the entries of $\mathbf{L}$. These methods include the FMM [3, 7] and variants of the Barnes–Hut method [1]. For uniform filament distributions, the FMM reduces the computational complexity to $O(m)$, and the Barnes–Hut variants achieve $O(m \log m)$ complexity. The Barnes–Hut approach uses filament-cluster interactions, whereas the FMM uses both filament-cluster and cluster-cluster interactions.

We use a variant of the FMM to compute the potential at each filament due to current flow in all the filaments. The algorithm works in two phases: the oct-tree construction phase and the potential evaluation phase. To construct the oct-tree, the domain is divided into eight equal nonoverlapping subdomains. The process is repeated on each subdomain recursively until every subdomain has at most s filaments, where s is a parameter chosen to maximize computational efficiency. A subdomain

is represented by a subtree whose leaf nodes contain the filaments in the subdomain. The potential evaluation phase consists of two traversals of the tree. During the up-traversal, multipole coefficients are computed at each node. These coefficients can be used to compute the potential due to all the filaments within the node's subdomain at a , , , point. During the down-traversal, the multipole coefficients are used to compute local coefficients at each node. These local coefficients can be used to compute the potential at any point inside a node's subdomain due to , , , filaments. Potential due to , , filaments is computed directly.

The implementation based on the preceding approach is a matrix-free code in which neither the system matrix nor the preconditioner matrix is ever computed. This reduces the storage requirement considerably, thereby allowing larger problems to be solved. The overall complexity of Algorithm 1 is $O(i_G m)$, where m is the number of filaments and i_G is the total number of GMRES iterations required to solve n_s instances of the linear system.

5.1. Comparison with FastHenry. It is instructive to compare the performance of the preconditioned solenoidal basis method with that of FastHenry. FastHenry uses mesh currents similar to the local solenoidal flows to generate a reduced system. This system is solved by the preconditioned GMRES method. Matrix-vector products with the dense matrix $\mathbf{L}$ are computed via the FMM. The main difference between the two algorithms lies in the preconditioning step. FastHenry uses preconditioners that are derived from incomplete factorizations of sparsified forms of the reduced system. These sparse approximations are constructed explicitly by restricting the off-diagonal nonzeros in each column to those resulting from coupling between specific filament pairs. These pairs may be in the same box at a particular level in the oct-tree or may be within a fixed distance of each other.

Table 5.1 shows the execution time and the number of iterations needed by the preconditioned GMRES method to solve several instances of the cross-over problem. The column marked "Iter." gives the range of iterations needed to solve n_s instances of the linear system. A tolerance of 10^{-3} was specified on the relative residual norm. Multipoles of degree 2 were used in all the FMM computations. In accordance with standard practice, it was ensured that the error in the entries of the inductance matrix $\mathbf{Z}$ was 2% of the values obtained by a more accurate calculation based on the FMM with a higher multipole degree. These experiments were conducted on a 2.4 GHz Pentium Workstation with 1 GB of memory.

FastHenry requires a significant amount of memory to construct the sparsified matrix and compute its incomplete LU factorization. The entries marked "—" indicate the inability of FastHenry to solve the problem within the available system memory.

TABLE 5.1
Comparison of the preconditioned solenoidal basis method with FastHenry.

Conductor layout	FastHenry		Solenoidal method	
	Iter.	Time (s)	Iter.	Time (s)
Mesh size: 32×320				
1	16	23.9	5	10.0
1 + 1	19–21	72.2	7–8	39.9
2 + 2	20–23	249.9	9	197
Mesh size: 64 × 640				
1	22	217.8	7	56.3
1 + 1	—	—	9–10	205.2
2 + 2	—	—	11–12	1020.4

Furthermore, a growth in the number of iterations with mesh size indicates a suboptimal preconditioning scheme. Efforts to reduce the storage requirements through greater sparsification tend to decrease the effectiveness of the preconditioner, leading to a higher execution time.

6. Conclusions. The dense, complex linear systems of equations arising in inductance extraction of VLSI circuits can be solved efficiently by the preconditioned solenoidal basis method. The method uses local solenoidal flows to convert the system into a reduced system that is solved by an iterative method. Although the coefficient matrix of the reduced system is never computed explicitly, one can construct very effective preconditioners based on the inductive coupling among filaments of the mesh. Hierarchical multipole-based methods should be used to compute matrix-vector products with the dense matrices that form the reduced system and the preconditioner. Numerical experiments indicate that for high frequency simulations, the number of iterations required by the GMRES method to solve the preconditioned system is almost independent of the mesh width and frequency. The preconditioned solenoidal basis method outperforms FastHenry, a well-known inductance extraction package, on typical benchmark problems.

MOVCOL4: A MOVING MESH CODE FOR FOURTH-ORDER TIME-DEPENDENT PARTIAL DIFFERENTIAL EQUATIONS*

R. D. RUSSELL†, J. F. WILLIAMS†, AND X. XU†

Abstract. In this paper we develop and analyze a moving mesh code for the adaptive simulation of fourth-order PDEs based on collocation. The scheme is shown to enforce discrete conservation for problems written in a generalized conservation form. To demonstrate the breadth of applicability we present examples from both Cahn–Hilliard and thin-film–type equations exhibiting metastable behavior, finite-time solution blow-up, finite-time extinction, and moving interfaces.

Key words. moving mesh methods, collocation discretization, adaptive numerical methods, finite-time singularities, blow-up, pinch-off, thin-film equation, higher-order equations

1. Introduction.

Well-chosen model equations play an indispensable role in the study of complex patterns in physical, mechanical, chemical, and biological systems. Classical model equations have typically been partial differential equations (PDEs) which are second-order in space because, even though they are often much simpler than the full equations describing physical processes, they capture the essential features of certain specific problems. Familiar examples are Laplace's equation, the general heat equation, and the wave equation, designed to shed light on physical processes such as diffusion, dispersion, absorption, or wave propagation, and their mutual interaction. Nevertheless, they are ultimately limited in their ability to describe certain complex features. To gain insight into the dynamics of rich spatial and temporal patterns in a wide range of physical and mechanical problems, fourth-order model equations and systems of fourth-order equations have been proposed.

Examples of physical applications of these include problems in thin-film theory, lubrication theory, convection-explosion theory, flame and wave propagation, phase transition at critical Lipschitz points, and bistable systems. In recent years, fourth-order problems have also become important in image processing and for modeling diffusion processes in physics and material sciences. Thus, fourth-order terms are increasingly recognized as being significant in many physical models, and this has led to a burgeoning literature, including the recent book [36], which lists a number of models and references to the development of analytical techniques for the study of certain fourth-order problems.

Unlike studies for second-order equations, the theoretical study of higher-order equations, even semilinear ones, is far from complete. The main reason is that many effective methods used in treating second-order equations, such as those based on maximum principles, variational structure, and self-adjointness properties, are not applicable for higher-order equations. As in other areas, where the analytical theory is underdeveloped, many crucial features have been first explored by careful numerical

experimentation. Examples include nonuniqueness in thin films [3], finite-time extinction in thin-film equations [10, 6], exact self-similar finite-time blow-up in higher-order semilinear parabolic equations [14], and solitary waves in nonlinear beam equations [22]. Generally, adaptive numerical methods must of necessity be brought to bear for the solution of these problems since important structures for many typical fourth-order problems occur at scales which change over the duration of the time period of interest, making a fixed grid inadequate for the task of efficiently obtaining an accurate final solution. While a number of numerical approaches have been used—e.g., see [7, 20, 15, 40, 4]—in our opinion the need to develop general numerical methods and software specifically for fourth-order problems is clear.

Generally speaking, there are three adaptive approaches for most numerical methods: h-refinement, whereby nodes are added to or removed from an existing mesh in such a way as to improve local grid resolution; p-refinement, whereby higher-order schemes are used to improve local accuracy when the solution is sufficiently smooth; and r-refinement, whereby a fixed number of nodes is moved along with the solution over the domain. These strategies may of course be used singly or in combination.

We consider r-refinement methods [28], which have recently been successfully used for solving a number of differential equations that involve large solution variations like the ones arising in fourth-order problems—e.g., extinction, boundary layers, and blow-up. In particular, in this paper we discuss the construction and implementation of a high resolution moving collocation scheme for the adaptive approximation of fourth-order (in space) evolutionary PDEs. The numerical method used is a generalization of the one developed in [32]. The adaptive strategy is largely based upon the basic moving mesh methods in [30, 31] and found to be particularly effective for scaling invariant problems of a type similar to many important fourth-order problems. With our approach, the numerical schemes are applied directly to the fourth-order differential equations instead of converting the equations to lower-order systems. This direct approach has proven useful in terms of efficiency and effectiveness for solving ordinary differential equations (ODEs) [1]. We believe it to be appropriate in the context of solving time-dependent PDEs in one spatial dimension (1D) as well, for much the same reasons, and because added difficulties arise using lower-order systems for moving mesh methods (cf. section 6).

The collocation-type method we use is based upon a 7th degree Hermite spline basis since this is a natural order of spline approximation for fourth-order problems [2], as is a 3rd degree Hermite basis for second-order problems [32]. The method is analyzed and the error analysis in [32] extended. The layout for this paper is as follows. In sections 2–4 we introduce the moving mesh method and its spatial Gauss point collocation discretization. In section 5 we describe the conservation properties of this method and analyze a related fully conservative strategy. Some properties of the resulting code MOVCOL4 as well as alternative methods for solving fourth-order PDEs are briefly discussed in section 6. Finally, in section 7 several problems are solved with MOVCOL4 which demonstrate the breadth of its applicability and the advantages of this approach.

2. 1D r-adaptivity for PDEs.

2.1. Equidistribution and optimal meshes. The main tool for optimal 1D adaptivity is to require that a local estimate of the error (e.g., the discretization error) be equalized over each computational cell [23], or [illegible]. If we define a [illegible] variable ξ and a monitor function $M(x) > 0$, then the equidistributed mapping satisfies [30]

$$\int_0^{x(\xi)} M(s)ds = \xi \int_0^1 M(s)ds. \tag{2.1}$$

Although not written explicitly here, $M(x)$ is also a function of t and the solution $u(x,t)$ of the underlying physical PDE (and/or its derivatives). Without loss of generality, if M is normalized such that $\int M = 1$, then differentiating with respect to ξ gives the differential form of the equidistribution principle

$$Mx_\xi = 1. \tag{2.2}$$

Note that this specifies a condition on the Jacobian of the mapping $x(\xi)$. For an appropriately chosen monitor function, the equidistributed grid is optimal with respect to a given error norm [23].

Solving (2.2) directly in concert with a PDE leads to a coupled highly nonlinear differential algebraic equation (DAE) system with the mesh equations being algebraic. To solve this difficult numerical problem, various regularizations have been proposed. The one we use here involves solving so-called moving mesh PDEs (MMPDEs), so that (2.2) is solved only approximately in time [31]. While there are many different MMPDEs [30], here we discuss only two. The first, MMPDE6, is

$$x_{t\xi\xi} = -\frac{1}{\tau}(Mx_\xi)_\xi. \tag{2.3}$$

The positive parameter $\tau \ll 1$ is a relaxation time determining the time-scale over which a mesh converges to steady-state (2.2). The second, MMPDE4, is

$$(Mx_{t\xi})_\xi = -\frac{1}{\tau}(Mx_\xi)_\xi, \tag{2.4}$$

which has different scaling properties than MMPDE6, and the suitability of one over another can be problem dependent. One can show that when solved exactly, neither produces mesh crossing, i.e., the mapping is well defined for all time [31].

A key to the success of an MMPDE method is the choice of monitor function. Monitor functions based on error control have been used in [4, 21], as have ones which cluster nodes based on qualitative solution properties, e.g., in [15, 40, 34]. A general methodology for constructing monitor functions to minimize errors in specified norms is presented in [29]. Scaling structure proves essential to many of the example problems listed here and elsewhere. One motivation for using a scale-invariant monitor function is the possibility of computing solutions with uniform error estimates, even for singular problems. For a general discussion of scale-invariant monitor functions and their role when using MMPDEs, see [15, 16, 18].

3. Moving collocation method. In the remainder of this paper, U and X will denote the numerical approximations for the spline solution parameters and the moving grid. The independent variables are the time t and the computational spatial variable ξ.

To solve time-dependent problems, we use a moving method of lines approach, first discretizing the physical PDE in space using Hermite collocation and the MMPDE using finite differences. Then the resulting system of ODEs in time is solved with an ODE solver. Our adaptive method is motivated by the desire to handle a variety of singular solution features for the problems under consideration. Because we are considering only problems in 1D, solving the MMPDE and physical PDE simultaneously for both the transformation $x(\xi,t)$ and physical solution $u(x(\xi,t),t)$ is

computationally realistic. This avoids the need to interpolate the solution between different grids, and the method of lines discretization for the entire system may be integrated with standard software. An alternate strategy is mesh decoupling for which the physical and mesh PDEs are solved alternately—e.g., see [4]. Using Hermite collocation for the physical PDE and only central finite differences for the mesh is also the approach taken in [32] with MOVCOL, a spline collocation code designed for second-order problems. Its success is predicated on the fact that, as experience indicates, the mesh usually need not be computed as accurately as the solution to the physical PDE. This can be motivated by noting that the physical solution can, in theory, be solved on any grid. As long as the mesh nodes do not cross, errors in the computation of the grid do not directly correspond to errors in the approximation of the physical PDE.

The code MOVCOL has proven flexible and robust in solving a large class of second-order problems, including ones with finite time blow-up [13, 17, 19]. Our objective is to develop a method which is an extension of that approach for fourth-order problems. In fact, many of the strengths of the coupling of collocation and MMPDEs are greatly enhanced for higher-order problems.

Spline collocation has several advantages over standard finite difference approximation: it affords a continuous representation of the solution and its first three spatial derivatives, provides a higher order of convergence, is simple and flexible to program, easily handles boundary conditions involving high derivatives, and gives errors independent of local mesh grading. This last point is one of the most important for a moving mesh method, particularly for higher-order problems. By using collocation, we are able to avoid the problem of approximating high order derivatives via differences over a wide nonuniform stencil (cf. [39]).

When considering a discretization with a coordinate transformation, one can either write the PDE in terms of the physical variable x and discretize on a nonuniform mesh, or solve a transformed PDE in terms of the computational variable ξ on a uniform mesh. The latter approach is typical of moving finite difference approximations; however, with the flexibility of the collocation method it is simpler in 1D to discretize the PDE directly with respect to the physical variable x.

Specifically, suppose that at a time t the mesh

$$x_L(t) = X_1(t) < X_2(t) < \cdots < X_{N+1}(t) = x_R(t)$$

is the solution of the discretized MMPDE. The physical solution $u(x,t)$ is approximated by the piecewise 7th-order Hermite polynomial

$$\begin{aligned} U(x,t) = {} & U_i(t)L_{0,0}(s) + U_{x,i}(t)H_i(t)L_{0,1}(s) + U_{xx,i}(t)H_i^2(t)L_{0,2}(s) \\ & + U_{xxx,i}(t)H_i^3(t)L_{0,3}(s) + U_{i+1}(t)L_{1,0}(s) + U_{x,i+1}(t)H_i(t)L_{1,1}(s) \\ & + U_{xx,i+1}(t)H_i^2(t)L_{1,2}(s) + U_{xxx,i+1}(t)H_i^3(t)L_{1,3}(s) \end{aligned} \tag{3.1}$$

for $x \in [X_i(t), X_{i+1}(t)]$, $i = 1, \ldots, N$, where $U_i(t), U_{x,i}(t), U_{xx,i}(t)$, and $U_{xxx,i}(t)$ denote $U(X_i(t),t), U_x(X_i(t),t), U_{xx}(X_i(t),t)$, and $U_{xxx}(X_i(t),t)$, respectively. The local coordinate s is defined by

$$s = \frac{x - X_i(t)}{H_i(t)} \in [0,1], \qquad H_i(t) = X_{i+1}(t) - X_i(t).$$

The functions L_{ik} satisfy the relations

$$\frac{d^p}{dx^p}L_{ik}(x_j) = \begin{cases} 1 & \text{if } i=j \text{ and } k=p, \\ 0 & \text{otherwise,} \end{cases} \tag{3.2}$$

where for completeness we give

(3.3)

$$\begin{aligned} L_{0,0}(s) &= \left(20s^3+10s^2+4s+1\right)(s-1)^4, & L_{0,1}(s) &= s\left(10s^2+4s+1\right)(s-1)^4, \\ L_{0,2}(s) &= \frac{s^2}{2}(4s+1)(s-1)^4, & L_{0,3}(s) &= \frac{s^3}{6}(s-1)^4, \\ L_{1,0}(s) &= -\left(20s^3-70s^2+84s-35\right)s^4, & L_{1,1}(s) &= s^4(s-1)\left(10s^2-24s+15\right), \\ L_{1,2}(s) &= -\frac{s^4}{2}(s-1)^2(4s-5), & L_{1,3}(s) &= \frac{s^4}{6}(s-1)^3. \end{aligned}$$

On $x \in [X_i(t), X_{i+1}(t)]$, derivatives of U are determined by direct differentiation of (3.1), e.g.,

$$\begin{aligned} U_x(x,t) = \frac{1}{H_i}\Bigg(& U_i(t)\frac{dL_{0,0}}{ds} + U_{x,i}(t)H_i(t)\frac{dL_{0,1}}{ds} + U_{xx,i}(t)H_i^2(t)\frac{dL_{0,2}}{ds} \\ & + U_{xxx,i}(t)H_i^3(t)\frac{dL_{0,3}}{ds} + U_{i+1}(t)\frac{dL_{1,0}}{ds} + U_{x,i+1}(t)H_i(t)\frac{dL_{1,1}}{ds} \\ & + U_{xx,i+1}(t)H_i^2(t)\frac{dL_{1,2}}{ds} + U_{xxx,i+1}(t)H_i^3(t)\frac{dL_{1,3}}{ds}\Bigg) \end{aligned} \tag{3.4}$$

and

(3.5)

$$\begin{aligned} U_t(x,t) = {} & \frac{dU_i}{dt}L_{0,0} + \left(\frac{dU_{x,i}}{dt}H_i + U_{x,i}\frac{dH_i}{dt}\right)L_{0,1} + \left(\frac{dU_{xx,i}}{dt}H_i^2 + 2U_{xx,i}H_i\frac{dH_i}{dt}\right)L_{0,2} \\ & + \left(\frac{dU_{xxx,i}}{dt}H_i^3 + 3U_{xxx,i}H_i^2\frac{dH_i}{dt}\right)L_{0,3} + \frac{dU_{i+1}}{dt}L_{1,0} \\ & + \left(\frac{dU_{x,i+1}}{dt}H_i + U_{x,i+1}\frac{dH_i}{dt}\right)L_{1,1} + \left(\frac{dU_{xx,i+1}}{dt}H_i^2 + 2U_{xx,i+1}H_i\frac{dH_i}{dt}\right)L_{1,2} \\ & + \left(\frac{dU_{xxx,i+1}}{dt}H_i^3 + 3U_{xxx,i+1}H_i^2\frac{dH_i}{dt}\right)L_{1,3} - U_x(x,t)\left(\frac{dX_i}{dt} + s^{(i)}\frac{dH_i}{dt}\right). \end{aligned}$$

There are several natural ways to derive a system of ODEs for determining the unknowns $U_i(t)$, $U_{x,i}(t)$, $U_{xx,i}(t)$, and $U_{xxx,i}(t)$. The first we consider is collocation at the Gauss points. The second scheme is a conservative method, which is a natural alternative choice for many physical problems.

4. Gauss point collocation. Consider the PDE

$$u_t = \mathcal{N}(t,x,u,u_x,u_{xx},u_{xxx},u_{xxxx}), \quad t>0,\ x\in I=(a,b), \tag{4.1}$$

supplemented with the initial condition

$$u(x,0) = u_0(x), \quad x\in(a,b),$$

and separated boundary conditions

$$B_{a,1} = 0,\ B_{a,2} = 0,\ B_{b,1} = 0,\ B_{b,2} = 0, \tag{4.2}$$

where $B_{y,i} = B_{y,i}(t, y, U_t(y), U(y), U_x(y), U_{xx}(y), U_{xxx}(y))$. The standard collocation approach would be to solve for the $(4+1)(N+1)$ unknowns consisting of the solution U and its first three spatial derivatives at the mesh points and the $(N+1)$ mesh points $X_i(t)$ themselves. One enforces the collocation condition

$$U_t - \mathcal{N}(t, x, U, U_x, U_{xx}, U_{xxx}, U_{xxxx}) = 0 \tag{4.3}$$

at the four Gauss points in each interval. The MMPDE is approximated with central differences at the $(N-1)$ interior points, e.g., for $X_{t,\xi\xi} = -\frac{1}{\tau}\left(MX_\xi\right)_\xi$ use

$$X_{t,i-1} - 2X_{t,i} + X_{t,i+1} = -\frac{1}{\tau}\left(M_{i+1/2}(X_{i+1} - X_i) - M_{i-1/2}(X_i - X_{i-1})\right).$$

Here $M_{i+1/2}$ and $M_{i-1/2}$ are approximations to the average of the monitor function over cells $I_i = (x_i, x_{i+1})$ and I_{i-1}, respectively. Satisfying the boundary conditions (4.2) and requiring $X_1 = a$, $X_{N+1} = b$, this gives a system of $5(N+1)$ equations in $5(N+1)$ unknowns. From the standard ODE error analysis for a spline collocation solution U to (4.1) at a fixed time level t [2], the spatial error satisfies

$$|u(x) - U(x)| = \mathcal{O}(h^8) \quad \text{for all } x \in I, \quad \text{where } h = \max_i h_i.$$

Frequently in practice a PDE occurs in the form

$$u_t = \left(g(t, x, u, u_x, u_{xx}, u_{xxx})\right)_x, \tag{4.4}$$

and on a physical basis one is often interested in preserving the conservation property

$$\frac{d}{dt}\int_I u = g(b) - g(a). \tag{4.5}$$

The above Gauss collocation method does not do so in general, but it does in special cases such as the following.

LEMMA 4.1. [illegible] (4.5) [illegible] (4.4) [illegible]

$$g(u, u_x, u_{xx}, u_{xxx}) = \alpha_1 u + \alpha_2 u_x + \alpha_3 u_{xx} + \alpha_4 u_{xxx}, \tag{4.6}$$

[illegible] α_i, $i = 1, \ldots, 4$ [illegible] Denoting $U_i^{(0)} = U_i$, $U_i^{(1)} = U_{x,i}$, $U_i^{(2)} = U_{xx,i}$, $U_i^{(3)} = U_{xxx,i}$, we have that

$$\begin{aligned}
\frac{d}{dt}\int_I U dx &= \int_I \alpha_1 U_x + \alpha_2 U_{xx} + \alpha_3 U_{xxx} + \alpha_4 U_{xxxx} dx \\
&= \sum_i \sum_j \alpha_j \left(\sum_{k=0}^{3} (H_i)^{k-j} \left(U_i^{(k)} \int_0^1 \frac{d^j}{ds^j} L_{0,k}(s) ds + U_{i+1}^{(k)} \int_0^1 \frac{d^j}{ds^j} L_{1,k}(s) ds \right) \right) \\
&= \sum_i \sum_j \alpha_j (U_{i+1}^{(j-1)} - U_i^{(j-1)}) \qquad \text{(from (3.2))} \\
&= \sum_j \alpha_j (U_{N+1}^{(j-1)} - U_1^{(j-1)}) \\
&= G(X_{N+1}) - G(X_1). \qquad \square
\end{aligned}$$

5. Conservative method. While Gauss point collocation performs well for many problems, here we construct another method which has the advantage of preserving general conservation properties. For this, we consider a more general PDE of the form

$$f(t,x,u_t,u,u_x,u_{xx},u_{xxx}) = (g(t,x,u,u_x,u_{xx},u_{xxx}))_x \tag{5.1}$$

and derive an approximation method for it which satisfies the generalized conservation property

$$\int_I f dx = g|_{x=b} - g|_{x=a}. \tag{5.2}$$

An additional advantage of treating the PDE (5.1) directly is that when solutions develop singularities, each successive spatial derivative becomes larger, and we can avoid the explicit computation of u_{xxxx} by using a cell-averaged form. As a result, one can often solve the problem more efficiently by reducing the stiffness of the ODE system compared to the standard Gauss scheme which requires fourth derivatives. Note, however, that a PDE (4.1) can be written in the form (5.1) in a number of ways.

To generate an approximation to u, we again approximate u by its Hermite interpolant U as defined in (3.1). To eliminate any dependence on U_{xxxx} in our system of ODEs and to enforce the conservation property (5.2) we use a cell-averaged approach for solving (5.1). We begin by approximating f by its Lagrange interpolant

$$F_i = \sum_{j=0}^{3} f_{ij}\tilde{L}_j, \tag{5.3}$$

where the canonical points are the four Gauss points on the unit interval

$$\rho_1 = \frac{1}{2} - \frac{\sqrt{525+70\sqrt{30}}}{70},\ \rho_2 = \frac{1}{2} - \frac{\sqrt{525-70\sqrt{30}}}{70},\ \rho_3 = 1-\rho_1,\ \rho_4 = 1-\rho_2, \tag{5.4}$$

and $f_{ij} = f(x_i + H_i\rho_j) = f(x_{ij})$. Equation (5.1) is integrated approximately using the five Lobatto points, which on the unit interval are

$$\tilde{\rho}_1 = 0,\ \ \tilde{\rho}_2 = \frac{1}{2} - \frac{\sqrt{21}}{14},\ \ \tilde{\rho}_3 = \frac{1}{2},\ \ \tilde{\rho}_4 = \frac{1}{2} + \frac{\sqrt{21}}{14},\ \ \tilde{\rho}_5 = 1. \tag{5.5}$$

Integrating the approximation (5.3) to f over each cell gives the system

$$A\boldsymbol{F}_i = B\boldsymbol{G}_i/H_i \tag{5.6}$$

in each interval I_i, where the matrices A, B are defined by

$$A_{jk} = \int_{\tilde{\rho}_j}^{\tilde{\rho}_j+1} \tilde{L}_k dt, \quad j,\, k = 1,2,3,4,$$

$$B_{jk} = \begin{cases} 1 \text{ if } j = k, \\ -1 \text{ if } k = j+1 \\ 0 \text{ else,} \end{cases} \qquad \text{for } j = 1,\dots,4 \text{ and } k = 1,\dots,5,$$

and the vectors $\boldsymbol{F}_i$, $\boldsymbol{G}_i$ are

$$(\boldsymbol{F}_i)_j = F_i(x_i + H_i\rho_j) = F_i(x_{ij}), \quad j = 1, 2, 3, 4,$$

$$(\boldsymbol{G}_i)_j = G_i(x_i + H_i\tilde{\rho}_j) = G_i(\tilde{x}_{ij}), \quad j = 1, 2, 3, 4, 5\ .$$

By direct construction we have enforcement of cell-averaging, i.e.,

$$\int_{I_i} F_i = G(X_{i+1}) - G(X_i),$$

and we have the following lemma.

LEMMA 5.1. [illegible] (5.6) [illegible]

$$\int_I F dx = \sum_i \int_{I_i} F_i dx = \sum_i G(X_{i+1}) - G(X_i) = G(X_{N+1}) - G(X_1). \qquad \square$$

The Hermite interpolant U is defined in (3.1) and is specified by choosing the coefficients $U_i(t), U_{x,i}(t), U_{xx,i}(t), U_{xxx,i}(t)$ such that in each interval,

$$H_i\boldsymbol{F}_i = W\boldsymbol{G}_i,$$

where the differentiation matrix $W = A^{-1}B$. This gives four equations in each cell, as in the standard Gauss collocation method, but they do not involve U_{xxxx}. Using the fact that the two extreme Lobatto points $\tilde{\rho}_1 = 0$ and $\tilde{\rho}_5 = 1$ coincide at successive intervals, an efficient implementation requires $8N+1$ function evaluations, twice that of the Gauss point formulation with $2N+1$ ODE function evaluations. However, in many cases the structure of g is much simpler than g_x, leading to fewer total floating point operations.

The spline collocation error analysis in [2] can, when suitably modified, be extended to give error bounds for the conservative scheme. We can find the local truncation error for our equations by considering the problem

$$g_x = f \tag{5.7}$$

as an equation for g. This approach extends the error estimate derived in [32], which is valid only at the Gauss points, to a spatially global one. Henceforth, we shall refer to this discretization of (5.7) as a "conservative collocation" scheme, although technically speaking it is not a collocation scheme, as we discuss below.

THEOREM 5.2. [illegible] (5.6) [illegible]. The results of Theorem 5.147 from [2] can be used to estimate the leading order term in $G_x - g_x$. There are $k = 5$ Lobatto points, with precision $p = 2k - 2 = 8$ to solve the first-order ($m = 1$) problem (5.7)

$$G_x - g_x \simeq H_i^5 \frac{g^{(6)}}{6!} \prod_{j=1}^{5} (s - \tilde{\rho}_j).$$

The error in the Lagrange approximation to f is given by

$$F - f \simeq \frac{f^{(4)}}{4!} \prod_{j=1}^{4} (s - \rho_j)$$

and thus the error is

$$e = |(G_x - F)| = |(G_x - g_x) - (F - f)|$$
$$\simeq \left| H_i^5 \frac{g^{(6)}}{6!} \prod_{j=1}^{5} (s - \tilde{\rho}_j) - H_i^4 \frac{g^{(5)}}{4!} \prod_{j=1}^{4} (s - \rho_j) \right| \tag{5.8}$$

for all points $x_i \le x \le x_i$, and $s = (x - x_i)/H_i$. □

Here we have used the fact that the exact solution satisfies $g_x = f$. At first glance this estimate may seem slightly strange—it is an estimate of the residual, something normally set to be identically zero in a collocation method. However, recall that there are two sources of error in the conservative method: one is an interpolation error for f, and the other is from the approximate solution to $g_x = f$. These errors vanish at different points in the domain, so there is no point where the residual is necessarily zero. This estimate may also be recovered by a standard Taylor series expansion, but that is far more cumbersome. This same construction can be used to extend the error estimate in [32] from the Gauss points to the entire solution domain.

For the standard Gauss collocation scheme we have explicit error estimates for $e_G = |u - U|$, whereas for the conservative scheme we have estimates only for the residual which, in the general case, requires information about the Green function to estimate $|u - U|$. We expect a similar estimate for $e = |u - U|$ to hold for both but leave a proof for future work and content ourselves now with a numerical test of the methods.

6. Implementation. MOVCOL4 is a Fortran code with the capability of using either the Gauss collocation or the conservative scheme described in the two previous sections. The user is provided the option of selecting either one and of solving the MMPDE in the form of either MMPDE4 or MMPDE6. The resulting equations are integrated with the software DASSL [37], a backward differentiation code designed to solve stiff DAEs. Other inputs provided by the user are the absolute error tolerance *atol* and relative error tolerance *rtol*, which are needed for DASSL, the number of mesh points *npts* and initial mesh $X_i : i = 1, \ldots, npts$, and the definition of the monitor function to be used in the MMPDE. The onus is on the user to ensure that the PDE is well-posed (e.g., not $u_t = u_{xxxx} + r(u)$, which is unstable like the backward heat equation). The code is designed to deal with very general systems of PDEs of the form

$$\boldsymbol{f}(t, x, \boldsymbol{u}, \boldsymbol{u}_t, \boldsymbol{u}_x, \boldsymbol{u}_{xx}, \boldsymbol{u}_{xxx}, \boldsymbol{u}_{xxxx}) = (\boldsymbol{g}(t, x, \boldsymbol{u}, \boldsymbol{u}_x, \boldsymbol{u}_{xx}, \boldsymbol{u}_{xxx}))_x, \tag{6.1}$$

although the form chosen can significantly affect the code's efficiency. One of the most important input parameters is the initial mesh. For many problems, it must be close to equidistributing in order for the integrator DASSL to start. To help alleviate this common difficulty, MOVCOL4, like MOVCOL, has an option to compute an equidistributing mesh corresponding to the initial data $u_0(x)$ before solving the PDE.

The user also has the option to choose different tolerances for the solution components. This is particularly effective for the higher derivatives which, because they appear in the solution definition multiplied by powers of the local grid spacing, have a lesser effect on the error in reconstructing the entire solution. Typically, one can take the most stringent tolerances for the solution only and demand less accuracy on the derivatives with no noticeable loss in the accuracy of the final solution.

A common approach for solving high order PDEs is to first convert them into lower-order systems and use a code designed for these lower-order problems. For

example, the fourth-order PDE

$$v_t = f(t, x, v, v_x, v_{xx}, v_{xxx}, v_{xxxx})$$

can be written as a second-order system in the variables $\boldsymbol{u} = (u_1, u_2)^T = (v, v_{xx})^T$. The equivalent system

$$(u_1)_t = f(t, x, u_1, (u_1)_x, u_2, (u_2)_x, (u_2)_{xx}),\ (u_1)_{xx} = u_2$$

is then solved. Discretization on a fixed grid gives a DAE system of index 1, where time differentiation of the algebraic equation once gives an ODE system with the second equation replaced by $(u_2)_t = (u_1)_{xxt}$. One could then employ a method of lines code designed for second-order problems which uses a time integration code such as DASSL, which is designed to solve index 1 DAEs under reasonable restrictions on the rate of change of step size [26]. However, when this approach is used for a moving grid we obtain

$$(u_2)_t = (u_1)_{xxt} + [(u_1)_{xxx} - (u_2)_x]\dot{x}(t).$$

Since u_2 and u_1 are approximated with different spline functions, U_1 and U_2 $(u_1)_{xx} = u_2$ does not imply that $(u_1)_{xxx} = (u_2)_x$. Indeed, experience has shown that the error can easily grow if this term is dropped. Consequently, both the third derivative term $(u_1)_{xxx}$ and the mesh speed $\dot{x}(t)$ must be dealt with, and a code for second-order problems like MOVCOL cannot be used directly. One can convert the PDE into the second-order system

$$\begin{aligned}
(u_1)_t &= f(t, x, u_1, (u_1)_x, u_2, (u_2)_x, (u_3)_x, (u_3)_{xx}),\\
(u_2)_t &= (u_1)_{xt} + [(u_1)_{xx} - (u_2)_x]\dot{x}(t),\\
(u_3)_t &= (u_2)_{xt} + [(u_2)_{xx} - (u_3)_x]\dot{x}(t),
\end{aligned}$$

although this form is clearly more awkward. In addition, this can be quite inefficient due to the need to handle the mesh speed term and the large number of additional unknowns as compared to the method applied directly to the high order equation. In our experience, applying the moving mesh code MOVCOL for lower-order systems has not generally warranted the associated cost nor achieved comparable accuracy to that with MOVCOL4 for fourth-order problems. Nevertheless, it remains an interesting question, both in the fixed grid and moving grid contexts, as to whether or not there are reformulations of high order problems as systems of lower order ones which are sufficiently stable (and well-posed) to warrant their use with codes designed for such low order problems.

7. Numerical examples. In this section we demonstrate the efficiency, accuracy, and robustness of MOVCOL4 by solving a variety of problems. Example 1 (equation (7.1)) has been chosen to illustrate the rate of convergence for a simple test case. The remaining examples have been chosen from applications to show the breadth of applicability of our approach. The first is the semilinear Cahn–Hilliard equation and the second concerns some quasi-linear thin-film equations. For both examples two different solution regimes are investigated.

One of the most difficult choices for the novice when using moving mesh methods is that of the monitor function. There are several competing strategies, and the different problems in this section motivate some of those different choices. The first problem is trivial and not particularly sensitive to the precise choice of monitor function.

In the examples we use monitor functions determined either by properties of the physical equations or by information about the particular solution features. Two cases exhibit finite-time blow-up, and for such problems preserving scale invariance in the moving mesh method works particularly well [15, 18]. One case has very delicate finite-time extinction, and the monitor function is constructed based loosely on asymptotic properties of the solution. For this case MMPDE6 is most appropriate as it allows adaptivity on the same time-scale as the monitor function, which is key for finite-time behavior. The remaining problem exhibits metastable fronts. Because solution features emerge on an $O(1)$ time-scale we use MMPDE4 and a monitor function prepared to place more points in any emergent layers. In this scenario, the time stepping is determined solely by the physical PDE and not by changes in magnitude of the monitor function.

7.1. A simple test problem. We begin with a simple test problem,

$$\text{Ex. 1} \quad \begin{cases} u_t = -\dfrac{\sin t}{\cos t + 3} u_{xxxx}, & x \in (0,\pi),\ 0 < t < \pi, \\ u(x,0) = 4c\cos(x), \\ u_x(0,t) = u_{xxx}(0,t) = 0, \\ u_x(\pi,t) = u_{xxx}(\pi,t) = 0, \end{cases} \tag{7.1}$$

which has the exact solution $u(x,t) = c(\cos(t)+3)\cos(x)$. We investigate the convergence properties of MOVCOL4 for this example.

The high order of the spatial discretization necessitates that the problem be designed very carefully in order for one to check the actual convergence rate. An advantage of the problem in this form is that there is only the fourth derivative term, which simplifies the form of the discretization error over mathematically equivalent, more complicated forms, although some care must be taken since this problem is ill-posed for $\sin t < 0$. Also, it is very hard to discern the rate of convergence before the time integration error and machine error become involved and play a significant role, so the absolute error tolerance and relative error tolerance for the time integration must be chosen to be extremely small—we choose $atol = 10^{-15}$, $rtol = 10^{-13}$. We solve the problem with 2 subintervals (3 mesh points), 4 subintervals (5 mesh points), and finally, 8 subintervals (9 mesh points). In order to see the global rate of convergence, we first compute the solution on $[0,\pi]$ using 3, 5, or 9 mesh points and then construct the solution on the whole interval using Hermite spline interpolation.

It is easiest to start the integration with a fixed grid using MMPDE6 and $\tau = 1.d-3$, where the smoothness of the solution and the monitor function $M(u) = 1+|u|$ prevent the mesh from becoming too skew and the temporal discretization error from strongly affecting the total error. In our tests we choose $c = 0.3$.

In the log-log plot of the L^∞ norm of the error versus the mesh size given in Figure 1, the slope of the straight line fit, that is, the rate of convergence, is approximately 8. In Table 1, we show computed rates of convergence

$$\mathrm{ROC}N_1N_2 = \frac{\log\left(\frac{\|E_{N_1}\|_\infty}{\|E_{N_2}\|_\infty}\right)}{\log\left(\frac{\pi/N_1}{\pi/N_2}\right)}.$$

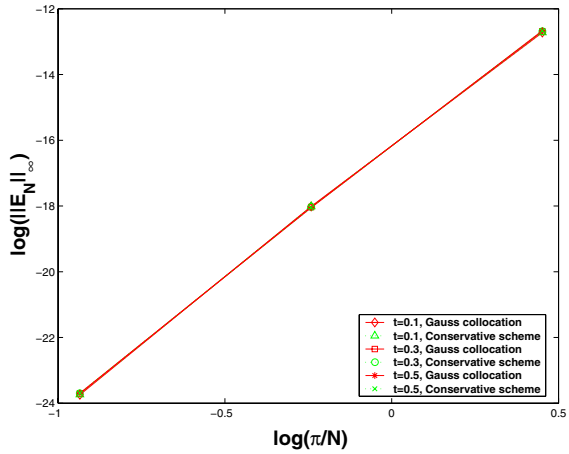

FIG. 1. *Rates of convergence, Gauss collocation method, and conservative collocation method. The errors for both methods are indistinguishable.*

TABLE 1
Rates of convergence.

Time	M	$\|E_2\|_\infty$	$\|E_4\|_\infty$	$\|E_8\|_\infty$	ROC42	ROC84	ROC82
$t = 0.1$	G	2.982353E-06	1.501874E-08	4.862577E-11	7.6335	8.2708	7.9522
	C	2.982353E-06	1.501874E-08	4.870682E-11	7.6335	8.2684	7.9510
$t = 0.3$	G	3.099078E-06	1.475483E-08	5.055389E-11	7.7145	8.1891	7.9518
	C	3.099078E-06	1.475483E-08	5.062472E-11	7.7145	8.1871	7.9508
$t = 0.5$	G	3.150803E-06	1.446814E-08	5.111500E-11	7.7667	8.1445	7.9558
	C	3.150803E-06	1.446855E-08	5.113077E-11	7.7667	8.1445	7.9556

For example,

$$\mathrm{ROC42} = \frac{\log\left(\frac{\|E_2\|_\infty}{\|E_4\|_\infty}\right)}{\log\left(\frac{\pi/2}{\pi/4}\right)},$$

where $\|E_2\|_\infty = \max_{i=1}^{101} |u_{\mathrm{comp}} - u_{\mathrm{exact}}|$ is measured by sampling the reconstructed and the exact solutions at 101 equally spaced points on $[0, \pi]$.

7.2. The Cahn–Hilliard equation. The Cahn–Hilliard equation is a classical semilinear fourth-order equation modeling phase separation. Many diffusive processes with a natural length scale, such as phase separation in binary alloys, growth and dispersal in population, or spreading of an oil film over a solid surface, can be described by this equation. The special form for the Cahn–Hilliard equation which we investigate here is

$$u_t = -(\gamma_1 u_{xx} - \gamma_2 u^3 + \gamma_3 u^2 + \gamma_4 u)_{xx}. \tag{7.2}$$

We consider two cases with strikingly different behaviors, both arising in various application areas.

7.2.1. Finite-time blow-up in the unstable regime. For the case of $\gamma_1 = 1, \gamma_2 = -1$, and $\gamma_3 = \gamma_4 = 0$ [25], the equation has a combination of a fourth-order diffusion operator and the classical second-order porous medium operator but posed

in time. This competition of effects can lead to finite time blow-up, where there exists $T < \infty$ such that

$$\lim_{t \to T} \|u(\cdot,t)\|_\infty = \infty \quad \text{and} \quad \|u(\cdot,t)\|_\infty < \infty \ \text{ for all } \ 0 \le t < T.$$

The complete problem is

$$\text{Ex. 2} \quad \begin{cases} u_t = -(u_{xx} + u^3)_{xx}, & x \in (0,6),\ t > 0, \\ u(x,0) = 2e^{-\frac{x^2}{2}}, \\ u_x(0,t) = u_{xxx}(0,t) = 0, \\ u_x(6,t) = u_{xxx}(6,t) = 0. \end{cases} \tag{7.3}$$

The problem is conservative, and conservation with blow-up implies that the blow-up can occur only at an isolated point (or set of isolated points). In this case the blow-up is self-similar in that there is a balance between the magnitude of and natural length-scale of the solution. The use of scaling invariant adaptivity is natural for problems such as this one, since as we see below the intrinsic length-scale of the solution is then automatically determined.

We take $npts = 41$, $rtol = atol = 10^{-5}$, and $\tau = 1e-4$. To resolve the blow-up solution we choose the monitor function

$$M(x,t) = u(x,t)^4 + \frac{1}{12}\int_0^6 u(x,t)^4\,dx$$

because it is scale invariant in the blow-up region; i.e., the MMPDE is invariant under the same scaling group as the physical PDE. The role of the second term for the monitor function is to ensure that there is an even distribution of mesh points inside and outside the blow-up region as blow-up is approached. The factor 1/12 is chosen to place approximately two-thirds of the grid points inside the blow-up region and one-third outside—for further discussion of scaling in constructing monitor functions, see [15] and [16]. This idea, first introduced by Beckett and Mackenzie [5], is analyzed theoretically for PDEs with finite-time singularities in [18].

Typical blow-up solutions are presented in Figure 2. (A comprehensive treatment of this problem is given in [25].) We compare the effectiveness of the two spatial discretizations in Table 2. Note that the conservative discretization is more efficient and can integrate marginally further into the blow-up regime. A comparison of the accuracy of conservation for the two approaches is presented for a more difficult problem in section 7.3.2.

7.2.2. Metastable fronts in the stable regime. While the Cahn–Hilliard equation can also give exponential decay (like the heat equation) or blow-up, we now concentrate on the metastable case [42]. The typical underlying physical context involves a melted binary alloy with a given concentration of components that is quenched to a temperature at which exactly two different concentration phases can coexist. For $\gamma_1 \to 0$, the qualitative features of the dynamics associated with (7.2) are as follows: Through a very intricate transient process, a pattern of internal layers forms from the initial data over an $O(1)$ time interval. Once this pattern is formed, the subsequent motion of the internal layers is exponentially slow and hence becomes metastable. For a study of a two-layer pattern in [38], the internal layers collapse at a time of order 10^{11} and the interesting dynamics then occur rapidly on an $O(1)$ timescale.

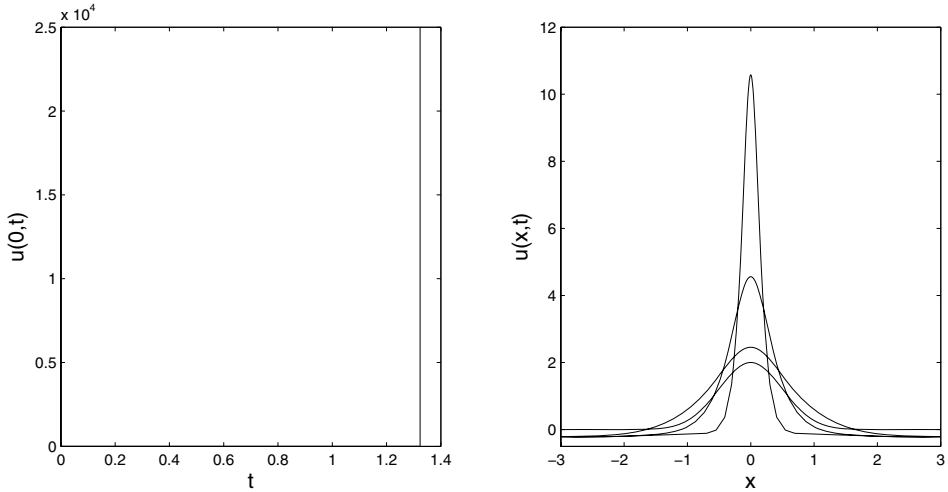

FIG. 2. *Blow-up in the unstable Cahn–Hilliard equation* (7.3). *Left: The solution magnitude. Right: Sample solutions.*

TABLE 2

	1000	1103	1998	167
	500	999	1729	161
	100	821	1279	131
	50	677	1199	121
Gauss point collocation	2.31e4	2731	4491	751
	1000	1499	3149	489
	500	1401	2691	390
	100	1121	1713	243
	50	720	1299	117

The form of the Cahn–Hilliard equation we consider is

$$\text{(7.4)} \qquad \text{Ex. 3} \quad \begin{cases} u_t = -(0.001u_{xx} + u - u^3)_{xx}, & x \in (-1,1),\ t > 0, \\ u(x,0) = 0.1\cos(2\pi x) + 0.02\cos(10\pi x), \\ u_x(-1,t) = u_{xxx}(-1,t) = 0, \\ u_x(1,t) = u_{xxx}(1,t) = 0. \end{cases}$$

Since the nonlinear term in (7.2), together with the fourth derivative term, make the Cahn–Hilliard equation very stiff, most finite difference schemes need to use time steps many orders of magnitude smaller than Δx. As a consequence, it is numerically expensive to reach the time scales where the interesting dynamics occur. In Figure 3 we show our numerical results for a finite difference scheme provided in [35]. With this approach, the resulting ODE system is linear and easily solved directly in MATLAB. We have observed that if the ODE from the finite difference scheme is not carefully

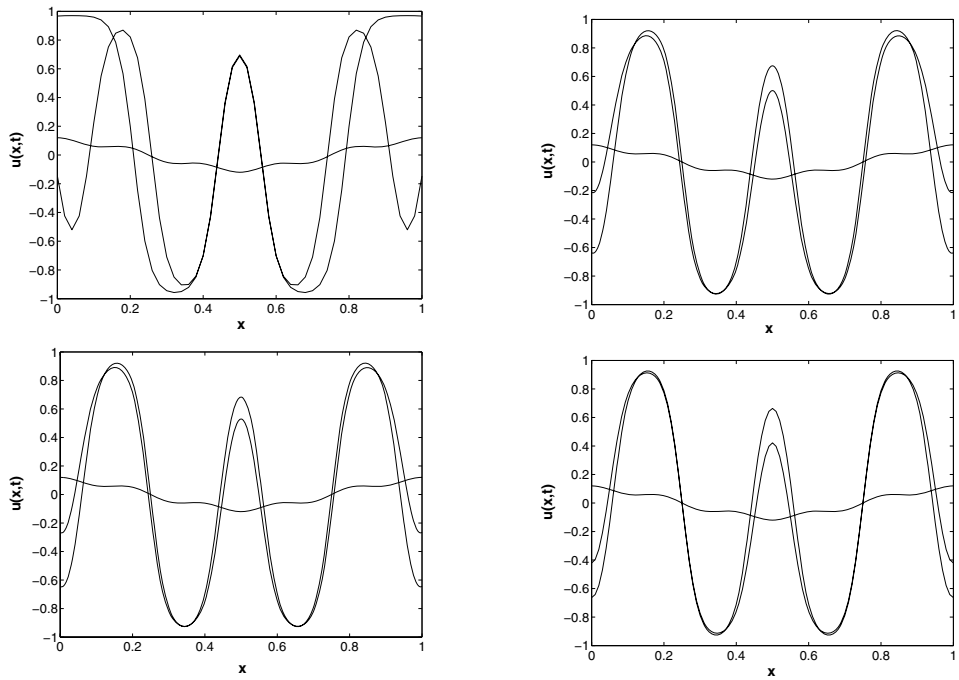

FIG. 3. *Solutions at* $t = 0, 0.05, 0.1$. *Finite difference scheme versus moving collocation scheme. Upper left: Finite difference scheme,* $\Delta x = 0.02, \Delta t = 1.d{-}6$. *Upper right: Finite difference scheme,* $\Delta x = 0.002, \Delta t = 1.d - 4$. *Lower left: Finite difference scheme,* $\Delta x = 0.002, \Delta t = 1.d - 8$. *Lower right: Moving collocation scheme,* $\Delta x = 0.05$, *variable time step size by DDASSL.*

resolved by using a large stencil and very small time step size, a two-layer pattern will be formed much faster than actually occurs. As we increase our stencil and decrease the time step size, the numerical solution obtained by the finite difference scheme converges to the numerical solution obtained by using the moving collocation scheme with only 21 points (but a system of 105 unknowns). If the number of points is increased from 21 to 101, the numerical solution for the moving collocation scheme remains almost the same, suggesting that a small number of mesh points can be used to investigate the metastable behavior of the solution efficiently. Generally speaking, a very accurate discretization is required for the resolution of metastable behavior; otherwise the dynamics will be driven by numerical error rather than the very slow analytical instability.

Figure 4 shows the solutions of (7.4) starting with a uniform mesh of 51 points. The solution is computed until $t = 1 \times 10^{10}$ with the monitor function chosen as $M = \sqrt{1 + u_x^2}$ to place more mesh points in the internal layer and $atol = rtol = 1 \times 10^{-6}$. The solution at $t = 1 \times 10^{10}$, shown in Figure 4, is indistinguishable from the one at $t = 1$.

Our computational tests have shown that the time at which the two metastable interfaces collapse is highly affected by the error tolerances, making it difficult to capture the precise time of collapse, particularly since it is usually of order 10^{11}. Furthermore, the role of adaptivity in computing metastable solutions is at best problematic, since a suitable monitor would need to incorporate information about the solution's sensitivity to the boundary conditions. Further investigation of this issue is

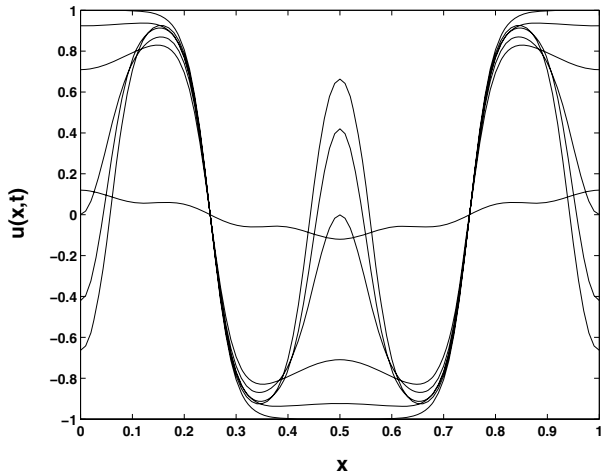

FIG. 4. *Solutions to* (7.4) *at different times:* $t = 0, 0.05, 0.1, 0.3, 0.5, 0.7, 1,\ 1 \times 10^{10}$.

needed before a code such as MOVCOL4 could be recommended over other adaptive (or nonadaptive) ones for a general study of metastability for such problems.

7.3. Equations of thin-film type. A fourth-order equation of wide interest is the thin-film equation

$$u_t = -(f(u)u_{xxx} + g(u)u_x)_x. \tag{7.5}$$

In most applications u represents the thickness of a thin fluid on a substrate. This equation has garnered much analytical and computational interest over the past 15 years (e.g., see [3, 6, 8, 10, 9, 12]), although many open problems remain. Typically, the nonlinearities are taken to be

$$f(u) = u^n \quad \text{and} \quad g(u) = u^m$$

for positive integers n, m. We consider the cases

$$\begin{aligned} f(u) &= u^{1/2} \quad \text{with} \quad g(u) = 0 \quad \text{and} \\ f(u) &= u \quad \text{with} \quad g(u) = 4u^3. \end{aligned}$$

For suitable initial boundary and free boundary conditions, (7.5) has compactly supported solutions which may spread or contract over time. In both of our examples we use (for both analysis and computation) a standard regularization of f,

$$f_\varepsilon(u_\varepsilon) = \frac{u_\varepsilon^4}{\varepsilon + u_\varepsilon^{4-n}}. \tag{7.6}$$

Because of this regularization one expects the solution to be bounded away from zero with

$$\min u_\varepsilon \sim O(\varepsilon^{1/(4-n)}),$$

where $f_\varepsilon(u) \sim O(u^n)$ as $u \to 0$ for $n < 4$. For $n \geq 4$ no such regularization is required. Moreover, in this regime the dynamics are dominated by the regularization, since if

$u_\varepsilon \ll u_\varepsilon^{4-n}$, then

$$f_\varepsilon \sim \frac{u_\varepsilon^4}{\varepsilon}.$$

With the appropriate boundary conditions, the solution to (7.5) satisfies the condition (5.2), or

$$\frac{d}{dt}\int_I u(x,t)\,dx = 0.$$

7.3.1. Moving contact lines in thin liquid films. For the form of the thin-film equation first studied,

$$u_t = -(u^n u_{xxx})_x,$$

the solutions do not blow up, but initially uniformly positive solutions can become extinct at some finite time. We consider this particular case because it is one where there is conjectured to be approximate self-similar behavior and because its numerical solution has been computed elsewhere, making it a reliable test problem.

For $n = 1/2$, the problem

$$\text{Ex. 4} \quad \begin{cases} u_t + (u^{1/2}u_{xxx})_x = 0, & x \in (-1,1),\ t > 0, \\ u(x,0) = 0.8 - \cos(\pi x) + 0.25\cos(2\pi x), \\ u_x(-1,t) = u_x(1,t) = 0, \\ u_{xxx}(-1,t) = u_{xxx}(1,t) = 0 \end{cases} \tag{7.7}$$

is considered in [10, 9, 43]. It is shown computationally in [9] that the solution exhibits finite-time extinction. Specifically, the solution becomes zero at an isolated point for some finite time, and there is simultaneous blow-up of higher derivatives there. Near the singular point the solution has a leading order asymptotic form [10]

$$u(x,t) \approx c(t_c - t) + \frac{p(x - x_c)^2}{2}, \tag{7.8}$$

where t_c is the time of extinction, x_c is the "pinch-point," and the constant p is the curvature of the interface at this time. The solution and its first two spatial derivatives are smooth here, while blow-up in higher derivatives is locally described by

$$u_{xxx} \approx \frac{cx}{\sqrt{c(t_c - t) + p(x - x_c)^2/2}}. \tag{7.9}$$

It is proven in [11, 9] that after the initial singularity time, there exists a nonnegative weak solution for (7.7) in the sense of distributions, and there exists a second critical time after which the solution is again uniformly positive and strong, decaying to its mean in the infinite time limit. Introducing the regularization (7.6), the regularized problem has global, positive, and smooth solutions [9]. The weak solution for (7.7) can then be obtained by finding the solution of the regularized problem and taking the regularization parameter ε to zero [12, 6, 8]. Many thin-film problems have been solved with finite element discretizations [3], but in [9] a careful finite difference static regridding computation starting with a fine initial grid of $2^{10} = 1024$ uniform intervals on [0,1] is used. Since the initial data are symmetric about $x = 0$ and the equation preserves the symmetry, the solution is computed only on $[0, 1]$, using reflection symmetry at the boundary. In order to resolve the smallest length-scale and keep the

numerical solution positive, regridding is done by adding 64 new mesh points whenever $u_{\min}^{1/2} \leq 64/1024$. At the end of the simulation, 55 levels of regridding have been done, with 3520 new points produced and the smallest grid spacing being 2^{-65}. We use M to automatically monitor quantities of interest and relocate the mesh points, making it a good test problem for the adaptive features of our high order moving mesh code MOVCOL4.

Our computation consists of two parts: computing the solution of the nonregularized problem very close to the singularity time to examine the formation of the third derivative jump discontinuity, and computing the regularized solution until it decays to its mean as dictated by the theory in [9]. In either case, we start with an initially uniform grid with $2^7 = 128$ intervals on $[0, 1]$, and hence a system of 640 equations for all time. For the monitor function, we basically choose $M(x, t) = 1/u$. It has been chosen to resolve the singularity as $\min_x u(x, t)$ approaches zero. The exact structure is based on the asymptotic form (7.8) which shows that the solution touches down proportionally to $(t - t_c)$. Hence, for MMPDE6, our monitor function scales in time the same way as the singularity. In other cases different powers of u may be required; a generic example is

$$M = \frac{1}{u^{1/p}} \qquad \text{when} \qquad u \simeq (t - t_c)^p.$$

By comparing (2.3) and (2.4), we can see that if the monitor function varies dramatically on the whole interval of interest, then the mesh evolves faster when MMPDE4 is used, but MMPDE6 is better at forcing the mesh to concentrate in the area where the monitor function has larger values. For the nonregularized problem, in order to resolve the spatial structure and solve the problem very close to the singularity time we use MMPDE6 with $\tau = 1 \times 10^{-3}$. To make it easier for the mesh to evolve, we modify the monitor function to be $M(x, t) = c/(u + d)$. Here, $c < 1$ rescales the basic monitor function and helps the mesh to evolve faster while d determines the "radius" of the area centered at the one-point singularity $u = 0$, where the mesh points concentrate. In the results shown in Figure 5, we use $c = 0.1$ and $d = 1 \times 10^{-8}$. The error tolerances for the time integrator are $atol = rtol = 1 \times 10^{-6}$.

Figure 5 displays the corresponding solutions and third derivatives at specified times close to the singularity time. These results closely agree with those found in [9, 10]. Figure 5 also shows that, by carefully choosing a suitable monitor function and an MMPDE, the mesh can in turn evolve along with the singularity and hence capture or resolve the spatial structure.

For the regularized system, in order to sufficiently resolve the spatial structure at all times, we use MMPDE4 with $\tau = 1 \times 10^{-3}$ and the basic monitor function $M(x, t) = 1/u$. The error tolerances for the time integrator are $atol = rtol = 1 \times 10^{-8}$ for the solution and $atol = rtol = 1 \times 10^{-4}$ for all its derivatives.

Figure 6 shows the corresponding solutions at specified times which are typical for this problem. These results are also in close agreement with those found in [9, 10]. With our methods, only 128 points on $[0, 1]$ are used. Furthermore, we are able to easily evaluate other potential quantities of interest. In particular, higher derivatives may be easily and much more reliably evaluated than with a moving finite difference approach. Also, because we are using the inverse of the solution as the monitor function, it is easy to track the movement of the minimum of the solution. This makes it very simple to test asymptotic hypotheses.

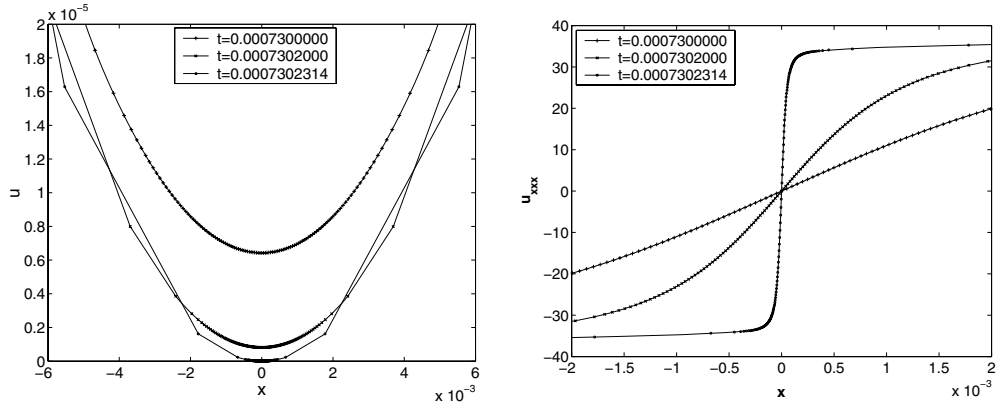

FIG. 5. *Solutions at times very close to the singularity time. Left: Solutions near the pinch-point. Right: Onset of initial singularity, formation of a jump discontinuity in the third derivative.*

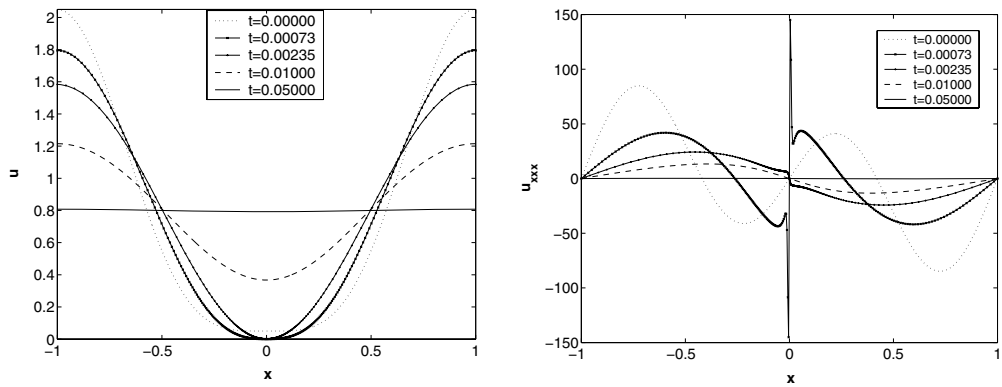

FIG. 6. *Solutions of the regularized system at typical times: $t = 0$, the initial profile, $t = 0.00073$, roughly the time when the pinch-off singularity occurs; $t = 0.002345$, roughly the time when the weak solution becomes strong and positive again; $t = 0.01$, strong solution decays to its mean; $t = 0.05$, solution almost decays to its mean $\bar{u} = 0.8$. Left: Typical solutions. Right: The third derivatives.*

7.3.2. Finite-time blow-up. Given the specific case when $f(u) = u$ and $g(u) = 4u^3$, (7.5) takes the form

$$u_t = -(uu_{xxx} + 4u^3 u_x)_x.$$

As for the unstable Cahn–Hilliard equation, the balance between a stable fourth-order operator and an unstable second-order one can lead to finite-time blow-up. This is particularly delicate here, as it is a critical case for blow-up [12, 41]. Given $f(u) = u$ and $g(u) = u^p$ we never have blow-up for $p < 3$, always have blow-up for $p > 3$, and sometimes have blow-up for $p = 3$. Moreover, the long time dynamics of solutions to this equation are very strongly determined by the mass of the initial data; for sufficient mass there is always blow-up, while for insufficient mass there is never blow-up. Not only that, but the set of allowable final-time blow-up profiles is also restricted by the initial mass [41].

Because of the combination of conservation of mass and finite-time blow-up, we immediately see that the singularity must form at a point. This problem is another

excellent test for our adaptive method, and in particular the adaptive [illegible] method.

We use both the conservative and Gauss collation methods when solving the problem

$$\text{Ex. 5} \quad \begin{cases} u_t = -(uu_{xxx} + 4u^3u_x)_x, \quad x \in (0,6),\ t > 0, \\ u_x(0,t) = u_{xxx}(0,t) = u_x(6,t) = u_{xxx}(6,t) = 0, \\ u(x,0) = \frac{m}{\sqrt{2\pi}} e^{-.5x^2}. \end{cases} \tag{7.10}$$

It is solved with $N = 41$ grid points, $atol = rtol = 1e-3$, and the monitor function

$$\tilde{M}(x,t) = u(x,t)^5 + |x^2 u_{xx}(x,t)|^5, \qquad M(x,t) = \tilde{M}(x,t) + \frac{1}{12}\int_0^6 \tilde{M}(s,t)ds.$$

Again, this particular monitor function has been chosen to be scale invariant in the blow-up region. One of the difficulties of this problem is that the solution approaches a blow-up profile which is compactly supported in the similarity variables, i.e.,

$$\lim_{t\to T}(T-t)^{1/5}u(x,t) = f(y) \quad \text{with} \quad y = \frac{x}{(T-t)^{1/5}},$$

where $f(y)$ is supported on a compact interval [41]. Moreover, there are only certain masses allowable for the similarity solution, so as in the previous example, a portion of the initial data must pinch-off if the initial data are sufficiently large. Depending on the initial data, this pinch-off may be before the blow-up time or else possibly precisely at the blow-up time. We have chosen the parameter $m = 2.65$ to illustrate this. Because of the pinch-off behavior near the boundary of the blow-up region, we cannot simply use the solution u for the monitor function but need the second-derivative as well to ensure that the numerical solution remains positive in the region where the curvature is very high. We have added the scaled curvature to place additional points near the edge of the support of the emerging similarity solution. This behavior is evident in Figure 7, where the spike forming at $x = 0$ is seen to detach from a small droplet. Eventually this droplet is lost due to lack of resolution. Figure 8 shows the grid on which these solutions were computed.

8. Conclusions. We have discussed the implementation of a high-resolution collocation method to integrate nonlinear fourth-order evolutionary equations on adaptive grids. By using a cell-averaged discretization we are able to satisfy a general discrete conservation property and also reduce stiffness in the associated ODE problem. By carefully choosing the monitor function we are also able to resolve very delicate solution features.

The resulting software, MOVCOL4, has been designed with a simple easily expandable interface making it appropriate for solving a general class of fourth-order problems which are of interest to an increasingly wide range of researchers working on PDEs involving high order equations. Advantages of MOVCOL4 include its ability to satisfy conservation equations, its high order accuracy, the local stencil (versus finite differences, which can cause difficulties for high order equations [39]), its relative ease of use, its ability to handle high derivatives (e.g., in boundary conditions) directly, its robust adaptivity, and its facility to build scale invariance into the MMPDE by a suitable choice of monitor function. We have demonstrated here that this code can be used to solve a variety of challenging problems with distinct features. We believe that it can be a useful tool for researchers from many different areas.

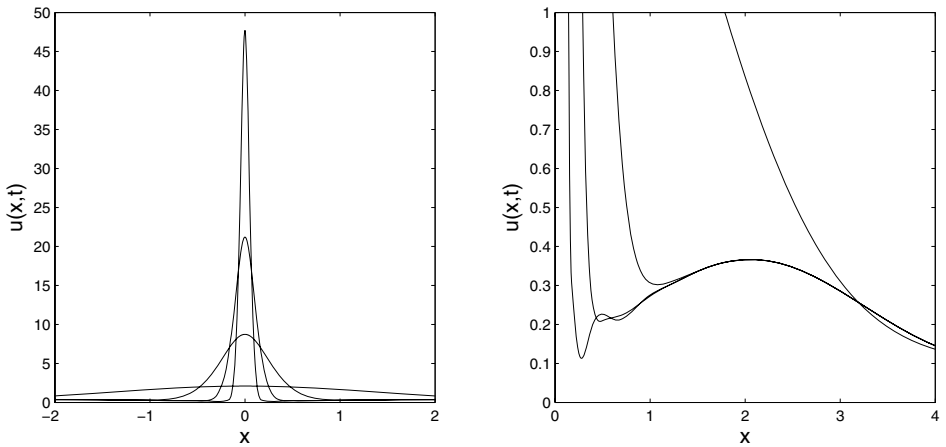

FIG. 7. *Blow-up solutions of an unstable thin-film equation. Left: Sample solutions. Right: Details near the edge of the support of the blow-up solution. As the magnitude of the solution increases at the origin, there is also a second singularity similar to the pinch-off singularity of the previous example. This point requires careful resolution.*

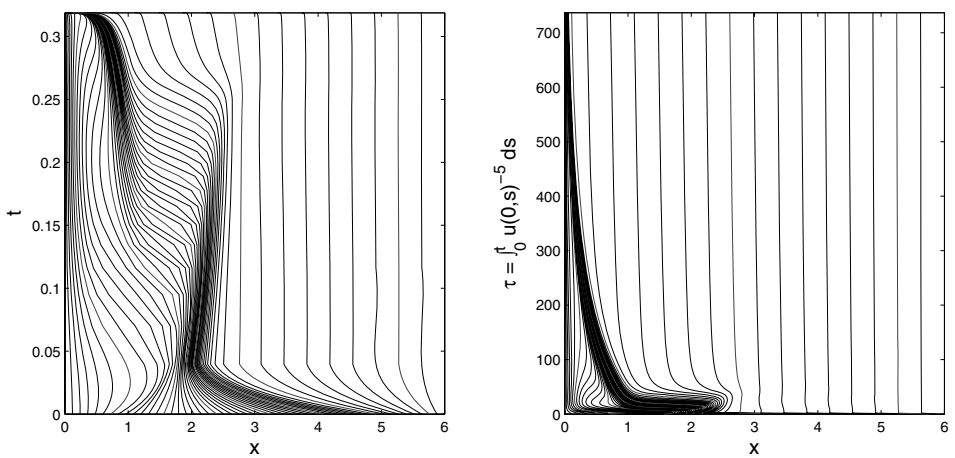

FIG. 8. *Left: Grid in the physical coordinates. Initially the points cluster where the second derivative of the initial data is large but eventually get pulled into the blow-up region. Right: Grid in physical coordinates and rescaled time. Notice in both cases the essentially uniform grid in the outer region away from the blow-up point. Also observe the smooth mesh trajectories in the rescaled time coordinate as blow-up is approached.*

There are a number of questions remaining about which formulations of fourth-order problems prove the most important and useful computationally. Overall solution complexity can increase when going from second to fourth order, so using the best formulation becomes correspondingly more important. Understanding of this issue will increase as experience is gained solving ever more challenging problems using codes such as this one.

It should be noted that MOVCOL4 and a related code have been used to compute

solutions to many other problems; e.g., see [17, 13, 19, 14, 27, 25]. Many of these demonstrate further flexibility in the codes, particularly for solving blow-up problems. In our limited experience, directly solving fourth-order problems with MOVCOL4 generally works at least as well as, and often substantially better than, a method applied to a converted system of second-order problems. In addition, for each of the problems, with solution features which vary over many different scales, having the adaptive features which require no a priori knowledge about the particular solution can be essential.

In conclusion, numerical methods are indispensable for solving the many challenging fourth-order problems having complex solution behavior, largely because the traditional theoretical tools are inapplicable. We expect that software like MOVCOL4 can be extremely useful both to underpin many of the numerical studies and, in other situations, to provide necessary verification of results for scientists who develop their own analytical and numerical methods with features tailored to their particular applications. Conversely, increased analysis of fourth-order problems will play an indispensable role in designing and refining codes such as MOVCOL4, as it would be naive to view current codes as a panacea for understanding the complex structures of these challenging nonlinear problems.

KINETIC FLUX VECTOR SPLITTING SCHEMES FOR IDEAL QUANTUM GAS DYNAMICS*

JAW-YEN YANG†, TSE-YANG HSIEH†, AND YU-HSIN SHI†

Abstract. Novel quantum kinetic flux vector splitting schemes are presented for the computation of ideal quantum gas dynamical flows. The quantum Boltzmann equation approach is adopted and both Bose–Einstein and Fermi–Dirac gases are considered. Formulas for one spatial dimension are first derived, and the resulting kinetic flux vector splitting scheme is tested for shock tube flows. A modified flux vector splitting based on the BGK model is also presented to reduce the numerical diffusion. Implementation of the efficient weighted essentially nonoscillatory method to yield a class of high resolution methods is also devised. Both the classical limit and the nearly degenerate limit are computed. The flow structures can all be accurately captured by the present kinetic flux vector splitting schemes. Results for one-dimensional boson gas under external potential are also included.

Key words. ideal quantum gases, quantum gas dynamics, kinetic flux vector splitting

1. Introduction.

In statistical mechanics, there are three kinds of equilibrium distributions for a system of N identical particles, namely, the Maxwell–Boltzmann, Bose–Einstein, and Fermi–Dirac distributions; the former one is for classical particles and the latter two are for quantum particles. The statistical properties of fermion and boson systems are profoundly different at a sufficiently low temperature. However, in the classical limit, both quantum distributions reduce to the Maxwell–Boltzmann distribution. The ideal classical gas dynamics can be described by the Maxwell–Boltzmann distribution which corresponds to the lowest order solution of the classical Boltzmann equation when the Chapman–Enskog procedure is employed (Chapman and Cowling, 1970). The conservation laws based on the Maxwell–Boltzmann distribution are the well-known Euler equations of classical gas dynamics. Analogous to the classical Boltzmann equation, a quantum Boltzmann equation for the transport phenomenon can be developed for fermions and bosons; see Kadanoff and Baym (1962). A formal solution procedure which generalizes the Chapman–Enskog method to solve the quantum Boltzmann equation was given by Uehling and Uhlenbeck (1933), where the first and second approximations of the distribution function and expressions for the viscosity and heat conductivity coefficients were given. The corresponding quantum gas dynamics can also be explored based on the quantum equilibrium distributions.

In the past 40 years, extensive theoretical and computational methods have been developed to solve the Euler equations of classical gas dynamics. Among the various methods, such as the exact and approximate Riemann solvers (see Hirsch 1988; Toro 1999), most are constructed based on the hyperbolic conservation laws of the Euler equations. Here, we shall denote numerical methods constructed based on distribution functions as kinetic methods. Some kinetic methods have been devised in the past to solve the Euler equations of classical gas dynamics. The beam scheme of

Sanders and Prendergast (1974), the equilibrium flux method of Pullin (1980), the method of Reitz (1981), and the kinetic flux vector splitting (KFVS) of Patterson (1971), Deshpande (1986), and Chou and Baganoff (1997) are some examples. More recent works on kinetic methods have been given by Xu and Prendergast (1994), Xu (1998), and Ohwada (2002). An interesting explicit scheme, which is called the beam scheme, has been presented by Sanders and Prendergast (1974) for solving the equilibrium limit of the classical Boltzmann equation. The derivation was based on the local thermodynamic Maxwell–Boltzmann equilibrium distribution and resulted in a novel method for solving the transport processes governed by the Euler equations of Newtonian gas dynamics. Later, the beam scheme was successfully extended to the relativistic Boltzmann transport equation based on the Jüttner distribution by Yang et al. (1997). Recently, the concept of beam scheme has been extended and generalized to ideal quantum gas dynamics by Yang and Shi (2006) based on the Bose–Einstein and Fermi–Dirac distributions. The beam scheme turns out to also be a flux vector splitting method and has all the desirable features of modern characteristics–based wave propagating numerical methods for hyperbolic conservation laws of gas dynamics. We note that the beam scheme is based on the equilibrium flow limit of the Boltzmann equation, while KFVS is based on the convectional Boltzmann equation which governs the free molecular flow. The basic KFVS scheme is of first order accuracy and thus numerically diffusive. Also, due to the lack of collisions in the evaluation of the numerical flux, KFVS schemes give a smeared solution, especially at the contact discontinuity. In order to include real particle collisions in the gas evolution to reduce overdiffusivity, the BGK relaxation time model (Bhatnagar, Gross, and Krook, 1954) was employed and a class of BGK-type KFVS schemes has been devised by Xu (1998) which improves the original KFVS scheme considerably. However, this numerical diffusion of first order KFVS (or any upwind) methods can also be significantly reduced by the implementation of higher-order methods.

In this work, we shall adopt and generalize the concept of the KFVS scheme to devise a numerical method for the computation of ideal quantum gas dynamics. We start with the quantum Boltzmann equation, in which the particles obey the quantum statistics and the particles of the system are in the excited states. It is well known that the boson or fermion particles in the excited states are in the gas phase and that in the low-density (or high temperature) limit ($\beta\mu \approx -\infty$) they behave like classical ideal gas governed by the Maxwell–Boltzmann distribution. Here μ is the chemical potential and $\beta = 1/k_B T$, with k_B the Boltzmann constant and T the temperature. At low temperatures, in the neighborhood of degeneracy temperature, T_0, corresponding to $n\lambda_B^3 = 1$ (here n is the number density and λ_B is the thermal de Broglie wavelength), the quantum effects become important. The present method considers both the Bose–Einstein and Fermi–Dirac gas behaviors in the regime between the nearly degenerate limit and the classical limit. In Bose–Einstein statistics, the condensed phase of boson gas is not considered. First, the KFVS scheme for ideal quantum gas dynamics is derived based on the solution of the initial value problem of the collisionless Boltzmann equation. Second, we follow Xu (1998) and devise a BGK-type KFVS scheme based on a collisional model Boltzmann equation. Both the basic KFVS and BGK-type KFVS schemes are of first order accuracy and thus numerically too diffusive for practical applications. Nevertheless, they are entropy-satisfying and can exclude the expansion shocks. Furthermore, this numerical diffusion of first order KFVS and BGK–KFVS methods can be significantly reduced by the implementation of higher-order methods. Here we adopt the efficient weighted essentially nonoscillatory (WENO) method of Jiang and Shu (1996) for our basic first order quantum KFVS scheme to yield a

class of high resolution entropy-satisfying methods for computing ideal quantum gas dynamical flows. Implementation of a higher-order BGK–KFVS scheme can be done following Xu (1998) and will not be presented here. Considering the existing extensive works on experimental and computational classical gas dynamics, the present quantum KFVS schemes can be potentially useful for revealing various dynamical aspects of ideal quantum gas through mathematical and physical analogies.

The paper is organized as follows. We first briefly describe the elements of the quantum Boltzmann transport equation in section 2. In section 3, the basic KFVS scheme in one spatial dimension is derived based on the convectional Boltzmann equation for bosons and fermions. In section 4, to reduce the diffusivity of the basic KFVS scheme, a modified KFVS scheme is considered based on the BGK model. Implementations of high-order methods using the WENO scheme are outlined in section 5. In section 6, numerical experiments with quantum shock tube flows in both classical and nearly degenerate limits and one-dimensional boson gas under harmonic potential are given to illustrate the method. Lastly, discussion and concluding remarks are given in section 7.

2. Elements of the quantum Boltzmann equation. In this section, we briefly describe the elements of the quantum Boltzmann transport equation relevant to the development of the present work. Following Kadanoff and Baym (1962), we consider the Boltzmann equation

$$\left(\frac{\partial}{\partial t} + \vec{u}\cdot\nabla_{\vec{x}} - \nabla V(\vec{x},t)\cdot\nabla_{\vec{u}}\right) f(\vec{x},\vec{u},t) = \left(\frac{\delta f}{\delta t}\right)_{col.}, \tag{2.1}$$

where $\vec{u}$ is the particle velocity, $V(\vec{x},t)$ is the externally applied field, and $f(\vec{x},\vec{u},t)$ is the distribution function which represents the average density of particles with velocity $\vec{u}$ at the space-time point $\vec{x}$, t. The $(\delta f/\delta t)_{col.}$ denotes the nonlinear integral collision term. The left-hand side of (2.1) represents the convection of particles in phase space under molecular motions and external forces and, with $(\delta f/\delta t)_{col.} = 0$, it will be denoted as the convectional Boltzmann equation in the present work. A formal solution procedure generalizing the Chapman–Enskog method to solve (2.1) was given by Uehling and Uhlenbeck (1933). In recent years, the development of numerical methods for solving the quantum Boltzmann equation has become an active research subject; see Garcia and Wagner (2003). A recent review on the numerical methods for the dynamics and transport of atomic quantum gases has been given (see Minguzzi et al. 2004 and the references therein). The major mathematical difficulty of solving (2.1) is due to the nonlinear integral collision term. Similar to the simple collision model given by a BGK approach for the classical gas dynamics, the relaxation time collision model has been extended to treat the scattering processes of electrons, phonons, and other quantum particles; see Chen (2005). A corresponding Wigner–BGK equation for the quantum moment equations has also been given by Degond and Ringhofer (2003). Here, we shall consider only the cases where the collision term can be neglected and demand that

$$\left(\frac{\delta f}{\delta t}\right)_{col.} = 0. \tag{2.2}$$

That means we consider the convectional Boltzmann equation for ideal quantum gases. This corresponds to two cases. The first case is the free molecular flow, where the mean free path of the gas system is very large or infinite, and the second is the

equilibrium flow, where the mean collision time is infinitely short and the distribution function is always in local equilibrium. The solution to (2.1) for the equilibrium flow is given by

$$f(\vec{x},\vec{u},t)=\left(\frac{m^4}{h^3}\right)\left\{\exp\left[\frac{m(\vec{u}-\vec{U}(\vec{x},t))^2}{2k_BT(\vec{x},t)}-\frac{\mu(\vec{x},t)}{k_BT(\vec{x},t)}\right]+\theta\right\}^{-1}, \tag{2.3}$$

where m is the particle mass, h is the Planck constant, and $\theta=+1$ denotes the Fermi–Dirac statistics and $\theta=-1$ the Bose–Einstein statistics. To complete the equilibrium solution, we have to determine the unknown functions, namely, the gas temperature, $T(\vec{x},t)$, chemical potential, $\mu(\vec{x},t)$, and velocity vector, $\vec{U}(\vec{x},t)$, which appear in (2.3). These flow parameters can be determined by making use of the conservation laws for number of particles, momentum, and energy. These conservation laws can be obtained by multiplying (2.1) by 1, $\vec{u}$, and $\frac{\vec{u}^2}{2}$ and then integrating the resulting equations over all $\vec{u}$. The integrals of the collision terms in all three cases vanish automatically, and we have the conservation laws for the conserved macroscopic quantities, i.e., the density ρ, momentum $\rho\vec{U}$, and energy density $\rho\epsilon$ as follows:

$$\frac{\partial\rho}{\partial t}+\nabla_{\vec{x}}\cdot\rho\vec{U}=0, \tag{2.4}$$

$$\frac{\partial\rho\vec{U}}{\partial t}+\nabla_{\vec{x}}\cdot(P+\rho\vec{U}\vec{U})=-\rho\nabla_{\vec{x}}V, \tag{2.5}$$

$$\frac{\partial\rho\epsilon}{\partial t}+\nabla_{\vec{x}}\cdot\left(\vec{U}\left(P+\frac{1}{2}\rho\vec{U}^2+e\right)\right)=-\rho\vec{U}\cdot\nabla_{\vec{x}}V, \tag{2.6}$$

where

$$\rho(\vec{x},t)=\int f(\vec{x},\vec{u},t)d\vec{u}, \tag{2.7}$$

$$\rho(\vec{x},t)\vec{U}(\vec{x},t)=\int\vec{u}f(\vec{x},\vec{u},t)d\vec{u}, \tag{2.8}$$

$$\rho\vec{U}\vec{U}=\int\vec{u}\vec{u}f(\vec{x},\vec{u},t)d\vec{u}, \tag{2.9}$$

$$\rho(\vec{x},t)\epsilon(\vec{x},t)=\int\frac{\vec{u}^2}{2}f(\vec{x},\vec{u},t)d\vec{u}. \tag{2.10}$$

Other higher-order moments can also be defined such as stress tensor and the heat flux vector. For the local equilibrium solution, one can obtain these macroscopic quantities in closed form in terms of the Bose or Fermi function (Huang 1987; Pathria 1996). To illustrate the KFVS scheme, we consider the following local quantum equilibrium distribution in one spatial dimension:

$$f(x,u,t)=\left(\frac{m^2}{h}\right)\left\{\frac{1}{z(x,t)}\exp\left\{\frac{m[u-U(x,t)]^2}{2k_BT(x,t)}\right\}+\theta\right\}^{-1}, \tag{2.11}$$

where $z(x,t)=exp\{\mu(x,t)/k_BT(x,t)\}$ is the fugacity. Then the density $\rho(x,t)$ is given by

$$\rho(x,t)=\int_{-\infty}^{\infty}f(x,u,t)du=\frac{m\mathcal{Q}_{\frac{1}{2}}(z)}{\lambda}, \tag{2.12}$$

the momentum $\rho(x,t)U(x,t)$ by

$$\rho(x,t)U(x,t) = \int_{-\infty}^{\infty} uf(x,u,t)du = \frac{m\mathcal{Q}_{\frac{1}{2}}(z)U(x,t)}{\lambda}, \tag{2.13}$$

and the energy density $\rho(x,t)\epsilon(x,t)$ by

$$\rho(x,t)\epsilon(x,t) = \int_{-\infty}^{\infty} \frac{u^2}{2} f(x,u,t)du = \frac{\mathcal{Q}_{\frac{3}{2}}(z)}{2\beta\lambda} + \frac{m\mathcal{Q}_{\frac{1}{2}}(z)U(x,t)^2}{2\lambda}, \tag{2.14}$$

where $\lambda = \sqrt{\frac{\beta h^2}{2\pi m}}$ is the thermal wavelength.

In the above, $\mathcal{Q}_\nu(z)$ denotes either the Bose–Einstein or the Fermi–Dirac function of order ν, which is defined by

$$\mathcal{Q}_\nu(z) = \begin{cases} \mathcal{G}_\nu(z) & \text{for Bose gas,} \\ \mathcal{F}_\nu(z) & \text{for Fermi gas,} \end{cases} \tag{2.15}$$

where $\mathcal{G}_\nu(z)$ denotes the Bose–Einstein integral and $\mathcal{F}_\nu(z)$ denotes the Fermi–Dirac integral of order ν,

$$\mathcal{G}_\nu(z) \equiv \frac{1}{\Gamma(\nu)} \int_0^\infty \frac{x^{\nu-1}}{z^{-1}e^x - 1} dx = \sum_{l=1}^{\infty} \frac{z^l}{l^\nu}, \tag{2.16}$$

$$\mathcal{F}_\nu(z) \equiv \frac{1}{\Gamma(\nu)} \int_0^\infty \frac{x^{\nu-1}}{z^{-1}e^x + 1} dx = \sum_{l=1}^{\infty} \frac{-(-z)^l}{l^\nu}, \tag{2.17}$$

and $\Gamma(\nu)$ is the Gamma function.

We note that the Bose–Einstein integral with $\nu \leq 1$ diverges as $z \to 1$ and that $g_{\frac{3}{2}}(z)$ remains finite at $z = 1$, but with infinite slope, while $g_\nu(z)$ with $\nu > \frac{3}{2}$ have finite values and slopes at $z = 1$. The Fermi-Dirac integral is $\mathcal{F}_\nu(z) \to z$ for small z. Since the chemical potential for a dilute system is large and negative, the classical limit corresponds to small z. Conversely, at low temperature the chemical potential approaches the Fermi energy so that the fugacity for a Fermi system is large. An asymptotic expansion of the Fermi function for large fugacity z due to Sommerfeld can be used.

It is also noted that thermodynamic functions, the Bose–Einstein condensation and the Fermi–Dirac degeneracy of an ideal (noninteracting) gas of N quantum particles, are peculiarly related to the space dimensionality (de Groot, Hooyman, and Ten Seldam 1950; Aguilera-Navarro, de Llano, and Solis 1999; Grether, de Llano, and Solis 2003). Although these results look quite similar, these two functions behave quite differently in the nearly degenerate limit. For example, in boson gas, the fugacity z could not be larger than 1 because of non-negative density, while in Fermi gas such a restriction does not exist.

3. Quantum KFVS scheme. In this section, the basic first order KFVS scheme is derived based on the convectional Boltzmann equation at the gas evolution stage. We consider the problems in one spatial dimension in which the macroscopic quantities are assumed to be functions of x and t. Divide the space into a number of cells. Each cell occupies a small space $x \in [x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}]$, where $j + \frac{1}{2}$ denotes the cell

interface between cells j and $j+1$, and the cell center is located at x_j. With the initial mass, momentum, and energy densities given inside each cell j,

$$\mathbf{W}_j = (\rho_j, \rho_j U_j, \rho_j \epsilon_j)^T, \tag{3.1}$$

the fugacity z_j is obtained from (2.12) and (2.14) through the following relationship:

$$2(\rho_j \epsilon_j) - \left(\frac{h^2}{2\pi m^2}\right)\left(\frac{\rho_j}{\mathcal{Q}_{\frac{1}{2}}(z_j)}\right)^3 \mathcal{Q}_{\frac{3}{2}}(z_j) - \frac{(\rho_j U_j)^2}{\rho_j} = 0. \tag{3.2}$$

With the temperature T_j obtained from (2.12),

$$T_j = \frac{2\pi k_B}{m}\left(\frac{\rho_j}{\mathcal{Q}_{\frac{1}{2}}(z_j)}\right)^2, \tag{3.3}$$

we can then define a local equilibrium state g_j within the jth cell, which is,

$$g_j = \left(\frac{m^2}{h}\right)\left\{z_j^{-1} \exp\left(\frac{m[u-U_j]^2}{2k_B T_j}\right) + \theta\right\}^{-1}. \tag{3.4}$$

Consider the one-dimensional convectional Boltzmann equation

$$\frac{\partial f}{\partial t} + u\frac{\partial f}{\partial x} = 0. \tag{3.5}$$

We get the following initial condition around the cell interface at $x = x_{j+\frac{1}{2}}$:

$$f(x, u, t=0) = f_1(x, u) = (1 - H(x - x_{j+\frac{1}{2}}))g_j + H(x - x_{j+\frac{1}{2}})g_{j+1}, \tag{3.6}$$

where $H(x)$ is the Heaviside function.

It is noted that the initial distribution functions on both sides of each cell interface are assumed to be in local equilibrium.

The solution of the above initial value problem, $f(x, u, t)$ at $x_{j+\frac{1}{2}}$ and time t, becomes

$$f(x_{j+\frac{1}{2}}, u, t) = f_1(x_{j+\frac{1}{2}} - ut, u) = H(u)g_j + (1 - H(u))g_{j+1}. \tag{3.7}$$

From the above distribution function, the numerical fluxes for the mass, momentum, and energy across the cell interface can be constructed, which are

$$\begin{aligned} F^1_{j+\frac{1}{2}} = \begin{pmatrix} F^1_\rho \\ F^1_{\rho U} \\ F^1_{\rho\epsilon} \end{pmatrix}_{j+\frac{1}{2}} &= \int u\psi_\alpha f(x_{j+\frac{1}{2}}, u, t)du \\ &= \int_{u\geq 0} u\psi_\alpha g_j du + \int_{u<0} u\psi_\alpha g_{j+1} du, \end{aligned} \tag{3.8}$$

where ψ_α stands for the moments $\psi_\alpha = (1, u, \frac{u^2}{2})^T$.

The fluxes can be further expressed as

$$F^1_{j+\frac{1}{2}} = F^+_j + F^-_{j+1}, \tag{3.9}$$

where

$$F_j^+ \equiv \int_{u\geq 0} u\psi_\alpha g_j du, \tag{3.10}$$
$$F_{j+1}^- \equiv \int_{u<0} u\psi_\alpha g_{j+1} du.$$

The details of the integrations in (3.10) can be directly obtained, and they are

$$F_j^\pm = \begin{pmatrix} \frac{\sqrt{\pi}}{2}\mathbf{K}_j^{\frac{1}{2}} U_j \mathbf{A}_j^\pm + \frac{1}{2}\mathbf{K}_j \mathbf{B}_j^\pm \\ \frac{\sqrt{\pi}}{2}\mathbf{K}_j^{\frac{1}{2}} U_j^2 \mathbf{A}_j^\pm + \mathbf{K}_j U_j \mathbf{B}_j^\pm + \frac{\sqrt{\pi}}{4}\mathbf{K}_j^{\frac{3}{2}} \mathbf{C}_j^\pm \\ \frac{\sqrt{\pi}}{4}\mathbf{K}_j^{\frac{1}{2}} U_j^3 \mathbf{A}_j^\pm + \frac{3}{4}\mathbf{K}_j U_j^2 \mathbf{B}_j^\pm + \frac{3\sqrt{\pi}}{8}\mathbf{K}_j^{\frac{3}{2}} U_j \mathbf{C}_j^\pm + \frac{1}{4}\mathbf{K}_j^2 \mathbf{D}_j^\pm \end{pmatrix}, \tag{3.11}$$

$$\mathbf{K}_j = \frac{2k_B T_j}{m}, \mathbf{A}_j^\pm = \frac{m^2}{h}(\mathcal{Q}_{\frac{1}{2}}(z_j) \pm sgn(U_j)\mathcal{Q}_{\frac{1}{2}}(h_j, z_j)),$$
$$\mathbf{B}_j^\pm = \pm\frac{m^2}{h}\tilde{\mathcal{Q}}_1(h_j, z_j), \mathbf{C}_j^\pm = \frac{m^2}{h}(\mathcal{Q}_{\frac{3}{2}}(z_j) \pm sgn(U_j)\mathcal{Q}_{\frac{3}{2}}(h_j, z_j)), \tag{3.12}$$
$$\mathbf{D}_j^\pm = \pm\frac{m^2}{h}\tilde{\mathcal{Q}}_2(h_j, z_j), h_j = \frac{mU_j^2}{2k_B T_j}.$$

Here, the sign function is defined as

$$sgn(U) = \begin{cases} +1, U \geq 0, \\ -1, U < 0, \end{cases} \tag{3.13}$$

and the definitions of $\mathcal{Q}_\nu(h,z)$ and $\tilde{\mathcal{Q}}_\nu(h,z)$ are given by

$$\mathcal{Q}_\nu(h,z) = \begin{cases} \mathcal{G}_\nu(h,z) \text{ for Bose gas,} \\ \mathcal{F}_\nu(h,z) \text{ for Fermi gas,} \end{cases}$$
$$\tilde{\mathcal{Q}}_\nu(h,z) = \begin{cases} \tilde{\mathcal{G}}_\nu(h,z) \text{ for Bose gas,} \\ \tilde{\mathcal{F}}_\nu(h,z) \text{ for Fermi gas,} \end{cases} \tag{3.14}$$

where the incomplete Bose–Einstein integrals $\mathcal{G}_\nu(h,z)$ and $\tilde{\mathcal{G}}_\nu(h,z)$ are defined as

$$\mathcal{G}_\nu(h,z) \equiv \frac{1}{\Gamma(\nu)}\int_0^h \frac{x^{\nu-1}}{z^{-1}e^x - 1}dx = \frac{1}{\Gamma(\nu)}\sum_{l=1}^\infty \Gamma(lh,\nu)\frac{z^l}{l^\nu}, \tag{3.15}$$
$$\tilde{\mathcal{G}}_\nu(h,z) \equiv \frac{1}{\Gamma(\nu)}\int_h^\infty \frac{x^{\nu-1}}{z^{-1}e^x - 1}dx = \mathcal{G}_\nu(z) - \mathcal{G}_\nu(h,z),$$

and $\Gamma(lh,\nu)$ is the incomplete Gamma function given in the IMSL (International Mathematical and Statistical Library).

The incomplete Fermi–Dirac integrals $\mathcal{F}_\nu(h,z)$ and $\tilde{\mathcal{F}}_\nu(h,z)$ are defined as

$$\mathcal{F}_\nu(h,z) \equiv \frac{1}{\Gamma(\nu)}\int_0^h \frac{x^{\nu-1}}{z^{-1}e^x + 1}dx = \frac{1}{\Gamma(\nu)}\sum_{l=1}^\infty \Gamma(lh,\nu)\frac{-(-z)^l}{l^\nu}, \tag{3.16}$$
$$\tilde{\mathcal{F}}_\nu(h,z) \equiv \frac{1}{\Gamma(\nu)}\int_h^\infty \frac{x^{\nu-1}}{z^{-1}e^x + 1}dx = \mathcal{F}_\nu(z) - \mathcal{F}_\nu(h,z).$$

Using the above numerical fluxes, the flow variables ρ_j, $\rho_j U_j$, $\rho_j \epsilon_j$ inside each cell can be updated as

$$\mathbf{W}_j^{n+1} = \mathbf{W}_j^n - \sigma\left(F^1_{j+\frac{1}{2}} - F^1_{j-\frac{1}{2}}\right) - \Delta t S_j, \tag{3.17}$$

where n is the time step number, and $\sigma = \Delta t/\Delta x$, where Δt is the time step size, and Δx is the mesh size and $S = (0, -\rho\frac{\partial V}{\partial x}, -\rho\epsilon\frac{\partial V}{\partial x})^T$.

The scheme defined by (3.17) can be considered as a first order upwind scheme (based on KFVS) for the following conservation laws:

$$\frac{\partial \mathbf{W}}{\partial t} + \frac{\partial F}{\partial x} = S, \tag{3.18}$$

where

$$\mathbf{W} = \begin{pmatrix} \rho \\ \rho U \\ \rho\epsilon \end{pmatrix},\ F = \begin{pmatrix} \rho U \\ \rho U^2 + P \\ U(\rho\epsilon + P) \end{pmatrix},\ S = \begin{pmatrix} o \\ -\rho\frac{\partial V}{\partial x} \\ -\rho U\frac{\partial V}{\partial x} \end{pmatrix}. \tag{3.19}$$

The Jacobians of the present kinetic flux vector split fluxes $F^{\pm}$ do not commute, and the Von Neumann stability analysis becomes nonobvious in this case. Here, we follow the approach given by Mandal and Deshpande (1994). The stability for the exact solution, (3.7), can be readily given by

$$\left| u\frac{\Delta t}{\Delta x} \right| \leq 1. \tag{3.20}$$

This condition imposes a rather severe restriction on particle velocity u for finite values of Δx and Δt. The moments of the distribution function in the moment method strategy in the KFVS scheme involve a particle velocity range from $-\infty$ to $+\infty$. Thus, the moments do not receive contributions due to particle velocities outside the cut-off bounds required by (3.20). A reasonable choice is to enlarge the range from $U - \chi c$ to $U + \chi c$ to guarantee the accurate evaluations of moments. The value of χ will be determined by numerical experience. Here we choose $\chi = 3$, and now the time step size can be chosen by the stability condition,

$$\Delta t \leq \frac{\Delta x}{\max(|U_j| + 3c_j)}, \tag{3.21}$$

where c_j is the local speed of sound,

$$c_j = \sqrt{\frac{3}{m\beta}\frac{\mathcal{Q}_{\frac{3}{2}}(z_j)}{\mathcal{Q}_{\frac{1}{2}}(z_j)}}. \tag{3.22}$$

The time step size can be decided by multiplying the right-hand side of (3.21) with a CFL number. With this stability condition, (3.21), for the present KFVS scheme, we can use CFL = 1 in the calculations given below.

At this stage, we have completed the description of the first order KFVS scheme for the ideal quantum gas.

In the computation, we employ dimensionless quantities, and they are defined by the following:

$$\hat{u} = \frac{u}{\xi}, \hat{c} = \frac{c}{\xi} = \sqrt{3\hat{T}\frac{\mathcal{Q}_{3/2}(z)}{\mathcal{Q}_{1/2}(z)}}, \tag{3.23}$$

$$\hat{\rho} = \frac{\rho}{(\Omega/h)}, \hat{\rho}\hat{U} = \frac{\rho U}{(\Omega\xi/h)}, \hat{\rho}\hat{\epsilon} = \frac{\rho\epsilon}{(\Omega\xi^2/h)},$$

where $\Omega = m\sqrt{2\pi m k_B T_{ref}}$, $\xi = \sqrt{(k_B T_{ref})/m}$, and $\hat{T} = T/T_{ref}$.

After each time step, we can get new macroscopic properties $(\rho_j,\ \rho_j U_j,\ \rho_j \epsilon_j)$. In each time step, we need to find the values of fugacity z using (3.2) and find the temperature T (or β) using (3.3) in each cell to determine the numerical fluxes. The dimensionless form of (3.2) is

$$2(\hat{\rho}\hat{\epsilon}) - \left(\frac{\hat{\rho}}{\mathcal{Q}_{\frac{1}{2}}(z)}\right)^3 \mathcal{Q}_{\frac{3}{2}}(z) - \frac{(\hat{\rho}\hat{U})^2}{\hat{\rho}} = 0. \tag{3.24}$$

The above equation can be solved for fugacity z by an iterative method.

After obtaining fugacity z, we can get temperature T, and thus we can construct the local equilibrium distribution function for each cell at the new time step, and finally advance the solution for the next time step by (3.7).

It is appropriate to note at this stage that the physical requirement for the transition from the quantum Boltzmann equation to the quantum Euler equations is based on the assumption of a local equilibrium state. In deriving the KFVS, although at the beginning of each time step the gas distribution in the KFVS scheme is a quantum equilibrium distribution function inside each cell, the real gas distribution function which is used to evaluate the numerical fluxes across the cell interfaces is not a full equilibrium distribution at all—it is composed of two half Bose–Einstein (or Fermi–Dirac) distributions in $u \geq 0$ and $u < 0$ regions separately, as can be seen from (3.7) and (3.8). This nonequilibrium distribution does not correspond to the quantum Euler solutions at all. In order to achieve the Euler solution, physically, the gas molecules encounter many collisions (with an infinitely short collision time) during a CFL time step Δt. The corresponding classical case has been analyzed by Xu (1998, 2001). In the next section, following Xu we shall include particle collisions in the gas evolution stage using a relaxation time model.

4. Kinetic flux vector splitting based on the BGK scheme. The KFVS scheme is based on the convectional Boltzmann equation in the gas evolution stage. Due to free transport dynamics in this stage, the KFVS scheme cannot properly capture the contact discontinuity wave and slip lines. The artificial collisions with collision time equal to the time step $\triangle t$ help the KFVS scheme to capture these waves. In order to include real particle collisions in the gas evolution model to reduce overdiffusivity in the KFVS scheme, following Xu (1998) we choose to use a relaxation model to approximate particle collisions. The classical BGK model (1954) will be used in the gas evolution stage to construct the numerical fluxes across the cell interfaces in each cell. We shall denote this BGK-type KFVS scheme as the BGK–KFVS scheme to distinguish it from the usual KFVS scheme. For one-dimensional problems, the first order BGK–KFVS scheme considers the BGK equation in the gas evolution stage,

$$\frac{\partial f(x,u,t)}{\partial t} + u\frac{\partial f(x,u,t)}{\partial x} = \frac{f_0 - f(x,u,t)}{\tau}, \tag{4.1}$$

where f_0 is the equilibrium distribution function and τ is the collision time. In a classical gas τ is related to gas properties by $\tau = \nu/P$, where ν is the dynamical viscosity and P is the gas pressure. In this work, the relaxation time τ is used purely for numerical purposes and does not have much specific physical meaning. A more rigorous theoretical derivation of the physical relaxation time for the quantum Boltzmann equation is needed, such as the Wigner–BGK equation by Degond and Ringhofer (2003). Other problems can be treated by solving the quantum Boltzmann

equation under the relaxation time approach including the electron and phonon transport in heterojunction structures and ballistic-diffusive phonon transport; see Chen (2005). We shall pursue this relaxation time approach for nanoscale energy transport in separate works.

Under the same initial condition, i.e., (3.6), around the cell interface $x = x_{j+\frac{1}{2}}$, the solution $f(x, u, t)$ based on the BGK equation at $x = x_{j+\frac{1}{2}}$ and time t now becomes

$$\begin{aligned} f(x,u,t) &= (1-e^{-t/\tau})f_0 + e^{-t/\tau} f_1(x_{j+\frac{1}{2}} - ut, u) \\ &= (1-e^{-t/\tau})f_0 + e^{-t/\tau}(g_j H(u) + g_{j+1}(1-H(u))), \end{aligned} \tag{4.2}$$

where $H(u)$ is the Heaviside function and f_1 is the same as that given in (3.7). The equilibrium state f_0 is constructed by applying the compatibility condition along the line ($x = x_{j+1/2}$, t)

$$\int_{-\infty}^{+\infty} \psi_\alpha f_0 du = \int_{u\geq 0} \psi_\alpha g_j du + \int_{u<0} \psi_\alpha g_{j+1} du. \tag{4.3}$$

The underlying physical assumption in the above equation is that the left and right moving particles collapse at the cell interface to form an equilibrium distribution function f_0.

Solution (4.2) is different from the solution that is based on the convectional Boltzmann equation without considering any effects due to collision. In the limit of $\tau \to 0$, (4.2) goes to $f = f_0$, which is an exact equilibrium distribution function at the cell interface. For $\tau \to \infty$, f is equal to $f(x, u, t = 0) = f_1$, which recovers the distribution function in the KFVS scheme (i.e., (3.7)). Thus, (4.2) is the bridge between these two kinds of distribution functions in the cell interface. In the first order BGK–KFVS scheme, $e^{-t/\tau}$ can be assumed to be a constant.

The distribution function at a cell interface for the first order BGK–KFVS scheme is based on the combination of two functions, which are the nonequilibrium initial gas distribution function $f(x, u, t = 0) = f_1$ and the equilibrium distribution function f_0. With the definition $\eta \equiv e^{-t/\tau}$, the final distribution function at $x = x_{j+\frac{1}{2}}$ is

$$f(x_{j+\frac{1}{2}}, u, t) = (1-\eta)f_0 + \eta f_1(x_{j+\frac{1}{2}} - ut, u). \tag{4.4}$$

We note that in this work we assume $0 < \eta < 1$ and that it is taken as a constant $\eta = 0.5$ in the following numerical calculations. The main role of the relaxation time τ is to provide a bridge between the KFVS scheme (based on f_1) and an equilibrium scheme (based on f_0). The scheme with both f_0 and f_1 is called a partially thermalized transport. For further discussion, see Xu (1998).

The procedures for the first order BGK–KFVS scheme are summarized as follows:

1. From the given macroscopic quantities $\mathbf{W}_j = (\rho_j, \rho_j U_j, \rho_j \epsilon_j)^T$ in cell j, we obtain z_j and T_j from (3.2) and (3.3), respectively. We then construct the quantum equilibrium distribution function g_j and set the nonequilibrium initial gas distribution function $f(x, u, t = 0) = f_1$ as given by (3.6).

2. Compute the numerical fluxes at each cell interface $F^1_{j+\frac{1}{2}}$ from the nonequilibrium distribution function. The fluxes are the same as in the previous KFVS scheme defined by (3.8).

3. Obtain the macroscopic quantities $\bar{\mathbf{W}} = (\bar{\rho}, \bar{\rho}\bar{U}, \bar{\rho}\bar{\epsilon})^T$ at the cell interface $x = x_{j+\frac{1}{2}}$ from the compatibility condition (4.3):

$$\bar{\rho}_{j+\frac{1}{2}} = \frac{\sqrt{\pi}}{2}\{\mathbf{K}_j^{\frac{1}{2}} \mathbf{A}_j^+ + \mathbf{K}_{j+1}^{\frac{1}{2}} \mathbf{A}_{j+1}^-\}, \tag{4.5}$$

$$\bar{\rho}_{j+\frac{1}{2}}\bar{U}_{j+\frac{1}{2}} = \frac{\sqrt{\pi}}{2}\{\mathbf{K}_j^{\frac{1}{2}}\mathbf{A}_j^+ + \mathbf{K}_{j+1}^{\frac{1}{2}}U_{j+1}\mathbf{A}_{j+1}^-\} + \frac{1}{2}\{\mathbf{K}_j\mathbf{B}_j^+ + \mathbf{K}_{j+1}\mathbf{B}_{j+1}^-\},$$

$$\bar{\rho}_{j+\frac{1}{2}}\bar{\epsilon}_{j+\frac{1}{2}} = \frac{\sqrt{\pi}}{4}\{\mathbf{K}_j^{\frac{1}{2}}U_j^2\mathbf{A}_j^+ + \mathbf{K}_{j+1}^{\frac{1}{2}}U_{j+1}^2\mathbf{A}_{j+1}^-\} + \frac{1}{2}\{\mathbf{K}_jU_j\mathbf{B}_j^+ + \mathbf{K}_{j+1}U_{j+1}\mathbf{B}_{j+1}^-\} + \frac{\sqrt{\pi}}{8}\{\mathbf{K}_j^{\frac{3}{2}}\mathbf{C}_j^+ + \mathbf{K}_{j+1}^{\frac{3}{2}}\mathbf{C}_{j+1}^-\},$$

where all the parameters $\mathbf{K}$, $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are defined in (3.12).

4. From the macroscopic quantities at the cell interface, $\bar{\mathbf{W}}_{j+\frac{1}{2}} = (\bar{\rho}, \bar{\rho}\bar{U}, \bar{\rho}\bar{\epsilon})^T$, we can get the value of the fugacity $\bar{z}_{j+\frac{1}{2}}$ and temperature $\bar{T}_{j+\frac{1}{2}}$. Then we can construct the equilibrium distribution function $f_{0,j+1/2}$ from (3.4),

$$f_{0,j+1/2} = \left(\frac{m^2}{h}\right)\left\{\bar{z}_{j+\frac{1}{2}}^{-1}\exp\left(\frac{m[u-\bar{U}_{j+\frac{1}{2}}]^2}{2k_B\bar{T}_{j+\frac{1}{2}}}\right) + \theta\right\}^{-1}. \tag{4.6}$$

5. Compute the numerical fluxes $F_{j+1/2}^0$ from the equilibrium distribution function $f_{0,j+1/2}$,

$$F_{j+\frac{1}{2}}^0 = \begin{pmatrix} \sqrt{\pi}\bar{\mathbf{K}}_{j+\frac{1}{2}}^{\frac{1}{2}}\bar{U}_{j+\frac{1}{2}}g_{\frac{1}{2}}(\bar{z}_{j+\frac{1}{2}}) \\ \sqrt{\pi}\bar{\mathbf{K}}_{j+\frac{1}{2}}\bar{U}_{j+\frac{1}{2}}^2g_{\frac{1}{2}}(\bar{z}_{j+\frac{1}{2}}) + \frac{\sqrt{\pi}}{2}\bar{\mathbf{K}}_{j+\frac{1}{2}}^{\frac{3}{2}}g_{\frac{3}{2}}(\bar{z}_{j+\frac{1}{2}}) \\ \frac{\sqrt{\pi}}{2}\bar{\mathbf{K}}_{j+\frac{1}{2}}^{\frac{1}{2}}\bar{U}_{j+\frac{1}{2}}^3g_{\frac{1}{2}}(\bar{z}_{j+\frac{1}{2}}) + \frac{3\sqrt{\pi}}{4}\bar{\mathbf{K}}_{j+\frac{1}{2}}^{\frac{3}{2}}\bar{U}_{j+\frac{1}{2}}g_{\frac{3}{2}}(\bar{z}_{j+\frac{1}{2}}) \end{pmatrix}, \tag{4.7}$$

where $\bar{\mathbf{K}}_{j+\frac{1}{2}} = 2k_B\bar{T}_{j+\frac{1}{2}}/m$.

6. The final flux vector across the cell interface is

$$F_{j+\frac{1}{2}}^2 = (1-\eta)F_{j+\frac{1}{2}}^0 + \eta F_{j+\frac{1}{2}}^1, \tag{4.8}$$

where η is a local constant with $\eta \in [0,1]$ and we use $\eta = 0.5$ in the first order BGK–KFVS scheme.

7. We finally get the first order BGK–KFVS scheme

$$\mathbf{W}_j^{n+1} = \mathbf{W}_j^n - \sigma(F_{j+\frac{1}{2}}^2 - F_{j-\frac{1}{2}}^2). \tag{4.9}$$

Now, we have completed the first order BGK–KFVS scheme for one-dimensional ideal quantum gas dynamics.

5. Implementation of WENO schemes. For the purpose of implementing high-order methods, we can further express the basic quantum KFVS scheme (without external potential) defined by (3.17) in terms of numerical flux as follows:

$$\mathbf{W}_j^{n+1} = \mathbf{W}_j^n - \sigma(F_{j+1/2}^1 - F_{j-1/2}^1), \tag{5.1}$$

where the numerical flux $F_{j+1/2}^1$ as is given in (3.8).

The above scheme is of first order accuracy and thus is very diffusive. In practical applications we need high-order methods. In this section, we apply the WENO interpolation method (Liu, Osher, and Chan 1994; Jiang and Shu 1996) to the basic first order quantum KFVS scheme to result in a class of high resolution methods for the

computation of quantum ideal gas dynamical flows. The numerical flux is expressed as

$$F^3_{j+1/2} = \widehat{F}^+_{j+1/2} + \widehat{F}^-_{j+1/2}. \tag{5.2}$$

Here we consider a fifth-order accurate ($r = 3$) WENO scheme for the spatial difference of numerical fluxes. The WENO scheme for $r = 3$, denoted as WENO3, can be expressed as

$$\widehat{F}^+_{j+1/2} = \omega^+_0\left(\frac{2}{6}F^+_{j-2} - \frac{7}{6}F^+_{j-1} + \frac{11}{6}F^+_j\right) + \omega^+_1\left(-\frac{1}{6}F^+_{j-1} + \frac{5}{6}F^+_j + \frac{2}{6}F^+_{j+1}\right) + \omega^+_2\left(\frac{2}{6}F^+_j + \frac{5}{6}F^+_{j+1} - \frac{1}{6}F^+_{j+2}\right), \tag{5.3}$$

$$\omega^+_k = \frac{\alpha^+_k}{\alpha^+_0 + \alpha^+_1 + \alpha^+_2}, \qquad k = 0, 1, 2, \tag{5.4}$$

$$\alpha^+_0 = \frac{1}{10(\epsilon + IS^+_0)^2}, \alpha^+_1 = \frac{6}{10(\epsilon + IS^+_1)^2}, \alpha^+_2 = \frac{3}{10(\epsilon + IS^+_2)^2}, \tag{5.5}$$

$$\begin{aligned} IS^+_0 &= \frac{13}{12}(F^+_{j-2} - 2F^+_{j-1} + F^+_j)^2 + \frac{1}{4}(F^+_{j-2} - 4F^+_{j-1} + 3F^+_j)^2, \\ IS^+_1 &= \frac{13}{12}(F^+_{j-1} - 2F^+_j + F^+_{j+1})^2 + \frac{1}{4}(F^+_{j-1} - F^+_{j+1})^2, \\ IS^+_2 &= \frac{13}{12}(F^+_j - 2F^+_{j+1} + F^+_j)^2 + \frac{1}{4}(3F^+_j - 4F^+_{j+1} + F^+_{j+2})^2. \end{aligned} \tag{5.6}$$

The numerical flux for the negative part is given by

$$\widehat{F}^-_{j+1/2} = \omega^-_0\left(-\frac{1}{6}F^-_{j-1} + \frac{5}{6}F^-_j + \frac{2}{6}F^-_{j+1}\right) + \omega^-_1\left(\frac{2}{6}F^-_j + \frac{5}{6}F^-_{j+1} - \frac{1}{6}F^-_{j+2}\right) + \omega^-_2\left(\frac{11}{6}F^-_{j+1} - \frac{7}{6}F^-_{j+2} + \frac{2}{6}F^-_{j+3}\right), \tag{5.7}$$

$$\omega^-_k = \frac{\alpha^-_k}{\alpha^-_0 + \alpha^-_1 + \alpha^-_2}, \qquad k = 0, 1, 2, \tag{5.8}$$

$$\alpha^-_0 = \frac{3}{10(\epsilon + IS^-_0)^2}, \alpha^-_1 = \frac{6}{10(\epsilon + IS^-_1)^2}, \alpha^-_2 = \frac{1}{10(\epsilon + IS^-_2)^2}, \tag{5.9}$$

$$\begin{aligned} IS^-_0 &= \frac{13}{12}(F^-_{j-1} - 2F^-_j + F^-_{j+1})^2 + \frac{1}{4}(F^-_{j-1} - 4F^-_j + 3F^-_{j+1})^2, \\ IS^-_1 &= \frac{13}{12}(F^-_j - 2F^-_{j+1} + F^-_{j+2})^2 + \frac{1}{4}(F^-_j - F^-_{j+2})^2, \\ IS^-_2 &= \frac{13}{12}(F^-_{j+1} - 2F^-_{j+2} + F^-_{j+3})^2 + \frac{1}{4}(3F^-_{j+1} - 4F^-_{j+2} + F^-_{j+3})^2. \end{aligned} \tag{5.10}$$

The details of the $F^\pm_j$ are listed in (3.11).

In the following, we shall denote by KFVS–WENO3 the KFVS scheme with WENO3 implementation. The implementation of the high-order method for the BGK–KFVS scheme will be different from that for KFVS and will be investigated separately; see Xu (1998).

6. Numerical experiments. In this section, we report some numerical experiments to illustrate the present quantum KFVS and BGK–KFVS schemes. We consider ideal quantum gas flows in a shock tube. Both Bose–Einstein and Fermi–Dirac gases are considered. In this problem a diaphragm is located at $x = 0.5$ and separates two regions, each of which remains in a constant equilibrium state at initial time $t = 0$. The macroscopic properties on both sides of the diaphragm are different. Then the diaphragm is removed and flow structures of moving shock wave, contact line, and expansion fan are generated, which are similar to those in the classical gas dynamics. We consider two cases for each quantum gas. The first and second cases are set up for boson gas in such a way that one corresponds to the classical limit and the other is set up with the condition that z is very close to unity, which corresponds to the nearly degenerate limit. The third and fourth cases are set up for fermion gas. One corresponds to the classical limit and the other is set up for large z, which is close to the nearly degenerate limit. Finally, we consider a one-dimensional ideal boson gas in a harmonic potential. The harmonic potential is important because of its relevance to the recent experiments on Bose–Einstein condensation and mathematical simplicity (see Ketterle and van Druten 1996 and Pethick and Smith 2002).

' . ,' 1 (boson gas in the near classical limit). The initial condition is specified with $\mathbf{W}_L = (\rho_L, \rho_L U_L, \rho_L \epsilon_L) = (2.337556, 0, 0.629285)$ for $0 < x \leq 0.5$ and $\mathbf{W}_R = (\rho_R, \rho_R U_R, \rho_R \epsilon_R) = (1.249672, 0, 0.248194)$ for $0.5 < x < 1$. This corresponds to $z_L = 0.8$ and $z_R = 0.7$, and we assume that $\mu_L = \mu_R$. The solution behaviors are similar to those in the classical limit. The results are output at time $t = 0.3$ (dimensionless time), and the CFL number used is 1. The computed density, temperature, fugacity, and chemical potential profiles are depicted in Figure 1 for several grid systems. The symbol $\square$ denotes the solution using 200 cells, the symbol $\triangle$ denotes the solution using 400 cells, and the symbol $\circ$ denotes the solution using 800 cells. The flow structures of moving shock, contact line, and expansion fan can be identified and captured by the present first order KFVS scheme. It can be seen from the figures that when the grid becomes finer, the profiles become crisper, which indicates the grid convergence of the solution. In Figure 2, we compare the results using first order KFVS, BGK–KFVS, and KFVS–WENO3 schemes with 200 cells. The symbol $\square$ denotes the solution using the KFVS scheme (CFL number is 1), the symbol $\triangle$ denotes the solution using the BGK–KFVS scheme (CFL number is 1), the symbol $\circ$ denotes the solution using the KFVS–WENO3 scheme (CFL number is 0.2), and the solid line denotes the Riemann solution. As can be seen, the BGK–KFVS solution shows slightly better resolution than that of KFVS, and the effect of the high-order method is clearly depicted. A plot of Bose–Einstein distribution functions at several stations at time $t = 0.3$ is also shown in Figure 2(d). Here, 20 lines are plotted for $0 \leq x \leq 1$ with equal spacing $\Delta x = 0.05$, and the range of u is $-2 \leq u \leq 2$. The profiles at most stations are close to Gaussian distribution in this near classical limit.

' . ,' 2 (boson gas in the nearly degenerate limit). The initial condition in this case is set with $\mathbf{W}_L = (\rho_L, \rho_L U_L, \rho_L \epsilon_L) = (16.221831, 0, 1.135830)$ for $0 < x \leq 0.5$ and $\mathbf{W}_R = (\rho_R, \rho_R U_R, \rho_R \epsilon_R) = (7.768344, 0, 0.375085)$ for $0.5 < x < 1$. We assume $\mu_L = \mu_R$ and set the values of fugacity as $z_L = 0.99$ and $z_R = 0.98$, which are quite close to unity. Although in one spatial dimension Bose–Einstein condensation does not occur because the excited states can accommodate an essentially infinite particle number, due to that, boson functions may diverge at $z = 1$. This example was selected to simulate the situation close to the degenerate limit.

The results are output at time $t = 0.3$ (dimensionless time), and the CFL number used is 1. The computed density, temperature, fugacity, and chemical potential

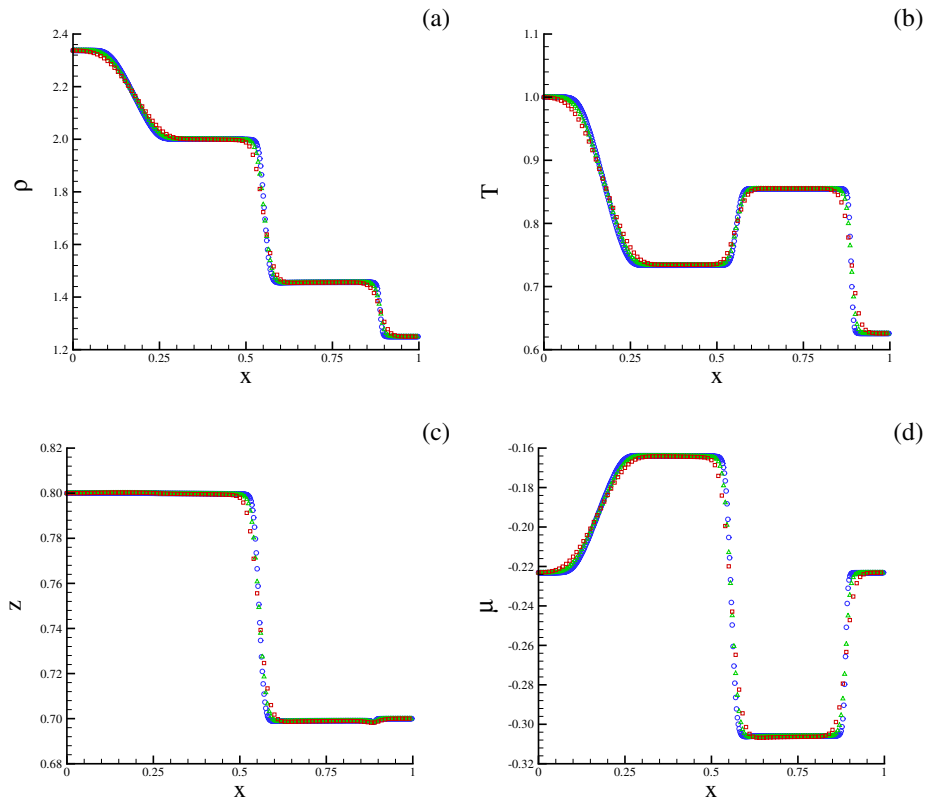

FIG. 1. *Quantum shock tube solution (Example 1).* (a) *density;* (b) *temperature;* (c) *fugacity;* (d) *chemical potential.*

profiles are depicted in Figure 3 for several grid systems. The symbol □ denotes the solution using 200 cells, the symbol △ denotes the solution using 400 cells, and the symbol ○ denotes the solution using 800 cells. The flow structures of moving shock, contact line, and expansion fan can be identified and captured by the present first order KFVS scheme. It can be seen from the figures that when the grid becomes finer, the profiles become crisper, which indicates the grid convergence of the solution. In Figure 4, we compare the results that use first order KFVS, BGK–KFVS, and KFVS–WENO3 schemes with 200 cells. The symbol □ denotes the solution using the first order KFVS scheme (CFL number is 1), the symbol △ denotes the solution using the first order BGK–KFVS scheme (CFL number is 1), the symbol ○ denotes the solution using the KFVS–WENO3 scheme (CFL number is 0.2), and the solid line denotes the Riemann solution. Again, the BGK–KFVS solution indicates slightly better resolution than that of KFVS, and the effect of the high-order method can be clearly observed. In Figure 4(d), a plot of Bose–Einstein distribution functions at several stations is shown. Here, 20 lines are plotted for $0 \le x \le 1$ with equal spacing $\Delta x = 0.05$, and the range of u is $-1 \le u \le 1$. It is noted that the peak values of this

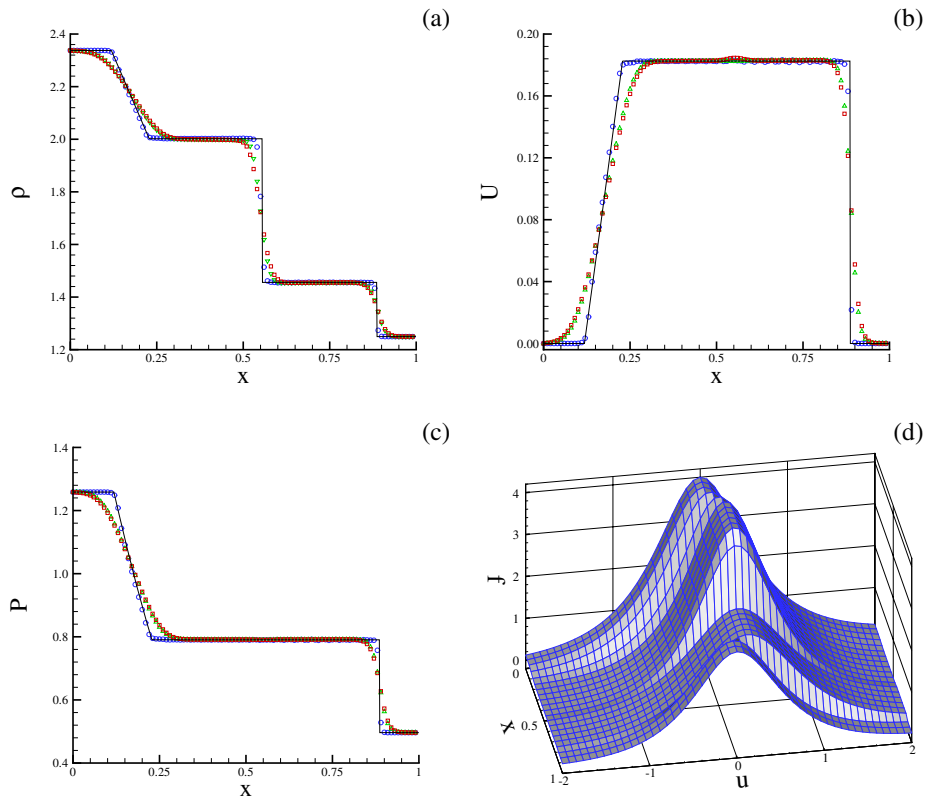

FIG. 2. *Quantum shock tube solution (Example 1).* (a) *density;* (b) *velocity;* (c) *pressure;* (d) *distribution function.*

case are much higher than that of Example 1, as shown in Figure 2(d), and the shape of the distribution function becomes more narrow.

3 (fermion gas in the near classical limit). The initial condition is specified with $\mathbf{W}_L = (\rho_L, \rho_L U_L, \rho_L \epsilon_L) = (0.523188, 0, 0.319701)$ for $0 < x \leq 0.5$ and $\mathbf{W}_R = (\rho_R, \rho_R U_R, \rho_R \epsilon_R) = (0.377659, 0, 0.141679)$ for $0.5 < x < 1$. This corresponds to $z_L = 0.8$ and $z_R = 0.7$, and we assume that $\mu_L = \mu_R$ and $m = 1$. The solution behaviors are similar to those in the classical limit. The results are output at time $t = 0.15$ (dimensionless time), and the CFL number used is 1. The computed density, temperature, fugacity, and chemical potential profiles are depicted in Figure 5 for several grid systems. The symbol □ denotes the solution using 200 cells, the symbol △ denotes the solution using 400 cells, and the symbol ∘ denotes the solution using 800 cells. The flow structures of moving shock, contact line, and expansion fan can be identified and captured by the present first order KFVS scheme. It can be seen from the figures that, again, the grid convergence of the solution is ensured. In Figure 6, we compare the results using the first order KFVS, BGK–KFVS, and KFVS–WENO3

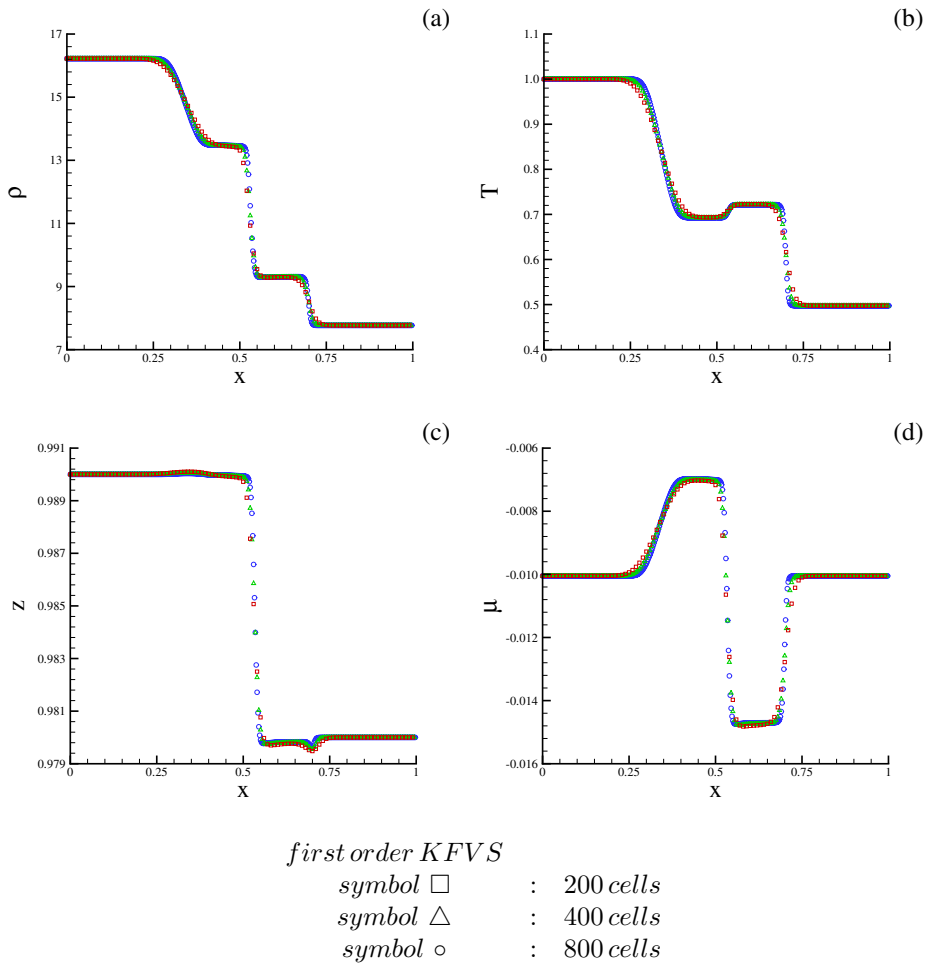

FIG. 3. *Quantum shock tube solution (Example 2).* (a) *density;* (b) *temperature;* (c) *fugacity;* (d) *chemical potential.*

schemes with 200 cells. The symbol □ denotes the solution using the first order KFVS scheme (CFL number is 1), the symbol △ denotes the solution using the first order BGK–KFVS scheme (CFL number is 1), the symbol ○ denotes the solution using the KFVS–WENO3 scheme (CFL number is 0.2), and the solid line denotes the Riemann solution. Again, the BGK–KFVS solution indicates moderately better resolution than that of the KFVS solution, and the effect of the high-order method can be clearly observed. In Figure 6(d), a plot of Fermi–Dirac distribution functions at several stations is shown. Here, 20 lines are plotted for $0 \le x \le 1$ with equal spacing $\Delta x = 0.05$, and the range of u is $-5 \le u \le 5$. The profiles at most stations are close to Gaussian distribution in this near classical limit.

' . ,' 4 (fermion gas in the nearly degenerate limit). The initial condition in this case is set with $\mathbf{W}_L = (\rho_L, \rho_L U_L, \rho_L \epsilon_L) = (3.086643, 0, 8.053134)$ for $0 < x \le 0.5$ and $\mathbf{W}_R = (\rho_R, \rho_R U_R, \rho_R \epsilon_R) = (3.084468, 0, 8.067159)$ for $0.5 < x < 1$. We assume $\mu_L = \mu_R$ and set the values of fugacity as $z_L = 2000$ and $z_R = 1500$, using Sommerfeld expansion to get Fermi function.

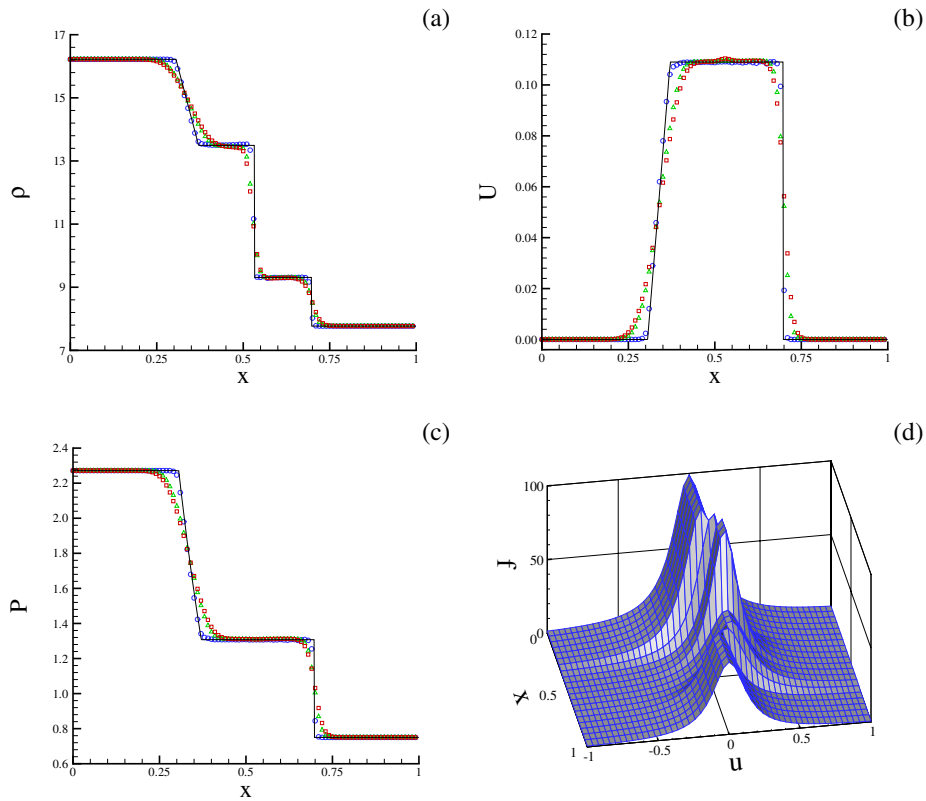

FIG. 4. *Quantum shock tube solution (Example 2).* (a) *density;* (b) *velocity;* (c) *pressure;* (d) *distribution function.*

The results are output at time $t = 0.1$ (dimensionless time), and the CFL number used is 1. The computed density, temperature, fugacity, and chemical potential profiles are depicted in Figure 7 for several grid systems. The symbol □ denotes the solution using 200 cells, the symbol △ denotes the solution using 400 cells, and the symbol ∘ denotes the solution using 800 cells. The flow structures of moving shock, contact line, and expansion fan can be identified and captured by the present first order KFVS scheme. It can be seen from the figures that, again, the grid convergence of the solutions is ensured. In Figure 8, we compare the results using the first order KFVS, BGK–KFVS, and KFVS–WENO3 schemes with 200 cells. The symbol □ denotes the solution using the KFVS scheme (CFL number is 1), the symbol △ denotes the solution using the BGK–KFVS scheme (CFL number is 1), the symbol ∘ denotes the solution using the KFVS–WENO3 scheme (CFL number is 0.2), and the solid line denotes the Riemann solution. In Figure 8(d), a plot of Fermi–Dirac distribution functions at several stations is shown. Here, 20 lines are plotted for $0 \le x \le 1$ with equal spacing $\Delta x = 0.05$, and the range of u is $-8 \le u \le 8$. The approach to the

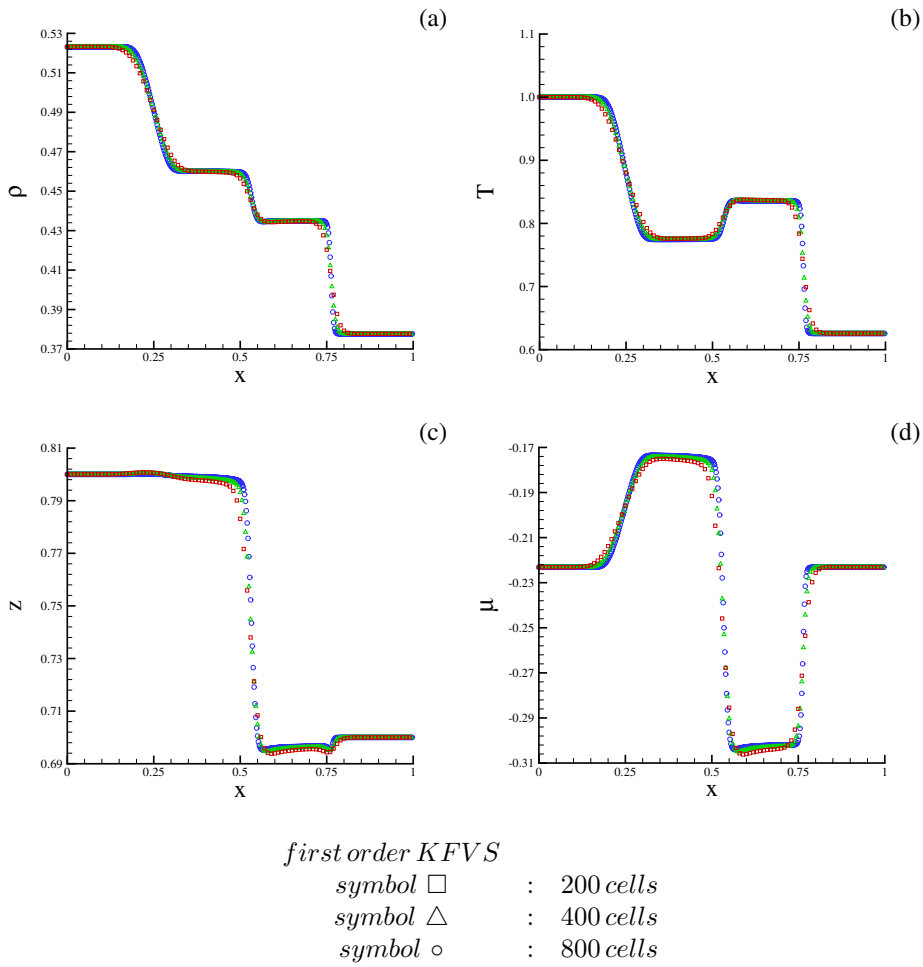

FIG. 5. *Quantum shock tube solution (Example 3).* (a) *density;* (b) *temperature;* (c) *fugacity;* (d) *chemical potential.*

typical double step function shape is well presented in this large fugacity limit.

' . ,' 5 (ideal Bose gas under an external potential). The initial condition for a Bose gas is set as $\mathbf{W} = (\rho, \rho U, \rho\epsilon) = (1.579938, 0, 0.501561)$ within $0 \le x \le L$. The corresponding fugacity and temperature in this case are $z = 0.7$ and $T = 1$. The gas is under the influence of an external potential $V(x)$. In center region $(L/4 \le x \le 3L/4)$, $V(x) = \frac{1}{2}\omega^2(x - L/2)^2$. In boundary regions $(0 \le x < L/4)$ and $(3L/4 < x \le L)$, $V(x) = \frac{1}{2}\omega^2(L/4)^2$. We use $\omega = 1$ and $L = 1$ in this example. At the domain boundaries $(x = 0)$ and $(x = L)$, we apply two different boundary conditions: one is a wall boundary condition and the other is a periodic boundary condition. The wall boundary condition assigns the ghost cells with the same density and pressure but with the velocity direction inverted at the boundary cells. The periodic boundary condition assigns the ghost cells with the same density, momentum, and energy density as the boundary cells that are one period away from the ghost cells. We use first order KFVS with 257 cells within the domain, and the CFL number is 1. The results with these two kinds of boundary conditions are plotted in Figure 9 and Figure 10, respectively.

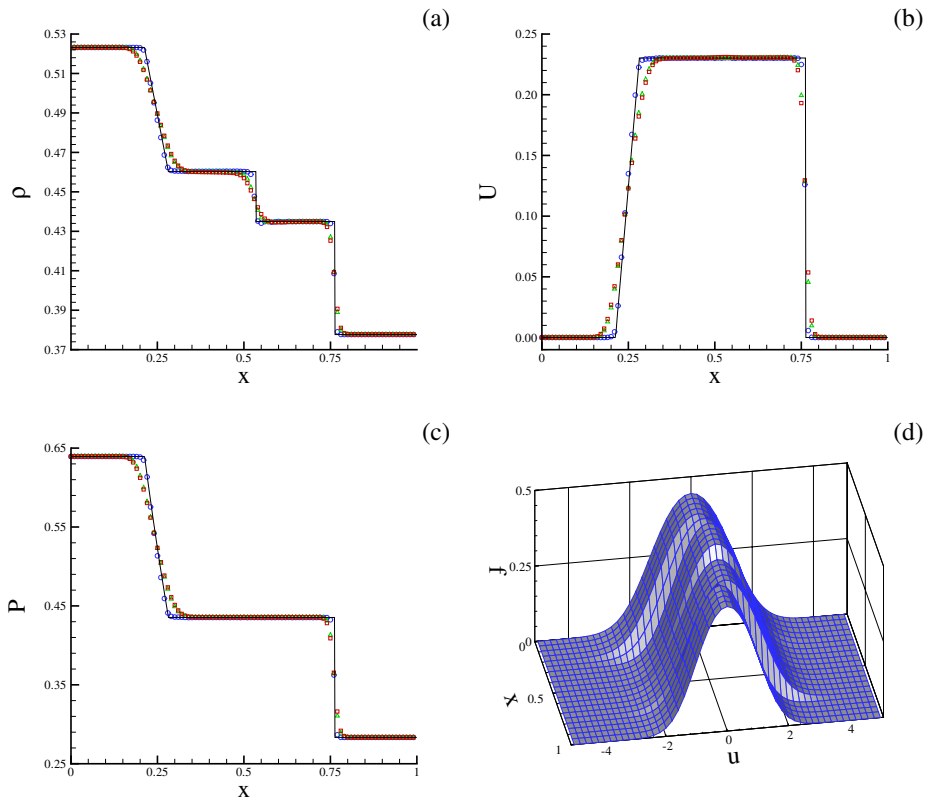

FIG. 6. *Quantum shock tube solution (Example 3).* (a) *density;* (b) *velocity;* (c) *pressure;* (d) *distribution function.*

In Figure 9, the results for the case with the wall boundary condition are exhibited for density, velocity, fugacity, and temperature at $t = 0, 400, 800, 1200$. We can assume that the Bose gas is confined in a box and influenced by a trap potential. We can observe that the density profiles are concentrated in the center region and decrease in the boundary regions (e.g., compare $t = 0$ and $t = 400$). Then, the density profiles decrease at the center region and increase at the boundary regions (t $= 400, 800, 1200$). The velocity profiles oscillate with larger amplitudes (not shown) initially due to the influence of the suddenly applied potential. Then, the velocity profiles are damped to an incline line within the center region. The fugacity rises in the center region and lowers at boundary regions; then, the profiles shift down with time. The temperature profiles rise in the center region and lower at boundary regions; then, the temperature profiles shift up with time, which implies the system is under constant energy input from the trap potential. Enlarged views are also plotted to indicate the final stages of calculations.

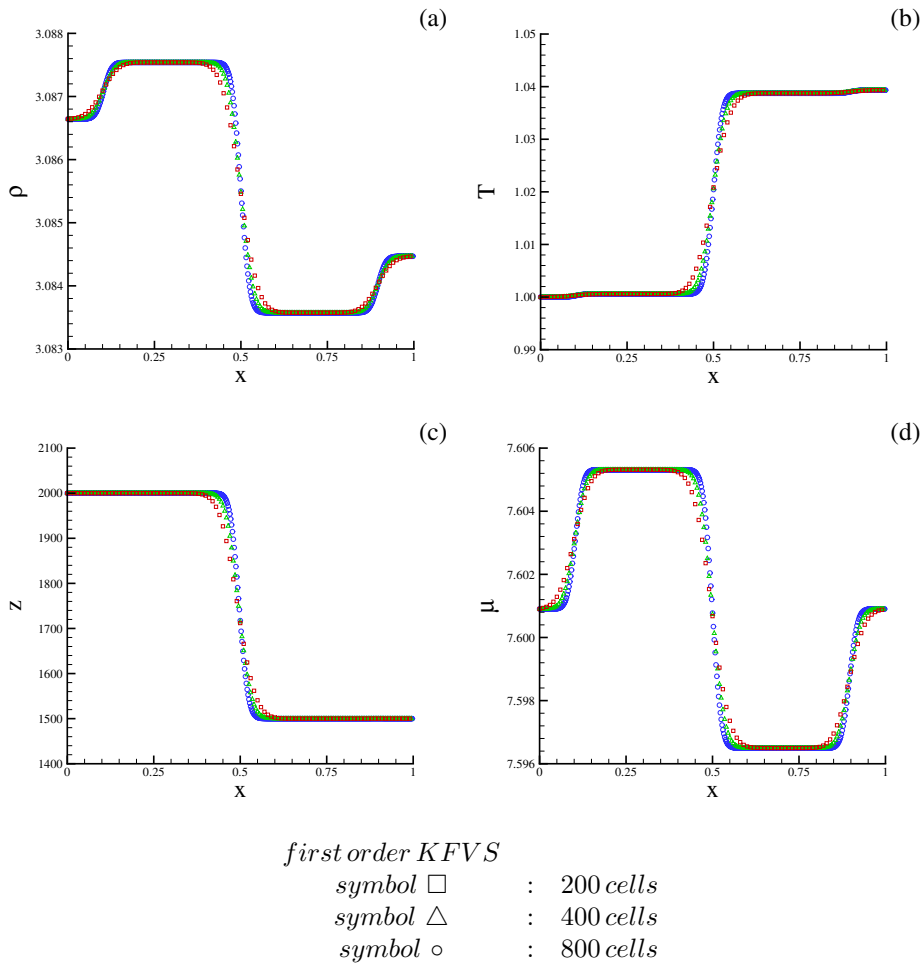

FIG. 7. *Quantum shock tube solution (Example 4).* (a) *density;* (b) *temperature;* (c) *fugacity;* (d) *chemical potential.*

In Figure 10, the results with the periodic boundary condition are exhibited. The density, velocity, fugacity, and temperature at $t = 0, 400, 800, 1200$ are plotted. We observe that the results with the periodic boundary condition are similar to those with wall boundary conditions. These imply that the velocity is always antisymmetric to the center point of the domain and other quantities are symmetric to the center point.

Although only one-dimensional schemes and results are presented here, the extension of the present numerical schemes to multiple dimensions can be done directly using Strang-type dimensional splitting (see Strang, 1968).

7. Concluding remarks. In this work, the basic first order kinetic flux vector splitting (KFVS) method for Newtonian gas dynamics developed by Patterson and by Deshpande have been successfully generalized to the ideal quantum gas dynamics based on the convectional Boltzmann equation for Bose–Einstein statistics and Fermi–Dirac statistics. To reduce the overdiffusivity of the KFVS scheme due to the inherent free transport mechanism, a modified KFVS scheme based on the BGK relaxation

solid line : *Riemann solution*

FIG. 8. *Quantum shock tube solution (Example 4).* (a) *density;* (b) *velocity;* (c) *pressure;* (d) *distribution function.*

time collision model is also considered. The KFVS and BGK–KFVS schemes are first derived for one spatial dimension and then tested and illustrated by computing shock tube flows in ideal quantum gases. The regimes in the classical limit and nearly degenerate limit are tested. Numerical experiments indicate that flow structures such as shock wave, contact line, and expansion fan can be properly captured using the present quantum KFVS schemes. To include the effect of external potential, boson gases under a harmonic trap in the one-dimensional case are also illustrated. Higher-order methods using the WENO scheme are implemented to yield a class of accurate and efficient KFVS schemes for the computation of ideal quantum gas dynamical flows. The present method applies for Bose–Einstein gases and Fermi–Dirac gases at temperatures above the critical temperature, provided that the hydrodynamic limit is applicable. Extension of the present method to multiple space dimensions is of no conceptual difficulty and is currently under investigation. The direct numerical solution of the quantum Boltzmann equation using the relaxation time approach for nanoscale energy transport will be considered elsewhere.

NUMERICAL METHODS FOR SECOND-ORDER STOCHASTIC DIFFERENTIAL EQUATIONS*

KEVIN BURRAGE†, IAN LENANE†, AND GRANT LYTHE‡

Abstract. We seek numerical methods for second-order stochastic differential equations that reproduce the stationary density accurately for all values of damping. A complete analysis is possible for scalar linear second-order equations (damped harmonic oscillators with additive noise), where the statistics are Gaussian and can be calculated exactly in the continuous-time and discrete-time cases. A matrix equation is given for the stationary variances and correlation for methods using one Gaussian random variable per timestep. The only Runge–Kutta method with a nonsingular tableau matrix that gives the exact steady state density for all values of damping is the implicit midpoint rule. Numerical experiments, comparing the implicit midpoint rule with Heun and leapfrog methods on nonlinear equations with additive or multiplicative noise, produce behavior similar to the linear case.

Key words. damped harmonic oscillators with noise, stationary distribution, stochastic Runge–Kutta methods, implicit midpoint rule, multiplicative noise

1. Introduction. Newton's second law of motion relates force to acceleration. Consequently, second-order differential equations are common in scientific applications, in the guise of "Langevin," "Monte Carlo," "molecular," or "dissipative particle" dynamics [1, 2, 3], and the study of methods for second-order ordinary differential equations is one of the most mature branches of numerical analysis [4]. The most exciting advances in recent decades have been the development of symplectic methods, capable of exactly preserving an energy-like quantity over very long times [5], and their extension to stochastic systems [6]. In the stochastic setting, the long-time dynamics of a typical physical system is governed by fluctuation-dissipation, so that the amount of time spent in different regions of phase space can be calculated from the stationary density [7]. This density can have a relatively simple explicit expression even when the dynamics is highly nonlinear [8]. Numerical methods replace continuous-time with discrete-time dynamics, generating values at times $t_0, t_1, \ldots$. Usually $t_{n+1} - t_n$ is a fixed number Δt. The criterion for a good numerical method that will be examined in this work is that its discrete-time dynamics has a stationary density as close as possible to that of the continuous-time system.

The differential equations describing second-order systems contain a parameter known as damping. The stationary density is independent of damping, but dynamical quantities, and the usefulness of numerical algorithms, are strongly dependent on it. In the infinite-damping limit, the system becomes first order. The limit of zero damping, on the other hand, corresponds to Hamiltonian systems, where symplectic methods can be applied. The aim in this paper is to devise methods capable of accurately reproducing the stationary density

We shall consider equations of the following form:

$$\ddot{x} = f(x) - \eta s^2(x)\dot{x} + \epsilon s(x)\xi(t), \tag{1.1}$$

where $\langle \xi(t)\xi(t') \rangle = \delta(t - t')$ and the damping parameter is denoted η. Angled brackets denote mean over realizations. The second-order stochastic differential equation (SDE) (1.1) describes the position of a particle subject to deterministic forcing $f(x)$ and random forcing $\xi(t)$. The deterministic forcing is related to the potential function $V(x)$ via $f(x) = -V'(x)$. The amplitude of the random forcing, ϵ, is related to the temperature T and damping coefficient η by the fluctuation-dissipation relation [8] $\epsilon^2 = 2\eta KT$.

We can write (1.1) as a pair of first-order equations for $\mathbf{X}_t$ and $\mathbf{V}_t$, the position and velocity variables:

$$\begin{aligned} \mathrm{d}\mathbf{X}_t &= \mathbf{V}_t \mathrm{d}t, \\ \mathrm{d}\mathbf{V}_t &= -\eta s^2(\mathbf{X}_t)\mathbf{V}_t \mathrm{d}t + f(\mathbf{X}_t)\mathrm{d}t + \epsilon s(\mathbf{X}_t)\mathrm{d}\mathbf{W}_t, \end{aligned} \tag{1.2}$$

where $\mathbf{W}_t$ is a Wiener process satisfying $\langle \mathbf{W}_t \mathbf{W}_s \rangle = \min(t, s)$. If $s(x)$ is not a constant, the noise amplitude is a function of position and the equation is commonly said to have "multiplicative noise." However, because the coefficient of $\mathrm{d}\mathbf{W}_t$ in the SDE for $\mathbf{V}_t$ is a function of $\mathbf{X}_t$ only, there is no difference between the Ito and Stratonovich (see Gardiner [8]) forms of (1.2). The probability density at time t is $P(x, v; t)$, where

$$P(x, v; t) = \frac{\mathrm{d}}{\mathrm{d}x}\frac{\mathrm{d}}{\mathrm{d}v}\mathrm{Prob}\left(\mathbf{X}_t < x, \mathbf{V}_t < v\right). \tag{1.3}$$

The stationary density, $P_\infty(x, v)$, defined as

$$P_\infty(x, v) = \lim_{t\to\infty} P(x, v; t), \tag{1.4}$$

has the following analytical form, independent of η and $s(x)$ as long as $\eta > 0$ and suitable conditions on $V(x)$ are satisfied [8]:

$$P_\infty(x, v) = N \exp\left(-v^2/2KT - V(x)/KT\right). \tag{1.5}$$

Thus the late-time statistics of the velocity are Gaussian and uncorrelated with the position. It is notable that the stationary density has a closed tractable form for many nonlinear functions $f(x)$ when analytical study of the full evolution is not possible.

In this paper we examine how faithfully the stationary density is reproduced by standard timestepping methods for SDEs. These methods produce approximate values for position X_n and velocity V_n at discrete times $t_0, t_1, \ldots$, where $t_{n+1} - t_n = \Delta t$. We consider the evolution of X_n and V_n, and their statistical properties as $t_n \to \infty$, and compare it with the exact form (1.4). In particular, we consider $P^*(y, u; t_n)$, the discrete-time analogue of (1.3), and compare the limit

$$P^*_\infty(y, u) = \lim_{t_n\to\infty} P^*(y, u; t_n),$$

where it exists, with $P_\infty(y, u)$. In this work we base our analysis on linear second-order equations, where the statistics are Gaussian and completely characterized by

three quantities: the mean squares of the position and velocity variables, and the correlation between the position and velocity.

The Euler and Heun methods simply treat (1.2) as a pair of SDEs, without attempting to take advantage of their special structure due to their origin in a single second-order differential equation. We shall show that they perform reasonably well at intermediate values of damping but fail at high damping, when the equations are stiff, and low damping, when it is important to conserve energy-like quantities over long times.

The Verlet algorithm [1, 9, 10] produces numerical solutions of second-order differential equations by updating the position variable without reference to the velocity variable. Extensions of this idea to Langevin equations [10, 11, 12, 13] have proved successful, and convergence properties may be analyzed using second-order difference equations [12, 14, 15]. The implicit midpoint rule cannot be written as a difference equation but can be written as a matrix equation [15]. Schurz [16, 17] studied multidimensional Ornstein–Uhlenbeck processes and showed that the implicit midpoint rule possesses the correct stationary distribution. Time-dependent properties of numerical algorithms for the class of linear equations considered in this paper can be considered by means of a modified frequency [15] or by the method of modified equations [18].

Recent analysis by Mannella [19, 20] of the stationary distribution resulting from numerical timestepping methods, based on an expansion of the exponent in (1.5), has led to a proposed modification of the leapfrog method. We shall take this method as one of our examples and find that it provides a notable improvement on the standard leapfrog method.

A slightly different system has been studied by Strømmen Melbø and Higham [21]. They considered a second-order system, but without a damping term. Rather than approaching a stationary density, the sum of the mean squared velocity and position grows proportional to time. Partitioned methods are superior to the Euler method for this system.

In section 2, we consider the case $f(x) = -gx$, where $g > 0$ is a constant, and $s(x) = 1$. That is, we consider linear second-order equations describing harmonic oscillators with additive white noise and damping. The statistics for linear systems are Gaussian, described by a covariance matrix, and can be calculated exactly in the continuous-time and discrete-time cases. A matrix equation is derived for the stationary variances and correlations resulting from a large class of numerical methods. We then calculate the stationary variances produced by some well-known methods. All methods we shall consider use one realization per timestep of a Gaussian distribution with mean zero and variance Δt. This framework includes many methods with multiple intermediate steps and implicit methods (which are in fact explicit for linear equations).

In section 3 we seek "measure-exact" methods for linear second-order SDEs, that is, methods that give the correct late-time mean square of the position and velocity and absence of correlation between them. In section 4, we restrict our consideration to Runge–Kutta methods for systems of additive noise SDEs and show that the unique measure-exact method is the implicit midpoint rule. In section 5 we report on numerical experiments carried out with $f(x) = x - x^3$ and $s(x) = 1$; in section 6 we report on numerical experiments carried out with $f(x) = x - x^3$ and $s(x) = x$. In both cases, of additive and of multiplicative noise in the double-well system, the implicit midpoint rule is the most satisfactory, with no error in two of the three quantities of

interest over the full range of values of damping. However, leapfrog methods have the benefit of being fully explicit.

2. Linear equation and matrix notation. If $f(x) = -gx$, then the stationary density (1.4) is

$$P_\infty(x,v) = N \exp\left(-g\,x^2/2KT - v^2/2KT\right).$$

The distributions of the position and velocity variables are Gaussian with

$$\lim_{t\to\infty} \left\langle \mathbf{X}_t{}^2 \right\rangle = \frac{1}{g} KT\ , \qquad \lim_{t\to\infty} \left\langle \mathbf{V}_t^2 \right\rangle = KT, \qquad \text{and} \qquad \lim_{t\to\infty} \left\langle \mathbf{X}_t \mathbf{V}_t \right\rangle = 0. \tag{2.1}$$

If $f(x) = -gx$ and $s(x) = 1$, then the linear second-order SDE can be written in matrix notation as

$$\mathrm{d}\begin{pmatrix} \mathbf{X}_t \\ \mathbf{V}_t \end{pmatrix} = Q \begin{pmatrix} \mathbf{X}_t \\ \mathbf{V}_t \end{pmatrix} \mathrm{d}t + \epsilon \begin{pmatrix} 0 \\ 1 \end{pmatrix} \mathrm{d}\mathbf{W}_t, \tag{2.2}$$

where

$$Q = \begin{pmatrix} 0 & 1 \\ -g & -\eta \end{pmatrix}. \tag{2.3}$$

We consider numerical updates for the linear system (2.2) that can be summarized as

$$\begin{pmatrix} X_{n+1} \\ V_{n+1} \end{pmatrix} = R \begin{pmatrix} X_n \\ V_n \end{pmatrix} + \epsilon r \Delta W_n, \tag{2.4}$$

where

$$R = \begin{pmatrix} r_{11} & r_{12} \\ r_{21} & r_{22} \end{pmatrix}, \qquad r = \begin{pmatrix} r_1 \\ r_2 \end{pmatrix}$$

and ΔW_n is sampled from a Gaussian distribution with mean zero and variance Δt, independently of ΔW_m for $n \neq m$. Since the numerical update (2.4) is a linear transformation, $P^*_\infty(x,v)$ is Gaussian. Let the correlation matrix be

$$\Sigma = \begin{pmatrix} \sigma_x^2 & \mu \\ \mu & \sigma_v^2 \end{pmatrix}, \tag{2.5}$$

where

$$\sigma_x^2 = \lim_{t_n\to\infty} \left\langle X_n^2 \right\rangle\ , \qquad \sigma_v^2 = \lim_{t_n\to\infty} \left\langle V_n^2 \right\rangle, \qquad \text{and} \qquad \mu = \lim_{t_n\to\infty} \left\langle X_n V_n \right\rangle.$$

Then

$$P^*_\infty(x,v) = \frac{1}{2\pi} |\Sigma^{-1}|^{\frac{1}{2}} \exp\left(-\frac{1}{2}(x,v)\Sigma^{-1} \begin{pmatrix} x \\ v \end{pmatrix} \right).$$

The stationary density $P^*_\infty(x,v)$ has the property of invariance under the transformation (2.4). Now, if $\binom{X_n}{V_n}$ is Gaussian with mean zero and correlation matrix Σ, then $R\binom{X_n}{V_n}$ is Gaussian with mean zero and correlation matrix $R\Sigma R^{\mathrm{T}}$. Thus the correlation

matrix that results from a method of the form (2.4) satisfies $\Sigma = R\Sigma R^{\mathrm{T}} + \epsilon^2 r r^{\mathrm{T}} \Delta t$, or

$$R\Sigma R^{\mathrm{T}} = \Sigma - \epsilon^2 r r^{\mathrm{T}} \Delta t. \tag{2.6}$$

In the remainder of this section, we shall use (2.6) to calculate the σ_x^2, μ, and σ_v^2 as a function of η and Δt under six numerical methods for the case $s(x) = 1$. We can rewrite (2.6) in a form suitable for inversion:

$$\begin{pmatrix} r_{11}^2 - 1 & 2r_{11}r_{12} & r_{12}^2 \\ r_{11}r_{21} & r_{11}r_{22} + r_{12}r_{21} - 1 & r_{12}r_{22} \\ r_{21}^2 & 2r_{21}r_{22} & r_{22}^2 - 1 \end{pmatrix} \begin{pmatrix} \sigma_x^2 \\ \mu \\ \sigma_v^2 \end{pmatrix} = -\epsilon^2 \Delta t \begin{pmatrix} r_1^2 \\ r_1 r_2 \\ r_2^2 \end{pmatrix}.$$

The stability boundaries of the methods are functions of the parameters $\eta\Delta t$ and $g\Delta t^2$. Of the methods discussed below, the implicit midpoint rule and the leapfrog methods have the virtue of reducing to a symplectic method if $\eta = 0$ [5]. Further explicit methods with this property have been devised [6].

2.1. Forward Euler method. Under the Euler method, the position and velocity variables are updated as follows:

$$X_{n+1} = X_n + V_n \, \Delta t,$$

$$V_{n+1} = V_n - \eta V_n \Delta t + f(X_n) \, \Delta t + \epsilon \Delta W_n.$$

With the notation of (2.4), $R = R_{\mathrm{E}}$ and $r = r_{\mathrm{E}}$, where

$$R_{\mathrm{E}} = 1 + \Delta t Q = \begin{pmatrix} 1 & \Delta t \\ -g\Delta t & 1 - \eta \Delta t \end{pmatrix}, \tag{2.7}$$

$r_{\mathrm{E}} = \binom{0}{1}$ and the solution of (2.6) yields

$$\Sigma_{\mathrm{E}} = \frac{KT}{1 - \frac{g}{\eta}\Delta t} \left(2 - \eta \Delta t + \frac{1}{2} g \Delta t^2 \right)^{-1} \begin{pmatrix} g^{-1}(2 - \eta\Delta t + g\Delta t^2) & -\Delta t \\ -\Delta t & 2 \end{pmatrix}. \tag{2.8}$$

In Figure 1 we display the differences between the stationary variances, obtained by applying the Euler method to the linear equation, and the exact values (2.1). The forward Euler method works best at intermediate values of η. It is unstable if $\eta\Delta t < g\Delta t^2$ or $\eta\Delta t > 2 + \frac{1}{2} g \Delta t^2$. In Figure 2, we plot the correlation between velocity and position, which is zero in the exact solution but is proportional to Δt under the Euler method.

2.2. The Heun method. Under the Heun method, intermediate values are obtained via the Euler method:

$$\hat{X} = X_n + V_n \, \Delta t,$$

$$\hat{V} = V_n - \eta V_n \Delta t + f(X_n) \, \Delta t + \epsilon \, \Delta W_n.$$

The update is

$$X_{n+1} = X_n + \frac{1}{2}(V_n + \hat{V}) \, \Delta t,$$

$$V_{n+1} = V_n - \frac{1}{2}\eta(V_n + \hat{V})\Delta t + \frac{1}{2}(f(X_n) + f(\hat{X})) \, \Delta t + \epsilon \, \Delta W_n.$$

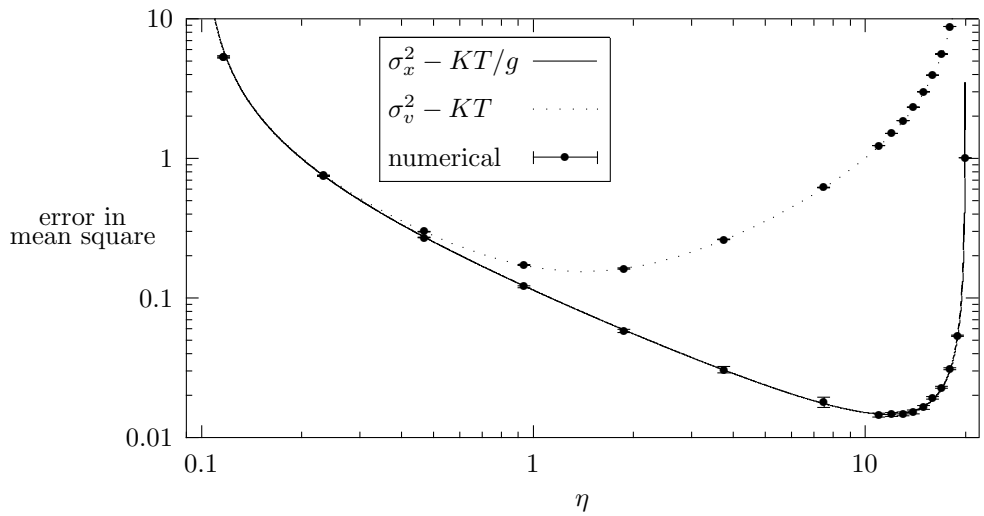

FIG. 1. *Mean squares versus damping for the forward Euler method. The differences between the late-time mean squares and the exact values are plotted against* η *for fixed* $\Delta t = 0.1$, $g = 1$, *and* $KT = 1.0$. *The lines use* (2.8). *Dots with error bars are obtained from the numerical solution of the linear SDE.*

With the notation of (2.4), $R = R_{\mathrm{H}}$ and $r = r_{\mathrm{H}}$, where

$$R_{\mathrm{H}} = I + \Delta t Q + \frac{1}{2}\Delta t^2 Q^2 = \begin{pmatrix} 1 - \frac{1}{2}g\Delta t^2 & \Delta t - \frac{1}{2}\eta\Delta t^2 \\ -g\Delta t + \frac{1}{2}\eta g\Delta t^2 & 1 - \eta\Delta t + \frac{1}{2}(-g+\eta^2)\Delta t^2 \end{pmatrix}$$

and

$$r_{\mathrm{H}} = \begin{pmatrix} \frac{1}{2}\Delta t \\ 1 - \frac{1}{2}\eta\Delta t \end{pmatrix}.$$

Let $k_1 = \eta\Delta t$ and $k_2 = g\Delta t^2$. Then, for the stochastic Heun method,

(2.9)

$$\sigma_x^2 = \frac{KT}{g}\frac{1 - \frac{1}{4}k_1 + \frac{1}{8}k_1^2 - \frac{1}{32}(k_1k_2 + k_1^3) + \frac{3}{64}k_1^2k_2 - \frac{1}{32}k_1k_2^2 + \frac{1}{128}k_2^3}{\left(1 - \frac{1}{2}k_1 + \frac{1}{4}(k_1^2 - k_2) - \frac{1}{8}k_1k_2^2 + \frac{1}{16}k_2^2\right)\left(1 - \frac{1}{2}k_1 + \frac{1}{2}k_2 - \frac{1}{4}k_2^2/k_1\right)},$$

$$\sigma_v^2 = KT\frac{(1 - \frac{1}{2}k_2)^2}{\left(1 - \frac{1}{2}k_1 + \frac{1}{4}(k_1^2 - k_2) - \frac{1}{8}k_1k_2^2 + \frac{1}{16}k_2^2\right)\left(1 - \frac{1}{2}k_1 + \frac{1}{2}k_2 - \frac{1}{4}k_2^2/k_1\right)},$$

$$\mu = KT\Delta t\left(k_1 - \frac{1}{2}k_2\right)\frac{1 - \frac{1}{2}k_1}{\left(1 - \frac{1}{2}k_1 + \frac{1}{4}(k_1^2 - k_2) - \frac{1}{8}k_1k_2^2 + \frac{1}{16}k_2^2\right)\left(1 - \frac{1}{2}k_1 + \frac{1}{2}k_2 - \frac{1}{4}k_2^2/k_1\right)}.$$

Compared with the Euler method, the upper limit on η for stability is little changed. The lower limit is, however, proportional to Δt^3. As $\Delta t \to 0$, the Heun method is stable if $(\frac{1}{2}g\Delta t^2)^2 < \eta\Delta t < 2$, and the correlation between position and velocity is proportional to Δt^2. See Figure 3.

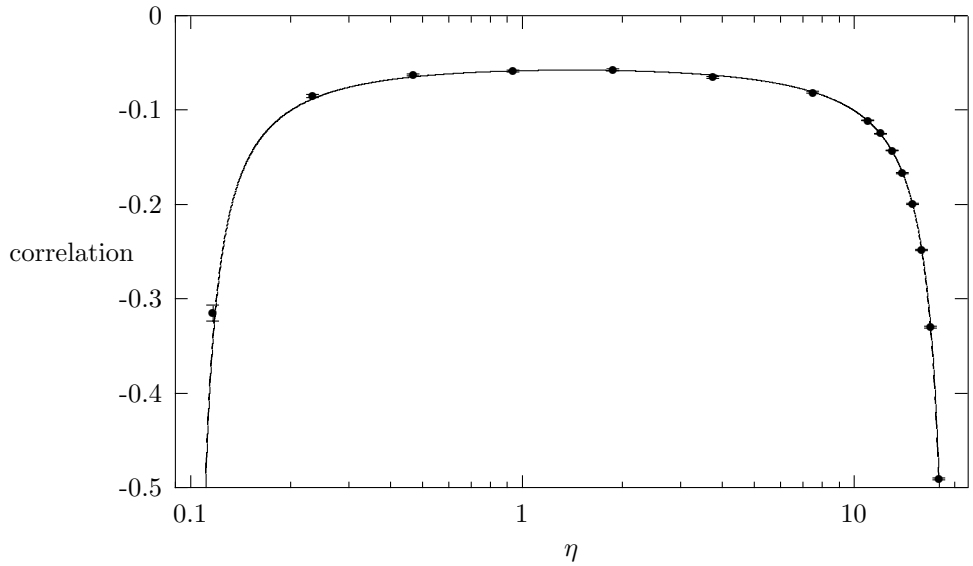

FIG. 2. *Position-velocity correlation versus damping for the forward Euler method. The late-time correlation, μ, obtained using the forward Euler method, is plotted against η for fixed $\Delta t = 0.1$, $g = 1$, and $KT = 1.0$. The line uses* (2.8). *Dots with error bars are obtained from the numerical solution of the linear SDE.*

2.3. The leapfrog method. Under leapfrog methods, velocity and position are updated successively rather than together. The simplest possible method is

$$\hat{X} = X_n + \frac{1}{2} V_n \Delta t,$$

$$V_{n+1} = V_n - \eta V_n \Delta t + f(\hat{X})\,\Delta t + \epsilon\,\Delta W_n,$$

$$X_{n+1} = \hat{X} + \frac{1}{2} V_{n+1} \Delta t. \tag{2.10}$$

Under this method, with the notation of (2.4), $R = R_{\mathrm{le}}$ and $r = r_{\mathrm{le}}$, where

$$R_{\mathrm{le}} = \begin{pmatrix} 1 - \frac{1}{2} g \Delta t^2 & \Delta t - \frac{1}{2}\eta \Delta t^2 - \frac{1}{4} g \Delta t^3 \\ -g\Delta t & 1 - \eta \Delta t - \frac{1}{2} g \Delta t^2 \end{pmatrix}$$

and

$$r_{\mathrm{le}} = \begin{pmatrix} \frac{1}{2}\Delta t \\ 1 \end{pmatrix}.$$

The leapfrog method maintains the independence of position and velocity and produces the exact stationary variance of the position variable. However, the error in σ_v^2 is an increasing function of η:

$$\Sigma_{\mathrm{le}} = KT \begin{pmatrix} g^{-1} & 0 \\ 0 & (1 - \frac{1}{2}\eta \Delta t - \frac{1}{4} g \Delta t^2)^{-1} \end{pmatrix}. \tag{2.11}$$

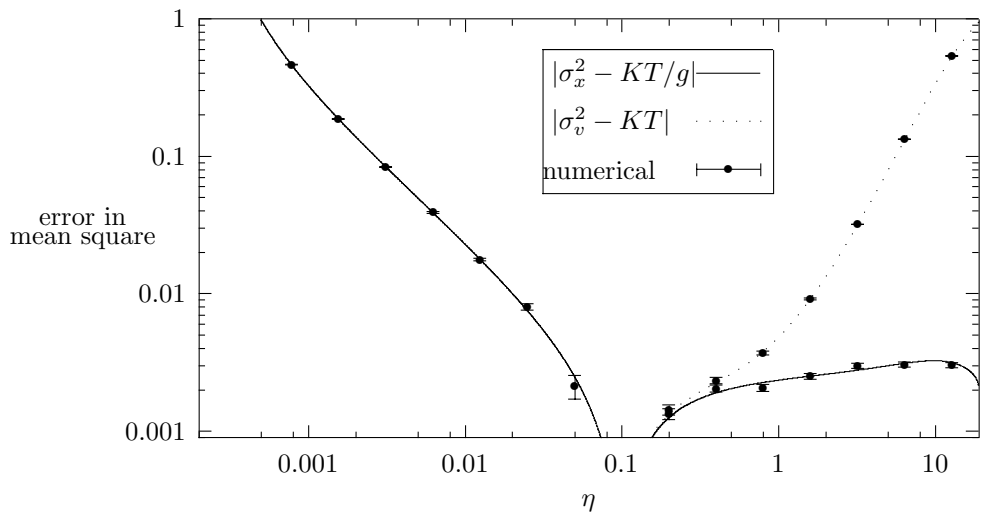

FIG. 3. *Mean squares versus damping for the Heun method. The differences between the late-time mean squares and the exact values are plotted against* η *for fixed* $\Delta t = 0.1$, $g = 1$, *and* $KT = 1.0$. *The lines use* (2.9). *Dots with error bars are obtained from the numerical solution of the linear SDE.*

Mannella [19, 20] has proposed the following modification of the leapfrog method:

$$\hat{X} = X_n + \frac{1}{2}V_n\Delta t,$$

$$V_{n+1} = c_2\left(c_1V_n + f(\hat{X})\,\Delta t + \epsilon\,\Delta W_n\right),$$

$$X_{n+1} = \hat{X} + \frac{1}{2}V_{n+1}\Delta t,$$

where $c_1 = 1 - \frac{1}{2}\eta\Delta t$ and $c_2 = (1 + \frac{1}{2}\eta\Delta t)^{-1}$. The corresponding quantities are

$$R_{\mathrm{M}} = \begin{pmatrix} 1 - c_2\frac{1}{2}g\Delta t^2 & \frac{1}{2}\Delta t\left(1 + c_1c_2 - \frac{1}{2}c_2\Delta t^2\right) \\ -c_2g\Delta t & c_1c_2 - \frac{1}{2}c_2g\Delta t^2 \end{pmatrix},$$

$$r_{\mathrm{M}} = c_2\begin{pmatrix} \frac{1}{2}\Delta t \\ 1 \end{pmatrix},$$

and

$$\Sigma_{\mathrm{M}} = KT\begin{pmatrix} g^{-1} & 0 \\ 0 & (1 - \frac{1}{4}g\Delta t^2)^{-1} \end{pmatrix}. \tag{2.12}$$

The only error, in σ_v^2, is independent of η.

2.4. The BBK method. Under the Brünger–Brooks–Karplus (BBK) method [11], the position variable is updated without reference to the velocity variable. The

two most recent values of the position variable need to be retained, and the update is

$$X_{n+1} = X_n + \frac{1-\frac{1}{2}\eta\Delta t}{1+\frac{1}{2}\eta\Delta t}(X_n - X_{n-1}) + \frac{\Delta t}{1+\frac{1}{2}\eta\Delta t}\left(f(X_n) + \epsilon\,\Delta W_n\right).$$

With the definition of velocity $V_n\Delta t = X_n - X_{n-1}$, proposed in [12], the BBK method can be written in the form (2.4) with [22]

$$R_{\mathrm{B}} = \begin{pmatrix} 1-\frac{g\Delta t^2}{1+\frac{1}{2}\eta\Delta t} & \frac{1-\frac{1}{2}\eta\Delta t}{1+\frac{1}{2}\eta\Delta t}\Delta t \\ -\frac{g\Delta t}{1+\frac{1}{2}\eta\Delta t} & \frac{1-\frac{1}{2}\eta\Delta t}{1+\frac{1}{2}\eta\Delta t} \end{pmatrix}$$

and

$$r_{\mathrm{B}} = \frac{1}{1+\frac{1}{2}\eta\Delta t}\begin{pmatrix}\Delta t \\ 1\end{pmatrix}.$$

Whatever the definition of velocity, we find [12, 15, 18]

$$\sigma_x^2 = \frac{KT}{g}\frac{1}{1-\frac{1}{4}g\Delta t^2}. \tag{2.13}$$

However, σ_v^2 and μ do depend on the definition of velocity. Note that, with the velocity definition $2V_n\Delta t = X_{n+1} - X_{n-1}$, the BBK update cannot be put into the form (2.4).

2.5. The implicit midpoint method. Under the implicit midpoint method, intermediate values are obtained via the implicit procedure

$$\hat{X} = X_n + \frac{1}{2}\hat{V}\,\Delta t,$$

$$\hat{V} = V_n - \frac{1}{2}\eta\hat{V}\Delta t + \frac{1}{2}f(\hat{X})\,\Delta t + \frac{1}{2}\epsilon\,\Delta W_n.$$

The update is

$$X_{n+1} = X_n + \hat{V}\,\Delta t,$$

$$V_{n+1} = V_n - \eta\hat{V}\Delta t + f(\hat{X})\,\Delta t + \epsilon\,\Delta W_n.$$

With the notation of (2.4), $R = R_{\mathrm{im}}$ and $r = r_{\mathrm{I}}$, where

$$R_{\mathrm{im}} = \left(I - \frac{1}{2}\Delta t Q\right)^{-1}\left(I + \frac{1}{2}\Delta t Q\right) = \begin{pmatrix} 1-\frac{1}{2}\kappa^{-1}g\Delta t^2 & \kappa^{-1}\Delta t \\ -\kappa^{-1}g\Delta t & 2\kappa^{-1}-1 \end{pmatrix},$$

and

$$r_{\mathrm{im}} = \kappa^{-1}\begin{pmatrix}\frac{1}{2}\Delta t \\ 1\end{pmatrix},$$

where $\kappa = 1 + \frac{1}{2}\eta\Delta t + \frac{1}{4}g\Delta t^2$. Thus

$$\Sigma_{\mathrm{im}} = KT\begin{pmatrix} g^{-1} & 0 \\ 0 & 1\end{pmatrix}. \tag{2.14}$$

Since R_{im} and r_{im} satisfy (2.6), the implicit midpoint method gives the exact stationary variances for all values of η. Only an algebraic error in Appendix A of [15] prevented this observation from being made by Mishra and Schlick. The behavior of the implicit midpoint method is explored further in section 4.

3. Measure-exact algorithms. We shall call a method "measure-exact" if its correlation matrix is the exact one for (2.2):

$$\Sigma_{\mathrm{e}} = KT \begin{pmatrix} g^{-1} & 0 \\ 0 & 1 \end{pmatrix}. \tag{3.1}$$

The R and r matrices for a measure-exact method satisfy (2.6) with $\Sigma = \Sigma_e$, that is,

$$R \begin{pmatrix} g^{-1} & 0 \\ 0 & 1 \end{pmatrix} R^{\mathrm{T}} = \begin{pmatrix} g^{-1} & 0 \\ 0 & 1 \end{pmatrix} - 2\eta r r^{\mathrm{T}} \Delta t. \tag{3.2}$$

We shall assume Σ is positive definite and let Δt be chosen small enough to ensure $G = \Sigma - \epsilon^2 r r^{\mathrm{T}} \Delta t$ is also positive definite. Matrices $\Sigma^{\frac{1}{2}}$ and $G^{\frac{1}{2}}$ can be constructed to satisfy $G = G^{\frac{1}{2}}(G^{\frac{1}{2}})^{\mathrm{T}}$ and $\Sigma = \Sigma^{\frac{1}{2}}(\Sigma^{\frac{1}{2}})^{\mathrm{T}}$. Let $\Sigma^{-\frac{1}{2}}$ and $G^{-\frac{1}{2}}$ be the inverses of $\Sigma^{\frac{1}{2}}$ and $G^{\frac{1}{2}}$. Condition (2.6) can then be rewritten as $PP^{\mathrm{T}} = I$, where $P = G^{-\frac{1}{2}} R \Sigma^{\frac{1}{2}}$ and I is the identity matrix. Any 2×2 orthogonal matrix P generates a solution of (3.2) as

$$R = G^{\frac{1}{2}} P \Sigma^{-\frac{1}{2}}. \tag{3.3}$$

A real 2×2 orthogonal matrix can be written as

$$P = \begin{pmatrix} (1-a^2)^{1/2} & a \\ -a & (1-a^2)^{1/2} \end{pmatrix},$$

for some $|a| \leq 1$. This form is convenient because we can take $a \propto \Delta t$, so that P reduces to the identity matrix when $a = 0$.

With Σ given by (3.1), we can choose

$$\Sigma^{\frac{1}{2}} = (KT)^{1/2} \begin{pmatrix} g^{-1/2} & 0 \\ 0 & 1 \end{pmatrix}.$$

So

$$G = \Sigma - r r^{\mathrm{T}} \Delta t = \begin{pmatrix} KT/g - r_1^2 \Delta t & -r_1 r_2 \Delta t \\ -r_1 r_2 \Delta t & KT - r_2^2 \Delta t \end{pmatrix},$$

and

$$G^{\frac{1}{2}} = \begin{pmatrix} \left(KT/g - r_1^2 \Delta t\right)^{\frac{1}{2}} & 0 \\ \frac{-r_1 r_2 \Delta t}{\left(KT/g - r_1^2 \Delta t\right)^{\frac{1}{2}}} & \left(KT - r_2^2 \Delta t + \frac{(r_1 r_2 \Delta t)^2}{KT/g - r_1^2 \Delta t}\right)^{\frac{1}{2}} \end{pmatrix}.$$

Any measure-exact method, using one Gaussian random variable per timestep, can be obtained from (3.3) with some choice of a, r_1, and r_2. For example, we may obtain a measure-exact Euler-like method by choosing $r = \binom{0}{1}$. That is,

$$G^{1/2} = (KT)^{1/2} \begin{pmatrix} g^{-1/2} & 0 \\ 0 & (1 - 2\eta \Delta t)^{1/2} \end{pmatrix}$$

and

$$R = G^{1/2} P \Sigma^{-1/2} = \begin{pmatrix} (1-a^2)^{1/2} & a g^{-1/2} \\ -a g^{1/2} (1 - 2\eta \Delta t)^{1/2} & (1-a^2)^{1/2} (1 - 2\eta \Delta t)^{1/2} \end{pmatrix}.$$

The Euler method is obtained as $\Delta t \to 0$ if $a = g^{1/2}\Delta t$. Thus

$$R = \begin{pmatrix} (1 - g\Delta t^2)^{1/2} & \Delta t \\ -g\Delta t(1 - 2\eta\Delta t)^{1/2} & (1 - g\Delta t^2)^{1/2}(1 - 2\eta\Delta t)^{1/2} \end{pmatrix}. \tag{3.4}$$

Notice that the difference between (3.4) and (2.7) is proportional to Δt^2. This modified Euler method reproduces the [illegible] as long as $2\eta\Delta t < 1$. As a next step, we may impose agreement of R with $\exp(\Delta t Q)$ to order Δt^2:

$$R = I + \Delta t Q + \frac{1}{2}\Delta t^2 Q^2 + \cdots .$$

Then $a = g^{\frac{1}{2}}\Delta t - \frac{1}{2}g^{\frac{1}{2}}\eta\Delta t^2$, $r_1 = \frac{1}{2}\Delta t + \cdots$, and $r_2 = 1 - \eta\frac{1}{2}\Delta t + \cdots$. Methods constructed in this way will have a stationary density differing from the exact density by some power of Δt.

Having established that measure-exact numerical methods do exist, in the next section we return to the question of solving condition (3.2) exactly, this time in the context of Runge–Kutta methods.

4. Runge–Kutta methods for additive noise. From the point of view of general Runge–Kutta methods, the system of two SDEs (1.2) with $s(x) = 1$ is a special case of the m-dimensional additive noise SDE that can be written [23]

$$\mathrm{d}\mathbf{Y}_t = f(\mathbf{Y}_t)\mathrm{d}t + \epsilon H \mathrm{d}\mathbf{B}_t,$$

where $\mathbf{Y}_t$ and $\mathbf{B}_t$ are $m \times 1$ column vectors, the entries of $\mathbf{B}_t$ are independent Wiener processes, and H is an $m \times m$ matrix with constant entries. Let the numerically generated approximations be denoted by column vectors y_n. Under an s-stage Runge–Kutta method, y_{n+1} is obtained from y_n as a weighted sum of s evaluations of the function f at intermediate values Y_i:

$$y_{n+1} = y_n + \sum_{j=1}^{s} b_j f(Y_j)\Delta t + \epsilon H \Delta B_n,$$

where $\sum_j b_j = 1$. The m entries of ΔB_n are drawn independently from a Gaussian distribution with mean zero and variance Δt. The column vectors of intermediate values satisfy

$$Y_i = y_n + \sum_{j=1}^{s} a_{ij} f(Y_j)\Delta t + \epsilon c_i H \Delta B_n. \tag{4.1}$$

Runge–Kutta methods for the case $s(x) \neq 1$ also exist [23].

We apply this general formalism to the linear equation (2.2) with $m = 2$. We have

$$y_n = \begin{pmatrix} X_n \\ V_v \end{pmatrix}, \ f(y) = Qy, \text{ and } H = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

Let $Y = (Y_1, Y_2, \ldots, Y_s)^{\mathrm{T}}$, $c = (c_1, c_2, \ldots, c_s)^{\mathrm{T}}$, $e = (1, 1, \ldots, 1)^{\mathrm{T}}$ and A be the $s \times s$ matrix whose entries are the a_{ij} in (4.1). Then (4.1) can be written

$$Y_i = e \otimes y_n + A \otimes Q Y_i \Delta t + \epsilon c \otimes \begin{pmatrix} 0 \\ 1 \end{pmatrix} \Delta W_n.$$

If $b = (b_1, b_2, \ldots, b_s)^{\mathrm{T}}$, we can write

$$\begin{aligned} y_{n+1} &= y_n + b^{\mathrm{T}} Y \otimes Q\Delta t + \epsilon \begin{pmatrix} 0 \\ 1 \end{pmatrix} \Delta W_n \\ &= y_n + b^{\mathrm{T}} \otimes Q\Delta t \left(I_s \otimes I_m - A \otimes Q\Delta t\right)^{-1} \left(e \otimes y_n + \epsilon c \otimes \begin{pmatrix} 0 \\ 1 \end{pmatrix} \Delta W_n \right) \\ &\qquad + \epsilon \begin{pmatrix} 0 \\ 1 \end{pmatrix} \Delta W_n \\ &= \left(I_m + b^{\mathrm{T}} \otimes Q\Delta t \left(I_s \otimes I_m - A \otimes Q\Delta t\right)^{-1} e \right) y_n \\ &\qquad + \epsilon \left(I_m + b^{\mathrm{T}} \otimes Q\Delta t \left(I_s \otimes I_m - A \otimes Q\Delta t\right)^{-1} c \right) \begin{pmatrix} 0 \\ 1 \end{pmatrix} \Delta W_n. \end{aligned}$$

Thus

$$y_{n+1} = R(\Delta t Q) y_n + R_1(\Delta t Q) \begin{pmatrix} 0 \\ 1 \end{pmatrix} \epsilon \Delta W_n,$$

where, for scalar z,

$$R(z) = 1 + b^{\mathrm{T}} z (I_s - Az)^{-1} e$$

and

$$R_1(z) = 1 + b^{\mathrm{T}} z (I_s - Az)^{-1} c.$$

In the notation of (2.4), $r = R_1 \binom{0}{1}$. For example, the Euler method has $R = \Delta t Q$ and $r^{\mathrm{T}} = \begin{pmatrix} 0 & 1 \end{pmatrix}$.

Let us now examine the condition for an exact stationary measure. We shall take $g = 1$, which can always be achieved by rescaling time, so

$$\Sigma_{\mathrm{e}} = KT \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

The equation to be satisfied is now

$$RR^{\mathrm{T}} - I + 2\eta \Delta t R_1 \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} R_1^{\mathrm{T}} = 0. \tag{4.2}$$

Let

$$R(\Delta t Q) = I + \sum_{i=1}^{\infty} \alpha_i (\Delta t Q)^i$$

and

$$R_1(\Delta t Q) = I + \sum_{i=1}^{\infty} \beta_i (\Delta t Q)^i.$$

Then (4.2) can be expanded in powers of Δt as

$$\begin{aligned}
&\Delta t\left(\alpha_1(Q+Q^{\mathrm{T}})+2\eta\begin{pmatrix}0&0\\0&1\end{pmatrix}\right)\\
&+\Delta t^2\left(\alpha_1^2QQ^{\mathrm{T}}+\alpha_2(Q^2+(Q^{\mathrm{T}})^2)+2\eta\beta_1\left(Q\begin{pmatrix}0&0\\0&1\end{pmatrix}+\begin{pmatrix}0&0\\0&1\end{pmatrix}Q^{\mathrm{T}}\right)\right)\\
&+\Delta t^3\Bigg(\alpha_3(Q^3+(Q^{\mathrm{T}})^3)+\alpha_1\alpha_2(Q^2Q^{\mathrm{T}}+Q(Q^2)^{\mathrm{T}})\\
&\qquad+2\eta\left(\beta_2Q^2\begin{pmatrix}0&0\\0&1\end{pmatrix}+\beta_2\begin{pmatrix}0&0\\0&1\end{pmatrix}(Q^{\mathrm{T}})^2+\beta_1^2Q\begin{pmatrix}0&0\\0&1\end{pmatrix}Q^{\mathrm{T}}\right)\Bigg)+\cdots=0.
\end{aligned}$$

If this equation is to be satisfied for all Δt, then each coefficient in the expansion must be zero. It is easily shown that this can hold if and only if $\alpha_i=(\frac{1}{2})^{i-1}$ and $\beta_i=(\frac{1}{2})^i$. Thus the family of Runge–Kutta methods that gives the exact stationary density is characterized by

$$R(\Delta tQ)=\left(I-\frac{1}{2}\Delta tQ\right)^{-1}\left(I+\frac{1}{2}\Delta tQ\right) \tag{4.3}$$

and

$$R_1(\Delta tQ)=(\Delta tQ)^{-1}(R(\Delta tQ)-I).$$

Explicitly, with Q given by (2.3),

$$r=R_1\begin{pmatrix}0\\1\end{pmatrix}=\Delta t^{-1}\begin{pmatrix}-r_{22}-\eta r_{12}+1\\ r_{12}\end{pmatrix}.$$

While Runge–Kutta methods with more than one stage can be constructed that have the stability function given by (4.3), they all have a singular tableau matrix.

The method also has the virtue of being symplectic in the limit $\eta\to 0$ [5]. For linear equations, the method is explicit.

In the case of (2.2), the implicit midpoint rule is implemented as follows. We first generate $\hat{X}$ and $\hat{V}$:

$$\hat{V}=\kappa^{-1}\left(V_n-gX_n\frac{1}{2}\Delta t+\frac{1}{2}\epsilon\,\Delta W_n\right) \tag{4.4}$$

$$\hat{X}=X_n+\hat{V}\,\frac{1}{2}\Delta t, \tag{4.5}$$

where $\kappa=1+\frac{1}{2}\eta\Delta t+\frac{1}{4}g\Delta t^2$. Then

$$X_{n+1}=X_n+\hat{V}\,\Delta t, \tag{4.6}$$

$$V_{n+1}=V_n-\eta\hat{V}\Delta t-g\hat{X}\,\Delta t+\epsilon\Delta W_n. \tag{4.7}$$

Steps (4.4)–(4.7) are carried out in the order given.

5. Double-well system: Additive noise. The good properties of the implicit midpoint and leapfrog methods applied to linear second-order SDEs prompt us to investigate their accuracy for nonlinear equations. In this section we take as our example system (1.2), with the double-well potential

$$V(x) = -\frac{1}{2}x^2 + \frac{1}{4}x^4 \tag{5.1}$$

and with $s(x) = 1$. The stationary density is given explicitly by (1.5). The statistics of the position variable are non-Gaussian, but the mean is zero and σ_x^2 can be evaluated to arbitrary accuracy by a numerical evaluation of an integral.

In general, using an implicit method on a nonlinear equation requires an iterative procedure at each timestep. However, the structure of second-order systems makes a very simple iteration possible. First, the intermediate value $\hat{X}$ is generated by fixed-point iteration with the starting value $\hat{X} = X_n$. This amounts to repeated evaluation of

$$\hat{X} = X_n + \left(1 + \frac{1}{2}\eta\Delta t\right)^{-1} \frac{1}{2}\Delta t \left(V_n + \frac{1}{2}\Delta t f(\hat{X}) + \frac{1}{2}\epsilon\Delta W_n\right). \tag{5.2}$$

The rest of the algorithm is explicit:

$$\hat{V} = \left(V_n + \frac{1}{2}f(\hat{X})\,\Delta t + \frac{1}{2}\epsilon\,\Delta W_n\right) \Big/ \left(1 + \frac{1}{2}\eta\Delta t\right),$$

$$X_{n+1} = X_n + \hat{V}\,\Delta t,$$

$$V_{n+1} = V_n - \eta\hat{V}\Delta t + f(\hat{X})\Delta t + \epsilon\Delta W_n.$$

In our numerical experiments with the double-well system we used six iterations of (5.2), which was not a large overhead, comparable to an explicit predictor-corrector approach. However, in larger systems, where evaluation of $f(x)$ is computationally expensive, the number of iterations needs to be considered along with Δt.

In Figure 4 we display results obtained at $KT = 0.1$, using the Heun, leapfrog, and implicit midpoint methods, as a function of η for $\Delta t = 0.1$. The Heun method is seen to be poor both at large and small values of damping, while the leapfrog method is accurate for small damping but inaccurate in σ_v^2 at large values of damping. The implicit midpoint method produces the exact values of σ_v^2 and μ at all values of damping but has a nonzero error in σ_x^2. Results for Mannella's modification of the leapfrog method are not shown in Figure 4 but are summarized as follows: the errors show little or no dependence on η, the error in σ_x^2 is comparable to that of the implicit midpoint method, while the error in σ_v^2 is similar to that of the standard leapfrog method as $\eta \to 0$.

In Figure 5 we display results obtained using the Heun and implicit midpoint methods, the standard leapfrog method, and Mannella's modified leapfrog method as a function of Δt, with $\eta = 1$ and $KT = 0.1$. Both leapfrog methods and the implicit midpoint method maintain the independence of position and velocity for all values of Δt. The implicit midpoint method also gives the exact value of the late-time mean square of the velocity variable. Mannella's modification of the leapfrog method leads to a reduced error in σ_v^2.

It is appropriate to compare numerical methods in a way that reflects their demand for computer resources. Figure 6 plots the errors in σ_x^2 and σ_v^2 as a function of

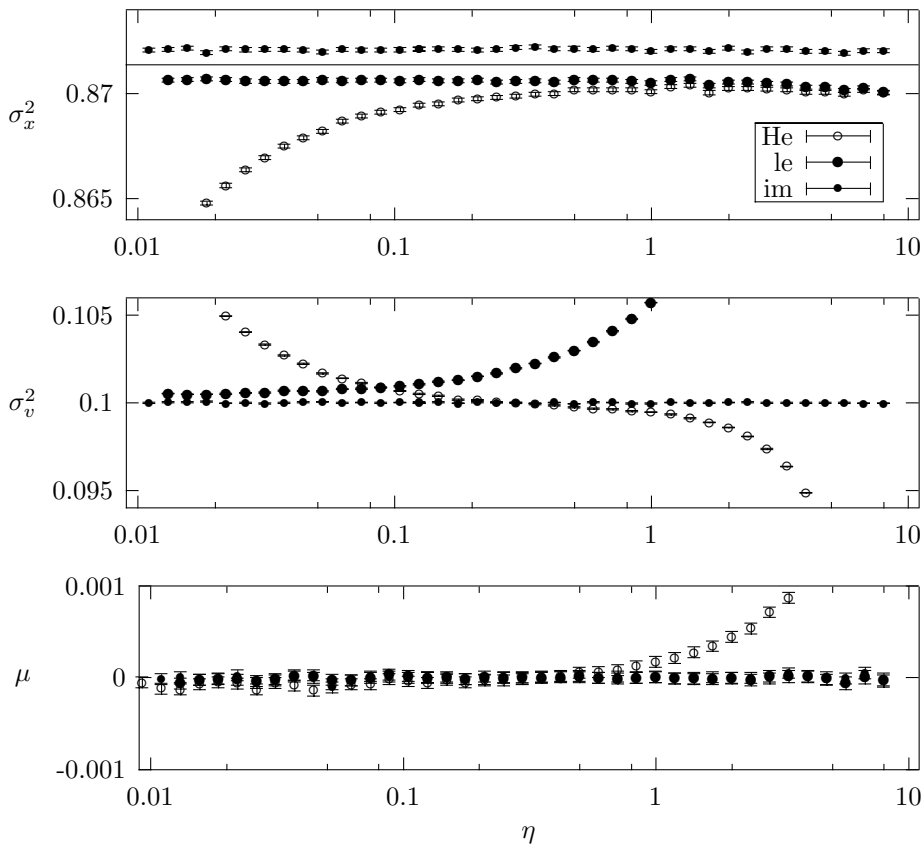

FIG. 4. *Mean squares and correlation versus damping: double-well system. Results obtained at* $KT = 0.1$ *using the Heun (circles), leapfrog (larger filled circles), and implicit midpoint (small filled circles) methods with* $\Delta t = 0.1$. *The top graph shows the late-time mean square of the position variable; the exact value is shown as a solid line. The middle graph shows the late-time mean square of the velocity variable; the exact value is* 0.1. *The lower graph shows the correlation between the position and velocity variables; the exact value is* 0.

the number of evaluations of $f(x)$ per time unit. In the cases of the leapfrog methods, the horizontal axis is simply Δt^{-1}. The Heun method requires two evaluations of $f(x)$ per timestep; the horizontal axis in this case is $2\Delta t^{-1}$. The implicit midpoint rule requires a total of eight such evaluations, six of them in the iterative step; the horizontal axis is thus $8\Delta t^{-1}$. All four methods have errors in σ_x^2 proportional to Δt^2; the extra computer time required for the iteration makes the implicit midpoint rule more expensive. On the other hand, the implicit midpoint rule reproduces the exact value of σ_v^2. Mannella's modification reduces the error in σ_v^2 associated with the leapfrog method.

6. Double-well system: Multiplicative noise. It is of interest to see how the methods analyzed and tested in this paper perform when extended to multiplicative noise systems, i.e., $s(x) \neq 1$. We first describe in the following steps how we have implemented them in our numerical experiments.

(i) Under the Heun method, intermediate values are obtained via the Euler

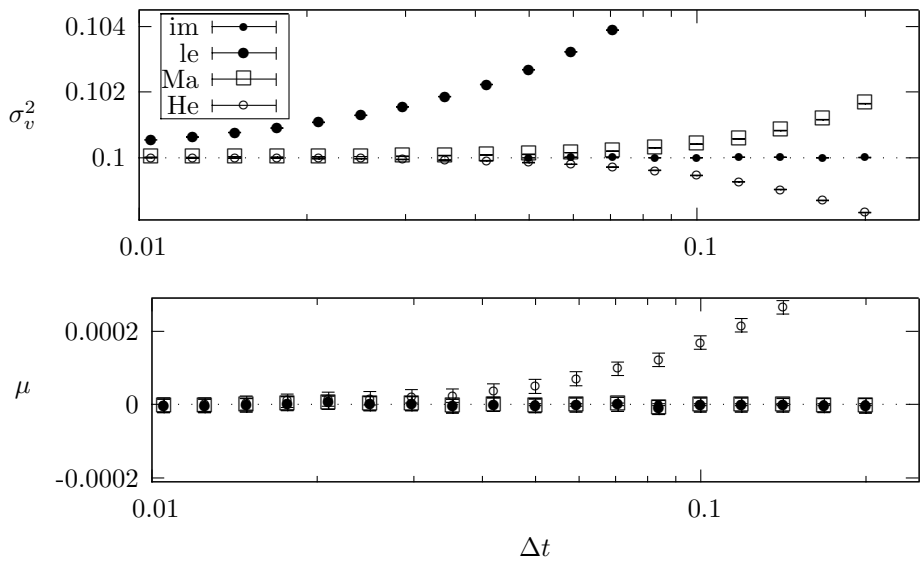

FIG. 5. *Mean-squared velocity and correlation versus Δt: double-well system. Results obtained at $KT = 0.1$ using the Heun method (circles), leapfrog method (larger filled circles), Mannella's modification (squares), and the implicit midpoint method (small filled circles) with $\eta = 1$. The top graph shows the late-time mean square of the velocity variable; the exact value is* 0.1. *The lower graph shows the correlation between the position and velocity variables.*

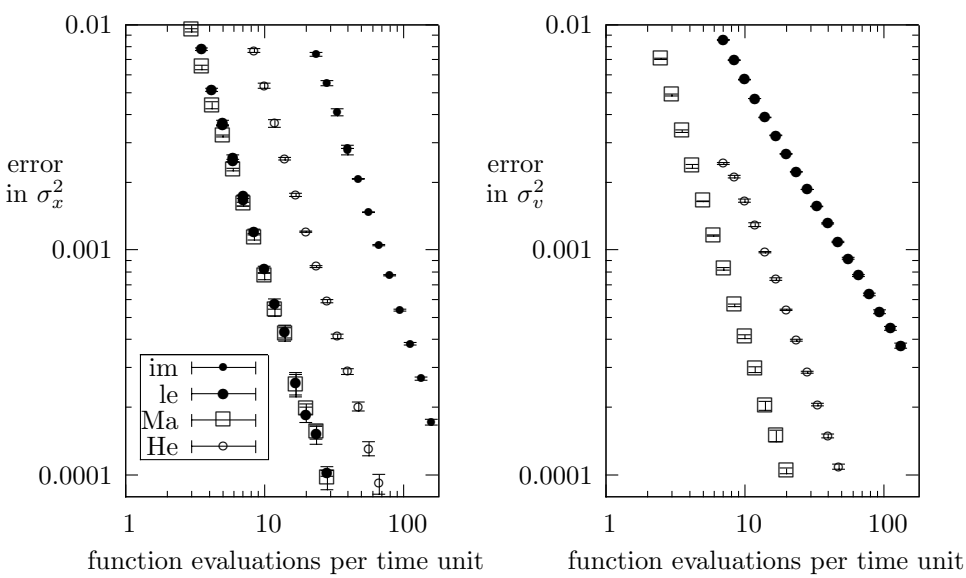

FIG. 6. *Error in mean squares: double-well system. Results obtained at $KT = 0.1$ and $\eta = 1$ using the Heun method (circles), leapfrog method (larger filled circles), Mannella's modification (squares), and the implicit midpoint method (small filled circles) with $\eta = 1$. The horizontal coordinate is Δt^{-1} multiplied by the number of evaluations of $f(x)$ per timestep.*

method:

$$\hat{X} = X_n + V_n\,\Delta t,$$

$$\hat{V} = V_n - \eta s^2(X_n)V_n\Delta t + f(X_n)\,\Delta t + s(X_n)\epsilon\,\Delta W_n.$$

The update is

$$X_{n+1} = X_n + \frac{1}{2}(V_n + \hat{V})\,\Delta t,$$

$$V_{n+1} = V_n - \frac{1}{2}\eta(s^2(X_n)V_n + s^2(\hat{X})\hat{V})\Delta t + \frac{1}{2}(f(X_n) + f(\hat{X}))\,\Delta t + \frac{1}{2}\epsilon(s(X_n) + s(\hat{X}))\Delta W_n.$$

(ii) The standard leapfrog method is now

$$\hat{X} = X_n + \frac{1}{2}V_n\Delta t,$$

$$V_{n+1} = V_n - \eta s^2(\hat{X})V_n\Delta t + f(\hat{X})\,\Delta t + \epsilon s(\hat{X})\Delta W_n,$$

$$X_{n+1} = \hat{X} + \frac{1}{2}V_{n+1}\Delta t.$$

(iii) Mannella's leapfrog method is now

$$\hat{X} = X_n + \frac{1}{2}V_n\Delta t,$$

$$V_{n+1} = \left(1 + \frac{1}{2}s^2(\hat{X})\eta\Delta t\right)^{-1}\left(\left(1 - \frac{1}{2}s^2(\hat{X})\eta\Delta t\right)V_n + f(\hat{X})\,\Delta t + \epsilon s(\hat{X})\Delta W_n\right),$$

$$X_{n+1} = \hat{X} + \frac{1}{2}V_{n+1}\Delta t.$$

(iv) When using the implicit midpoint method, intermediate values $\hat{X}$ are generated by repeated evaluation of

$$\hat{X} = X_n + \left(1 + \frac{1}{2}s(\hat{X})^2\eta\Delta t\right)^{-1}\frac{1}{2}\Delta t\left(V_n + \frac{1}{2}\Delta t f(\hat{X}) + \frac{1}{2}\epsilon s(\hat{X})\Delta W_n\right),$$

with the starting value $\hat{X} = X_n$. The rest of the algorithm is explicit:

$$\begin{aligned}\hat{V} &= V_n + \frac{1}{2}\Delta t\hat{X},\\ X_{n+1} &= X_n + \hat{V}\,\Delta t,\\ V_{n+1} &= V_n - \eta s^2(X_{n+1})\hat{V}\Delta t + f(\hat{X})\Delta t + s(X_{n+1})\epsilon\Delta W_n.\end{aligned}$$

We have performed numerical experiments with $s(x) = x$. In Figure 7 we display results obtained at $KT = 0.1$, using the Heun method, Mannella's modification of the leapfrog method, and the implicit midpoint method, as a function of η for $\Delta t = 0.1$.

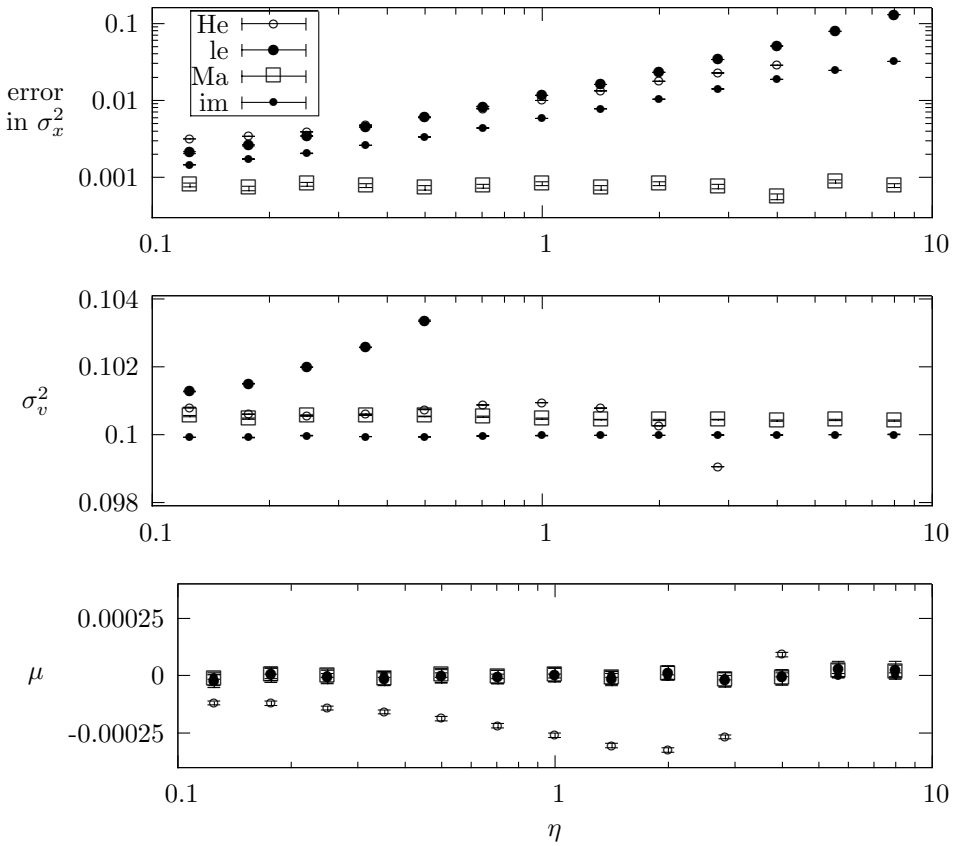

FIG. 7. *Mean squares and correlation versus damping: double-well system with multiplicative noise. Results obtained at* $KT = 0.1$ *and* $\Delta t = 0.1$ *using the Heun method (circles), the leapfrog method (larger filled circles), Mannella's modification of the leapfrog method (squares), and the implicit midpoint method (small filled circles). The top graph shows the error in the late-time mean square of the position variable (log scale). The middle graph shows the late-time mean square of the velocity variable; the exact value is* 0.1. *The lower graph shows the correlation between the position and velocity variables.*

In terms of the error in σ_x^2, Mannella's method performs best. The implicit midpoint method, however, is the only one that appears to give the exact value of σ_v^2 at all values of η. In Figure 8 we display numerical results with $KT = 0.1$ and $\eta = 1$ as a function of Δt. Mannella's method is the only one that has second-order convergence in σ_x^2, but the implicit midpoint method is more accurate in σ_v^2.

Note that, for systems of SDEs where there is a difference between Ito and Stratonovich forms, the implicit midpoint rule will converge to the Stratonovich form. However, it will only have strong order 0.5 for noncommutative SDEs with more than one noise term, in which case other approaches are needed to obtain a strong order of 1 [23, 24].

7. Conclusion. Exact calculations for linear equations are of interest in their own right and because the qualitative form of the error as a function of Δt and η carries over to the nonlinear equations used as examples here. The implicit midpoint rule is the only Runge–Kutta method with a nonsingular tableau matrix that reproduces

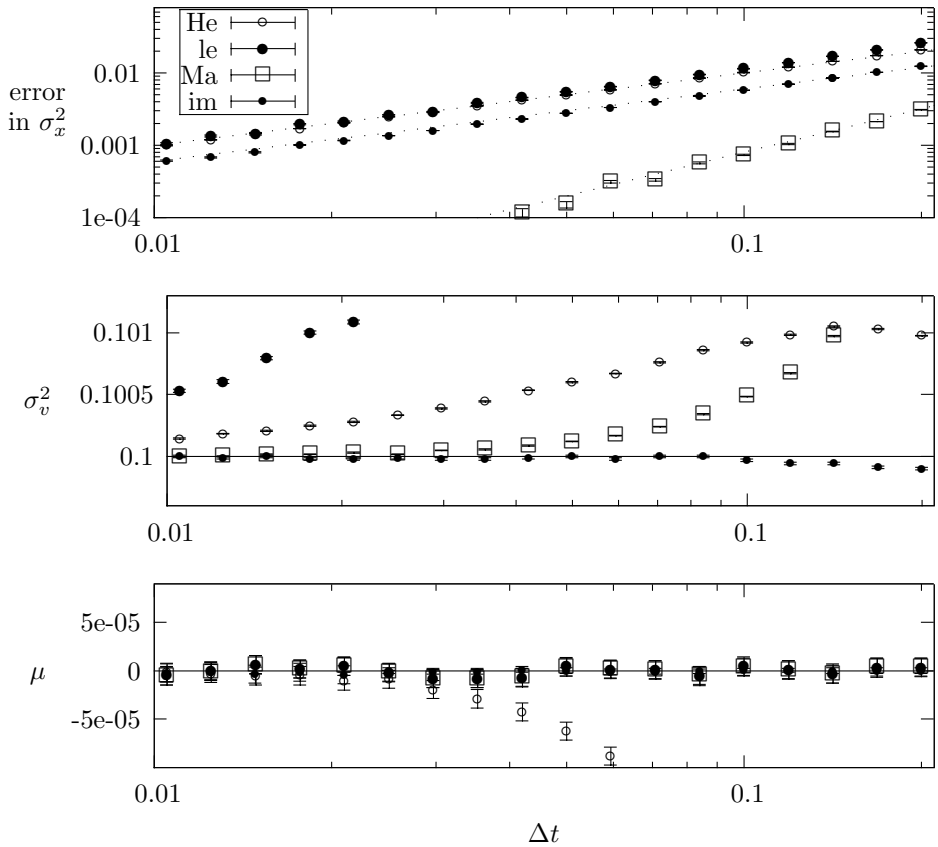

FIG. 8. *Mean squares and correlation versus Δt: double-well system with multiplicative noise. Results obtained at $KT = 0.1$ and $\eta = 1$ using the Heun method (circles), the leapfrog method (larger filled circles), Mannella's modification of the leapfrog method (squares), and the implicit midpoint method (small filled circles). The top graph shows the error in the late-time mean square of the position variable (log scale); the dotted lines are $0.1\Delta t$, $0.06\Delta t$, and $0.08\Delta t^2$. The middle graph shows the late-time mean square of the velocity variable; the exact value is 0.1. The lower graph shows the correlation between the position and velocity variables.*

the exact stationary distribution for all values of damping. It also performs well when applied to second-order nonlinear and multiplicative noise equations, with no apparent error in the stationary mean square of the velocity variable even for the nonlinear double-well system with multiplicative noise. However, leapfrog-type methods have the advantage of being fully explicit even for nonlinear equations. In particular, they require only one evaluation of the deterministic force per timestep.

Applied to linear equations, the simplest leapfrog method gives the exact stationary variance of the position variable and maintains the independence of position and velocity. Mannella's modification of the leapfrog method maintains this virtue while reducing the magnitude of the error in the variance of the velocity variable. We found similar qualitative behavior in our numerical experiments on the nonlinear double-well system: the implicit midpoint method and Mannella's method perform best, the former being superior in the error in σ_v^2 and the latter in σ_x^2.

In the deterministic case when solving separable Hamiltonian problems, explicit partitioned Runge–Kutta methods can be constructed that are symplectic. A chal-

lenge is to extend the idea in a stochastic setting to construct explicit partitioned methods that approximate the stationary correlation matrix with high-order accuracy.

STABILITY THROUGH SYNCHRONIZATION IN NONLINEAR MULTISCALE TRANSFORMATIONS*

FRANCESC ARÀNDIGA† AND ROSA DONAT†

Abstract. Nonlinear analogues of classical wavelet transformations have been designed within spatially oriented multiresolution frameworks such as Harten's framework [*J. Appl. Numer. Math.*, 12 (1993), pp. 153–193] and the lifting framework [R. L. Claypoole et al., *IEEE Trans. Image Process.*, 12 (2003), pp. 1449–1459]. In designing and using nonlinear multiscale transformations for data compression purposes, the main issue is that of ensuring stability. In [*J. Appl. Numer. Math.*, 12 (1993), pp. 153–193], Harten ensures stability by designing a special error-control mechanism that provides estimates for the compression error. In [R. L. Claypoole et al., *IEEE Trans. Image Process.*, 12 (2003), pp. 1449–1459] no theoretical results are provided, but the authors argue that stability is a consequence of synchronization between the nonlinear decisions made by the prediction operators in the direct and inverse transformations. By interpreting the nonlinear multiscale transformation of R. L. Claypoole et al. within Harten's cell-average framework, we are able to provide stability bounds for the scheme of R. L. Claypoole et al. and establish a theoretical basis for comparison between both nonlinear multiresolution schemes.

1. Introduction.

Multiscale transformations have recently been used in the first step of transform coding algorithms for image compression. A multiscale transformation allows for an [illegible] representation of the image data since, typically, a significant number of the transform coefficients are small and can be quantized or discarded with little loss of real information. A lossy multiresolution-based compression scheme acting on a sequence of data sampled at a given resolution, v^L, can be schematically described as follows:

$$v^L \longrightarrow v_d = Mv^L = (v^0, d^1, \ldots, d^L) \longrightarrow \hat{v}_d = Q_{\bar{\varepsilon}} Mv^L = (\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^L). \tag{1.1}$$

Here Mv^L is the multiresolution representation of the signal v^L and $Q_{\bar{\varepsilon}}$ is the [illegible], which proceeds by quantizing or truncating the elements of Mv^L with respect to a set of user-dependent parameters $\bar{\varepsilon} = (\varepsilon_0, \ldots, \varepsilon_L)$ and then coding the resulting representation.

Even though compression is achieved through $Q_{\bar{\varepsilon}}$, and not during the transformation step, the properties of the multiscale transformation, M, are most important in the overall performance of the transform coding algorithm. Mv^L is composed by v^0, which corresponds to a sampling of the data at a much coarser resolution, and a sequence of details $(d^1, \ldots, d^L)$. Each d^k represents the intermediate information which is necessary to recover the data sampled at level k, v^k from the data sampled at level $k-1$, v^{k-1}. Multiresolution transforms are designed in such a way that most

of these coefficients are small and can be quantized or discarded with little loss of global information content. Wavelet bases typically employed for image compression (such as the Daubechies $(7, 9)$ system) use smooth scaling and wavelet functions and are very efficient for smooth signals; however, they produce many large transform coefficients around the edges in an image which reduces the efficiency of the transform coding algorithm.

To avoid this loss in efficiency, one would like to adapt the multiscale transformation so that the local properties of the image are taken into account, which leads up to considering data-dependent (nonlinear) multiscale transforms. Adaptivity is a hard issue when the basic design of a multiscale transform is done through the standard wavelet technology. However, data-dependent multiscale transformations have been successfully designed within Harten's framework for multiresolution (see [2, 1, 4, 14, 15]) and within the (modified) lifting framework [7].

Under conditions of uniformity, these two frameworks can be seen as alternate implementations of classical wavelet transforms, however, and in contrast with the traditional frequency-domain construction, their design is intrinsically [illegible]. The detail coefficients are obtained as [illegible] that take into account local correlations present in the signal. The spatial construction of the prediction operator is the key advantage in building multiscale transformations specifically adapted to complex geometries and irregular sampling, as well as data-dependent multiscale transformations. It is shown in [2, 1, 4, 14, 15, 7] that a more [illegible] performance around edges in an image can be obtained when using nonlinear multiresolution transformations obtained from data-dependent prediction schemes.

The practical use of a lossy compression scheme, such as (1.1), relies on its stability. It is mandatory that the error in the reconstructed signal obtained from the decoder, i.e., $\hat{v}^L = M^{-1}Q_{\bar{\varepsilon}}Mv^L$, and the original signal, v^L, be somehow compatible with the error made in the uninvertible processing step.

The compression operator $Q_{\bar{\varepsilon}}$ is designed so that v_d and $\hat{v}_d$ in (1.1) are [illegible], in the sense that for some prescribed discrete norm $||\cdot||$,

$$||\hat{v}^0 - v^0|| \le \varepsilon_0, \quad ||\hat{d}^k - d^k|| \le \varepsilon_k, \quad 1 \le k \le L,$$

as is the case in, for example, [illegible] or simple [illegible]. Stability follows if it is possible to establish a relation such as

$$||\hat{v}^L - v^L|| \le \sigma(\varepsilon_0, \varepsilon_1, \ldots, \varepsilon_L), \quad \text{with} \quad \lim_{\varepsilon_l \to 0, 0 \le l \le L} \sigma(\varepsilon_0, \varepsilon_1, \ldots, \varepsilon_L) = 0. \tag{1.2}$$

For linear multiresolution transformations, stability is analyzed in terms of the underlying basis functions of the wavelet system. However, such techniques are no longer applicable to nonlinear transformations, for which linear superposition does not hold. Ensuring stability becomes hence the major issue in practical applications involving nonlinear multiscale transformations.

In Harten's framework, data-dependent prediction operators have been constructed following the design principles of the essentially nonoscillatory (ENO) interpolation technique described in [16]. The solution proposed by Harten to ensure the stability of the nonlinear multiresolution transformations that result from using ENO-type prediction operators involves a modification of the direct transform, with the ultimate goal of controlling the accumulation of errors due to the compression mechanism. Because of this feature, Harten named the modified algorithm an [illegible] (EC) multiresolution transform.

Throughout this paper we shall denote Harten's modified transformation as $\widetilde{M}_{\bar{\varepsilon}}$, because it merges the direct transformation with the processing procedure (quantization or truncation). In [14], Harten shows that (1.2) holds for $\hat{v}^L = M^{-1}\widetilde{M}_{\bar{\varepsilon}} v^L$, which guarantees stability. Harten's EC strategies in various multiresolution frameworks have been analyzed and the error bounds in [14] improved in [4, 1].

In the lifting framework, data-dependent predictors are constructed in [7] by adaptively choosing a linear filter, from a finite pool, at each spatial location where a detail coefficient must be computed. Close to an edge in an image, the length of the filter is reduced so that no data across the edge is used in the prediction step, in an attempt to avoid the large prediction errors associated to the use of linear filters across edges.

It is well known, however, that the use of locally adapted filters can cause a series of incorrect filter choices in the decoder, leading to serious reconstruction errors (see, e.g., [7] and the references therein). In [7], Claypoole et al. argue that the stability of the transform coding algorithm must follow from encoder/decoder [illegible], i.e., from ensuring that the same choice of filter is made at a given location and resolution level in both the encoder and the decoder. For efficiency reasons, this encoder/decoder synchronization must be achieved [illegible], i.e., no side information should be attached to the transform coefficients.

The analysis in [7] shows that it is impossible to guarantee synchronization within the classical split-predict-update lifting routine when using data-dependent prediction schemes. As a solution, Claypoole et al. propose switching instead to an [illegible] form of lifting which is based on Donoho's average-interpolation setting [10], which fits precisely within Harten's cell-average framework.

Once the connection has been established, it is fairly simple to realize that the nonlinear multiscale transformation introduced in [7] is similar in nature to the nonlinear transformations within Harten's framework obtained from ENO prediction operators. In both cases, the nonlinearity is a consequence of the use of a (nonlinear) selection function to adaptively choose a linear filter among a finite pool.

The central subject of this paper is the comparison of the synchronization strategy proposed in [7] with Harten's EC strategy for the cell-average framework [14, 1]. Indeed, although independently developed, the basic structure of the synchronized nonlinear transformation described in [7] is precisely the cell-average EC strategy described by Harten in [14], the main difference lying in the computation of the scale coefficients.

The analysis in this paper shows that the essential ingredient for stability is, in fact, the [illegible] between the prediction choices carried out in the direct transformation and in the inverse transformation at each particular location. In addition, we analyze the different possibilities for the computation of the scale coefficients from a theoretical as well as computational point of view and conclude that Harten's original choice for the scale coefficients provides the best balance between theoretical and practical effectiveness.

The paper is organized as follows: In section 2 we briefly review Harten's cell-average framework for multiresolution and establish its relation with the lifting schemes in [7]. In section 3 we recall the class of prediction operators that are obtained by considering piecewise polynomial reconstruction techniques, linear as well as nonlinear. In section 4 we study the relation between stability and encoder/decoder synchronization for nonlinear prediction schemes based on the use of an adaptive, position-dependent filter selection. In section 5 we give specific stability bounds for several [illegible]

nonlinear multiresolution transformations. The corresponding tensor-product extensions to two-dimensional (2D) signals, used for image compression, are briefly described in section 6. Numerical experiments are presented in section 7. Finally some conclusions are drawn in section 8.

2. The cell-average setting as an update-first lifting scheme. Harten's general framework for multiresolution [15] relies on two operators, decimation and prediction, that define the basic interscale relations. These operators act on linear vector spaces, V^j, that represent the different resolution levels (j increasing implies more resolution)

$$\text{(2.1)} \qquad \text{(a)} \quad D^j : V^j \to V^{j-1}, \qquad \text{(b)} \quad P_j : V^{j-1} \to V^j,$$

and must satisfy two requirements of algebraic nature: (a) D^j must be a [illegible] operator and (b) $D^j P_j = I_{V^{j-1}}$ [illegible], i.e., the identity operator on the lower resolution level represented by V^{j-1}. For all practical purposes in this paper, V^j shall be considered a space of finite-dimensional sequences.

Using these two operators, a vector (i.e., a discrete sequence) $v^j \in V^j$ can be decomposed and reassembled as follows:

$$\text{(2.2)} \qquad \text{(a)} \quad \begin{array}{rcl} v^j & \to & v^{j-1} = D^j v^j \\ & \searrow & e^j = v^j - P_j v^{j-1} \end{array}, \qquad \text{(b)} \quad v^j = P_j v^{j-1} + e^j.$$

The consistency requirement implies that the prediction errors e^j satisfy $D^j e^j = 0$. The detail coefficients are computed as the nonredundant information contained in the prediction error.

To be more precise, and to establish the correspondence with the modified lifting scheme of [7], we concentrate on the one-dimensional (1D) cell-average setting, in which the levels of resolution are specified by a set of uniform nested dyadic grids on the interval $[0,1]$, $\{X^j\}$, $j \geq 0$, of size $h_j = 2^{-j} h_0$: $X^j = \{x_i^j = i h_j\}_{i=0}^{N_j}$, $N_j \cdot h_j = 1$. The cell-average setting is characterized by the interpretation of the discrete data at level j as cell-averages of a function on the grid X^j. Hence, the decimation operator is given as (see, e.g., [14, 4] for full details)

$$\text{(2.3)} \qquad (D^j v^j)_i = \frac{1}{2}(v^j_{2i-1} + v^j_{2i}), \qquad 1 \leq i \leq N_j.$$

The consistency requirement for P_j becomes

$$\text{(2.4)} \qquad v_i^{j-1} = (D^j P_j v^{j-1})_i = \frac{1}{2}\left[(P_j v^{j-1})_{2i-1} + (P_j v^{j-1})_{2i}\right].$$

Hence, if $v^{j-1} = D^j v^j$, then (2.3) and (2.4) imply that

$$e^j_{2i-1} = v^j_{2i-1} - (P_j v^{j-1})_{2i-1} = (P_j v^{j-1})_{2i} - v^j_{2i} = -e^j_{2i},$$

which shows the redundancy inherent in the prediction error. By considering only the prediction errors at (for example) the odd points of the grid X^j, one immediately obtains a one-to-one correspondence between the sets $\{v^j\}_i \leftrightarrow (\{v^{j-1}\}_i, \{d^j\}_i)$, where $d_i^j = e^j_{2i-1}$ and $v^{j-1} = D^j v^j$.

$$\text{(2.5)} \qquad \left\{ \begin{array}{l} v_i^{j-1} = (v^j_{2i} + v^j_{2i-1})/2 \\ d_i^j = v^j_{2i-1} - (P_j v^{j-1})_{2i-1} \end{array} \right\} \iff \left\{ \begin{array}{l} v^j_{2i-1} = (P_j v^{j-1})_{2i-1} + d_i^j \\ v^j_{2i} = 2v_i^{j-1} - v^j_{2i-1} \end{array} \right\}.$$

By repeating the two-step transformation for all levels, we immediately get a multiresolution transformation, M, and its corresponding inverse, M^{-1}.

When comparing with the classical split-predict-update (SPU) form of the lifting schemes, we observe that the design strategy is conceptually different. In the SPU-lifting routine the signal v^j is split into even and odd polyphase coefficients and the prediction operator acts only on even coefficients v^j_{2i}; then the scale coefficients d^j_i represent the prediction residuals at odd locations. The update step is necessary in order to recover a low-pass downsampled version of the original signal.

If the order of the predict and update steps in the lifting scheme is reversed, a low-pass downsampled version of the original signal (i.e., $v^{j-1} = D^j v^j$) is produced first and is subsequently used to predict the odd samples: This is the precise structure of Harten's two-step invertible transformation (2.5), and hence the update-first lifting scheme proposed in [7] has the exact same structure of Harten's framework.

It should be noted, anyhow, that the multiscale transformations obtained from the repeated application of (2.5) share common features with the lifting framework: First, the inverse transformation is computed by undoing the steps made in the direct transform. Second, the computations can be done "in place," i.e., no auxiliary memory is needed. In addition, in both frameworks, the prediction operator can be adjusted to account for boundaries (see [15, 4, 18] for details).

3. Prediction via piecewise-polynomial average interpolation. A well-known construction of prediction operators in the cell-average setting is based on the so-called [illegible] interpolation [14, 10]: For each $1 \le i \le N_{j-1}$ on level $j-1$, construct a polynomial $p_i(x)$ of fixed degree, say R, by specifying its averages on a [illegible] of cells $\mathcal{S}_i = \{i-A, \ldots, i+B\}$.

$$\frac{1}{h_{j-1}} \int_{x^{j-1}_{l-1}}^{x^{j-1}_l} p_i(x)dx = v^{j-1}_l \quad \text{for } l = i-A, \ldots, i+B; \qquad \begin{cases} R = A+B, \\ A \ge 0, B \ge 0. \end{cases} \tag{3.1}$$

The $A+B+1$ relations in (3.1) lead always to a solvable linear system for the coefficients of $p_i(x)$.

The prediction operator is defined by considering the averages of the polynomial piece $p_i(x)$ on the next finer grid as follows:

$$(P_j v^{j-1})_{2i} := \frac{1}{h_j} \int_{x^j_{2i-1}}^{x^j_{2i}} p_i(x)dx, \qquad (P_j v^{j-1})_{2i-1} := \frac{1}{h_j} \int_{x^j_{2i-2}}^{x^j_{2i-1}} p_i(x)dx. \tag{3.2}$$

Since $i \in \mathcal{S}_i$, definition (3.2) clearly implies that P_j satisfies the consistency relation (2.4). Hence, $(P_j v^{j-1})_{2i}$ can easily be computed as $(P_j v^{j-1})_{2i} = 2v^{j-1}_i - (P_j v^{j-1})_{2i-1}$.

For the construction above, a straightforward calculation leads to (see, e.g., [15])

(3.3)

$$\text{(a) } (P_j v^{j-1})_{2i-1} = \sum_{l=-A}^{B} \beta_l v^{j-1}_{i+l}, \quad \text{(b) } \beta_l = \begin{cases} 2\sum_{k=l}^{B} L^{(A,B)}_k\left(-\frac{1}{2}\right), & 0 \le l \le B, \\ -2\sum_{k=-(A+1)}^{l-1} L^{(A,B)}_k\left(-\frac{1}{2}\right), & -A \le l \le -1, \end{cases}$$

where $L^{(A,B)}_m(y)$, $m = -(A+1), \ldots, B$, is the standard Lagrange interpolatory basis for the stencil of points $\{-(A+1), \ldots, B\}$. Then $(P_j v^{j-1})_{2i-1}$ is obtained as the result of applying a particular filter to the lower resolution data v^{j-1}. The filter coefficients

depend solely on $\mathcal{S}_i$, the stencil assigned to the polynomial piece $p_i(x)$. We shall write $p_i(x) = p_i(x, v^{j-1}, \mathcal{S}_i)$ when necessary.

3.1. Let $v_i^j = \frac{1}{h_j} \int_{x_{i-1}^j}^{x_i^j} f(x)dx$, $f(x)$ being a piecewise smooth function. Then

$$f(x) = p_i(x, v^j, \mathcal{S}_i) + O(h_j^{R+1}), \qquad x \in [x_{i-1}^j, x_i^j],$$

if and only if the convex hull of the stencil $\mathcal{S}_i$ is entirely contained in a region of smoothness of $f(x)$ [4]. The corresponding prediction scheme is then $(R+1)$st order accurate on smooth functions.

3.1. Data-independent stencils: Linear prediction operators. A classical prediction follows from considering $\mathcal{S}_i = \{i-s, \ldots, i+s\}$ for all i, where s is a fixed integer. Since $A = B = s$ for all i, the coefficients in (3.3) are independent of the spatial location, i.e., the same filter is used at all odd locations. The resulting prediction scheme is then a linear operator, intimately related to the interpolatory subdivision schemes of Deslauries and Dubuc [9, 10],

It was noticed by Harten [15] and proven later (see, e.g., [12]) that the multiscale transformations in the cell-average setting associated to this class of prediction operators turn out to be the $(1, M = 2s+1)$ branch of the Cohen–Daubechies–Feauveau biorthogonal wavelet (CDF-$(1, M)$) family [8].

3.2. Data-dependent stencils: Nonlinear ENO prediction operators. On the contrary, if the stencil is chosen in a data-dependent way, a nonlinear prediction operator results. The corresponding multiscale transformation then becomes a nonlinear analogue of the CDF$(1, M)$ family [4].

ENO interpolatory techniques [16] have often been used in the construction of $p_i(x)$ in (3.1) [14, 4, 2, 1]. Once R, the accuracy parameter, is chosen, the practical implementation of an ENO-type prediction operator is done in two steps. The first step is the stencil selection mechanism: Given v^{j-1}, we denote by $\mathcal{S}_i(v^{j-1}) =: \mathcal{S}_i^{v^{j-1}}$ the (data-dependent) stencil corresponding to the polynomial piece $p_i(x)$. The stencil $\mathcal{S}_i^{v^{j-1}}$ determines the particular filter to be used at location $2i-1$ through (3.3)(b). The second step is the actual computation of $(P_j v^{j-1})_{2i-1}$ as in (3.3)(a).

There are several algorithms for an ENO selection of stencil, but all involve a nonlinear decision process based on the use of the divided differences of the data (see, e.g., [4] and the references therein for details on various ENO stencil selection mechanisms). For ENO prediction operators of accuracy $R+1$ there is a finite pool of $R+1$ filters that can be chosen at location $2i-1$ (see the examples below).

It is important to remark that the nonlinearity of ENO prediction schemes lies exclusively in the use of a nonlinear selection function to adaptively choose between a finite pool of linear predictors at each spatial location. Indeed, the computation of $(P_j v^{j-1})_{2i-1}$ is carried out by applying the chosen filter on the data v^{j-1}.

A distinctive feature of ENO predictors is that all filters in the pool have and, hence, the same spatial accuracy.

3.2. The data used for the filter selection can be different from the data used in the interpolation process: Let $\hat{v}^{j-1}$ be the data set to be used in the stencil-selection step, and v^{j-1} the data to be interpolated (in the cell-average sense). Then the polynomial pieces $p_i(x) = p_i(x, v^{j-1}, \mathcal{S}_i^{\hat{v}^{j-1}})$ can be uniquely determined for any pair of data sets v^{j-1}, $\hat{v}^{j-1}$. To denote the nonlinear dependence of the prediction scheme from the data set $\hat{v}^{j-1}$, we shall use the notation $P_j = P_{\hat{v}^{j-1}}$ when appropriate.

As mentioned before, $P_{\hat{v}^{j-1}}$ acts on the data in V^{j-1}, i.e.,

$$P_{\hat{v}^{j-1}}u^{j-1} + P_{\hat{v}^{j-1}}w^{j-1} = P_{\hat{v}^{j-1}}(u^{j-1} + w^{j-1}). \tag{3.4}$$

For $R = 2$, there are three possible stencil selections for each i. Each one leads to a different filter to be applied to the interpolation data:

$$(P_j v^{j-1})_{2i-1} = \begin{cases} -\frac{1}{8}v_{i-2}^{j-1} + \frac{1}{2}v_{i-1}^{j-1} + \frac{5}{8}v_i^{j-1} & \text{if } \mathcal{S}_i^{\hat{v}^{j-1}} = \{i-2, i-1, i\}, \\ \frac{1}{8}v_{i-1}^{j-1} + v_i^{j-1} - \frac{1}{8}v_{i+1}^{j-1} & \text{if } \mathcal{S}_i^{\hat{v}^{j-1}} = \{i-1, i, i+1\}, \\ \frac{11}{8}v_i^{j-1} - \frac{1}{2}v_{i+1}^{j-1} + \frac{1}{8}v_{i+2}^{j-1} & \text{if } \mathcal{S}_i^{\hat{v}^{j-1}} = \{i, i+1, i+2\}. \end{cases} \tag{3.5}$$

To obtain $(P_j v^{j-1})_{2i}$ we simply use (2.4).

For $R = 4$, there are five different possibilities:

(3.6)

$$(P_j v^{j-1})_{2i-1} \begin{cases} -\frac{7}{128}v_{i-4}^{j-1} + \frac{19}{64}v_{i-3}^{j-1} + \frac{11}{16}v_{i-2}^{j-1} - \frac{61}{64}v_{i-1}^{j-1} + \frac{63}{128}v_i^{j-1}, & z_i = i-4, \\ \frac{3}{128}v_{i-3}^{j-1} - \frac{9}{64}v_{i-2}^{j-1} + \frac{13}{32}v_{i-1}^{j-1} + \frac{49}{64}v_i^{j-1} - \frac{7}{128}v_{i+1}^{j-1}, & z_i = i-3, \\ -\frac{3}{128}v_{i-2}^{j-1} + \frac{11}{64}v_{i-1}^{j-1} + v_i^{j-1} - \frac{11}{64}v_{i+1}^{j-1} + \frac{3}{128}v_{i+2}^{j-1}, & z_i = i-2, \\ \frac{7}{128}v_{i-1}^{j-1} + \frac{79}{64}v_i^{j-1} - \frac{13}{32}v_{i+1}^{j-1} + \frac{9}{64}v_{i+2}^{j-1} - \frac{3}{128}v_{i+3}^{j-1}, & z_i = i-1, \\ \frac{193}{128}v_i^{j-1} - \frac{61}{64}v_{i+1}^{j-1} + \frac{11}{16}v_{i+2}^{j-1} - \frac{19}{64}v_{i+3}^{j-1} + \frac{7}{128}v_{i+4}^{j-1}, & z_i = i, \end{cases}$$

where $(\mathcal{S}_i^{\hat{v}^{j-1}}) = \{z_i, \ldots, z_i + R\}$.

3.3. Other adaptive prediction schemes. In [7], Claypoole et al. propose reducing the length of the prediction filters near edges in order to avoid using data across image edges in the prediction step. The main goal in their adaptive scheme is to maintain high accuracy away from edges while avoiding large errors in their vicinity. The nonlinearity thus introduced is similar to that considered in ENO-type prediction operators; i.e., at each location and scale a nonlinear selection function is used to choose a linear predictor from a finite set. In this case, the filters in the pool have different lengths and, thus, different orders of accuracy.

A more involved nonlinear prediction scheme is obtained by considering the ENO-SR (ENO with subcell resolution) technique. This technique, introduced in [13], elaborates on the ENO interpolation in order to account for discontinuities within a cell. The nonlinearity in an ENO-SR prediction operator also derives from the use of a nonlinear procedure (slightly more involved than the one in ENO predictors) that selects a particular filter from a finite pool of filters of the same length (and order). When the polynomial pieces are of degree R, the pool is composed of $R + 3$ different filters. We refer the reader to [4, 2, 1] for more information on the ENO-SR technique and its application in multiscale transformations.

Remark 3.2 applies also to all these adaptive prediction schemes.

4. Synchronization and stability in nonlinear multiscale transformations. In lossy multiresolution-based compression algorithms, the original signal v^L is transformed and processed in such a way that the data available in the decoder, $\hat{v}_d = (\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^L)$, is no longer equivalent to v^L. Stability ensures that the difference $v^L - M^{-1}\hat{v}_d$ can be adequately controlled through the compression parameters.

It is well known (see [7] and the references therein) that the cascading of quantization errors, due to incorrect filter choices in nonlinear prediction schemes, prevents

one from obtaining stable data-dependent multiscale transformations. In order to avoid this phenomenon, Claypoole et al. argue that the nonlinear decisions made by the prediction scheme at a particular location and scale must be [illegible] both in the encoder and in the decoder; i.e., [illegible] is a necessary requirement for stability.

Only $\hat{v}_d = (\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^L)$ is available in the decoder; therefore the nonlinear decisions made there are based on [illegible] $\hat{v}^j = M^{-1}(\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^j)$. Synchronization will follow only if (a) the [illegible] data $\hat{v}^j = M^{-1}(\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^j)$ are also made available to the encoder; and (b) the nonlinear decisions involved in the application of the prediction operator in the direct transformation are based on $\hat{v}^j$ instead of on the original low-pass data $v^j = D^j D^{j+1} \ldots D^L v^L$.

As explained in [7], the usual SPU-lifting routine does not allow automatic synchronization. The authors switch then to the update-first strategy, i.e., to Harten's framework, and start the prediction [illegible], i.e., from the lowest resolution level. Working from coarse to fine scales makes it possible to have the processed data $\hat{v}^j$ already available in the encoder and ensure synchronization. Claypoole et al. relate their synchronized nonlinear multiscale transformation with the Laplacian pyramid of Burt and Adelson [6] and the work of Gerek and Cetin [11], but they apparently did not realize the intrinsic similarity between their approach and the EC algorithms developed by Harten in [14].

In order to establish the specific similarities and differences between Harten's EC algorithm and the synchronized transformation in [7], we now give a schematic description of the EC-modified transformation for the cell-average framework (see [1]),

(4.1)

$$v^L \longrightarrow \hat{v}_d = \widetilde{M}_{\bar{\varepsilon}} v^L = \{\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^L\} \qquad \left\{ \begin{array}{l} \text{for} \quad j = L, \ldots, 1 \\ \quad v^{j-1} = D^j v^j \\ \text{end} \\ \hat{v}^0 = \mathbf{pr}(v^0, \varepsilon_0) \\ \text{for} \quad j = 1, \ldots, L \\ \quad [\hat{v}^j, \hat{d}^j] = \mathbf{ECj}(\hat{v}^{j-1}, v^{j-1}, v^j; \varepsilon_j) \\ \text{end.} \end{array} \right.$$

The first step consists in iterating the linear procedure (the decimation, or, equivalently, the update, operator) to obtain v^0, which is subsequently processed to $\hat{v}^0$ and sent. Then the processed coefficients $\hat{d}^j$ are computed in reverse order [illegible], together with [illegible] j-level values $\hat{v}^j$, in such a way that $\hat{v}^j = M^{-1}(\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^j)$.

Again, to establish similarities and differences between the cell-average [illegible] routine (**ECj** henceforth) in [14, 1] and in [7], we provide next a schematic description of **ECj**:

(4.2)

$$[\hat{v}^j, \hat{d}^j] = \mathbf{ECj}(\hat{v}^{j-1}, v^{j-1}, v^j; \varepsilon_j) \left\{ \begin{array}{l} \tilde{d}^j = \mathbf{pe}(v^j, v^{j-1}, \hat{v}^{j-1}) \\ \hat{d}^j = \mathbf{proc}(\tilde{d}^j, \varepsilon_j) \\ \text{for } i = 1, \ldots, N_{j-1} \\ \quad \hat{v}^j_{2i-1} = (P_{\hat{v}^{j-1}} \hat{v}^{j-1})_{2i-1} + \hat{d}^j_i; \\ \quad \hat{v}^j_{2i} = (P_{\hat{v}^{j-1}} \hat{v}^{j-1})_{2i} - \hat{d}^j_i \quad (\equiv 2\hat{v}^{j-1}_i - \hat{v}^j_{2i-1}); \\ \text{end.} \end{array} \right.$$

First, it proceeds by computing a set of $\tilde{d}^j = \mathbf{pe}(v^j, v^{j-1}, \hat{v}^{j-1})$. This set has the same cardinality as d^j in the direct transformation M and should represent the error in predicting v^j from $\hat{v}^{j-1}$ at level $j-1$. The set $\tilde{d}^j$ is subsequently **proc**essed to obtain $\hat{d}^j$.

The modified j-level values $\hat{v}^j$ are computed in such a way that $\hat{v}^j = M^{-1}(\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^j)$. This is easily checked by adding up the two equalities in the for-loop of (4.2) and taking into account the consistency relation (2.4),

$$\hat{v}^j_{2i-1} + \hat{v}^j_{2i} = (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i-1} + (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i} = 2\hat{v}^{j-1}_i.$$

This implies that $D^j\hat{v}^j = \hat{v}^{j-1}$, $j = 1, \ldots, L$. Moreover,

$$\hat{d}^j_i = \hat{v}^j_{2i-1} - (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i-1} = -(\hat{v}^j_{2i} - (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i});$$

hence, the detail coefficients, $\{\hat{d}^j\}_{j=1}^L$, are the prediction errors for the data, $\{\hat{v}^j\}_{j=0}^L$. As a consequence, we have

$$M\hat{v}^j = (\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^j) \equiv M^{-1}(\hat{v}^0, \hat{d}^1, \ldots \hat{d}^j) = \hat{v}^j, \qquad j = 1, \ldots, L. \tag{4.3}$$

By embedding the quantizer into the transformation, as specified in **ECj**, synchronization follows: are used in both the encoder and the decoder in the decision step of the nonlinear prediction operator at each resolution level. This guarantees that exactly the same filter will be used at each location and resolution level both in the encoder and in the decoder.

We note the fact that synchronization in $\widetilde{M}_{\bar{\varepsilon}}$ is achieved of the definition of $\tilde{d}^j$, and that it will be attained independently of the source of the perturbation, as long as the perturbation can be correctly modeled in the encoder by the **proc** routine. For example $\hat{d}^j$ might represent the scale coefficients available in the decoder after compression effects and transmission errors have been taken into account. Clearly, random transmission errors will inevitably lead to a loss of synchronization.

4.1. Harten versus lifting: The definition of the prediction residuals. Written in the form (4.1) and (4.2), it is apparent that the difference between Harten's EC algorithms in [14] and the nonlinear lifting scheme in [7] lies precisely in the definition of $\tilde{d}^j$.

In [14], $\tilde{d}^j_i$ is defined as the average of odd and even prediction errors (**hc** stands for Harten's choice):

$$\tilde{d}^j = \mathbf{hc}(v^j, \hat{v}^{j-1}) \quad \begin{cases} \text{for } i = 1, \ldots, N_{j-1} \\ \quad \tilde{d}^j_i = \dfrac{1}{2}[(v^j_{2i-1} - (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i-1}) - (v^j_{2i} - (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i})] \\ \text{end,} \end{cases} \tag{4.4}$$

while in [7] two different definitions are considered:

$$\tilde{d}^j = \mathbf{pe1}(v^j, \hat{v}^{j-1}) \quad \begin{cases} \text{for } i = 1, \ldots, N_{j-1} \\ \quad \tilde{d}^j_i = v^j_{2i-1} - (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i-1} \\ \text{end,} \end{cases} \tag{4.5}$$

$$\tilde{d}^j = \mathbf{pe2}(v^j, v^{j-1}, \hat{v}^{j-1}) \quad \begin{cases} \text{for } i = 1, \ldots, N_{j-1} \\ \quad \tilde{d}^j_i = v^j_{2i-1} - (P_{\hat{v}^{j-1}}v^{j-1})_{2i-1} \\ \text{end.} \end{cases} \tag{4.6}$$

Notice that **pe1** and **hc** do not use the raw low-pass data v^{j-1}. Indeed the choice **pe1** is discarded in [7] and substituted by **pe2** because numerical experiments revealed that, even for moderate quantization levels, the prediction errors for **pe1** tend to be large, regardless of the prediction filter, thus reducing the compression potential of the adaptive algorithm.

Even though encoder/decoder synchronization is achieved independently of the definition of $\tilde{d}^j$, the following basic consistency requirement must be imposed: when no processing takes place, i.e., $\varepsilon_j = 0$ for all j, the modified transformation produces exactly the same outcome as the direct transformation, i.e., $\widetilde{M}_{\bar{0}} = M = MQ_{\bar{0}}$. If no compression is needed, the modified transformation becomes an alternative way to compute the multiscale representation Mv^L: it is simply a reordering in the computation of the detail coefficients.

PROPOSITION 4.1. [illegible] $\tilde{d}^j$ [illegible] (4.4), (4.5) [illegible] (4.6) [illegible] $\widetilde{M}_{\bar{\epsilon}}$ [illegible] $\widetilde{M}_{\bar{0}} = M$ [illegible]. For **pe1**, we easily deduce that

$$v^j_{2i-1} - \hat{v}^j_{2i-1} = \tilde{d}^j_i - \hat{d}^j_i, \qquad v^j_{2i} - \hat{v}^j_{2i} = 2(v^{j-1}_i - \hat{v}^{j-1}_i) - (\tilde{d}^j_i - \hat{d}^j_i). \tag{4.7}$$

For **hc** we have instead

$$\begin{aligned}(v^j - \hat{v}^j)_{2i-1} - (v^j - \hat{v}^j)_{2i} &= 2(\tilde{d}^j - \hat{d}^j)_i,\\ (v^j - \hat{v}^j)_{2i-1} + (v^j - \hat{v}^j)_{2i} &= 2(v^{j-1} - \hat{v}^{j-1})_i,\end{aligned}$$

and hence

$$v^j_{2i-1} - \hat{v}^j_{2i-1} = (v^{j-1}_i - \hat{v}^{j-1}_i) + (\tilde{d}^j_i - \hat{d}^j_i), \qquad v^j_{2i} - \hat{v}^j_{2i} = (v^{j-1}_i - \hat{v}^{j-1}_i) - (\tilde{d}^j_i - \hat{d}^j_i). \tag{4.8}$$

For **pe2**, we easily deduce from (4.6)

$$\begin{aligned}v^j_{2i-1} - \hat{v}^j_{2i-1} &= (P_{\hat{v}^{j-1}} v^{j-1})_{2i-1} - (P_{\hat{v}^{j-1}} \hat{v}^{j-1})_{2i-1} + \tilde{d}^j_i - \hat{d}^j_i,\\ v^j_{2i} - \hat{v}^j_{2i} &= (P_{\hat{v}^{j-1}} v^{j-1})_{2i} - (P_{\hat{v}^{j-1}} \hat{v}^{j-1})_{2i} - (\tilde{d}^j_i - \hat{d}^j_i).\end{aligned} \tag{4.9}$$

If no processing takes place, i.e., $\hat{v}^0 = v^0$ and $\hat{d}^j = \tilde{d}^j$, then either (4.7), (4.8), or (4.9) directly imply that $v^j_{2i-1} = \hat{v}^j_{2i-1}$ and $v^j_{2i} = \hat{v}^j_{2i}$. Therefore $\hat{v}^j = v^j$ for all j, i.e., $\widetilde{M}_{\bar{0}} \equiv M$ in all three cases. □

Relations (4.7), (4.8), (4.9) hold the key to the behavior of the resulting adaptive multiscale transformation. It is important to recall that the detail coefficients $\tilde{d}^j$ should correctly represent the error in predicting "raw" data at level j, from "known" data at level $j-1$. For **pe1** and **hc** the prediction error is $e^j = v^j - P_{\hat{v}^{j-1}} \hat{v}^{j-1}$. Consistency of the prediction operator implies $D^j e^j = v^{j-1} - \hat{v}^{j-1}$, and hence the even and odd components no longer satisfy $e^j_{2i} = -e^j_{2i-1}$. Thus, the **pe1** choice, which keeps only the odd prediction residuals, does not correctly represent the full prediction error; this, most likely, is the cause of the bad behavior observed in the numerical experiments reported in [7] when this choice of scale coefficients was implemented. On the other hand, in Harten's choice, **hc**, $\tilde{d}^j$ is computed as the average between the even and odd components of e^j, hence yielding a better representation of the the full prediction error.

For the choice in (4.6), the prediction error is $e^j = v^j - P_{\hat{v}^{j-1}} v^{j-1}$; hence as a consequence of the consistence of the prediction operator,

$$(P_{\hat{v}^{j-1}} v^{j-1})_{2i-1} + (P_{\hat{v}^{j-1}} v^{j-1})_{2i} = 2v^{j-1}_i = v^j_{2i-1} + v^j_{2i}$$

so that

$$v^j_{2i-1} - (P_{\hat{v}^{j-1}} v^{j-1})_{2i-1} = -(v^j_{2i} - (P_{\hat{v}^{j-1}} v^{j-1})_{2i}) \tag{4.10}$$

and we recover $e^j_{2i} = -e^j_{2i-1}$.

4.1. Notice that, in light of the observation above on the prediction error $v^j - P_{\hat{v}^{j-1}} v^{j-1}$, a fourth obvious alternative becomes equivalent to **pe2**

$$\tilde{d}^j_i = \frac{1}{2}[(v^j_{2i-1} - (P_{\hat{v}^{j-1}} v^{j-1})_{2i-1}) - (v^j_{2i} - (P_{\hat{v}^{j-1}} v^{j-1})_{2i})] = v^j_{2i-1} - (P_{\hat{v}^{j-1}} v^{j-1})_{2i-1}.$$

In [7], the authors provide no specific error bounds on the compression error. We shall exploit the connection between the synchronized nonlinear multiscale transformation in [7] and Harten's cell-average EC algorithms to demonstrate that the claim that stability follows from synchronization is essentially correct, at least for the type of nonlinear prediction schemes considered in section 3.

5. Error estimates for compression schemes based on the modified multiscale transformation. The goal in this section is to obtain precise estimates of the error between the original signal v^L and the signal obtained from decoding its compressed multiscale representation, i.e., $\hat{v}^L = M^{-1}\widetilde{M}_{\bar{\varepsilon}} v^L$, with $\widetilde{M}_{\bar{\epsilon}}$ as specified in (4.1)–(4.2).

For ease of reference we fix the notation as follows:

- UFL1 refers to $\widetilde{M}_{\bar{\epsilon}}$ with **pe** = **pe1** as specified in (4.5). This is the first (discarded) choice for scale coefficients in [7], and hence the acronym stands for update-first lifting, choice 1.
- HC refers to $\widetilde{M}_{\bar{\epsilon}}$ with **pe** = **hc** as specified in (4.4). This corresponds to Harten's original choice of scale coefficients in his EC algorithms.
- UFL2 refers to $\widetilde{M}_{\bar{\epsilon}}$ with **pe** = **pe2** as specified in (4.6). This corresponds to the preferred choice of scale coefficients in [7], and the acronym stands for update-first lifting, choice 2.

For the remainder of the paper we use the same notation as in [14, 15, 1]: Given a $v^j \in V^j$, a finite-dimensional signal with N_j samples, we define

$$\|v^j\|_\infty = \sup_i |v^j_i|; \quad \|v^j\|_1 = \frac{1}{N_j}\left(\sum_i^{N_j} |v^j_i|\right); \quad \|v^j\|_2^2 = \frac{1}{N_j}\left(\sum_i^{N_j} |v^j_i|^2\right) \tag{5.1}$$

and give two types of error estimates. We obtain first [illegible] error estimates, i.e., error estimates obtained in terms of the differences $\|\hat{d}^i - \tilde{d}^i\|$, $\|\hat{v}^0 - v^0\|$, which can be computed as the algorithm proceeds. They provide estimates on the accumulated compression error $||v^j - \hat{v}^j||$ at each resolution level and, hence, a bound on the global compression error already at the encoder. From these, we can easily deduce error bounds in terms of the threshold parameters $\bar{\varepsilon} = (\varepsilon_0, \ldots, \varepsilon_L)$ which could be used to ensure a certain accuracy in the decoded representation a priori and, hence, are referred to as [illegible] error bounds.

The compression error bounds obtained next reveal that Harten's choice seems to be optimal: distributing evenly the quantization error between odd and even locations, as done in **hc**, allows us to obtain more accurate global bounds on the compression error. It is a remarkable fact, which Harten did not notice, that the [illegible] of the 2-norm of the compression error can be computed in the encoder (see Remark 5.1 and [1]).

5.1. A posteriori error bounds. The structure of the modified transformation allows us to prove that estimates of the form

$$||v^L - \hat{v}^L|| \le C_0||v^0 - \hat{v}^0|| + \sum_{j=1}^{L} C_j||\tilde{d}^j - \hat{d}^j||$$

hold for the UFL1, HC, and UFL2 algorithms. For the latter, the estimates are obtained provided the prediction operators satisfy certain uniform bounds. The constants depend on the choice made for $\tilde{d}^j$ and the norm considered.

PROPOSITION 5.1. [illegible] v^L [illegible] $\hat{v}_d = \widetilde{M}_{\bar{\epsilon}} v^L = (\hat{v}^0, \hat{d}^1, \dots, \hat{d}^L)$ [illegible] $\hat{v}^L = M^{-1}\hat{v}_d$ [illegible] M^{-1} [illegible] (2.5) [illegible] $\widetilde{M}_{\bar{\epsilon}}$ [illegible] (4.1)–(4.2) [illegible] (4.5), (4.4), [illegible] (4.6) [illegible]

$$\|v^L - \hat{v}^L\|_p \le C_{0,p}\|v^0 - \hat{v}^0\|_p + \sum_{j=1}^{L} C_{j,p}\|\tilde{d}^j - \hat{d}^j\|_p, \quad p = \infty, 1, \tag{5.2}$$

$$\|v^L - \hat{v}^L\|_2^2 \le C_{0,2}\|v^0 - \hat{v}^0\|_2^2 + \sum_{j=1}^{L} C_{j,2}\|\tilde{d}^j - \hat{d}^j\|_2^2, \tag{5.3}$$

[illegible]

$C_{0,p}$	[illegible] 1	[illegible]	[illegible] 2
$p = \infty$	2^L	1	$\mathcal{B}_\infty^L$
$p = 1$	1	1	$\mathcal{B}_1^L$
$p = 2$	3^L	1	$2^L\mathcal{B}_2^{2L}$

$C_{j,p}$	[illegible] 1	[illegible]	[illegible] 2
$p = \infty$	2^{L-j}	1	$\mathcal{B}_\infty^{L-j}$
$p = 1$	1	1	$\mathcal{B}_1^{L-j}$
$p = 2$	$2 \cdot 3^{L-j}$	1	$2(2\mathcal{B}_2^2)^{L-j}$

[illegible] $\mathcal{B}_p$ [illegible] j [illegible]

$$||P_{\hat{v}^j}(w^j)||_p \le \mathcal{B}_p||w^j||_p, \quad \forall \hat{v}^j \in V^j. \tag{5.4}$$

[illegible] $P_{\hat{v}^j}$ We shall establish two-level estimates in all three cases. The global estimates are easily found by setting $j = L$ and applying recursively the two-level estimates.

Let us consider first the UFL1 choice. At each level, we use (4.7) to obtain

$$\begin{aligned}
&\max\{|v_{2i-1}^j - \hat{v}_{2i-1}^j|, |v_{2i}^j - \hat{v}_{2i}^j|\} \le 2|v_i^{j-1} - \hat{v}_i^{j-1}| + |\tilde{d}_i^j - \hat{d}_i^j|,\\
&(|v_{2i-1}^j - \hat{v}_{2i-1}^j| + |v_{2i}^j - \hat{v}_{2i}^j|) \le (2|\tilde{d}_i^j - \hat{d}_i^j| + 2|v_i^{j-1} - \hat{v}_i^{j-1}|),\\
&(v_{2i-1}^j - \hat{v}_{2i-1}^j)^2 + (v_{2i}^j - \hat{v}_{2i}^j)^2 = 4(v_i^{j-1} - \hat{v}_i^{j-1})^2 + 2(\tilde{d}_i^j - \hat{d}_i^j)^2 - 4(v_i^{j-1} - \hat{v}_i^{j-1})(\tilde{d}_i^j - \hat{d}_i^j)\\
&\qquad\qquad \le 6(v_i^{j-1} - \hat{v}_i^{j-1})^2 + 4(\tilde{d}_i^j - \hat{d}_i^j)^2.
\end{aligned}$$

Hence

$$\|v^j - \hat{v}^j\|_\infty \le 2\|v^{j-1} - \hat{v}^{j-1}\|_\infty + \|\tilde{d}^j - \hat{d}^j\|_\infty,$$

$$\|v^j - \hat{v}^j\|_1 = \frac{1}{N_j}\sum_{i=1}^{N_{j-1}}(|v^j_{2i-1} - \hat{v}^j_{2i-1}| + |v^j_{2i} - \hat{v}^j_{2i}|)$$
$$\leq \frac{1}{2N_{j-1}}\sum_{i=1}^{N_{j-1}}(2|\tilde{d}^j_i - \hat{d}^j_i| + 2|v^{j-1}_i - \hat{v}^{j-1}_i|) = \|\tilde{d}^j - \hat{d}^j\|_1 + \|v^{j-1} - \hat{v}^{j-1}\|_1,$$
$$\|v^j - \hat{v}^j\|_2^2 = \frac{1}{N_j}\sum_{i=1}^{N_{j-1}}(|v^j_{2i-1} - \hat{v}^j_{2i-1}|^2 + |v^j_{2i} - \hat{v}^j_{2i}|^2)$$
$$\leq 3\|v^{j-1} - \hat{v}^{j-1}\|_2^2 + 2\|\tilde{d}^j - \hat{d}^j\|_2^2.$$

For Harten's original choice, HC, we use the equality $\max(|a|,|b|) = (|a+b|+|a-b|)/2$ together with relation (4.8) to obtain

$$\max\{|v^j_{2i-1} - \hat{v}^j_{2i-1}|, |v^j_{2i} - \hat{v}^j_{2i}|\} = |\tilde{d}^j_i - \hat{d}^j_i| + |v^{j-1}_i - \hat{v}^{j-1}_i|,$$

$$|v^j_{2i-1} - \hat{v}^j_{2i-1}| + |v^j_{2i} - \hat{v}^j_{2i}| = \max(|\tilde{d}^j_i - \hat{d}^j_i|, |v^{j-1}_i - \hat{v}^{j-1}_i|),$$

$$|v^j_{2i-1} - \hat{v}^j_{2i-1}|^2 + |v^j_{2i} - \hat{v}^j_{2i}|^2 = (2|\tilde{d}^j_i - \hat{d}^j_i|^2 + 2|v^{j-1}_i - \hat{v}^{j-1}_i|^2).$$

Hence

$$\|v^j - \hat{v}^j\|_\infty \;\leq\; \|v^{j-1} - \hat{v}^{j-1}\|_\infty + \|\tilde{d}^j - \hat{d}^j\|_\infty,$$

$$\|v^j - \hat{v}^j\|_1 = \frac{1}{N_{j-1}}\sum_{i=1}^{N_{j-1}}\max(|\tilde{d}^j_i - \hat{d}^j_i|, |v^{j-1}_i - \hat{v}^{j-1}_i|)$$
$$\leq \frac{1}{N_{j-1}}\sum_{i=1}^{N_{j-1}}|\tilde{d}^j_i - \hat{d}^j_i| + |v^{j-1}_i - \hat{v}^{j-1}_i| = \|\tilde{d}^j - \hat{d}^j\|_1 + \|v^{j-1} - \hat{v}^{j-1}\|_1,$$

$$\|v^j - \hat{v}^j\|_2^2 = \frac{1}{2N_{j-1}}\sum_{i=1}^{N_{j-1}}(2|\tilde{d}^j_i - \hat{d}^j_i|^2 + 2|v^{j-1}_i - \hat{v}^{j-1}_i|^2) = \|\tilde{d}^j - \hat{d}^j\|_2^2 + \|v^{j-1} - \hat{v}^{j-1}\|_2^2,$$

from which (5.5) follows.

We consider lastly the UFL2 choice. Notice that $P_{\hat{v}^j}$ acts linearly on the data, and hence we have

$$(P_{\hat{v}^{j-1}}v^{j-1})_k - (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_k = (P_{\hat{v}^{j-1}}(v^{j-1} - \hat{v}^{j-1}))_k$$

so that under the hypothesis of the proposition

$$||P_{\hat{v}^{j-1}}v^{j-1} - P_{\hat{v}^{j-1}}\hat{v}^{j-1}||_p \leq \mathcal{B}_p||v^{j-1} - \hat{v}^{j-1}||_p.$$

From (4.9) we get

$$\max_i|v^j_{2i-1} - \hat{v}^j_{2i-1}| \leq \max_i|\tilde{d}^j_i - \hat{d}^j_i| + \max_i|(P_{\hat{v}^{j-1}}v^{j-1})_{2i-1} - (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i-1}|,$$

$$\max_i|v^j_{2i} - \hat{v}^j_{2i}| \leq \max_i|\tilde{d}^j_i - \hat{d}^j_i| + \max_i|(P_{\hat{v}^{j-1}}v^{j-1})_{2i} - (P_{\hat{v}^{j-1}}\hat{v}^{j-1})_{2i}|.$$

Hence

$$||v^j - \hat{v}^j||_\infty \leq ||\tilde{d}^j - \hat{d}^j||_\infty + \mathcal{B}_\infty ||v^{j-1} - \hat{v}^{j-1}||_\infty,$$

$$\begin{aligned}\|v^j - \hat{v}^j\|_1 &\leq \frac{1}{2N_{j-1}} \sum_{i=1}^{N_{j-1}} 2|\tilde{d}_i^j - \hat{d}_i^j| + \frac{1}{N_j} \sum_{i=1}^{N_j} |(P_{\hat{v}^{j-1}} v^{j-1})_i - (P_{\hat{v}^{j-1}} \hat{v}^{j-1})_i| \\ &= \|\tilde{d}^j - \hat{d}^j\|_1 + \|P_{\hat{v}^{j-1}}(v^{j-1} - \hat{v}^{j-1})\|_1 \leq \|\tilde{d}^j - \hat{d}^j\|_1 + \mathcal{B}_1 \|v^{j-1} - \hat{v}^{j-1}\|_1,\end{aligned}$$

$$\begin{aligned}\|v^j - \hat{v}^j\|_2^2 &\leq \frac{1}{N_j} \sum_{i=1}^{N_{j-1}} 4(\tilde{d}_i^j - \hat{d}_i^j)^2 + 2\frac{1}{N_j} \sum_{i=1}^{N_j} ((P_{\hat{v}^{j-1}} v^{j-1})_i - (P_{\hat{v}^{j-1}} \hat{v}^{j-1})_i)^2 \\ &= 2\|\tilde{d}^j - \hat{d}^j\|_2^2 + 2\|P_{\hat{v}^{j-1}}(v^{j-1} - \hat{v}^{j-1})\|_2^2 \\ &\leq 2\|\tilde{d}^j - \hat{d}^j\|_2^2 + 2(\mathcal{B}_2)^2 \|v^{j-1} - \hat{v}^{j-1}\|_2^2. \qquad \square\end{aligned}$$

[illegible] 5.1. Notice that for HC (and [illegible] for HC) we obtain

$$\|v^L - \hat{v}^L\|_2^2 = \|v^0 - \hat{v}^0\|_2^2 + \sum_{j=1}^{L} \|\tilde{d}^j - \hat{d}^j\|_2^2. \tag{5.5}$$

Therefore, the 2-compression error $||v^L - M^{-1}\widetilde{M}_\varepsilon v^L||_2$ can be exactly known at the encoder.

Uniform bounds as described in (5.4) can be computed for all the nonlinear prediction operators of the type considered in section 3, as well as those in [7], as follows: Recall that for a fixed v^j, the operator $P_{v^j} : V^j \to V^{j+1}$ is linear. Since V^j is a linear vector space of dimension N_j, P_{v^j} can be reinterpreted as a linear mapping $P_{v^j} : \mathbb{R}^{N_j} \longrightarrow \mathbb{R}^{N_{j+1}}$, and hence it can be represented as an $N_{j+1} \times N_j$ matrix. To compute the uniform bounds, we simply use standard linear algebra results for matrix norms. We take into account that the relation between the p-norms in $\mathbb{R}^{N_j}$ and the p-norms defined in (5.1) is as follows:

(5.6)
$$||w^j||_{l^\infty(\mathbb{R}^{N_j})} = ||w^j||_\infty, \qquad ||w^j||_{l^1(\mathbb{R}^{N_j})} = N_j ||w^j||_1, \qquad ||w^j||^2_{l^2(\mathbb{R}^{N_j})} = N_j ||w^j||_2^2.$$

Proposition 5.2. [illegible] 5.1 [illegible]

$$\mathcal{B}_\infty = \sup\{||P_{v^j}||_{l^\infty(\mathbb{R}^{N_j}, \mathbb{R}^{N_{j+1}})}, \quad v^j \in \mathbb{R}^{N_j}\}, \tag{5.7}$$

$$\mathcal{B}_1 = \frac{1}{2} \sup\{||P_{v^j}||_{l^1(\mathbb{R}^{N_j}, \mathbb{R}^{N_{j+1}})}, \ v^j \in \mathbb{R}^{N_j}\}, \tag{5.8}$$

$$\mathcal{B}_2 = \frac{1}{\sqrt{2}} \sup\{||P_{v^j}||_{l^2(\mathbb{R}^{N_j}, \mathbb{R}^{N_{j+1}})}, \ v^j \in \mathbb{R}^{N_j}\}. \tag{5.9}$$

[illegible] Since $P_{v^j} : \mathbb{R}^{N_j} \longrightarrow \mathbb{R}^{N_{j+1}}$ is a linear mapping, we have

$$||P_{v^j} w^j||_{l^p(\mathbb{R}^{N_{j+1}})} \leq ||P_{v^j}||_{l^p(\mathbb{R}^{N_j}, \mathbb{R}^{N_{j+1}})} ||w^j||_{l^p(\mathbb{R}^{N_j})}.$$

Using the relation between the p-norms in $\mathbb{R}^{N_j}$ and the p-norms in V^j, we easily obtain the result. $\square$

TABLE 5.1
Coefficients $\mathcal{B}_p$, $p = \infty, 1, 2$, for various prediction operators.

Prediction	$\mathcal{B}_\infty$	$\mathcal{B}_1$	$\mathcal{B}_2$
Linear-2	1.25	1.25	1.0308
ENO-2	2	2.25	1.5416
ENO-SR-2	7	11	6.0725
Linear-4	1.3907	1.3907	1.0614
ENO-4	3.5	4.8750	3.009
ENO-SR-4	19.25	25.3438	18.4715

For data-dependent prediction schemes of the type considered in [7] and in this paper, P_{v^j} can be represented as a banded matrix whose rows are composed of a finite number of nonzero entries. The rows depend on the data v^j but can only be chosen from a finite pool; e.g., for ENO predictors of degree R, the pool is composed of $R+1$ filters; for ENO-SR predictors the pool has $R+3$ filters (see section 3).

A simple MATLAB program can grind up the $\mathcal{B}_p$ uniform bounds. Some of these bounds are compiled in Table 5.1. We have also included the data-independent biorthogonal wavelet prediction operator (linear-R). In this case $P_{\hat{v}^{j-1}} = P_j$ is a specific $N_{j+1} \times N_j$ banded matrix and $\mathcal{B}_p = \|P_j\|_p$.

5.2. "A priori" error bounds. In applications, the processing step for the detail coefficients is carried out in such a way that $||\tilde{d}^j - \hat{d}^j|| \le \varepsilon_j$, $||v^0 - \hat{v}^0|| \le \varepsilon_0$ is ensured for a predetermined norm. Then Proposition 5.1 leads to simple error bounds that depend only on the processing parameters ε_j and that can be used to guarantee, a priori, a certain accuracy in the decoded signal.

COROLLARY 5.3. [illegible] 5.1 [illegible]

$$||\tilde{d}^j - \hat{d}^j|| \le \varepsilon_j, \quad ||v^0 - \hat{v}^0|| \le \varepsilon_0,$$

[illegible]
[illegible] 1 [illegible]

$$||v^L - \hat{v}^L||_\infty \le \sum_{j=0}^{L} 2^{L-j}\varepsilon_j, \quad ||v^L - \hat{v}^L||_1 \le \sum_{j=0}^{L} \varepsilon_j, \quad ||v^L - \hat{v}^L||_2^2 \le 3^L\varepsilon_0^2 + 2\sum_{j=1}^{L} 3^{L-j}\varepsilon_j^2.$$

[illegible]

$$||v^L - \hat{v}^L||_p \le \sum_{j=0}^{L} \varepsilon_j, \quad p = \infty, 1, \qquad ||v^L - \hat{v}^L||_2^2 \le \sum_{j=0}^{L} \varepsilon_j^2.$$

[illegible] 2 [illegible]

$$||v^L - \hat{v}^L||_p \le \sum_{j=0}^{L} (\mathcal{B}_p)^{L-j}\varepsilon_j, \quad p = \infty, 1, \qquad ||v^L - \hat{v}^L||_2^2 \le \sum_{j=0}^{L} (2(\mathcal{B}_2)^2)^{L-j}\varepsilon_j^2.$$

This corollary suggests appropriate processing strategies to ensure a target accuracy in the decompressed signal. In particular, choosing the processing parameters of the form

$$\varepsilon_j = \varepsilon/q^{L-j},$$

with q a given number, leads to a priori estimates of the form

$$||v^L - \hat{v}^L|| \leq \varepsilon \sum_{j=0}^{L} \alpha^{L-j},$$

where, according to Corollary 5.3, α depends on the specific strategy being used. In order to have an a priori error estimate independent of L we need $\alpha < 1$. It is worth noting that $q = 2$ is "appropriate" for the HC strategy, while the "appropriate" q for the UFL2 strategy would depend on the quantities $\mathcal{B}_p$.

6. Tensor product algorithms in two dimensions. In the 2D tensor-product extension of the algorithms described in section 4, synchronization follows, exactly as in the 1D case, from the fact that $M^{-1}(\hat{v}^0, \hat{d}^1, \ldots, \hat{d}^j) = \hat{v}^j$, $j = 1, \ldots, L$. This is due to the structure of the **ECj** routine, independently of the definition for $\tilde{d}^j$. It should be remarked that, due to the intertwined structure of the error control algorithm, the details, $\tilde{d}^j$, will be different (but of the same order of magnitude) if one acts first on the rows or first on the columns. This, however, does not affect the synchrony between the prediction in the encoder and decoder, or the error bounds obtained.

A 2D tensor-product version of the modified transformation $\widetilde{M}_{\bar{\varepsilon}}$ together with the **hc** strategy has been described in [1], where the authors carry out a computational study on the performance of this particular algorithm for various linear and nonlinear prediction operators. The tensor product strategy allows us to obtain 2D error bounds in much the same way as in the 1D case. A posteriori bounds relate the global accumulated error $||v^L - M^{-1}\widetilde{M}_{\bar{\varepsilon}} v^L||$ to the differences $||v^0 - \hat{v}^0||$ and $||\tilde{d}^j - \hat{d}^j||$ for a given norm. A priori error bounds relate the global accumulated error to the processing parameters ε_j.

In the following proposition the modified transformation $\widetilde{M}_{\bar{\varepsilon}}$ is the 2D tensor product extension of Algorithm 1, as described in [1]. The acronyms are the same as in last section and the norm definitions for 2D signals are [15, 1]

(6.1)

$$\|v^j\|_\infty = \sup_{k,l} |v^j_{k,l}|; \quad \|v^j\|_1 = \frac{1}{N_j^2} \left(\sum_{k,l}^{N_j} |v^j_{k,l}| \right); \quad \|v^j\|_2^2 = \frac{1}{N_j^2} \left(\sum_{k,l}^{N_j} |v^j_{k,l}|^2 \right).$$

As in [15, 1], we assume that the processing strategy for the scale coefficients is such that

$$\|\tilde{d}^j(m) - \hat{d}^j(m)\|_p \leq \varepsilon_j, \qquad m = 1, 2, 3. \tag{6.2}$$

PROPOSITION 6.1. [illegible] 2 [illegible] v^L [illegible] $\hat{v}_d = \widetilde{M}_{\bar{\varepsilon}} v^L$ [illegible] $\hat{v}^L = M^{-1}\hat{v}_d$ [illegible]

$$\begin{aligned} \|v^L - \hat{v}^L\|_\infty \leq C_{0,\infty} \|v^0 - \hat{v}^0\|_\infty + \sum_{j=1}^{L} C^2_{j,\infty} \|\tilde{d}^j(2) - \hat{d}^j(2)\|_\infty \\ + \sum_{j=1}^{L} C^*_{j,\infty} \max \left\{ \|\tilde{d}^j(1) - \hat{d}^j(1)\|_\infty, \|\tilde{d}^j(3) - \hat{d}^j(3)\|_\infty \right\}, \end{aligned} \tag{6.3}$$

6.1 $\mathcal{B}_p$ 1 (5.4)

Proofs for the HC strategy can be found in [1]; the proofs corresponding to the other two cases are found exactly in the same manner, using the corresponding estimates for the univariate case.

For the HC-strategy, it is worth mentioning that, as in the univariate case, the 2-norm of the compression error can be computed (the a posteriori error estimate in the proposition above is indeed an equality; see [1] for details).

From the a posteriori estimates, it is easy to obtain a priori bounds. As in the univariate case, these lead to estimates of the form

$$\|v^L-\hat v^L\|_p \le C_p\varepsilon$$

for appropriate choices of the parameter vector $\bar\epsilon = (\varepsilon_0,\dots,\varepsilon_L)$. These bounds, however, seem to be useless for the practical compression of 2D signals, except for the case of the HC strategy.

7. Numerical experiments. The theoretical study carried out in the previous sections allows us to conclude that the modified transformation $\widetilde{M}_{\bar\varepsilon}$ ensures an explicit control on the compression error, independently of the particular form used for the computation of the prediction residuals. In this section, we carry out a numerical comparison of the different techniques considered in this paper for the computation of the scale coefficients in $\widetilde{M}_{\bar\varepsilon}$.

The results in Proposition 5.1 point out that the UFL1 and HC versions of $\widetilde{M}_{\bar\varepsilon}$ lead to error bounds that are independent of the prediction operators, while a strong dependence on the specific form of the prediction scheme is to be expected for the UFL2 version. We shall numerically demonstrate this dependence by performing a series of numerical tests on the image depicted in the leftmost corner of Figure 7.5. The image has 512×512 pixel values and we shall consider $L=4$ in the multiscale transformations.

In our numerical tests, we use prediction operators derived from piecewise polynomial average interpolation, as described in section 3, with $R = 2s$. Each prediction scheme is identified by an acronym which refers to the type of reconstruction that serves to define it, as follows:

- FcS-R: Fixed (centered) stencil polynomial pieces of degree R, as specified in section 3.1.
- ENO-R: ENO polynomial pieces of degree R as described in section 3.2.
- ENO-SR-R: ENO-R polynomial pieces, together with the subcell resolution technique (see section 3.3).

The order of the corresponding prediction schemes is $R + 1$ in all cases.

Once the prediction scheme is specified, the compressed multiscale representation of the image, i.e., $\hat{v}_d$, can be obtained in two different ways:

1. the [illegible] way (acronym ST henceforth), i.e., $\hat{v}_d^{ST} = Q_{\bar{\epsilon}} M v^L$, M being the direct multiscale transformation specified in (2.5);
2. using the synchronized [illegible] transformation described in (4.1), i.e., $\hat{v}_d^M = \widetilde{M}_{\bar{\epsilon}} v^L$.

In the latter case, the choice made for the computation of $\tilde{d}^j$ identifies the multiresolution scheme, as in section 5. We recall the acronyms that shall be used throughout this section:

- UFL1 refers to $\widetilde{M}_{\bar{\epsilon}}$ with $\mathbf{pe} = \mathbf{pe1}$ as specified in (4.5).
- HC (Harten's choice) refers to $\widetilde{M}_{\bar{\epsilon}}$ with $\mathbf{pe} = \mathbf{hc}$ as specified in (4.4).
- UFL2 (update-first-lifting choice) refers to $\widetilde{M}_{\bar{\epsilon}}$ with $\mathbf{pe} = \mathbf{pe2}$ as specified in (4.6).

The notation used in the caption of each of the figures should be self-explanatory, e.g., UFL1-ENO-2 refers to computing $\hat{v}_d = \widetilde{M}_{\bar{\epsilon}} v^L$ with (4.5) for the definition of $\tilde{d}^j$ and an ENO nonlinear prediction operator with polynomial pieces of degree $R = 2$. On the other hand ST-ENO-2 refers to computing $\hat{v}^d = Q_{\bar{\epsilon}} M v^L$ with an ENO-2 prediction operator in the direct transformation M.

The reconstructed image is always obtained from the compressed representation by applying the inverse multiscale transformation, i.e., $\hat{v}^L = M^{-1} \hat{v}_d$.

[illegible] 7.1. We recall that the multiscale transformation M obtained from a prediction operator based on FcS-R with $R = 2s$ corresponds to the biorthogonal wavelet $(1, R + 1 = 2s + 1)$ transformation. Hence ST-FcS-R will always be referred to as BOW$(1, R + 1)$.

For the sake of simplicity we shall consider only the simplest processing technique: thresholding according to a level-dependent parameter vector, $\bar{\varepsilon} = (\varepsilon_0, \varepsilon_1, \ldots, \varepsilon_L)$,

$$\hat{d}^j = \mathbf{proc}(\tilde{d}^j, \varepsilon_j) = \begin{cases} 0 & \text{if } |\tilde{d}^j| \le \varepsilon_j, \\ \tilde{d}^j & \text{otherwise.} \end{cases} \tag{7.1}$$

In all cases, we choose the parameter vector as $\varepsilon_j = \varepsilon / 2^{L-j+1}$, or, equivalently, $\varepsilon_L = \varepsilon/2$, $\varepsilon_j = \varepsilon_{j+1}/2$; in addition, and unless specifically stated, we use $v^0 = \hat{v}^0$. In this manner, ε is the only free parameter in the compression algorithm.

7.1. Stability bounds. In Figure 7.1 we plot the 2-norm of the compression error, $||v^L - \hat{v}^L||_2$, versus the compression parameter ε. In the left plot we show the results when using a linear (data-independent) prediction scheme, FcS-2 in this case. We readily observe that computing the compressed representation as $\hat{v}_d^{ST} = Q_{\bar{\epsilon}} M v^L$ or as $\hat{v}_d^M = \widetilde{M}_{\bar{\epsilon}} v^L$ does not alter the stability properties of the transform coding algorithm. In particular, the stability-behavior of the transform coding algorithm

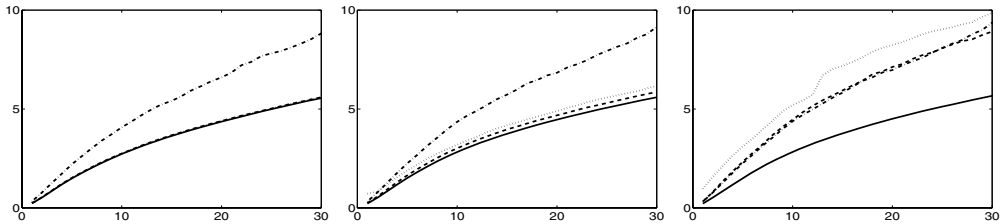

FIG. 7.1. *Plots of the compression error,* $||v^L - \hat{v}^L||_2$*, versus* ε *for the peppers image. Line convention: the* dotted line *corresponds to* $\hat{v}^L = M^{-1}Q_{\tilde{\epsilon}}Mv^L$ *(ST). Other cases,* $\hat{v}^L = M^{-1}\widetilde{M}_{\tilde{\epsilon}}v^L$ *with UFL1 (dash-dot), UFL2 (dashed), HC (solid). Left plot: FcS-2 prediction. Middle plot: ENO-2 prediction. Right plot: ENO-SR-2 prediction.*

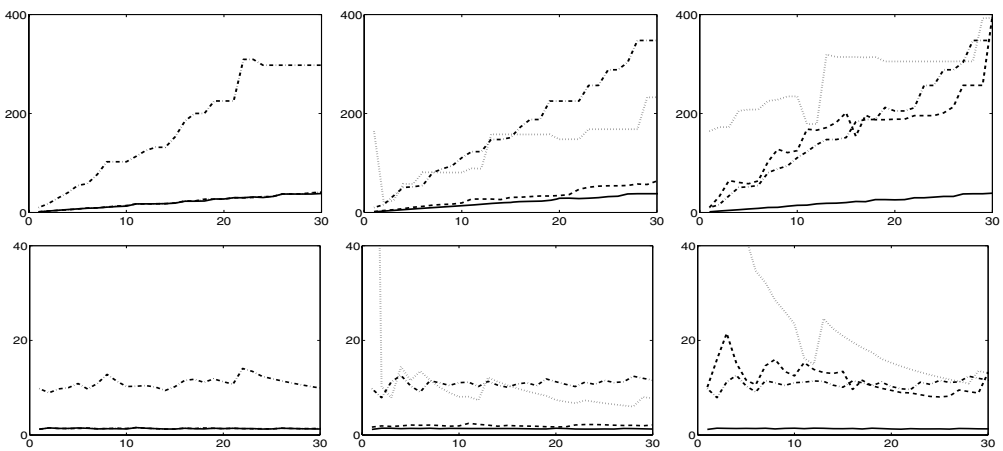

FIG. 7.2. *Top:* $||v^L - \hat{v}^L||_\infty$ *versus* $\varepsilon(q = 2)$*. Bottom:* $||v^L - \hat{v}^L||_\infty/\varepsilon$ *versus* $\varepsilon(q = 2)$*. Peppers image. is absolutely equivalent for either ST or the HC and UFL2 versions of the modified transform. We shall see in further tests that this is always the case for linear prediction operators (see also [1] for further comparisons between HC and ST).

The middle and right plots in Figure 7.1 correspond to nonlinear prediction operators of the same order, in this case ENO-2 and ENO-SR-2, respectively. The behavior of the dotted line, which corresponds to ST, confirms a relatively well-known fact: the compression error $||v^L - M^{-1}\hat{v}_d^{ST}||$ does not tend to zero with ϵ when using ENO and ENO-SR nonlinear prediction schemes in the direct multiscale transformation M. The same behavior is observed for the ∞-norm, in the top row of Figure 7.2, and also for the 1-norm (not shown).

In Figures 7.2 (bottom row) and 7.3, we plot $||v^L - \hat{v}^L||_p/\epsilon$ $(p = \infty, 2)$. The plots on the middle and right of Figure 7.3 further confirm that a bound of type $||v^L - \hat{v}^L||_2 \leq C\epsilon$ does not hold when using a nonlinear prediction operator to compute $\hat{v}_d = Q_{\tilde{\epsilon}}Mv^L$.

This should be compared with the stable behavior, in the sense of (1.2), displayed by all the versions of the modified transformation $\widetilde{M}_{\tilde{\epsilon}}$ described in section 5. In Figures 7.1, 7.2, and 7.3, it can be readily appreciated that the stability bounds for HC are not influenced by the choice of prediction scheme: exactly the same behavior

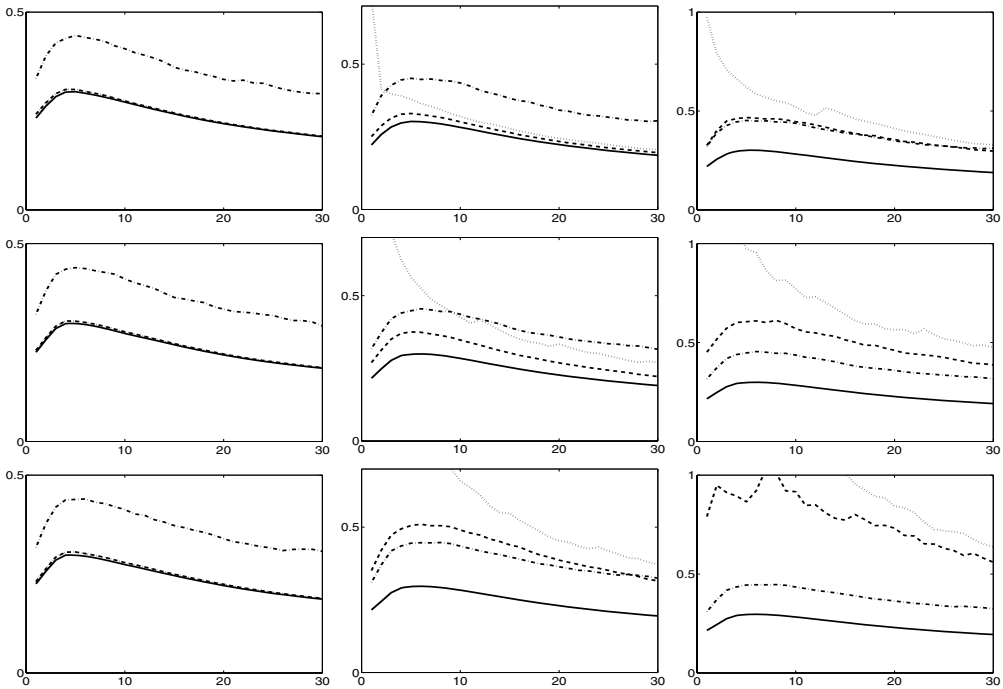

FIG. 7.3. *Plot of* $||v^L - \hat{v}^L||_2/\varepsilon$ *versus* ε *for the peppers image. Same line convention as in Figure* 7.1. *Left column: FcS-R prediction scheme. Middle column: ENO-R prediction scheme. Right column: ENO-SR-R prediction scheme. Top row:* $R = 2$. *Middle row:* $R = 4$. *Bottom row:* $R = 6$.

is observed for the linear or nonlinear prediction operators, independently of their order. The same can be said of UFL1, although the stability bounds are larger for this choice (in agreement with the theoretical observations). It is here where we find the most important difference between HC and UFL2: the UFL2 choice displays a heavy dependence on the specific form of the prediction scheme. As mentioned before, it is interesting to note that the behavior of HC and UFL2 is absolutely similar for [illegible] (FcS-R). It is only when using nonlinear prediction schemes that the two choices behave differently.

Our numerical tests (in particular results in Figures 7.3 and 7.4) seem to indicate that nonlinear predictors such as those used in [7], which reduce the length of the filter when approaching a previously detected edge, should be more appropriate than ENO predictors, which maintain the length of the filter and the order of the reconstruction close to the edges, when using the UFL2 version of the modified transformation, as proposed by Claypoole et al. A full comparison between the prediction proposed in [7] and ENO predictors is, however, beyond the scope of this paper.

A comment on the reliability and sharpness of the error bounds is appropriate here: The results on the peppers image show that we have $||v^L - \hat{v}^L||_2 \leq 0.4\epsilon$ for the HC strategy. This is consistent with the numerical experiments presented in [2, 1], and the same behavior has been observed in all other images for which the algorithm has been applied. This "experimental" bound is smaller than the theoretical error bound of section 6, but of the same order of magnitude. Hence, the theoretical error bounds can still be used for the HC strategy, while they are useless overestimations for the UFL1 and UFL2 cases.

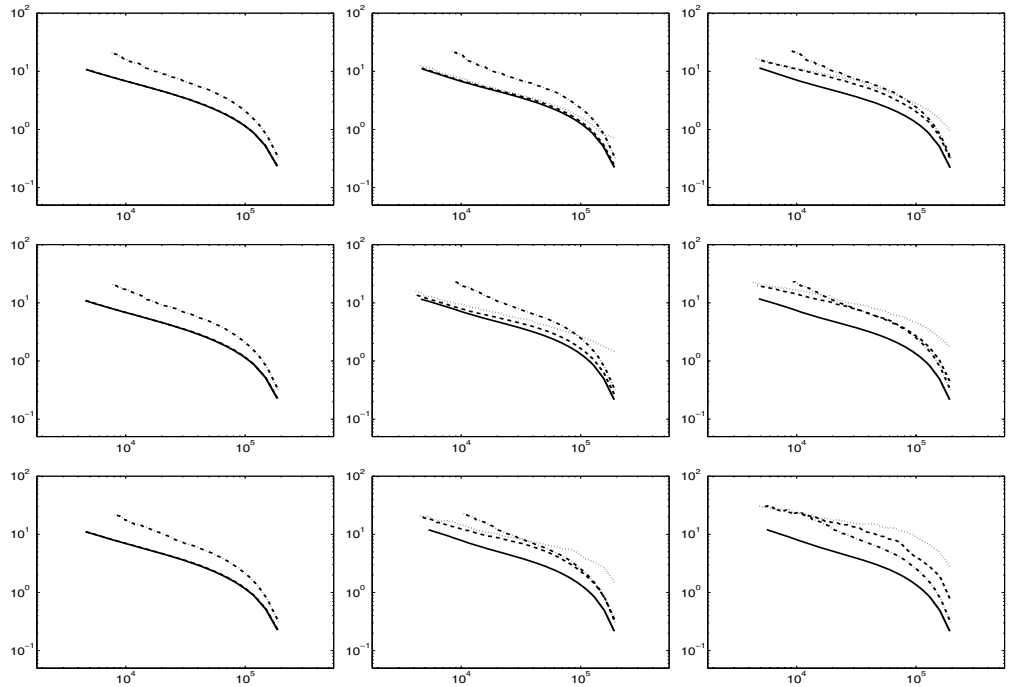

FIG. 7.4. $\log ||v^L - \hat{v}^L||_2$ *versus the number of nonzero details in* $\hat{v}^L$ *for the peppers image. Same line convention as in Figure* 7.1. *Left column: FcS-R prediction scheme. Middle column: ENO-R prediction scheme. Right column: ENO-SR-R prediction scheme. Top row:* $R = 2$. *Middle row:* $R = 4$. *Bottom row:* $R = 6$.

7.2. Compression performance versus quality. To compare the compression performance of the different synchronization strategies we focus on the error curves with respect to the number of preserved coefficients.

Some results are displayed in Figure 7.4 for $R = 2, 4$, and 6. Here, we also observe that UFL2, HC, and ST are essentially equivalent for linear prediction schemes. For ENO predictors, HC is more efficient than UFL2 (smaller error for the same compression rate), and the difference between both alternatives becomes more important for higher order predictors. For the ENO-SR case, the HC alternative is always clearly superior to the others.

We focus next on the [illegible] of the reconstructed images. In Figure 7.5 we show the original peppers image and, for the sake of comparison, the reconstructed figure $\hat{v}^L = M^{-1}Q_{\bar{\epsilon}}Mv^L$ with M a linear BOW$(1, 3)$-transform. The latter has been obtained from approximately 4000 nonzero details (see Table 7.1), and we readily observe the typical [illegible] effect at the image edges, characteristic of compression schemes based on linear multiscale transformations.

Since ENO-SR predictors seem to accentuate the differences between the various compression strategies, we display in Figure 7.6 the reconstructed images obtained (from approximately 4000 nonzero details; see Table 7.1) when using ENO-SR-2 prediction schemes in $\widetilde{M}_{\bar{\epsilon}}$ for each one of the options under consideration. The actual compression errors in various norms are also shown in Table 7.1 (right).

From the results compiled in the table, we observe that [illegible] the HC algorithm maintains the best accuracy not only on the L_2-norm, but also on the L_∞-norm.

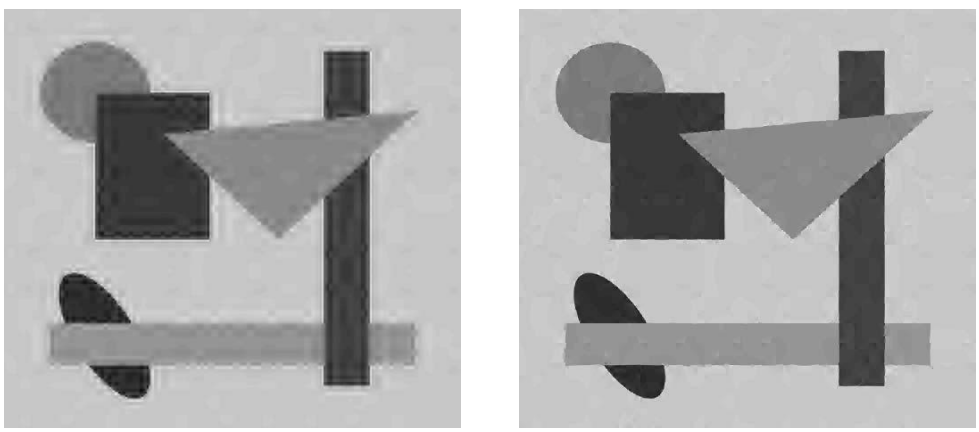

FIG. 7.7. *Reconstruction with* ≈ 2000 *coefficients for the geotex image. Left: HC-FcS-2. Right: HC-ENO-SR-2.*

Notice, in addition, the sharp reconstruction of image edges aligned with the tensor-product underlying grid obtained by the HC-ENO-SR-2. In the larger pepper, however, we can observe an example of the bad handling of texture-dominated areas by ENO-SR predictors. It is interesting to compare this image with the one obtained from the HC-FcS-2 algorithm (essentially the $(1, 3)$ biorthogonal wavelet algorithm). Here, the texture regions look "better," but on the other hand, all edges are blurred. For consistency, all our predictors have the same accuracy on smooth signals, but we emphasize that our goal in this section is merely to illustrate the theoretical results in sections 4 and 5, and that a full comparison between prediction schemes is beyond the scope of the present paper. It is worth mentioning, however, that the "rugged" behavior in texture areas obtained by the ENO-SR prediction scheme, which is caused by the detection of "false edges" ("false alarms"), has recently been the subject of active research [3, 17]. These works have lead to a "robust" ENO-SR-based prediction scheme that is able to eliminate many of these false alarms.

Table 7.1 shows compression errors, $||v^L - \hat{v}^L||_p$ for $p = \infty, 1$, and 2, for different prediction schemes of the same order $R + 1 = 3$. We carry out the computation for

the peppers image and also for a geometric image obtained by superimposing (white noise) texture on shapes of different magnitudes and orientations. This synthetic image (with white noise) is referred to as (for metric image with ture).

For geotex, the ENO-SR prediction combined with the HC algorithm gives the minimum number of coefficients for a given accuracy. This property of the ENO-SR prediction operator in the case of geometric images was already observed in [4, 2, 1], and we observe here that the addition of a moderate amount of noise does not significantly alter the good reconstruction properties of the ENO-SR technique. In Figure 7.7 we display the reconstructed image using approximately 2000 coefficients (the original image is 512×512) with HC-FcS-2 and HC-ENO-SR-2. In the latter case, the reconstructed image is free from edge-blurring and other visually detectable artifacts.

8. Conclusions and further perspectives. We analyze the synchronization mechanism proposed in [7] and observe that it essentially coincides with Harten's EC multiresolution algorithms (see [14, 4, 1]). We theoretically demonstrate that the EC multiscale transformation always leads to encoder/decoder synchronization and provide explicit stability bounds on the resulting cumulative compression errors in the corresponding transform coding algorithm.

The error bounds obtained depend on the specific strategy chosen to compute the detail coefficients. The numerical experiments confirm this dependence. For the preferred strategy proposed in [7], the characteristics of the synchronized compression algorithm depend heavily on the type of prediction scheme, and this is confirmed by a series of numerical tests. On the other hand, Harten's original choice seems to provide the best balance between theoretical and practical effectiveness.

The EC transformations become a useful tool when there is a need to exert a specific control on the cumulative compression error. A potential application lies in compression algorithms, as explored in [5] within the interpolatory multiresolution framework. It could also be potentially used for "optimal quantization," i.e., tuning the quantization mechanism in a dynamical manner so that the total effect on future coefficients is minimized.

Acknowledgments. We would like to thank Richard Baraniuk and Albert Cohen for reading various drafts of this paper. Their comments, as well as the comments of the anonymous referees, have been very valuable to us.

INEXACT DATA-SPARSE BOUNDARY ELEMENT TEARING AND INTERCONNECTING METHODS*

U. LANGER†§, G. OF‡, O. STEINBACH‡, AND W. ZULEHNER§

Abstract. The boundary element tearing and interconnecting (BETI) methods have recently been introduced as boundary element counterparts of the well-established finite element tearing and interconnecting (FETI) methods. In this paper we present inexact data-sparse versions of the BETI methods which avoid the elimination of the primal unknowns and dense matrices. However, instead of symmetric and positive definite systems, we finally have to solve twofold saddle point problems. The proposed iterative solvers and preconditioners result in almost optimal solvers whose complexity is proportional to the number of unknowns on the skeleton up to some polylogarithmical factor. Moreover, the solvers are robust with respect to large coefficient jumps.

1. Introduction.

The finite element tearing and interconnecting (FETI) methods were introduced by Farhat and Roux [18] in 1991 as a dual version of the classical iterative substructuring methods (see also the survey paper [19] by the same authors). Meanwhile the classical FETI methods and, in particular, the more recently developed dual-primal FETI (FETI-DP) and balanced domain decomposition by constraints (BDDC) methods are well established as powerful and robust parallel solvers for large-scale finite element equations in different fields of applications; see, e.g., [15, 16, 17, 57]. The practical success of the FETI, FETI-DP, and BDDC methods in real-life applications is supported by a rigorous theoretical analysis [6, 13, 38, 39, 46, 47]. In particular, for second-order self-adjoint elliptic problems such as the potential equation or the linear elasticity problem, the iteration numbers of the conjugate gradient solver preconditioned by a properly scaled FETI preconditioner grow only like $\mathcal{O}(1+\log(H/h))$, where H and h denote the usual scalings of the subdomains and the finite elements, respectively. Furthermore, the iteration process is insensitive to large jumps in the coefficients of the partial differential equations (PDEs). The latter property is very important for many practical applications, e.g., in electromagnetics, where we frequently have to solve interface problems with large jumps in the material coefficients. We refer the reader to the recently published monograph [64] by Toselli and Widlund for more informations about the analysis of FETI methods.

Recently, the boundary element tearing and interconnecting (BETI) methods [43] and the coupled BETI/FETI methods [44] have been introduced. The dual-primal version of the BETI method (BETI-DP) can be introduced along the same lines as the FETI-DP method. It is widely recognized that boundary element methods (BEM) have some advantages over the finite element methods (FEM) in the treatment of unbounded regions. But we can also benefit from the BEM in some other situations such as in the case of large air subdomains without sources in electromagnetics or in the case of moving parts or interfaces in magnetomechanics [34]. The coupling of BEM and FEM within a domain decomposition framework seems to be very attractive (see, e.g., [24] and [60]). We also refer to some early papers on FEM-BEM coupling by Brezzi and Johnson [7] and Johnson and Nédélec [33]. The symmetric FEM-BEM coupling technique was originally proposed by Costabel [10]. The symmetric coupling technique was then used by Hsiao and Wendland to construct a (primal) boundary element substructuring method [32]; see also [31]. As in the finite element substructuring method, they eliminate the interior subdomain unknowns, which are the fluxes (tractions) in the BEM, and arrive at the symmetric and positive definite boundary element Schur complement system that can be solved by a direct or an iterative method. For large-scale problems, a preconditioned conjugate gradient method should be used for efficiency reasons. However, in every iteration step, the interior boundary element subdomain unknowns must be eliminated; i.e., a discrete single layer potential must be inverted to compute the solution of a Dirichlet boundary value problem in every subdomain. To avoid the expensive elimination of these interior boundary element unknowns, an inexact boundary element substructuring method was introduced in [40] which requires the solution of a saddle point problem. The saddle point problem was solved by the preconditioned conjugate gradient method proposed by Bramble and Pasciak for solving systems of algebraic equations with symmetric but indefinite system matrices [4]. The availability of good preconditioners is very essential for the efficiency of the solver. In the inexact boundary element substructuring case, preconditioners are needed for the local (subdomain) discrete single layer potential operators and for the global boundary element Schur complement. The latter usually provides the global information exchange. In [9] such preconditioners were constructed and analyzed. Inexact finite element substructuring solvers were proposed and investigated in [3, 25, 26, 27]. The first inexact FETI solver was introduced by Klawonn in [35] and analyzed by Klawonn and Widlund in [37]. Recently, inexact FETI-DP methods and inexact BDDC methods have been considered in [36] and [14, 45], respectively. Let us mention that inexact versions are usually more efficient than Schur complement techniques, especially in the case of sufficiently large local problems. This is typical for really large-scale problems. Midsize problems on PC clusters can also benefit from inexact solution techniques.

In this paper we introduce inexact BETI methods which lead to threefold saddle point problems in the first instance. However, applying an appropriate projection, we can reduce the threefold saddle point problem to a twofold saddle point problem. Following the approach given in [67] we present preconditioned Krylov subspace solution methods for twofold saddle point problems and give sharp convergence rate estimates. Similar questions arise when considering the Hu–Washizu principle for linear elasticity problems [21]. The standard boundary element discretization of boundary integral operators with nonlocal kernel functions would lead to fully populated matrices. This is totally unacceptable for three-dimensional boundary value problems. Indeed, already the matrix-vector multiplication costs $\mathcal{O}(N_h^2)$ arithmetical operations in the case of dense matrices. Here N_h denotes the number of boundary unknowns which is

of the order $\mathcal{O}(h^{-(d-1)})$, where h denotes the usual mesh size parameter and d is the spatial dimension ($d = 2$, or $d = 3$). The same complexity is required for the storage. Data-sparse approximations of the system matrix, such as multipole techniques [8, 58], panel clustering methods [29], $\mathcal{H}$-matrix approaches [28], and adaptive cross approximation (ACA) methods [1, 2], can reduce the complexity to almost $\mathcal{O}(N_h)$, except for a polylogarithmic factor, for both the arithmetic and the memory costs. Here we use the fast multipole method, developed in [53], to approximate the single layer potential, the double layer potential, and the hypersingular boundary integral operators which appear in the symmetric boundary integral domain decomposition formulation. Our preconditioned Krylov subspace solvers for twofold saddle point problems require appropriately scaled preconditioners for the local discrete single layer potential operators, for the local boundary element Schur complements, and for the BETI matrix in their data-sparse (fast multipole) representations. We propose data-sparse preconditioners which result in an almost optimal solver requiring $\mathcal{O}((H/h)^{(d-1)}(1+\log(H/h))^s \log \varepsilon^{-1})$ arithmetic operations in a parallel regime and $\mathcal{O}((H/h)^{(d-1)}(1+\log(H/h))^2)$ memory per processor, where $s \in \{3,4,5\}$ depending on the quality of the preconditioners for the local problems, and $\varepsilon \in (0,1)$ is the relative accuracy of the iteration error in a suitable norm. Moreover, our solvers are insensitive to large jumps in the coefficients of the potential equation which serves as our model problem.

The rest of the paper is organized as follows: In section 2, we introduce the data-sparse symmetric boundary element domain decomposition method. Section 3 is devoted to the inexact BETI approach that results in a twofold saddle-point problem after a suitable subspace projection. In section 4, we present and analyze iterative methods for solving twofold saddle point problems. Optimal data-sparse boundary element preconditioners required by the solvers presented in section 4 are given in section 5. This completes the solution procedure. Finally, we discuss some numerical results in section 6 and draw some conclusions in section 7.

2. Data-sparse boundary element domain decomposition methods. As a model problem we consider the Dirichlet boundary value problem for the potential equation

$$-\mathrm{div}[\alpha(x)\nabla\hat{u}(x)] = 0 \quad \text{for } x \in \Omega \subset \mathbb{R}^3, \quad \hat{u}(x) = g(x) \quad \text{for } x \in \Gamma = \partial\Omega, \tag{2.1}$$

where Ω is a bounded Lipschitz domain that is assumed to be decomposed into p nonoverlapping subdomains Ω_i with Lipschitz boundaries $\Gamma_i = \partial\Omega_i$. We further assume that the coefficient function $\alpha(\cdot)$ in the potential equation (2.1) is piecewise constant with $\alpha(x) = \alpha_i > 0$ for $x \in \Omega_i$, $i = 1, \ldots, p$. The variational formulation of the boundary value problem (2.1) reads as follows: find $\hat{u} \in H^1(\Omega)$ with $\hat{u}_{|\Gamma} = g$ such that the variational equation

$$\sum_{i=1}^{p} \alpha_i \int_{\Omega_i} \nabla\hat{u}(x)\,\nabla v(x)dx \;=\; 0 \tag{2.2}$$

is satisfied for all test functions $v \in H^1_0(\Omega)$, where g is a given function from $H^{1/2}(\Gamma)$. Applying Green's first formula with respect to the local subdomains Ω_i gives

$$\sum_{i=1}^{p} \alpha_i \int_{\Gamma_i} \frac{\partial}{\partial n_i}\hat{u}(x)v(x)ds_x \;=\; 0 \quad \text{for all } v \in H^1_0(\Omega) \tag{2.3}$$

due to $-\Delta\hat{u}(x) = 0$ for $x \in \Omega_i$, where $n_i = n_{i,x}$ denotes the exterior normal vector to Γ_i at $x \in \Gamma_i$. For $x \in \Omega_i$ the solution of the local Laplace equation is given by the local representation formula

$$\hat{u}(x) = \int_{\Gamma_i} U^*(x,y) \frac{\partial}{\partial n_{i,y}} \hat{u}(y) ds_y - \int_{\Gamma_i} \frac{\partial}{\partial n_{i,y}} U^*(x,y) \hat{u}(y) ds_y, \tag{2.4}$$

where

$$U^*(x,y) = \frac{1}{4\pi} \frac{1}{|x-y|}$$

is the fundamental solution of the Laplace operator; see, e.g., [61]. Taking the trace and the normal derivative of the local representation formula (2.4) we obtain the Calderon system

$$\begin{pmatrix} u_i \\ t_i \end{pmatrix} = \begin{pmatrix} \frac{1}{2} I - K_i & V_i \\ D_i & \frac{1}{2} I + K_i' \end{pmatrix} \begin{pmatrix} u_i \\ t_i \end{pmatrix} \tag{2.5}$$

of local boundary integral equations on Γ_i for the Cauchy data $u_i = \hat{u}_{|\Gamma_i} \in H^{1/2}(\Gamma_i)$ and $t_i = n_i \cdot \nabla \hat{u}_{|\Gamma_i} \in H^{-1/2}(\Gamma_i)$, where the local single layer potential operator $V_i : H^{-1/2}(\Gamma_i) \to H^{1/2}(\Gamma_i)$, the local double layer potential operator $K_i : H^{1/2}(\Gamma_i) \to H^{1/2}(\Gamma_i)$, its adjoint $K_i' : H^{-1/2}(\Gamma_i) \to H^{-1/2}(\Gamma_i)$, and the local hypersingular boundary integral operator $D_i : H^{1/2}(\Gamma_i) \to H^{-1/2}(\Gamma_i)$ are defined by

$$\begin{aligned}
(V_i t_i)(x) &= \int_{\Gamma_i} U^*(x,y) t_i(y) ds_y, \\
(K_i u_i)(x) &= \int_{\Gamma_i} \frac{\partial}{\partial n_{i,y}} U^*(x,y) u_i(y) ds_y, \\
(K_i' t_i)(x) &= \int_{\Gamma_i} \frac{\partial}{\partial n_{i,x}} U^*(x,y) t_i(y) ds_y, \\
(D_i u_i)(x) &= -\frac{\partial}{\partial n_{i,x}} \int_{\Gamma_i} \frac{\partial}{\partial n_{i,y}} U^*(x,y) u_i(y) ds_y,
\end{aligned}$$

respectively. The mapping properties of these boundary integral operators are now well known; see, e.g., [11, 48, 61]. In particular, the local single layer potential operators V_i are self-adjoint and $H^{-1/2}(\Gamma_i)$-elliptic. The local hypersingular operators D_i are self-adjoint as well, but only positive semidefinite. Indeed, the kernel $\ker D_i$ of the hypersingular operator D_i is spanned by all constant functions; i.e., $\ker D_i = \operatorname{span}\{1\}$.

Let us denote the skeleton of the domain decomposition by $\Gamma_S = \cup_{i=1}^p \Gamma_i$ and the skeleton trace space by $H^{1/2}(\Gamma_S) = \{v_{|\Gamma_S} : v \in H^1(\Omega)\}$. Inserting the second boundary integral equation of (2.5) into (2.3), we have to find $\hat{u} \in H^{1/2}(\Gamma_S)$ with $\hat{u}_{|\Gamma} = g$ such that

$$\sum_{i=1}^p \alpha_i \left[\langle D_i \hat{u}_{|\Gamma_i}, v_{|\Gamma_i} \rangle_{\Gamma_i} + \left\langle \left(\frac{1}{2} I + K_i' \right) t_i, v_{|\Gamma_i} \right\rangle_{\Gamma_i} \right] = 0 \tag{2.6}$$

for all test functions $v \in H_0^{1/2}(\Gamma_S) = \{v \in H^{1/2}(\Gamma_S) : v_{|\Gamma} = 0\}$, where $t_i \in H^{-1/2}(\Gamma_i)$ are the unique solutions of the local variational problems

$$\alpha_i \left[\langle V_i t_i, w_i \rangle_{\Gamma_i} - \left\langle \left(\frac{1}{2} I + K_i \right) \hat{u}_{|\Gamma_i}, w_i \right\rangle_{\Gamma_i} \right] = 0 \tag{2.7}$$

for all test functions $w_i \in H^{-1/2}(\Gamma_i)$, where $\langle \cdot, \cdot \rangle_{\Gamma_i}$ denotes the duality pairing in $H^{-1/2}(\Gamma_i) \times H^{1/2}(\Gamma_i)$ that is the extension of the scalar product in $L_2(\Gamma_i)$ for $i = 1, 2, \ldots, p$. After homogenization of the Dirichlet boundary condition via the ansatz $\hat{u} = \hat{g} + u$ with some extension $\hat{g}_{|\Gamma} = g$ and $u_{|\Gamma} = 0$, we can rewrite (2.6) and (2.7) as a mixed variational problem to find $t = (t_1, t_2, \ldots, t_p) \in T = T_1 \times T_2 \times \cdots \times T_p = H^{-1/2}(\Gamma_1) \times H^{-1/2}(\Gamma_2) \times \cdots \times H^{-1/2}(\Gamma_p)$ and $u \in U = H_0^{1/2}(\Gamma_S)$ such that

$$\alpha_i \left[\langle w_i, V_i t_i \rangle_{\Gamma_i} - \left\langle w_i, \left(\frac{1}{2} I + K_i \right) u_{|\Gamma_i} \right\rangle_{\Gamma_i} \right] = \alpha_i \left\langle w_i, \left(\frac{1}{2} I + K_i \right) \hat{g}_{|\Gamma_i} \right\rangle_{\Gamma_i} \tag{2.8}$$

for all $w_i \in T_i$, $i = 1, 2, \ldots, p$, and

$$\sum_{i=1}^{p} \alpha_i \left[- \left\langle \left(\frac{1}{2} I + K_i' \right) t_i, v_{|\Gamma_i} \right\rangle_{\Gamma_i} - \langle D_i u_{|\Gamma_i}, v_{|\Gamma_i} \rangle_{\Gamma_i} \right] = \sum_{i=1}^{p} \alpha_i \langle D_i \hat{g}_{|\Gamma_i}, v_{|\Gamma_i} \rangle_{\Gamma_i} \tag{2.9}$$

for all $v \in U$. It is well known that the mixed variational problem (2.8) and (2.9) is uniquely solvable [32]. Therefore, problem (2.6)–(2.7), which is equivalent to problem (2.8)–(2.9), is also uniquely solvable.

Let us now introduce the boundary element trial spaces

$$U_h = S_h^1(\Gamma_S) = \operatorname{span}\{\varphi_m\}_{m=1}^{M} \subset U = H_0^{1/2}(\Gamma_S) \tag{2.10}$$

and

$$T_{i,h} = S_h^0(\Gamma_i) = \operatorname{span}\{\psi_k^i\}_{k=1}^{N_i} \subset T_i = H^{-1/2}(\Gamma_i) \tag{2.11}$$

spanned by continuous piecewise linear basis functions φ_m and by piecewise constant basis functions ψ_k^i with respect to a regular globally quasi-uniform boundary element mesh $\Gamma_i = \cup_{\ell=1}^{N_i} \tau_\ell^i$ with the average mesh size h on Γ_S and Γ_i, respectively. The restriction of the global trial space U_h onto the local subdomain boundaries Γ_i is denoted by

$$U_{i,h} = S_h^1(\Gamma_i) = S_h^1(\Gamma_S)_{|\Gamma_i} = \operatorname{span}\{\varphi_m^i\}_{m=1}^{M_i} \subset H_0^{1/2}(\Gamma_i), \tag{2.12}$$

where $H_0^{1/2}(\Gamma_i) = \{v_{|\Gamma_i} : v \in H_0^{1/2}(\Gamma_S)\}$. The Galerkin discretization of the symmetric mixed variational formulation (2.8) and (2.9) now gives immediately the mixed boundary element equations to find $t_h = (t_{1,h}, t_{2,h}, \ldots, t_{p,h}) \in T_h = T_{1,h} \times T_{2,h} \times \cdots \times T_{p,h}$ and $u_h \in U_h$ such that

$$\alpha_i \left[\langle w_{i,h}, V_i t_{i,h} \rangle_{\Gamma_i} - \left\langle w_{i,h}, \left(\frac{1}{2} I + K_i \right) u_{h|\Gamma_i} \right\rangle_{\Gamma_i} \right] = \alpha_i \left\langle w_{i,h}, \left(\frac{1}{2} I + K_i \right) \hat{g}_{|\Gamma_i} \right\rangle \tag{2.13}$$

for all $w_{i,h} \in T_{i,h}$, $i = 1, 2, \ldots, p$, and

$$\sum_{i=1}^{p} \alpha_i \left[- \left\langle \left(\frac{1}{2} I + K_i' \right) t_{i,h}, v_{h|\Gamma_i} \right\rangle_{\Gamma_i} - \langle D_i u_{h|\Gamma_i}, v_{h|\Gamma_i} \rangle_{\Gamma_i} \right] = \sum_{i=1}^{p} \alpha_i \langle D_i \hat{g}_{|\Gamma_i}, v_{h|\Gamma_i} \rangle_{\Gamma_i} \tag{2.14}$$

for all $v_h \in U_h$. Applying standard arguments, it follows that the mixed boundary element equations (2.13) and (2.14) admit a unique solution. Moreover, the discretization error is bounded by the approximation error,

$$\|u-u_h\|_U^2 + \|t-t_h\|_T^2 \le c \left\{ \inf_{v_h \in U_h} \|u-v_h\|_U^2 + \inf_{w_h \in T_h} \|t-w_h\|_T^2 \right\}.$$

From the approximation properties of the boundary element trial spaces U_h and T_h we then obtain the a priori error estimate

$$\|u-u_h\|_U^2 + \|t-t_h\|_T^2 \;\le\; c\, h^{2s+1} \left[\|u\|_{H^{s+1}(\Gamma_S)}^2 + \sum_{i=1}^{p} \|t_i\|_{H^s_{\mathrm{pw}}(\Gamma_i)}^2 \right] \tag{2.15}$$

for a sufficiently smooth solution (u,t) with $u \in H^{s+1}(\Gamma_S)$ and $t_i \in H^s_{\mathrm{pw}}(\Gamma_i)$, $i = 1,2,\ldots,p$, for some $s \in (0,1]$. Here the subscript pw indicates the piecewise definition of the corresponding smoothness; see [61, p. 43] for the precise definition of these spaces. Estimate (2.15) gives an optimal convergence rate of $\mathcal{O}(h^{3/2})$; see, e.g., [61]. Here and in the following, c denotes a generic constant that is always independent of the discretization parameters.

Once the basis functions are chosen, the boundary element equations (2.13) and (2.14) are equivalent to the following system of algebraic equations: Find the coefficient vectors $\underline{t}_i = [t_{i,k}]_{k=1}^{N_i} \in \mathbb{R}^{N_i}$ for $i = 1,2,\ldots,p$ and $\underline{u} = [u_m]_{m=1}^{M} \in \mathbb{R}^M$ of the boundary element functions $t_{i,h} = \sum_{k=1}^{N_i} t_{i,k}\psi_k^i$ and $u_h = \sum_{m=1}^{M} u_m \varphi_m$ as the unique solution of the Galerkin system

$$\begin{pmatrix} \alpha_1 V_{1,h} & & & -\alpha_1 \bar{K}_{1,h} R_{1,h} \\ & \ddots & & \vdots \\ & & \alpha_p V_{p,h} & -\alpha_p \bar{K}_{p,h} R_{p,h} \\ -\alpha_1 R_{1,h}^\top \bar{K}_{1,h}^\top & \ldots & -\alpha_p R_{p,h}^\top \bar{K}_{p,h}^\top & -D_h \end{pmatrix} \begin{pmatrix} \underline{t}_1 \\ \vdots \\ \underline{t}_p \\ \underline{u} \end{pmatrix} = \begin{pmatrix} \alpha_1 \underline{g}_1 \\ \vdots \\ \alpha_p \underline{g}_p \\ \underline{f} \end{pmatrix}, \tag{2.16}$$

where

$$D_h = \sum_{i=1}^{p} \alpha_i R_{i,h}^\top D_{i,h} R_{i,h} \quad \text{and} \quad \underline{f} = \sum_{i=1}^{p} \alpha_i R_{i,h}^\top \underline{f}_i. \tag{2.17}$$

The entries of the matrices $V_{i,h}$, $\bar{K}_{i,h}$, $D_{i,h}$ and the coefficients of the right-hand sides $\underline{g}_i$ and $\underline{f}$ are defined by the relations

$$\begin{aligned} V_{i,h}[\ell,k] &= \langle \psi_\ell^i, V_i \psi_k^i \rangle_{\Gamma_i}, \\ \bar{K}_{i,h}[\ell,m] &= \left\langle \psi_\ell^i, \left(\frac{1}{2} I + K_i \right) \varphi_m^i \right\rangle_{\Gamma_i}, \\ D_{i,h}[n,m] &= \langle \varphi_n^i, D_i \varphi_m^i \rangle_{\Gamma_i} \end{aligned}$$

and $g_{i,\ell} = \langle \psi_\ell^i, (\frac{1}{2} I + K_i)\hat{g}_{|\Gamma_i} \rangle_{\Gamma_i}$, $f_{i,n} = \langle D_i \hat{g}_{|\Gamma_i}, \varphi_n^i \rangle_{\Gamma_i}$ for all $k,\ell = 1,\ldots,N_i$ and $m,n = 1,\ldots,M_i$, respectively. The restriction operator $R_{i,h}$ maps any global coefficient vector $\underline{v} \in \mathbb{R}^M$ to the local vector $\underline{v}_i \in \mathbb{R}^{M_i}$ containing those components of $\underline{v}$ which correspond to Γ_i only, $i = 1,2,\ldots,p$. The matrices $R_{i,h}$ are Boolean matrices which are sometimes also called subdomain connectivity matrices.

The system matrix of (2.16) is symmetric but indefinite. The matrices $V_{i,h}$ are symmetric and positive definite, while the blocks $D_{i,h}$ are symmetric but in general only positive semidefinite, where the kernel is spanned by all vectors with constant entries. Unfortunately, all matrix blocks involved in (2.16) are fully populated due to the nonlocal fundamental solution. Especially for three-dimensional boundary value problems, this fact would require unacceptable large resources of memory and already a high complexity of a single matrix-vector multiplication. Since the latter operation is the basic operation in every iteration method, we need some data-sparse approximation of these matrices that reduces the quadratic complexity with respect to the number of unknowns to an almost linear one, but without affecting the accuracy given by the quasi-optimal error estimate (2.15).

As already pointed out in the introduction, there exist several possibilities of fast BEM to reduce the computational costs, for example, panel clustering [29], algebraic approximation techniques such as the ACA method [2], and hierarchical matrices [28] or wavelets [12]. Following [53], we describe here the application of the fast multipole method to the discrete boundary integral operators introduced above. We will mainly use the original version of the fast multipole method as described in [22, 23], but the main difference in our version of the method will be the use of reformulated spherical harmonics [55, 65, 66].

As already mentioned above, when using an iterative solver it is necessary to efficiently perform the matrix-by-vector multiplications of the local stiffness matrices with given vectors. In particular, if the vectors $\underline{r}_1^i \in \mathbb{R}^{N_i}$ and $\underline{r}_2^i \in \mathbb{R}^{M_i}$ are given, we need a fast computation of the matrix-vector products $\underline{w}_1^i = V_{i,h}\underline{r}_1^i \in \mathbb{R}^{N_i}$, $\underline{w}_2^i = K_{i,h}\underline{r}_2^i \in \mathbb{R}^{N_i}$, $\underline{v}_1^i = D_{i,h}\underline{r}_2^i \in \mathbb{R}^{M_i}$, and $\underline{v}_2^i = K_{i,h}^\top \underline{r}_1^i \in \mathbb{R}^{M_i}$.

We begin with the local matrix-vector product $\underline{w}_1^i = V_{i,h}\underline{r}_1^i$ defined componentwise as follows:

$$w_{1,\ell}^i \;=\; \sum_{k=1}^{N_i} V_{i,h}[\ell,k] r_{1,k}^i \;=\; \sum_{k=1}^{N_i} \frac{r_{1,k}^i}{4\pi} \int_{\tau_\ell^i} \int_{\tau_k^i} \frac{1}{|x-y|} ds_y ds_x \quad \text{for } \ell = 1,\dots,N_i.$$

As in most of the fast BEM, one first substitutes the kernel function by an appropriate series expansion separating the integration variables x and y from each other. The kernel of the single layer potential can be written in terms of Legendre polynomials:

$$k(x,y) \;=\; \frac{1}{|x-y|} \;=\; \sum_{n=0}^{\infty} \frac{|x|^n}{|y|^{n+1}} P_n(\hat{x}\cdot\hat{y}), \quad \hat{x} = \frac{x}{|x|}, \quad \hat{y} = \frac{y}{|y|},$$

where

$$P_n(u) \;=\; \frac{1}{2^n n!} \frac{d^n}{du^n}(u^2-1)^n \quad \text{for } |u| \le 1.$$

An approximation of the kernel function $k(x,y)$ is then defined by truncating the infinite sum at certain expansion degree ϱ:

$$k_\varrho(x,y) \;=\; \sum_{n=0}^{\varrho} \frac{|x|^n}{|y|^{n+1}} P_n(\hat{x}\cdot\hat{y}). \tag{2.18}$$

Note that for $|y| > |x|$ the following error estimate holds:

$$|k(x,y) - k_\varrho(x,y)| \;\le\; \frac{1}{|y|-|x|} \left(\frac{|x|}{|y|}\right)^{\varrho+1}. \tag{2.19}$$

Since the product of the normalized integration variables $\hat{x}$ and $\hat{y}$ still appears as an argument of the Legendre polynomials in (2.18), one may instead use spherical harmonics [30] to obtain the kernel approximation

$$k_\varrho(x,y) \;=\; \sum_{n=0}^{\varrho}\sum_{m=-n}^{n} \frac{|x|^n}{|y|^{n+1}} Y_n^{-m}(\hat{x}) Y_n^m(\hat{y}) \;=\; \sum_{n=0}^{\varrho}\sum_{m=-n}^{n} \overline{S_n^m}(y) R_n^m(x) \tag{2.20}$$

when assuming $|y| > |x|$. The truncated series expansion (2.20) is the first ingredient of this fast multipole method. The second is the use of an artificial geometric hierarchy which is built upon the boundary elements. All boundary elements $\tau_k^i \subset \Gamma_i$ belong to a cluster $\omega_{i,1}^0$ which is a box containing the whole subdomain Ω_i. The clusters of the level $\lambda+1$ are constructed by the refinement of all boxes $\omega_{i,j}^\lambda$ into eight similar subboxes $\omega_{i,j'}^{\lambda+1}$. The clusters $\omega_{i,j'}^{\lambda+1}$ are called the sons of the father cluster $\omega_{i,j}^\lambda$. This recursive process is repeated until a maximum level L is attained. Clusters containing no boundary elements are neglected. All boundary elements $\{\tau_k^i\}_{k=1}^{N_i}$ are assigned to the cluster $\omega_{i,j}^L$ with respect to their midpoints.

Since the expansion (2.20) is valid only for $|x| < |y|$, one has to distinguish the farfield (FF), where this expansion is admissible, from the nearfield (NF), where the standard kernel has to be used. A cluster ω_j^λ on the same level λ is said to be in the NF of the cluster ω_i^λ if the condition

$$\operatorname{dist}\{C_i^\lambda, C_j^\lambda\} \;\le\; (d+1)\max\{r_i^\lambda, r_j^\lambda\} \tag{2.21}$$

is satisfied with $d > 1$ a suitably chosen parameter. C_i^λ denotes the center and r_i^λ is the radius of the cluster ω_i^λ which is determined by the cluster center and the extension of the boundary elements τ_k contained in ω_i^λ.

Hence we obtain the approximate local matrix-vector product

$$\begin{aligned}\widetilde{w}_{1,\ell}^i &= \sum_{k\in \mathrm{NF}(\ell)} V_{i,h}[\ell,k] r_{1,k}^i + \sum_{k\in \mathrm{FF}(\ell)} \frac{r_{1,k}^i}{4\pi} \int_{\tau_\ell}\int_{\tau_k} \sum_{n=0}^{\varrho}\sum_{m=-n}^{n} \overline{S_n^m}(y) R_n^m(x)\, ds_x\, ds_y \\ &= \sum_{k\in \mathrm{NF}(\ell)} V_{i,h}[\ell,k] r_{1,k}^i + \sum_{n=0}^{\varrho}\sum_{m=-n}^{n}\sum_{k\in \mathrm{FF}(\ell)} \frac{r_{1,k}^i}{4\pi} \int_{\tau_k} R_n^m(x)\, ds_x \int_{\tau_\ell} \overline{S_n^m}(y)\, ds_y\end{aligned}$$

for all $\ell = 1,\dots,N_i$. As the FFs differ from each other for most indices ℓ, the question arises of how to compute the coefficients of the series expansion for different ℓ efficiently. This can be done by using the cluster hierarchy constructed above. Starting on the finest level all coefficients for the corresponding clusters are computed and later translated to their common fathers on the coarser levels up to level zero. Next, these multipole expansions are converted into local expansions in terms of their coefficients on the highest level, in which the kernel expansion is admissible. This results in an algorithm of $\mathcal{O}(N_i \log^2 N_i)$ complexity. For a more detailed description of the efficient matrix-vector multiplication, see [53] and the references given there.

In what follows we will focus on the stability and error analysis of the approximate matrix-vector product $\underline{\widetilde{w}}_1^i = \widetilde{V}_{i,h}\underline{r}_1^i$ in the case of a fixed NF parameter $d > 0$.

LEMMA 2.1 (see [53, Lemma 4.1]). [illegible] $\varrho = \mathcal{O}(\log N_i)$ [illegible] $\widetilde{V}_i$ [illegible]

$$\|(V_i - \widetilde{V}_i) t_{i,h}\|_{L_2(\Gamma_i)} \;\le\; c\, h^2 \|t_{i,h}\|_{L_2(\Gamma_i)} \quad \text{[illegible]} \quad t_{i,h} \in S_h^0(\Gamma_i) \subset L_2(\Gamma_i).$$

From the previous lemma and an inverse inequality we see that it is possible to choose the expansion degree $\varrho = \mathcal{O}(\log N_i)$ such that the approximate single layer potential $\widetilde{V}_{i,h}$ is $S_h^0(\Gamma_i)$-elliptic,

$$\langle \widetilde{V}_{i,h} w_{i,h}, w_{i,h} \rangle_{\Gamma_i} \geq c_1^{\widetilde{V}_i} \|w_{i,h}\|^2_{H^{-1/2}(\Gamma)} \quad \text{for all } w_{i,h} \in S_h^0(\Gamma_i).$$

The multipole expansion of the double layer potential operator $\widetilde{K}_i$ can be computed by applying the normal derivative to the expansion (2.20) of the single layer potential V_i. In the case of the adjoint double layer potential K_i', the normal derivative has to be applied to the coefficients in the evaluation of the expansions. Therefore the transposition property between the Galerkin matrices of the double layer potential and its adjoint operator will be maintained if the same expansion degree p is chosen for both. As for the approximate single layer potential $\widetilde{V}_{i,h}$, corresponding error estimates follow; see [53, Lemmas 4.3 and 4.4].

The hypersingular boundary integral operator D_i is treated via integration by parts [50]. The bilinear form of the hypersingular integral operator D_i can be written as a sum of bilinear forms of the single layer potential V_i,

$$\langle D_i u_i, v_i \rangle_{\Gamma_i} = \sum_{k=1}^{3} \langle V_i \underline{\mathrm{curl}}_{|\Gamma_i} u_{i|k}, \underline{\mathrm{curl}}_{|\Gamma_i} v_{i|k} \rangle_{\Gamma_i},$$

with the surface curl $\underline{\mathrm{curl}}_{|\Gamma_i} u_i(x) = n_x \times \nabla u^*_{i,\Gamma_i}(x)$ defined for a constant extension $u^*_{i|\Gamma_i}$ of $u(x)$ along the normal n_x into a small neighborhood of Γ_i. In the case of piecewise linear, continuous basis functions $\varphi_m^i(x)$ and plane triangles as boundary elements, the vector $\underline{\mathrm{curl}}_{\Gamma_i} \varphi_m^i(x)$ is piecewise constant and constant on each boundary element. Therefore the Galerkin matrix of the single layer potential V_i for piecewise constant basis functions ψ_k^i can be reused here, leading to the approximate bilinear form

$$\langle \widetilde{D}_{i,h} u_{i,h}, v_{i,h} \rangle_{\Gamma_i} = \sum_{k=1}^{3} \langle \widetilde{V}_{i,h} \underline{\mathrm{curl}}_{|\Gamma_i} u_{i,h|k}, \underline{\mathrm{curl}}_{|\Gamma_i} v_{i,h|k} \rangle_{\Gamma_i}. \tag{2.22}$$

The stability and error analysis for the approximation $\widetilde{D}_{i,h}$ then follows as for the approximate single layer potential.

Using the fast multipole approximations for the application of the discrete boundary integral operators, instead of (2.16) we have to solve the perturbed linear system

$$\begin{pmatrix} \alpha_1 \widetilde{V}_{1,h} & & & -\alpha_1 \widetilde{K}_{1,h} R_{1,h} \\ & \ddots & & \vdots \\ & & \alpha_p \widetilde{V}_{p,h} & -\alpha_p \widetilde{K}_{p,h} R_{p,h} \\ -\alpha_1 R_{1,h}^\top \widetilde{K}_{1,h}^\top & \dots & -\alpha_p R_{p,h}^\top \widetilde{K}_{p,h}^\top & -\widetilde{D}_h \end{pmatrix} \begin{pmatrix} \widetilde{\underline{t}}_1 \\ \vdots \\ \widetilde{\underline{t}}_p \\ \widetilde{\underline{u}} \end{pmatrix} = \begin{pmatrix} \alpha_1 \widetilde{\underline{g}}_1 \\ \vdots \\ \alpha_p \widetilde{\underline{g}}_p \\ \widetilde{\underline{f}} \end{pmatrix}. \tag{2.23}$$

As in the case of the symmetric boundary integral formulation considered in [53, Theorem 4.1], we obtain the unique solvability of (2.23) as well as the quasi-optimal error estimate

$$\|u - \widetilde{u}_h\|_U^2 + \|t - \widetilde{t}_h\|_T^2 \leq c\, h^{2s+1} \left[\|u\|^2_{H^{s+1}(\Gamma_S)} + \sum_{i=1}^{p} \|t_i\|^2_{H^s_{\mathrm{pw}}(\Gamma_i)} \right] \tag{2.24}$$

for the associated approximate solutions $\widetilde{t}_h \in T_h$ and $\widetilde{u}_h \in U_h$ when assuming $\varrho = \mathcal{O}(\log N_i)$ and smooth solutions as in (2.15), i.e., $s \in (0,1]$. Hence we can ensure the same asymptotic behavior as for the solution of the standard Galerkin boundary element method.

A standard approach to solving the linear system (2.23) is to consider its Schur complement system

$$\sum_{i=1}^{p} \alpha_i R_{i,h}^{\top} \left[\widetilde{D}_{i,h} + \widetilde{K}_{i,h}^{\top} \widetilde{V}_{i,h}^{-1} \widetilde{K}_{i,h} \right] R_{i,h} \underline{u} = -\sum_{i=1}^{p} \alpha_i R_{i,h}^{\top} \left[\underline{f}_i + \widetilde{K}_{i,h}^{\top} \widetilde{V}_{i,h}^{-1} \underline{g}_i \right] \tag{2.25}$$

with the symmetric and positive definite system matrix

$$\widetilde{S}_h = \sum_{i=1}^{p} \alpha_i R_{i,h}^{\top} \widetilde{S}_{i,h} R_{i,h}, \quad \widetilde{S}_{i,h} = \widetilde{D}_{i,h} + \widetilde{K}_{i,h}^{\top} \widetilde{V}_{i,h}^{-1} \widetilde{K}_{i,h}.$$

The linear system (2.25) can be solved by the preconditioned conjugate gradient method where a possible preconditioner is given by

$$C_S^{-1} = \sum_{i=1}^{p} \frac{1}{\alpha_i} R_{i,h}^{\top} \bar{V}_{i,h} R_{i,h}. \tag{2.26}$$

Here $\bar{V}_{i,h}$ is the single layer potential discretized by piecewise linear continuous basis functions and approximated by means of a fast multipole method. In the case of many subdomains a coarse grid solver must be added in order to ensure a global information exchange. Note that each application of the discrete Steklov–Poincaré operators $\widetilde{S}_{i,h}$ within one step of the conjugate gradient scheme requires one inversion of the discrete single layer potential $\widetilde{V}_{i,h}$ which can be realized by an interior conjugate gradient scheme.

3. Inexact BETI methods. In order to avoid assembled matrices and vectors, we tear the global potential vector $\underline{u}$ on the subdomain boundaries Γ_i by introducing the individual local unknowns

$$\underline{u}_i = R_{i,h} \underline{u}. \tag{3.1}$$

Conversely, the global continuity of the potentials is enforced by the constraints

$$\sum_{i=1}^{p} B_i \underline{u}_i = \underline{0} \tag{3.2}$$

interconnecting the local potential vectors across the subdomain boundaries. Each row of the matrix $B = (B_1, \ldots, B_p)$ is connected with a pair of matching nodes across the subdomain boundaries. The entries of such a row are 1 and -1 for the indices corresponding to the matching nodes on the interface (coupling boundaries) $\Gamma_C = \Gamma_S \setminus \Gamma$ and are 0 otherwise. Therefore, (3.2) implies that the corresponding boundary element functions $u_{i,h}$ are continuous across the interface Γ_C; i.e., $u_{i,h} = u_{j,h}$ on $\Gamma_i \cap \Gamma_j \neq \emptyset$. We assume here that the number of constraints at any such matching node is equal to the number of matching subdomains minus one. This method with a minimal number of constraints (respectively, multipliers) is called nonredundant; see, e.g., [38] for the use of redundant constraints.

By introducing Lagrange multipliers $\underline{\lambda} \in \mathbb{R}^L$, the linear system (2.23) is equivalent to

$$\begin{pmatrix} \alpha_1\widetilde{V}_{1,h} & & & -\alpha_1\widetilde{K}_{1,h} & & & \\ & \ddots & & & \ddots & & \\ & & \alpha_p\widetilde{V}_{p,h} & & & -\alpha_p\widetilde{K}_{p,h} & \\ -\alpha_1\widetilde{K}_{1,h}^\top & & & -\alpha_1\widetilde{D}_{1,h} & & & B_1^\top \\ & \ddots & & & \ddots & & \vdots \\ & & -\alpha_p\widetilde{K}_{p,h}^\top & & & -\alpha_p\widetilde{D}_{p,h} & B_p^\top \\ & & & B_1 & \dots & B_p & \end{pmatrix} \begin{pmatrix} \underline{\widetilde{t}}_1 \\ \vdots \\ \underline{\widetilde{t}}_p \\ \underline{\widetilde{u}}_1 \\ \vdots \\ \underline{\widetilde{u}}_p \\ \underline{\lambda} \end{pmatrix} = \begin{pmatrix} \alpha_1\underline{g}_1 \\ \vdots \\ \alpha_p\underline{g}_p \\ \alpha_1\underline{f}_1 \\ \vdots \\ \alpha_p\underline{f}_p \\ \underline{0} \end{pmatrix}.$$

Setting $V = \operatorname{diag}(\alpha_i\widetilde{V}_{i,h})$, $K = \operatorname{diag}(\alpha_i\widetilde{K}_{i,h})$, $D = \operatorname{diag}(\alpha_i\widetilde{D}_{i,h})$ as well as $B = (B_1, \dots, B_p)$, we have to solve the twofold saddle point problem

$$\begin{pmatrix} V & -K & 0 \\ -K^\top & -D & B^\top \\ 0 & B & 0 \end{pmatrix} \begin{pmatrix} \underline{t} \\ \underline{u} \\ \underline{\lambda} \end{pmatrix} = \begin{pmatrix} \underline{g} \\ \underline{f} \\ \underline{0} \end{pmatrix} \tag{3.3}$$

after ordering the vectors in an appropriate way. The matrix $\widetilde{D}_{i,h}$ is symmetric and positive definite if and only if the corresponding subdomain Ω_i is nonfloating. A subdomain Ω_i is called floating if the subdomain boundary Γ_i does not touch the Dirichlet boundary part Γ_D that equals Γ for our model problem (2.1). Otherwise the subdomain is called nonfloating. For a floating subdomain Ω_i the kernel of the matrix $\widetilde{D}_{i,h}$ is spanned by the vector $\underline{e}_i = (1, \dots, 1)^\top \in \mathbb{R}^{M_i}$; i.e., $\ker \widetilde{D}_{i,h} = \operatorname{span}\{\underline{e}_i\}$. Let us assume for simplicity that the first q ($q < p$) subdomains are floating and the remaining subdomains are nonfloating. The case $q = 0$ (no floating subdomains) is trivial and does not need any discussion. In order to avoid singular block entries $\widetilde{D}_{i,h}$ and, therefore, singular Schur complements $\widetilde{S}_{i,h} = \alpha_i(\widetilde{D}_{i,h} + \widetilde{K}_{i,h}^\top \widetilde{V}_{i,h}^{-1} \widetilde{K}_{i,h})$ for the floating subdomains, we replace the singular blocks $\widetilde{D}_{i,h}$ by the regularized matrices $\widetilde{D}_{i,h} + \beta_i \underline{e}_i \underline{e}_i^\top$ with appropriately chosen positive constants β_i for $i = 1, \dots, q$. We note that

$$\widetilde{K}_{i,h}\underline{e}_i = \underline{0} \quad \text{for } i = 1, \dots, q. \tag{3.4}$$

Let us denote the unique solutions of the regularized equations

$$\alpha_i(\widetilde{D}_{i,h} + \beta_i \underline{e}_i \underline{e}_i^\top)\underline{v}_i \;=\; -\alpha_i \underline{f}_i + B_i\underline{\lambda} - \alpha_i \widetilde{K}_{i,h}^\top \underline{t}_i \tag{3.5}$$

by $\underline{v}_i$, $i = 1, \dots, q$. If the right-hand side of (3.5) fulfills the solvability conditions for the original equations without the regularization term,

$$\underline{e}_i^\top(-\alpha_i \underline{f}_i + B_i\underline{\lambda} - \alpha_i \widetilde{K}_{i,h}^\top \underline{t}_i) \;=\; \underline{e}_i^\top(-\alpha_i \underline{f}_i + B_i\underline{\lambda}) \;=\; 0, \tag{3.6}$$

then the solution $\underline{v}_i$ of (3.5) is orthogonal to $\ker \widetilde{D}_{i,h}$; i.e.,

$$\underline{e}_i^\top \underline{v}_i = 0. \tag{3.7}$$

Now the solution $\underline{u} = (\underline{u}_1, \dots, \underline{u}_p)^\top$ of the original system (3.3) can be recovered by the formulae

$$\underline{u}_i = \underline{v}_i + \gamma_i \underline{e}_i, \tag{3.8}$$

with $\gamma_i = 0$ for $i = q+1, \ldots, p$ and appropriately chosen γ_i for $i = 1, \ldots, q$. Taking (3.4)–(3.8) into account, we easily observe that the unique solution $\underline{t} \in \mathbb{R}^M$, $\underline{v} \in \mathbb{R}^N$, $\underline{\lambda} \in \mathbb{R}^L$, and $\underline{\gamma} \in \mathbb{R}^q$ of the threefold saddle point problem

$$\begin{pmatrix} V & -K & 0 & 0 \\ -K^\top & -D & B^\top & 0 \\ 0 & B & 0 & G \\ 0 & 0 & G^\top & 0 \end{pmatrix} \begin{pmatrix} \underline{t} \\ \underline{v} \\ \underline{\lambda} \\ \underline{\gamma} \end{pmatrix} = \begin{pmatrix} \underline{g} \\ \underline{f} \\ \underline{0} \\ \underline{e} \end{pmatrix} \tag{3.9}$$

immediately yields the solution $(\underline{t}, \underline{u}, \underline{\lambda})$ of the twofold saddle point problem (3.3), where now D is symmetric and positive definite since we have replaced the singular blocks $\widetilde{D}_{j,h}$ by the regularized ones. The last equation in (3.9) is nothing but the solvability condition (3.6). Note that the $L \times q$ matrix G and the vector $\underline{e} \in \mathbb{R}^q$ are defined by the relations

$$G = (B_1 \underline{e}_1, \ldots, B_q \underline{e}_1) \quad \text{and} \quad \underline{e} = (\alpha_1 \underline{e}_1^\top \underline{f}_1, \ldots, \alpha_q \underline{e}_q^\top \underline{f}_q)^\top. \tag{3.10}$$

Now we use a subspace projection in order to separate the determination of $\underline{\gamma}$ from the determination of the rest of the unknowns in (3.9). Thus, we introduce the orthogonal projection

$$P = I - G(G^\top G)^{-1} G^\top \tag{3.11}$$

from the space $\Lambda := \mathbb{R}^M$ onto the subspace $\Lambda_0 = \ker G^\top = (\operatorname{range} G)^\perp$ with respect to the scalar product $(\cdot, \cdot) = (\cdot, \cdot)_\Lambda = (\cdot, \cdot)_{\mathbb{R}^M}$. We mention that in case of large jumps in the coefficients of the PDE the scalar product in Λ has to be changed according to the approach proposed in [38]; see also [6] and [64]. Of course, the change of the scalar product changes the orthoprojection P too.

Since $PG = 0$, the application of P to the third equation of (3.9) gives $PG\underline{\gamma} = 0$ that excludes $\underline{\gamma}$ from the first three equations of (3.9). Let us represent $\underline{\lambda}$ in the form

$$\underline{\lambda} = T_0 \underline{\lambda}_0 + \underline{\lambda}_e \tag{3.12}$$

with known $\underline{\lambda}_e = G(G^\top G)^{-1} \underline{e} \in (\ker G^\top)^\perp = \operatorname{range} G$, fulfilling the constraints $G^\top \underline{\lambda}_e = \underline{e}$, and an unknown $T_0 \underline{\lambda}_0 \in \ker G^\top$, i.e., $G^\top T_0 \underline{\lambda}_0 = 0$, where $\underline{\lambda}_0 \in \mathbb{R}^{L_0}$ and $L_0 = \dim \Lambda_0$. The columns of T_0 span a basis of Λ_0. We refer to Remark 3.1 for the practical implementation of the determination of $\underline{\lambda}_0$ by a subspace iteration. We can now define $\underline{t}$, $\underline{v}$, and $\underline{\lambda}_0$ from the twofold saddle point problem

$$\begin{pmatrix} V & -K & 0 \\ -K^\top & -D & B^\top P^\top T_0 \\ 0 & T_0^\top P B & 0 \end{pmatrix} \begin{pmatrix} \underline{t} \\ \underline{v} \\ \underline{\lambda}_0 \end{pmatrix} = \begin{pmatrix} \underline{g} \\ \underline{d} \\ \underline{0} \end{pmatrix}, \tag{3.13}$$

where here $\underline{d} = \underline{f} - B^\top \underline{\lambda}_e$. Once the vectors $\underline{t}$, $\underline{v}$, and $\underline{\lambda}_0$ are defined from (3.13), we get $\underline{\lambda}$ from (3.12), $\underline{\gamma}$ from the third equation of (3.9), i.e.,

$$\underline{\gamma} = -(G^\top G)^{-1} G^\top B \underline{v}, \tag{3.14}$$

and, finally, $\underline{u}$ from (3.8).

Remark 3.1. We mention that the iteration updates for $\underline{\lambda}$ completely live in the subspace Λ_0 if the initial guess is chosen as $\underline{\lambda}_e$. Therefore, a basis of Λ_0, forming the

columns of T_0, is not explicitly needed in the computation (see also Algorithm 1 in section 5).

Since $V = \mathrm{diag}(\alpha_i \widetilde{V}_{i,h})$ is block diagonal and therefore easily invertible we also may eliminate the vector $\underline{t}$ in (3.13) to obtain

$$\begin{pmatrix} S & -B^\top P^\top T_0 \\ -T_0^\top P B & 0 \end{pmatrix} \begin{pmatrix} \underline{v} \\ \underline{\lambda}_0 \end{pmatrix} = \begin{pmatrix} -\underline{d} - K^\top V^{-1} \underline{g} \\ \underline{0} \end{pmatrix} \tag{3.15}$$

with

$$S = \mathrm{diag}(\alpha_i \widetilde{S}_{i,h}), \quad \widetilde{S}_{i,h} = \widetilde{D}_{i,h} + \widetilde{K}_{i,h}^\top \widetilde{V}_{i,h}^{-1} \widetilde{K}_{i,h}.$$

Eliminating $\underline{v}$ we have to solve the Schur complement system of (3.15),

$$\hat{F} \underline{\lambda}_0 = T_0^\top P B S^{-1} B^\top P^\top T_0 \underline{\lambda}_0 = T_0^\top P B S^{-1} [\underline{d} + K^\top V^{-1} \underline{g}]. \tag{3.16}$$

Appropriate strategies for solving (3.16) have been considered in [43]; another choice is the application of a Bramble–Pasciak conjugate gradient scheme to the onefold saddle point problem (3.15). Note that appropriate preconditioners for both methods are given by preconditioners already needed for solving (3.13); see section 5.

4. Solution of twofold saddle point problems. In this section we construct and analyze preconditioned CG-like iterative methods for solving twofold saddle point problems possessing exactly the structure and the properties of the twofold saddle point problem (3.13), namely,

$$\begin{pmatrix} A_1 & B_1^\top & 0 \\ B_1 & -A_2 & B_2^\top \\ 0 & B_2 & 0 \end{pmatrix} \begin{pmatrix} \underline{x}_1 \\ \underline{x}_2 \\ \underline{x}_3 \end{pmatrix} = \begin{pmatrix} \underline{b}_1 \\ \underline{b}_2 \\ \underline{b}_3 \end{pmatrix}, \tag{4.1}$$

where $S_1 = A_1$, A_2, $S_2 = A_2 + B_1 A_1^{-1} B_1^\top$, and $S_3 = B_2 S_2^{-1} B_2^\top$ are symmetric and positive definite. It is easy to see that the system matrix

$$\mathcal{K}_3 = \begin{pmatrix} A_1 & B_1^\top & 0 \\ B_1 & -A_2 & B_2^\top \\ 0 & B_2 & 0 \end{pmatrix}$$

of (4.1) possesses a block LU-decomposition:

$$\mathcal{K}_3 = \mathcal{L}_3 \mathcal{U}_3 \tag{4.2}$$

with

$$\mathcal{L}_3 = \begin{pmatrix} S_1 & & \\ B_1 & -S_2 & \\ & B_2 & -S_3 \end{pmatrix} \quad \text{and} \quad \mathcal{U}_3 = \begin{pmatrix} I & S_1^{-1} B_1^T & \\ & I & -S_2^{-1} B_2^T \\ & & I \end{pmatrix}.$$

The factor $\mathcal{L}_3$ motivates the following construction of a preconditioner $\hat{\mathcal{L}}_3$: Start by replacing S_1, S_2, and S_3 by preconditioners $\hat{S}_1$, $\hat{S}_2$, and $\hat{S}_3$. Additionally, we introduce two scaling factors. First the left upper block is premultiplied by some factor $\tau_1 > 0$ leading to a block 2×2 submatrix

$$\hat{\mathcal{L}}_2 = \begin{pmatrix} \tau_1 \hat{S}_1 & \\ B_1 & -\hat{S}_2 \end{pmatrix}.$$

We end up with the final form of the preconditioner by premultiplying this submatrix by a second scaling factor $\tau_2 > 0$:

$$\hat{\mathcal{L}}_3 = \begin{pmatrix} \tau_2 \hat{\mathcal{L}}_2 & \\ B_2 \mathsf{E}_2 & \hat{S}_3 \end{pmatrix} = \begin{pmatrix} \tau_2\tau_1 \hat{S}_1 & & \\ \tau_2 B_1 & -\tau_2 \hat{S}_2 & \\ & B_2 & \hat{S}_3 \end{pmatrix}$$

with $\mathsf{E}_2 = \begin{pmatrix} 0 & I \end{pmatrix}$. Now we have the following theorem.

THEOREM 4.1. [illegible] τ_1 [illegible]

$$0 < \tau_1 < \lambda_{\min}(\hat{S}_1^{-1} A_1),$$

[illegible] $\hat{\mathcal{L}}_2^{-1}\mathcal{K}_2$ [illegible] $(u, v)_2 = (\mathcal{D}_2 u, v)_{\ell_2}$ [illegible]

$$\mathcal{K}_2 = \begin{pmatrix} A_1 & B_1^T \\ B_1 & -A_2 \end{pmatrix} \qquad \mathcal{D}_2 = \begin{pmatrix} A_1 - \tau_1 \hat{S}_1 & \\ & \hat{S}_2 \end{pmatrix}.$$

[illegible] τ_2 [illegible]

$$0 < \tau_2 < \lambda_{\min}(\hat{\mathcal{L}}_2^{-1}\mathcal{K}_2),$$

[illegible] $\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3$ [illegible] $(u, v)_3 = (\mathcal{D}_3 u, v)_{\ell_2}$ [illegible]

$$\mathcal{D}_3 = \begin{pmatrix} \mathcal{D}_2(\hat{\mathcal{L}}_2^{-1}\mathcal{K}_2 - \tau_2 I) & 0 \\ 0 & \hat{S}_3 \end{pmatrix}.$$

For the proof, see [68].

This theorem shows that we can apply the standard conjugate gradient method in the scalar product $(u, v)_3 = (\mathcal{D}_3 u, v)_{\ell_2}$ to the preconditioned system

$$\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3 \, \underline{x} = \hat{\mathcal{L}}_3^{-1} \underline{b},$$

which is equivalent to (4.1), with $\underline{x} = (\underline{x}_1, \underline{x}_2, \underline{x}_3)^\top$ and $\underline{b} = (\underline{b}_1, \underline{b}_2, \underline{b}_3)^\top$. Then we obtain the following well-known error estimate for the nth iterate $x^{(n)}$ of the conjugate gradient method in the corresponding energy norm:

$$\|x - x^{(n)}\|_{\mathcal{D}_3 \hat{\mathcal{L}}_3^{-1}\mathcal{K}_3} \leq \frac{2q^n}{1 + q^{2n}} \|x - x^{(0)}\|_{\mathcal{D}_3 \hat{\mathcal{L}}_3^{-1}\mathcal{K}_3}$$

with $q = (\sqrt{\kappa(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3)} - 1)/(\sqrt{\kappa(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3)} + 1)$, where $\kappa(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3)$ denotes the relative condition number, $\kappa(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3) = \lambda_{\max}(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3)/\lambda_{\min}(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3)$. In the following we call this preconditioned conjugate gradient method for twofold saddle point problems 2SPCG.

The next theorem provides an estimate for this relative condition number depending on the quality of the preconditioners for the Schur complements.

THEOREM 4.2. [illegible]

$$\underline{\sigma}_1 \hat{S}_1 \leq S_1 \leq \overline{\sigma}_1 \hat{S}_1, \quad \underline{\sigma}_2 \hat{S}_2 \leq S_2 \leq \overline{\sigma}_2 \hat{S}_2, \quad \underline{\sigma}_3 \hat{S}_3 \leq S_3 \leq \overline{\sigma}_3 \hat{S}_3,$$

[illegible] τ_1 [illegible] τ_2 [illegible]

$$\tau_1 < \underline{\lambda}_1, \quad \tau_2 < \underline{\lambda}_2,$$

$\hat{\mathcal{L}}_2^{-1}\mathcal{K}_2$ $\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3$ $(\cdot,\cdot)_2$ $(\cdot,\cdot)_3$

$$\lambda_{\min}(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3) \geq \underline{\lambda}_3, \quad \lambda_{\max}(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3) \leq \overline{\lambda}_3, \qquad \kappa(\hat{\mathcal{L}}_3^{-1}\mathcal{K}_3) \leq \frac{\overline{\lambda}_3}{\underline{\lambda}_3},$$

$\underline{\lambda}_1 = \underline{\sigma}_1$

$$\underline{\lambda}_{i+1} = \frac{1}{2\tau_i}\left(\overline{\sigma}_i(\underline{\sigma}_{i+1}+1) - \sqrt{\overline{\sigma}_i^2(\underline{\sigma}_{i+1}+1)^2 - 4\tau_i\overline{\sigma}_i\underline{\sigma}_{i+1}}\right) \quad i = 1, 2,$$

$\overline{\lambda}_3$

$$\overline{\theta}_3(\lambda) = -\frac{\lambda}{\overline{\sigma}_3} + \cfrac{1-\lambda}{-\cfrac{\tau_2\lambda}{\overline{\sigma}_2} + \cfrac{1-\tau_2\lambda}{-\cfrac{\tau_1\tau_2\lambda}{\overline{\sigma}_1}+1}}.$$

For the proof, see [68].

4.1.

1. It is necessary to keep the parameters τ_1 and τ_2 below the limiting values $\underline{\lambda}_1$ and $\underline{\lambda}_2$ in order to guarantee a well-defined scalar product $(u, v)_3$. On the other hand, the closer these parameters are to their limiting values, the better it is, i.e., the smaller is the upper bound $\overline{\lambda}_3/\underline{\lambda}_3$ for the relative condition number.

2. If the parameters τ_1 and τ_2 are chosen close to their limiting values $\underline{\lambda}_1$ and $\underline{\lambda}_2$ in the sense

$$\frac{\underline{\lambda}_i}{\tau_i} = \mathcal{O}(1) \quad \text{for } i = 1, 2$$

and if the spectral bounds are reasonably scaled, i.e.,

$$1 + \underline{\sigma}_i\overline{\sigma}_i \leq \mathcal{O}(\overline{\sigma}_i) \quad \text{for } i = 1, 2, 3,$$

it can be shown (see [68]) that

$$\frac{\overline{\lambda}_3}{\underline{\lambda}_3} = \mathcal{O}\left(\frac{\overline{\sigma}_1}{\underline{\sigma}_1}\frac{\overline{\sigma}_2}{\underline{\sigma}_2}\frac{\overline{\sigma}_3}{\underline{\sigma}_3}\right).$$

5. Data-sparse BEM preconditioners. As seen in the previous section, we need appropriate preconditioners C_{V_i}, C_{S_i}, and C_F for the local discrete single layer potentials $\widetilde{V}_{i,h}$, the local discrete Schur complements $\widetilde{S}_{i,h}$, and the assembled BETI Schur complement $\hat{F}$, respectively.

Since the bilinear form of the local approximate discrete single layer potential $\widetilde{V}_{i,h}$ is spectrally equivalent to the Galerkin matrix $V_{i,h}$ and therefore to the $H^{-1/2}(\Gamma_i)$-norm, we may use any multilevel representation of an equivalent norm in $H^{-1/2}(\Gamma_i)$ [20, 54]. A suitable multilevel [5] operator is defined by

$$C_{V_i}^{-1}w_{i,h} = \sum_{j=0}^{J} h_{i,j}(Q_{i,j} - Q_{i,j-1})w_{i,h}$$

for $w_{i,h} \in T_{i,h} = T_{i,J}$, where $T_{i,0} \subset T_{i,1} \subset \cdots \subset T_{i,J} = T_{i,h} \subset \cdots$ is a nested sequence of boundary element spaces of piecewise constant basis functions with related mesh

sizes $h_{i,j} = \frac{1}{2}h_{i,j-1}$. Moreover, $Q_{i,j} : L_2(\Gamma_i) \to T_{i,j}$ is the L_2 Galerkin projection onto $T_{i,j}$.

LEMMA 5.1 (see [54, Theorem 2]).

$$c_1^{V_i}\, J^{-2}\, \langle C_{V_i} w_{i,h}, w_{i,h}\rangle_{\Gamma_i} \;\le\; (\widetilde{V}_{i,h}\underline{w}_i, \underline{w}_i) \;\le\; c_2^{V_i}\, \langle C_{V_i} w_{i,h}, w_{i,h}\rangle_{\Gamma_i}$$

$w_{i,h} \in T_{i,J} = T_{i,h}$ $J = \mathcal{O}(1 + \log(H/h))$

Note that in the case of piecewise constant basis functions the L_2 projections $Q_{i,j}w_i$ can be computed directly by inverting diagonal matrices.

The crucial issue in the multilevel preconditioning approach is the availability of a nested hierarchy of boundary element spaces $T_{i,j}$. Starting from a coarse mesh with an associated space $T_{i,0}$, one can define all boundary element spaces $T_{i,j}$ and therefore $T_{i,h} = T_{i,J}$ by a recursive refinement procedure. Instead of this more academic situation we now consider the case where the boundary element space $T_{i,h} = T_{i,J}$ is already given and no further refinement is applicable. In this case we have to construct an artificial mesh hierarchy to define an appropriate multilevel operator. For this we will again use ideas from fast BEM; in particular we will introduce an appropriate clustering hierarchy of all boundary elements as is used in the fast multipole method itself. Using a recursive bisection algorithm, all boundary elements τ_k^i belonging to a subdomain boundary Γ_i can be clustered hierarchically. Since the boundary element spaces $T_{i,h}$ are spanned by piecewise constant basis functions, one can define corresponding piecewise constant coarse grid functions with respect to the cluster of underlying boundary elements. This results in an artificial hierarchy of piecewise constant trial spaces which can be used for the definition of the multilevel operator for preconditioning [59].

To construct preconditioning matrices C_{S_i} for the local discrete Schur complement matrices $\widetilde{S}_{i,h} = \widetilde{D}_{i,h} + \widetilde{K}_{i,h}^\top \widetilde{V}_{i,h}^{-1} \widetilde{K}_{i,h}$, we will apply the concept of boundary integral operators of the opposite order [62]. Based on the local trial space $U_{i,h} = S_h^1(\Gamma_i)$ of piecewise linear basis functions φ_m^i as used for the Galerkin discretization of the local hypersingular boundary integral operators D_i, we define the Galerkin matrices

$$\bar{V}_{i,h}[n,m] \;=\; \langle \varphi_n^i, V\varphi_m^i\rangle_{\Gamma_i}, \quad \bar{M}_{i,h}[n,m] \;=\; \langle \varphi_n^i, \varphi_m^i\rangle_{\Gamma_i}$$

for $m, n = 1, \ldots, M_i$, and the application of the resulting preconditioning matrix is given by

$$C_{S_i}^{-1} \;=\; \bar{M}_{i,h}^{-1} \bar{V}_{i,h} \bar{M}_{i,h}^{-1} \quad \text{for } i = 1, \ldots, p. \tag{5.1}$$

When the application of the discrete single layer potential $\bar{V}_{i,h}$ is realized by using a fast multipole method as described in section 2, this results in an approximate preconditioning matrix $\widetilde{C}_{S_i}$.

LEMMA 5.2. Ω_i $\Gamma_i \cap \Gamma \neq \emptyset$

$$c_1^{S_i}\, [1 + \log(H/h)]^{-2}\, (\widetilde{C}_{S_i}\underline{v}_i, \underline{v}_i) \;\le\; (\widetilde{S}_{i,h}\underline{v}_i, \underline{v}_i) \;\le\; c_2^{S_i} (\widetilde{C}_{S_i}\underline{v}_i, \underline{v}_i) \tag{5.2}$$

$\underline{v}_i \in \mathbb{R}^{M_i}$ Ω_i $\Gamma_i \cap \Gamma = \emptyset$

$$c_1^{S_i}\, (\widetilde{C}_{S_i}\underline{v}_i, \underline{v}_i) \;\le\; (\widetilde{S}_{i,h}\underline{v}_i, \underline{v}_i) \;\le\; c_2^{S_i} (\widetilde{C}_{S_i}\underline{v}_i, \underline{v}_i) \tag{5.3}$$

$\underline{v}_i \in \mathbb{R}^{M_i}$ [illegible] $\underline{e}_i^\top \underline{v}_i = 0$ [illegible] $c_1^{S_i}$ [illegible] $c_2^{S_i}$ [illegible] h [illegible] H [illegible]. Since the approximated discrete single layer potential $\widetilde{V}_{i,h}$ is spectrally equivalent to the Galerkin matrix $V_{i,h}$ and therefore positive definite, and using the representation (2.22) of the approximate hypersingular boundary integral operator $\widetilde{D}_i$, we first conclude that

$$\begin{aligned}(\widetilde{S}_{i,h}\underline{v}_i, \underline{v}_i) &\geq (\widetilde{D}_{i,h}\underline{v}_i, \underline{v}_i) + (\widetilde{V}_{i,h}^{-1}\widetilde{K}_{i,h}\underline{v}_i, \widetilde{K}_{i,h}\underline{v}_i) \;\geq\; (\widetilde{D}_{i,h}\underline{v}_i, \underline{v}_i) \\ &= \sum_{k=1}^{3} \langle \widetilde{V}_{i,h}\underline{\mathrm{curl}}_{|\Gamma_i} v_{i,h|k}, \underline{\mathrm{curl}}_{|\Gamma_i} v_{i,h|k}\rangle_{\Gamma_i} \\ &\geq c \sum_{k=1}^{3} \langle V_i \underline{\mathrm{curl}}_{|\Gamma_i} v_{i,h|k}, \underline{\mathrm{curl}}_{|\Gamma_i} v_{i,h|k}\rangle_{\Gamma_i} \;=\; c\,(D_{i,h}\underline{v}_i, \underline{v}_i)\end{aligned}$$

for all $\underline{v}_i \in \mathbb{R}^{M_i}$. The approximate discrete Steklov–Poincaré operator $\widetilde{S}_{i,h}$ is also bounded from above [9, 60]; i.e.,

$$(\widetilde{S}_{i,h}\underline{v}_i, \underline{v}_i) \;\leq\; (S_{i,h}\underline{v}_i, \underline{v}_i) \;=\; \langle S_i v_{i,h}, v_{i,h}\rangle_{\Gamma_i} \;\leq\; c\,\langle D_i v_{i,h}, v_{i,h}\rangle_{\Gamma_i} \;=\; c\,(D_{i,h}\underline{v}_i, \underline{v}_i)$$

holds for all $\underline{v}_i \in \mathbb{R}^{M_i}$. Hence, in order to find a preconditioner for $\widetilde{S}_{i,h}$ it is sufficient to find a preconditioner for the discrete hypersingular integral operator $D_{i,h}$. In the case of a floating subdomain Ω_i, the preconditioning matrix $C_{S_i} = \bar{M}_{i,h}\bar{V}_{i,h}M_{i,h}$ is spectrally equivalent to the discrete hypersingular integral operator $D_{i,h}$ [62], and since the multipole approximation of $\bar{V}_{i,h}$ is spectrally equivalent to $\bar{V}_{i,h}$, the same is true for the approximate preconditioner $\widetilde{C}_{S_i}$; see also [52]. Hence we obtain the spectral equivalence inequalities (5.3).

If the subdomain Ω_i is a nonfloating subdomain, then we have to use the trial space $U_{i,h} \subset \widetilde{H}^{1/2}(\Gamma_i \backslash (\Gamma \cap \Gamma_i))$ of piecewise linear basis functions vanishing on the Dirichlet boundary Γ. Due to the mapping properties of the boundary integral operators

$$\begin{aligned}D_i &: \widetilde{H}^{1/2}(\Gamma_i \backslash (\Gamma \cap \Gamma_i)) \to H^{-1/2}(\Gamma_i \backslash (\Gamma \cap \Gamma_i)), \\ V_i &: \widetilde{H}^{-1/2}(\Gamma_i \backslash (\Gamma \cap \Gamma_i)) \to H^{1/2}(\Gamma_i \backslash (\Gamma \cap \Gamma_i)),\end{aligned}$$

we have to consider the discrete embedding

$$\|v_h\|^2_{H^{1/2}(\Gamma_i \backslash (\Gamma \cap \Gamma_i))} \;\leq\; c\,[1 + \log(H/h)]^2\, \|v_h\|^2_{\widetilde{H}^{1/2}(\Gamma_i \backslash (\Gamma \cap \Gamma_i))}$$

for $v_h \in U_{i,h}$ yielding the spectral equivalence inequalities (5.2); see [49] together with an appropriate scaling argument. □

We finally have to describe a suitable preconditioning matrix for the BETI Schur complement

$$F \;=\; \sum_{i=1}^{q} \frac{1}{\alpha_i} B_i [\widetilde{S}_{i,h} + \beta_i \underline{e}_i \underline{e}_i^\top]^{-1} B_i^\top \;+\; \sum_{i=q+1}^{p} \frac{1}{\alpha_i} B_i \widetilde{S}_{i,h}^{-1} B_i^\top \,.$$

Following [43] we can define the scaled sparse hypersingular BETI preconditioner

$$C_F^{-1} = (BC_\alpha^{-1}B^T)^{-1} BC_\alpha^{-1} \widetilde{D}_h C_\alpha^{-1} B^T (BC_\alpha^{-1}B^\top)^{-1}. \tag{5.4}$$

LEMMA 5.3 (see [43, Theorem 3.2]).

(5.4)

$$c_1^F\,(C_F\underline{\mu},\underline{\mu}) \le (F\underline{\mu},\underline{\mu}) \le c_2^F\,(1+\log(H/h))^2\,(C_F\underline{\mu},\underline{\mu}) \tag{5.5}$$

$\underline{\mu} \in \Lambda_0 = \ker G^\top$ c_1^F c_2^F
h H p α_i

Combining Theorem 4.2 with the results of Lemmata 5.1–5.3 and taking into account the complexity estimate for the fast multipole method, we finally arrive at our main theorem.

THEOREM 5.4. (3.13) 2
C_V C_S
C_F $I(\varepsilon) = \mathcal{O}((1+\log(H/h))^3 \log \varepsilon^{-1})$
$(\varepsilon) = \mathcal{O}((H/h)^2(1+\log(H/h))^5 \log \varepsilon^{-1})$
$\varepsilon \in (0,1)$
$I(\varepsilon)$
$\mathcal{O}((H/h)^2(1+\log(H/h))^2)$

Note that the complexity estimates given in Theorem 5.4 do not take into account the costs for the projection (3.11) that involves the global information exchange.

5.1. If we use optimal preconditioners $\widetilde{C}_{V_i}$ for the local single layer potentials $\widetilde{V}_{i,h}$ and $\widetilde{C}_{S_i}$ for the local boundary element Schur complements $\widetilde{S}_{i,h}$, the number of iterations $I(\varepsilon)$ of our 2SPCG solver would behave like $\mathcal{O}((1+\log(H/h))\log\varepsilon^{-1})$, and the arithmetical complexity would decrease from $\mathcal{O}((H/h)^2(1+\log(H/h))^5\log\varepsilon^{-1})$ to $\mathcal{O}((H/h)^2(1+\log(H/h))^3\log\varepsilon^{-1})$. Such preconditioners are available; see, e.g., [42, 56, 62, 63]. If we convert the nonfloating subdomains having a Dirichlet boundary part to floating subdomains by including the Dirichlet boundary condition into the constraints (all-floating BETI), then the data-sparse opposite order preconditioners $\widetilde{\mathcal{S}}_{i,h}$ given above would be optimal.

We mention that h/H can be replaced by $\max\{h_i/H_i\}$, where H_i and h_i are now the scaling parameters of Ω_i and the mesh on Γ_i. Therefore, the global quasi-uniformity assumption can be replaced by a local one.

Applying the 2SPCG introduced in section 4 to our twofold saddle point problem (3.13) with the preconditioners presented above and taking Remark 3.1 into account, we obtain a subspace iteration version of the 2SPCG that can be rewritten in the algorithmic form given in Algorithm 1.

Note that, for an efficient implementation, the applications of $\hat{\mathcal{L}}_3^{-1}$ and $\mathcal{D}_3\hat{\mathcal{L}}_3^{-1}$ have to be concatenated; see [61, 68]. Here, we have used the notation of section 4 for the matrix in (3.13) and a vector $\underline{x} = (\underline{x}_1, \underline{x}_2, \underline{x}_3)^T$, where $\underline{x}_i$ corresponds to the ith block of the system (3.13).

Algorithm 1 was used in our numerical experiments, the results of which are given in the next section.

6. Numerical results. For the numerical examples we consider the unit cube which is subdivided into eight similar subdomains as shown in Figure 6.1. The given Dirichlet data $g(x)$ is chosen as the trace of a regular solution of the boundary value problem (2.1). This allows us to check the convergence of the computed numerical solution to the exact one.

In Table 6.1, the geometric information about the domain decomposition and the discretization is listed for the refinement levels L used. Starting from the coarsest grid with 192 triangles for the whole domain Ω, the refined meshes are recursively

constructed by subdividing each triangle into four smaller similar triangles. N and M are the total numbers of triangles and nodes, respectively. M_c is the total number of coupling nodes. The numbers of local triangles and nodes of a single subdomain Ω_i are given by N_i and M_i, respectively. If the boundary mesh of one subdomain Ω_i with 98304 triangles was uniformly extended to the interior of the subdomain, the corresponding FEM grid would consist of 6291456 tetrahedra. For the whole domain, more than 50 million tetrahedra would be used in a finite element discretization.

In all following tables, a unified notation is used. L again denotes the refinement level. Table 6.1 provides the corresponding information about the grids. The times t_1 and t_2 are the measured times in seconds for setting up the systems of linear equations

and for their solution. The column shows the number of iterations needed to solve the corresponding system of linear equations with a relative accuracy of $\varepsilon = 10^{-8}$. In the column the error $\|u - u_h\|_{L_2(\Gamma_i)}$ is listed for the different levels considered.

The effects of the preconditioners for inverting the single layer potential in the representation of the Steklov–Poincaré operator and for the Schur complement system (2.25) by the preconditioner (2.26) are shown in Table 6.2. Setting up the preconditioners takes some time as can be seen in the differences of t_1 for the unpreconditioned and preconditioned cases. But the preconditioning pays off as the numbers of iterations are reduced significantly. In parentheses, the average numbers of iterations are given for the inversion of the local single layer potentials. Accordingly, the times t_2 for solving the system of linear equations are reduced, while the errors are about the same. These calculations have been executed on a standard PC cluster with 3.06 MHz Intel processors and 1 GB of RAM.

Next, the Schur complement system (2.25) will be compared to three different BETI formulations. Since the times t_1 to set up the system of linear equations differ only slightly from each other, only the times t_2 for solving and the numbers *it* of iterations will be compared in Table 6.3. Only the numbers for the preconditioned systems are treated. The numbers of iterations differ slightly from those of Table 6.2, as a slightly different preconditioner C_V^{-1} was used for the inversion of the local single layer potentials $\widetilde{V}_{i,h}$. The computational times are a little bit higher than in the example of Table 6.2 as the computations have been executed on a different cluster and different boundary data have been used. All further computations have been executed in parallel with one processor per subdomain on the Mozart cluster of the Chair of Simulation of Large Systems and the Chair of Numerics for Supercomputers at the University of Stuttgart. The cluster consists of 64 nodes with 2 CPU Intel Xeon 3,066 and 4 GB RAM each. The errors are almost the same for the different formulations.

6	8267	30(43)	123454	16(25(43))	25759	47(42)	15038	116

The first BETI formulation is the Schur complement system (3.16). This system involves two recursive inversions in each iteration step. The iteration numbers given in parentheses are average numbers needed to invert the local Steklov–Poincaré operators and the local single layer potential, respectively, while the other number is the number of iterations for solving the BETI Schur complement system (3.16). For example, on the sixth refinement level about $16 \cdot 25$ inversions of the local single layer potentials are executed, and the average number of iterations needed for such an inversion is 43.

The second BETI formulation is the saddle point problem (3.15). This system needs only the inversions of the local single layer potentials in each iteration step of the system, while the local potentials $\underline{u}_i$ are determined simultaneously in the global system. Due to the larger number of unknowns in the global system, the number of iterations increases but not too strongly. Therefore the total number of applications of the Galerkin matrices of the local boundary integral operators is less than that of the BETI Schur complement system. Correspondingly, the improvement on the times t_2 for solving the system is significant.

A further improvement on the times t_2 can be made by using the third BETI formulation, the twofold saddle point problem given by (3.3). In this formulation, no inner inversion is needed, but the number of unknowns in the system is increased to almost 800000 for the local fluxes $\underline{t}_i$ on the sixth level. Therefore, the number of iterations again increases. Correspondingly, the number of applications of the Galerkin matrices of the local single layer potentials is again decreased. The benefit of solving the system is smaller than in the case before, as the number of applications of the Galerkin matrices of the other boundary integral operator increases. Unfortunately, these applications are more expensive. The twofold saddle point formulation (3.3) results in the most efficient BETI algorithm in comparison with algorithms based on the other BETI formulations. But it still performs worse than the Schur complement system (2.25).

The systems (3.15) and (3.3) have been solved as the transformed systems described in section 4 by using Algorithm 1. The preconditioners used have been scaled optimally according to the estimates of the eigenvalues of the transformed systems given by Theorem 4.2.

The BETI methods perform much better when considering jumping coefficients instead of constant coefficients as in the previous example. In Table 6.4, the times t_2 for solving the linear systems and the corresponding numbers of iterations are itemized for the coefficients $\alpha_1 = 1$ and $\alpha_2 = 10^5$ distributed on the subdomains as on a checkerboard. Again, the three different BETI formulations are compared to the Schur complement system (2.25).

Comparing the iteration numbers in Tables 6.3 and 6.4, we observe that the scaled

TABLE 6.4

version of the BETI preconditioner performs even better. Moreover, this example confirms the independence of the iteration numbers from the jumps in the coefficients as predicted by the theory presented in sections 4 and 5. On the other hand, the iteration numbers for solving the Schur complement system of (2.16) increase in the case of jumping coefficients, even though the preconditioner still works.

Comparing the times t_2 for solving the corresponding systems, the numbers are a lot better for the BETI method. The twofold saddle point formulation (3.3) of the BETI method outperforms the Schur complement system (2.25) on the sixth refinement level, and one would expect an even larger difference on the seventh level.

The improvement of the preconditioners C_{V_i} for the single layer potential blocks $\widetilde{V}_{i,h}$ leads to a significant improvement of the preconditioner for the complete twofold BETI saddle point system (see [41], where AMG preconditioners are used for $\widetilde{V}_{i,h}$).

7. Conclusions and final remarks. In this paper, we have presented inexact data-sparse boundary element tearing and interconnecting domain decomposition methods for solving boundary value problems for the potential equation with piecewise constant coefficients. In contrast to the classical approach we have avoided the elimination of local unknowns $\underline{t}_i$ and $\underline{u}_i$. This finally led us to a twofold saddle point problem. We have presented preconditioned CG-like iterative methods for solving such twofold saddle point problems and have given a rigorous analysis of the preconditioning problem resulting in precise CG-like convergence rate estimates. Furthermore, we have presented data-sparse preconditioners which yield almost optimal iterative solvers for the inexact data-sparse BETI equations. Moreover, the convergence rate is not affected by large jumps in the coefficients of the PDE. This is confirmed by all our numerical experiments. The data-sparse preconditioners proposed in this paper do not need special constructions since they are available in the BETI discretization anyway. Thus, they are completely algebraic. This is very important for the practical acceptance of our method. It is clear that inexact data-sparse BETI allows us to solve really large-scale problems with several million boundary unknowns on distributed memory parallel computers very efficiently.

The treatment of the exterior Dirichlet problem and other boundary conditions is straightforward. The generalization of our method to linear elasticity problems with piecewise constant materials is also possible [51]. The all-floating BETI method that has recently been proposed by Of in [51] provides a unified framework for treating mixed boundary value problems. Using the symmetric coupling technique proposed by Costabel [10] and combining the results of this paper with the results obtained by Klawonn and Widlund [37], we can easily construct and analyze inexact FETI-BETI solvers for large-scale coupled finite and boundary element equations. Exact FETI-BETI solvers were already proposed and analyzed in [44].

Acknowledgment. The authors would like to express their thanks to the anonymous referees for many helpful hints and suggestions.

A PROJECTION-BASED APPROACH TO GENERAL-FORM TIKHONOV REGULARIZATION*

MISHA E. KILMER†, PER CHRISTIAN HANSEN‡, AND MALENA I. ESPAÑOL†

Abstract. We present a projection-based iterative algorithm for computing general-form Tikhonov regularized solutions to the problem $\min_x\{\|Ax-b\|_2^2+\lambda^2\|Lx\|_2^2\}$, where the regularization matrix L is not the identity. Our algorithm is designed for the common case where λ is not known a priori. It is based on a joint bidiagonalization algorithm and is appropriate for large-scale problems when it is computationally infeasible to transform the regularized problem to standard form. By considering the projected problem, we show how estimates of the corresponding optimal regularization parameter can be efficiently obtained. Numerical results illustrate the promise of our projection-based approach.

Key words. general-form Tikhonov regularization, iterative bidiagonalization methods

AMS subject classification. 65F22

DOI. 10.1137/050645592

1. Introduction.

This paper presents a new iterative algorithm for computing an approximate solution to a Tikhonov regularized, linear discrete ill-posed problem with a general smoothing term. Linear ill-posed problems in the form of first-kind Fredholm integral equations occur frequently in the physical sciences, where they model situations where hidden information is computed from external observations [6]. The term discrete ill-posed problem refers to a discretization of such an integral equation, taking the form

$$Ax \approx b = b_{\text{true}} + e, \qquad b_{\text{true}} = Ax_{\text{true}}, \tag{1.1}$$

where A is a discretization of the integral operator, x_{true} is the true solution, and e denotes noise which we here assume to be white noise (i.e., the covariance matrix for e is a scaled identity matrix). In discrete ill-posed problems the singular values of A always decay gradually towards zero, and often there are many singular values at the machine precision level. This renders the least squares solution to the system (1.1) worthless, in the sense that the least squares solution does not approximate the solution x_{true} to the noise-free problem.

A popular technique for computing approximations to the true solution in the presence of noise is to compute the Tikhonov regularized solution:

$$x_\lambda = \operatorname{argmin}_x \left\{\|Ax-b\|_2^2+\lambda^2\|Lx\|_2^2\right\} = \operatorname{argmin}_x \left\| \begin{bmatrix} A \\ \lambda L \end{bmatrix} x - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2. \tag{1.2}$$

Here A is $m \times n$ with $m \geq n$, L is a $p \times n$ regularization matrix which defines the smoothing term $\|Lx\|_2$, and λ is a positive scalar called the [illegible]

There are no restrictions on the dimensions of L, and we assume that the null spaces of A and L intersect trivially such that the matrix $[A^T \ L^T]$ has full rank and the solution x_λ in (1.2) is unique. If λ and L are chosen appropriately, the solution to the Tikhonov problem should approximate the desired solution x_{true}.

We emphasize that there are many examples of inverse problems where $L = I$ is not suited, such as two-dimensional (2D) spline interpolation [2], geophysics [4], and heat distribution [13]. The matrix L is problem dependent, and typical choices for L include (scaled) discrete first or second derivative operators in the appropriate dimension. The most common situation is that these L matrices are rectangular.

For large-scale problems, x_λ is usually computed by applying an iterative least squares method, such as CGLS or LSQR, to (1.2)—possibly supplemented with an appropriate preconditioner. However, this approach is computationally very demanding if the regularization parameter is not known a priori, and many different values of λ must be tried. Moreover, as we shall see shortly, the Krylov subspace underlying this approach is not necessarily the right choice.

When $L = I$ (the standard-form case) one can instead use a [illegible], where the problem is first projected onto a lower-dimensional subspace—typically a Krylov subspace—and then Tikhonov regularization combined with a parameter-choice method is applied to the projected problem. Finally the solution is transformed back to the original domain, and the result is an approximation to the Tikhonov solution. The projection is typically implemented via Lanczos bidiagonalization applied to A, with starting vector b, and the projected problem involves a lower bidiagonal matrix; cf. [14] for details.

The common approach to treating the general case with $L \neq I$ is to use a standard-form transformation. If L is invertible, then we can use the substitution $y = Lx$. Otherwise—and this is the common situation—we must use the A-weighted pseudoinverse of L, formally given by $L_A^\dagger = (I - (A(I - L^\dagger L))^\dagger A)L^\dagger$; cf. [3]. The standard-form problem is then

$$y_\lambda = \text{argmin}_y \left\{ \|AL_A^\dagger y - b\|_2^2 + \lambda^2 \|y\|_2^2 \right\}, \qquad x_\lambda = L_A^\dagger y_\lambda + x_0, \tag{1.3}$$

in which x_0 is the component of the solution in the null space of L. The key idea is to apply the bidiagonalization algorithm to the matrix $AL_A^\dagger$ and again use the regularization and parameter-choice algorithms on the projected problem. Multiplication with $L_A^\dagger$ involves solving a least squares problem followed by an oblique projection; see, e.g., [11] or [13] for some implementation details. This approach is useful from a practical standpoint whenever it is possible to implement these operations efficiently.

However, there are many problems for which it is complicated to work with $L_A^\dagger$. This is often the case for higher-dimensional problems, e.g., when the matrix L is a sum of Kronecker products. Therefore we are interested in an alternative projection-based approach that avoids the use of $L_A^\dagger$, which involves only multiplications with L and L^T and is based on a suited Krylov subspace.

This paper describes a new projection method which simultaneously bidiagonalizes both A and L in such a way that we can easily apply Tikhonov regularization and parameter-choice methods to the projected problem involving the two bidiagonal matrices. The algorithm is inspired by a bidiagonalization algorithm by Zha [17] for computing principal generalized singular values and vectors of a matrix pair, but our algorithm and the underlying theory are different.

Our paper is organized as follows. In section 2 we give the basic notation and state several decompositions that we will make use of throughout the paper. In section 3

we introduce the iterative algorithm for approximately solving (1.2) and consider how to select a suitable λ as the iterative method progresses. In section 4 some insight is presented which helps to interpret the outcome of the iterative method. Numerical results are presented in section 5, and section 6 contains our conclusions.

2. Background. This section summarizes the facts and decompositions that are the basis for our algorithm. Throughout the rest of the paper, we assume that L and A are real and have been scaled so that the norms of A and L are of the same order of magnitude. We also assume that the exact right-hand side b_{true} satisfies the discrete Picard condition, as specified below.

2.1. GSVD and regularization. To understand why (1.2) produces a reasonable approximate solution to the noisy problem (1.1), it is convenient to look at the generalized singular value decomposition (GSVD) of the matrix pair $\{A, L\}$. First, consider the special QR factorization of the stacked matrix:

$$\begin{bmatrix} A \\ L \end{bmatrix} = QR = \begin{bmatrix} Q_A \\ Q_L \end{bmatrix} R, \qquad Q_A^T Q_A + Q_L^T Q_L = I, \tag{2.1}$$

where $R \in \mathbb{R}^{n\times n}$ is upper triangular and $Q \in \mathbb{R}^{(m+p)\times n}$ has orthonormal columns. We partition Q such that $Q_A \in \mathbb{R}^{m\times n}$ and $Q_L \in \mathbb{R}^{p\times n}$, and therefore $A = Q_A R$ and $L = Q_L R$. Now let

$$Q_A = P_A C_A W^T, \qquad Q_L = P_L S_L W^T \tag{2.2}$$

be the CS decomposition of $\{Q_A, Q_L\}$ (see, e.g., [1, section 4.2] or [5, section 2.6]), where $P_A \in \mathbb{R}^{m\times m}$, $P_L \in \mathbb{R}^{p\times p}$, and $W \in \mathbb{R}^{n\times n}$ are orthogonal matrices, and $C_A \in \mathbb{R}^{m\times n}$ and $S_L \in \mathbb{R}^{p\times n}$ are diagonal matrices (not necessarily square) satisfying $C_A^T C_A + S_L^T S_L = I$. Then the GSVD of $\{A, L\}$ is defined as

$$A = P_A C_A G^{-1}, \qquad L = P_L S_L G^{-1} \qquad \text{with} \qquad G = R^{-1} W, \tag{2.3}$$

where the invertibility of G follows from the assumption that $[A^T \ L^T]$ has full rank. For convenience, we order the entries of the diagonal matrices C_A and S_L so that

$$1 \geq c_1 \geq \cdots \geq c_{\min(n,p)} \geq 0, \qquad c_{\min(n,p)+1} = \cdots = c_n = 1,$$

$$0 \leq s_1 \leq \cdots \leq s_{\min(n,p)} \leq 1,$$

which differs from the order usually found in the literature. We do this so that the quantities $c_1, \ldots, c_{\min(n,p)}$ appear in nonincreasing order, similar to the standard SVD. Using this decomposition, the Tikhonov solution takes the form

$$\begin{aligned} x_\lambda &= (A^T A + \lambda^2 L^T L)^{-1} A^T b = G\,(C_A^T C_A + \lambda^2 S_L^T S_L)^{-1} C_A^T P_A^T b \\ &= \sum_{i=1}^{\min(n,p)} \frac{c_i^2}{c_i^2 + \lambda^2 s_i^2} \frac{p_{A,i}^T b}{c_i}\, g_i + \sum_{i=\min(n,p)+1}^{n} p_{A,i}^T b\, g_i, \end{aligned} \tag{2.4}$$

where $p_{A,i}$ and g_i are the columns of P_A and G, respectively. The last term, which vanishes when $p \geq n$, consists of components in the null space of L which are not influenced by the regularization. The discrete Picard condition [10] says that the values $|p_{A,i}^T b_{\text{true}}|$ must, on average, decay faster than the c_i. Hence the values $|p_{A,i}^T b|$ also, on average, decay until we reach an index i such that noise components become

TABLE 2.1
The ingredients of the two algorithms BIDIAG-1 *and* BIDIAG-2.

Matrix	Size	Details
B_k	$(k+1) \times k$	$(B_k)_{i,i} = \alpha_i \quad (B_k)_{i+1,i} = \beta_{i+1}$
$\widehat{B}_k$	$k \times k$	$(\widehat{B}_k)_{i,i} = \hat{\alpha}_i \quad (\widehat{B}_k)_{i,i+1} = \hat{\beta}_i$
U_{k+1}	$m \times (k+1)$	$(u_1, \ldots, u_{k+1})$
$\widehat{U}_k$	$p \times k$	$(\hat{u}_1, \ldots, \hat{u}_k)$
V_k	$n \times k$	$(v_1, \ldots, v_k)$
$\widehat{V}_k$	$n \times k$	$(\hat{v}_1, \ldots, \hat{v}_k)$

dominant; beyond that point $|p_{A,i}^T b|$ becomes roughly constant independent of i, due to our assumption about the noise e being white. The recoverable "signal" is contained primarily in the subspace spanned by the g_i's for small i, and a good value of λ should have the effect of filtering (or damping) the terms in the sum for larger values of i. The solution produced by our algorithm must resemble such a filtered GSVD solution.

2.2. Joint bidiagonalization. Consider the reduced QR factorization in (2.1). Zha [17, section 4.1] derived an algorithm for joint reduction of Q_A and Q_L to upper bidiagonal form, given a common right starting vector. Similar to Zha's algorithm, we do not need the QR factorization explicitly, but to make our presentation clearer we start by formulating our algorithm explicitly in terms of Q_A and Q_L.

Our algorithm is intended for solving systems of equations, and it is crucial to use the right-hand side b as a left starting vector for a , , . bidiagonal reduction of Q_A; therefore we must use the BIDIAG-1 algorithm from [15] (which underlies the LSQR algorithm). We combine this with the algorithm BIDIAG-2 from [15] for the joint , , , bidiagonal reduction of Q_L.

BIDIAG-1. Starting vector b; reduction of Q_A to lower bidiagonal form:
$\beta_1 u_1 = b$
$\alpha_1 v_1 = Q_A^T u_1$
for $i = 1, 2, \ldots, n-1$
  $\beta_{i+1} u_{i+1} = Q_A v_i - \alpha_i u_i$
  $\alpha_{i+1} v_{i+1} = Q_A^T u_{i+1} - \beta_{i+1} v_i$.

BIDIAG-2. Starting vector v_1; reduction of Q_L to upper bidiagonal form:
$\hat{v}_1 = v_1$
$\hat{\alpha}_1 \hat{u}_1 = Q_L \hat{v}_1$
for $i = 1, 2, \ldots, \min(p, n) - 1$
  $\hat{\beta}_i \hat{v}_{i+1} = Q_L^T \hat{u}_i - \hat{\alpha}_i \hat{v}_i$
  $\hat{\alpha}_{i+1} \hat{u}_{i+1} = Q_L \hat{v}_{i+1} - \hat{\beta}_i \hat{u}_i$.

In both algorithms the scalars α_i, β_i, $\hat{\alpha}_i$, and $\hat{\beta}_i$ are chosen so that u_i, v_i, $\hat{u}_i$, and $\hat{v}_i$ have unit 2-norm. From the kth step of the two algorithms we obtain

$$Q_A V_k = U_{k+1} B_k, \qquad Q_A^T U_{k+1} = V_k B_k^T + \alpha_{k+1} v_{k+1} e_{k+1}^T, \tag{2.5}$$

$$Q_L \widehat{V}_k = \widehat{U}_k \widehat{B}_k, \qquad Q_L^T \widehat{U}_k = \widehat{V}_k \widehat{B}_k^T + \hat{\beta}_k \hat{v}_{k+1} e_k^T, \tag{2.6}$$

where e_{k+1} and e_k are the last columns of the identity matrices of orders $k+1$ and k, respectively. The remaining ingredients of the two equations are listed in Table 2.1.

The following theorem, the proof of which follows along the lines of a related proof in [17], gives the relationship between the joint bidiagonalization of Q_A and Q_L computed by the two algorithms above.

THEOREM 2.1. [illegible] Q_A [illegible] Q_L [illegible] BIDIAG-1 [illegible] BIDIAG-2 [illegible]

$$\hat{v}_{j+1} = (-1)^j v_{j+1}, \qquad \hat{\alpha}_j\hat{\beta}_j = \alpha_{j+1}\beta_{j+1}, \qquad j = 1, 2, \ldots, \min(p, n) - 1.$$

[illegible]. We prove Theorem 2.1 by induction. Consider the base case $j = 1$ and note that $\hat{v}_1 = v_1$ by construction. We assume that $\hat{\alpha}_1$, $\hat{\beta}_1$, α_2, and β_2 are strictly positive, and we must show that $\hat{v}_2 = -v_2$ and $\hat{\alpha}_1\hat{\beta}_1 = \alpha_2\beta_2$. Since $\hat{\beta}_1\hat{v}_2 = Q_L^T\hat{u}_1 - \hat{\alpha}_1\hat{v}_1$, we get

$$\hat{\alpha}_1\hat{\beta}_1\hat{v}_2 = Q_L^T(Q_L\hat{v}_1) - \hat{\alpha}_1^2\hat{v}_1 = v_1 - Q_A^TQ_Av_1 - \hat{\alpha}_1^2v_1,$$

where we have used that $Q_L^TQ_L = I - Q_A^TQ_A$ and $v_1 = \hat{v}_1$. Similarly, we find

$$\beta_2\alpha_2v_2 = Q_A^T(Q_Av_1 - \alpha_1u_1) - \beta_2^2v_1 = Q_A^TQ_Av_1 - \alpha_1^2v_1 - \beta_2^2v_1.$$

Adding these two equations, we obtain

$$\hat{\alpha}_1\hat{\beta}_1\hat{v}_2 + \alpha_2\beta_2v_2 = (1 - \hat{\alpha}_1^2 - \alpha_1^2 - \beta_2^2)v_1.$$

Both $\hat{v}_2$ and v_2 are orthogonal to v_1 by construction, and each has unit norm. Therefore, multiplying on the left by v_2^T (likewise $\hat{v}_2^T$) and rearranging give

$$v_2^T\hat{v}_2 = -\frac{\alpha_2\beta_2}{\hat{\alpha}_1\hat{\beta}_1}, \qquad \hat{v}_2^Tv_2 = -\frac{\hat{\alpha}_1\hat{\beta}_1}{\alpha_2\beta_2}.$$

Since $\hat{\alpha}_1$, $\hat{\beta}_1$, α_2, and β_2 are positive, this implies the two relations $\hat{\alpha}_1\hat{\beta}_1 = \alpha_2\beta_2$ and $\hat{v}_2 = -v_2$, and the base case is proved.

Next, suppose the hypothesis is true for indices up to j. We need to show that $\hat{v}_{j+1} = (-1)^jv_{j+1}$ and $\hat{\alpha}_j\hat{\beta}_j = \alpha_{j+1}\beta_{j+1}$. Let $P_j = \mathrm{diag}(1, -1, 1, -1, \ldots) \in \mathbb{R}^{j\times j}$ (note that P_j is orthogonal). Then the induction hypothesis gives $\hat{V}_j = V_jP_j$. Using this fact, the relation $Q_A^TQ_A + Q_L^TQ_L = I$, and (2.5) and (2.6), it is straightforward to show that

$$I_j = B_j^TB_j + P_j\widehat{B}_j^T\widehat{B}_jP_j.$$

Multiplying the leftmost equation in (2.5) by Q_A^T and using the rightmost equation, we obtain

$$Q_A^TQ_AV_j = V_jB_j^TB_j + \alpha_{j+1}\beta_{j+1}v_{j+1}e_j^T.$$

Likewise, we get $Q_L^TQ_L\widehat{V}_j = \widehat{V}_j\widehat{B}_j^T\widehat{B}_j + \hat{\alpha}_j\hat{\beta}_j\hat{v}_{j+1}e_j^T$, which yields

$$Q_L^TQ_LV_j = V_jP_j\widehat{B}_j^T\widehat{B}_jP_j + \hat{\alpha}_j\hat{\beta}_j(-1)^{j+1}\hat{v}_{j+1}e_j^T.$$

Adding the above two equations, we get

$$\overbrace{(Q_A^TQ_A + Q_L^TQ_L)}^{I}V_j = V_j\overbrace{(B_j^TB_j + P_j\widehat{B}_j^T\widehat{B}_jP_j)}^{I_j} + \left(\alpha_{j+1}\beta_{j+1}v_{j+1} + \hat{\alpha}_j\hat{\beta}_j\hat{v}_{j+1}(-1)^{j+1}\right)e_j^T,$$

which means the last term in the sum on the right must vanish. Since the $\hat{\alpha}_j$, $\hat{\beta}_j$, α_{j+1}, and β_{j+1} are nonnegative and since v_{j+1} and $\hat{v}_{j+1}$ have unit norm, this implies $\hat{v}_{j+1} = (-1)^j v_{j+1}$ and $\hat{\alpha}_j \hat{\beta}_j = \alpha_{j+1}\beta_{j+1}$ as desired. ∎

From the above theorem and the relation of Q_A and Q_L to A and L, it follows that A and L can be jointly bidiagonalized.

THEOREM 2.2. $A \in \mathbb{R}^{m\times n}$ $L \in \mathbb{R}^{p\times n}$ $m \geq n$ $U \in \mathbb{R}^{m\times m}$ $\widehat{U} \in \mathbb{R}^{p\times p}$ $V \in \mathbb{R}^{n\times n}$ $B \in R^{m\times n}$ $\bar{B} \in R^{p\times n}$ $n \times n$ Z

$$A = UBZ^{-1}, \qquad L = \widehat{U}\bar{B}Z^{-1}, \qquad Z = R^{-1}V, \tag{2.7}$$

R (2.1) $\bar{B} = \widehat{B}P$ $P = \mathrm{diag}(1, -1, 1, -1, \dots)$ $p < n$ $p+1, \dots, n$ $\bar{B}$. The proof follows by simple insertion. ∎

3. An iterative algorithm. In [17], a joint bidiagonalization (different from ours) was used to estimate generalized singular triplets. In this work we utilize our new joint bidiagonalization to obtain a low-storage, inner-outer iterative technique for computing approximate Tikhonov solutions to (1.2) for multiple values of λ simultaneously.

3.1. Derivation of the projection-based algorithm. First, we replace the Tikhonov problem (1.2) by an approximate problem:

$$x_k^\lambda = \mathrm{argmin}_{x\in\mathcal{Z}_k} \left\| \begin{bmatrix} A \\ \lambda L \end{bmatrix} x - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2, \qquad \mathcal{Z}_k = \mathrm{span}\{z_1, \dots, z_k\}; \tag{3.1}$$

i.e., x_k^λ is a linear combination of the first k columns of the matrix Z from (2.7). The superscript is used to emphasize that this vector depends on λ, since it is an approximation to the Tikhonov solution.

Now from Theorem 2.2 it follows that $AZ_k = U_{k+1}B_k$ and $LZ_k = \widehat{U}_k\bar{B}_k$, where $Z_k = (z_1, \dots, z_k)$. Notice that

$$U_{k+1}(\beta_1 e_1) = b, \qquad \beta_1 = \|b\|_2, \tag{3.2}$$

where e_1 is the first canonical unit vector of length $k+1$. Then, with $x_k^\lambda = Z_k y_k^\lambda$,

$$\begin{aligned} \left\| \begin{bmatrix} A \\ \lambda L \end{bmatrix} x_k^\lambda - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2 &= \left\| \begin{bmatrix} AZ_k \\ \lambda L Z_k \end{bmatrix} y_k^\lambda - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2 \\ &= \left\| \begin{bmatrix} U_{k+1} & 0 \\ 0 & \hat{U}_k \end{bmatrix} \left(\begin{bmatrix} B_k \\ \lambda \bar{B}_k \end{bmatrix} y_k^\lambda - \begin{bmatrix} \beta_1 e_1 \\ 0 \end{bmatrix} \right) \right\|_2 \\ &= \left\| \begin{bmatrix} B_k \\ \lambda \bar{B}_k \end{bmatrix} y_k^\lambda - \begin{bmatrix} \beta_1 e_1 \\ 0 \end{bmatrix} \right\|_2 . \end{aligned}$$

Hence, the minimization problem (3.1) is equivalent to computing

$$x_k^\lambda = Z_k y_k^\lambda \qquad \text{with} \qquad y_k^\lambda = \mathrm{argmin}_y \left\| \begin{bmatrix} B_k \\ \lambda \bar{B}_k \end{bmatrix} y - \begin{bmatrix} \beta_1 e_1 \\ 0 \end{bmatrix} \right\|_2 . \tag{3.3}$$

We refer to (3.3) as the projected problem with regularization. The key point here is that the B_k $\bar{B}_k$ λ.

The main idea is that once k is large enough, the projected problem will capture the main features/components of the original problem. To be more precise, let $x_{\lambda^{\text{opt}}}$ denote the Tikhonov solution to the original problem, where λ^{opt} is the optimal regularization parameter. Then there is good hope that—for large enough k—there exists a parameter $\lambda^{k,*}$ such that the corresponding solution $x_k^{\lambda^{k,*}}$ to (3.1) will be a good approximation to $x_{\lambda^{\text{opt}}}$.

Projection-Based General-Form Tikhonov Regularization.

For $k = 1, 2, \ldots$

(a) compute the kth step of the joint bidiagonalization,

(b) compute y_k^λ (and x_k^λ, if desired),

(c) update residual norm and seminorm; check for convergence.

Efficient implementation details are described below. As we will see, step (a) in this algorithm will require an inner iteration to compute orthogonal projections QQ^Tv. In this way, we avoid computing the QR factorization of the stacked matrix explicitly.

We emphasize that for a fixed λ, the solution x_k^λ computed via (3.3) is different from the solution obtained by applying k steps of LSQR to (1.2). In LSQR the stacked matrix $[A^T\ \lambda L^T]^T$ is reduced to a single bidiagonal matrix whose entries depend on λ, and the solution lies in the Krylov subspace

$$\begin{aligned}\mathcal{S}_{k,\text{LSQR}} &= \text{span}\{(A^TA + \lambda^2 L^TL)^i A^Tb\}_{i=0}^{k-1} \\ &= \text{span}\{G^{-T}\left((C_A^TC_A + \lambda^2 S_L^TS_L)(G^TG)^{-1}\right)^i C_A^TP_A^Tb\}_{i=0}^{k-1}.\end{aligned}$$

All the matrices in the above expression are from the GSVD (2.3) of $\{A, L\}$. The subspace $\mathcal{S}_{k,\text{LSQR}}$ is not directly related to the GSVD basis (the columns of G) for the Tikhonov solution unless $L = I$, in which case $\mathcal{S}_{k,\text{LSQR}}$ is spanned by A's right singular vectors. Our algorithm, on the other hand, is based on a bidiagonalization of Q_A, and our solution lies in the subspace

$$\mathcal{S}_{k,\text{new}} = \text{span}\{G(C_A^TC_A)^iC_A^TP_A^Tb\}_{i=0}^{k-1}. \tag{3.4}$$

To see this, note that the solution $x_k = Z_ky_k = R^{-1}V_ky_k$, where V_k is a basis for the Krylov subspace of dimension k generated by Q_A and b (see also Theorem 4.3). However, since $Q_A = P_AC_AW^T$ is the SVD of Q_A (except for a permutation when $p < n$), it follows that this subspace is

$$\text{span}\{W(C_A^TC_A)^iC_A^TP_A^Tb\}_{i=0}^{k-1}.$$

Using the fact that $W = RG$ and $x_k = R^{-1}V_ky_k$, the result follows. Note that the subspace in (3.4) is more directly related to the GSVD solution subspace. Hence, we expect that the iterates living here are a better approximation to the desired solution.

3.2. Joint bidiagonalization. For reasons of efficiency and storage, we do not want to compute the QR factorization in (2.1). Therefore Q_A and Q_L are not available, and it is not possible to execute Bidiag-1 and Bidiag-2 directly. The solution to this dilemma is to use a change of variables in Bidiag-1, together with the results of Theorems 2.1 and 2.2.

The change-of-variables approach we advocate is the approach introduced in [17, pp. 396, 399] for a slightly different form of Lanczos bidiagonalization. We note that

$$Q_A = \begin{bmatrix} I_m\,,\ 0_{m\times p}\end{bmatrix}Q \qquad \text{and} \qquad Q_L = \begin{bmatrix} 0_{p\times m}\,,\ I_p\end{bmatrix}Q$$

and we set

$$\tilde{u}_j = \begin{bmatrix} I_m \\ 0_{p\times m} \end{bmatrix} u_j = \begin{bmatrix} u_j \\ 0_p \end{bmatrix}, \quad \tilde{v}_j = Qv_j, \quad \bar{u}_j = \begin{bmatrix} 0_{m\times p} \\ I_p \end{bmatrix} \hat{u}_j = \begin{bmatrix} 0_m \\ \hat{u}_j \end{bmatrix}, \quad \bar{v}_j = Q\hat{v}_j.$$

Using these relations and multiplying through by Q, $\begin{bmatrix} I_m \,,\, 0_{m\times p} \end{bmatrix}^T$, or $\begin{bmatrix} 0_{p\times m} \,,\, I_p \end{bmatrix}^T$ as appropriate, we obtain modified versions of Bidiag-1 and Bidiag-2, due to Theorem 2.1. The modified algorithms for bidiagonalization of Q_A and Q_L take the following form.

Modified Bidiag-1.
$\beta_1\tilde{u}_1 = \begin{bmatrix} I_m \,,\, 0_{m\times p} \end{bmatrix}^T b$
$\alpha_1\tilde{v}_1 = QQ^T\tilde{u}_1$
For $i = 1, 2, \ldots$
$\quad \beta_{i+1}\tilde{u}_{i+1} = \begin{bmatrix} I_m \,,\, 0_{m\times p} \end{bmatrix}^T \begin{bmatrix} I_m \,,\, 0_{m\times p} \end{bmatrix} \tilde{v}_i - \alpha_i\tilde{u}_i$
$\quad \alpha_{i+1}\tilde{v}_{i+1} = QQ^T\tilde{u}_{i+1} - \beta_{i+1}\tilde{v}_i.$

Modified Bidiag-2.
$\bar{v}_1 = \tilde{v}_1$
$\hat{\alpha}_1\bar{u}_1 = \begin{bmatrix} 0_{p\times m} \,,\, I_p \end{bmatrix}^T \begin{bmatrix} 0_{p\times m} \,,\, I_p \end{bmatrix} \bar{v}_1$
For $i = 1, 2, \ldots$
$\quad \hat{\beta}_i = (\alpha_{i+1}\beta_{i+1})/\hat{\alpha}_i$
$\quad \bar{v}_{i+1} = (-1)^i\tilde{v}_{i+1}$
$\quad \hat{\alpha}_{i+1}\bar{u}_{i+1} = \begin{bmatrix} 0_{p\times m} \,,\, I_p \end{bmatrix}^T \begin{bmatrix} 0_{p\times m} \,,\, I_p \end{bmatrix} \bar{v}_{i+1} - \hat{\beta}_i\bar{u}_i.$

In practice, we merge the two iterations and take advantage of the zero blocks in the matrices and vectors. This leads to the final combined algorithm.

Joint Bidiagonalization Algorithm.
$\beta_1 u_1 = b$
$\alpha_1\tilde{v}_1 = QQ^T \begin{bmatrix} u_1 \\ 0_p \end{bmatrix}$
$\hat{\alpha}_1\hat{u}_1 = \tilde{v}_1(m+1\colon m+p)$
For $i = 1, 2, \ldots$
$\quad \beta_{i+1}u_{i+1} = \tilde{v}_i(1\colon m) - \alpha_i u_i$
$\quad \alpha_{i+1}\tilde{v}_{i+1} = QQ^T \begin{bmatrix} u_{i+1} \\ 0_p \end{bmatrix} - \beta_{i+1}\tilde{v}_i$
$\quad \hat{\beta}_i = (\alpha_{i+1}\beta_{i+1})/\hat{\alpha}_i$
$\quad \hat{\alpha}_{i+1}\hat{u}_{i+1} = (-1)^i\tilde{v}_{i+1}(m+1\colon m+p) - \hat{\beta}_i\hat{u}_i.$

Note that the only computation that involves the matrices A and L is the action of QQ^T on a vector. This is an orthogonal projection that can be computed using the LSQR algorithm, as described by Saunders [16], which [illegible] the need to compute the QR factorization explicitly. With the scaling that we have assumed, if L is reasonably well conditioned, then so is $[A^T\ L^T]$. Also, efficient preconditioners for matrices of this form exist [7], [12]. Hence, we do not expect this step to be overly time consuming.

3.3. Working with the projected problem. Assume that we do not have a priori knowledge of a suited value of the regularization parameter and that we want to try many values of λ at the kth step. It is straightforward to compute the solution y_k^λ of the projected problem (3.3) via the QR factorization

$$\begin{bmatrix} B_k & \beta_1 e_1 \\ \lambda\bar{B}_k & 0 \end{bmatrix} = Q_k^\lambda \begin{bmatrix} R_k^\lambda & f_k^\lambda \\ 0 & h_k^\lambda \end{bmatrix}. \tag{3.5}$$

Here, R_k^λ is an upper bidiagonal matrix of size $k \times k$, while f_k^λ and h_k^λ are vectors of length k and $k+1$, respectively. These quantities can be computed in $O(k)$ flops by means of "strategic" Givens rotations, and Q_k^λ is not needed. Then y_k^λ is computed by solving the upper bidiagonal system

$$R_k^\lambda y_k^\lambda = f_k^\lambda,$$

which also requires only $O(k)$ flops.

Many parameter selection techniques for choosing an appropriate value of λ, such as the L-curve criterion or the discrepancy principle, need estimates of the residual norm and seminorm as functions of λ. Fortunately, these norms can be obtained directly from the projected problem. It is straightforward to show that both the residual norm $\|Ax_k^\lambda - b\|_2$ and the seminorm $\|Lx_k^\lambda\|_2$ can be expressed in terms of the projected problem, as shown below, and therefore also computed in $O(k)$ flops.

THEOREM 3.1.

$$\|Ax_k^\lambda - b\|_2 = \|B_k y_k^\lambda - \beta_1 e_1\|_2 = \left(\|h_k^\lambda\|_2^2 - \lambda^2 \|\bar{B}_k y_k^\lambda\|_2^2\right)^{1/2}$$

$$\|Lx_k^\lambda\|_2 = \|\bar{B}_k y_k^\lambda\|_2.$$

. The first equality for the residual norm follows from (2.5) and (3.2), $x_k^\lambda = Z_k y_k^\lambda$, and $U^T U = I$, while the second equality follows from the relation $\|B_k y_k^\lambda - \beta_1 e_1\|_2^2 + \lambda^2 \|\bar{B}_k y_k^\lambda\|_2^2 = \|h_k^\lambda\|_2^2$. The equality for the seminorm follows from (2.6), $x_k^\lambda = Z_k y_k^\lambda$, and $\widehat{U}^T \widehat{U} = I$. □

Once the final number of iterations has been reached (determining this final number of iterations is a subject for future research), then we need to compute the solution x_k^λ. This step is only needed once. Let $\tilde{V}_k = [\tilde{v}_1, \ldots, \tilde{v}_k]$, where the vectors $\tilde{v}_k \in \mathbb{R}^{m+p}$ are generated by the joint bidiagonalization algorithm. Then

$$\widetilde{V}_k = QV_k = QR(R^{-1}V_k) = \begin{bmatrix} A \\ L \end{bmatrix} Z_k.$$

Multiplying on the right by y_k^λ and using that $y_k^\lambda = (R_k^\lambda)^{-1} f_k^\lambda$, we obtain

$$\begin{bmatrix} A \\ L \end{bmatrix} x_k^\lambda = \tilde{V}_k y_k^\lambda. \tag{3.6}$$

The right-hand side of this system, $\tilde{V}_k y_k^\lambda$, is computed in $O((m+p)k)$ flops, and we compute x_k^λ by solving the reasonably well-conditioned system by means of CGLS or LSQR (possibly using the same preconditioner as in the QQ^T computations).

3.4. Updating issues. Alternatively, we can a priori fix a set of λ-values and derive updating formulas for all the quantities (i.e., solutions, residual norms, and constraint norms) associated with these λ-values, similar to how they are computed in [15] for regularized least squares problems with $L = I$.

Note that if we introduce the matrix $D_k^\lambda = \widetilde{V}_k (R_k^\lambda)^{-1}$, then we can write

$$\begin{bmatrix} A \\ L \end{bmatrix} x_k^\lambda = \widetilde{V}_k y_k^\lambda = s_k^\lambda \qquad \text{with} \qquad s_k^\lambda = \widetilde{V}_k (R_k^\lambda)^{-1} f_k^\lambda = D_k^\lambda f_k^\lambda.$$

Hence, if we can derive a recurrence relation for s_k^λ, then we have an easy way to update the vectors Ax_k^λ and Lx_k^λ as k increases.

The key to deriving the recurrence relations is to observe that the matrix in (3.5) has the following structure:

$$\begin{bmatrix} R_k^\lambda & f_k^\lambda \\ 0 & h_k^\lambda \end{bmatrix} = \left[\begin{array}{cc|c} R_{k-1}^\lambda & r_{k-1,k}^\lambda e_{k-1} & f_{k-1}^\lambda \\ 0 & r_{k,k}^\lambda & \phi_k^\lambda \\ \hline 0 & 0 & h_k^\lambda \end{array}\right];$$

i.e., the leading $(k-1)\times(k-1)$ block of R_k^λ is R_{k-1}^λ, and f_k^λ agrees in its first $k-1$ components with f_{k-1}^λ. Consider first the relation $\widetilde{V}_k = D_k^\lambda R_k^\lambda$:

$$[\,\widetilde{V}_{k-1}\,,\,\tilde{v}_k\,] = [\,D_{k-1}^\lambda\,,\,d_k^\lambda\,]\begin{bmatrix} R_{k-1}^\lambda & r_{k-1,k}^\lambda e_{k-1} \\ 0 & r_{k,k}^\lambda \end{bmatrix}$$

from which we see that $\widetilde{V}_{k-1} = D_{k-1}^\lambda R_{k-1}^\lambda$ and

$$d_k^\lambda = \frac{\tilde{v}_k - d_{k-1}^\lambda r_{k-1,k}^\lambda}{r_{k,k}^\lambda},$$

which is a recurrence in the d_k^λ-vectors that needs only the most recent vector $\tilde{v}_k$. Then, from the relation between the elements of f_k^λ we get

$$s_k^\lambda = D_{k-1}^\lambda f_{k-1}^\lambda + d_k^\lambda \phi_k^\lambda = s_{k-1}^\lambda + \phi_k^\lambda d_k^\lambda.$$

Given these recurrences for d_k^λ and s_k^λ, we also automatically have recurrence relations for the residual vector $b - Ax_k^\lambda$ and the vector Lx_k^λ, since

$$b - Ax_k^\lambda = b - s_k^\lambda(1\colon m), \qquad Lx_k^\lambda = s_k^\lambda(m+1\colon m+p).$$

These quantities can also be important for some parameter-choice methods, such as the one recently proposed in [8] which is based on a statistical analysis of the residual vector for the discrete ill-posed problem.

We note that if the recurrence relations are not used, then we must store the matrix $\widetilde{V}_k$ because it is needed to compute x_k^λ in (3.6). So another advantage of the recurrence relations is that we explicitly have the right-hand side of (3.6) in the form of the vector s_k^λ.

The conclusion is that if a set of λ-values is defined a priori, then we can carry along a set of recursions for these values and select the best of them via a method such as the L-curve criterion—again without having to compute every solution x_k^λ. For example, for each k an L-curve can be determined and the value of the parameter on the "corner" can then be computed. As k increases, the overall behavior of A and L becomes adequately captured in the corresponding projections B_k and $\bar{B}_k$, and the λ-value at the corner should stagnate, signifying that the iterations can be terminated. Then $x_k^{\lambda^{k,*}}$ should be taken as the approximate solution to the original Tikhonov problem, where $\lambda^{k,*}$ corresponds to the corner at the final iteration k. Note that $\lambda^{k,*}$ may not correspond to the optimal parameter for the original Tikhonov problem.

4. Insight. In this section we demonstrate why we can expect our new algorithm to generate a reasonable regularized solution for $k \ll n$. We note that this section is intended only to gain some insight into the properties of the algorithm and not as a rigorous analysis. To do this, we must also consider why the projected problem (i.e., $B_k y \approx \beta_1 e_1$) needs Tikhonov regularization as in (3.3). We note that this section may be skipped on a first reading.

Our argument proceeds as follows. First, we show that Q_A inherits properties of the matrix A in the sense that the singular values of Q_A follow the same pattern as those of A (decaying toward zero, with no gap in the spectrum) and that the singular vectors of Q_A have the property that they increase in frequency as the size of the singular values decrease. We use these facts to deduce that the singular values of B_k approximate the singular values of Q_A in their natural order (i.e., largest to smallest), with the so-called Ritz vectors as approximations of the corresponding singular vectors of Q_A. This means that for k large enough, systems involving B_k must be regularized, hence the need for the regularized projected problem (3.3). Furthermore, we show that since the CS decomposition of $\{Q_A, Q_L\}$ effectively gives the SVDs of Q_A and Q_L (appropriately ordered), our algorithm must be generating approximations of the GSVD of $\{A, L\}$ in an ordering consistent with what is needed to produce a regularized solution (refer to section 2.1); thus, $x_k^{\lambda^{k,*}}$ is a reasonable approximation to $x_{\lambda^{\text{opt}}}$ (although $\lambda^{k,*}$ may not be equal to λ^{opt}).

From the QR factorization in (2.1) we have that $\text{cond}(R) = \text{cond}([A^T \; L^T])$, and it follows from the analysis in [9] that if L is well conditioned, then so is $[A^T \; L^T]$ and thus R. Moreover, since

$$\text{cond}(A) = \text{cond}(Q_A R) \le \text{cond}(Q_A)\,\text{cond}(R) \quad \Rightarrow \quad \text{cond}(Q_A) \ge \frac{\text{cond}(A)}{\text{cond}(R)},$$

we can conclude that the ill conditioning of A must carry over to the matrix Q_A. In fact, we can say something stronger about the actual decay rate of the singular values in Q_A relative to the singular values in A.

LEMMA 4.1. σ_i A c_i C_A Q_A $i = 1, \ldots, n$

$$\sigma_i \le c_i \, \|R\|_2 \le \sigma_i \, \text{cond}(R).$$

. The proof follows immediately from Theorem 2.4 in [9] and $\|R\|_2 = \|[A^T \; L^T]\|_2$. □

Let $p_{A,i}$ denote the ith column of the matrix P_A, which is the left singular matrix of Q_A and also the left generalized singular matrix of A. The behavior of these vectors is closely related to that of the ordinary left singular vectors of A.

THEOREM 4.2. σ_i A $A = \check{U}\Sigma\check{V}^T$ $p_{A,i}$ $\check{U}$

$$p_{A,i} = \check{U}\xi_i, \qquad \text{where} \qquad \xi_i = \check{U}^T p_{A,i}.$$

i $(\xi_i)_j$ ξ_i

$$|(\xi_i)_j| \le \frac{\sigma_i}{\sigma_j}\,\text{cond}(R).$$

. Consider the vector $A^T p_{A,i}$. Using the SVD A, we can write

$$A^T p_{A,i} = \check{V}\Sigma\check{U}^T p_{A,i} = \check{V}\Sigma\xi_i = \sum_{j=1}^{n} \sigma_j \, (\xi_i)_j \, \check{v}_j,$$

and since the absolute value of each element in a vector is bounded by its norm, we have $|\sigma_j\,(\xi_i)_j| \le \|A^T p_{A,i}\|_2$ and thus $|(\xi_i)_j| \le \|A^T p_{A,i}\|_2 \,/\, \sigma_j$. Using the GSVD we can also write

$$A^T p_{A,i} = G^{-T} C_A^T P_A^T p_{A,i} = c_i\,\theta_i,$$

where θ_i is the ith column of G^{-T}, and thus

$$\|A^T p_{A,i}\|_2 = c_i\,\|\theta_i\|_2 \le c_i\,\|G^{-T}\|_2 = c_i\,\|R\|_2 \le \sigma_i\,\mathrm{cond}(R),$$

where we used Lemma 4.1. The result is obtained by combining the two results. ∎

The conclusion is that for a given i, the coefficients $|(\xi_i)_j|$ for $j < i$ cannot be large (because R is well conditioned). Indeed they must be small if σ_i/σ_j is small enough. Hence the vector $p_{A,i}$ is dominated by those left singular vectors $\check{u}_j$ for which $j > i$. As i increases, $p_{A,i}$ will be more and more dominated by singular vectors $\check{u}_j$ corresponding to small singular values σ_j. As the vectors $\check{u}_j$ become more and more oscillatory as j increases, this feature must carry over to the vectors $p_{A,i}$.

If we set $\lambda = 0$ and $w = Rx$, then the relation

$$\min_x \|Ax - b\|_2 = \min_w \|Q_A w - b\|_2$$

shows that we can use our BIDIAG-1 algorithm to compute approximate least squares solutions. Since Q_A inherits the spectral features of A, BIDIAG-1 produces a sequence of matrices B_k whose larger singular values approximate the larger singular values of A, but progressively smaller singular values of A are also picked up. The appearance of these components forces the need for regularization of the projected problem $B_k y_k^\lambda \approx \beta_1 e_1$.

Likewise, we transform the regularization problem (1.2) to the regularization problem

$$\min_w \left\| \begin{bmatrix} Q_A \\ \lambda Q_L \end{bmatrix} w - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2 . \tag{4.1}$$

This justifies the choice $x_k^\lambda = R^{-1} w_k^\lambda$, where w_k^λ is an approximate solution to (4.1). The next theorem shows that in defining $x_k^\lambda = Z_k y_k^\lambda$, where y_k^λ is the solution to the regularized projected problem, we achieve this goal.

THEOREM 4.3. [illegible] x_k^λ [illegible]

$$x_k^\lambda = R^{-1} w_k^\lambda \qquad \text{with} \qquad w_k^\lambda = \min_{w \in \mathcal{K}_k} \left\| \begin{bmatrix} Q_A \\ \lambda Q_L \end{bmatrix} w - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2 ,$$

[illegible] $\mathcal{K}_k$ [illegible]

$$\mathcal{K}_k = \mathrm{span}\{Q_A^T b, Q_A^T Q_A\, Q_A^T b, (Q_A^T Q_A)^2 Q_A^T b, \ldots, (Q_A^T Q_A)^{k-1} Q_A^T b\}.$$

[illegible] Write $w = V_k y$; then

$$\min_{w \in \mathcal{K}_k} \left\| \begin{bmatrix} Q_A \\ \lambda Q_L \end{bmatrix} w - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\| = \min_y \left\| \begin{bmatrix} B_k \\ \lambda \bar{B}_k \end{bmatrix} y - \begin{bmatrix} \beta_1 e_1 \\ 0 \end{bmatrix} \right\|,$$

where $\mathrm{range}(V_k) = \mathcal{K}_k$ is generated by applying BIDIAG-1 to the (ill-posed) problem $\min \|Q_A w - b\|_2$. But by definition of Z_k, $x_k^\lambda = Z_k y_k^\lambda = (R^{-1} V_k) y_k^\lambda = R^{-1} w_k^\lambda$. ∎

The intuitive analysis given above has shown that the Krylov subspace $\mathcal{K}_k$ is a legitimate subspace in which to look for a solution to the regularized problem (1.2). The conclusion is that the columns of Z_k form a well-suited basis in which to construct our regularized solution x_k^λ to (1.1).

5. Numerical results. We conclude with an illustration of the performance of our algorithm. All computations were performed in MATLAB.

Our example is a 2D image deblurring problem which consists of recovering the original $N \times N$ image from an image blurred by the optical system used to record it. The matrix A is a symmetric $N^2 \times N^2$ doubly Toeplitz matrix given by $A = (2\pi\sigma^2)^{-1} T \otimes T$, where T is an $N \times N$ symmetric banded Toeplitz matrix whose first row is

$$\texttt{z = [exp(-([0:band-1].\^{}2)/(2*}\sigma^2\texttt{));zeros(1,N-band)].}$$

The parameter `band` is the half-bandwidth of the matrix T, and the parameter σ controls the width of the underlying Gaussian point spread function

$$h(x,y) = \frac{1}{2\pi\sigma^2} \exp\left(\frac{x^2+y^2}{2\sigma^2}\right)$$

that models the degradation of the image and consequently its smoothness. Thus, a larger σ implies a wider Gaussian and thus a more ill-posed problem. We use $N = 64$ and the parameters `band` $= 16$ and $\sigma = 2$. The condition number of A is $2 \cdot 10^{16}$.

The exact image, represented by x_{true}, is a 64×64 subimage of the image `rice` from MATLAB's Image Processing Toolbox, shown as the left image in Figure 5.1. The noise-free blurred image, represented by b_{true}, is computed as $b_{\text{true}} = Ax_{\text{true}}$. The elements of the noise vector e are normally distributed with zero mean, and the standard deviation is chosen such that $\|e\|_2/\|b_{\text{true}}\|_2 = 10^{-2}$. The noisy right-hand side of our system is then $b = b_{\text{true}} + e$; it is shown as the middle image in Figure 5.1.

For the seminorm $\|Lx\|_2$, we use the matrix

$$L = \begin{bmatrix} I \otimes L_1 \\ L_1 \otimes I \end{bmatrix}, \qquad L_1 = \begin{bmatrix} 1 & -1 & & & \\ & 1 & -1 & & \\ & & \ddots & \ddots & \\ & & & 1 & -1 \end{bmatrix},$$

where $L_1 \in \mathbb{R}^{63\times 64}$ is a discrete approximation to the first derivative operator on a regular grid, with no assumptions on boundary conditions. The two matrices A and L are scaled such that $\|A\|_2 = \|L\|_2 = 1$, and $\text{cond}([A^T\ L^T]) = 6.2$.

We define 30 logarithmically spaced values of λ from 10^{-5} to 1 and run 50 iterations of our joint bidiagonalization algorithm using the updating formulas from section 3.4. The right image in Figure 5.1 shows the optimal reconstruction $x_k^{\lambda^{k,\text{opt}}}$ for $k = 50$ with $\lambda^{k,\text{opt}}$ chosen among the 30 candidates such that $\|x_{\text{true}} - x_k^{\lambda^{k,\text{opt}}}\|_2$ is

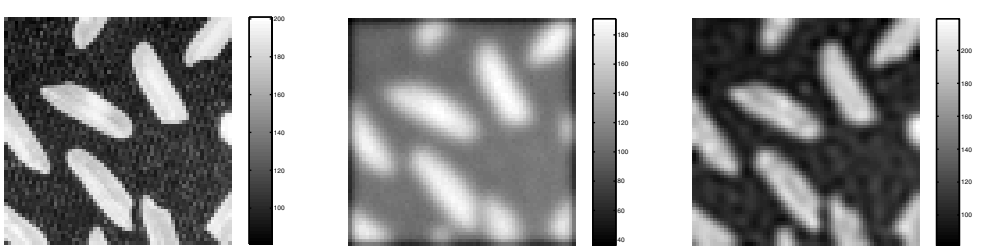

FIG. 5.1. *Exact image x_{true} (left), noisy and blurred image b (middle), and best restoration x_k^{λ} using $L \neq I$ (right).*

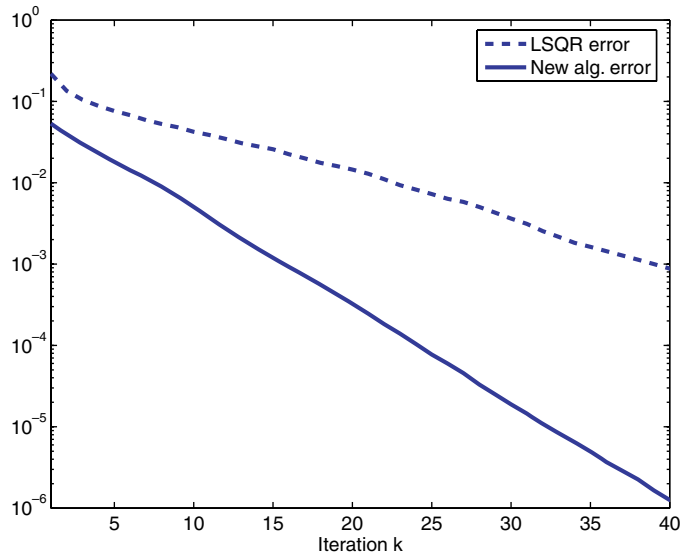

FIG. 5.2. *Error histories as a function of k for a fixed value of λ. The solid line shows the relative error* $\|x_\lambda - x_k^\lambda\|_2/\|x_\lambda\|_2$ *for our new algorithm, while the dotted line shows the relative error* $\|x_\lambda - x_{k,\mathrm{LSQR}}^\lambda\|_2/\|x_\lambda\|_2$ *for LSQR applied to the least squares Tikhonov problem.*

minimum. This image is a very good approximation to the Tikhonov solution which, in turn, is a good approximation to the exact image.

Next, we illustrate the quality of the basis we are using to construct our approximate solution relative to the quality of the basis that is used by standard LSQR for a fixed value of the regularization parameter. We consider the convergence of our approximate Tikhonov solution x_k^λ, for $\lambda = \lambda^{\mathrm{opt}}$ independent of k, to the Tikhonov solution $x_{\lambda^{\mathrm{opt}}}$ (as computed directly through a QR factorization). Recall that λ^{opt} refers to the one of 30 values of λ for which the Tikhonov solution is a minimum. For comparison we also consider the convergence of the approximation $x_{k,\mathrm{LSQR}}^\lambda$ obtained by applying LSQR directly to the Tikhonov least squares problem (again using the same λ). Figure 5.2 shows the relative errors

$$\|x_\lambda - x_k^\lambda\|_2/\|x_\lambda\|_2 \qquad \text{and} \qquad \|x_\lambda - x_{k,\mathrm{LSQR}}^\lambda\|_2/\|x_\lambda\|_2$$

for $\lambda = \lambda^{\mathrm{opt}}$, which is [illegible] k, for iterations $k = 1, 2, \ldots, 40$, where the exact Tikhonov solution x_λ was computed by means of a (computationally tedious) QR factorization. Clearly, our algorithm takes fewer iterations to converge—primarily because the subspace underlying our projection method is better suited for regularization problems than the Krylov subspace underlying LSQR when $L \neq I$. In other words, if one needs an approximate Tikhonov solution with about three correct digits, then our algorithm needs about 15 iterations, while LSQR needs about 40 iterations! We note that, for a fixed λ, the cost of an individual iteration for our algorithm differs from the cost of an individual iteration of LSQR (as our method requires a projection inner iteration, it is more expensive) and that the use of iteration number, as opposed to computational time or complexity, was deliberate in order to illustrate the superior approximation properties of the underlying subspaces in the new approach.

Figure 5.3 shows the "progression" of the L-curve (for the 30 values of λ used in this example) as the number of iterations k increases. We see that after just 10 iterations, the flatter part of the L-curve has become stable, showing that our algo-

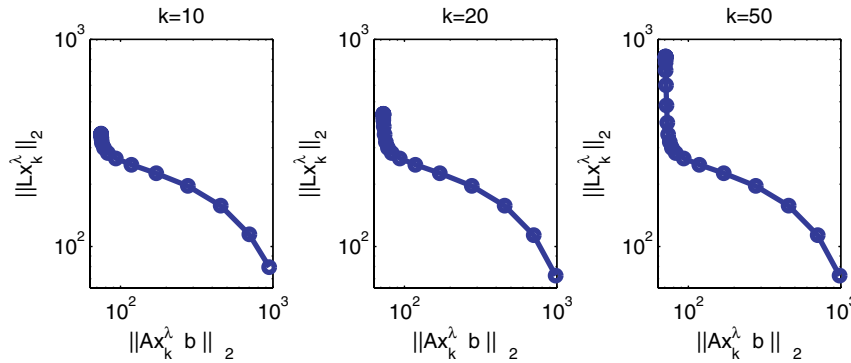

FIG. 5.3. *The "progression" of the L-curves for the solutions x_k^λ as k increases.*

rithm has already captured most of the smooth spectral components of the solution. After 50 iterations, our algorithm has captured so many spectral components that the whole region of the L-curve near the "corner" has become stable, indicating that all the corresponding spectral components have been captured. It is therefore safe to stop the iterations here and use the value of λ chosen by the parameter-choice algorithm applied to the projected problem.

We caution that in showing the graphs in Figure 5.3, our goal is not to advocate the L-curve criterion for choosing the regularization parameter λ. We simply desire to point out that our algorithm provides a cheap mechanism to compute residual norms and seminorms at each k for a set of λ-values. Whether or not the corner of the L-curve corresponds to a near-optimal solution (where optimality is meant in the sense of the solution with minimum 2-norm relative error), the L-curve gives useful qualitative information. That is, the presence of a corner and growth of the vertical component indicates the presence of noise in the basis and thus the need for additional regularization. In this example, the minimal 2-norm solution over the discrete set of λ-values used does in fact correspond to the λ-value at the corner.

6. Conclusion. As has been observed elsewhere in the literature, it is important in some cases to use general-form Tikhonov regularization with $L \neq I$. We presented an iterative algorithm for approximating the solution to the Tikhonov problem in an efficient way which avoids the need to transform to the standard form of the Tikhonov regularization problem and which produces solutions in a subspace which is well suited for general-form Tikhonov regularization. Furthermore, because the regularization is essentially applied to a projected problem, it allows for the possibility of finding the regularization parameter cheaply; that is, λ need not be known a priori. If a set of λ-values is specified a priori, we have given short-term recurrences that allow us to easily update the residual and constraint term for each λ at iterations k, as well as solve for the solution for the desired λ, k pair without storing the Lanczos vectors. Although we have not investigated the potential effects of loss of orthogonality, in our experience with the algorithm so far, it has not been necessary to reorthogonalize at any stage of the algorithm. Finally, we analyzed the regularizing properties of the algorithm and gave an example of its performance for an image deblurring problem.

Acknowledgments. We thank Julianne Chung, Jim Nagy, and Zdeněk Strakoš for their careful reading of an earlier version of the manuscript and for valuable comments and suggestions that helped to improve the paper.

ANALYSIS OF NUMERICALLY INDUCED OSCILLATIONS IN 2D FINITE-ELEMENT SHALLOW-WATER MODELS PART I: INERTIA-GRAVITY WAVES*

DANIEL Y. LE ROUX†, VIRGILE ROSTAND†, AND BENOIT POULIOT†

Abstract. The numerical approximation of shallow-water models is a delicate problem. For most of the discretization schemes, the coupling between the momentum and the continuity equations usually leads to anomalous dispersion in the representation of fast waves. A dispersion relation analysis is employed here to ascertain the presence and determine the form of spurious modes as well as the dispersive nature of the finite-element Galerkin mixed formulation of the two-dimensional linearized shallow-water equations. Nine popular finite-element pairs are considered using a variety of mixed interpolation schemes. For each pair the frequency or dispersion relation is obtained and analyzed, and the dispersion properties are compared analytically and graphically with the continuous case. It is shown that certain choices of mixed interpolation schemes may lead to significant phase and group velocity errors and spurious solutions in the calculation of fast waves. The $P_1^{NC} - P_1$ and RT0 pairs are identified as a promising compromise, provided the grid resolution is high relative to the Rossby radius of deformation for the RT0 element. The numerical solutions of two test problems to simulate fast waves are in good agreement with the analytical results.

1. Introduction.

The shallow-water (SW) equations describe the behavior of a shallow homogeneous incompressible and inviscid fluid layer. They are derived from the depth-averaged Navier–Stokes equations under Boussinesq and hydrostatic pressure assumptions. The SW system is extensively used in environmental studies to model hydrodynamics in lakes, estuaries, coastal regions, and other applications.

Galerkin techniques have gradually evolved to become a popular method for this problem class including the finite-element (FE) [14, 18, 27, 31, 32, 36, 44], the spectral-element [28, 43], the finite-volume (FV) [4, 15, 16, 19, 26], and the discontinuous Galerkin [3, 8, 17, 20, 41] methods. Indeed, unstructured elements offer the enhanced flexibility of using grids of variable sizes, shapes, and orientation for representing the boundaries of complex domains and a natural treatment of boundary conditions. Calculations on graded meshes of unstructured grids are hence standard practice [5, 18, 19, 20, 33, 46, 47].

For most numerical methods, including the finite-difference (FD), FV, and FE schemes, the coupling between the momentum and continuity equations is a delicate problem. One of the issues associated with mixed formulations is the possibility of spurious modes that may arise for certain choices of grids and bases. For example, the piecewise linear Galerkin discretization of the SW equations (for velocity and elevation variables) is usually plagued by spurious oscillations [28, 45]. The appearance of such oscillations is mainly due to an inappropriate placement of variables on the grid and/or a bad choice of approximation function spaces. Improvements have been achieved

through the use of suitable FD grids [6, 39], a variety of mixed-order FE interpolation schemes [2, 28, 27, 32, 33, 48], and a wave equation formulation [29, 36].

This difficulty with mixed methods is not specific to the SW problem alone but is well known also in other contexts such as primitive variable viscous flows where it has been extensively investigated for the Galerkin FE method [13, 23]. However, the situation in the mixed SW problem is different and, as noted initially in [45] and in subsequent studies [27, 32, 47], an analysis of the dispersion relation for a given formulation will explicitly ascertain the presence and determine the form of spurious modes as well as the dissipative/dispersive nature of a given formulation.

The dispersion relation analysis assumes that the solution of the differential equations can be separated and formulated as periodic in space and time. It differs from the Fourier analysis in that the time variable remains continuous by using the harmonic form of the equations. Consequently, a Fourier expansion is performed only for the nodal unknowns that appear in the discrete equations. The analysis results in a dispersion relation where the magnitude of the temporal frequency is expressed in terms of wave numbers. Such a technique was applied early on to the SW model in [38].

Two-dimensional dispersion analysis of FE SW discretizations using the same linear basis functions for all variables was examined first. One grid configuration is considered in [45], while the influence of grid configuration on the dispersion properties is analyzed in [9, 10, 21] for the mixed primitive variable form and in [37] in the case of the wave equation formulation. Phase behavior of FV SW discretizations has been studied in [24, 42]. To our knowledge, the two-dimensional dispersion relation analysis of the SW equations using the $P_1^{NC} - P_1$ FE pair [35] was the first study analyzing the dispersion relation of a FE scheme using different approximation spaces for the velocity and surface-elevation fields on meshes made up of triangles. The aim of the present study is to extend the two-dimensional dispersion relation analysis of the FE SW equations to a variety of mixed-order interpolation schemes. Because all the aforementioned problems occur primarily in the context of linear formulations, solving linear equations is sufficient for our purpose.

The paper is developed as follows: The linear SW equations and the Galerkin FE discretization schemes are presented in section 2. The discrete operators are computed in section 3 and the dispersion relations are obtained. The latter are compared analytically and graphically with the continuous case in section 4. This dispersion analysis is followed by numerical tests in section 5. Some concluding remarks complete the study.

2. Discretization of the linear SW equations.

2.1. Governing equations. Let Ω be the model domain with boundary Γ. The inviscid linear SW equations are expressed in Cartesian coordinates [30] as

$$\bar{\mathbf{u}}_t + f\,\mathbf{k} \times \bar{\mathbf{u}} + g\,\nabla\bar{\eta} = 0\,, \tag{2.1}$$

$$\bar{\eta}_t + H\,\nabla \cdot \bar{\mathbf{u}} = 0\,, \tag{2.2}$$

where $\bar{\mathbf{u}} = (\bar{u}, \bar{v})$ is the velocity field, $\bar{\eta}$ is the surface elevation with respect to the reference level $z = 0$, g is the gravitational acceleration, $\mathbf{k}$ is a unit vector in the vertical direction, and the mean depth H and the Coriolis parameter f are assumed constant. Note that $\bar{\eta}$ would be the pressure in the Navier–Stokes equations. For a contained flow, (2.1) and (2.2) are solved subject to the no-normal flow boundary condition $\bar{\mathbf{u}} \cdot \mathbf{n} = 0$ on Γ, where $\mathbf{n}$ is the outward pointing normal at the boundary.

For this analysis we seek periodic solutions of (2.1)–(2.2) of the form

$$\bar{\mathbf{u}}(x,y,t) = \mathbf{u}(x,y)e^{i\omega t}, \quad \bar{\eta}(x,y,t) = \eta(x,y)e^{i\omega t}, \tag{2.3}$$

where $\mathbf{u} = (u, v)$, η are amplitudes, and ω is the angular frequency, and we obtain

$$i\omega\,\mathbf{u} + f\,\mathbf{k}\times\mathbf{u} + g\,\nabla\eta = 0, \tag{2.4}$$

$$i\omega\,\eta + H\,\nabla\cdot\mathbf{u} = 0. \tag{2.5}$$

2.2. Spatial discretization.

2.2.1. The weak formulation. We assume $\mathbf{u}$ and η belong to the spaces $\mathbf{V}$ and Q, respectively, with Q and $\mathbf{V}$ being either the square-integrable space $L^2(\Omega)$ or the Sobolev space $H^1(\Omega)$, i.e., the space of functions in $L^2(\Omega)$ whose first derivatives belong to $L^2(\Omega)$. The weak formulation of (2.4) and (2.5) requires the test functions $\boldsymbol{\varphi}$ (whose x- or y-component is formally denoted by φ) and ψ to be sufficiently regular and to belong, respectively, to the same function space as $\mathbf{u}$ and η, such that

$$i\omega\int_\Omega \mathbf{u}\cdot\boldsymbol{\varphi}\,d\Omega + \int_\Omega f(\mathbf{k}\times\mathbf{u})\cdot\boldsymbol{\varphi}\,d\Omega + g\int_\Omega \nabla\eta\cdot\boldsymbol{\varphi}\,d\Omega = 0, \tag{2.6}$$

$$i\omega\int_\Omega \eta\,\psi\,d\Omega + H\int_\Omega \nabla\cdot\mathbf{u}\,\psi\,d\Omega = 0, \tag{2.7}$$

where $d\Omega$ is the area element.

Depending on the regularity of functions $\mathbf{u}$ and η, the terms containing derivatives in (2.6) and (2.7) may be integrated by parts using Green's theorem. In this way, (2.6) is rewritten if needed as

$$i\omega\int_\Omega \mathbf{u}\cdot\boldsymbol{\varphi}\,d\Omega + \int_\Omega f(\mathbf{k}\times\mathbf{u})\cdot\boldsymbol{\varphi}\,d\Omega - g\int_\Omega \eta\,\nabla\cdot\boldsymbol{\varphi}\,d\Omega = 0, \tag{2.8}$$

and for (2.7) we obtain

$$i\omega\int_\Omega \eta\,\psi\,d\Omega - H\int_\Omega \mathbf{u}\cdot\nabla\psi\,d\Omega = 0, \tag{2.9}$$

by letting $\mathbf{u}\cdot\mathbf{n} = 0$ on Γ for all $\mathbf{u}$ belonging to $\mathbf{V}$. Hence, we also have $\boldsymbol{\varphi}\cdot\mathbf{n} = 0$ on Γ.

2.2.2. Galerkin FE discretization. The Galerkin method approximates the solution of (2.6) and (2.7), and eventually (2.8) and (2.9) if integration by parts needs to be performed, in finite-dimensional subspaces. Consider a FE triangulation $\mathcal{T}_h$, of the polygonal domain Ω, where h is a representative meshlength parameter that measures resolution. For triangle $K \in \mathcal{T}_h$, let $P_n(K)$ denote the space of polynomials of degree n on K.

The discrete solutions $\mathbf{u}_h$ and η_h sought belong to finite-dimensional spaces $\mathbf{V}_h$ and Q_h, respectively, whose restrictions on K belong to $P_k(K)\times P_k(K)$ for $\mathbf{u}_h$ and to $P_l(K)$ for η_h. The components of $\mathbf{u}_h$ and η_h are represented over a triangle K_i by interpolating functions $\varphi(x,y)$ of degree k and $\psi(x,y)$ of degree l (in the x- and y-components), respectively, with $\boldsymbol{\varphi}(x,y)$ belonging to $\mathbf{V}_h$ and $\psi(x,y)$ belonging to Q_h. We thus have

$$\mathbf{u}_h = \sum_{j\in S^{\mathbf{u}}_{K_i}} \mathbf{u}_j\,\varphi_j, \quad \eta_h = \sum_{j\in S^{\eta}_{K_i}} = \eta_j\,\psi_j, \tag{2.10}$$

where j represents a node of K_i and $S^{\mathbf{u}}_{K_i}$ and $S^{\eta}_{K_i}$ denote the set of nodes of K_i.

The expansions of $\mathbf{u}_h$ and η_h over the whole domain Ω are then obtained by summing (2.10) over all triangles K_i of the triangulation $\mathcal{T}_h$. Introducing the FE basis leads to a FE statement as in (2.6) and (2.7), and eventually in (2.8) and (2.9), but with $\mathbf{u}, \eta$ replaced by the FE trial functions $\mathbf{u}_h, \eta_h$ and φ, ψ replaced by the corresponding FE test functions. We then decompose the integrals in (2.6) and (2.7) into triangle contributions.

For the purposes of the following analysis we consider a uniform mesh made up of biased right triangles as in the figures of section 3, and h is thus taken as a constant in the x- and y-directions.

2.2.3. The FE pairs. We now introduce the schemes that are used for the spatial discretization. Nine candidate FE pairs for representing velocity and surface elevation are described and evaluated in the remainder of this paper. Conventional FE terminology is adopted to describe the FE pairs. The nomenclature $P_m - P_n$ means that velocity components and surface elevation are represented, respectively, as piecewise-defined polynomials of degree m and n. Enhancements of this basic terminology are introduced as needed.

Common to the first six FE velocity/surface-elevation pairs (as shown in Figures 4.2(d) and 4.3) is a piecewise-linear continuous representation of surface elevation, and they differ from one another in their representation of velocity. The $P_1 - P_1$ pair has velocity colocated at triangle vertices, and the corresponding basis functions are piecewise-linear. The MINI element [7] also has continuous piecewise-linear basis functions at the vertices, but bubble functions are added at the barycenters for velocity in order to stabilize the pair. The $P_1^{NC} - P_1$ pair [27, 35] has velocity nodes at triangle edge midpoints, and linear basis functions are used to approximate the two velocity components on the element's two-triangle support. Since this particular representation of velocity is continuous only across triangle boundaries at midpoint nodes, and discontinuous everywhere else around a triangle boundary, this element is termed nonconforming (NC) in the FE literature. The $P_1 \,\mathrm{iso}\, P_2 - P_1$ element pair [12] has piecewise linear basis functions for velocity on a refined triangulation obtained by dividing each triangle into four subtriangles using the midpoints of triangle sides. There are thus six velocity nodes over each unrefined triangle, the same as for a quadratic approximation of velocity, termed P_2. The designation P_1 in $P_1 \,\mathrm{iso}\, P_2$ denotes linear velocity elements on subtriangles, whereas $\mathrm{iso}\, P_2$ indicates that the nodal placement is that associated with quadratic elements on unrefined triangles. The $P_2 - P_1$ pair [25], also known in the literature as the Taylor–Hood element, has quadratic velocity basis functions. Finally, the $P_0 - P_1$ pair, shown in Figure 4.2(d), has a piecewise-constant representation of velocity.

Common to the last three pairs (shown in Figures 4.2(a)–(c)) is a discontinuous piecewise-constant representation of surface elevation. The RT0 element, also called low-order Raviart–Thomas element [40], is based on flux conservation on element edges and has normal velocity components at triangle midedge points. Finally, the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs have, respectively, P_1^{NC} and P_2 representations of velocity.

3. Computation of the dispersion relations.

3.1. Matrix computations. For all FE pairs having a piecewise-constant representation of surface-elevation an integration by parts of $\nabla\eta$ in the left-hand side of (2.6) is performed, and hence (2.8) is employed. For the $P_1^{NC} - P_1$ and $P_0 - P_1$ pairs, the term $\nabla \cdot \mathbf{u}$ appearing in (2.7) is integrated by parts to avoid computing u

and v derivatives, and (2.9) is used instead.

After substitution of $\mathbf{u}_h$ and η_h from (2.10) into (2.6) and (2.7), the discrete formulation is obtained. We then need to compute

$$M_{i,j} = \int \boldsymbol{\varphi} \cdot \boldsymbol{\varphi} \; d\Omega, \quad G_{i,j} = \int \nabla \psi_i \cdot \boldsymbol{\varphi} \; d\Omega, \quad D_{i,j} = \int \nabla \cdot \boldsymbol{\varphi} \; \psi_j \, d\Omega, \tag{3.1}$$

where $M_{i,j}, G_{i,j}$, and $D_{i,j}$ represent the mass, gradient, and divergence elementary FE matrices, respectively. When (2.8) is employed instead of (2.6) the elementary gradient matrix is then $-D_{j,i}$, and if (2.9) is used, the elementary divergence matrix becomes $-G_{j,i}$. Assembling the elementary matrices leads to the stencils of Figures 3.1, 3.2, 3.3, 3.4, and 3.5 for the pairs examined here. The symbols • and black arrows indicate the location of velocity and normal velocity nodes, respectively. The arrow points in the direction of the chosen normal. When these symbols are represented in grey this means that velocity and normal velocities have zero values at the corresponding nodes. The symbol ○ indicates nodes for surface elevation and dotted circles mean that the elevation is zero at those nodes.

For the subsequent dispersion analysis we consider two possible types of barycenters, corresponding to lower left and upper right triangles, and three types of faces: horizontal, vertical, and diagonal. Note that for the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs in Figure 3.2, the x- (resp., y-) component of the surface elevation gradient is zero on horizontal (resp., vertical) faces. Further, in Figure 3.4 for the $P_2 - P_1$ pair, the surface-elevation gradient is zero at vertex nodes.

3.2. The continuous case. The free modes of (2.4)–(2.5) are examined by perturbing about the basic state $u = v = \eta = 0$. Because the governing equations are linear, the solution may be examined by considering the behavior of one Fourier mode. We then seek solutions of (2.4)–(2.5) of the form $(u, v, \eta) = (\tilde{u}, \tilde{v}, \tilde{\eta})\, e^{i(kx+ly)}$, where k and l are the wave numbers in the x- and y-directions, respectively. Substitution into (2.4)–(2.5) leads to a square matrix system for the amplitudes $\tilde{u}, \tilde{v}, \tilde{\eta}$. For a nontrivial solution to exist, the determinant of the matrix must equal zero, and this constraint leads to a relationship between the two wave numbers k and l and the frequency ω. The so-called dispersion relation is then obtained for the frequency

$$\omega \, (\, \omega^2 - f^2 - g \, H \, (\, k^2 + l^2 \,) \,) = 0 \, . \tag{3.2}$$

The first solution $\omega = 0$ is the geostrophic mode, and it would correspond to the slow Rossby mode on a β-plane, while the other two solutions

$$\omega_{AN} = \pm \sqrt{f^2 + g \, H \, (\, k^2 + l^2 \,)} \tag{3.3}$$

correspond to the free-surface gravitational modes with rotational correction. Since ω is purely real, all modes are neutrally stable and neither amplify nor decay.

3.3. The discrete case. For each FE pair, the discrete momentum and continuity equations are obtained from the stencils of Figures 3.1, 3.2, 3.3, 3.4, and 3.5. As previously mentioned, the following analysis will consider a uniform mesh made up of biased right triangles as in the figures of section 3, and h is thus taken as a constant in the x- and y-directions. Because nodal unknowns may be located on different types of nodes, i.e., vertices, faces, and barycenters, selected discrete equations for each type of node are retained. For example, the $P_2 - P_1$ pair leads to considering four discrete momentum equations, one at a typical vertex node and three on the three possible

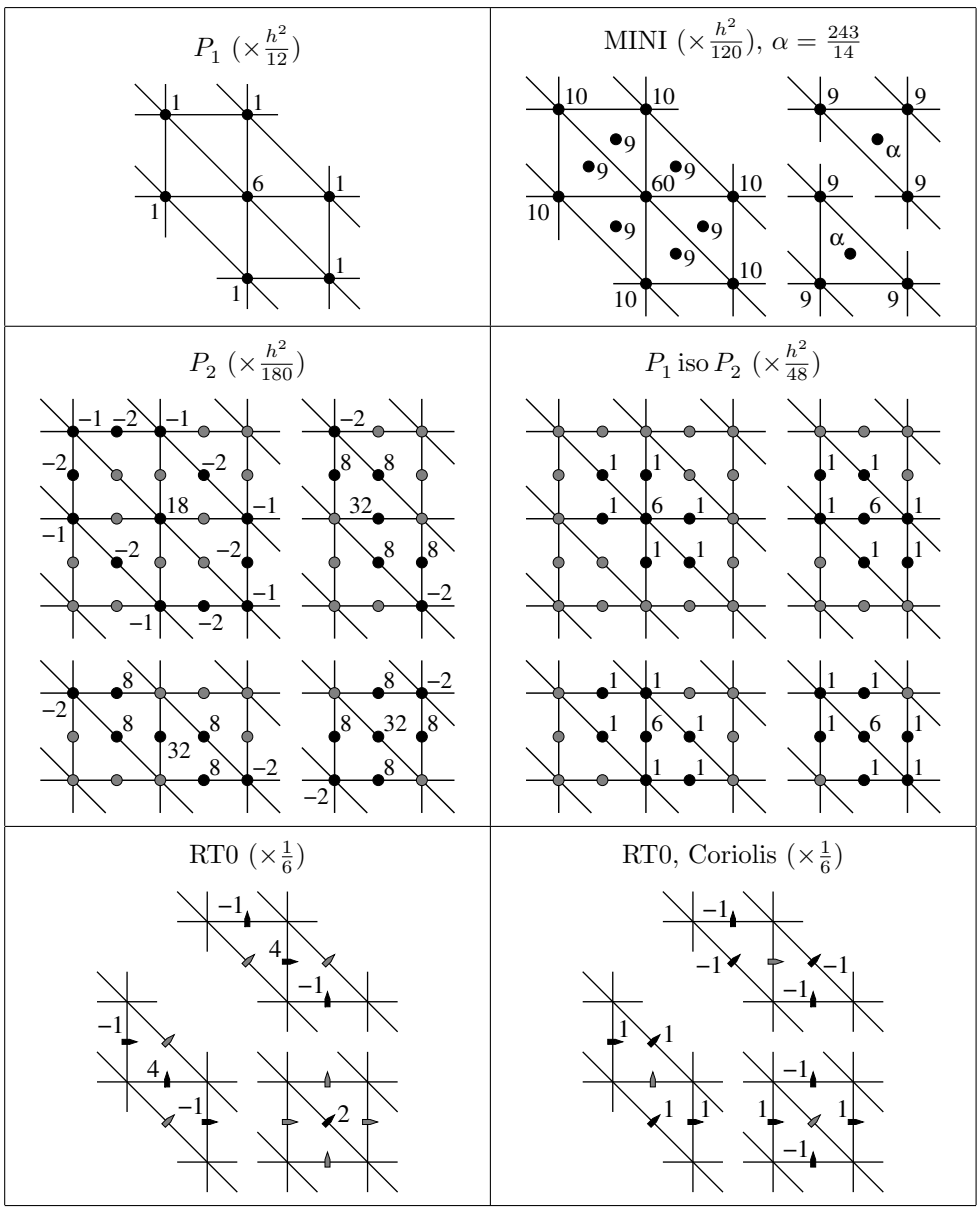

FIG. 3.1. *Mass stencils for several FE discretizations. The symbols ● and black arrows indicate the location of velocity and normal velocity nodes, respectively. The arrow points in the direction of the chosen normal. Grey symbols mean that velocity and normal velocities have zero values at the corresponding nodes.*

types of faces, i.e., horizontal, vertical, and diagonal (written as H, V, and D, respectively, in the following), and only one discrete continuity equation at a typical vertex node (written as S in the following). For the $P_0 - P_1$ pair, two discrete momentum equations are retained at the two possible types of barycenters (corresponding to lower left and upper right triangles, written as C_1 and C_2, respectively, in the following). More details are given in [10, 21] for the $P_1 - P_1$ pair, and in [35] for the $P_1^{NC} - P_1$

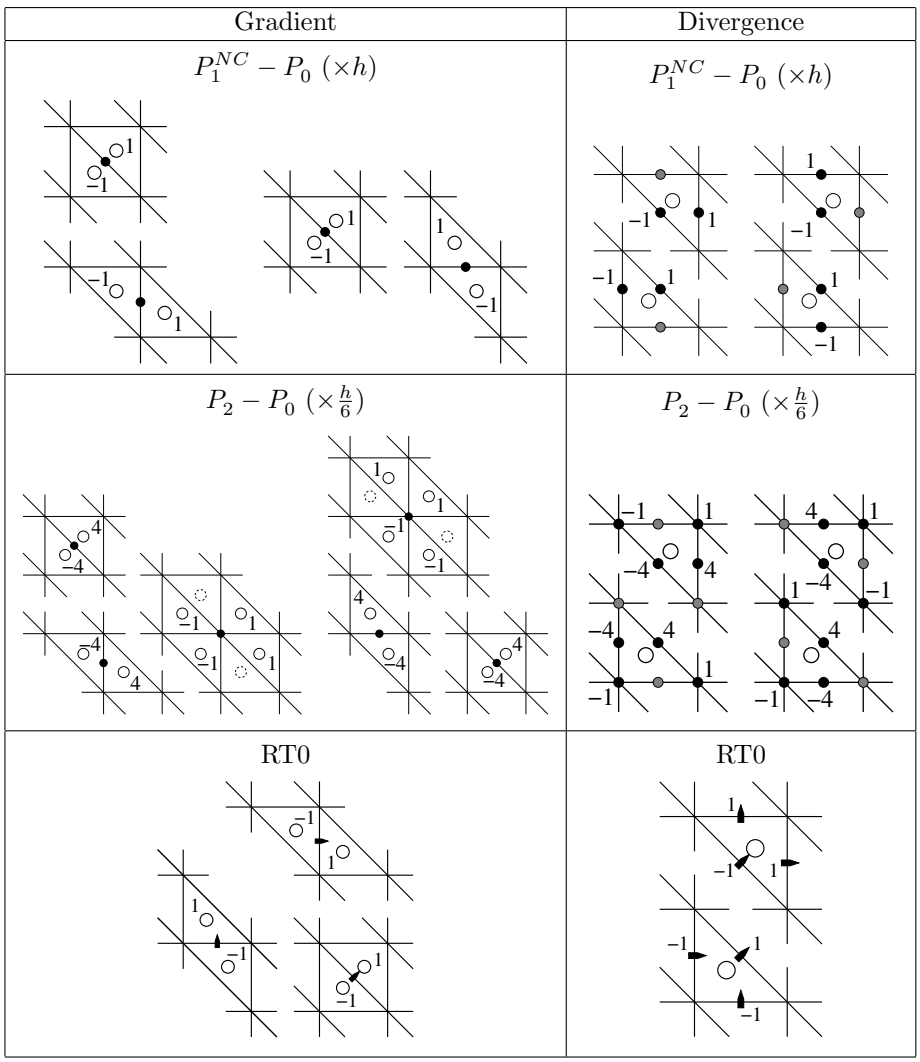

FIG. 3.2. *As for Figure* 3.1 *but for the gradient and divergence stencils of the* $P_1^{NC} - P_0$, $P_2 - P_0$, *and RT*0 *pairs. For the* $P_1^{NC} - P_0$ *and* $P_2 - P_0$ *pairs, the x- and y-components are on the left and right sides, respectively. one, to compute their dispersion relations. For all pairs, the typical nodes belonging to the same set (vertices, faces, midedge points, or barycenters) are hence distributed on a regular grid of size h.

As for the continuum case, the dispersion relation for the discrete scheme is found through a Fourier expansion. The discrete solutions corresponding to $(u_j, v_j, \eta_j) = (\tilde{u}, \tilde{v}, \tilde{\eta})\, e^{i(kx_j + ly_j)}$ are sought at node j ($j = 1, 2, 3 \ldots$), where (u_j, v_j, η_j) are the nodal unknowns that appear in the selected discrete equations and $(\tilde{u}, \tilde{v}, \tilde{\eta})$ are amplitudes. The (x_j, y_j) coordinates are expressed in terms of a distance to a reference node. Substitution into the discrete equations leads to a square matrix system for the Fourier amplitudes. The dispersion relation is then obtained by setting the determinant of the matrix system to zero.

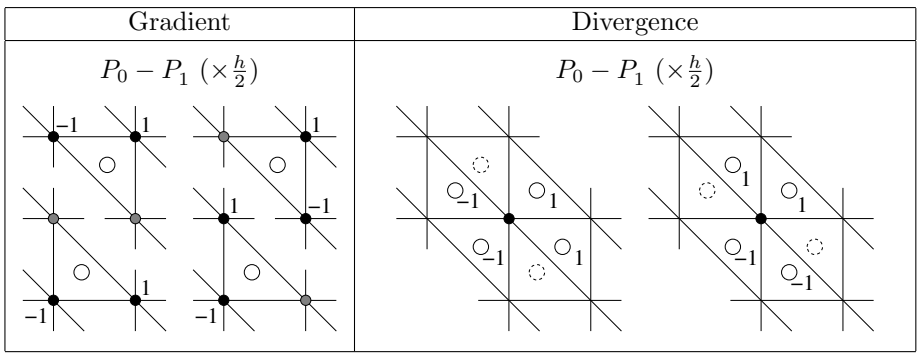

FIG. 3.3. *As for Figure* 3.2 *but for the* $P_0 - P_1$ *pair.*

We let I_n be the $n \times n$ identity matrix, M an $m \times n$ matrix with m and n two positive integers, and $M^* = \overline{M}^T$ the conjugate transpose of M, and we define

$$a = \frac{1}{3}(\,3 + \cos kh + \cos lh + \cos(k-l)h\,), \quad A = \begin{pmatrix} i\omega & -f \\ f & i\omega \end{pmatrix},$$

with $a \geq \frac{1}{2}$ for all k and l.

We now examine the dispersion relations corresponding to the nine pairs that are considered in this study.

3.4. The $P_1^{NC} - P_0$ pair. The selected discrete equations are written in the matrix form

$$\begin{pmatrix} A & 0 & 0 & \\ 0 & A & 0 & -g\,B^* \\ 0 & 0 & A & \\ & HB & & \frac{3}{2}i\omega I_2 \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_H \\ \tilde{\mathbf{u}}_V \\ \tilde{\mathbf{u}}_D \\ \tilde{\boldsymbol{\eta}} \end{pmatrix} = 0, \tag{3.4}$$

where $\tilde{\boldsymbol{\eta}} = (\tilde{\eta}_{C_1}, \tilde{\eta}_{C_2})$, and

$$B = \frac{3}{h} \begin{pmatrix} 0 & -b_1 & -\overline{b}_3 & 0 & b_2 & b_2 \\ 0 & \overline{b}_1 & b_3 & 0 & -\overline{b}_2 & -\overline{b}_2 \end{pmatrix},$$

with

$$b_1 = e^{i(k-2l)\frac{h}{6}}, \quad b_2 = e^{i(k+l)\frac{h}{6}}, \quad b_3 = e^{i(2k-l)\frac{h}{6}}.$$

Vanishing the above 8×8 determinant leads to

$$\omega_{1,2} = 0, \;\; \omega_{3,4} = \pm f, \;\; \omega_{5,6} = \pm\sqrt{f^2 + 6\frac{gH}{h^2}\,(4-\alpha)}, \;\; \omega_{7,8} = \pm\sqrt{f^2 + 6\frac{gH}{h^2}\,(4+\alpha)},$$

with $\alpha = \sqrt{2(3a + \cos kh + \cos lh)}$. For infinitesimal mesh spacing we obtain

$$\omega_{5,6} = \pm\sqrt{f^2 + gH\left(\frac{9}{4}(k^2+l^2) - \frac{3}{2}kl\right)} + O(h^2), \tag{3.5}$$

$$\omega_{7,8} = \pm 4\sqrt{3}\frac{\sqrt{gH}}{h} + O(h). \tag{3.6}$$

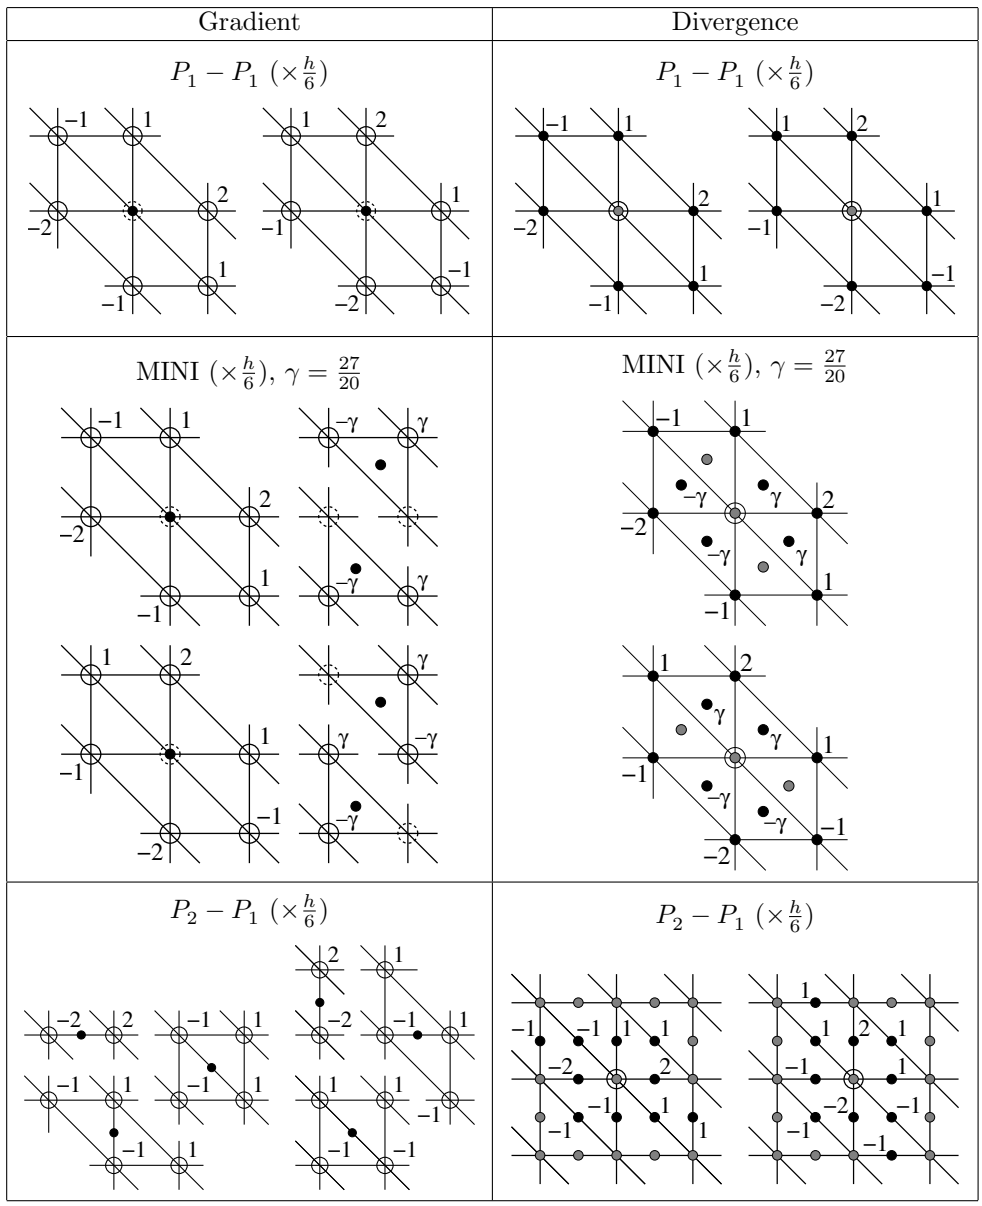

FIG. 3.4. *As for Figure* 3.2 *but for the* $P_1 - P_1$*, MINI and* $P_2 - P_1$ *pairs. For the* $P_1 - P_1$ *and* $P_2 - P_1$ *pairs, the x- and y-components are on the left and right sides, respectively, and they are at the top and bottom, respectively, for MINI.*

Note that neither $\omega_{5,6}$ nor $\omega_{7,8}$ coincide with the continuous solution obtained from (3.2) in the limit as mesh spacing $h \to 0$. The roots $\omega_{7,8}$ correspond to a spurious mode from the $P_1^{NC} - P_0$ discretization scheme. Such a mode of type $O(\frac{1}{h})$ has already been observed in [34], where the one-dimensional SW equations are discretized using the discontinuous Galerkin method. Finally, the roots $\omega_{3,4}$ represent spurious inertial oscillations. It has been shown in [1] for the FD CD-grid and in [35] for the $P_1^{NC} - P_1$ pair that such spurious modes take the form of propagating inertial oscillations and

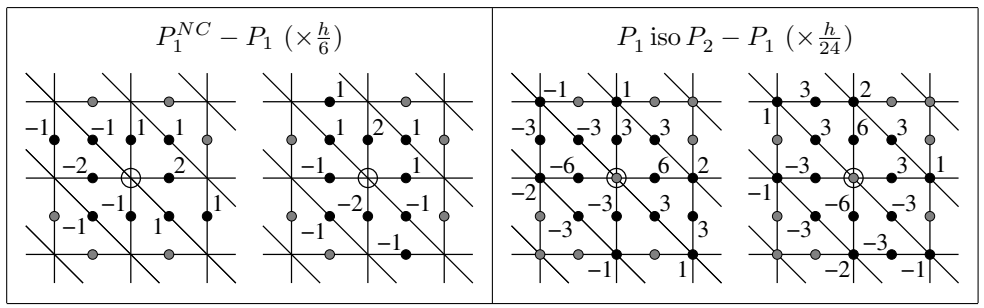

FIG. 3.5. *Divergence stencils for the $P_1^{NC} - P_1$ and P_1 iso $P_2 - P_1$ pairs. For each pair, the x- and y-components are on the left and right sides, respectively.*

have no particular spatial characteristics. They are a consequence of using more velocity nodes than surface-elevation nodes.

3.5. The $P_2 - P_0$ pair. The selected discrete equations lead to

$$\begin{pmatrix} a_1A & a_3A & a_4A & a_2A & \\ a_3A & a_8A & a_7A & a_6A & \\ a_4A & a_7A & a_8A & a_5A & -gB^* \\ a_2A & a_6A & a_5A & a_8A & \\ \multicolumn{4}{c}{HB} & \frac{i\omega}{2}I_2 \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_S \\ \tilde{\mathbf{u}}_H \\ \tilde{\mathbf{u}}_V \\ \tilde{\mathbf{u}}_D \\ \tilde{\boldsymbol{\eta}} \end{pmatrix} = 0, \tag{3.7}$$

where $\tilde{\boldsymbol{\eta}} = (\tilde{\eta}_{C_1}, \tilde{\eta}_{C_2})$,

$$B = \frac{1}{6h} \begin{pmatrix} -\bar{b}_1 + \bar{b}_2 & -\bar{b}_1 + \bar{b}_5 & 0 & -4\bar{b}_6 & -4\bar{b}_4 & 0 & 4\bar{b}_3 & 4\bar{b}_3 \\ b_1 - b_2 & b_1 - b_5 & 0 & 4b_6 & 4b_4 & 0 & -4b_3 & -4b_3 \end{pmatrix},$$

with $a_1 = \frac{1}{30}(4-a)$, $a_8 = \frac{8}{45}$, and

$$\begin{aligned} a_2 &= -\tfrac{1}{45}\cos\tfrac{(k+l)h}{2}, & a_5 &= \tfrac{4}{45}\cos\tfrac{kh}{2}, & b_1 &= e^{i(k+l)\frac{h}{3}}, & b_4 &= e^{i(2k-l)\frac{h}{6}}, \\ a_3 &= -\tfrac{1}{45}\cos(\tfrac{k-2l}{2})h, & a_6 &= \tfrac{4}{45}\cos\tfrac{lh}{2}, & b_2 &= e^{-i(2k-l)\frac{h}{3}}, & b_5 &= e^{i(k-2l)\frac{h}{3}}, \\ a_4 &= -\tfrac{1}{45}\cos\tfrac{(2k-l)h}{2}, & a_7 &= \tfrac{4}{45}\cos\tfrac{(k-l)h}{2}, & b_3 &= e^{-i(k+l)\frac{h}{6}}, & b_6 &= e^{-i(k-2l)\frac{h}{6}}. \end{aligned}$$

Vanishing the above 10×10 determinant leads to a polynomial in ω of the form

$$(\omega^2 - f^2)^2 \left(c_6\,\omega^6 + c_4\,\omega^4 + c_2\,\omega^2 + c_0 \right) = 0,$$

where c_0, c_2, c_4, and c_6 are functions of k and l. We then obtain

$$\omega_{1,2} = \pm O(h), \quad \omega_{3,4,5,6} = \pm f \text{ (double root)}, \quad \omega_{7,8} = \pm O(1), \quad \omega_{9,10} = \pm O\left(\frac{1}{h}\right).$$

We have found that $c_0 \neq 0$, and hence $\omega = 0$ is no longer a solution to the dispersion relation, and the possibility of damped or growing slow modes occurs. However, we note the appearance of modes $\omega_{1,2} = \pm O(h)$ which are expected to be close to zero in the limit as mesh spacing $h \to 0$. As for the $P_1^{NC} - P_0$ pair, the roots $\omega_{3,4,5,6}$ represent

spurious inertial oscillations. They are again due to an imbalance in the number of degrees of freedom between velocity and surface-elevation nodes. We have also found, as for the $P_1^{NC} - P_0$ pair, that the frequencies corresponding to inertia-gravity modes, here $\omega_{7,8}$, do not coincide with the continuous solution obtained from (3.2) in the limit as mesh spacing $h \to 0$. Finally, the frequencies $\omega_{9,10}$ again correspond to a spurious mode from the $P_2 - P_0$ discretization scheme, as for the $P_1^{NC} - P_0$ pair.

3.6. The RT0 pair. The discrete equations lead to the following system:

$$\begin{pmatrix} A_{\mathrm{RT0}} & -g\,B^* \\ HB & i\omega\frac{h^2}{2}I_2 \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{J}} \\ \tilde{\boldsymbol{\eta}} \end{pmatrix} = 0, \tag{3.8}$$

where $\tilde{\mathbf{J}} = (\tilde{J}_H, \tilde{J}_D, \tilde{J}_V)$ and J_p is the velocity flux through the edge containing node p (here H, D, or V), with $J_p = \tilde{J}_p\, e^{i(kx_p + ly_p)}$. We also have $\tilde{\boldsymbol{\eta}} = (\tilde{\eta}_{C_1}, \tilde{\eta}_{C_2})$,

$$A_{\mathrm{RT0}} = \frac{1}{3}\begin{pmatrix} 2i\omega & a_2 f & -a_3(i\omega - f) \\ -a_2 f & i\omega & a_1 f \\ -a_3(i\omega + f) & -a_1 f & 2i\omega \end{pmatrix},\quad B = \begin{pmatrix} -b_1 & b_2 & -b_3 \\ \bar{b}_1 & -\bar{b}_2 & \bar{b}_3 \end{pmatrix},$$

and

$$\begin{aligned} a_1 &= \cos\tfrac{kh}{2}, \qquad a_2 = \cos\tfrac{lh}{2}, \qquad a_3 = \cos\tfrac{(k-l)h}{2}, \\ b_1 &= e^{i(k-2l)\frac{h}{6}}, \quad b_2 = e^{i(k+l)\frac{h}{6}}, \quad b_3 = e^{-i(2k-l)\frac{h}{6}}. \end{aligned}$$

For the 5×5 determinant to vanish we obtain $\omega = 0$ and four additional roots corresponding to gravity modes. For infinitesimal mesh spacing we have

$$\omega_1 = 0, \quad \omega_{2,3} = \omega_{AN} + O(h^2), \quad \omega_{4,5} = \pm 6\frac{\sqrt{gH}}{h} + O(h).$$

Note that only $\omega_{2,3}$ coincide with the continuous solution obtained from (3.2) in the limit as mesh spacing $h \to 0$, while $\omega_{4,5}$ presumably correspond to spurious modes from the RT0 discretization scheme.

3.7. The $P_0 - P_1$ pair. The selected discrete equations are written in the matrix form

$$\begin{pmatrix} A & 0 & \\ 0 & A & -gB^* \\ & HB & ia\omega \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_{C_1} \\ \tilde{\mathbf{u}}_{C_2} \\ \tilde{\eta}_S \end{pmatrix} = 0, \tag{3.9}$$

where $B = \frac{1}{h}\begin{pmatrix} b_1 & b_2 & -\bar{b}_1 & -\bar{b}_2 \end{pmatrix}$, with

$$b_1 = e^{i(k+l)\frac{h}{3}}(1 - e^{-ikh}), \quad b_2 = e^{i(k+l)\frac{h}{3}}(1 - e^{-ilh}).$$

Vanishing the above 5×5 determinant leads to

$$\omega_1 = 0, \quad \omega_{2,3} = \pm f, \quad \omega_{4,5} = \pm\sqrt{f^2 + 4\frac{gH}{h^2}\left(\frac{2 - \cos kh - \cos lh}{a}\right)}.$$

For infinitesimal mesh spacing the frequencies $\omega_{4,5}$ coincide with the continuous solution obtained from (3.2) in the limit as mesh spacing $h \to 0$, and we have $\omega_{4,5} = \omega_{AN} + O(h^2)$. Again, the roots $\omega_{2,3}$ represent spurious inertial oscillations.

3.8. The $P_1 - P_1$ pair. The selected discrete equations lead to

$$\begin{pmatrix} aA & -g\,B^* \\ H\,B & ia\omega \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_S \\ \tilde{\eta}_S \end{pmatrix} = 0, \tag{3.10}$$

where $B = \frac{2i}{3h} \begin{pmatrix} b_1 & b_2 \end{pmatrix}$, with

$$b_1 = 2\sin kh + \sin lh + \sin(k-l)h, \quad b_2 = \sin kh + 2\sin lh - \sin(k-l)h.$$

For a nontrivial solution to exist, the 3×3 determinant of the coefficient matrix above must vanish. This condition implies

$$\omega_1 = 0, \quad \omega_{2,3} = \pm\sqrt{f^2 + \frac{4}{9}\frac{gH}{h^2}\frac{(b_1^2+b_2^2)}{a^2}}.$$

For infinitesimal mesh spacing we obtain $\omega_{2,3} = \omega_{AN} + O(h^4)$. In the case $f = 0$, corresponding to the propagation of pure gravity waves, we may have $\omega_{2,3} = 0$ if $b_1 = b_2 = 0$. This occurs, in particular, when $kh = lh = \pi$ (wavelength $2h$) or when $kh = -lh = \frac{2\pi}{3}$ (wavelength $3h$). The waves of length $2h$ and $3h$ hence lead to $\omega_{2,3} = 0$ and do not propagate, but they are trapped within the model grid. They are numerical artifacts introduced by the spatial discretization scheme and describe oscillations of wavelength $2h$ and $3h$. Such waves are identified as spurious surface-elevation modes corresponding to physical eigenmodes which have their phase speed reduced to zero by the numerical scheme and appear as stationary oscillations [45, 21]. They can cause an accumulation of energy in the smallest-resolvable scale, leading to noisy solutions.

3.9. The MINI pair. If a cubic bubble is employed, the discrete equations lead to the following system:

$$\begin{pmatrix} aA & \overline{a}_1 A & a_1 A & \\ a_1 A & a_2 A & 0 & -g\,B^* \\ \overline{a}_1 A & 0 & a_2 A & \\ & HB & & ia\omega \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_S \\ \tilde{\mathbf{u}}_{C_1} \\ \tilde{\mathbf{u}}_{C_2} \\ \tilde{\eta}_S \end{pmatrix} = 0, \tag{3.11}$$

where $B = \frac{1}{h} \begin{pmatrix} b_1 & b_2 & b_3 & b_4 & -\overline{b}_3 & -\overline{b}_4 \end{pmatrix}$, with

$$a_1 = \tfrac{3}{20} e^{i(k+l)\frac{h}{6}} \left(2\cos\tfrac{(k-l)h}{2} + e^{\frac{-i}{2}(k+l)h}\right), \quad a_2 = \tfrac{81}{280},$$
$$b_1 = \tfrac{2i}{3}(2\sin kh + \sin lh + \sin(k-l)h), \qquad b_2 = \tfrac{2i}{3}(2\sin lh + \sin kh + \sin(l-k)h),$$
$$b_3 = \tfrac{9}{20} e^{i(k+l)\frac{h}{3}}(1 - e^{-ikh}), \qquad b_4 = \tfrac{9}{20} e^{i(k+l)\frac{h}{3}}(1 - e^{-ilh}).$$

For the 7×7 determinant to vanish we obtain

$$\omega_1 = 0, \quad \omega_{2,3,4,5} = \pm f \text{ (double root)}, \quad \omega_{6,7} = O(1).$$

For infinitesimal mesh spacing we have $\omega_{6,7} = \omega_{AN} + O(h^2)$, and the roots $\omega_{2,3,4,5}$ represent spurious inertial oscillations.

The MINI discretization offers the particularity that equations associated with bubble nodes on an element depend only on the values of the solution on that element. This permits us to eliminate the bubble unknowns at the element level through a

procedure called static condensation [22]. The linear system (3.11) reduces to a 3×3 one after static condensation, and for the corresponding 3×3 determinant to vanish we exactly obtain the solutions ω_1 and $\omega_{6,7}$. Because the factor $(\omega^2 - f^2)^{-2}$ arises during the procedure, the solutions $\omega_{2,3,4,5}$ also need to be considered. Finally, we have also performed the calculations and numerical experiments with a linear bubble, instead of a cubic one, and insignificant differences have been observed.

3.10. The $P_1^{NC} - P_1$ pair. The selected discrete equations are written in the matrix form

$$\begin{pmatrix} A & 0 & 0 & \\ 0 & A & 0 & -g\,B^* \\ 0 & 0 & A & \\ & HB & & \frac{3}{2}ia\omega \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_H \\ \tilde{\mathbf{u}}_V \\ \tilde{\mathbf{u}}_D \\ \tilde{\eta}_S \end{pmatrix} = 0, \tag{3.12}$$

where $B = \frac{1}{h} \begin{pmatrix} b_1 & b_2 & b_3 & b_4 & b_5 & b_6 \end{pmatrix}$, with

$$b_1 = 2i \sin \tfrac{kh}{2}, \quad b_2 = 2i \sin \tfrac{lh}{2} \cos \tfrac{(k-l)h}{2}, \quad b_3 = 2i \sin \tfrac{kh}{2} \cos \tfrac{(k-l)h}{2},$$
$$b_4 = 2i \sin \tfrac{lh}{2}, \quad b_5 = 2i \sin \tfrac{kh}{2} \cos \tfrac{lh}{2}, \qquad b_6 = 2i \sin \tfrac{lh}{2} \cos \tfrac{kh}{2}.$$

Vanishing the above 7×7 determinant leads to

$$\omega_1 = 0, \quad \omega_{2,3,4,5} = \pm f \text{ (double root)}, \quad \omega_{6,7} = \pm \sqrt{f^2 + 4 \frac{gH}{h^2} \alpha},$$

with

$$\alpha = \sin^2 \frac{kh}{2} + \sin^2 \frac{lh}{2} + \frac{2}{3a} \left[\sin^4 \frac{kh}{2} + \sin^4 \frac{lh}{2} \right].$$

The above frequencies coincide with those found in [35], where temporally discretized SW equations are considered, in the limit as time step $\Delta t \to 0$. For infinitesimal mesh spacing we obtain $\omega_{6,7} = \omega_{AN} + O(h^4)$.

3.11. The P_1 iso $P_2 - P_1$ pair. The selected discrete equations lead to

$$\begin{pmatrix} 3A & a_1 A & a_2 A & a_3 A & \\ a_1 A & 3A & a_3 A & a_2 A & \\ a_2 A & a_3 A & 3A & a_1 A & -gB^* \\ a_3 A & a_2 A & a_1 A & 3A & \\ & HB & & & 12ia\omega \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_S \\ \tilde{\mathbf{u}}_H \\ \tilde{\mathbf{u}}_V \\ \tilde{\mathbf{u}}_D \\ \tilde{\eta}_S \end{pmatrix} = 0, \tag{3.13}$$

where $B = \frac{1}{h} \begin{pmatrix} b_1 & b_2 & b_3 & b_4 & b_5 & b_6 & b_7 & b_8 \end{pmatrix}$, with

$$a_1 = \cos \tfrac{kh}{2}, \quad a_2 = \cos \tfrac{lh}{2}, \quad a_3 = \cos \tfrac{(k-l)h}{2}, \quad b_4 = 6i(\sin \tfrac{kh}{2} - \sin \tfrac{(k-2l)h}{2}),$$
$$b_1 = 2i(2 \sin kh + \sin lh + \sin(k-l)h), \qquad b_5 = 6i(\sin \tfrac{lh}{2} + \sin \tfrac{(2k-l)h}{2}),$$
$$b_2 = 2i(2 \sin lh + \sin kh - \sin(k-l)h), \qquad b_7 = 6i(\sin \tfrac{(k-l)h}{2} + \sin \tfrac{(k+l)h}{2}),$$
$$b_3 = 12i \sin \tfrac{kh}{2}, \quad b_6 = 12i \sin \tfrac{lh}{2}, \qquad b_8 = 6i(\sin \tfrac{(k+l)h}{2} - \sin \tfrac{(k-l)h}{2}).$$

For the 9×9 determinant to vanish we obtain

$$\omega_1 = 0, \quad \omega_{2,3,4,5,6,7} = \pm f \text{ (triple root)}, \quad \omega_{8,9} = O(1).$$

For infinitesimal mesh spacing we have $\omega_{8,9} = \omega_{AN} + O(h^2)$.

3.12. The $P_2 - P_1$ pair. The discrete equations lead to the following system:

$$\begin{pmatrix} a_1A & a_4A & a_5A & a_3A & & \\ a_4A & a_2A & a_8A & a_7A & & -gB^* \\ a_5A & a_8A & a_2A & a_6A & & \\ a_3A & a_7A & a_6A & a_2A & & \\ & & HB & & \frac{1}{2}ia\omega & \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_S \\ \tilde{\mathbf{u}}_H \\ \tilde{\mathbf{u}}_V \\ \tilde{\mathbf{u}}_D \\ \tilde{\eta}_S \end{pmatrix} = 0, \tag{3.14}$$

where $B = \frac{1}{h}\begin{pmatrix} 0 & 0 & b_1 & b_2 & b_3 & b_4 & b_5 & b_6 \end{pmatrix}$, with $a_1 = \frac{1}{30}(4-a)$, $a_2 = \frac{8}{45}$, and

$$\begin{aligned} a_3 &= \tfrac{-1}{45}\cos\tfrac{(k+l)h}{2}, & a_4 &= \tfrac{-1}{45}\cos\tfrac{(k-2l)h}{2}, & a_5 &= \tfrac{-1}{45}\cos\tfrac{(2k-l)h}{2}, \\ a_6 &= \tfrac{4}{45}\cos\tfrac{kh}{2}, & a_7 &= \tfrac{4}{45}\cos\tfrac{lh}{2}, & a_8 &= \tfrac{4}{45}\cos\tfrac{(k-l)h}{2}, \\ b_1 &= \tfrac{2i}{3}\sin\tfrac{kh}{2}, & b_2 &= \tfrac{2i}{3}\sin\tfrac{lh}{2}\cos\tfrac{(k-l)h}{2}, & b_3 &= \tfrac{2i}{3}\sin\tfrac{kh}{2}\cos\tfrac{(k-l)h}{2}, \\ b_4 &= \tfrac{2i}{3}\sin\tfrac{lh}{2}, & b_5 &= \tfrac{2i}{3}\sin\tfrac{kh}{2}\cos\tfrac{lh}{2}, & b_6 &= \tfrac{2i}{3}\sin\tfrac{lh}{2}\cos\tfrac{kh}{2}. \end{aligned}$$

Vanishing the above 9×9 determinant leads to

$$\omega_1 = 0, \quad \omega_{2,3,4,5,6,7} = \pm f \text{ (triple root)}, \quad \omega_{8,9} = O(1).$$

For infinitesimal mesh spacing we obtain $\omega_{8,9} = \omega_{AN} + O(h^2)$.

3.13. Summary of discrete frequencies. The previous results are summarized in Table 3.1, where n is the degree of the dispersion relation, and hence the total number of discrete frequencies, for the nine FE schemes examined in section 3.

TABLE 3.1
Number of frequencies of type $\omega = 0$, $O(1)$, $O(\frac{1}{h})$, $O(h)$, $\pm f$, solutions of the dispersion relation of degree n for the nine FE schemes examined in section 3.

FE pair	n	$\omega = 0$	$O(1)$	$O(1) \to \omega_{AN}$ when $h \to 0$	$O(\frac{1}{h})$	$O(h)$	f	$-f$
$P_1^{NC} - P_0$	8	2	2	no	2	0	1	1
$P_2 - P_0$	10	0	2	no	2	2	2	2
RT0	5	1	2	yes	2	0	0	0
$P_0 - P_1$	5	1	2	yes	0	0	1	1
$P_1 - P_1$	3	1	2	yes	0	0	0	0
MINI	7	1	2	yes	0	0	2	2
$P_1^{NC} - P_1$	7	1	2	yes	0	0	2	2
P_1 iso $P_2 - P_1$	9	1	2	yes	0	0	3	3
$P_2 - P_1$	9	1	2	yes	0	0	3	3

We mention whether frequencies of type $O(1)$, corresponding to inertia-gravity modes, coincide with the analytical solution ω_{AN} in the limit as mesh parameter $h \to 0$. This is the case for all FE pairs, except for the $P_1^{NC} - P_0$ and $P_2 - P_0$ schemes, i.e., when n is even. We also notice the presence of spurious frequencies of type $O(\frac{1}{h})$ for the $P_1^{NC} - P_0$, $P_2 - P_0$, and RT0 pairs, i.e., when a piecewise-constant representation of the surface elevation is employed. Such solutions have already been observed in [34], where the one-dimensional SW equations are discretized using the discontinuous Galerkin method. The slow mode corresponding to $\omega = 0$ is not present

for the $P_2 - P_0$ pair; however, a mode of type $O(h)$ appears instead, while $\omega = 0$ is a double root for the $P_1^{NC} - P_0$ pair. Finally, the solutions $\pm f$ are propagating spurious inertial oscillations that have no particular spatial characteristics. They are a consequence of using more velocity nodes than surface-elevation nodes [35] and are present for all schemes except for the $P_1 - P_1$ and RT0 pairs.

4. Analysis of the dispersion relations. We now analyze the computed frequencies obtained from the dispersion relations for the nine FE pairs examined in section 3. We first consider the gravity wave limit, where $f = 0$, and will then comment on the cases $f \neq 0$ and other modes.

4.1. Gravity wave limit. We let $f = 0$, and examine the computed frequencies, denoted by ω_{CP}, corresponding to pure gravity modes of type $O(1)$, as functions of kh and lh. From (3.3) and the results of section 3, we determine the analytical and computed phase speeds, denoted by c_{AN} and c_{CP}, respectively,

$$c_{AN} \equiv \frac{\omega_{AN}}{\sqrt{k^2 + l^2}} = \pm\sqrt{gH}, \quad c_{CP} \equiv \frac{\omega_{CP}}{\sqrt{k^2 + l^2}}.$$

We then obtain the phase speed ratio of the computed phase speed to the analytical one, denoted by r_{PH}, with

$$r_{PH} \equiv \frac{|c_{CP}|}{|c_{AN}|} = \frac{|\omega_{CP}|}{|\omega_{AN}|} = \frac{|\omega_{CP}|}{\sqrt{gH(k^2 + l^2)}}. \tag{4.1}$$

Note that we should have $r_{PH} = 1$ in the absence of numerical dispersion. We show r_{PH} as a surface function depending on kh and lh, and along the selected axes OX, OY, OD1, and OD2 (vertical section), in Figures 4.2 and 4.3, respectively, for the FE schemes previously examined. As in [21], the values of kh and lh vary over their complete domain $[-\pi, \pi]$. However, the phase speed ratio along selected axes is plotted only on $[0, \pi]$, and the solution is then deduced on $[-\pi, 0]$ by symmetry through the origin. The directions OX, OY, OD1, and OD2 are shown in Figure 4.1.

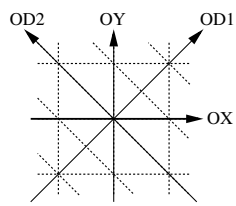

FIG. 4.1. *Definition of the directions OX, OY, OD*1*, and OD*2 *on a uniform mesh made up of biased right triangles.*

The directions OX and OY correspond to waves travelling in the x- and y-directions, for $lh = 0$ and $kh = 0$, respectively, while the directions OD1 and OD2 correspond to waves travelling along the diagonal axes, for $kh = lh$ and $lh = -kh$, respectively.

For the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs in Figure 4.2, r_{PH} is unexpectedly greater than 1 for small values of $|kh|$ and $|lh|$. Indeed, depending on the direction the wave numbers tend to zero, the phase speed ratio ranges from 1.2 to 1.7 for the $P_1^{NC} - P_0$ pair and from 1.8 to 2.5 for the $P_2 - P_0$ one. We notice that for both pairs r_{PH} decreases for increasing values of $|kh|$ and $|lh|$, implying that gravity modes propagate

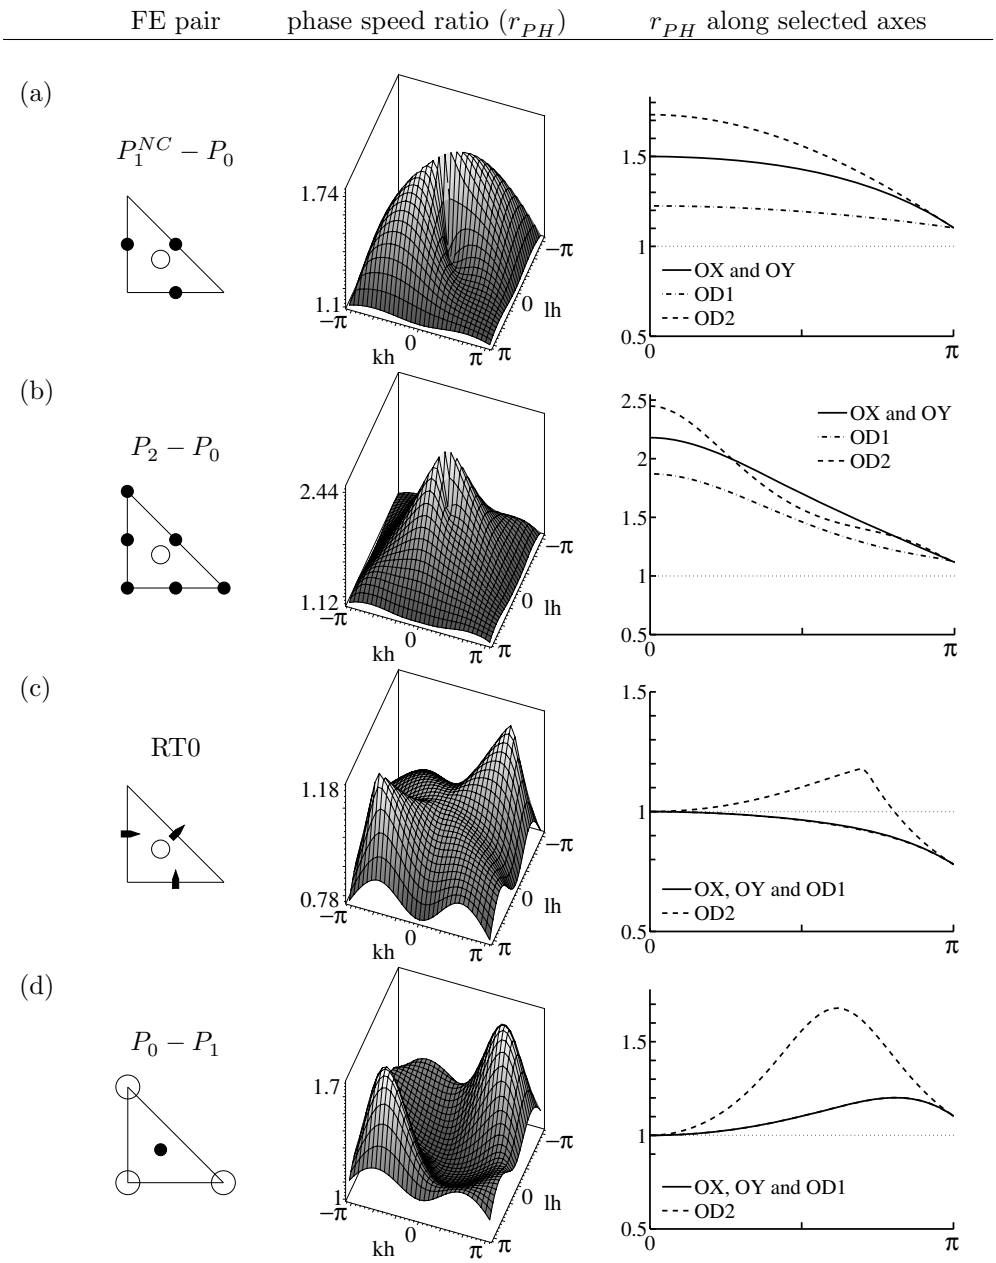

FIG. 4.2. *The phase speed ratio is plotted as a surface function and along selected axes (OX, OY, OD*1*, and OD*2*) for the* (a) $P_1^{NC} - P_0$, (b) $P_2 - P_0$, (c) *RT*0*, and* (d) $P_0 - P_1$ *pairs.*

more rapidly for small wave numbers. Consequently, both pairs poorly represent the propagation of pure gravity waves.

For the $P_1 - P_1$ pair in Figure 4.3, we obtain $r_{PH} \leq 1$ for all values of kh and lh. Hence, the waves are travelling slower than expected, and this is particularly true for large values of $|kh|$ and $|lh|$. We have $r_{PH} = 0$ in the OX, OY, and OD1 directions at the following values of (kh, lh), $(0, \pm\pi)$, $(\pm\pi, 0)$, $(\pm\pi, \pm\pi)$ (waves of length $2h$),

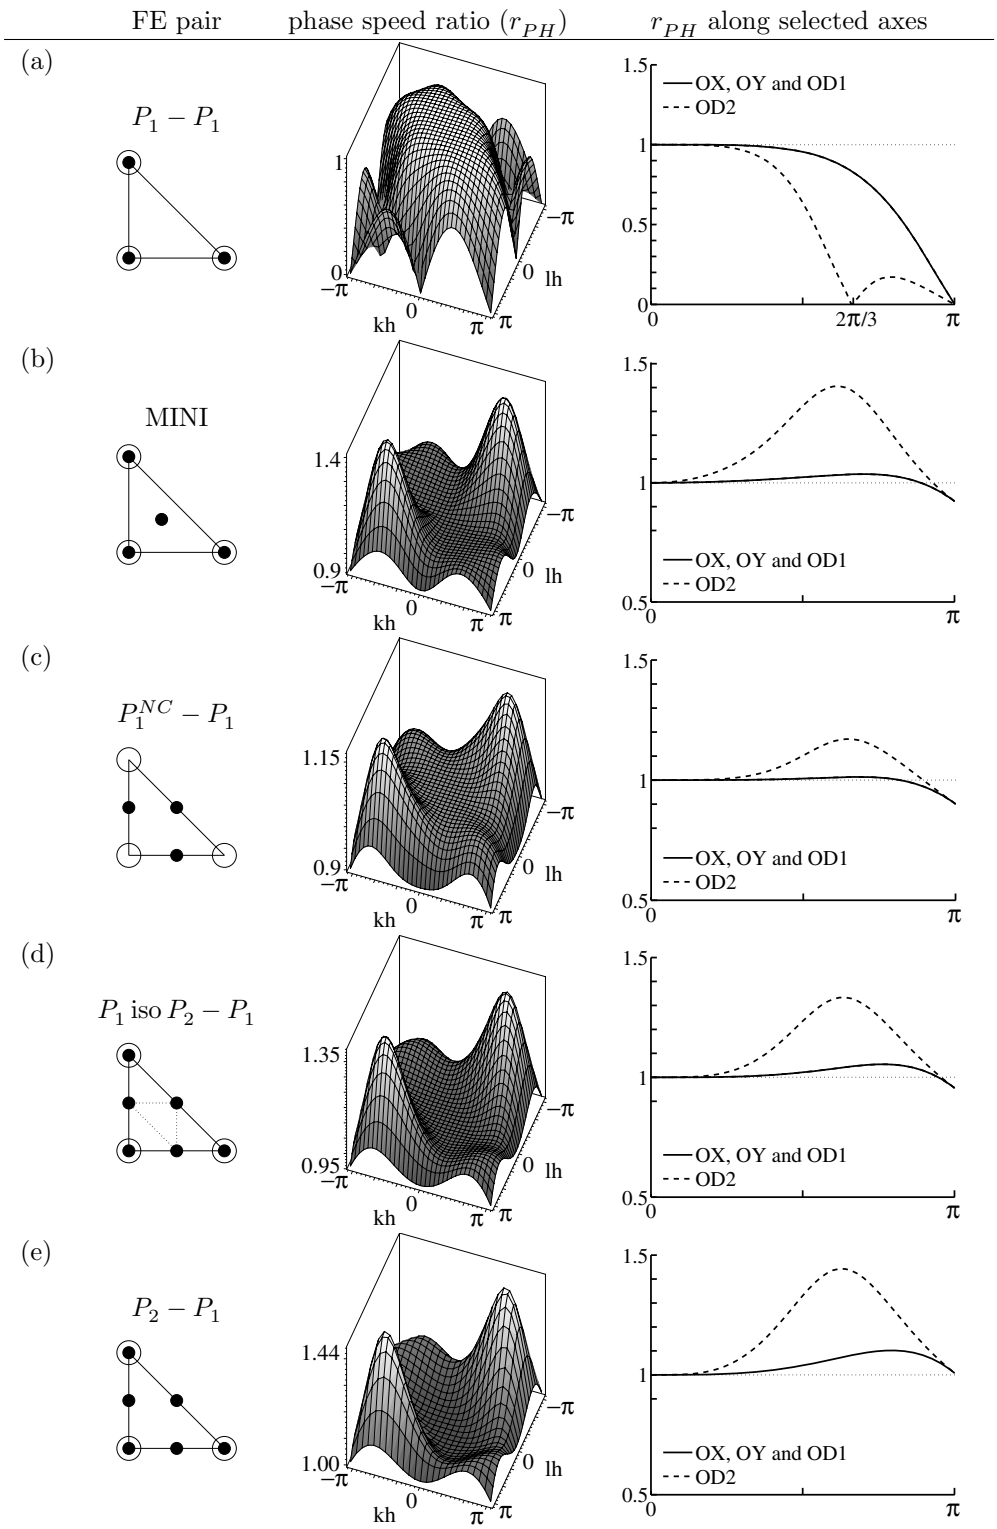

FIG. 4.3. *As for Figure* 4.2 *but for the* (a) $P_1 - P_1$, (b) *MINI,* (c) $P_1^{NC} - P_1$, (d) P_1 *iso* $P_2 - P_1$, *and* (e) $P_2 - P_1$ *pairs.*

and also in the OD2 direction for $|kh| = |lh| = \frac{2\pi}{3}$ (waves of length $3h$). This is a consequence of having zero frequency for waves of length $2h$ and $3h$, as shown previously in section 3.8. Such waves do not propagate and describe oscillations of wavelengths $2h$ and $3h$. They are spurious surface-elevation modes introduced by the spatial discretization scheme. Hence, the $P_1 - P_1$ pair is usually not used to solve the SW system, unless a wave equation formulation or a stabilization procedure is employed [18, 36].

For the remaining FE pairs in Figures 4.2 and 4.3, we have r_{PH} close to 1 for small values of $|kh|$ and $|lh|$ in all directions. However, for increasing values of $|kh|$ and $|lh|$, corresponding to wavelengths ranging from $2h$ to $4h$, r_{PH} departs moderately from 1 in the OX, OY, and OD1 directions for the RT0 element (waves decelerate) and the $P_0 - P_1$ pair (waves accelerate). In the OD2 direction, except for wavelengths ranging from $2h$ to $3h$, r_{PH} strongly departs from 1 for the $P_0 - P_1$, MINI, P_1 iso $P_2 - P_1$, and $P_2 - P_1$ pairs, and moderately for the RT0 and $P_1^{NC} - P_1$ pairs, for increasing values of $|kh|$ and $|lh|$, and the waves will accelerate.

From (3.3) and the results of section 3, we now determine the analytical and computed group velocities, $\mathbf{c}_{g,AN}$ and $\mathbf{c}_{g,CP}$, respectively, i.e., the velocity at which the energy is carried by the waves, with

$$\mathbf{c}_{g,AN} = \left(\frac{\partial \omega_{AN}}{\partial k}, \frac{\partial \omega_{AN}}{\partial l} \right), \quad \mathbf{c}_{g,CP} = \left(\frac{\partial \omega_{CP}}{\partial k}, \frac{\partial \omega_{CP}}{\partial l} \right).$$

We also calculate the directional derivatives $\mathbf{c}_{g,AN} \cdot \mathbf{d}$ and $\mathbf{c}_{g,CP} \cdot \mathbf{d}$, where $\mathbf{d}$ is a unit vector in the OX, OY, OD1, or OD2 directions. For the continuous case and the nine FE pairs of section 3, the group velocities (left panels) and the directional derivatives normalized by the factor $\sqrt{gH}$ (right panels) are shown in Figures 4.4, 4.5, and 4.6.

For the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs in Figure 4.4, the normalized directional derivatives $\mathbf{c}_{g,CP} \cdot \mathbf{d}$ unexpectedly depart from 1 in all directions for small values of $|kh|$ and $|lh|$. Hence, $\mathbf{c}_{g,CP}$ is not consistent with the analytic solution for both pairs as kh and lh tend to zero, and large inaccuracies can be expected in the speed of energy propagation. For the $P_1 - P_1$ pair in Figure 4.4, the group velocity is zero for waves of length $3h$ in the OX, OY, and OD1 directions, and for wavelengths ranging from $2h$ to $3h$ the group velocity has the wrong sign. In the OD2 direction, because the group velocity is zero three times for waves longer than $2h$, it has alternatively right and wrong signs. This is a consequence of having zero frequency for waves of length $2h$ and $3h$, as shown in section 3.8.

For the remaining pairs of Figures 4.5 and 4.6, the group velocity is consistent with the analytic solution as kh and lh are small. However, at the following values of (kh, lh), $(0, \pm\pi)$, $(\pm\pi, 0)$, $(\pm\pi, \pm\pi)$ (waves of length $2h$), we have $\mathbf{c}_{g,CP} = \mathbf{0}$ contrarily to the analytic case, and hence although waves of length $2h$ are propagating, the associated energy is not. For the RT0, $P_0 - P_1$, and MINI pairs in Figure 4.5 and for the $P_2 - P_1$ pair in Figure 4.6, we observe that $\mathbf{c}_{g,CP} \cdot \mathbf{d}$ has a negative (wrong) sign in the OD2 direction for wavelengths greater than $2h$ and smaller than $3h$. Finally, for all pairs in the OD2 direction, the magnitude of the group velocity reaches a peak ranging from 1.5 (for the $P_1^{NC} - P_1$ and RT0 pairs) to 2.5 (for the $P_0 - P_1$ pair) times the analytical value for wavelengths close to $4h$, leading to inaccuracies if such waves are generated and sustained in a numerical model.

4.2. Inertia-gravity waves and other modes. We now assume $f \neq 0$ and note $\lambda \equiv \sqrt{gH}/f$, the Rossby radius of deformation. Within a numerical factor, it is the distance covered by a wave travelling at the speed $\sqrt{gH}$ during one inertial period

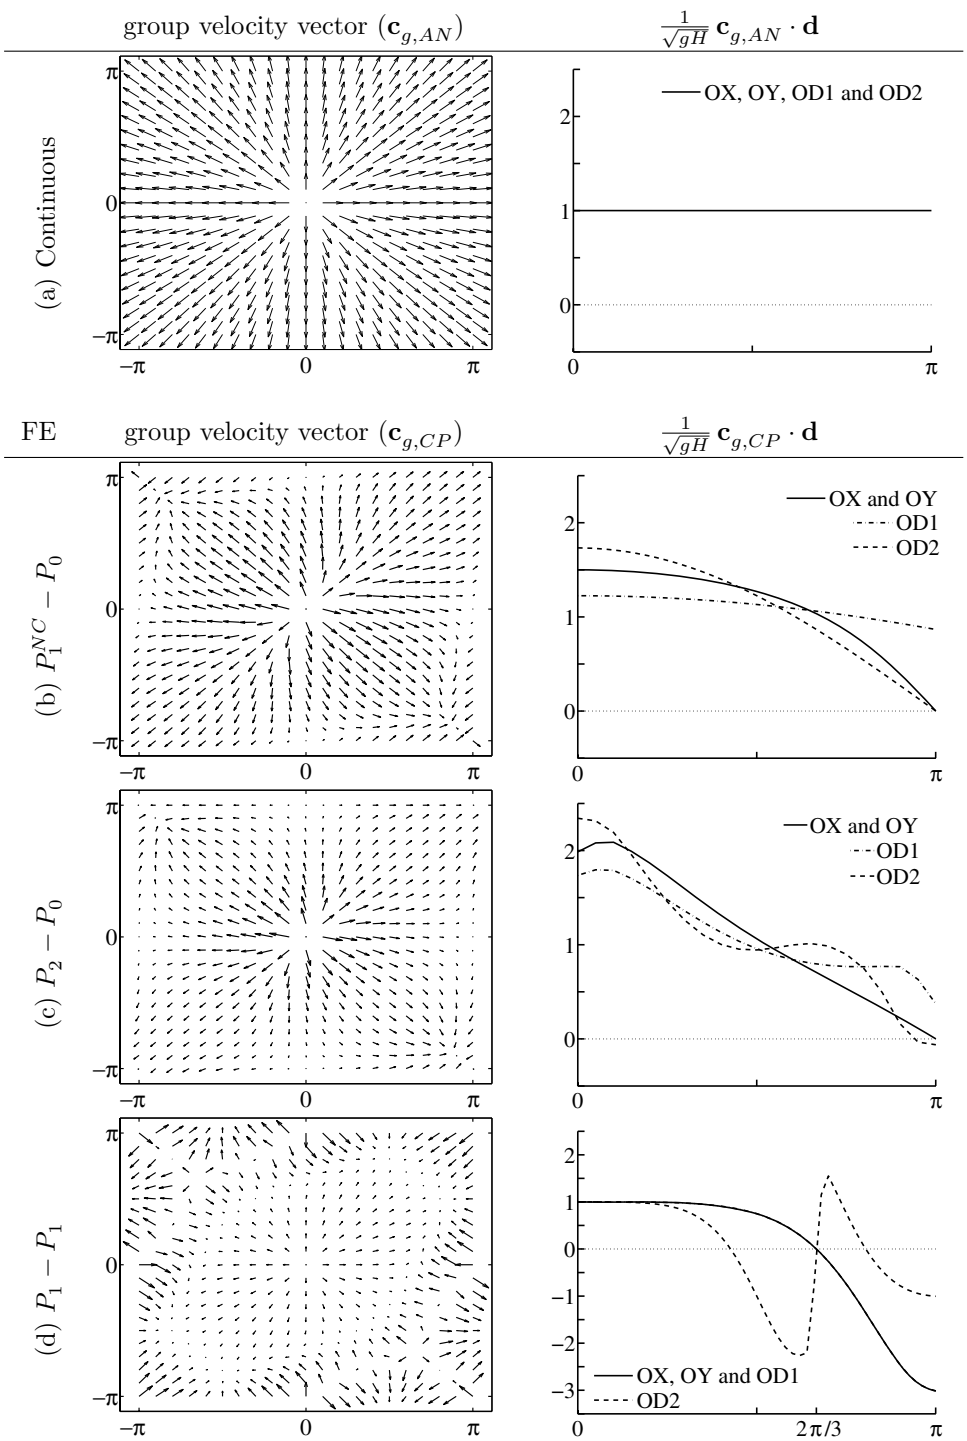

FIG. 4.4. *The group velocity vector (left panels) where the Cartesian coordinate axes are kh and lh, and the normalized directional derivative* $\frac{1}{\sqrt{gH}}\,\mathbf{c}_g\cdot\mathbf{d}$ *(right panels), where* $\mathbf{d}$ *is a unit vector in the OX, OY, OD*1*, or OD*2 *direction, for* (a) *the continuous case and the* (b) $P_1^{NC}-P_0$, (c) P_2-P_0, *and* (d) P_1-P_1 *pairs.*

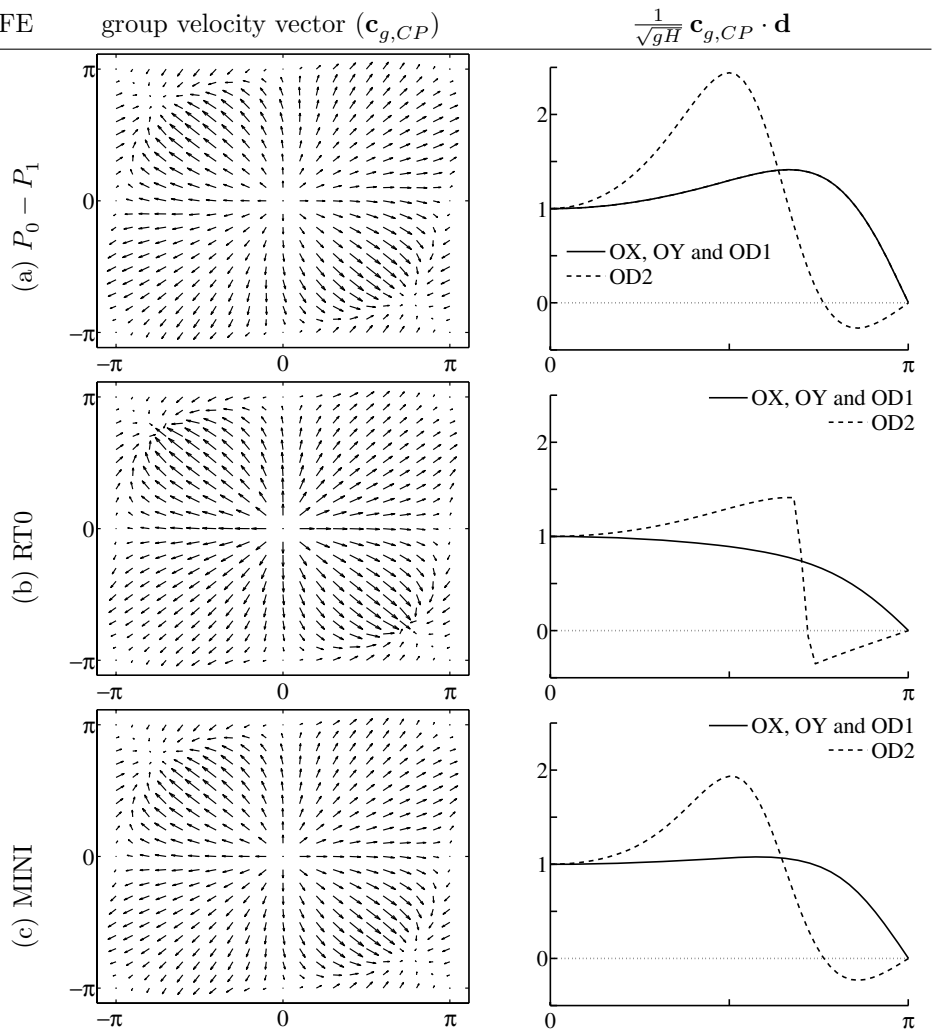

FIG. 4.5. *As for Figure* 4.4 *but for the* (a) $P_0 - P_1$, (b) *RT*0, *and* (c) *MINI pairs.*

$(2\pi/f)$. Using (3.3) and the results of section 3 we now obtain the phase speed ratio

$$r^f_{PH} \equiv \frac{|c_{CP}|}{|c_{AN}|} = \frac{|\omega_{CP}|}{|\omega_{AN}|} = \frac{f\sqrt{1+\left(\frac{\lambda}{h}\right)^2 t(kh,lh)}}{f\sqrt{1+\left(\frac{\lambda}{h}\right)^2 (k^2h^2+l^2h^2)}}, \tag{4.2}$$

where ω_{CP} corresponds to an inertia-gravity mode of type $O(1)$, as in (4.1) but now with $f \neq 0$, and $t(kh, lh)$ is a trigonometric expression depending on kh and lh.

For the $P_1 - P_1$, $P_0 - P_1$, $P_1^{NC} - P_1$, P_1 iso $P_2 - P_1$, MINI, and $P_2 - P_1$ pairs, a realistic positive value for f would have little effect on the plots of Figures 4.2 to 4.6 when $\lambda/h \gg 1$ (high resolution), as $t(kh, lh)$ is bounded in (4.2) for $0 \leq kh \leq \pi$ and $0 \leq lh \leq \pi$. Hence, we have $r^f_{PH} \simeq r_{PH}$ for $\lambda/h \gg 1$. In the case $\lambda/h \ll 1$ (coarse resolution), we deduce from (4.2) that $r^f_{PH} \simeq 1$. However, the results obtained for r_{PH} in Figures 4.2 to 4.6 are roughly preserved but at smaller scales.

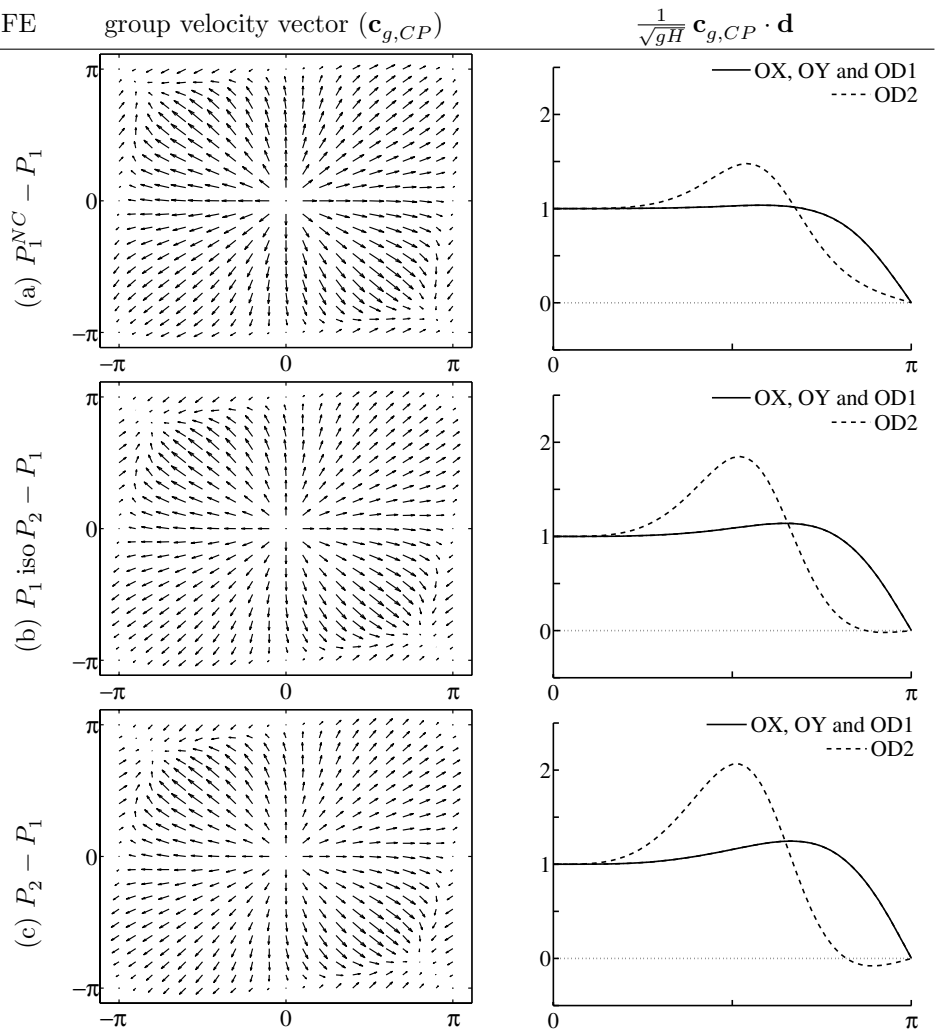

FIG. 4.6. *As for Figure* 4.4 *but for the* (a) $P_1^{NC}-P_1$, (b) P_1 *iso* P_2-P_1, *and* (c) P_2-P_1 *pairs.*

The remaining $P_1^{NC}-P_0$, P_2-P_0, and RT0 pairs, as mentioned in Table 3.1, lead to discrete frequencies of type $O(\frac{1}{h})$, and additionally in $O(h)$ for the P_2-P_0 pair. The nondimensional frequency ω_{CP}/f, corresponding to modes in $O(1)$, $O(\frac{1}{h})$, and $O(h)$ along selected axes (OX, OY, OD1, and OD2), is plotted for these pairs in Figures 4.7 and 4.8 and is compared with the continuous case. We consider λ/h ranging from 1/10 (coarse resolution) to 2 (high resolution).

For the $P_1^{NC}-P_0$ and P_2-P_0 pairs in Figure 4.7, the mode of type $O(\frac{1}{h})$ is a spurious mode appearing as an approximate mirror image of the mode in $O(1)$. For the P_2-P_0 pair, the mode in $O(h)$ is trapped close to zero, and this is especially true when the Rossby radius is resolved (high resolution). Because the P_2-P_0 pair is the only one in Table 3.1 to have a mode in $O(h)$ and no mode corresponding to the geostrophic mode $\omega=0$ in (3.2), we suggest considering the mode in $O(h)$ as a spurious one which coincides with the geostrophic mode as mesh spacing $h\to 0$. Recall that the geostrophic mode would correspond to the slow Rossby mode on a

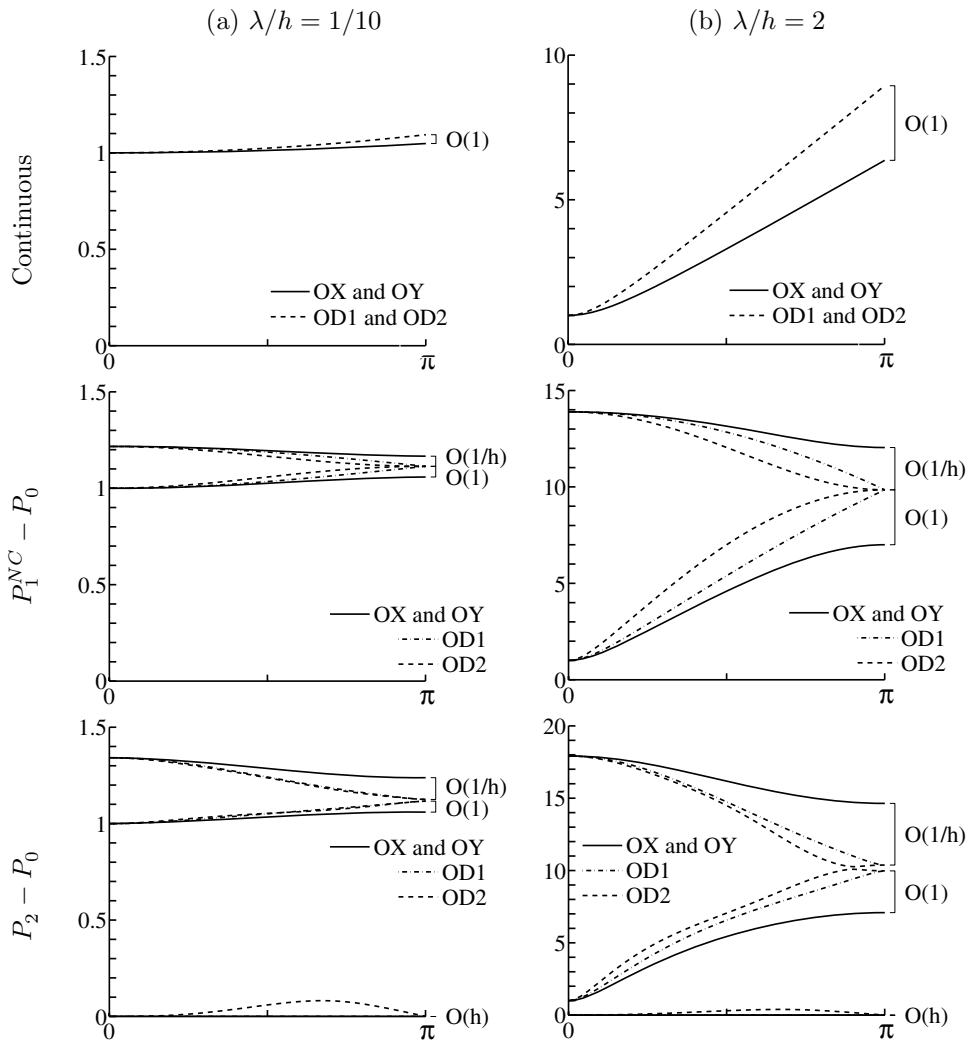

FIG. 4.7. *The nondimensional frequency ω_{CP}/f, corresponding to modes in $O(1)$, $O(\frac{1}{h})$, and $O(h)$ along selected axes (OX, OY, OD1, and OD2), for the continuous case and the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs. We note $\lambda \equiv \sqrt{gH}/f$, the radius of deformation (Rossby radius), and two cases are considered, namely, $\lambda/h = 1/10$ (coarse resolution) and $\lambda/h = 2$ (high resolution).*

β-plane.

For the RT0 pair in Figure 4.8 the mode in $O(\frac{1}{h})$ behaves quite differently from the corresponding ones for the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs in Figure 4.7. Indeed, for values of λ/h below 0.2 (obtained numerically), the mode in $O(\frac{1}{h})$ is much closer to the continuous solution in Figure 4.8 than the $O(1)$ one. Moreover, the mode in $O(1)$ is uniformly zero for all kh and lh in the inertial limit ($g = 0$, i.e., $\lambda/h = 0$), but it tends to draw closer to the continuous solution as the values of λ/h progressively increase. However, in order for the mode in $O(1)$ to be monotonic in kh and lh, as for the continuous one, λ/h has to be chosen greater than 0.45 (obtained numerically). The modes in $O(\frac{1}{h})$ and in $O(1)$ have no common intersection except locally, when $\lambda/h = 1/6$ and $kh = lh = 0$, as shown in Figure 4.8(c). Note the mode in $O(\frac{1}{h})$

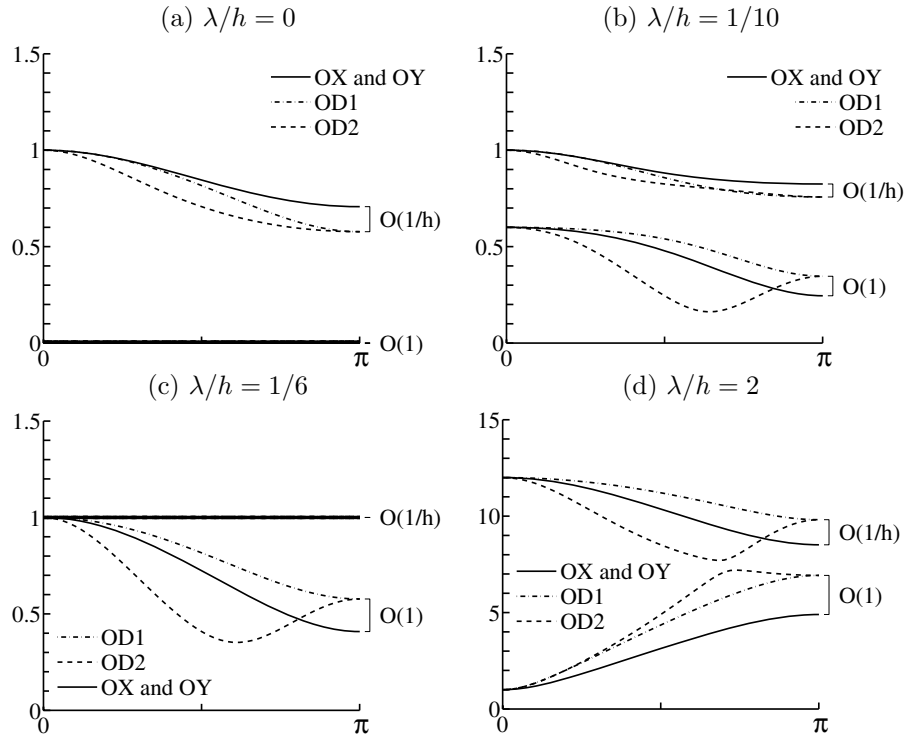

FIG. 4.8. *As for Figure* 4.7 *but for the RT*0 *element in the cases* $\lambda/h = 0$, 1/10, 1/6, *and* 2.

is uniformly one for all kh and lh in the case $\lambda/h = 1/6$, and as λ/h progressively increases (above 1/6), it appears as an approximate mirror image of the mode in $O(1)$, i.e., as a spurious mode. Finally, in the OD2 direction both the $O(\frac{1}{h})$ and $O(1)$ modes exhibit nonmonotonic curves for a wide range of λ/h.

5. Numerical results. The results of two tests using (2.1) and (2.2) are now presented. The first test is performed in [11] for FD grids. It is reproduced here to examine the consequences of the distortion observed in Figure 4.8 in the dispersion relation of the RT0 element for small values of λ/h (coarse resolution).

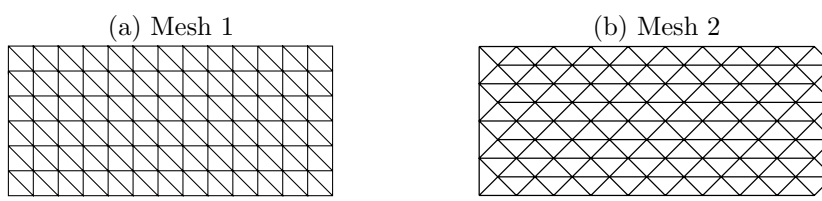

FIG. 5.1. *A window of* (a) *Mesh* 1, *made up of biased right isosceles triangles, and* (b) *Mesh* 2, *obtained from Mesh* 1 *by rotation.*

The main point of interest is to verify whether or not the RT0 discretization properly simulates the geostrophic adjustment process, in which the dispersion of the inertia-gravity waves leads to the establishment of a geostrophic balance.

The square domain extent is 5500 km × 5500 km, and it is discretized using biased right isosceles triangles (as in Figure 5.1(a)) with a uniform node spacing $h = 220$

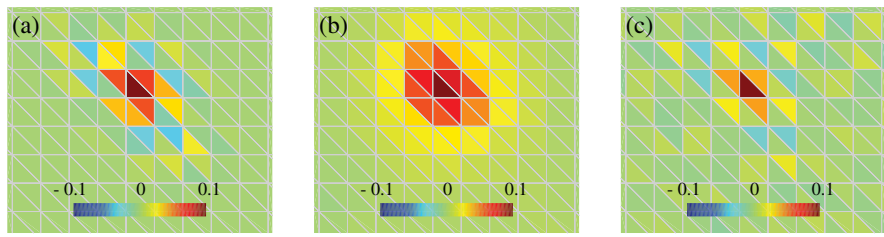

FIG. 5.2. *Window of the surface-elevation field around the point mass source* (0.1 m) *for the RT*0 *pair; after* 1 *day of simulation and* (a) $\lambda/h = 1/6$ *(coarse resolution),* (b) $\lambda/h = 2$ *(high resolution);* (c) *after* 10 *days of simulation and* $\lambda/h = 1/12$ *(coarse resolution).*

km, leading to a 25×25 mesh. The fluid is initially at rest, and zero normal velocity is specified at the lateral boundaries. A point mass source and a point mass sink of 0.1 m and -0.1 m, respectively, are prescribed at fixed locations $12\,h$ apart at each time step; otherwise the initial surface elevation field is uniform. The Coriolis parameter is held constant and evaluated close to $45°$ N, with $f = 10^{-4}\,\mathrm{s}^{-1}$, and the time step is 450 s. The surface-elevation field is shown after one day of simulation, which is approximately the time required for geostrophic adjustment to occur, in Figures 5.2(a) and (b). In Figure 5.2(a), for $\lambda/h = 1/6$ (coarse resolution) with $\sqrt{gH} = 11/3\,\mathrm{m\,s}^{-1}$, and also for $\lambda/h \leq 1/2$, the RT0 scheme exhibits a checkerboard-like pattern of noise in the elevation field around the mass source and sink points, shown by an irregular alternation of positive and negative height areas (that are constant per triangle). Note that such a pattern is not observed for the other pairs. Due to the symmetry, only the result around the point mass source is shown. We believe the checkerboard-like appearance is probably due to the distortion observed in Figure 4.8 in the dispersion relation for small values of λ/h (coarse resolution). In Figure 5.2(b) for $\lambda/h = 2$ (high resolution) with $\sqrt{gH} = 44\,\mathrm{m\,s}^{-1}$, the surface-elevation distribution exhibits a regular and expected pattern as for the other pairs, except for the $P_1 - P_1$ one (due to the spurious surface-elevation mode). We also conducted the experiment over 10 days, and the result is shown in Figure 5.2(c) for $\lambda/h = 1/12$ (coarse resolution) with $\sqrt{gH} = 11/6\,\mathrm{m\,s}^{-1}$. The checkerboard-like pattern is more apparent than in Figure 5.2(a), particularly when considering the alternation of blue and yellow triangles surrounding the four centered ones (red and orange) in the OX, OY, and OD2 directions. Note that in all cases the gravitational Courant number is small (≤ 0.1) and the use of a forward Euler and a Crank–Nicolson time stepping schemes yields essentially the same results.

In the second test, (2.1) and (2.2) are solved using $f = 0$. The purpose of the experiment is to validate the analytical results obtained in section 4.1 on two meshes, Mesh 1 and Mesh 2, shown in Figure 5.1. Mesh 1 is made up of biased right triangles and Mesh 2 is obtained from Mesh 1 by a rotation of $\pi/4$. Such meshes are used in order to simulate gravity-wave propagation: along the OX and OY directions for Mesh 1 and along the OD2 direction for Mesh 2. The domain extent is 7000 km $\times$ 280 km for Mesh 1 and $5000\sqrt{2}$ km $\times$ $200\sqrt{2}$ km for Mesh 2. In both cases the resolution is $h = 10$ km, along the x- or y-axis for Mesh 1 and along the diagonal for Mesh 2. The fluid is initially at rest and zero normal velocity is specified at the lateral boundaries, except at the western one. The conditions $\eta = 1$ m and $u = 0.1\,\mathrm{m\,s}^{-1}$ (i.e., $u = \sqrt{\frac{g}{H}} \times 1$ m) are prescribed at each time step at the western boundary, with $H = 1000$ m and $g = 10\,\mathrm{m\,s}^{-2}$, i.e., $\sqrt{gH} = 100\,\mathrm{m\,s}^{-1}$. Note that the velocity has been imposed weakly at the western boundary for the $P_0 - P_1$ pair. The time step is set to 10 s, and the gravitational Courant number is thus 0.1.

In Figures 5.3 and 5.4 the vertical cross-sections (on the x, z-plane) and the isolines of the wave propagation are displayed for graphical convenience, after 2000 s and 10000 s, respectively, on the two meshes. For all pairs, except the $P_1^{NC} - P_0$ and $P_2 - P_0$ ones, the wave front propagates at the analytical speed $100\,\mathrm{m\,s}^{-1}$. This is because r_{PH} is close to 1 for small values of $|kh|$ and $|lh|$ in all directions as shown in Figures 4.2 and 4.3. However, the maximum values observed for r_{PH} in the OX and OD2 directions are 1.5 and 1.73, respectively, for the $P_1^{NC} - P_0$ pair, and 2.18 and 2.45, respectively, for the $P_2 - P_0$ one. For the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs, the wave front speeds are thus expected to be $150\,\mathrm{m\,s}^{-1}$ and $218\,\mathrm{m\,s}^{-1}$, respectively, in the OX direction, and $173\,\mathrm{m\,s}^{-1}$ and $245\,\mathrm{m\,s}^{-1}$, respectively, in the OD2 direction. These analytical values are in good agreement with the computed ones, observed in

Figures 5.3 and 5.4. Indeed, for the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs, the computed wave front speeds are $141\,\mathrm{m\,s^{-1}}$ and $209\,\mathrm{m\,s^{-1}}$, respectively, on Mesh 1, and $172\,\mathrm{m\,s^{-1}}$ and $242\,\mathrm{m\,s^{-1}}$, respectively, on Mesh 2, with a mesurement error of about $2\,\mathrm{m\,s^{-1}}$. The loss of symmetry observed in the front propagation for the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs on Mesh 1 is likely due to a faster propagation in the OD2 direction. This explains the observed southeast orientation of the front and hence its partial propagation in the OD1 direction. Consequently, due to the results of Figure 4.2 in the OD1 direction, the computed wave speed is slightly smaller than the analytic one on Mesh 1. On Mesh 2, because the faster (dominant) propagation is along the OD2 direction, the front is not tilted and the analytical and computed values nearly coincide.

There is also a good agreement between the numerical dispersion observed in Figures 4.2 and 4.3 and the simulation results shown in Figures 5.3 and 5.4, except for the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs due to the incorrect position of the front. Indeed, in the OX, OY, and OD1 directions we have $r_{PH} \simeq 1$ for the $P_1^{NC} - P_1$ pair in Figure 4.3(c), and a small amount of numerical dispersion is observed in Figure 5.4 on Mesh 1. For the MINI, P_1 iso $P_2 - P_1$, $P_2 - P_1$, and $P_0 - P_1$ pairs in the previous directions, r_{PH} progressively increases from 1.03 (MINI) up to 1.2 ($P_0 - P_1$) as observed in Figures 4.2 and 4.3. Hence, we have $|c_{CP}| \geq |c_{AN}|$ and increasing dispersion is noticeable upstream the front in Figures 5.3 and 5.4 for these pairs on Mesh 1. For the RT0 and $P_1 - P_1$ pairs in the previous directions, we have $r_{PH} \leq 1$ in Figures 4.2 and 4.3, and hence $|c_{CP}| \leq |c_{AN}|$, leading to dispersion effects downstream the front as shown in Figures 5.3 and 5.4 on Mesh 1. In the OD2 direction, we still have $r_{PH} \leq 1$ for the $P_1 - P_1$ pair, and oscillations are again present downstream the front on Mesh 2 as shown in Figure 5.4. For the RT0 pair we now have $r_{PH} \geq 1$ in the OD2 direction (except for small wavelengths), and the dispersion effects are noticeable upstream the front in Figure 5.3 on Mesh 2. For the $P_1^{NC} - P_1$, P_1 iso $P_2 - P_1$, MINI, $P_2 - P_1$, and $P_0 - P_1$ pairs in the OD2 direction, r_{PH} progressively increases from 1.15 ($P_1^{NC} - P_1$) up to 1.7 ($P_0 - P_1$) as observed in Figures 4.2 and 4.3. We thus have $|c_{CP}| \geq |c_{AN}|$, and increasing dispersion is noticeable for these pairs upstream the front in Figures 5.3 and 5.4 on Mesh 2.

Spurious elevation modes are not observed in Figure 5.4 for the $P_1 - P_1$ pair. This is because a constant value of H is used. However, when $H = 1000$ m if $x \leq 400$ km, when $H = 800$ m if $x \geq 600$ km, and by assuming H is linear if 400 km $\leq x \leq 600$ km, a spurious surface elevation mode of wavelength $3h$ is triggered, as shown in Figure 5.5 on Mesh 2. This agrees well with the result predicted by theory in Figure 4.3(a) in the OD2 direction.

Finally, the second test has also been performed on unstructured meshes. Two main features are observed for all pairs: the numerical dispersion upstream the front is more significant than on Mesh 1 but less than on Mesh 2, and additional noise is generated downstream the front. Further, the loss of symmetry observed in the front propagation in Figure 5.3 for the $P_1^{NC} - P_0$ and $P_2 - P_0$ is only marginally present.

6. Conclusions. This appears to be the first study of the dispersion relation and spurious mode behavior for FE solutions of the two-dimensional linearized SW equations based on the examination of a variety of mixed FE pairs. For each pair the frequency wave number or dispersion relation is obtained and analyzed, and the dispersion properties are compared analytically and graphically with the continuous case to illustrate the main points of interest. Two numerical tests, concerning the propagation of gravity waves, are performed. In the first experiment, the simulation of the geostrophic adjustment process, the RT0 element exhibits a checkerboard-like pattern of noise in the elevation field when the grid resolution is low relative to the

Rossby radius of deformation. Such a pattern has not been observed for the other pairs. The second test illustrates the analytical dispersion results by simulating the propagation of pure gravity waves in a long channel. In particular, for the $P_1^{NC} - P_0$ and $P_2 - P_0$ pairs, the wave front propagates much faster than the analytical speed. These results can be compared with those in [32] for the geostrophic balance. We also notice the presence of spurious frequencies of type $O(\frac{1}{h})$ for the FE pairs having a piecewise-constant representation of the surface elevation. Such solutions have already been observed in [34], where the one-dimensional SW equations are discretized using the discontinuous Galerkin method, and they will be analyzed in a further study.

The preceding analysis illustrates how phase and group velocity accuracy can help in the selection of a spatial discretization scheme. In particular, the $P_1^{NC} - P_1$ and RT0 pairs have been identified as a promising compromise for the discretization of the inviscid linear SW equations, provided the grid resolution is high relative to the Rossby radius of deformation for the RT0 element. However, because of its restrictive nature, due to the use of constant values for h and H, such an analysis should be only one step of the selection process. The use of nonconstant h and H will be analyzed in subsequent studies. Further, the implementation of a time stepping technique can change the relative accuracy and merits of two spatial discretization schemes.

ORDER-OPTIMAL PRECONDITIONERS FOR IMPLICIT RUNGE–KUTTA SCHEMES APPLIED TO PARABOLIC PDES*

K.-A. MARDAL†, T. K. NILSSEN‡, AND G. A. STAFF†

Abstract. In this paper we show that standard preconditioners for parabolic PDEs discretized by implicit Euler or Crank–Nicolson schemes can be reused for higher-order fully implicit Runge–Kutta time discretization schemes. We prove that the suggested block diagonal preconditioners are order-optimal for A-stable and irreducible Runge–Kutta schemes with invertible coefficient matrices. The theoretical investigations are confirmed by numerical experiments.

Key words. preconditioners, Runge–Kutta schemes, parabolic PDE

1. Introduction.

Let Ω be a bounded polygonal domain in $\mathbb{R}^d$, with $d = 2$ or 3, and boundary $\partial\Omega$. In this paper we will consider a parabolic PDE of the form

$$\frac{\partial u}{\partial t} = \Delta u + f \quad \text{in } \Omega,\ t > 0, \tag{1}$$

$$u = 0 \quad \text{on } \partial\Omega,\ t \geq 0, \tag{2}$$

$$u = u^0 \quad \text{in } \Omega,\ t = 0. \tag{3}$$

Equations (1)–(3) are discretized in space, by a finite element method, which gives a system of ODEs to be solved,

$$M\frac{du_h}{dt} = -Ku_h + f_h, \quad t > 0, \tag{4}$$

$$u_h = u_h^0, \quad t = 0, \tag{5}$$

where M is the mass matrix and K is the stiffness matrix. Higher-order time discretization schemes based on fully implicit Runge–Kutta schemes are rarely used when discretizing (4)–(5), due to the additional cost of solving a larger and more complicated system of equations. The lack of efficient solution algorithms for such systems has prevented these algorithms from widespread use for PDEs, despite the many appealing properties of such schemes. However, the lack of efficient algorithms applies not only to PDEs, but to ODEs in general—a fact we emphasize by quoting as follows from some standard ODE textbooks:

(1) [illegible] [8, p. 118].

(2) [illegible] [2, pp. 103, 104].

In this paper we will see how one can reuse fast solution algorithms developed for low-order time discretizations, in the case of a parabolic PDE.

When (4)–(5) are discretized by lower-order time discretization schemes such as implicit Euler, we arrive at the following sequence of linear systems to be solved at each time step:

$$(M + \delta t K) u_h^n = M u^{n-1} + \delta t f_h^n, \tag{6}$$

where δt is the time stepping parameter. Order-optimal solution algorithms for this system have been found for most spatial discretization methods. The goal in this paper is to reuse such preconditioners for fully implicit Runge–Kutta schemes. In that way the method will have implementational similarities to BDF (backward differentiation formulae) and DIRK (diagonally implicit Runge–Kutta) methods, but still will have the stability and convergence of the chosen fully implicit Runge–Kutta method. Furthermore, we will prove that these preconditioners are order optimal with respect to δt and h and demonstrate their efficiency by several numerical experiments. Order-optimality in s, where s is the number of stage values in the Runge–Kutta schemes, is not obtained. However, we demonstrate that the s-dependency is weak compared to the accuracy gained. Furthermore, we have in [19] numerically demonstrated that this s-dependency can be reduced by generalizing a Gauss–Seidel preconditioner with certain coefficients determined by a simple optimization principle.

Except for BDF and DIRK methods, which require only the solution of systems of the form (6), the authors know of only a few other works on solution algorithms for higher-order time discretization schemes in the context of PDEs (see [5], [7], [11], [12], [13], [14], and [15]). References [12] and [13] present an inexact block LU preconditioner when using the W-transformation on the Runge–Kutta schemes. Block Jacobi and Gauss–Seidel preconditioners for generalized Adams methods are studied in [11]. In [15], we discussed preconditioners for higher-order Padé formulations of parabolic PDEs, where the matrix was a polynomial of $(M + \delta t K)$-like matrices, of the form $\Pi_{i=1}^{n}(M + a_i \delta t K)^i$. In this work, we instead consider linear systems of $(M + \delta t K)$-like matrices.

In the recent work [14], multigrid methods for Runge–Kutta methods were studied. A key idea in this work was to employ block smoothers, simultaneously updating all unknowns related to a spatial grid point. A convergence rate independent of the number of quadrature nodes of the Runge–Kutta scheme, s, was obtained, but the smoothers require the solution of $s \times s$ systems at each spatial grid point. Our approach is different in the sense that we employ standard preconditioners (e.g., multigrid with pointwise smoothers or domain decomposition) for (6) on each of the blocks in the block matrix arising from the Runge–Kutta discretization.

The order-optimality of the method proposed here is proved by viewing the differential operator as an isomorphism in appropriate spaces. This gives an upper bound on the condition number of the preconditioned system, and therefore an upper bound on the number of iterations. Other works taking the same approach are [1], [9], and [17].

The preconditioners discussed in this paper can be (and have been) implemented as a block diagonal matrix of standard preconditioners. Practical details concerning

the implementation of block preconditioners (in the C++ library Diffpack) can be found in [16]. More numerical experiments can be found in [19]. Here, numerical experiments also in three dimensions verify the order-optimality. Furthermore, it is shown numerically that block Gauss–Seidel preconditioners can improve the efficiency of the preconditioner.

The remaining part of the paper is organized as follows. In section 2 we review some useful concepts. In section 3 we prove that the continuous version of the time stepping operator for Runge–Kutta methods is an isomorphism bounded independent of δt, when using the proper interpolation spaces. This enables us to construct order-optimal preconditioners in the discrete case in section 4. Section 5 presents some numerical experiments.

2. Preliminaries. Let $H^1 = H^1(\Omega)$ be the Sobolev space with first-order derivatives in $L^2 = L^2(\Omega)$, with norm $\|\cdot\|_1$. The space H_0^1 is the closure of C_0^∞ in H^1, with norm $\|\cdot\|_{H_0^1} = |\cdot|_1$, which is the L_2 norm of the first-order derivatives. The $|\cdot|_1$ norm is equivalent to the standard H^1 norm on H_0^1. The space H^{-1} is the dual space of H_0^1. Vector valued functions and spaces are denoted by boldface symbols. The inner product of both scalars, vectors, and matrices, as well as the duality pairing of H_0^1 and H^{-1} and their corresponding vector spaces, are denoted by $(\cdot,\cdot)$, and the corresponding norm is denoted by $\|\cdot\|$. The operators Δ and ∇ are applied to both scalars and vectors, where the scalar versions are standard and the vector versions are defined as

$$(\Delta \boldsymbol{u})_i = \Delta u_i \quad \text{and } (\nabla \boldsymbol{u})_{i,j} = \frac{\partial u_i}{\partial x_j} \quad \text{for } 1 \le i \le s,\ 1 \le j \le d,$$

where u_i is the ith component of $\boldsymbol{u}$. Notice that $\nabla \boldsymbol{u}$ is an $s \times d$ matrix. The spaces involving time are defined by

$$\|u\|_{L^2(0,T;X)} = \left(\int_0^T \|u(t)\|_X^2 dt \right)^{1/2},$$

where $\|\cdot\|_X$ is the spatial norm in the space X (which is either H_0^1, H^{-1}, or L^2). The weak form of (1)–(3) is as follows:

Find $u \in L^2(0,T;H_0^1)$ with $\frac{\partial u}{\partial t} \in L^2(0,T;H^{-1})$ such that

$$\left(\frac{\partial u}{\partial t}, v\right) + (\nabla u, \nabla v) = (f, v) \quad \forall v \in H_0^1, \quad t > 0, \tag{7}$$

$$u = u_0, \quad t = 0. \tag{8}$$

Similarly, the finite element formulation is defined by seeking an approximation $u_h(t)$ in a finite element subspace $V_h \subset H_0^1$ by the following:

Find $u_h \in L^2(0,T;V_h)$ with $\frac{\partial u_h}{\partial t} \in L^2(0,T;V_h)$ such that

$$\left(\frac{\partial u_h}{\partial t}, v\right) + (\nabla u_h, \nabla v) = (f, v) \quad \forall v \in V_h, \quad t > 0,$$

$$u = u_0, \quad t = 0.$$

This can be written as a linear system of ODEs,

$$I_h \frac{\partial u_h}{\partial t} - \Delta_h u_h = f_h,$$

where I_h is the identity operator (the mass matrix M) and Δ_h is the Δ operator (the negative stiffness matrix $-K$) on V_h. The right-hand side f_h is the L_2-projection of f on V_h (often approximated by the mass matrix times a vector with the values of f evaluated at nodal points). We may write this system as

$$\frac{\partial u_h}{\partial t} - I_h^{-1}\Delta_h u_h = I_h^{-1} f_h,$$

and the eigenvalues of $-I_h^{-1}\Delta_h$ are real and positive.

The unknown $u_h(t)$ is approximated by a Runge–Kutta method,

$$u_h^n = u_h^{n-1} + \delta t \sum_{i=1}^{s} b_i u_{h,i}^n,$$

where

$$I_h u_{h,i}^n = \Delta_h \left(u_h^{n-1} + \delta t \sum_{j=1}^{s} a_{ij} u_{h,j}^n \right) + f_h(t_{n-1} + c_i \delta t), \quad 1 \le i \le s, \tag{9}$$

where $u_{h,i}^n$ is the intermediate stage value approximating the time derivative of u at a given quadrature node (we use the slightly confusing variable name $u_{h,i}^n$ for the time derivatives of u, since $u_{h,i}^n$ is the unknown that appears in our linear system). This system can be written as

$$(\boldsymbol{I}^{s,s} \otimes I_h - \delta t A \otimes \Delta_h)\boldsymbol{u}_h^n = -\boldsymbol{I}^{s,s} \otimes \Delta_h \boldsymbol{u}_h^{n-1} + \boldsymbol{f}_h^n,$$

where $\boldsymbol{f}_h^n = (f_{h,1}^n, \ldots, f_{h,s}^n)^T$, $f_{h,i}^n = f_h(t_{n-1} + c_i \delta t)$; $\boldsymbol{u}_h^n$ is the vector of intermediate stage values $\boldsymbol{u}_h^n = (u_{h,1}^n, \ldots, u_{h,s}^n)^T$; $\boldsymbol{I}^{s,s}$ is the identity matrix in $\mathbb{R}^{s,s}$; A, b, and c are the Runge–Kutta coefficients, weights, and nodes; and $\otimes$ is the Kronecker tensor product,

$$A \otimes B = \begin{pmatrix} a_{11}B & \ldots & a_{1n}B \\ \vdots & \ddots & \vdots \\ a_{n1}B & \ldots & a_{nn}B \end{pmatrix}.$$

A Runge–Kutta scheme is A-stable if the stability function

$$R(z) = 1 + z b^T (I - zA)^{-1} \mathbf{1}$$

satisfies $|R(z)| \le 1$ when $\mathrm{Re}(z) < 0$, where $\mathbf{1} \in \mathbb{R}^s$ is a vector of ones. In this paper we will assume that the Runge–Kutta methods are A-stable, irreducible, and have invertible A, such as Gauss, LobattoIIIC, RadauIA, and RadauIIA; cf., e.g., [8]. We will also assume that the diagonal entries of A are positive. We refer to [6] for a description of parabolic PDEs and to [20] for corresponding discretization methods.

We use the common definition of an order-optimal preconditioner, which is that $\mathcal{B}_k$ is an order-optimal preconditioner for $\mathcal{A}_k$, with respect to the parameter k, given that the condition number of $\mathcal{B}_k\mathcal{A}_k$ is bounded independently of the parameter k, and that the evaluation and storage of $\mathcal{B}_k$ are similar to that of $\mathcal{A}_k$. In this paper we will show that the considered preconditioners are order optimal with respect to both the parameters h and δt.

Finally, we will need the intersection and sum of Hilbert spaces. If X and Y are Hilbert spaces, both continuously contained in some larger Hilbert space, then the intersection $X \cap Y$ and the sum $X + Y$ are Hilbert spaces, and the norms are defined as

$$\|z\|_{X\cap Y} = (\|z\|_X^2 + \|z\|_Y^2)^{1/2}$$

and

$$\|z\|_{X+Y} = \inf_{\substack{z=x+y \\ x\in X,\, y\in Y}} (\|x\|_X^2 + \|y\|_Y^2)^{1/2}.$$

Furthermore, if $X \cap Y$ is dense in both X and Y, then $(X \cap Y)^* = X^* + Y^*$. We refer to [4, Chapter 2] for these results. We will use the space $L^2 \cap \delta t H_0^1$ and its dual space $L^2 + \frac{1}{\delta t} H^{-1}$, and their vector spaces, $\boldsymbol{L}^2 \cap \delta t \boldsymbol{H}_0^1$ and $\boldsymbol{L}^2 + \frac{1}{\delta t} \boldsymbol{H}^{-1}$, with dimension s. We remark that for $\delta t > 0$, $L^2 \cap \delta t H_0^1$ is equal to H^1 as a set, but as $\delta t \to 0$, the norm degenerates to L^2. Since the spaces will appear many times, we have adopted the following shorthand notation:

$$V = L^2 \cap \delta t H_0^1,$$

$$V^* = L^2 + \frac{1}{\delta t} H^{-1},$$

$$\boldsymbol{V} = \boldsymbol{L}^2 \cap \delta t \boldsymbol{H}_0^1,$$

$$\boldsymbol{V}^* = \boldsymbol{L}^2 + \frac{1}{\delta t} \boldsymbol{H}^{-1}.$$

3. An existence result. The purpose of this paper is to introduce preconditioners for Runge–Kutta schemes applied to parabolic PDEs that are uniform in both space and time (but not in the number of stages). To do this we will employ the spaces introduced in the previous section to describe the spatial problem to be solved at each time step.

We start with the following implicit Euler time discretization of (1) to explain the problem:

Find $u^n \in V$, such that

$$a^E(u^n, v) = b^n(v) \quad \forall v \in V,$$

where

$$a^E(u^n, v) = (u^n, v) + \delta t(\nabla u^n, \nabla v),$$

$$b^n(v) = (u^{n-1}, v) + \delta t(f^n, v).$$

It then follows that

$$a^E(u, v) \le c_1^E \|u\|_V \|v\|_V,$$

$$a^E(u, u) \ge \frac{1}{c_2^E} \|u\|_V^2.$$

From the Lax–Milgram theorem (or the Riesz representation theorem since a^E is symmetric) we know that there exists a unique solution in V, depending continuously on b^n in V^*. Hence, if we let $\mathcal{A}^E$ be defined by

$$(\mathcal{A}^E u, v) = a^E(u, v),$$

where

$$\mathcal{A}^E = I - \delta t \Delta,$$

then $\mathcal{A}^E$ is an isomorphism mapping V to V^* bounded independently of δt, i.e.,

$$\|\mathcal{A}^E\|_{\mathcal{L}(V,V^*)} \le c_1^E \quad \text{and} \quad \|(\mathcal{A}^E)^{-1}\|_{\mathcal{L}(V^*,V)} \le c_2^E.$$

In contrast, if we had considered $\mathcal{A}^E$ as a mapping from H_0^1 to H^{-1}, then c_1^E and c_2^E would depend on δt.

Similarly, the implicit Runge–Kutta method (i.e., the continuous version of (9)) can be written in the following form:

Find $\boldsymbol{u}^n \in \boldsymbol{V}$, such that

$$(\boldsymbol{u}^n, \boldsymbol{v}) + \delta t(A \otimes \Delta \boldsymbol{u}^n, \boldsymbol{v}) = (-\boldsymbol{I}^{s,s} \Delta \boldsymbol{u}^{n-1}, \boldsymbol{v}) + \delta t(\boldsymbol{f}^n, \boldsymbol{v}) \quad \forall \boldsymbol{v} \in \boldsymbol{V}. \tag{10}$$

The solution u^n is obtain by

$$u^{n+1} = u^n + \delta t \sum_{i=1}^{s} b_i u_i^n.$$

Equation (10) may be written as

$$\mathcal{A}\boldsymbol{u} = \boldsymbol{f},$$

where

$$\mathcal{A} = I - \delta t A \otimes \Delta.$$

In this section we will show that $\mathcal{A} : \boldsymbol{V} \to \boldsymbol{V}^*$ is an isomorphism,

$$\|\mathcal{A}\|_{\mathcal{L}(\boldsymbol{V},\boldsymbol{V}^*)} \le c_1 \quad \text{and} \quad \|\mathcal{A}^{-1}\|_{\mathcal{L}(\boldsymbol{V}^*,\boldsymbol{V})} \le c_2, \tag{11}$$

where both c_2 and c_1 are independent of δt. The associated bilinear form is

$$\begin{aligned} a(\boldsymbol{u}, \boldsymbol{v}) &= (\mathcal{A}\boldsymbol{u}, \boldsymbol{v}) = ((I - \delta t A \otimes \Delta)\boldsymbol{u}, \boldsymbol{v}) \\ &= (\boldsymbol{u}, \boldsymbol{v}) - \delta t(A\Delta \boldsymbol{u}, \boldsymbol{v}) \\ &= (\boldsymbol{u}, \boldsymbol{v}) + \delta t(A\nabla \boldsymbol{u}, \nabla \boldsymbol{v}). \end{aligned}$$

We remark that $a(\cdot, \cdot)$ is neither positive nor symmetric for a general A arising from a Runge–Kutta scheme. Therefore we cannot use the theorems of Riesz or Lax and Milgram. To be able to prove that $\mathcal{A}$ is an isomorphism, we need the theorem of Babuska and Aziz [3], which in our setting reads as follows.

THEOREM 3.1. *A* $\boldsymbol{V}$ $\boldsymbol{V}^*$

- c_1 δt

$$|a(\boldsymbol{u},\boldsymbol{v})| \le c_1 \|\boldsymbol{u}\|_{\boldsymbol{V}} \|\boldsymbol{v}\|_{\boldsymbol{V}} \quad \forall \boldsymbol{u},\boldsymbol{v} \in \boldsymbol{V}. \tag{12}$$

- c_2 δt (inf-sup)

$$\sup_{\boldsymbol{v}\in\boldsymbol{V}} \frac{a(\boldsymbol{u},\boldsymbol{v})}{\|\boldsymbol{v}\|_{\boldsymbol{V}}} \ge \frac{1}{c_2}\|\boldsymbol{u}\|_{\boldsymbol{V}} \quad \forall \boldsymbol{u} \in \boldsymbol{V}. \tag{13}$$

- $\boldsymbol{v} \in \boldsymbol{V}$ $\boldsymbol{u} \in \boldsymbol{V}$

$$a(\boldsymbol{u},\boldsymbol{v}) \neq 0. \tag{14}$$

. See [3]. □

Hence, it remains to prove (12)–(14). The first two properties are proven in the following lemmas.

LEMMA 3.1. c_1 δt

$$|a(\boldsymbol{u},\boldsymbol{v})| \le c_1 \|\boldsymbol{u}\|_{\boldsymbol{V}} \|\boldsymbol{v}\|_{\boldsymbol{V}}.$$

. To show (12) we see that

$$\begin{aligned}
a(\boldsymbol{u},\boldsymbol{v}) &= ((I - \delta t A \otimes \Delta)\boldsymbol{u},\boldsymbol{v}) \\
&= (\boldsymbol{u},\boldsymbol{v}) - \delta t \sum_{i,j\le s} a_{ij} \left(\Delta u_i, v_j\right) \\
&= (\boldsymbol{u},\boldsymbol{v}) + \delta t \sum_{i,j\le s} a_{ij} \left(\nabla u_i, \nabla v_j\right) \\
&\le a_{max} \left(\|\boldsymbol{u}\|\|\boldsymbol{v}\| + \delta t \sum_{i,j\le s} \|\nabla u_i\|\|\nabla v_j\| \right) \qquad (15) \\
&\le c_1 \left(\|\boldsymbol{u}\|\|\boldsymbol{v}\| + \delta t \|\nabla \boldsymbol{u}\|\|\nabla \boldsymbol{v}\| \right) \qquad (16) \\
&\le c_1 \left(\|\boldsymbol{u}\|^2 + \delta t \|\nabla \boldsymbol{u}\|^2 \right)^{\frac{1}{2}} \left(\|\boldsymbol{v}\|^2 + \delta t \|\nabla \boldsymbol{v}\|^2 \right)^{\frac{1}{2}} \\
&= c_1 \|\boldsymbol{u}\|_V \|\boldsymbol{v}\|_V,
\end{aligned}$$

where (15) follows by the Cauchy–Schwarz inequality and the definition

$$a_{max} = \max\left(\max_{ij} |a_{ij}|, 1 \right),$$

and (16) comes from the fact that

$$\begin{aligned}
\sum_{i,j\le s} \|\nabla u_i\|\|\nabla v_j\| &= \sum_{i\le s} \|\nabla u_i\| \sum_{j\le s} \|\nabla v_j\| \\
&\le s \|\nabla \boldsymbol{u}\|\|\nabla \boldsymbol{v}\|, \qquad (17)
\end{aligned}$$

where (17) follows from the equivalence ℓ^1 and ℓ^2 norms on $\mathbb{R}^s$. □

To prove the inf-sup condition we introduce a family of matrices which we will refer to as weakly positive definite. These matrices are defined as follows.

DEFINITION 3.1. [illegible] $A \in \mathbb{R}^{s,s}$ [illegible] $C \in \mathbb{R}^{s,s}$ [illegible]

$$x^T C x > 0 \quad \forall x \in \mathbb{R}^s, \tag{18}$$

$$x^T C A x > 0 \quad \forall x \in \mathbb{R}^s. \tag{19}$$

LEMMA 3.2. [illegible]

The proof of this lemma can be found in [18]. Weakly positive matrices can be seen as a generalization of the diagonally stable matrices discussed in, e.g., [10].

In the following calculations we need the existence of a positive number α such that

$$x^T C x \geq \alpha \|x\|^2 \quad \forall x \in \mathbb{R}^s, \tag{20}$$

$$x^T C A x \geq \alpha \|x\|^2 \quad \forall x \in \mathbb{R}^s. \tag{21}$$

This follows since C and CA are positive definite (not necessarily symmetric). To see that (18) leads to (20), let $x = \frac{y}{\|y\|}$ and use linearity to obtain the equivalent statement that $x^T C x > \alpha$ for $\|x\| = 1$. Furthermore, since $x^T C x$ is a continuous function of x and the set defined by $\|x\| = 1$ is compact, $x^T C x$ will have a lower bound, and therefore (20) follows from (18). Similarly, (21) follows from (19).

In the next lemma we use that the Runge–Kutta coefficient matrix A is weakly positive definite; i.e., there exists a positive definite matrix C such that CA is positive definite. By Lemma 3.2 this is true as long as the arguments of the eigenvalues of A differ from π. However, for A-stable irreducible Runge–Kutta methods with an invertible A a stronger result is known, namely, that the real parts of the eigenvalues of A are positive. To see this, notice that the stability function of a Runge–Kutta method is given by

$$R(z) = \frac{\det(I - zA + z\mathbf{1}b^T)}{\det(I - zA)}.$$

Irreducibility gives that the fraction cannot be reduced. Assume that there exists an eigenvalue μ of A with $Re(\mu) < 0$. Then the stability function will have a pole in $z = 1/\mu$, which also lies in the left half plane. This contradicts with the A-stability, which requires that $|R(z)| \leq 1$ for all z in the left half plane. Furthermore, A is invertible; therefore zero is not an eigenvalue. We therefore conclude that the real part of the eigenvalues must be positive.

LEMMA 3.3. [illegible] c_2 [illegible] δt [illegible]

$$\sup_{\boldsymbol{v} \in \boldsymbol{V}} \frac{a(\boldsymbol{u}, \boldsymbol{v})}{\|\boldsymbol{v}\|_{\boldsymbol{V}}} \geq \frac{1}{c_2} \|\boldsymbol{u}\|_{\boldsymbol{V}} \quad \forall \boldsymbol{u} \in \boldsymbol{V}.$$

[illegible]. Define

$$\alpha = \min \left(\min_{\|x\|=1} x^T C x, \min_{\|x\|=1} x^T C A x \right).$$

Given $\boldsymbol{u} \in \boldsymbol{V}$, let $\boldsymbol{v} = C^T \boldsymbol{u}$, where C is constructed such that we have (20)–(21) with A being the Runge–Kutta coefficient matrix. Then,

$$\begin{aligned}
\sup_{\boldsymbol{v}\in\boldsymbol{V}} \frac{(\mathcal{A}\boldsymbol{u},\boldsymbol{v})_{L^2}}{\|\boldsymbol{u}\|_{\boldsymbol{V}}\|\boldsymbol{v}\|_{\boldsymbol{V}}} &\geq \frac{(\mathcal{A}\boldsymbol{u}, C^T\boldsymbol{u})_{L^2}}{\|\boldsymbol{u}\|_{\boldsymbol{V}}\|C^T\boldsymbol{u}\|_{\boldsymbol{V}}} \\
&= \frac{(C\mathcal{A}\boldsymbol{u},\boldsymbol{u})_{L^2}}{\|\boldsymbol{u}\|_{\boldsymbol{V}}\|C^T\boldsymbol{u}\|_{\boldsymbol{V}}} \\
&= \frac{(C\boldsymbol{u},\boldsymbol{u})_{L^2} - \delta t((CA\otimes\Delta)\boldsymbol{u},\boldsymbol{u})_{L^2}}{\|\boldsymbol{u}\|_{\boldsymbol{V}}\|C^T\boldsymbol{u}\|_{\boldsymbol{V}}} \\
&\geq \frac{1}{\|C\|}\frac{(C\boldsymbol{u},\boldsymbol{u})_{L^2} + \delta t(CA\nabla\boldsymbol{u},\nabla\boldsymbol{u})_{L^2}}{\|\boldsymbol{u}\|_{\boldsymbol{V}}\|\boldsymbol{u}\|_{\boldsymbol{V}}} \\
&\geq \frac{\alpha}{\|C\|}\frac{\|\boldsymbol{u}\|_{L^2}^2 + \delta t\|\nabla\boldsymbol{u}\|_{L^2}^2}{\|\boldsymbol{u}\|_{\boldsymbol{V}}^2} \\
&= \frac{\alpha}{\|C\|} \\
&> 0,
\end{aligned}$$

where $\|C\|$ is the L^2 matrix norm. Hence, $c_2 = \frac{\|C\|}{\alpha}$ in (13). □

Finally, (14) follows by an argument similar to the proof of (13) in Lemma 3.3. First, we notice that A^T and A share the same set of eigenvalues, and therefore A^T is also weakly positive definite. By Lemma 3.2 we now have that there exists a D such that both D and DA^T are positive definite. Further let $\boldsymbol{v}$ be given and let $\boldsymbol{u} = D^T\boldsymbol{v}$. Then we have

$$\begin{aligned}
a(\boldsymbol{u},\boldsymbol{v}) = a(D^T\boldsymbol{v},\boldsymbol{v}) &= ((I - A\otimes\Delta)D^T\boldsymbol{v},\boldsymbol{v}) = ((D^T - AD^T\otimes\Delta)\boldsymbol{v},\boldsymbol{v}) \\
&= (\boldsymbol{v}, D\boldsymbol{v}) + (\nabla\boldsymbol{v}, DA^T\nabla\boldsymbol{v}) > 0.
\end{aligned}$$

We therefore conclude that $\mathcal{A}$ is an isomorphism (11).

4. The preconditioner. The preconditioner for the continuous operator is constructed based on the weighted Sobolev spaces. The discrete preconditioner can be viewed as an operator acting on discrete subspaces. Other works taking the same approach are [1], [9], and [17].

Let $\mathcal{B} : \boldsymbol{V}^* \to \boldsymbol{V}$ be

$$\mathcal{B} = (I - \delta t\,\mathrm{diag}(A)\otimes\Delta)^{-1}, \tag{22}$$

where we assume that the diagonal of A is always strictly positive. It follows from the definition of $\boldsymbol{V}$ and $\boldsymbol{V}^*$ that

$$\|\mathcal{B}\|_{\mathcal{L}(\boldsymbol{V}^*,\boldsymbol{V})} \leq d_1 \quad \text{and} \quad \|\mathcal{B}^{-1}\|_{\mathcal{L}(\boldsymbol{V},\boldsymbol{V}^*)} \leq d_2, \tag{23}$$

where d_1 and d_2 are independent of δt. Hence,

$$\mathcal{B}\mathcal{A} : \boldsymbol{V} \to \boldsymbol{V}$$

and

$$\|\mathcal{BA}\|_{\mathcal{L}(\boldsymbol{V},\boldsymbol{V})} \le c_1 d_1 \quad \text{and} \quad \|(\mathcal{BA})^{-1}\|_{\mathcal{L}(\boldsymbol{V},\boldsymbol{V})} \le c_2 d_2. \tag{24}$$

This means that the condition number of the continuous operator is bounded, i.e.,

$$\kappa(\mathcal{BA}) = \|\mathcal{BA}\|_{\mathcal{L}(\boldsymbol{V},\boldsymbol{V})}\|(\mathcal{BA})^{-1}\|_{\mathcal{L}(\boldsymbol{V},\boldsymbol{V})} \le c_1 d_1 c_2 d_2. \tag{25}$$

In the following we study the condition number in the discrete case. Let Ω_h be a triangulation of Ω. Furthermore, let V_h be a finite element space $V_h \subset H_0^1$, while $\boldsymbol{V}_h = (V_h)^s \subset \boldsymbol{H}_0^1$ is the corresponding vector finite element space. The discrete counterparts of $\mathcal{A}$ and $\mathcal{B}$ are defined by

$$(\mathcal{A}_h \boldsymbol{u}_h, \boldsymbol{v}_h) = (\boldsymbol{u}_h, \boldsymbol{v}_h) + \delta t (A\nabla \boldsymbol{u}_h, \nabla \boldsymbol{v}_h) \qquad \forall \boldsymbol{u}_h, \boldsymbol{v}_h \in \boldsymbol{V}_h, \tag{26}$$

$$(\mathcal{B}_h^{-1} \boldsymbol{u}_h, \boldsymbol{v}_h) = (\boldsymbol{u}_h, \boldsymbol{v}_h) + \delta t \,\mathrm{diag}(A)(\nabla \boldsymbol{u}_h, \nabla \boldsymbol{v}_h) \qquad \forall \boldsymbol{u}_h, \boldsymbol{v}_h \in \boldsymbol{V}_h. \tag{27}$$

Since $\boldsymbol{V}_h$ is a subspace of $\boldsymbol{V}$ we get that

$$\kappa(\mathcal{B}_h \mathcal{A}_h) \le \kappa(\mathcal{BA}). \tag{28}$$

Let $\tilde{B}_i$ be a cheap approximation of $B_i = (I - \delta t a_{ii} \Delta_h)^{-1}$ constructed by, e.g., multigrid or domain decomposition. This is the standard preconditioner which is used for the implicit Euler step. It is then well known that $\tilde{B}_i$ may be constructed such that it is symmetric and spectrally equivalent to B_i, i.e.,

$$c_3(\tilde{B}_i^{-1} v, v) \le ((I - \delta t a_{ii} \Delta_h)v, v) \le c_4(\tilde{B}_i^{-1} v, v) \quad \forall v \in V_h. \tag{29}$$

Let c_3 and c_4 be chosen such that (29) is valid for all i. Let further the full preconditioner be denoted

$$\tilde{\mathcal{B}}_h = \begin{pmatrix} \tilde{B}_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \tilde{B}_s \end{pmatrix}.$$

We have that the condition number fulfills the Cauchy–Schwarz-like property $\kappa(CD) \le \kappa(C)\kappa(D)$ for two matrices C and D, since

$$\kappa(CD) = \|CD\|\|(CD)^{-1}\| \le \|C\|\|D\|\|C^{-1}\|\|D^{-1}\| = \kappa(C)\kappa(D).$$

Therefore we get

$$\kappa(\tilde{\mathcal{B}}_h \mathcal{A}_h) \le \kappa(\tilde{\mathcal{B}}_h \mathcal{B}_h^{-1}) \kappa(\mathcal{B}_h \mathcal{A}_h).$$

By using (25) and (29), we get

$$\kappa(\tilde{B}_h \mathcal{A}_h) \le \frac{c_1 d_1 c_2 d_2 c_4}{c_3}. \tag{30}$$

5. Numerical experiments. In this section we test our preconditioner in a series of numerical experiments. We test three families of fully implicit Runge–Kutta schemes: Gauss, Radau, and Lobatto. The different families have different properties when it comes to the order of the approximation and the stability. We will give only a brief description here and refer the reader to [8] for a more thorough description.

By using Gauss quadrature rules, we get the implicit Runge–Kutta Gauss methods. They have a global error estimate of $\mathcal{O}(\delta t^{2s})$, where s is the number of quadrature points. Notice that the single-node Gauss method is the implicit midpoint method and is equal to the Crank–Nicolson scheme in our example.

Using Radau quadrature, which requires one end point among the quadrature nodes, the global error estimate is $\mathcal{O}(\delta t^{2s-1})$. These methods will be named RadauIA and RadauIIA, where the start or the end point is among the quadrature nodes, respectively. Notice that implicit Euler is the single-node method, where the end point is the quadrature node.

Finally, one can require that both the start and end points are quadrature nodes, which is called Lobatto quadrature. There exist three different subfamilies of the Lobatto scheme, where the coefficient matrix A differs among them. They have different properties regarding, e.g., stability, but they all have a global error estimate of $\mathcal{O}(\delta t^{2s-2})$. Two of the subfamilies have one explicit step. These methods are not studied here since they have a singular A-matrix. We will consider only the LobattoIIIC methods.

All the methods are A-stable, but only the Radau methods and the LobattoIIIC methods are L-stable, which is an attractive property for stiff problems, such as a semidiscretized heat equation. In addition, the RadauIIA and LobattoIIIC methods are stiffly accurate.

It is well known from standard ODE theory that in the case of very stiff problems, where $\delta t \to 0$ while $z = \lambda \delta t \to \infty$, where λ is an eigenvalue of $I_h^{-1}\Delta_h$, the order of the implicit Runge–Kutta schemes is reduced. This is known as B-convergence and is more thoroughly described in [8]. This does, however, affect only the order of convergence for the Runge–Kutta scheme and not the performance of our preconditioner. In our numerical tests, we did not experience order reduction.

5.1. The condition number. First, we want to verify numerically the order-optimality of the preconditioner with respect to the spatial discretization parameter h and the time step δt. This is done for a three-node RadauIIA method. We solve a 1D problem, where linear finite elements are used in space. The preconditioner is the inverse of the submatrices on the diagonal. The results are presented in Table 1 and Figure 1.

TABLE 1

The condition number $\kappa(\mathcal{BA})$ for the 1D problem (1)–(3) using linear finite elements in space, and using the three-node RadauIIA method in time. The preconditioner is constructed by inverting the diagonal blocks exactly.

$\delta t/h$	2^{-2}	2^{-3}	2^{-4}	2^{-5}	2^{-6}	2^{-7}	2^{-8}	2^{-9}
0.1	8.23	13.40	14.93	15.32	15.42	15.44	15.45	15.45
0.05	5.49	11.79	14.44	15.19	15.38	15.43	15.44	15.45

0.001	1.08	1.47	3.24	8.08	12.71	14.67	15.25	15.40

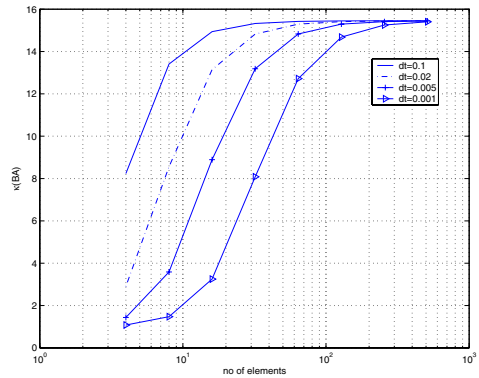

FIG. 1. *The condition number* $\kappa(\mathcal{BA})$ *for the* 1*D problem* (1)–(3) *using linear finite elements in space, and using the three-node RadauIIA method in time. The preconditioner is inverted exactly.*

If the time step δt is sufficiently small compared to the spatial discretization parameter h, the Helmholtz operator is close to the mass matrix, and the condition number is small. For a sufficiently small spatial discretization compared to the time step, the condition number $\kappa(\mathcal{BA})$ of the preconditioned system seems to reach an asymptotic value of about 15.4. The next section concerns the asymptotic value for this and other schemes in both one and two dimensions using multigrid preconditioners. In [19] we have also shown experiments in three dimensions.

The results clearly confirm that the preconditioner is order optimal with respect to both the spatial discretization parameter h and the time step δt.

5.2. Multigrid preconditioning. We will use multigrid to approximate the preconditioner. All computations will be done on a domain $\Omega = (0,1)^d$, where d is the number of spatial dimensions. A sequence of meshes is constructed by uniform refinement of a 2 or 2×2 partition of the domain Ω. The preconditioner $\tilde{\mathcal{B}}$ is computed using a standard V-cycle with a symmetric Gauss–Seidel smoother. Gaussian elimination is used as the coarse grid solver.

We estimate the condition number using one multigrid V-cycle as the preconditioner. The results are shown in Table 2 for both one and two dimensions. The discretization parameters δt and h are chosen such that the condition number is close to the asymptotic value. In our case $\delta t = 0.1$ and $h = 2^{-9}$ have been appropriate. The results for multigrid in two dimensions are better than the results for multigrid in one dimension, and this seems a bit strange. We have tested this multigrid method also in the case of a Poisson equation, and similar results were obtained here. However, it is probably possible to tune the parameters in the 1D multgrid method such that it performs better, but we have not done this, since the results are good.

The single stage methods are included as a point of reference. In two dimensions, the multigrid preconditioner is much better than in one, and the condition numbers are roughly 10% higher than the exact 1D case.

Clearly our preconditioner is not optimal with respect to the number of quadrature nodes in the Runge–Kutta scheme. In fact, it seems that the growth in the condition number with respect to s is slightly above quadratic. But remember that an increase in the number of nodes by one implies an increase in the order of two. So an increase in the number of iterations may be subordinate to the decrease in the number of required

TABLE 2
Estimates of the condition number $\kappa(\mathcal{BA})$ for various implicit Runge–Kutta schemes.

Method	Exact 1D	MG 1D	MG 2D
Gauss 1 node (Implicit midpoint)	1.0	1.9	1.1
Gauss 2 nodes	4.8	9.1	5.2
Gauss 3 nodes	11.8	22.0	12.8
Gauss 4 nodes	22.4	41.2	24.2
Gauss 5 nodes	37.2	67.8	40.0
Gauss 6 nodes	56.6	102.0	60.4
RadauIA 1 node	1.0	1.9	1.1
RadauIA 2 nodes	1.5	2.6	1.5
RadauIA 3 nodes	7.2	13.6	7.8
RadauIIA 1 node (Implicit Euler)	1.0	1.9	1.1
RadauIIA 2 nodes	6.8	12.9	7.4
RadauIIA 3 nodes	15.4	29.0	16.8
RadauIIA 4 nodes	27.1	50.1	29.3
RadauIIA 5 nodes	41.2	75.2	44.3
RadauIIA 6 nodes	57.5	104	61.5
LobattoIIIC 2 nodes	1.3	1.9	1.4
LobattoIIIC 3 nodes	11.2	21.4	12.2
LobattoIIIC 4 nodes	21.6	40.6	23.5

time steps. This is what we will investigate in the next example. Notice also that in [19] we studied Gauss–Seidel preconditioners, which have far better performance with respect to s.

5.3. Iteration count for a test problem. Finally, we compare the actual CPU time for a given test problem. We solve (1)–(3), with a source term f such that the exact solution is

$$u(x,y,t) = \sin(\omega_x x)\sin(\omega_y y)\sin(\omega_t \pi t)e^{xy}, \quad (\omega_x,\omega_y,\omega_t) = (\pi,\pi,20.5\pi).$$

The high number of oscillations in time is to generate a certain degree of complexity in time. We solve the problem from $T = 0.0$ to $T = 1.0$ on the unit square. In space we discretize using linear finite elements. Both the element size h and the time step δt are chosen such that the error is of order 10^{-5}, measured in the following discrete $L^2(0,T;L^2)$ norm:

$$\|e\|_{L^2(0,T,L^2)} = \left(\sum_{k=0}^{n} e(t_k)^T M e(t_k)\,\delta t\right)^{1/2},$$

where $e(t_k)$ is the error vector at nodal points at time t_k, M is the mass matrix, and n is the number of time steps. In space we discretized using 2^{16} bilinear finite elements over the entire domain.

The preconditioner is one geometric multigrid V-cycle, and the linear system is solved using the GMRES method with restart after five search vectors (for RadauIIA and Gauss with one node we used conjugated gradients) with the stopping criterion that $\|r_k\| < 10^{-7}$. The result is displayed in Table 3. Notice that the residual is evaluated only before the restart. This means that the system is possibly overiterated, but the computational time is in general smaller due to the high cost of evaluating the residual every iteration.

TABLE 3

The total computational time measured in minutes (wct), the time spent to solve the linear system (lst), and the average number of iterations (for all time steps) for solving the heat equations (1)–(3) *for schemes with various numbers of stages. The discretization parameters are chosen such that the error from the discretizations is approximately* 10^{-5}. *The preconditioner is approximated using one multigrid V-cycle. For comparison, the same simulations are also done without a preconditioner.*

		With MG prec			No prec

LobattoIIIC 4 nodes	1/43	23.4	64.5	19.5	—	>5000	—

The results are computed on a Linux machine with an AMD Athlon 64 2.2GHz processor with 2GB RAM using the C++ library Diffpack.

The number of iterations stated is an average over all the iterations. The three-node Gauss scheme is the fastest, while the four-node Gauss is almost equally fast. In general, the higher-order schemes are more efficient than the lower-order schemes for all three classes of Runge–Kutta schemes.

The cost of doing a preconditioned GMRES iteration is approximately 2.5 the cost of doing an unpreconditioned iteration. The cost of evaluating the right-hand side for each time step is equal to several preconditioned iterations due to the complexity of the function f. This is noticeable for the schemes in which the number of required iterations is low, where the time to solve the linear systems (lst) is much smaller than the total solution time (wct).

Note that this is only an indication that high-order Runge–Kutta methods may be efficient compared to low-order methods. But which solver is the most efficient depends on several properties such as the regularity of the solution, the required accuracy, the implementation, and others.

6. Final remarks. In this paper we have shown that the systems arising from fully implicit Runge–Kutta schemes applied to parabolic equations can be efficiently preconditioned with a block preconditioner. The block preconditioner is block diagonal and has blocks that are standard elliptic preconditioners. It is well known that such preconditioners are order optimal when constructed by, e.g., multigrid or domain decomposition methods. The proposed preconditioner is proven to be order optimal when constructed from an order-optimal preconditioner for a backward Euler scheme.

In several numerical experiments we have demonstrated that the condition numbers for the preconditioned systems are bounded. We have also seen that higher-order methods are beneficial, when using efficient preconditioners, even for problems with relatively fast dynamics and modest accuracy requirements.

Acknowledgments. The authors are grateful to Professors Brynjulf Owren and Syvert P. Nørsett of the Department of Mathematical Science, Norwegian University of Science and Technology, Norway, for many useful discussions.

A SEMICLASSICAL COUPLED MODEL FOR THE TRANSIENT SIMULATION OF SEMICONDUCTOR DEVICES*

PHILIPPE BECHOUCHE† AND LAURENT GOSSE‡

Abstract. We consider the approximation of a microelectronic device corresponding to an $n^+ - n - n^+$ diode consisting of a channel flanked on both sides by two highly doped regions. This is modeled through a system of equations: ballistic for the channel and drift-diffusion elsewhere. The overall coupling stems from the Poisson equation for the self-consistent potential. We propose an original numerical method for its processing, being realizable, explicit in time, and nonnegativity preserving on the density. In particular, the boundary conditions at the junctions express the continuity of the current and do not destabilize the general scheme. Efficiency is shown by presenting results on test cases of some practical interest.

Key words. drift-diffusion equation, Schrödinger–Poisson equation, WKB ansatz, open quantum system, Robin boundary condition

1. Introduction and modeling.

1.1. Preliminaries. We develop a fast, efficient, and stable approach to 1D semiconductor component computations directly processing any kind of kinetic equation; only moment-type approximations are to be used, in "high-field regime," in order to cope with "submicronic standards."

It is a well-known fact nowadays that a whole hierarchy of mathematical models ranges from quantum mechanics to transport equations and eventually leads to "fluid-like" models; see, e.g., [7, 20, 33]. Two main tools exist for performing the first step, namely, WKB and Wigner measures methods; see [3, 5, 6, 30, 31, 32]; the correct way to interpret the WKB classical system is through a Vlasov equation; see [22, 26]. It is then at this "mesoscopic scale" that one introduces collisions between electrons and impurities (i.e., phonons, quantum representations of the crystal's vibrations) which thermalize the carriers population. This is rendered through a collision operator put on the right-hand side of the kinetic equation, which is now meant to relax toward a local equilibrium called by analogy with Boltzmann's theory of rarefied gases, [14]. The passage from kinetic models to coarser ones always stems from prescribing a peculiar dependence of the kinetic density in its velocity variable; such a simplification can sometimes be justified by means of convenient time/space rescalings; consult [33] for a survey.

At this level, we take advantage of former results, mainly [13, 11, 2]; in these papers, coexistence of several qualitatively different areas has been clearly evidenced inside a standard n^+nn^+ diode [10], under reasonable voltage biases. To each of these regions can be associated a particular rescaling of the kinetic transport model;

roughly speaking, heavily doped zones (the [illegible] and the [illegible]) exhibit "low-field" diffusive behavior, whereas inside the [illegible] "high-field" ballistic transport takes place. To some extent, a schematic but acceptable picture goes as follows: carriers move inside the channel according to monokinetic solutions of the Vlasov–Poisson equation (because they accelerate, no shock is likely to appear, at least at steady state), whereas they are "nearly Maxwellian" inside the source/drain regions, where their position densities can be computed by means of a drift-diffusion approximation. We obviously expect to observe stabilization of transient dynamics leading to convergence onto some steady time-asymptotic regime (see, e.g., [15, 34] for direct steady-state computations). We stress that our goal here is to devise a time-marching strategy.

Such a program clearly raises the issue of time-stepping compatibility—and this whatever the boundary conditions on each side of the channel. Indeed, any drift-diffusion equation, being of parabolic type, asks for a CFL restriction like $\Delta t = O(\Delta x^2)$, whereas the ballistic regime is essentially of a hyperbolic nature (signals travel at finite speed), thus requiring $\Delta t = O(\Delta x)$ instead. Of course, imposing the smallest value of Δt everywhere, despite ensuring stability, would result in an overwhelming smearing of the sharp profiles inside the channel. We thus selected a mixed implicit/explicit numerical strategy as described in section 4.1. The channel is flanked on each side by low-field areas, and thus deriving appropriate boundary conditions connecting these regions was necessary to keep oscillations from developing. It has been observed that Dirichlet conditions are not conclusive as they do not allow for the scheme to relax toward a steady state; however, imposing the current's continuity at the junctions leads to a nonlinear Robin boundary condition [1, 17, 18, 19] for the drift-diffusion equations: it also remains stable and easy to implement; see section 4.3. Obviously Dirichlet conditions are imposed on each side of the device and for the Poisson equation.

The remainder of the paper is devoted to numerical experiments as an outcome of the aforementioned general framework. A careful rescaling of a well-known GaAs device has been performed in section 3 and practical results are displayed in section 5. In particular, we observe stabilization in time toward a steady profile together with a satisfying residue decay. We also show the way current settles inside the device for large times; a reasonably constant current is the main goal in order to achieve reliable intensity/voltage diagrams (see especially Figure 6 in section 6, where an original derivation leading to a real improvement of ballistic currents is proposed). We are not aware of any time-marching scheme able to stabilize onto steady states with perfectly flat currents for such models. Presently, we found that Ohm's law, stipulating a linear dependence between currents and biases, is satisfied as soon as potential drops are strong enough. This was to be somehow expected as we developed the present approach for a high-field setting in which low biases do not really fit.

1.2. From quantum models to kinetic equations. We briefly recall the different levels for the modeling of charge carriers; the finest one here is nonrelativistic quantum mechanics. One considers thus a mixed state, i.e., a statistical repartition of quantum states $\psi_\ell \in \mathbb{C}$ indexed by the (quantized) energy levels solution of the 1D Schrödinger–Poisson equation in the parabolic band approximation (m^* stands for the effective mass of the electron in the material under consideration):

$$i\hbar\partial_t\psi_\ell + \frac{\hbar^2}{2m^*}\partial_{xx}\psi_\ell = eU(t,x)\psi_\ell, \qquad \varepsilon_s\partial_{xx}U = e(\varrho - D). \tag{1.1}$$

The wave function $\psi_\ell(t,x)$ corresponds to an energy level E_ℓ of the homogeneous Hamiltonian; $\hbar$, e, and m^* stand for Planck's constant, the charge, and the effective mass of the electron in the considered material, respectively. The Hartree equation renders a mean-field approximation of the Coulombian forces, with ε_0 being the dielectric permittivity of the medium. D is the given doping concentration and $\varrho(t,x)$ is the electrons' density, which reads

$$\varrho(t,x) = \sum_\ell F(E_\ell)|\psi_\ell(t,x)|^2,$$

with, e.g., $F(E) = (1+\exp((E-E_F)/k_B\theta_0))^{-1}$ in the case of Fermi–Dirac statistics, where E_F is usually called the Fermi energy.[1] θ_0 is the ambient temperature, and k_B is the Boltzmann constant. The sum ranges therefore over the whole spectrum of the Hamiltonian consisting of an orthonormal basis of L^2; hence (1.1) is indeed a system of equations all coupled by the Poisson term U. With the next level of modeling, the Wigner transform comes into play:

$$w(t,x,p) = \frac{1}{2\pi}\int_{\mathbb{R}} z\left(t, x+\frac{\hbar y}{2}, x-\frac{\hbar y}{2}\right)\exp(iyp).dy,$$

where

$$z(t,x,y) = \sum_\ell F(E_\ell)\psi_\ell(t,x)\overline{\psi_\ell(t,y)}.$$

One observes at once that

$$\varrho(t,x) = \int_{\mathbb{R}} w(t,x,p).dp = z(t,x,x).$$

The Wigner transform solves the (pseudodifferential) Wigner equation,

$$\partial_t w + \frac{p}{\hbar m^*}\partial_x w - e\Theta[U]f = 0,\ \Theta[V] = \frac{i}{\hbar}\left\{U\left(t, x+\frac{\hbar}{2i}\partial_x\right) - U\left(t, x-\frac{\hbar}{2i}\partial_x\right)\right\},$$

completed by the Poisson equation as in (1.1). Passing to the (semi)classical limit $\hbar \to 0$, $w \rightharpoonup f(t,x,\xi) \geq 0$ in the sense of measures [31], and the pseudodifferential operator Θ becomes the standard Vlasov term $\partial_x U.\partial_\xi f$. It is usually at this intermediate level that electron-phonon collisions are introduced in the models (see, however, [3, 23]) by means of an integral operator on the right-hand side:

$$\partial_t f + \xi\partial_x f + \frac{e}{m^*}\partial_x U\partial_\xi f = \mathcal{Q}(f), \qquad \varepsilon_s\partial_{xx}U = e(\varrho - D), \qquad E = -\partial_x U. \tag{1.2}$$

We shall not enter the details of $\mathcal{Q}(f)$ since different models exist such as BGK (Bhatnagar–Gross–Krook) and Fokker–Planck; however, they share the interesting property of admitting the same Maxwellian distribution, a fact that will be extensively used in the next section. At this level of description the electron and current densities are the moments of f:

$$\varrho(t,x) = \int_{\mathbb{R}} f(t,x,\xi)d\xi, \qquad J(t,x) = \int_{\mathbb{R}} \xi f(t,x,\xi)d\xi.$$

[1] It corresponds to an energy level for which the occupation probability is exactly one half.

2. Low- and high-field scalings inside an n^+nn^+ device. Our 1D problem combines two distinct zones according to the importance which is given to the phenomena rendered through $\mathcal{Q}$ in (1.2); purely ballistic transport means $\mathcal{Q} \equiv 0$. However, we begin with the opposite case and mainly follow [11] in our presentation. Let us first recall some conventions: $L > 0$ stands for the characteristic device's length, whereas $\varrho_0 \geq 0$ and $\theta_0 = k_B T/m^* \geq 0$ for an average value of the doping profile $D(x)$ and the lattice temperature. $U_{th} = k_B T/e$ is the thermal potential. Four (possibly) different velocity magnitudes appear: $v_{th} = \sqrt{\theta_0}$ is the [illegible]. If τ_0 stands for an average value of the relaxation times,[2] $\tau(x)$ inside the device, $v_{relax} = L/\tau_0$, is the [illegible]. Similarly, if $[\Phi]$ is the bias applied at the contacts, one defines the reference magnitude for the [illegible] as

$$v_{drift} = \tau_0 \frac{e[\Phi]}{m^* L}, \tag{2.1}$$

whereas the [illegible] reads

$$v_{bal} = \sqrt{\frac{2e[\Phi]}{m^*}}.$$

In a 1D framework, it is reasonable to render collisions by mean of a linear relaxation time operator; thus we can start from the following kinetic equation to describe the dynamic of the electrons in the device:

$$\partial_t f + \xi \partial_x f - \frac{e}{m^*} E(t,x) \partial_\xi f = \frac{1}{\tau}\Big(\mathcal{M}(\theta_0)\varrho(x) - f\Big), \tag{2.2}$$

where the Maxwellian reads

$$\mathcal{M}(\theta_0) = \frac{1}{\sqrt{2\pi\theta_0}} \exp\left(-\frac{\xi^2}{2\theta_0}\right) \overset{\theta_0 \to 0}{\to} \delta,$$

where δ stands for the Dirac mass in zero; the electric field $E(t,x)$ is coupled to the Poisson equation by

$$\varepsilon_s \partial_{xx} U = e(\varrho(x) - D(x)), \qquad E(t,x) = -\partial_x U. \tag{2.3}$$

[illegible] 1. Starting from here, we assume that junctions are rendered through sharp interfaces inside the device. Some quantities, such as the temperature, for example, will obviously be discontinuous across them. This modeling has already been widely used; see, for instance, [2, 8, 11, 12, 15].

2.1. Drift-diffusion approximation. It is convenient to normalize the doping concentration and the potential bias: $D(x) = \varrho_0 \hat{D}(\hat{x})$ and $U(t,x) = [\Phi]\hat{U}(\hat{t},\hat{x})$, where we make use of rescaled variables defined as follows:

$$x = L\hat{x}, \qquad \xi = v_{th}\hat{\xi}, \qquad t = v_{drift}\frac{\hat{t}}{L}, \qquad \tau(x) = \tau_0 \hat{\tau}(\hat{x}).$$

Moreover the kinetic density can be rewritten as

$$f(t,x,\xi) = \frac{\varrho_0}{v_{th}} \hat{f}(\hat{t},\hat{x},\hat{\xi}).$$

[2]For instance, in the case when $\mathcal{Q}$ is given by a BGK model.

The main assumption in this approximation is $v_{drift} \ll v_{th} \ll v_{relax}$; hence two small parameters naturally appear:

$$\epsilon = \frac{v_{th}}{v_{relax}}, \qquad \eta = \frac{v_{drift}}{v_{th}}, \tag{2.4}$$

which we suppose to be of the same order of magnitude.

Then "low-field" is precisely meant to be the limit $\eta \simeq \epsilon \to 0$; thus (2.2) can be rewritten as

$$\epsilon \partial_t f + \xi \partial_x f - \frac{e}{m^*} E(t,x) \partial_\xi f = \frac{1}{\epsilon \tau} (\mathcal{M}(1)\varrho - f). \tag{2.5}$$

This regime describes the flow in highly doped areas (source and drain); (2.5) admits asymptotic expansions which allow us to compute the two first moments of f in closed form. Since collisions are dominant, drift velocity is much smaller than thermal velocity, and the mean free path can be considered infinitesimal, i.e., $o(1)$. Hilbert expansion leads to

$$\partial_t \varrho + \partial_x J = 0, \qquad J = -d_n(x) \partial_x \varrho - \mu_n(x) E \varrho. \tag{2.6}$$

There, $\mu_n(x) = e\tau(x)/m^*$ is the electron mobility and $d_n(x) = \tau(x)\theta_0 = \mu_n U_{th} \geq 0$ appears to be a diffusion coefficient. In this regime, it is tacitly assumed that the solution of (2.5) is "nearly Maxwellian", i.e.,

$$f(t,x,\xi) = \varrho(t,x)\mathcal{M}_{\theta_0}(\xi) + o(\epsilon).$$

2.2. Shur–Eastman/WKB ansatz for ballistic regime. This is somehow the opposite of the drift-diffusion approximation; we consider now the following variables:

$$x = L\hat{x}, \qquad \xi = v_{bal}\hat{\xi}, \qquad t = v_{bal}\frac{\hat{t}}{L}, \qquad \tau(x) = \tau_0 \hat{\tau}(\hat{x}).$$

The kinetic density reads, accordingly,

$$f(t,x,\xi) = \frac{\varrho_0}{v_{bal}} \hat{f}(\hat{t},\hat{x},\hat{\xi}).$$

The main assumption in this approximation is $v_{th} \ll v_{bal} \simeq v_{drift}$, which leads to the limit $\beta = v_{th}/v_{bal} \to 0$, while $\alpha = v_{drift}/v_{bal} = O(1)$. Thus

$$\partial_t f + \xi \partial_x f + \frac{e}{m^*} \partial_x U . \partial_\xi f = \frac{1}{2\alpha\tau} \mathcal{Q}(f), \qquad \theta_0 \to 0, \quad \partial_{xx} U = \gamma(\varrho - D). \tag{2.7}$$

Clearly, neither Hilbert nor Chapman–Enskog expansions are likely to lead to a diffusion-like equation. Instead, one obtains formally a Vlasov–Poisson system for which the kinetic density is of the [illegible] form at zero temperature (see [35] and [2, section 5]). This can be approximated by the so-called "WKB system" as in [25],

$$\partial_t \varrho + \partial_x \left(\frac{\partial_x \varphi}{m^*} \varrho \right) = 0, \qquad \partial_t \varphi + \frac{1}{2m^*} |\partial_x \varphi|^2 + eU = 0, \tag{2.8}$$

assuming that the wave functions behave like $\sqrt{\varrho}\exp(i\varphi/\hbar)$, or equivalently, that the solution of (2.7) reads $f(t,x,\xi) = \varrho(t,x)\delta(\xi - \partial_x\varphi(t,x))$; see [31]. Of course,

$u = \frac{1}{m^*}\partial_x\varphi$ is meant to remain smooth[3] and this holds in particular for the accelerating particles $\partial_x u(t,x) \geq 0$ inside the channel. In section 5 of [2], Arnold et al. suggest that the distribution f should be of the type $\delta(\xi - E\tau)$, which boils down to assuming that $u(t,x) \simeq \tau(x)E(t,x)$, at least after some time. This is indeed what we observe in the numerical results (in constrast with [11], where E and u look quite different at steady state); see section 5.4.

3. Rescaling the device. First, let us remark that the device does not have the same physical characteristics in the channel (ballistic zone), where there is a low doping concentration relative to the source and the drain (drift-diffusion zone). This implies that the electron mobility is higher in the channel, as in the source and drain. The same occurs for the relaxation time in the same proportion. More precisely, let μ_1 be the mobility in the source and drain and μ_2 in the channel. We have

$$\frac{\mu_1}{\mu_2} = \frac{\tau_1}{\tau_2} = \frac{v_2}{v_1} \tag{3.1}$$

if we suppose that τ_1 (resp., τ_1) is proportional to L/v_1 (resp., to L/v_2). This means that if we want to see phenomena evolve at the same velocity, we have to scale the time in this proportion. Another way to explain this is if we scale the drift-diffusion equation first (with mobility μ_1); then we have to scale the ballistic equation with the same scaling obtained in the drift-diffusion equation but with the mobility μ_2.

3.1. Rescaling the drift-diffusion equation. According to (2.6), the physical drift-diffusion model reads, for $x \in [0,L]$, $t \geq 0$,

$$\varepsilon_s \partial_{xx} U = e(\varrho - D), \qquad \partial_t \varrho = \partial_x \left(\mu_1 U_{th} \partial_x \varrho - \mu_1 \varrho \partial_x U\right). \tag{3.2}$$

The first equation in (3.2) is Poisson's completed by a continuity equation. In the device's variables, the current density is given by $J(t,x) = -d_1 \partial_x \varrho + \mu_1 \varrho \partial_x U$. The first part of the current is the diffusion term ($d_1 = \mu_1 U_{th}$) and the second part is the drift term. The general way to process (3.2) starts by rescaling space and time variables according to the size of the device, and to some characteristic velocity which is to be chosen for convenience:

$$\hat{x} = \frac{x}{L}, \quad \hat{t} = \frac{t}{L/v_1}. \tag{3.3}$$

We can deduce an adimensionalized density ρ and a potential $\hat{U}$ as follows:

$$\varrho(t,x) = \varrho_0 \hat{\rho}(\hat{t},\hat{x}), \qquad U(t,x) = U_0 \hat{U}(\hat{t},\hat{x}). \tag{3.4}$$

The doping concentration is obviously treated accordingly:

$$D(x) = \varrho_0 \hat{D}(\hat{x}).$$

Here ϱ_0 stands for a mean density inside the device (obtained by, e.g., the doping concentration's arithmetic or geometric average) and U_0 is a reference value for the potential. We first rescale the Poisson equation so as to obtain

$$\frac{\varepsilon_s U_0}{e\varrho_0 L^2} \frac{\partial^2 \hat{U}}{\partial \hat{x}^2} = \hat{\rho} - \hat{D}.$$

[3] If not, breakup occurs and multibranch solutions are to be sought instead, as in [22, 26, 29].

If we denote by $[\Phi_0]$ the applied bias, the scaled [illegible] is given by

$$\gamma = \frac{\varepsilon_s[\Phi_0]}{e\varrho_0 L^2}.$$

At this level, we decide to choose $U_0 = \frac{e\varrho_0 L^2}{\varepsilon_s} = \gamma[\Phi_0]$ in order to scale the coefficient to 1. Thus the scaled Poisson equation can be rewritten as

$$\frac{\partial^2 \hat{U}}{\partial \hat{x}^2} = \hat{\rho} - \hat{D}. \tag{3.5}$$

Let us now rescale the continuity equation in (3.2); the outcome reads

$$\frac{\partial \hat{\rho}}{\partial \hat{t}} = \frac{\partial}{\partial \hat{x}} \left(\frac{\mu_1 U_{th}}{v_1 L} \frac{\partial \hat{\rho}}{\partial \hat{x}} - \frac{\mu_1 U_0}{v_1 L} \hat{\rho} \frac{\partial \hat{U}}{\partial \hat{x}} \right). \tag{3.6}$$

A relevant quantity is the ratio between the diffusion and drift current: here it is U_{th}/U_0. We observe that in general, it is not possible to simultaneously scale to unit the scaled Debye length, the drift and diffusion terms. So in the present framework, we chose to scale to unit the scaled Debye length and the scaled drift term. Let us choose v_1 such that the drift velocity coefficient scales to 1, i.e., $\frac{\mu_1 U_0}{v_1 L} = 1$. In such a way (3.6) transforms into

$$\frac{\partial \hat{\rho}}{\partial \hat{t}} = \frac{\partial}{\partial \hat{x}} \left(\frac{U_{th}}{U_0} \frac{\partial \hat{\rho}}{\partial \hat{x}} - \hat{\rho} \frac{\partial \hat{U}}{\partial \hat{x}} \right). \tag{3.7}$$

The scaled current density therefore reads

$$J(\hat{t}, \hat{x}) = -\frac{U_{th}}{U_0} \frac{\partial \hat{\rho}}{\partial \hat{x}} + \hat{\rho} \frac{\partial \hat{U}}{\partial \hat{x}}, \tag{3.8}$$

and (3.7)–(3.8) should be completed with the rescaled potential equation (3.5). A short computation with the numerical values given below shows that for high concentrations of doping, the drift term is more important than the diffusion term; for a concentration of doping of $10^{19}/m^3$, both terms are of the same order of magnitude, and for a lower concentration of doping, the diffusion term is dominant.

3.2. Rescaling the ballistic equation. Let us now scale the (2.8) with the same scaling (3.3) in space and time but with v_2 instead of v_1 and (3.4) for the density and potential. Moreover we assume that the phase scales in the following way:

$$\varphi(t, x) = \varphi_0 \hat{\varphi}(\hat{t}, \hat{x}). \tag{3.9}$$

With this scaling, (2.8) become

$$\frac{\partial \hat{\rho}}{\partial \hat{t}} + \frac{\partial}{\partial \hat{x}} \left(\frac{\varphi_0}{m^* L v_2} \frac{\partial \hat{\varphi}}{\partial \hat{x}} \hat{\rho} \right) = 0,$$

$$\frac{\partial}{\partial \hat{t}} \frac{\partial}{\partial \hat{x}} \left(\frac{\varphi_0 \hat{\varphi}}{m^* L v_2} \right) + \frac{1}{2} \frac{\partial}{\partial \hat{x}} \left(\frac{\varphi_0^2}{(m^*)^2 L^2 v_2^2} |\partial_{\hat{x}} \hat{\varphi}|^2 \right) + \frac{e U_0}{m^* v_2^2} \frac{\partial \hat{U}}{\partial \hat{x}} = 0.$$

Note that we have derived w.r.t. $\hat{x}$ the second equation. In order to work with the same time scale as in the drift-diffusion case, we have to choose v_2 such that (3.1) is verified. Let us set $u = \frac{\varphi_0}{m^* L v_2}\partial_{\hat{x}}\hat{\varphi}$. We can choose φ_0 such that $\frac{\varphi_0}{m^* L v_2} = 1$. We set for the scaled current $\hat{J} = \hat{\rho}u$. Then the scaled WKB equation (2.8) becomes

$$\frac{\partial \hat{\rho}}{\partial \hat{t}} + \frac{\partial}{\partial \hat{x}}(\hat{\rho}u) = 0, \qquad \frac{\partial}{\partial \hat{t}}u + \frac{1}{2}\frac{\partial}{\partial \hat{x}}u^2 + \frac{eU_0}{m^* v_2^2}\frac{\partial \hat{U}}{\partial \hat{x}} = 0.$$

From now on, we shall always work with scaled quantities; thus it makes sense to remove the "hats."

. . . . 2 (numerical values). Let us take the same test case as in [4, 11], that is, $m^* = 0.065 \times 9.109 \times 10^{-31} Kg$, $e = 1.602 \times 10^{-19} C$, $k_B = 1.38 \times 10^{-23} J/K$, $\varepsilon_s = 13.2 \times 8.85418 \times 10^{-12} F/m$, $T_0 = 300K$, $L = 0.8 \times 10^{-6} m$. Moreover in the classical zone, we take for the doping concentration $D = 10^{24}/m^3$, and for the electron mobility $\mu_1 = \tau_1 e/m^* = 0.75$. In the ballistic zone, $D = 2 \times 10^{21}/m^3$ and $\mu_2 = \tau_2 e/m^* = 4$. These values imply that $\varrho_0 = 5 \times 10^{23}/m^3$, $U_0 = \frac{e\varrho_o L^2}{\varepsilon_s} = 438.6$. Concerning the velocity, $v_1 = \frac{\mu_1 U_0}{L} = 4.111 \times 10^8 m/s$ which implies $v_2 = v_1\mu_1/\mu_2 = 7.71 \times 10^7 m/s$. The scaled diffusion coefficient is $d_1 = \frac{U_{th}}{U_0} = 5.9 \times 10^{-5}$ (and the scaled drift coefficient is $\mu = 1$). Finally we have $eU_0/(m^* v_2^2) = 0.2$.

3.3. The kinetic equation. We finally rewrite the kinetic model (2.2); let us rescale the variables as follows:

$$x = L\hat{x}, \qquad \xi = v_{th}\hat{\xi}, \qquad t = v\frac{\hat{t}}{L}, \qquad \tau(x) = \tau_0 \hat{\tau}(\hat{x}),$$

where v is a velocity that is to be set according to the scaling which has been chosen. Moreover the adimensioned kinetic density can be rewritten as

$$f(t, x, \xi) = \frac{\varrho_0}{v_{th}}\hat{f}(\hat{t}, \hat{x}, \hat{\xi}).$$

As usual, we define an adimensioned density ρ and a potential Φ as follows:

$$\varrho(t, x) = \varrho_0 \rho(\hat{t}, \hat{x}), \qquad U(t, x) = \Phi_0 \Phi(\hat{t}, \hat{x}). \tag{3.10}$$

With this notation the adimensioned form of (2.2) reads

$$\partial_{\hat{t}}\hat{f} + \left(\frac{v_{th}}{v}\right)\hat{\xi}\cdot\partial_{\hat{x}}\hat{f} - \left(\frac{U_0}{U_{th}}\frac{v_{th}}{v}\right)\partial_{\hat{x}}\Phi\cdot\partial_{\hat{\xi}}\hat{f} = \frac{v_{relax}}{v}\Big(\mathcal{M}(\theta_0)\hat{\varrho}(\hat{x}) - \hat{f}\Big). \tag{3.11}$$

According to Remark 2, v can be chosen to be, e.g., between $100 v_{th}$ and $1000 v_{th}$.

4. A staggered scheme for the coupled model. Hereafter we always consider working with the rescaled equations derived in the preceding section.

4.1. A semi-implicit discretization. We now aim at describing in full detail the numerical recipe we propose for solving the following adimensionalized problems:

$$\text{(CL)} \qquad \begin{cases} \partial_t \varrho + \partial_x J = 0, \\ J = -d\partial_x \varrho - \varrho \partial_x U, \ \varrho(t, x = 0) = 1, \end{cases} \qquad x \in]0, x_L[;$$

$$\text{(B)} \qquad \begin{cases} \partial_t \varrho + \partial_x J = 0, \\ \partial_t u + u\partial_x u + \partial_x U = 0, \quad J = \varrho u, \end{cases} \qquad x \in]x_L, x_R[;$$

$$\text{(CR)} \qquad \begin{cases} \partial_t \varrho + \partial_x J = 0, \\ J = -d\partial_x \varrho - \varrho \partial_x U, \ \varrho(t, x = 1) = 1, \end{cases} \qquad x \in]x_R, 1[,$$

where all these PDEs are coupled through the Poisson equation:

$$\text{(P)} \qquad \begin{cases} -\partial_{xx}U = \varrho - D(x), \\ U(t, x=0) = 0, \quad U(t, x=1) = U_0 \le 0, \end{cases} \qquad x \in]0,1[.$$

We are given initial data $\varrho(t=0,.) = \varrho_0 \ge 0$, $D(x) \ge 0$ and $u(t=0,.)$; we usually take zero. We shall develop implementation of boundary conditions in $x = x_L, x_R$, rendering the junctions in section 3.3. First, let us say that (CL) and (CR) will be solved implicitly, whereas (B) will be processed explicitly in time. Another important feature is that ϱ and u will not be known at the same abscissae (hence the use of "staggered"). The computational domain is the half-stripe $\mathbb{R}^+ \times]0,1[$, which is parametrized by $\Delta x = \frac{1}{N} > 0$; we define

$$x_j = j\Delta x = \frac{j}{N}, \qquad j = 0, \dots, N.$$

We also define the following domains:

$$\begin{cases} \mathcal{B} = \{x_Q, x_{Q+1}, \dots, 1 - x_Q\}, \qquad x_Q = x_q + \frac{\Delta x}{2}, 1 - x_Q = x_{N-q} - \frac{\Delta x}{2}, \\ \mathcal{C}_L = \{x_0, x_2, \dots, x_q\}, \qquad \mathcal{C}_R = \{x_{N-q}, \dots, x_N\}. \end{cases}$$

Thus $\vec{\varrho}_{n=0} = (\varrho_0(x_j))_{j=0,\dots,N} \in \mathbb{R}_+^{N+1}$. The boundary conditions read, at the discrete level, $\varrho_{0,n} = \varrho(t_n, 0)$ and $\varrho_{N,n} = \varrho(t_n, x_N) = \varrho(t_n, 1)$.

4.2. Choosing the time-step Δt. We select a standard centered discretization for (CL) and (CR) that reads (n the time index, j the space one)

$$\begin{aligned} &\varrho_{j,n+1} - \Delta t \tfrac{d(\varrho_{j+1,n+1} - \varrho_{j,n+1}) - d(\varrho_{j,n+1} - \varrho_{j-1,n+1})}{\Delta x^2} \\ &\qquad = \varrho_{j,n} + \tfrac{\Delta t}{\Delta x}\Big(\Big\langle \mathbf{F}_{j+\frac12,n}, \mathbf{R}_{j+\frac12,n} \Big\rangle_{\mathbb{R}^2} - \Big\langle \mathbf{F}_{j-\frac12,n}, \mathbf{R}_{j-\frac12,n} \Big\rangle_{\mathbb{R}^2}\Big), \end{aligned} \tag{4.1}$$

where the following notations have been used:

$$\mathbf{F}_{j+\frac12,n} := \left\{ \max\left(0, \frac{U_{j+1,n} - U_{j,n}}{\Delta x}\right), \min\left(0, \frac{U_{j+1,n} - U_{j,n}}{\Delta x}\right) \right\},$$

$$\mathbf{R}_{j+\frac12,n} := \{\varrho_{j,n}, \varrho_{j+1,n}\}.$$

Clearly, $\langle , \rangle_{\mathbb{R}^2}$ stands for the standard $\mathbb{R}^2$ scalar product. At this stage, we tacitly assume that $\vec{\varrho}_n$ is known, and we already have a way to produce the two borderline values $\varrho_{q+1,n+1}$ and $\varrho_{N-q-1,n+1}$. Thus, the scheme boils down to inverting a tri-diagonal $q \times q$ matrix, reading

$$\mathbf{M}_q = \begin{pmatrix} 1 + \frac{\alpha d\Delta t}{\Delta x^2} & -\frac{d\Delta t}{\Delta x^2} & 0 & \cdots & \\ -\frac{d\Delta t}{\Delta x^2} & 1 + \frac{2d\Delta t}{\Delta x^2} & -\frac{d\Delta t}{\Delta x^2} & 0 & \\ 0 & \ddots & \ddots & \ddots & \\ & & 0 & -\frac{d\Delta t}{\Delta x^2} & 1 + \frac{\beta d\Delta t}{\Delta x^2} \end{pmatrix},$$

where α, β can be 1 or 2 depending on whether (4.1) is meant to approximate (CL) or (CR) because of the boundary conditions. Anyway, it is clearly unconditionally invertible since it is strictly diagonally dominant; thus the discretization (4.1) will

remain stable as long as its right-hand side will be a convex combination, i.e., for a time-step $\Delta t = O(\Delta x)$. In order to produce $\varrho_{q+1,n+1}$ and $\varrho_{N-q-1,n+1}$, we solve (B) by means of an explicit time-marching scheme already used in [24, 25], except that we set it up with a well-balanced strategy, as in [21] for the handling of the electric field. More precisely, from [24],

$$\varrho_{j,n+1} = \varrho_{j,n} - \frac{\Delta t}{\Delta x}\Big(\Big\langle \mathbf{A}_{j+\frac12,n}, \mathbf{R}_{j+\frac12,n}\Big\rangle_{\mathbb{R}^2} - \Big\langle \mathbf{A}_{j-\frac12,n}, \mathbf{R}_{j-\frac12,n}\Big\rangle_{\mathbb{R}^2}\Big), \tag{4.2}$$

with $j = q, \dots, N-q-1$ and

$$\mathbf{A}_{j+\frac12,n} := \left\{\max\left(0, u_{j+\frac12,n}\right), \min\left(0, u_{j+\frac12,n}\right)\right\}.$$

Now the velocity values $u_{j+\frac12,n}$ are sought on the staggered computational grid by means of a simple, well-balanced upwind scheme:

$$u_{j+\frac12,n+1} = u_{j+\frac12,n} - \frac{\Delta t}{\Delta x}\Big(\mathcal{F}(u_{j+\frac12,n}, \tilde u_{j+\frac32,n}) - \mathcal{F}(\tilde u_{j-\frac12,n}, u_{j+\frac12,n})\Big). \tag{4.3}$$

$\mathcal{F}(u,v) = \frac12(\max(u,0)^2 + \min(v,0)^2)$ is the standard upwind scheme, and the modified values $\tilde u_{j-\frac12,n}$, $\tilde u_{j+\frac32,n}$ are computed according to the steady-state equation $u\partial_x u + \partial_x U = 0$ far from resonance points; see the appendix and [21] for details. We know from [21, 24, 25] that this approach for solving (B) will be stable for a time-step $\Delta t = O(\Delta x)$.

Hence the algorithm proceeds as follows: Knowing all $\vec\varrho_n$ and $u_{j+\frac12,n}$ ($j = q, \dots, N-q-1$) at some time $t^n = n\Delta t$, we first update $u_{j+\frac12,n+1}$ inside $\mathcal{B}$ with (4.3) in order to deduce $\varrho_{j,n+1}$ by means of (4.2). Then, knowing $\varrho_{q+1,n+1}$ and $\varrho_{N-q-1,n+1}$, we can invert the implicit scheme (4.1) as soon as we have chosen a correct boundary condition to render the junction between the diffusive/ballistic zones.

4.3. A (nonlinear) Robin boundary condition. Let us mention first that junctions have been put at staggered abscissae, $x_{q+\frac12}, x_{N-q-1-\frac12}$, which correspond to the velocity unknowns. At these points, imposing Dirichlet boundary conditions leads to some kind of inconsistency because of a somewhat redundant definition of the current J between, e.g., (CL) and (B). Numerically, it produced some spurious oscillations eventually leading to general instability. Moreover in order to observe a constant current everywhere inside the device at steady state, it sounds reasonable to impose its value at the junctions between diffusive and ballistic areas. That is, at $x_{q+\frac12}$,

$$u_{q+\frac12,n+1} = -d\frac{\varrho_{q+1,n+1} - \varrho_{q,n+1}}{\Delta x \varrho_{q+\frac12,n+1}} - \frac{U_{q+1,n+1} - U_{q,n+1}}{\Delta x},$$

which implies

$$-d\frac{\varrho_{q+1,n+1} - \varrho_{q,n+1}}{\Delta x} = \varrho_{q+\frac12,n+1}\Big(u_{q+\frac12,n+1} + \frac{U_{q+1,n+1} - U_{q,n+1}}{\Delta x}\Big),$$

which we can approximate by means of

$$\begin{aligned} -d\frac{\varrho_{q+1,n+1} - \varrho_{q,n+1}}{\Delta x} \\ = \big(\theta\varrho_{q+1,n+1} + (1-\theta)\varrho_{q,n+1}\big)\Big(u_{q+\frac12,n+1} + \frac{U_{q+1,n+1} - U_{q,n+1}}{\Delta x}\Big), \end{aligned} \tag{4.4}$$

for $\theta \in [0,1]$. Hence one recognizes on the left-hand side of (4.4) the unknown flux which appears in (4.1) and the $\mathbf{M}_q$ matrix, and the right-hand side contains only values which can be deduced from the outcome of the explicit schemes used inside $\mathcal{B}$. Actually, only the average value $\varrho_{q+\frac{1}{2},n+1}$ has to be arbitrarily chosen as, e.g., the arithmetic average $\frac{1}{2}(\varrho_{q+1,n+1}+\varrho_{q,n+1})$, $\varrho_{q,n+1}$, or $\varrho_{q+1,n+1}$, corresponding to $\theta=\frac{1}{2}$, $\theta=0$, and $\theta=1$, respectively.

REMARK 3. This choice of boundary conditions corresponds to solving the following problem for the drift-diffusion equation (CL):

$$\begin{cases} \partial_t \varrho + \partial_x J = 0, & J = -d\partial_x \varrho - \varrho \partial_x U, \qquad x \in]0, x_L[, \\ \varrho(t, x=0) = D(x=0), & -\partial_x \ln(\varrho)(t, x=x_L) = u + \partial_x U, \end{cases}$$

where $u(t, x=x_L)$ is deduced from (B). This is a mixed (nonlinear) Robin-type boundary condition for a strictly parabolic equation. The well-posedness theory for problems of this flavor is quite recent; it started with the paper by Evans [17] and was then developed further in [1, 18, 19].

Of course, we presented everything in $x = x_{q+\frac{1}{2}}$, but the right junction $x = x_{N-q-1-\frac{1}{2}}$ is completely equivalent (with maybe a different choice of θ, however).

4.4. Some stability results. First of all, we wish to state a result from [19] which we adapt to our situation involving only a uniformly elliptic linear operator.

THEOREM 4.1 (see Goldstein and Goldstein [19]). Let $\beta_j(\xi)$ [illegible] be two nondecreasing Lipschitz continuous functions on $\mathbb{R}$ [illegible] and consider the problem

$$\begin{cases} \partial_t u = \partial_{xx} u, & x, t \in (0,1) \times \mathbb{R}^+, \\ (-1)^j \partial_x u(., x) = \beta_j(u), & x = j \in \{0,1\}, \\ u(t=0, x) = f(x) \in L^1(0,1), & x \in (0,1), \end{cases}$$

[illegible] u [illegible] $(0,1) \times [0,T]$ [illegible] $T > 0$ [illegible] $u(t,.) \in L^\infty(0,1)$ and $\partial_t u(t,.) \in L^2(0,1)$.

Clearly in order to be complete, a full study of the coupled problem (even if neglecting the Poisson coupling equation) would be necessary before concluding the stability of the whole model given by (CL)–(B)–(CR). However, the former theorem is a stepping stone in this direction. An interesting feature of our numerical approach (4.1)–(4.2) lies in a nonnegativity-preserving property for the density.

THEOREM 4.2. Let $\theta = 0$, (4.4) $\max_{j,n}(|u_{j+\frac{1}{2},n}| + |U_{j+1,n+1} - U_{j,n+1}|/\Delta x)\Delta t \leq \Delta x$ and $\vec{\varrho}_n \in (\mathbb{R}_+)^N$ [illegible] (4.1)–(4.2) [illegible] $\vec{\varrho}_{n+1} \in (\mathbb{R}_+)^N$.

Actually, we never used (4.1)–(4.2) with $\theta = 0$ because it appears to be the less accurate choice. However, we were unable to prove Theorem 4.2 for $\theta > 0$.

PROOF. The proof proceeds in three steps, namely, the explicit part, the implicit part, and the occurrences at the junctions.

- We first observe that, thanks to the prescribed CFL condition, the explicit parts of both schemes (4.1) and (4.2) turn out to be convex combinations of the values showing up on their right-hand sides. This has been precisely shown in previous papers; see, e.g., Proposition 4.6 in [24] or section 4.3 in [25].
- The implicit part of (4.1) is given by $\mathbf{M}_q$ which is an M-matrix in the terminology of [9], that is, its entries satisfy

$$m_{i,i} > 0, \qquad m_{i,j\neq i} \leq 0, \qquad |m_{i,i}| > \sum_{j \neq i} |m_{i,j}|.$$

So let us suppose we solve $\mathbf{M}_q \vec{x} = \vec{b}$, where $\vec{b}$ has nonnegative components; it is a classical fact that $\vec{x}$ will have only nonnegative components too. For completeness we recall its (quick) proof: Let i_0 correspond to the smallest component of $\vec{x}$, $x_{i_0} := \min(\vec{x})$. There holds

$$m_{i_0,i_0} x_{i_0} = b_{i_0} - \sum_{j \neq i_0} m_{i_0,j} x_j \geq b_{i_0} - x_{i_0} \sum_{j \neq i_0} m_{i_0,j},$$

which implies

$$x_{i_0} \geq \frac{b_{i_0}}{m_{i_0,i_0} + \sum_{j \neq i_0} m_{i_0,j}} \geq 0.$$

- It remains to observe that choosing $\theta = 0$ in (4.4) means that the boundary condition shows up only in the implicit part of (4.1). Let us focus on the left junction: Inside $\mathbf{M}_q$, we have $\alpha = 2$ and $\beta = 1$. Condition (4.4) gives us another term which reads $u_{q+\frac{1}{2},n+1} + \frac{U_{q+1,n+1} - U_{q,n+1}}{\Delta x}$, but thanks to the CFL condition, we know that $\mathbf{M}_q$ remains diagonal dominant even on this line. Hence the preceding computation guarantees the nonnegativity-preserving property, and we are done. □

These computations are based on convexity arguments; hence they somehow open the way to compactness for the whole scheme. However, we do not yet have any precise theory at the continuous level for (CL)–(B)–(CR). This might constitute a direction for further investigation.

4. Actually the choice of the parameter θ is quite a delicate task when considering its importance in stabilizing the numerical scheme on a steady-state regime with flat currents (as can be seen on the numerical figures). Here is what we implemented in order to produce the numerical results of section 5: First, we distinguished between the left junction where the solution is Lipschitz continuous, and the right, where it generally involves a discontinuity. Then we observed that it was not possible to code directly $\partial_x \ln(\varrho) = u + \partial_x U$, simply because it would require applying the change of variable $v = \ln(\varrho)$ while solving the drift-diffusion equation, which is not easy. Hence it becomes necessary to linearize the $\ln(.)$ function, and this is where the $\theta \in [0,1]$ parameter comes into play through the midpoint rule. In the case when this linearization occurs in a smooth location, $\theta = \frac{1}{2}$ gives a second-order accuracy and is therefore sufficient. In the case when a discontinuity shows up, the upwind value is often the right choice, that is, the weight should go to the point from where the signal comes from (generally, it is the left side).

5. Numerical validation with doping $5 \times 10^{22} m^{-3}$. In this section, we display some numerical results at steady state for a standard GaAs device as already considered in [11, 2, 10, 35]. We took a discontinuous doping profile equal to 1 inside $x \in [0, 0.25[\cup]0.75, 1]$ and equal to 0.002 elsewhere. We iterated the marching schemes presented in section 3.2 until residues on $\vec{\varrho}_n$ decayed lower than 10^{-15}. The resulting parameters are $d_1 = 0.00118$ and $eU_0/(m^* v_2^2) = 4$. We stress that neither drift-diffusion nor mixed currents are flat in the whole computational domain at steady state; so in order to derive the current–voltage relations, we computed arithmetic averages of the results coming from both discretizations; we shall, however, propose a more interesting derivation in section 5.5 by relying on well-balanced ideas. 255 points have been used to sample the $[0,1]$ interval, and the time step is chosen adaptively in order to minimize the mixed scheme's numerical diffusion. The main difference

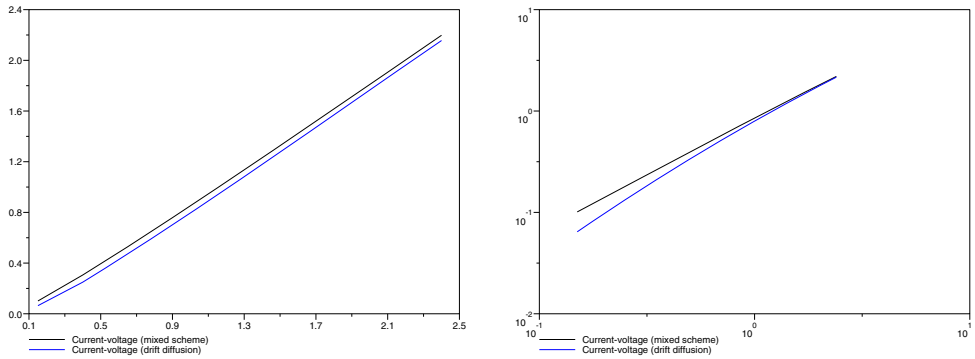

FIG. 1. *Current–voltage relation with doping* $5 \times 10^{22} m^{-3}$ *(left, normal scale; right, log scale).*

between both curves in Figure 1 lies in slightly lower values for the drift-diffusion currents. Apart from that, both approaches appear to agree. However, we are about to see that despite the current–voltage relations may look similar, the densities and velocities are rather different.

. . . . 5. It may seem reasonable to think about directly simulating (2.2), at least to validate the outcome of our mixed scheme since in one dimension, the computational cost still can be considered reasonable. Indeed, performing the rescalings as in section 3 leads to the following problem:

$$v\partial_t f + v_{th}\xi\partial_x f + v_{th}\frac{U_0}{U_{th}}\partial_x U\partial_\xi f = v_{relax}(\mathcal{M}(\theta_0)\varrho - f),$$

supplemented by (3.5) and with v being a free parameter. Actually, it is also possible to evaluate all the parameters involved: $\epsilon \simeq 0.09$, $\eta \simeq 0.3$ (tending to zero in section 3.1) and $\beta \simeq 0.1$, $\alpha \simeq 2$ (being $o(1)$ and $O(1)$, respectively, in section 3.2). However, there is at least one obstacle in the way: the problem still involves two different time scales and two different Maxwellian distributions. Hence a direct upwind discretization of (3.11) is unstable because some boundary conditions are needed at each junction: a way out may consist of numerically implementing formulas (16)–(17) in [8] (see also [16] for related questions). The schemes should also be asymptotic preserving in the sense of [28, 27]. Finally, we notice from [12] that direct kinetic simulations deliver results quite similar to drift-diffusion ones.

5.1. Weak bias: $[\Phi] = -0.2$. Essentially, the main difference between the mixed approach and the global drift-diffusion solution is that the last one always produces continuous solutions, whereas jumps show up in the mixed approach. This is clearly demonstrated by the results in Figure 2, which hold even if the corresponding diffusion coefficient turns out to be relatively small. Velocities and densities turn out to be rather different for both approaches, especially when compared to the Poisson potential and the resulting electric field. We can observe that our prescribed boundary condition for the junction works fine for continuous solutions, but is unable to produce a flat current close to a shock. This can come from the fact that it involves an average value, $\varrho_{q+\frac{1}{2},n+1}$, which should perhaps be derived more precisely. However, outside the junctions, currents look satisfying.

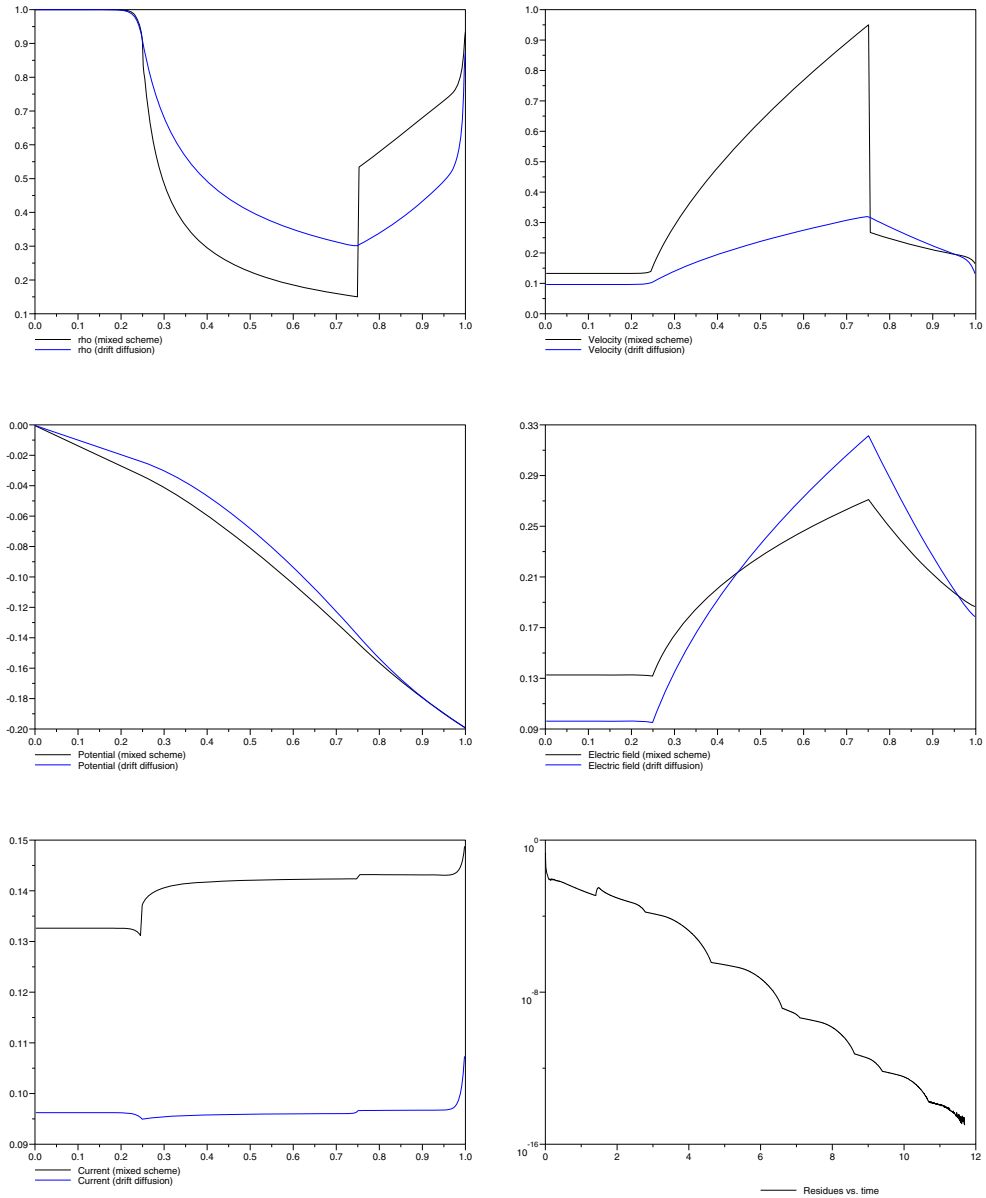

FIG. 2. *Carriers density, velocity, potential, electric field, current, and residues for an applied bias of* $[\Phi] = -0.2$.

5.2. Moderate bias: $[\Phi] = -0.35$. In this case, the higher bias accelerates electrons; the outcome of both schemes is presented in Figure 3. The residue decay is satisfying and the steady-state currents are reasonably flat. Densities and velocities are again very different for both approaches, quantitatively and qualitatively.

5.3. Higher bias: $[\Phi] = -0.5$. In this last case, the higher bias tends to flatten more the "mixed current" (see Figure 4) despite some sort of boundary layer on the

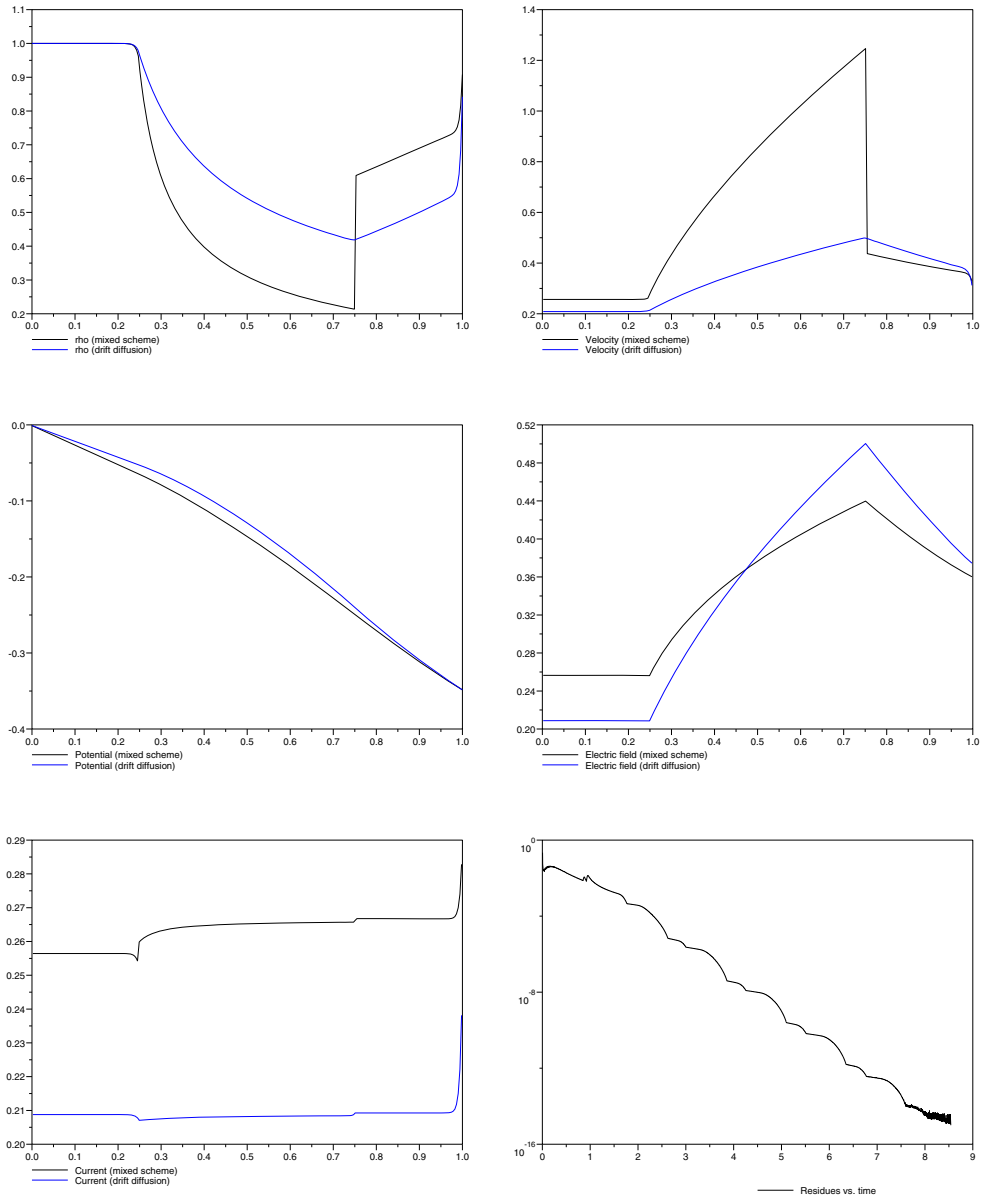

FIG. 3. *Carriers density, velocity, potential, electric field, current, and residues for an applied bias of* $[\Phi] = -0.35$.

right side. The potentials and the electric fields are quite similar for both approaches even if velocities and densities are still very different. Convergence in time is obtained in half the time it asked for with $[\Phi] = -0.2$.

5.4. Electric field and velocities inside the device. For completeness, we finally plot the fraction $u(x)/E(x)$ at steady state since this quantity measures the conductivity as a function of the applied bias; see Figure 5. We observe that,

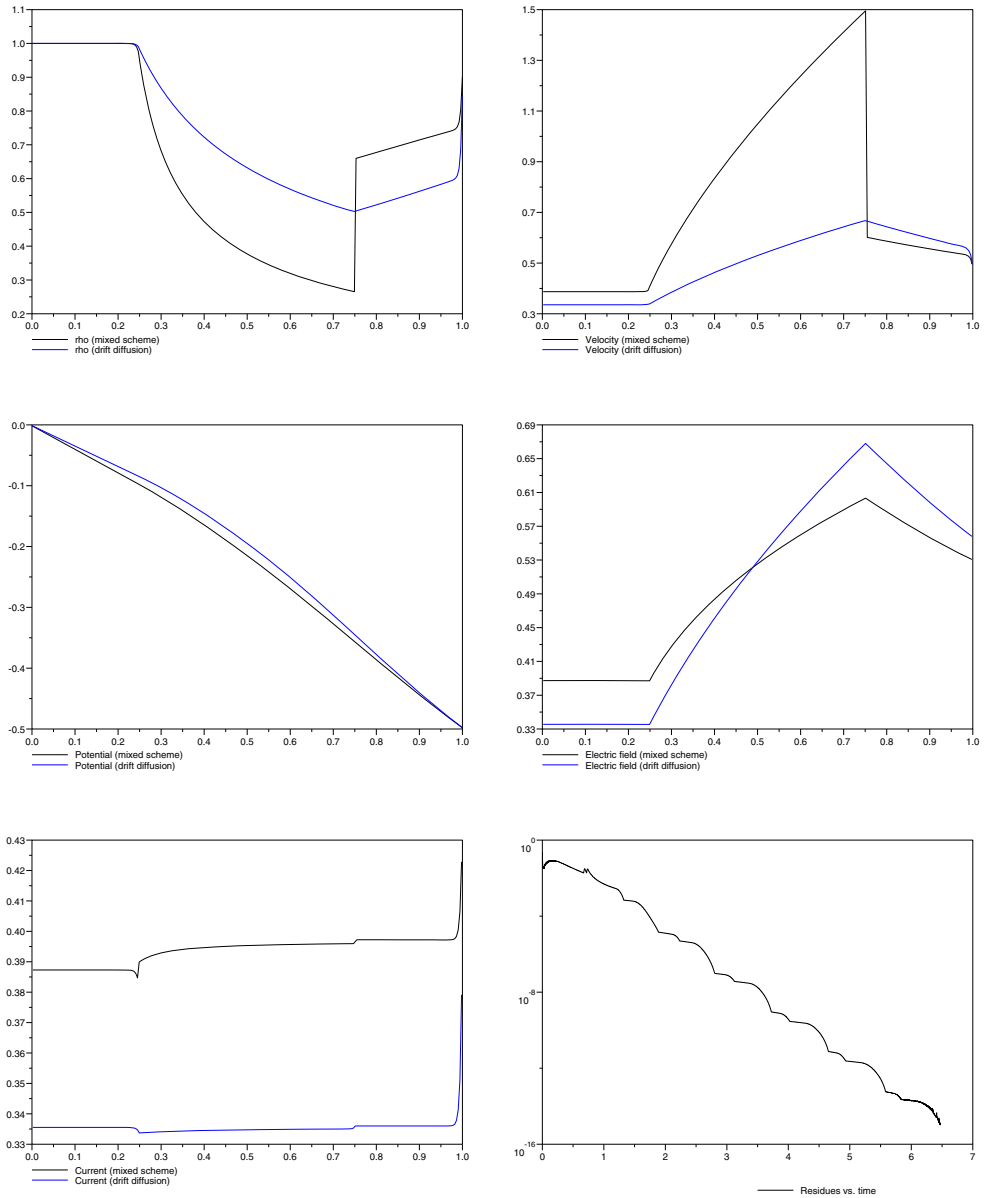

FIG. 4. *Carriers density, velocity, potential, electric field, current, and residues for an applied bias of* $[\Phi] = -0.5$.

independently of the bias, this fraction is practically constant in the zones where the drift-diffusion algorithm is used (this reflects the smallness of the diffusion coefficient for high doping). However, it falls down strongly inside the channel even if increasing the bias improves things. Junctions are slightly visible, but the corresponding discontinuities do not seem to have strong effects on the global picture.

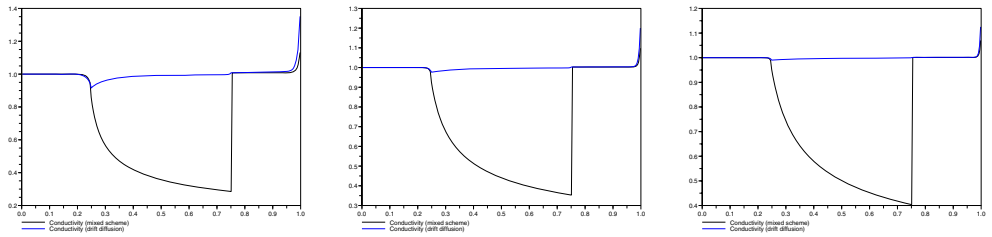

FIG. 5. *Steady-state fraction* $u(x)/E(x)$ *for applied biases* $[\Phi] = -0.2, -0.35, -0.5$ *(left to right).*

5.5. A different way to compute currents in the device. We finally propose a new way to compute steady-state currents inside the device, owing to the fact that a well-balanced discretization is used to solve the ballistic part (B) of the problem; see the appendix for details. Actually, assuming (B) is stationary, one derives easily that the following equality holds:

$$J_{bal}(x) = \varrho(x)u(x) = \varrho(x)\sqrt{-2(U(x) - U(x_L)) + u(x_L)^2}. \tag{5.1}$$

In the same way, one actually can compute stationary drift-diffusion:

$$J_{DD} = -\varrho(d\partial_x \ln(\varrho) + \partial_x U). \tag{5.2}$$

In Figure 6, we compare the outcome of the usual arithmetic averages with formulas (5.1)–(5.2). One clearly sees that inside the ballistic channel, the resulting currents are , which to the authors' knowledge has never been obtained before. Even the drift-diffusion currents are rendered in a slightly better way: for $[\Phi] = -0.35$, there is no jump around $x = x_R$. Nevertheless, this is not meant to improve the treatment of the junctions where small discontinuities still appear. We believe that only a discretization of type (6.1) can solve this issue.

6. Conclusion and outlook. We presented in this paper a first attempt to develop a robust mixed approach to transient semiconductor computations relying on a simple time-marching strategy. The two main obstructions to circumvent were the choice of a time step which would ensure the compatibility of both the parabolic (drift-diffusion) and hyperbolic (ballistic) areas, and the derivation of a stable boundary condition at the junctions between the source/drain and the channel. For completeness, we display here the current–voltage relation for a doping value of $10^{24}m^{-3}$, see Figure 7. With a diffusion coefficient so low, both curves look very similar.

There exist several ways of extending such an approach: one could be the inclusion of the energy bands, which is more accurate than the simple "effective mass" approximation made in (1.1). Indeed, such a simplification makes the whole model very close to the so-called "Drude theory of conduction" (see [3]), which is known to be quite crude. In order to improve the overall accuracy, an efficient algorithm to compute the Bloch decomposition in one dimension has already been studied in [26]. It may also be interesting to use the sophisticated "multibranch" routines of [22, 26] in this present context to achieve more precise simulations inside the ballistic channel. A routine able to handle phonons has been recently proposed in [23].

From the perspective of the "well-balanced" aspect of things, the big step would be to succeed in working with a good set of variables which would prevent us from

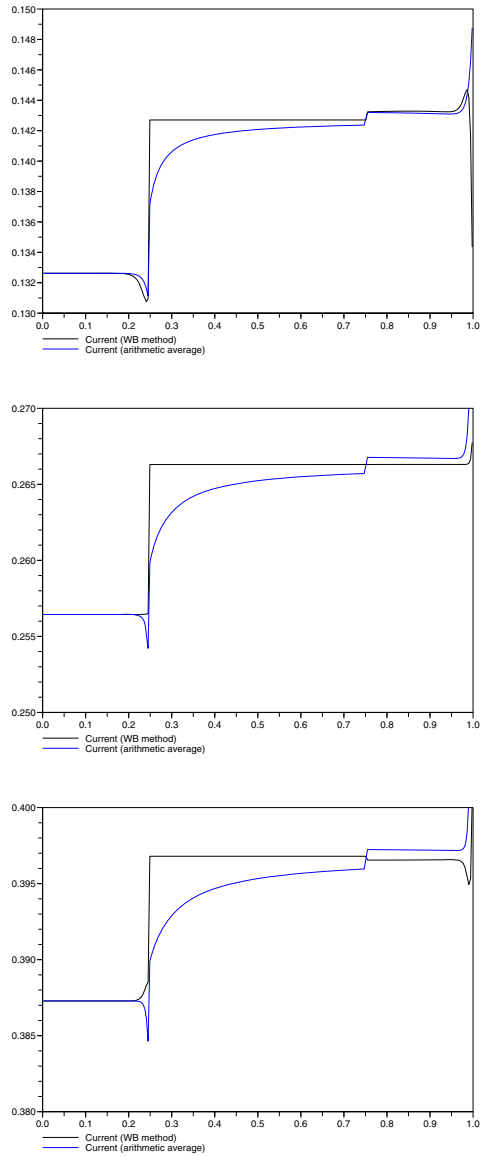

FIG. 6. *Steady-state currents for the mixed scheme with* $[\Phi] = -0.2, -0.35, -0.5$ *(top to bottom).*

linearizing at the junctions (recall the delicate choice of the θ parameter; see Remarks 3 and 4). The first idea could be to replace the ϱ variable in (CL) and (CR) with $z = \ln \varrho$. However, the price to pay is to make these drift-diffusion problems nonlinear; indeed, in the z variable the equations become

$$\text{(6.1)} \qquad \begin{cases} \partial_t z + d\big(\partial_{xx} z + |\partial_x z|^2\big) + \partial_{xx} U + \partial_x U \ \partial_x z = 0, \\ \exp(z)(\cdot, x = 0) = 1, \quad \partial_x z(\cdot, x = x_L) = u + \partial_x U, \end{cases}$$

where the left junction is rendered through the last boundary condition. However, the nonlinear term is first order; hence it asks only for a mild CFL restriction.

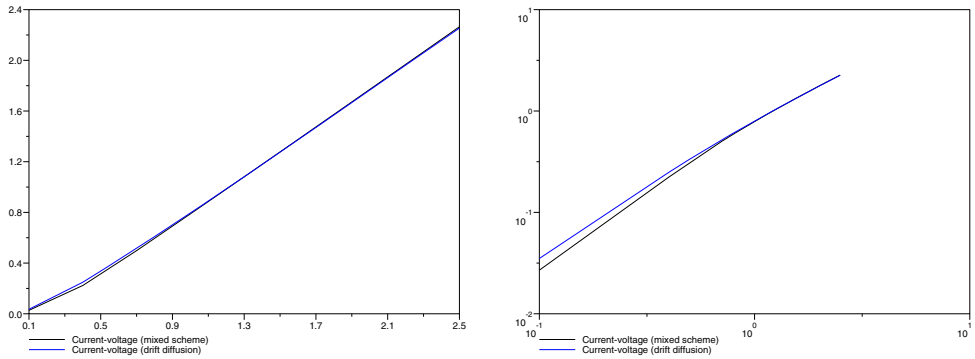

FIG. 7. *Current–voltage relation with strong doping (left, normal scale; right, log scale).*

Appendix. Well-balanced scheme for (B) in a nutshell. In this short section, we follow [21] in order to quickly explain how to manage the forced Burgers equation appearing in (B) in such a way to approximate steady states as best as possible. Let us suppose that $u(t,.) > 0$ holds (this appears to be completely fair in the kind of steady regimes we have in mind to reproduce); we can rewrite the scalar balance law the following way:

$$\partial_t u + \partial_x\Big(\frac{u^2}{2} + U(t,x)\Big) = 0.$$

This clearly shows that steady states with $u \neq 0$ are given by the conservation law $\frac{u^2}{2} + U \equiv C^t \in \mathbb{R}$. At this point, it is easy to include the Poisson potential U in the upwind fluxes in order to maintain this property; thus we obtain the modified fluxes,

$$\mathcal{F}(u_l, u_r; U_l, U_r) = \frac{1}{2}\Big(\max(\tilde{u}_l, 0)^2 + \min(\tilde{u}_r, 0)^2\Big),$$

with the upwinded values,

$$\tilde{u}_l = \sqrt{u_l^2 - 2(U_r - U_l)} \geq 0, \qquad \tilde{u}_r = -\sqrt{u_r^2 + 2(U_r - U_l)} \leq 0.$$

TIME-STEP-SIZE-INDEPENDENT CONDITIONING AND SENSITIVITY TO PERTURBATIONS IN THE NUMERICAL SOLUTION OF INDEX THREE DIFFERENTIAL ALGEBRAIC EQUATIONS*

CARLO L. BOTTASSO†, OLIVIER A. BAUCHAU‡, AND ALBERTO CARDONA§

Abstract. We propose a simple preconditioning for the equations of motion of constrained mechanical systems in index three form. The scaling transformation is applied to the displacement-velocity-multiplier and to the reduced displacement-multiplier forms. The analysis of the transformed system shows that conditioning and sensitivity to perturbations become independent of the time step size, as in the case of well-behaved ordinary differential equations. The new scaling transformation is simple to implement and does not require the rewriting of the system equations as other approaches do. The theoretical analysis is confirmed by numerical examples.

Key words. differential algebraic equations, constraints, Lagrange multipliers, multibody systems, high index

DOI. 10.1137/050638503

1. Introduction.

It is well known that the amplification of small errors and perturbations in the solution of high index differential algebraic equations (DAEs) causes severe numerical difficulties. For example, Petzold and Lötstedt have shown in [1] that index three DAEs for constrained mechanical (multibody) systems are severely ill conditioned for small time step sizes when discretized using backward differentiation formulas (BDFs). Their analysis indicates that, unless corrective actions are taken, the condition number of the iteration matrix is $\mathcal{O}(h^{-3})$. Furthermore, errors propagate in the displacement, velocity, and multiplier fields at rates which are shown to be $\mathcal{O}(h^{-1})$, $\mathcal{O}(h^{-2})$, and $\mathcal{O}(h^{-3})$, respectively. A related perturbation analysis that deals with the propagation of the error in the satisfaction of the constraint equations is described in Arnold [2], which also considers systems with friction. These results indicate that errors will grow very rapidly as the time step size is reduced, preventing in practice the use of time refinement procedures, and imposing a very tight tolerance on the solution of the nonlinear discrete equations. Furthermore, the ill conditioning of the linear system does not favor the use of iterative solvers.

Several methods have been proposed in the literature to address these problems. For example, the system can be recast in index two form, by replacing the displacement level constraints with the velocity level ones. While the index two form is more robust to perturbations [2], this approach suffers from the well-known drift effect, which calls for further adhoc corrective actions.

An alternative approach is to rewrite the governing equations so as to include, together with the position level constraints, their derivatives, as in the Gear, Leimkuhler, and Gupta (GGL) [3] and embedded projection (EP) [4] methods. These methods, however, require additional multipliers which imply a somewhat increased problem size and, hence, a possibly higher computational cost.

Petzold and Lötstedt [1] discuss a simple scaling transformation of the index three governing equations which yields a condition number $\mathcal{O}(h^{-2})$ and an improvement of one order in the errors for all solution fields. Although the sensitivity to perturbations is reduced with respect to the unscaled problem, difficulties can still be expected in practice.

In this paper we propose a solution to the conditioning and error propagation problems that is based on a left and right preconditioning. The left preconditioning amounts to a scaling of the dynamic equilibrium and constraint equations, while the right preconditioning amounts to a scaling of the unknowns. The proposed procedure is trivially implemented in an existing code and does not require the rewriting of the equations of motion as in the GGL and EP methods.

The new scaling transformation is applied first to the equations in the standard displacement-velocity-multiplier form, using a scaling of the sole Lagrange multipliers. A similar scaling was previously considered in Cardona and Géradin [5] in the context of the Hilbert, Hughes, and Taylor (HHT) scheme. The analysis of the present paper shows that errors propagate in the displacement, velocity, and multiplier fields at rates equal to $\mathcal{O}(h^0)$, $\mathcal{O}(h^{-1})$, and $\mathcal{O}(h^0)$, respectively, while the condition number is $\mathcal{O}(h^{-1})$. Next, it is shown that if the velocities are scaled together with the Lagrange multipliers, one can achieve perfect time step size independence ($\mathcal{O}(h^0)$) for error propagation and conditioning.

Finally, we analyze the displacement-multiplier form, obtained by static condensation of the velocities at each time step. This form of the equations is more computationally interesting than the full form for applications denoted by a large number of degrees of freedom, since it leads to the solution of smaller linear problems. Even in this case, the preconditioning of the reduced form leads to perfect time step size independence for both the conditioning and the error propagation in the displacement-multiplier solution variables.

These results indicate that index three DAEs are as easy to integrate as well-behaved ordinary differential equations (ODEs), once they are recast in one of the $\mathcal{O}(h^0)$ forms.

The paper is organized as follows. In section 2 we formulate the equations of motion of multibody systems in index three three-field form for BDF-type schemes, and we derive their sensitivity to perturbations and conditioning. Preconditioning by scaling of the discretized equations is presented in section 3; the left preconditioning strategy is detailed in section 3.1, while the left and right preconditioning is described in section 3.2. The classical pendulum problem in section 3.3 numerically confirms the results of the analysis and concludes this section. The two-field form of the problem is discussed in section 4, the left preconditioning is described in section 4.2, the left and right preconditioning is given in section 4.2, and the pendulum problem verifies the analysis in section 4.3. Finally, a more complex contact-impact problem for a flexible multibody system is presented in section 5 to show the importance of scaling in complex problems involving time step size refinement. The paper closes with section 6, which reports the main conclusions and findings of this work.

2. Sensitivity to perturbations and conditioning of multibody system equations. The governing DAEs for multibody systems are written as

$$\boldsymbol{u}' = \boldsymbol{v}, \tag{1a}$$

$$\boldsymbol{v}' = \boldsymbol{f} + \boldsymbol{G}\boldsymbol{\lambda}, \tag{1b}$$

$$\boldsymbol{\phi} = \boldsymbol{0}, \tag{1c}$$

where (1a) are the kinematic equations, (1b) represent the equations of dynamic equilibrium, $\boldsymbol{u}$ are generalized coordinates, $\boldsymbol{v}$ are generalized velocities, $\boldsymbol{\lambda}$ are Lagrange multipliers that enforce the constraints (1c), and finally $\boldsymbol{G}^T = \boldsymbol{\phi}_{,\boldsymbol{u}}$ is the constraint Jacobian. Following [1], we have considered for simplicity an identity mass matrix in (1b) without loss of generality.

The solution of (1) is sought by means of a k-step BDF method [6], where temporal derivatives in (1a) and (1b) are replaced with the following difference approximation:

$$(\bullet)'_n = \frac{1}{h}\sum_{i=0}^{k} \alpha_i (\bullet)_{n-i}. \tag{2}$$

Although the analysis here is restricted to BDF methods, similar results and conclusions can be reached for other integration schemes for DAEs. For example, the case of the Newmark family of integrators is analyzed in Bottasso, Dopico, and Trainelli [7].

Using a Newton-type method, at each time step one solves a linear system of equations in the form

$$\boldsymbol{A}\boldsymbol{z} = \boldsymbol{b}, \tag{3}$$

where the iteration matrix is

$$\boldsymbol{A} = h\boldsymbol{J}_n = \begin{bmatrix} \alpha_0\boldsymbol{I} & -h\boldsymbol{I} & \boldsymbol{0} \\ h\boldsymbol{X} & \alpha_0\boldsymbol{I} + h\boldsymbol{Y} & -h\boldsymbol{G} \\ h\boldsymbol{G}^T & \boldsymbol{0} & \boldsymbol{0} \end{bmatrix}, \tag{4}$$

with

$$\boldsymbol{X} = -\boldsymbol{f}_{,\boldsymbol{u}} - \boldsymbol{G}_{,\boldsymbol{u}}\boldsymbol{\lambda}, \tag{5a}$$

$$\boldsymbol{Y} = -\boldsymbol{f}_{,\boldsymbol{v}}. \tag{5b}$$

The three block rows of this matrix correspond to the kinematic, equilibrium, and constraint equations of system (1), while the three block columns correspond to the $\boldsymbol{u}$, $\boldsymbol{v}$, and $\boldsymbol{\lambda}$ variables, respectively.

Petzold and Lötstedt [1] show that, by using Gaussian elimination with partial pivoting, the accuracy in the ith component of the solution can be estimated as

$$|\Delta z_i| \leq r\varepsilon \sum_j |(\boldsymbol{A}^{-1})_{ij}| \parallel \boldsymbol{A} \parallel_\infty \parallel \boldsymbol{z} + \Delta\boldsymbol{z} \parallel_\infty, \tag{6}$$

where r is an unknown coefficient, ε is the machine accuracy, and

$$(\boldsymbol{A} + \Delta\boldsymbol{A})(\boldsymbol{z} + \Delta\boldsymbol{z}) = \boldsymbol{b}, \tag{7}$$

with

$$\parallel \Delta\boldsymbol{A} \parallel_\infty \leq r\varepsilon \parallel \boldsymbol{A} \parallel_\infty . \tag{8}$$

The leading terms in the inverse of the iteration matrix (4) were derived in [1] as

$$\boldsymbol{A}^{-1} = (h\boldsymbol{J}_n)^{-1} = \frac{1}{\alpha_0} \begin{bmatrix} \boldsymbol{I} - \boldsymbol{T} & \gamma(\boldsymbol{I} - \boldsymbol{T})\boldsymbol{R}^{-1} & \gamma^{-1}\boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S} \\ -\gamma^{-1}\boldsymbol{T} & (\boldsymbol{I} - \boldsymbol{T})\boldsymbol{R}^{-1} & \gamma^{-2}\boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S} \\ -\gamma^{-2}\boldsymbol{S}\boldsymbol{G}^T & -\gamma^{-1}\boldsymbol{S}\boldsymbol{G}^T\boldsymbol{R}^{-1} & \gamma^{-3}\boldsymbol{S} \end{bmatrix}, \tag{9}$$

where $\gamma = h/\alpha_0$ and

$$\boldsymbol{R} = \boldsymbol{I} + \gamma\boldsymbol{Y} + \gamma^2\boldsymbol{X}, \tag{10a}$$

$$\boldsymbol{S} = (\boldsymbol{G}^T\boldsymbol{R}^{-1}\boldsymbol{G})^{-1}, \tag{10b}$$

$$\boldsymbol{T} = \boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S}\boldsymbol{G}^T. \tag{10c}$$

Therefore, using (6) and (9), we conclude that the roundoff errors in the solution are

$$\Delta u_i = \mathcal{O}(h^{-1}), \tag{11a}$$

$$\Delta v_i = \mathcal{O}(h^{-2}), \tag{11b}$$

$$\Delta \lambda_i = \mathcal{O}(h^{-3}). \tag{11c}$$

This shows that, as $h \to 0$, the accuracy in the Lagrange multipliers deteriorates quickly. Furthermore, it is readily verified that

$$\| \boldsymbol{A} \|_\infty = \mathcal{O}(h^0), \tag{12a}$$

$$\| \boldsymbol{A}^{-1} \|_\infty = \mathcal{O}(h^{-3}). \tag{12b}$$

Hence, the condition number $C = \| \boldsymbol{A} \|_\infty \| \boldsymbol{A}^{-1} \|_\infty$ becomes

$$C = \mathcal{O}(h^{-3}), \tag{13}$$

and the iteration matrix becomes severely ill conditioned for small h. The $\mathcal{O}(h^{-3})$ dependence of roundoff errors and conditioning on the time step size pose limitations to the practical use of variable step size solvers and time refinement procedures.

3. Preconditioning by scaling.

3.1. Left preconditioning. As suggested in [1], this situation can be improved by considering a left diagonal scaling transformation of the equations. The scaled system can be written as

$$\widetilde{\boldsymbol{A}}\boldsymbol{z} = \widetilde{\boldsymbol{b}}, \tag{14}$$

where

$$\widetilde{\boldsymbol{A}} = \boldsymbol{D}\boldsymbol{A}, \tag{15a}$$

$$\widetilde{\boldsymbol{b}} = \boldsymbol{D}\boldsymbol{b}, \tag{15b}$$

and $\boldsymbol{D}$ is a diagonal scaling matrix defined as

$$\boldsymbol{D} = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & h^{-1}\boldsymbol{I} \end{bmatrix}. \tag{16}$$

The inverse of the iteration matrix is in this case

$$\widetilde{\boldsymbol{A}}^{-1} = \frac{1}{\alpha_0}\begin{bmatrix} \boldsymbol{I}-\boldsymbol{T} & \gamma(\boldsymbol{I}-\boldsymbol{T})\boldsymbol{R}^{-1} & \alpha_0\boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S} \\ -\gamma^{-1}\boldsymbol{T} & (\boldsymbol{I}-\boldsymbol{T})\boldsymbol{R}^{-1} & \alpha_0\gamma^{-1}\boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S} \\ -\gamma^{-2}\boldsymbol{S}\boldsymbol{G}^T & -\gamma^{-1}\boldsymbol{S}\boldsymbol{G}^T\boldsymbol{R}^{-1} & \alpha_0\gamma^{-2}\boldsymbol{S} \end{bmatrix}, \tag{17}$$

and, using (6) again, we find

$$\Delta u_i = \mathcal{O}(h^0), \tag{18a}$$

$$\Delta v_i = \mathcal{O}(h^{-1}), \tag{18b}$$

$$\Delta \lambda_i = \mathcal{O}(h^{-2}). \tag{18c}$$

The situation is improved with respect to the original (unscaled) system, but the error in the Lagrange multipliers still grows rapidly as $h \to 0$ even for the left preconditioned problem. Similarly, we find $\| \widetilde{\boldsymbol{A}} \|_\infty = \mathcal{O}(h^0)$ and $\| \widetilde{\boldsymbol{A}}^{-1} \|_\infty = \mathcal{O}(h^{-2})$, which leads to the conclusion that the condition number is

$$C = \mathcal{O}(h^{-2}), \tag{19}$$

which is again not a favorable behavior.

3.2. Left and right preconditioning. A further improvement on the situation expressed by (18) can be obtained by considering a left and right preconditioning, i.e., a scaling of the equations together with a scaling of the unknowns. In particular, since the Lagrange multipliers are affected by the largest roundoff errors according to (18), the governing equations are here rewritten in the form

$$\boldsymbol{u}' = \boldsymbol{v}, \tag{20a}$$

$$\boldsymbol{v}' = \boldsymbol{f} + s\boldsymbol{G}\hat{\boldsymbol{\lambda}}, \tag{20b}$$

$$\boldsymbol{\phi} = \boldsymbol{0}, \tag{20c}$$

where $\hat{\boldsymbol{\lambda}} = \boldsymbol{\lambda}/s$ are scaled Lagrange multipliers, and the scaling factor is $s = \mathcal{O}(h^{-2})$. The idea is now to solve the problem in terms of the scaled multipliers $\hat{\boldsymbol{\lambda}}$ and generalized coordinates $\boldsymbol{u}$ and velocities $\boldsymbol{v}$, and to recover the values of $\boldsymbol{\lambda}$ once at convergence.

Consider first for simplicity $s = 1/h^2$. The linear iteration problem for the left and right preconditioned system can be written as

$$\hat{\boldsymbol{A}}\hat{\boldsymbol{z}} = \hat{\boldsymbol{b}}, \tag{21}$$

where

$$\hat{\boldsymbol{A}} = \boldsymbol{D}_L\boldsymbol{A}\boldsymbol{D}_R, \tag{22a}$$

$$\hat{\boldsymbol{z}} = \boldsymbol{D}_R^{-1}\boldsymbol{z}, \tag{22b}$$

$$\hat{\boldsymbol{b}} = \boldsymbol{D}_L\boldsymbol{b}. \tag{22c}$$

The left diagonal scaling matrix $\boldsymbol{D}_L$ is defined as

$$\boldsymbol{D}_L = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & h\boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & h^{-1}\boldsymbol{I} \end{bmatrix}. \tag{23}$$

The scaling of the third block rows is the same as in [1], while the scaling of the second block rows is needed to ensure $\| \hat{\boldsymbol{A}} \|_\infty = \mathcal{O}(h^0)$, which is beneficial for the condition number. The right diagonal transformation $\boldsymbol{D}_R$ which scales the Lagrange multipliers is defined as

$$\boldsymbol{D}_R = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & h^{-2}\boldsymbol{I} \end{bmatrix}. \tag{24}$$

This gives the following form for the inverse of the iteration matrix:

$$\hat{\boldsymbol{A}}^{-1} = \frac{1}{\alpha_0} \begin{bmatrix} \boldsymbol{I}-\boldsymbol{T} & \alpha_0^{-1}(\boldsymbol{I}-\boldsymbol{T})\boldsymbol{R}^{-1} & \alpha_0 \boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S} \\ -\gamma^{-1}\boldsymbol{T} & \alpha_0^{-1}\gamma^{-1}(\boldsymbol{I}-\boldsymbol{T})\boldsymbol{R}^{-1} & \alpha_0\gamma^{-1}\boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S} \\ -\alpha_0^2 \boldsymbol{S}\boldsymbol{G}^T & -\alpha_0 \boldsymbol{S}\boldsymbol{G}^T\boldsymbol{R}^{-1} & \alpha_0^3 \boldsymbol{S} \end{bmatrix}. \tag{25}$$

Using (6), the roundoff errors for the three solution fields are in this case

$$\Delta u_i = \mathcal{O}(h^0), \tag{26a}$$

$$\Delta v_i = \mathcal{O}(h^{-1}), \tag{26b}$$

$$\Delta \hat{\lambda}_i = \mathcal{O}(h^0). \tag{26c}$$

Notice that the roundoff errors in the displacement field and in the scaled Lagrange multipliers are now insensitive to the time step size, while the condition number is

$$C = \mathcal{O}(h^{-1}). \tag{27}$$

The Lagrange multipliers are recovered at convergence of the Newton process from the scaled multipliers using $\boldsymbol{\lambda} = s\hat{\boldsymbol{\lambda}}$. The scaled multipliers will be affected by an error due to machine accuracy and to the Newton termination tolerance, error which is $\mathcal{O}(h^0)$ for the results above. Since s is $\mathcal{O}(h^{-2})$, then $\boldsymbol{\lambda}$ will be affected by an error $\mathcal{O}(h^{-2})$ due to the recovery process. However, the reduced accuracy of the multipliers cannot affect the iterative Newton process, since this is formulated in terms of the scaled variables. Hence, the Newton iterations can be carried out until as tight a tolerance as necessary has been achieved.

A more general form for the multiplier scaling factor can be derived based on a dimensional argument. Recall that in general the dynamic equilibrium equations (1b) express the balance of inertial forces, elastic forces, constraint reactions, and externally applied forces. To reflect the different nature of these forces, s is selected as

$$s = k_{\text{ave}} + \frac{m_{\text{ave}}}{h^2}, \tag{28}$$

where k_{ave} represents an average stiffness term for the system and m_{ave} an average mass term. To understand the dimensional effect of this scaling, let u_{ave} denote a representative displacement of the system, $F_{\text{ave}}^{\text{elas}}$ a representative value of the elastic forces, and finally $F_{\text{ave}}^{\text{iner}}$ a representative value of the inertial forces. For large time step sizes, $s \approx k_{\text{ave}}$, and $\hat{\boldsymbol{\lambda}} \approx \boldsymbol{\lambda}/k_{\text{ave}}$. Then the ratio of the constraint reactions and of the elastic forces is approximately $s\boldsymbol{G}\hat{\boldsymbol{\lambda}}/F_{\text{ave}}^{\text{elas}} \approx k_{\text{ave}}\boldsymbol{G}\hat{\boldsymbol{\lambda}}/(k_{\text{ave}}u_{\text{ave}}) \approx \boldsymbol{G}\hat{\boldsymbol{\lambda}}/u_{\text{ave}}$; this means that the scaled Lagrange multipliers will be roughly of the same order of magnitude as the displacements, balancing the magnitude of all the unknowns of the problem. For very small time step sizes, $s \approx m_{\text{ave}}/h^2$, and $\hat{\boldsymbol{\lambda}} \approx \boldsymbol{\lambda}/(m_{\text{ave}}/h^2)$. It then

follows that $s\boldsymbol{G}\hat{\boldsymbol{\lambda}}/F_{\text{ave}}^{\text{iner}} \approx (m_{\text{ave}}\boldsymbol{G}\hat{\boldsymbol{\lambda}}/h^2)/(m_{\text{ave}}u_{\text{ave}}/h^2) \approx \boldsymbol{G}\hat{\boldsymbol{\lambda}}/u_{\text{ave}}$; this means that even in this case the scaled Lagrange multipliers will be roughly of the same order of magnitude as the displacements, balancing again the magnitude of all the unknowns of the problem.

The roundoff errors and the conditioning of the left and right scaled system are much improved with respect to the unscaled or the left scaled ones. Yet, the velocity field still shows a mild dependence on the time step size, which in turn induces the same behavior in the conditioning. This effect can be eliminated by considering a scaling of the unknowns that includes, together with the scaling of the Lagrange multipliers, also a scaling of the velocities, as suggested by Arnold [8]. This amounts to the following redefinition of the right diagonal transformation $\boldsymbol{D}_R$:

$$\boldsymbol{D}_R = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & h^{-1}\boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & h^{-2}\boldsymbol{I} \end{bmatrix}. \tag{29}$$

The inverse of the iteration matrix is readily found as

$$\hat{\boldsymbol{A}}^{-1} = \frac{1}{\alpha_0} \begin{bmatrix} \boldsymbol{I}-\boldsymbol{T} & \alpha_0^{-1}(\boldsymbol{I}-\boldsymbol{T})\boldsymbol{R}^{-1} & \alpha_0\boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S} \\ -\alpha_0\boldsymbol{T} & (\boldsymbol{I}-\boldsymbol{T})\boldsymbol{R}^{-1} & \alpha_0^2\boldsymbol{R}^{-1}\boldsymbol{G}\boldsymbol{S} \\ -\alpha_0^2\boldsymbol{S}\boldsymbol{G}^T & -\alpha_0\boldsymbol{S}\boldsymbol{G}^T\boldsymbol{R}^{-1} & \alpha_0^3\boldsymbol{S} \end{bmatrix}, \tag{30}$$

which is not dependent on h. Hence, the roundoff errors in all solution variables and the conditioning are $\mathcal{O}(h^0)$.

3.3. Numerical example. We consider the problem of the pendulum, with equations

$$u_x' = v_x, \tag{31a}$$
$$u_y' = v_y, \tag{31b}$$
$$v_x' = \lambda u_x, \tag{31c}$$
$$v_y' = \lambda u_y - 1, \tag{31d}$$
$$0 = \frac{1}{2}(u_x^2 + u_y^2 - 1), \tag{31e}$$

where u_x, u_y are the Cartesian coordinates of the point mass, and v_x, v_y the mass velocity components. Bar length, point mass, and acceleration of gravity are all equal to 1. The point mass is initially at rest with $u_x = 1$ and $u_y = 0$ and falls under the action of gravity. The integration of (31) is performed using the two-step BDF formula until time $t = 1 \cdot 10^{-3}$, using the time step sizes $h = \{1 \cdot 10^{-4}, 1 \cdot 10^{-5}, 1 \cdot 10^{-6}, 1 \cdot 10^{-7}, 1 \cdot 10^{-8}\}$.

At each time step, the nonlinear discrete equations are solved using Newton method. At the jth Newton iteration of time step n, we solve the linear system of equations

$$\boldsymbol{A}_n^j \boldsymbol{z}_n^j = \boldsymbol{b}_n^j, \tag{32}$$

which yields the corrections $\boldsymbol{z}_n^j$. Typically, the norm of the corrections will decrease at each Newton step, until the accumulation of roundoff errors leads to a saturation value. If further iterations are carried out, one typically observes an oscillation of the correction norm around its saturation value. An example of this behavior is given in

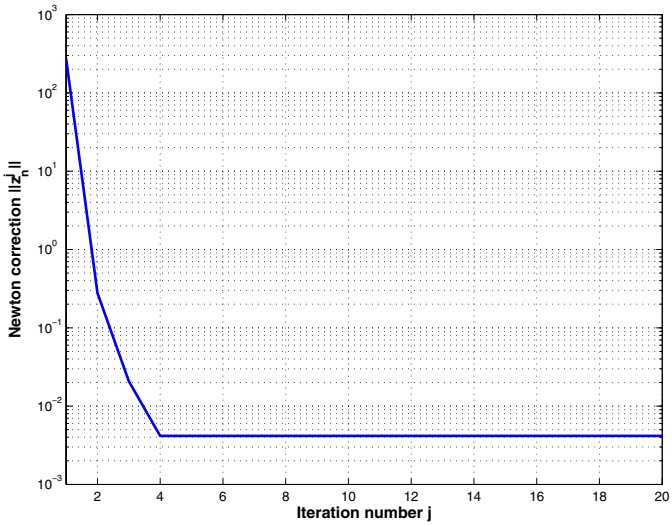

FIG. 1. *Convergence and saturation for the norm of the Newton corrections* $\boldsymbol{z}_n^j$ *plotted versus the Newton iteration* j *for the scheme without preconditioning and* $h = 1 \cdot 10^{-7}$.

Figure 1, which shows $\| \boldsymbol{z}_n^j \|$ versus the Newton iteration j for the scheme without preconditioning and $h = 1 \cdot 10^{-7}$. In this case, the saturation is reached at the fourth iteration, after which the correction norm has very small oscillations around a saturation value of approximatively $4 \cdot 10^{-3}$. To quantify this effect of roundoff errors, in this work iterations are arrested when the Newton corrections stop decreasing, i.e., when we detect the condition

$$\| \boldsymbol{z}_n^{j+1} \| \geq \| \boldsymbol{z}_n^j \| . \tag{33}$$

Hence, the magnitude of the last decreasing Newton correction gives an indication of the tightest achievable convergence of the Newton iterations, which cannot be further improved no matter how many iterations one carries out.

At first, we consider the scaling of the sole Lagrange multipliers based on the simple choice $s = 1/h^2$, and we use the definition of $\boldsymbol{D}_R$ given in (24). Figure 2 shows the maximum throughout each simulation of the 2-norm of the last decreasing Newton corrections versus the time step size, i.e., $\max_n \| \boldsymbol{z}_n^j \|$ versus h. The results obtained with the left preconditioned problem are shown with the $\square$ symbol, while the ones of the left and right preconditioning are shown with the $\circ$ symbol. Notice that with left preconditioning alone it is in fact impossible to solve the nonlinear iteration with a tight tolerance for small values of the time step.

Figure 3 shows the maximum throughout each simulation of the absolute value of the last decreasing Newton corrections by field type, i.e., $\max_n \max(|z^j_{u_x,n}|, |z^j_{u_y,n}|)$, $\max_n \max(|z^j_{v_x,n}|, |z^j_{v_y,n}|)$, $\max_n |z^j_{\lambda,n}|$. These results are in accordance with the analysis of the previous sections.

Finally, Figure 4 shows the condition number C versus h. The condition number is computed by means of the singular value decomposition of the iteration matrix at convergence, i.e., at the last decreasing Newton iteration. Here again, a substantial improvement is observed for the left and right preconditioning with respect to the left preconditioning alone.

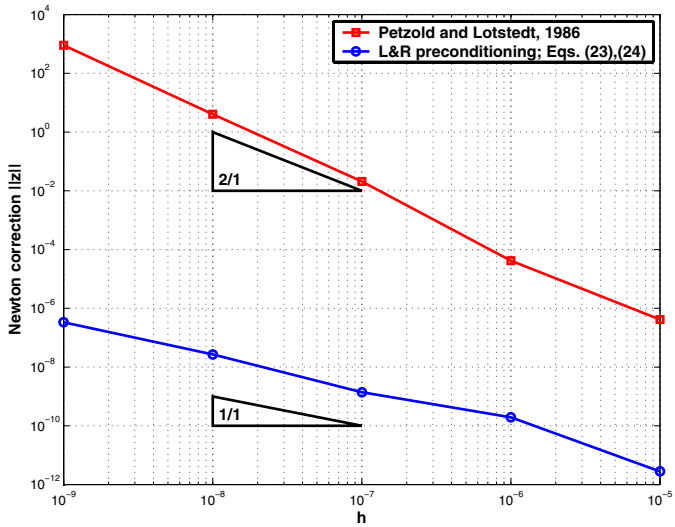

FIG. 2. *Last decreasing Newton corrections versus time step size.*

Next, we consider the previous scaling of the multipliers together with the scaling of the velocities, with $\boldsymbol{D}_R$ as given in (29). Figure 5 shows the maximum throughout each simulation of the 2-norm of the last decreasing Newton corrections versus the time step size, while Figure 6 shows the condition number C versus h. In both cases, the solution of the left and right preconditioned problem does not depend on h, as predicted by the analysis.

4. Displacement based form. For large scale applications denoted by many degrees of freedom, the displacement-velocity-multiplier form discussed in the previous section leads to the solution of large linear systems. For example, this is the case when the governing DAEs (1) are obtained by spatial discretization using the finite element method of a flexible mechanical system. A substantial performance increase can be obtained by implementing the integration scheme in displacement-multiplier form, which is simply achieved by statically eliminating the velocity unknowns at each time step. In fact, considering again the k-step BDF method, velocities at time t_n are computed from the kinematic equations (1a) using the difference approximation (2) as

$$\boldsymbol{u}'_n = \boldsymbol{v}_n = \frac{1}{h}\sum_{i=0}^{k} \alpha_i \boldsymbol{u}_{n-i}. \tag{34}$$

Inserting this expression into the accelerations of the dynamic equilibrium equations (1b), we get

$$\boldsymbol{v}'_n = \frac{1}{h}\sum_{i=0}^{k} \alpha_i \boldsymbol{v}_{n-i} = \frac{1}{h}\left(\frac{\alpha_0}{h}\sum_{i=0}^{k} \alpha_i \boldsymbol{u}_{n-i} + \sum_{i=1}^{k} \alpha_i \boldsymbol{v}_{n-i}\right). \tag{35}$$

Using Newton's method, one solves the reduced system of linear equations

$$\boldsymbol{B}\boldsymbol{y} = \boldsymbol{c}, \tag{36}$$

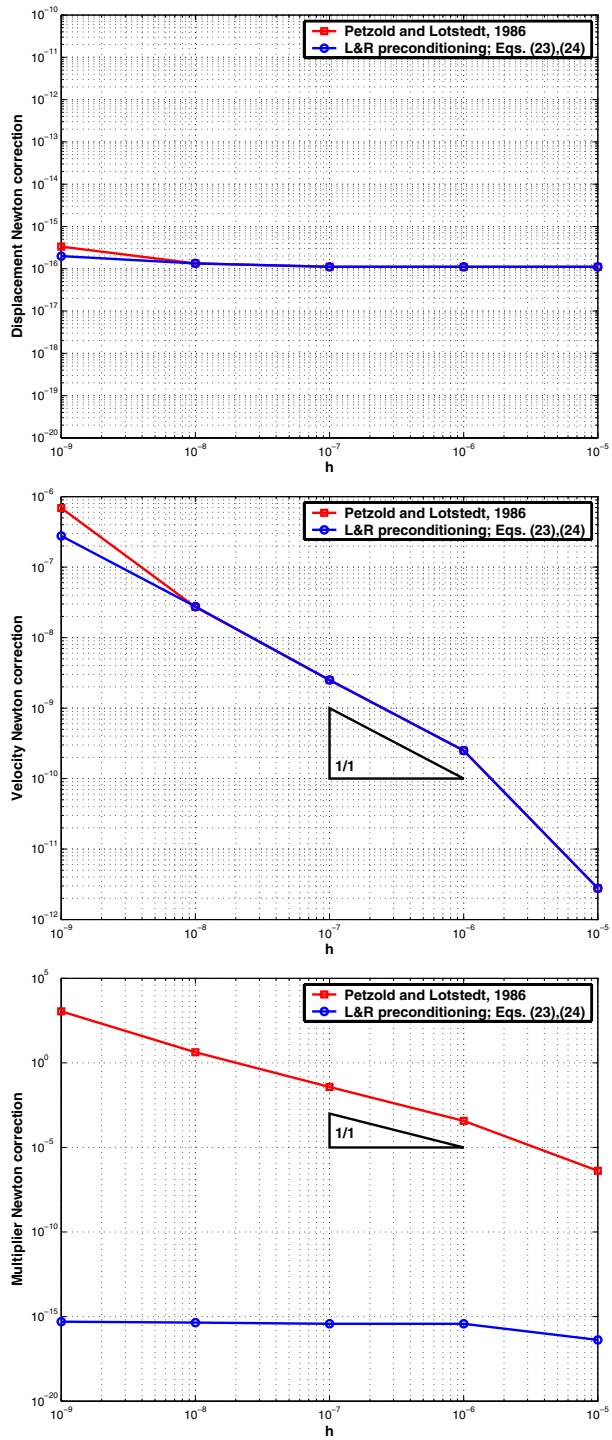

FIG. 3. *Last decreasing Newton corrections by field type versus time step size. Top: Displacements. Center: Velocities. Bottom: Lagrange multipliers.*

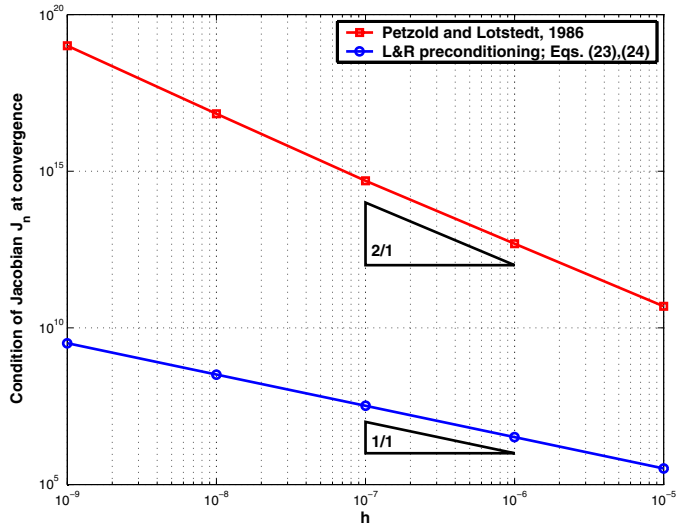

FIG. 4. *Condition number of Jacobian at convergence versus time step size.*

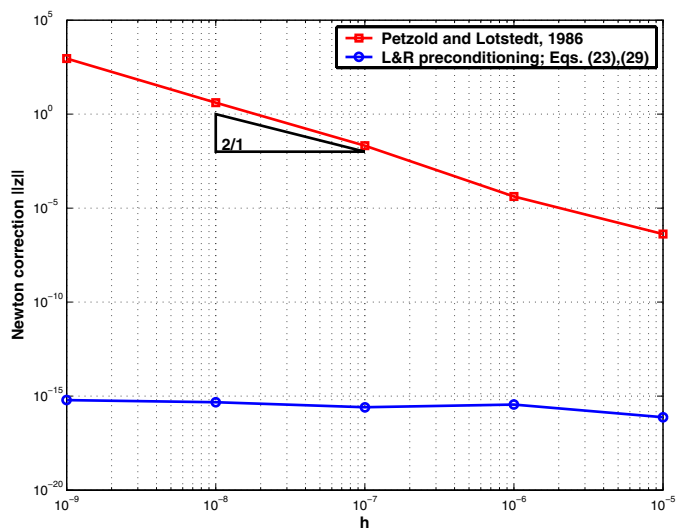

FIG. 5. *Last decreasing Newton corrections versus time step size. Left and right preconditioning based on* (23) *and* (29).

where the iteration matrix is in this case

$$\boldsymbol{B} = h\boldsymbol{J}_n = \begin{bmatrix} \alpha_0 \boldsymbol{U} & -h\boldsymbol{G} \\ h\boldsymbol{G}^T & \boldsymbol{0} \end{bmatrix}, \tag{37}$$

with

$$\boldsymbol{U} = \gamma^{-1}\boldsymbol{I} + \boldsymbol{Y} + \gamma \boldsymbol{X}. \tag{38}$$

The first block rows of this matrix correspond to the equilibrium equations in displacement-based form, while the second block rows correspond to the constraint

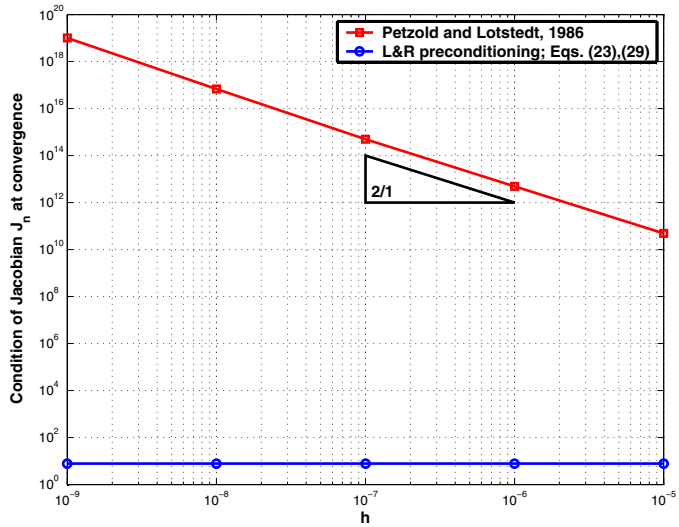

FIG. 6. *Condition number of Jacobian at convergence versus time step size. Left and right preconditioning based on* (23) *and* (29).

conditions. The two block columns correspond to the $\boldsymbol{u}$ and $\boldsymbol{\lambda}$ variables, respectively. Once at convergence, velocities are recovered using the vector relationship (34).

The inverse of the iteration matrix is

$$\boldsymbol{B}^{-1} = \frac{1}{\alpha_0} \begin{bmatrix} (\boldsymbol{I} - \boldsymbol{W})\boldsymbol{U}^{-1} & \gamma^{-1}\boldsymbol{U}^{-1}\boldsymbol{G}\boldsymbol{V} \\ -\gamma^{-1}\boldsymbol{V}\boldsymbol{G}^T\boldsymbol{U}^{-1} & \gamma^{-2}\boldsymbol{V} \end{bmatrix}, \tag{39}$$

where

$$\boldsymbol{V} = (\boldsymbol{G}^T\boldsymbol{U}^{-1}\boldsymbol{G})^{-1}, \tag{40a}$$

$$\boldsymbol{W} = \boldsymbol{U}^{-1}\boldsymbol{G}\boldsymbol{V}\boldsymbol{G}^T. \tag{40b}$$

Using (6), and considering that

$$\lim_{h\to 0} \boldsymbol{U}^{-1} = \mathcal{O}(h), \tag{41a}$$

$$\lim_{h\to 0} \boldsymbol{V} = \mathcal{O}(h^{-1}), \tag{41b}$$

the roundoff errors in the primary solution variables are found to be

$$\Delta u_i = \mathcal{O}(h^{-1}), \tag{42a}$$

$$\Delta \lambda_i = \mathcal{O}(h^{-3}), \tag{42b}$$

while the condition number C becomes

$$C = \mathcal{O}(h^{-4}); \tag{43}$$

again these are very unfavorable behaviors with respect to the time step size.

4.1. Left preconditioning. Even in this case, the simple left preconditioning of Petzold and Lötstedt [1] gives a modest benefit with respect to the unpreconditioned problem. In fact, defining the left scaling transformation as

$$\boldsymbol{D} = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & h^{-1}\boldsymbol{I} \end{bmatrix}, \tag{44}$$

we find

$$\widetilde{\boldsymbol{B}}^{-1} = \frac{1}{\alpha_0} \begin{bmatrix} (\boldsymbol{I} - \boldsymbol{W})\boldsymbol{U}^{-1} & \alpha_0 \boldsymbol{U}^{-1}\boldsymbol{G}\boldsymbol{V} \\ -\gamma^{-1}\boldsymbol{V}\boldsymbol{G}^T\boldsymbol{U}^{-1} & \alpha_0\gamma^{-1}\boldsymbol{V} \end{bmatrix}, \tag{45}$$

which gives for the propagation of errors

$$\Delta u_i = \mathcal{O}(h^0), \tag{46a}$$

$$\Delta \lambda_i = \mathcal{O}(h^{-2}), \tag{46b}$$

while the conditioning is

$$C = \mathcal{O}(h^{-3}). \tag{47}$$

4.2. Left and right preconditioning. The left and right scaling matrices for the reduced problem are simply obtained from (21)–(24) and are defined as

$$\boldsymbol{D}_L = \begin{bmatrix} h\boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & h^{-1}\boldsymbol{I} \end{bmatrix} \tag{48}$$

and

$$\boldsymbol{D}_R = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & h^{-2}\boldsymbol{I} \end{bmatrix}, \tag{49}$$

where we have considered again the simple choice $s = 1/h^2$. This gives

$$\hat{\boldsymbol{B}}^{-1} = \frac{1}{\alpha_0} \begin{bmatrix} \alpha_0^{-1}\gamma^{-1}(\boldsymbol{I} - \boldsymbol{W})\boldsymbol{U}^{-1} & \alpha_0 \boldsymbol{U}^{-1}\boldsymbol{G}\boldsymbol{V} \\ -\alpha_0 \boldsymbol{V}\boldsymbol{G}^T\boldsymbol{U}^{-1} & \alpha_0^3\gamma\boldsymbol{V} \end{bmatrix}, \tag{50}$$

which yields time-step-size-independent sensitivity to perturbations of the primary variables

$$\Delta u_i = \mathcal{O}(h^0), \tag{51a}$$

$$\Delta \hat{\lambda}_i = \mathcal{O}(h^0), \tag{51b}$$

and a time-step-size-independent conditioning, i.e.,

$$C = \mathcal{O}(h^0), \tag{52}$$

which is the best possible behavior that can be expected of a numerical method.

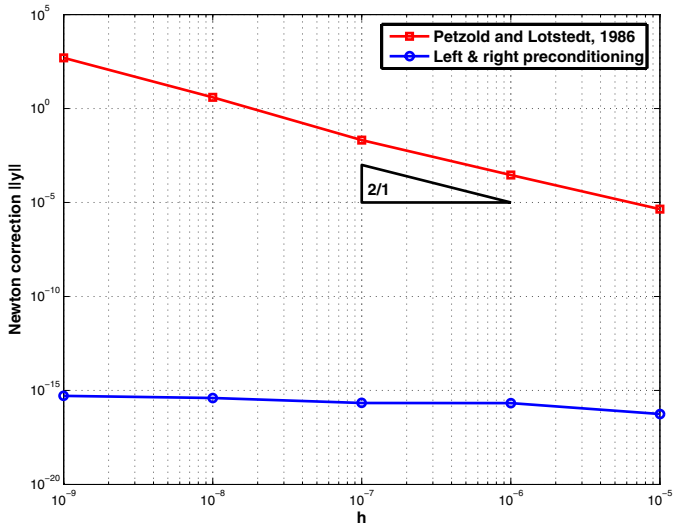

FIG. 7. *Last decreasing Newton corrections versus time step size for the displacement-multiplier form.*

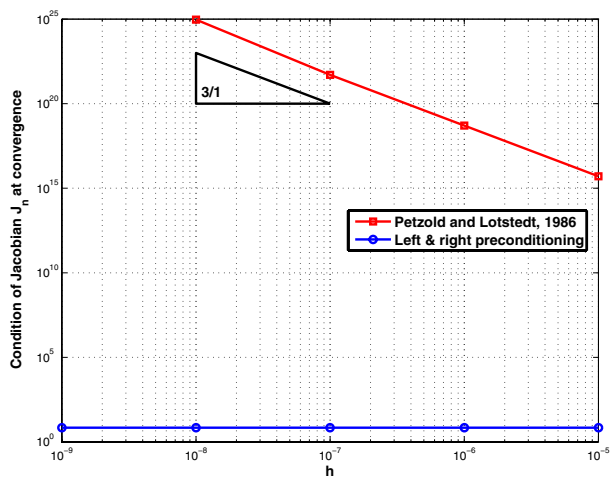

FIG. 8. *Condition number of Jacobian at convergence versus time step size for the displacement-multiplier form.*

4.3. Numerical example. We consider again the model problem (31), using the same data. At the jth Newton iteration of time step n, we solve the linear system of equations

$$\boldsymbol{B}_n^j \boldsymbol{y}_n^j = \boldsymbol{c}_n^j, \tag{53}$$

which yields the corrections $\boldsymbol{y}_n^j$. As in the previous case, iterations are arrested only when the Newton corrections stop decreasing.

The results of the analysis are confirmed by Figures 7 and 8. In particular, the former shows the maximum throughout each simulation of the 2-norm of the last decreasing Newton corrections versus the time step size, $\max_n \parallel \boldsymbol{z}_n^j \parallel$ versus

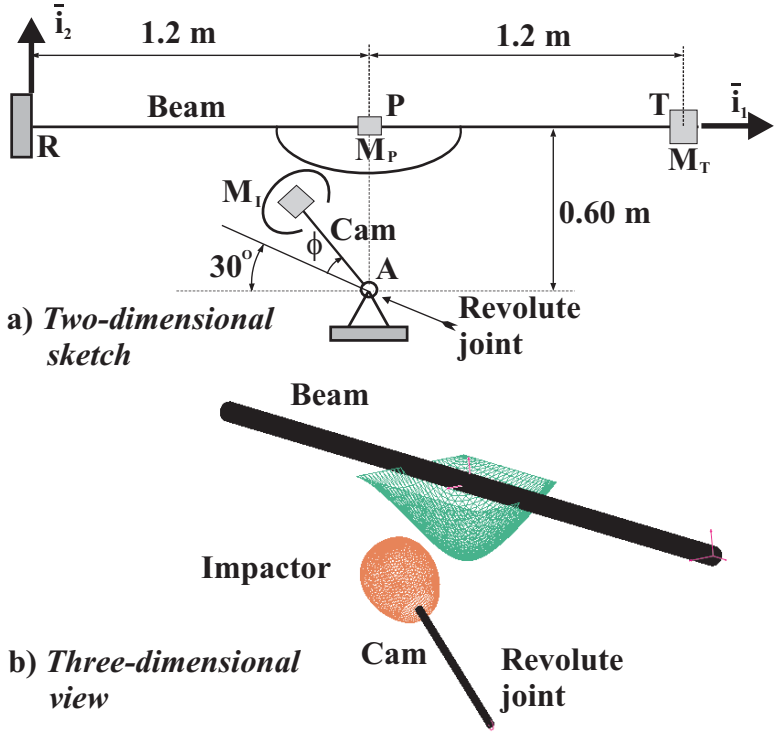

FIG. 9. *Configuration of the contact problem.*

h, while the latter reports the condition number C versus h. For the left and right preconditioning, exact time step size independence is achieved.

5. Numerical example: The need for scaling in contact-impact analysis of flexible multibody systems. In this section we consider a more challenging problem involving a flexible multibody system subjected to unilateral contact conditions. In general, to accurately determine the contact events and for resolving the large gradients in the interactional forces at contact, time step size refinement procedures must be used for contact problems. However, whenever small values of the time steps are used, formulations in index three form will suffer from the problems discussed in the previous sections.

Figure 9(a) depicts a cam of length 0.4 m connected to the ground at point A by means of a revolute joint. The relative rotation in the joint is prescribed to be $\phi(t) = \phi_0(1-\cos\Omega t)$, where $\phi_0 = \pi/3$ rad, and $\Omega = 2\pi/3$ rad/sec. A rigid impactor of total mass $M_I = 4$ kg is attached at the tip of the cam. A flexible beam of length 2.4 m is clamped to the ground at point R, and a point mass $M_T = 40$ kg is attached at its free end, point T. Finally, a rigid body of total mass $M_P = 4$ kg is attached at the middle point P of the beam. As the impactor moves, it contacts the outer surface of this rigid body, as shown in Figure 9(b). The physical properties of the flexible beam are axial stiffness $EA = 44000$ kN, bending stiffnesses $I_{22} = 300$ and $I_{33} = 23$ kN·m^2, torsional stiffness $GJ = 28$ kN·m^2, and mass per unit span $m = 1.6$ kg/m. The bending stiffnesses of the cam are $I_{22} = 23$, $I_{33} = 300$ kN·m^2, and the axial stiffness, torsional stiffness, and mass per unit span are the same as those of the beam.

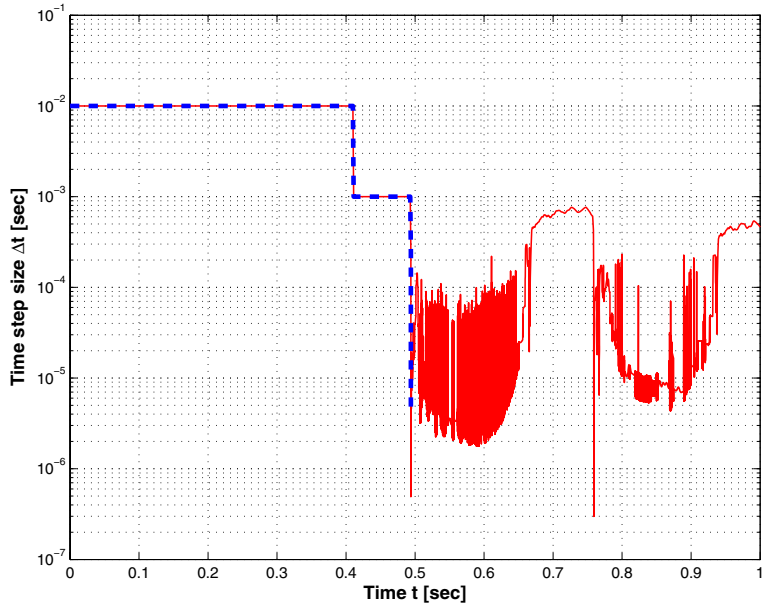

FIG. 10. *Time step size as a function of time.* $m_{\text{ave}} = 0$*: Thick dashed line.* $m_{\text{ave}} = 1$*: Thin solid line.*

When the two bodies come in contact, a contact model and friction model are used to define the normal and tangential contact forces, respectively. A linear spring with a stiffness constant $k = 2$ GN/m in parallel with a viscous damper of constant $\mu = 10^{-3}$ were used to evaluate the normal contact force. The friction force was computed with the help of the LuGre model, using the following parameters: $\sigma_0 = 10^5$ m^{-1}, $\sigma_1 = \sigma_2 = 0$ sec/m, $v_s = 10^{-3}$ m/sec, $\mu_k = 0.30$, $\mu_s = 0.30$, and $\gamma = 2$. More details about this modeling technique and the definition of these parameters can be found in Bauchau and Ju [9].

The simulation was conducted for a 1 sec duration. From $t = 0$ to 0.4 sec a constant time step size, $h = 10^{-2}$ sec, was used and at that point, an automated time step size adaptivity algorithm was activated [10]; the desired local error was set to $\varepsilon_{\text{loc}} = 10^{-7}$. In light of (28), the scaling factor was selected as $s = k_{\text{ave}} + m_{\text{ave}}/h^2$, where $k_{\text{ave}} = 10^3$ and $m_{\text{ave}} = 0$ or 1. When $m_{\text{ave}} = 0$, the scaling is independent of the time step size, whereas it becomes time step dependent when $m_{\text{ave}} = 1$.

For the problem at hand, large time step sizes were used before contact occurs, i.e., when $t < 0.494$ sec. This portion of the simulation is not challenging and both scaling factors performed equally well. At time $t \approx 0.494$ the time step size was drastically reduced by the adaptivity algorithm to decrease the large contact force gradients that would result from using a constant time step. Figure 10 depicts the time step size as a function of time during the simulation, for both $m_{\text{ave}} = 0$ and 1. As should be expected from the analysis developed in this paper, when $m_{\text{ave}} = 0$, the simulation fails to converge as soon as the time step size becomes small, whereas for $m_{\text{ave}} = 1$, convergence is achieved at each time step, despite the complex dynamic behavior of the system after impact. Figure 11 shows the corresponding history of the scaling factor. Note that scaling factors of the order of 10^{13} were needed at the

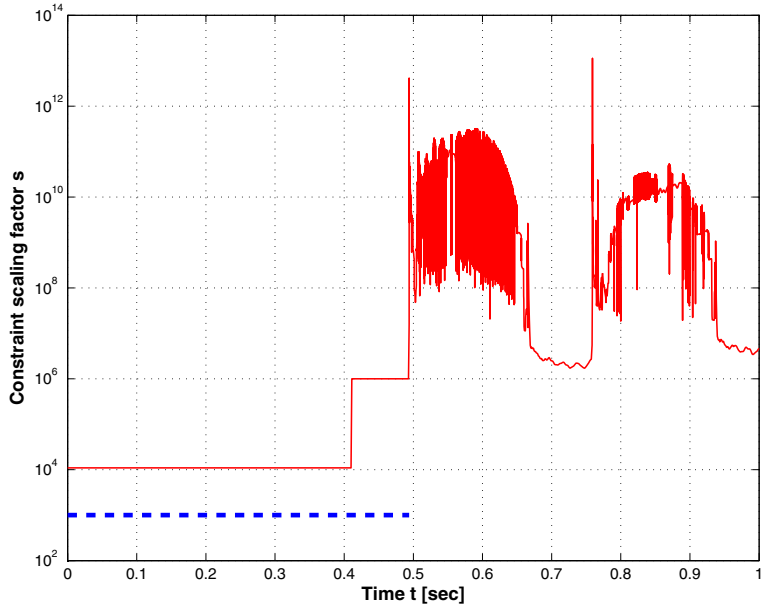

FIG. 11. *Constraint scaling factor* s. $m_{\text{ave}} = 0$*: Thick dashed line.* $m = 1$*: Thin solid line.*

instant of contact; after impact, the highly vibratory response of the system required small time steps and the scaling factor was in the range of $s \in [10^8,\ 10^{11}]$.

6. Conclusions. We have proposed a simple scaling transformation for the index three DAEs describing constrained multibody dynamical systems. The approach amounts to a left and right preconditioning of the iteration matrix, which has the goal of making the solution less sensitive to the propagation of perturbations and of improving the condition number.

Using the left preconditioning, the constraint equations are divided by the time step size as already proposed by [1], while the dynamic equilibrium equations are multiplied by the same quantity. The right preconditioning amounts to a definition of a set of modified unknowns: modified multipliers are obtained by scaling with the square of the time step size of the original Lagrange multipliers, while modified velocities are obtained by scaling with the time step size.

The new scaling was applied to the displacement-velocity-multiplier and to the reduced displacement-multiplier forms. In both cases, we obtain the remarkable results that both error propagations and conditioning are $\mathcal{O}(h^0)$; i.e., the numerical solution of index three DAEs behaves as in the case of regular ODEs.

The simple problem of the pendulum was used to numerically confirm the results of the analysis, while a more challenging problem dealing with the contact-impact analysis of a flexible multibody system was used to illustrate the effect of scaling when using time refinement procedures.

Although other approaches are available to deal with the problem of ill conditioning and error propagation for high index DAEs, the present approach has the possible advantages of being trivial to implement and of not requiring a rewriting of the equations of motion, and furthermore it does not introduce additional unknowns.

ON PRECONDITIONED ITERATIVE METHODS FOR BURGERS EQUATIONS*

ZHONG-ZHI BAI†, YU-MEI HUANG‡, AND MICHAEL K. NG‡

Abstract. We study the Newton method and a fixed-point method for solving the system of nonlinear equations arising from the Sinc–Galerkin discretization of the Burgers equations. In each step of the Newton method or the fixed-point method, a structured subsystem of linear equations is obtained and needs to be solved numerically. In this paper, preconditioning techniques are applied to solve such linear subsystems. The bounds for eigenvalues of the preconditioned matrices are derived and numerical examples are given to illustrate the effectiveness of the proposed methods. We also find that a combination of the Newton/fixed-point iteration with the preconditioned GMRES method is quite efficient for the Sinc–Galerkin discretization of the Burgers equations.

1. Introduction.

We consider an iterative solution of the system of nonlinear equations

$$\mathbf{F}(\mathbf{u}) \equiv B\mathbf{u} + C\Psi(\mathbf{u}) - \mathbf{b} = 0, \tag{1.1}$$

where B and C are n-by-n matrices, $\mathbf{b}$ is a given n-vector, and $\Psi : \mathbb{R}^n \to \mathbb{R}^n$, with

$$\Psi(\mathbf{u}) = (\psi_1(u_1), \psi_2(u_2), \ldots, \psi_n(u_n))^T \quad \text{and} \quad \mathbf{u} = (u_1, u_2, \ldots, u_n)^T, \tag{1.2}$$

is a continuous diagonal mapping defined on the open ball

$$\mathcal{U}_\delta := \{u \in \mathbb{R}^n \mid \|\mathbf{u}\| < \delta\}.$$

See [19] for general background and applications about the system of mildly nonlinear equations.

Nonlinear systems such as (1.1)–(1.2) may also arise from the Sinc–Galerkin discretization of the Burgers equation [15]:

(1.3)
$$\begin{cases} \mathcal{P}^{(2)}u(x,t) \equiv \dfrac{\partial u}{\partial t}(x,t) + u(x,t)\dfrac{\partial u}{\partial x}(x,t) - \varepsilon\dfrac{\partial^2 u}{\partial x^2}(x,t) = f(x,t), & a < x < b,\ t \geq 0, \\ u(a,t) = \gamma(t) \quad \text{and} \quad u(b,t) = \delta(t), & t \geq 0, \\ u(x,0) = g(x), & a \leq x \leq b. \end{cases}$$

In the Sinc–Galerkin method, we approximate u by

$$\widehat{u} = \sum_{j=-m_t-1}^{n_t} \sum_{i=-m_x-1}^{n_x+1} u_{ij}\chi_i(x)\theta_j(t),$$

where the functions $\chi_i(x)$ and $\theta_j(t)$ are bases in the spatial space and the temporal space, respectively, with

$$\chi_i(x) = \begin{cases} \dfrac{b-x}{b-a}, & i = -m_x - 1, \\ \mathcal{S}(i, h_x) \circ \phi_x(x), & -m_x \le i \le n_x, \\ \dfrac{x-a}{b-a}, & i = n_x + 1, \end{cases}$$

and

$$\mathcal{S}(i, h_x) \circ \phi_x(x) := \operatorname{sinc}\left[\frac{\phi_x(x) - ih_x}{h_x}\right],$$

$$\theta_j(t) = \begin{cases} \dfrac{t+1}{t^2+1}, & j = -m_t - 1, \\ \mathcal{S}(j, h_t) \circ \phi_t(t), & -m_t \le j \le n_t; \end{cases}$$

see [15] for details. Here, $\phi_x(x)$ and $\phi_t(t)$ are the restrictions of the conformal mapping $\phi_z(z)$ onto the real intervals (a, b) and $(0, +\infty)$, respectively, with $\phi_z(z)$ a mapping from a simply connected domain $\mathcal{D}$ onto

$$\mathcal{D}_d := \{z \mid z = x + \imath y, |y| < d, d > 0\},$$

with $\imath$ the imaginary unit. We remark that the first and second derivatives of $\phi_z(z)$ with respect to the variable z will be denoted as $\phi_z^{'}(z)$ and $\phi_z^{''}(z)$, respectively.

The Galerkin method enables us to determine

$$u_{ij}, \quad -m_x - 1 \le i \le n_x + 1, \quad -m_t - 1 \le j \le n_t,$$

through solving the system of nonlinear equations

$$\langle \mathcal{P}^{(2)}\widehat{u} - f, \mathcal{S}_{kl} \rangle = 0,$$

where the inner product is defined as

$$\langle f, g \rangle = \int_0^{\infty} \int_a^b f(x,t)g(x,t)\omega_x(x)\omega_t(t)dxdt,$$

with $\omega_x(x)$ and $\omega_t(t)$ being two weighting functions with respect to the spatial and the temporal variables, respectively, and $\mathcal{S}_{kl} = \mathcal{S}(k, h_x)\mathcal{S}(l, h_t)$; see [15].

The most distinctive feature of the Sinc basis is that it can lead to exponential decreasing rate of the error. Moreover, the decreasing rate is maintained when the solution of the boundary value problem has boundary singularities.

In the form of (1.1)–(1.2), the resulting Sinc–Galerkin system can be described as follows; see [15] for more details. Now, the mapping Ψ is given by

$$\Psi(\mathbf{u}) = (u_1^2, u_2^2, \ldots, u_n^2)^T, \quad \text{with} \quad \mathbf{u} = (u_1, u_2, \ldots, u_n)^T, \tag{1.4}$$

the matrices B and C are given by

$$B = (\varepsilon(T_x^{(2)} + D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)} + D_x^{(2)})) \otimes Q_t + Q_x \otimes (D_t^{(3)}T_t^{(1)} + T_t^{(1)}D_t^{(3)} + D_t^{(4)}), \tag{1.5}$$

and

$$C = (D_x^{(3)}T_x^{(1)} + T_x^{(1)}D_x^{(3)} + D_x^{(4)}) \otimes Q_t, \tag{1.6}$$

where $T_z^{(i)}$ $(i = 1, 2$ and $z \in \{x, t\})$ are $(m_z + n_z + 1)$-by-$(m_z + n_z + 1)$ Toeplitz matrices, with

$$T_z^{(1)} = \begin{bmatrix} 0 & -1 & \frac{1}{2} & \cdots & \frac{(-1)^{m_z+n_z}}{m_z+n_z} \\ 1 & & & & \vdots \\ -\frac{1}{2} & & \ddots & & \frac{1}{2} \\ \vdots & & & & -1 \\ \frac{(-1)^{m_z+n_z}}{m_z+n_z} & \cdots & -\frac{1}{2} & 1 & 0 \end{bmatrix}, \tag{1.7}$$

$$T_z^{(2)} = \begin{bmatrix} \frac{\pi^2}{3} & -2 & \frac{2}{2^2} & \cdots & \frac{(-1)^{m_z+n_z}2}{(m_z+n_z)^2} \\ -2 & & & & \vdots \\ \frac{2}{2^2} & & \ddots & & \frac{2}{2^2} \\ \vdots & & & & -2 \\ \frac{(-1)^{m_z+n_z}2}{(m_z+n_z)^2} & \cdots & \frac{2}{2^2} & -2 & \frac{\pi^2}{3} \end{bmatrix}, \tag{1.8}$$

and $D_z^{(i)}$ and Q_z $(i = 1, 2, 3, 4$ and $z \in \{x, t\})$ are $(m_z + n_z + 1)$-by-$(m_z + n_z + 1)$ diagonal matrices, with

$$D_z^{(1)} = \frac{h_z}{2} \cdot \operatorname{diag}\left[\left\{-\frac{\phi_z''(z)}{(\phi_z'(z))^2} - \frac{2\omega_z'(z)}{\phi'(z)\omega_z(z)}\right\}_{z=-m_z}^{n_z}\right], \tag{1.9}$$

$$D_z^{(2)} = \frac{h_z^2}{2} \cdot \operatorname{diag}\left[\left\{-\frac{\omega_z''(z)}{(\phi_z'(z))^2\omega_z(z)}\right\}_{z=-m_z}^{n_z}\right], \tag{1.10}$$

$$D_z^{(3)} = \frac{h_z}{2} \cdot \operatorname{diag}\left[\{-\omega_z(z)\}_{z=-m_z}^{n_z}\right], \tag{1.11}$$

$$D_z^{(4)} = \frac{h_z^2}{2} \cdot \operatorname{diag}\left[\left\{-\frac{\omega_z'(z)}{\phi_z'(z)}\right\}_{z=-m_z}^{n_z}\right], \tag{1.12}$$

and

$$Q_z = \operatorname{diag}\left[\left\{\frac{\omega_z(z)}{\phi_z'(z)}\right\}_{z=-m_z}^{n_z}\right]. \tag{1.13}$$

There are two classes of methods for computing the solution of the system of nonlinear equations (1.1). One casts this problem as a general nonlinear system and uses a nonlinear solver such as the Newton method [15] to solve it, and the other considers this problem as a special system of nonlinear equations

$$B\mathbf{u} = \mathbf{b} - C\mathbf{u} \odot \mathbf{u},$$

where $\odot$ is the entrywise multiplication, and uses the fixed-point method to solve it. It has been shown in [15] that the spectral radius of the inverse of the coefficient matrix B is bounded above by $1/(4\varepsilon)$. Evidently, as ε decreases, the iterative method used to solve this nonlinear system deteriorates. See also [1, 2, 3, 4, 8, 9, 10, 21, 22] and references therein for sequential and parallel matrix splitting iteration methods for solving the system of nonlinear equations (1.1).

For both Newton and fixed-point iterations employed to solve the system of nonlinear equations (1.1), at each step we need to solve a subsystem of linear equations of the form

$$(B + CD)\mathbf{z} = \mathbf{r}, \tag{1.14}$$

where D is a diagonal matrix. A straightforward application of the Gaussian elimination to the linear system (1.14) will result in an algorithm of $\mathcal{O}(n^6)$ complexity, where n is the size of the matrix $T_z^{(i)}$ $(i = 1, 2)$, $D_z^{(i)}$ $(i = 1, 2, 3, 4)$, or Q_z, $z \in \{x, t\}$. For an n-by-n Toeplitz linear system, fast direct solvers of complexity $\mathcal{O}(n^2)$ have been developed; see, for instance, Levinson [14]. However, there does not exist fast direct solver for Toeplitz-plus-diagonal linear systems yet, since the displacement rank of a Toeplitz-plus-diagonal matrix can take any value between 0 and n. Hence, fast direct Toeplitz solvers that are based on small displacement rank matrices are not applicable to the Toeplitz-plus-diagonal linear systems or to the block Toeplitz-like-plus-diagonal linear systems. For details about displacement ranks, we refer the reader to Kailath and Sayed [13].

However, we note that for any n^2-vector $\mathbf{q}$, the matrix-vector product $(B+CD)\mathbf{q}$ can be computed in $\mathcal{O}(n^2 \log n)$ operations. In fact, for $i = 1, 2$ and $z \in \{x, t\}$ the matrix-vector product $T_z^{(i)}\mathbf{q}$ can be obtained by first embedding $T_z^{(i)}$ into a $2n$-by-$2n$ circulant matrix and then using [illegible] (FFTs) to compute it [12]. Since for all $i \in \{1, 2, 3, 4\}$ and $z \in \{x, t\}$, $D_z^{(i)}$ is a diagonal matrix, the matrix-vector product $D_z^{(i)}\mathbf{q}$ can be computed in $\mathcal{O}(n^2)$ operations. Thus, iterative methods such as GMRES [20] can be employed to economically solve the linear system (1.14). Usually, in order to accelerate the convergence speed of GMRES, we need to precondition the linear system (1.14) by an approximate matrix with respect to the coefficient matrix $B + CD$. Therefore, to solve the original linear system, we turn to solving the preconditioned linear system instead; see [17, 7] and the references therein.

The outline of this paper is as follows. In section 2, we demonstrate some basic properties about the system of nonlinear equations (1.1). In section 3, we construct preconditioners for the coefficient matrix of the linear system (1.14); in addition, we study preconditioning properties of the preconditioned matrix and show that its eigenvalues are tightly and uniformly bounded in a rectangular on the complex plane independent of the size of the matrix. Several numerical examples are used to show the effectiveness of the proposed methods in section 4. Finally, in section 5, we end this paper with some concluding remarks.

2. Preliminary results. In this section, we give a few theoretical properties of the system of nonlinear equations (1.1).

THEOREM 2.1. [illegible] $B \in \mathbb{R}^{n\times n}$ [illegible] $\Psi : \mathbb{R}^n \to \mathbb{R}^n$ [illegible]

$$\|\Psi(\mathbf{u})\| \le \gamma \|\mathbf{u}\|^p \quad \forall \mathbf{u} \in \mathcal{U}_\delta,$$

[illegible] γ [illegible] $p \ge 2$ [illegible] $\|\cdot\|$ [illegible]
[illegible] $\mathcal{U}_\delta$ [illegible] δ [illegible]

$$\alpha = \|B^{-1}C\| \qquad \beta = \|B^{-1}b\|,$$

[illegible]

$$\alpha\beta^{p-1}\gamma < (p-1)^{p-1}p^{-p}.$$

[illegible] $\mathbf{u}_* \in \mathcal{U}_\delta$ [illegible] (1.1), [illegible] $\mathbf{u}_* \in \mathcal{U}_{\delta_0}$
[illegible] δ_0 [illegible]

$$\alpha\gamma t^p - t + \beta = 0.$$

[illegible]. Define

$$g(t) = \alpha\gamma t^p - t + \beta$$

and

$$t_0 = (\alpha\gamma p)^{-\frac{1}{p-1}}.$$

Then we have

$$\begin{cases} g(0) = \beta > 0, & g(t_0) = (\alpha\gamma)^{-\frac{1}{p-1}}[(\alpha\beta^{p-1}\gamma)^{\frac{1}{p-1}} - (p-1)p^{-\frac{p}{p-1}}] < 0, \\ g'(t_0) = 0, & g'(t)(t-t_0) > 0 \quad \forall t \in (0,+\infty). \end{cases}$$

It follows that $g(t)$ has two positive roots; we denote the smallest one as δ_0. Therefore, $g(t) \ge 0$ for $t \in [0, \delta_0]$. Since $\mathbf{u}_* \in \mathcal{U}_\delta$ is a solution of the system of nonlinear equations (1.1), it holds that

$$B\mathbf{u}_* + C\Psi(\mathbf{u}_*) = \mathbf{b},$$

or equivalently,

$$\mathbf{u}_* + B^{-1}C\Psi(\mathbf{u}_*) = B^{-1}\mathbf{b}.$$

Therefore,

$$\|B^{-1}b\| \ge \|\mathbf{u}_*\| - \|B^{-1}C\|\|\Psi(\mathbf{u}_*)\| \ge \|\mathbf{u}_*\| - \gamma\|B^{-1}C\|\|\mathbf{u}_*\|^p,$$

i.e.,

$$\alpha\gamma\|\mathbf{u}_*\|^p - \|\mathbf{u}_*\| + \|B^{-1}b\| \ge 0.$$

We immediately know that this inequality holds when $\|\mathbf{u}_*\| \le \delta_0$ or $\mathbf{u}_* \in \mathcal{U}_{\delta_0}$. ∎

COROLLARY 2.2. 2.1 $\Psi(\mathbf{u}) = (u_1^2, u_2^2, \ldots, u_n^2)^T$ $\mathbf{u} = (u_1, u_2, \ldots, u_n)^T$ $\gamma = 1$

$$\delta_0 = \frac{1}{2\alpha}\left[1 - \sqrt{1 - 4\alpha\beta}\right],$$

$\alpha\beta < \frac{1}{4}$

THEOREM 2.3. $B \in \mathbb{R}^{n\times n}$ $\alpha = \|B^{-1}C\|$ $\beta = \|B^{-1}b\|$ $\|\cdot\|$ $\Psi : \mathbb{R}^n \to \mathbb{R}^n$

(i) $\|\Psi(\mathbf{u})\| \le \gamma\|\mathbf{u}\|^p \ \forall \mathbf{u} \in \mathcal{U}_\delta$ $\mathcal{U}_\delta$ δ γ $p \ge 2$

$$\alpha\beta^{p-1}\gamma < (p-1)^{p-1}p^{-p};$$

(ii) $\|\Psi(\mathbf{u}) - \Psi(\mathbf{v})\| \le \tau\|\mathbf{u} - \mathbf{v}\| \ \forall \mathbf{u}, \mathbf{v} \in \mathcal{U}_{\delta_0}$ $\tau > 0$ δ_0

$$\alpha\gamma t^p - t + \beta = 0.$$

$\alpha\tau < 1$ (1.1) $\mathbf{u}_* \in \mathcal{U}_{\delta_0}$. Define $\mathbf{G} : \mathcal{U}_{\delta_0} \subset \mathbb{R}^n \to \mathbb{R}^n$ as

$$\mathbf{G}(\mathbf{u}) = B^{-1}b - B^{-1}C\Psi(\mathbf{u}).$$

Then $\mathbf{G}$ is a contraction mapping defined on $\mathcal{U}_{\delta_0}$ as

$$\|\mathbf{G}(\mathbf{u}) - \mathbf{G}(\mathbf{v})\| = \|B^{-1}C[\Psi(\mathbf{u}) - \Psi(\mathbf{v})]\| \le \alpha\tau\|\mathbf{u} - \mathbf{v}\|.$$

Therefore, $\mathbf{G}$ has a unique fixed point $\mathbf{u}_*$ in $\mathcal{U}_{\delta_0}$. It then follows from Theorem 2.1 that the system of nonlinear equations (1.1) has a unique solution $\mathbf{u}_*$ in $\mathcal{U}_{\delta_0}$. □

COROLLARY 2.4. 2.3 $\alpha\beta < \frac{1}{4}$ $\Psi(\mathbf{u}) = (u_1^2, u_2^2, \ldots, u_n^2)^T$ $\mathbf{u} = (u_1, u_2, \ldots, u_n)^T$

$$\alpha\tau \le 2\alpha\delta_0 = 1 - \sqrt{1 - 4\alpha\beta} < 1.$$

$$B\mathbf{u} + C\mathbf{u} \odot \mathbf{u} = \mathbf{b}$$

$\mathbf{u}_*$ $\mathcal{U}_{\delta_0}$

3. The preconditioners. In this section, we will solve the system of nonlinear equations

$$B\mathbf{u} + C\mathbf{u} \odot \mathbf{u} = \mathbf{b} \tag{3.1}$$

by the Newton or the fixed-point iteration method.

3.1. The Newton and fixed-point iterations. Let $\Omega \in \mathbb{R}^{n\times n}$ be a diagonal matrix such that $B + C\Omega$ is nonsingular. Then we consider the following Newton iteration for solving the system of nonlinear equations (3.1):

$$\mathbf{u}^{(k+1)} = \mathbf{u}^{(k)} - (B + 2C\,\mathrm{diag}(\mathbf{u}^k))^{-1}(B\mathbf{u}^{(k)} + C\mathbf{u}^{(k)} \odot \mathbf{u}^{(k)} - \mathbf{b}), \quad k = 0, 1, 2, \ldots.$$

If $\mathbf{u}_* \in \mathcal{U}_{\delta_0}$ is a solution of the nonlinear system (3.1), then it holds that $\{\mathbf{u}^{(k)}\} \subset \mathcal{U}_{\delta_0}$ and $\lim_{k\to\infty} \mathbf{u}^{(k)} = \mathbf{u}_*$, with the convergence speed being at least quadratic, provided $\mathbf{u}^{(0)}$ is in a neighborhood of $\mathbf{u}_*$.

The fixed-point iteration for the system of nonlinear equations (3.1) is as follows:

$$(B + C\Omega)\mathbf{u}^{(k+1)} = C[\Omega\mathbf{u}^{(k)} - \mathbf{u}^{(k)} \odot \mathbf{u}^{(k)}] + \mathbf{b}, \quad k = 0, 1, 2, \ldots,$$

or equivalently,

$$\mathbf{u}^{(k+1)} = (B + C\Omega)^{-1}C[\Omega\mathbf{u}^{(k)} - \mathbf{u}^{(k)} \odot \mathbf{u}^{(k)}] + (B + C\Omega)^{-1}\mathbf{b}, \quad k = 0, 1, 2, \ldots.$$

If $\mathbf{u}_* \in \mathcal{U}_{\delta_0}$ is a solution of the nonlinear system (3.1), then it holds that $\{\mathbf{u}^{(k)}\} \subset \mathcal{U}_{\delta_0}$ and $\lim_{k\to\infty} \mathbf{u}^{(k)} = \mathbf{u}_*$, provided $\mathbf{u}^{(0)}$ is in a neighborhood of $\mathbf{u}_*$ and

$$\rho((B + C\Omega)^{-1}C(\Omega - 2\ \mathrm{diag}(\mathbf{u}_*))) < 1,$$

where $\mathrm{diag}(\mathbf{u}_*)$ is the diagonal matrix with its ith diagonal entries being $[\mathbf{u}_*]_i$, and $\rho(\cdot)$ denotes the spectral radius of the corresponding matrix. See [19] for details.

3.2. Construction of the preconditioners. For both fixed-point and Newton iterations, at each step we need to solve a subsystem of linear equations of the form

$$A\mathbf{z} \equiv (B + CD)\mathbf{z} = \mathbf{r}. \tag{3.2}$$

This kind of linear system may be efficiently solved by the preconditioned GMRES method. The key point here is constructing a high-quality preconditioner M for the coefficient matrix A by making use of its concrete properties and special structure.

Consider the system of nonlinear equations (1.1) with the function $\Psi(\mathbf{u})$ as given in (1.4) and the matrices B and C as given in (1.5) and (1.6), respectively, where $T_z^{(i)}$ and $D_z^{(i)}$ ($i = 1, 2, 3, 4$ and $z \in \{x, t\}$), and Q_z ($z \in \{x, t\}$) are defined as in (1.7)–(1.13). Let $\Omega = \mathrm{diag}(\omega_{\mathbf{i}})$ be a positive definite matrix such that $D := I \otimes \Omega$ is an approximation to the Jacobian of $\Psi(\mathbf{u})$, i.e., $D\mathbf{u} \approx \boldsymbol{\Psi}(\mathbf{u})$. Then the target matrix under consideration is

$$\begin{aligned} A &= B + CD \\ &= \varepsilon(T_x^{(2)} + D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)} + D_x^{(2)}) \otimes Q_t \\ &\quad + Q_x \otimes (D_t^{(3)}T_t^{(1)} + T_t^{(1)}D_t^{(3)} + D_t^{(4)}) \\ &\quad + (D_x^{(3)}T_x^{(1)} + T_x^{(1)}D_x^{(3)} + D_x^{(4)}) \otimes (Q_t\Omega). \end{aligned} \tag{3.3}$$

By utilizing the special structure of the matrix A, we can construct its preconditioner M as

$$\begin{aligned} M &= \hat{B} + \hat{C}D \\ &= \varepsilon(B_x^{(2)} + D_x^{(1)}B_x^{(1)} + B_x^{(1)}D_x^{(1)} + D_x^{(2)}) \otimes Q_t \\ &\quad + Q_x \otimes (D_t^{(3)}B_t^{(1)} + B_t^{(1)}D_t^{(3)} + D_t^{(4)}) \\ &\quad + (D_x^{(3)}B_x^{(1)} + B_x^{(1)}D_x^{(3)} + D_x^{(4)}) \otimes (Q_t\Omega), \end{aligned} \tag{3.4}$$

where

$$\hat{B} = (\varepsilon(B_x^{(2)} + D_x^{(1)}B_x^{(1)} + B_x^{(1)}D_x^{(1)} + D_x^{(2)})) \otimes Q_t + Q_x \otimes (D_t^{(3)}B_t^{(1)} + B_t^{(1)}D_t^{(3)} + D_t^{(4)})$$

and

$$\hat{C} = (D_x^{(3)}B_x^{(1)} + B_x^{(1)}D_x^{(3)} + D_x^{(4)}) \otimes Q_t,$$

and, for $z \in \{x, t\}$,

$$B_z^{(1)} = \text{tridiag}\left[\frac{1}{2}, 0, -\frac{1}{2}\right] \quad \text{and} \quad B_z^{(2)} = \text{tridiag}\,[-1, 2, -1]$$

are tridiagonal approximations to $T_z^{(1)}$ and $T_z^{(2)}$, respectively.

We remark that the preconditioner M is a block tridiagonal matrix, and is usually of mild size because, compared with the finite-difference system, the Sinc–Galerkin system need not be very large in order to achieve the same discretization accuracy [16, 18]. Therefore, for any given vector $\mathbf{r}$, the generalized residual equation $M\mathbf{w} = \mathbf{r}$ involved in the preconditioned GMRES iteration method can be solved in $\mathcal{O}(N_x N_t^2)$ or $\mathcal{O}(N_x^2 N_t)$ operations by using a variety of linear solvers such as the sparse direct methods, where $N_z = m_z + n_z + 1$, with $z \in \{x, t\}$; see also [6, 5] and the references therein.

3.3. Analysis of the preconditioning matrix. In this subsection, we will demonstrate the positive definiteness of the matrix A defined in (3.3) and its preconditioning matrix M defined in (3.4). In addition, we will derive precise bounds for the eigenvalues of the preconditioned matrix $M^{-1}A$ by making use of the generalized Bendixson theorem established in [7].

To this end, in what follows we use $(\cdot)^*$ to denote the conjugate transpose of either a vector or a square matrix. For a given square matrix X, we use $\mathcal{H}(X)$ and $\mathcal{S}(X)$ to denote, respectively, its Hermitian and skew-Hermitian parts [6], and use $\lambda(X)$ to denote its spectral set. In particular, when X is Hermitian or real symmetric, we use $\lambda_{\max}(X)$ to represent its largest eigenvalue.

THEOREM 3.1. $D_z^{(i)}$ $(i = 2, 4$ $z \in \{x, t\})$ $\mathcal{H}(A)$ $\mathcal{H}(M)$ [illegible] 1 A M [illegible]. The Hermitian and the skew-Hermitian parts of A and M are

$$\mathcal{H}(A) = \frac{1}{2}(A + A^*) = \varepsilon(T_x^{(2)} + D_x^{(2)}) \otimes Q_t + Q_x \otimes D_t^{(4)} + D_x^{(4)} \otimes (Q_t\Omega),$$

$$\mathcal{S}(A) = \frac{1}{2}(A - A^*) = \varepsilon(D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)}) \otimes Q_t + Q_x \otimes (D_t^{(3)}T_t^{(1)} + T_t^{(1)}D_t^{(3)}) + (D_x^{(3)}T_x^{(1)} + T_x^{(1)}D_x^{(3)}) \otimes (Q_t\Omega),$$

[1] A matrix is positive definite if its Hermitian part is positive definite. Note that a positive definite matrix is not necessarily Hermitian; see [6, 5].

and

$$\begin{aligned}\mathcal{H}(M) &= \frac{1}{2}(M + M^*)\\ &= \varepsilon(B_x^{(2)} + D_x^{(2)}) \otimes Q_t + Q_x \otimes D_t^{(4)} + D_x^{(4)} \otimes (Q_t\Omega),\end{aligned}$$

$$\begin{aligned}\mathcal{S}(M) &= \frac{1}{2}(M - M^*)\\ &= \varepsilon(D_x^{(1)}B_x^{(1)} + B_x^{(1)}D_x^{(1)}) \otimes Q_t + Q_x \otimes (D_t^{(3)}B_t^{(1)} + B_t^{(1)}D_t^{(3)})\\ &\quad +(D_x^{(3)}B_x^{(1)} + B_x^{(1)}D_x^{(3)}) \otimes (Q_t\Omega).\end{aligned}$$

Because the diagonal matrices $D_z^{(i)}$ ($i = 2, 4$ and $z \in \{x, t\}$) are positive semidefinite, and the Toeplitz matrices $T_x^{(2)}$ and the diagonal matrices Q_z ($z \in \{x, t\}$) are symmetric positive definite [12], we know that $\mathcal{H}(A)$ is symmetric positive definite. Therefore, A is a positive definite matrix and, thus, is nonsingular.

By applying the same arguments to the preconditioning matrix M, we can immediately show that M is positive definite and nonsingular, too. □

The following [illegible], established in [7], is essential for us to derive a rectangular domain for bounding the eigenvalues of the preconditioned matrix $M^{-1}A$.

THEOREM 3.2 ([7, Theorem 2.4]). [illegible] $A, M \in C^{n\times n}$ [illegible] n [illegible] $v \in C^n \setminus \{0\}$ $v^*\mathcal{H}(A)v \neq 0$ [illegible] $v^*\mathcal{H}(M)v \neq 0$ [illegible] $h(v)$ $f_A(v)$ [illegible] $f_M(v)$ [illegible]

$$h(v) = \frac{v^*\mathcal{H}(A)v}{v^*\mathcal{H}(M)v}, \quad f_A(v) = \frac{1}{i} \cdot \frac{v^*\mathcal{S}(A)v}{v^*\mathcal{H}(A)v}, \quad \text{and} \quad f_M(v) = \frac{1}{i} \cdot \frac{v^*\mathcal{S}(M)v}{v^*\mathcal{H}(M)v}.$$

[illegible] γ_1 [illegible] γ_2 [illegible]

$$\gamma_1 \leq h(v) \leq \gamma_2 \quad \forall\, v \in C^n \setminus \{0\},$$

[illegible] η [illegible] μ [illegible]

$$-\eta \leq f_A(v) \leq \eta \quad \text{and} \quad -\mu \leq f_M(v) \leq \mu \quad \forall\, v \in C^n \setminus \{0\}.$$

[illegible] $\eta\mu \leq 1$ [illegible]

$$\begin{cases} \frac{(1-\eta\mu)\gamma_1}{1+\mu^2} \leq \ \mathrm{Re}(\lambda(M^{-1}A)) \leq (1+\eta\mu)\gamma_2, \\ -(\eta+\mu)\gamma_2 \leq \ \mathrm{Im}(\lambda(M^{-1}A)) \leq (\eta+\mu)\gamma_2. \end{cases}$$

[illegible] $\mathrm{Re}(\cdot)$ [illegible] $\mathrm{Im}(\cdot)$ [illegible]

In [7] the following estimates about the bounds of the function $h(v)$ have been derived.

LEMMA 3.3 (see [7, Lemma 4.2]). [illegible] $D_z^{(i)}(i = 2, 4$ [illegible] $z \in \{x, t\})$ [illegible]

$$1 \leq \frac{v^*\mathcal{H}(A)v}{v^*\mathcal{H}(M)v} \leq \frac{\pi^2}{4} \quad \forall v \in \mathbb{C}^n \setminus \{0\}.$$

To obtain the bounds for the functions $f_A(v)$ and $f_M(v)$, we need to establish the following estimates.

LEMMA 3.4. [illegible] $D_z^{(i)}(i = 2, 4 \quad z \in \{x, t\}), Q_z(z \in \{x, t\})$ [illegible] Ω [illegible] $z \in \{x, t\}$ [illegible] $N_z = m_z + n_z + 1$ [illegible]

$$d_z^{(1)} = \max_{1 \le j \le N_z} \{|[D_z^{(1)}]_{jj}|, \ |[D_z^{(3)}]_{jj}|\}, \quad d_z^{(2)} = \min_{1 \le j \le N_z} \{|[D_z^{(2)}]_{jj}|, \ |[D_z^{(4)}]_{jj}|\},$$

$$\mu^{(1)} = \max_{z \in \{x,t\}} \left\{ \frac{2\pi d_z^{(1)}}{\sqrt{(\pi^2 + d_z^{(2)}) d_z^{(2)}}}, \quad \frac{2\pi d_z^{(1)}}{d_z^{(2)}} \right\},$$

$$\mu^{(2)} = \max_{z \in \{x,t\}} \left\{ d_z^{(1)} \left(\sqrt{1 + \frac{4}{d_z^{(2)}}} - 1 \right), \quad \frac{2 d_z^{(1)}}{d_z^{(2)}} \right\}.$$

[illegible] $v \in \mathbb{C}^n \setminus \{0\}$ [illegible]

$$\left| \frac{v^*[(D_x^{(1)} T_x^{(1)} + T_x^{(1)} D_x^{(1)}) \otimes Q_t] v}{v^*[(T_x^{(2)} + D_x^{(2)}) \otimes Q_t] v} \right| \le \mu^{(1)}, \tag{3.5}$$

$$\left| \frac{v^*[(D_x^{(1)} B_x^{(1)} + B_x^{(1)} D_x^{(1)}) \otimes Q_t] v}{v^*[(B_x^{(2)} + D_x^{(2)}) \otimes Q_t] v} \right| \le \mu^{(2)}, \tag{3.6}$$

$$\left| \frac{v^*[Q_x \otimes (D_t^{(3)} T_t^{(1)} + T_t^{(1)} D_t^{(3)})] v}{v^*[Q_x \otimes D_t^{(4)}] v} \right| \le \mu^{(1)}, \tag{3.7}$$

$$\left| \frac{v^*[Q_x \otimes (D_t^{(3)} B_t^{(1)} + B_t^{(1)} D_t^{(3)})] v}{v^*[Q_x \otimes D_t^{(4)}] v} \right| \le \mu^{(2)}, \tag{3.8}$$

$$\left| \frac{v^*[(D_x^{(3)} T_x^{(1)} + T_x^{(1)} D_x^{(3)}) \otimes (Q_t \Omega)] v}{v^*[D_x^{(4)} \otimes (Q_t \Omega)] v} \right| \le \mu^{(1)}, \tag{3.9}$$

$$\left| \frac{v^*[(D_x^{(3)} B_x^{(1)} + B_x^{(1)} D_x^{(3)}) \otimes (Q_t \Omega)] v}{v^*[D_x^{(4)} \otimes (Q_t \Omega)] v} \right| \le \mu^{(2)}. \tag{3.10}$$

[illegible] We first prove (3.5) and (3.6). Because $D_x^{(1)} T_x^{(1)} + T_x^{(1)} D_x^{(1)}$ is a skew-symmetric matrix and $T_x^{(2)} + D_x^{(2)}$ is a symmetric positive definite matrix, for all

$v \neq 0$, by direct computations we can obtain

$$\begin{aligned}
&\left| \frac{v^*[(D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)}) \otimes Q_t]v}{v^*[(T_x^{(2)} + D_x^{(2)}) \otimes Q_t]v} \right| \\
&\quad \leq \max_{v \neq 0} \left\{ \left| \frac{\frac{1}{\imath} v^*[(D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)}) \otimes Q_t]v}{v^*[(T_x^{(2)} + D_x^{(2)}) \otimes Q_t]v} \right| \right\} \\
&\quad \leq \left| \lambda_{\max} \left(\frac{1}{\imath} (T_x^{(2)} + D_x^{(2)})^{-1/2} (D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)}) (T_x^{(2)} + D_x^{(2)})^{-1/2} \right) \right| \\
&\quad \leq \left\| (T_x^{(2)} + D_x^{(2)})^{-1/2} (D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)}) (T_x^{(2)} + D_x^{(2)})^{-1/2} \right\|_2 \\
&\quad \leq \left\| (T_x^{(2)} + D_x^{(2)})^{-1/2} D_x^{(1)}T_x^{(1)} (T_x^{(2)} + D_x^{(2)})^{-1/2} \right\|_2 \\
&\qquad + \left\| (T_x^{(2)} + D_x^{(2)})^{-1/2} T_x^{(1)}D_x^{(1)} (T_x^{(2)} + D_x^{(2)})^{-1/2} \right\|_2 \\
&\quad \leq \left\| (T_x^{(2)} + D_x^{(2)})^{-1/2} (T_x^{(2)} + d_x^{(2)}I)^{1/2} \right\|_2 \cdot \left\| (T_x^{(2)} + d_x^{(2)}I)^{-1/2} \right\|_2 \\
&\qquad \cdot \left\| D_x^{(1)} \right\|_2 \cdot \left\| (T_x^{(2)} + d_x^{(2)}I)^{1/2} (T_x^{(2)} + D_x^{(2)})^{-1/2} \right\|_2 \\
&\qquad \cdot \left[\left\| T_x^{(1)} (T_x^{(2)} + d_x^{(2)}I)^{-1/2} \right\|_2 + \left\| (T_x^{(2)} + d_x^{(2)}I)^{-1/2} T_x^{(1)} \right\|_2 \right] \\
&\quad \leq \left\| (T_x^{(2)} + d_x^{(2)}I)^{-1/2} \right\|_2 \cdot \left\| D_x^{(1)} \right\|_2 \\
&\qquad \cdot \left[\left\| T_x^{(1)} (T_x^{(2)} + d_x^{(2)}I)^{-1/2} \right\|_2 + \left\| (T_x^{(2)} + d_x^{(2)}I)^{-1/2} T_x^{(1)} \right\|_2 \right]. \qquad (3.11)
\end{aligned}$$

Here, we have applied the fact

$$\begin{aligned}
&\left\| (T_x^{(2)} + D_x^{(2)})^{-1/2} (T_x^{(2)} + d_x^{(2)}I)^{1/2} \right\|_2^2 \\
&\quad = \left\| (T_x^{(2)} + d_x^{(2)}I)^{1/2} (T_x^{(2)} + D_x^{(2)})^{-1/2} \right\|_2^2 \\
&\quad = \lambda_{\max} \left((T_x^{(2)} + D_x^{(2)})^{-1/2} (T_x^{(2)} + d_x^{(2)}I) (T_x^{(2)} + D_x^{(2)})^{-1/2} \right) \\
&\quad = \max_{w \neq 0} \left\{ \frac{w^*(T_x^{(2)} + D_x^{(2)})^{-1/2} (T_x^{(2)} + d_x^{(2)}I) (T_x^{(2)} + D_x^{(2)})^{-1/2} w}{w^*w} \right\} \\
&\quad = \max_{w \neq 0} \left\{ \frac{w^*(T_x^{(2)} + d_x^{(2)}I)w}{w^*(T_x^{(2)} + D_x^{(2)})w} \right\} \\
&\quad \leq \max \left\{ 1, \quad d_x^{(2)} \cdot \max_{w \neq 0} \frac{w^*w}{w^*D_x^{(2)}w} \right\} \\
&\quad \leq \ 1.
\end{aligned}$$

Now, we estimate the terms $\|(T_x^{(2)} + d_x^{(2)}I)^{-1/2}\|_2$, $\|T_x^{(1)}(T_x^{(2)} + d_x^{(2)}I)^{-1/2}\|_2$ and $\|(T_x^{(2)} + d_x^{(2)}I)^{-1/2}T_x^{(1)}\|_2$ involved in (3.11).

As the generating function of the Toeplitz matrix $T_x^{(2)}$ is θ^2, we have

$$\begin{aligned}\left\|(T_x^{(2)}+d_x^{(2)}I)^{-1/2}\right\|_2^2 &= \lambda_{\max}\left((T_x^{(2)}+d_x^{(2)}I)^{-1}\right)\\ &= \max_{w\neq 0}\left\{\frac{w^*(T_x^{(2)}+d_x^{(2)}I)^{-1}w}{w^*w}\right\}\\ &< \max_{-\pi\le\theta\le\pi}\left\{\frac{1}{\theta^2+d_x^{(2)}}\right\}\\ &= \frac{1}{d_x^{(2)}}.\end{aligned}$$

Therefore,

$$\left\|(T_x^{(2)}+d_x^{(2)}I)^{-1/2}\right\|_2 < \frac{1}{\sqrt{d_x^{(2)}}}.$$

In addition, we have

$$\begin{aligned}&\left\|T_x^{(1)}(T_x^{(2)}+d_x^{(2)}I)^{-1/2}\right\|_2^2\\ &= \left\|(T_x^{(2)}+d_x^{(2)}I)^{-1/2}T_x^{(1)}\right\|_2^2\\ &= \lambda_{\max}\left((T_x^{(2)}+d_x^{(2)}I)^{-1/2}T_x^{(1)}(T_x^{(1)})^*(T_x^{(2)}+d_x^{(2)}I)^{-1/2}\right)\\ &= \max_{w\neq 0}\left\{\frac{w^*(T_x^{(2)}+d_x^{(2)}I)^{-1/2}T_x^{(1)}(T_x^{(1)})^*(T_x^{(2)}+d_x^{(2)}I)^{-1/2}w}{w^*w}\right\}\\ &= \max_{w\neq 0}\left\{\frac{w^*T_x^{(1)}(T_x^{(1)})^*w}{w^*(T_x^{(2)}+d_x^{(2)}I)w}\right\}.\end{aligned}$$

By making use of Theorems 3.1 and 3.3 in [11], we know that for any $\epsilon>0$ there exist a positive semidefinite matrix R_x of fixed rank and a matrix E_x of small norm such that $\|E_x\|<d_x^{(2)}\epsilon$, and

$$T_x^{(1)}(T_x^{(1)})^*+R_x+E_x=T_x^{(3)},$$

where $T_x^{(3)}$ is the Toeplitz matrix generated by the positive function θ^2. We remark that the generating function of $T_x^{(1)}$ is $\imath\theta$ and $T_x^{(1)}$ is a skew-symmetric matrix. Because

$$\frac{w^*R_xw}{w^*(T_x^{(2)}+d_x^{(2)}I)w}\ge 0 \quad\text{and}\quad \left|\frac{w^*E_xw}{w^*(T_x^{(2)}+d_x^{(2)}I)w}\right|\le\epsilon \quad \forall w\neq 0,$$

it follows from the above matrix decomposition that

$$\max_{w\neq 0}\left\{\frac{w^*T_x^{(1)}(T_x^{(1)})^*w}{w^*(T_x^{(2)}+d_x^{(2)}I)w}\right\} < \max_{w\neq 0}\left\{\frac{w^*T_x^{(3)}w}{w^*(T_x^{(2)}+d_x^{(2)}I)w}\right\}+\epsilon.$$

Since ϵ can be arbitrarily small, it holds that

$$\begin{aligned}\max_{w\neq 0}\left\{\frac{w^*T_x^{(1)}(T_x^{(1)})^*w}{w^*(T_x^{(2)}+d_x^{(2)}I)w}\right\} &\le \max_{w\neq 0}\left\{\frac{w^*T_x^{(3)}w}{w^*(T_x^{(2)}+d_x^{(2)}I)w}\right\}\\ &< \max_{-\pi\le\theta\le\pi}\left\{\frac{\theta^2}{\theta^2+d_x^{(2)}}\right\}\\ &= \frac{\pi^2}{\pi^2+d_x^{(2)}}. \end{aligned}\tag{3.12}$$

Therefore,

$$\left\|T_x^{(1)}(T_x^{(2)}+d_x^{(2)}I)^{-1/2}\right\|_2 = \left\|(T_x^{(2)}+d_x^{(2)}I)^{-1/2}T_x^{(1)}\right\|_2 < \frac{\pi}{\sqrt{\pi^2+d_x^{(2)}}}.$$

Based upon (3.11) we immediately have

$$\begin{aligned}\left|\frac{v^*[(D_x^{(1)}T_x^{(1)}+T_x^{(1)}D_x^{(1)})\otimes Q_t]v}{v^*[(T_x^{(2)}+D_x^{(2)})\otimes Q_t]v}\right| &\le \frac{1}{\sqrt{d_x^{(2)}}}\cdot d_x^{(1)}\cdot\frac{2\pi}{\sqrt{\pi^2+d_x^{(2)}}}\\ &= \frac{2\pi d_x^{(1)}}{\sqrt{(\pi^2+d_x^{(2)})d_x^{(2)}}}\\ &\le \mu^{(1)}.\end{aligned}$$

This shows that (3.5) holds true.

Analogously to (3.11), for all $v\neq 0$ we can obtain

$$\begin{aligned}&\left|\frac{v^*[(D_x^{(1)}B_x^{(1)}+B_x^{(1)}D_x^{(1)})\otimes Q_t]v}{v^*[(B_x^{(2)}+D_x^{(2)})\otimes Q_t]v}\right|\\ &\quad\le \left\|(B_x^{(2)}+d_x^{(2)}I)^{-1/2}\right\|_2\cdot\left\|D_x^{(1)}\right\|_2\\ &\quad\quad\cdot\left[\left\|B_x^{(1)}(B_x^{(2)}+d_x^{(2)}I)^{-1/2}\right\|_2+\left\|(B_x^{(2)}+d_x^{(2)}I)^{-1/2}B_x^{(1)}\right\|_2\right].\end{aligned}\tag{3.13}$$

Here, we have applied the fact

$$\left\|(B_x^{(2)}+D_x^{(2)})^{-1/2}(B_x^{(2)}+d_x^{(2)}I)^{1/2}\right\|_2^2 = \left\|(B_x^{(2)}+d_x^{(2)}I)^{1/2}(B_x^{(2)}+D_x^{(2)})^{-1/2}\right\|_2^2 \le 1.$$

Now, we estimate the terms $\|(B_x^{(2)}+d_x^{(2)}I)^{-1/2}\|_2$, $\|B_x^{(1)}(B_x^{(2)}+d_x^{(2)}I)^{-1/2}\|_2$, and $\|(B_x^{(2)}+d_x^{(2)}I)^{-1/2}B_x^{(1)}\|_2$ involved in (3.13).

As the generating function of the Toeplitz matrix $B_x^{(2)}$ is $2-2\cos\theta$, we have

$$\begin{aligned}\left\|(B_x^{(2)}+d_x^{(2)}I)^{-1/2}\right\|_2^2 &= \lambda_{\max}\left((B_x^{(2)}+d_x^{(2)}I)^{-1}\right)\\ &= \max_{w\neq 0}\left\{\frac{w^*(B_x^{(2)}+d_x^{(2)}I)^{-1}w}{w^*w}\right\}\\ &< \max_{-\pi\le\theta\le\pi}\left\{\frac{1}{2(1-\cos\theta)+d_x^{(2)}}\right\}\\ &= \frac{1}{d_x^{(2)}}.\end{aligned}$$

Therefore,

$$\left\|(B_x^{(2)} + d_x^{(2)} I)^{-1/2}\right\|_2 < \frac{1}{\sqrt{d_x^{(2)}}}.$$

By making use of Theorem 3.1 in [11] again, we know that there exists a positive semidefinite matrix R_x of fixed rank such that

$$B_x^{(1)}(B_x^{(1)})^* + R_x = B_x^{(3)},$$

where $B_x^{(3)}$ is the Toeplitz matrix generated by the positive function $\sin^2\theta$. We remark that the generating function of $B_x^{(1)}$ is $\imath \sin\theta$ and $B_x^{(1)}$ is a skew-symmetric matrix. Because

$$\frac{w^* R_x w}{w^*(B_x^{(2)} + d_x^{(2)} I)w} \geq 0 \quad \forall w \neq 0,$$

it follows from the above matrix decomposition that

$$\begin{aligned}
&\left\|B_x^{(1)}(B_x^{(2)} + d_x^{(2)} I)^{-1/2}\right\|_2^2 \\
&\quad = \left\|(B_x^{(2)} + d_x^{(2)} I)^{-1/2} B_x^{(1)}\right\|_2^2 \\
&\quad = \lambda_{\max}\left((B_x^{(2)} + d_x^{(2)} I)^{-1/2} B_x^{(1)}(B_x^{(1)})^*(B_x^{(2)} + d_x^{(2)} I)^{-1/2}\right) \\
&\quad = \max_{w\neq 0}\left\{\frac{w^*(B_x^{(2)} + d_x^{(2)} I)^{-1/2} B_x^{(1)}(B_x^{(1)})^*(B_x^{(2)} + d_x^{(2)} I)^{-1/2} w}{w^* w}\right\} \\
&\quad = \max_{w\neq 0}\left\{\frac{w^* B_x^{(1)}(B_x^{(1)})^* w}{w^*(B_x^{(2)} + d_x^{(2)} I)w}\right\} \\
&\quad \leq \max_{w\neq 0}\left\{\frac{w^* B_x^{(3)} w}{w^*(B_x^{(2)} + d_x^{(2)} I)w}\right\} \\
&\quad < \max_{-\pi\leq\theta\leq\pi}\left\{\frac{\sin^2\theta}{2(1-\cos\theta) + d_x^{(2)}}\right\} \\
&\quad = 1 + \frac{d_x^{(2)}}{2} - \frac{1}{2}\sqrt{(d_x^{(2)} + 4) d_x^{(2)}} \\
&\quad = \frac{1}{4}\left(\sqrt{d_x^{(2)} + 4} - \sqrt{d_x^{(2)}}\right)^2. \qquad (3.14)
\end{aligned}$$

Therefore,

$$\left\|B_x^{(1)}(B_x^{(2)} + d_x^{(2)} I)^{-1/2}\right\|_2 = \left\|(B_x^{(2)} + d_x^{(2)} I)^{-1/2} B_x^{(1)}\right\|_2 < \frac{1}{2}\left(\sqrt{d_x^{(2)} + 4} - \sqrt{d_x^{(2)}}\right).$$

Based upon (3.13) we immediately have

$$\left|\frac{v^*[(D_x^{(1)}B_x^{(1)}+B_x^{(1)}D_x^{(1)})\otimes Q_t]v}{v^*[(B_x^{(2)}+D_x^{(2)})\otimes Q_t]v}\right| \le \frac{1}{\sqrt{d_x^{(2)}}}\cdot d_x^{(1)}\cdot\left(\sqrt{d_x^{(2)}+4}-\sqrt{d_x^{(2)}}\right)$$
$$= d_x^{(1)}\cdot\left(\sqrt{1+\frac{4}{d_x^{(2)}}}-1\right)$$
$$\le \mu^{(2)}.$$

This shows the validity of (3.6).

We remark that the last bound in (3.14) is obtained by using the maximum value of the one-variable function

$$\varphi(\theta)=\frac{\sin^2\theta}{2(1-\cos\theta)+d_x^{(2)}}$$

attained at the stationary point

$$\theta_*=\arccos\left(\frac{2+d_x^{(2)}-\sqrt{(d_x^{(2)})^2+4d_x^{(2)}}}{2}\right).$$

Now, we are going to prove (3.7)–(3.10). Analogously, for all $v\neq 0$, by straightforward computations we obtain

$$\left|\frac{v^*[Q_x\otimes(D_t^{(3)}T_t^{(1)}+T_t^{(1)}D_t^{(3)})]v}{v^*[Q_x\otimes D_t^{(4)}]v}\right|$$
$$\le \max_{v\neq 0}\left\{\left|\frac{\frac{1}{i}v^*[Q_x\otimes(D_t^{(3)}T_t^{(1)}+T_t^{(1)}D_t^{(3)})]v}{v^*[Q_x\otimes D_t^{(4)}]v}\right|\right\}$$
$$\le \left|\lambda_{\max}\left(\frac{1}{i}(D_t^{(4)})^{-\frac12}(D_t^{(3)}T_t^{(1)}+T_t^{(1)}D_t^{(3)})(D_t^{(4)})^{-\frac12}\right)\right|$$
$$\le \left\|(D_t^{(4)})^{-\frac12}(D_t^{(3)}T_t^{(1)}+T_t^{(1)}D_t^{(3)})(D_t^{(4)})^{-\frac12}\right\|_2$$
$$\le \left\|(D_t^{(4)})^{-\frac12}(d_t^{(2)}I)^{\frac12}\right\|_2\left\|(d_t^{(2)}I)^{-\frac12}\right\|_2\left\|D_t^{(3)}\right\|_2\left\|(d_t^{(2)}I)^{\frac12}(D_t^{(4)})^{-\frac12}\right\|_2$$
$$\cdot\left[\left\|T_t^{(1)}(d_t^{(2)}I)^{-\frac12}\right\|_2+\left\|(d_t^{(2)}I)^{-\frac12}T_t^{(1)}\right\|_2\right]. \tag{3.15}$$

It is straightforward that

$$\left\|(D_t^{(4)})^{-\frac12}(d_t^{(2)}I)^{\frac12}\right\|_2\le 1 \quad\text{and}\quad \left\|(d_t^{(2)}I)^{\frac12}(D_t^{(4)})^{-\frac12}\right\|_2\le 1 \tag{3.16}$$

hold true, and it follows from

$$\begin{aligned}\left\|T_t^{(1)}(d_t^{(2)}I)^{-\frac{1}{2}}\right\|_2^2 &= \left\|(d_t^{(2)}I)^{-\frac{1}{2}}T_t^{(1)}\right\|_2^2\\ &\le \max_{v\neq 0}\left\{\frac{v^*T_t^{(1)}(T_t^{(1)})^*v}{v^*(d_t^{(2)}I)v}\right\}\\ &\le \max_{-\pi\le\theta\le\pi}\left\{\frac{\theta^2}{d_t^{(2)}}\right\}\\ &= \frac{\pi^2}{d_t^{(2)}}\end{aligned}$$

that

$$\left\|T_t^{(1)}(d_t^{(2)}I)^{-\frac{1}{2}}\right\|_2 = \left\|(d_t^{(2)}I)^{-\frac{1}{2}}T_t^{(1)}\right\|_2 < \frac{\pi}{\sqrt{d_t^{(2)}}};$$

see (3.12). By substituting these bounds into (3.15) we know that (3.7) holds true.

Similar arguments can lead to the estimate

$$\left|\frac{v^*[(D_x^{(3)}T_x^{(1)}+T_x^{(1)}D_x^{(3)})\otimes(Q_t\Omega)]v}{v^*[D_x^{(4)}\otimes(Q_t\Omega)]v}\right| \le \frac{2\pi d_x^{(1)}}{d_x^{(2)}} \le \mu^{(1)},$$

which is exactly (3.9).

Moreover, it follows from (3.14) and (3.16) that

$$\begin{aligned}&\left|\frac{v^*[Q_x\otimes(D_t^{(3)}B_t^{(1)}+B_t^{(1)}D_t^{(3)})]v}{v^*[Q_x\otimes D_t^{(4)}]v}\right|\\ &\le \left\|(D_t^{(4)})^{-\frac{1}{2}}(d_t^{(2)}I)^{\frac{1}{2}}\right\|_2\left\|(d_t^{(2)}I)^{-\frac{1}{2}}\right\|_2\left\|D_t^{(3)}\right\|_2\left\|(d_t^{(2)}I)^{\frac{1}{2}}(D_t^{(4)})^{-\frac{1}{2}}\right\|_2\\ &\quad\cdot\left[\left\|B_t^{(1)}(d_t^{(2)}I)^{-\frac{1}{2}}\right\|_2+\left\|(d_t^{(2)}I)^{-\frac{1}{2}}B_t^{(1)}\right\|_2\right]\\ &\le \frac{1}{\sqrt{d_t^{(2)}}}\cdot d_t^{(1)}\cdot 2\cdot\max_{-\pi\le\theta\le\pi}\left\{\frac{|\sin\theta|}{\sqrt{d_t^{(2)}}}\right\}\\ &\le \frac{2d_t^{(1)}}{d_t^{(2)}}\\ &\le \mu^{(2)}\end{aligned}$$

and

$$\left|\frac{v^*[(D_x^{(3)}B_x^{(1)}+B_x^{(1)}D_x^{(3)})\otimes(Q_t\Omega)]v}{v^*[D_x^{(4)}\otimes(Q_t\Omega)]v}\right| \le \frac{2d_x^{(1)}}{d_x^{(2)}} \le \mu^{(2)}$$

hold true, which are exactly (3.8) and (3.10), respectively. □

Lemma 3.4 immediately implies the following bounds about the functions $f_A(v)$ and $f_M(v)$ defined in Theorem 3.2.

THEOREM 3.5. $D_z^{(i)}(i = 2, 4 \quad z \in \{x, t\}), Q_z(z \in \{x, t\})$ Ω $d_z^{(i)}(i = 1, 2$ $z \in \{x, t\})$ 3.4 $f_A(v)$ $f_M(v)$ 3.2

$$|f_A(v)| \le \mu^{(1)} \qquad |f_M(v)| \le \mu^{(2)}.$$

. Based on Lemmas 3.3 and 3.4, by straightforward computations we have

$$|f_A(v)| = \left|\frac{v^*\mathcal{S}(A)v}{v^*\mathcal{H}(A)v}\right| =$$

$$\left|\frac{v^*[\varepsilon(D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)}) \otimes Q_t + Q_x \otimes (D_t^{(3)}T_t^{(1)} + T_t^{(1)}D_t^{(3)}) + (D_x^{(3)}T_x^{(1)} + T_x^{(1)}D_x^{(3)}) \otimes (Q_t\Omega)]v}{v^*[\varepsilon(T_x^{(2)} + D_x^{(2)}) \otimes Q_t + Q_x \otimes D_t^{(4)} + D_x^{(4)} \otimes (Q_t\Omega)]v}\right|$$

$$\le \max_{v\neq 0}\left\{\left|\frac{v^*[\varepsilon(D_x^{(1)}T_x^{(1)} + T_x^{(1)}D_x^{(1)}) \otimes Q_t]v}{v^*[\varepsilon(T_x^{(2)} + D_x^{(2)}) \otimes Q_t]v}\right|, \left|\frac{v^*[Q_x \otimes (D_t^{(3)}T_t^{(1)} + T_t^{(1)}D_t^{(3)})]v}{v^*(Q_x \otimes D_t^{(4)})v}\right|,\right.$$

$$\left.\left|\frac{v^*[(D_x^{(3)}T_x^{(1)} + T_x^{(1)}D_x^{(3)}) \otimes (Q_t\Omega)]v}{v^*(D_x^{(4)} \otimes (Q_t\Omega))v}\right|\right\}$$

$$\le \mu^{(1)}$$

and, similarly,

$$|f_M(v)| = \left|\frac{v^*\mathcal{S}(M)v}{v^*\mathcal{H}(M)v}\right| \le \mu^{(2)}.$$

Here, we have used the inequality

$$\frac{\alpha_1 + \alpha_2 + \alpha_3}{\beta_1 + \beta_2 + \beta_3} \le \max_{1\le i\le 3}\left\{\frac{\alpha_i}{\beta_i}\right\},$$

with α_i and β_i, $i = 1, 2, 3$, being positive reals. □

By using Theorems 3.2 and 3.5, and Lemmas 3.3 and 3.4, we can straightforwardly obtain the main theorem of this paper.

THEOREM 3.6. $D_z^{(i)}(i = 2, 4 \quad z \in \{x, t\})$ $Q_z(z \in \{x, t\})$ Ω

$$\frac{1 - \mu^{(1)}\mu^{(2)}}{1 + (\mu^{(2)})^2} \le \mathrm{Re}(\lambda(M^{-1}A)) \le \frac{\pi^2(1 + \mu^{(1)}\mu^{(2)})}{4} \quad \mu^{(1)}\mu^{(2)} < 1,$$

$$-\frac{\pi^2(\mu^{(1)} + \mu^{(2)})}{4} \le \mathrm{Im}(\lambda(M^{-1}A)) \le \frac{\pi^2(\mu^{(1)} + \mu^{(2)})}{4}.$$

Based on Theorem 3.6, we can immediately obtain a theoretical estimate about the asymptotic convergence rate of the preconditioned GMRES method with the preconditioner M in (3.4) for solving the system of linear equations (3.2). Here, we should suitably scale the Burgers equation (1.3) and appropriately choose the weighting functions $\omega_x(x)$ and $\omega_t(t)$ and the conformal mappings $\phi_x(x)$ and $\phi_t(t)$ such that $\mu^{(1)}\mu^{(2)} < 1$. For details, we refer to [20, 7].

4. Numerical examples. In this section, we illustrate the effectiveness of the proposed preconditioner when it is used to precondition the linear subsystems involved in each step of the Newton or the fixed-point iteration for solving the system of nonlinear equations (1.1).

In our experiments, the initial guess is taken to be zero, and each iteration process is terminated when the current residual $r^{(j)}$ satisfies

$$\frac{\|r^{(j)}\|_2}{\|r^{(0)}\|_2} \leq 10^{-6}.$$

The GMRES method is applied to solve the preconditioned linear subsystems of the form

$$M^{-1}A\mathbf{z} = M^{-1}\mathbf{r},$$

which forms the inner iteration process for solving the linear subsystems involved in each step of the Newton or the fixed-point method. Here, the stopping criterion for the preconditioned GMRES is that the relative reduction on the norm of the residual is less than 10^{-6}. Besides, all codes are written in MATLAB 7.01, and all experiments are tested on a PC with 0.99G memory.

The following two examples of the Burgers equation (1.3) are used to examine the numerical performance of our new preconditioner M defined in (3.4):

(i) The Burgers equation

$$\begin{cases} \dfrac{\partial u}{\partial t}(x,t) + u(x,t)\dfrac{\partial u}{\partial x}(x,t) - \epsilon\dfrac{\partial^2 u}{\partial x^2}(x,t) & \\ \quad = e^{-\pi^2 t}\sin(\pi x) & \\ \qquad \cdot(1-\pi^2 t + \pi t^2 e^{-\pi^2 t}\cos(\pi x) + \epsilon\pi^2 t), & 0 < x < 1 \ \text{ and } \ t \geq 0, \\ u(0,t) = 0 \quad \text{and} \quad u(1,t) = 0, & t \geq 0, \\ u(x,0) = 0, & 0 \leq x \leq 1. \end{cases}$$

(ii) The Burgers equation

$$\begin{cases} \dfrac{\partial u}{\partial t}(x,t) + u(x,t)\dfrac{\partial u}{\partial x}(x,t) - \epsilon\dfrac{\partial^2 u}{\partial x^2}(x,t) & \\ \quad = e^{x-t}(1-t+t^2e^{x-t}-\epsilon t) & \\ \qquad -e^{-t}(1-t)(1-x+ex) & \\ \qquad -t^2e^{-2t}(e-1)(1-x+xe), & 0 < x < 1 \ \text{ and } \ t \geq 0, \\ u(0,t) = te^{-t} \quad \text{and} \quad u(1,t) = te^{1-t}, & t \geq 0, \\ u(x,0) = 0, & 0 \leq x \leq 1. \end{cases}$$

The conformal mappings are chosen as $\phi(z) = \ln(\frac{z}{1-z})$ and $\psi(z) = \ln(\sinh(z))$ so that their restrictions onto the real intervals $(0,1)$ and $(0,+\infty)$ are $\phi_x(x) := \phi(x) = \ln(\frac{x}{1-x})$ and $\phi_t(t) := \psi(t) = \ln(\sinh(t))$, which are used for the discretizations of the x and t variables, respectively. The weighting functions are chosen to be $\omega_x(x) = 1/\phi_x^{'}(x)$ and $\omega_t(t) = 1/\phi_t^{'}(t)$.

In the numerical tables, the symbol "I" means that no preconditioner is used when solving the linear subsystems involved in the nonlinear iterations, while "M" represents that the preconditioner M defined in (3.4) is used. We use "N" to denote the number of the Newton iteration steps, "F" the number of the fixed-point iteration steps, "G" the average number of GMRES iteration steps in each Newton or

fixed-point iteration, "CPU" the total computing times, "Se" the maximum absolute discretization error at the Sinc grid points, and "Ue" the maximum absolute discretization error on the corresponding uniform grid points, while we use "average Se" and "average Ue" to represent the average absolute errors at all the Sinc grid points and at all the uniform grid points, respectively. In addition, the symbol "$*$" is used to denote that the iteration does not satisfy the terminating criterion within 50 steps of the Newton or the fixed-point iteration, while "+" means that the inner iteration does not satisfy the GMRES terminating criterion within 1000 iteration steps.

With respect to different ϵ, Tables 4.1–4.6 list the numbers of iteration steps and the CPU times required for the convergence of the Newton iteration, and Tables 4.7–4.12 list those required for the convergence of the fixed-point iteration, respectively, when they are applied to solve the system of nonlinear equations (1.1) resulting from the Sinc–Galerkin discretization of example (i). Some errors for reflecting the accuracy of the computed solutions are also listed in these tables. From these tables, we can see that our new preconditioner can considerably improve the convergence properties of both iteration methods and greatly reduce the running times. Moreover, with increasing of the problem size m, the number of the Newton or the fixed-point iteration steps almost remains the same if the inner iteration solver GMRES is preconditioned by the new preconditioner. The GMRES cannot achieve the prescribed tolerance within 1000 iteration steps and, therefore, the Newton or the fixed-point iteration cannot achieve the prescribed tolerance within 50 iteration steps, if the inner iteration solver GMRES is employed without using a preconditioner. Therefore, the new preconditioning technique substantially improves the convergence behaviors of both Newton and fixed-point iterations and, consequently, leads to fast convergent methods for solving the Sinc–Galerkin nonlinear systems of the Burgers equations.

may be very slowly convergent or even divergent, while the matrices with preconditioning have tightly clustered eigenvalues and, thus, are well conditioned; as a result, the corresponding preconditioned GMRES method may converge quickly to the exact solutions of the subsystems of linear equations and, consequently, may lead to a fast convergent Newton or fixed-point method for solving the Sinc–Galerkin nonlinear systems of the Burgers equations.

In Figures 4.2, 4.4, and 4.6, we plot the exact and computed solutions of examples (i) and (ii) corresponding to the cases shown in the Figures 4.1, 4.3, and 4.5, respectively, where the computed solution is obtained by using the Newton or the fixed-point iteration method. Figures 4.2, 4.4, and 4.6 further show that our new methods can compute reasonably accurate results.

5. Concluding remarks. We have constructed a structured preconditioner that can efficiently improve the convergence property of the GMRES iteration employed to inexactly solve the subsystem of linear equations involved in each Newton or fixed-point iteration for solving the system of nonlinear equations resulting from the Sinc–Galerkin discretization of the Burgers equation. The bounds of the eigenvalues of the preconditioned matrix have been precisely estimated by making use of the generalized Bendixson theorem. Numerical experiments have shown the effectiveness of this new preconditioner.

EFFICIENT HIERARCHICAL APPROXIMATION OF HIGH-DIMENSIONAL OPTION PRICING PROBLEMS*

CHRISTOPH REISINGER† AND GABRIEL WITTUM‡

Abstract. A major challenge in computational finance is the pricing of options that depend on a large number of risk factors. Prominent examples are basket or index options where dozens or even hundreds of stocks constitute the underlying asset and determine the dimensionality of the corresponding degenerate parabolic equation. The objective of this article is to show how an efficient discretization can be achieved by hierarchical approximation as well as asymptotic expansions of the underlying continuous problem. The relation to a number of state-of-the-art methods is highlighted.

Key words. sparse grids, multigrid methods, option pricing, asymptotic expansions, dimension reduction

1. Introduction.

Financial options are an essential element of today's risk management. They give the holder the right (but not the obligation) to perform a specific transaction on a risky asset X (an equity, for instance) or a number of assets $\mathbf{X} = (X_1, \dots, X_n)^T$ at some point(s) or time span in the future for a price that is agreed upon now, the [illegible] price K.

This work focuses on the cases where either the asset can only be exercised at the expiry T ([illegible] option), which means the holder may then buy ([illegible]) or sell ([illegible]) the asset for the strike K, or the asset can be exercised at any time up to T ([illegible] option).

For a put on a claim g the price u of the option at expiry (the [illegible]) is clearly

$$u(\mathbf{X}, T) = (K - g(\mathbf{X}))_+ = \max(K - g(\mathbf{X}), 0),$$

and analogously for the call. At any point up to then the value of the option depends decisively on the stochastic nature of the process.

1.1. Model framework.

The most common models for the underlying assets fall into the class of [illegible]

$$\mathrm{d}X_i = \beta_i^X(\mathbf{X}, \mathbf{Y})\,\mathrm{d}t + \alpha_i^X(\mathbf{X}, \mathbf{Y})\,\mathrm{d}W_i^X, \tag{1}$$

with correlated [illegible] W_i^X, where $\mathbf{Y} = (Y_1, \dots, Y_m)^T$ is a set of parameters. Traditionally market parameters have been assumed constant, but time series data in many markets reveal that some characteristics can be captured appropriately only if they are themselves modeled as stochastic differential equations (SDEs):

$$\mathrm{d}Y_i = \beta_i^Y(\mathbf{X}, \mathbf{Y})\,\mathrm{d}t + \alpha_i^Y(\mathbf{X}, \mathbf{Y})\,\mathrm{d}W_i^Y.$$

‡Simulation in Technology Center, Heidelberg University, Im Neuenheimer Feld 368, 69120 Heidelberg, Germany (wittum@uni-hd.de).

Let us write $\mathbf{Z} = (\mathbf{X}, \mathbf{Y})$, $\boldsymbol{\alpha} = (\boldsymbol{\alpha}^X, \boldsymbol{\alpha}^Y)$, $\boldsymbol{\beta} = (\boldsymbol{\beta}^X, \boldsymbol{\beta}^Y)$, $\mathbf{W} = (\mathbf{W}^X, \mathbf{W}^Y)$ and denote by ρ_{ij}, $1 \le i, j \le d := n + m$, the correlation of these Wiener processes.

In many cases assets and parameters are bounded by positivity constraints (equities, exchange rates, etc.), and this can be guaranteed by conditions of the form

$$\boldsymbol{\beta} \cdot \mathbf{n} \le 0, \qquad \boldsymbol{\alpha} \cdot \mathbf{n} = 0 \tag{2}$$

on the boundary Γ of the positive quadrant $\mathbb{R}^d_+$ with outward normal $\mathbf{n}$ and sufficiently smooth coefficients ($\boldsymbol{\alpha} \cdot \mathbf{n}$ must be of order at least $1/2$ at the boundary).

If $m = 0$, that is, parameters are deterministic, the pay-off can be replicated by a dynamic trading strategy with the assets X_i and a money market account with risk-free instantaneous interest rate r (assumed constant or more generally modeled by one of the parameter processes). This has the consequence that the price of an option can be seen as the expectation of the pay-off under a unique so-called [illegible] measure, which turns the stock price process (1), discounted by the risk-free interest rate r, into a martingale. For details of this, see, for example, [7] or [16]. The corresponding Feynman–Kac PDE for the option price reads

$$\frac{\partial u}{\partial t} + \sum_{i,j=1}^{d} a_{ij}(\mathbf{Z}, t) \frac{\partial^2 u}{\partial Z_i \partial Z_j} + \sum_{i=1}^{d} b_i(\mathbf{Z}, t) \frac{\partial u}{\partial Z_i} + c(\mathbf{Z}, t) u = 0, \tag{3}$$

which is a linear advection-diffusion-reaction equation with coefficients

$$\begin{aligned} a_{ij}(\mathbf{Z}, t) &= \rho_{ij} \alpha_i(\mathbf{Z}, t) \alpha_j(\mathbf{Z}, t), \quad 1 \le i, j \le d, \\ c(\mathbf{Z}, t) &= -r. \end{aligned}$$

The advective term $\mathbf{b}(\mathbf{Z}, t)$ depends on the product-specific hedge that creates a risk-free investment (the change of measure). Examples will be given in the next section. Condition (2) on the boundary translates to

$$\mathbf{a}(\mathbf{Z}, t) \cdot \mathbf{n}(\mathbf{Z}) = 0 \quad \text{and} \quad \mathbf{b}(\mathbf{Z}, t) \cdot \mathbf{n}(\mathbf{Z}) \ge 0 \quad \text{for } \mathbf{Z} \in \Gamma \tag{4}$$

and guarantees uniqueness of the solution without boundary conditions [24]. Equation (3) is an antidiffusion equation that is solved backwards in time and is thus parabolic and well-posed.

Equations similar to (3) can be derived in the presence of stochastic parameters ($m \ne 0$), which are often not traded in the market themselves (like volatilities) and sometimes cannot be directly observed. To hedge the additional risk introduced by the stochastic components of $\mathbf{Y}$, options with different expiration dates have to be traded dynamically, and an ad hoc assumption on the market price of risk has to be made from practical considerations.

It has to be remarked that in practice it is often not feasible to trade options dynamically due to transaction costs (for pricing under transaction costs, see, e.g., [14] and the references therein). In the case of static positions in the option a perfect hedge is no longer possible, but instead the expected utility can be optimized and the option price is adjusted such that the buyer/seller is indifferent to such a deal. This gives rise to (nonlinear) Hamilton–Jacobi–Bellmann equations [6]. In the scope of this article we will restrict ourselves to the linear setting.

1.2. Examples.

1.2.1. FX option. We consider an option on the exchange rate X between a domestic and a foreign currency, which is driven by the short rates r_d ( ) and r_f ( ) in both markets according to

$$\mathrm{d}X = (r_d - r_f)X\,\mathrm{d}t + \sigma_X X\,\mathrm{d}W$$

with volatility σ_X. In practice typically a time- and state-dependent volatility surface is calibrated to quoted option prices with different maturities and strikes. For short maturities (typically under 3 years) interest rates may be assumed constant in good approximation and the following equation for u is obtained by standard arguments:

$$\frac{\partial u}{\partial t} + \frac{1}{2}\sigma_X^2 X^2 \frac{\partial^2 u}{\partial X^2} + (r_d - r_f)X\frac{\partial u}{\partial X} - r_d u = 0. \tag{5}$$

In the more interesting case of longer time horizons the spot rate dynamics are relevant. Commonly used models are of the type

$$\mathrm{d}r_i = \mu_i(r_i, t)\,\mathrm{d}t + \nu_i(r_i, t)\,\mathrm{d}W_i,$$

where $(i = d, f)$

$$\mu_i(r_i, t) = \kappa_i(\theta_i(t) - r_i), \tag{6}$$

$$\nu_i(r_i, t) = r_i^{\beta_i}\sigma_i(t) \tag{7}$$

with positive parameters κ_i, β_i and a time-dependent reversion level θ_i, which can be calibrated to the term structure of interest rates. The corresponding PDE reads $(\mathbf{Z} = (X, r_d, r_f))$

$$\frac{\partial u}{\partial t} + \frac{1}{2}\sum_{i,j=1}^{3}\nu_i\nu_j\rho_{ij}\frac{\partial^2 u}{\partial Z_i \partial Z_j} + \sum_{i=1}^{3}\mu_i\frac{\partial u}{\partial Z_i} + \rho_{31}\nu_3\nu_1\frac{\partial u}{\partial Z_3} - Z_2 u = 0, \tag{8}$$

where $\nu_1 = \sigma_X Z_1$ and ρ_{ij}, $1 \le i, j \le 3$, are again the correlations of the Wiener processes.

For $\beta_i \ge 1/2$ the interest rates stay nonnegative and the PDE is solved backwards on $\mathbb{R}^3_+$ from the terminal condition (put)

$$u(\mathbf{Z}, T) = (K - Z_1)_+ .$$

1.2.2. Equity basket. A classical high-dimensional application is a basket (linear combination) of d stocks, assumed to follow a geometric Brownian motion

$$\mathrm{d}S_i = \mu_i S_i\,\mathrm{d}t + \sigma_i S_i\,\mathrm{d}W_i,$$

as in [1], with Brownian motions W_i with correlation $\langle \mathrm{d}W_i, \mathrm{d}W_j\rangle = \rho_{ij}$. Denote by r again the constant risk-free interest rate. The price (the price that does not allow any instantaneous risk-free return) of a European option follows the

$$\frac{\partial u}{\partial t} = \mathcal{L}_{BS}u := -\frac{1}{2}\sum_{i,j=1}^{d}\sigma_i\sigma_j\rho_{ij}S_iS_j\frac{\partial^2 u}{\partial S_i \partial S_j} - r\sum_{i=1}^{d}S_i\frac{\partial u}{\partial S_i} + ru. \tag{9}$$

A put on the basket $\sum_i \mu_i S_i$ with positive weights μ_i has terminal value

$$u(\mathbf{S}, T) = g(\mathbf{S}) := \Big(K - \sum_{i=1}^{d} \mu_i S_i\Big)_+, \qquad \mathbf{S} \in \mathbb{R}^d_+.$$

American options, which can be exercised at any time up to T, solve the linear complementarity problem

$$\frac{\partial u}{\partial t} + \mathcal{L}_{BS} u \le 0, \tag{10}$$

$$u \ge g, \tag{11}$$

$$\left(\frac{\partial u}{\partial t} + \mathcal{L}_{BS} u\right) \cdot (u - g) = 0 \tag{12}$$

(see, e.g., [22]). A free boundary separates the exercise region and the continuation region of the option.

1.3. Curse of dimensionality, Monte Carlo, and sparse grids. The dimension of (3) can be very large, depending on the number d of stochastic components considered. The complexity of a standard grid-based approach to compute the option price with a desired accuracy ε is

$$W(\varepsilon, d) = \mathcal{O}(\varepsilon^{-d/p})$$

for a discretization of convergence order p and grows exponentially with the dimension d of the problem. This is referred to as the [illegible].

As a result of this the vast majority of problems in financial practice—and virtually all with dimension larger than three—are solved by Monte Carlo or related approaches [10]. The practical drawbacks of these methods, in addition to the somewhat disturbing fact that error bounds can only be specified in a probabilistic sense, are the following:

1. The convergence of the method, although it depends only very weakly on the dimension of the problem, is very slow. Typically if N is the number of simulated paths,

   $$\varepsilon = \mathcal{O}(N^{-\frac{1}{2}}), \tag{13}$$

   where ε has to be read as the standard deviation of the result.
2. Standard Monte Carlo methods have difficulties yielding accurate sensitivities of the solution with respect to the underlying stocks, which are important trading parameters (and directly given by the partial derivatives of the PDE solution). This is particularly the case if the option exhibits [illegible] characteristics, that is, the option ceases to exist if the stock crosses a certain [illegible]. Note that such features fit very naturally in the PDE context where only the boundary conditions need to be changed.
3. Early exercise features like those in the American case do not fit into the "forward" simulation paradigm, and the determination of the free boundary by regression of the value function [13] is very costly, whereas the modification of the PDE to a linear complementarity problem is usually straightforward.

In contrast, quasi-Monte Carlo methods are based on (deterministic) low-discrepancy point sequences and thus restricted to integration problems. They exhibit the same disadvantages 2 and 3 above, but improve the asymptotic complexity (13) to

$$\varepsilon = \mathcal{O}\left((\log N)^{d-1} N^{-1}\right)$$

with N points of the sequence, requiring higher smoothness (bounded variation) of the integrand [15].

Lattice rules exploit even higher regularity and yield error bounds

$$\varepsilon = \mathcal{O}\left((\log N)^{d-1} N^{-r}\right)$$

for integrands with r derivatives [15].

A further progression in this direction is the Smolyak construction [20] of quadrature rules in spaces with bounded mixed derivatives, which was more recently studied numerically in the context of financial derivatives [8] and extended to a dimension adaptive procedure in [9].

The approximation property of sparse grids was first employed for the solution of PDEs by finite elements in [23] and was subsequently studied extensively for model problems in [3, 4], where convergence of the form

$$\varepsilon = \mathcal{O}(|\log h|^{d-1} h^p) \tag{14}$$

for grid size h is shown for elements of order p. Recently sparse wavelet bases have been analyzed in the context of parabolic problems with nonsmooth initial data in [21].

A very attractive variant from a practical viewpoint, the combination technique [12] requires only solution of the original equation on conventional subspaces defined on Cartesian grids and a subsequent extrapolation step, but still retains the convergence order (14). This approach, analyzed in [18], is the method of choice here, and details are given in the following section.

2. Discretization on sparse grids.

2.1. The combination technique. Consider now the d-dimensional unit cube and the family of (anisotropic) grids with grid sizes $h_k = 2^{-i_k}$ in direction k, $i_k \in \mathbb{N}_0$. We write the vector of grid sizes as $\mathbf{h} = 2^{-\mathbf{i}}$ with $\mathbf{i} = (i_1, \ldots, i_d) \in \mathbb{N}_0^d$ and denote numerical solutions on these grids by $u_{\mathbf{h}}$. In the present context we will consider piecewise linear interpolants of finite difference solutions. This defines a hierarchy of grid solutions $U = (u_{2^{-\mathbf{i}}})_{\mathbf{i}\in\mathbb{N}_0^d}$, depicted in Figure 1 for the first levels in the two-dimensional case.

The sparse grid solution at level n is then defined as

$$u_n = \sum_{l=n}^{n+d-1} a_{l-n} \sum_{i_1+\cdots+i_d=l} U(\mathbf{i}) \tag{15}$$

with

$$a_i := (-1)^{d-1-i} \begin{pmatrix} d-1 \\ i \end{pmatrix}, \quad 0 \le i \le d-1. \tag{16}$$

The grid solutions involved in the inner sum of (15) all have $i_1 + \cdots + i_d = l$ and correspond to columns of grids in Figure 1. The number of elements in each of these grids is 2^l, regardless of the dimension, and the number of grid solutions in this sum is $\binom{l+d-1}{d-1}$ and grows like l^{d-1}. Therefore the dimension of the sparse grid space on level n is

$$N = \mathcal{O}\left(2^n n^{d-1}\right) = \mathcal{O}\left(h^{-1} |\log h|^{d-1}\right) \tag{17}$$

if $h = 2^{-n}$ is the finest grid size. This compares to $N = \mathcal{O}(2^{dn}) = \mathcal{O}(h^{-d})$ for the full grid.

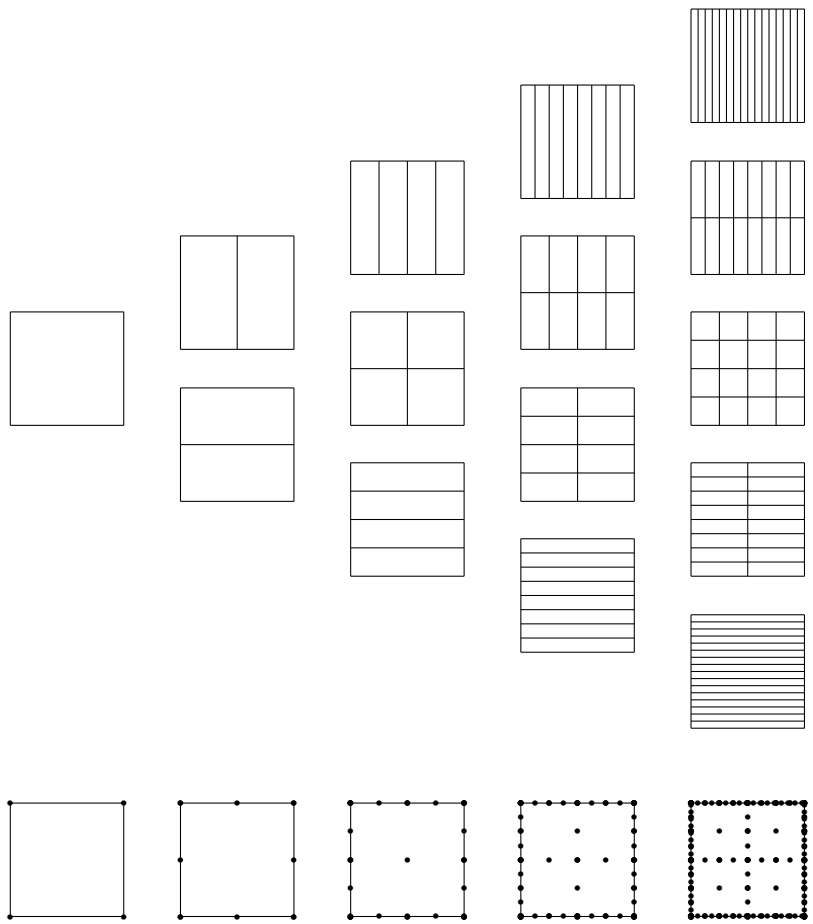

FIG. 1. *Two-dimensional sparse grid hierarchy for levels $n = 0, 1, \ldots, 4$. The grids on level n are obtained by bisection from level $n-1$ and all have 2^n elements. The number of grids on this level is $n+1$. In the bottom the degrees of freedom are shown for a vertex centered scheme.*

This approach has two crucial advantages over a conventional grid-based method: First, the asymptotic complexity of the discretized problem is reduced substantially to the complexity of a one-dimensional problem (up to polynomial factors). Thus the curse of dimensionality can be dampened to some extent. Second, the discrete system of equations decouples into much smaller conventional problems on tensor product grids, which can be solved efficiently in parallel and then superimposed using (15).

2.2. Discretization error. It remains to analyze how the reduction of the approximation space affects the convergence of the approximations. The extrapolation character of the combination technique necessitates a detailed analysis of the discretization error on the grids involved. It was already understood in [12] that for the numerical approximation $u_{\mathbf{h}}$ from a second order method on structured grid with mesh sizes $h_1, \ldots, h_d$, expansions of the form

$$u - u_{\mathbf{h}} = \sum_{m=1}^{d} \sum_{\substack{\{j_1, \ldots, j_m\} \\ \subset \{1, \ldots, d\}}} h_{j_1}^2 \cdot \ldots \cdot h_{j_m}^2 \cdot \gamma_{j_1, \ldots, j_m}(.; h_{j_1}, \ldots, h_{j_m}) \tag{18}$$

are crucial for second order convergence on the sparse grid. Such a representation with pointwise bounds $|\gamma_{j_1,\ldots,j_m}| \leq K$ is found for the two-dimensional Poisson equation in [5] and more generally for elliptic and parabolic equations in higher dimensions in [18].

The essential principle of the extrapolation is that all lower order terms cancel out in the combination formula (15) and only the highest order terms $h_1^2 \cdot \ldots \cdot h_d^2 = 4^{-n}$ remain. Taking advantage of this cancellation mechanism, Griebel, Schneider, and Zenger derive in [12] from (18) a pointwise error estimate for the three-dimensional case

$$|u - u_n| \leq K 4^{-n} \left(1 + \frac{65}{32}n + \frac{25}{32}n^2\right).$$

In [18] the following result for the general case is shown:

$$|u - u_n| \leq \frac{2K}{(d-1)!}\left(\frac{5}{2}\right)^{d-1}(n + 2(d-1))^{d-1}4^{-n}; \tag{19}$$

in fact the asymptotic behavior is

$$u - u_n = \gamma_0 \left(\frac{3}{4}\right)^{d-1} \frac{n^{d-1}}{(d-1)!}4^{-n} + \mathcal{O}(n^{d-2}4^{-n}). \tag{20}$$

For parabolic problems, it is shown in [18] that $\gamma_0 := \gamma_{1,\ldots,d}(.; 0, \ldots, 0) = 0$ depends on certain mixed derivatives of the solution and the magnitude of the error therefore depends on their behavior for high dimensions.

In particular, the case $\gamma_0 = 0$ indicates a lower superposition dimension of the solution—we shall return to this point later.

2.3. Numerical examples. We now investigate in detail the performance of sparse grids for important practical examples that arose out of the project "Analytical Methods and Efficient Numerical Algorithms for Financial Derivatives" with the Dresdner Bank AG.[1]

The examples involve equity and exchange rate derivatives and appear to be diffusion dominant with grid Péclet numbers smaller than 2 on all Cartesian grids such that central finite differences can be used. Sufficiently many time steps of the fractional-step-θ scheme are performed such that the time discretization error is negligible. This scheme, which was first introduced in [11] and for each time step δt consists of three substeps of the standard θ-scheme with step sizes $\tau_1 = (\sqrt{2}-1)\delta t$, $\tau_2 = \tau_3 = (1-\sqrt{2}/2)\delta t$ and parameters $\theta_1 = \sqrt{2}-1$, $\theta_2 = \theta_3 = 2-\sqrt{2}$, is second order accurate like the Crank–Nicolson scheme, but has more favorable stability properties (is strongly A-stable). The linear systems in each time step are solved with sufficient accuracy by multigrid techniques as outlined in section 4.1.

2.3.1. FX option. We specify model (8) further by choosing the Hull–White model for the interest rate dynamics ($\beta_i = 0$ in (7)), and for simplicity we assume that the processes are uncorrelated. The equation becomes

$$\frac{\partial u}{\partial t} + \frac{1}{2}\sigma_X^2 X^2 \frac{\partial^2 u}{\partial X^2} + \frac{1}{2}\sum_{i=d,f}\sigma_{r_i}^2 \frac{\partial^2 u}{\partial {r_i}^2} + (r_d - r_f)X\frac{\partial u}{\partial X} + \sum_{i=d,f}\kappa_i(\theta_i - r_i)\frac{\partial u}{\partial r_i} - r_d u = 0.$$

[1]The authors would like to thank Jürgen Linde for many discussions on appropriate models and for providing the data used here.

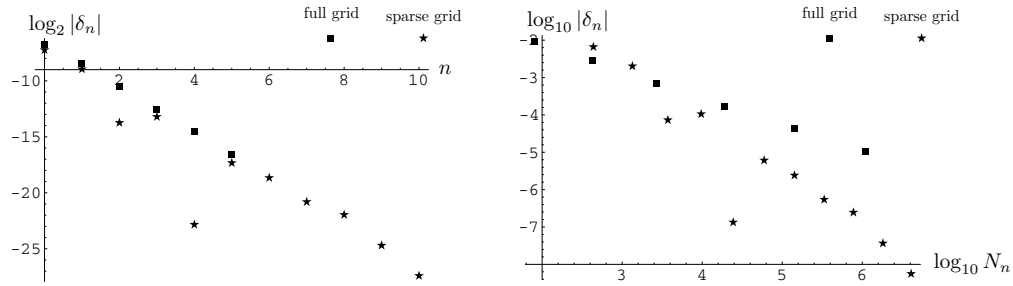

FIG. 2. *Left: Pointwise difference δ_n between levels n and $n+1$ for full and sparse grids. Regression of the curve $\log_2 |\delta_n| \approx -pn + q \log_2 n$ yields $p = 1$, $q = -3.8$, instead of the theoretically expected $p = 2$, $q = d - 1 = 2$. However, if the logarithmic term (which is difficult to estimate) is neglected, one obtains $p = 1.81$, and even $p = 1.99$ if only the last 6 values are used for the regression. Right: The same data, now shown versus the number of degrees of freedom N_n. Here the full grid data have slope $-2/3$ due to the second order convergence in three dimensions, whereas the sparse grid data still show slope -2. Hence the sparse grid method behaves like a sixth order method on the full grid.*

The other parameters are set to $\theta_i = 0.045$, $\kappa_i = 0.5$, $\sigma_X = \sigma_d = \sigma_f = 0.15$. The interest rates fluctuate around the constant level θ_i (Vasicec model); they are not bounded and become negative with (small, but) positive probability in this commonly used model. The domain is truncated to $[0, 4K] \times [0, 2\theta_d] \times [0, 2\theta_f]$, where $K = 0.25$ is the strike price. For $X = 0$ natural boundary conditions hold (note that the relevant coefficients vanish) for $X \to \infty$ $u \to 0$, and thus we set $u = 0$ for $X = 4K$, which is almost 20 standard deviations away from the strike. For the other boundaries homogeneous Neumann conditions are set.

We look at the pointwise convergence of the price of a European put with maturity $T = 1$ year, evaluated at the spot rates $X(0) = 0.9$, $r_d(0) = r_f(0) = 0.05$ (e.g., EUR/USD), which is the practically interesting measure of accuracy. Two refinement strategies, a full refinement with bisection in all directions and a sparse grid hierarchy, are compared. We start from a coarse grid that has four elements in the X direction, such that the piecewise linear initial condition with a kink at the strike is captured exactly on all grids. The difference δ_n between the solution on subsequent refinement levels of the sparse and the full grid is plotted in Figure 2. On the same levels n the errors almost coincide asymptotically, but the sparse grid can be refined much further in practice due to the reduced number of nodes. Hence if the error is plotted versus the number of degrees of freedom (right), the superior complexity of the sparse grid becomes apparent.

Figure 3 (left) shows the nodes of the sparse grid on an intermediate level. The density of nodes of a full grid on the same level can be seen from the nodes at the boundary edges.

We also solve the 1-factor model (5) where the interest rates are assumed constant at $r_d(0) = 0.05$, $r_f(0) = 0.05$ over the life span of the option, and compare in Figure 3 (right) the solution to the one on the full 3-factor model evaluated at the line $(x, r_d(0) = 0.05, r_f(0) = 0.05)$, $x \in [0, 1]$ (the coordinates have been scaled to the unit cube; the strike lies at 0.25). The deviation in the interesting range is significant and stresses the importance of including the interest rate dynamics.

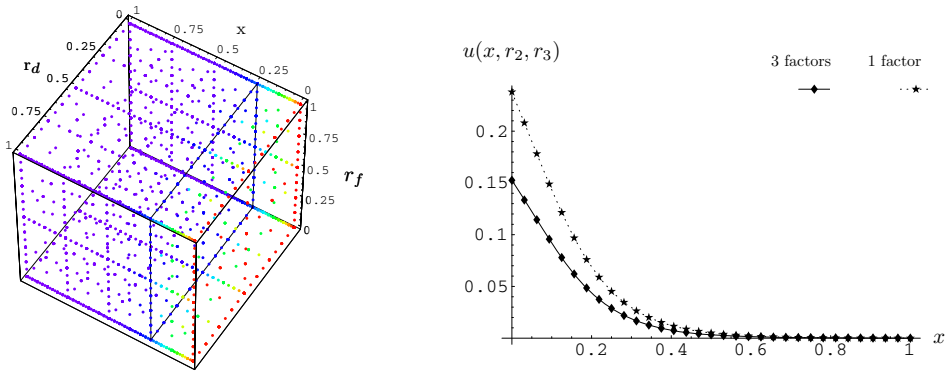

FIG. 3. *Left: Sparse grid for the* 3*-factor model with* 3726 *nodes (colored with the solution). Right: Comparison of the solution for fixed* r_i *with the* 1*-factor model.*

2.3.2. Basket option. In the rest of the paper we will be concerned with higher-dimensional applications, where no reference solutions on full grids exist. We focus on an option on a basket consisting of five assets, which is specified in Table 1.

TABLE 1
Basket of five equities with volatilities σ_i *and correlations* ρ_{ij}*, which have been estimated from historical time series. The weights* μ_i *are chosen as in the DAX.*

Equity	i	μ_i	σ_i	ρ_{ij}				
Deutsche Bank	1	38.1	0.518	1.00	0.79	0.82	0.91	0.84
Hypo-Vereinsbank	2	6.5	0.648	0.79	1.00	0.73	0.80	0.76
Commerzbank	3	5.7	0.623	0.82	0.73	1.00	0.77	0.72
Allianz	4	27.0	0.570	0.91	0.80	0.77	1.00	0.90
Münchner Rück	5	22.7	0.530	0.84	0.76	0.72	0.90	1.00

We next observe that the Black–Scholes equation for the put

$$\frac{\partial u}{\partial t} + \frac{1}{2}\sum_{i,j=1}^{d} \sigma_i\sigma_j\rho_{ij}S_iS_j\frac{\partial^2 u}{\partial S_i\partial S_j} + r\sum_{i=1}^{d} S_i\frac{\partial u}{\partial S_i} - ru = 0, \quad (\mathbf{S},t) \in \mathbb{R}^d_+ \times (0,T),$$

$$u(\mathbf{S},T) = \Big(K - \sum_{i=1}^{d}\mu_i S_i\Big)_+, \quad \mathbf{S} \in \mathbb{R}^d_+,$$

admits a transformation to the heat equation, which is composed of a change to logarithmic coordinates $\log \mathbf{S}$, a rotation with the eigenvectors $\mathbf{Q} = (\mathbf{q}_1, \ldots, \mathbf{q}_d)$ of the covariance matrix, a translation to eliminate the drift,

$$\mathbf{x} = \mathbf{Q}\ln\mathbf{S} - \mathbf{b}t,$$

where $b_i = \sum_{j=1}^{d} q_{ij}(r - 1/2\sigma_j^2)$, and a reversion of the time axis $t \to T - t$. This results in

$$\frac{\partial u}{\partial t} - \frac{1}{2}\sum_{i=1}^{d}\lambda_i\frac{\partial^2 u}{\partial {x_i}^2} + ru = 0, \quad (\mathbf{x},t) \in \mathbb{R}^d \times (0,T), \tag{21}$$

$$u(\mathbf{x},0) = \Big(K - \sum_{i=1}^{d}\mu_i e^{\sum_{j=1}^{d} q_{ji}x_j}\Big)_+, \quad \mathbf{x} \in \mathbb{R}^d, \tag{22}$$

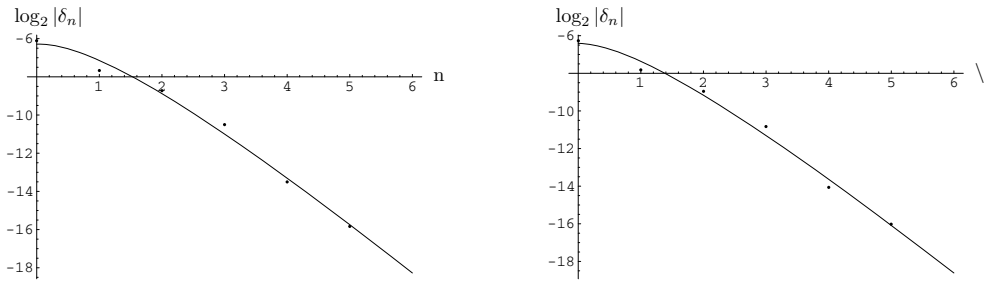

FIG. 4. *Left: Pointwise difference δ_n between the spot value on refinement levels n for the European 5 asset basket option. The asymptotic curve $-pn + q \log n$ was estimated by regression, where $p = 2.085$, $q = 3.115$ correspond well with the theoretical $p = 2$, $q = d - 1 = 4$. Right: The same analysis for the American put shows almost identical results with $p = 2.066$, $q = 2.915$. In both cases the option was evaluated at-the-money, that is, with the spot initially at the exercise boundary, with maturity $T = 1$ year.*

with the spectrum $\boldsymbol{\lambda}$ of the covariance matrix. The linear reaction term can be eliminated by introducing a discounting factor e^{-rt}. The domain in the new coordinates has to be localized, which is usually done by introducing upper bounds for the coordinates and setting asymptotic values. Instead we use a transformation

$$x_i \to \frac{1}{\pi} \arctan L x_i + \frac{1}{2}$$

of $\mathbb{R}^d$ to the unit cube ($L > 0$). Due to the nature of the transformation, the diffusion vanishes over the boundaries and no artificial conditions need to be set (see section 1.1), which would introduce additional errors that need to be controlled. Along the boundary faces the equation reduces naturally to a lower-dimensional one.

The convergence for the sparse grid combination technique, again with central differences, is shown in Figure 4. The number of unknowns on the finest grid is 372 909 780, which have been computed in parallel on 200 processors (see section 4.2).

The same numerical convergence analysis was performed for the American option, where the corresponding linear complementarity problem was solved by the techniques described in section 4.1. Despite the reduced regularity due to the presence of the free boundary, no deterioration of the convergence can be observed practically.

2.3.3. Considerations about higher dimensions. As seen in previous sections, the theoretically predicted convergence was recovered well even in cases lacking the required smoothness. In view of the asymptotic formula (17) it appears that given a certain refinement level n, the number of degrees of freedom only grows very weakly with the dimensionality. At the same time, in (19) the error only seems to deteriorate very weakly with increasing d, which is confirmed by the numerical results. Equation (20) even suggests that the prefactor goes down with increasing d. However, this asymptotic expansion is only a good approximation for $n \gg d$, and from Stirling's formula one sees that the prefactor actually grows like $(5e)^d/\sqrt{d}$.

Moreover, nothing has been said so far about the d-dependence of the "constant" K in (19), which depends crucially on higher mixed derivatives as derived in [18]. We return to this question to some extent in the context of dimension reduction techniques later.

Regarding the complexity of the method, although the total number of elements only increases asymptotically by a factor of two from one refinement level to the

next (regardless of the dimension!), this is again an asymptotic statement and the prefactors in (17) blow up with d as well.

To estimate the highest dimensions that can be handled, we consider the coarsest possible sparse grids at dimension d. In the combination technique d levels of grids are combined and it is only on level $d+1$ that the first inner point arises, yielding a grid of 3^d nodes. In terms of nodes this is in fact the smallest among the ν_d grids on that level, the largest grid having $m_d = 2^{d-1} \cdot \left(2^d + 1\right)$ nodes. A rough estimation shows that already in eight dimensions the coarsest reasonable sparse grid yields about 200 million unknowns, and in fact this was the highest dimension where this coarsest sparse grid fit into the main memory of the HELICS cluster, where the computations were performed (see section 4.2). It may be remarked that for the computations not all grids need be kept in memory simultaneously; however, it is clear that the computation time also increases proportionally. Further, the number of nonzero matrix entries in the discretized systems increases with d as well.

The above consideration also implies for Dirichlet problems that on levels lower than d the solution is interpolated only from the boundary data. Nevertheless in several cases good approximation may be achieved on much coarser levels and [21] reports relative errors below 5% in up to 20 dimensions for parabolic problems with sparse wavelets of only level $n = 5$. It has to be kept in mind that such results are not evidence for asymptotic convergence, but rather indicate an approximate lower-dimensional structure of the solution. In the following section we investigate such behavior theoretically and derive from a principal component analysis of typical financial data an approximation of the problem on a much smaller subspace of the sparse grid space.

3. Asymptotic expansions. To attribute the error components to the different dimensions we reconsider the error expansion

$$u - u_{\mathbf{h}} = \sum_{m=1}^{d} \sum_{\substack{\{j_1,\ldots,j_m\} \\ \subset \{1,\ldots,d\}}} h_{j_1}^2 \cdot \ldots \cdot h_{j_m}^2 \cdot \gamma_{j_1,\ldots,j_m}(.; h_{j_1}, \ldots, h_{j_m}). \tag{23}$$

Not only does (23) express the smoothness of the solution in terms of a multivariate Taylor expansion, but at the same time it decomposes the error into terms corresponding to lower-dimensional subspaces.

An obvious consequence is that if the solution is captured exactly in direction k, all terms containing h_k drop out and the expression reduces to a lower-dimensional one. In particular it is straightforward to reduce the problem if u has a representation of the form

$$u(\mathbf{x}, t) = u^{(m)}(x_{i_1}, \ldots, x_{i_m}, t), \tag{24}$$

and in that case u is said to have [illegible] m. Likewise, if u has a representation of the form

$$u(\mathbf{x}, t) = \sum_{\substack{\{i_1,\ldots,i_m\} \\ \subset \{1,\ldots,d\}}} u^{(i_1,\ldots,i_m)}(x_{i_1}, \ldots, x_{i_m}, t), \tag{25}$$

i.e., u has [illegible] m, again all terms containing more than m factors drop out of (23) and only m-dimensional problems need to be computed. We will now show how a representation of this sort can be obtained approximately for diffusion problems.

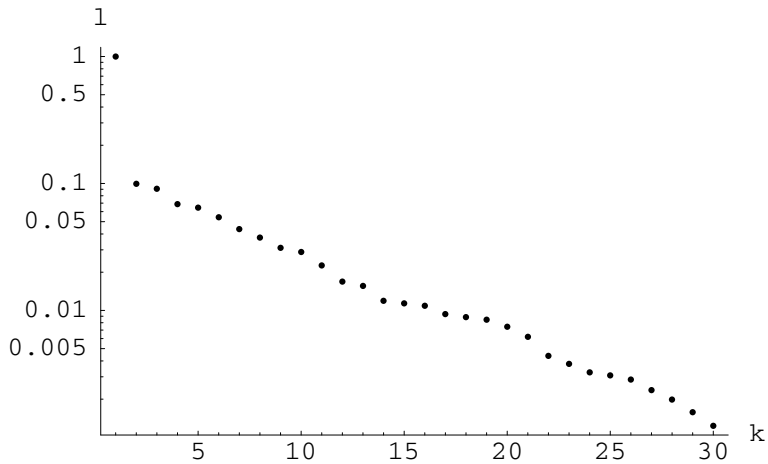

FIG. 5. *Ordered spectrum* $\{\lambda_k\}$ *of the covariance matrix of the* 30 *DAX assets from January* 16, 2003. *The volatilities* $\sigma_t = \sqrt{\frac{1}{T}\sum_{k=0}^{T-1} \varepsilon_{t-k}^2}$ *and correlations are estimated from the daily log-returns* ε_t *over a period of* $T = 250$ *days. The largest eigenvalue was scaled to* 1.

3.1. Data analysis. The geometric Brownian motion for the stocks

$$\mathrm{d}S_i/S_i = \mu_i \,\mathrm{d}t + \sigma_i \,\mathrm{d}W_i$$

is characterized by the covariance matrix of the Wiener process. The following discussion, illustrated by data from the German stock index DAX, is representative for many index and basket products and can be adapted for cases involving LIBOR rates or other correlated assets. In practice the high-dimensional driving process is often approximated by a small number of factors, for instance, in the case of equity indices by a single geometric Brownian motion, describing the movement of the index as a whole with an effective [illegible]. Often, particularly if the number of factors is moderate and they have nonnegligible idiosyncratic components, the deviation in the price is significant and such a procedure is inconsistent with the pricing of derivatives on single assets.

To allow for corrections (and to estimate the error) we study the spectrum $\boldsymbol{\lambda}$ of the covariance matrix and express the dependence of the solution on the vector $\boldsymbol{\lambda}$ of eigenvalues explicitly by $u(\boldsymbol{\lambda}, \mathbf{x}, t)$. For the DAX the spectrum is shown in Figure 5. A gap is observed after the first dominating eigenvalue that corresponds to the movement of the "market" itself. Note that in this example all correlations are positive so from Perron and Frobenius all entries of the first eigenvector are also positive.

The numerical approximations to the DAX options will be compared with results from Monte Carlo simulations.[2] The price found from sufficiently many ($N = 40000000$) Monte Carlo runs (see Table 2) for a European put option on the DAX with $T = 1$ (year), interest rate $r = 0.05$, and $K = 1$ [illegible] is

$$u(\mathbf{S}_0, 0) \approx 0.135323$$

with four significant digits.

[2]Thanks to Jürgen Schumacher from the Institute for Computer Science, Bonn University, for performing the simulations.

TABLE 2
Convergence of the Monte Carlo result u_N for a put on the DAX with N simulations, requiring CPU time t. The standard deviation of the result is $\sigma(u_N) \sim 1/\sqrt{N}$.

N	10^5	10^6	10^7	$2 \cdot 10^7$	$4 \cdot 10^7$
u_N	0.135083	0.135251	0.135343	0.135372	0.135323
$\sigma(u_N)$	5.36 e-4	1.69 e-4	5.36 e-5	3.79 e-5	2.68 e-5
t [sec]	7.7	76.9	768	1537	—

To assess the approximation quality in more detail we also study the five-factor basket already introduced in Table 1. This example was chosen because it is computationally fully tractable, and very accurate sparse grid solutions can be given. At the same time it shows the same characteristic features as higher-dimensional examples. There the spectrum is

$$\{1.409, 0.113, 0.101, 0.0388, 0.0213\},$$

and the eigenvector corresponding to the largest eigenvalue is

$$(0.41185, 0.49201, 0.46551, 0.45490, 0.40580)$$

and has (again positive) entries of similar magnitude. The price of a put on this subbasket (with the same other data) is

$$u(\mathbf{S}_0, 0) \approx 0.175866.$$

3.2. Principal component analysis. In (21) the Black–Scholes problem was expressed in terms of the eigensystem of the covariance matrix. This equation is now approximated by lower-dimensional ones by truncating the parameter vector $\boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_d)$ to $\boldsymbol{\lambda}^{(n)}$ with

$$\lambda_i^{(n)} := \begin{cases} \lambda_i, & 1 \le i \le n, \\ 0 & \text{else.} \end{cases} \tag{26}$$

The corresponding solution

$$u^{(n)}(\mathbf{x}, t) := u(\mathbf{x}, t, \boldsymbol{\lambda}^{(n)}) \tag{27}$$

solves

$$\frac{\partial u}{\partial t} = \frac{1}{2} \sum_{i=1}^{n} \lambda_i \frac{\partial^2 u}{\partial {x_i}^2} - ru, \quad (\mathbf{x}, t) \in \mathbb{R}^n \times (0, T), \tag{28}$$

$$u(x_1, \dots, x_n, 0) = \left(K - \sum_{i=1}^{d} \tilde{\mu}_i \mathrm{e}^{\sum_{j \le n} q_{ji} x_j} \right)_+, \quad \mathbf{x} \in \mathbb{R}^n. \tag{29}$$

Here $\tilde{\mu}_i = \mu_i \exp(\sum_{n<j\le d} q_{ji} x_j)$.

Note that if the solution is required only at a specific point $\mathbf{x}_0$ (in our context the option price is meaningful only at the current stock price $\mathbf{S}_0$), $x_j = x_j(\mathbf{S}_0, t)$ are kept fixed for $j > n$. It is sufficient to solve the PDE at an n-dimensional plane through $\mathbf{x}_0$. Table 3 shows the corresponding results for the five-factor basket which have been obtained with sufficient accuracy on sparse grids.

Note that approximations (27) do not indicate any truncation dimension in the sense of (24), because the solution is parameterized by the point $\mathbf{z}_0$. However, if we are interested in the solution at $\mathbf{z}_0$ alone, the consequences for the computation are the same.

TABLE 3
Approximations of dimension $n = 1, \dots, 4$ to the five-factor basket as in (27).

n	1	2	3	4	5
$u(\mathbf{S}_0, T)$	0.1806	0.1796	0.1777	0.1764	0.1758
rel. error	2.7 %	2.2 %	1.1 %	0.38 %	—

3.3. Asymptotic expansion. The results of the previous section show that additional components do not significantly improve the result, because the decay in the spectrum is rather slow. For problems of higher dimension this will not result in a reasonable approach, for many components will be required for reasonable accuracy and a sparse grid approximation would be practically impossible. We conclude that the smaller contributions cannot be entirely neglected, but possibly can be approximated linearly as

$$u(\mathbf{x}, t, \boldsymbol{\lambda}) = u^{(1)}(\mathbf{x}, t) + \sum_{j=2}^{d} \lambda_j \left.\frac{\partial u}{\partial \lambda_j}(\mathbf{x}, t, \boldsymbol{\lambda})\right|_{\boldsymbol{\lambda}=\boldsymbol{\lambda}^{(1)}} + \mathcal{O}\left(\|\boldsymbol{\lambda} - \boldsymbol{\lambda}^{(1)}\|^2\right) \tag{30}$$

with $\boldsymbol{\lambda}^{(1)}$ as in (26). This requires differentiability of the solution with respect to λ_j for $j > 1$ in $\boldsymbol{\lambda} = \boldsymbol{\lambda}^{(1)}$, which can be shown for sufficiently regular pay-offs. In the case of the basket option this means that the kink in the pay-off is not aligned with the principal component [17]. In fact in the Black–Scholes case the directional derivatives $\frac{\partial u}{\partial \lambda_j}$ can be explicitly expressed via Green's function of the heat equation.

Here we follow a more general approach and substitute a finite difference

$$\left.\frac{\partial u}{\partial \lambda_j}(\mathbf{x}, t, \boldsymbol{\lambda})\right|_{\boldsymbol{\lambda}=\boldsymbol{\lambda}^{(j)}} = \frac{u^{(1,j)}(\mathbf{x}, t) - u^{(1)}(\mathbf{x}, t)}{\lambda_j} + \mathcal{O}(\lambda_j^2),$$

where

$$u^{(1,j)}(\mathbf{x}, t) = u(\mathbf{x}, t, \boldsymbol{\lambda}^{(1,j)}) \quad \text{with}$$
$$\lambda_i^{(1,j)} = \begin{cases} \lambda_i, & i = 1 \vee i = j, \\ 0 & \text{else} \end{cases}$$

can be computed by solving a two-dimensional problem that results from a perturbation of the one-dimensional equation for $u^{(1)}$ by λ_j. Substitution in (30) yields

$$u(\mathbf{x}, t) = u^{(1)}(\mathbf{x}, t) + \sum_{j=2}^{d} \left(u^{(1,j)}(\mathbf{x}, t) - u^{(1)}(\mathbf{x}, t)\right) + \mathcal{O}\left(\|\boldsymbol{\lambda} - \boldsymbol{\lambda}^{(1)}\|^2\right). \tag{31}$$

The crucial point is that the value $u(\mathbf{x}_0, t)$ that is the solution of the full d-dimensional equation can be expressed up to second order errors in λ_j $(j > 1)$ by the solution of one- and two-dimensional equations.

Application to the five-dimensional basket gives the results in Table 4, where the corrections to the one-dimensional approximation are compiled. The resulting approximation for $u(\mathbf{x}_0, t)$ is 0.175972 with an absolute error of 0.000106, i.e., 0.06%. For the full DAX the result is 0.135393 with comparable error 0.000073, i.e., 0.06%.

Note that even for the thirty-dimensional DAX only one one-dimensional and twenty-nine two-dimensional equations need to be solved. This number increases

TABLE 4
Corrections to the one-dimensional approximation $u^{(1)}$ according to (31).

k	2	3	4	5
$u^{(1,k)}$	0.179264	0.180095	0.178896	0.179344
$u^{(1,k)} - u^{(1)}$	-1.3810^{-3}	-5.5210^{-4}	-1.7510^{-3}	-1.0110^{-3}

linearly in d. The computational cost, however, increases superlinearly due to the evaluation of the transformation which is hidden in the initial condition and from the coordinate rotation yields an order d^2. Hence the total complexity is asymptotically $\mathcal{O}(d^3)$, which is not visible for low dimensions where the cost is dominated by the actual solution algorithm (solution of the linear systems in each time step) and not the transformation. Consequently even problems with hundreds of dimensions can be solved very quickly and accurately.

Finally it can be observed that the representation (31) is a special case of a hierarchical grid-based approach where the solution is assumed constant in all but two directions and is effectively represented by a single element in these directions. This can be the basis for a [illegible] procedure, which automatically detects lower-dimensional structures of this type by estimation of the hierarchical surplus.

4. Implementation issues. In connection with the reduction of the computational complexity it seems worthwhile pointing out a few key ingredients for the fast and robust solution of the implicit equations and an efficient implementation of the presented schemes. To fully benefit from the optimal approximation results and inherent parallelism, it is essential that the discrete systems are solved robustly in linear complexity and that a reasonable load balancing algorithm can be devised.

4.1. Multigrid. The main characteristics that arise in the discrete systems are related to the anisotropy of the grids and equations. In addition to the notion of grid size independent convergence rates over a specific refinement path, it is crucial here that these rates are robust with respect to the anisotropic refinements. In the transformed system (21) additional anisotropies of similar type enter through the diffusion coefficients and both effects can be dealt with by semicoarsening. In most practical cases where no transformation to constant coefficients exists, and especially if the diffusion operator comes from a bounded process or stretched grids and transformations to finite domains are employed, local degeneracy and anisotropies are inherently present (see, e.g., (9)). In [19] smoothers have been developed that generalize the concepts of line and plane smoothing to higher dimensions and are robust with respect to the effects just outlined. For the linear complementarity problems of types (10) to (12) (American options), projected smoothers and transfer operators that are adapted at the free boundary give results comparable to the European case.

As an example we consider the three-dimensional Black–Scholes equation for uncorrelated assets with $\sigma_i = 0.4$, $r = 0.05$, $T = 1$ (one time-step). Plane smoothing in the $V(1,1)$ cycle, where the plane systems are solved approximately by a single multigrid step with line smoothing, was used. The solution time is recorded in Table 5 for various grids with $N = \left(2^{l_1}+1\right) \cdot \left(2^{l_2}+1\right) \cdot \left(2^{l_3}+1\right)$ points, where $l_1 + l_2 + l_3 = 15$. These are the type of grids required for the combination technique. Ideally T/N would be constant over all grids, which is achieved within a factor of about 3. The consequences for load balancing are explained in section 4.2.

TABLE 5

CPU time T (on one node of the HELICS cluster; see below) for a relative error reduction by 10^{-12} for multigrid with the smoother explained above. On refinement levels (l_1, l_2, l_3) the $2^{l_i} + 1$ points in direction i give different totals of N, although the number of elements is equal for all grids. The sum of levels l_i is constant at 15 as in a sparse grid of that level.

l_1	l_2	l_3	N	T	T/N

4.2. Parallelization. The combination technique has an inherent coarse-grain parallelism: the PDE is solved independently on a family of grids, which need to be combined linearly in the end only. In the present case, where we are interested in the evaluation of the solution at a single point, the numerical solution on each grid is interpolated at this point and then added up with the appropriate weights. The communication between processors is restricted to a single concentration step for a scalar value.

Table 6 collects data for the (largest) five-dimensional sparse grid used in the simulation of Figure 4. Evidently the large number of nodes is distributed over a large number of grids that can be solved fully in parallel, and the remaining problem is efficient load balancing. In the implementation that produced the data of this section the grids were numbered level by level in their canonical order and then distributed in as many loops as required over the processors. That way each processor obtained roughly an equal number of unknowns, where the deviation was of the order of magnitude of the largest single grid. A more sophisticated a priori distribution which minimized the memory imbalance did not necessarily lead to shorter CPU times.

The parallel computations were performed on the Heidelberg Linux Cluster System (HELICS, http://helics.iwr.uni-heidelberg.de).

From the distribution of solution times of the single processors in a 200 processor simulation (Figure 6) we see that the difference to the ideal case (in which all processors would finish at the same time) is about one-third. This comes from two reasons. First, a perfectly even distribution of the unknowns is not possible, but bounded by the number of unknowns on the finest grids in the combination technique. In this case

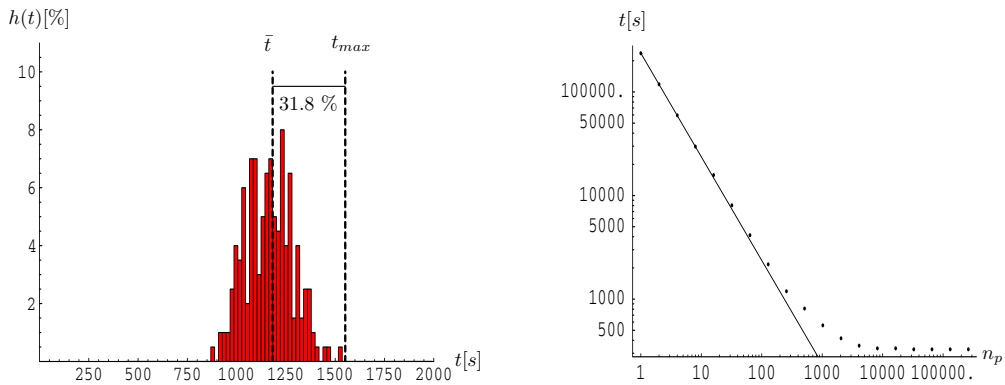

FIG. 6. *Histogram $h(t)$ of CPU time t of each of* 200 *processors and mean $\bar{t}$ (left) and scaling with increasing number n_p of processors (right; see also Table* 7*).*

TABLE 7
Scaling of CPU time t with number of processors n_p.

$\log_2 n_p$	1	2	3	4	5	6	7	
	8	9	10	11	12	13	14,15	≥ 16
$t[s]$	2.37 e+5	11.8 e+5	5.94 e+4	2.98 e+4	1.58 e+4	8.04 e+3	4.14 e+3	
	2.17 e+3	1.19 e+3	8.11 e+2	5.59 e+2	4.18 e+2	3.55 e+2	3.34 e+2	3.27 e+2

the number of grids per processor, which corresponded to the finest level, was either six or seven. This can be expected to account for about half of the observed difference. Second, and more importantly, due to the anisotropic structure of the discrete problems, even the presented robust and asymptotically linear solver is of course not exactly linear for finitely many unknowns.

Since the communication between processors is negligible, it is possible to predict the efficiency of a parallelization strategy for a certain number of processors, even if such a large number is actually not available, given the solution time on all the grids involved in the combination technique. Table 7 was compiled through this procedure; the data are also plotted in Figure 6. It shows that the speedup is almost optimal as long as the number of grids to distribute is large compared to the number of processors. In the given example very good results were observed for up to 100 processors. Clearly if there are more processors than grids, there is no improvement and the curve flattens out. In this case the problem is just too small for the computer. From a more reasonable viewpoint one would then increase the problem size linearly with the number of nodes and then the speedup remains constant at the given level.

Finally an a posteriori analysis which identified a CPU-time optimal distribution after the computation showed that no significant improvement to the simple original scheme can be achieved in most cases.

5. Discussion and outlook. We have seen that there are two seemingly complementary aspects to the sparse grid combination technique. On the one hand, if the problem can be well approximated by a sum of lower-dimensional functions, the hierarchical representation is well suited to decompose the solution in this way and the complexity is reduced accordingly. On the other hand, for a fully high-dimensional structure, sparse grids provide an asymptotically optimal approximation (see [4]), for

which the complexity grows only very weakly with the dimension of the problem. This can be combined in an adaptive algorithm which identifies refinement directions from already computed hierarchical surpluses. Such a strategy has been applied to quadrature in [9]; a robust strategy that automatically reduces to the cases presented in this article (in the respective setting) is currently under investigation by the authors.

In financial practice a central question is the calibration of the models, and often time-dependent and local parameters are fitted such that the model hits quoted option prices for different strikes and maturities. The same ideas illustrated here can be carried forward to the solution of the resulting PDEs with nonconstant coefficients, and in fact the FX-option model was such an example. Principal component analysis has to be performed locally in such a setting. A further open question is then the interplay between calibration and hierarchical approximation.

As an example of products with a more complicated cash-flow structure, interest rate derivatives have been studied in [2]. Swaptions are options on interest rate swaps between fixed and floating interest rates at predefined dates, often with Bermudan features such that the option may also be exercised at these tenor dates. This results in update conditions at these dates, between which a parabolic equation is satisfied. Dimension reduction for such a correlation structure between forward rates with similar time horizons is currently being investigated.

Along similar lines, extensions of the results for basket options to basket credit derivatives are the subject of ongoing research.

STRING GRADIENT WEIGHTED MOVING FINITE ELEMENTS IN MULTIPLE DIMENSIONS WITH APPLICATIONS IN TWO DIMENSIONS*

A. WACHER† AND I. SOBEY‡

Abstract. We formulate the string gradient weighted moving finite element method (SGWMFE) for systems of PDEs in multiple dimensions. Then we illustrate implementation issues for the method using two dimensions. The method is applied successfully to solve the highly nonlinear unsteady porous medium equation in two dimensions and the results are compared to exact solutions. We proceed to present results for the method when applied to the Gray Scott chemical reaction diffusion model in two dimensions. Finally, we apply the method to the shallow water equations in two dimensions and compare the meshes produced with those produced using gradient weighted finite element methods (GWMFE). Our conclusion is that SGWMFE is an easily applied member of the group of moving finite element methods.

Key words. moving finite elements, mesh adaptation

AMS subject classifications. 74S05, 65M60, 65M50

DOI. 10.1137/040619557

1. Introduction.

This paper has two objectives. The first is to present the general formulation for a string gradient weighted moving finite element method (SGWMFE) in multiple space dimensions. The second is to demonstrate the implementation of SGWMFE in several nonlinear systems of PDEs, the porous medium equation, the Gray Scott equations, and the shallow water equations. Solutions of each problem can be found using other methods, and we are not suggesting or attempting to demonstrate that SGWMFE is better or worse than other moving (or nonmoving) finite element or discretization methods; rather, it is an implementation of gradient weighted moving finite elements (GWMFE) with an elegant general form that is straightforward to use.

Moving finite element methods (MFE), originally introduced in [14], are well established to provide reliable solutions to unsteady systems of PDEs, often with less computational cost than fixed mesh methods. There is a wide literature dealing with moving mesh methods, both for finite elements and for finite differences. The text of [1] gives an extensive view of MFE and [5, 11, 15, 16] describe recent applications of moving mesh methods. GWMFE were developed in detail in [8] and [9], and the string version, suggested in [12], was implemented in [17]. For other background on moving mesh methods, see [17], where there is an extended reference list on moving mesh methods including MFE, GWMFE, and moving finite difference type methods. Here our interest is however in developing details of SGWMFE for systems of PDEs in two or more dimensions. Using a projection matrix, a very general form of the method can be developed and details are illustrated for a system of two PDEs. There

are a number of implementation issues for MFE and the details of implementation of SGWMFE are examined for a number of commonly occurring terms in first and second order PDEs.

In the remainder of this section we set out the three test problems that are considered in this paper. In the second section we develop a mathematical formulation for SGWMFE that is elegant and easily generalized to arbitrary systems of evolutionary PDEs in multiple space dimensions. The third section considers implementation issues for a system two independent variables in two space dimensions, focusing the theory from section two for this case and showing details of how different terms are treated. The fourth section gives solutions for the three test problems using SGWMFE.

1.1. Porous medium equation. The first test problem we consider is the application to the porous medium equation in two space dimensions. While this is a single PDE rather than a system, it admits an exact similarity solution under some initial conditions so that the results of applying SGWMFE can be compared to the exact solution.

The porous medium equation is well known (see [6] or [4]) but in computational terms represents a hard problem because under some parameter values, the solution develops a singularity in the slope of an advancing front. The porous medium equation in two dimensions is given by

$$u_t = \nabla \cdot (u^m \nabla u), \tag{1.1}$$

and we consider the problem with $u = 0$ imposed at the boundary.

This is a problem with a known set of similarity solutions when the initial data has circular symmetry. The symmetric self-similar solutions used are of the same form as in [2] and originally from [4]. Earlier studies on self-similar numerical solutions of the porous medium equation can be found in [6] and [7]. The following form represents the solutions for the one- ($d = 1$), two- ($d = 2$), and three- ($d = 3$) dimensional problems for an initial distribution centered at the origin and starting at time t_0:

$$u(r,t) = \left\{ \begin{array}{ll} \dfrac{1}{\lambda^d(t)}\left(1 - \left(\dfrac{r}{r_0\lambda(t)}\right)^2\right)^{1/m}, & r \le r_0\lambda(t) \\ 0, & r > r_0\lambda(t) \end{array} \right\}, \tag{1.2}$$

where r is distance from the origin, m is an integer greater than 0, and

$$\lambda(t) = \left(\frac{t}{t_0}\right)^{\frac{1}{2+md}} \quad \text{with} \quad t_0 = \frac{r_0^2 m}{2(2+md)} \ . \tag{1.3}$$

The computations described below are for times $T = t - t_0 > 0$. The computational difficulty with this problem is that the slope of the solution at the moving front, $r = r_0\lambda(t)$, is singular when $m > 1$.

1.2. Gray Scott equations. The Gray Scott equations are a model for chemical species undergoing reaction and diffusion. Reaction and diffusion of chemical species can lead to a variety of patterns which have beautiful and interesting solutions. For a description of the physics of the model studied here, see [10]. The reader is also referred to [20] for a comparison of results for the following problem using a different class of moving mesh method.

The chemical reaction we consider is that given by

$$\begin{aligned} U + 2V &\to 3V, \\ V &\to P, \end{aligned}$$

where U, V, and P are chemical species. The PDEs that model this process are

$$\begin{aligned} u_t &= r_u \nabla^2 u - uv^2 + f(1-u), \\ v_t &= r_v \nabla^2 v + uv^2 - (f+k)v, \end{aligned} \tag{1.4}$$

where u and v represent their concentrations, r_u and r_v are their diffusion rates, k represents the rate of conversion of V to P, and f represents the rate of the process that feeds U and drains U, V, and P.

The initial conditions considered are block functions for each of the chemical concentrations over the domain $[0,1] \times [0,1]$:

$$u(x,y,t) = \left\{ \begin{array}{ll} 0.5, & 0.3 \le (x,y) \le 0.7 \\ 1 & \text{elsewhere} \end{array} \right\}, \tag{1.5}$$

$$v(x,y,t) = \left\{ \begin{array}{ll} 0.25, & 0.3 \le (x,y) \le 0.7 \\ 0 & \text{elsewhere} \end{array} \right\}. \tag{1.6}$$

The coefficients chosen for this problem are $r_u = 8(10^{-5})$, $r_v = 4(10^{-5})$, $f = 0.024$, and $k = 0.06$ with Dirichlet boundary conditions prescribed on all four boundaries of the domain.

1.3. Shallow water equations. The nonlinear shallow water equations provide a further model problem to test SGWMFE. It is also possible to compare the results with those obtained from the GWMFE code used in [8]. In our shallow water problem, a "hump" of stationary water is released at time zero in the center of a square box. As the hump subsides under gravity, a wave propagates away from the center, collides with the reflective boundaries, and propagates back to the center of the box. As they travel, a wave front steepens, forming a shock in the absence of viscosity. In this problem a simulation should capture the shape of the wave front, the wave height, and the front speed.

The nonlinear shallow water equations studied here are, in nondimensional terms, given by

$$\begin{aligned} u_t &= -\nabla \cdot \mathbf{f} + \epsilon \nabla^2 u, \\ v_t &= -\nabla \cdot \mathbf{g} + \epsilon \nabla^2 v, \\ w_t &= -\nabla \cdot \mathbf{h} + \epsilon \nabla^2 w. \end{aligned} \tag{1.7}$$

The physical domain is given by $0 \le x \le 5$, $0 \le y \le 5$, time $t \ge 0$, u is the height of the fluid from the flat bottom, v is the fluid momentum in the x direction, and w is the fluid momentum in the y direction.

The vector functions in (1.7) are

$$\mathbf{f} = (v, w), \quad \mathbf{g} = \left(\frac{v^2}{u} + \frac{u^2}{2}, \frac{vw}{u} \right), \quad \mathbf{h} = \left(\frac{vw}{u}, \frac{w^2}{u} + \frac{u^2}{2} \right). \tag{1.8}$$

The initial conditions assigned are

$$u = 0.2 + e^{-((x-2.5)^2 + (y-2.5)^2)}, \tag{1.9}$$

$$v = 0, \tag{1.10}$$

$$w = 0. \tag{1.11}$$

On the south and north of the domain, the boundary conditions are that $u_y = 0$, $v_y = 0$, and $w = 0$. On the east and west of the domain, the boundary conditions are that $u_x = 0$, $w_x = 0$, and $v = 0$.

2. Formulation of SGWMFE in multiple dimensions. We consider a system of n PDEs in k dimensions with independent variables $x = (x_1, \dots, x_k)$ and dependent variables $u = (u_1, \dots, u_n)$ satisfying

$$\frac{\partial u_l}{\partial t} = L_l(u_1, \dots, u_n), \qquad l = 1, \dots n, \tag{2.1}$$

where the differential operators L_l are first or second order nonlinear differential operators in space.

The solution u can be considered as an n-dimensional manifold in $(n + k)$-dimensional space; that is,

$$\mathbf{s} = (x_1, \dots, x_k, u_1, \dots, u_n)^{\mathrm{T}}. \tag{2.2}$$

Consider a parameterization of the manifold $\xi = (\xi_1, \dots, \xi_k)$ so that the solution manifold is described by

$$\mathbf{s}(\xi, t) = (x_m(\xi, t), m = 1 \dots k, u_l(x_j(\xi, t), j = 1 \dots k, t), l = 1 \dots n)^{\mathrm{T}}. \tag{2.3}$$

The velocity of the manifold, $\dot{\mathbf{s}}$, is not computed directly; rather, the normal component of the velocity, $\dot{\mathbf{s}}_n$ (not to be confused with the rate of change of the normal to the manifold, so that $\dot{\mathbf{s}}_n \equiv [\dot{\mathbf{s}}]_n$), is calculated, and normal movement of the manifold is deduced from that velocity. Tangential movement of the manifold is not considered since the location of the nodes is not affected.

In order to compute the normal velocity it is necessary to be able to evaluate the normal component of vectors on the manifold. This can be done by defining k tangent vectors to the manifold $\mathbf{X}_m = (0 \dots 1 \dots 0, \frac{\partial u_l}{\partial x_m}, l = 1 \dots n)^{\mathrm{T}}$, $m = 1, \dots, k$, where the unit value occurs in the mth row. These tangent vectors are always nonparallel and nonzero. Define matrices

$$X = [\mathbf{X}_1, \dots, \mathbf{X}_k], \quad V = (\mathbf{X}_l^{\mathrm{T}} \mathbf{X}_m) = X^{\mathrm{T}} X,$$

and the properties of the component vectors (nonzero and nonparallel) will guarantee that V^{-1} will exist. Define D by

$$D = \det(V). \tag{2.4}$$

LEMMA 2.1. [illegible] $\mathbf{s}_n$ [illegible] $\mathbf{s}$ [illegible]

$$\mathbf{s}_n = P\mathbf{s}, \tag{2.5}$$

[illegible] P [illegible]

$$P = I - XV^{-1}X^{\mathrm{T}}. \tag{2.6}$$

[illegible]. If $\mathbf{s}_n = \mathbf{s} - \sum_{l=1}^{k} a_l \mathbf{X}_l = \mathbf{s} - X\mathbf{a}$ then choosing $\mathbf{a}$ so that $\mathbf{s}_n \cdot \mathbf{X}_m = 0$ for $m = 1, \dots, k$ gives $\mathbf{a} = V^{-1}X^{\mathrm{T}}\mathbf{s}$ and hence the equation for P. □

Note that $P\mathbf{X}_m = 0$ for $m = 1, \dots, k$ trivially as the tangent vectors have no normal component.

Having identified the normal component of a vector on the manifold, the normal velocity can be determined. To do this, use

$$\dot{x}_m = \frac{\partial x_m(\xi, t)}{\partial t}, \quad m = 1, \dots, k, \tag{2.7}$$

and

$$\dot{u}_l = \frac{\partial u_l}{\partial t} + \sum_{j=1}^{k} \frac{\partial u_l}{\partial x_j}\dot{x}_j, \quad l = 1, \ldots, n, \tag{2.8}$$

and rearrangement gives that, if

$$R = \begin{pmatrix} 0_{k\times k} & 0_{k\times n} \\ [-u_{l,m}]_{n\times k} & I_{n\times n} \end{pmatrix}, \tag{2.9}$$

where $0_{k\times n}$ is a k-row, n-column matrix of zeros, $I_{n\times n}$ is an n by n identity matrix, and $[-u_{l,m}]$ is an n-row, k-column matrix with entries $-\frac{\partial u_l}{\partial x_m}$, then

$$R\dot{\mathbf{s}} = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ \frac{\partial u_1}{\partial t} \\ \vdots \\ \frac{\partial u_n}{\partial t} \end{pmatrix}. \tag{2.10}$$

LEMMA 2.2. [illegible] P [illegible] R [illegible]

$$PR = P. \tag{2.11}$$

[illegible]. The matrix R is rewritten as $R = I - [\mathbf{X}_1 \cdots \mathbf{X}_k \mathbf{0} \cdots \mathbf{0}]$, and then we use $P\mathbf{X}_m = 0$. □

Thus we obtain

$$\dot{\mathbf{s}}_n = P\dot{\mathbf{s}} = PR\dot{\mathbf{s}} = P\begin{pmatrix} 0 \\ \vdots \\ 0 \\ \frac{\partial u_1}{\partial t} \\ \vdots \\ \frac{\partial u_n}{\partial t} \end{pmatrix} = P\begin{pmatrix} 0 \\ \vdots \\ 0 \\ L_1 \\ \vdots \\ L_n \end{pmatrix} = P\mathbf{L}, \tag{2.12}$$

with $\mathbf{L} = (0, \ldots, 0, L_1, \ldots, L_n)^{\mathrm{T}}$. Thus the normal motion of the manifold is determined by

$$P\big[\dot{\mathbf{s}} - \mathbf{L}\big] = \mathbf{0}. \tag{2.13}$$

This system is central to the solution method since the original n PDEs have been replaced by $n + k$ equations for the manifold velocities $(\dot{x}_1, \ldots, \dot{x}_k, \dot{u}_1, \ldots, \dot{u}_n)$ and upon space discretization, these will become $n + k$ nonlinear ODEs in time.

3. Implementation of SGWMFE in two dimensions. Having considered the very general formulation, in this section we look at the details of implementing the method for a system of two PDEs in two dimensions. For simplicity, denote the independent variables x and y and the dependent variables u and v, and let them be governed by

$$u_t = L_1(u, v), \qquad v_t = L_2(u, v). \tag{3.1}$$

The solution (u, v) can be considered as a two-dimensional manifold in four-dimensional space; that is,

$$\mathbf{s} = (x, y, u, v)^{\mathrm{T}}. \tag{3.2}$$

Two tangent vectors to the manifold will be $\mathbf{X}^{\mathrm{T}} = (1, 0, u_x, v_x)$ and $\mathbf{Y}^{\mathrm{T}} = (0, 1, u_y, v_y)$, and the determinant D is

$$D = |\mathbf{X}|^2|\mathbf{Y}|^2 - (\mathbf{X} \cdot \mathbf{Y})^2 = (|\mathbf{X}||\mathbf{Y}||\sin(\theta)|)^2, \tag{3.3}$$

where θ is the angle between $\mathbf{X}$ and $\mathbf{Y}$.

The normal $\mathbf{s}_n$ to the manifold $\mathbf{s}$ is given by

$$\mathbf{s}_n = P\mathbf{s} \tag{3.4}$$

(see (2.5)), where the matrix P from (2.6) is given by

$$P = I - \frac{1}{D}[|\mathbf{Y}|^2(\mathbf{X}\mathbf{X}^T) - (\mathbf{X} \cdot \mathbf{Y})(\mathbf{X}\mathbf{Y}^T) + |\mathbf{X}|^2(\mathbf{Y}\mathbf{Y}^T) - (\mathbf{X} \cdot \mathbf{Y})(\mathbf{Y}\mathbf{X}^T)]. \tag{3.5}$$

The matrix R is

$$R = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -u_x & -u_y & 1 & 0 \\ -v_x & -v_y & 0 & 1 \end{pmatrix} \tag{3.6}$$

so that

$$R\dot{\mathbf{s}} = R \begin{pmatrix} \dot{x} \\ \dot{y} \\ \dot{u} \\ \dot{v} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ u_t \\ v_t \end{pmatrix}. \tag{3.7}$$

As in the general case, obtain

$$\dot{\mathbf{s}}_n = P\dot{\mathbf{s}} = PR\dot{\mathbf{s}} = P \begin{pmatrix} 0 \\ 0 \\ u_t \\ v_t \end{pmatrix} = P \begin{pmatrix} 0 \\ 0 \\ L_1 \\ L_2 \end{pmatrix} = P\mathbf{L}, \tag{3.8}$$

with $\mathbf{L} = (0, 0, L_1, L_2)^{\mathrm{T}}$. Thus, as before, the normal motion of the manifold is determined by

$$P\big[\dot{\mathbf{s}} - \mathbf{L}\big] = \mathbf{0}. \tag{3.9}$$

Discretization of this system can be cast in a finite element framework by using appropriate test functions—in this case the piecewise linear basis functions which are used also to discretize the solutions for (u, v) at time varying (x, y) nodal locations. If the basis functions are denoted α^i then the discrete equations for the normal motion of the manifold are

$$\int_{\text{manifold}} P(\dot{\mathbf{s}} - \mathbf{L})\alpha^i \mathrm{d}S = \mathbf{0}, \tag{3.10}$$

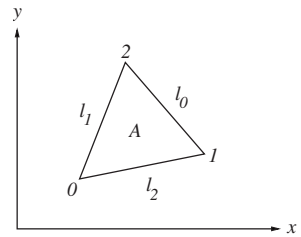

FIGURE 3.1. *Triangle T, showing the orientation of nodes 0, 1, and 2, the projected $x-y$ area A, and the edge lengths ℓ_0, ℓ_1, and ℓ_2.*

where $\mathrm{d}S$ is an element of the manifold and the superscript i ranges over the basis functions. In two dimensions, a triangular cell T can be used, as in Figure 3.1, and then, after piecewise linear discretization, u_x, v_x, u_y, v_y, and hence also P are constant on each cell. The parameterization used for the implementation of SGWMFE is $\xi_1 = x$ and $\xi_2 = y$, so that two infinitesimal vectors $\mathbf{X}\mathrm{d}x$ and $\mathbf{Y}\mathrm{d}y$ span a parallelogram in $4-D$ of area

$$\mathrm{d}S = |\mathbf{X}\mathrm{d}x||\mathbf{Y}\mathrm{d}y||\sin(\theta)| = \sqrt{D}\mathrm{d}x\mathrm{d}y. \tag{3.11}$$

It can also be noted that this SGWMFE formulation is equivalent to a variational formulation which chooses to minimize the functional

$$\psi = \int ||P(\dot{\mathbf{s}} - \mathbf{L})||^2 \mathrm{d}S, \tag{3.12}$$

with respect to the nodal velocities $\dot{\mathbf{s}}_i = (\dot{x}_i, \dot{y}_i, \dot{u}_i, \dot{v}_i)$.

In order to solve the discrete system of ODEs, an algorithm such as the well-known backward differentiation formula 2 (BDF2) found in [3] can be used. The BDF2 integrator is a robust stiff integrator which is necessary for the stiff systems arising in SGWMFE; however, any robust stiff integrator may be used. The BDF2 integration code developed and made available by Carlson and Miller was used for the results in this paper. A detailed outline of the BDF2 integrator routine is in [8].

3.1. Implementation. The implementation of SGWMFE requires some notation for the average value of a scalar or vector valued function f on a cell or an edge. An element of area on the manifold, $\mathrm{d}S$, is related to the projected $x-y$ area by (3.11), and since D is constant on each element, the projected area A of an element with area S is related by $S = \sqrt{D}A$. Hence the average of a function f over a triangular cell T is given by

$$[f]_T = \frac{1}{A}\int_T f\mathrm{d}x\mathrm{d}y = \frac{1}{S}\int_T f\mathrm{d}S. \tag{3.13}$$

We will also assume that the three nodes of the triangle T are labeled $0, 1, 2$, as in Figure 3.1.

The average of f over an edge E of length ℓ is given by

$$[f]_E = \frac{1}{\ell}\int_E f\mathrm{d}s, \tag{3.14}$$

where the integrand is with respect to the infinitesimal length along the edge: $\mathrm{d}s = \sqrt{\mathrm{d}x^2 + \mathrm{d}y^2}$.

3.2. Time derivative terms. As P is constant on an element, the components of the system for time derivatives on a triangular cell T are given by

$$\int_T P\dot{\mathbf{s}}\alpha^0 \mathrm{d}S = P\int_T \dot{\mathbf{s}}\alpha^0 \mathrm{d}S. \tag{3.15}$$

Similar contributions will occur for nodes 1 and 2 of the cell. Since the $\dot{\mathbf{s}}$ and α^0 are linear functions of the two-dimensional parameter ξ, the integrand in (3.15) is quadratic in the components of ξ and hence can be evaluated by the "edge-midpoint rule" which is exact for quadratic functions.

3.3. Flux terms. Since many systems of interest contain a flux term, consider the case where $L_1 = \nabla\cdot\mathbf{f}$. For the given triangular cell T, the contributions from this flux term from the cell onto its 0 node are

$$\int_T P\begin{pmatrix}0\\0\\-\nabla\cdot\mathbf{f}\\0\end{pmatrix}\alpha^0\mathrm{d}S = \sqrt{D}P\begin{pmatrix}0\\0\\1\\0\end{pmatrix}\int_T(-\nabla\cdot\mathbf{f})\alpha^0\mathrm{d}x\mathrm{d}y, \tag{3.16}$$

where, again, the constancy of P and D on each cell enables these to be taken out of the integral. The scalar integral expression may be integrated by parts, as in [9]:

$$\int_T -\nabla\cdot\mathbf{f}\alpha^0\mathrm{d}x\mathrm{d}y = \int_T \mathbf{f}\cdot\nabla\alpha^0\mathrm{d}x\mathrm{d}y - \int_{E_1}\alpha^0\mathbf{f}\cdot\widehat{\nu}_1\mathrm{d}s - \int_{E_2}\alpha^0\mathbf{f}\cdot\widehat{\nu}_2\mathrm{d}s, \tag{3.17}$$

where E_1 and E_2 are edges adjacent to node 0 and $\widehat{\nu}_1$, $\widehat{\nu}_2$ are outward normals to those edges (α^0 is zero on the third edge).

This component can be simplified by using average values. Defining ℓ_i as the $x-y$ projected lengths of the corresponding edge E_i, (3.17) is rewritten in terms of average values as

$$\int_T -\nabla\cdot\mathbf{f}\alpha^0\mathrm{d}x\mathrm{d}y = A\nabla\alpha^0\cdot[\mathbf{f}]_T - l_1\widehat{\nu}_1\cdot[\alpha^0\mathbf{f}]_{E_1} - l_2\widehat{\nu}_2\cdot[\alpha^0\mathbf{f}]_{E_2}. \tag{3.18}$$

3.4. Constant coefficient diffusion terms. Another common component of the differential operators L_1 and L_2 is a diffusion term. We consider first the case of constant diffusion; the second case of nonconstant or nonlinear diffusion is considered later. In order to evaluate the integrals of the Laplacian terms, mollification is used. For piecewise linear approximations, the Laplacian is singular at an edge. In order to overcome this, consider the integrals in neighborhoods of each edge and assume that the piecewise linear approximation is the limit of an approximation which can be differentiated twice; that is, the piecewise linear representations of the solution variables need to be mollified so that the first derivatives vary smoothly from cell to cell in a neighborhood whose thickness will be allowed to vanish. The principle here is the same as in the two-dimensional paper of [9]. To do this, some of the same labels as in that paper are used to define cells, edges, endpoints, and unit normal vectors.

Without loss of generality, assume that the 0 to 1 edge E is aligned in the y direction as shown in Figure 3.2. This is done so that the unit outward normal vector to E is $\widehat{\nu} = \widehat{x}$, and the unit tangent vector to E is $\widehat{\tau} = \widehat{y}$. Then on crossing the edge, the values u_y and v_y stay constant, but u_x and v_x are functions of x, which increase by $2a$ and $2b$, respectively, with mean values m_u and m_v. Now assume all three are

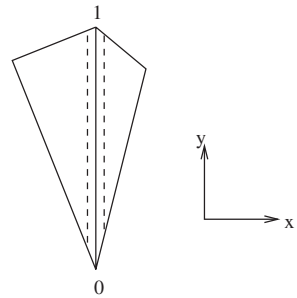

FIGURE 3.2. *Mollification of edge of two triangles.*

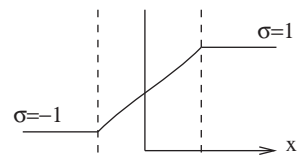

FIGURE 3.3. $\sigma(x)$.

mollified equally; that is, the "**X**" tangent vector to the two-dimensional manifold in four dimensions is

$$\mathbf{X}(x) = \mathbf{M} + \sigma(x)\mathbf{A} = \begin{pmatrix} 1 \\ 0 \\ u_x \\ v_x \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \\ m_u \\ m_v \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ a \\ b \end{pmatrix} \sigma(x), \tag{3.19}$$

where $\sigma(x)$ varies from -1 to 1 in the neighborhood of the edge as shown in Figure 3.3. Thus the Laplacian contribution is

$$\mathbf{L} \equiv \begin{pmatrix} 0 \\ 0 \\ u_{xx} + u_{yy} \\ v_{xx} + v_{yy} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ a \\ b \end{pmatrix} \sigma'(x). \tag{3.20}$$

The "**Y**" tangent vector to the two-dimensional manifold is the constant vector

$$\mathbf{Y} = \begin{pmatrix} 0 \\ 1 \\ u_y \\ v_y \end{pmatrix}. \tag{3.21}$$

Note that the integrals are considered only in a small neighborhood *nbd* of the edge—that is, the neighborhood of the $x - y$ projection of edge E. This is because u_{xx} and v_{xx} are identically zero away from the edge neighborhood where the rapid variation occurs. First use the same approach as in the section on constant coefficient diffusion terms—that of assuming the edge E is aligned with the y axis and then rotating the results accordingly. We note that α^0 is equivalent to a function of y alone in an infinitesimal neighborhood of the edge E. Now take the integral $\int\int P\mathbf{L}\alpha^0 \mathrm{d}S$ over the neighborhood *nbd* to get

(3.22)
$$\begin{aligned}\int\int_{nbd} P\begin{pmatrix}0\\0\\u_{xx}\\v_{xx}\end{pmatrix}\alpha^0(y)\mathrm{d}S &= \int\int_{nbd}\sqrt{D}P\begin{pmatrix}0\\0\\a\\b\end{pmatrix}\sigma'(x)\alpha^0(y)\mathrm{d}x\mathrm{d}y\\ &= \int_{y=0}^{y=\ell_{01}}\left(\int_{x_{nbd}}\sqrt{D}P\begin{pmatrix}0\\0\\a\\b\end{pmatrix}\sigma'(x)\mathrm{d}x\right)\alpha^0(y)\mathrm{d}y\\ &= \frac{\ell_{01}}{2}\int_{\sigma=-1}^{\sigma=1}\sqrt{D(\sigma)}P(\sigma)\mathbf{A}\mathrm{d}\sigma,\end{aligned}$$

where ℓ_{01} is the length of the edge joining node 0 and node 1, as in Figure 3.2. Further, once the matrix $P(\sigma)$ has been postmultiplied through by the vector $\mathbf{A}$ (defined in (3.19)) and by $\sqrt{D(\sigma)}$, then

$$\sqrt{D(\sigma)}P(\sigma)\mathbf{A} = \frac{1}{\sqrt{D(\sigma)}}[D(\sigma)\mathbf{A} - D_1(\sigma)\mathbf{X}(\sigma) - D_2(\sigma)\mathbf{Y}], \tag{3.23}$$

where the vector $\mathbf{X}(\sigma)$ and variables $D(\sigma), D_1(\sigma)$, and $D_2(\sigma)$ are functions of σ:

$$\begin{aligned}\mathbf{X}(\sigma) &= \mathbf{M} + \mathbf{A}\sigma,\\ D(\sigma) &= |\mathbf{X}(\sigma)|^2|\mathbf{Y}|^2 - (\mathbf{X}(\sigma)\cdot\mathbf{Y})^2,\\ D_1(\sigma) &= (\mathbf{X}(\sigma)\cdot\mathbf{A})|\mathbf{Y}|^2 - (\mathbf{Y}\cdot\mathbf{A})(\mathbf{Y}\cdot\mathbf{X}(\sigma)),\\ D_2(\sigma) &= (\mathbf{Y}\cdot\mathbf{A})|\mathbf{X}(\sigma)|^2 - (\mathbf{X}\cdot\mathbf{A})(\mathbf{X}(\sigma)\cdot\mathbf{Y}).\end{aligned} \tag{3.24}$$

Simplifying, the expression $D(\sigma)\mathbf{A} - D_1(\sigma)\mathbf{X}(\sigma) - D_2(\sigma)\mathbf{Y}$ is linear in σ as quadratic terms cancel and may be written as $\mathbf{G} + \mathbf{H}\sigma$, where $\mathbf{G}$ and $\mathbf{H}$ are constant vectors in σ. Also notice that $D(\sigma)$ is quadratic in σ and may be written as $c_1 + c_2\sigma + c_3\sigma^2$, where c_1, c_2, and c_3 are constants in σ. Using this information, the integral $\int_{-1}^{1}\sqrt{D(\sigma)}P(\sigma)\mathbf{A}\mathrm{d}\sigma$ may thus be written as

$$\mathbf{G}\int_{-1}^{1}\frac{1}{\sqrt{c_1 + c_2\sigma + c_3\sigma^2}}\mathrm{d}\sigma + \mathbf{H}\int_{-1}^{1}\frac{\sigma}{\sqrt{c_1 + c_2\sigma + c_3\sigma^2}}\mathrm{d}\sigma. \tag{3.25}$$

In the one-dimensional theory of SGWMFE both the integrals multiplied by $\mathbf{G}$ and $\mathbf{H}$, respectively, were expressed analytically in [19] and [17], since they were necessary for the calculation of the contributions from the Laplacian terms in one dimension; however, sixteen point Gauss quadrature is used for the integrals for the studies carried out for this paper. Once the terms of the vector have been calculated, it is necessary to rotate the x and y components to the correct orientation, since the calculations were made based on the assumption that the $x-y$ projection of the edge E was aligned with the y axis.

This rotation is done by replacing the first two components of the vector (corresponding to its x and y components) and multiplying by a rotation matrix:

$$\begin{pmatrix}\dfrac{\mathrm{d}y}{\ell_i} & \dfrac{\mathrm{d}x}{\ell_i}\\ \dfrac{-\mathrm{d}x}{\ell_i} & \dfrac{\mathrm{d}y}{\ell_i}\end{pmatrix}. \tag{3.26}$$

3.5. Source terms. The contributions over a cell from a source term, say, $S_1(u,v)$ in L_1 onto its 0th node, are obtained as follows:

$$\int_T P \begin{pmatrix} 0 \\ 0 \\ S_1(u,v) \\ 0 \end{pmatrix} \alpha^0 \mathrm{d}S = \sqrt{D} P \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix} \int_T S_1(u,v) \alpha^0 \mathrm{d}x\mathrm{d}y, \tag{3.27}$$

resulting in the equivalent compact form

$$\int_T S_1(u,v) \alpha^0 \mathrm{d}x\mathrm{d}y = A[\alpha^0 S_1(u,v)]_T. \tag{3.28}$$

3.6. Nonuniform diffusion terms in conservative form. Consider a nonconstant or nonlinear diffusion term of the form $L_1 = \nabla\cdot(a\nabla u)$, where $a = a(x,y,u,v)$. The contributions from this term in the cell onto its 0th node are obtained as follows:

$$\int_T P \begin{pmatrix} 0 \\ 0 \\ \nabla\cdot(a\nabla u) \\ 0 \end{pmatrix} \alpha^0 \mathrm{d}S = \int_T P \begin{pmatrix} 0 \\ 0 \\ a\nabla^2 u \\ 0 \end{pmatrix} \alpha^0 \mathrm{d}S + \int_T P \begin{pmatrix} 0 \\ 0 \\ \nabla a \cdot \nabla u \\ 0 \end{pmatrix} \alpha^0 \mathrm{d}S. \tag{3.29}$$

Consider the first integral on the right-hand side, noting that the term $\nabla^2 u$ is zero on each cell not including the edges. So the contributions from this first integral need only be considered in the δ-neighborhood of the edges in the support of α^0, as is the case for the constant coefficient Laplacian, as discussed in the section about constant coefficient diffusion terms. It will suffice to express the integral here for one edge E. Again we use the same approach as in the section on constant coefficient diffusion terms—that of assuming the edge E is aligned with the y axis and then rotating the results accordingly. As in [9] we note that, like α^0, $a(x,y,u,v)$ is equivalent to a function of y alone in an infinitesimal neighborhood of the edge E. Thus

$$\int_T P \begin{pmatrix} 0 \\ 0 \\ a\nabla^2 u \\ 0 \end{pmatrix} \alpha^0 \mathrm{d}S = \int_{y=0}^{y=\ell_{01}} \left(\int_{x_{nbd}} \sqrt{D} P \begin{pmatrix} 0 \\ 0 \\ \nabla^2 u \\ 0 \end{pmatrix} \mathrm{d}x \right) a(y) \alpha^0(y) \mathrm{d}y, \tag{3.30}$$

and the integral thus becomes (using the notation from (3.14))

$$\ell_{01}[a\alpha^0]_E \left(\int_{x_{nbd}} \sqrt{D} P \begin{pmatrix} 0 \\ 0 \\ \nabla^2 u \\ 0 \end{pmatrix} \mathrm{d}x \right). \tag{3.31}$$

The integral over the x_{nbd} is identical to the one derived for the Laplacian in (3.22), and thus the details will not be repeated here. The second integral in (3.29) can be treated as a source term:

$$\int P \begin{pmatrix} 0 \\ 0 \\ \nabla a \cdot \nabla u \\ 0 \end{pmatrix} \alpha^0 \mathrm{d}S. \tag{3.32}$$

Since P is constant over each cell and the term $\nabla a \cdot \nabla u$ is assumed bounded on each cell (u is constant on each cell and a is assumed continuous and bounded), then it is only necessary to consider the integral over each cell. For each cell T, use the theory derived for source terms with $S_1(u, v) = \nabla a \cdot \nabla u$, and similarly if there are equivalent terms in the second PDE $S_2(u, v) = \nabla a \cdot \nabla v$.

3.7. Regularization. As in the one-dimensional SGWMFE approach it may be necessary to add regularization terms in order to remove any degeneracies which may occur in the discrete system of ODEs. The regularization terms used here are similar to the terms introduced as pressure regularization in [8], as opposed to the internodal viscosity regularization terms more commonly known. As in the one-dimensional case, the need for regularization may arise when the solution has two consecutive cells with the same slope or when two nodes run into each other or overlap causing a degeneracy in the system of equations (see [17] for one-dimensional analysis). In order to remove the possibility of this happening, in [12] and [8] it was shown that adding regularization terms which are proportional to nodal velocities (described by Miller as internodal viscosities) is successful in two dimensions. These internodal viscosities are not needed for the porous medium equation; however, in some instances when the solution has an infinite slope it is necessary to use the pressure regularization terms as suggested by [13], added to keep nodes from overlapping.

The pressure terms used are derived from a quality functional. That is, the terms added are a constant times the negative gradient of a mesh quality functional Q, where the gradient is with respect to the discrete nodal velocities $[\dot{\mathrm{x}}_i, \dot{\mathrm{y}}_i, \dot{\mathrm{u}}_i, \dot{\mathrm{v}}_i]$. The quality functional used here is

$$Q = \frac{P^2}{\Delta S}, \tag{3.33}$$

on each cell T, where P is the perimeter of the triangular cell and ΔS is the area of the triangle in the four-dimensional space as introduced in (3.11). Thus for a four-dimensional set of ODEs resulting from the SGWMFE discretization, the pressure terms added to the equations at each node is

$$-C^2 \begin{pmatrix} \dfrac{\mathrm{d}Q}{\mathrm{d}x_i} \\ \dfrac{\mathrm{d}Q}{\mathrm{d}y_i} \\ \dfrac{\mathrm{d}Q}{\mathrm{d}u_i} \\ \dfrac{\mathrm{d}Q}{\mathrm{d}v_i} \end{pmatrix}. \tag{3.34}$$

The solutions are not very sensitive to the value of the pressure regularization parameter C^2, so long as C^2 is much smaller than the error tolerance, that is, so that the regularization terms added are well below the order of accuracy required. For the porous medium equation when the pressure terms are not needed, the addition of these terms makes no difference to the solution within the error tolerance. These terms are not needed for the case when $m = 1$ in the porous medium equation. However, as explained later, there are some cases when these terms are needed and the C^2 is set to $(tol/10)^2$, where tol is the local truncation error tolerance of the time integrator.

4. Results.

4.1. Porous medium equation. The parameter m in (1.1) determines the strength of the nonlinearity in the diffusion. In this paper we consider two cases, $m = 1$ and $m = 3$. For both cases the problem is started with an initial condition of $r_0 = 1/2$ and the initial profile is obtained from the similarity solution using this information. It is worthwhile noting that the choice of m is not limited; while not all possible integer values for $m > 0$ were tested, some integer values larger than 3 were tested, such as the problem with $m = 5$, which produced results in agreement with (1.2), as in the cases presented in this paper. The key point that makes the cases $m = 1$ and $m > 1$ different is that for the first case the slopes of the solutions are finite over the domain for this problem, and for cases $m > 1$ the solutions have infinite slopes at the moving boundary. In all cases, SGWMFE performs well.

The results illustrated in Figures 4.1 and 4.2 show the differences between the cases $m = 1$, which clearly diffuses faster, and $m = 3$, which has infinite slope near the moving boundary. The solutions were computed in the first quadrant using a two-dimensional SGWMFE code and the graphs show the solutions reflected onto the three remaining quadrants. This is because the problem is axially symmetric. The mesh plots are on the actual computational domain (see Figures 4.3 and 4.4), where it is seen that the SGWMFE code does indeed produce axially symmetric results. The speed of the spreading of the solutions can also be seen more clearly from the mesh plots. For both problems ($m = 1$ and $m = 3$) the initial conditions begin with an arced domain of radius 1/2. However, in the case $m = 1$, the solution boundary reaches a radius of almost 1.5, and in the case $m = 3$, the radius reaches a value of around 0.8 in the same amount of time. It is interesting that, regardless of the initial mesh chosen, for the porous medium equation, the meshes converge almost instantly, so that at any particular later time, the meshes will be the same; i.e., the mesh acts as an attractor. This can be seen in Figures 4.5 and 4.6.

It is worth mentioning that the case of $m = 3$ required use of pressure regularization terms. This is because the slopes are infinite and in the two-dimensional case (as in the one-dimensional case found in [17, 18]) the nodes tend to bunch up

toward the infinite slope. In this case, it is so severe that the regularization pressure terms are needed in order to keep the nodes from overlapping and thus maintaining a well-defined mesh. The regularization pressure terms used for this problem are very small—much smaller than the time integrator tolerance used for this problem, which was chosen at 10^{-4}. Also this is the only problem presented in this paper where regularization terms were not needed, regardless of the value of m and regardless of the dimension in which the problem was solved. This is because the problem is diffusive and has its own natural diffusivity in the nonlinear terms, thus keeping the solution smooth. This is different from the shallow water equations because artificial viscosity was added for the purpose of maintaining a smooth solution in the numerical calculation.

Convergence results for SGWMFE applied to the porous medium equation in two dimensions are shown. In the two-dimensional cases (regardless of the value of m) the slopes of the convergence lines for all the times shown are close to 1. Since the relation between N and the average mesh parameter h is $h = \sqrt{area(\Omega)/N}$, or $N \sim h^{-2}$ (where Ω is the area of the computational domain), this result corresponds to an h^2 rate of convergence, which is optimal for linear finite elements.

The L_∞ norm is chosen here for simplicity and to avoid introducing error from the numerical calculation of the L_1 norm over the nonuniform moving triangular grid. The L_∞ error norms are shown in Figures 4.7 and 4.8. As expected from the results shown in the one-dimensional cases in [17, 18], the convergence rates are the same

regardless of the time to which the problem is solved. Thus only the convergence results for solutions calculated at time $T = 2$ are presented here.

The results in Figure 4.8 show more data results, from solving the problem using more nodes, than used to produce Figure 4.7 since originally it was not clear if the order of convergence of the radius was the same as the error over the entire solution

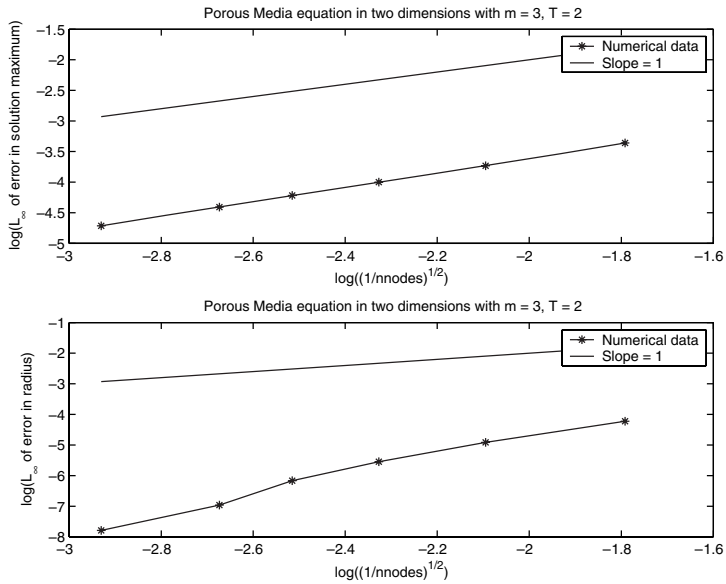

FIGURE 4.8. *Errors in SGWMFE solutions for the two-dimensional porous medium equation with parameter* $m = 3$. *The solutions were obtained using meshes with a varying number of nodes at time* $T = 2$. *Viscous* (A^2) *regularization terms were not needed for this problem and pressure regularization terms of* $C^2 = (10)^{-10}$ *were used for this problem.* $nnodes$ = *number of nodes.*

domain, or if it was better for the case when $m = 3$. The extra data was needed since from the graph of the convergence rate, Figure 4.8, shows a higher order convergence rate than the case when $m = 1$ as the number of nodes are increased. However, since the error tolerance used for this problem is 10^{-4}, using more nodes than used to produce the convergence results will not be more conclusive, since the results shown are already of the same order as the error tolerance. If all the data were to be reproduced with a lower truncation error tolerance, this would lead to more accurate solutions, though the results would not necessarily show convergence rates that are significantly different.

4.2. Gray Scott equations. First we examine the convergence of the method on the Gray Scott equations. Since an analytic solution is not available, we construct a reference solution (to be regarded as the "exact solution") by using an extremely fine discretization—much finer than that used for the actual computation. Solutions with variable nodes are compared pointwise to solutions on a fine reference mesh with 55 by 55 nodes. We then define the error measure in the component u as

$$E = \| u_{ref} - u \| / \| u_{ref} \|, \tag{4.1}$$

where u is the actual SGWMFE solution, u_{ref} is the reference solution, and $\| \cdot \|$ is the discrete L_2 norm. Note that the values used for calculating the norms in (4.1) are mapped onto a fixed uniform fine mesh (using the linear shape functions) in order to enable objective comparison of the various meshes. Figure 4.9 shows the convergence curves of $E(N)$ on a log-log scale, where N is the total number of nodal points, showing that the solutions with a variable number of nodes converge to the solution on the finest mesh. Similar results have been obtained when applying this procedure to the shallow water equations.

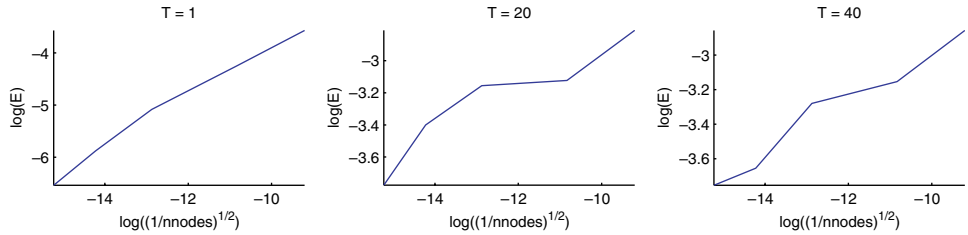

FIGURE 4.9. *SGWMFE convergence in u for the Gray Scott equations at times (from left to right): $T = 1$, 20, and 40. The error tolerance used is 10^{-4}. The corresponding viscous regularization terms of $A^2 = 5(10)^{-8}$ and pressure regularization terms of $C^2 = (10)^{-8}$ were used for this problem. nnodes = number of nodes.*

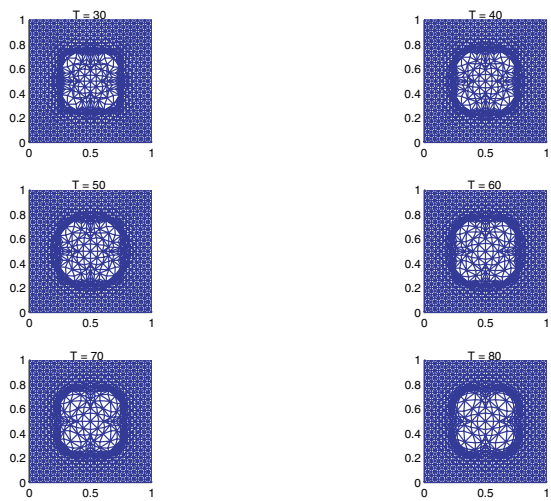

FIGURE 4.10. *SGWMFE meshes produced when solving the Gray Scott equations with 35 by 35 nodes. The error tolerance used is 10^{-4}. The corresponding viscous regularization terms of $A^2 = 5(10)^{-8}$ and pressure regularization terms of $C^2 = (10)^{-8}$ were used for this problem.*

Next we show mesh plots at several times for SGWMFE solutions of the Gray Scott equations using 35 by 35 nodes, much fewer nodes than for the solution plots following, for the sake of clarity of the figure. It is clear in Figure 4.10 that the mesh is attracted to the reaction fronts. See Figures 4.11 and 4.12 for contours of the solutions of the component u at corresponding times. The patterns observed in the solution figures are similar to those found in [20]. However, the meshes obtained for SGWMFE as compared to those shown in [20] are quite different, noting that for SGWMFE there is a much richer concentration of the nodes at the reaction front in comparison to the meshes produced by the method in [20].

4.3. Shallow water equations. Figure 4.13 shows SGWMFE results for the shallow water equations in two dimensions. The mesh plots are shown on the computational domain in order to make clearer comparisons between the mesh produced by SGWMFE and those produced by GWMFE. All of the numerical results for this problem conserve "mass" (the integral of the variable u over the domain) within the error tolerance. SGWMFE solutions are visually the same in comparison to the results obtained using GWMFE, though the meshes produced by each method differ.

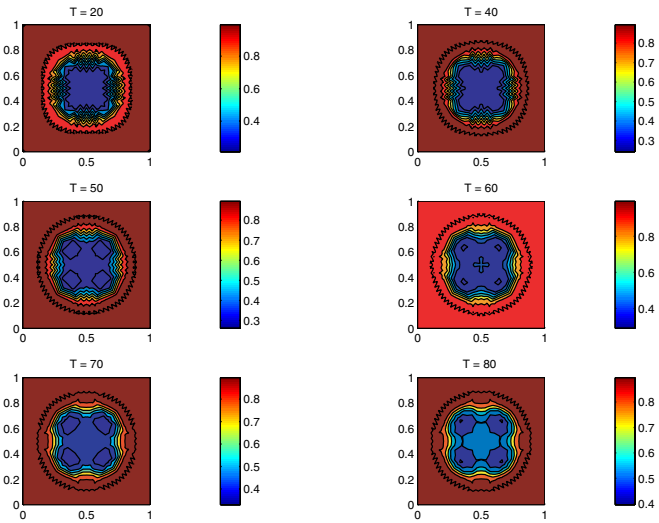

FIGURE 4.11. *SGWMFE solutions produced when solving the Gray Scott equations with* 45 *by* 45 *nodes. The error tolerance used is* 10^{-4}. *The corresponding viscous regularization terms of* $A^2 = 5(10)^{-8}$ *and pressure regularization terms of* $C^2 = (10)^{-8}$ *were used for this problem.*

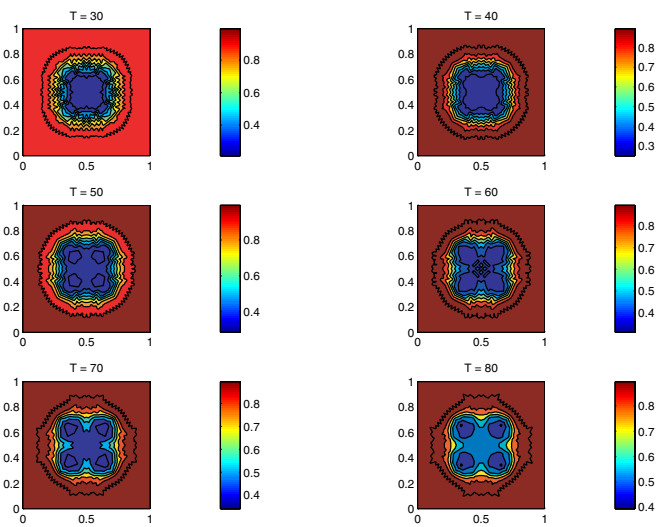

FIGURE 4.12. *SGWMFE solutions produced when solving the Gray Scott equations with* 55 *by* 55 *nodes. The error tolerance used is* 10^{-4}. *The corresponding viscous regularization terms of* $A^2 = 5(10)^{-8}$ *and pressure regularization terms of* $C^2 = (10)^{-8}$ *were used for this problem.*

The results shown here are calculated to the user-chosen tolerance, which was chosen to be 10^{-3} in this case. The solutions were in agreement with those obtained with the GWMFE code used in [9]. Further noting that the solutions are in agreement with GWMFE, it is worth discussing the uniqueness of the meshes produced. The meshes obtained for the shallow water equations are not "unique." In Figures 4.14 and 4.15, it is shown that with different initial meshes for solving the two-dimensional shallow water equations (with the same artificial viscosity), at various times, different

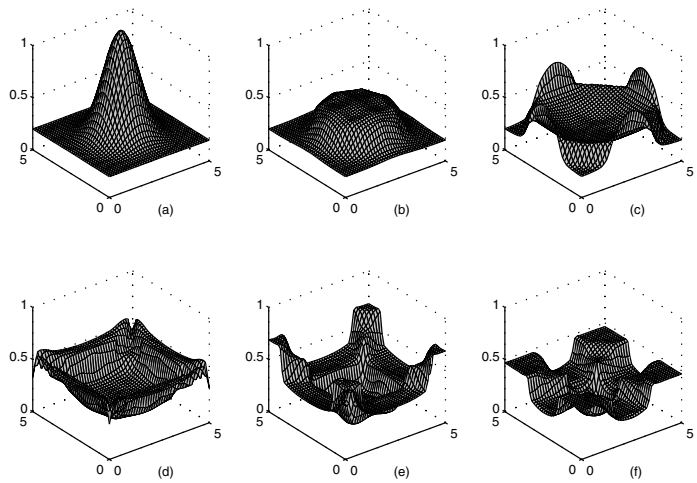

FIGURE 4.13. *SGWMFE solutions for the shallow water equations with artificial viscosity* $\epsilon = (10)^{-2}$ *at times* $T = 0, 1, 2, 3, 4, 5$. *Solutions were obtained with* 289 *nodes using the viscous regularization terms* $A^2 = 5(10)^{-5}$. *Regularization pressure terms were not needed for this problem.*

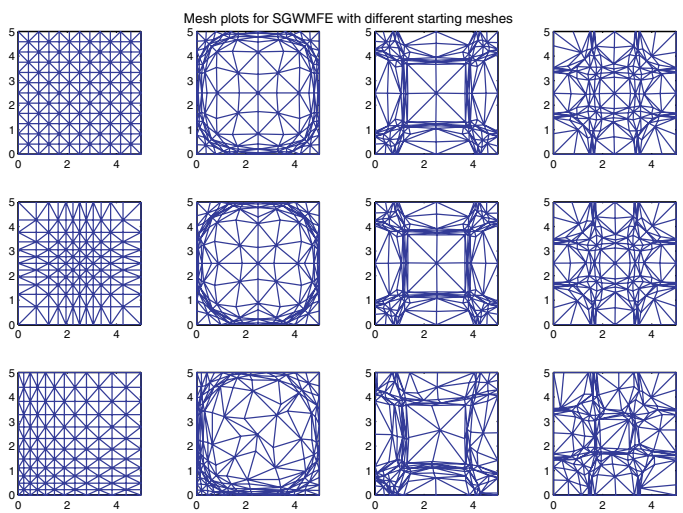

FIGURE 4.14. *SGWMFE meshes corresponding to solutions for the shallow water equations with artificial viscosity* $\epsilon = (10)^{-2}$ *at times* $T = 0, 2, 4, 5$. *Solutions were obtained with* 289 *nodes using the viscous regularization terms* $A^2 = 5(10)^{-5}$. *Pressure regularization terms were not needed for this problem.*

meshes are obtained (although the methods converge to solutions within the same accuracy, regardless of the initial mesh). It can also be seen in Figures 4.14 and 4.15, as expected, that the GWMFE and SGWMFE produce different meshes. This is true for both the one-dimensional and two-dimensional formulations of the shallow water equations. This could have been shown using results obtained for the one-dimensional shallow water equations; however, the results in two dimensions, presented here, are more demonstrative of the differences.

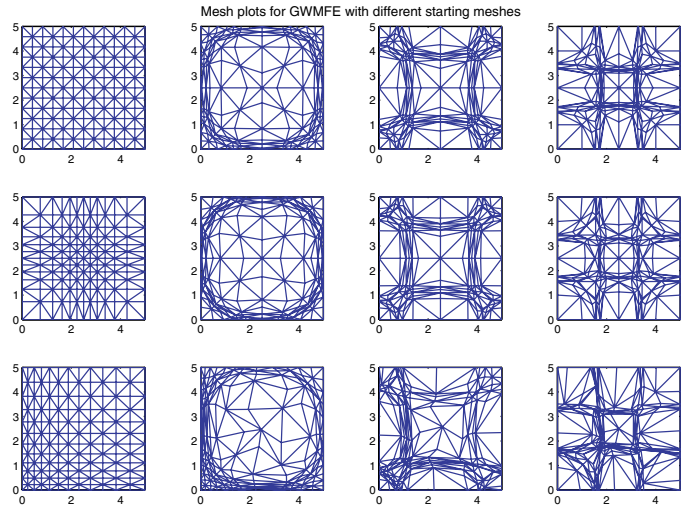

FIGURE 4.15. *GWMFE meshes corresponding to solutions for the shallow water equations with artificial viscosity* $\epsilon = (10)^{-2}$ *at times* $T = 0, 2, 4, 5$. *Solutions were obtained with* 289 *nodes using the viscous regularization terms* $A^2 = 5(10)^{-5}$. *Pressure regularization terms were not needed for this problem.*

5. Conclusions. The equations for SGWMFE have been presented using a projection matrix, making the underlying formulation easy to understand. The resulting equations resulting for SGWMFE are an elegant extension to existing gradient weighted methods. A convergence study of the method was carried out for the porous medium equation in two dimensions. The results show accurate solutions that correspond to an h^2 rate of convergence, which is optimal for linear finite elements. Further results were shown for the Gray Scott equations agreeing with results of a different moving mesh method and solutions of the nonlinear shallow water equations for both SGWMFE and GWMFE, obtaining equally accurate results on the different meshes produced by each corresponding method.

In [17] further calculations are given for the shallow water equations in both one and two dimensions, as well as for reaction diffusion equations in one dimension. In each case SGWMFE was straightforward to implement and gave reliable solutions for relatively little computational effort.

In conclusion, derivation and implementation of SGWMFE is straightforward and the formulation is easily generalized for arbitrary systems of PDEs in multiple dimensions. The method has proved to solve the problems presented here with steep moving fronts and a chemical reaction diffusion problem with pattern formation, both of which are difficult numerical problems. For such problems, SGWMFE can produce accurate results efficiently with respect to the number of nodes used as well as the calculation time.

6. Acknowledgments. This work has been motivated and to some extent, guided, by Keith Miller, whose pioneering work on gradient weighted methods contains the origins of SGWMFE, and we are immensely grateful to him for his help and advice. We are also very grateful to Andy Wathen and Mike Baines for discussions about moving finite element methods and to Mike Baines for suggesting a study of the porous medium equation.

NEARLY OPTIMAL PRECONDITIONED METHODS FOR HERMITIAN EIGENPROBLEMS UNDER LIMITED MEMORY. PART I: SEEKING ONE EIGENVALUE*

ANDREAS STATHOPOULOS†

Abstract. Large, sparse, Hermitian eigenvalue problems are still some of the most computationally challenging tasks. Despite the need for a robust, nearly optimal preconditioned iterative method that can operate under severe memory limitations, no such method has surfaced as a clear winner. In this research we approach the eigenproblem from the nonlinear perspective, which helps us develop two nearly optimal methods. The first extends the recent Jacobi–Davidson conjugate gradient (JDCG) method to JDQMR, improving robustness and efficiency. The second method, generalized-Davidson+1 (GD+1), utilizes the locally optimal conjugate gradient recurrence as a restarting technique to achieve almost optimal convergence. We describe both methods within a unifying framework and provide theoretical justification for their near optimality. A choice between the most efficient of the two can be made at runtime. Our extensive experiments confirm the robustness, the near optimality, and the efficiency of our multimethod over other state-of-the-art methods.

Key words. Jacobi–Davidson, eigenvalues, Newton, conjugate gradient, optimality, preconditioning

1. Introduction.

The numerical solution of large, sparse, Hermitian, and real symmetric eigenvalue problems is central to many applications in science and engineering. It is also one of the most time-consuming tasks. Recently, electronic structure calculations, with eigenproblems at their core, have displaced quantum chromodynamics as the top supercomputer cycle user. The symmetric eigenvalue problem seems deceptively simple to solve, given well-conditioned eigenvalues and a wealth of theoretical knowledge. However, these advantages have enabled researchers to push modeling accuracy to unprecedented levels, routinely solving for a few extreme eigenvalues of matrices of size more than a million, while an order of a billion has also been tried [48].

The sheer size of these problems can only be addressed by iterative methods. At the same time, the size imposes limits on the memory available to these methods. Moreover, preconditioning becomes imperative for reducing the total number of iterations. While many eigenvalue iterative methods have been proposed, there is little consensus on which method is the best and in what situations. The unrestarted Lanczos method is known to be optimal for solving Hermitian eigenvalue problems, but, unlike the conjugate gradient (CG) method for linear systems, it requires unlimited storage of its iteration vectors. With preconditioning, or under limited storage, the question of optimality remains open. Furthermore, there is a noticeable scarcity of high quality, general purpose software for preconditioned eigensolvers. In this research we seek an optimal, or nearly optimal, method that can utilize preconditioning and that can be implemented in robust software that is also flexible.

In the particular case of seeking one eigenpair, if the eigenvalue were known, solving a linear system using CG to obtain the corresponding eigenvector would yield the optimal Lanczos convergence. In practice both the eigenvalue and the eigenvector are unknown, so the appropriate way to approach this problem is through the resulting slight nonlinearity, which then helps us to identify practical and near optimal methods. Currently, the best methods follow this approach, adopting either the Newton point of view or the nonlinear conjugate gradients (NLCG) point of view.

In the first part of this paper we argue that regardless of the approach (Newton or NLCG), the underlying iterative method should be the generalized Davidson (GD) method. In the second part, we examine the optimality from the Newton point of view, and identify a truncated Newton version followed by the Jacobi–Davidson conjugate gradient (JDCG) method [46] as within a small factor of optimal. In fact, we argue that this factor is less than three and usually much less than two. We then extend JDCG to JDQMR by adapting the quasi-minimal residual (QMR) instead of CG, which allows for better stopping criteria of the inner iteration, for indefinite preconditioners, interior eigenvalues, and improved robustness. In the third part of the paper, we study the NLCG point of view and, in particular, the related locally optimal CG recurrence. The approach can be used for short recurrences (as in LOBPCG [32]) or for restarting the subspace accelerated GD+1 [44, 68]. We show why local optimality of the Ritz value extends also to the Ritz vector, and we provide new intuition on the performance of GD+1 by relating it to the limited memory quasi-Newton methods (such as L-BFGS) [45]. In the fourth part, we present one of the most extensive sets of experiments in the literature, comparing our methods with state-of-the-art methods.

One conclusion to be drawn from our experiments is that both GD+1 and JDQMR always solve a given problem, regardless of the difficulty, and one of the two is always the fastest method. Over all the methods tested, GD+1 typically yields the smallest number of iterations, often matching the optimal convergence. The cheaper inner iteration of JDQMR benefits cases where the preconditioner and the matrix-vector operations are inexpensive. As this expense can be measured at runtime, an implementation based on the common GD driver can switch dynamically between GD+1 and JDQMR to make the most effective use of these two nearly optimal methods.

We note that this is not a review paper, although a substantial amount of review material is used to identify, build, and provide new intuition on the various components of the desired method. To keep the paper tractable both in size and readability, we focus on finding only one eigenpair. The additional problems of deflation, locking, correction equation projectors, blocking, and subspace acceleration which are relevant when a large number of eigenvalues are required will be addressed in a separate paper.

2. The GD as an outer iteration model. There is a plethora of iterative methods for large, sparse, symmetric eigenvalue problems. Invariably, these are Krylov or Krylov-like subspace methods that approximate the required eigenvectors from a subspace that usually grows in size as it is iteratively updated. The methods host a variety of differentiating features, of which two are the defining features for our research: We need methods that can utilize arbitrary preconditioners and that can operate on a limited memory space.

Shift-and-invert is probably the most well-studied and powerful preconditioning approach [52], which when coupled with a Lanczos-type method can produce robust, industrial strength methods [27]. In this research we assume that an exact factorization for shift-and-invert is not possible because of the size of the problem. In such

cases, approximations to $(A-\eta I)^{-1}$ are often used as preconditioners to linear solvers for the inverse iteration (INVIT), Rayleigh quotient iteration (RQI), or the (Jacobi–) Davidson methods [52, 71, 43, 60]. Although the accuracy of the term "eigenvalue preconditioning" for this approach has received some scrutiny [15, 31], the resulting methods improve convergence similarly to the corresponding preconditioned linear system solvers. Moreover, there are many established and tunable ways to produce such preconditioners [56]. Some applications may use different types of preconditioners, including polynomial transformations, frequency filtering or smoothing, or other techniques that do not correspond to approximately solving a linear system [55, 67].

The GD method was one of the first methods to cater to such an arbitrary selection of preconditioners [43]. Extending the original Davidson method [11], at every iteration GD applies a user-defined function on the residual of the sought eigenpair to "precondition" it—or to enrich it in the required directions. The vector is then used to enlarge the search space from which a new approximation is obtained through the Rayleigh–Ritz procedure [52]. When the search space exhausts the available memory, the method restarts with the best approximations of the required eigenvectors and possibly with additional information to improve convergence. Algorithm 2.1 depicts a version of the basic GD algorithm for finding one, smallest eigenpair $(\lambda_1, \mathbf{x}_1)$ of a real symmetric matrix, A.

Despite many efforts over two decades, the theory behind the convergence of the GD algorithm is still not well understood [43, 10, 69, 60]. For some recent, promising results see [49, 50, 34, 47]. One of the early unsettling issues with the GD algorithm had been the stagnation of the method if an accurate enough approximation to $(A-\theta^{(m)}I)^{-1}$, where $\theta^{(m)}$ is the Ritz value, is used as a preconditioner. An elegant resolution to this problem has been given by Sleijpen and van der Vorst with the Jacobi–Davidson (JD) method [60]. Instead of inverting $(A-\eta I)$, they showed that the appropriate form for this preconditioning should be an approximate solution to the correction equation:

$$(I-\mathbf{u}^{(m)}\mathbf{u}^{(m)T})(A-\eta I)(I-\mathbf{u}^{(m)}\mathbf{u}^{(m)T})\mathbf{t}^{(m)} = -\mathbf{r}^{(m)} = \theta^{(m)}\mathbf{u}^{(m)} - A\mathbf{u}^{(m)}, \tag{2.1}$$

where η is a shift close to the wanted eigenvalue. Thus, by working orthogonally to the Ritz vector $\mathbf{u}^{(m)}$, JD avoids stagnation. Among many known properties for this correction equation, one that is relevant to this paper is that if (2.1) is solved accurately, the new vector $\mathbf{u}^{(m)}+\mathbf{t}^{(m)}$ is collinear to the iterate produced by INVIT [41, 60, 58, 15, 74]. In addition, if $\eta=\theta^{(m)}$, the method is equivalent to RQI with subspace acceleration of all previous iterates. The true flexibility of GD and JD, however, is that they converge even when (2.1) is solved approximately through an iterative method such as CG. A preconditioner K can also be used as long as it is inverted orthogonally to the space of $Q=\mathbf{u}^{(m)}$. To this effect, the pseudoinverse of such a preconditioner can be written as

$$\left((I-QQ^T)K(I-QQ^T)\right)^+ = (I-K^{-1}Q(Q^TK^{-1}Q)^{-1}Q^T)K^{-1}(I-QQ^T) \tag{2.2}$$

$$= K^{-1}(I-Q(Q^TK^{-1}Q)^{-1}Q^TK^{-1})(I-QQ^T). \tag{2.3}$$

Moreover, CG can be implemented efficiently with only one projection with Q per iteration. See [17, 60, 3] for details.

Algorithm 2.1 is identical to the JD algorithm as provided in [3], except for step (19), which is handled specially in JD. In this sense, we can view JD as a subcase of GD. Practitioners, however, usually refer to GD as a [illegible] application of the available

ALGORITHM 2.1.
(1) [illegible] $\mathbf{v}_0$ [illegible]
(2) $\mathbf{t}^{(0)} = \mathbf{v}_0,\ m = 0,\ nmv = 0$
(3) **while** $nmv < max_num_matvecs$
(5) [illegible] $\mathbf{t}^{(m)}$ [illegible] $\mathbf{v}_i, i = 1, \ldots, m$
(6) $m = m + 1$; $nmv = nmv + 1$; $\mathbf{v}_m = \mathbf{t}^{(m-1)}$; $\mathbf{w}_m = A\mathbf{v}_m$
(7) $H_{i,m} = \mathbf{v}_i^T \mathbf{w}_m$ [illegible] $i = 1, \ldots, m$
(8) [illegible] $H = S\Theta S^T$ [illegible] $\theta_1 \leq \theta_2 \leq \cdots \leq \theta_m$
(9) $\mathbf{u}^{(m)} = Vs_1$; $\theta^{(m)} = \theta_1$; $\mathbf{w}^{(m)} = Ws_1$
(10) $\mathbf{r}^{(m)} = \mathbf{w}^{(m)} - \theta^{(m)}\mathbf{u}^{(m)}$
(11) **if** $\|\mathbf{r}^{(m)}\| \leq tol$ **return** $\theta^{(m)}, \mathbf{u}^{(m)}$
(12) **if** $m \geq m_{max}$ [illegible]
(13) $H = 0$
(14) **for** $i = 2, \ldots, m_{min}$
(15) $\mathbf{v}_i = Vs_i$; $\mathbf{w}_i = Ws_i$; $H_{ii} = \theta_i$
(16) **end for**
(17) $\mathbf{v}_1 = \mathbf{u}^{(m)}$; $\mathbf{w}_1 = \mathbf{w}^{(m)}$; $H_{11} = \theta^{(m)}$; $m = m_{min}$
(18) **end if**

(20) **end while**

preconditioner K^{-1} to the residual. In that case, preconditioning orthogonally to $\mathbf{u}^{(m)}$, using (2.2)–(2.3), is usually called Olsen's method [48] (or JD with no inner iterations), and it involves two operations with K^{-1} which can be very expensive. In practice, K does not often approximate $(A - \theta^{(m)}I)$, but A, and even when it does it is rarely accurate enough to require or even benefit from the JD projections, and thus GD is widely used in many applications [74, 2]. Exceptions exist for "non-standard" cases and when there is an inner iterative method as discussed in [61] and more extensively in [47]. In the remainder of this paper, we will use GD to refer to the method that preconditions the residual without Olsen's method.

Generality is an additional reason for considering GD as our basic iterative framework. Algorithm 2.1 is strikingly similar to an Arnoldi method with a flexible preconditioner, making GD a chameleon method. Without preconditioning, GD is equivalent to Arnoldi, albeit with an expensive implementation, that facilitates not only the testing of software correctness, but also a common platform for comparison between methods, abstracting from the implementation details. For example, the restarted, unpreconditioned GD method is mathematically equivalent to implicitly restarted Lanczos (IRL) and thick restarted Lanczos [63, 38, 42, 70, 73]. A block GD implementation is also possible [39, 65, 23], yielding the equivalents of block Lanczos [52] and subspace iteration [9] (without preconditioning), or preconditioned subspace iteration [3]. In addition, combining a block GD with our earlier GD+k restarting scheme [68], which we study closer in section 4.3, allows an equivalent and stable implementation of the LOBPCG method [32]. Needless to say, with an appropriate solution to the correction equation, the algorithm is identical to many variants of RQI, INVIT, JD, and the more recent JDCG of Notay that we study closely in the following section [46]. Beyond emulating the above methods, GD can enhance them with block, subspace acceleration, while working under given memory constraints.

Often the choice of algorithm and its parameters depends on the particular prob-

lem solved. The above discussion supports the argument that if there is to be one general purpose method that allows for arbitrary preconditioning and converges near optimally for a given problem, that algorithm must follow the GD template. The rest of the paper presents arguments why the tuning of the GD parameters, a task dreaded by practitioners, can be almost fully automated in the symmetric case.

3. The Newton view. Central to our discussion is the slight nonlinearity of the eigenvalue problem, i.e., both eigenvectors and eigenvalues are unknown. If the required eigenvalue λ_1 were known, the problem would degenerate to a symmetric linear system of equations $(A - \lambda_1 I)x_1 = 0$. This singular system can be solved optimally with CG or some other three-term recurrence method, provided that our initial guess x^0 is not defective in the direction of x_1, i.e., $x^0 = x_1 + y$ with $x_1 \perp y \in \text{Range}(A - \lambda_1 I)$. A Krylov solver approximates the correction y from the subspace $\mathcal{K}((A - \lambda_1 I), (A - \lambda_1 I)y)$. Because $\mathcal{K}((A - \lambda_1 I), (A - \lambda_1 I)y) \subseteq \text{Range}(A - \lambda_1 I)$, the solver will converge to x_1 with rate determined by the condition number of the deflated system: λ_{max}/λ_2. The optimality of CG implies that this is the ultimate convergence rate that any Krylov eigensolver can reach for finding the smallest eigenvalue [31, 33]. Note that unrestarted Lanczos achieves this rate, because the space that includes y yields also the eigenvalue λ_1. Equivalently, but more stably, we could solve (2.1) for $t = y$ with $\eta = \lambda_1$, obtaining the same optimal rate and converging in one outer JD step. Because we use symmetric QMR, we call this benchmark QMRopt. In general, before reaching that rate, an eigensolver would also have to find λ_1.

This nonlinearity can be resolved by applying the Newton method on the Grassmann manifold (to enforce normalization of the eigenvectors), which is equivalent both to RQI and to the JD method with no subspace acceleration and with accurate solution of the correction equation [59, 74, 15, 57]. Convergence of the outer iterations is known to be ultimately cubic when the initial guess is sufficiently close to x_1 [52]. In the absence of a good initial guess, truncated Newton methods or a subspace method such as Lanczos or GD must be used to ensure global convergence.

It has long been noticed that using iterative methods to solve the linear equation in RQI and INVIT beyond some level of accuracy does not decrease the number of outer iterations, while increasing the overall number of matrix-vector multiplications which typically correlates to the computational cost of the method. Interestingly, solving the linear equation approximately through a constant number of inner iterations has been shown to be equivalent to truncated (inexact) Newton methods [58]. However, the equivalence does not hold if the linear system in RQI is solved inexactly to a certain accuracy. Analysis of the stopping criteria for these inner-outer methods has been the focus of considerable research [53, 36, 21, 37, 62, 26, 25]. Because the solution vector for RQI and INVIT grows in norm the closer it is to the actual eigenvector, all proposed techniques test the convergence of the linear system relative to the norm of the solution vector. This norm can be monitored during the inner iteration.

The JD method is a better representative of inexact Newton minimization methods, because these apply the pseudoinverse of the Hessian to the gradient of the function. This is equivalent to solving (2.1) through a certain number of inner iterations or to a specified accuracy. Hence various stopping criteria for truncated Newton methods have been used in JD [60, 13]. Still, the objective is the convergence of the eigenvector, not of the linear system. Recently, an analysis for the interplay of inner-outer iterations was given by Notay [46]. Notay provided theoretical and experimental arguments on why his method, JDCG, provides nearly optimal convergence.

3.1. The JDCG approach. To simplify the notation we denote the projected operators as

$$A_{\eta,u^{(m)}} = (I - \mathbf{u}^{(m)}\mathbf{u}^{(m)T})(A - \eta I)(I - \mathbf{u}^{(m)}\mathbf{u}^{(m)T}), \tag{3.1}$$

$$K_{u^{(m)}} = (I - \mathbf{u}^{(m)}\mathbf{u}^{(m)T})K(I - \mathbf{u}^{(m)}\mathbf{u}^{(m)T}). \tag{3.2}$$

Assume that a Krylov iterative method (e.g., CG) is used to solve (2.1) and that no Rayleigh–Ritz is performed in the outer JD step, so the method is similar to the unaccelerated Newton method [58]. The latter assumption facilitates an inexpensive way to monitor the eigenvalue convergence inside the linear solver, while being a worst-case scenario for the subspace accelerated JD. At the kth inner iteration, the linear system residual is

$$\mathbf{g}_k = \mathbf{r}^{(m)} + A_{\eta,u^{(m)}}\mathbf{t}_k, \tag{3.3}$$

where $\mathbf{t}_k$ is the current approximate solution to the correction equation. If the linear solver were stopped at the kth step, the corrected eigenvector, its Rayleigh quotient, and its residual would be

$$\mathbf{u}_k^{(m+1)} = (\mathbf{u}^{(m)} + \mathbf{t}_k)/\|\mathbf{u}^{(m)} + \mathbf{t}_k\|, \tag{3.4}$$

$$\theta_k^{(m+1)} = \mathbf{u}_k^{(m+1)T} A \mathbf{u}_k^{(m+1)}, \tag{3.5}$$

$$\mathbf{r}_k^{(m+1)} = A\mathbf{u}_k^{(m+1)} - \theta_k^{(m+1)}\mathbf{u}_k^{(m+1)}. \tag{3.6}$$

Note that although $\mathbf{g}_k \to 0$, as $k \to \infty$, the eigenresidual $\mathbf{r}_k^{(m+1)}$ converges not to zero but to the eigenvalue residual of the next INVIT iterate: $\mathbf{r}_\infty^{(m+1)}$. Notay showed that $\|\mathbf{g}_k\|$ and $\|\mathbf{r}_k^{(m+1)}\|$ converge at similar rates up to the point where $\|\mathbf{r}_k^{(m+1)}\|$ approaches $\|\mathbf{r}_\infty^{(m+1)}\|$. Beyond this point, there is no benefit in continuing the inner linear solver, and this is the main idea behind JDCG. Notay also developed an inexpensive way to express the norm of the eigenresidual $\|\mathbf{r}_k^{(m+1)}\|$ as a function of the linear system residual $\|\mathbf{g}_k\|$ when CG is the inner solver. When the linear system residual starts to converge at a faster rate than the corresponding eigenvalue residual, the inner iteration is stopped.

Notay showed that for extremal eigenvalues JDCG demonstrates the same convergence as a periodically restarted CG method. Because the number of restarts is small, corresponding to the number of Newton steps rather than to the size of the search space, JDCG achieves near optimality, converging within a small factor of optimal. In section 5.2 we provide intuition on how to quantify this small factor. Notay also showed that if the Ritz value $\theta^{(m)}$ is closer to λ_1 than to λ_2, then (2.1) with $\eta = \theta^{(m)}$ is positive definite and CG can be used safely. See [40] for a similar result.

However, positive definiteness of the correction equation can be a limiting factor for a general purpose eigenvalue solver based on JDCG. There are several reasons. First, when good initial guesses are not available, $\theta^{(m)}$ can be well inside the spectrum causing (2.1) to be indefinite. Second, eigensolvers of the GD/JD type can be easily modified to find interior eigenvalues closer to a given shift η. Regardless of the quality of the initial guess, JDCG cannot be used in this case, and we have to rely on methods such as MINRES or SYMMLQ [51]. Third, and perhaps most importantly, the preconditioner K cannot be guaranteed to be positive definite. Practitioners solving linear systems would rarely choose an indefinite preconditioner, but for eigenvalue problems good approximations to the shifted matrix $(A - \theta^{(m)}I)$ arise naturally in

many applications. Examples include strongly diagonal dominant matrices, for which the Davidson method was originally developed [11], and discretizations of PDEs with spectral or Fourier bases (see experiments in section 5.5). Unfortunately, neither CG nor MINRES can utilize an indefinite preconditioner.

In the following section, we extend the JDCG ideas to the symmetric QMR of Freund and Nachtigal [18, 19] which allows for both indefinite operator and preconditioner. In addition, the monotonic convergence of the linear system quasi-residual allows for more intuitive and efficient stopping criteria than those used in JDCG.

3.2. The JDQMR method. In case of indefinite correction equation or preconditioner, GMRES or BiCGSTAB have been suggested as robust inner solvers [3]. GMRES, however, requires either storage of its whole search space or frequent restarts that degrade its convergence. BiCGSTAB, on the other hand, does have a short-term recurrence, capable of generating a large Krylov space implicitly, but it is oblivious to the symmetry of the matrix and thus twice as expensive per step as CG. Although convergence may be also twice as fast as that of BiCG [72] in the general case, for symmetric matrices this benefit may be smaller as the squared polynomial of BiCGSTAB is clearly suboptimal to the same degree polynomial obtained through an [illegible] method based on the Lanczos recurrence.

3.2.1. Symmetric QMR. The QMR method for nonsymmetric matrices uses the BiCG [4] short-term recurrence but obtains the approximations by a quasi-minimization of the residual over the available terms. Although there is no global optimality property, and the actual residual norm is not minimized, convergence is much smoother than with BiCG. Freund and Nachtigal noticed in [18] that when the matrix is symmetric, the simplification of the Lanczos process gives rise to a symmetric version of BiCG that can be used with any symmetric, possibly indefinite preconditioner. Based on this symmetric BiCG, they proposed the symmetric QMR (sQMR) algorithm. sQMR improves the functionality of MINRES, while keeping the same computational requirements. sQMR and MINRES are equivalent without preconditioning.

Assume the correction equation with operator $A_{\eta,u^{(m)}}$, preconditioner $K_{u^{(m)}}$, and the right-hand side $-\mathbf{r}^{(m)}$. As is typical in the JD method, assume that the initial guess is zero. Algorithm 3.1 shows the sQMR algorithm for solving the above correction equation with right preconditioning.

Similarly to CG, the $\mathbf{d}_k$ are the $A_{\eta,u^{(m)}}$ conjugate vectors that BiCG produces, and $\mathbf{r}_k$ are the BiCG residuals of the linear system at the kth step. Hence (see [4])

$$d_i^T A_{\eta,u^{(m)}} d_k = 0 \quad \forall i = 0, \ldots, k-1, \tag{3.7}$$

$$d_i^T r_k = 0 \quad \forall i = 0, \ldots, k-1. \tag{3.8}$$

Note that the sQMR residual, $\mathbf{g}_k$, and its norm $g_k = \|\mathbf{g}_k\| = \|\mathbf{r}^{(m)} + A_{\eta,u^{(m)}}\mathbf{t}_k\|$ are [illegible] computed during the algorithm, but only the norm from the quasi-minimization $\hat{g}_k$. The actual norm g_k, although typically larger than $\hat{g}_k$, is bounded by

$$g_k \leq \sqrt{k+1}\ \hat{g}_k. \tag{3.9}$$

Without preconditioning, $g_k = \hat{g}_k$, and depending on the preconditioner the above bound can be sharp. The actual norm g_k could be computed at the expense of two additional vector updates and one inner product, and by storing an extra vector for $A_{\eta,u^{(m)}}\boldsymbol{\delta}_k$. However, as we show in section 3.4, this expense is not justified. In the following section, we consider only the actual residual norm g_k.

ALGORITHM 3.1.
$A_{\eta,u^{(m)}}, K_{u^{(m)}}, -\mathbf{r}^{(m)}, maxiter$
t_k
(1) $\mathbf{t}_0^{(m)} = 0, \boldsymbol{\delta}_0 = 0, \mathbf{r}_0 = -\mathbf{r}^{(m)}, \mathbf{d}_0 = K_{u^{(m)}}^{-1}\mathbf{r}_0$
(2) $\hat{g}_0 = \|\mathbf{r}_0\|, \Theta_0 = 0, \rho_0 = \mathbf{r}_0^T\mathbf{d}_0$
(3) **if** $(maxiter = 0)$ $\mathbf{t}_0 = \mathbf{d}_0$ **return**
(4) **for** $k = 1, \ldots, maxiter$
(5) $\mathbf{w} = A_{\eta,u^{(m)}}\mathbf{d}_{k-1}$
(6) $\sigma_{k-1} = \mathbf{d}_{k-1}^T\mathbf{w}$ **if** $(\sigma_{k-1} = 0)$ **return**
(7) $\alpha_{k-1} = \frac{\rho_{k-1}}{\sigma_{k-1}}$
(8) $\mathbf{r}_k = \mathbf{r}_{k-1} - \alpha_{k-1}\mathbf{w}$
(9) $\Theta_k = \frac{\|\mathbf{r}_k\|}{\hat{g}_{k-1}}, c_k = \frac{1}{\sqrt{1+\Theta_k^2}}, \hat{g}_k = \hat{g}_{k-1}\Theta_k c_k$
(10) $\boldsymbol{\delta}_k = (c_k^2\Theta_{k-1}^2)\boldsymbol{\delta}_{k-1} + (c_k^2\alpha_{k-1})\mathbf{d}_{k-1}$
(11) $\mathbf{t}_k = \mathbf{t}_{k-1} + \boldsymbol{\delta}_k$
(12) **if** $\hat{g}_k$ [illegible] $\rho_{k-1} = 0)$ **return**
(13) $\mathbf{w} = K_{u^{(m)}}^{-1}\mathbf{r}_k, \rho_k = \mathbf{r}_k^T\mathbf{w}, \beta_k = \frac{\rho_k}{\rho_{k-1}}$
(14) $\mathbf{d}_k = \mathbf{w} + \beta_k\mathbf{d}_{k-1}$
(15) **end for**

Finally, note that we have used right preconditioning so that the norm g_k corresponds to the original correction equation, not the preconditioned one (see [18]). This is desirable, as we want to relate the eigenvalue residual to the monotonically decreasing linear system residual.

3.2.2. Monitoring the eigenresidual in sQMR. Replacing CG with sQMR results in a method which we call JDQMR. As with JDCG, we must provide expressions for $\theta_k^{(m+1)}$ and $\|\mathbf{r}_k^{(m+1)}\|$ of (3.4)–(3.6) that can be calculated through short recurrences in sQMR and without additional matrix-vector, preconditioning, or vector operations. The difference between the expressions for JDCG and JDQMR is strictly due to the projection process. Similarly to [46], we consider a simplified JD process where the Ritz vector is updated through (3.4) and not through a Rayleigh–Ritz procedure in the whole search space. A subspace accelerated JDQMR would improve the Ritz value, $\theta_k^{(m+1)}$, but not necessarily the residual norm, $\|\mathbf{r}_k^{(m+1)}\|$. This simplification, therefore, constitutes a worst-case scenario for the complete JDQMR, and it also keeps the expressions inexpensive and tractable.

THEOREM 3.1. [illegible] 3.1 [illegible] (2.1) [illegible] (3.1)–(3.6) [illegible]

$$\mathrm{B}_k = \mathbf{t}_k^T(A - \eta I)\mathbf{u}^{(m)}, \tag{3.10}$$

$$\Gamma_k = \mathbf{t}_k^T(A - \eta I)\mathbf{t}_k = \mathbf{t}_k^T A_{\eta,u^{(m)}}\mathbf{t}_k, \tag{3.11}$$

$$\Delta_k = \boldsymbol{\delta}_k^T\mathbf{r}^{(m)} = -\boldsymbol{\delta}_k^T\mathbf{r}_0, \tag{3.12}$$

$$\Phi_k = \boldsymbol{\delta}_k^T(A - \eta I)\boldsymbol{\delta}_k = \boldsymbol{\delta}_k^T A_{\eta,u^{(m)}}\boldsymbol{\delta}_k, \tag{3.13}$$

$$\Psi_k = \mathbf{t}_{k-1}^T(A - \eta I)\boldsymbol{\delta}_k = \mathbf{t}_{k-1}^T A_{\eta,u^{(m)}}\boldsymbol{\delta}_k, \tag{3.14}$$

$$\gamma_k = c_k^2\Theta_{k-1}^2, \ \xi_k = c_k^2\alpha_{k-1}. \tag{3.15}$$

$$\theta_k^{(m+1)} = \eta + \frac{\left(\theta^{(m)} - \eta + 2\mathrm{B}_k + \Gamma_k\right)}{1 + \|\mathbf{t}_k\|^2}, \tag{3.16}$$

$$\|\mathbf{r}_k^{(m+1)}\|^2 = \frac{\|\mathbf{g}_k\|^2}{1 + \|\mathbf{t}_k\|^2} + \frac{(\theta^{(m)} - \eta + \mathrm{B}_k)^2}{1 + \|\mathbf{t}_k\|^2} - (\theta_k^{(m+1)} - \eta)^2, \tag{3.17}$$

B_k Γ_k

$$\Delta_k = \gamma_k \Delta_{k-1} - \xi_k \rho_{k-1}, \tag{3.18}$$

$$\mathrm{B}_k = \mathrm{B}_{k-1} + \Delta_k, \tag{3.19}$$

$$\Gamma_k = \Gamma_{k-1} + 2\Psi_k + \Phi_k, \tag{3.20}$$

$$\Phi_k = \gamma_k^2 \Phi_{k-1} + \xi_k^2 \sigma_{k-1}, \tag{3.21}$$

$$\Psi_k = \gamma_k \Psi_{k-1} + \gamma_k \Phi_{k-1}, \tag{3.22}$$

$\mathrm{B}_0 = \Delta_0 = \Gamma_0 = \Phi_0 = \Psi_0 = 0$

From (3.4)–(3.5), $\theta^{(m)} = \mathbf{u}^{(m)T} A \mathbf{u}^{(m)}$, $\|\mathbf{u}^{(m)}\| = 1$, the symmetry of A, and the fact that $\mathbf{t}_k^T \mathbf{u}^{(m)} = 0$, we obtain $\|\mathbf{u}^{(m)} + \mathbf{t}_k\|^2 = 1 + \|\mathbf{t}_k\|^2$ and (3.16):

$$\begin{aligned}\theta_k^{(m+1)} &= (\mathbf{u}^{(m)} + \mathbf{t}_k)^T A (\mathbf{u}^{(m)} + \mathbf{t}_k)/(1 + \|\mathbf{t}_k\|^2) \\ &= \eta + (\theta^{(m)} - \eta + 2\mathbf{t}_k^T (A - \eta I)\mathbf{u}^{(m)} + \mathbf{t}_k^T A_{\eta, u^{(m)}} \mathbf{t}_k)/(1 + \|\mathbf{t}_k\|^2).\end{aligned}$$

Because $\mathbf{r}_k^{(m+1)} \perp \mathbf{u}_k^{(m+1)}$ we derive (3.17) as in (23)–(25) from [46]:

$$\begin{aligned}\|\mathbf{r}_k^{(m+1)}\|^2 &= \|(A - \eta I)(\mathbf{u}^{(m)} + \mathbf{t}_k)\|^2/(1 + \|\mathbf{t}_k\|^2) - (\theta_k^{(m+1)} - \eta)^2 \\ &= \Big(\|(I - \mathbf{u}^{(m)}\mathbf{u}^{(m)T})(A - \eta I)(\mathbf{u}^{(m)} + \mathbf{t}_k)\|^2 \\ &\quad + \|\mathbf{u}^{(m)}\mathbf{u}^{(m)T}(A - \eta I)(\mathbf{u}^{(m)} + \mathbf{t}_k)\|^2\Big)/(1 + \|\mathbf{t}_k\|^2) - (\theta_k^{(m+1)} - \eta)^2 \\ &= (\|\mathbf{g}_k\|^2 + (\theta^{(m)} - \eta + \mathrm{B}_k)^2)/(1 + \|\mathbf{t}_k\|^2) - (\theta_k^{(m+1)} - \eta)^2.\end{aligned}$$

The recurrences are obtained through the vector update formulas in sQMR.

$$\begin{aligned}\mathrm{B}_k &= \mathbf{t}_k^T (A - \eta I)\mathbf{u}^{(m)} = \mathbf{t}_k^T (A - \theta^{(m)} I)\mathbf{u}^{(m)} = \mathbf{t}_k^T \mathbf{r}^{(m)} \\ &= (\mathbf{t}_{k-1} + \boldsymbol{\delta}_k)^T \mathbf{r}^{(m)} = \mathrm{B}_{k-1} + \Delta_k, \\ \Delta_k &= \boldsymbol{\delta}_k^T \mathbf{r}^{(m)} = (\gamma_k \boldsymbol{\delta}_{k-1} + \xi_k \mathbf{d}_{k-1})^T \mathbf{r}^{(m)} = \gamma_k \Delta_{k-1} + \xi_k (\mathbf{d}_{k-1}^T \mathbf{r}^{(m)}).\end{aligned}$$

Notice that $\mathbf{r}^{(m)} = -\mathbf{r}_0 = -\mathbf{r}_{k-1} - A_{\eta, u^{(m)}} \mathbf{t}_{k-1}^{bcg}$, where $\mathbf{r}_{k-1}, \mathbf{t}_{k-1}^{bcg}$ are the residual and the solution that the BiCG process produces at the $k-1$ inner step. We know that the BiCG solution $\mathbf{t}_{k-1}^{bcg}$ is a linear combination of the first $\mathbf{d}_{i, i=0:k-2}$ BiCG vectors, and from (3.7) we have $\mathbf{d}_{k-1}^T A_{\eta, u^{(m)}} \mathbf{t}_{k-1}^{bcg} = 0$. Thus, using the update formula of $\mathbf{d}_{k-1}$ in sQMR and (3.8), we obtain (3.18):

$$\begin{aligned}\Delta_k &= \gamma_k \Delta_{k-1} - \xi_k \mathbf{d}_{k-1}^T \mathbf{r}_{k-1} = \gamma_k \Delta_{k-1} - \xi_k (\mathbf{r}_{k-1}^T K_{u^{(m)}}^{-1} \mathbf{r}_{k-1} + \beta_{k-1} \mathbf{d}_{k-2}^T \mathbf{r}_{k-1}) \\ &= \gamma_k \Delta_{k-1} - \xi_k \mathbf{r}_{k-1}^T K_{u^{(m)}}^{-1} \mathbf{r}_{k-1} = \gamma_k \Delta_{k-1} - \xi_k \rho_{k-1}.\end{aligned}$$

The recurrence for Γ_k is decomposed as follows:

$$\Gamma_k = (\mathbf{t}_{k-1} + \boldsymbol{\delta}_k)^T A_{\eta, u^{(m)}} (\mathbf{t}_{k-1} + \boldsymbol{\delta}_k) = \Gamma_{k-1} + 2\Psi_k + \Phi_k.$$

We first consider Φ_k. Notice that from the sQMR algorithm that $\boldsymbol{\delta}_k$ is a linear combination of the $\mathbf{d}_{i,i=0:k-1}$. Therefore $\boldsymbol{\delta}_i$ are also conjugate to $\mathbf{d}_i$, i.e.,

$$\boldsymbol{\delta}_{k-1}^T A_{\eta,u^{(m)}} \mathbf{d}_{k-1} = 0. \tag{3.23}$$

Then, we can derive (3.21) as follows:

$$\begin{aligned}\Phi_k &= (\gamma_k \boldsymbol{\delta}_{k-1} + \xi_k \mathbf{d}_{k-1})^T A_{\eta,u^{(m)}} (\gamma_k \boldsymbol{\delta}_{k-1} + \xi_k \mathbf{d}_{k-1}) \\ &= \gamma_k^2 \Phi_{k-1} + \xi_k^2 \mathbf{d}_{k-1}^T A_{\eta,u^{(m)}} \mathbf{d}_{k-1} = \gamma_k^2 \Phi_{k-1} + \xi_k^2 \sigma_{k-1}.\end{aligned}$$

Now, we consider Ψ_k. We observe that the sQMR solution vector $\mathbf{t}_k$ is a linear combination of the $\boldsymbol{\delta}_{i,i=0:k}$ vectors. Using the conjugacy of $\boldsymbol{\delta}_i$ with $\mathbf{d}_i$ in (3.23), we have $\mathbf{t}_k^T A_{\eta,u^{(m)}} \mathbf{d}_k = 0$. Then (3.22) is obtained as

$$\begin{aligned}\Psi_k &= \mathbf{t}_{k-1}^T A_{\eta,u^{(m)}} (\gamma_k \boldsymbol{\delta}_{k-1} + \xi_k \mathbf{d}_{k-1}) = \gamma_k \mathbf{t}_{k-1}^T A_{\eta,u^{(m)}} \boldsymbol{\delta}_{k-1} \\ &= \gamma_k \mathbf{t}_{k-2}^T A_{\eta,u^{(m)}} \boldsymbol{\delta}_{k-1} + \gamma_k \boldsymbol{\delta}_{k-1}^T A_{\eta,u^{(m)}} \boldsymbol{\delta}_{k-1} = \gamma_k (\Psi_{k-1} + \Phi_{k-1}).\end{aligned}$$

Finally, it can be simply verified that for $k = 0$ the above scalar quantities have the value of zero. ∎

3.3. Stopping criteria. The above theorem provides the means to dynamically and inexpensively monitor the eigenvector convergence inside the linear solver. It also characterizes the convergence behavior of both the linear system and the eigenvalue residual. We first consider the unpreconditioned case, where the sQMR is equivalent to MINRES, and $g_k = \hat{g}_k$. To simplify the discussion we introduce the following notation where nonboldface letters are used to denote the norms of the vectors with corresponding boldface letters. Specifically,

$$r_k^{(m+1)} = \|\mathbf{r}_k^{(m+1)}\|, \tag{3.24}$$

$$r_\infty^{(m+1)} = \|\mathbf{r}_\infty\| = \|\lim_{k\to\infty} \mathbf{r}_k^{(m+1)}\|, \tag{3.25}$$

$$g_k = \|\mathbf{g}_k\|, \tag{3.26}$$

$$t_k = \|\mathbf{t}_k\|, \tag{3.27}$$

$$p_k = \frac{(\theta^{(m)} - \eta + \mathrm{B}_k)^2}{1 + \|\mathbf{t}_k\|^2} - (\theta_k^{(m+1)} - \eta)^2. \tag{3.28}$$

Equation (3.17) suggests that as the linear system is solved, $g_k \to 0$, $r_k^{(m+1)} \to r_\infty^{(m+1)}$, and $p_k \to (r_\infty^{(m+1)})^2$. Note that p_k could be negative initially, but converges to a positive limit with a rate similar to that of g_k. In addition, Notay showed for a similar equation for the CG that p_k is much smaller than $(r_k^{(m+1)})^2$. Therefore, $r_k^{(m+1)}$ stays close to g_k until the proximity of the limit. Notay proposed stopping the inner solver when convergence rates start to deviate: $g_k/g_{k-1} < (r_k^{(m+1)}/r_{k-1}^{(m+1)})^{\alpha'}$ for some user-defined α', say 0.9. The lack of monotonic convergence of g_k in CG complicates the above stopping criterion, and the practical JDCG algorithm introduces several different tests and user-defined parameters. The smooth convergence of the JDQMR residuals allows for a much more accurate use of convergence rates. Moreover, we show how to provide a set of almost parameter-free, adaptive stopping criteria.

First rewrite (3.17) as

$$r_k^{(m+1)2} = \frac{g_k^2}{1 + t_k^2} + p_k. \tag{3.29}$$

We want to quantify how accurate an approximation of the INVIT iterate we should obtain, or, equivalently, to identify an α, such that we stop when

$$r_k^{(m+1)} \leq \alpha \; r_\infty^{(m+1)}, \text{ with } \alpha > 1. \tag{3.30}$$

Based on our discussion above, the results in [46], and the fact that in the domain of Newton convergence (for the outer iteration), $r_\infty^{(m+1)}$ is much smaller than $r_0^{(m+1)}$, we can assume that $p_k \approx r_\infty^{(m+1)2}$ even for relatively small k, and in particular for k close to the required stopping point. Thus, we can turn condition (3.30) into a testable condition involving only g_k and $r_k^{(m+1)}$:

$$\begin{aligned} r_k^{(m+1)2} \leq \alpha^2 \; p_k &= \alpha^2 r_k^{(m+1)2} - \alpha^2 g_k^2/(1+t_k^2) \\ &\Leftrightarrow g_k \leq r_k^{(m+1)} \sqrt{\frac{\alpha^2-1}{\alpha^2}} \sqrt{1+t_k^2}. \end{aligned} \tag{3.31}$$

Because the norm of the correction is typically $t_k \ll 1$, especially close to convergence, the above condition is determined by the factor based on α. A first approach to obtaining this factor is to observe that when the two terms $g_k^2/(1+t_k^2)$ and p_k in (3.29) become equal, $r_k^{(m+1)}$ is approximately within a factor of $\sqrt{2}$ from its limit. Thus, we could stop if the linear system residual is smaller than $0.707\sqrt{1+t_k^2}$ of the eigenresidual. Our experiments, however, have shown this not to be an effective factor. Indeed, a factor close to $0.99\sqrt{1+t_k^2}$ has yielded consistently better results.

To identify an appropriate factor α, we should first understand its effects on the global convergence of the method. On exit from the inner iteration, the eigenvalue errors satisfy the Bauer–Fike bounds:

$$|\theta_k^{(m+1)} - \lambda_1| \leq r_k^{(m+1)}, \tag{3.32}$$

$$|\theta_\infty^{(m+1)} - \lambda_1| \leq r_\infty^{(m+1)}. \tag{3.33}$$

We avoid using the tighter bounds of [52] because λ_1 may not be sufficiently separated from the spectrum relative to $r_k^{(m+1)}$. After completing the following outer step, exact INVIT will reduce the eigenvalue error by a factor f, i.e., $f r_\infty^{(m+1)}$. Therefore, a small enough value of α—obviously smaller than $1/f$—is needed for the inexact INVIT to guarantee convergence. An analysis of the bounds that such a value has to satisfy and some heuristics are presented in [62] (see also [6]). Similarly, exact RQI will yield an eigenvalue error $f|\theta_\infty^{(m+1)} - \lambda_1|^2$ for some factor f. As Smit and Paardekooper derive in [62], quadratic convergence in inexact RQI is maintained even for relatively large values of α, especially during the later stages of the iteration, as long as sufficiently small ones are used in the first few iterations.

In the first few outer iterations, the JDQMR may not have a good estimate of the eigenvalue, suggesting the contrary, i.e., that the correction equation should not be solved accurately at all. This presents no problem, because JDQMR is more flexible than INVIT/RQI, in that even if no accuracy is required in the solution of the correction equation (zero inner iterations), the subspace accelerated algorithm still converges as fast as Arnoldi or GD (with preconditioning). The outer step, however, can be rather expensive compared with the recurrence-based inner solver. For this reason, it is beneficial to postpone exiting from the QMR as much as possible to achieve an outer convergence similar to that of the exact INVIT/RQI. This implies that $r_k^{(m+1)}$ and $r_\infty^{(m+1)}$ should be of the same order of magnitude, e.g., for INVIT

$\alpha < \min(1/f, 10)$. We have chosen $\alpha = 7$, which yields the parameter 0.99 of the previous paragraph. The choice of α that gives an optimal total number of inner iterations, i.e., number of matrix-vector operations, is beyond the scope of this paper and is the focus of current research. We note, however, that preliminary results with an RQI model based on (3.29) and (3.31) have confirmed that when a constant α is to be used its value should be 8, which is close to our experimental choice.

The criterion (3.31) can be complemented for the case where the convergence of the linear system solver is very slow or experiences plateaus. In that case, we want $r_k^{(m+1)}$ to be even closer to g_k relative to the convergence rate of g_k and not only by a constant factor. We demand, therefore, that the average convergence rate of the eigenresidual $(r_k^{(m+1)}/r_0)^{1/k} = (r_k^{(m+1)}/g_0)^{1/k}$ is no more (i.e., not slower) than the geometric average of the last two average rates of the linear system, i.e., stop when

$$\sqrt{\frac{g_k}{g_0}\frac{g_{k-1}}{g_0}} < \frac{r_k^{(m+1)}}{g_0} \Leftrightarrow$$

$$g_k < r_k^{(m+1)}\sqrt{g_k/g_{k-1}}. \tag{3.34}$$

Putting together inequalities (3.31) and (3.34) we obtain our first stopping criterion:

$$g_k \le r_k^{(m+1)} \max\left(0.99\sqrt{1+t_k^2}, \sqrt{g_k/g_{k-1}}\right). \tag{3.35}$$

As we discuss in section 5.2, despite the optimality of the above criteria, sQMR may experience convergence plateaus in more than one outer JD iteration. During these plateaus it attempts to resolve certain eigencomponents that prevent convergence for the specific correction equation. Although this plateau would be built even by our QMRopt benchmark, repeating it every outer iteration would be wasteful—wasteful in a different sense than what we have studied till now. The g_k and $r_k^{(m+1)}$ may still be close and the inner iteration may still offer improvements to the correction, but to do so it needs components that it keeps rebuilding for different correction equations at every outer step. Although not severe, this is sometimes observed in problems with slow convergence. In such cases, we have found it beneficial to stop when r_0 is reduced by a certain factor of, say,

$$r_k^{(m+1)} < 0.1\ r_0. \tag{3.36}$$

Note that this is very different from the traditional $g_k < 0.1\ g_0$ and that it should be used in conjunction with the criteria that guarantee closeness of g_k and $r_k^{(m+1)}$.

For extreme eigenvalues, the variational principle guarantees monotonic convergence of the Ritz value at the outer step, but not of the approximation $\theta_k^{(m+1)}$ during the execution of QMR. We have found it beneficial, however, to stop QMR when

$$\theta_k^{(m+1)} > \theta_{k-1}^{(m+1)}. \tag{3.37}$$

If $\theta_k^{(m+1)}$ increases, an eigenvalue was missed and the solver is trying to retarget convergence to the missed one. It is thus beneficial to exit the inner iteration and let the outer step improve on the new Ritz value through the Rayleigh–Ritz procedure, providing a better correction equation during the next inner solution.

Finally, we should stop the inner iteration when the required tolerance has been achieved (or the maximum number of iterations reached). Although $g_k < r_k^{(m+1)}$,

except possibly for a few initial steps, it is safer to check both g_k and $r_k^{(m+1)} < \epsilon_{inn}$. The threshold for the inner iterations, ϵ_{inn}, could be the same as the user-defined threshold, ϵ, for the eigenresiduals. The $r_k^{(m+1)}$, however, is the residual norm of the corrected Ritz vector, and not from the outer Rayleigh–Ritz method on the basis V that includes the correction. Thus the residual norm computed by the outer method could be slightly larger than ϵ, causing the inner method to be called again to provide a very small correction. This restarting could force QMR to build again certain vector components, wasting some iterations. Therefore, we suggest $\epsilon_{inn} = \epsilon/2$, while making sure that this is achievable within the machine's precision, $\epsilon_{\text{machine}}$. Estimating the norm of A by the largest Ritz value seen thus far, we stop QMR if

$$g_k < \epsilon_{inn} \text{ OR } r_k^{(m+1)} < \epsilon_{inn}, \tag{3.38}$$

$$\text{with } \epsilon_{inn} = \max(\epsilon/2, \epsilon_{\text{machine}}\|A\|). \tag{3.39}$$

3.4. The effect of quasi-minimization. With a preconditioner K, the BiCG residuals $\mathbf{r}_k$ in Algorithm 3.1 are K^{-1}-orthogonal, but unlike MINRES, which implicitly considers the orthogonal basis $K^{-1/2}\mathbf{r}_k$, sQMR uses the $\mathbf{r}_k$, and thus the actual norm g_k of the sQMR residual is bounded as shown in inequality (3.9). A natural question is whether the above stopping criteria would be adversely affected by using the readily computed $\hat{g}_k$ instead of g_k.

The only quantity in Theorem 3.1 that is affected by replacing g_k with $\hat{g}_k$ is the eigenresidual norm $r_k^{(m+1)}$. Neither the eigenvalue estimate $\theta_k^{(m+1)}$ nor the p_k term of (3.29) depends on the choice of g_k. Let $g_k = c_k\hat{g}_k$, with $1 \le c_k \le \sqrt{k+1}$. We do not consider the possibility $0 \le c_k < 1$, because in the rare case that this occurs, c_k would still be very close to 1. Denote by $\hat{r}_k^{(m+1)}$ the eigenresidual norm approximation computed through (3.29) using $\hat{g}_k$. We can express $r_k^{(m+1)}$ as a function of the approximate $\hat{r}_k^{(m+1)2}$ as follows:

$$\begin{aligned} r_k^{(m+1)2} &= \frac{g_k^2}{1+t_k^2} + p_k = c_k^2 \frac{\hat{g}_k^2}{1+t_k^2} + p_k = c_k^2(\hat{r}_k^{(m+1)2} - p_k) + p_k \\ &= c_k^2 \hat{r}_k^{(m+1)2} - (c_k^2 - 1)p_k. \end{aligned} \tag{3.40}$$

Ideally, criterion (3.35) should check the ratio of the exact residuals $g_k/r_k^{(m+1)}$. Denoting $R = \max(0.99\sqrt{1+t_k^2}, \sqrt{g_k/g_{k-1}})$ and using (3.40) we should check the following:

$$\frac{g_k^2}{r_k^{(m+1)2}} = \frac{c_k^2\hat{g}_k^2}{c_k^2\hat{r}_k^{(m+1)2} - (c_k^2-1)p_k} = \frac{\hat{g}_k^2}{\hat{r}_k^{(m+1)2}} \frac{1}{1 - \frac{(c_k^2-1)}{c_k^2}\frac{p_k}{\hat{r}_k^{(m+1)2}}} < R^2.$$

Equivalently, using our computed residual approximations we should check

$$\hat{g}_k < \hat{r}_k^{(m+1)}\ R\sqrt{1 - \frac{(c_k^2-1)}{c_k^2}\frac{p_k}{\hat{r}_k^{(m+1)2}}}. \tag{3.41}$$

In practice, because c_k is not known, we can only check

$$\hat{g}_k < \hat{r}_k^{(m+1)}\ R. \tag{3.42}$$

We have used the same R in both ideal and practical tests, because $\hat{g}_k/\hat{g}_{k-1} = (c_{k-1}/c_k)g_k/g_{k-1} \approx g_k/g_{k-1}$ as c_k can change only slowly between successive steps.

When $\hat{r}_k^{(m+1)}$ is far from convergence, $p_k \ll \hat{r}_k^{(m+1)2}$, and since $(c_k^2-1)/c_k 2 < 1$, the factor multiplying R in (3.41) is almost one, and the approximate criterion (3.42) is practically equivalent to (3.41). Near convergence, $\hat{r}_k^{(m+1)2} \to r_\infty^{(m+1)2} \approx p_k$, so a large c_k could yield a substantially small factor, thus invalidating the approximate criterion. Two issues prevent this.

First, criterion (3.35) was derived from the condition that $r_k^{(m+1)2}$ should not come closer than α^2 to p_k. This gave rise to (3.30)–(3.31). Working backwards from R we have $\alpha^2 = 1/(1-R^2)$, so at any time before criterion (3.35) exits, it holds that

$$\frac{p_k}{r_k^{(m+1)}} < 1 - R^2. \tag{3.43}$$

Substituting $r_k^{(m+1)2}$ for $\hat{r}_k^{(m+1)2}$ from (3.40) and using (3.43), we can bound $\frac{p_k}{\hat{r}_k^{(m+1)}}$:

$$\frac{p_k}{\hat{r}_k^{(m+1)}} = \frac{p_k c_k^2}{r_k^{(m+1)} + p_k(c_k^2-1)} < \frac{c_k^2(1-R^2)}{1+(1-R^2)(c_k^2-1)}. \tag{3.44}$$

Then the factor multiplying R in the ideal bound (3.41) is bounded from below:

$$\sqrt{1 - \frac{(c_k^2-1)}{c_k^2}\frac{p_k}{\hat{r}_k^{(m+1)2}}} > \sqrt{\frac{1}{1+(1-R^2)(c_k^2-1)}}. \tag{3.45}$$

The above factor is always very close to 1, so checking (3.42) instead of (3.41) is a good approximation. For example, given that $R \geq 0.99$, it requires an excess of 1000 sQMR iterations, and a c_{1000} close to the bound (3.9) to require a stopping criterion of 0.95 instead of the used 0.99.

The second reason preventing a small factor (3.45) is that the term of $1 - R^2 = 1 - g_k/g_{k-1}$ becomes increasingly small with slow linear system convergence. Thus, it compensates for a possible increase in the term $c_k^2 - 1$ that could result from a large number of sQMR iterations, keeping the overall term $1 + (1-R^2)(c_k^2-1) \approx 1$.

Finally, even if the factor (3.45) does become slightly less than one, the inner sQMR is stopped a few iterations earlier than if the correct residual norms were used. This, in fact, may be beneficial because no time is wasted overconverging the inner iteration when more outer iterations are needed. On the contrary, using the upper bound $\sqrt{k+1}\,\hat{g}_k$ as the norm estimate requires more iterations to satisfy the stopping criterion and has consistently underperformed the $\hat{g}_k$ choice in our experiments.

The use of the approximate $\hat{g}_k$ and $\hat{r}_k^{(m+1)}$ may also affect criterion (3.39). Convergence may be signaled a few iterations earlier than it is actually achieved, which could cause an additional correction equation to be solved through a few additional sQMR iterations. However, this does not affect the overall convergence behavior of the algorithm. Moreover, as without preconditioning, the inner tolerance ϵ_{inn} can be chosen heuristically to reduce the number of unnecessary iterations. For example, the norm ratio $\hat{c}_k = \hat{r}_k^{(m)}/r^{(m)}$ from the previous outer iteration can be used to estimate c_k and converge to $\epsilon_{inn} = \hat{c}_k \epsilon$. In our experiments the simple criterion from (3.39) was used and performed consistently well.

3.5. The JDQMR algorithm. Our stopping criteria and the recurrences of Theorem 3.1 can be implemented trivially into the sQMR Algorithm 3.1, which in turn is called at step (19) of Algorithm 2.1. Algorithm 3.2 provides the additional lines required in Algorithm 3.1. Except for the initializations, only line (12) is replaced.

ALGORITHM 3.2.
(2.1) $\mathrm{B}_0 = \Delta_0 = \Gamma_0 = \Phi_0 = \Psi_0 = 0$

(12.0) $\gamma_k = c_k^2 \Theta_{k-1}^2,\ \xi_k = c_k^2 \alpha_{k-1}, f = 1 + \|\mathbf{t}_k\|^2$
(12.1) $\Psi_k = \gamma_k(\Psi_{k-1} + \Phi_{k-1})$
(12.2) $\Phi_k = \gamma_k^2 \Phi_{k-1} + \xi_k^2 \sigma_{k-1}$
(12.3) $\Gamma_k = \Gamma_{k-1} + 2\Psi_k + \Phi_k$
(12.4) $\Delta_k = \gamma_k \Delta_{k-1} - \xi_k \rho_{k-1}$
(12.5) $\mathrm{B}_k = \mathrm{B}_{k-1} + \Delta_k$
(12.6) $p = \left(\theta^{(m)} - \eta + 2\mathrm{B}_k + \Gamma_k\right)/f$
(12.7) $\theta_k^{(m+1)} = \eta + p$
(12.8) $p_k = (\theta^{(m)} - \eta + \mathrm{B}_k)^2/f - p^2$
(12.9) $r_k^{(m+1)} = \sqrt{g_k^2/f + p_k}$
(12.10) **if** ρ_{k-1} **return**
(12.11) **if** $r_k^{(m+1)}$ $r_k^{(m+1)} = \sqrt{g_k^2/f}$
(12.12) **if** $g_k \le r_k^{(m+1)} \max\left(0.99\sqrt{f}, \sqrt{g_k/g_{k-1}}\right)$
$\theta_k^{(m+1)} > \theta_{k-1}^{(m+1)}$ $r_k^{(m+1)} < 0.1 r_0$
$g_k < \epsilon_{inn}$ $r_k^{(m+1)} < \epsilon_{inn}$
then return $\mathbf{t}_k$

The GD outer algorithm can be implemented with storage for $2m_{max}$ long vectors of size N. If JDQMR is used, there is an additional requirement of 5 long vectors.

Excluding matvec and preconditioning operations, the expense of the outer GD Algorithm 2.1 can be calculated as a function of flops. Following classic literature, each of the steps takes: reorthogonalization $O(8Nm + 2N)$ (step (5)), updating of H $O(2mN)$ (step (7)), the small eigenproblem $O(4/3m^3)$ (step (8)), Ritz vector computation $O(2Nm)$ (step (9)), residual computation $O(2Nm + 4N)$ (steps (9)–(10)), norm computation $O(2N)$ (step (11)), and the restarting cost is $O(4Nm_{max}m_{min})$ (steps (12)–(19)). Averaging over $m = m_{min} \ldots m_{max}$ and setting $\mu = m_{min}/m_{max}$, we have the average cost per step:

$$\mathrm{GDcost} = O\left(\frac{7 + 4\mu - 7\mu^2}{1 - \mu} N m_{max} + \frac{13 + \mu}{1 - \mu} N + 1/3 m_{max}^3\right).$$

Typically, $m_{min} = m_{max}/3$, in which case $\mathrm{GDouter} = 11.3Nm_{max} + 20N + m_{max}^3/3$. These are mostly BLAS level 2 and level 1 operations. Similarly, we can obtain the cost for each QMR step, including the JD projectors: $\mathrm{QMRcost} = 24N$. However, these are strictly level 1 BLAS operations. The QMR part of JDQMR is about 15% more expensive than the CG part of JDCG, but this is justified by the increased robustness and efficiency.

4. The conjugate gradients view. An alternative to Newton is the use of the nonlinear conjugate gradient (NLCG) method to minimize the quadratic form of the Rayleigh quotient on the unit ball. As with the Newton approach, the NLCG must be applied on the Grassmann (or Stiefel) manifold for this constrained minimization problem. The appropriate forms of the constrained version for the NLCG and for the case of many required eigenvalues are given in [15]. Researchers have been using similar types of recurrences quite successfully for many decades; see Bradbury and Fletcher's seminal work [8], the long list of references in [15], as well as work in [20, 5].

NLCG methods build iterates within a Krylov space as they only utilize gradient information. Therefore they cannot converge faster than unrestarted Lanczos or the optimal QMR benchmark. NLCG, however, uses a three-term recurrence to compute both eigenvalue and eigenvector without storing all the intermediate iterates. Therefore, NLCG can often find one eigenpair in less time than the Lanczos method despite a larger number of iterations.

Although the relations between NLCG, Newton, and quasi-Newton methods are well documented [45], the question whether truncated Newton methods are more efficient than NLCG (or quasi-Newton) is problem dependent. In the extreme case of a linear unconstrained problem the NLCG is equivalent to CG, and since only one Newton step is required in that case, NLCG and truncated Newton are equivalent. For eigenvalue problems, the nonlinearity is not severe and the above NLCG variants perform quite well. Given that JDQMR is a truncated Newton method with a number of matrix-vector products within a small factor of optimal, we would like to explore its relation to NLCG variants.

4.1. The locally optimal recurrence. Most NLCG approaches consider minimization of the functional along a search direction which is usually conjugate to the previous search direction with respect to some variation of the Hessian. Although not usually expressed like this, the approximation $\mathbf{u}^{(m+1)}$ at the $(m+1)$th step belongs in the space $L = \left\{\mathbf{u}^{(m-1)}, \mathbf{u}^{(m)}, \mathbf{r}^{(m)}\right\}$, where $\mathbf{r}^{(m)} = A\mathbf{u}^{(m)} - \theta^{(m)}\mathbf{u}^{(m)}$ is the residual of $\mathbf{u}^{(m)}$. It is natural to consider a method that minimizes the Rayleigh quotient on the whole space L instead of only along one search direction. The method

$$\mathbf{u}^{(m+1)} = \text{Rayleigh–Ritz}\left(\{\mathbf{u}^{(m-1)}, \mathbf{u}^{(m)}, \mathbf{r}^{(m)}\}\right), \quad m > 1, \tag{4.1}$$

was proposed by D'yakonov in 1983 [14] and was studied further under the name locally optimal conjugate gradient (LOCG) in [30]. It is captivating in its simplicity, especially because it avoids the question of how to pick the search directions. Most importantly, the method seems to consistently outperform other NLCG-type methods.

Yet, for many years since its inception, LOCG was plagued by numerical instability problems. Obviously, a converging vector $\mathbf{u}^{(m)}$ implies an increasingly linearly dependent basis for the Rayleigh–Ritz process. Orthogonalization of the basis was not considered, mainly to keep recurrence costs low, but also because orthogonalizing two almost identical vectors would result primarily in a noise vector. In that case, the effectiveness of the method can be no worse than steepest descent. However, these problems do not arise until a good level of convergence has already been achieved. An extension to this method for many eigenvalues, and with a more stable recurrence (using $\mathbf{u}^{(m)} - \tau^{(m)}\mathbf{u}^{(m-1)}$ for some weight $\tau^{(m)}$ instead of $\mathbf{u}^{(m-1)}$) is the more recently proposed locally optimal block preconditioned CG (LOBPCG) method [32].

4.2. The locally optimal restarting. Restarting Krylov and Krylov-like methods every k iterations can have detrimental effects on their convergence, as the minimization of the Rayleigh quotient occurs only over the last k basis vectors. In the extreme case of $k = 1$ the method is simply the steepest descent. In linear systems of equations, CG has the remarkable property of implicitly remembering all the visited directions. Although the Lanczos method has the same memory, the Lanczos vectors must be revisited to compute the eigenvector. For symmetric problems, a larger subspace acceleration of steepest descent (larger k) yields better convergence, although beyond a certain basis size orthogonalization and restarting costs start to dominate.

Thick restarting [70] is a technique that improves convergence of restarted iterative methods by keeping more than the required Ritz vectors at restart ($m_{min} > nev$). The technique harnesses the superlinear convergence of Lanczos as nearby Ritz vectors are improved, and therefore are gradually deflated. It is theoretically equivalent to implicit restarting [63], and it has proved particularly effective when more than one eigenvalue is required. Still, by itself, thick restarting cannot capture the memory of directions that CG captures so well.

In [44], Murray, Racine, and Davidson proposed restarting the Davidson method with not only the required Ritz vector at the current step ($\mathbf{u}^{(m_{max})}$), but also with the Ritz vector at the previous step ($\mathbf{u}^{(m_{max}-1)}$). The motivation was to maintain the same three-term space L that CG uses to get its optimal approximation when solving a linear system of equations. However, it was unclear what this linear system is, and without the obvious connection to NLCG the method went relatively unnoticed for some years. Also, the suggested implementation was orthogonalization-heavy, requiring even extra matrix-vector products. On the other hand, the convergence improvements for Davidson, with or without preconditioning, were impressive.

4.3. The GD+k method. In [68], we showed a theoretical justification of the connection of the above restarting scheme, which we called GD+1, to CG. For completeness we mention the following two pertinent results. Proofs and additional discussion are given in [68, 64].

THEOREM 4.1. $\mathbf{u}^{(0)}$ $\|\mathbf{u}^{(0)}\| = 1$ $\theta^{(0)} = \mathbf{u}^{(0)T} A \mathbf{u}^{(0)}$ $\eta \in \Re$ $(\theta^{(j)}, \mathbf{u}^{(j)})$ j $\mathbf{u}^{(0)}$ $\mathbf{u}_j^{(1)} = \mathbf{u}^{(0)} + \mathbf{t}_j$ $\mathbf{t}_j$ j (2.1) $(m = 0)$

$$\mathbf{u}_j^{(1)} = \mathbf{u}^{(j)} \Leftrightarrow \eta = \theta^{(j)}.$$

The theorem says that if we knew the Ritz value $\theta^{(j)}$ at any Lanczos step, we could construct a (CG) three-term recurrence to yield the corresponding Ritz vector. Intermediate vector iterates would differ in general. This is similar to the relation between the iterates obtained by the optimal QMR process ($\eta = \lambda$) and the Ritz vectors of the unrestarted Lanczos. The effectiveness of the GD+1 restarting technique is attributed to the fact that the Lanczos Ritz vectors approximate the CG iterates as $\theta^{(j)}$ converges. For the smallest eigenvalue λ_1 we have the following.

LEMMA 4.2. $\gamma = \lambda_2 - \lambda_1$ $|\theta^{(0)} - \lambda_1| < \delta$ $\delta < \gamma/2$ (2.1)

$$\frac{\|\mathbf{u}^{(j)} - \mathbf{u}_j^{(1)}\|}{\|\mathbf{u}_j^{(1)}\|} \leq \frac{|\theta^{(j)} - \eta|}{\gamma - 2\delta}.$$

If we were to restart GD at the m_{max} step, the Ritz value at the $(m_{max} + 1)$ step would be minimum over only $\mathbf{u}^{(m_{max})}$ and $\mathbf{r}^{(m_{max})}$. If we also kept $\mathbf{u}^{(m_{max}-1)}$, the three-vector subspace would be similar to the three-term CG recurrence subspace that yields the exact $\mathbf{u}^{(m_{max}+1)}$. $GD+1$ $(m_{max}+1)$ $O(|\theta^{(m_{max}-1)} - \theta^{(m_{max}+1)}|)$ This justifies a stronger local optimality of the GD+1, not only with respect to the Rayleigh quotient as in LOCG, but also to the Ritz vectors.

ALGORITHM 4.1. [illegible] 2.1 [illegible]

(7.1) $s_i^{old} = s_i,\ i = 1, \ldots, m$

(12.1) [illegible] $s_i^{old},\ i = 1, \ldots, k$ [illegible]
[illegible] $s_i,\ i = 1, \ldots, m_{min}$

(12.2) [illegible] $H_{sub} = s^{oldT} H s^{old}$

(12.3) [illegible] $s = [s_1, \ldots, s_{m_{min}}, s_1^{old}, \ldots, s_k^{old}]$

(14) **for** $i = 2, \ldots, m_{min} + k$

(17.1) $H(m_{min} + 1 : m_{min} + k, m_{min} + 1 : m_{min} + k) = H_{sub}$

(17.2) $m = m_{min} + k$

In [68], we extended GD+1 to GD+k and combined it with thick restarting. By GD(m_{min}, m_{max})+k we denote the GD method with basis size m_{max}, where at restart we retain m_{min} smallest Ritz vectors from step m_{max} and in addition k smallest Ritz vectors from step $m_{max} - 1$. The special case GD(1, 3)+1 is mathematically equivalent to LOCG (and in general a block GD($k, 3k$)+k with block size k is equivalent to LOBPCG). We also provided an implementation that requires no additional orthogonalization of long vectors and no extra matrix-vector products by working exclusively with the Rayleigh–Ritz coefficients. The modifications required to the GD Algorithm 2.1 are shown in Algorithm 4.1. The expense in terms of flops of steps (12.1)–(12.3) is $O(m_{max}k^2)$ and thus insignificant for large problems. The only additional expense over GD is that we have to restart with a basis size of $m_{min} + k$ (step (14)). Because convergence improves significantly, even with $k = 1$, a much smaller m_{min} can be used than regular GD, and thus GD+1 can be less expensive per step than GD.

We emphasize that the GD+k stability stems from the orthogonality of the basis V. Typically, the small coefficient vectors s_1 and s_1^{old} will be very close. Orthogonalizing s_1^{old} against s_1 will produce a vector that may not lie exactly in the span of s_1^{old}, but it will be orthogonal to s_1. This orthogonality is bequeathed to Vs (as $V^TV = I$), which becomes a stable basis for the LOCG recurrence. In contrast, the LOBPCG method considers the vector $V(s_1 - s_1^{old})$ (with $V^TV \neq I$), which is not exactly orthogonal to Vs_1, and so the Rayleigh–Ritz procedure gives rise to a generalized eigenvalue problem, with inferior stability properties. The dangers of a nonorthogonal basis in LOBPCG have been pointed out in [28].

4.4. Global optimality and subspace acceleration. Despite the local optimality of GD+1, from both the Ritz value and Ritz vector viewpoints, there is no theoretical result showing that GD(1, 3)+1 (or equivalently LOCG) is within a small factor of optimal QMR. Extensive numerical experiments in [68, 64, 32] and in this paper suggest that this is true for the majority of cases. The above theory can provide some intuition for this. Because the eigenvalue error in symmetric problems converges as the square of the residual norm, the Ritz value quickly approximates the eigenvalue, and therefore the LOCG recurrence approximates well the optimal CG method (i.e., solving (2.1) with $\eta = \lambda_1$). Interestingly, even when the Ritz value nearly stagnates over many steps, Lemma 4.2 suggests that the LOCG recurrence can effectively build a space similar to the unrestarted Lanczos. When the algorithm realizes that it is targeting the wrong eigenvalue, the global optimality of the algorithm is lost. This is similar to terminating the inner iteration of the JDQMR to update the shift in the correction equation. Unlike JDQMR, however, each step of GD+1 involves the most current Ritz value, which may explain its faster observed convergence.

Yet, for some spectrum distributions or adversely chosen initial guesses, the Ritz

value may vary substantially, often locked temporarily on various interior eigenvalues. The result is several breaks in the global optimality of LOCG, similarly to many outer steps of a JDQMR (or RQI) algorithm. For such cases subspace acceleration and thicker restarting can improve convergence dramatically. The GD(m_{min}, m_{max})+1 method takes advantage of the global optimality when this is present, and when not, it maintains the subspace convergence of the restarted GD/Lanczos for required and nearby eigenvalues. This in turn makes the Ritz value converge faster, thus expediting the return to benefiting from the LOCG recurrence. See also [50] for the effects of subspace acceleration on classic GD. Finally, although GD(m_{min}, m_{max})+1 is a stable implementation, convergence of the coefficient vectors s_1 and s_1^{old} in Algorithm 4.1 yields a basis V which, although orthogonal, may not fully correspond to the ideal three-term space of the LOCG recurrence. Without subspace acceleration, GD(1, 3)+1 or LOBPCG revert back to steepest descent in these cases.

There is an interesting analogue from the nonlinear viewpoint. NLCG is close to optimal when the nonlinearity of the problem is not severe. When it is, e.g., when the minimization function gets trapped in various saddle points (interior eigenvalues), quasi-Newton methods almost always converge faster than NLCG [24]. These methods use the vector iterates to construct incrementally an approximation to the Hessian. A less expensive—but equally effective in terms of convergence—alternative is to use only the last few vector iterates as in the popular L-BFGS method, which is a limited memory version of the Broyden–Fletcher–Goldfarb–Shanno method [45]. In the context of eigenvalue problems, implementing L-BFGS is similar to the subspace acceleration of the restarted GD+1 method, the only difference being the minimization occurring over lines instead of the whole subspace in GD. At one extreme, L-BFGS with memory 1 (in addition to the current iterate) is equivalent to NLCG and similar to GD(1, 3)+1, while at the other extreme unlimited memory BFGS is similar to unrestarted GD (or Arnoldi). In the case of a strictly convex, quadratic objective function the equivalence extends between certain forms of L-BFGS, NLCG, and the usual CG [35]. Similar connections between quasi-Newton methods and iterative methods for linear systems have been studied. For example, the Broyden method for linear systems gives rise to the Eirola–Nevanlinna method, which is equivalent to GMRES [16]. In conclusion, we expect the subspace accelerated GD(m_{min}, m_{max})+1 to be more robust and more effective than simple recurrences (such as LOBPCG).

5. Experiments. Our first goal in the experiments is to verify that JDQMR and GD+1 are indeed within a small factor of the optimal method QMRopt. QMRopt refers to the JDQMR method where the exact eigenvalue is given as shift. Thus, one JDQMR outer step, with QMR solving (2.1), resolves the smallest eigenpair. Our second goal is to show the robustness and consistency of the JDQMR and GD+1 algorithms in a variety of situations, including also interior eigenvalue problems. Third, we provide extensive comparisons with JDCG, JDQR, ARPACK, LOBPCG, JDBSYM, and various versions of shift-invert Lanczos, with and without preconditioning. Fourth, as JDQMR and GD+1 arise as the methods of choice, we assess their relative merits. This allows for a dynamic choice between the two methods, as they both share the same implementation, leading to an overall nearly optimal method.

5.1. Tests and environment. Most of the algorithms used in our experiments are implemented in MATLAB. Our JDQMR/GD+1 code implements Algorithms 2.1–3.2 relatively closely by modifying the JDCG code of [46], which in turn is a modification of the code in [17]. To compare with ARPACK we use the MATLAB built-in function `eigs()`, and for LOBPCG we use Revision 4.0, Beta 4, with the modification

TABLE 5.1

The matrices used in the experiments. Most matrices come from Matrix Market (MM) [7], the University of Florida matrix repository (UF) maintained by Tim Davis [12], and the FEAP collection by Mark Adams [1]. SPARSKIT (SKIT) [54] was used to generate a five-point finite difference Laplacian on the unit three-dimensional cube with Dirichlet conditions. nd3kf and or56f are difficult eigenvalue problems from Yang et al. [75].

that `eig(A,B)` is used instead of `eig(A,B,'chol')` for numerical stability. We also provide a set of experiments with three packages written in C: our PRIMME multimethod package that implements also GD+1 and JDQMR;[1] BLOPEX, which is a LOBPCG implementation [29]; and JDBSYM, a block JD implementation [22].

In all experiments we seek only one, smallest algebraic eigenpair. For GD-based methods (GD+1, JDCG, JDQMR, JDQR) we use $m_{min} = 6$ and $m_{max} = 18$. With `eigs()` we select a basis size of 36 so that it requires the same storage as GD+1. LOBPCG requires storage for 6 vectors. The SI-eigs implements the shift-invert Lanczos by calling QMR to perform the inversions at each step of `eigs()`. A shift very close to the eigenvalue ensures that only a few outer eigs steps are needed. Because for LOBPCG we have found it far more stable to scale the matrix first, we always use $A = A/\|A\|_F$, where $\|A\|_F$ is the Frobenius norm of the matrix. Then we iterate all methods until the residual norm falls below 10^{-15}. The tolerance for `eigs()` is also set to 10^{-15}. All methods start with the same random initial guess. When there is a preconditioner, this is always the MATLAB function `cholinc(A+sI,1e-3)`, except for NASASRB, for which the threshold is `1e-5`. The shift `s` is chosen for each matrix so that the incomplete Choleski factorization can be carried out stably. Experiments are run in MATLAB 7 (R14SP3) on an Apple G5 with 1 GB of memory and two 2GHz processors, each with 512 MB L2 cache. For the C experiments we do not scale the matrix, but converge until the residual norm falls below $\|A\|_F 10^{-15}$. Experiments are run on the same Apple G5, using the gcc-4.0.0 compiler with -O flags, but without optimized BLAS/LAPACK libraries.

One of our goals is to provide experiments that can be confirmed independently by other researchers, but are also representative of various classes of problems. Thus, we have selected thirteen different matrix problems available in the following repositories: Matrix Market, University of Florida, and the FEAP collection. Two of these matrices (LUNDA and NASASRB) stem from eigenvalue computations, while the rest have spectra that present various levels of difficulty to iterative methods and the preconditioner. In addition, we have selected three matrices from eigenvalue applications, two from vibrational analysis of molecular structures [75], and the usual five-point Laplacian operator on the unit cube. A larger five-point Laplacian is used for the C experiments. Our test problems cover ranges from easy to difficult, from small to relatively large, and from sparse to relatively dense. Table 5.1 shows the name, sizes, and source for each matrix.

[1] Available at http://www.cs.wm.edu/∼andreas/software.

5.2. Nearly optimal convergence. First, we present results from matrices 1138BUS and NASASRB, as they are quite representative and demonstrate both the near optimality and robustness of GD+1 and JDQMR. Figures 5.1 and 5.2 show, for 1138BUS and NASASRB, respectively, the convergence history of the residual norm for several unpreconditioned methods as a function of matvec operations (top graphs) and as a function of time (bottom graphs). As expected, the QMRopt is the fastest method both in matvecs and in actual time, since it basically solves one linear system with QMR. Nevertheless, both JDQMR and GD+1 are very close to QMRopt.

For matrix 1138BUS, QMRopt displays superlinear convergence after about 800 matvecs, which is expected despite the highly clustered eigenvalues as the matrix is of small dimension. At the other extreme, LOBPCG achieves a linear convergence similar to the initial phase of QMRopt, but it never switches to superlinear convergence. Despite the limited basis size of 18, GD+1 manages to capture enough spectral characteristics and converges much faster than LOBPCG and similar to JDCG. The importance of the +1 restarting scheme is notable: a thick restarted, larger basis `eigs()` takes 38376 matvecs (7 times more than GD+1) to converge. Note also that the time for GD+1 is only slightly faster than that for LOBPCG because the matrix is extremely sparse and minimizing the number of matvecs does not substantially outweigh the more expensive iteration step. Similarly, JDQMR convergence is faster than JDCG, but their times are similar. Both JDQMR and JDCG convergence curves are very close to the QMRopt one.

For matrix NASASRB, LOBPCG does not converge fast enough, and `eigs()` stagnates after a large number of steps. Yet, the convergence of GD+1, JDCG, and JDQMR is almost identical to the one of QMRopt! There is one exception: JDCG has been converging to the second lowest eigenvalue and only realized it near convergence. At that point, JDCG retargets, and convergence is delayed accordingly. Besides slower convergence, this behavior may cause misidentification of eigenvalues for larger tolerances. We have noticed this JDCG behavior in a few of the other matrices we have studied. Our stopping criteria are apparently more robust in this direction, making JDQMR the fastest method (and closest to QMRopt) for this matrix.

Figure 5.3 shows a summary of our results from applying several methods on all 16 matrices without preconditioning. For each matrix, the bars show the ratios of matvecs and time (top and lower graphs, respectively) taken by each method over the QMRopt method. For completeness, we also provide the actual matvecs taken by QMRopt, GD+1, and eigs in Table 5.2. The results are surprisingly consistent, and they reflect also our experience with a larger number of different test problems. The main conclusion is that truncated Newton methods (JDCG/JDQMR) are much more efficient in finding one eigenvalue than `eigs()` (and much more so than LOBPCG) [illegible] This goes against the common wisdom that one should use the Lanczos method if no preconditioner is available. For most cases, JDQMR requires slightly fewer matvecs than JDCG, but JDCG is slightly faster because of the 15% more expensive iteration of QMR over CG. However, in three cases JDQMR is much faster than JDCG, justifying it as the more robust, general purpose method. In the absence of a preconditioner, the matvec operation in sparse matrices is rarely dense enough to justify the more expensive step of GD+1. Yet, the matvecs in GD+1 are usually the closest (and often equal) to those of QMRopt. Therefore, a runtime check in the program can assess the expense of the matvec operation, and if it is relatively high, as in matrices nd3kf and or56f, we choose GD+1 over JDQMR.

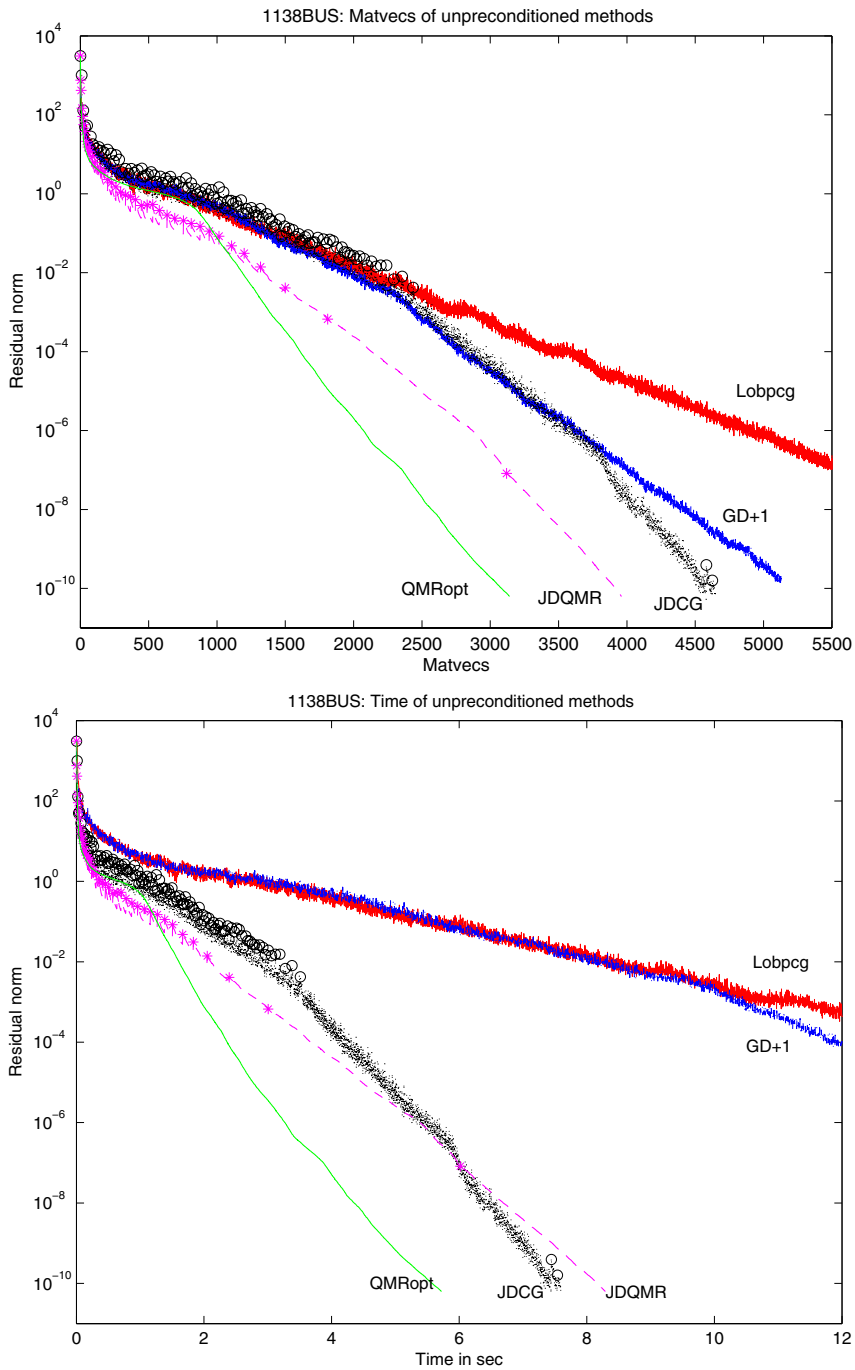

FIG. 5.1. *Residual convergence history for various methods without preconditioning for matrix* 1138*BUS* (*see Table* 5.1). (∗) *and* (○) *designate the residual norms at outer steps of JDQMR and JDCG, respectively. JDQMR improves convergence over JDCG, and GD*+1*, while being within a factor of* 1.26 *of the optimal QMR method. Because of the very inexpensive matrix-vector operation for* 1138*BUS, the convergence advantages of JDQMR are amortized by a slightly more expensive inner iteration over JDCG. This observation is amplified for the GD*+1*, which improves only on LOBPCG. eigs and SI-eigs require about* 40000 *matvecs and* 18 *seconds each.*

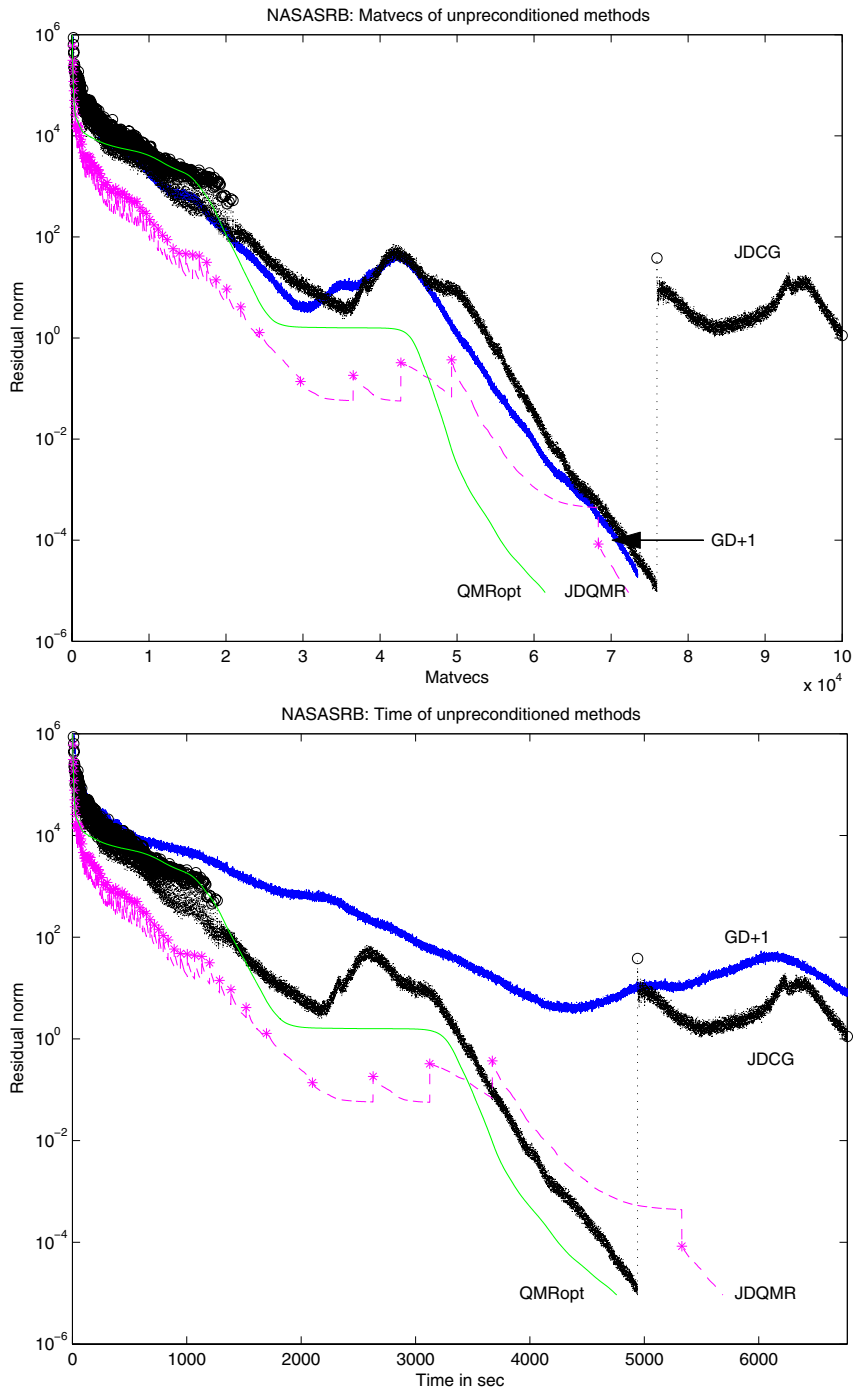

FIG. 5.2. *Residual convergence history for various methods without preconditioning for matrix NASASRB. The smallest eigenvalues are extremely hard to find. eigs seems to stagnate after* 300000 *matvecs. JDQMR is within* 1.17 *of the optimal QMR, and so is GD+1. JDCG converges similarly to GD+1 up to* 76000 *matvecs, at which point the outer step realizes that the correction vector did not correspond to the lowest eigenvalue. We have noticed this behavior also on other matrices. A relatively inexpensive matrix-vector operation plagues the time of GD+1. Convergence for LOBPCG was far slower and is not shown.*

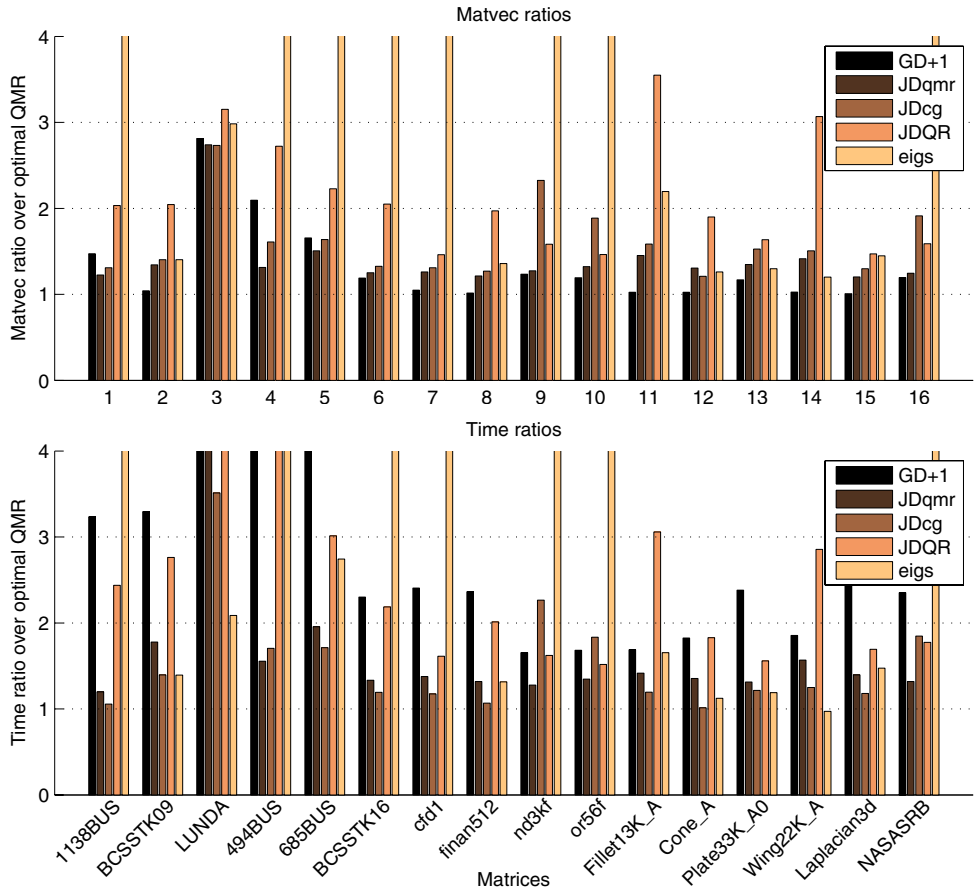

FIG. 5.3. *Ratios of matrix-vector operations (top graph) and time (bottom graph) taken by each of the five unpreconditioned methods over the the corresponding matvecs and time taken by the QMRopt. We show GD+1, JDQMR, JDCG, JDQR with* 10 *inner steps of QMR, and* `eigs()`. *LOBPCG was not competitive in these tests and is not shown. Matvecs for GD+1 are very close to QMRopt, followed closely by JDQMR. JDQMR is best timewise, because of a less expensive inner step and sparse matrix vector products.*

TABLE 5.2

Number of matrix-vector operations performed for each test matrix by three unpreconditioned methods: the optimal QMRopt, GD+1, and ARPACK (eigs).

Matrix No.	1	2	3	4	5	6	7	8
Opt QMR	3468	359	362	1798	733	439	2437	318
GD+1	5105	374	1018	3767	1214	522	2558	323
`eigs()`	38376	504	1080	17032	3293	2142	9864	432

Matrix No.	9	10	11	12	13	14	15	16
Opt QMR	8518	4765	82	200	610	75	858	61448
GD+1	10506	5687	84	205	713	77	864	73474
`eigs()`	80910	30636	180	252	792	90	1242	–

Preconditioners, when available, tend to dominate the expense at each step. In addition, as fewer iterations are needed with preconditioning, the effects of restarting are less dramatic. In such cases, we expect the GD+1 method to have an advantage.

Figure 5.4 shows the convergence history of various preconditioned methods on NASASRB. All methods perform within a factor of two of optimal, but GD+1 convergence is identical to optimal! Moreover, their relative convergence behaviors extend also to execution time, as the application of the `cholinc` preconditioner for this matrix dominates the costs. Based on the same principles, JDQMR and JDCG are similarly effective, with JDQMR slightly better.

Figure 5.5 shows a summary of results from applying five methods on our 16 matrices using preconditioning. We also provide the actual matvecs taken by QMRopt, GD+1, and SI-eigs in Table 5.3. Similarly to NASASRB, GD+1 is the clear winner in all cases, both iteration- and timewise. Moreover, for all but two cases (nd3kf and or56f) its convergence is almost identical to optimal. Even for nd3kf and or56f, convergence is well within a factor of 2 from optimal. Clearly, inner-outer SI-eigs is far from competitive. Even adaptive inner-outer schemes for RQI and INVIT as in [62, 6] cannot be any better than the subspace accelerated JDQMR.

Valuable intuition on the JDQMR convergence can be obtained through a closer look at its convergence curve in Figure 5.4. Recall that the CG/QMR convergence is usually described by three phases; an initial linear, a plateau, and a final superlinear. At the beginning of the JDQMR curve, while the easiest components of the spectrum are being identified, stopping the inner QMR process frequently does not have any negative effects on the convergence. Later, the inner QMR builds a plateau from step 100 until it is stopped at step 160. This stopping causes the inner QMR to rebuild this plateau from step 180 to step 240. In Figure 5.4, this second plateau accounts primarily for the slowdown over the optimal method. Fortunately, for the inner QMR to start to plateau, the outer JD must have reached the neighborhood of an eigenvalue. After that point, its convergence is cubic, similarly to RQI, and thus two or three outer steps are sufficient. A plateau is usually not expected during the third outer step, which is the one yielding the full accuracy. Therefore, we conjecture that JDQMR-type methods cannot be more than three times slower than the optimal method, and usually they are significantly less than two times slower. All our experiments support this conjecture. Avoiding this repetition with truncated Newton methods (such as JDQMR) is an open problem that methods of quasi-Newton type (such as GD+1) do not seem to have. Our criterion (3.36) alleviates this problem.

5.3. The effects of subspace acceleration. We provide a set of experiments that shows the effects of increasing the basis size in the GD(m_{min}, m_{max})+1 method. In Table 5.4 we report the number of matvecs and running time for GD+1 with various basis sizes, and for LOBPCG on five matrices without preconditioning. First, we observe that GD(1, 3)+1 and LOBPCG converge similarly, and often identically, supporting the theoretical equivalence of the two methods. The differences in timings are due to their different implementations and cache behaviors. Second, convergence improves drastically with a small subspace acceleration ($m_{max} = 6, 8$), but increasing m_{max} further only offers rapidly diminishing additional improvements. Consequently, the best time is achieved usually with $m_{max} = 6, 8$, unless the problem is too difficult and the matrix vector operator too expensive (see the nd3kf case).

Similar results are reported in Table 5.5 using the same preconditioner as in section 5.2. Again even a small subspace acceleration on LOCG achieves a nearly optimal convergence. Note that the orthogonal basis of GD(1, 3)+1 may improve numerical

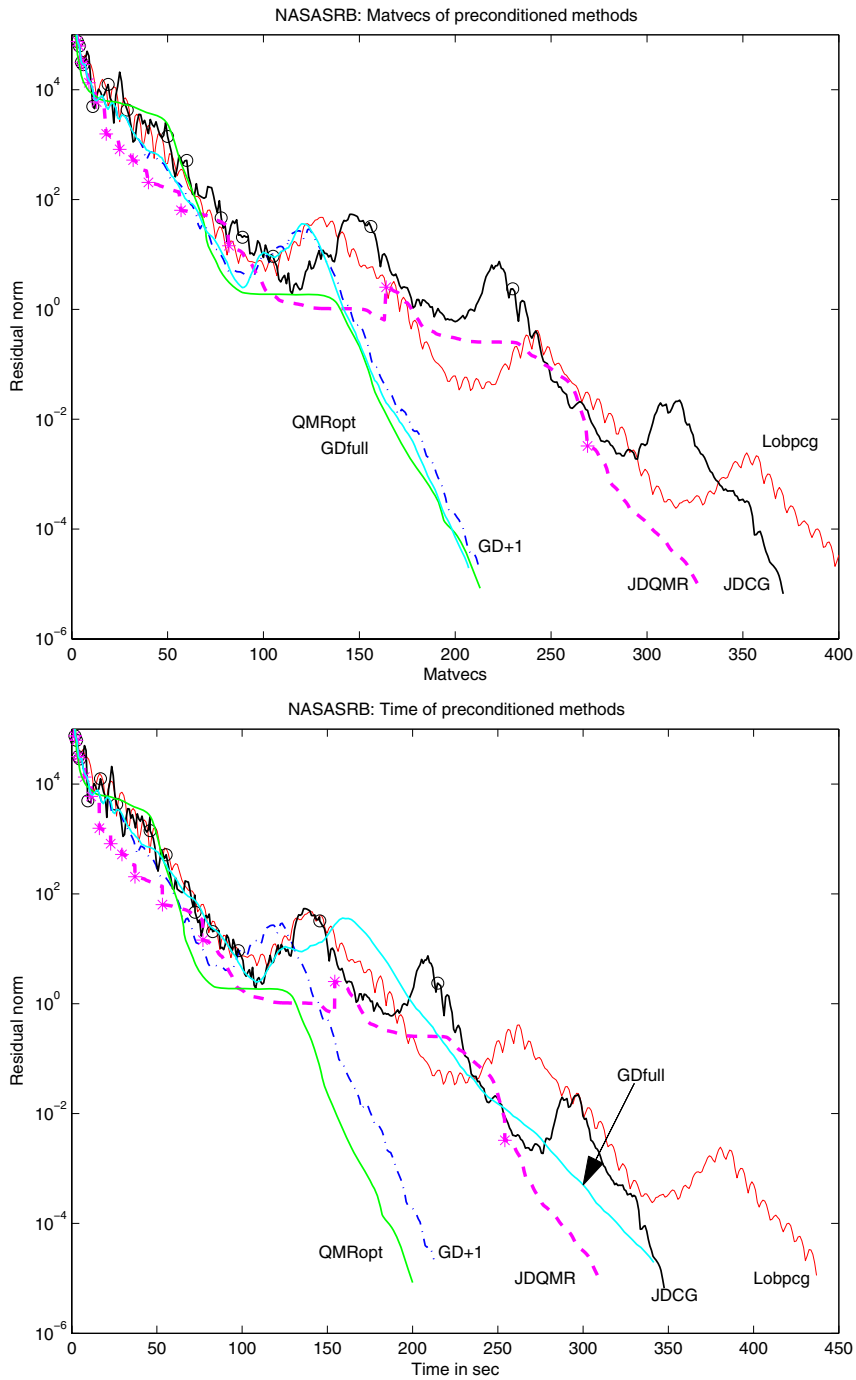

FIG. 5.4. *Residual convergence history for various preconditioned methods for matrix NASASRB. GD+1 converges identically to QMRopt and to the unrestarted GD. This shows the remarkable effectiveness of the +1 restarting scheme when coupled with subspace acceleration. LOBPCG is more than twice as slow. JDQMR and JDCG are also effective but not as much as GD+1. The inexpensive step of JDQMR/JDCG cannot outweigh the fewer applications of an expensive matrix-vector and preconditioning operators.*

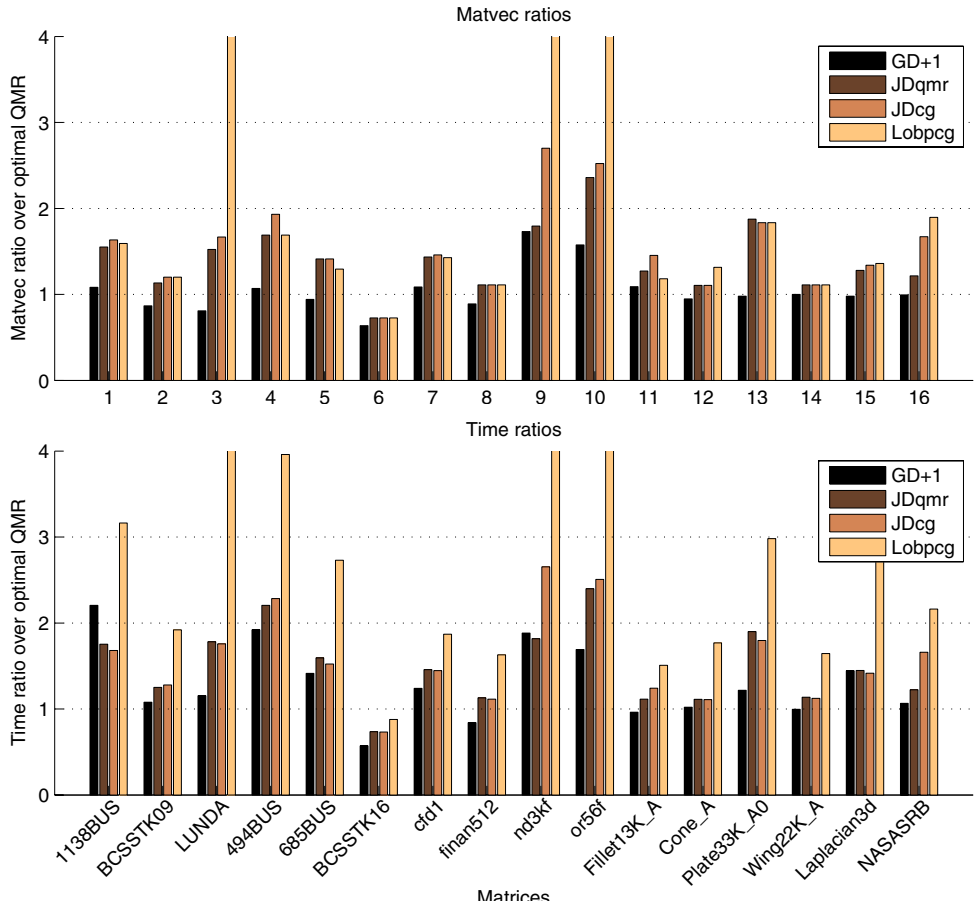

FIG. 5.5. *Ratios of matrix-vector operations (top graph) and time (bottom graph) taken by each of the four preconditioned methods over the the corresponding matvecs and time taken by the QMRopt. We show GD+1, JDQMR, JDCG, and LOBPCG. JDQR with* 10 *inner steps of QMR was not competitive in these examples and is not shown. Matvecs for GD+1 are impressively close to QMRopt and often lower, always improving on LOBPCG. JDQMR and JDCG are also very effective, but usually slower than GD+1.*

stability in some problems (see the next section), but not necessarily convergence (first two cases in Table 5.5). Finally, we note that the timings for GD$(6, 18)$+1 in the previous section could improve if a smaller m_{max} of 6 or 8 were to be used.

5.4. Experiments with PRIMME. In Table 5.6 we provide comparisons between three state-of-the-art eigenvalue packages for symmetric eigenvalue problems. Our goal in developing PRIMME (PReconditioned Iterative MultiMethod Eigensolver) was to provide a robust and nearly optimal multimethod software for which users are not required to set any parameters. The adaptivity of the JDQMR and the relatively robust choices of parameters for GD+1 make these two methods excellent candidates for default eigensolvers. We compare against BLOPEX and JDBSYM. The first three matrices are preconditioned with ILUT [54] with its parameters chosen to provide a stable factorization. The last two matrices are unpreconditioned.

First, we observe that BLOPEX (LOPBCG), although it requires no parameter

TABLE 5.3

Number of matrix-vector (equivalently preconditioning) operations performed for each test matrix by three methods: the optimal QMRopt, the GD+1, and the SI-eigs using preconditioned QMR to solve for $(A-\eta I)^{-1}$ at every step. The top table shows those matrices that required at least one restart for GD+1. The performance of GD+1 is very close to optimal. When restarting is not needed (lower table) the full subspace optimization of GD+1 even improves on the QMR recurrence. Every step of the SI-eigs requires about as many matvecs as the optimal QMR method. Thus, even if only 2 steps were required, SI-eigs would not have been competitive with GD+1. Similar results are expected with inner-outer implementations of INVIT or RQI.

setting, is not competitive. In addition, in the cases where it failed to converge, it had reached a residual norm of $\|A\|_F 10^{-10}$ but then encountered numerical problems. The JDBSYM was used with a symmetric QMR as inner solver, so the primary difference from JDQMR is the stopping criteria. The experiments confirm that when the JDBSYM criteria [13] capture the Newton convergence well, JDBSYM is close to JDQMR and sometimes competitive (unpreconditioned cfd1). The results in parentheses, however, show cases where JDBSYM could not converge, until the user provided a shift for the correction equation that was very close to the desired eigenvalue. GD+1 and JDQMR always converge, in the least time, and with no a priori information.

TABLE 5.6
Comparison of three state-of-the-art preconditioned eigensolver codes. BLOPEX implements LOBPCG, JDBSYM implements JD with sQMR as inner solver, and our PRIMME software includes both JDQMR and GD+1, which provide almost parameter-free near optimality.

5.5. Interior eigenproblem with indefinite preconditioner. We borrow a model problem from [illegible] calculations that are common in many fields such as computational chemistry and materials science. In these applications, the Schrödinger operator is a sum of the Laplacian and certain local and nonlocal potential functions. We consider the eigenvalue problem stemming from the simplified operator

$$(-\nabla^2 + V)\psi = \epsilon\psi, \tag{5.1}$$

where V is a local potential. In some cases, a few lowest eigenvalues are needed corresponding to the ground (most stable) states of the system. In many cases, however, we need a few eigenvalues around the Fermi energy level, a small energy gap that separates occupied from unoccupied states. Obtaining all eigenvalues lower than the Fermi level becomes extremely expensive for systems with a large number of particles, suggesting that an interior eigenmethod should be preferable.

In real space discretizations V is a diagonal matrix. In planewave (Fourier) discretizations, however, ∇^2 becomes a diagonal matrix (and thus easily invertible) and V a dense matrix. Many planewave codes exploit this property, performing preconditioning with $(\nabla^2)^{-1}$ in Fourier space, while operating with V in real space.

Consider (5.1) in the two-dimensional unit square, with Neumann boundary conditions, and with a potential inversely proportional to the distance from z_0: $V(x) = 1/\|x - z_0\|$, with $z_0, x \in \Re^2$. We discretize the operator with a uniform finite difference, five-point stencil, yielding the usual five-diagonal Laplacian matrix with V added on the diagonal. We use $n = 110$ points in each direction, for a matrix dimension of 12100, and place the largest potential in the middle of the grid-square closest to 0: $z_0 = [0.5/n,\ 0.5/n]^T$. We look (arbitrarily) for the eigenvalue closest to 0.86, which is beyond the 800th lowest eigenvalue of our matrix. All computations are performed in real space, except preconditioning. To precondition a vector $\mathbf{r}$, we transform it through a fast sine transform to Fourier space, where the preconditioner

$$K^{-1} = (\nabla^2 - \eta_K I)^{-1} \tag{5.2}$$

is diagonal. An inverse sine transform returns the preconditioned vector to real space.

Naturally, JDCG cannot be used if the shift η in the correction (2.1) is inside the spectrum. Moreover, JD with MINRES as inner solver cannot be used either if η_K makes the preconditioner (5.2) indefinite. The question is whether treating the problem as an interior with indefinite preconditioner is beneficial. Table 5.7 shows the performance as the number of preconditioning operations (equivalently matrix vector products) for various methods. Because our MATLAB implementation of the preconditioner is very expensive we do not report times.

GD+1 is the closest to the QMRopt method that uses the exact eigenvalue both in (2.1) and in (5.2). Note that the threefold factor in slowdown does not reflect a

TABLE 5.7

The benefits of JDQMR for finding one interior eigenvalue closest to 0.86. *The lowest eigenvalue of A is greater than* -0.05. *In the upper table an interior problem is solved, where both preconditioner and correction equation can be indefinite. A positive definite preconditioner* ($\eta_K = -0.05$), *as required by MINRES, does not converge. JDCG does not converge either when solving the correction equation for the extreme eigenvalue. The lower table shows that the transformation into an extreme eigenproblem for* $(A - 0.86I)^2$ *is not a good alternative, even though JDQMR is far better than JDCG. ARPACK* (*eigs*) *without preconditioning cannot converge.*

Seek eigenvalue closest to $\sigma = 0.86$. ($\lambda_{exact} = 0.859768$), $-0.05 < \lambda_i < 7.99$

JDCG			12736	
eigs			$\gg 30000$	(no preconditioning)

decrease in convergence rate but rather the fact that the solver spends most of the time trying to identify the proper eigenvalue to target. Once the eigenvalue is located, the convergence rate is similar to the optimal method. We have not investigated the use of harmonic Ritz values that could improve this identification. JDQMR converges in roughly 70% more iterations than GD+1. However, JDQMR too spends most of its time identifying the eigenpair, in fact exiting after one inner iteration. The astute reader may have noticed that in such cases the JDQMR is simply GD+1, only with two preconditioning operations per step. A more economical implementation is possible, but beyond our current discussion. As expected, fixing one or both of the shifts η, η_K makes convergence slightly worse, as demonstrated by various adaptive versions of INVIT. Without inner-outer adaptivity, the SI-eigs is an order of magnitude slower than JDQMR. For this example, JDMINRES with a positive definite preconditioner, or JDCG on a definite correction equation do not converge.

A common practice for interior eigenproblems is to solve for the smallest eigenvalue of $(A - \sigma I)^2$. This approach is attractively simple, but rarely competitive because of worse conditioning. The lower half of Table 5.7 shows the performance of four methods on the squared matrix with a similarly squared preconditioner. The ratio between GD+1 and JDQMR iterations is the same as in the interior method, while the JDCG converges but significantly slower. As it cannot exploit preconditioning, `eigs()` cannot converge in tractable time.

6. Conclusions. Our goal is to develop a method, or multimethod, that converges near optimally and robustly for large, difficult eigenvalue problems. The

method must operate under limited memory and be capable of using various preconditioners. We showed that such a method should approach the eigenvalue problem from the nonlinear perspective, either through the truncated Newton or through the limited memory quasi-Newton techniques. Regardless of the technique, however, the underlying outer method must follow the GD outer scheme.

We described a truncated Newton technique, JDQMR, which extends the previously proposed JDCG method. JDQMR can work with indefinite correction equation and preconditioners, and thus can be used for finding interior eigenvalues, while providing better stopping criteria that improve robustness. In addition, we argued why JDQMR converges within a small factor (2 or 3) of optimal.

We also described methods that use the locally optimal CG either as a recurrence (LOBPCG) or as a restarting (GD+1) and unified them under the framework of limited memory quasi-Newton. This framework, together with our previous theoretical results, provided new intuition on both the global and local convergence of these methods, for instance, explaining why GD+1 improves on unaccelerated recurrence methods such as LOBPCG.

A rather unexpected conclusion from our experiments is that limited memory BFGS-type methods (GD+1) outperform truncated Newton methods (such as JDCG or JDQMR) in terms of convergence, even with a small acceleration basis. Equally impressive is the fact that GD+1 usually matches the convergence, both asymptotic and global, of the optimal QMRopt benchmark.

As the acceleration basis shrinks, the convergence of JDQMR, which is less sensitive to acceleration, matches or surpasses the convergence of GD+1, which, in turn, is always better than the extreme of using no acceleration basis (LOBPCG). Furthermore, when the preconditioner and matrix-vector operations are inexpensive, the cheaper inner iteration of JDQMR requires less overall time than GD+1. The advantage of our approach is that the GD driver implements both methods, switching at runtime when the actual expense of the user-provided operators is measured.

Finally, we have provided an extensive set of experiments. We considered a variety of problems and methods, with and without preconditioning, and problems that involved finding an interior eigenpair using indefinite preconditioning. Interestingly, both the theory and our experiments suggest that even without preconditioning, our multimethod should be preferred over ARPACK. Our results and conclusions extend also to finding a small number of eigenpairs. When many eigenvalues are required, the challenges and results are different; these topics are addressed in a companion paper [66].

Acknowledgments. The author would like to thank the two anonymous referees for their significant contribution to the clarity of the presentation and for prompting the analysis in section 3.4. The presentation also benefited from comments from the editor, Dr. T. Kolda, and the author's colleagues, Profs. V. Torczon and P. Stockmeyer.

A BLOCH DECOMPOSITION–BASED SPLIT-STEP PSEUDOSPECTRAL METHOD FOR QUANTUM DYNAMICS WITH PERIODIC POTENTIALS*

ZHONGYI HUANG†, SHI JIN‡, PETER A. MARKOWICH§, AND CHRISTOF SPARBER§

Abstract. We present a new numerical method for accurate computations of solutions to (linear) one-dimensional Schrödinger equations with periodic potentials. This is a prominent model in solid state physics where we also allow for perturbations by nonperiodic potentials describing external electric fields. Our approach is based on the classical Bloch decomposition method, which allows us to diagonalize the periodic part of the Hamiltonian operator. Hence, the dominant effects from dispersion and periodic lattice potential are computed together, while the nonperiodic potential acts only as a perturbation. Because the split-step communicator error between the periodic and nonperiodic parts is relatively small, the step size can be chosen substantially larger than for the traditional splitting of the dispersion and potential operators. Indeed it is shown by the given examples that our method is unconditionally stable and more efficient than the traditional split-step pseudospectral schemes. To this end a particular focus is on the semiclassical regime, where the new algorithm naturally incorporates the adiabatic splitting of slow and fast degrees of freedom.

Key words. Schrödinger equation, Bloch decomposition, time-splitting spectral method, semiclassical asymptotics, lattice potential

1. Introduction.

One of the main problems in solid state physics is to describe the motion of electrons within the periodic potentials generated by the ionic cores. This problem has been studied from a physical as well as a mathematical point of view in, e.g., [1, 8, 28, 29, 33], resulting in a profound theoretical understanding of the novel dynamical features. Indeed one of the most striking effects, known as [illegible], is a modification of the dispersion relation for Schrödinger's equation, where the classical energy relation $E_{\text{free}}(k) = \frac{1}{2}|k|^2$ has to be replaced by $E_m(k)$, $m \in \mathbb{N}$, the energy corresponding to the mth [illegible] [7]. The basic idea behind this replacement is a separation of scales which is present in this context. More precisely one recognizes that experimentally imposed, and thus called external, electromagnetic fields typically vary on much [illegible] spatial scales than the periodic potential generated by the cores. Moreover, this external field can be considered [illegible] in comparison to the periodic fields of the cores [2].

To study this problem, consider the Schrödinger equation for the electrons in a

asymptotic scaling [11, 29, 31], i.e., in $d = 1$ dimensions,

$$\begin{cases} \mathrm{i}\varepsilon\partial_t\psi = -\dfrac{\varepsilon^2}{2}\,\partial_{xx}\psi + V_\Gamma\left(\dfrac{x}{\varepsilon}\right)\psi + U(x)\psi, \quad x \in \mathbb{R},\ t \in \mathbb{R}, \\ \psi\big|_{t=0} = \psi_{\mathrm{in}}(x), \end{cases} \tag{1.1}$$

where $0 < \varepsilon \ll 1$ denotes the small describing the microscopic/macroscopic scale ratio. The (dimensionless) equation (1.1) consequently describes the motion of the electrons on the macroscopic scales induced by the external potential $U(x) \in \mathbb{R}$. The highly oscillating $V_\Gamma(y) \in \mathbb{R}$ is assumed to be with respect to some Γ. For definiteness we shall assume that

$$V_\Gamma(y + 2\pi) = V_\Gamma(y) \quad \forall\, y \in \mathbb{R}, \tag{1.2}$$

i.e., $\Gamma = 2\pi\mathbb{Z}$. In the following we shall assume $\psi_{\mathrm{in}} \in L^2(\mathbb{R})$, such that the is $\mathrm{M}_{\mathrm{in}} \equiv \|\psi_{\mathrm{in}}\|_{L^2} = 1$, a normalization which is henceforth preserved by the evolution.

The mathematically precise asymptotic description of $\psi(t)$, solution to (1.1), as $\varepsilon \to 0$, has been intensively studied in, e.g., [6, 16, 20, 29], relying on different analytical tools. On the other hand the numerical literature on these issues is not so abundant [17, 18, 19]. Here we shall present a novel approach to the numerical treatment of (1.1) relying on the classical method, as explained in more detail below. The main idea is to treat in one step the purely dispersive part $\propto \partial_{xx}$ of the Schrödinger equation together with the periodic potential V_Γ, since this combined operator allows for some sort of "diagonalization" via the Bloch transformation. The corresponding numerics is mainly concerned with the case $\varepsilon \ll 1$, but we shall also show examples for a rather large $\varepsilon = \frac{1}{2}$. Our numerical experiments show that the new method converges with $\Delta x = \mathcal{O}(\varepsilon)$ and $\Delta t = \mathcal{O}(1)$, the latter being a huge advantage in comparison with the more standard time-splitting method used in [17, 18, 19], and which usually requires $\Delta t = \mathcal{O}(\varepsilon)$. Moreover, we find that the use of only a few Bloch bands is mostly enough to achieve very high accuracy, even in cases where $U(x)$ is no longer smooth. We note that our method is unconditionally stable and comprises spectral convergence for the space discretization as well as second order convergence in time. The only drawback of the method is that we first have to compute the energy bands for a given periodic potential, although this is needed only in a preprocessing step rather than during the time marching. On the other hand, this preprocessing also handles a possible lack of regularity in V_Γ, which consequently does not lead to numerical problems during the time-evolution. In any case the numerical cost of this preliminary step is much smaller than the costs spent in computing the time-evolution, and this holds true for whatever method we choose.

We remark that linear and nonlinear evolutionary PDEs with periodic coefficients also arise in the study of photonic crystals, laser optics, and Bose–Einstein condensates in optical lattices; cf. [9, 11, 21] and the references given therein. We expect that our algorithm can be adapted to these kinds of problems too. Also note that in the case of a so-called (see, e.g., [6, 5]), an adaptation of our code to higher dimensions is very likely. Finally, the use of the Bloch transformation in problems of has been discussed in [12, 14] and numerically studied in [13] for elliptic problems. Our algorithm might be useful in similar time-dependent numerical homogenization problems.

The paper is organized as follows: In section 2, we recall in detail the Bloch decomposition method and show how to numerically calculate the corresponding energy

bands. Then, in section 3 we present our new algorithm, as well as the usual time-splitting spectral method for Schrödinger equations. In section 4, we show several numerical experiments and compare both methods. Different examples of U and V_Γ are considered, including the nonsmooth cases. Finally we shall also study a Wentzel–Kramers–Brillouin (WKB) type semiclassical approximation in section 5 and compare its numerical solution to the solution of the full problem. This section is mainly included since it gives a more transparent description of the Bloch transformation, at least in cases where a semiclassical approximation is justified.

2. The emergence of Bloch bands. First, let us introduce some notation used throughout this paper and recall some basic definitions used when dealing with periodic Schrödinger operators [2, 6, 31, 32].

With V_Γ obeying (1.2) we have the following:

- The fundamental domain of our lattice $\Gamma = 2\pi\mathbb{Z}$ is $\mathcal{C} = (0, 2\pi)$.
- The [illegible] Γ^* can then be defined as the set of all wave numbers $k \in \mathbb{R}$, for which plane waves of the form $\exp(\mathrm{i}kx)$ have the same periodicity as the potential V_Γ. This yields $\Gamma^* = \mathbb{Z}$ in our case.
- The fundamental domain of the dual lattice, i.e., the (first) [illegible], $\mathcal{B} = \mathcal{C}^*$ is the set of all $k \in \mathbb{R}$ closer to zero than to any other dual lattice point. In our case, that is $\mathcal{B} = \left(-\frac{1}{2}, \frac{1}{2}\right)$.

2.1. Recapitulation of Bloch's decomposition method. One of our main points in all that follows is that the dynamical behavior of (1.1) is mainly governed by the periodic part of the Hamiltonian, in particular for $\varepsilon \ll 1$. Thus it will be important to study its spectral properties. To this end consider the periodic [illegible] (where for the moment we set $y = x/\varepsilon$ for simplicity)

$$H = -\frac{1}{2}\,\partial_{yy} + V_\Gamma(y)\,, \tag{2.1}$$

which we will regard here only on $L^2(\mathcal{C})$. This is possible due to the periodicity of V_Γ, which allows us then to cover all of $\mathbb{R}$ by simple translations. More precisely, for $k \in \overline{\mathcal{B}} = \left[-\frac{1}{2}, \frac{1}{2}\right]$ we equip the operator H with the following [illegible] boundary conditions:

$$\begin{cases} \psi(t, y + 2\pi) = \mathrm{e}^{2\mathrm{i}k\pi}\psi(t, y) \quad \forall\, y \in \mathbb{R},\ k \in \overline{\mathcal{B}}, \\ \partial_y\psi(t, y + 2\pi) = \mathrm{e}^{2\mathrm{i}k\pi}\partial_y\psi(t, y) \quad \forall\, y \in \mathbb{R},\ k \in \overline{\mathcal{B}}. \end{cases} \tag{2.2}$$

It is well known [32] that under very mild conditions on V_Γ, the operator H admits a complete set of eigenfunctions $\varphi_m(y, k), m \in \mathbb{N}$, providing, for each fixed $k \in \overline{\mathcal{B}}$, an orthonormal basis in $L^2(\mathcal{C})$. Correspondingly there exists a countable family of real-valued eigenvalues which can be ordered according to $E_1(k) \le E_2(k) \le \cdots \le E_m(k) \le \ldots$, $m \in \mathbb{N}$, including the respective multiplicity. The set $\{E_m(k) \,|\, k \in \mathcal{B}\} \subset \mathbb{R}$ is called the mth [illegible] of the operator H and the eigenfunctions $\varphi_m(\cdot, k)$ are usually called the [illegible]. (In the following the index $m \in \mathbb{N}$ will [illegible] denote the [illegible].) Concerning the dependence on $k \in \mathcal{B}$, it has been shown [32] that for any $m \in \mathbb{N}$ there exists a closed subset $\mathcal{A} \subset \mathcal{B}$ such that $E_m(k)$ is analytic and $\varphi_m(\cdot, k)$ can be chosen to be the real analytic function for all $k \in \overline{\mathcal{B}}\backslash\mathcal{A}$. Moreover,

$$E_{m-1} < E_m(k) < E_{m+1}(k) \quad \forall\, k \in \overline{\mathcal{B}}\backslash\mathcal{A}. \tag{2.3}$$

If this condition indeed holds for all $k \in \mathcal{B}$, then $E_m(k)$ is called an [illegible] [31]. Moreover, it is known that

$$\operatorname{meas}\mathcal{A} = \operatorname{meas}\{k \in \overline{\mathcal{B}} \mid E_n(k) = E_m(k),\ n \neq m\} = 0. \tag{2.4}$$

In this set of measure zero, one encounters so-called [illegible]. Note that due to (2.2) we can rewrite $\varphi_m(y,k)$ as

$$\varphi_m(y,k) = \mathrm{e}^{\mathrm{i}ky}\chi_m(y,k) \quad \forall\, m \in \mathbb{N} \tag{2.5}$$

for some 2π-periodic function $\chi_m(\cdot,k)$. In terms of $\chi_m(y,k)$ the [illegible] reads

$$\begin{cases} H(k)\chi_m(y,k) = E_m(k)\chi_m(y,k), \\ \chi_m(y+2\pi,k) = \chi_m(y,k) \quad \forall\, k \in \mathcal{B}, \end{cases} \tag{2.6}$$

where $H(k)$ denotes the shifted Hamiltonian

$$H(k) := \frac{1}{2}(-\mathrm{i}\partial_y + k)^2 + V_\Gamma(y). \tag{2.7}$$

Let us now introduce the so-called [illegible] $\mathcal{T}$ of some function $\psi(t,\cdot) \in L^2(\mathbb{R})$ for any fixed $t \in \mathbb{R}$, as can be found in, e.g., [29, 31]. (Some other variants of this transformation can also be found in the literature.) The Bloch transformation $\mathcal{T}$ is just the regular Fourier transform $\mathcal{F}$ on the factor $\ell^2(\Gamma)$ followed by a multiplication with $\mathrm{e}^{-\mathrm{i}yk}$, i.e.,

$$(\mathcal{T}\psi)(t,k,y) := \sum_{\gamma\in\mathbb{Z}} \psi(t, y+2\pi\gamma)\,\mathrm{e}^{-\mathrm{i}k(2\pi\gamma+y)}, \quad y \in \mathcal{C},\ k \in \mathcal{B}. \tag{2.8}$$

It is then easy to see that

$$\mathcal{T}H\mathcal{T}^{-1} = H(k), \tag{2.9}$$

which (upon rescaling) provides a link between the eigenvalue problem (2.6) and the periodic part of our Schrödinger equation acting on $\psi(t,\cdot)$.

Most importantly, though, the Bloch transformation allows us to decompose our original Hilbert space $\mathcal{H} = L^2(\mathbb{R})$ into a direct sum of so-called [illegible], i.e.,

$$L^2(\mathbb{R}) = \bigoplus_{m=1}^{\infty} \mathcal{H}_m, \quad \mathcal{H}_m := \left\{ \psi_m(t,y) = \int_{\mathcal{B}} f(t,k)\,\varphi_m(y,k)\,\mathrm{d}k,\ f(t,\cdot) \in L^2(\mathcal{B}) \right\} \tag{2.10}$$

for any fixed $t \in \mathbb{R}$. This is the well-known [illegible], which implies that

$$\forall\, \psi(t,\cdot) \in L^2(\mathbb{R}): \quad \psi(t,y) = \sum_{m\in\mathbb{N}} \psi_m(t,y), \quad \psi_m \in \mathcal{H}_m. \tag{2.11}$$

The corresponding projection of $\psi(t)$ onto the mth band space is thereby given as

$$\psi_m(t,y) \equiv (\mathbb{P}_m\psi)(t,y) = \int_{\mathcal{B}} \left(\int_{\mathbb{R}} \psi(t,\zeta)\overline{\varphi}_m(\zeta,k)\,\mathrm{d}\zeta \right) \varphi_m(y,k)\,\mathrm{d}k, \tag{2.12}$$

and we consequently denote by

$$C_m(t,k) := \int_{\mathbb{R}} \psi(t,\zeta)\overline{\varphi}_m(\zeta,k)\,\mathrm{d}\zeta \tag{2.13}$$

the coefficients of the Bloch decomposition. For a complete description and a rigorous mathematical proof of this decomposition we refer to, e.g., [30, Chapter XI]. Here it is important to note only that the Bloch transformation allows us to obtain a spectral decomposition of our periodic Hamiltonians H upon solving the eigenvalue problem (2.6). Roughly speaking $\mathcal{T}$ can be seen as some sort of Fourier transform adapted to the inclusion of periodic coefficients (potentials).

This consequently implies that if $U(x) \equiv 0$, we can indeed Bloch transform the whole evolution problem (1.1) and decompose it into the corresponding band spaces $\mathcal{H}_m$, i.e., we gain some sort of "diagonalization" for our evolution problem. In this case each $\psi_m(t,\cdot) \in \mathcal{H}_m$ then evolves according to the newly obtained PDE

$$\begin{cases} \mathrm{i}\varepsilon\partial_t\psi_m = E_m(-\mathrm{i}\partial_y)\psi_m, & y \in \mathbb{R},\ t \in \mathbb{R}, \\ \psi_m\big|_{t=0} = (\mathbb{P}_m\psi_{\mathrm{in}})(y). \end{cases} \tag{2.14}$$

Here $E_m(-\mathrm{i}\partial_y)$ denotes the pseudodifferential operator corresponding to the (Fourier) symbol $E_m(k)$ (cf. [16, 29, 31]). The above given evolution equation comprises a rigorous justification of Peierls substitution. Moreover, (2.14) is easily solved invoking the standard Fourier transformation $\mathcal{F}$ on $L^2(\mathbb{R})$, which yields

$$\psi_m(t,y) = \mathcal{F}^{-1}(\mathrm{e}^{-\mathrm{i}E_m(k)t/\varepsilon}(\mathcal{F}(\mathbb{P}_m\psi_{\mathrm{in}}))(k)). \tag{2.15}$$

Here the energy band $E_m(k)$ is understood to be periodically extended on all of $\mathbb{R}$. Note that the relation

$$C_m(t,k) = \mathrm{e}^{-\mathrm{i}E_m(k)t/\varepsilon}C_m(0,k) \tag{2.16}$$

holds, as can be shown by a lengthy but straightforward calculation.

Of course if $U(x) \neq 0$ (the nonperiodic part of the potential), the time evolution (1.1) in general [illegible] all band spaces $\mathcal{H}_m$, i.e., we can no longer hope to be able to diagonalize the whole Hamiltonian operator (which now also involves nonperiodic coefficients). On the other hand, since $U(x) = U(\varepsilon y)$ varies only slowly on the fast (periodic) scale $y = x/\varepsilon$, one might hope that even if $U(x) \neq 0$, the [illegible]

$$\begin{cases} \mathrm{i}\varepsilon\partial_t\psi_m^{\mathrm{eff}} = E_m(-\mathrm{i}\partial_y)\psi_m^{\mathrm{eff}} + U(\varepsilon y)\psi_m^{\mathrm{eff}}, & y \in \mathbb{R},\ t \in \mathbb{R}, \\ \psi_m^{\mathrm{eff}}\big|_{t=0} = (\mathbb{P}_m\psi_{\mathrm{in}})(y) \end{cases} \tag{2.17}$$

holds true, at least approximately for small $\varepsilon \ll 1$. In other words, we expect the slowly varying external potential to be almost constant on the lattice scale and thus yielding only a small perturbation of the band structure determined via (2.1). Indeed this is the case as has been rigorously proved in [11, 20, 29], using different analytical approaches (for a broader overview, see [31] and the references given therein), where it is shown that

$$\sup_{t\in I} \big\|(\mathbb{P}_m\psi)(t) - \psi_m^{\mathrm{eff}}(t)\big\|_{L^2(\mathbb{R})} \leq \mathcal{O}(\varepsilon) \tag{2.18}$$

holds true for any finite time-interval $I \subset \mathbb{R}$. Here $\psi(t)$ is the solution of the full Schrödinger equation (1.1) and $\psi_m^{\mathrm{eff}}(t)$ is the solution of the effective model (2.17) for the mth energy band. To this end one has to assume that the mth energy band is [illegible] from the rest of the spectrum though. If this is not the case, energy transfer of order $\mathcal{O}(1)$ can occur at band crossings, the so-called Landau–Zener phenomena. In all that follows, the mth band is assumed to be isolated.

2.2. Numerical computation of the Bloch bands. As a preparatory step for our algorithm we shall first calculate the Bloch energy bands $E_m(k)$ numerically as follows. Analogously to [18, 26], we consider the potential $V_\Gamma \in C^1(\mathbb{R})$ and expand it in its Fourier series, i.e.,

$$V_\Gamma(y) = \sum_{\lambda\in\mathbb{Z}} \widehat{V}(\lambda)\,\mathrm{e}^{\mathrm{i}\lambda y}, \quad \widehat{V}(\lambda) = \frac{1}{2\pi}\int_0^{2\pi} V_\Gamma(y)\,\mathrm{e}^{-\mathrm{i}\lambda y}\,\mathrm{d}y. \tag{2.19}$$

Likewise, we expand any Bloch eigenfunctions $\chi_m(\cdot,k)$ in its respective Fourier series

$$\chi_m(y,k) = \sum_{\lambda\in\mathbb{Z}} \widehat{\chi}_m(\lambda,k)\,\mathrm{e}^{\mathrm{i}\lambda y}, \quad \widehat{\chi}_m(\lambda,k) = \frac{1}{2\pi}\int_0^{2\pi} \chi_m(y,k)\,\mathrm{e}^{-\mathrm{i}\lambda y}\,\mathrm{d}y. \tag{2.20}$$

(The latter should be confused with the so-called , which are given as the Fourier transformation of φ_m with respect to $k \in \mathcal{B}$.) Clearly the Fourier approximation of V_Γ, and thus also the one of χ_m, depends on the regularity of V_Γ. If $V_\Gamma \in C^\infty(\mathbb{R})$, the corresponding Fourier coefficients $\widehat{V}(\lambda)$ decay faster than any power, as $\lambda \to \pm\infty$, and thus we only need to take into account a few coefficients in this case.

For $\lambda \in \{-\Lambda, \dots, \Lambda-1\} \subset \mathbb{Z}$, we consequently aim to approximate the Sturm–Liouville problem (2.6) by the algebraic eigenvalue problem

$$\mathbf{H}(k)\begin{pmatrix} \widehat{\chi}_m(-\Lambda) \\ \widehat{\chi}_m(1-\Lambda) \\ \vdots \\ \widehat{\chi}_m(\Lambda-1) \end{pmatrix} = E_m(k)\begin{pmatrix} \widehat{\chi}_m(-\Lambda) \\ \widehat{\chi}_m(1-\Lambda) \\ \vdots \\ \widehat{\chi}_m(\Lambda-1) \end{pmatrix}, \tag{2.21}$$

where the $2\Lambda \times 2\Lambda$ matrix $\mathbf{H}(k)$ is given by

$$\mathbf{H}(k) = \begin{pmatrix} \widehat{V}(0) + \frac{(k-\Lambda)^2}{2} & \widehat{V}(-1) & \cdots & \widehat{V}(1-2\Lambda) \\ \widehat{V}(1) & \widehat{V}(0) + \frac{(k-\Lambda+1)^2}{2} & \cdots & \widehat{V}(2-2\Lambda) \\ \vdots & \vdots & \ddots & \vdots \\ \widehat{V}(2\Lambda-1) & \widehat{V}(2\Lambda-2) & \cdots & \widehat{V}(0) + \frac{(k+\Lambda-1)^2}{2} \end{pmatrix}. \tag{2.22}$$

The above given matrix $\mathbf{H}(k)$ comprises 2Λ eigenvalues. Clearly, this number has to be large enough such that all the eigenvalues $E_m(k)$ which we need to use in our simulations below are counted, i.e., we need $m \le 2\Lambda$. The numerical cost for this algebraic problem is about $\mathcal{O}(\Lambda^3)$; cf. [22]. Note, however, that this is the most expensive case, which becomes considerably smaller if one exploits possible symmetries within the potential V_Γ; cf. Example 4.1 below (see also [9, 26, 21, 34]). In any case the number Λ is of the spatial grid, and thus the numerical costs of this eigenvalue problem are almost negligible compared to those spend in the evolutionary algorithms below. The approximate numerical computations of the Bloch bands $E_m(k)$ can be seen as a preprocessing, to be done only once and remain unchanged as time evolves.

2.1. Accurate computations of the energy bands needed in practical applications, i.e., in more than one spatial dimension and for different kinds of (composite) material, become a highly nontrivial task. Nowadays, though, there already exists a huge amount of numerical data comprising the energy band structure of the most important materials used in, e.g., the design of semiconductor devices;

cf. [15, 25, 27]. We note that some of these data is available online via the websites http://www.research.ibm.com/DAMOCLES/home.html, or http://cmt.dur.ac.uk/sjc, and also http://cms.mpi.univie.ac.at/vasp/vasp/vasp.html. In the context of photonic crystals the situation is similar [21]. Thus, relying on such data one can in principle avoid the above given eigenvalue computations (and its generalizations to more dimensions) completely. To this end, one should also note that given the energy bands $E_m(k)$, we do not need any knowledge about V_Γ in order to solve (1.1) numerically; cf. the algorithm described below.

3. Bloch decomposition–based algorithm vs. time-splitting spectral methods. For the convenience of computations, we shall consider (1.1) on a bounded domain $\mathcal{D}$, say on the interval $\mathcal{D} = [-\kappa_1, \kappa_2]$, for some large enough $\kappa_1, \kappa_2 > 0$. Moreover, we shall equip $\mathcal{D}$ with periodic boundary conditions. However, this periodic computational domain $\mathcal{D}$ should not be confused with the periodic structure induced by the lattice potential. Without loss of any generality, we assume that $\mathcal{D} = [0, 2\pi]$.

For practical reasons we shall now introduce, for any fixed $t \in \mathbb{R}$, a new unitary transformation of $\psi(t, \cdot) \in L^2(\mathbb{R})$,

$$\widetilde{\psi}(t, y, k) := \sum_{\gamma \in \mathbb{Z}} \psi(t, \varepsilon(y + 2\pi\gamma))\, \mathrm{e}^{-\mathrm{i}2\pi k\gamma}, \quad y \in \mathcal{C},\ k \in \mathcal{B}, \tag{3.1}$$

which has the properties that $\widetilde{\psi}$ is quasi-periodic with respect to $y \in \Gamma$ and periodic with respect to $k \in \Gamma^*$, i.e.,

$$\widetilde{\psi}(t, y + 2\pi, k) = \mathrm{e}^{\mathrm{i}2\pi k}\, \widetilde{\psi}(t, y, k), \quad \widetilde{\psi}(t, y, k + 1) = \widetilde{\psi}(t, y, k). \tag{3.2}$$

One should note that $\widetilde{\psi}$ is not the standard Bloch transform of ψ, i.e., $\mathcal{T}$, as defined in (2.8), but it is indeed closely related to it, for $\varepsilon = 1$, via

$$(\mathcal{T}\psi)(t, y, k) = \widetilde{\psi}(t, y, k)\mathrm{e}^{-\mathrm{i}yk}, \quad k \in \mathcal{B}. \tag{3.3}$$

Furthermore, we have the inversion formula

$$\psi(t, \varepsilon(y + 2\pi\gamma)) = \int_{\mathcal{B}} \widetilde{\psi}(t, y, k)\mathrm{e}^{\mathrm{i}2\pi k\gamma} dk, \tag{3.4}$$

which is again very similar to the one of the standard Bloch transformation [31]. The main advantage in using $\widetilde{\psi}$ instead of $\mathcal{T}\psi$ itself is that we can rely on a standard fast Fourier transform (FFT) in the numerical algorithm below. If one aims to use $\mathcal{T}\psi$ directly, one would be forced to modify a given FFT code accordingly. A straightforward computation then shows that

$$C_m(t, k) = \int_{\mathcal{C}} \widetilde{\psi}(t, \zeta, k)\overline{\varphi}_m(\zeta, k)\, \mathrm{d}\zeta, \tag{3.5}$$

where $C_m(t, k)$ is the Bloch coefficient, defined in (2.13).

In what follows, let the time step be $\Delta t = T/N$ for some $N \in \mathbb{N}$, $T > 0$. Suppose that there are $L \in \mathbb{N}$ lattice cells within the computational domain $\mathcal{D} = [0, 2\pi]$. In this domain, the wave function ψ is numerically computed at $L \times R$ grid points for some $R \in \mathbb{N}$. In other words we assume that there are R grid points in each lattice cell, which yields the discretization

$$\begin{cases} k_\ell = -\dfrac{1}{2} + \dfrac{\ell - 1}{L}, & \text{where } \ell = \{1, \dots, L\} \subset \mathbb{N}, \\ y_r = \dfrac{2\pi(r - 1)}{R}, & \text{where } r = \{1, \dots, R\} \subset \mathbb{N}, \end{cases} \tag{3.6}$$

and thus we finally evaluate $\psi^n = \psi(t_n)$ at the grid points $x = \varepsilon(2\pi\gamma + y)$, i.e.,

$$x_{\ell,r} = \varepsilon(2\pi(\ell - 1) + y_r). \tag{3.7}$$

We remark that in our numerical computations we can use $R \ll L$, whenever $\varepsilon \ll 1$, i.e., we use only a few grid points within each cell. Now we shall describe precisely the Bloch decomposition–based algorithm used to solve (1.1).

3.1. The Bloch decomposition–based algorithm (BD). Suppose that at time t_n we are given $\psi(t_n, x_{\ell,r}) \approx \psi^n_{\ell,r}$. Then $\psi^{n+1}_{\ell,r}$, i.e., the solution at the (next) time step $t_{n+1} = t_n + \Delta t$, is obtained as follows.

, , 1. First, we solve the equation

$$\mathrm{i}\varepsilon\partial_t\psi = -\frac{\varepsilon^2}{2}\,\partial_{xx}\psi + V_\Gamma\left(\frac{x}{\varepsilon}\right)\psi \tag{3.8}$$

on a fixed time-interval Δt. To this end we shall heavily use the Bloch decomposition method; see below.

, , 2. In a second step, solve the ordinary differential equation (ODE)

$$\mathrm{i}\varepsilon\partial_t\psi = U(x)\psi \tag{3.9}$$

on the same time-interval, where the solution obtained in Step 1 serves as the initial condition for Step 2. We easily obtain the exact solution for this linear ODE by

$$\psi(t, x) = \psi(0, x)\,\mathrm{e}^{-\mathrm{i}U(x)t/\varepsilon}. \tag{3.10}$$

, , , 3.1. Clearly, the algorithm given above is first order in time. But we could easily obtain a second order scheme also by the Strang splitting method, which means that we use Step 1 with time step $\triangle t/2$, then Step 2 with time step $\triangle t$, and finally integrate Step 1 again with $\triangle t/2$. Note that in both cases the scheme conserves the particle density $\rho(t, x) := |\psi(t, x)|^2$ also on the fully discrete level.

Indeed Step 1 consists of several intermediate steps which we shall present as follows.

, , 1.1. We first compute $\widetilde{\psi}$ at time t^n by

$$\widetilde{\psi}^n_{\ell,r} = \sum_{j=1}^{L} \psi^n_{j,r}\,\mathrm{e}^{-\mathrm{i}k_\ell\cdot x_{j,1}}. \tag{3.11}$$

, , 1.2. Next, we compute the mth band Bloch coefficient $C_m(t, k)$, at time t^n, via (3.5), i.e.,

$$\begin{aligned} C_m(t_n, k_\ell) \approx C^n_{m,\ell} &= \frac{2\pi}{R}\sum_{r=1}^{R} \widetilde{\psi}^n_{\ell,r}\overline{\chi_m}(y_r, k_\ell)\,\mathrm{e}^{-\mathrm{i}k_\ell y_r} \\ &\approx \frac{2\pi}{R}\sum_{r=1}^{R} \widetilde{\psi}^n_{\ell,r}\sum_{\lambda=-R/2}^{R/2-1} \overline{\widehat{\chi}_m}(\lambda, k_\ell)\,\mathrm{e}^{-\mathrm{i}(k_\ell+\lambda)y_r}, \end{aligned} \tag{3.12}$$

where for the second line we simply inserted the Fourier expansion of χ_m, given in (2.20). Note that in total we have R Fourier coefficients for χ_m. Clearly this implies that we need $\Lambda > R/2$ to hold, where Λ is the number of Fourier modes

required in the numerical approximation of Bloch's eigenvalue problem as discussed in section 2.2. Here we take only the R lowest frequency Fourier coefficients.

, , 1.3. The obtained Bloch coefficients are then evolved up to the time t^{n+1}, according to the explicit solution formula (2.15), taking into account (2.16). This yields

$$C_{m,\ell}^{n+1} = C_{m,\ell}^{n}\, \mathrm{e}^{-\mathrm{i}E_m(k_\ell)\Delta t/\varepsilon}. \tag{3.13}$$

, , 1.4. From here, we consequently compute $\widetilde{\psi}$ at the new time t^{n+1} by summing up all band contributions and using the analytical formulas (2.12) and (2.13), i.e.,

$$\widetilde{\psi}_{\ell,r}^{n+1} = \sum_{m=1}^{M} (\mathbb{P}_m \widetilde{\psi})_{\ell,r}^{n+1} \approx \sum_{m=1}^{M} C_{m,\ell}^{n+1} \sum_{\lambda=-R/2}^{R/2-1} \widehat{\chi}_m(\lambda, k_\ell)\, \mathrm{e}^{\mathrm{i}(k_\ell+\lambda)y_r}. \tag{3.14}$$

, , 1.5. Finally we numerically perform the inverse transformation to (3.1), i.e., we compute $\psi_{\ell,r}^{n+1}$ from $\widetilde{\psi}_{\ell,r}^{n+1}$. Thus from (3.4), we get

$$\psi_{\ell,r}^{n+1} = \frac{1}{L} \sum_{j=1}^{L} \widetilde{\psi}_{j,r}^{n+1}\, \mathrm{e}^{\mathrm{i}k_j x_{\ell,1}}. \tag{3.15}$$

Note that in the BD algorithm, the main numerical costs are introduced via the FFT in Steps 1.1 and 1.5. This also implies that on the same spatial grid, the numerical costs of our Bloch transform–based algorithm is of the same order as the classical time-splitting spectral method below. Moreover, we want to stress the fact that if there is no external potential, i.e., $U(x) \equiv 0$, then the above given algorithm numerically computes the , , , solution of the evolutionary problem (1.1), which can be seen analogous to a standard spectral method, adapted to periodic potentials. In particular this fact allows us to solve the Schrödinger equation (1.1) for very long time steps, even if ε is small (see the results given below). Moreover, one should note that a possible lack of regularity in V_Γ requires numerical care only when approximating (2.6) by the algebraic problem (2.21). In particular, V_Γ itself does not enter in the time evolution but only $E_m(k)$.

3.2. A simple time-splitting spectral method (TS). Ignoring for a moment the additional structure provided by the periodic potential V_Γ, one might wish to solve (1.1) by using a classical time-splitting spectral scheme. Such schemes already proved to be successful in similar circumstances; see, e.g., [3, 4, 18, 23]. For the purpose of a detailed comparison, we present this method here.

, , 1. In the first step we solve the equation

$$\mathrm{i}\varepsilon \partial_t \psi = -\frac{\varepsilon^2}{2}\, \partial_{xx}\psi \tag{3.16}$$

on a fixed time-interval Δt, relying on the pseudospectral method.

, , 2. Then, in a second step, we solve the ODE

$$\mathrm{i}\varepsilon \partial_t \psi = \left(V_\Gamma\left(\frac{x}{\varepsilon}\right) + U(x) \right) \psi \tag{3.17}$$

on the same time-interval, where the solution obtained in Step 1 serves as the initial condition for Step 2. Again it is easily seen that such a scheme conserves the particle

density. It is clear, however, that due to the inclusion of $V_\Gamma\left(\frac{x}{\varepsilon}\right)$, the exact solution of (3.17),

$$\psi(t,x) = \psi_{\rm in}(x)\,\mathrm{e}^{-\mathrm{i}(V_\Gamma(x/\varepsilon)+U(x))t/\varepsilon}, \tag{3.18}$$

involves high oscillations on [illegible] length- and time-scales as $\varepsilon \to 0$ (which one has to resolve), in contrast to (3.10), where only t/ε-oscillations are present. In our BD algorithm, we compute the dominant effects from dispersion and periodic lattice potential in one step, and treat the nonperiodic potential as a perturbation. Because the split-step communicator error between the periodic and nonperiodic parts is relatively small, the step size can be chosen considerably larger than for the SP algorithm.

[illegible] 3.2. Clearly, if there is no lattice potential, i.e., $V_\Gamma(y) \equiv 0$, the BD algorithm simplifies to the described time-splitting method TS. Moreover, a second order scheme (based on the Strang splitting algorithm) can be obtained analogously to the one described above (see Remark 3.1), and a comparison of these second order schemes gives similar results to those shown in the following.

For the BD algorithm, the complexities of Steps 1.1 and 1.5 are $\mathcal{O}(RL\log(L))$, the complexities of Steps 1.2 and 1.4 are $\mathcal{O}(MLR\log(R))$, and for Step 1.3 we have $\mathcal{O}(ML)$. Also the complexity of the eigenvalue problem (2.21) is $\mathcal{O}(\Lambda^3)$. However, since Λ (or R) is independent of ε and since we only need to solve the eigenvalue problem (2.21) once in a preparatory step, the computation costs for this problem are negligible. On the other hand, for the TS algorithm, the complexities of Steps 1 and 2 are $\mathcal{O}(RL\log(RL))$ and $\mathcal{O}(RL)$, respectively. As M and R are independent of ε, we can use $R \ll L$ and $M \ll L$ whenever $\varepsilon \ll 1$. Finally the complexities of the BD and TS algorithms in each time step are comparable.

4. Numerical experiments. In this section, we shall use several numerical examples to show the efficiency of our algorithm. We shall choose for (1.1) initial data $\psi_{\rm in} \in \mathcal{S}(\mathbb{R})$ of the form

$$\psi_{\rm in}(x) = \left(\frac{10}{\pi}\right)^{1/4} \mathrm{e}^{-5(x-\pi)^2}. \tag{4.1}$$

Let us perform a decomposition of $\psi_{\rm in}$ in terms of the Bloch bands, and take a summation of the first $m = 1, \ldots, M_0$ energy bands for some finite (cut-off) number $M_0 \in \mathbb{N}$. A picture of the corresponding band densities $\rho_m^\varepsilon := |\mathbb{P}_m^\varepsilon \psi_{\rm in}|^2$ is given in Figure 1 for $m = 1, \ldots, 4$. Since $\psi_{\rm in}$ is smooth we expect that only very few bands have to be taken into account in the Bloch decomposition. Indeed we observe that the amount of mass corresponding to $\mathbb{P}_m^\varepsilon \psi_{\rm in}$, i.e., the mass concentration in each Bloch band, decays rapidly as $m \to \infty$; see Table 1. In other words, the number M_0 is essentially determined by the regularity of $\psi_{\rm in}$ in each cell. Note that M_0 is independent of ε.

To compute the evolution of these initial data we shall take into account $M \geq M_0$ bands. Note that only in cases where $U(x) \equiv 0$ can one take M to be identical to M_0, the initial band cut-off. The reason is that if $U(x)$ is nonzero, Step 2 in the BD algorithm given above mixes all bands. In particular all the $\psi_m(t)$ are no longer orthogonal to each other. Roughly speaking, however, if ε is very small, all band spaces $\mathcal{H}_m$ remain "almost orthogonal" and thus the mass within each Bloch band, i.e., $\mathrm{M}_m^\varepsilon(t) := \left\| \mathbb{P}_m^\varepsilon \psi(t) \right\|^2_{L^2(\mathbb{R})}$, is "almost conserved." More precisely it is conserved up to errors $\mathcal{O}(\varepsilon)$ on time-scales $\mathcal{O}(1)$. Thus, by checking mass conservation after each

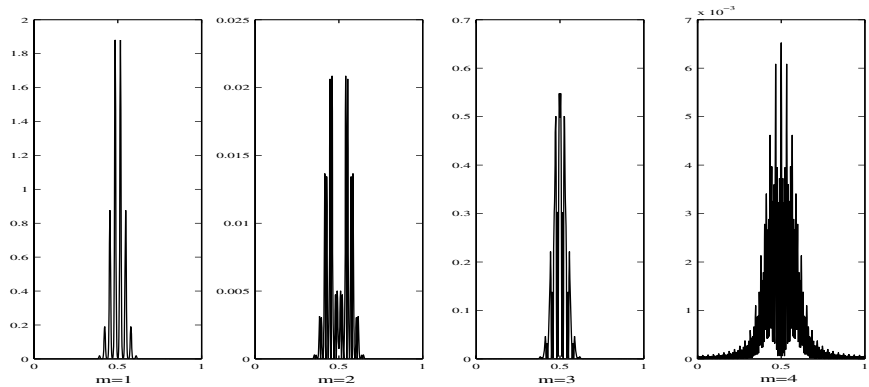

FIG. 1. $|\mathbb{P}^\varepsilon_m \psi_{\rm in}|^2$, $m = 1, \dots, 4$, *for* $\varepsilon = \frac{1}{32}$.

TABLE 1
The values of $\mathrm{M}^\varepsilon_m := \left\| \mathbb{P}^\varepsilon_m \psi_{\rm in} \right\|_{L^2(\mathbb{R})}$ *for* $\varepsilon = \frac{1}{32}$.

m	1	2	3	4
M^ε_m	7.91E − 1	1.11E − 1	5.92E − 1	8.80E − 2
m	5	6	7	8
M^ε_m	8.67E − 2	2.81E − 3	2.80E − 3	4.98E − 5

time step one gets a rather reliable measure on the amount of mixing of the bands. In other words if the mass conservation after some time steps gets worse, one has to take into account more bands to proceed.

We find numerically that the use of $M = M_0 \approx 8$ bands already yields satisfactory results for $\varepsilon = \frac{1}{32}$. In the following, though, we shall even compute $M = 32$ energy bands, which is by far sufficient for our purposes (even if $\varepsilon = \frac{1}{2}$). Note that the number of required bands M depends on the regularity properties of $U(x)$, as well as on the considered time-scales (which might be even longer than $\mathcal{O}(1)$, the case considered here). This approximation problem is more or less analogous to the one appearing in spectral schemes for PDEs with nonsmooth coefficients.

Concerning slowly varying, external potentials U, we shall choose, on the one hand, smooth functions which are either of the form

$$U(x) = \mathcal{E}x, \tag{4.2}$$

modeling a constant (electric) force field $\mathcal{E} \in \mathbb{R}$, or given by a [illegible]–type potential

$$U(x) = |x - \pi|^2. \tag{4.3}$$

On the other hand, we shall also consider the case of an external (nonsmooth) [illegible], i.e.,

$$U(x) = \begin{cases} 1, & x \in \left[\frac{\pi}{2}, \frac{3\pi}{2}\right], \\ 0 & \text{else.} \end{cases} \tag{4.4}$$

Within the setting described above, we shall focus on two particular choices for the lattice potential, namely, the following two examples.

EXAMPLE 4.1 (Mathieu model). The so-called [illegible], i.e.,

$$V_\Gamma(x) = \cos(x), \tag{4.5}$$

as already considered in [18]. (For applications in solid state physics this is rather unrealistic; however, it fits quite well with experiments on Bose–Einstein condensates in optical lattices.) In this case all Fourier coefficients $\widehat{V}(\lambda)$ appearing in (2.19) are zero, except for $\widehat{V}(\pm 1) = \frac{1}{2}$, and thus $\mathbf{H}(k)$, given in (2.22), simplifies to a tridiagonal matrix.

EXAMPLE 4.2 (Kronig–Penney model). The so-called [illegible], i.e.,

$$V_\Gamma(x) = 1 - \sum_{\gamma\in\mathbb{Z}} \mathbf{1}_{x\in\left[\frac{\pi}{2}+2\pi\gamma,\,\frac{3\pi}{2}+2\pi\gamma\right]}, \tag{4.6}$$

where $\mathbf{1}_\Omega$ denotes the characteristic function of a set $\Omega \subset \mathbb{R}$. In contrast to Mathieu's model this case comprises a nonsmooth lattice potential. The corresponding Bloch eigenvalue problem is known to be explicitly solvable (see, e.g., [18]).

In order to compare the different numerical algorithms we denote by $\psi^{\mathrm{ts}}(t,x)$ the solution gained from the time-splitting spectral method, whereas $\psi^{\mathrm{bd}}(t,x)$ denotes the solution obtained via the new method base on Bloch's decomposition. Both methods will be compared to the "exact" solution $\psi^{\mathrm{ex}}(t,x)$, which is obtained using a very fine spatial grid. We consider the errors

$$\begin{aligned} \Delta_\infty^{\mathrm{bd/ts}}(t) &:= \left\| \psi^{\mathrm{ex}}(t,\cdot) - \psi^{\mathrm{bd/ts}}(t,\cdot)\right\|_{L^\infty(\mathbb{R})}, \\ \Delta_2^{\mathrm{bd/ts}}(t) &:= \left\| \psi^{\mathrm{ex}}(t,\cdot) - \psi^{\mathrm{bd/ts}}(t,\cdot)\right\|_{L^2(\mathbb{R})} \end{aligned} \tag{4.7}$$

between the "exact solution" and the corresponding solutions obtained via the Bloch decomposition–based algorithm, respectively, the classical time splitting spectral method. The numerical experiments are now done in a series of three different settings:

- First we shall study both cases of V_Γ, imposing additionally $U(x) \equiv 0$, i.e., no external potential. The obtained results are given in Table 2, where $\varepsilon = \frac{1}{2}$, $\frac{1}{32}$, and $\frac{1}{1024}$, respectively. In the last case the oscillations are extremely spurious. As discussed before, we can use only one step in time to obtain the numerical solution, because the Bloch decomposition method indeed is "exact" in this case (independently of ε). Thus, even if we would refine the time steps in the BD algorithm, we would not get more accurate approximations. On the other hand, by using the usual time-splitting method, one has to refine the time steps (depending on ε) as well as the mesh size in order to achieve the same accuracy. More precisely we find that $\Delta t = \mathcal{O}(\varepsilon)$, $\Delta x = \mathcal{O}(\varepsilon^\alpha)$, for some $\alpha \geq 1$, is needed when using TS (see also the computations given in [18]). In particular $\alpha > 1$ is required for the case of a nonsmooth lattice potential V_Γ. (Note that if $V_\Gamma = 0$, it is well known that $\Delta x = \mathcal{O}(\varepsilon)$ is sufficient; cf. [3, 4, 23].)
- In a second series of numerical experiments we shall consider only Example 4.1 for the periodic potential but taking into account all three cases of the external potentials U, as given above. In Figures 2–7 and Table 3, we show the obtained numerical results for $\varepsilon = \frac{1}{2}$, and $\varepsilon = \frac{1}{1024}$, respectively. We observe that if $\varepsilon = \mathcal{O}(1)$, the Bloch decomposition method gives almost the same results as the time-splitting spectral method. However, if $\varepsilon \ll 1$, we can achieve quite good accuracy by using the Bloch decomposition method with

all three cases for the external potential U. The cases $\varepsilon=\frac{1}{2}$ and $\frac{1}{1024}$ are studied and the obtained results are given in Figures 8–13 and Table 4, respectively. We observe that the results of the Bloch decomposition are much better than the time-splitting spectral method, even if $\varepsilon=\frac{1}{2}$. Moreover, as ε gets smaller, the advantages of the Bloch decomposition method are even better visible.

To convince ourselves that only a few Bloch bands contribute to $\|\psi\|_{L^2(\mathbb{R})}$, even after time steps $\mathcal{O}(1)$, we show in Table 5 the numerical values of $\mathrm{M}_m^\varepsilon(t)=\left\|\mathbb{P}_m^\varepsilon\psi(t)\right\|^2_{L^2(\mathbb{R})}$ for $m=1,\dots,8$, corresponding to the solution of Example 4.1 with U given by (4.3).

We also check the conservation of the total (discrete) mass, i.e., $\|\psi(t)\|_{l^2(\mathcal{D})}$. We find that numerically it is of the order 10^{-6} for the smooth lattice potential (4.5) and 10^{-3} for the nonsmooth case (4.6). The latter, however, can be improved by using a refined spatial grid and more time steps.

In summary we find (at least for our one-dimensional computations) that, relying on the new Bloch decomposition–based algorithm, one can use much larger time steps, and sometimes even a coarser spatial grid, to achieve the same accuracy as that for the usual time-splitting spectral method. This is particularly visible in cases where the lattice potential is no longer smooth and $\varepsilon\ll 1$. Indeed in these cases the BD algorithm turns out to be [illegible] than the TS method.

[illegible] 4.1. In view of our results the earlier numerical studies based on TS methods [18, 17, 19] should be taken with some care, in particular when comparing the full Schrödinger solution to the semiclassical approximation beyond caustics.

5. Asymptotic analysis in the semiclassical regime. For completeness we shall also compare the numerical solution of the Schrödinger equation (1.1) with its semiclassical asymptotic description. To this end we shall rely on a multiple scales

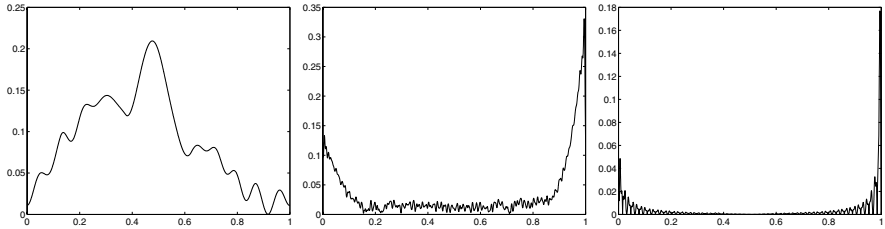
WKB-type expansion methods, even though there are currently more advanced tools at hand; cf. [16, 29, 31]. The WKB method, however, has the advantage of giving a rather simple and transparent description of $\psi(t)$, solution to (1.1), for $\varepsilon \ll 1$ (at least locally in-time). Since the Bloch decomposition method itself is rather abstract we include this approximative description here too, so that the reader gets a better feeling for the appearing quantities. Moreover, this two-scale WKB method can also be used for [illegible] Schrödinger dynamics [11], a problem we shall study numerically in an upcoming work.

5.1. The WKB formalism. To this end let us suppose that the initial condition is of (two-scale) [illegible]. More precisely assume

$$\psi_{\rm in}(x) = \sum_{m=1}^{M} u_m\left(x, \frac{x}{\varepsilon}\right) {\rm e}^{i\phi(x)/\varepsilon}, \tag{5.1}$$

with some given [illegible] $\phi \in C^\infty(\mathbb{R})$ and some given initial (complex-valued) [illegible] $u_m(x, y + 2\pi) = u_m(x, y)$, each of which admits an asymptotic de-



$|\psi^{\rm ex}(t,x)|^2$, $|\psi^{\rm ex}(t,x)-\psi^{\rm ts}(t,x)|$ and $|\psi^{\rm ex}(t,x)-\psi^{\rm bd}(t,x)|$ at $t=1.0$

FIG. 8. *Numerical results for Example* 4.2 *with* $U(x)$ *given by* (4.2), $\varepsilon=\frac{1}{2}$. *We use* $\triangle t=\frac{1}{100}$, $\triangle x=\frac{1}{64}$ *for the TS method,* $\triangle t=\frac{1}{2}$, $\triangle x=\frac{1}{32}$ *for the BD method, and* $\triangle t=\frac{1}{100000}$, $\triangle x=\frac{1}{8192}$ *for the "exact" solution.*

5.1. Note that we consider only a single initial WKB phase $\phi(x)$ for all bands $m\in\mathbb{N}$. We could of course also allow for more general cases, like one WKB phase for each band or even a superposition of WKB states within each band. However, in order to keep the presentation clean we hesitate to do so. The standard WKB approximation, for nonperiodic problems, involves real-valued amplitudes $\tilde{u}^0(x),\tilde{u}^1(x),\dots$ which depend only on the slow scale.

TABLE 4
The results of Example 4.2 *with harmonic external potential* (4.3).

TABLE 5
The mass of $\psi(t,x)$*, solution to Example* 4.1 *with external potential* (4.3)*, decomposed into the Bloch bands for* $\varepsilon = \frac{1}{32}$ *at time* $t = 1$.

m	1	2	3	4
$\mathrm{M}^{\varepsilon}_m$	7.89E − 1	1.10E − 2	5.92E − 1	9.38E − 2
m	5	6	7	8
$\mathrm{M}^{\varepsilon}_m$	7.15E − 2	3.50E − 3	1.80E − 3	5.63E − 5

It is well known then (cf. [11, 20]) that the leading order term u^0_m, $m \in \mathbb{N}$, can be decomposed as

$$u^0_m\left(x, \frac{x}{\varepsilon}\right) = f_m(x)\chi_m\left(\frac{x}{\varepsilon}, \partial_x\phi(x)\right), \tag{5.3}$$

where we assume $f_m \in \mathcal{S}(\mathbb{R})$. In other words, there is an adiabatic decoupling between the slow scale x and fast scale x/ε. Indeed, a lengthy calculation, invoking the classical stationary phase argument (cf. [6, Chapter 4.7]), shows that the band projection $\mathbb{P}^{\varepsilon}_m\psi$

can be approximated via

$$\mathbb{P}^{\varepsilon}_m \psi(x) \sim f_m(x)\, \chi_m\left(\frac{x}{\varepsilon}, \partial_x \phi(x)\right) \mathrm{e}^{i\phi(x)/\varepsilon} + \mathcal{O}(\varepsilon). \tag{5.4}$$

This approximate formula shows the origin of the high oscillations induced either by V_Γ, described by χ_m, or by the dispersion, described by $\phi(x)$. We note that in general the higher order terms (in ε), such as u^1_m, etc., are of a more complicated structure than (5.3), but we shall neglect these terms in what follows (see, e.g., [11] for more details). One consequently finds that $\psi(t)$ obeys a leading order asymptotic description of the form

$$\psi(t,x) \sim \sum_{m=1}^{M} a_m(t,x)\, \chi_m\left(\frac{x}{\varepsilon}, \partial_x \phi_m(t,x)\right) \mathrm{e}^{i\phi_m(t,x)/\varepsilon} + \mathcal{O}(\varepsilon), \tag{5.5}$$

where $\phi_m(t,x) \in C^\infty([0,t_c)\times\mathbb{R})$ satisfies the mth band

$$\begin{cases} \partial_t \phi_m(t,x) + E_m(\partial_x \phi_m) + U(x) = 0, \quad m \in \mathbb{N}, \\ \phi_m\big|_{t=0} = \phi(x). \end{cases} \tag{5.6}$$

Also, the (complex-valued) leading order WKB amplitude $a_m(t,x) \in C^\infty([0,t_c)\times\mathbb{R})$ satisfies the

$$\begin{cases} \partial_t a_m + \partial_k E_m(\partial_x\phi_m)\partial_x a_m + \dfrac{1}{2}\,\partial_x(\partial_k E_m(\partial_x\phi_m))a_m \\ \qquad -(\beta_m(t,x)\partial_x U(x))\, a_m = 0, \quad a_m\big|_{t=0} = f_m(x), \end{cases} \tag{5.7}$$

with $\beta_m(t,x) := \langle \chi_m(y,k), \partial_k \chi_m(y,k)\rangle_{L^2(\mathcal{C})}$, evaluated at $k = \partial_x\phi_m$, the so-called

5.2. Note that the Berry term is purely imaginary, i.e., $\beta_m(t,x) \in \mathrm{i}\mathbb{R}$, which implies the following conservation law:

$$\partial_t |a_m|^2 + \partial_x\left(\partial_k E_m(\partial_x\phi_m)|a_m|^2\right) = 0 \quad \forall\, m \in \mathbb{N}. \tag{5.8}$$

Of course the above WKB-type expansion method is valid only up to (in general finite) time $0 \le t_c < \infty$, the in the solution of (5.6). Here we shall simply assume that $t_c > 0$ holds, i.e., no caustic is formed at time $t = 0$, which is very well possible in general. We note that in the considered numerical examples below we indeed have $t_c > 0$ and we refer to [10] for a broader discussion on this. For $t \ge t_c$ one would need to superimpose several WKB-type solutions corresponding to the multivalued solutions of the flow map $(x,t) \mapsto X_t(x) \equiv X_t(x; \partial_x\phi(x))$, where

$$\begin{cases} \dot{X}_t = \partial_k E_m(\Xi_t), \quad X_0 = x, \\ \dot{\Xi}_t = -\partial_x U(X_t), \quad \Xi_0 = \partial_x\phi(x). \end{cases} \tag{5.9}$$

Numerically we shall use the relaxation method introduced in [24] to solve the Hamilton–Jacobi equation (5.6). Consequently we can solve the system of transport equations (5.7) by a time-splitting spectral scheme similar to the ones used above.

5.2. Numerical examples. We shall finally study the WKB approach, briefly described above, using some numerical examples. Denote by

$$\psi^{\mathrm{sc}}(t,x) := \sum_{m=1}^{M} f_m(t,x)\chi_m\left(\frac{x}{\varepsilon}, \partial_x\phi_m\right) e^{i\phi_m(t,x)/\varepsilon} \tag{5.10}$$

TABLE 6

$\sup_{0\le t\le 1} \| \psi(t,x) - \psi^{\mathrm{sc}}(t,x) \|_{L^\infty(\mathbb{R})}$	5.57E − 2	2.38E − 3

TABLE 7
Difference between the asymptotic solution and the Schrödinger equation for Example 5.2 *for initial condition* (5.11) *($\triangle t = 10^{-4}$, $\triangle x = 1/32768$).*

ε	1/32	1/1024
$\sup_{0\le t\le 0.1} \| \psi(t,x) - \psi^{\mathrm{sc}}(t,x) \|_{L^2(\mathbb{R})}$	1.18E − 2	1.08E − 3
$\sup_{0\le t\le 0.1} \| \psi(t,x) - \psi^{\mathrm{sc}}(t,x) \|_{L^\infty(\mathbb{R})}$	9.34E − 2	7.74E − 3

the approximate semiclassical solution to the Schrödinger equation (1.1). In the following examples we only take into account a harmonic external potential of the form (4.3).

EXAMPLE 5.1 (Mathieu's model). We first consider Mathieu's model (4.5) and choose the initial condition in the form

$$\psi_{\mathrm{in}}(x) = \mathrm{e}^{-5(x-\pi)^2} \chi_1\left(\frac{x}{\varepsilon}, 0\right), \tag{5.11}$$

i.e., we choose $\phi(x) = 0$ and restrict ourselves to the case of only one band with index $m = 1$. (The analytical results of [6, 11, 20] then imply that we can neglect the contributions from all other bands $m > 1$ up to errors of order $\mathcal{O}(\varepsilon)$ in $L^2(\mathbb{R}) \cap L^\infty(\mathbb{R})$, uniformly on compact time-intervals.) In this case, we numerically find that no caustic is formed within the solution of (5.6) at least up to $t = 1$, the largest time in our computation. Note that (5.11) concentrates at the minimum of the first Bloch band, where it is known that

$$E_m(k) \approx \frac{|k|^2}{2m^*} + E_m(0). \tag{5.12}$$

This is the so-called effective mass theorem, yielding an effective mass $m^* \in \mathbb{R}$. In Table 6, we show the results with an additional harmonic external potential (cf. (4.3)) for $\varepsilon = \frac{1}{32}$ and $\varepsilon = \frac{1}{1024}$, respectively. Note that these numerical experiments, together with those given below, confirm the analytical results given in [6, 11, 20].

EXAMPLE 5.2 (Kronig–Penney model). Here, we consider again the Kronig–Penney model (4.6). First we use the same initial condition as given in (5.11) but with $m = 2$. The corresponding numerical results for $\varepsilon = \frac{1}{32}$ and $\frac{1}{1024}$ are shown in Table 7. In a second case, we alternatively choose initial data of the form

$$\psi_{\mathrm{in}}(x) = \mathrm{e}^{-5(x-\pi)^2} \chi_2\left(\frac{x}{\varepsilon}, \sin(x)\right) \mathrm{e}^{-\mathrm{i}\cos(x)/\varepsilon}, \tag{5.13}$$

i.e., $\phi(x) = -\cos(x)$. Here we find (numerically) that the caustic onset time is roughly given by $t_c \approx 0.24$; cf. Figure 14. The corresponding numerical results are given in Figure 15 and Table 8.

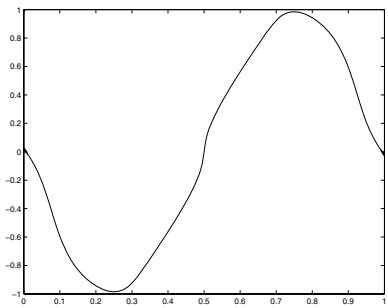

FIG. 14. *The graph of* $\partial_x \phi_2(t,x)$ *at* $t = 0.24$.

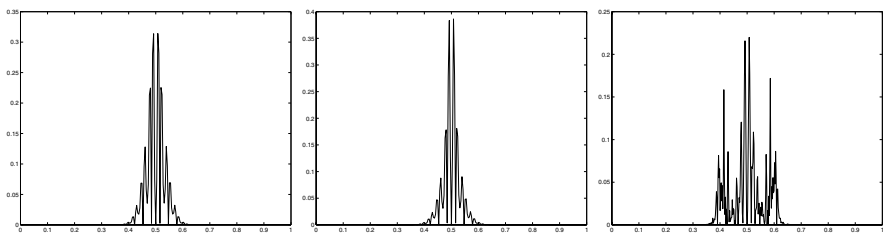

$|\psi^{\rm sc}(x,0.1)|^2$, $|\psi^{\rm sc}(x,0.25)|^2$, and $|\psi^{\rm sc}(x,0.5)|^2$, $\varepsilon = \frac{1}{32}$.

NUMERICAL APPROXIMATION OF A MACROSCOPIC MODEL OF PEDESTRIAN FLOWS*

CHRISTOPHE CHALONS†

Abstract. This paper is concerned with the numerical approximation of the solutions of a macroscopic model for the description of the flow of pedestrians. Solutions of the associated Riemann problem are known to be possibly *nonclassical* in the sense that the underlying discontinuities may well violate the Lax inequalities, which makes their numerical approximation very sensitive. This study proposes to extend the transport-equilibrium strategy proposed in [C. Chalons, *C. R. Acad. Sci. Paris Ser.* I, 342 (2006), pp. 623–626] and [C. Chalons, *Transport-equilibrium schemes for computing nonclassical shocks.* I. *Scalar conservation laws*, submitted] for computing the nonclassical solutions of scalar conservation laws with either a *concave-convex* or a *convex-concave* flux function and supplemented with an *invertible* kinetic function. These strong properties are not fulfilled in the present setting, since the flow function admits several inflection points and the kinetic function is not invertible. We nevertheless succeed in obtaining an efficient numerical scheme. Numerical evidence is provided.

Key words. macroscopic pedestrian flows, nonclassical shocks in conservation laws, kinetic function, transport-equilibrium schemes

1. Introduction.

In this paper, we are interested in the numerical approximation of the weak solutions of a scalar conservation law arising in the description of the flow of pedestrians. The model reads

$$\begin{cases} \partial_t \rho + \partial_x q(\rho) = 0, \ \ \rho(x,t) \in \mathbb{R}, \ \ (x,t) \in \mathbb{R}\times]0,+\infty[, \\ \rho(x,0) = \rho_0(x), \ \ x \in \mathbb{R}, \end{cases} \tag{1}$$

where $\rho \geq 0$ is the pedestrian density and $q : \mathbb{R}^+ \to \mathbb{R}^+$ is the flow function. Generally speaking, the solutions of (1) may develop discontinuities in finite time, however smooth the function q and the initial data ρ_0 may be. Then it turns out that the weak solutions (in the integral sense) of (1) are not uniquely determined by initial data ρ_0. In order to single out the solution of interest, various admissibility principles are used in the literature, depending on the geometric properties of the function q. For instance, one may require that the discontinuities of (1) separating two constant states ρ_- and ρ_+ and propagating with speed σ given by the Rankine–Hugoniot relation, $\sigma = [q(\rho_+) - q(\rho_-)] / [\rho_+ - \rho_-]$, obey Oleinik's inequalities:

$$\frac{q(\rho) - q(\rho_-)}{\rho - \rho_-} \geq \frac{q(\rho_+) - q(\rho_-)}{\rho_+ - \rho_-} \quad \text{for all } \rho \text{ between } \rho_- \text{ and } \rho_+. \tag{2}$$

Observe that (2) coincides with Liu's criterion [16] for scalar conservation laws. Another usual criterion is based on the Lax inequalities:

$$q'(\rho_-) \geq \sigma \geq q'(\rho_+). \tag{3}$$

In particular, we note that Oleinik's inequalities (2) imply the Lax inequalities (3). Discontinuities satisfying (3) are said to be [illegible].

When q is convex (or concave), conditions (2) and (3) are equivalent and select a unique solution of the so-called Riemann problem associated with (1), i.e., problem (1) when considering the particular initial data

$$\rho_0(x) = \begin{cases} \rho_l & \text{if } x < 0, \\ \rho_r & \text{if } x > 0. \end{cases} \tag{4}$$

If q is neither convex nor concave, Oleinik's inequalities still lead to a unique solution, and, following [12], this solution is called the [illegible]. Recall that the classical solution of (1)–(4) satisfies a maximum principle, which means that for all $x \in \mathbb{R}$ and $t \geq 0$, $\rho(x,t) \in [\min(\rho_l, \rho_r), \max(\rho_l, \rho_r)]$. However, PDE (1) naturally generates shock waves violating the Lax inequalities (3) (and then Oleinik's inequalities) when q fails to be convex (or concave), and these are to be considered. Such waves are referred to in [12] as [illegible] or as [illegible], and a solution which contains such a shock is said to be [illegible]. The uniqueness of the [illegible] weak solution of problem (1)–(4) is generally restored by means of a [illegible] imposed along each undercompressive discontinuity connecting a left state ρ_- to a right state ρ_+. It takes the form $\rho_+ = \psi(\rho_-)$, where ψ is the so-called [illegible]. In this context, note that the solution no longer obeys a [illegible] and has in general a total variation larger than its initial data. We refer the reader to [12] for a general theory of the classical and nonclassical solutions.

The precise model that we consider in this study was introduced recently by Colombo and Rosini [8]. It is based on the well-known Lighthill–Whitam [15] and Richards [17] model and takes the form of (1) as an immediate consequence of two basic assumptions, namely the conservation of the total number of pedestrians and a given speed law which depends only on the density $\rho \in [0, R]$ (R denotes the maximal density). However, this model was first dedicated to car flows, and so it is not able to reproduce important features of pedestrian flows, at least when considering typical concave increasing-decreasing flow functions. For instance, let us mention the [illegible] phenomenon in a crowd, or the fall of pedestrians in the outflow through a door of a crowd in panic. In order to overcome this difficulty, Colombo and Rosini [8] first proposed modifying the typical shape of the flow function q by introducing another characteristic density $R^\star > R$ for the maximal density in exceptional situations of panic. The flow function now looks like a concave-convex and increasing-decreasing function on $[0, R]$ and a convex-concave and increasing-decreasing function on $[R, R^\star]$ (like in Figure 1 (left)). In particular, discontinuities satisfying the usual Rankine–Hugoniot condition but violating standard admissibility conditions such as the Lax inequalities (3) are present in the model. Then, the same authors defined a unique Riemann solver using such undercompressive shocks. The main motivation in considering nonclassical solutions is to allow panic states ($\rho \in]R, R^\star]$) to appear in a calm situation ($\rho \in [0, R]$), because of a sharp increase in the density, for instance. Note that the [illegible] in classical solutions prevents such panic situations from arising.

From a numerical point of view, the approximation of nonclassical solutions is known to be very challenging and still constitutes (generally speaking) an open problem nowadays (see, for instance, [9], [10], [13], [4], [5], [6], but also [1] and the references within). The main difficulty is to enforce the validity of the kinetic relation at the discrete level. Very recently, a new efficient numerical strategy has been proposed in

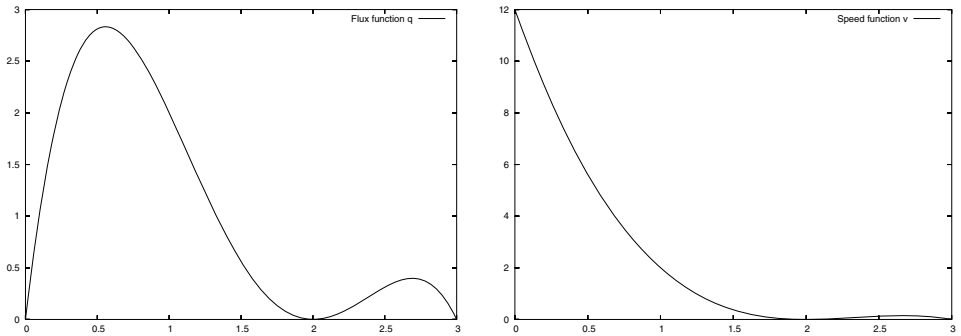

FIG. 1. *Closure relations:* $\rho \to q(\rho)$ *(left) and* $\rho \to v(\rho) = q(\rho)/\rho$ *(right).*

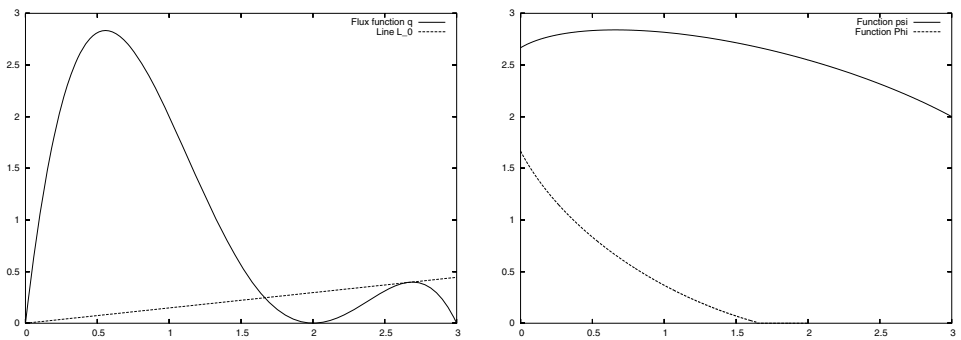

FIG. 2. *Function* q *and line* L_0 *(left); functions* ψ *and* Φ *(right).*

[3] for computing nonclassical solutions of scalar conservation laws in the situation when the flux function is concave-convex or convex-concave and, in an important way, when the kinetic function is an invertible function from $\mathbb{R}$ to $\mathbb{R}$. The algorithm proposed in [3] heavily relies on the latter property. Roughly speaking, the corresponding finite volume scheme is based on two steps, namely an [illegible], which treats each undercompressive shock as a nonmoving discontinuity, and a [illegible] for propagating these discontinuities. Here, it turns out that, on the one hand, the flow function q admits several inflexion points and, on the other hand, the kinetic function ψ (defined in (10) and represented in Figure 2 (right)) is neither defined on the whole domain $\mathbb{R}$ nor invertible. In this paper, we thus propose to adapt the transport-equilibrium scheme developed in [3] to the present setting. The resulting scheme still provides numerical solutions in full agreement with the exact ones.

2. Governing equation and closure relation. In this section, we present the model we use for describing the flow of pedestrians. Our approach considers the well-known Lighthill–Whitam [15] and Richards [17] model as a basic model. According to (1), it takes the form

$$\begin{cases} \partial_t \rho + \partial_x q(\rho) = 0, \quad q(\rho) = \rho v(\rho), \ \ (x,t) \in \mathbb{R} \times]0, +\infty[, \\ \rho(x,0) = \rho_0(x), \ \ x \in \mathbb{R}, \end{cases} \tag{5}$$

where ρ denotes the pedestrian density, v the pedestrian speed, and q the flux function. This equation expresses the conservation of the number of pedestrians in the space

domain, while the speed v is assumed to depend only on the density ρ. Let us recall that this model was first dedicated to car flows and so is not a priori in position to account for specific features of human flows, like the [illegible] phenomenon due to panic. For that reason, following [8], we introduce two remarkable values R and $R^\star$ ($R < R^\star$) for the density ρ. The first one represents a natural bound of ρ in situations with little or no panic ($\rho \in [0, R]$), and the second one is a maximal value of ρ in situations of great panic ($\rho \in]R, R^\star]$). In each of these two regions, the flow function q typically increases at first and then decreases. More precisely, the following assumptions are made in [8]:

$$
(6)\quad \begin{cases} \text{(i)} & q : [0, R^\star] \to [0, +\infty[\text{ belongs to } \mathcal{C}^0([0, R^\star]) \cap \mathcal{C}^2([0, R[\cup]R, R^\star]), \\ \text{(ii)} & q(\rho) = 0 \text{ if and only if } q \in \{0, R, R^\star\}, \\ \text{(iii)} & q' \text{ is bounded and vanishes exactly twice, once in } R_M \in]0, R[\\ & \text{and once in } R_M^\star \in]R, R^\star[, \\ \text{(iv)} & q \text{ has at most one inflection point } R_I \in]R_M, R[, \text{ and at most} \\ & \text{another one } R_I^\star \in]R, R_M^\star[. \end{cases}
$$

For the sake of illustration, we mention here that the numerical experiments in section 5 are performed with

$$
(7)\qquad q(\rho) = -\rho(\rho - R)^2(\rho - R^\star), \quad R = 2, \quad R^\star = 3,
$$

so that

$$
(8)\qquad R_M \simeq 0.5570, \quad R_M^\star \simeq 2.6930, \quad R_I \simeq 1.1208, \quad R_I^\star \simeq 2.3792.
$$

Both the graphs of this flux function $\rho \to q(\rho)$ and the corresponding speed function $\rho \to v(\rho) = q(\rho)/\rho$ are plotted in Figure 1. In particular, note that the speed function $\rho \to v(\rho)$ is decreasing on $[0, R]$, while it is first increasing, then decreasing on $[R, R^\star]$.

3. The Riemann solver. This section aims at defining a (unique) weak solution of (5)–(6) defined for all $(x, t) \in \mathbb{R} \times \mathbb{R}^{+,*}$ when initial data $x \to \rho_0(x)$ is made of only two constant states ρ_l and ρ_r, unspecified in $[0, R^\star]$ and separated by a discontinuity located at $x = 0$:

$$
(9)\qquad \rho_0(x) = \begin{cases} \rho_l & \text{if } x < 0, \\ \rho_r & \text{if } x > 0. \end{cases}
$$

With this in mind and following [8] and [12], we define two functions $\psi : [0, R^\star] \to [R, R^\star]$ and $\Phi : [0, R] \to [0, R]$ related to the graph of the function q in the (ρ, q)-plane. We proceed as follows: as soon as it is possible, $\psi(\rho)$ is such that the line that passes through the points with coordinates $(\rho, q(\rho))$ and $(\psi(\rho), q(\psi(\rho)))$ is tangent to the graph of the function q at point $(\psi(\rho), q(\psi(\rho)))$, while $\Phi(\rho)$ is such that this line intersects the curve $q = q(\rho)$ at a further point with coordinates $(\Phi(\rho), q(\Phi(\rho)))$; otherwise, these functions are extended by continuity as follows:

$$
(10)\qquad \psi(\rho) = \begin{cases} r \text{ such that } q'(r) = \frac{q(r) - q(\rho)}{r - \rho} & \text{if possible,} \\ R_I^\star & \text{if } \rho = R_I^\star, \\ R \text{ or } R^\star & \text{otherwise} \end{cases}
$$

and

$$
(11)\qquad \Phi(\rho) = \begin{cases} r \text{ such that } \frac{q(r) - q(\rho)}{r - \rho} = \frac{q(\rho) - q(\psi(\rho))}{\rho - \psi(\rho)} & \text{if possible,} \\ 0 & \text{otherwise.} \end{cases}
$$

Note that the required continuity property of the function $\rho \to \psi(\rho)$ actually selects a unique value between R and $R^\star$ in the last situation of (10) (see [8] for an example). Moreover, the inflection point $R_I^\star$ does not necessarily exist in (6)(iv). In this case, we set $R_I^\star = R$.

Figure 2 is concerned with the functions ψ and Φ when q is given by (7). On the left, we have plotted both the function q and line L_0 passing through the points with coordinates $(0, q(0) = 0)$, $(\Phi(0), q(\Phi(0)))$, and $(\psi(0), q(\psi(0)))$. Of course, we observe that L_0 is actually tangent to the graph of the function q at point $(\psi(0), q(\psi(0)))$ and cuts this graph at point $(\Phi(0), q(\Phi(0)))$. From a numerical point of view, we have

$$\psi(0) = \frac{8}{3} \simeq 2.6667 \quad \text{and} \quad \Phi(0) = \frac{5}{3} \simeq 1.6667. \tag{12}$$

On the right are represented the functions $\rho \to \psi(\rho)$ and $\rho \to \Phi(\rho)$ on their whole interval of definition.

The next theorem, first stated and proved by Colombo and Rosini [8], now defines a unique Riemann solver for (5)–(6).

THEOREM 1. [illegible] Δs [illegible]

$$s \in]0, R_M[\qquad \Delta s \in]0, R - s[. \tag{13}$$

[illegible] $(\rho_l, \rho_r) \in [0, R^\star]^2$ [illegible] $(x,t) \in \mathbb{R} \times \mathbb{R}^+ \to \rho(x,t) \in [0, R^\star]$ [illegible] (5) (6) (9) [illegible]

A. ρ_l [illegible] ρ_r [illegible] (ρ_l, ρ_r) [illegible] A [illegible]

$$A = \{(\rho_l, \rho_r) \in [0, R^\star]^2 \,/\, s \le \rho_l \le R,\ \Phi(\rho_l) < \rho_r \le R,\ (\rho_r - \rho_l) > \Delta s\}. \tag{14}$$

[illegible] ρ_l [illegible] $\psi(\rho_l)$ [illegible] [illegible] $\psi(\rho_l)$ [illegible] ρ_r

B. ρ_l [illegible] ρ_r [illegible] (ρ_l, ρ_r) [illegible] B [illegible]

$$B = \{(\rho_l, \rho_r) \in [0, R^\star]^2 \,/\, \rho_r > R,\ \rho_r > \rho_l,\ \rho_r < \psi(\rho_l)\}. \tag{15}$$

[illegible] ρ_l [illegible] $\psi(\rho_l)$ [illegible] [illegible] $\psi(\rho_l)$ [illegible] ρ_r

C. ρ_l [illegible] ρ_r [illegible] (ρ_l, ρ_r) [illegible] C [illegible]

$$C = \{(\rho_l, \rho_r) \in [0, R^\star]^2 \,/\, \rho_r > R,\ \rho_r > \rho_l,\ \rho_r \ge \psi(\rho_l)\}. \tag{16}$$

[illegible] ρ_l [illegible] ρ_r

Before addressing the numerical approximation of the solutions of (5)–(6), let us briefly comment on this theorem. First, it is important to notice that the conditions (14)–(15)–(16) in the Riemann solver separate data leading to classical solutions from those generating nonclassical behaviors. In other words, and following [12], [14], or [3], these conditions represent in some sense a [illegible], which determines when the solution becomes nonclassical. As may be expected, this nucleation condition will play a central part in the numerical strategy. Then, a physical interpretation

may be given to situation A. In this case, ρ_r is sufficiently close to the border between calm and panic, and ρ_l is sufficiently both large and far from ρ_r to create a panic state when facing ρ_r. An undercompressive shock between ρ_l and $\psi(\rho_l)$ expresses the corresponding violation of the usual maximum principle. In cases B and C, we have $\rho_r \in]0, R^\star]$. Thus, we observe that if $\rho_l \in [0, R]$, the two distinct regions associated with calm and panic are joined by a nonclassical behavior, using an undercompressive shock, either from ρ_l to $\psi(\rho_l)$ if possible, or from ρ_l to ρ_r otherwise. In some sense, one thus sees that Theorem 1 makes the function ψ play the part of [illegible] as soon as possible. Finally, we refer the reader to [8] for additional properties of interest satisfied (or not) by the Riemann solver proposed in Theorem 1.

4. Numerical approximation. In this section, we derive a relevant algorithm for approximating the nonclassical solutions of (5)–(6). To that end, the only information we rely on about the Riemann solver given in the previous section is the nucleation condition (14)–(15)–(16). In particular, and contrary to Godunov's or Glimm's scheme, for instance, we are not explicitly using the knowledge of the Riemann solutions. We follow the same approach as in [3]. The scheme is composed of two steps: an equilibrium step and a transport step. In the equilibrium step, our aim is to put at equilibrium all the admissible undercompressive discontinuities by modifying any given consistent and conservative scheme for (5). Then, the transport step takes into account the dynamics of these discontinuities and propagates them.

Let Δt and Δx be the time and the space steps. Introducing the interfaces $x_{j+1/2} = j\Delta x$ for $j \in \mathbb{Z}$ and the intermediate times $t^n = n\Delta t$ for $n \in \mathbb{N}$, we classically seek at each time t^n an approximation ρ_j^n of the solution $x \to \rho(x, t^n)$ on each interval $C_j = [x_{j-1/2}; x_{j+1/2})$, $j \in \mathbb{Z}$. The middle point of C_j is noted $x_j = 0.5\,(x_{j-1/2} + x_{j+1/2})$. In this context, we assume as given a two-point (without loss of generality) numerical flux function $(u, v) \to g(u, v)$ consistent with the flux function q, and we set $\lambda = \Delta t/\Delta x$. See also Remark 2 below. Let us start by motivating our algorithm.

4.1. Preliminary motivation. Our scheme is designed on the basis of the following observations. A natural discretization of the Riemann initial data (9) consists of setting

$$\rho_j^0 = \begin{cases} \rho_l & \text{if } j \leq 0, \\ \rho_r & \text{if } j \geq 1. \end{cases} \tag{17}$$

By Theorem 1, we know that if (ρ_l, ρ_r) obeys (16), the solution is an undercompressive shock connecting ρ_l to ρ_r and propagating with speed $\sigma(\rho_l, \rho_r)$ given by the Rankine–Hugoniot jump relation

$$\sigma(\rho_l, \rho_r) = \frac{q(\rho_r) - q(\rho_l)}{\rho_r - \rho_l}. \tag{18}$$

In particular, $\rho(x, t)$ always equals either ρ_l or ρ_r. From a numerical standpoint, we are tempted to take the usual conservative update formula associated with the numerical flux g, that is,

$$\rho_j^{n+1} = \rho_j^n - \lambda(g_{j+1/2} - g_{j-1/2}), \quad j \in \mathbb{Z}, \tag{19}$$

with $g_{j+1/2} = g(\rho_j^n, \rho_{j+1}^n)$ for all $j \in \mathbb{Z}$. It gives

$$\rho_j^1 = \begin{cases} \rho_l - \lambda(g(\rho_l, \rho_l) - g(\rho_l, \rho_l)) = \rho_l & \text{if } j \leq -1, \\ \rho_l - \lambda(g(\rho_l, \rho_r) - g(\rho_l, \rho_l)) & \text{if } j = 0, \\ \rho_r - \lambda(g(\rho_r, \rho_r) - g(\rho_l, \rho_r)) & \text{if } j = 1, \\ \rho_r - \lambda(g(\rho_r, \rho_r) - g(\rho_r, \rho_r)) = \rho_r & \text{if } j \geq 2, \end{cases}$$

with, generally speaking, $\rho_0^1 \notin \{\rho_l, \rho_r\}$ and $\rho_1^1 \notin \{\rho_l, \rho_r\}$. After the first time iteration, two intermediate states have thus been created by the conservative scheme (19). In order to avoid such spurious values, we are thus led to replace (19). We suggest this nonconservative formula:

$$\rho_j^{n+1} = \rho_j^n - \lambda(g_{j+1/2}^L - g_{j-1/2}^R), \quad j \in \mathbb{Z}, \tag{20}$$

where the numerical fluxes $g_{j+1/2}^L = g_{j+1/2}^L(\rho_j^n, \rho_{j+1}^n)$ and $g_{j+1/2}^R = g_{j+1/2}^R(\rho_j^n, \rho_{j+1}^n)$ have to be suitably defined. First, it is natural to set

$$g_{j+1/2}^L(\rho, \rho) = g_{j+1/2}^R(\rho, \rho) = g(\rho, \rho), \quad j \in \mathbb{Z},$$

for all ρ. Then, if (ρ_l, ρ_r) satisfies (16) with, in addition, $\rho_r = \psi(\rho_l)$, setting

$$g_{j+1/2}^L(\rho_l, \rho_r) = g(\rho_l, \rho_l) \quad \text{and} \quad g_{j+1/2}^R(\rho_l, \rho_r) = g(\psi(\rho_l), \rho_r), \quad j \in \mathbb{Z}, \tag{21}$$

is sufficient to avoid intermediate values since we get

$$\begin{cases} \rho_0^1 = \rho_l - \lambda(g_{1/2}^L(\rho_l, \rho_r) - g_{-1/2}^R(\rho_l, \rho_l)) = \rho_l - \lambda(g(\rho_l, \rho_l) - g(\rho_l, \rho_l)) = \rho_l, \\ \rho_1^1 = \rho_r - \lambda(g_{3/2}^L(\rho_r, \rho_r) - g_{1/2}^L(\rho_l, \rho_r)) = \rho_r - \lambda(g(\rho_r, \rho_r) - g(\psi(\rho_l), \rho_r)) = \rho_r. \end{cases}$$

In the same way, if (ρ_l, ρ_r) satisfies (16) but $\rho_r \neq \psi(\rho_l)$, setting

$$g_{j+1/2}^L(\rho_l, \rho_r) = g(\rho_l, \rho_l) \quad \text{and} \quad g_{j+1/2}^R(\rho_l, \rho_r) = g(\rho_r, \rho_r), \quad j \in \mathbb{Z}, \tag{22}$$

is fitting since

$$\begin{cases} \rho_0^1 = \rho_l - \lambda(g_{1/2}^L(\rho_l, \rho_r) - g_{-1/2}^R(\rho_l, \rho_l)) = \rho_l - \lambda(g(\rho_l, \rho_l) - g(\rho_l, \rho_l)) = \rho_l, \\ \rho_1^1 = \rho_r - \lambda(g_{3/2}^L(\rho_r, \rho_r) - g_{1/2}^L(\rho_l, \rho_r)) = \rho_r - \lambda(g(\rho_r, \rho_r) - g(\rho_r, \rho_r)) = \rho_r. \end{cases}$$

Thanks to the new update formula (20), we are thus able to remove nondesired values. Nevertheless, it is clear at this stage that the initial discontinuity (17) is made stationary by our new update formula. Instead, it should be moving at speed $\sigma(\rho_l, \rho_r)$ given in (18). This is the reason for which a transport step must be included in our algorithm. A sampling strategy will be proposed in the next section, again in order to avoid the emergence of spurious values (see just below for more details).

4.2. Transport-equilibrium scheme. We now describe the two steps of our numerical strategy in details. As motivated in the previous subsection, the central idea is to modify the numerical flux $g_{j+1/2}(\rho_j^n, \rho_{j+1}^n)$ by means of two fluxes $g_{j+1/2}^L(\rho_j^n, \rho_{j+1}^n)$ and $g_{j+1/2}^R(\rho_j^n, \rho_{j+1}^n)$ each time that an undercompressive shock appears in the solution of the Riemann problem (5)–(6)–(9) associated with $\rho_l = \rho_j^n$ and $\rho_r = \rho_{j+1}^n$. According to whether this undercompressive shock connects the states ρ_j^n and $\psi(\rho_j^n)$ or not, that is, depending on whether $(\rho_j^n, \rho_{j+1}^n) \in A \cup B$ or $(\rho_j^n, \rho_{j+1}^n) \in C$, we will use the formulas (21) or (22), respectively. However, we have shown in the previous section that with such a modification, the undercompressive discontinuities are made stationary. We will then introduce a transport step in order to make moving these discontinuities with the right speed.

Equilibrium step ($t^n \to t^{n+1-}$). This first step aims at making stationary the admissible undercompressive discontinuities of (5)–(6) (see Theorem 1). We thus consider the nonconservative version of (19) given by (20), where the numerical fluxes $g_{j+1/2}^L$ and

$g^R_{j+1/2}$ are defined as follows with the aid of the nucleation condition (14)–(15)–(16) and for all $j \in \mathbb{Z}$:

$$g^L_{j+1/2} = \begin{cases} g(\rho^n_j, \rho^n_j) & \text{if } (\rho^n_j, \rho^n_{j+1}) \in A \cup B \cup C, \\ g(\rho^n_j, \rho^n_{j+1}) & \text{otherwise,} \end{cases} \tag{23}$$

and

$$g^R_{j+1/2} = \begin{cases} g(\psi(\rho^n_j), \rho^n_{j+1}) & \text{if } (\rho^n_j, \rho^n_{j+1}) \in A \cup B, \\ g(\rho^n_{j+1}, \rho^n_{j+1}) & \text{if } (\rho^n_j, \rho^n_{j+1}) \in C, \\ g(\rho^n_j, \rho^n_{j+1}) & \text{otherwise.} \end{cases} \tag{24}$$

With these definitions, we easily check (see also previous subsection) that discontinuities separating two states ρ_- and ρ_+ such that $(\rho_-, \rho_+) \in C$ (that is, in particular when $\rho_+ = \psi(\rho_-)$) are kept at stationary equilibrium during this first step.

$(t^{n+1-} \to t^{n+1})$. This step is concerned with the dynamics of the discontinuities left stationary during the first step. Recall that the speed of propagation $\sigma(\rho_-, \rho_+)$ of a discontinuity between ρ_- and ρ_+ is given by the Rankine–Hugoniot relation (18). We then decide to define at each interface $x_{j+1/2}$ a speed of propagation $\sigma_{j+1/2}$:

$$\sigma_{j+1/2} = \begin{cases} \sigma(\rho^{n+1-}_j, \rho^{n+1-}_{j+1}) & \text{if } (\rho^n_j, \rho^n_{j+1}) \in A \cup B \cup C, \\ 0 & \text{otherwise,} \end{cases} \tag{25}$$

and solve locally (at each discontinuity $x_{j+1/2}$) a transport equation with speed $\sigma_{j+1/2}$. If Δt is chosen sufficiently small to avoid wave interactions, we can glue together the corresponding solutions to define a solution in the whole domain. In order to get a new approximation ρ^{n+1}_j at time $t^{n+1} = t^n + \Delta t$, we propose to pick up randomly on the interval $[x_{j-1/2}, x_{j+1/2}[$ a value at time Δt in this solution. In particular, such a sampling strategy prevents the emergence of spurious intermediate values with respect to those obtained at time t^{n+1-}. Given a well distributed random sequence (a_n) within the interval $(0, 1)$, this amounts to setting

$$\rho^{n+1}_j = \begin{cases} \rho^{n+1-}_{j-1} & \text{if } a_{n+1} \in [0, \lambda\sigma^+_{j-1/2}[, \\ \rho^{n+1-}_j & \text{if } a_{n+1} \in [\lambda\sigma^+_{j-1/2}, 1 + \lambda\sigma^-_{j+1/2}[, \\ \rho^{n+1-}_{j+1} & \text{if } a_{n+1} \in [1 + \lambda\sigma^-_{j+1/2}, 1[, \end{cases} \tag{26}$$

with $\sigma^+_{j+1/2} = \max(\sigma_{j+1/2}, 0)$ and $\sigma^-_{j+1/2} = \min(\sigma_{j+1/2}, 0)$ for all $j \in \mathbb{Z}$. The description of our numerical strategy is now completed.

1. Let us consider the Riemann initial data (9), naturally discretized by (17), such that ρ_l and ρ_r are joined by an undercompressive discontinuity. Then, the definitions of $g^L_{j+1/2}$ and $g^R_{j+1/2}$ make invisible the first step of the method ($\rho^{n+1-}_j = \rho^n_j$ for all j), and only the second step operates. This second step propagates the discontinuity using a sampling strategy. We conclude that, in this particular case, our method reduces to Glimm's random choice scheme. In addition, note that the speed of propagation $\sigma(\rho_l, \rho_r)$ intervening in the second step is exact since it is calculated from the Rankine–Hugoniot relation between ρ_l and ρ_r.

Let us now consider the Riemann initial data (9), again naturally discretized by (17), but with ρ_l and ρ_r such that the Riemann solution is classical, that is, $(\rho_l, \rho_r) \notin A \cup B \cup C$. Then $g^L_{j+1/2} = g^R_{j+1/2} = g_{j+1/2}$ and $\sigma_{j+1/2} = 0$ at each time

step. In this particular case, our method thus reduces to the usual conservative scheme (19).

We conclude this section by highlighting the main difference between the present algorithm and the one proposed in [3]. The latter actually uses the property that the kinetic function is invertible to define $g^L_{j+1/2}$ when an undercompressive shock is present in the Riemann solution associated with the initial states ρ^n_j and ρ^n_{j+1}. More precisely and using the notation of the present paper, it writes $g^L_{j+1/2} = g(\rho^n_j, \psi^{-1}(\rho^n_{j+1}))$ instead of $g^L_{j+1/2} = g(\rho^n_j, \rho^n_j)$ in (23). Basically, it turns out that this definition of $g^L_{j+1/2}$ is actually crucial in [3] for obtaining good numerical results, but only in the situation when the flux is convex-concave. In this case, the undercompressive shock in the Riemann solution associated with states ρ^n_j and ρ^n_{j+1} indeed always connects the states $\psi^{-1}(\rho^n_{j+1})$ and ρ^n_{j+1}. It is then important to involve ψ^{-1} in the definition of the numerical scheme. But in the present situation, we remark (see Theorem 1) that the undercompressive shocks always get ρ^n_j as their left state, and then (necessarily) $\psi(\rho^n_j)$ as their right state. We thus expect that the definition of $g^R_{j+1/2}$ in (24) involving ψ is sufficient to properly capture such discontinuities.

5. Numerical experiments. This section is devoted to the validation of the transport-equilibrium scheme we have proposed. To that purpose and without restriction, we consider a relaxation scheme as a basic numerical flux g, that is,

$$g(u,v) = \frac{1}{2}(q(u)+q(v)) + \frac{a(u,v)}{2}(u-v) \quad \text{with} \quad a(u,v) = \max_{[\min(u,v),\max(u,v)]} |q'| \tag{27}$$

(see [11], for instance), and we use the following standard CFL condition for computing the time step Δt at each time iteration:

$$\Delta t = \frac{1}{2} \times \frac{\Delta x}{\max_j |a(\rho^n_j, \rho^n_{j+1})|}.$$

. . .. 2. At this stage, it is important to notice that, generally speaking, both the numerical flux g and the time step Δt must be chosen so that the standard conservative scheme (19) (i) generates the classical solution of (5), in order to be relevant in situations where the solution is classical and the transport-equilibrium scheme simply reduces to (19); (ii) obeys a discrete version of the maximum principle; that is, for all n, j we have $\rho^n_j \in [\min_j \rho^0_j, \max_j \rho^0_j]$. Indeed, imagine that ρ_0 has the particular form (9) with $(\rho_l, \rho_r) \in [0, R]^2$ but $(\rho_l, \rho_r) \notin A$; the corresponding solution to (5) is classical by Theorem 1 and stays in the interval $[0, R]$. Then, if the conservative scheme (19) fails in satisfying a discrete maximum principle, a value $\rho^n_j > R$ may well appear for some n, j with the (very bad) consequence of starting the nonconservative transport-equilibrium scheme (that is, g^L and g^R no longer equal g in the whole domain) so as to generate a nonclassical solution.

Following a proposal by Colella [7], we consider the van der Corput random sequence (a_n) defined by

$$a_n = \sum_{k=0}^{m} i_k 2^{-(k+1)},$$

where $n = \sum_{k=0}^{m} i_k 2^k$, $i_k = 0, 1$, denotes the binary expansion of the integers $n = 1, 2, \ldots$. We easily find that the first few elements of this sequence are

$$\begin{array}{llll} a_1 = 0.5, & a_2 = 0.25, & a_3 = 0.75, & a_4 = 0.125, \\ a_5 = 0.625, & a_6 = 0.375, & a_7 = 0.875, & a_8 = 0.0625. \end{array}$$

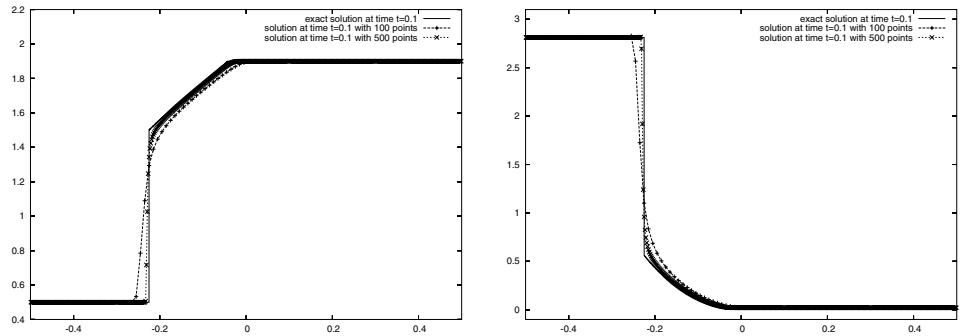

FIG. 3. *Test* 1—*classical solution:* $x \to \rho(x)$ *(left) and* $x \to q(\rho)(x)$ *(right).*

This sequence is actually well distributed within the interval $(0, 1)$. Moreover, one can prove, for instance, that $a_i < 0.5$ for i even and $a_i > 0.5$ for i odd. This well-known sequence is often preferred since it leads to very good results in the smooth parts of the solutions (see [7] and [6] for an illustration).

The closure relations for the numerical simulations are as follows. First of all, the flux function q is chosen as in (7) (see also (8) and Figure 1 for the graphs of the functions q, ψ, and Φ). Then, the thresholds s and Δs in the Theorem 1 are chosen to be

$$\Delta s = \Phi(0) = \frac{5}{3}, \quad s = \frac{1}{2}(R - \Delta s) = \frac{1}{6},$$

so that the condition (13) holds true. Finally, we mention that the computations are performed on two grids, containing respectively 100 ($\Delta x = 0.01$) and 500 ($\Delta x = 0.002$) points per unit interval. Let us now consider several typical behaviors of the Riemann solution given in the Theorem 1. Note that the discontinuity in the Riemann initial data is still located at $x = 0$ (see (9)).

The first test (Test 1) corresponds to the choice $\rho_l = 0.5$ and $\rho_r = 1.9$, so that $(\rho_l, \rho_r) \in [0, R]^2$ but $(\rho_l, \rho_r) \notin A$ since $(\rho_r - \rho_l) < \Delta s$. The solution thus coincides with the classical one. More precisely, we observe in Figure 3 that it is made of a classical shock attached to a rarefaction wave.

For Test 2, we choose $\rho_l = 0.2$ and $\rho_r = 1.9$ so that it is easily checked that $(\rho_l, \rho_r) \in [0, R]^2$ and $(\rho_l, \rho_r) \in A$. In such a situation, panic arises, and the solution is composed of an undercompressive discontinuity between $\rho_l = 0.2$ and $\psi(\rho_l) \simeq 2.7744$, followed by a classical part made of a rarefaction wave and a classical shock attached to the rarefaction. We observe in Figure 4 that our algorithm properly captures this nonclassical solution. Note also that the undercompressive discontinuity from ρ_l to $\psi(\rho_l)$ is sharp: there is no point in the profile. For the sake of comparison, Figure 5 shows that the usual relaxation scheme defined by the update formula (19) generates a (classical) solution which lies entirely in the interval $[0, R]$ and so is far from the expected one. This proves both the need for modifying classical conservative approaches and the good design of our strategy.

In the third test case (Test 3), we choose $\rho_l = 5/2$ and $\rho_r = 1$ so that $\rho_r < \rho_l$, and the solution is classical. In Figure 6, we see that the panic state ρ_l is connected to ρ_r by means of a single classical shock.

For Test 4, we choose $\rho_l = 0.2$ and $\rho_r = 5/2$ so that $(\rho_l, \rho_r) \in B$ (recall that $\psi(\rho_l) \simeq 2.7744 > \rho_r$). By Theorem 1, we know that the solution is composed of an

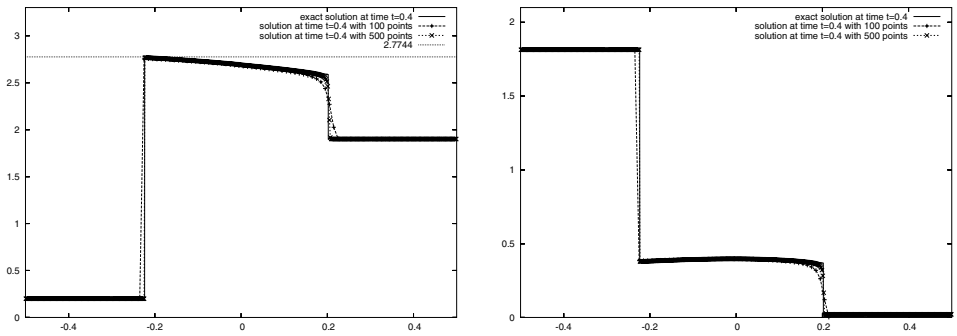

FIG. 4. *Test* 2—*nonclassical solution:* $x \to \rho(x)$ (*left*) *and* $x \to q(\rho)(x)$ (*right*).

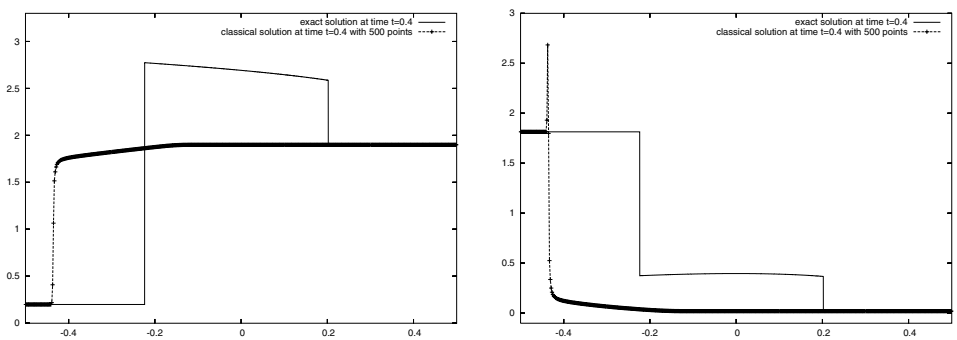

FIG. 5. *Test* 2, (*classical*) *solution generated by standard relaxation method:* $x \to \rho(x)$ (*left*) *and* $x \to q(\rho)(x)$ (*right*).

undercompressive discontinuity between ρ_l and $\psi(\rho_l)$, followed by a rarefaction wave. Here again, we observe in Figure 7 that our algorithm provides a numerical solution in agreement with the exact one, with, in addition, a sharp transition from ρ_l to $\psi(\rho_l)$. In contrast, the usual relaxation scheme would generate a classical behavior really different from the nonclassical one (the result is not presented here).

In the fifth test case (Test 5), we take $\rho_l = 0.2$ and $\rho_r = 2.9$ so that we now have $(\rho_l, \rho_r) \in C$. By Theorem 1, the solution is a single undercompressive shock connecting ρ_l to ρ_r. Figure 8 shows that our algorithm again sharply captures this undercompressive discontinuity. Note that it and Glimm's random choice scheme are identical for this test case since the first step is clearly transparent.

. . . 3. In certain figures, some undershoots and overshoots are observed near the shocks for the q component. Recall that q is calculated as a function of ρ (the conservative unknown). Then, these undershoots and overshoots are due to the numerical diffusion of the method and to the property that the function $\rho \to q(\rho)$ is not monotone between the left and right states of the discontinuity in general. Then, depending on the densities that appear in the numerical profile of the discontinuity, an oscillation is created. Observe that having removed the numerical diffusion of the undercompressive shocks with our algorithm implies that there are not oscillations around these discontinuities.

We finish this section by giving particular attention to the speed of propagation

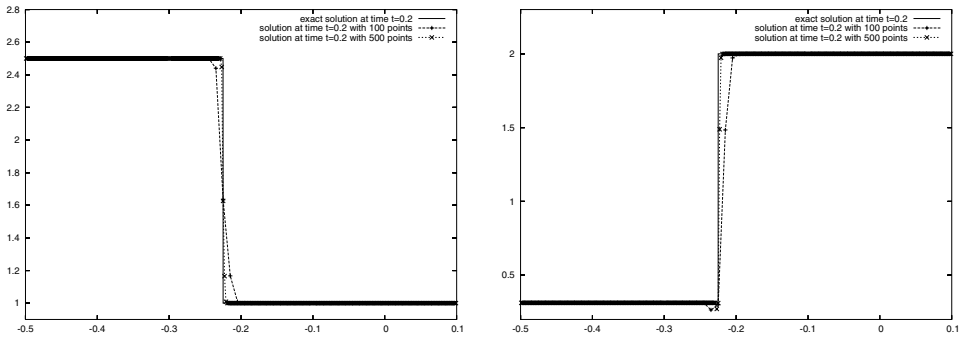

FIG. 6. *Test* 3—*classical solution:* $x \to \rho(x)$ (*left*) *and* $x \to q(\rho)(x)$ (*right*).

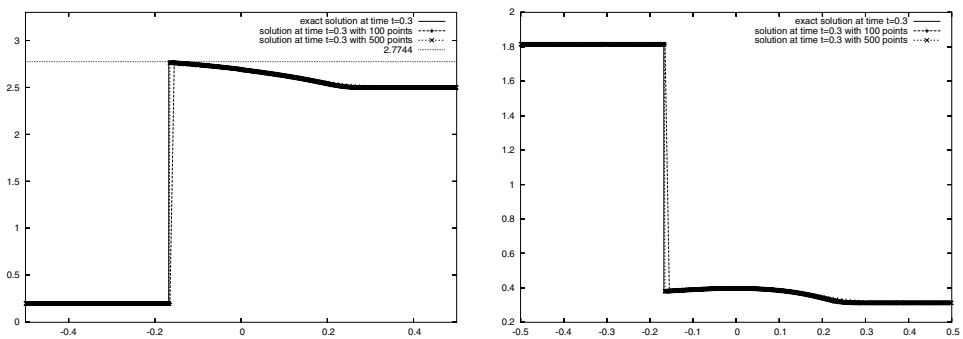

FIG. 7. *Test* 4—*nonclassical solution:* $x \to \rho(x)$ (*left*) *and* $x \to q(\rho)(x)$ (*right*).

provided by the second step of the algorithm. This speed is calculated at each time iteration and may well vary, while in reality the speed of propagation of each undercompressive shock is constant. Let us first consider the fifth test case, for which the left and right states ρ_l and ρ_r are connected by a single undercompressive discontinuity. In this case, the speed of propagation of the method is [illegible] in time and rightly calculated; see Remark 1 above. In Tests 2 and 4, the situation is different since only the left state $\rho_l = 0.2$ of the undercompressive shock is present in the initial data, but not the right state $\psi(\rho_l) \simeq 2.7744$. The latter is created by the method after some time iterations (this state behaves like an equilibrium point of the strategy), and during this process, the corresponding speed of propagation is changing to eventually reach the expected value. In Figure 9, we have plotted for Tests 2 (left) and 4 (right) the values taken by this speed of propagation in the course of the computations (from time $t = 0$ to the final time) and for several meshes. We observe that the method needs only a few times for correctly approaching the exact speed of propagation. For instance, the relative error is around 0.01% at the final time, which explains the good results of the method.

6. Quantitative evaluation of the method. In this section, we propose to evaluate the numerical solutions obtained for the five Riemann problems we have considered above through quantitative tests. We begin with the computation of the conservation errors, and then we study the order of convergence of the method through

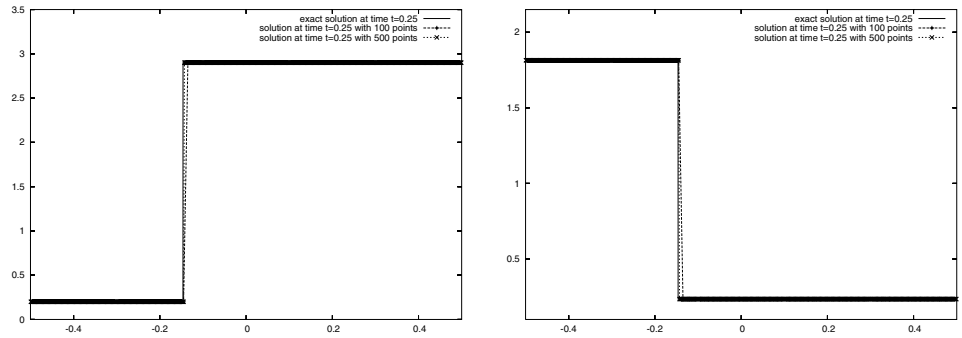

FIG. 8. *Test* 5*—nonclassical solution:* $x \to \rho(x)$ (*left*) *and* $x \to q(\rho)(x)$ (*right*).

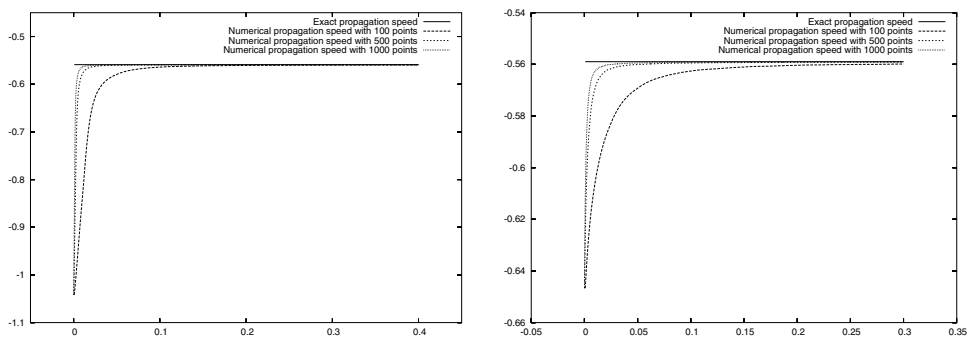

FIG. 9. *Numerical propagation speed of the undercompressive shock versus time: Test* 2 (*left*) *and Test* 4 (*right*).

the L^1-norm.

6.1. Conservation errors. It is obvious that our method is nonconservative since, first, two numerical fluxes g^L and g^R are used in the first step and, second, the transport step is based on a random sampling. We then propose to measure the conservation error on piecewise constant numerical solution ρ_λ defined as

$$\rho_\lambda(x,t) = \rho_j^n \quad \text{if } (x,t) \in [x_{j-1/2}, x_{j+1/2}) \times [t^n, t^{n+1}),$$

between the times $t = 0$ and, let us say, $t = T > 0$. For that, we denote by $[x_m, x_M]$ the computational domain, and we proceed exactly as in [3] by comparing with 0 the function $E : T \in \mathbb{R}^+ \to E(T) \in \mathbb{R}$, with $E(T)$ defined by the relation

$$\int_{x_m}^{x_M} \rho_\lambda(x,T)dx \times E(T) = \int_{x_m}^{x_M} \rho_\lambda(x,T)dx - \int_{x_m}^{x_M} \rho_\lambda(x,0)dx + \int_0^T q(\rho_\lambda(x_M,t))dt - \int_0^T q(\rho_\lambda(x_m,t))dt. \tag{28}$$

Figures 10, 11, 12, 13 and 14 show the function $T \to E(T)$ for the five test cases considered in the previous section. We used $x_m = -0.5$ and $x_M = 0.5$.

For the first test case (Figure 10), no conservation error is made since the solution is classical, so that our algorithm exactly reduces to the standard (conservative)

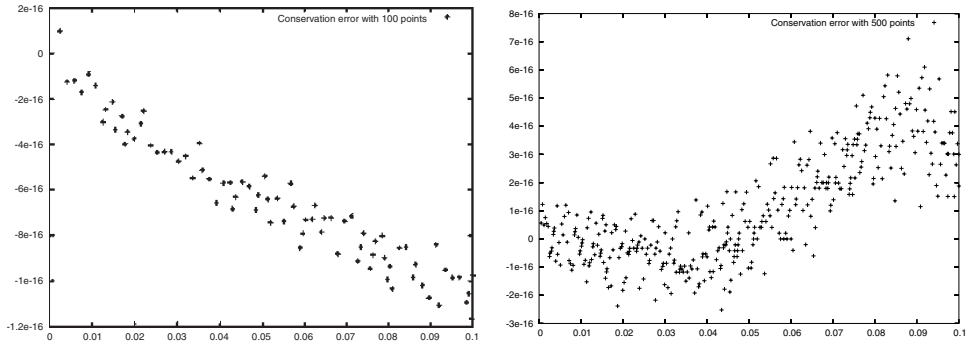

FIG. 10. *Test* 1—*conservation error with* 100 (*left*) *and* 500 (*right*) *points in the mesh.*

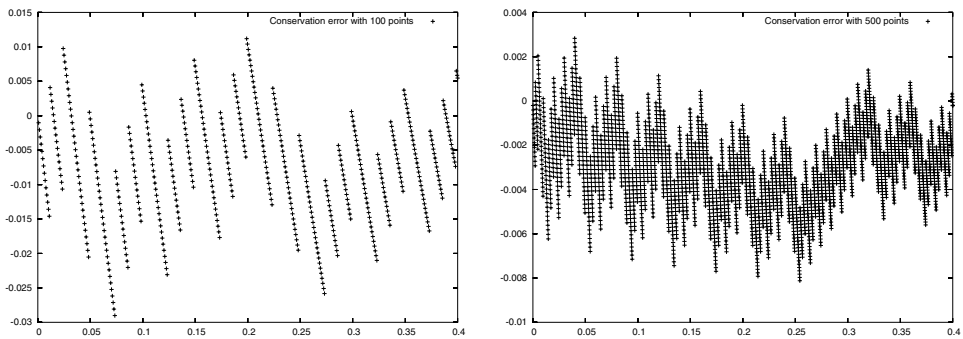

FIG. 11. *Test* 2—*conservation error with* 100 (*left*) *and* 500 (*right*) *points in the mesh.*

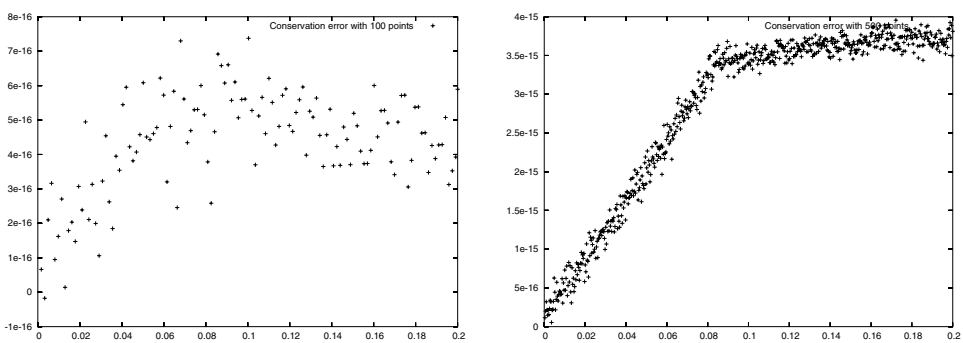

FIG. 12. *Test* 3—*conservation error with* 100 (*left*) *and* 500 (*right*) *points in the mesh.*

relaxation scheme. The same happens for Test 3; see Figure 12.

In Tests 2 and 4, for which the solution is nonclassical, we observe in Figures 11 and 13 that we have a very small conservation error: it seems to stay around 1% and 2% with 100 points in the mesh, and around 0.3% and 0.5% with 500 points in the mesh.

Finally, in the last test case (Figure 14), we observe that the conservation error is once more low and stays around 2.2% with 100 points and around 0.5% with 500 points.

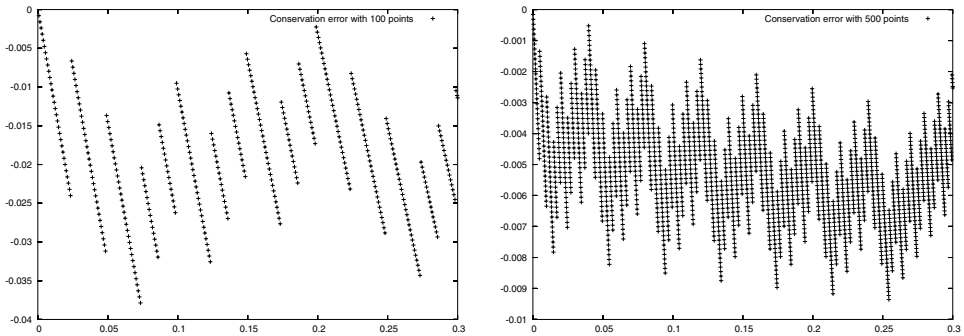

FIG. 13. *Test* 4—*conservation error with* 100 (*left*) *and* 500 (*right*) *points in the mesh.*

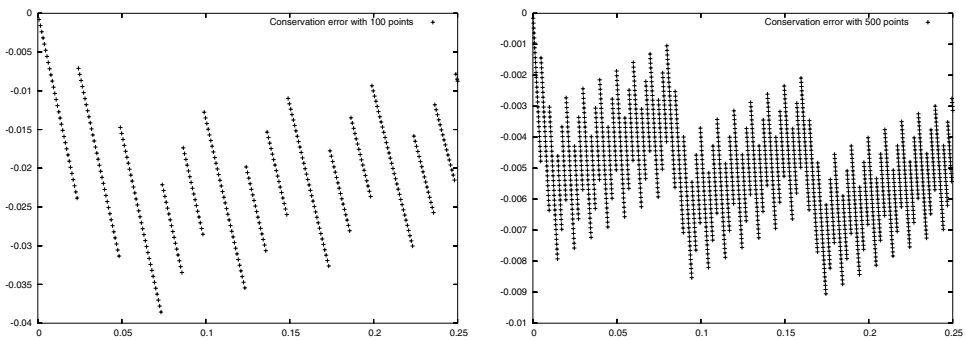

FIG. 14. *Test* 5—*conservation error with* 100 (*left*) *and* 500 (*right*) *points in the mesh.*

To conclude this section, we now address this lack of conservation in term of the number of pedestrians. Let us first notice that the exact solution obeys

$$0 = \int_{x_m}^{x_M} \rho(x,T)dx - \int_{x_m}^{x_M} \rho(x,0)dx + \int_0^T q(\rho(x_M,t))dt - \int_0^T q(\rho(x_m,t))dt,$$

so that, provided the dynamics of the numerical solution has not reached x_m and x_M (which means $q(\rho_\lambda(x_m,t)) = q(\rho(x_m,t))$ and $q(\rho_\lambda(x_M,t)) = q(\rho(x_M,t))$), we get

$$E(T) = \frac{\int_{x_m}^{x_M} \rho_\lambda(x,T)dx - \int_{x_m}^{x_M} \rho(x,T)dx}{\int_{x_m}^{x_M} \rho_\lambda(x,T)dx}.$$

Then, $E(T)$ represents the relative conservation error of ρ at time T on the interval $[x_m, x_M]$, and $\int_{x_m}^{x_M} \rho_\lambda(x,T)dx \times E(T)$ gives the number of persons lost in each computation. At the final time, we found that this number equals 0.0097, -0.0203, and -0.0169 for Tests 2, 4, and 5, respectively (and for 100 points only). This represents only a small portion of a person. Since to get integer numbers of people we have to round these results, we then eventually recover the conservation property (nobody is lost).

6.2. Convergence rate. We now numerically investigate the convergence rate of the method for all the Riemann problems considered until now. We measure the

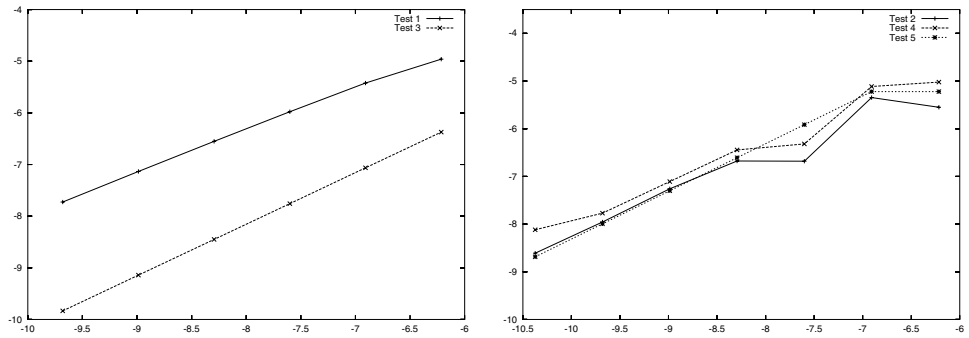

FIG. 15. $\ln(E_{L^1})$ *versus* $\ln(\Delta x)$.

L^1-norm E_{L^1} of the difference between the exact and the numerical solutions by the following usual formula:

$$E_{L^1} = \Delta x \sum_{j \in \mathbb{Z}} |\rho_\lambda(x_j, T_f) - \rho(x_j, T_f)|,$$

where T_f is the final time of the computation. This quantity is evaluated for several space steps Δx, and the results are presented on a graph relating $\ln(E_{L^1})$ to $\ln(\Delta x)$.

Figure 15(left) is concerned with Tests 1 and 3, for which the solutions are classical. In this case, we have already underlined (see Remark 1) that our algorithm is equivalent to the conservative scheme given by the numerical flux g. Then what we are measuring here is nothing but the convergence rate of the numerical solution to the exact solution for the relaxation scheme (27). The meshes we have used contain $2^i \times 500$ nodes per unit interval, with an integer i varying from 0 to 5. The solution of Test 3 is a pure classical shock, and we obtain a convergence rate of approximately 0.999. In contrast, for Test 1 the solution is a classical shock followed by an attached rarefaction wave. The convergence rate observed for this wave is around 0.845, less than for the pure shock.

Figure 15(right) shows the results for Tests 2, 4, and 5, for which the solutions develop an undercompressive shock. The meshes now contain $2^i \times 500$ nodes per unit interval, with i varying from 0 to 6. Let us begin with Test 5. The solution is a pure undercompressive shock, and our method is identical to Glimm's random choice scheme in this case (see again Remark 1). We get a convergence rate of 1, which is expected for this scheme. For Tests 2 and 4 the patterns of the solutions are more complicated, since the undercompressive shock is not pure anymore but attached to a rarefaction wave. Around this undercompressive discontinuity, our method then actually blends Glimm's random choice scheme and the relaxation scheme. We observe that the experimental order of convergence for Test 2 is close to 1, while for Test 4 it is not yet established but convergence seems secured.

7. Conclusion. We have proposed a very efficient numerical strategy for computing the nonclassical solutions of a particular nongenuinely nonlinear scalar conservation law (q is neither convex nor concave), recently introduced by Colombo and Rosini [8] for simulating human flows. The validation has been (successfully) carried out using several relevant Riemann initial data. The fact is that our approach is nonconservative, but measurements have shown that the loss of mass is extremely low,

while the numerical solutions fully agree with the exact ones. Now it would be of interest to use the method on initial data associated with concrete situations.

Acknowledgments. The author is very grateful to the referees and the editor of this paper, which benefited hugely from their reports and comments.

ANALYSIS OF THE PARAREAL TIME-PARALLEL TIME-INTEGRATION METHOD*

MARTIN J. GANDER† AND STEFAN VANDEWALLE‡

Abstract. The parareal algorithm is a method to solve time-dependent problems parallel in time: it approximates parts of the solution later in time simultaneously to parts of the solution earlier in time. In this paper the relation of the parareal algorithm to space-time multigrid and multiple shooting methods is first briefly discussed. The focus of the paper is on new convergence results that show superlinear convergence of the algorithm when used on bounded time intervals, and linear convergence for unbounded intervals.

Key words. time-parallel time-integration, parareal, convergence analysis, shooting, multigrid, deferred correction

DOI. 10.1137/05064607X

1. Introduction.

The parareal algorithm was presented by Lions, Maday, and Turinici in [19] as a numerical method to solve evolution problems in parallel. The name was chosen to indicate that the algorithm is well suited for parallel real time computations of evolution problems whose solution cannot be obtained in real time using one processor only. The method approximates successfully the solution later in time before having fully accurate approximations from earlier times. The algorithm has received a lot of attention over the past few years, especially in the domain decomposition literature [18]. Extensive experiments can be found for fluid and structure problems in [8], for the Navier–Stokes equations in [9], and for reservoir simulation in [10]. Several variants of the method have been proposed, e.g., in [11, 8]. The algorithm has been further analyzed in [21, 22], and its stability is investigated in [29, 2].

Parareal is not the first algorithm to propose the solution of evolution problems in a time-parallel fashion. Already in 1964, Nievergelt suggested a parallel time-integration algorithm [24], which eventually developed into the multiple shooting method for boundary value problems; see [16]. The idea is to decompose the time-integration interval into subintervals, to solve an initial value problem on each subinterval concurrently, and to force continuity of the solution branches on successive intervals by means of a Newton procedure. This approach has also been proposed at a fine grain level, where the shooting intervals correspond to the step size of a one-step method [4]. Parallel multiple shooting for initial value problems was further studied in [6, 17].

In 1967, Miranker and Liniger [23] proposed a family of predictor-corrector methods, in which the prediction and correction steps can be performed in parallel over a number of time steps. Their idea was to "widen the computational front," i.e., to allow processors to compute solution values on several time steps concurrently. A

similar motivation led to the block time-integration methods by Shampine and Watts [27]. More recently, [26] and [33] considered the time-parallel application of iterative methods to the system of equations derived with implicit time-integration schemes applied to parabolic partial differential equations (PDEs). Instead of iterating until convergence over each time step before moving on to the next, they showed that it is possible to iterate over a number of time steps at once. Thus a different processor can be assigned to each time step and they all iterate simultaneously. This class of methods was analyzed for its parallel potential in [7]. The authors of that paper showed that the increase in parallel efficiency is often offset by an increased amount of computational work, because of slow information propagation forward in time. The acceleration of such methods by means of a multigrid technique led to the class of parabolic multigrid methods, as introduced by Hackbusch in [12]. The time-parallel multigrid method [13], the multigrid waveform relaxation method [20, 32], and the space-time multigrid method [14] also belong to that class. In [31], a time-parallel variant was shown to achieve excellent speedups on a computer with 512 processors; while run as a sequential algorithm the method is comparable to the best classical time marching schemes. Experiments with time-parallel parabolic multigrid methods on a system with 2^{14} processors are reported in [15].

Our paper is organized as follows. In section 2, we present a new and natural derivation of the parareal algorithm and some of its variants. It is shown that these techniques can be seen as practical implementations of the multiple shooting method. In section 3, we show that the algorithm also fits into the framework of time-multigrid methods. In particular the method is identified as a two-level full approximation scheme with an aggressive time-coarsening. In section 4, we develop new convergence results for scalar linear model problems, on bounded and unbounded time intervals. A number of practically relevant parareal methods are discussed in detail. In section 5, these convergence results are extended to two model PDEs: the heat equation and the pure advection equation. Numerical experiments that illustrate and clarify the theory are reported in section 6. We end in section 7 with some concluding remarks.

2. Parareal as a multiple shooting method. The parareal algorithm is a parallel method for computing the numerical solution for general systems of ordinary differential equations (ODEs) of the form

$$\boldsymbol{u}' = \boldsymbol{f}(\boldsymbol{u}), \quad \boldsymbol{u}(0) = \boldsymbol{u}_0, \quad t \in [0, T]. \tag{2.1}$$

The parareal algorithm is defined using two propagation operators. The operator $G(t_2, t_1, \boldsymbol{u}_1)$ provides a rough approximation to $\boldsymbol{u}(t_2)$ of the solution of (2.1) with initial condition $\boldsymbol{u}(t_1) = \boldsymbol{u}_1$, whereas operator $F(t_2, t_1, \boldsymbol{u}_1)$ provides a more accurate approximation of $\boldsymbol{u}(t_2)$. The algorithm starts with an initial approximation $\boldsymbol{U}_n^0$, $n = 0, 1, \ldots, N$, at time $t_0, t_1, \ldots, t_N$ given, for example, by the sequential computation of $\boldsymbol{U}_{n+1}^0 = G(t_{n+1}, t_n, \boldsymbol{U}_n^0)$, with $\boldsymbol{U}_0^0 = \boldsymbol{u}_0$, and then performs for $k = 0, 1, 2, \ldots$ the correction iteration

$$\boldsymbol{U}_{n+1}^{k+1} = G(t_{n+1}, t_n, \boldsymbol{U}_n^{k+1}) + F(t_{n+1}, t_n, \boldsymbol{U}_n^k) - G(t_{n+1}, t_n, \boldsymbol{U}_n^k). \tag{2.2}$$

Note that for $k \to \infty$ the parareal algorithm (2.2) will upon convergence generate a series of values $\boldsymbol{U}_n$ that satisfy $\boldsymbol{U}_{n+1} = F(t_{n+1}, t_n, \boldsymbol{U}_n)$. That is, the approximation at the time-points t_n will have achieved the accuracy of the F-propagator.

The algorithm can be interpreted most naturally as a classical deferred correction method [28]. In such a method, the solution to a "hard" problem $A(\boldsymbol{u}) = \boldsymbol{0}$ is

computed iteratively by solving a series of "easier" problems of the form $B(\boldsymbol{u}) = \boldsymbol{g}$. More precisely, starting with some approximation $\boldsymbol{u}^0$ to $\boldsymbol{u}$, one solves

$$B(\boldsymbol{u}^{k+1}) = B(\boldsymbol{u}^k) - A(\boldsymbol{u}^k) \quad \text{for } k = 0, 1, \ldots. \tag{2.3}$$

This iteration can be identified with (2.2) if $\boldsymbol{u} = (\boldsymbol{U}_1, \boldsymbol{U}_2, \ldots, \boldsymbol{U}_N)^T$ and if $A(\boldsymbol{u})$ and $B(\boldsymbol{u})$ are vectors of length N times the size of system (2.1), whose components $A(\boldsymbol{u})_{n+1}$ and $B(\boldsymbol{u})_{n+1}$, for $n = 0, \ldots, N-1$, are vectors given, respectively, by

$$A(\boldsymbol{u})_{n+1} = \boldsymbol{U}_{n+1} - F(t_{n+1}, t_n, \boldsymbol{U}_n) \quad \text{and} \quad B(\boldsymbol{u})_{n+1} = \boldsymbol{U}_{n+1} - G(t_{n+1}, t_n, \boldsymbol{U}_n).$$

The parareal method first appeared in [19] for a linear scalar model problem, and it was applied to a linear PDE, and to a nonlinear one by linearization. A different formulation for the nonlinear case appeared first in [3] and then in the mathematically equivalent but simplified form (2.2) in [1]. The original linearized formulation of [19] was rederived in a more general setting, analyzed, and tested on realistic problems in [8]. Here, we will not recall how the different variants have been derived in the literature. Instead, we will present a new, simple, and unified approach for their derivation based on the multiple shooting method applied to (2.1).

In the multiple shooting method the time interval $[0, T]$ is partitioned into N subintervals, not necessarily of equal length, determined by the time-points $0 = t_0 < t_1 < \cdots < t_{N-1} < t_N = T$. A system of N separate initial value problems is posed,

$$\left\{ \begin{array}{rclrcl} \boldsymbol{u}_0' &=& \boldsymbol{f}(\boldsymbol{u}_0), & \boldsymbol{u}_0(0) &=& \boldsymbol{U}_0, \\ \boldsymbol{u}_1' &=& \boldsymbol{f}(\boldsymbol{u}_1), & \boldsymbol{u}_1(t_1) &=& \boldsymbol{U}_1, \\ & \vdots & & & \vdots & \\ \boldsymbol{u}_{N-1}' &=& \boldsymbol{f}(\boldsymbol{u}_{N-1}), & \boldsymbol{u}_{N-1}(t_{N-1}) &=& \boldsymbol{U}_{N-1}, \end{array} \right. \tag{2.4}$$

together with the matching conditions

$$\boldsymbol{U}_0 - \boldsymbol{u}_0 = 0, \quad \boldsymbol{U}_1 - \boldsymbol{u}_0(t_1, \boldsymbol{U}_0) = 0, \quad \ldots, \quad \boldsymbol{U}_N - \boldsymbol{u}_{N-1}(T, \boldsymbol{U}_{N-1}) = 0. \tag{2.5}$$

These matching conditions form a nonlinear system of equations

$$\boldsymbol{F}(\boldsymbol{U}) = \boldsymbol{0}, \quad \boldsymbol{U} = (\boldsymbol{U}_0, \boldsymbol{U}_1, \ldots, \boldsymbol{U}_N)^T. \tag{2.6}$$

Solving this system with Newton's method leads to

$$\boldsymbol{U}^{k+1} = \boldsymbol{U}^k - J_F^{-1}(\boldsymbol{U}^k)\boldsymbol{F}(\boldsymbol{U}^k), \tag{2.7}$$

where J_F denotes the Jacobian of $\boldsymbol{F}$. Using the particular structure of the function $\boldsymbol{F}$ in (2.5), we can write the Newton update $J_F^{-1}(\boldsymbol{U}^k)\boldsymbol{F}(\boldsymbol{U}^k)$ in the form

$$\begin{bmatrix} I & & & & \\ -\frac{\partial u_0}{\partial U_0}(t_1, U_0^k) & I & & & \\ & -\frac{\partial u_1}{\partial U_1}(t_2, U_1^k) & I & & \\ & & \ddots & \ddots & \\ & & & -\frac{\partial u_{N-1}}{\partial U_{N-1}}(t_{n-1}, U_{N-1}^k) & I \end{bmatrix}^{-1} \begin{pmatrix} U_0^k - u_0 \\ U_1^k - u_1(t_1, U_0^k) \\ U_2^k - u_1(t_2, U_1^k) \\ \vdots \\ U_N^k - u_{N-1}(T, U_1^k) \end{pmatrix}.$$

Rearranging (2.7) by multiplying through by the Jacobian, we find the basic recurrence of the multiple shooting method applied to initial value problems,

$$\left\{ \begin{array}{rcl} \boldsymbol{U}_0^{k+1} &=& \boldsymbol{u}_0, \\ \boldsymbol{U}_{n+1}^{k+1} &=& \boldsymbol{u}_n(t_{n+1}, \boldsymbol{U}_n^k) + \frac{\partial \boldsymbol{u}_n}{\partial \boldsymbol{U}_n}(t_{n+1}, \boldsymbol{U}_n^k)(\boldsymbol{U}_n^{k+1} - \boldsymbol{U}_n^k). \end{array} \right. \tag{2.8}$$

While the formulation of (2.8) is entirely at the continuous level, to apply the multiple shooting algorithm one usually needs to discretize the differential equations on each subinterval. That is, one needs to select a numerical method for computing $\boldsymbol{u}_n(t_{n+1}, \boldsymbol{U}_n^k)$. In addition, one has to decide on how to compute or approximate the terms $\frac{\partial \boldsymbol{u}_n}{\partial \boldsymbol{U}_n}(t_{n+1}, \boldsymbol{U}_n^k)$, or the action of those terms on the difference $\boldsymbol{U}_n^{k+1} - \boldsymbol{U}_n^k$.

We will show in a series of remarks that different choices of these approximations have led to different parareal versions.

. . .. 2.1. If in the multiple shooting method one approximates the subinterval solves by $\boldsymbol{u}_n(t_{n+1}, \boldsymbol{U}_n^k) = F(t_{n+1}, t_n, \boldsymbol{U}_n^k)$, and if one approximates the second term in the right-hand side of (2.8) in a finite difference way using the G-propagator,

$$\frac{\partial \boldsymbol{u}_n}{\partial \boldsymbol{U}_n}(t_{n+1}, \boldsymbol{U}_n^k)(\boldsymbol{U}_n^{k+1} - \boldsymbol{U}_n^k) = G(t_{n+1}, t_n, \boldsymbol{U}_n^{k+1}) - G(t_{n+1}, t_n, \boldsymbol{U}_n^k),$$

then the multiple shooting algorithm (2.8) and the parareal algorithm (2.2) coincide.

. . .. 2.2. In [4], Bellen and Zennaro describe a parallel solver for the computation of a general first order recurrence relation of the form $y_{n+1} = F_{n+1}(y_n)$. The function F_{n+1} represents, for example, a one-step numerical discretization of an initial value problem. The method of [4] can be recovered from the multiple shooting algorithm (2.8) if the computation of $\boldsymbol{u}_n(t_{k+1}, \boldsymbol{U}_n^k)$ is approximated as $F_{n+1}(\boldsymbol{U}_n^k)$ and if the columns of the matrix $\frac{\partial \boldsymbol{u}_n}{\partial \boldsymbol{U}_n}(t_{n+1}, \boldsymbol{U}_n^k)$ are approximated individually by a finite difference method. As the authors point out, these columns can be approximated concurrently on d processors, where d is the dimension of (2.1), by applying the function F_{n+1} to d vectors that are each single component perturbations of $\boldsymbol{U}_n^k$.

. . .. 2.3. In shooting methods, the Jacobian may be computed by solving the so-called variational equations, which, in our case, are given by

$$\left(\frac{\partial \boldsymbol{u}_n}{\partial \boldsymbol{U}_n}\right)' = \boldsymbol{f}'(\boldsymbol{u}_n)\frac{\partial \boldsymbol{u}_n}{\partial \boldsymbol{U}_n}, \quad \frac{\partial \boldsymbol{u}_n}{\partial \boldsymbol{U}_n}(t_n) = I, \qquad n = 0, 1, \ldots, N-1. \tag{2.9}$$

Here, I denotes the identity matrix. These linear equations are in general matrix equations, where the matrix size corresponds to the size of the system of equations (2.1). They are classically solved simultaneously with the shooting equations (2.4) using the same method, since the trajectory values $\boldsymbol{u}_n$ are needed in (2.9). If one approximates these equations on the coarse mesh t_n, $n = 0, 1, \ldots, N$, only, then one obtains the original version of the parareal algorithm proposed for nonlinear problems in [19]. Since (2.9) is a matrix equation and one needs only the action of the Jacobian on the vector of differences in (2.8), it is computationally more effective to approximate on the coarse grid the vector valued equation

$$\boldsymbol{v}_n' = \boldsymbol{f}'(\boldsymbol{u}_n)\boldsymbol{v}_n, \quad \boldsymbol{v}_n(t_n) = \boldsymbol{U}_n^{k+1} - \boldsymbol{U}_n^k, \qquad n = 0, 1, \ldots, N-1, \tag{2.10}$$

to obtain $\boldsymbol{v}_n(t_{n+1}) = \frac{\partial \boldsymbol{u}_n}{\partial \boldsymbol{U}_n}(t_{n+1}, \boldsymbol{U}_n^k)(\boldsymbol{U}_n^{k+1} - \boldsymbol{U}_n^k)$. This is done in the so-called PITA algorithm for nonlinear problems proposed in [8] and is mathematically equivalent to approximating (2.9) on the coarse mesh, before applying the matrix valued solution to $\boldsymbol{U}_n^{k+1} - \boldsymbol{U}_n^k$. For linear problems, this approach coincides with formulation (2.2) of the parareal algorithm.

3. Parareal as a time-multigrid method. We will show in this section that iteration (2.2) can be cast into the classical framework of nonlinear multigrid methods. Consider a nonlinear system of equations of the form

$$A_h(\boldsymbol{u}) = \boldsymbol{b}. \tag{3.1}$$

Typically, this system is derived by discretization of a PDE on a mesh Ω_h. The two-grid variant of the so-called full approximation storage (FAS) multigrid method for this problem can be written as follows (see [5]):

$$\left\{\begin{array}{rcl} \tilde{\boldsymbol{u}}^k &=& S(\boldsymbol{u}^k, \boldsymbol{b}), \\ A_H(\boldsymbol{U}^{k+1}) &=& I_h^H(\boldsymbol{b} - A_h(\tilde{\boldsymbol{u}}^k)) + A_H(I_h^H \tilde{\boldsymbol{u}}^k), \\ \boldsymbol{u}^{k+1} &=& \tilde{\boldsymbol{u}}^k + I_H^h(\boldsymbol{U}^{k+1} - I_h^H \tilde{\boldsymbol{u}}^k). \end{array}\right. \tag{3.2}$$

The algorithm is used to compute a series of approximations $\boldsymbol{u}^k$ for $k = 1, 2, \ldots$, starting from a given initial estimate $\boldsymbol{u}^0$, to the solution of problem (3.1). The first step in the two-grid algorithm is called the smoothing step and is fully defined by the smoothing operator S. The second equation in (3.2) defines a coarse grid problem and is characterized by the operator A_H. This operator is usually a discretization of a partial differential operator on a coarse mesh Ω_H. Operator I_h^H is called the restriction operator and transfers discrete functions from the fine mesh Ω_h to the coarse one. Finally, the third step of the algorithm is the correction step. There, the approximation $\tilde{\boldsymbol{u}}^k$ generated by the smoother is updated by transferring a correction from the coarse mesh to the fine mesh by using a prolongation operator I_H^h.

We will show that the FAS components can be selected in such a way that the iteration defined by (3.2) is identical to the parareal iteration given in (2.2). First, we consider the operators A_h and A_H. They are defined by a discretization of the possibly nonlinear evolution equation (2.1) on a fine mesh and on a coarse mesh, respectively. For notational convenience, we will assume those meshes to be regular, with step size h for Ω_h and with step size Mh for Ω_H for some integer $M > 1$. We introduce two arbitrary one-step methods: for the fine grid approximation,

$$\boldsymbol{u}_m = \phi_m(\boldsymbol{u}_{m-1}) + \boldsymbol{b}_m, \quad \boldsymbol{u}_m \approx \boldsymbol{u}(mh), \quad m = 1, 2, \ldots, MN, \tag{3.3}$$

and for the coarse grid approximation,

$$\boldsymbol{U}_n = \Phi_n(\boldsymbol{U}_{n-1}) + \boldsymbol{B}_n, \quad \boldsymbol{U}_n \approx \boldsymbol{u}(nH), \quad n = 1, 2, \ldots, N. \tag{3.4}$$

In the case of a linear problem, the function $\phi_m(\cdot)$ corresponds to a matrix-vector product, with a matrix which we shall denote as ϕ_m. The vector $\boldsymbol{b}_m$ is a vector that collects known, solution independent values. We will extend the sets of equations (3.3) and (3.4) with an additional equation of the form $\boldsymbol{u}_0 = \boldsymbol{b}_0$, or $\boldsymbol{U}_0 = \boldsymbol{B}_0$, where both $\boldsymbol{b}_0$ and $\boldsymbol{B}_0$ are equal to the initial condition. Collecting the vectors of the fine grid approximation $\boldsymbol{u}_m$ in one large vector $\boldsymbol{u}$ and the vectors of the coarse grid approximation in one large vector $\boldsymbol{U}$, we can write the recurrence relation for the fine and coarse grid approximations in the form $A_h(\boldsymbol{u}) = \boldsymbol{b}$ and $A_H(\boldsymbol{u}) = \boldsymbol{B}$, respectively. In the case of a linear problem, we can write the former as a linear matrix equation of the form $A_h \boldsymbol{u} = \boldsymbol{b}$, with

$$A_h := \begin{bmatrix} I & & & \\ -\phi_1 & I & & \\ & \ddots & \ddots & \\ & & -\phi_{MN} & I \end{bmatrix}, \quad \boldsymbol{u} = \begin{pmatrix} \boldsymbol{u}_0 \\ \boldsymbol{u}_1 \\ \vdots \\ \boldsymbol{u}_{NM} \end{pmatrix}, \quad \text{and } \boldsymbol{b} = \begin{pmatrix} \boldsymbol{b}_0 \\ \boldsymbol{b}_1 \\ \vdots \\ \boldsymbol{b}_{NM} \end{pmatrix}. \tag{3.5}$$

A similar notation could be used for the coarse mesh problem $A_H(\boldsymbol{U}) = \boldsymbol{B}$.

We will now demonstrate that parareal coincides with a time-multigrid method for a particular—be it somewhat unusual—choice of smoother, restriction, and interpolation operators. The smoother is defined recursively as follows:

$$\begin{cases} S(\boldsymbol{u}^k, \boldsymbol{b})_{nM} := \boldsymbol{u}^k_{nM} \quad \text{for } n = 0, 1, \ldots, N, \\ S(\boldsymbol{u}^k, \boldsymbol{b})_{nM+m} := \phi_{nM+m}(S(\boldsymbol{u}^k, \boldsymbol{b})_{nM+m-1}) + \boldsymbol{b}_{nM+m} \\ \qquad\qquad \text{for } m = 1, \ldots, M-1 \text{ and } n = 0, 1, \ldots, N-1. \end{cases} \tag{3.6}$$

That is, the smoother leaves the components of $\boldsymbol{u}^k$ with indices nM for $n = 0, 1, \ldots, N$ unchanged and fills out the intermediate components by using the recurrence (3.3). In the linear case, this smoother can be written in a more classical matrix formulation. To this end, we define a block Jacobi splitting of A_h,

$$A_h = M_{jac} + N_{jac}, \tag{3.7}$$

where the blocks are of size $M \times M$, except for the first block, which is of size $(M+1) \times (M+1)$, since it also includes the initial condition. We also introduce the matrix E, which is the identity of the same size as A_h, except for zeros on the diagonal at positions $0, M, 2M, \ldots, NM$. With this notation, we have

$$S(\boldsymbol{u}^k, b) := \boldsymbol{u}^k + EM^{-1}_{jac}(\boldsymbol{b} - A_h \boldsymbol{u}^k). \tag{3.8}$$

The method is based on a classical block Jacobi method, but the update of the $\boldsymbol{u}^k_{nM}$ values is prevented by means of the multiplication with the matrix E. Alternatively, the smoother can be interpreted as one phase of a classical two-color scheme, e.g., a red-black method. Let the mesh points be partitioned into a set of "black" points, in our case the points with indices nM, and let the remaining points be in the set of "red" points. One iteration of a standard red-black relaxation method would consist of an update of the red points, followed by an update of the black points. The smoother as defined in (3.6) corresponds to the first, i.e., red, step only.

For the analogy with the parareal scheme to go through, we need the restriction and prolongation operators to be, respectively, the standard injection operator and its transpose. More precisely,

$$(I^H_h \boldsymbol{u})_n := \boldsymbol{u}_{nM} \text{ and } (I^h_H \boldsymbol{U})_{nM+m} := \begin{cases} \boldsymbol{U}_n & \text{for } m = 0, \\ 0 & \text{for } m = 1, 2, \ldots, M-1. \end{cases} \tag{3.9}$$

That is, the restriction selects the entries at positions $0, M, \ldots, NM$ in the vector to which it is applied. The prolongation operator applied to a vector of length $N+1$ copies its entries into a vector of length $NM+1$ at the positions $0, M, \ldots, NM$, and fills in zero values in between. With all of the operators of the FAS method defined, we can now specify the components of the parareal algorithm. We consider $F(t_{n+1}, t_n, \cdot)$ to be composed of a sequence of steps of the form (3.3). More precisely,

$$\begin{cases} F(t_{n+1}, t_n, \boldsymbol{U}_n) := \boldsymbol{u}_{(n+1)M}, \text{ with } \quad \boldsymbol{u}_{nM} = \boldsymbol{U}_n, \\ \text{and } \quad \boldsymbol{u}_m = \phi_m(\boldsymbol{u}_{m-1}) + \boldsymbol{b}_m \text{ for } m = nM+1, \ldots, (n+1)M. \end{cases} \tag{3.10}$$

In a similar way, the propagator $G(t_{n+1}, t_n, \cdot)$ is defined as a single step of (3.4), i.e.,

$$G(t_{n+1}, t_n, \boldsymbol{U}_n) := \Phi_{n+1}(\boldsymbol{U}_n) + \boldsymbol{B}_{n+1}. \tag{3.11}$$

THEOREM 3.1. F G (3.10) (3.11). (3.8) (3.9), $A_h(\cdot)$ $A_H(\cdot)$ (3.3) (3.4). $\boldsymbol{u}^0$ $\boldsymbol{u}^0_{nM} = \boldsymbol{U}^0_n$ $n = 0, 1, \ldots, N$ (2.2) (2.1) (3.2) (3.1), $\boldsymbol{U}^k_n = \boldsymbol{u}^k_{nM}$ $n = 0, 1, \ldots, N$ $k \geq 0$.

. We shall prove the result by induction on k; i.e., we show that $\boldsymbol{U}^{k+1}_n = \boldsymbol{u}^{k+1}_{nM}$ if $\boldsymbol{U}^k_n = \boldsymbol{u}^k_{nM}$. For $k = 0$, the equality holds by the assumption of the theorem.

We rewrite each of the terms in the second equation of the FAS scheme (3.2). For the nth element of the left-hand side, we find

$$\left(A_H(\boldsymbol{U}^{k+1})\right)_n = -\Phi_n(\boldsymbol{U}^{k+1}_{n-1}) + \boldsymbol{U}^{k+1}_n.$$

The first term on the right-hand side leads to

$$\left(I^H_h(\boldsymbol{b} - A_h(\tilde{\boldsymbol{u}}^k))\right)_n = \left(\boldsymbol{b} - A_h(\tilde{\boldsymbol{u}}^k)\right)_{nM} = \boldsymbol{b}_{nM} + \phi_{nM}(\tilde{\boldsymbol{u}}^k_{nM-1}) - \tilde{\boldsymbol{u}}^k_{nM}.$$

For the second term on the right-hand side we find

$$\left(A_H(I^H_h\tilde{\boldsymbol{u}}^k)\right)_n = -\Phi_n((I^H_h\tilde{\boldsymbol{u}}^k)_{n-1}) + (I^H_h\tilde{\boldsymbol{u}}^k)_n = -\Phi_n(\tilde{\boldsymbol{u}}^k_{(n-1)M}) + \tilde{\boldsymbol{u}}^k_{nM}.$$

Hence, the second equation of (3.2) can be rewritten componentwise as

$$-\Phi_n(\boldsymbol{U}^{k+1}_{n-1}) + \boldsymbol{U}^{k+1}_n = \boldsymbol{b}_{nM} + \phi_{nM}(\tilde{\boldsymbol{u}}^k_{nM-1}) - \Phi_n(\boldsymbol{u}^k_{(n-1)M}),$$

where we have used the property that the smoother leaves the elements at positions nM, for $n = 0, 1, \ldots, N$, unchanged. Adding and subtracting $\boldsymbol{B}_n$, we obtain, after rearranging terms,

$$\boldsymbol{U}^{k+1}_n = \Phi_n(\boldsymbol{U}^{k+1}_{n-1}) + \boldsymbol{B}_n + \phi_{nM}(\tilde{\boldsymbol{u}}^k_{nM-1}) + \boldsymbol{b}_{nM} - \Phi_n(\boldsymbol{u}^k_{(n-1)M}) - \boldsymbol{B}_n.$$

By using the induction hypothesis, i.e., $\boldsymbol{U}^k_n = \boldsymbol{u}^k_{nM}$, and the definition of the F- and G-propagators and the smoother, we get

$$\boldsymbol{U}^{k+1}_n = G(t_n, t_{n-1}, \boldsymbol{U}^{k+1}_{n-1}) + F(t_n, t_{n-1}, \boldsymbol{U}^k_{n-1}) - G(t_n, t_{n-1}, \boldsymbol{U}^k_{n-1}).$$

This proves that the coarse grid FAS solution is precisely the solution generated by the parareal algorithm (2.2). Finally, we consider the last equation of (3.2),

$$\boldsymbol{u}^{k+1}_{nM} = \left(\tilde{\boldsymbol{u}}^k + I^h_H(\boldsymbol{U}^{k+1} - I^H_h\tilde{\boldsymbol{u}}^k)\right)_{nM} = (I^h_H\boldsymbol{U}^{k+1})_{nM} = \boldsymbol{U}^{k+1}_n,$$

where the second equality follows from the fact that the operator $I^h_H I^H_h$ acts as the identity on the components $\boldsymbol{u}_{nM}$ of any vector $\boldsymbol{u}$ to which it is applied. This proves the theorem. □

. . . 3.2. The coarse grid problem defined in the second equation of (3.2) is of the same type as the fine grid problem $A_h(\boldsymbol{u}) = \boldsymbol{b}$. Hence, it could be solved by a recursive application of the same method, as in classical multigrid.

. . . 3.3. Note that the smoother (3.6) is not convergent (but not divergent either). Actually, in the linear case, it can easily be shown that the spectral radius of

the iteration matrix is equal to one. This type of smoother, which operates only on the fine grid points and leaves the coarse points unchanged, is sometimes called an F-smoother; see [30].

[illegible] 3.4. With the multigrid components as defined above, the iteration (3.2) is consistent with the fine grid problem. That is, the solution of $A_h(\boldsymbol{u}) = \boldsymbol{b}$ is a fixed point of the iteration. The convergence of the algorithm towards that solution is proved in the next two sections.

4. Convergence analysis: The scalar ODE case. In this section, we first recall a convergence result presented earlier in the literature and then derive two new convergence theorems. The first result is valid on bounded time intervals, $T < \infty$, whereas the second one also holds for unbounded time intervals.

4.1. Some results from the literature. The purpose of our study is to derive the conditions under which the algorithm will converge and to derive an expression for the convergence speed. Our results are different from those in the literature, where typically the number of iterations of (2.2) is fixed to a finite value, and the convergence is studied as ΔT goes to zero. In the fixed number of iterations case, (2.2) defines a new time-integration scheme. The accuracy of the $\boldsymbol{U}_n^k$ values is characterized in a proposition from the first publication on the parareal algorithm [19], which applies for a scalar linear problem of the form

$$u' = au, \quad u(0) = u_0, \quad t \in [0, T] \ \text{ with } \ a \in \mathbb{C}. \tag{4.1}$$

PROPOSITION 4.1. [illegible] $\Delta T = T/N$ $t_n = n\Delta T$ [illegible] $n = 0, 1, \ldots, N$ [illegible] (4.1) [illegible] $a \in \mathbb{R}$ [illegible] $F(t_{n+1}, t_n, U_n^k)$ [illegible] [illegible] t_{n+1} [illegible] (4.1) [illegible] $u(t_n) = U_n^k$ [illegible] $G(t_{n+1}, t_n, U_n^k)$ [illegible] [illegible] ΔT [illegible]

$$\max_{1 \le n \le N} |u(t_n) - U_n^k| \le C_k \Delta T^{k+1}. \tag{4.2}$$

Hence, for a fixed iteration step k, the algorithm behaves in ΔT like an $O(\Delta T^{k+1})$ method. This theorem was extended to more general and, in particular, higher order time-integration schemes in [3, 2]. In those papers it was shown that parareal is a method of $O(\Delta T^{p(k+1)})$ when a method of order p is used as the coarse propagator, combined with an exact solver or a sufficiently accurate solver as the fine propagator.

In our analysis we will fix ΔT and study the algorithm's behavior as k goes to infinity. This case is not covered by the above theorem, because the constant C_k in (4.1) grows with k in the estimate of the proof in [19].

4.2. Some preparatory lemmas. In our analysis an important role will be played by a strictly lower triangular Toeplitz matrix $M := M(\beta)$ of size N. Its elements are fully defined by the values of the elements in its first column,

$$M_{i1} = \begin{cases} 0 & \text{if } \ i = 1, \\ \beta^{i-2} & \text{if } \ 2 \le i \le N \end{cases} \tag{4.3}$$

for some $\beta \in \mathbb{C}$. The analysis will involve the powers of the matrix M. Those matrices maintain the strictly lower triangular Toeplitz structure of M. The elements of those matrices, their norms, and a bound on their norms are identified in the lemmas below.

LEMMA 4.2. [illegible] k [illegible] M [illegible]

$$M_{i,1}^k = \begin{cases} 0 & \text{if } 1 \le i \le k, \\ \binom{i-2}{k-1}\beta^{i-1-k} & \text{if } k+1 \le i \le N. \end{cases} \tag{4.4}$$

[illegible]. The proof is based on induction on k. The matrix M is strictly lower triangular with a nonzero first subdiagonal. Hence, the multiplication of M^{k-1} with M generates exactly one additional zero subdiagonal. This leads to a total of k zero subdiagonals for the matrix M^k, which proves the first part of the lemma.

The ith element in the first column of M^k, for $i \ge k+1$, can be computed as follows:

$$M_{i,1}^k = \sum_{j=1}^{N} M_{i,j}^{k-1} \cdot M_{j,1} = \sum_{j=2}^{i-k+1} M_{i+1-j,1}^{k-1} \cdot M_{j,1} = \sum_{j=0}^{i-k-1} M_{i-1-j,1}^{k-1} \cdot M_{j+2,1},$$

where we have used the zero structure of M^{k-1} and M, and the Toeplitz nature of M^{k-1}. Using the induction hypothesis and (4.3), we can assign values to the matrix elements in the above sum; then we reverse the summation order to find

$$M_{i,1}^k = \sum_{j=0}^{i-k-1} \binom{i-3-j}{k-2} \beta^{i-k-1} = \sum_{J=0}^{i-k-1} \binom{J+k-2}{k-2} \beta^{i-k-1}.$$

The result now follows by applying the well-known summation formula

$$\sum_{s=0}^{r} \binom{n+s}{n} = \binom{n+r+1}{n+1}, \tag{4.5}$$

with $s = J$, $r = i-k-1$, and $n = k-2$. □

LEMMA 4.3. [illegible] k [illegible] M [illegible]

$$||M^k||_\infty = \begin{cases} \binom{N-1}{k} & \text{[illegible] } |\beta| = 1, \\ \dfrac{1}{(k-1)!} \dfrac{d^{k-1}}{dz^{k-1}} \left(\dfrac{z^{N-1}-1}{z-1} \right) \text{[illegible] } z = |\beta| & \text{[illegible] } |\beta| \ne 1. \end{cases} \tag{4.6}$$

[illegible]. The largest row sum of the entries in modulus, i.e., $||M^k||_\infty$, is the row sum in modulus of the last row, since all of the other rows contain less of the same entries than the last one by the structure of M^k. Because of the strictly lower triangular Toeplitz structure, we actually have $||M^k||_\infty = ||M^k||_1$. Hence,

$$||M^k||_\infty = \sum_{i=k+1}^{N} |M_{i,1}^k| = \sum_{i=k+1}^{N} \binom{i-2}{k-1} |\beta|^{i-1-k} = \sum_{i=0}^{N-k-1} \binom{i+k-1}{k-1} |\beta|^i . \tag{4.7}$$

The result for $|\beta| = 1$ now follows by applying (4.5) with $n = k-1$ and $r = N-k-1$. If $|\beta| \ne 1$, we proceed as follows:

$$||M^k||_\infty = \frac{1}{(k-1)!} \sum_{i=0}^{N-k-1} (i+k-1)(i+k-2)\dots(i+1)|\beta|^i$$

$$= \frac{1}{(k-1)!} \sum_{i=0}^{N-k-1} \frac{d^{k-1}}{dz^{k-1}} z^{i+k-1} \quad \text{for } z = |\beta|$$

$$= \frac{1}{(k-1)!} \frac{d^{k-1}}{dz^{k-1}} \sum_{i=0}^{N-k-1} z^{i+k-1} \quad \text{for } z = |\beta|$$

$$= \frac{1}{(k-1)!} \frac{d^{k-1}}{dz^{k-1}} \sum_{I=0}^{N-2} z^{I} \quad \text{for } z = |\beta|.$$

Summing the geometric series leads to the desired result. ∎

LEMMA 4.4. [illegible] k [illegible] M [illegible]

$$||M^k||_\infty \le \begin{cases} \min\left\{ \left(\dfrac{1-|\beta|^{N-1}}{1-|\beta|} \right)^k, \dbinom{N-1}{k} \right\} & \text{[illegible]} \quad |\beta| < 1, \\ |\beta|^{N-k-1} \dbinom{N-1}{k} & \text{[illegible]} \quad |\beta| \ge 1. \end{cases} \tag{4.8}$$

[illegible] The bound for $|\beta| \ge 1$ follows from (4.7) by replacing $|\beta|^i$ by the larger value $|\beta|^{N-k-1}$ and by using (4.5) to evaluate the summation.

Part of the bound for $|\beta| < 1$ follows from (4.7) by replacing $|\beta|^i$ by its upper bound 1. The other part can be derived as follows:

$$||M^k||_\infty \le ||M||_\infty^k = \left(\sum_{i=0}^{N-2} |\beta|^i \right)^k = \left(\frac{1-|\beta|^{N-1}}{1-|\beta|} \right)^k. \quad \blacksquare$$

4.3. A superlinear convergence result on bounded intervals. We derive the conditions for convergence of the parareal algorithm and an estimate for the convergence speed. We consider the classical model problem (4.1) and, initially, assume that the F-propagator is an exact solver. This restriction will be removed in section 4.5, where we consider the use of an approximate F-propagator. The coarse G-propagator is assumed to be a one-step method $G(t_{n+1}, t_n, U_n^k) = R(a\Delta T)U_n^k$, characterized by its stability function $R(z)$. For example, for a Runge–Kutta method with the Butcher tableau coefficients contained in the matrix $A = [a_{ij}]$ and the vector $\boldsymbol{b} = [b_j]$, we have

$$R(z) = 1 + z\boldsymbol{b}^T(I - zA)^{-1}\mathbf{1},$$

where I denotes the identity matrix, and $\mathbf{1}$ the vector containing all 1's.

THEOREM 4.5. [illegible] $T < \infty$ $\Delta T = T/N$ [illegible] $t_n = n\Delta T$ [illegible] $n = 0, 1, \ldots, N$ [illegible] $F(t_{n+1}, t_n, U_n^k)$ [illegible] t_{n+1} [illegible] (4.1) [illegible] $u(t_n) = U_n^k$ [illegible] $G(t_{n+1}, t_n, U_n^k) = R(a\Delta T)U_n^k$ [illegible] $M(\beta)$ [illegible] (4.3), [illegible]

$$\max_{1 \le n \le N} |u(t_n) - U_n^k| \le |e^{a\Delta T} - R(a\Delta T)|^k \|M^k(R(a\Delta T))\|_\infty \max_{1 \le n \le N} |u(t_n) - U_n^0|. \tag{4.9}$$

[illegible] We denote by e_n^k the error at iteration step k of the parareal algorithm at time t_n; i.e., $e_n^k := u(t_n) - U_n^k$. With (2.2) and an induction argument on n, this error

satisfies

$$e_n^{k+1} = R(a\Delta T)e_{n-1}^{k+1} + (e^{a\Delta T} - R(a\Delta T))e_{n-1}^k$$
$$= (e^{a\Delta T} - R(a\Delta T)) \sum_{j=1}^{n-1} R(a\Delta T)^{n-j-1} e_j^k.$$

This relation can be written in matrix form by collecting the error components of the kth iterate e_n^k in the vector $\boldsymbol{e}^k = (e_1^k, e_2^k \ldots, e_N^k)^T$, which leads to

$$\boldsymbol{e}^{k+1} = (e^{a\Delta T} - R(a\Delta T))M(R(a\Delta T))\boldsymbol{e}^k. \tag{4.10}$$

By induction on k in (4.10), we obtain

$$\boldsymbol{e}^k = (e^{a\Delta T} - R(a\Delta T))^k \left(M(R(a\Delta T))\right)^k \boldsymbol{e}^0, \tag{4.11}$$

and taking norms, the result follows. ∎

The bound in (4.9) can be computed by replacing the norm of $M^k(R(a\Delta T))$ by its value as given in Lemma 4.3 or by the bound given in Lemma 4.4. Of particular interest is the case of a one-step method used in its region of absolute stability, i.e., with $|R(a\Delta T)| < 1$.

COROLLARY 4.6. [illegible] $T < \infty$ $\Delta T = T/N$ [illegible] $t_n = n\Delta T$ [illegible] $n = 0, 1, \ldots, N$ [illegible] $F(t_{n+1}, t_n, U_n^k)$ [illegible] t_{n+1} [illegible] (4.1) [illegible] $u(t_n) = U_n^k$ [illegible] $G(t_{n+1}, t_n, U_n^k) = R(a\Delta T)U_n^k$ [illegible]

$$\max_{1\le n\le N} |u(t_n) - U_n^k| \le \frac{|e^{a\Delta T} - R(a\Delta T)|^k}{k!} \prod_{j=1}^{k} (N-j) \max_{1\le n\le N} |u(t_n) - U_n^0|. \tag{4.12}$$

[illegible] G [illegible] $C\Delta T^{p+1}$ [illegible] $p > 0$ [illegible] C [illegible] ΔT [illegible]

$$\max_{1\le n\le N} |u(t_n) - U_n^k| \le \frac{(CT)^k}{k!} \Delta T^{pk} \max_{1\le n\le N} |u(t_n) - U_n^0|. \tag{4.13}$$

[illegible] The first result follows from (4.9) and the norm estimate in Lemma 4.4 for $\beta := R(a\Delta T)$, considering that $|\beta| < 1$. The bound (4.13) follows from the bound on the local truncation error together with a simple estimate of the product,

$$\frac{|e^{a\Delta T} - R(a\Delta T)|^k}{k!} \prod_{j=1}^{k} (N-j) \le \frac{C^k \Delta T^{(p+1)k}}{k!} N^k = \frac{(CT)^k}{k!} \Delta T^{pk}. \qquad \blacksquare$$

[illegible] 4.7. The product term in (4.12) shows that the parareal algorithm terminates with a converged solution for any ΔT on any bounded time interval in at most $N-1$ steps. This property actually holds without restriction on the magnitude of $R(a\Delta T)$ or the quality of the G-operator. Typically, however, one would like to stop the iteration with a converged or sufficiently accurate solution well before $N-1$ iteration steps, since otherwise there is no speedup in the parallel process.

[illegible] 4.8. Observe that the algorithm converges superlinearly, as the division by $k!$ in (4.12) shows. This follows also from the value of the spectral radius of the error propagation operator in (4.10), which is zero.

4.4. A linear convergence result on long time intervals. Next we consider the parareal algorithm as a time-integration method on an infinitely long time interval. In the first theorem of this section we show that the convergence is not worse than linear, and we construct an upper bound for the iteration error. In the second theorem we show that the bound is asymptotically sharp. That is, the asymptotic convergence rate is exactly linear.

THEOREM 4.9. [illegible] ΔT [illegible] $t_n = n\Delta T$, [illegible] $n = 0, 1, \ldots$ [illegible] $F(t_{n+1}, t_n, U_n^k)$ [illegible] t_{n+1} [illegible] (4.1) [illegible] $u(t_n) = U_n^k$ [illegible] $G(t_{n+1}, t_n, U_n^k) = R(a\Delta T)U_n^k$ [illegible]

$$\sup_{n>0} |u(t_n) - U_n^k| \leq \left(\frac{|e^{a\Delta T} - R(a\Delta T)|}{1 - |R(a\Delta T)|} \right)^k \sup_{n>0} |u(t_n) - U_n^0|. \tag{4.14}$$

[illegible] G [illegible] $C\Delta T^{p+1}$ [illegible] $p > 0$ [illegible] C [illegible] ΔT [illegible]

$$\sup_{n>0} |u(t_n) - U_n^k| \leq \left(\frac{C\Delta T^p}{\Re(-a) + O(\Delta T)} \right)^k \sup_{n>0} |u(t_n) - U_n^0|. \tag{4.15}$$

[illegible] In the present case M, as defined in (4.3), is an infinite dimensional Toeplitz operator. Its infinity norm is given by

$$||M(a\Delta T)||_\infty = \sum_{j=0}^{\infty} |R(a\Delta T)|^j = \frac{1}{1 - |R(a\Delta T)|},$$

where we have used that $|R(a\Delta T)| < 1$; i.e., G operates in its region of absolute stability. Using (4.10), we obtain for the error vectors $\boldsymbol{e}^k$ of infinite length the relation

$$||\boldsymbol{e}^k||_\infty \leq |e^{a\Delta T} - R(a\Delta T)|^k ||M||_\infty^k ||\boldsymbol{e}^0||_\infty = \left(\frac{|e^{a\Delta T} - R(a\Delta T)|}{1 - |R(a\Delta T)|} \right)^k ||\boldsymbol{e}^0||_\infty,$$

which proves the first result.

Next, we can use the bound on the local truncation error in order to estimate the numerator of (4.14), i.e., $|e^{a\Delta T} - R(a\Delta T)| \leq C\Delta T^{p+1}$. This bound implies for a strictly positive integer p that $R(a\Delta T) = 1 + a\Delta T + O(\Delta T^2)$. From this, we find

$$\begin{aligned} |R(a\Delta T)| &= R(a\Delta T)^{1/2} \overline{R(a\Delta T)}^{1/2} \\ &= (1 + 1/2 a\Delta T + O(\Delta T^2))(1 + 1/2 \bar{a}\Delta T + O(\Delta T^2)), \end{aligned}$$

which implies $1 - |R(a\Delta T)| = \Re(-a)\Delta T + O(\Delta T^2)$. Thus, (4.15) follows. ∎

The parareal algorithm can be seen as an iteration which maps infinite sequences into infinite sequences. More precisely, it maps the discrete sequence $U^k := \{U_n^k\}_{n=0}^\infty$ into the discrete sequence $U^{k+1} := \{U_n^{k+1}\}_{n=0}^\infty$. In operator notation we can write the iteration compactly as $U^{k+1} = \mathcal{K}(a\Delta T)U^k$, with $\mathcal{K}(a\Delta T)$ the infinite dimensional iteration operator. When applied to model problem (4.1), the parareal iteration operator becomes an infinite dimensional triangular Toeplitz operator or, equivalently, a discrete convolution operator. Such an operator is fully characterized by the elements of its first column a_i, $i = 1, 2, \ldots$. The spectral radius ρ of a Toeplitz operator $\mathcal{T}$ is

known to be related to the operator $T(z) := \sum_{i=1}^{\infty} a_i z^{i-1}$. In particular, when $\sum_{i=1}^{\infty} |a_i| < \infty$, we have that

$$\rho(\mathcal{T}) = \max_{|z|\le 1} | T(z) | = \max_{|z|=1} | T(z) | ; \tag{4.16}$$

see, e.g., [25, Theorem 2.1] for a proof.

THEOREM 4.10. ΔT $t_n = n\Delta T$ $n = 0, 1, \ldots$ $F(t_{n+1}, t_n, U_n^k)$ t_{n+1} (4.1) $u(t_n) = U_n^k$ $G(t_{n+1}, t_n, U_n^k) = R(a\Delta T)U_n^k$

$$\rho(\mathcal{K}(a\Delta T)) = \frac{|e^{a\Delta T} - R(a\Delta T)|}{1 - |R(a\Delta T)|}. \tag{4.17}$$

The parareal iteration operator is characterized by the elements a_i in its first column. From (4.10) we have

$$a_i = (e^{a\Delta T} - R(a\Delta T))M_{i,1}(a\Delta T), \ i = 1, 2, \ldots .$$

Hence, using (4.3) and (4.16) we find

$$\begin{aligned}
\rho(\mathcal{K}(a\Delta T)) &= \max_{|z|=1} \left| (e^{a\Delta T} - R(a\Delta T)) \sum_{i=2}^{\infty} R(a\Delta T)^{i-2} z^{i-1} \right| \\
&= \max_{|z|=1} \frac{|e^{a\Delta T} - R(a\Delta T)|}{|1 - R(a\Delta T)z|} \\
&= \max_{\theta\in[0,2\pi]} \frac{|e^{a\Delta T} - R(a\Delta T)|}{|1 - |R(a\Delta T)|e^{i(\arg R(a\Delta T)+\theta)}|}.
\end{aligned}$$

The maximum is found for $\theta = -\arg R(a\Delta T)$, which proves the result. ∎

4.11. Note that (4.17) is not necessarily smaller than 1. We have that $\rho(\mathcal{K}(a\Delta T)) < 1$ if and only if $|e^{a\Delta T} - R(a\Delta T)| + |R(a\Delta T)| < 1$ for $a \in \mathbb{R}_0^-$. This is equivalent to the condition

$$\frac{e^{a\Delta T} - 1}{2} < R(a\Delta T) < \frac{e^{a\Delta T} + 1}{2}. \tag{4.18}$$

Note that (4.18) is essentially equivalent to the stability condition derived in [29].

4.5. Discussion of the fully discrete case. We consider the case where instead of an exact solution on the subintervals an approximate solver is used as the F-propagator. Typically, this would be a fine grid approximation obtained by repeated application of the G-propagator on a series of small time steps. Alternatively, it could also be the application of one or more steps of a method of higher order than the G-propagator. In those cases the proofs of the theorems derived in sections 4.3 and 4.4 remain valid with some minor modifications. It suffices to replace the term $e^{a\Delta T}$ representing the exact solution by a term of the form $R_f(a\Delta T)$. Here, the function $R_f(z)$ denotes the stability function of the F-propagator as a solver for (4.1) over an interval in time of length ΔT. For example, if the approximation is obtained by M steps of the fine solver, we have $R_f(a\Delta T) = R(a\Delta T/M)^M$.

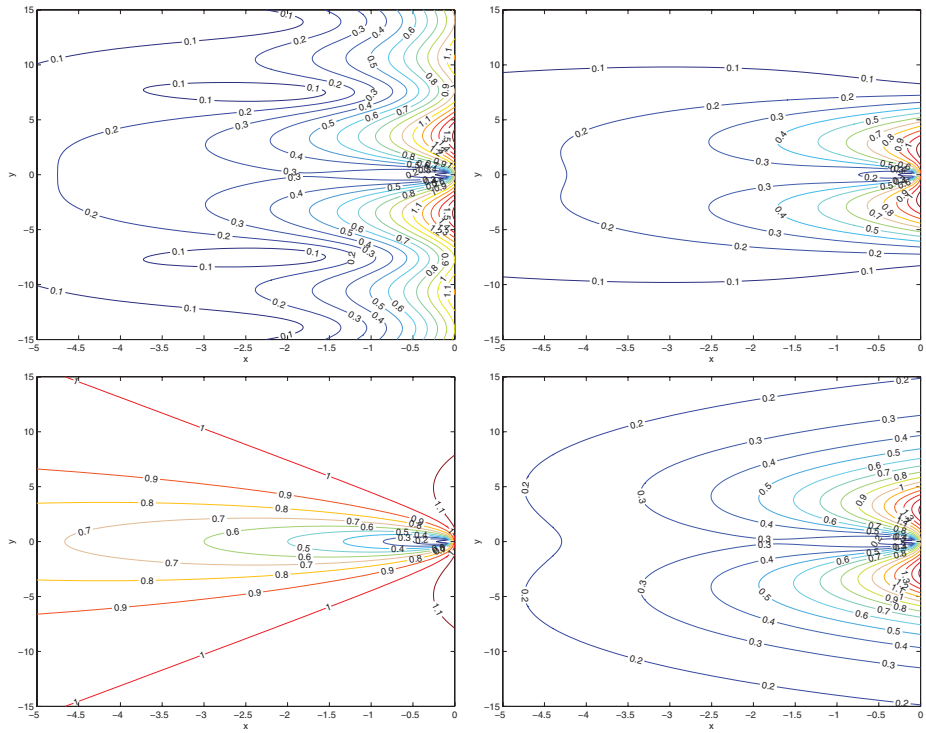

FIG. 4.1. *Contour plots of the convergence factor* $\rho(\mathcal{K}(z))$ *with* $z := a\Delta T \in \mathbb{C}^-$, *for* 4 *different F-propagator/G-propagator combinations: exact solution/backward Euler (top left), backward Euler* ($M = 10$)*/backward Euler (top right), trapezoidal rule* ($M = 1$)*/backward Euler (bottom left), and Radau* IIA ($M = 1$)*/backward Euler (bottom right).*

In Figure 4.1 on the top left, we show a contour plot of the function $\rho(\mathcal{K}(z))$ for $z := a\Delta T \in \mathbb{C}^-$, as defined in (4.17), with $R(z)$ the stability function of the backward Euler method. Contour plots of the linear convergence factor of the fully discrete parareal operator, i.e.,

$$\rho(\mathcal{K}(z)) = \frac{|R_f(z) - R(z)|}{1 - |R(z)|}, \tag{4.19}$$

as a function of $z \in \mathbb{C}^-$, are given in the other three parts of the figure. Each of these illustrates a combination of the backward Euler scheme as the G-propagator with a different F-propagator. On the top right, the effect of using an F-propagator consisting of ten backward Euler steps is shown. On the bottom left, the case of a single step of the trapezoidal rule is illustrated, while on the bottom right, the case of a single step of the three-stage Radau IIA method is considered. Note that when the number M is increased and, hence, the F-propagator becomes more accurate, the value of the fully discrete convergence factor will approach that of (4.17).

Of special interest is the case $a \in \mathbb{R}_0^-$. For this case, four combinations of propagators are considered in Figure 4.2. The top left picture illustrates the use of backward Euler as a coarse solver, and M steps of backward Euler as a fine solver for $M = 2, \ldots, 10$. The top curve in that picture corresponds to an exact fine solve. On the top right, we show the same plot with Radau IIA as a fine solver. On the bottom left, we show the trapezoidal rule as fine solver. On the bottom right, we illustrate

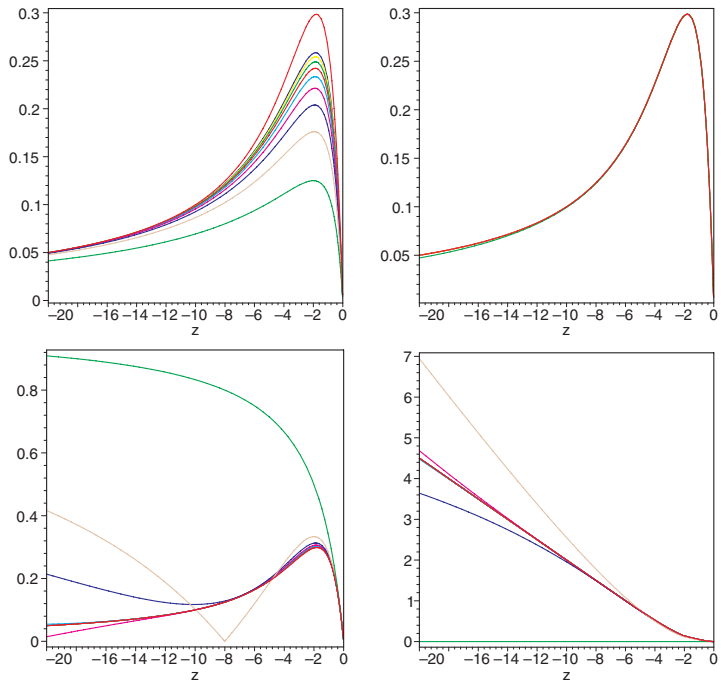

FIG. 4.2. *Value of the fully discrete convergence factor* $\rho(\mathcal{K}(z))$ *with* $z := a\Delta T \in \mathbb{R}_0^-$ *for* 4 *different* F*-propagator/*G*-propagator combinations: backward Euler/backward Euler (top left), Radau* IIA*/backward Euler (top right), trapezoidal rule/backward Euler (bottom left), and trapezoidal rule/trapezoidal rule (bottom right).*

the case where the trapezoidal rule is used for both the coarse and fine solve.

REMARK 4.12. These experiments indicate that for certain combinations, the continuous result derived in the earlier sections is an upper bound for the fully discretized algorithm. This can be shown rigorously in certain cases, but does not hold in general. For example, for the backward Euler scheme we have that $R(a\Delta T) = 1/(1 - a\Delta T)$. For $a \in \mathbb{R}_0^-$ it can easily be verified that

$$\frac{|R(a\Delta T/M)^M - R(a\Delta T)|}{1 - |R(a\Delta T)|} \leq \frac{|e^{a\Delta T} - R(a\Delta T)|}{1 - |R(a\Delta T)|}.$$

Hence, in that case the convergence rate of the fully discrete parareal operator is bounded by the convergence rate of the parareal solver with an exact solve as F-propagator. This is illustrated in the top left picture of Figure 4.2. This does not, however, continue to hold for all $a \in \mathbb{C}^-$.

REMARK 4.13. The stability function of the trapezoidal rule is known to be $R(z) = \frac{1+z/2}{1-z/2}$. From this, it is readily seen that the convergence rate of the combination trapezoidal rule/backward Euler tends to 1 when $z \to -\infty$. For a fixed value of $a\Delta T$, however, the convergence rate tends to the continuous limit with increasing m. This can be observed in the bottom left picture of Figure 4.2. For the trapezoidal rule/trapezoidal rule combination in the bottom right picture of Figure 4.2, the convergence rate actually becomes bigger than 1 for z sufficiently negative.

REMARK 4.14. The necessary and sufficient condition for convergence on infinite length time windows as given in Remark 4.11 can be generalized to the fully discrete

case. With (4.19), we see that convergence is guaranteed for $a \in \mathbb{R}_0^-$ if and only if $|R_f(a\Delta T) - R(a\Delta T)| + |R(a\Delta T)| < 1$. This, in turn, is equivalent to the conditions

$$-1 < R_f(a\Delta T) < 1 \quad \text{and} \quad \frac{R_f(a\Delta T) - 1}{2} < R(a\Delta T) < \frac{R_f(a\Delta T) + 1}{2}. \tag{4.20}$$

The first condition is equivalent to a requirement of stability for the F-propagator and will naturally be satisfied.

5. Convergence analysis for partial differential equations. We now use the results derived in section 4 to investigate the performance of the parareal algorithm on PDEs. We consider two model problems, a diffusion problem and an advection problem.

5.1. Convergence analysis for a diffusion equation. For the diffusion case, we consider the heat equation, without loss of generality in one dimension,

$$u_t = u_{xx} \quad \text{in } \Omega = \mathbb{R}, \quad u(0,x) \in L^2(\Omega). \tag{5.1}$$

Using a Fourier transform in space, this equation becomes a system of decoupled ODEs for each Fourier mode ω,

$$\hat{u}_t = -\omega^2 \hat{u}, \tag{5.2}$$

and hence the convergence results for scalar ODEs can be directly applied. In the theorem below, we assume that the heat equation is discretized in time using a one-step method that is stable on the negative real axis (A_0-stable). In the present case, this is a minimal necessary requirement for any time-integrator to produce meaningful results.

THEOREM 5.1. $F(t_{n+1}, t_n, U_n^k)$ t_{n+1} (5.1) $u(t_n) = U_n^k$ $G(t_{n+1}, t_n, U_n^k)$ A_0

$$\max_{1\le n\le N} ||u(t_n) - U_n^k||_2 \le \frac{\gamma_s^k}{k!} \prod_{j=1}^{k} (N-j) \max_{1\le n\le N} ||u(t_n) - U_n^0||_2, \tag{5.3}$$

$||\cdot||_2$ γ_s $|R(-\infty)| = c < 1$

$$\sup_{n>0} ||u(t_n) - U_n^k||_2 \le \gamma_l^k \sup_{n>0} ||u(t_n) - U_n^0||_2, \tag{5.4}$$

γ_l The numerator in the superlinear bound (4.12) when applied to (5.2) is a continuous function of $z := -\omega^2 \Delta T$. It is zero at $z = 0$ and, because of the A_0-stability assumption, it is bounded for $z \to -\infty$ along the real axis. Hence, the numerator is uniformly bounded, and we can define its supremum as

$$\gamma_s := \sup_{z \in \mathbb{R}^-} |e^z - R(z)|. \tag{5.5}$$

This leads to (5.3) by using the Parseval–Plancherel identity.

TABLE 5.1
Superlinear and linear convergence constants.

	Backward Euler	Trapezoidal rule	SDIRK	Radau IIA
γ_s	0.2036321888	1	0.1717941220	0.0634592650
γ_l	0.2984256075	∞	0.2338191487	0.0677592165

The convergence factor in the linear bound (4.15) applied to (5.2) can be bounded as a function of $z := -\omega^2 \Delta T$,

$$\gamma_l := \sup_{z \in \mathbb{R}^-} \frac{|e^z - R(z)|}{1 - |R(z)|}. \tag{5.6}$$

This bound is finite because of the assumptions on the one-step method. This leads to (5.4) using the Parseval–Plancherel identity. □

The constants γ_s and γ_l can easily be computed numerically. The values of these constants for the backward Euler method, the trapezoidal rule, the two-stage singly diagonally implicit Runge–Kutta (SDIRK) method, and the three-stage Radau IIA method are presented in Table 5.1. The assumptions on the one-step method specified in the theorem are necessary but not sufficient to guarantee convergence of the parareal algorithm as a solver on unbounded time intervals. That is, the constant γ_l may well be greater than 1. A necessary and sufficient condition for convergence follows from Remark 4.11.

COROLLARY 5.2.

$$\frac{e^z - 1}{2} < R(z) < \frac{e^z + 1}{2} \qquad z \in \mathbb{R}^-. \tag{5.7}$$

5.3. A necessary and sufficient condition for convergence in the fully discrete case is found by replacing e^z by $R_f(z)$ in (5.7) and by adding the condition $|R_f(z)| < 1$.

5.4. In practice, the heat equation is usually posed on a finite spatial domain, and a spatial discretization is applied. If the spatial discretization is such that the resulting ODE system has only negative real eigenvalues, the bound derived in Theorem 5.1 continues to hold, as it is a uniform bound for all $-\omega^2 \Delta T$.

5.5. From the results in Table 5.1, we see that the SDIRK and Radau IIA methods have better convergence factors than the lower order methods. This shows that using these higher order methods on the coarse grid is speeding up the convergence of the parareal algorithm. However, this comes at the cost of a more expensive evaluation of the G-propagator.

5.2. Convergence of parareal for an advection equation. Next, we consider a pure advection problem,

$$u_t = u_x \quad \text{in } \Omega = \mathbb{R}, \quad u(0, x) \in L^2(\Omega). \tag{5.8}$$

Using a Fourier transform in space, this equation becomes a decoupled system of differential equations for each Fourier mode ω,

$$\hat{u}_t = -i\omega \hat{u}. \tag{5.9}$$

TABLE 5.2
Superlinear and linear convergence constants for the advection equation.

	Backward Euler	Trapezoidal rule	SDIRK	Radau IIA
α_s	1.224353426	2	1.185652097	1.362526017
α_l	1.632645559	∞	∞	2.231320732

We will again apply the convergence results obtained earlier for scalar ODEs. We assume that the advection equation is discretized in time using a one-step method that is stable on the whole of the imaginary axis. In the present case, this is a necessary requirement for the method to produce bounded results.

THEOREM 5.6. $F(t_{n+1}, t_n, U_n^k)$ (5.9) $u(t_n) = U_n^k$ $G(t_{n+1}, t_n, U_n^k)$ $|R(z)| \leq 1$ z

$$\max_{1\leq n\leq N} ||u(t_n) - U_n^k||_2 \leq \frac{\alpha_s^k}{k!} \prod_{j=1}^{k} (N-j) \max_{1\leq n\leq N} ||u(t_n) - U_n^0||_2, \tag{5.10}$$

α_s The numerator in the superlinear bound (4.12) when applied to (5.2) is a continuous function of $z := -\omega\Delta T$. It is zero at $z = 0$ and, because of the boundedness of $|R(z)|$ along the imaginary axis, it is bounded at infinity. Hence, the numerator is uniformly bounded, and we can define its supremum as

$$\alpha_s := \sup_{z\in\mathbb{R}} |e^{iz} - R(iz)|. \tag{5.11}$$

This leads to (5.10) by using the Parseval–Plancherel identity. □

5.7. Typically, there is no convergence result for (5.8) on unbounded intervals. Formally, we can compute the constant α_l defined as

$$\alpha_l := \sup_{z\in\mathbb{R}} \frac{|e^{iz} - R(iz)|}{1 - |R(iz)|}. \tag{5.12}$$

However, this value will mostly be greater than 1, if not infinite.

As before, the constants α_s and α_l can be computed numerically. The values of these constants for a number of one-step methods are given in Table 5.2.

5.8. In practice, the advection problem is usually posed on a finite spatial interval, and a spatial discretization is applied. If the spatial discretization is such that the resulting ODE system has only purely imaginary eigenvalues, the bound derived in Theorem 5.6 continues to hold, as it is a uniform bound for all $i\omega\Delta T$.

5.9. The bound in Theorem 5.6 needs to become small for k less than N for the algorithm to be interesting. To see if this is possible, we study the function

$$g(\alpha, N, k) := \frac{\alpha^k}{k!} \prod_{j=1}^{k} (N-j) = \frac{(-\alpha)^k \, \Gamma(k+1-N)}{k! \, \Gamma(1-N)},$$

where Γ denotes the Gamma-function. In Figure 5.1, we show, for two values of α and various values of N, how the function $g(\alpha, N, k)$ becomes small as k grows from 1 up to N. This shows that even though there is superlinear convergence in the advection

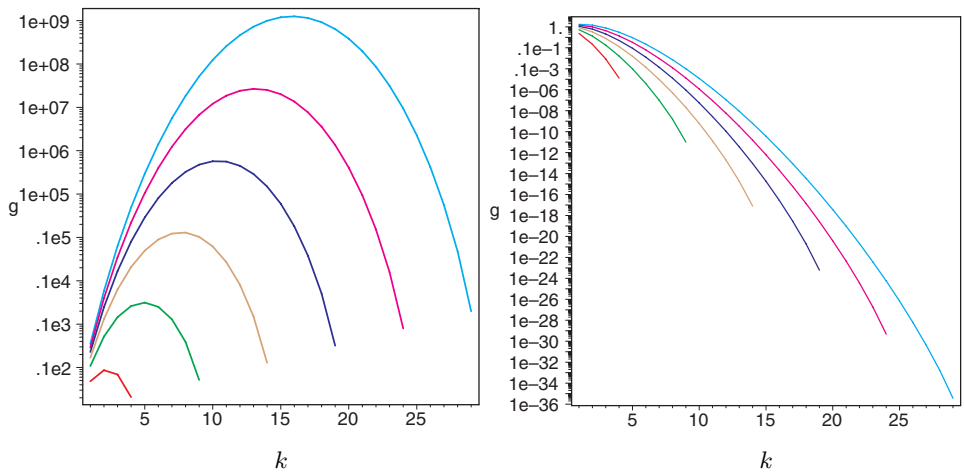

FIG. 5.1. *Behavior of the superlinear convergence factor for* $\alpha = 1.2$ *on the left and* $\alpha = 0.06$ *on the right, as a function of the iteration number* k*, for the values of* $N = 5, 10, 15, 20, 25, 30$.

case, the constants α_s of the various methods do not permit a speedup of the parareal algorithm. In the diffusion case, however, there is substantial speedup, as the constant for the Radau IIA method shows.

. . .. 5.10. If one considers the pure advection case on a sufficiently bounded domain with a Dirichlet boundary condition, it is the boundary condition which largely determines the solution. In such a case, our numerical experiments show that the parareal algorithm converges linearly.

6. Numerical experiments. In order to illustrate the theoretical results, we first show some numerical experiments for the scalar model problem (4.1) with $f = 0$, $a = -1$, $u_0 = 1$. These results are graphically displayed in Figure 6.1. The backward Euler method is chosen for both the coarse approximation and the fine approximation, with time step ΔT and $\Delta T/M$, respectively. In the top left, top right, and bottom left pictures, we show the convergence results obtained for $T = 1$, $T = 10$, and $T = 50$, respectively, using $N = 10$ and $M = 20$ in each case. In each picture the L^∞-norm of the true error is plotted as a function of the iteration index k, together with the bounds as presented in Proposition 4.1 (earlier bound), in Corollary 4.6 (superlinear bound) and in Theorem 4.9 (linear bound).

One can clearly see that parareal has two different convergence regimes: for $T = 1$, the algorithm converges superlinearly, and the superlinear bound is quite sharp; for $T = 10$, the convergence rate is initially linear, and then a transition occurs to the superlinear convergence regime. Finally, for $T = 50$, the algorithm is in the linear convergence regime and the linear bound from Theorem 4.9 is quite sharp. Note also that the earlier bound from Proposition 4.1 indicates stagnation for $T = 10$, since $\Delta T = 1$, and divergence for $T = 50$, since then $\Delta T > 1$. The parareal algorithm does, however, also converge for $\Delta T \geq 1$.

From our analysis, one can also see that the convergence factor is small for small ΔT, then becomes bigger and reaches a maximum, and finally becomes smaller again for large ΔT; see Figure 4.2, for example. This effect is demonstrated in the bottom right picture of Figure 6.1 for the same model problem as before. Again, the backward Euler discretization is used for both the coarse and fine solver. For each case the same F-propagator is used, defined by $\Delta t = 1/20$.

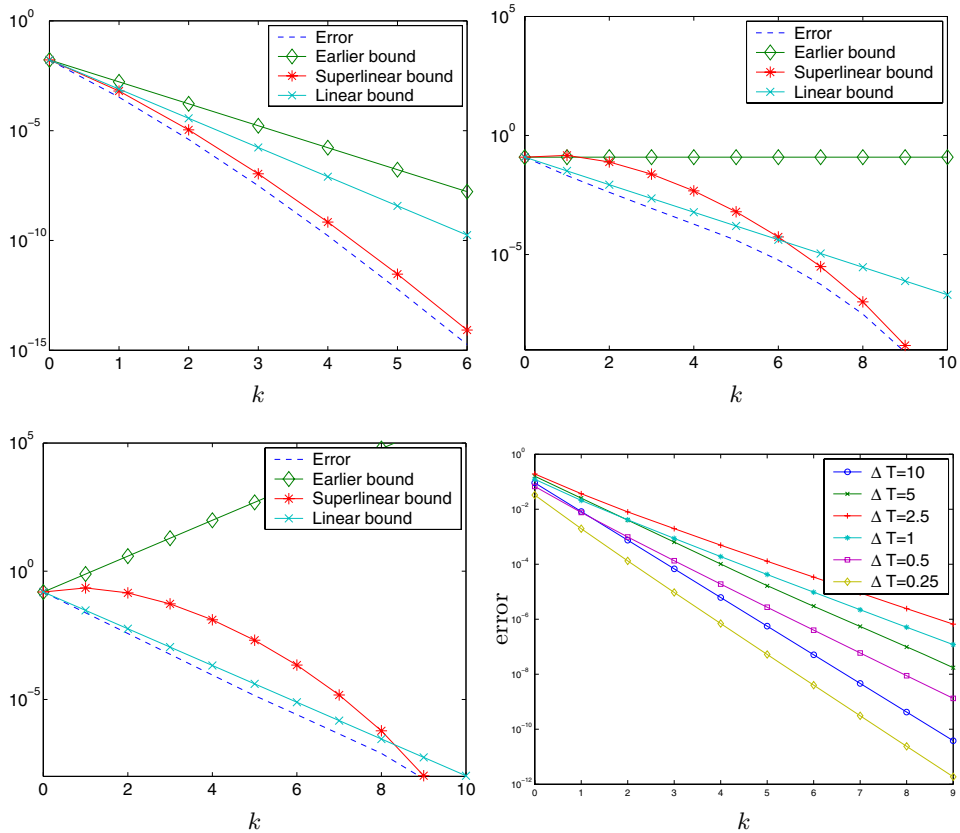

FIG. 6.1. *Parareal convergence for* (4.1): L^∞*-norm of the error as a function of the iteration index* k *on a short (top left), medium (top right), and long (bottom left) time interval; dependence of the convergence speed on* ΔT *(bottom right).*

We now turn our attention to the PDE case and show some experiments for the heat equation $u_t = u_{xx} + f$ in $(0, L) \times (0, T]$ with homogeneous initial and boundary conditions and with $f = x^4(1-x) + t^2$. We use backward Euler for the integration in time and choose the domain size L such that the problem contains a frequency where the linear convergence bound for backward Euler is attained; see Figure 4.2, top left. With $\Delta T = 1/2$ and $M = 10$ we obtain the results shown in Figure 6.2. On the left, results are shown for $T = 4$, where the algorithm with $\Delta T = 1/2$ will converge in 8 steps. One can see that this is clearly the case. Before that, the algorithm is in the superlinear convergence regime, as predicted by the superlinear bound. Note that the latter bound indicates zero as the error at the eighth step and thus cannot be plotted on the logarithmic scale. On the right, the error is shown for $T = 8$, and the algorithm is now in the linear convergence regime.

We finally show four experiments for the advection equation $u_t = u_x + f$ in $(0, L) \times (0, T]$. To emulate the situation of an unbounded domain, we impose in the first two experiments periodic boundary conditions. We use as initial condition $u(x, 0) = e^{-20(x-\frac{L}{2})^2}$ and the forcing function $f \equiv 0$. With $\Delta T = 1/2$, $T = 4$, and $M = 30$, we obtain the results in Figure 6.3 on the left.

In the top left panel of Figure 6.3, we have chosen the domain size L for the worst-case behavior of our superlinear bound, and in the bottom left panel of Figure 6.3 we

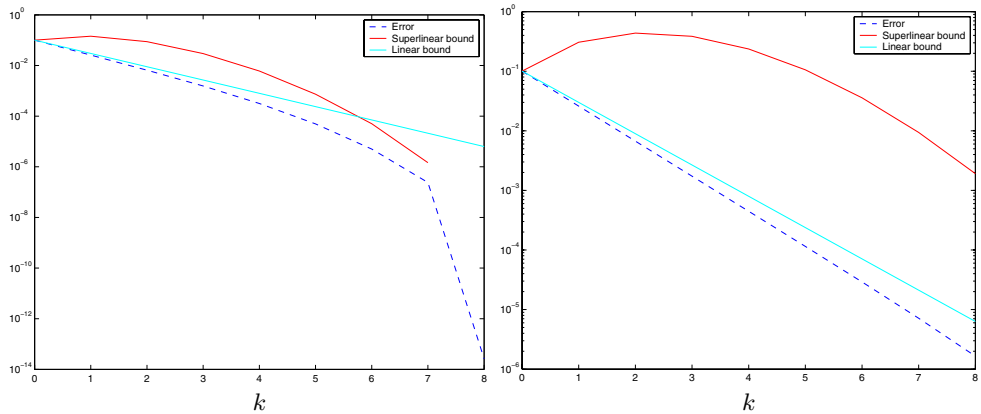

FIG. 6.2. *Error in the L^∞-norm in time and L^2-norm in space for the parareal algorithm applied to the heat equation, on a short (left) and long (right) interval.*

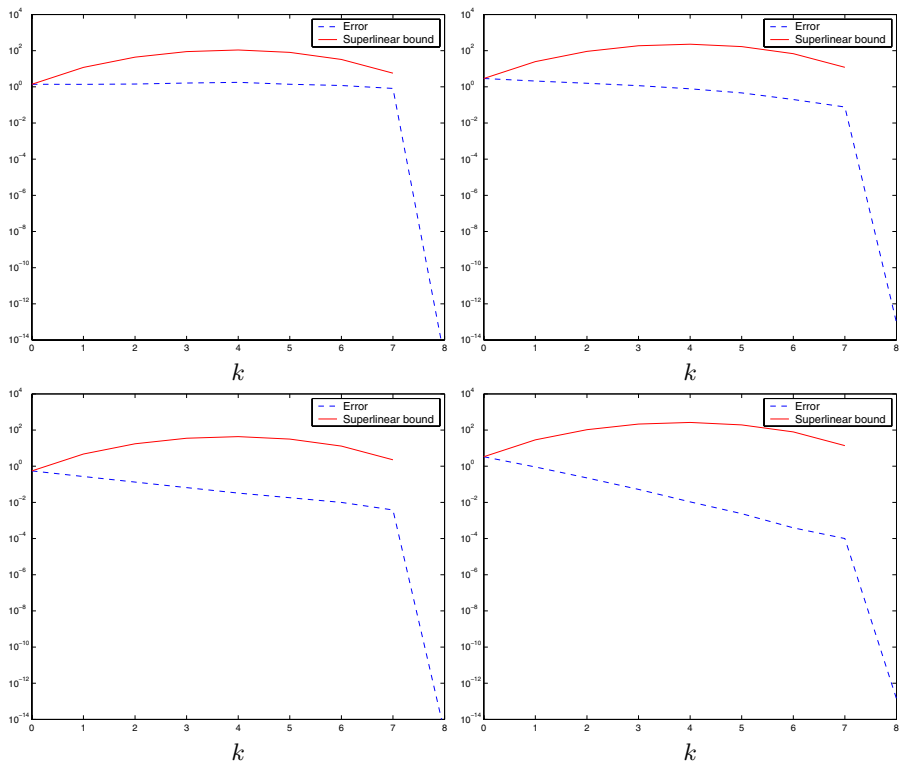

FIG. 6.3. *Error in the L^∞-norm in time and L^2-norm in space for the parareal algorithm applied to the advection equation, with periodic boundary conditions in the graphs on the left, and a Dirichlet condition in the graphs on the right. In the top row the domain size L is chosen for worst-case behavior, and in the bottom row $L = \frac{1}{2}$.*

set $L = \frac{1}{2}$. In the former case, the algorithm stagnates and converges only in step 8, when the fine solution has been computed through sequentially. In the latter case we observe slow, linear convergence. We now repeat the same two experiments but with a boundary condition $u(L,t) = \sin(5t)$. As one can see in Figure 6.3 on the right,

the boundary condition improves the behavior of the parareal algorithm applied to the advection equation, as discussed in Remark 5.10. This is expected based on the information propagation along characteristics.

7. Concluding remarks. We have pointed out how the parareal algorithm relates to some earlier algorithms that have appeared in the literature on time-parallel time-integration methods. We showed that parareal can be seen as a variant of the multiple shooting method, with a Jacobian matrix that is computed approximately by finite differences on a coarse mesh. As a Newton-type method for solving a nonlinear system of equations, its superlinear convergence on bounded time intervals is not unexpected. This convergence behavior was studied in detail in section 4.3.

We also showed that the algorithm can be rewritten as a two-level multigrid-in-time method of full approximation storage type. It is characterized by a possibly aggressive coarsening in time: the coarsening ratio M is not restricted to a small integer for the method to be effective. The algorithm uses a rather unusual smoother which corresponds to a single phase in a two-color relaxation scheme, combined with most simple restriction and prolongation operators. As a multigrid method for general time-dependent problems, parareal can be interpreted as a type of parabolic multigrid method, a class of solvers for parabolic PDEs that includes the space-time multigrid, time-parallel multigrid, and multigrid waveform relaxation methods. All of these can be written in the framework of formula (3.2) and differ only in the details of the multigrid components. With those methods, parareal has in common the linear convergence rate on long time intervals, as studied in section 4.4. In contrast to those methods, which are only effective for parabolic PDEs, parareal is applicable to a much wider range of problems.

Recently new parareal variants have appeared, e.g., genuinely multigrid versions, with more than two grid levels and methods that combine coarsening in time with coarsening in space. Promising results with such methods have already been reported in the literature, e.g., in [9, 11]. Possibly, insights from the present paper may prove to be useful in the study of the theoretical properties of these new algorithms; perhaps, they may direct us to still more general or effective time-parallel time-integration methods. This will be the subject of further investigation.

HIGH-RESOLUTION FLUX-BASED LEVEL SET METHOD*

PETER FROLKOVIČ† AND KAROL MIKULA‡

Abstract. A new high-resolution flux-based finite volume method for general advection equations in nondivergent form including a level set equation for moving interfaces is introduced. The method is applicable to the case of nondivergence free velocity and to general unstructured grids in higher dimensions. We show that the method is consistent and that the numerical solution fulfills the discrete minimum/maximum principle. Numerical experiments show its second order accuracy for smooth solutions as well as for solutions with discontinuous derivatives and on general unstructured meshes. Numerical examples for passive transport and shrinking of dynamic interfaces, including examples with topological changes, are presented using locally adapted two-dimensional and three-dimensional grids.

Key words. level set method, finite volume method, high resolution, evolving interfaces, unstructured grids

DOI. 10.1137/050646561

1. Introduction.

The basic task of level set methods is to describe the evolution of dynamic interfaces. Particular forms of the level set equations and corresponding computational simulations have a tremendous number of different applications; see [31, 32, 38, 39] for details and references.

The level set equation for the moving interface advected by a velocity field $\vec{V}$ can be written in the form

$$\partial_t \phi + \vec{V} \cdot \nabla \phi = 0\,, \quad \phi(t^0, x) = \phi^0(x)\,, \tag{1.1}$$

where the level set function $\phi = \phi(t, x)$ describes the evolving interface implicitly by its zero level set (contour line in two dimensions and isosurface in three dimensions).

Depending on the type of application, the velocity $\vec{V}$ in (1.1) can be given in several ways. For instance, in tracking of dynamic interfaces between two immiscible fluids, the velocity field $\vec{V} = \vec{V}(x)$ describes some external fluid movement; see [44, 45, 16, 17, 24] for some examples. Typically, $\vec{V}$ is obtained as a numerical solution of some PDE describing a conservation law for fluid flow, e.g., $\nabla \cdot \vec{V} = 0$.

Further applications result from problems of geometric evolution equations, appearing among others in crystal growth, combustion, or image segmentation, where $\vec{V} = \delta \vec{N}$ with $\vec{N}$ being the unit normal vector to the interface given by $\vec{N} = \nabla\phi/|\nabla\phi|$, and $\delta = \delta(x)$ describes the speed of motion in normal direction $\vec{N}$. In this case, (1.1) is usually written in the form

$$\partial_t \phi + \delta |\nabla \phi| = 0\,, \tag{1.2}$$

and even higher order terms such as (mean) curvature or intrinsic Laplacian of curvature can be included in the definition of δ; cf. [39].

Finally, if there is a nonzero right-hand side f in (1.2) and one is searching for its stationary solutions, the so-called Eikonal equation

$$\delta|\nabla\phi| = f, \tag{1.3}$$

with some appropriate boundary conditions, has to be solved.

These important applications of (1.1) with $\vec{V} = \vec{V}(x, \nabla\phi)$ are solved using different numerical techniques. The main objective of this paper is to derive a consistent high-resolution flux-based finite volume method that can be used for such applications (including nondivergence free velocities) on general unstructured computational grids in any space dimension.

Nowadays, the finite volume techniques are very popular discretization methods for conservation laws. They preserve many useful properties of numerical solutions known from the analytical case, such as the mass conservation and the minimum/maximum principle.

The level set equations that model the movement of interface in normal direction are very often solved by the finite difference methods. Such numerical techniques can be described as solutions to the so-called Hamilton–Jacobi equation,

$$\partial_t\phi + H(\nabla\phi) = 0, \tag{1.4}$$

with $H(\nabla\phi) = \delta|\nabla\phi|$ for (1.2). Numerical discretizations of (1.4) can be then formally written in the form

$$\phi_i^{n+1} = \phi_i^n - \Delta t^n \, \mathcal{H}_i(\nabla_i^n\phi)\,, \tag{1.5}$$

where $\mathcal{H}_i$ is numerical Hamiltonian and numerical gradients $\nabla_i^n\phi$ are determined typically by some special finite difference approximations of $\nabla\phi$ in the time-space grid point (t^n, x_i). Popularity of such finite difference level set methods for structured grids dates from [33], and these methods have reached high level quality using the Hamilton–Jacobi essentially nonoscillatory (ENO) [34], weighted ENO (WENO) [19], or high-resolution central schemes [23].

Later, several discretization techniques were developed for two-dimensional unstructured triangular meshes that are described in the form (1.5). In [1, 2] the so-called monotonic Lax–Friedrichs Hamiltonian $\mathcal{H}_i$ was proposed, and similar ideas were used to derive WENO schemes [47] or central WENO schemes [22] for triangular meshes. In [20] the approximative gradients $\nabla_i^n\phi$ in (1.5) are found by an averaging over finite volumes that are dual to finite element mesh, and in [4] by an averaging over finite elements surrounding the nodes. In all these papers, only triangular meshes are considered.

A different approach to solve level set problems is taken by semi-Lagrangian [11, 10, 41] or particle tracking methods [9]. The main idea of such methods is to work directly with the formulation (1.1) by approximating the related characteristic curves. Note that these methods can still be viewed as pointwise (particle) based numerical techniques.

One drawback of all mentioned finite difference based level set methods is that they are not conservative if applied with passive transport having divergence free velocity $\vec{V}$. For such applications, some combinations of level set methods with other methods to improve the mass preservation were proposed, such as reinitialization

techniques to recover numerical signed distance function [42], the coupled level set and volume-of-fluid method [43], or the hybrid particle level set method [8]; see also a comprehensive review in [24]. Recently, a few papers have proposed using standard numerical conservative methods for level set equation (1.1) with divergence free velocity such as finite volume methods [30] or discontinuous Galerkin discretizations [35, 48, 25].

Finite volume or finite element methods, which are very useful for conservation laws on unstructured grids, cannot be used directly for (1.1) or (1.4), because the Hamilton–Jacobi equation "cannot be written in a conservation form, suitable for integration by parts, which is the backbone of finite volume and finite element methods" [47]. A new approach was proposed in [14, 15] to overcome this difficulty, where the level set problem (1.1) was reformulated to a conservation form with a source term. At the same time, a flux-based finite volume scheme using integration by parts was described, and the standard CFL restriction on time step was relaxed using a recursive algorithm.

The flux-based level set method proposed in [15] is based on the first order accurate approximation. In this paper, we extend it to a high-resolution method based on second order approximations using the concept of "high-resolution finite volume methods" as discussed in detail in, e.g., [21]. Our high-resolution scheme involves in a natural way also the first order scheme given in [15] and, in such a way, is able to approximate well not only problems with smooth solutions but also problems that exhibit solutions with discontinuous derivatives. We can prove that the high-resolution flux-based level set method is consistent on general grids and that the discrete minimum/maximum principle is valid under natural assumptions. To make valid such assumptions in general, well-known limiting procedures can be applied.

Several numerical experiments will be given that illustrate the robustness and order of convergence of our new method, including examples with smooth solutions, solutions with discontinuous derivatives, and solutions with topological changes. Among others, unstructured grids made of rectangles and triangles in two dimensions, and hexahedra, pyramids, and tetrahedra in three dimensions are used. No reinitialization techniques are applied to recover a numerical signed distance function. A comparison with an ENO scheme (second order in space and time) using [26] for an example of a rotating solid body shows better performance of our method. Finally, more complex examples of Zalesak's disk rotation and vortex-in-a-box are presented.

The paper is organized as follows. In section 2 we derive a general consistent flux-based finite volume discretization scheme for solving (1.1). In section 3 we present particular (first and second order accurate) discretization schemes. In section 4, experimental order of convergence of the method and various numerical experiments are discussed.

2. General consistent discretization scheme. In this section we derive a finite volume discretization method for the model problem of the advection equation in nondivergent form,

$$\partial_t \phi + \vec{V} \cdot \nabla \phi = 0\,, \quad \phi(t^0, x) = \phi^0(x)\,, \tag{2.1}$$

where the function $\phi = \phi(t, x)$ has to be determined for $t > t^0 \in \mathbf{R}$ and for $x \in \Omega \subset \mathbf{R}^d$ with $d = 2$ or $d = 3$. The domain Ω is supposed to be polygonal with boundary $\partial\Omega$. For the moment, we skip a description of boundary conditions.

The advection equation (2.1) is solved on subintervals (t^n, t^{n+1}) of the time interval of interest and is related to (1.1) by considering $\vec{V}(x) = \vec{V}(x, \nabla\phi(t^n, x))$.

If one introduces characteristic curves $X = X_x^n(t)$ defined in a backward manner,

$$X_x^n(t) = x - \int_{t^n}^{t} \vec{V}(X_x^n(s))\, ds\,,$$

one can express the solution of (2.1) using the simple formula

$$\phi(t,x) = \phi(t^n, X_x^n(t))\,. \tag{2.2}$$

Several numerical methods, such as the modified method of characteristics [7] or semi-Lagrangian methods [10], treat (2.1) by solving (or approximating) the relation (2.2) in each grid point $x = x_i$ of a discrete mesh.

To apply a finite volume method to approximate (2.1), we suppose that Ω is covered by a mesh of nonempty, nonoverlapping, polygonal computational cells (finite volumes) $\Omega_i \subset \Omega$, $i = 1, 2, \ldots, I$. Furthermore, $\Delta t^n = t^{n+1} - t^n$, $n = 0, 1, \ldots$.

There are several types of finite volume schemes for solving advective equations; cf. [21, 3]. The cell-based finite volume method can be obtained by integrating (2.2) over Ω_i in $t = t^{n+1}$; see [21, 37, 27, 36] for some reviews and references. In order to derive the flux-based finite volume discretization, we rewrite (2.1) to the divergent form with nonzero right-hand side,

$$\partial_t \phi + \nabla \cdot \left(\vec{V}\phi\right) = \phi \nabla \cdot \vec{V}\,. \tag{2.3}$$

If one integrates (2.3) over Ω_i and time interval (t^n, t^{n+1}), the following integral equation can be derived:

$$\int_{\Omega_i} \phi(t^{n+1}, x) = \int_{\Omega_i} \phi(t^n, x) - \int_{t^n}^{t^{n+1}} \int_{\partial\Omega_i} \vec{n}_i \cdot \vec{V}\phi(t,\gamma) + \int_{t^n}^{t^{n+1}} \int_{\Omega_i} \phi(t,x) \nabla \cdot \vec{V}\,, \tag{2.4}$$

where $\vec{n}_i = \vec{n}_i(\gamma)$, $\gamma \in \partial\Omega_i$ is the normal outward unit vector. The integral form (2.4) can be viewed formally as a conservation law with a source term. In what follows we will derive a general discretization scheme for solving (2.1) by applying numerical quadrature rules for integrals in (2.4). To do so, let us suppose that the numerical solution at $t = t^n$ is given as a function $\phi^n(x) \approx \phi(t^n, x), x \in \Omega$.

The first integral on the right-hand side of (2.4) is approximated by

$$\int_{\Omega_i} \phi(t^n, x)\, dx \approx |\Omega_i| \phi_i^n\,, \tag{2.5}$$

where $\phi_i^n = \phi^n(x_i)$ for some point $x_i \in \Omega_i$ that will be specified later. An analogous approximation is used for the integral on the left-hand side of (2.4).

Before describing an approximation of the second integral in the right-hand side of (2.4), we introduce some notation. The common boundary (of nonzero measure) of two neighboring finite volumes Ω_i and Ω_j will be denoted by $\Gamma_{ij} := \partial\Omega_i \cap \partial\Omega_j$, $|\Gamma_{ij}| > 0$, and $\Gamma_{i0} := \partial\Omega_i \cap \partial\Omega$, $|\Gamma_{i0}| > 0$. Moreover, we suppose that Γ_{ij} consists of (possibly several) $\Gamma_{ij}^e \subset \Gamma_{ij}$ such that Γ_{ij}^e is a straight line if $d = 2$, or a flat polygon if $d = 3$. Consequently, one has

$$\partial\Omega_i = \bigcup_{(e,j)\in\Lambda_i} \overline{\Gamma_{ij}^e}\,, \quad \Lambda_i := \left\{(e,j) \,:\, |\Gamma_{ij}^e| > 0\right\}.$$

The integral over $\partial\Omega_i$ can now be expressed as the sum of boundary integrals over Γ_{ij}^e. Let $\gamma_{ij}^e \in \Gamma_{ij}^e$ be the barycenter of Γ_{ij}^e, i.e., the integration point of a quadrature

formula for integrals over Γ_{ij}^e that is exact for linear polynomials. In what follows, we will use the approximation

$$\int_{\Omega_i} \nabla \cdot \vec{V}(x)\, dx = \int_{\partial\Omega_i} \vec{n}_i(\gamma) \cdot \vec{V}(\gamma)\, d\gamma \approx \sum_{(e,j)\in\Lambda_i} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e\,, \tag{2.6}$$

where $\vec{n}_{ij}^e := \vec{n}_i(\gamma_{ij}^e) = -\vec{n}_j(\gamma_{ij}^e) = -\vec{n}_{ji}^e$ and $\vec{V}_{ji}^e \equiv \vec{V}_{ij}^e := \vec{V}(\gamma_{ij}^e)$.

Similarly to (2.6), for the second integral in the right-hand side of (2.4), we get the following approximation:

$$\int_{t^n}^{t^{n+1}} \int_{\partial\Omega_i} \vec{n}_i \cdot \vec{V} \phi(t,\gamma) d\gamma dt \approx \Delta t^n \sum_{(e,j)\in\Lambda_i} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e\, \phi_{ij}^e(t^{n+1/2}), \tag{2.7}$$

where

$$\phi_{ij}^e(t^{n+1/2}) \approx \phi^n(X_{\gamma_{ij}^e}^n(t^{n+1/2}))\,, \quad t^{n+1/2} := t^n + \Delta t^n/2\,. \tag{2.8}$$

Finally, the third integral in the right-hand side of (2.4) is approximated by

$$\int_{t^n}^{t^{n+1}} \int_{\Omega_i} \phi(t,x)\, \nabla \cdot \vec{V}(x) \approx \Delta t^n\, \phi_i^{n+1/2} \sum_{(e,j)\in\Lambda_i} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e\,, \tag{2.9}$$

where $\phi_i^{n+1/2}$ approximates the averaged value of $\phi(t^{n+1/2}, x)$, $x \in \Omega_i$. The simplest choice is $\phi_i^{n+1/2} = \phi_i^n$, which can be seen as the first order accurate approximation of the integral in (2.9). Other choices will be introduced later.

Combining approximations (2.5), (2.7), and (2.9), we end up with the following [illegible] for solving (2.1):

$$\phi_i^{n+1} = \phi_i^n - \frac{\Delta t^n}{|\Omega_i|} \sum_{(e,j)\in\Lambda_i} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e \left(\phi_{ij}^e(t^{n+1/2}) - \phi_i^{n+1/2}\right). \tag{2.10}$$

Note that the scheme (2.10) represents a fully explicit discretization method.

Similarly to [6, 4], we define the notion of consistency for a numerical scheme approximating (2.1).

DEFINITION 2.1. [illegible] (2.10) [illegible] (2.1) [illegible] $\vec{V}$ [illegible] $\phi^n(x)$ $x \in \Omega$ [illegible]

$$\phi_i^{n+1} = \phi_i^n - \Delta t^n\, \vec{V} \cdot \nabla \phi^n\,. \tag{2.11}$$

To derive a specific form of general scheme (2.10) that has the consistency property, we use piecewise linear approximating functions $\phi^n(x)$ of the form

$$\phi^n(x) = \phi_i^n + \nabla\phi_i^n \cdot (x - x_i)\,, \quad x \in \Omega_i\,, \tag{2.12}$$

where $\nabla\phi_i^n \approx \nabla\phi^n(x_i)$. Then we introduce a particular form of (2.8) by defining the function $\phi_{ij}^e(t)$ for $t \in [t^n, t^{n+1})$ as follows:

$$\phi_{ij}^e(t) := \begin{cases} \phi_i^n + \nabla\phi_i^n \cdot (\gamma_{ij}^e - x_i - (t-t^n)\vec{V}_i), & \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e > 0, \\ \phi_j^n + \nabla\phi_j^n \cdot (\gamma_{ij}^e - x_j - (t-t^n)\vec{V}_j), & \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e < 0, \end{cases} \tag{2.13}$$

and $\vec{V}_i := \vec{V}(x_i) = \vec{V}(x_i, \nabla\phi_i^n)$. Note that the approximation (2.13) follows the conservation law principle as $\phi_{ij}^e(t) = \phi_{ji}^e(t)$. For the case $\gamma_{i0}^e \in \partial\Omega$, one can extend the definition (2.13) by choosing

$$\phi_{i0}^e(t) := \phi_i^n + \nabla\phi_i^n \cdot \left(\gamma_{i0}^e - x_i - (t - t^n)\vec{V}_i\right), \quad \vec{n}_{i0}^e \cdot \vec{V}_{i0}^e < 0\,. \tag{2.14}$$

LEMMA 2.2. [illegible] (2.13)–(2.14) [illegible] (2.10) [illegible] (2.1) [illegible] After substituting constant vectors $\vec{V}$ and $\nabla\phi^n$ in (2.10) and using (2.13) to obtain $\phi_{ij}^e(t^n) = \phi_i^n + \nabla\phi^n \cdot (\gamma_{ij}^e - x_i) = \phi^n(\gamma_{ij}^e)$, one has

$$\phi_i^{n+1} = \phi_i^n - \frac{\Delta t^n}{|\Omega_i|}\vec{V} \cdot \sum_{(e,j)\in\Lambda_i} |\Gamma_{ij}^e| \vec{n}_{ij}^e \phi^n(\gamma_{ij}^e)$$
$$+ \frac{\Delta t^n}{|\Omega_i|}\left(\frac{\Delta t^n}{2}\vec{V} \cdot \nabla\phi^n + \phi_i^{n+1/2}\right) \sum_{(e,j)\in\Lambda_i} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V} = \phi_i^n - \Delta t^n \vec{V} \cdot \nabla\phi^n,$$

because of (2.6) and

$$\sum_{(e,j)\in\Lambda_i} |\Gamma_{ij}^e| \vec{n}_{ij}^e \phi^n(\gamma_{ij}^e) = \int_{\partial\Omega_i} \vec{n}_i(\gamma)\phi^n(\gamma)d\gamma = \int_{\Omega_i} \nabla\phi^n dx = |\Omega_i|\nabla\phi^n\,. \qquad \square$$

3. Particular forms of general discretization scheme (2.10).

3.1. First order discretization scheme. Formally, the general discretization scheme (2.10) also covers the case of piecewise constant numerical solution $\phi^n(x)$, when (2.12) takes the simple form

$$\phi^n(x) = \phi_i^n\,, \quad x \in \Omega_i \quad \Rightarrow \quad \nabla\phi^n \equiv \vec{0}\,, \quad x \in \Omega_i\,.$$

Consequently, one obtains from (2.13) that for $t \in [t^n, t^{n+1})$

$$\phi_{ij}^e(t) = \begin{cases} \phi_i^n, & \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e > 0, \\ \phi_j^n, & \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e < 0, \end{cases} \tag{3.1}$$

which is nothing else but the standard first order upwind approximation. If one also chooses $\phi_i^{n+1/2} = \phi_i^n$, the scheme (2.10) takes the form

$$\phi_i^{n+1} = \phi_i^n - \frac{\Delta t^n}{|\Omega_i|} \sum_{(e,j)\in\Lambda_i^{in}} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e \left(\phi_j^n - \phi_i^n\right), \tag{3.2}$$

where

$$\Lambda_i^{in} := \{(e,j) \in \Lambda_i\,,\, \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e < 0\}\,, \quad \Lambda_i^{out} := \Lambda_i \setminus \Lambda_i^{in}\,. \tag{3.3}$$

Of course, one cannot expect in general that the discretization scheme (3.2) is consistent in the sense of Definition 2.1. The lack of consistency can be illustrated by a simple one-dimensional example with $\Omega_i = (x_i - 0.5h_i, x_i + 0.5h_i)$, $\vec{V} = V = \text{const} < 0$, when it can be written as

$$h_i\phi_i^{n+1} = h_i\phi_i^n - \Delta t^n V(\phi_{i+1}^n - \phi_i^n)\,, \tag{3.4}$$

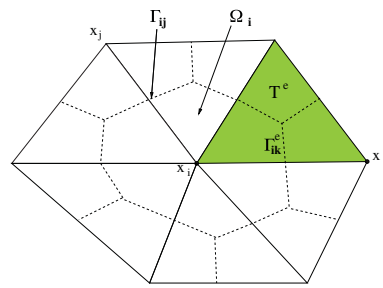

FIG. 3.1. *Illustration of 2D vertex-centered finite volume mesh.*

$i = 1, \ldots, I$. It is easy to see that the method (3.4) is consistent only if $h_i \equiv h$. Similarly, the scheme (3.2) in higher dimensional cases is consistent only for uniform grids with $\Omega_i = (x_i - h/2, x_i + h/2)^d$, i.e., when $|\Omega_i| \equiv h^d$ and $|\Gamma_{ij}| \equiv h^{d-1}$.

Due to stability reasons, the CFL restriction on Δt^n in (3.2) must be fulfilled. It can be formulated by requiring that

$$\Delta t^n \leq \min_i \tau_i \,, \tag{3.5}$$

where τ_i represents the local residence time for Ω_i (or critical time step; cf. [15]) given by

$$\tau_i := -\frac{|\Omega_i|}{V_i^{in}} \,, \quad V_i^{in} := \sum_{(e,j)\in\Lambda_i^{in}} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e \,, \quad i = 1, 2, \ldots, I \,. \tag{3.6}$$

If (3.5) is fulfilled, then the local discrete minimum/maximum principle is valid:

$$\min\{\phi_i^n,\ \phi_j^n,\ j \in \Lambda_i^{in}\} \leq \phi_i^{n+1} \leq \max\{\phi_i^n,\ \phi_j^n,\ j \in \Lambda_i^{in}\} \,. \tag{3.7}$$

The method (3.2) was developed by the authors in [15] and applied on uniform grids to nontrivial examples of curve and surface evolution. The method was realized with the vertex-centered finite volume method that is described in the next section. Moreover, a recursive procedure removing the CFL restriction (3.5) has been introduced to the method in [15].

3.2. High-resolution discretization scheme. First, we reconstruct the piecewise linear approximating function $\phi^n(x)$ in (2.12) by following, e.g., [40]. To do so, we suppose that the finite volume mesh Ω_i, $i = 1, \ldots, I$, is complementary to some conforming finite element mesh $T^e \subset \Omega$ with $e = 1, \ldots, E$ and vertices x_i, $i = 1, \ldots, I$. We use the barycentered form of such vertex-centered control volumes Ω_i, where the polygonal boundary $\partial\Omega_i$ is obtained by connecting the barycenters of elements with middle points of element edges; see, e.g., [12, 3] for some details and Figure 3.1 for an illustration.

The standard finite element interpolation of nodal values ϕ_i^n is used to define

$$\hat{\phi}^n(x) := \sum_{i=1}^{I} \phi_i^n N_i(x) \,, \tag{3.8}$$

where $N_i(x)$ denote finite element basis functions with $N_i(x_j) = \delta_{ij}$.

To reconstruct the piecewise constant gradient of $\phi^n(x)$ in (2.12), we apply

$$\nabla\phi_i^n := \sum_e \frac{\beta_{i,e}^n}{|\Omega_i \cap T^e|} \int_{\Omega_i \cap T^e} \nabla\hat{\phi}^n(x)\, dx\,. \tag{3.9}$$

The preferable choice for $\beta_{i,e}^n \in [0,1]$ (such that $\sum_e \beta_{i,e}^n \leq 1$) is

$$\beta_{i,e}^n = |\Omega_i \cap T^e|/|\Omega_i|\,, \tag{3.10}$$

but other choices can be used in a limiting procedure (see Remark 1).

The velocity $\vec{V}$ is approximated at integration points γ_{ij}^e by $\vec{V}_{ij}^e := \vec{V}(\gamma_{ij}^e, \nabla\hat{\phi}^n(\gamma_{ij}^e))$.

To define $\phi_i^{n+1/2}$ in the general scheme (2.10), we introduce the total outflow and inflow fluxes (see also (3.3)),

$$V_i^{out} := \sum_{(e,j)\in\Lambda_i^{out}} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e\,, \quad V_i^{in} := \sum_{(e,j)\in\Lambda_i^{in}} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e\,. \tag{3.11}$$

Furthermore, if $V_i^{out} > 0$, we define time-dependent averaged outflow value,

$$\phi_i^{out}(t) := \frac{1}{V_i^{out}} \sum_{(e,j)\in\Lambda_i^{out}} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e\, \phi_{ij}^e(t), \tag{3.12}$$

and analogously for averaged inflow value (if $V_i^{in} < 0$),

$$\phi_i^{in}(t) := \frac{1}{V_i^{in}} \sum_{(e,j)\in\Lambda_i^{in}} |\Gamma_{ij}^e| \vec{n}_{ij}^e \cdot \vec{V}_{ij}^e\, \phi_{ij}^e(t). \tag{3.13}$$

Finally, let us define $\phi_i^{n+1/2} = \alpha_i \phi_i^{out}(t^{n+1/2}) + (1-\alpha_i)\phi_i^{in}(t^{n+1/2})$, $\alpha_i \in [0.5, 1]$, and

$$V_i := (1-\alpha_i)V_i^{out} - \alpha_i V_i^{in}\,, \tag{3.14}$$

and the scheme (2.10) can be written as

$$\phi_i^{n+1} = \phi_i^n - \frac{\Delta t^n V_i}{|\Omega_i|} \left(\phi_i^{out}(t^{n+1/2}) - \phi_i^{in}(t^{n+1/2})\right)\,. \tag{3.15}$$

The preferable choice of α_i in (3.14) is $\alpha_i = 0.5$. Note that the parameters α_i in (3.14) and β_i in (3.9) can be chosen independently of each other.

Denoting the residence time $\tau_i := |\Omega_i|/V_i$, the scheme (3.15) also can be written in the form

$$\phi_i^{n+1} = \phi_i^n - \Delta t^n \frac{\phi_i^{out}(t^{n+1/2}) - \phi_i^{in}(t^{n+1/2})}{\tau_i}\,.$$

Note that the first order accurate method (3.2) can be obtained from (3.15) by setting $\beta_{i,e}^n = 0$ in (3.9) and $\alpha_i = 1$ in (3.14), $i = 1, \ldots, I$. Such a form of (3.15) can be used only locally, when it takes the form

$$\phi_i^{n+1} = \phi_i^n - \frac{\Delta t^n V_i^{in}}{|\Omega_i|} \left(\phi_i^n - \phi_i^{in}(t^{n+1/2})\right)\,. \tag{3.16}$$

We choose (3.16) instead of (3.15) for special cases $V_i^{out} = 0$ or $V_i^{in} = 0$, when (3.15) is not well defined. Note that for $V_i^{in} = 0$, (3.16) turns to $\phi_i^{n+1} = \phi_i^n$.

The following local discrete minimum/maximum principle can be proved for ϕ_i^{n+1} by showing that (3.15) and (3.16) can be viewed as positive coefficient schemes [3, 4].

THEOREM 3.1.

$$\phi_{i,\min}^n := \min\{\phi_i^n, \{\phi_j^n, (j,e) \in \Lambda_i \quad \exists (k,e) \in \Lambda_i^{in}\}\},$$

$$\phi_{i,\max}^n := \max\{\phi_i^n, \{\phi_j^n, (j,e) \in \Lambda_i \quad \exists (k,e) \in \Lambda_i^{in}\}\}.$$

$$\phi_{i,\min}^n < \phi_i^{in}(t^n) < \phi_{i,\max}^n \tag{3.17}$$

$$\phi_{i,\min}^n < \phi_i^n < \phi_{i,\max}^n, \tag{3.18}$$

ϕ_i^{n+1} (3.15)

$$\phi_{i,\min}^n \le \phi_i^{n+1} \le \phi_{i,\max}^n \tag{3.19}$$

$\Delta t^n > 0$
(3.17) ϕ_i^{n+1} (3.16) (3.19)
. First, we prove (3.19) for the solution given by (3.15). To do so, let us denote

$$\omega(t) := \frac{\phi_i^n - \phi_{i,\min}^n}{\phi_i^{out}(t) - \phi_{i,\min}^n}. \tag{3.20}$$

If $\phi_i^{out}(t^n) > \phi_i^n$ or $\phi_i^{out}(t) \ge \phi_i^n$ for $t \ge t^n$, one obtains that $\omega(t^{n+1/2}) \in (0,1]$ for sufficiently small $\Delta t^n > 0$. From (3.20) one has

$$\phi_i^{out}(t) = \frac{1}{\omega(t)}\phi_i^n - \frac{1-\omega(t)}{\omega(t)}\phi_{i,\min}^n, \tag{3.21}$$

and (3.15) can be written in the form of positive coefficient scheme

$$\begin{aligned}\phi_i^{n+1} = &\left(1 - \frac{\Delta t^n}{\omega(t^{n+1/2})\tau_i}\right)\phi_i^n \\ &+ \frac{(1-\omega(t^{n+1/2}))\Delta t^n}{\omega(t^{n+1/2})\tau_i}\phi_{i,\min}^n + \frac{\Delta t^n}{\tau_i}\phi_i^{in}(t^{n+1/2})\end{aligned} \tag{3.22}$$

if $\Delta t^n \le \min\{\omega(t^n), \omega(t^{n+1/2})\}\tau_i$. Consequently, the property (3.19) is valid.

For the case that $\phi_i^{out}(t^n) < \phi_i^n$ or $\phi_i^{out}(t) \le \phi_i^n$ for $t \ge t^n$, one can proceed analogously by defining

$$\omega(t) := \frac{\phi_i^n - \phi_{i,\max}^n}{\phi_i^{out}(t) - \phi_{i,\max}^n}. \tag{3.23}$$

For ϕ_i^{n+1} obtained from (3.16) the proof is straightforward. □

1. The results of Theorem 3.1 can be used to control any standard limiter procedure; see, e.g., [21, 3, 13] for flux or slope limiter procedures. For instance, the assumption (3.17) can be made valid by setting (in an extreme case) $\beta_{j,e}^n = 0$, $j \in \Lambda_i^{in}$, in (3.10).

TABLE 4.1

Errors in $L_2((0,T),L_2(S^2))$-norm and EOC for the example of a shrinking sphere using the first order scheme (3.2) *(third and fourth columns) and using the high-resolution scheme* (3.15) *(fifth and sixth columns). Analogously, the errors in $L_1((0,T),L_1(S^2))$-norm and EOC for the example of a shrinking cube are presented (seventh and eighth columns). In both cases, the high-resolution scheme gives the second order accuracy.*

4. Numerical experiments. In the following subsections, we present various numerical experiments to illustrate the behavior of the high-resolution flux-based level set method. Note that in all examples no limiting procedures and no reinitializations of the level set function were used.

4.1. Comparison with exact solutions on a three-dimensional uniform grid. In this subsection we give a comparison with simple exact solutions of the surface evolution problem.

First we show experimental order of convergence (EOC) for an evolving sphere computed on a subsequently refined uniform rectangular grid in three dimensions. For $\delta = -1$ in (1.2), the exact radius of a shrinking sphere is given by $r(t) = r(0) - t$, $t \in [0,T]$, where $r(0)$ is an initial radius and the solution is well defined for $T \leq r(0)$. We use the spatial domain $\Omega = [-1.25, 1.25]^3$, which is split into E^3 cubic elements T^e with the side length $h = 2.5/E$. The time step is given by $\tau = T/N$.

To compare numerical and exact solutions, we find all zero crossing points $x_k^n, k = 1,\dots,K$, of a piecewise linear representation of the numerical solution with finite element grid lines in every discrete time step $n = 0,\dots,N$. Then, in the case of a shrinking sphere, we compute Euclidean distances $r_k^n = |x_k^n|$ from the origin of all $x_k^n, k = 1,\dots,K$, and compare them with the exact radius of the shrinking sphere. Summing for all discrete time steps, we get the formula

$$\text{Error} = \left(\sum_{n=0}^{N} \tau \frac{1}{K} \sum_{k=1}^{K} (r_k^n - r(n\tau))^2 \right)^{\frac{1}{2}} \tag{4.1}$$

which is used as the $L_2((0,T),L_2(S^2))$-norm of the difference of exact and numerical surfaces, where S^2 is a unit sphere. In the experiment presented in Table 4.1 we use $r(0) = 1$ and $T = 0.4$.

In the case of a shrinking cube centered at origin, we compute $m_k^n = \max(|x_1^n|, |x_2^n|, |x_3^n|)$ for all zero crossing points $x_k^n = (x_1^n, x_2^n, x_3^n)_k$, $k = 1,\dots,K$. The value m_k^n is compared with the corresponding exact quantity, a distance $m(t)$ of the faces of the exactly shrinking cube from the origin. Note that $m(t) = m(0) - t$. Points on the exactly and numerically evolved surfaces correspond to points on the unit sphere (using the radial coordinate). Therefore, analogously to (4.1), we can define the formula

$$\text{Error} = \sum_{n=0}^{N} \tau \frac{1}{K} \sum_{i=1}^{K} |m_i^n - m(n\tau)| \tag{4.2}$$

which is used as the $L_1((0,T), L_1(S^2))$-norm of the error in surface motion. This norm is used for nonsmooth solutions due to the corners in the evolving isosurface. In the experiment presented in Table 4.1 we use $m(0) = 1$, $T = 0.4$, and further parameters are the same as in the case of the shrinking sphere.

Table 4.1 shows that the method (3.15) is $O(h^2)$ for both examples, compared to the method from (3.2), which is only first order accurate.

4.2. Comparison with exact solutions on two-dimensional unstructured grids. We present two-dimensional examples with known analytical solutions to demonstrate the high-resolution accuracy of our method on unstructured grids. Implementations were realized with software toolbox UG [5]. The domain is a square $\Omega := (-0.5, 0.5)^2$. The velocity is given as a sum of the divergence free part (the rotation) and the part causing shrinking or expanding of the interface in normal direction,

$$\vec{V} = \begin{pmatrix} -y \\ x \end{pmatrix} + \delta \frac{\nabla \phi}{|\nabla \phi|}, \tag{4.3}$$

where δ is a constant to be specified later. The initial condition and the Dirichlet boundary conditions will be prescribed using the exact solution Φ of a particular problem.

First, an example of a circle that rotates and shrinks is considered:

$$\Phi(t, x_1, x_2) = \sqrt{\tilde{x}_1^2 + \tilde{x}_2^2} - r_0 + \delta t \tag{4.4}$$

and

$$\tilde{x}_1 := x_1 \cos(t) + x_2 \sin(t) + 0.25, \;\; \tilde{x}_2 := x_2 \cos(t) - x_1 \sin(t). \tag{4.5}$$

The initial radius is chosen as $r_0 = 0.2$. The parameter δ is chosen such that after half rotation, i.e., $t = \pi$, the radius of circle is halved; i.e., $\delta = -0.1/\pi$.

Figure 4.1 shows an initial finite element mesh of 28 triangles representing the grid level 0. The grid is subsequently refined by dividing each triangle into 4 subtriangles. The finest grid is obtained after 6 uniform refinements (i.e., the grid level equals 6) and contains 114688 triangles. The picture in the middle of Figure 4.1 presents the numerical solution at $t = 0$ and $t = \pi$ for the grid level 6.

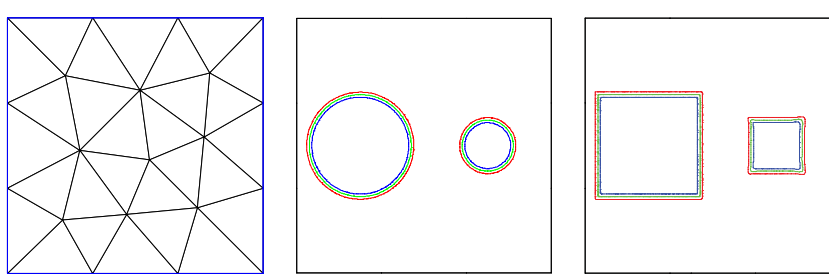

FIG. 4.1. *Initial coarse grid (left) and three contour lines ($\phi = -0.01, 0.0$ and 0.01) of numerical solutions at $t = 0$ and $t = \pi$ for the circle example (middle) and the square example (right). In this resolution, almost no difference between exact and numerical zero isolines would be visible.*

Table 4.2 shows an L_1-norm of numerical error at $t = t^N = T$,

$$\text{Error} = \int_\Omega |\Phi(T, x_1, x_2) - \sum_{i=1}^{I} \phi_i^N N_i(x_1, x_2)| \, dx_1 dx_2, \tag{4.6}$$

for each grid level; see also (3.8). Note that the error (4.6) is computed on the whole domain and not only on the interface. The L_1 error of the interface position at $t = T$ is computed using

$$\text{Error} = \sum_{k=1}^{K} |\Gamma^k| \left| r^k - r_{\text{exact}} \right|, \tag{4.7}$$

where the numerical interface is reconstructed as a polygon made of K segments Γ^k, and the Euclidean distance r^k is computed between the middle point (x_1^k, x_2^k) of Γ^k and the center (x_1^c, x_2^c). For this example, one has $r_{\text{exact}} = 0.1$ and $(x_1^c, x_2^c) = (0.25, 0.0)$. Moreover, the error between the exact area 0.01π of the circle at $t = \pi$ and the area given by the numerical solution is presented in Table 4.2.

An analogous numerical experiment is realized using a level set function (not a distance function) describing a square that is transported by the same velocity (4.3), the results of which are presented in Figure 4.1 (right) and Table 4.3. The exact solution is given by

$$\Phi(t, x_1, x_2) := \begin{cases} \tilde{x}_2 - r_0 - \delta t, & \tilde{x}_2 \geq 0 \quad \text{and} \quad \tilde{x}_2 \geq |\tilde{x}_1|, \\ -\tilde{x}_2 - r_0 - \delta t, & \tilde{x}_2 \leq 0 \quad \text{and} \quad -\tilde{x}_2 \geq |\tilde{x}_1|, \\ \tilde{x}_1 - r_0 - \delta t, & \tilde{x}_1 \geq 0 \quad \text{and} \quad \tilde{x}_1 \geq |\tilde{x}_2|, \\ -\tilde{x}_1 - r_0 - \delta t, & \tilde{x}_1 \leq 0 \quad \text{and} \quad -\tilde{x}_1 \geq |\tilde{x}_2|, \end{cases} \tag{4.8}$$

where $r_0 = 0.2$ (see also (4.5)) and the corners of the square remain sharp, producing discontinuous derivatives of the solution. The error (4.7) on the interface ($r_{\text{exact}} = 0.1$ and $(x_1^c, x_2^c) = (0.25, 0.0)$), where $r^k = \max(|x_1^k - x_1^c|, |x_2^k - x_2^c|)$, and the error between the exact area 0.04 and the area determined by the numerical solution are included in Table 4.3.

Next, analogous numerical experiments with expanding characteristics are presented. First, an example of the expanding and rotating circle is chosen where the exact solution $\Phi(\pi, x_1, x_2)$ is given by (4.4) with $r_0 = 0.1$, $\delta = 0.1/\pi$ for $(x_1, x_2) \notin S((0.25, 0.0), 0.1)$, and $\Phi(\pi, x_1, x_2) \equiv -0.1$ otherwise, where $S((0.25, 0.0), 0.1)$ is a circle centered at $(0.25, 0.0)$ with the radius 0.1.

Note that for this example the high-resolution method gives EOC in the error (4.6) that is less than 2. One of the reasons is a constant region that is developed in the

TABLE 4.4
Numerical errors and EOC for the expanding and rotating circle example.

Level	N	Error (4.6)	EOC	Error (4.7)	EOC	Area error	EOC

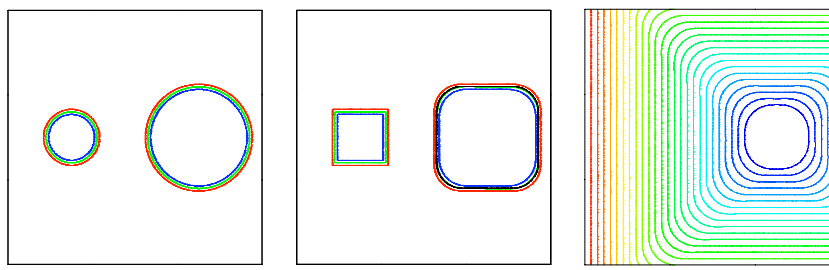

FIG. 4.2. *The left picture shows three contour lines ($\phi = -0.01, 0.0$, and 0.01) of numerical solutions at $t = 0$ and $t = \pi$ for the expanding and rotating circle example (in this resolution no difference between the exact and the numerical zero isolines could be visible). The middle picture presents analogous results for the expanding and rotating square, where additionally the exact zero level line (black) is presented. The right picture shows the level lines of the numerical solution distributed uniformly between -0.075 and 0.55.*

TABLE 4.5
Numerical errors and EOC for the expanding and rotating square example.

Level	N	Error (4.6)	EOC	Error (4.7)	EOC	Area error	EOC
3	80	3.9579E-3		9.9274E-3		6.3885E-3	
4	160	1.8124E-3	1.13	5.1273E-3	0.95	3.9632E-3	0.69
5	320	0.8203E-3	1.14	2.2505E-3	1.19	1.8900E-3	1.07
6	640	0.3733E-3	1.14	1.0654E-3	1.08	0.9554E-3	0.98

exact solution. Nevertheless, the error (4.7) on the interface diminishes quadratically; see Table 4.4, where the difference between the exact area 0.04π and the numerical one is also presented. The initial and final circular interface is presented in the picture at the left of Figure 4.2.

Finally, an example of the expanding and rotating square is computed. The initial function $\Phi(0, x_1, x_2)$ is given by (4.8) with $r_0 = 0.1$ and $\delta = 0.1\pi$. The exact solution can be simply constructed using the Huygens principle; see also the picture at the right of Figure 4.2. The global numerical error (4.6), the local one (4.7), and the difference between the exact area $0.12 + 0.01\pi$ and the numerical one are presented in Table 4.5. The numerical solution at $t = \pi$ is plotted in the middle picture of Figure 4.2 (three isolines where the interface is located) and in the right picture (isocontours plot of the final level set function). For this example, the high-resolution method seems to be slightly better than first order accurate.

4.3. Numerical experiments using locally adapted grids. The example with the rotating and shrinking square was repeated with a locally adapted grid by refining (and coarsening) in each time step only elements in the neighborhood of the zero contour line; see Figure 4.3. Note that mixed grids consisting of squares

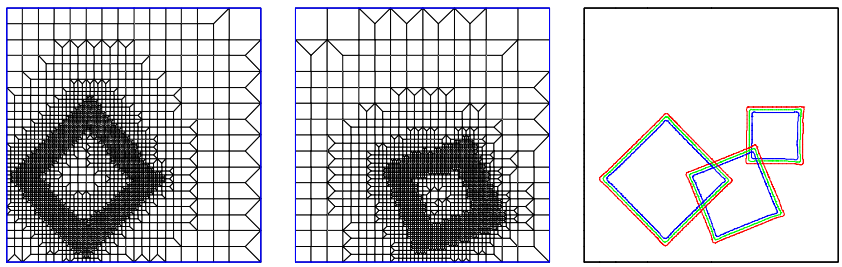

FIG. 4.3. *Locally adapted grid at $t = \pi/4$ (left) and $t = 5\pi/8$ (middle) and numerical solutions at $t = \pi/4$, $t = 5\pi/8$, and $t = \pi$ (right).*

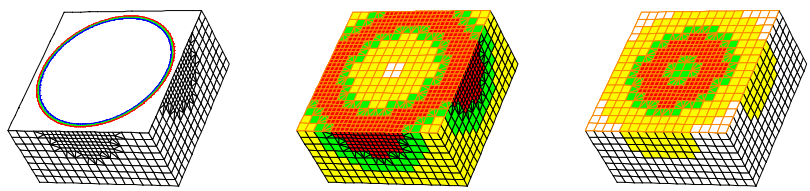

FIG. 4.4. *A cross section of numerical solution (left) and locally adapted grid used in the first (middle) and last (right) time step for the example of a shrinking sphere.*

and triangles were used. The simulation used 3290 finite elements at the beginning and 1547 at the end of computations and took considerably less time to realize than computations with corresponding uniformly refined grids.

To illustrate the capability of UG [5] for three-dimensional grids, Figure 4.4 shows the numerical solution (a shrinking sphere) and the grids before the first and last time step. Note that mixed grids consisting of hexahedra, pyramids, and tetrahedra were used.

Finally, in a nontrivial experiment we evolve an initial curve in the form of a shrinking quatrefoil [15]. The quatrefoil is the zero level set of the initial level set function (not a signed distance function) constructed by the formula

$$\phi^0(x_1, x_2) = -0.5 + \sqrt{x_1^2 + x_2^2}/r_L, \quad r_L = 0.6 + 0.4 \sin\left(4 \operatorname{arctg}\left(\frac{x_2}{x_1}\right)\right).$$

In this experiment, topological changes of the evolving curve occur; see Figure 4.5.

4.4. Benchmarks with divergence free velocity. In this section, we present numerical results for two standard benchmark examples with divergence free velocity field to illustrate the behavior of our method for such types of problems. The main application of level set equation (1.1) with externally given velocity $\vec{V}$ such that $\nabla \cdot \vec{V} = 0$ are problems of two-phase flow where the evolving level set function describes a moving interface between two incompressible fluids. Note that for this type of problem, the level set equation can be written in a conservative form (2.3) with zero right-hand side. For such a classical scalar linear hyperbolic equation describing

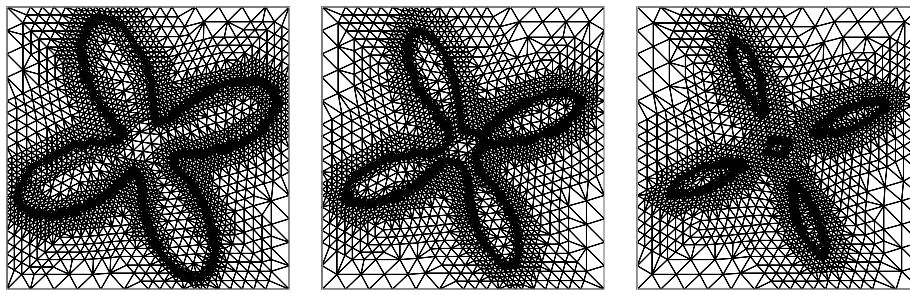

FIG. 4.5. *Shrinking of a quatrefoil with topological changes; the zero contour line of the numerical solution and the used grid are plotted for three different time steps.*

conservation law there exist an enormous number of sophisticated numerical methods and recently some of them were devoted directly to level set applications [30, 35, 25].

Before presenting our numerical results, we illustrate a better performance of the finite volume based scheme (3.15) as compared to the finite difference based ENO scheme [31] for a test example of a rotating circle. The high-resolution flux-based level set method (3.15) was implemented in the MATLAB toolbox of level set methods [26] and compared with the existing implementation of the ENO scheme of second order in time and space.

The example is defined on a square $(-1,1)^2$, and the rotation is given in the clockwise direction. Dirichlet boundary conditions given by the exact values of a signed distance function were used in both methods.

Figure 4.6 shows numerical solutions on a coarse grid with $(I+1)^2$ nodes, $I = 20$, where the differences between two methods can be clearly recognized. Table 4.6 shows the simple discrete L_1-norm

$$\text{Error} = \frac{4}{I^2} \sum_{i=1}^{(I+1)^2} |\phi_i^0 - \phi_i^N|,$$

which is computed from the differences of numerical solutions in grid points at $t = 0$ and the time after one rotation.

In what follows, we present results of our scheme in solving two complex examples known from the literature, namely for the Zalesak's disk rotation and the vortex-in-a-box examples. In the literature, to improve a finite difference level set

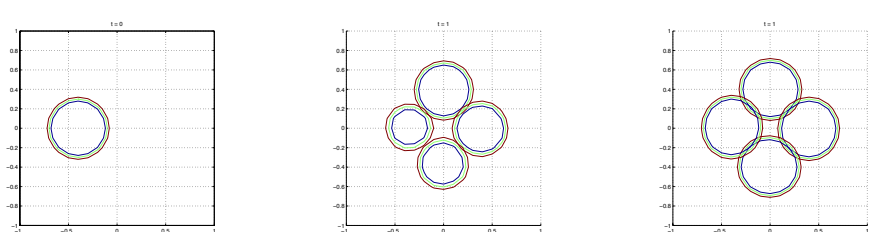

FIG. 4.6. *Initial condition (left), numerical solution obtained by the second order ENO scheme (middle) and by the high-resolution scheme FB-LSM* (3.15) *(right) for* 4 *different times on a coarse mesh of* 21×21 *grid points. The rotation occurs in the clockwise direction.*

TABLE 4.6
Numerical error of flux-based level set method (FB-LSM) and ENO scheme for a rotating circle.

I	N	Error FB-LSM	Error ENO
20	140	104.046E-4	708.131E-4
40	280	28.726E-4	235.063E-4
80	560	7.899E-4	71.060E-4

approximation of the interface, additional numerical techniques, such as redistancing algorithms [44, 42, 48], particle tracking techniques [8, 9, 18], volume-of-fluid methods [46], or discontinuous Galerkin methods [48, 25], were introduced; see also a review in [24].

In our opinion, the results obtained by the flux-based level set method (2.10), presented in this section, are qualitatively comparable to those of published studies, especially if one takes into the account that no additional numerical techniques, mentioned before, were applied in our computations to improve the level set approximation of the interface. In this way, the flux-based level set method can produce satisfactory results for reasonable meshes by preserving its simple form. Nevertheless, in contradiction to quoted papers, the primal field of applications of our flux-based level set method are problems that involve geometric evolution equations and that might also include the evolution described by external flow; see, e.g., the boat-sail distance problem [28, 29].

First, the example of the solid body rotation of the so-called Zalesak's disk is presented; see, e.g., [42, 8, 9, 18, 25, 46]. The initial interface is a circle with radius 0.15 centered at $(0.5, 0.75)$ with a vertical rectangular cut of the width and length equal to 0.05 and 0.25, respectively. The slotted disk rotates in the counterclockwise direction with a constant angular velocity and returns to the origin position after one rotation.

The example is simulated on a unit square. The initial level set function is given by a signed distance function to Zalesak's disk, and exact Dirichlet boundary conditions are used during simulations. The initial coarse grid (referred to later as the grid level 0) consists of 4 right triangles that are obtained by connecting the corners of the square with the middle point of the square. Afterwards, the grid is refined uniformly by dividing each triangle into 4 subtriangles, creating subsequent grid levels. Numerical results are presented for the grid levels 7 (consisting of 65536 triangles with 33025 vertices, 720 uniform time steps) and 8 (consisting of 262144 triangles with 131585 vertices, 1440 uniform time steps).

In Figure 4.7 a comparison of the numerically and exactly computed interface after one rotation can be found for grid levels 7 and 8. The corresponding L_1 errors (4.6) are presented in Table 4.7.

As expected, one can observe a smoothing of initially sharp corners in the numerical solution of Zalesak's disk problem. The area of the disk surrounded by the zero isoline of the numerical level set function at grid level 8 is 5.8216E-2 for $t = 0$ and 5.7893E-2 for $t = T$, which corresponds to the loss of 0.55%.

Finally, an example of a single vortex in a box is presented; see, e.g., [9, 18, 25, 46]. The time-dependent velocity with nonzero vorticity is given by

$$\vec{V} = 2\cos\left(\frac{\pi t}{8}\right)\left(-\sin^2(\pi x)\sin(\pi y)\cos(\pi y)\,,\ \sin^2(\pi y)\sin(\pi x)\cos(\pi x)\right). \tag{4.9}$$

The time dependency of $\vec{V}$ in (4.9) was resolved by evaluating it at $t = t^n + 0.5\Delta t$ for

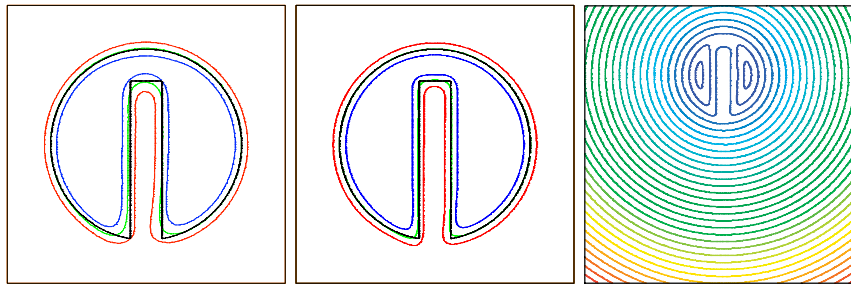

FIG. 4.7. *The left picture shows a detail of three level lines ($\phi = -0.01, 0.0$, and 0.01) of the numerical solution and the exact zero line (black) after one rotation at grid level 7 for Zalesak's example. The middle picture presents analogous results for grid level 8. The right picture shows level lines of the numerical solution in the whole domain (distributed uniformly from -0.05 to 0.75) after one rotation for grid level 8.*

TABLE 4.7
Numerical errors and EOC for the Zalesak example and the single vortex example.

Level	N	Error (4.6)	EOC	N	Error (4.6)	EOC

7	720	2.2406E-4	1.50	1600	0.4461E-2	1.46
8	1440	0.9224E-4	1.28	3200	0.1246E-2	1.84

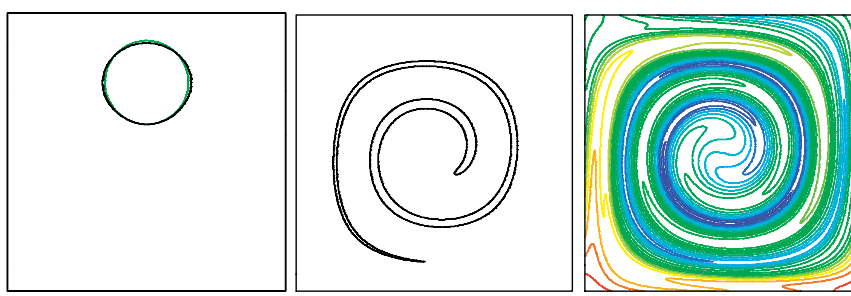

FIG. 4.8. *The left picture shows the exact circular interface (green) and the computed interface (black) at $t = 8$ of the single vortex example for grid level 8. The middle picture presents the zero level line of the numerical solution at $t = 4$, and the right picture shows level lines in the whole domain distributed uniformly between -0.1 and 0.75.*

each time step to obtain $\vec{V}$ in (1.1).

The initial interface is a circle with radius 0.15 and centered at $(0.5, 0.75)$ in a unit square $(0, 1)^2$. The interface stretched during simulations by wrapping around the center of the box, reaching a maximal deformation at $t = 4$ and returning to the initial circular form at $t = 8$.

The computations were realized using a signed distance function as an initial level set function and exact Dirichlet boundary conditions during simulations. The coarse grid and subsequent grid levels were chosen analogously to Zalesak's disk example. A uniform time step was chosen by setting $\Delta t^n = \Delta t = 8/N$.

Numerical results for the single vortex example are plotted in Figure 4.8, and the numerical L_1 error (4.6) is presented in Table 4.7. The area of the circle at $t = 8$ equals 7.2302E-2, which corresponds to a gain of 2.3% with respect to the exact area

7.0686E-2. Note that again no extension to our level set method was used. For instance, no redistancing was applied in simulations; see the picture at the right of Figure 4.7 where the numerical level set function at $t = 4$ is presented.

Acknowledgment. The authors would like to thank Christian Wehner, a student at the University of Heidelberg, for providing numerical results comparing the flux-based level set method and the ENO scheme.

CONSTRUCTING ROBUST GOOD LATTICE RULES FOR COMPUTATIONAL FINANCE*

XIAOQUN WANG†

Abstract. The valuation of many financial derivatives leads to high-dimensional integrals. The constructions of *robust* or *universal* good lattice rules for financial applications are both important and challenging. An important *common* feature of the integrands in computational finance is that they can often be well approximated by a sum of low-dimensional functions, i.e., functions that depend on only a small number of variables (usually just two variables). For numerical integration of such functions the quality of the low-order (i.e., low-dimensional) projections of the node set is crucial. In this paper we propose methods to construct good lattice points with "optimal" low-order projections. The quality of a point set is measured by a new measure called *elementary order-ℓ discrepancy*, which measures the quality of all order-ℓ projections and is more informative than usual measures. Two constructions, namely the Korobov and the component-by-component constructions, are studied such that the low-order projections are optimized. Numerical experiments demonstrate that even in high dimensions it is possible to construct new good lattice points with order-2 projections that are better than those of the Sobol' points and random points and with higher-order projections that are no worse (while the Sobol' points lost the advantage over random points in order-2 projections on the average). The new lattice rules have the potential to improve upon the accuracy for favorable functions, while doing no harm for unfavorable ones. Their applications for pricing path-dependent options and American options (based on the least-square Monte Carlo method) are studied and their high efficiency is demonstrated. A nice surprise revealed is the *robustness property* of such lattice rules: the good projection property and the suitability for a large range of problems. The potential possibility and limitations of good lattice points in achieving good quality of moderate- and high-order projections is investigated. The reason why classical lattice rules may not be efficient for high-dimensional finance problems is also discussed.

Key words. quasi-Monte Carlo methods, good lattice rules, multivariate integration, option pricing, American options

1. Introduction.

Many practical problems can be transformed into the computations of multivariate integrals:

$$I_s(f) = \int_{[0,1]^s} f(\mathbf{x})\, d\mathbf{x}.$$

Typical examples are the valuations of financial derivatives. In principle, any stochastic simulation whose purpose is to estimate an expectation fits this framework. High-dimensional integrals are usually approximated by Monte Carlo (MC) or quasi-Monte Carlo (QMC) algorithms:

$$Q_{n,s}(f) := Q_{n,s}(f; P) := \frac{1}{n} \sum_{k=0}^{n-1} f(\mathbf{x}_k),$$

where $P := \{\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{n-1}\}$ is a set of random points in MC or deterministic [illegible] in QMC. The MC methods converge as $O(n^{-1/2})$, independently of s. QMC methods try to take the points more uniformly distributed and have the potential to improve the convergence rate for some classes of functions. Digital nets and good lattice points are two important classes of QMC; see [18, 20]. For example, a rank-1 lattice rule has the form

$$Q_{n,s}(f) = \frac{1}{n} \sum_{k=0}^{n-1} f\left(\left\{\frac{k\mathbf{z}}{n}\right\}\right),$$

where $\mathbf{z} = (z_1, z_2, \ldots, z_s)$ is the [illegible] with no factor in common with n and the notation $\{\mathbf{x}\}$ means the vector whose components are the fractional part of x_j. The central topic in the field of lattice rules is to find a "good" generating vector; see [12, 18, 20].

In financial applications, it is often observed that while the nominal dimension of the problems can be very large, the [illegible] is often small; i.e., the underlying functions are nearly a superposition of low-dimensional functions, especially when dimension reduction techniques are used (see [3, 27]). More precisely, the analysis of variance (ANOVA) expansion up to the second order,

$$f(\mathbf{x}) \approx f_0 + \sum_{j=1}^{s} f_j(x_j) + \sum_{1 \le i < j \le s} f_{ij}(x_i, x_j),$$

can usually provide a quite satisfactory approximation, where $f_j(x_j)$ and $f_{ij}(x_i, x_j)$ represent the individual and the cooperative effects. For numerical integration of such functions the quality of low-order (especially the order-1 and order-2) projections of the node set is crucial. QMC point sets should be constructed to be as well distributed as possible in their low-order projections. We believe that good quality in order-2 projections of a lattice point set is necessary and sufficient for many problems in finance. Point sets with optimal order-1 projections are not difficult to obtain (an arbitrary lattice point set has perfect order-1 projections). However, it is not so easy (or even impossible) to obtain point sets with optimal projections of various orders simultaneously.

It was shown in [29] that in high dimensions (say, $s \ge 50$) common quasi-random numbers, such as the Sobol's [25], have excellent order-1 projections (as expected), but often exhibit patterns in order-2 and higher-order projections and that these projections are [illegible] on the average than those of random points for practical n (which may contradict common intuition). In fact, this nonuniformity is typical for quasi-random numbers [16]. It is interesting to know whether good lattice points could provide better order- 2 and higher-order projections than digital nets do. What is the optimal situation (i.e., the logical limit) which can be achieved by a construction, say, the Korobov construction [12]? How does one construct lattice points with "optimal" low-order (or some specific order) projections? How efficient and robust are they for practical applications? The method in [6] provides a theoretical basis for answering these questions (but no generators are published there).

Confronted with such issues, the objectives of this paper are to explore the potential possibility of good lattice points in achieving good low-order projections (aiming at constructing robust lattice rules) and to study their applications to finance. Lattice rules are usually found by minimizing some quality measures; thus the choice of measure is important [7, 14, 8, 9, 28, 30]. To construct lattice points with low-order

projections as well distributed as possible, one needs a suitable measure. The classical quality measure P_α (see [20]) was found to be not suitable in high dimensions for this purpose (though it may not be bad in small dimensions, say $s \leq 8$), since it treats implicitly higher-order projections as more important than lower-order ones and does not put special emphasis on low-order projections, which may cause serious problems in high dimensions; see [28]. It was shown in [28] that the lattice rules constructed based on P_α may not give good results for high-dimensional problems (in fact, they can be even worse than MC, and this is why lattice rules are not so popular for finance problems). The reason will become clear in section 4.

In [28] an attempt was made to choose suitable weights involved in the weighted version of P_α by relating the weights to the sensitivity indices of a particular problem. The weighted version of P_α is related to the worst-case error of certain [illegible]. We refer to [23] for the theory of weighted function spaces. A principal difficulty of using the theory of weighted space for practical applications is in choosing appropriate weights. The lattice rules constructed in [28] are extremely effective, but they are [illegible]. The high efficiency of those rules is achieved by focusing on important dimensions and low-order projections. Based on a similar idea, in this paper we attempt to construct [illegible] lattice points, which are of acceptable quality for a wide range of problems.

This paper is organized as follows. In section 2 we introduce weighted Sobolev spaces and discuss the relationship of the uniformity of the projections with the quadrature error. In section 3 we discuss quality measures for lattice rules and present methods to construct lattice rules with "optimal" low-order (or some specific order) projections. Numerical comparisons on the quality of projections of various orders are presented in section 4. The potential possibility and the limitations of lattice rules (i.e., what lattice rules can do and cannot do) are investigated. Applications to the valuation of path-dependent options and American options (based on the least-square MC [15]) are demonstrated in section 5. Numerical experiments in sections 4 and 5 show the robustness property of our lattice rules. Concluding remarks are presented in section 6. Some generators of lattice rules with optimal order-2 projections are provided in the appendix.

2. Weighted Sobolev space and quadrature error. In this section we present some background on weighted function spaces and discuss the factors that affect QMC quadrature errors.

2.1. Background on reproducing kernel Hilbert space. Let $H(K)$ be a reproducing kernel Hilbert space (RKHS) with reproducing kernel $K(\mathbf{x}, \mathbf{y})$. The kernel $K(\mathbf{x}, \mathbf{y})$ has the following properties:

$$K(\mathbf{x}, \mathbf{y}) = K(\mathbf{y}, \mathbf{x}), \quad K(\cdot, \mathbf{y}) \in H(K) \qquad \forall\, \mathbf{x}, \mathbf{y} \in [0,1]^s$$

and

$$f(\mathbf{y}) = \langle f, K(\cdot, \mathbf{y}) \rangle \qquad \forall\, f \in H(K),\ \mathbf{y} \in [0,1]^s,$$

where $\langle \cdot, \cdot \rangle$ is the inner product of $H(K)$ and $||f||_{H(K)} = \langle f, f \rangle^{1/2}$. Let

$$h_s(\mathbf{x}) = \int_{[0,1]^s} K(\mathbf{x}, \mathbf{y})\, d\mathbf{y} \qquad \forall\, \mathbf{x} \in [0,1]^s.$$

We assume that $h_s \in H(K)$. Then I_s is a continuous linear functional with the reproducer h_s, i.e.,

$$I_s(f) \,=\, \langle f, h_s \rangle \qquad \forall\, f \in H(K).$$

Let P be a set of n points in the s-dimensional unit cube:

$$P := \{\mathbf{x}_k = (x_{k,1}, \ldots, x_{k,s}) : \ k = 0, 1, \ldots, n-1\} \subset [0,1]^s. \tag{1}$$

The [illegible] of the algorithm $Q_{n,s}(f;P)$ over the unit ball of $H(K)$, or the [illegible] of the set P with respect to the kernel K, is defined by

$$D(P; H(K)) = \sup\{|I_s(f) - Q_{n,s}(f;P)| : \ f \in H(K), \ ||f||_{H(K)} \le 1\}.$$

Since $H(K)$ is an RKHS, the square worst-case error can be expressed in terms of the reproducing kernel (see [9, 23]):

$$D^2(P; H(K)) = \int_{[0,1]^{2s}} K(\mathbf{x}, \mathbf{y})\, d\mathbf{x} d\mathbf{y} - \frac{2}{n} \sum_{i=0}^{n-1} \int_{[0,1]^s} K(\mathbf{x}_i, \mathbf{x})\, d\mathbf{x} + \frac{1}{n^2} \sum_{i,k=0}^{n-1} K(\mathbf{x}_i, \mathbf{x}_k). \tag{2}$$

Due to the linearity of $I_s(f) - Q_{n,s}(f)$, we have the error bound

$$|I_s(f) - Q_{n,s}(f)| \le D(P; H(K))\ ||f||_{H(K)} \qquad \forall f \in H(K). \tag{3}$$

2.2. A weighted Sobolev space. Weighted Sobolev space was introduced in [23]. Here we specify a particular RKHS with the following reproducing kernel:

$$K_{s,\gamma}(\mathbf{x}, \mathbf{y}) = 1 + \sum_{\emptyset \ne u \subseteq \mathcal{A}} K_u(\mathbf{x}_u, \mathbf{y}_u), \tag{4}$$

where $\mathcal{A} = \{1, \ldots, s\}$ and

$$K_u(\mathbf{x}_u, \mathbf{y}_u) = \gamma_{s,u} \prod_{j \in u} \eta(x_j, y_j),$$

with

$$\eta(x, y) = \frac{1}{2} B_2(\{x - y\}) + \left(x - \frac{1}{2}\right)\left(y - \frac{1}{2}\right),$$

where $B_2(x) = x^2 - x + 1/6$ is the Bernoulli polynomial of degree 2 and $\gamma := \{\gamma_{s,u}\}$ is a sequence of positive numbers (the weights sequence). One can take $\gamma_{s,u} = 0$ as the limiting case of positive $\gamma_{s,u}$'s. The weighted Sobolev space with [illegible] weights is related to the weighted Korobov space with general weights studied in [6]; see section 3.

The inner product in the space $H(K_{s,\gamma})$ is

$$\langle f, g \rangle_{H(K_{s,\gamma})} = \sum_{u \subseteq \mathcal{A}} \gamma_{s,u}^{-1} \int_{[0,1]^{|u|}} \left(\int_{[0,1]^{s-|u|}} \frac{\partial^{|u|} f}{\partial \mathbf{x}_u} d\mathbf{x}_{-u} \right) \left(\int_{[0,1]^{s-|u|}} \frac{\partial^{|u|} g}{\partial \mathbf{x}_u} d\mathbf{x}_{-u} \right) d\mathbf{x}_u,$$

where $\mathbf{x}_u$ denotes the vector of the coordinates of $\mathbf{x}$ with indices in u, $-u$ denotes the complementary set $\mathcal{A} - u$, and $|u|$ denotes the cardinality. The term corresponding to $u = \emptyset$ in the inner product is interpreted as $\int_{[0,1]^s} f(\mathbf{x}) d\mathbf{x} \int_{[0,1]^s} g(\mathbf{x}) d\mathbf{x}$. (We assume that $\gamma_{s,\emptyset} = 1$.) The weight $\gamma_{s,u}$ measures the importance of the group of variables in u. If $||f||_{H(K_{s,\gamma})} \le 1$ and $\gamma_{s,u}$ is small, then $\frac{\partial^{|u|} f}{\partial \mathbf{x}_u}$ is small.

Based on (2), the square worst-case error is

$$D^2(P; H(K_{s,\gamma})) = \frac{1}{n^2} \sum_{i,k=0}^{n-1} \sum_{\emptyset \neq u \subseteq \mathcal{A}} \gamma_{s,u} \prod_{j \in u} \eta(x_{i,j}, x_{k,j}).$$

The most well-studied form of weights are the product weights:

$$\gamma_{s,u} = \prod_{j \in u} \gamma_{s,j} \quad \text{for} \quad \text{some} \quad \{\gamma_{s,j}\}. \tag{5}$$

In this case, the kernel (4) can be written as a product

$$K_{s,\gamma}(\mathbf{x}, \mathbf{y}) = \prod_{j=1}^{s} [1 + \gamma_{s,j}\, \eta(x_j, y_j)],$$

and the square worst-case error is

$$D^2(P; H(K_{s,\gamma})) = -1 + \frac{1}{n^2} \sum_{i,k=0}^{n-1} \prod_{j=1}^{s} [1 + \gamma_{s,j}\, \eta(x_{i,j}, x_{k,j})].$$

2.3. Projections of a point set and QMC quadrature error. We discuss how the uniformity of the projections of a point set affects the quadrature error (see [9]). Observe that $K_u(\mathbf{x}_u, \mathbf{y}_u)$ is also a reproducing kernel. The associated RKHS is denoted by $H(K_u)$. The inner product in $H(K_u)$ is

$$\langle f, g \rangle_{H(K_u)} = \gamma_{s,u}^{-1} \int_{[0,1]^{|u|}} \frac{\partial^{|u|} f(\mathbf{x}_u)}{\partial \mathbf{x}_u} \frac{\partial^{|u|} g(\mathbf{x}_u)}{\partial \mathbf{x}_u}\, d\mathbf{x}_u \qquad \forall f, g \in H(K_u).$$

It is known (see [10]) that the original RKHS $H(K_{s,\gamma})$ can be written as the direct sum of the spaces $H(K_u)$:

$$H(K_{s,\gamma}) = \bigoplus_{u \subseteq \mathcal{A}} H(K_u).$$

Therefore, an arbitrary function $f \in H(K_{s,\gamma})$ has a unique projection decomposition (similar to the ANOVA decomposition described below):

$$f(\mathbf{x}) = \sum_{u \subseteq \mathcal{A}} f_u(\mathbf{x}_u) \qquad \text{with} \quad f_u \in H(K_u), \tag{6}$$

and

$$||f||^2_{H(K_{s,\gamma})} = \sum_{u \subseteq \mathcal{A}} ||f_u||^2_{H(K_{s,\gamma})}.$$

Note that for any $f \in H(K_u)$, we have $||f||_{H(K_u)} = ||f||_{H(K_{s,\gamma})}$.

For functions of $H(K_{s,\gamma})$ the projection decomposition (6) coincides with the ANOVA decomposition; see [5]. The ANOVA decomposition of a function is defined recursively by

$$f_u(\mathbf{x}) = \int_{[0,1]^{s-|u|}} f(\mathbf{x}) d\mathbf{x}_{-u} - \sum_{v \subset u} f_v(\mathbf{x}) \quad \text{for} \quad \emptyset \neq u \subseteq \mathcal{A},$$

with $f_\emptyset(\mathbf{x}) = I_s(f)$. The ANOVA decomposition is used in QMC to explore the dimension structure of functions such as the effective dimensions; see [3, 26, 27].

For a point set P, let P_u denote its projection on the space with coordinate indices in u. From (3) it is obvious that

$$|I_s(f_u) - Q_{n,s}(f_u)| \le D(P_u; H(K_u))\ ||f_u||_{H(K_{s,\gamma})},$$

where

$$D^2(P_u; H(K_u)) = \frac{\gamma_{s,u}}{n^2} \sum_{i,k=0}^{n-1} \prod_{j\in u} \eta(x_{i,j}, x_{k,j}).$$

Therefore, for $f \in H(K_{s,\gamma})$ we have

$$\begin{aligned} |I_s(f) - Q_{n,s}(f)| &\le \sum_{\emptyset\ne u\subseteq\mathcal{A}} |I_s(f_u) - Q_{n,s}(f_u)| \\ &\le \sum_{\emptyset\ne u\subseteq\mathcal{A}} D(P_u; H(K_u))\ ||f_u||_{H(K_{s,\gamma})}. \end{aligned} \tag{7}$$

This demonstrates a relationship of the quadrature error with the uniformity of the projections P_u and the ANOVA terms f_u. If a QMC point set has good projections P_u for the subsets u that correspond to important terms f_u, then a good result can be expected. It would be nice to find a point set P such that $D(P_u; H(K_u))$ is minimized for each nonempty subset $u \subseteq \mathcal{A}$. However, there are $2^s - 1$ nonempty subsets of $\mathcal{A}$, making the optimization problem too difficult.

2.4. Measuring the uniformity of projections of the same order. By defining

$$\mathcal{D}^2_{(\ell)}(P) := \sum_{u\subseteq\mathcal{A},\,|u|=\ell} D^2(P_u; H(K_u)), \quad \ell = 1, 2, \ldots, s,$$

the integration error $I_s(f) - Q_{n,s}(f)$ can be bounded in terms of $\mathcal{D}_{(\ell)}(P)$ (after using the Cauchy–Schwarz inequality in (7)):

$$|I_s(f) - Q_{n,s}(f)| \le \sum_{\ell=1}^{s} \mathcal{D}_{(\ell)}(P)\ ||f_{(\ell)}||,$$

where

$$||f_{(\ell)}||^2 = \sum_{u\subseteq\mathcal{A},\,|u|=\ell} ||f_u||^2_{H(K_{s,\gamma})}. \tag{8}$$

The quantity $\mathcal{D}_{(\ell)}(P)$ is called the [illegible] ; see [29]. It measures the uniformity of the projections of order-ℓ taken together and is the worst-case error of the algorithm $Q_{n,s}(f)$ over the unit ball of the RKHS $H(K_{(\ell)})$, i.e.,

$$\mathcal{D}_{(\ell)}(P) = D(P; K_{(\ell)}),$$

where $K_{(\ell)}(\mathbf{x}, \mathbf{y})$ is the reproducing kernel

$$K_{(\ell)}(\mathbf{x}, \mathbf{y}) := \sum_{u\subseteq\mathcal{A},\,|u|=\ell} K_u(\mathbf{x}_u, \mathbf{y}_u) \tag{9}$$

and (8) gives the square norm of functions in the RKHS $H(K_{(\ell)})$.

Instead of trying to find point sets P such that $D(P_u; H(K_u))$ is small for all $u \subseteq \mathcal{A}$, one may try to find P such that $\mathcal{D}_{(\ell)}(P)$ is small for $\ell = 1, 2, \ldots, s$ or at least for $\ell \le 3$. It is shown that for relatively small n (in 1000's) and large s (say, $s = 64$), the Sobol' points have order-2 and higher-order discrepancies no smaller than those of random points [29]. It is challenging to construct point sets with smaller order-2 and higher-order discrepancies. We are interested in whether good lattice points can do better.

The order-ℓ discrepancy has two drawbacks. First, for an arbitrary point set P and arbitrary weights $\gamma_{s,u}$, computing $\mathcal{D}_{(\ell)}(P)$ is expensive: direct computation based on its definition is equivalent to computing $D(P_u; H(K_u))$ for each subset $u \subseteq \mathcal{A}$ with $|u| = \ell$, the number of which is $O(s^\ell)$. Second, the order-ℓ discrepancy does not have the shift-invariant property: for a point set P, its shifted version $P + \Delta := \{\{\mathbf{x}_k + \Delta\}, k = 1, \ldots, n-1\}$, where $\Delta \in [0,1)^s$, may have a different order-ℓ discrepancy. For example, consider a point set $P := \{k/n : k = 0, \ldots, n-1\}$ in $[0,1]$. It is easy to calculate that $\mathcal{D}_{(1)}(P) = \sqrt{3}/(3n)$. However, for $\Delta = 1/(2n)$, the shifted point set is $P + \Delta = \{(2k+1)/(2n) : k = 0, \ldots, n-1\}$ and $\mathcal{D}_{(1)}(P+\Delta) = \sqrt{3}/(6n) = \mathcal{D}_{(1)}(P)/2$.

The first drawback can be overcome if we use product weights (5) or [illegible]; see the next section. The second deficiency can be avoided by using the [illegible] (the mean is taken over all random shifts), defined by

$$\int_{[0,1]^s} \mathcal{D}^2_{(\ell)}(P + \Delta)\, d\Delta.$$

It turns out that this is related to the theory of the shift-invariant kernel.

3. The construction of good lattice rules. We are interested in constructing good lattice points such that their mean-squared order-ℓ discrepancies (as defined above) are small, at least for $\ell \le 3$. A suitable quality measure is crucial for this purpose. The theory of the shift-invariant kernel is useful.

3.1. Shift-invariant kernel. For an arbitrary reproducing kernel $K(\mathbf{x}, \mathbf{y})$, its associated shift-invariant kernel is defined as

$$K^{\mathrm{sh}}(\mathbf{x}, \mathbf{y}) := \int_{[0,1]^s} K(\{\mathbf{x} + \Delta\}, \{\mathbf{y} + \Delta\})\, d\Delta.$$

By shift-invariant, we mean that for arbitrary $\Delta \in [0,1)^s$,

$$K^{\mathrm{sh}}(\mathbf{x}, \mathbf{y}) = K^{\mathrm{sh}}(\{\mathbf{x} + \Delta\}, \{\mathbf{y} + \Delta\}) \qquad \forall \mathbf{x}, \mathbf{y} \in [0,1]^s.$$

It is shown in [9, 11] that for a point set P in (1), we have

$$\int_{[0,1]^s} D^2(P + \Delta; H(K))\, d\Delta = D^2(P; H(K^{\mathrm{sh}})). \tag{10}$$

This implies that there exists a shift $\Delta \in [0,1)^s$ such that

$$D(P + \Delta; H(K)) \le D(P; H(K^{\mathrm{sh}})).$$

In other words, $D(P; H(K^{\mathrm{sh}}))$ gives an upper bound on the value of $D(P+\Delta; H(K))$ with a good choice of Δ and measures the average performance of $D(P + \Delta; H(K))$

with respect to the random shifts Δ. Moreover, $D(P; H(K^{\rm sh}))$ is shift-invariant: i.e., $D(P+\Delta; H(K^{\rm sh})) = D(P; H(K^{\rm sh}))$ for any shift $\Delta \in [0,1)^s$. There is an added benefit to using the shift-invariant kernel: for a rank-1 lattice point set

$$P := P(\mathbf{z}) := \left\{ \left\{ \frac{k\mathbf{z}}{n} \right\} : k = 0, \ldots, n-1 \right\}, \tag{11}$$

the computational cost of evaluating the worst-case error $D(P(\mathbf{z}); H(K^{\rm sh}))$ is reduced. Indeed, from (2) and from the shift-invariant property of $K^{\rm sh}(\mathbf{x}, \mathbf{y})$, we have (see [9])

$$D^2(P(\mathbf{z}); H(K^{\rm sh})) = -\int_{[0,1]^s} K^{\rm sh}(\mathbf{x}, \mathbf{0})\, d\mathbf{x} + \frac{1}{n} \sum_{k=0}^{n-1} K^{\rm sh}(\mathbf{x}_k, \mathbf{0}). \tag{12}$$

Although $D(P; H(K))$ typically takes an $O(n^2)$ operation to evaluate for a general point set (see (2)), $D(P(\mathbf{z}); H(K^{\rm sh}))$ takes only an $O(n)$ operation to evaluate for a lattice point set.

3.2. Quality measures of lattice rules. In dimension $s \geq 3$ one normally finds lattice rules by computer searches based on some criterion of "goodness." There are a number of such criteria available; see [9, 18, 20]. Here we will use a criterion based on the worst-case error of the RKHS, whose kernel is the shift-invariant kernel of the kernel given in (4).

For the kernel (4), its associated shift-invariant kernel can easily be found to be

$$K^{\rm sh}_{s,\gamma}(\mathbf{x}, \mathbf{y}) = 1 + \sum_{\emptyset \neq u \subseteq \mathcal{A}} \gamma_{s,u} \prod_{j \in u} B_2(\{x_j - y_j\}),$$

where we have used $\int_0^1 \eta(\{x+\Delta\}, \{y+\Delta\}) d\Delta = B_2(\{x-y\})$. For an arbitrary point set P in (1), from (2) it follows that

$$D^2(P; H(K^{\rm sh}_{s,\gamma})) = \frac{1}{n^2} \sum_{i,k=0}^{n-1} \sum_{\emptyset \neq u \subseteq \mathcal{A}} \gamma_{s,u} \prod_{j \in u} B_2(\{x_{i,j} - x_{k,j}\}).$$

For the rank-1 lattice point set $P(\mathbf{z})$ in (11), based on (12) we have a simplification

$$D^2(P(\mathbf{z}); H(K^{\rm sh}_{s,\gamma})) = \frac{1}{n} \sum_{k=0}^{n-1} \sum_{\emptyset \neq u \subseteq \mathcal{A}} \gamma_{s,u} \prod_{j \in u} B_2\left(\left\{ \frac{kz_j}{n} \right\} \right).$$

Note that if the weights $\gamma_{s,u}$ are of the product form (5), the computation of the quantity $D^2(P; H(K^{\rm sh}_{s,\gamma}))$ is simpler. For example, for the rank-1 lattice point set $P(\mathbf{z})$ in (11), we have

$$D^2(P(\mathbf{z}); H(K^{\rm sh}_{s,\gamma})) = -1 + \frac{1}{n} \sum_{k=0}^{n-1} \prod_{j=1}^{s} \left[1 + \gamma_{s,j} B_2\left(\left\{ \frac{kz_j}{n} \right\} \right) \right]. \tag{13}$$

From the general relation (10) we have

$$\int_{[0,1]^s} D^2(P+\Delta; H(K_{s,\gamma}))\, d\Delta = D^2(P; H(K^{\rm sh}_{s,\gamma})).$$

We will use the worst-case error corresponding to the shift-invariant kernel $K^{\rm sh}_{s,\gamma}(\mathbf{x},\mathbf{y})$, i.e., $D(P;H(K^{\rm sh}_{s,\gamma}))$, as a quality measure for lattice rules. It depends on the weights $\gamma_{s,u}$ and is a mixture of the uniformity of various projections. Judged by such a measure, the goodness of a lattice point set depends not only on the point set itself, but also on the weights. A lattice point set with small $D(P;H(K^{\rm sh}_{s,\gamma}))$ does not necessarily have good low-order projections, say, order-2 projections; see section 4. Our purpose is to choose appropriate weights $\gamma_{s,u}$, such that good low-order projections are achieved, or such that the projections of some specific orders are optimized.

. . .. 1. Since the Bernoulli polynomial of degree 2 can be expressed as

$$B_2(x) = \frac{1}{2\pi^2} \sum_{h=-\infty}^{\infty}{}' \frac{e^{2\pi i h x}}{h^2}, \qquad x \in [0,1], \tag{14}$$

where the prime on the sum indicates that the $h = 0$ term is omitted, the shift-invariant kernel $K^{\rm sh}_{s,\gamma}(\mathbf{x},\mathbf{y})$ can be written as

$$K^{\rm sh}_{s,\gamma}(\mathbf{x},\mathbf{y}) = 1 + \sum_{\emptyset\ne u\subseteq\mathcal{A}} \hat\gamma_{s,u} \prod_{j\in u} \sum_{h=-\infty}^{\infty}{}' \frac{e^{2\pi i h(x_j-y_j)}}{h^2},$$

where

$$\hat\gamma_{s,u} = \frac{\gamma_{s,u}}{(2\pi^2)^{|u|}}.$$

This is the reproducing kernel of a [illegible] with the weights $\hat\gamma_{s,u}$ and $\alpha = 2$; see [6]. If the weights $\gamma_{s,u}$ are of the product form (5), then the weights $\hat\gamma_{s,u}$ are also of the product form

$$\hat\gamma_{s,u} = \prod_{j\in u} \hat\gamma_{s,j} \quad \text{with} \quad \hat\gamma_{s,j} = \frac{\gamma_{s,j}}{2\pi^2},$$

and the kernel $K^{\rm sh}_{s,\gamma}(\mathbf{x},\mathbf{y})$ can be written as

$$K^{\rm sh}_{s,\gamma}(\mathbf{x},\mathbf{y}) = \prod_{j=1}^{s} \left(1 + \hat\gamma_{s,j} \sum_{h=-\infty}^{\infty}{}' \frac{e^{2\pi i h(x_j-y_j)}}{h^2}\right).$$

This is a special case of Korobov kernel considered in [24].

Now consider the reproducing kernel $K_{(\ell)}(\mathbf{x},\mathbf{y})$ given in (9), which is related to the order-ℓ discrepancy defined in section 2.4. Its associated shift-invariant kernel is

$$K^{\rm sh}_{(\ell)}(\mathbf{x},\mathbf{y}) = \sum_{u\subseteq\mathcal{A},\,|u|=\ell} \gamma_{s,u} \prod_{j\in u} B_2(\{x_j - y_j\}).$$

For an arbitrary point set P in (1), from (2) we have

$$D^2(P;H(K^{\rm sh}_{(\ell)})) = \frac{1}{n^2} \sum_{i,k=0}^{n-1} \sum_{u\subseteq\mathcal{A},\,|u|=\ell} \gamma_{s,u} \prod_{j\in u} B_2(\{x_{i,j} - x_{k,j}\}). \tag{15}$$

For the rank-1 lattice point set $P(\mathbf{z})$ in (11), from (12) we have a simplification

$$D^2(P(\mathbf{z});K^{\rm sh}_{(\ell)}) = \frac{1}{n} \sum_{k=0}^{n-1} \sum_{u\subseteq\mathcal{A},\,|u|=\ell} \gamma_{s,u} \prod_{j\in u} B_2\left(\left\{\frac{kz_j}{n}\right\}\right).$$

Based on (10), it is obvious that $D(P;K^{\rm sh}_{(\ell)})$ gives an upper bound on the order-ℓ discrepancy of the shifted point set $P+\Delta$ by a good choice of Δ.

3.3. The elementary order-ℓ discrepancy. In the rest of this paper we are interested in the [illegible] weights (see [6]), that is,

$$\gamma_{s,\emptyset} = 1,\ \gamma_{s,u} := \Gamma_{|u|}, \tag{16}$$

for some nonnegative numbers $\Gamma_1, \ldots, \Gamma_s$ (they may depend on the dimension s). The order-dependent weights depend on u only through its order. A benefit of using order-dependent weights is that there exists a fast algorithm to compute $D(P; H(K^{\mathrm{sh}}_{(\ell)}))$ as shown below. The order-dependent weights are also of the product form if and only if $\Gamma_\ell = \beta^\ell$ for some constant β.

For an arbitrary point set P in (1), its [illegible] ℓ [illegible], denoted by $G_{(\ell)}(P)$, is defined as

$$G^2_{(\ell)}(P) := \frac{1}{n^2} \sum_{i,k=0}^{n-1} \sum_{u \subseteq \mathcal{A},\, |u|=\ell} \prod_{j \in u} B_2(\{x_{i,j} - x_{k,j}\}).$$

The value of $G_{(\ell)}(P)$ is equal to $D(P; H(K^{\mathrm{sh}}_{(\ell)}))$ in (15) with $\gamma_{s,u} = 1$ for all $u \subseteq \mathcal{A}$ with $|u| = \ell$. If P is a lattice point set (11), then

$$G^2_{(\ell)}(P(\mathbf{z})) = \frac{1}{n} \sum_{k=0}^{n-1} \sum_{u \subseteq \mathcal{A},\, |u|=\ell} \prod_{j \in u} B_2\left(\left\{\frac{kz_j}{n}\right\}\right).$$

If P is a set of independent samples from the uniform distribution over $[0,1]^s$, then

$$E[G^2_{(\ell)}(P)] = \frac{1}{6^\ell n} \binom{s}{\ell}. \tag{17}$$

Obviously, for order-dependent weights (16), $D(P; H(K^{\mathrm{sh}}_{(\ell)}))$ given in (15) can be expressed in terms of the elementary order-ℓ discrepancies:

$$D^2(P; H(K^{\mathrm{sh}}_{(\ell)})) = \Gamma_\ell\, G^2_{(\ell)}(P),$$

and the worst-case error $D(P; H(K^{\mathrm{sh}}_{s,\gamma}))$ can then be expressed as the weighted sum of the elementary order-ℓ discrepancies:

$$D^2(P; H(K^{\mathrm{sh}}_{s,\gamma})) = \sum_{\ell=1}^{s} D^2(P; K^{\mathrm{sh}}_{(\ell)}) = \sum_{\ell=1}^{s} \Gamma_\ell\, G^2_{(\ell)}(P). \tag{18}$$

The elementary order-ℓ discrepancy $G_{(\ell)}(P)$ measures the quality of all order-ℓ projections taken together. Its advantage is that it does not depend on any weight (it depends only on the point set itself). We will use it to compare different (lattice) point sets. We will show that such a measure is more informative than the worst-case error.

The formulas for the elementary order-ℓ discrepancies involve quantities of the form

$$\sum_{u \subseteq \mathcal{A},\, |u|=\ell} \prod_{j \in u} C_j \quad \text{for some} \quad C_1, C_2, \ldots, C_s.$$

Such quantities can be efficiently computed using a recursive formula as shown in [6]. This recursive method will be used in our algorithms below.

3.4. The construction algorithms. Two constructions of lattice rules will be considered: the Korobov and the component-by-component (CBC) constructions. They are studied in [12] and [22] under the classical quality measure P_α. Here we use a weighted version of P_α with a good choice of weights. The theory of weighted function spaces yields rich results on the constructions of lattice rules. For practical applications, the principal difficulty is to choose appropriate weights. An attempt to choose product weights was made in [28] using a matching strategy. It should be emphasized that the resulting generator using a weighted version of P_α will almost always be quite different from that produced by using P_α (see section 4). We assume that n is a prime and the weights are order-dependent.

ALGORITHM 1 (Korobov construction).

For a fixed dimension s and for given order-dependent weights $\Gamma_1, \Gamma_2, \ldots$, find the optimal Korobov-form generator

$$\mathbf{z}(a_s) := (1, a_s, \ldots, a_s^{s-1}) \,(\mathrm{mod}\, n),$$

with $a_s \in \{1, \ldots, n-1\}$, by minimizing the square of the worst-case error

$$D^2(P(\mathbf{z}(a_s)); H(K^{\mathrm{sh}}_{s,\gamma})) = \frac{1}{n} \sum_{\ell=1}^{s} \sum_{k=0}^{n-1} \Gamma_\ell \sum_{u \subseteq \mathcal{A},\, |u|=\ell} \prod_{j \in u} B_2\left(\left\{\frac{k a_s^{j-1}}{n}\right\}\right).$$

ALGORITHM 2 (component-by-component construction).

For given weights $\Gamma_1, \Gamma_2, \ldots$, the generator $\mathbf{z}$ is found one component at a time:

1. Set z_1, the first component of $\mathbf{z}$, to 1.

2. For $s = 2, \ldots, s_{\max}$, with the components $z_1, \ldots, z_{s-1}$ fixed, find $z_s \in \{1, \ldots, n-1\}$ such that

$$D^2(P(z_1, \ldots, z_s); H(K^{\mathrm{sh}}_{s,\gamma})) = \frac{1}{n} \sum_{\ell=1}^{s} \sum_{k=0}^{n-1} \Gamma_\ell \sum_{u \subseteq \mathcal{A},\, |u|=\ell} \prod_{j \in u} B_2\left(\left\{\frac{k z_j}{n}\right\}\right) \tag{19}$$

is minimized.

The CBC lattice rules have the advantage of being extensible in dimension s if the weights are independent of s, and they achieve the (strong) tractability error bound under appropriate conditions on the weights [6]. A faster CBC algorithm was developed in [19]. The error bounds of Korobov rules in weighted spaces were studied in [30] for product weights (the same analysis applies to nonproduct weights). Faster Korobov algorithms are also desirable. We are mainly interested in the potential possibility of these constructions in achieving good elementary order-ℓ discrepancies by suitably choosing the weights $\Gamma_1, \Gamma_2, \ldots$.

If the order-dependent weights are also of the product form, i.e., $\Gamma_\ell = \beta^\ell$ for some β, then a more efficient way to compute $D^2(P(\mathbf{z}); H(K^{\mathrm{sh}}_{s,\gamma}))$ is to use the formula (13). In this case, the quality of low-order projections of the resulting lattice points can be [illegible] to the parameter β, and thus this parameter should be chosen carefully to reflect the relative importance of ANOVA terms of different orders (for this reason, product weights are not the focus of this paper).

4. Good lattice points in high dimensions: How well are their projections distributed? We take a completely different strategy from [6] to investigate the quality of good lattice points; namely, we focus on the [illegible] of different orders. This allows us to assess the quality of the projections of some selected orders

and to examine the possible advantages of lattice points over digital nets and random points. Note that an [illegible] lattice point set (11) with prime n has the same order-1 projections, namely, $\{k/n : k = 0, 1, \ldots, n-1\}$, which are [illegible] perfectly distributed. Thus we need only focus on order-2 and higher-order projections.

The formula (18) indicates that the square worst-case error $D^2(P; H(K^{\mathrm{sh}}_{s,\gamma}))$ is the [illegible] of the square elementary order-ℓ discrepancies. The weights allow greater or smaller emphasis on the projections of different orders and affect the goodness of projections of various orders. The choice of the weights should reflect the characteristic of the problems at hand. We consider two choices of order-dependent weights:

- [illegible] (A): $\Gamma_1 = \Gamma_2 = 1$, and $\Gamma_\ell = 0$ for $\ell \geq 3$.
- [illegible] (B): $\Gamma_1 = \Gamma_2 = \Gamma_3 = 1$, and $\Gamma_\ell = 0$ for $\ell \geq 4$.

The corresponding lattice rule (found by Algorithm 1 or 2) is known as (Korobov or CBC) lattice rule (A) or (B). The choice (A) puts all emphasis on order-2 projections and thus may result in lattice rules with optimal order-2 projections, while the choice (B) puts emphasis on both order-2 and order-3 projections. The relative size of Γ_3 with respect to Γ_2 is important. The choice in (B) is intended for use with finance problems in section 5 and is based on the matching strategy in [28].

We compare the Korobov or CBC lattice rule (A) or (B) with the Sobol' points [25] by comparing their elementary order-ℓ discrepancies. The root mean-squared elementary order-ℓ discrepancy (see (17)), is included as a benchmark.

We are also interested in the following problem: given a method of construction, say, the Korobov or CBC construction, with the freedom of choosing order-dependent weights, what is the [illegible] of the elementary order-ℓ discrepancy which can be achieved by this construction for a [illegible] ℓ? This value and the mean value for a random point set can be used as benchmarks. They indicate how good (or bad) the order-ℓ projections in the optimal (or average) case can be, implying the possibility or impossibility of good lattice points.

It turns out that for a [illegible] ℓ with $1 < \ell \leq s$, the optimal elementary order-ℓ discrepancy, which can be achieved by the Korobov or CBC method, can be easily found: one just chooses the weights to be

$$\Gamma_\ell = 1, \quad \text{but} \quad \Gamma_j = 0 \quad \text{for} \quad j \neq \ell. \tag{20}$$

This choice of weights in the Korobov or CBC algorithm results in lattice points achieving the minimum elementary order-ℓ discrepancy among all possible order-dependent weights using the Korobov or CBC algorithm, respectively. (An interesting problem is the following: what is the minimum value of the elementary order-ℓ discrepancy without restricting a method of construction?)

Table 1 presents the comparisons of the elementary order-ℓ discrepancies for $s = 64$. The optimal values of the elementary order-ℓ discrepancies (obtained as indicated above) for the Korobov or CBC construction are also included. The comparisons clearly indicate the potential possibility and limitations of good lattice points. We observe the following:

- For $\ell = 1$, lattice points (A) and (B) (and Sobol' points) have elementary order-1 discrepancies and convergence order much better than those of random points.
- For $\ell = 2$, lattice points (A) and (B) have elementary order-2 discrepancies much better than those of the Sobol' points and random points. The convergence order of the elementary order-2 discrepancies of lattice points (A)

TABLE 1

Shown are the elementary order-ℓ discrepancies and the convergence orders in dimension $s = 64$. For the Sobol' points, $n = 2^8, 2^{10}$, and 2^{12}. The convergence order (i.e., the value r in an expression of the form $O(n^{-r})$) is estimated from linear regression on the empirical data. "Mean" in the third column is the root mean square elementary order-ℓ discrepancy; see (17)*. The optimal values of the elementary order-ℓ discrepancies are obtained (for the Korobov and CBC constructions) using the weights* (20) *for each fixed ℓ.*

and (B) is much faster than that of the Sobol' points (the Sobol' points lost the advantage over random points in order-2 projections on average). Lattice points (A) give the best elementary order-2 discrepancies.

- For $\ell = 3$, the elementary order-3 discrepancies of lattice points (A) and (B) are similar to those of the Sobol' points and random points and are close to the optimal values. Lattice points (B) have elementary order-3 discrepancies better than those of lattice points (A).
- For $\ell \geq 4$, lattice points (A) and (B) have order-ℓ projections [illegible] than those of random points (this is a surprise). For $\ell \geq 4$, even the optimal elementary order-ℓ discrepancy, which can be achieved by the Korobov or CBC construction, is only slightly better than the mean values for random points (in Table 1 we do not give the numerical results for $\ell > 4$). It seems that for $\ell \geq 4$, if n is small (say, in 1000's) and s is large (say, $s > 50$), one should not expect to achieve much better order-ℓ projections than those of random points. There exists a limit for given n and s. This indicates the difficulty in achieving good higher-order projections.
- In all cases, the Korobov and CBC lattice points have similar behavior.

[illegible] 2. A lattice point set which achieves the optimal elementary order-ℓ discrepancy with $\ell > 2$ (see (20) for the construction of such a point set) may have very bad elementary order-2 discrepancy. For example, the lattice points which achieve the optimal elementary order-4 discrepancy have very bad elementary order-2 discrepancy. Thus the Korobov or CBC lattice points which achieve the optimal elementary order-ℓ discrepancy for $\ell \geq 4$ can be useful only when the integrand is dominated by order-ℓ ANOVA terms (and the possible advantage is very limited). Our interest in them is just due to the motivation to know what is the best possible order-ℓ discrepancy for a given ℓ and n. On the other hand, the lattice points found with the weights (A) and (B) have not only very good (order-1 and) order-2 projections but also higher-order projections no worse than those of random points. Note that an alternative

choice of weights $\Gamma_\ell = \beta^\ell$ with a "small" parameter β may also produce lattice points with good order-2 projections. The corresponding algorithm is more efficient but less robust (since the parameter β has strong influence on the quality as mentioned above).

The attempt to improve the elementary order-ℓ discrepancies for $\ell \geq 4$ does not turn out to be rewarding for small n in high dimensions. To achieve better higher-order projections, one has to enlarge n (or find better construction beyond Korobov or CBC). In practice, we recommend using lattice rules (A). Due to their good projection property, it is reasonable to expect that they have good performance for favorable functions (dominated by order-1 and order-2 terms), while doing no harm for unfavorable ones (say, functions dominated by high-order terms). In this sense they are robust, perhaps opening the way to wider use.

We turn to the classical lattice rules. By "classical lattice rules" we mean the rules found by using the classical quality measure P_α in searching algorithms. For simplicity of presentation, we assume $\alpha = 2$; then P_2 has the following form (see [20]):

$$P_2 = \sum_{\mathbf{h}\cdot\mathbf{z}\equiv 0}{}' \frac{1}{\overline{h}_1^{\,2} \cdots \overline{h}_s^{\,2}},$$

where $\mathbf{h} = (h_1, \ldots, h_s)$, $\mathbf{h} \cdot \mathbf{z} = h_1 z_1 + \cdots + h_s x_s$, and $\overline{h}_j = \max(1, |h_j|)$.

Algorithms 1 and 2 in section 3 have parallels when P_2 is used; see [22]. Table 2 gives a comparison of the elementary order-ℓ discrepancies for the classical lattice rules in dimension $s = 64$. We observe that both the Korobov and CBC lattice points constructed based on P_2 [illegible]. Moreover, the CBC lattice rules also have very bad elementary higher-order discrepancies. Such a phenomenon may occur even in a relatively small dimension, say $s = 15$.

Why does the use of the classical quality measure P_2 result in lattice rules with such a poor distribution property? The reason is that the measure P_2 is the square worst-case error $D^2(P(\mathbf{z}); H(K^{\mathrm{sh}}_{s,\gamma}))$ given in (19) with a special choice of order-dependent weights:

$$\Gamma_j = (2\pi^2)^j, \quad j = 1, \ldots, s. \tag{21}$$

(Note that this choice is equivalent to product weights: $\gamma_{s,j} = 2\pi^2, j = 1, \ldots, s$. See also [8].) Indeed, with this choice of order-dependent weights, from (19) and (14), we

have

$$
\begin{aligned}
D^2(P(\mathbf{z}); H(K^{\mathrm{sh}}_{s,\gamma})) &= -1 + \frac{1}{n}\sum_{k=0}^{n-1}\prod_{j=1}^{s}\left(1 + 2\pi^2 B_2\left(\left\{\frac{kz_j}{n}\right\}\right)\right) \\
&= -1 + \frac{1}{n}\sum_{k=0}^{n-1}\prod_{j=1}^{s}\left(1 + {\sum_{h=-\infty}^{\infty}}' \frac{\exp(2\pi i h k z_j/n)}{h^2}\right) \\
&= -1 + \frac{1}{n}\sum_{k=0}^{n-1}\sum_{\mathbf{h}\in\mathbf{Z}^s}\prod_{j=1}^{s}\frac{\exp(2\pi i h_j k z_j/n)}{\overline{h}_j^{\,2}} \\
&= -1 + \sum_{\mathbf{h}\in\mathbf{Z}^s}\frac{1}{n}\sum_{k=0}^{n-1}\frac{(\exp(2\pi i \mathbf{h}\cdot\mathbf{z}/n))^k}{\prod_{j=1}^{s}\overline{h}_j^{\,2}} \\
&= -1 + \sum_{\mathbf{h}\cdot\mathbf{z}\equiv 0}\frac{1}{\overline{h}_1^{\,2}\cdots\overline{h}_s^{\,2}} \\
&= {\sum_{\mathbf{h}\cdot\mathbf{z}\equiv 0}}' \frac{1}{\overline{h}_1^{\,2}\cdots\overline{h}_s^{\,2}} = P_2,
\end{aligned}
$$

where $\mathbf{Z}^s$ is the set of all s-dimensional vectors of integers.

Thus using P_2 as a quality measure in the optimizing search is equivalent to using the worst-case error $D(P(\mathbf{z}); H(K^{\mathrm{sh}}_{s,\gamma}))$ with the very special order-dependent weights given in (21). The choice of weights (21) puts much more significant emphasis on higher-order projections than on lower-order ones. As we showed, an emphasis on higher-order projections does not seem to improve the elementary higher-order discrepancies but may [illegible] 2 [illegible]. In other words, the classical weights are too large to yield good results. We believe that this is the reason why the classical lattice rules may be not suitable for high-dimensional finance problems, for which the order-1 and order-2 ANOVA terms play the dominant role [28]. The classical lattice rules are optimal for certain [illegible] function classes (see [20]), but they need not be good for practical use. The functions in such an artificial class have dimension structure quite different from that of the functions from finance as analyzed in [28].

5. Pricing path-dependent options and American options. The Korobov or CBC lattice points (A) and (B) constructed in the previous section have good performance in their low-order projections even in high dimensions: they have elementary order-1 and order-2 discrepancies much better than those of the Sobol' points and random points and have elementary order-3 and higher-order discrepancies no worse. It is known that in finance applications, while the nominal dimension can be very large, the effective dimension in the superposition sense is often very small; see [26, 27]. This strongly motivates us to use lattice points with good low-order projections. In this section, we demonstrate the practical performance of the new lattice points. The finance problems we consider consist in pricing arithmetic Asian options and pricing American put options and American-Bermudan-Asian options. We test the robustness of the new lattice points by comparing their performance on different problems and on different model parameters.

5.1. Arithmetic Asian options. Consider an Asian call option based on the arithmetic average of the underlying asset. The terminal payoff is

$$g_A(S_{t_1},\dots,S_{t_s}) = \max\left(0, \frac{1}{s}\sum_{j=1}^{s} S_{t_j} - K\right),$$

where K is the strike price at the expiration date T and S_{t_j} are the prices of the underlying asset at equally spaced times $t_j = j\Delta t,\ j = 1,\dots,s,\ \Delta t = T/s$. We assume that under the risk-neutral measure the asset follows geometric Brownian motion (Black–Scholes model):

$$dS_t = rS_t dt + \sigma S_t dB_t, \tag{22}$$

where r is the risk-free interest rate, σ is the volatility, and B_t is the standard Brownian motion. The value of the option at $t = 0$ is

$$C_0 = E_Q[e^{-rT} g_A(S_{t_1},\dots,S_{t_s})],$$

where $E_Q[\cdot]$ is the expectation under the risk-neutral measure Q. The simulation method is based on the analytical solution to (22)

$$S_t = S_0 \exp((r - \sigma^2/2)t + \sigma B_t)$$

and on a generation of the Brownian motion

$$(B_{t_1},\dots,B_{t_s})^T = A\,(z_1,\dots,z_s)^T,$$

where $z_j \sim N(0,1),\ j = 1,\dots,s$, are independent and identically distributed standard normal variables and A is an $s \times s$ matrix A satisfying $AA^T = V$ with $V = (\min(t_i,t_j))_{i,j=1}^{s}$. The standard construction (i.e., sequential sampling) takes A to be the Cholesky decomposition of V.

5.1.1. The efficiency improvement techniques. To improve QMC, we use dimension reduction techniques, such as the Brownian bridge (BB) (see [3, 17]), and the principal component analysis (PCA) (see [1]), and variance reduction techniques, such as antithetic variates, control variates, and their combination. We take the payoff of the geometric average Asian call option (which is analytically tractable) as a control variable: $g_G(S_{t_1},\dots,S_{t_s}) = \max(0, \prod_{j=1}^{s} S_{t_j}^{1/s} - K)$. Note that

$$E_Q[g_A(\cdot)] = E_Q\left[g_A(\cdot) - b\, g_G(\cdot)\right] + b\, E_Q[g_G(\cdot)],$$

where b is some multiplier b. The optimal b^* is obtained by minimizing the variance of $g_A - bg_G$. The same multiplier b^* will be used in QMC. Importance sampling and weighted importance sampling in QMC can also be effectively used by choosing a suitable importance density. This problem will be studied in the future.

5.1.2. The algorithms and the error estimation. We compare the efficiency of the following QMC algorithms with that of MC:

- the Korobov and CBC lattice rules (A) and (B);
- the classical Korobov or CBC lattice rules constructed based on P_2 (see [22]).
- the QMC algorithm based on the Sobol' points.

In order to get an estimation of the accuracy for each method, we compute the sample variance and the standard deviations. For the Sobol' points, we use a digital-scrambling method as used in [28]. For lattice point set $P := \{\mathbf{x}_k\}$, we use a random shift method; see [21]. Define

$$Q_{n,s}(f;\Delta) := \frac{1}{n}\sum_{k=0}^{n-1} f(\{\mathbf{x}_k + \Delta\})$$

and

$$\overline{Q}_{n,s}(f) := \frac{1}{m}\sum_{j=1}^{m} Q_{n,s}(f;\Delta_j), \tag{23}$$

where $\Delta_1, \cdots, \Delta_m$ are independent and identically distributed random vectors, uniformly distributed over $[0,1]^s$. The sample variance of the estimate (23) is estimated by

$$\widetilde{\mathrm{Var}}[\overline{Q}_{n,s}(f)] = \frac{1}{m(m-1)}\sum_{j=1}^{m}[Q_{n,s}(f;\Delta_j) - \overline{Q}_{n,s}(f)]^2.$$

The standard deviation is just the square root of the sample variance. The [illegible] or the [illegible] of the estimate (23) with respect to the crude MC estimate (i.e., without variance reduction and dimension reduction) is defined by

$$\text{Eff}\ [\overline{Q}_{n,s}] := \widetilde{\mathrm{Var}}(Q_{\mathrm{crudeMC}}(f))/\widetilde{\mathrm{Var}}[\overline{Q}_{n,s}(f)],$$

where $\widetilde{\mathrm{Var}}(Q_{\mathrm{crudeMC}}(f))$ is the sample variance of the crude MC estimate based on mn samples. The numerical results are presented in Tables 3 and 4.

5.1.3. The numerical results. Tables 3 and 4 present the comparisons for pricing arithmetic Asian options. The experiments show the following:

- The classical Korobov or CBC lattice rules constructed based on P_2 behave very badly. Their performance can be worse than that of MC. The reason is that they have very bad elementary order-2 discrepancies as shown in section 4. Thus such rules are unsuitable for functions for which order-2 ANOVA terms are important.
- The efficiency of lattice rules (A) and (B) is dramatically improved. They are more efficient than the Sobol' points when standard construction is used to generate the Brownian motion, and are at the same level of accuracy with the Sobol' points if dimension reduction techniques are used (since the possible bad order-2 and higher-order projections of Sobol' points in latter dimensions now have less influence due to the reduced effective dimensions).
- The relative efficiency of QMC algorithms is affected by the strike price K: the smaller the K is, the more efficient the QMC algorithms are. This is consistent with the fact that a smaller K leads to functions of lower superposition dimension (small K leads to integrands dominated mainly by order-1 ANOVA terms); see [27].
- Dimension reduction and variance reduction techniques provide further significant improvement for QMC (dimension reduction techniques are useless in MC). In most cases, lattice rules (A) and (B) combined with these techniques are more efficient than the Sobol' points combined with the same techniques.

TABLE 3

Shown are the standard deviations and relative efficiency (in parentheses) with respect to crude MC for the arithmetic Asian option with $m = 100$ replications for $s = 64$ ($n = 4001$ for MC and good lattice points, $n = 4096$ for the Sobol' points). The parameters are $S_0 = 100, \sigma = 0.2, T = 1.0, r = 0.1$. In the second column are the path generation methods: STD—standard construction (sequential sampling), BB—Brownian bridge, PCA—principal component analysis.

5.2. American options. American options are derivative securities for which the holder of the security can choose the time of exercise. The American option's additional complication—finding the optimal time for exercise—makes pricing it one of the most challenging problems in finance. Recently, several simulation methods are proposed for the valuation of American options (see, among others, [2, 15]). Our experiments are based on the least-square Monte Carlo (LSM) method [15].

Consider an American option which can be exercised only at discrete times $t_j = j\Delta t,\ j = 1, \ldots, s,\ \Delta t = T/s$ (such options are sometimes called Bermudan options). The payoff function is assumed to be $g(t, S_t)$, where S_t is the asset price. The risk-neutral dynamics for the asset price are the same as in (22). There are several major steps in the LSM method (see [15] for a more detailed description):

- Generate N realization paths $\{S_t^i, t = 0, t_1, \ldots, t_s; i = 1, \ldots, N\}$.

- Determine for each path i the optimal exercise time τ_i^*. This is done by comparing (i) the payoff from immediate exercise and (ii) the expected payoff from keeping the option alive (i.e., the continuation value). The continuation value is estimated by a least-square regression using the cross-sectional information provided by simulation. This procedure is repeated recursively going back in time from T.
- Estimate the option's price by

$$\hat{p} = \frac{1}{N} \sum_{i=1}^{N} e^{-r\tau_i^*} g(\tau_i^*, S_{\tau_i^*}),$$

where τ_i^* is the optimal exercise time for the ith path.

Note that the problem of pricing American options does not fit the framework of multivariate integration. However, we may still hope that the better distribution property of quasi-random numbers may lead to a more accurate estimate. Instead of using random points in the path generation in LSM, one may try to use quasi-random numbers and BB in path generation; see [4, 13]. In our experiments, we use good lattice points with good low-order projections and the Sobol' points. Moreover, we will also try to use principal component analysis (PCA) to generate the paths. The same method for error estimation as in section 5.1 is used here. All results for the examples below are obtained using the same basis functions as in [15].

We first look at American put options. The results are presented in Table 5 for $K = 100,\ \sigma = 0.2,\ T = 1.0,\ r = 0.1$ (with 64 exercise periods). We observe that with the standard construction the Korobov or CBC lattice points (A) and (B) consistently reduce the variance compared to crude MC (i.e., LSM based on random points) by factors of about 3 and are more efficient than the Sobol' points. Moreover, by using BB or PCA, their efficiency can be further increased in most cases, with the variance reduction factor up to 10 (but BB does not seem to improve Korobov lattice (B) in this experiment). In BB or PCA, the lattice points (A) and (B) have similar performance with the Sobol' points.

Following [15], we now consider an American-Bermudan-Asian option on the average of the stock prices during a given time horizon. It matures in one year and it cannot be exercised during the first quarter. The payoff function of this option at time t is given by $\max(0, A_t - K)$, where K is the strike price and A_t is the arithmetic average of the underlying asset during the period three months prior to time 0 (the valuation date) to time t. The results are presented in Table 6 for different pairs (A_0, S_0) and for $K = 100,\ \sigma = 0.2,\ T = 1.0,\ r = 0.1$ (the time is discretized into 64 steps). We observe, once more, that the Korobov or CBC lattice points (A) and (B) consistently reduce the variance compared to crude MC by factors up to 50 (with standard construction), and are more efficient than the Sobol' points. In the case of BB or PCA construction, the lattice points reduce the variance by factors up to 300 and have performance similar to that of the Sobol' points.

In both examples, quasi-random numbers and dimension reduction techniques in LSM have good performance. The potential difficulty with correlations between the paths did not turn to be much of a problem. The theoretical basis for using quasi-random numbers and dimension reduction in LSM is under investigation. More complicated American-type securities are worth considering, both empirically and theoretically.

A remarkable property of (Korobov or CBC) lattice points (A) is their robustness, since they are useful in a broad sense for financial simulations. Such lattice points

TABLE 5

Shown are the standard deviations and relative efficiency (in parentheses) with respect to crude MC for American put option with $m = 100$ replications ($n = 4001$ for MC and good lattice point, and $n = 4096$ for the Sobol' points). The parameters are $K = 100, \sigma = 0.2, T = 1.0, r = 0.1$. The exercise periods are $s = 64$. In the second column are the path generation methods (STD—standard construction).

are different from the ones constructed in [28], which are problem-dependent (they have similar efficiency). Also, the difficulty of choosing suitable weights is partially avoided (since we could use the same weights regardless of the problems at hand, the dimension, and the methods of path generation). We thus recommend using lattice points (A) in practice and present in the appendix (see Tables 7 and 8) some generators (Korobov and CBC) for $n = 1009$ and $n = 4001$ up to dimensions $s = 128$ (faster searching for generators for larger n and s is an important future work). Note that once the generators are found (or given), lattice points are much easier to generate than random points and other quasi-random numbers.

6. Conclusions. The classical constructions of lattice points are not as good as they ought to be, since they do not put special emphasis on lower-order projections. Good lattice rules can be nonuniversal or universal. Nonuniversal rules depend on the specific problem at hand and thus are of limited interest. Universal rules do not depend on a particular problem (but may depend on some feature of a wide range of problems) and thus have great importance. This paper focuses on universal good lattice rules.

Because of the common feature of low superposition dimension for high-dimensional integrands in finance, we proposed methods to construct good lattice points whose low-order projections are well-behaved. The new lattice points are shown to have better two-dimensional projections than Sobol' points and random points even in high dimensions. It turns out that a superior distribution property in order-2 projections of a lattice point set is sufficient and necessary to achieve high efficiency for many high-dimensional finance problems. Indeed, the new lattice points are significantly more efficient than MC and are more efficient than the Sobol' points in most cases for pricing path-dependent options and American options. A nice surprise revealed is the robustness property of the new lattice rules; i.e., they have a good projection property and are useful for a wide range of problems. In searching for robust lattices, the lattice points (A) offer a good compromise, since they are efficient for problems for which the order-1 and order-2 ANOVA terms play the dominant role. Such problems occur naturally in finance (especially when a dimension reduction technique is used); see [27].

We stress that the quality measure is very important for searching good lattice points in high dimensions. If the worst-case error of certain weighted Korobov space is used as a quality measure, then the choice of weights is crucial [28]. A bad choice of weights may lead to bad lattice points. Large weights on the higher-order terms may lead to lattice points with poor quality of order-2 projections which are inappropriate for functions from finance. If there is no information a priori about the integrand, then it is safer to use lattice points with good low-order projections as constructed in this paper, since they can improve the accuracy for favorable functions, while doing no harm for unfavorable ones. In high dimensions, the lattice points constructed based on the classical measure P_α are especially dangerous because of the bad order-2 (and possibly higher-order) projections due to the large weights. Note that the uniformity on some specific order of projections is measured by the elementary order-ℓ discrepancy, which allows us to assess the quality of the projections of some selected orders and is more informative than usual quality measure. The new measure is especially useful for comparing the goodness of different point sets.

The construction of point sets with good low- and moderate-order projections deserves further attention. For American options, though the new lattice points and the dimension reduction techniques improve the LSM method, the theoretical basis of such procedures for the LSM method is yet unknown and is worth studying. This would be helpful for better understanding the question of which QMC point set is better adopted to American options, and would be helpful for finding better techniques to improve the efficiency.

Appendix. Generators of Korobov and CBC with the weights (A).

TABLE 7

Shown are generators with the optimal order-2 projections (with the weights (A)*) up to dimension* $s = 128$ *for* $n = 1009$. *The optimal Korobov generator* $(1, a_s, \ldots, a_s^{s-1}) \pmod n$ *is determined separately for each dimension* s. *The CBC generator* $(z_1, z_2, \ldots, z_s)$ *is found sequentially, one component at a time.*

FAST NUMERICAL METHODS FOR BERNOULLI FREE BOUNDARY PROBLEMS*

CHRISTOPHER M. KUSTER†, PIERRE A. GREMAUD†, AND RACHID TOUZANI‡

Abstract. The numerical solution of the free boundary Bernoulli problem is addressed. An iterative method based on a level-set formulation and boundary element method is proposed. Issues related to the implementation, the accuracy, and the generality of the method are discussed. The efficiency of the approach is illustrated by numerical results.

Key words. Bernoulli, free boundary, level set, boundary elements

AMS subject classifications. 65N38, 35R35, 76B99

DOI. 10.1137/06065444X

1. Introduction.

Bernoulli free boundary problems find their origin in the description of free surfaces for ideal fluids [12]. There are, however, numerous other applications leading to similar formulations; see, for instance, [11]. For concreteness, we focus on the exterior Bernoulli problem. Let Ω be a bounded domain in $\mathbb{R}^2$. The exterior Bernoulli problem consists in seeking a bounded domain $A \supset \Omega$ and a function u defined on $\bar{A} \setminus \Omega$ such that

$$\Delta u = 0 \qquad \text{in } A \setminus \overline{\Omega}, \tag{1.1}$$

$$u = 1 \qquad \text{on } \partial\Omega, \tag{1.2}$$

$$u = 0 \qquad \text{on } \partial A, \tag{1.3}$$

$$\frac{\partial u}{\partial n} = \mu \qquad \text{on } \partial A, \tag{1.4}$$

where μ is given. In the previous example, one can think of u as a streamfunction and of Ω as an obstacle. Taking into account (1.3), condition (1.4) can be written as $|\nabla u| = |\mu|$ and corresponds, for fluid applications, to Bernoulli's principle; see, for instance, [9].

The above problem has been extensively studied; see [11] for general remarks. For a convex simply connected bounded domain Ω, it is known that for any negative constant $\mu < 0$, the above problem admits a unique classical solution. Further, the free boundary ∂A has regularity $\mathcal{C}^{2,\alpha}$; see [21, Theorem 1.1].[1] The convexity assumption is necessary for uniqueness, as counterexamples show (see [11, Example 13]). The study of the interior Bernoulli problem is more delicate, and not even convexity can ensure uniqueness.

[1]The result is, in fact, established in the more general case of the p-Laplacian in [21] and is generalized to nonconstant μ in [22].

There are roughly two ways of tackling such problems numerically. First, a variational formulation may be considered and the corresponding cost function minimized [19, 23, 28]; this requires the calculations of shape gradients. Second, a fixed point-type approach can be set up where a sequence of elliptic problems is solved in a sequence of converging domains, those domains being obtained through some updating rule at each iteration [6, 11, 24]. The method studied in this paper falls in the latter category.

Two simple generic numerical tools are combined. First, the interface is represented through a level-set formulation as described in section 2. Second, the elliptic part of the problem is solved through the use of a boundary element method; see section 3 (see [14] for another example of a method involving those two tools in a different setting). The proposed method is thus conceptually simpler than the shape optimization approach. Since it requires, in principle, only the calculations of quantities being defined on the interface or close to it, it is potentially faster than the finite difference approaches of, for instance, [6, 11, 24] or more generally of immersed interface-type methods [27]. The feasibility of the algorithm and its complexity are investigated in section 4.

A general overview of the strategy is as follows: the potential problem is solved with one of the conditions on the free boundary omitted, and then the omitted condition is used to update the location of the free boundary. More specifically, given an initial domain $A_0 \supset \bar{\Omega}$, the simplest variant of this type consists in solving the sequence of problems

$$\Delta u_k = 0 \qquad \text{in } A_k \setminus \overline{\Omega}, \qquad k = 0, 1, 2, \ldots, \tag{1.5}$$

$$u_k = 1 \qquad \text{on } \partial\Omega, \tag{1.6}$$

$$\partial_n u_k = \mu \qquad \text{on } \partial A_k. \tag{1.7}$$

For a given domain A_k, it is well known that problem (1.5)–(1.7) admits a unique solution; see, for instance, [15, Theorem 5.1]. The new domain A_{k+1} is found by moving ∂A_k in its normal direction so that u_k vanishes there. Let $P_k \in \partial A_k$; to first order, we have

$$u_k(P_{k+1}) \approx u_k(P_k) + \mu\, d_k,$$

where $P_{k+1} = P_k + n_k d_k$, n_k being the outer unit normal to ∂A_k at P_k. The new point P_{k+1}, or similarly the distance d_k, is determined by the requirement $u_k(P_{k+1}) = 0$, i.e., $d_k = \frac{-u_k(P_k)}{\mu}$. The free boundary is thus updated according to[2]

$$\partial A_{k+1} = \partial A_k - \frac{u_k}{\mu}\, n_k. \tag{1.8}$$

2. Level-set representation of the interface. In the above iterative process, the interface ∂A_k has to be updated as long as the residual $u_k|_{\partial A_k}$ is not (numerically) zero. Relation (1.8) indicates that the boundary should be moved in the normal direction by an amount proportional to the residual.

[2]The present iterative process can be modified by imposing the Neumann condition (1.7) on the "next" boundary ∂A_{k+1} instead of ∂A_k [11, 13]. However, in the formulation adopted here, those modifications are of little use, as they require information such as curvature which complicates the calculation of the "evolution" of the interface.

If the residual is considered as a normal speed, a time-dependent problem can be set up for the "evolution" (or correction) of the domain A_k. We denote the domain so generated $A_k(t)$ with $A_k(0) = A_k$. Let $F : \mathbb{R}^2 \to \mathbb{R}$ be an extension of the residual away from A_k (see subsection 2.3 below). We want the interface $\Gamma(t) = \partial A_k(t)$ to be characterized by

$$\Gamma(0) = \partial A_k, \qquad \Gamma(t) = \{(x(t), t); x(0) = x_0, x_0 \in \partial A_k\} \quad \text{for } t > 0,$$

where

$$\frac{dx}{dt} = Fn, \qquad x(0) = x_0,$$

n being the unit outer normal to $\partial A_k(t)$. A level-set approach, as pioneered in [30] (see also [29, 34]), consists in representing the interface $\{\Gamma(t)\}_{t\geq 0}$ as the zero level set of family of level-set functions $\{\phi(\cdot, t)\}_{t\geq 0}$ with the property

$$A_k(t) = \{x \in \mathbb{R}^2; \phi(x, t) < 0\}, \qquad \Gamma(t) = \partial A_k(t) = \{x \in \mathbb{R}^2; \phi(x, t) = 0\},$$

where $A_k(t)$ denotes the domain stemming from the evolution of A_k through the above process. By taking the time derivative of the relation $\phi(x(t), t) = 0$, the level-set equation is obtained:

$$\partial_t \phi + F|\nabla \phi| = 0, \tag{2.1}$$

$$\phi(\cdot, 0) = \phi_0, \tag{2.2}$$

where ϕ_0 is a level-set function corresponding to ∂A_k.

Several points related to the implementation of the above method now have to be considered. The fixed boundary $\partial\Omega$ is approximated by a piecewise linear curve $\partial\Omega_h$ with N elements. The size of the smallest element of $\partial\Omega_h$ is denoted Δx. Let $B \subset \mathbb{R}^2$ be a square domain of size $M\Delta x \times M\Delta x$, where M is chosen large enough so that B contains A. We associate with B, in a natural way, a uniform Cartesian mesh B_h of size Δx. In the following, the level-set functions are characterized by their nodal values on the mesh B_h. Two kinds of interpolation operators are considered on B_h. In the contouring step (subsection 2.1), a classical $\mathcal{P}_1$ interpolation is used. In the projection step (subsection 2.2), a classical local $\mathcal{Q}_2$ interpolation is considered.

2.1. Contouring. In many applications of the level-set method, the actual reconstruction of the interfaces is not needed. This is not the case here, as the elliptic problem (1.5)–(1.7) has to be solved in a family of successive domains defined by those interfaces. Let ϕ be a given level-set function and $I_{\mathcal{P}}\phi$ its $\mathcal{P}_1$-interpolant on B_h. By contouring, we mean the operation that associates with the nodal values of ϕ the zero level set of $I_{\mathcal{P}}\phi$. More precisely, each square cell of the underlying Cartesian grid is divided into two triangular elements,[3] and on each of those triangles, the unique polynomial of degree 1 agreeing with the values of the level-set function at the vertices is considered. Contour lines are then constructed by connecting the zeros of $I_{\mathcal{P}}\phi$ on the grid lines. This process is facilitated by two facts: first, each triangle contains at most one contour line passing through it, and, second, the gradient of $I_{\mathcal{P}}\phi$ is piecewise constant on the grid elements, yielding an outward normal to $A_k(t)$. Note that both properties fail in general for the local $\mathcal{Q}_2$ interpolant considered in the projection step below.

If $I_{\mathcal{P}}\phi$ is uniformly equal to zero on a given triangle, then the problem is underresolved (Δx is too large) and the algorithm fails.

[3] Any such decomposition is acceptable.

2.2. Projection. As mentioned above, some quantities such as the normal speed need to be extended away from the interface. The first step in this process consists again in an accurate reconstruction of the boundary. A loop through the mesh is done to determine which nodes are "close to" the interface. Here a node is close to the interface if it has a primary neighbor where ϕ has opposite sign.

With each node x_i, we associate its eight closest neighbors and construct on this set of nine nodes the unique polynomial of degree 2 in each variable agreeing with the values of ϕ there. This local $\mathcal{Q}_2$ interpolant is denoted $I_{\mathcal{Q},x_i}\phi$. For each node x_i close to the interface, the closest point $x^\star$ to x_i on the zero level set of $I_{\mathcal{Q},x_i}\phi$ is computed. The square of the Cartesian distance, i.e., $|x - x_i|^2$, is minimized subject to the constraint $I_{\mathcal{Q},x_i}\phi = 0$. The Lagrangian for this problem is

$$\mathcal{L}(x,\lambda) = |x - x_i|^2 + \lambda\, I_{\mathcal{Q},x_i}\phi(x). \tag{2.3}$$

To find the point $x^\star$, the system

$$\nabla_{x,\lambda}\mathcal{L}(x,\lambda) = 0 \tag{2.4}$$

is solved by Newton's method with Armijo line search [25]. This projection method was introduced and discussed in [17]. It roughly corresponds to a simpler version of the method proposed in [8] which is based on cubic splines; see [26] for more comments and comparisons. The above algorithm can fail if the interface is underresolved.

The projection step could potentially be used to reconstruct the interface, i.e., as another contouring step. However, while it is locally more accurate than the above contouring algorithm (and is thus ideal when used in conjunction with the extension step described below), it has several disadvantages as a contouring tool (local character, nonconstant elementwise gradient).

2.3. Extension. This step extends the speed F away from the interface, so that (2.1), (2.2) can be solved. Let Γ be the interface obtained from the contouring step. By construction, Γ is a closed (for the problems considered here), possibly multiconnected, piecewise linear (on the triangular mesh derived from B_h) curve in B. The boundary nodes corresponding to Γ are denoted $\{\xi_j\}$; i.e., the ξ_j's are the end points of the line segments that form Γ. Further, through the elliptic step (see section 3), the value of F at the center point of each linear segment of Γ is known; the center point nodes are denoted $\{\bar{\xi}_j\}$.

First, the values of F at the midpoint boundary nodes $\{\bar{\xi}_j\}$ are extended to the set of Cartesian nodes $\{x_i\}$ that form the vertices of the triangles containing the nodes $\{\bar{\xi}_j\}$.

More precisely, consider the node $\bar{\xi}_j$ in Figure 1, left. This local extension step is based on the analysis of the "domain of influence" of the nodes $\{\bar{\xi}_j\}$. This domain of influence is taken here as the set of all the points in B whose orthogonal projection on the line containing the segment through $\bar{\xi}_j$ belongs to that segment. If a node x_i belongs to the domain of influence of $\bar{\xi}_j$, then F is extended at x_i by the value $F(\bar{\xi}_j)$ as in Figure 1, left. If instead the node x_i is in the domain of influence of more than one midpoint boundary node, as would be the case in the dark grey area in Figure 1, left, then the value at the midpoint of the closest segment to x_i is retained. Finally, if x_i does not belong to the domain of influence of any midpoint boundary node, as in the light grey area in Figure 1, right, then the value of F at x_i is taken as

$$F(x_j) = \frac{\beta}{\alpha+\beta}F_{j-1} + \frac{\alpha}{\alpha+\beta}F_j,$$

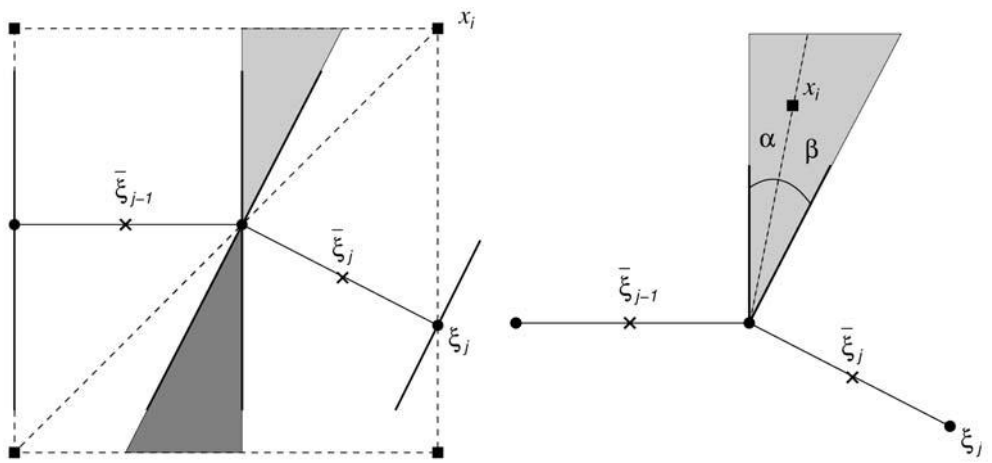

FIG. 1. *Left: general view of the geometry involved in the local extension step and corresponding "domains of influence" (dark grey area: shock-like domain, light grey area: rarefaction-like domain); right: definition of the local angles α and β.*

where F_{j-1} and F_j are the values of F at the midpoint boundary nodes $\bar{\xi}_{j-1}$ and $\bar{\xi}_j$, respectively, and where the angles α and β are defined as in Figure 1, right. This way of defining the local extension of F is compatible with the global extension (2.7).

Second, a renormalized function $\tilde{\phi}$ is initialized as a signed distance function at the same Cartesian nodes at which F has just been extended. The projection step is used to do this.

We emphasize that both of those local extension steps for F and $\tilde{\phi}$ take place only on the nodes adjacent to the interface; the corresponding values are then used as starting points for the extension to the rest of the Cartesian nodes. This is accomplished using the fast marching method [2] to solve

$$|\nabla\tilde{\phi}| = 1 \qquad \text{in } B, \tag{2.5}$$

$$\tilde{\phi} = 0 \qquad \text{on } \Gamma, \tag{2.6}$$

$$\nabla\tilde{F}\cdot\nabla\tilde{\phi} = 0 \qquad \text{in } B, \tag{2.7}$$

$$\tilde{F} = F \qquad \text{on } \Gamma. \tag{2.8}$$

A fully upwind mixed first/second order discretization of the above equations is applied on the mesh B_h; see [18, 35, 36] for more details.

2.4. Updating the interface. The interface is moved by updating the corresponding level-set function through (2.1), (2.2). More precisely, after the extension step, the level-set function $\tilde{\phi}$ corresponding to the current interface Γ is a signed distance function, and, in particular, $|\nabla\tilde{\phi}| = 1$. Therefore, (2.1), (2.2) here reads

$$\partial_t\phi + \tilde{F} = 0,$$

$$\phi(\cdot,0) = \tilde{\phi}.$$

The update is then trivially computed by taking one forward Euler step,

$$\phi_{\text{new}} = \tilde{\phi} - \Delta t\,\tilde{F}, \tag{2.9}$$

where $\Delta t = -\frac{1}{2\mu}$. Note that this corresponds to half the optimal time step given by (1.8); taking the "optimal" value from (1.8) may lead to overshoots in the position of the interface and may, in fact, result in slowing down the convergence of the global iterative process.

2.5. Initial interface. An initial guess of the interface's position, ∂A_0, needs to be provided. This can be done in an ad hoc way. In section 4, ∂A_0 is taken as a curve of constant distance to Ω.

3. Boundary element method. Consider again the problem (1.5)–(1.7). For the sake of simplicity, the subscript k is dropped in this section. We assume both ∂A and $\partial\Omega$ to be simple closed curves and let $\Gamma = \partial A \cup \partial\Omega$. The region of interest $A \setminus \bar{\Omega}$ being interior to ∂A and exterior to $\partial\Omega$, ∂A is oriented counterclockwise, while $\partial\Omega$ is clockwise.

Multiplying (1.5) by the fundamental solution $G(x,y) := -\frac{1}{2\pi}\log|x-y|$ and integrating twice by parts leads to

$$u(x) = \int_\Gamma G(x,y)\,\frac{\partial u}{\partial n_y}(y)\,ds(y) - \int_\Gamma \frac{\partial G}{\partial n_y}(x,y)\,u(y)\,ds(y), \tag{3.1}$$

where n is the unit outer normal to $A \setminus \bar{\Omega}$ at y. The above integral representation is valid for $x \in A \setminus \bar{\Omega}$. To treat the case $x \in \Gamma$, we define the linear operator $\mathcal{L} : L^2(\Gamma) \to L^2(\Gamma)$ by

$$\mathcal{L}v(x) = \begin{cases} \frac{v(x)}{2} + \displaystyle\int_{\partial A} \frac{\partial G}{\partial n_y}(x,y)\,v(y)\,ds(y) - \int_{\partial\Omega} G(x,y)\,v(y)\,ds(y) & \text{for } x \in \partial A, \\ \displaystyle\int_{\partial A} \frac{\partial G}{\partial n_y}(x,y)\,v(y)\,ds(y) - \int_{\partial\Omega} G(x,y)\,v(y)\,ds(y) & \text{for } x \in \partial\Omega \end{cases}$$

and the function $\mathcal{F} \in L^2(\Gamma)$ by

$$\mathcal{F}(x) = \begin{cases} \mu \displaystyle\int_{\partial A} G(x,y)\,ds(y) - \int_{\partial\Omega} \frac{\partial G}{\partial n_y}(x,y)\,ds(y) & \text{for } x \in \partial A, \\ \mu \displaystyle\int_{\partial A} G(x,y)\,ds(y) - \int_{\partial\Omega} \frac{\partial G}{\partial n_y}(x,y)\,ds(y) - \frac{1}{2} & \text{for } x \in \partial\Omega. \end{cases}$$

Taking into account the boundary conditions (1.6) and (1.7), it is then standard to check that if

$$w(x) = \begin{cases} u(x) & \text{for } x \in \partial A, \\ \frac{\partial u}{\partial n}(x) & \text{for } x \in \partial\Omega, \end{cases}$$

where u is the solution to (1.5)–(1.7), then

$$\mathcal{L}w(x) = \mathcal{F}(x) \qquad \forall x \in \Gamma. \tag{3.2}$$

Problem (3.2) is discretized as follows. The interface $\partial A = \partial A_h$ is obtained through contouring of a given level-set function, see section 2, and piecewise constant elements are considered. The function w solution to (3.2) is approximated by w_h such that

$$w_h(x) = w_e \qquad \forall x \in e,$$

where e is an edge of either ∂A_h or $\partial\Omega_h$ and where w_e is the constant value of w_h on that edge. Equation (3.2) is then collocated at the midpoints of the edges. In other words, for a generic piecewise constant function v_h, we define

$$\mathcal{L}_h v_h(\bar{\xi}_e) = \begin{cases} \frac{v_h(\bar{\xi}_e)}{2} + \displaystyle\int_{\partial A_h} \frac{\partial G}{\partial n_y}(\bar{\xi}_e, y)\, v_h(y)\, ds(y) - \int_{\partial\Omega_h} G(\bar{\xi}_e, y)\, v_h(y)\, ds(y) \\ \qquad \text{for } \bar{\xi}_e \in \partial A_h, \\ \displaystyle\int_{\partial A_h} \frac{\partial G}{\partial n_y}(\bar{\xi}_e, y)\, v_h(y)\, ds(y) - \int_{\partial\Omega_h} G(\bar{\xi}_e, y)\, v_h(y)\, ds(y) \\ \qquad \text{for } \bar{\xi}_e \in \partial\Omega_h, \end{cases}$$

where $\bar{\xi}_e$ is the midpoint of the edge e. Similarly, we also have

$$\mathcal{F}_h(\bar{\xi}_e) = \begin{cases} \mu \displaystyle\int_{\partial A_h} G(\bar{\xi}_e, y)\, ds(y) - \int_{\partial\Omega_h} \frac{\partial G}{\partial n_y}(\bar{\xi}_e, y)\, ds(y) & \text{for } \bar{\xi}_e \in \partial A_h, \\ \mu \displaystyle\int_{\partial A_h} G(\bar{\xi}_e, y)\, ds(y) - \int_{\partial\Omega_h} \frac{\partial G}{\partial n_y}(\bar{\xi}_e, y)\, ds(y) - \frac{1}{2} & \text{for } \bar{\xi}_e \in \partial\Omega_h. \end{cases}$$

The approximate solution w_h is the solution to

$$\mathcal{L}_h w_h(\bar{\xi}_e) = \mathcal{F}_h(\bar{\xi}_e) \qquad \forall \bar{\xi}_e \in \partial A_h \cup \partial\Omega_h. \tag{3.3}$$

The above integrals are computed exactly in the present implementation, in the sense of the Cauchy principal value where appropriate; see [4] for more details.

Both the integral equation (3.2) and the linear problem (3.3) are well conditioned with one exception: 0 is an eigenvalue of $\mathcal{L}$ if and only if the transfinite diameter of A is 1 [20]. This can be avoided by appropriate rescaling if necessary. It can be verified that $\mathcal{L}_h$ admits eigenvalues and singular values that are bounded independent of the mesh; see, e.g., [20] or [31] for explicit expressions of the eigenvalues in some specific cases. Further, in spite of the fact that the elements of ∂A_h are allowed to be arbitrarily small, the condition number of $\mathcal{L}_h$ has been numerically verified to be of order N, which would correspond to the uniform mesh case [3]. The condition number of the matrices corresponding to the numerical tests of section 4 are on the order of 100. The resulting linear system is solved by GMRES [25, 33], which is consequently expected to perform well here even without preconditioning; see also [7] for a general convergence result for GMRES applied to integral equations. GMRES is restarted after 20 steps (i.e., the solver is GMRES(20)) and is stopped on small relative residuals; more precisely, the stopping criterion is

$$\|\mathcal{F}_h - \mathcal{L}_h w\|_2 \leq 10^{-10} \|\mathcal{F}_h\|_2,$$

where w denotes the current iterate. With the above parameters, GMRES has been observed to perform slightly better than other CG-like methods such as QMR and Bi-CGSTAB [25] on the test problems of section 4.

4. Numerical results.

4.1. Algorithm. To solve the external Bernoulli problem, we use the following algorithm:

Input: a discretization of the boundary $\partial\Omega$, $\partial\Omega_h$, μ
Create the underlying Cartesian grid B_h
Create a level set function ϕ on B_h corresponding to ∂A_0
$k = 0$
$R_{-1} = 10^{10}$ (initial residual)
loop
  Contour ϕ (subsection 2.1) to find ∂A_k
  Solve (3.3) to get u
  $R_k = \max$ of $|u|$ on ∂A_k
  if $(R_{k-1} - R_k)/R_k < 10^{-3}$ (small residual decrease) **then**
    STOP
  end if
  Set $F = u$ on ∂A_k
  Extend ϕ and F (subsections 2.2 and 2.3)
  Move boundary (subsection 2.4)
  $k = k + 1$
end loop

Several remarks are in order.

- Profiling reveals that for reasonable meshes the relative costs of contouring and interface updating are very low (less than 1%), while most of the time is spent constructing and solving the linear system (3.3) (about 90%) and extending the solution (about 10%). Methods such as fast multipoles [5, 32] can be used to bring down the asymptotic complexity of the linear solver from $\mathcal{O}(N^2)$ to $\mathcal{O}(N)$, where N is the number of elements of $\partial\Omega_h$. However, this results in increased efficiency only for very large values of N; see [26, Appendix] for more details; see also [16] for a large-scale two-dimensional example. Fast summation methods should be considered for three-dimensional problems.
- Progressive mesh refinement can be considered; i.e., a coarse mesh solution can be used as the starting point. A strategy of this type is, for instance, used in [23] for a similar type of problem but for a different numerical approach.
- In solving (3.3), the "missing" condition (1.3) can be used when choosing the initial iterate for GMRES. This results in faster convergence (fewer GMRES iterates) as the algorithm progresses.
- The extension step through fast marching (subsection 2.3) is done in the whole computational domain B. The corresponding complexity is $\mathcal{O}(M^2 \log M)$, where M^2 is the total number of nodes in the Cartesian grid B_h. A narrow band/computational tube implementation [2, 37] could be considered to speed up the algorithm. However, the global complexity of the problem would not change: if the width of the band is a constant multiple of Δx, say $n\Delta x$, then by (2.9), Δt should be reduced from $\frac{-1}{2\mu}$ to a value less than $\frac{n\Delta x}{|\tilde{F}|}$ since the band has to contain the boundary.
- Higher order boundary element methods can be used [4]. While second order convergence is observed in section 4, this is a result of the solution being constant on the outer free boundary. Piecewise linear elements should be used to ensure second order convergence for more general cases. To the authors' knowledge, the present work is one of very few published results regarding the accuracy of a combined level-set boundary element method; see, for instance, [14].

TABLE 1
Convergence and complexity rates for Example 1 (radial case); N is number of elements on $\partial\Omega_h$, L^∞ error refers to the Hausdorff distance between exact and computed boundaries, k is the number of nonlinear iterations (see section 4.1), Time is the runtime in seconds.

N	$\max\|u\|$ on Γ	Rate	L^∞ error	Rate	k	Time	Rate
25	1.64(−2)	–	1.53(−2)	–	6	0.71	–
50	5.07(−3)	1.7	4.40(−3)	1.8	8	4.1	2.5
100	1.30(−3)	2.0	1.12(−3)	2.0	10	19	2.2
200	3.34(−4)	2.0	2.85(−4)	2.0	11	76	2.0
400	8.18(−5)	2.0	7.10(−5)	2.0	12	372	2.1
800	1.92(−5)	2.1	1.74(−5)	2.0	14	1465	2.0

- The use of second order fast marching is not crucial for the accuracy of the method which is dictated by both the contouring and boundary element methods. It was observed that first order fast marching may lead to more iterations (domain updates), and, hence, due to the very little difference in cost per iteration, the use of second order fast marching is advocated.
- The numerical solutions are observed to be remarkably independent of the initial domain ∂A_0 (for problems with unique solutions [11]). More iterations can be expected in case of poor initial guesses (for instance if the smoothness properties of ∂A_0 are vastly different from those of ∂A).

4.2. Example 1. Following [11], a quick look at the radial case is instructive. Let Ω be the unit ball. We consider the problem (1.1)–(1.4) with Ω as above and $\mu = -2$. The solution to (1.1)–(1.3) with A being the ball of radius R centered at the origin is

$$u(r) = -2\,R\log r + 1,$$

expressed in polar coordinates. An iterative process similar to the one above can then be considered. Taking (1.8) into account, the kth step of the algorithm reads

$$R_{k+1} = R_k - R_k \log R_k + \frac{1}{2}, \qquad k = 1, 2, \ldots.$$

Therefore, in the fully radial case, the problem amounts to finding a fixed point to the function $f(R) = R - R\log R + \frac{1}{2}$. The function f has a unique fixed point $\bar{R}$, where

$$\bar{R} = \frac{1}{2\,W(\frac{1}{2})},$$

the function W being the Lambert W function[4] [10].

Table 1 shows second order convergence in the L^∞ norm. Full second order convergence is obtained even though the elliptic solver is based on a piecewise constant discretization. This is due to the fact that the exact solution is constant on both the inner and outer boundaries. Further, when measured with respect to runtime, the complexity is also second order.

The convergence history is instructive. Figure 2, left, displays the error (maximum of $|u|$ on the free boundary) through the iterations. The behavior of the first iterates is governed by the geometry, see (2.9), and is only weakly dependent on the mesh size

[4]The Lambert W function is the inverse of $W \mapsto z = W\,e^W$.

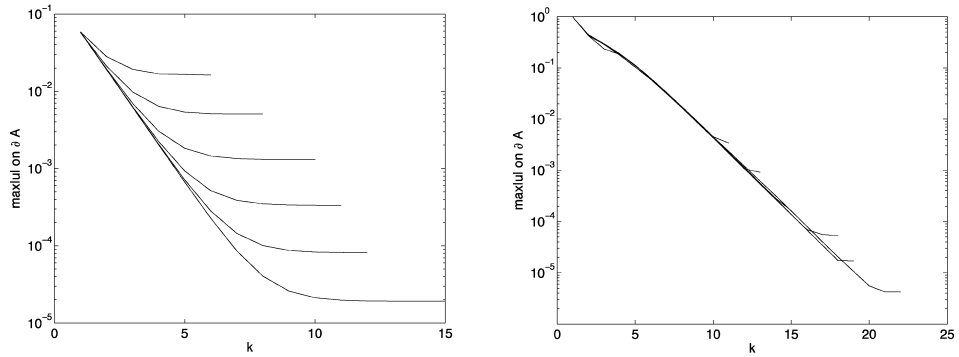

FIG. 2. *Convergence history of the iterations: maximum value of* $|u|$ *on the current interface as a function of the iteration number; left: Example* 1*, right: Example* 2*. The convergence curves are in the obvious order: from top to bottom,* $N = 25, 50, 100, 200, 400, 800$.

Δx. The later iterations during which the fine structure of the boundary is determined do depend on Δx. This explains the mesh dependency of the number of iterations observed in Table 1.

4.3. Example 2. We consider here the problem (1.1)–(1.4) with Ω consisting of two disks of radius 1, one centered at $(-2, 2)$ and one at $(2, -2)$; further, $\mu = -1/4$. The initial boundary is taken as two circles of radius 1.1, one around each of the inner disks. Note that for this choice of μ, the exact boundary is simply connected. A couple of iterates are displayed in Figure 3. One can note that after the first step the correct topology of the interface has already been achieved.

No exact solution is available for the present example. In Table 2, the maximum of u on the boundary is reported. By construction, this maximum should vanish for the converged solution. The complexity, as measured from the runtimes, is also reported. In both cases, the rates are about two.

Convergence history is displayed in Figure 2, right; a behavior similar as that of Example 1 is observed.

5. Conclusion. Solutions of the Bernoulli free boundary problem can be efficiently computed by the method presented here. Providing a Green's function is available, the method can be used to solve other free boundary problems. For instance, it can be applied with only minor modifications to the Prandtl–Batchelor problem (see [1] and the references therein), which consists in looking for a domain A which is now interior to the fixed domain Ω such that for a given function σ,

$$|\nabla u_A|^2 - |\nabla u_\Omega|^2 = \sigma \qquad \text{on } \partial A,$$

where u_A and u_Ω solve

$$\begin{cases} \Delta u_A = -\omega & \text{in } A, \\ u_A = 0 & \text{on } \partial A, \end{cases} \qquad \begin{cases} \Delta u_\Omega = 0 & \text{in } \Omega, \\ u_\Omega = 0 & \text{on } \partial A, \\ u_\Omega = \mu & \text{on } \partial\Omega, \end{cases}$$

μ and ω being positive constants.[5]

[5]To avoid the calculation of a bulk due to the inhomogeneity, a particular solution to $\Delta u_0 = -\omega$ (for instance $u_0 = -\frac{\omega}{4}(x^2 + y^2)$) can easily be subtracted from u_A. This restores homogeneity but renders the boundary condition nonconstant.

COMPUTING THE NEAREST DOUBLY STOCHASTIC MATRIX WITH A PRESCRIBED ENTRY*

ZHENG-JIAN BAI†, DELIN CHU‡, AND ROGER C. E. TAN‡

Abstract. In this paper a nearest doubly stochastic matrix problem is studied. This problem is to find the closest doubly stochastic matrix with the prescribed $(1,1)$ entry to a given matrix. According to the well-established dual theory in optimization, the dual of the underlying problem is an unconstrained differentiable, but not twice differentiable, convex optimization problem. A Newton-type method is used for solving the associated dual problem, and then the desired nearest doubly stochastic matrix is obtained. Under some mild assumptions, the quadratic convergence of the proposed Newton method is proved. The numerical performance of the method is also demonstrated by numerical examples.

Key words. doubly stochastic matrix, generalized Jacobian, Newton's method, quadratic convergence

1. Introduction. A matrix $A \in \mathbb{R}^{n\times n}$ is called doubly stochastic if it is nonnegative and all its row and column sums are equal to one. Doubly stochastic matrices have found many important applications in probability and statistics, quantum mechanics, the study of hypergroups, economics and operation research, physical chemistry, communication theory and graph theory, etc.; see [15, 3, 17, 19, 23] and the references therein.

In this paper, we are interested in the best approximation problem related to doubly stochastic matrices: Given a matrix $T \in \mathbb{R}^{n\times n}$, find its nearest doubly stochastic matrix with the same $(1,1)$ entry as the given matrix T. This problem can be mathematically stated as follows:

$$\text{(1)} \qquad \begin{cases} \min & \frac{1}{2}\|M-T\|_F^2 \\ \text{s.t.} & M\mathbf{e}=\mathbf{e}, \quad \mathbf{e}^T M=\mathbf{e}^T, \\ & \mathbf{e}_1^T M\,\mathbf{e}_1=\mathbf{e}_1^T T\mathbf{e}_1, \\ & M\geq 0, \end{cases}$$

where

$$\mathbf{e}=(1,\ldots,1)^T\in\mathbb{R}^n, \qquad \mathbf{e}_1=(1,0,\ldots,0)^T\in\mathbb{R}^n,$$

and $M \geq 0$ means that M is nonnegative. Problem (1) was originally suggested by Professor Zhaojun Bai (Department of Computer Science, UC Davis). It arose from

numerical simulation of large (semiconductor, electronic) circuit networks. Padé approximation technique using the Lanczos process is very powerful for computing a lower order approximation to the linear system matrix describing the large linear network [1, 9]. The matrix T produced by the Lanczos process is in general not a doubly stochastic matrix. Suppose that the original system matrix is doubly stochastic; then we need to find the nearest doubly stochastic matrix M to T and at the same time match the moments.

Problem (1) has been studied in [10] based on the alternating projection method [2]. In [10, 14], problem (1) is simplified by removing the requirements on the $(1,1)$ entry and the nonnegativity of the matrix M. In this case, the solution can be obtained explicitly. We will revisit problem (1). Based on the dual approach in optimization [16], we will first reformulate (1) as an unconstrained differentiable but not twice differentiable convex optimization problem, next apply Newton's method to solve this convex problem, and then obtain the desired nearest doubly stochastic matrix. Under some mild assumptions, we will show that the proposed Newton method is quadratically convergent. We will also demonstrate the numerical performance of the method by numerical examples.

Throughout this paper, the following notation will be used:

- $$T = \begin{bmatrix} t_{1,1} & \cdots & t_{1,n} \\ \vdots & \ldots & \vdots \\ t_{n,1} & \cdots & t_{n,n} \end{bmatrix}.$$
- $A \geq 0$ ($A > 0$) means that A is nonnegative (positive).
- $$\mathcal{K} = \{A : \ A \in \mathbb{R}^{n\times n}, \ A \geq 0\}, \quad (z)_+ = \max\{0, z\}.$$
- $\Pi_{\mathcal{K}}(X)$ denotes the metric projection of X onto $\mathcal{K}$, i.e.,

$$\Pi_{\mathcal{K}}(X) = \begin{bmatrix} (x_{1,1})_+ & \cdots & (x_{1,n})_+ \\ \vdots & \ldots & \vdots \\ (x_{n,1})_+ & \cdots & (x_{n,n})_+ \end{bmatrix} \quad \forall\ X = \begin{bmatrix} x_{1,1} & \cdots & x_{1,n} \\ \vdots & \ldots & \vdots \\ x_{n,1} & \cdots & x_{n,n} \end{bmatrix} \in \mathbb{R}^{n\times n}.$$

2. Newton's method. In this section we consider a Newton-type method for computing the solution of problem (1).

Let

$$f(M) := \frac{1}{2}\|M - T\|_F^2, \quad \mathcal{A}(M) := \begin{bmatrix} M\mathbf{e} \\ \begin{bmatrix} I_{n-1} & 0 \end{bmatrix} M^T\mathbf{e} \\ \mathbf{e}_1^T M \mathbf{e}_1 \end{bmatrix}, \quad b := \begin{bmatrix} \mathbf{e} \\ \begin{bmatrix} I_{n-1} & 0 \end{bmatrix} \mathbf{e} \\ \mathbf{e}_1^T T \mathbf{e}_1 \end{bmatrix};$$

then problem (1) is equivalent to

$$\text{(2)} \qquad \begin{cases} \min & f(M) \\ \text{s.t.} & \mathcal{A}(M) = b, \\ & M \in \mathcal{K}. \end{cases}$$

The dual problem [16] of (2) is

$$\begin{cases} \sup & -\theta(x) \\ \text{s.t.} & x \in \mathbb{R}^{2n}, \end{cases} \tag{3}$$

where

$$\theta(x) = \frac{1}{2}\|\Pi_{\mathcal{K}}(T + \mathcal{A}^\star(x))\|_F^2 - x^T b - \frac{1}{2}\|T\|_F^2,$$

and $\mathcal{A}^\star$ is the adjoint of A and is defined by

$$\begin{aligned} \mathcal{A}^\star(x) &= \begin{bmatrix} I_n & 0 \end{bmatrix} x\mathbf{e}^T + \mathbf{e}x^T \begin{bmatrix} 0_{n\times(n-1)} & 0 \\ I_{n-1} & 0 \\ 0 & 0 \end{bmatrix} + \mathbf{e}_1 \begin{bmatrix} 0 & 1 \end{bmatrix} x\mathbf{e}_1^T \\ &= \begin{bmatrix} x_1 + x_{n+1} + x_{2n} & x_1 + x_{n+2} & \cdots & x_1 + x_{2n-1} & x_1 \\ x_2 + x_{n+1} & x_2 + x_{n+2} & \cdots & x_2 + x_{2n-1} & x_2 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ x_n + x_{n+1} & x_n + x_{n+2} & \cdots & x_n + x_{2n-1} & x_n \end{bmatrix} \\ &\forall x = \begin{bmatrix} x_1 \\ \vdots \\ x_{2n} \end{bmatrix} \in \mathbb{R}^{2n}. \end{aligned}$$

The relation between the values of (2) at its minimum and of the dual (3) at its maximum is stated in the following theorem.

THEOREM 2.1. [illegible] $M \in \mathbb{R}^{n\times n}$ [illegible] $\mathcal{K}$ [illegible] $\mathcal{A}(M) = b$ [illegible]

$$0 < \mathbf{e}_1^T T \mathbf{e}_1 < 1. \tag{4}$$

[illegible] (4)

(i) [illegible] (2) [illegible] $M^\star$.

(ii) [illegible] (3) [illegible] $x^\star$ [illegible]

$$M^\star = \Pi_{\mathcal{K}}(T + \mathcal{A}^\star(x^\star)). \tag{5}$$

[illegible]. If M is in the topological interior of $\mathcal{K}$ and $\mathcal{A}(M) = b$, then (4) follows directly from the properties that

$$\mathbf{e}_1^T T \mathbf{e}_1 = \mathbf{e}_1^T M \mathbf{e}_1 > 0, \quad \mathbf{e}_1^T M \mathbf{e} = 1,$$

and all entries of $\mathbf{e}_1^T M$ are positive. Conversely, if (4) holds, then it is clear that the matrix M defined by

$$M := \frac{1}{n-1} \begin{bmatrix} r_0 & r & \cdots & r & r \\ r & r_0 & \ddots & & r \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ r & & \ddots & \ddots & r \\ r & r & \cdots & r & r_0 \end{bmatrix}, \tag{6}$$

$$\text{with } r_0 = (n-1)\,\mathbf{e}_1^T T \mathbf{e}_1 > 0, \quad r = 1 - \mathbf{e}_1^T T \mathbf{e}_1 > 0,$$

satisfies that M is in the topological interior of $\mathcal{K}$ and $\mathcal{A}(M) = b$. Hence Theorem 2.1 follows.

Under the condition (4), parts (i) and (ii) of the theorem are now well known; see [12, 16, 21]. □

. . .. 1. In [12], the condition ensuring that there exists a matrix $M \in \mathbb{R}^{n\times n}$ in the topological interior of $\mathcal{K}$ such that $\mathcal{A}(M) = b$ is called the . . . . . for (2). Hence, we can regard (4) as the Slater condition for (2).

According to Theorem 2.1, once we can compute an optimal solution $x^\star$ of the dual problem (3), then we can obtain the optimal solution $M^\star$ of problem (2) by using (5).

Define

$$F(x) := \mathcal{A}(\Pi_{\mathcal{K}}(T + \mathcal{A}^\star(x))) - b \tag{7}$$

$$= \begin{bmatrix} (t_{1,1} + x_1 + x_{n+1} + x_{2n})_+ + \sum_{i=2}^{n-1}(t_{1,i} + x_1 + x_{n+i})_+ + (t_{1,n} + x_1)_+ \\ \sum_{i=1}^{n-1}(t_{2,i} + x_2 + x_{n+i})_+ + (t_{2,n} + x_2)_+ \\ \vdots \\ \sum_{i=1}^{n-1}(t_{n,i} + x_n + x_{n+i})_+ + (t_{n,n} + x_n)_+ \\ (t_{1,1} + x_1 + x_{n+1} + x_{2n})_+ + \sum_{j=2}^{n}(t_{j,1} + x_j + x_{n+1})_+ \\ \sum_{j=1}^{n}(t_{j,2} + x_j + x_{n+2})_+ \\ \vdots \\ \sum_{j=1}^{n}(t_{j,n-1} + x_j + x_{2n-1})_+ \\ (t_{1,1} + x_1 + x_{n+1} + x_{2n})_+ \end{bmatrix} - \begin{bmatrix} 1 \\ 1 \\ \vdots \\ 1 \\ 1 \\ 1 \\ \vdots \\ 1 \\ t_{11} \end{bmatrix}$$

for any

$$x = \begin{bmatrix} x_1 \\ \vdots \\ x_{2n} \end{bmatrix} \in \mathbb{R}^{2n}.$$

It is easy to know that the function $\theta(x)$ is continuously differentiable and that its gradient $\nabla\theta(x) = F(x)$ is globally Lipschitz continuous. Thus, both gradient-type methods and quasi-Newton methods can be directly employed to solve (3). However, since $\theta(x)$ is not twice continuously differentiable, the convergence rates of these methods are at most linear.

Since $\theta(x)$ is convex and differentiable, at solution $x^\star$ of (3),

$$\nabla\theta(x^\star) = 0; \qquad \text{i.e., } F(x^\star) = 0.$$

This indicates that we can obtain a solution of (3) by solving the equation $F(x) = 0$. $F(x)$ is globally Lipschitz continuous. According to Rademacher's theorem [22, Chapter 9.J], $F(x)$ is Fréchet differentiable almost everywhere. Let Ω_{F} be the set of points at which F is Fréchet differentiable. Denote the Jacobian of $F(x)$ at $x \in \Omega_{\mathrm{F}}$ by $F'(x)$. The generalized Jacobian $\partial F(x)$ of F at $x \in \mathbb{R}^{2n}$ in the sense of Clarke [6] is defined by

$$\partial F(x) := \mathrm{conv}\{\partial_B F(x)\},$$

where "conv" denotes the convex hull and

$$\partial_B F(x) := \left\{ V \in \mathbb{R}^{2n\times 2n} : \ V \text{ is an accumulation point of } F'(x^{(k)}),\ x^{(k)} \to x,\ x^{(k)} \in \Omega_{\mathrm{F}} \right\}.$$

The nonsmooth Newton method for solving equation

$$F(x) = 0 \tag{8}$$

is given by

$$x^{(k+1)} = x^{(k)} - V_k^{-1} F(x^{(k)}), \quad V_k \in \partial F(x^{(k)}). \tag{9}$$

The following result was established in [20].

THEOREM 2.2 (see [20]). [illegible] $F(x) = 0$ [illegible] $V \in \partial F(x^\star)$ [illegible] F [illegible] $x^\star$ [illegible] F [illegible] $x^\star$ [illegible] $V \in \partial F(x^\star + \delta x)$ [illegible] $\delta x \to 0$

$$F(x^\star + \delta x) - F(x^\star) - V(\delta x) = o(\|\delta x\|_F),$$

[illegible] (9) [illegible] $x^\star$ [illegible] $x^{(0)}$ [illegible] $x^\star$ [illegible] F [illegible] $x^\star$ [illegible] F [illegible] $x^\star$

$$F(x^\star + \delta x) - F(x^\star) - V(\delta x) = o(\|\delta x\|_F^2) \quad \forall\, V \in \partial F(x^\star + \delta x),\ \delta x \to 0,$$

[illegible]

Motivated by Theorem 2.2, in the following we discuss the strong semismoothness of F and the nonsingularity of all $V \in \partial F(x^\star)$ at a solution $x^\star$ of $F(x) = 0$.

Since

$$x = \begin{bmatrix} x_1 \\ \vdots \\ x_{2n} \end{bmatrix} \in \Omega_F,$$

i.e., $F'(x)$ exists if and only if

$$\begin{cases} t_{11} + x_1 + x_{n+1} + x_{2n} \neq 0, \\ t_{1,j} + x_1 + x_{n+j} \neq 0, \quad j = 2, \ldots, n-1, \\ t_{i,j} + x_i + x_{n+j} \neq 0, \quad i = 2, \ldots, n,\ j = 1, \ldots, n-1, \\ t_{i,n} + x_i \neq 0, \quad i = 1, \ldots, n, \end{cases}$$

in the case that the inequalities above hold,

$$\begin{aligned} a_{1,1} :&= \frac{\partial (t_{11} + x_1 + x_{n+1} + x_{2n})_+}{\partial x_1} = \frac{\partial (t_{11} + x_1 + x_{n+1} + x_{2n})_+}{\partial x_{n+1}} \\ &= \frac{\partial (t_{11} + x_1 + x_{n+1} + x_{2n})_+}{\partial x_{2n}} = \begin{cases} 1 & \text{if } t_{11} + x_1 + x_{n+1} + x_{2n} > 0, \\ 0 & \text{if } t_{11} + x_1 + x_{n+1} + x_{2n} < 0, \end{cases} \\ a_{1,j} :&= \frac{\partial (t_{1,j} + x_1 + x_{n+j})_+}{\partial x_1} = \frac{\partial (t_{1,j} + x_1 + x_{n+j})_+}{\partial x_{n+j}} \\ &= \begin{cases} 1 & \text{if } t_{1,j} + x_1 + x_{n+j} > 0, \\ 0 & \text{if } t_{1,j} + x_1 + x_{n+j} < 0, \end{cases} \quad j = 2, \ldots, n-1, \\ a_{i,j} :&= \frac{\partial (t_{i,j} + x_i + x_{n+j})_+}{\partial x_i} = \frac{\partial (t_{i,j} + x_i + x_{n+j})_+}{\partial x_{n+j}} \\ &= \begin{cases} 1 & \text{if } t_{i,j} + x_i + x_{n+j} > 0, \\ 0 & \text{if } t_{i,j} + x_i + x_{n+j} < 0, \end{cases} \quad \begin{aligned} &i = 2, \ldots, n, \\ &j = 1, \ldots, n-1, \end{aligned} \\ a_{i,n} :&= \frac{\partial (t_{i,n} + x_i)_+}{x_i} = \begin{cases} 1 & \text{if } t_{i,n} + x_i > 0, \\ 0 & \text{if } t_{i,n} + x_i < 0, \end{cases} \quad i = 1, \ldots, n, \end{aligned}$$

and

$$F'(x) = \left[\begin{array}{cccc|cccc|c} \sum_{i=1}^n a_{1,i} & & & & a_{1,1} & a_{1,2} & \cdots & a_{1,n-1} & a_{1,1} \\ & \sum_{i=1}^n a_{2,i} & & & a_{2,1} & a_{2,2} & \cdots & a_{2,n-1} & 0 \\ & & \ddots & & \vdots & \vdots & \cdots & \vdots & \vdots \\ & & & \sum_{i=1}^n a_{n,i} & a_{n,1} & a_{n,2} & \cdots & a_{n,n-1} & 0 \\ \hline a_{1,1} & a_{2,1} & \cdots & a_{n,1} & \sum_{i=1}^n a_{i,1} & & & & a_{1,1} \\ a_{1,2} & a_{2,2} & \cdots & a_{n,2} & & \sum_{i=1}^n a_{i,2} & & & 0 \\ \vdots & \vdots & \cdots & \vdots & & & \ddots & & \vdots \\ a_{1,n-1} & a_{2,n-1} & \cdots & a_{n,n-1} & & & & \sum_{i=1}^n a_{i,n-1} & 0 \\ \hline a_{1,1} & 0 & \cdots & 0 & a_{1,1} & 0 & \cdots & 0 & a_{1,1} \end{array}\right].$$

Thus, for any

$$x = \begin{bmatrix} x_1 \\ \vdots \\ x_{2n} \end{bmatrix} \in \mathbb{R}^{2n},$$

(10)

$$V \in \partial_B F(x) \Leftrightarrow V = \left[\begin{array}{cccc|cccc|c} \sum_{i=1}^n b_{1,i} & & & & b_{1,1} & b_{1,2} & \cdots & b_{1,n-1} & b_{1,1} \\ & \sum_{i=1}^n b_{2,i} & & & b_{2,1} & b_{2,2} & \cdots & b_{2,n-1} & 0 \\ & & \ddots & & \vdots & \vdots & \cdots & \vdots & \vdots \\ & & & \sum_{i=1}^n b_{n,i} & b_{n,1} & b_{n,2} & \cdots & b_{n,n-1} & 0 \\ \hline b_{1,1} & b_{2,1} & \cdots & b_{n,1} & \sum_{i=1}^n b_{i,1} & & & & b_{1,1} \\ b_{1,2} & b_{2,2} & \cdots & b_{n,2} & & \sum_{i=1}^n b_{i,2} & & & 0 \\ \vdots & \vdots & \cdots & \vdots & & & \ddots & & \vdots \\ b_{1,n-1} & b_{2,n-1} & \cdots & b_{n,n-1} & & & & \sum_{i=1}^n b_{i,n-1} & 0 \\ \hline b_{1,1} & 0 & \cdots & 0 & b_{1,1} & 0 & \cdots & 0 & b_{1,1} \end{array}\right],$$

where

$$\left\{\begin{array}{ll} b_{1,1} = 1 & \text{if } t_{11} + x_1 + x_{n+1} + x_{2n} > 0, \\ b_{1,1} \in \{0,1\} & \text{if } t_{11} + x_1 + x_{n+1} + x_{2n} = 0, \\ b_{1,1} = 0 & \text{if } t_{11} + x_1 + x_{n+1} + x_{2n} < 0, \end{array}\right.$$

$$\left\{\begin{array}{ll} b_{1,j} = 1 & \text{if } t_{1,j} + x_1 + x_{n+j} > 0, \\ b_{1,j} \in \{0,1\} & \text{if } t_{1,j} + x_1 + x_{n+j} = 0, \quad j = 2, \ldots, n-1, \\ b_{1,j} = 0 & \text{if } t_{1,j} + x_1 + x_{n+j} < 0, \end{array}\right.$$

(11)

$$\left\{\begin{array}{ll} b_{i,j} = 1 & \text{if } t_{i,j} + x_i + x_{n+j} > 0, \\ b_{i,j} \in \{0,1\} & \text{if } t_{i,j} + x_i + x_{n+j} = 0, \\ b_{i,j} = 0 & \text{if } t_{i,j} + x_i + x_{n+j} < 0, \end{array}\right. \quad \begin{array}{l} i = 2, \ldots, n, \\ j = 1, \ldots, n-1, \end{array}$$

$$\left\{\begin{array}{ll} b_{i,n} = 1 & \text{if } t_{i,n} + x_i > 0, \\ b_{i,n} \in \{0,1\} & \text{if } t_{i,n} + x_i = 0, \quad i = 1, \ldots, n. \\ b_{i,n} = 0 & \text{if } t_{i,n} + x_i < 0, \end{array}\right.$$

As a result, we obtain the following result.

THEOREM 2.3. $V \in \partial F(x)$ [illegible] V [illegible]

(12) $V =$

$$\left[\begin{array}{cccc|cccc|c} \sum_{i=1}^n v_{1,i} & & & & v_{1,1} & v_{1,2} & \cdots & v_{1,n-1} & v_{1,1} \\ & \sum_{i=1}^n v_{2,i} & & & v_{2,1} & v_{2,2} & \cdots & v_{2,n-1} & 0 \\ & & \ddots & & \vdots & \vdots & \cdots & \vdots & \vdots \\ & & & \sum_{i=1}^n v_{n,i} & v_{n,1} & v_{n,2} & \cdots & v_{n,n-1} & 0 \\ \hline v_{1,1} & v_{2,1} & \cdots & v_{n,1} & \sum_{i=1}^n v_{i,1} & & & & v_{1,1} \\ v_{1,2} & v_{2,2} & \cdots & v_{n,2} & & \sum_{i=1}^n v_{i,2} & & & 0 \\ \vdots & \vdots & \cdots & \vdots & & & \ddots & & \vdots \\ v_{1,n-1} & v_{2,n-1} & \cdots & v_{n,n-1} & & & & \sum_{i=1}^n v_{i,n-1} & 0 \\ \hline v_{1,1} & 0 & \cdots & 0 & v_{1,1} & 0 & \cdots & 0 & v_{1,1} \end{array}\right],$$

[illegible]

$$\left\{\begin{array}{ll} v_{1,1} = 1 & \text{if } t_{11} + x_1 + x_{n+1} + x_{2n} > 0, \\ v_{1,1} \in [0,\ 1] & \text{if } t_{11} + x_1 + x_{n+1} + x_{2n} = 0, \\ v_{1,1} = 0 & \text{if } t_{11} + x_1 + x_{n+1} + x_{2n} < 0, \end{array}\right.$$

$$\left\{\begin{array}{ll} v_{1,j} = 1 & \text{if } t_{1,j} + x_1 + x_{n+j} > 0, \\ v_{1,j} \in [0,\ 1] & \text{if } t_{1,j} + x_1 + x_{n+j} = 0, \quad j = 2, \ldots, n-1, \\ v_{1,j} = 0 & \text{if } t_{1,j} + x_1 + x_{n+j} < 0, \end{array}\right.$$

$$\left\{\begin{array}{ll} v_{i,j} = 1 & \text{if } t_{i,j} + x_i + x_{n+j} > 0, \\ v_{i,j} \in [0,\ 1] & \text{if } t_{i,j} + x_i + x_{n+j} = 0, \\ v_{i,j} = 0 & \text{if } t_{i,j} + x_i + x_{n+j} < 0, \end{array}\right. \quad \begin{array}{l} i = 2, \ldots, n, \\ j = 1, \ldots, n-1, \end{array} \tag{13}$$

$$\left\{\begin{array}{ll} v_{i,n} = 1 & \text{if } t_{i,n} + x_i > 0, \\ v_{i,n} \in [0,\ 1] & \text{if } t_{i,n} + x_i = 0, \quad i = 1, \ldots, n. \\ v_{i,n} = 0 & \text{if } t_{i,n} + x_i < 0, \end{array}\right.$$

We are now ready to present our results on the strong semismoothness of F and the nonsingularity of all $V \in \partial F(x)$.

THEOREM 2.4. [illegible] $x \in \mathbb{R}^{2n}$ $F(x)$ [illegible]

$$F(x + \delta x) - F(x) - V\delta x = 0 \quad \forall\ V \in \partial F(x + \delta x),\ \delta x \to 0. \tag{14}$$

[illegible] F [illegible] $x \in \mathbb{R}^{2n}$ [illegible]. A simple calculation yields that

$$\lim_{t \to 0^+} \frac{F(x + th) - F(x)}{t}$$

exists for any $x, h \in \mathbb{R}^{2n}$, and so $F(x)$ is directionally differentiable at any point $x \in \mathbb{R}^{2n}$. In addition, it can be verified using (10) and (11) that

$$F(x + \delta x) - F(x) - V\delta x = 0 \quad \forall\ V \in \partial_B F(x + \delta x),\ \delta x \to 0.$$

Since any $V \in \partial F(x + \delta x)$ is just a convex combination of elements in $\partial_B F(x + \delta x)$, (14) holds. □

THEOREM 2.5. [illegible]

$$x = \begin{bmatrix} x_1 \\ \\ x_{2n} \end{bmatrix} \in \mathbb{R}^{2n},$$

$$M := \begin{bmatrix} m_{1,1} & \cdots & m_{1,n} \\ & \cdots & \\ m_{n,1} & \cdots & m_{n,n} \end{bmatrix} = \Pi_{\mathcal{K}}(T + \mathcal{A}^{\star}(x))$$

$$= \Pi_{\mathcal{K}} \left(\begin{bmatrix} t_{1,1} + x_1 + x_{n+1} + x_{2n} & t_{1,2} + x_1 + x_{n+2} & \cdots & t_{1,n-1} + x_1 + x_{2n-1} & t_{1,n} + x_1 \\ t_{2,1} + x_2 + x_{n+1} & t_{2,2} + x_2 + x_{n+2} & \cdots & t_{2,n-1} + x_2 + x_{2n-1} & t_{2,n} + x_2 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ t_{n,1} + x_n + x_{n+1} & t_{n,2} + x_n + x_{n+2} & \cdots & t_{n,n-1} + x_n + x_{2n-1} & t_{n,n} + x_n \end{bmatrix} \right)$$

$N_M =$

$$\left[\begin{array}{cccc|cccc|c} \sum_{i=1}^n m_{1,i} & & & & m_{1,1} & m_{1,2} & \cdots & m_{1,n-1} & m_{1,1} \\ & \sum_{i=1}^n m_{2,i} & & & m_{2,1} & m_{2,2} & \cdots & m_{2,n-1} & 0 \\ & & \ddots & & \vdots & \vdots & \cdots & \vdots & \vdots \\ & & & \sum_{i=1}^n m_{n,i} & m_{n,1} & m_{n,2} & \cdots & m_{n,n-1} & 0 \\ \hline m_{1,1} & m_{2,1} & \cdots & m_{n,1} & \sum_{i=1}^n m_{i,1} & & & & m_{1,1} \\ m_{1,2} & m_{2,2} & \cdots & m_{n,2} & & \sum_{i=1}^n m_{i,2} & & & 0 \\ \vdots & \vdots & \cdots & \vdots & & & \ddots & & \vdots \\ m_{1,n-1} & m_{2,n-1} & \cdots & m_{n,n-1} & & & & \sum_{i=1}^n m_{i,n-1} & 0 \\ \hline m_{1,1} & 0 & \cdots & 0 & m_{1,1} & 0 & \cdots & 0 & m_{1,1} \end{array}\right].$$

(i) N_M

(ii) $V \in \partial F(x)$ N_M

(i) Since

$$m_{i,j} \geq 0, \quad i, j = 1, \ldots, n,$$

for any

$$h = \begin{bmatrix} h_1 \\ \vdots \\ h_{2n} \end{bmatrix} \in \mathbb{R}^{2n}$$

we find

$$h^T N_M h = m_{1,1} (h_1 + h_{n+1} + h_{2n})^2 + \sum_{i=2}^{n} m_{i,1}(h_i + h_{n+1})^2 + \sum_{j=2}^{n-1} \sum_{i=1}^{n} m_{i,j}(h_i + h_{n+j})^2 + \sum_{i=1}^{n} m_{i,n} h_i^2 \geq 0$$

and N_M is symmetric, so N_M is symmetric and positive semidefinite.

(ii) Among all $V \in \partial F(x)$, we consider the following one:

(15) $$V_{min} =$$

$$\left[\begin{array}{cccc|ccccc}
\sum_{i=1}^{n} v_{1,i}^{(min)} & & & & v_{1,1}^{(min)} & v_{1,2}^{(min)} & \cdots & v_{1,n-1}^{(min)} & v_{1,1}^{(min)} \\
& \sum_{i=1}^{n} v_{2,i}^{(min)} & & & v_{2,1}^{(min)} & v_{2,2}^{(min)} & \cdots & v_{2,n-1}^{(min)} & 0 \\
& & \ddots & & \vdots & \vdots & \cdots & \vdots & \vdots \\
& & & \sum_{i=1}^{n} v_{n,i}^{(min)} & v_{n,1}^{(min)} & v_{n,2}^{(min)} & \cdots & v_{n,n-1}^{(min)} & 0 \\
\hline
v_{1,1}^{(min)} & v_{2,1}^{(min)} & \cdots & v_{n,1}^{(min)} & \sum_{i=1}^{n} v_{i,1}^{(min)} & & & & v_{1,1}^{(min)} \\
v_{1,2}^{(min)} & v_{2,2}^{(min)} & \cdots & v_{n,2}^{(min)} & & \sum_{i=1}^{n} v_{i,2}^{(min)} & & & 0 \\
\vdots & \vdots & \cdots & \vdots & & & \ddots & & \vdots \\
v_{1,n-1}^{(min)} & v_{2,n-1}^{(min)} & \cdots & v_{n,n-1}^{(min)} & & & & \sum_{i=1}^{n} v_{i,n-1}^{(min)} & 0 \\
\hline
v_{1,1}^{(min)} & 0 & \cdots & 0 & v_{1,1}^{(min)} & 0 & \cdots & 0 & v_{1,1}^{(min)}
\end{array}\right],$$

where

$$\left\{\begin{array}{l} v_{1,1}^{(min)} = 1 \quad \text{if } m_{1,1} = (t_{11} + x_1 + x_{n+1} + x_{2n})_+ > 0, \\ v_{1,1}^{(min)} = 0 \quad \text{if } m_{1,1} = (t_{11} + x_1 + x_{n+1} + x_{2n})_+ = 0, \end{array}\right.$$

$$\left\{\begin{array}{l} v_{1,j}^{(min)} = 1 \quad \text{if } m_{1,j} = (t_{1,j} + x_1 + x_{n+j})_+ > 0, \\ v_{1,j}^{(min)} = 0 \quad \text{if } m_{1,j} = (t_{1,j} + x_1 + x_{n+j})_+ = 0, \end{array}\right. \qquad j = 2, \ldots, n-1,$$

(16)
$$\left\{\begin{array}{l} v_{i,j}^{(min)} = 1 \quad \text{if } m_{i,j} = (t_{i,j} + x_i + x_{n+j})_+ > 0, \\ v_{i,j}^{(min)} = 0 \quad \text{if } m_{i,j} = (t_{i,j} + x_i + x_{n+j})_+ = 0, \end{array}\right. \qquad \begin{array}{l} i = 2, \ldots, n, \\ j = 1, \ldots, n-1, \end{array}$$

$$\left\{\begin{array}{l} v_{i,n}^{(min)} = 1 \quad \text{if } m_{i,n} = (t_{i,n} + x_i)_+ > 0, \\ v_{i,n}^{(min)} = 0 \quad \text{if } m_{i,n} = (t_{i,n} + x_i)_+ = 0, \end{array}\right. \qquad i = 1, \ldots, n,$$

V_{min} and $V - V_{min}$ are symmetric and positive semidefinite since all $V \in \partial F(x)$ are given by (12) and (13),

$$v_{i,j}^{(min)} \geq 0, \qquad v_{i,j} - v_{i,j}^{(min)} \geq 0,$$

and for any

$$h = \begin{bmatrix} h_1 \\ \vdots \\ h_{2n} \end{bmatrix} \in \mathbb{R}^{2n},$$

we find

$$h^T V_{min} h = v_{1,1}^{(min)} (h_1 + h_{n+1} + h_{2n})^2 + \sum_{i=2}^{n} v_{i,1}^{(min)} (h_i + h_{n+1})^2 + \sum_{j=2}^{n-1} \sum_{i=1}^{n} v_{i,j}^{(min)} (h_i + h_{n+j})^2 + \sum_{i=1}^{n} v_{i,n}^{(min)} h_i^2 \geq 0,$$

$$h^T (V - V_{min}) h = (v_{1,1} - v_{1,1}^{(min)})(h_1 + h_{n+1} + h_{2n})^2 + \sum_{i=2}^{n} (v_{i,1} - v_{i,1}^{(min)})(h_i + h_{n+1})^2 + \sum_{j=2}^{n-1} \sum_{i=1}^{n} (v_{i,j} - v_{i,j}^{(min)})(h_i + h_{n+j})^2 + \sum_{i=1}^{n} (v_{i,n} - v_{i,n}^{(min)}) h_i^2 \geq 0.$$

Thus, all $V \in \partial F(x)$ are nonsingular if and only if V_{min} is positive definite.

Recall that $v_{i,j}^{(min)} > 0$ if and only if $m_{i,j} > 0$, $i, j = 1, \ldots, n$, and for any

$$h = \begin{bmatrix} h_1 \\ \vdots \\ h_{2n} \end{bmatrix} \in \mathbb{R}^{2n},$$

we have

$$\begin{aligned} h^T V_{min} h = v_{1,1}^{(min)} (h_1 + h_{n+1} + h_{2n})^2 + \sum_{i=2}^{n} v_{i,1}^{(min)} (h_i + h_{n+1})^2 \\ + \sum_{j=2}^{n-1} \sum_{i=1}^{n} v_{i,j}^{(min)} (h_i + h_{n+j})^2 + \sum_{i=1}^{n} v_{i,n}^{(min)} h_i^2, \\ h^T N_M h = m_{1,1} (h_1 + h_{n+1} + h_{2n})^2 + \sum_{i=2}^{n} m_{i,1} (h_i + h_{n+1})^2 \\ + \sum_{j=2}^{n-1} \sum_{i=1}^{n} m_{i,j} (h_i + h_{n+j})^2 + \sum_{i=1}^{n} m_{i,n} h_i^2, \end{aligned}$$

so that we get that $h^T V_{min} h > 0$ if and only if $h^T N_M h > 0$. This implies that V_{min} is positive definite if and only if N_M is positive definite. Hence, part (ii) is proved. □

2. The positive semidefiniteness of N_M can be proved[1] alternatively as follows: Let

$$\mathcal{N}_1 = \left[\begin{array}{cccc|cccc|c} \sum_{i=2}^n m_{1,i} & & & & 0 & m_{1,2} & \cdots & m_{1,n-1} & 0 \\ & \sum_{i=1}^n m_{2,i} & & & m_{2,1} & m_{2,2} & \cdots & m_{2,n-1} & 0 \\ & & \ddots & & \vdots & \vdots & \cdots & \vdots & \vdots \\ & & & \sum_{i=1}^n m_{n,i} & m_{n,1} & m_{n,2} & \cdots & m_{n,n-1} & 0 \\ \hline 0 & m_{2,1} & \cdots & m_{n,1} & \sum_{i=2}^n m_{i,1} & & & & 0 \\ m_{1,2} & m_{2,2} & \cdots & m_{n,2} & & \sum_{i=1}^n m_{i,2} & & & 0 \\ \vdots & \vdots & \cdots & \vdots & & & \ddots & & \vdots \\ m_{1,n-1} & m_{2,n-1} & \cdots & m_{n,n-1} & & & & \sum_{i=1}^n m_{i,n-1} & 0 \\ \hline 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0 & 0 \end{array}\right]$$

and

$$\mathcal{N}_2 = \left[\begin{array}{cccc|cccc|c} m_{1,1} & & & & m_{1,1} & 0 & \cdots & 0 & m_{1,1} \\ & 0 & & & 0 & 0 & \cdots & 0 & 0 \\ & & \ddots & & \vdots & \vdots & \cdots & \vdots & \vdots \\ & & & 0 & 0 & 0 & \cdots & 0 & 0 \\ \hline m_{1,1} & 0 & \cdots & 0 & m_{1,1} & & & & m_{1,1} \\ 0 & 0 & \cdots & 0 & & 0 & & & 0 \\ \vdots & \vdots & \cdots & \vdots & & & \ddots & & \vdots \\ 0 & 0 & \cdots & 0 & & & & 0 & 0 \\ \hline m_{1,1} & 0 & \cdots & 0 & m_{1,1} & 0 & \cdots & 0 & m_{1,1} \end{array}\right].$$

[1]This alternative proof was suggested by an anonymous referee.

Then

$$N_M = \mathcal{N}_1 + \mathcal{N}_2.$$

Obviously, $\mathcal{N}_2$ is positive semidefinite. Furthermore, $\mathcal{N}_1$ is nonnegative, symmetric, and weakly diagonally dominant, so the well-known Gershgorin theorem [13] gives that all eigenvalues of $\mathcal{N}_1$ are nonnegative. Thus, $\mathcal{N}_1$ is positive semidefinite. Hence, $N_M = \mathcal{N}_1 + \mathcal{N}_2$ is also positive semidefinite.

If $x = x^\star$ with $F(x^\star) = 0$, then Theorem 2.5(ii) can be simplified significantly, as shown in the next result.

THEOREM 2.6. $M^\star$ (2) $x^\star \in \mathbb{R}^{2n}$ $F(x^\star) = 0$

$$M^\star =: \begin{bmatrix} t_{1,1} & m^\star_{1,2} & \cdots & m^\star_{1,n-1} & m^\star_{1,n} \\ m^\star_{2,1} & m^\star_{2,2} & \cdots & m^\star_{2,n-1} & m^\star_{2,n} \\ & & \cdots & & \\ m^\star_{n,1} & m^\star_{n,2} & \cdots & m^\star_{n,n-1} & m^\star_{n,n} \end{bmatrix}, \tag{17}$$

$$L^\star := \begin{bmatrix} \frac{1}{\sqrt{1-t_{1,1}}} & \\ & I \end{bmatrix} \begin{bmatrix} 0 & m^\star_{1,2} & \cdots & m^\star_{1,n-1} \\ m^\star_{2,1} & m^\star_{2,2} & \cdots & m^\star_{2,n-1} \\ & & \cdots & \\ m^\star_{n,1} & m^\star_{n,2} & \cdots & m^\star_{n,n-1} \end{bmatrix} \begin{bmatrix} \frac{1}{\sqrt{1-t_{1,1}}} & \\ & I \end{bmatrix}. \tag{18}$$

(i)

$$\|L^\star\|_2 \le 1. \tag{19}$$

(ii) $V \in \partial F(x^\star)$

$$\|L^\star\|_2 < 1. \tag{20}$$

We have from Theorem 2.5(i) that $N_{M^\star}$ is symmetric and positive semidefinite. Now $0 < t_{1,1} < 1$, and $M^\star$ satisfies that

$$\begin{cases} 0 < m^\star_{1,1} = t_{1,1} < 1, \quad \sum_{i=2}^n m^\star_{1,i} = 1 - t_{1,1}, \quad \sum_{i=2}^n m^\star_{i,1} = 1 - t_{1,1}, \\ \sum_{i=1}^n m^\star_{j,i} = 1, \quad j = 2, \ldots, n, \\ \sum_{i=1}^n m^\star_{i,j} = 1, \quad j = 2, \ldots, n-1, \end{cases} \tag{21}$$

and thus we obtain, by using the positive semidefiniteness of $N_{M^\star}$, that the matrix

$$\mathcal{N}_{M^\star} := \left[\begin{array}{cccc|cccc} 1-t_{1,1} & & & & 0 & m^\star_{1,2} & \cdots & m^\star_{1,n-1} \\ & 1 & & & m^\star_{2,1} & m^\star_{2,2} & \cdots & m^\star_{2,n-1} \\ & & \ddots & & \vdots & \vdots & \cdots & \vdots \\ & & & 1 & m^\star_{n,1} & m^\star_{n,2} & \cdots & m^\star_{n,n-1} \\ \hline 0 & m^\star_{2,1} & \cdots & m^\star_{n,1} & 1-t_{1,1} & & & \\ m^\star_{1,2} & m^\star_{2,2} & \cdots & m^\star_{n,2} & & 1 & & \\ \vdots & \vdots & \cdots & \vdots & & & \ddots & \\ m^\star_{1,n-1} & m^\star_{2,n-1} & \cdots & m^\star_{n,n-1} & & & & 1 \end{array}\right] \tag{22}$$

is positive semidefinite. Equivalently, (19) holds.

(ii) By Theorem 2.5(ii) we know that all $V \in \partial F(x^\star)$ are nonsingular if and only if $N_{M^\star}$ is positive definite, which is equivalent to saying that the matrix $\mathcal{N}_{M^\star}$ defined by (22) is positive definite. Therefore, part (ii) follows directly from the property that $\mathcal{N}_{M^\star}$ is positive definite if and only if (20) holds. □

Theorem 2.6 is very pleasant because it indicates that for almost all $T \in \mathbb{R}^{n\times n}$, all $V \in \partial F(x^\star)$ are nonsingular for the solution $x^\star$ of the equation $F(x) = 0$.

The following corollary contains two important sufficient conditions ensuring that all $V \in \partial F(x^\star)$ are nonsingular for the solution $x^\star$ of the equation $F(x) = 0$.

COROLLARY 2.7. [illegible] 2.6 [illegible] $M^\star e_i > 0$ [illegible] $1 \le i \le n$ [illegible] $e_j^T M^\star > 0$ [illegible] $1 \le j \le n$ [illegible] $V \in \partial F(x^\star)$ [illegible] e_i [illegible] e_j [illegible] i [illegible] j [illegible] I_n [illegible]. By Theorem 2.6 and its proof we need to show only that $\mathcal{N}_{M^\star}$ defined by (22) is positive definite, provided $M^\star e_i > 0$ for some $1 \le i \le n$ (or $e_j^T M^\star > 0$ for some $1 \le j \le n$).

In the following we assume only that $M^\star e_i > 0$ for some $1 \le i \le n$ because the case that $e_j^T M^\star > 0$ for some $1 \le j \le n$ can be discussed similarly.

First, we have

$$0 < t_{1,1} < 1, \quad 0 \le m^\star_{1,j} < 1, \quad 0 \le m^\star_{j,1} < 1, \quad j = 2, \dots, n,$$

and for any

$$h = \begin{bmatrix} h_1 \\ \vdots \\ h_{2n-1} \end{bmatrix} \in \mathbb{R}^{2n-1},$$

we find

$$h^T \mathcal{N}_{M^\star} h = \sum_{i=2}^{n} m^\star_{i,1}(h_i + h_{n+1})^2 + \sum_{j=2}^{n-1}\sum_{i=1}^{n} m^\star_{i,j}(h_i + h_{n+j})^2 + \sum_{i=1}^{n} m^\star_{i,n} h_i^2. \tag{23}$$

Next, we show by considering three different cases that $h^T \mathcal{N}_{M^\star} h = 0$ only if $h = 0$, as follows.

[illegible] 1: $m^\star_{2,1} \ne 0, \dots, m^\star_{n,1} \ne 0$. In this case

$$\begin{aligned}
& h^T \mathcal{N}_{M^\star} h = 0 \\
\Longrightarrow & \begin{cases} h_2 = \cdots = h_n = -h_{n+1}, \\ h^T \mathcal{N}_{M^\star} h = \sum_{j=2}^{n-1}(h_{n+1} - h_{n+j})^2 \sum_{i=2}^{n} m^\star_{i,j} + h_{n+1}^2 \sum_{i=2}^{n} m^\star_{i,n} \\ \qquad\qquad + \sum_{j=2}^{n-1} m^\star_{1,j}(h_1 + h_{n+j})^2 + m^\star_{1,n} h_1^2 = 0 \end{cases} \\
\Longrightarrow & \begin{cases} h_2 = \cdots = h_n = -h_{n+1} = \cdots = -h_{2n-1} = 0, \\ h^T \mathcal{N}_{M^\star} h = h_1^2 \sum_{j=2}^{n} m^\star_{1,j} = 0 \end{cases} \\
& \qquad \left(\text{since } 0 < \sum_{i=2}^{n} m^\star_{i,j} = 1 - m^\star_{1,j} \le 1,\ j = 2, \dots, n \right) \\
\Longrightarrow & h_1 = \cdots = h_{2n-1} = 0 \quad \left(\text{since } 0 < \sum_{j=2}^{n} m^\star_{1,j} = 1 - t_{1,1} < 1 \right) \\
\Longrightarrow & h = 0.
\end{aligned}$$

• Case 2: $m^\star_{1,k} \neq 0, \ldots, m^\star_{n,k} \neq 0$ for some k with $2 \le k \le n-1$. In this case, we have

$$
\begin{aligned}
& h^T \mathcal{N}_{M^\star} h = 0 \\
\Longrightarrow & \begin{cases} h_1 = \cdots = h_n = -h_{n+k}, \\ h^T \mathcal{N}_{M^\star} h = (h_{n+k} - h_{n+1})^2 \sum_{i=2}^n m^\star_{i,1} + \sum_{j=2}^{k-1} (h_{n+k} - h_{n+j})^2 \sum_{i=1}^n m^\star_{i,j} \\ \qquad\qquad + \sum_{j=k+1}^{n-1} (h_{n+k} - h_{n+j})^2 \sum_{i=1}^n m^\star_{i,j} + h_{n+k}^2 \sum_{i=1}^n m^\star_{i,n} \end{cases} \\
\Longrightarrow & h_1 = \cdots = h_{2n-1} = 0 \\
& \Bigg(\text{since } 0 < \sum_{i=2}^n m^\star_{i,1} = 1 - t_{1,1} \neq 0,\ \sum_{i=1}^n m^\star_{i,n} = 1,\ \sum_{i=1}^n m^\star_{i,j} = 1, \\
& \qquad j = 2, \ldots, k-1, k+1, \ldots, n-1 \Bigg) \\
\Longrightarrow & h = 0.
\end{aligned}
$$

• Case 3: $m^\star_{1,n} \neq 0, \ldots, m^\star_{n,n} \neq 0$. In this case, we have

$$
\begin{aligned}
& h^T \mathcal{N}_{M^\star} h = 0 \\
\Longrightarrow & \begin{cases} h_1 = \cdots = h_n = 0, \\ h^T \mathcal{N}_{M^\star} h = h_{n+1}^2 \sum_{i=2}^n m^\star_{i,1} + \sum_{j=2}^{n-1} h_{n+j}^2 \sum_{i=1}^n m^\star_{i,j} \end{cases} \\
\Longrightarrow & h_1 = \cdots = h_n = 0,\ h_{n+1} = \cdots = h_{2n-1} = 0 \\
& \left(\text{since } 0 < \sum_{i=2}^n m^\star_{i,1} = 1 - t_{1,1} \neq 0,\ \sum_{i=1}^n m^\star_{i,j} = 1,\ j = 2, \ldots, n-1 \right) \\
\Longrightarrow & h = 0.
\end{aligned}
$$

Now we have shown that $h^T \mathcal{N}_{M^\star} h = 0$ only if $h = 0$. This means that $\mathcal{N}_{M^\star}$ is positive definite. □

Remark 3. Corollary 2.7 can be proved[2] alternatively as follows: Consider nonnegative matrix

$$
Z = \begin{bmatrix} D & R \\ R^T & D \end{bmatrix},
$$

where $D = \left[\begin{smallmatrix} t_{1,1} & 0 \\ 0 & 0 \end{smallmatrix}\right] \in \mathbb{R}^{n \times n}$ and R is obtained from the matrix $M^\star$ by replacing its $(1,1)$ entry with 0. Then Z is symmetric doubly stochastic with the largest eigenvalue equal to 1. If $M^\star$ has a nonzero row or a nonzero column, then Z is irreducible. Thus, up to a multiple,

$$
\begin{bmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{bmatrix} \in \mathbb{R}^{2n}
$$

is its only eigenvector corresponding to the largest eigenvalue 1. Now, let us remove the last row and the last column of Z to get the matrix $\tilde{Z} \in \mathbb{R}^{(2n-1)\times(2n-1)}$; then

[2]This alternative proof was also provided by an anonymous referee.

there is no positive vector $v \in \mathbb{R}^{2n-1}$ such that $\tilde{v} = v$. In other words, the largest eigenvalue of $\tilde{Z}$ is less than 1. Hence, $I_{2n-1} - \tilde{Z}$ is positive definite, and so is

$$\mathcal{N}_{M^\star} = (-I_n \oplus I_{n-1})(I_{2n-1} - \tilde{Z})(-I_n \oplus I_{n+1}).$$

An important consequence of Theorems 2.4 and 2.6 is on the convergence of Newton's method (9).

THEOREM 2.8. [illegible] $x^\star \in \mathbb{R}^{2n}$ [illegible] $F(x) = 0$ [illegible] (20) [illegible] (9) [illegible] $x^{(0)}$ [illegible] $x^\star$

3. Numerical algorithm. In our numerical implementation we use the following globalized version of Newton's method for solving the dual problem (3). Recall that $\nabla\theta(x) = F(x)$ for any $x \in \mathbb{R}^{2n}$.

ALGORITHM 1 (nonsmooth Newton's method).

Step 0. [illegible] $x^{(0)} \in \mathbb{R}^{2n}$ $\eta \in (0,1)$ $\rho, \delta \in (0, 1/2)$ $k := 0$

Step 1 (Newton's iteration). [illegible] $V_{min}^{(k)}$ [illegible] (15) [illegible] (16) [illegible] x [illegible] $x^{(k)}$ [illegible] [11, Algorithm 10.2.1] [illegible] $\Delta x^{(k)} \in \mathbb{R}^{2n}$ [illegible]

$$F(x^{(k)}) + V_{min}^{(k)} \Delta x = 0 \tag{24}$$

[illegible]

$$\|F(x^{(k)}) + V_{min}^{(k)} \Delta x^{(k)}\|_F \le \min\{\eta, \|F(x^{(k)}\|_F\} \|F(x^{(k)})\|_F \tag{25}$$

[illegible] $V_{min}^{(k)}$ [illegible] [illegible] [illegible] (25) [illegible]

$$(\Delta x^{(k)})^T F(x^{(k)}) \le -\min\{\eta, \|F(x^{(k)}\|_F\} (\Delta x^{(k)})^T \Delta x^{(k)} \tag{26}$$

[illegible] $V_{min}^{(k)}$ [illegible]

$$\Delta x^{(k)} = -F(x^{(k)}).$$

Step 2 (line search in the descent direction $\Delta x^{(k)}$ of $\theta(x)$ at $x^{(k)}$). [illegible] s_k [illegible] [illegible] s [illegible]

$$\theta(x^{(k)} + \rho^s \Delta x^{(k)}) - \theta(x^{(k)}) \le \delta \rho^s (\Delta x^{(k)})^T F(x^{(k)}).$$

[illegible]

$$x^{(k+1)} := x^{(k)} + \rho^{s_k} \Delta x^{(k)}.$$

Step 3. [illegible] k [illegible] $k+1$ [illegible] 1

In Algorithm 1, we choose the starting point $x^{(0)}$ as the solution of the following simplified version of (2):

$$\begin{aligned} \min \quad & \tfrac{1}{2}\|M - T\|_F^2 \\ \text{s.t.} \quad & \mathcal{A}(M) = b. \end{aligned} \tag{27}$$

This simplified problem has been studied in [10]. As in section 2, by the dual approach, we know that the unique solution M^0 to problem (27) is given by

$$M^0 = T + \mathcal{A}^*(x^{(0)}), \tag{28}$$

where $x^{(0)} \in R^{2n}$ is a solution of

$$\mathcal{A}\left(T + \mathcal{A}^*(x)\right) = b. \tag{29}$$

$x^{(0)}$ can be obtained by applying the CG method to

$$\begin{bmatrix} n & & & & 1 & \cdots & 1 & 1 \\ & n & & & 1 & \cdots & 1 & 0 \\ & & \ddots & & \vdots & \cdots & \vdots & \vdots \\ & & & n & 1 & \cdots & 1 & 0 \\ 1 & 1 & \cdots & 1 & n & & & 1 \\ \vdots & \vdots & \cdots & \vdots & & \ddots & & \vdots \\ 1 & 1 & \cdots & 1 & & & n & \\ 1 & 1 & \cdots & 1 & 1 & & & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \\ x_{n+1} \\ \vdots \\ x_{2n-1} \\ x_{2n} \end{bmatrix} = \begin{bmatrix} 1 - \sum_{i=1}^n t_{1,i} \\ 1 - \sum_{i=1}^n t_{2,i} \\ \vdots \\ 1 - \sum_{i=1}^n t_{n,i} \\ 1 - \sum_{i=1}^n t_{i,1} \\ \vdots \\ 1 - \sum_{i=1}^n t_{i,n-1} \\ 0 \end{bmatrix}. \tag{30}$$

THEOREM 3.1. [illegible] (20) [illegible] $\{x^{(k)}\}$ [illegible] 1 [illegible] $x^\star$ [illegible] $F(x) = 0$ [illegible]. Since for any $k \geq 0$, $\Delta x^{(k)}$ is always a descent direction of $\theta(x)$ at $x = x^{(k)}$, and since $\theta(x)$ is convex, we know that $\{x^{(k)}\}$ is bounded. Thus, we obtain by using Theorem 6.3.3 in [7], that

$$\lim_{k \to \infty} \nabla\theta(x^{(k)}) = 0,$$

which, in return, together with the convexity of $\theta(x)$ and the boundedness of $\{x^{(k)}\}$, yields that $x^{(k)} \to x^\star$ for some $x^\star$ satisfying $F(x^\star) = 0$.

Note that (20) holds, by Theorem 2.6(ii), and all $V \in \partial F(x^\star)$ are nonsingular. Since $x^{(k)} \to x^\star$, by Proposition 3.1 in [20], for all k sufficiently large, $V_{min}^{(k)}$ is positive definite and $\{\|V_{min}^{(k)}\|_F\}$ and $\{\|(V_{min}^{(k)})^{-1}\|_F\}$ are uniformly bounded. Thus, for all k sufficiently large, $\Delta x^{(k)}$ can satisfy (25) and (26), and moreover, (14) and that $F(x^\star) = 0$ yields

$$F(x^{(k)}) - F(x^\star) - V_{min}^{(k)}(x^{(k)} - x^\star) = 0, \quad \text{i.e., } F(x^{(k)}) = V_{min}^{(k)}(x^{(k)} - x^\star).$$

Hence, for all k sufficiently large,

$$\begin{aligned} \|x^{(k)} + \Delta x^{(k)} - x^\star\|_F &= \|(V_{min}^{(k)})^{-1}(F(x^{(k)}) + V_{min}^{(k)}\Delta x^{(k)})\|_F \\ &\leq \|(V_{min}^{(k)})^{-1}\|_F \|F(x^{(k)}) + V_{min}^{(k)}\Delta x^{(k)}\|_F \\ &\leq \|(V_{min}^{(k)})^{-1}\|_F \min\{\eta, \|F(x^{(k)})\|_F\}\|F(x^{(k)})\|_F \\ &\leq \|(V_{min}^{(k)})^{-1}\|_F \|F(x^{(k)}\|_F^2 \\ &\leq \|(V_{min}^{(k)})^{-1}\|_F \|V_{min}^{(k)}\|_F^2 \|x^{(k)} - x^\star\|_F^2 \\ &= O(\|x^{(k)} - x^\star\|_F^2). \end{aligned}$$

Then, for all k sufficiently large, $s_k = 0$, $\rho^{s_k} = 1$, and

$$x^{(k+1)} = x^{(k)} + \Delta x^{(k)}.$$

Therefore, the quadratic convergence follows. □

In the rest of this section, we report our numerical results for solving (1) by Algorithm 1. All the tests are implemented in MATLAB 7.0.1 running on a P4 PC with a 2.40GHz CPU. We also compare the performance of our method with that of the alternating projection method proposed in [10].

In our experiments, we tested the following two classes of problems.

1. Let M be given by (6). Set

$$T := M + \tau R,$$

where R is a random $n \times n$ real matrix with entries in $[-1.0, 1.0]$ and $\tau \in \mathbb{R}$ is a perturbed parameter. Here, we set $t_{1,1} = 0.5 < 1$ to ensure that (4) holds. We report our numerical results for $n = 500, 1000, 1500, 2000, 2500, 3000, 3500, 4000, 4500, 5000$, and $\tau = 0.1, 1.0, 10.0$.

2. The matrix T is generated randomly with entries uniformly distributed between -10.0 and 10.0, but we set $t_{1,1} = 0.5 < 1$. We give our numerical results for $n = 500, 1000, 1500, 2000, 2500, 3000, 3500, 4000, 4500, 5000$.

To demonstrate the performance of Algorithm 1, the linear systems (24) and (30) are solved with provision for lower (inexact) and higher (approximately exact) accuracy requirements.[3] To do this, in our numerical experiments we set the parameters used in our algorithm as either

(a) $\texttt{Tol} = 10^{-6},\ \eta = 10^{-6},\ \rho = 0.5,$ and $\delta = 10^{-4}$, or

(b) $\texttt{Tol} = 10^{-10},\ \eta = 10^{-15},\ \rho = 0.5,$ and $\delta = 10^{-4}$.

Here, Tol is the required tolerance used in the stopping criterion defined by

$$\|\nabla\theta(x^{(k)})\|_F = \|F(x^{(k)}\|_F \le \texttt{Tol}.$$

Our numerical results are given in Tables 1–4, where Time, Iter., Res0., Res*., and Err*. stand for the CPU times required for convergence, the number of iterations, the residuals $\|\nabla\theta(\cdot)\|_F$ at the starting point $x^{(0)}$ and the final iterate of Algorithm 1, and the error

$$\left\| \begin{bmatrix} M\mathbf{e} \\ M^T\mathbf{e} \\ \mathbf{e}_1^T M\mathbf{e}_1 \end{bmatrix} - \begin{bmatrix} \mathbf{e} \\ \mathbf{e} \\ \mathbf{e}_1^T T\mathbf{e}_1 \end{bmatrix} \right\|_F$$

at the computed solution M^*, respectively.

In our experiments, the quadratic convergence of Algorithm 1 is observed. From Tables 1–4, we note that if we solve the linear system (24) with a lower accuracy, it needs less CPU time, but we can obtain a coarser solution. Conversely, if we solve the linear system (24) with a higher accuracy, we can obtain a relatively more precise solution, but it needs relatively more CPU time. Finally, in our experiments, the largest numerical examples contain $25,000,000$ unknowns in the primal problem (1) and $10,000$ unknowns in the dual problem (3). This shows that Algorithm 1 is very efficient for large scale problems.

Next, we compare the performance of our Algorithm 1 with that of the alternating projection method in [10]. For the purpose of comparison, we set the stopping tolerance for both algorithms at

$$\left\| \begin{bmatrix} M\mathbf{e} \\ M^T\mathbf{e} \\ \mathbf{e}_1^T M\mathbf{e}_1 \end{bmatrix} - \begin{bmatrix} \mathbf{e} \\ \mathbf{e} \\ \mathbf{e}_1^T T\mathbf{e}_1 \end{bmatrix} \right\|_F \le \texttt{Tol}.$$

[3] As an anonymous referee pointed out, the linear system (30) can also be solved in linear time by using the direct methods exploiting the structure of the coefficient matrix of (30) [4, 5, 8, 18].

	5,000	27 m 14 s	11	1.2×10^{6}	2.5×10^{-10}	2.5×10^{-10}

Here, we choose $\texttt{Tol}$ to be different values, e.g., $\texttt{Tol} = 10^{-6}, 10^{-10}$, etc. Consequently, in Algorithm 1 (24) is solved with varying accuracies; see $\eta = 10^{-6}, 10^{-15}$, etc. The values of the remaining parameters used in Algorithm 1 are set as above. Tables 5–6 list the numerical results for Example 1 with varying n, $\texttt{Tol}$, and η, where $\texttt{Dist}$ is the distance between T and the computed closest matrix M in the Frobenius norm. Here, we report the numerical results only for $\tau = 0.1$ and $n = 500, 1000, 1500, 2000$, 2500, 3000, and 3500, as the other cases behave similarly.

From Tables 5–6 we observe that Algorithm 1 is much more efficient than the alternating projection method in [10].

4. Conclusions. In this paper we proposed to solve the dual problem (3) by Algorithm 1 in order to obtain the solution of the nearest doubly stochastic matrix problem (1). Under the mild assumptions (4) and (20), we have shown that Algorithm 1 is quadratically convergent. We have also demonstrated its numerical performance by some examples.

In problem (1), only the $(1, 1)$ entry of the matrix M is fixed to be identical to the given matrix T. This is an assumption without loss of generality, since the framework we establish in this paper can be easily applied to the nearest doubly stochastic matrix problem with k prescribed entries. In fact, consider the following problem:

$$f(M) := \frac{1}{2}\|M - T\|_F^2, \quad \mathcal{B}(M) := \begin{bmatrix} M\mathbf{e} \\ \begin{bmatrix} I_{n-1} & 0 \end{bmatrix} M^T\mathbf{e} \\ \mathbf{e}_{i_1}^T M \mathbf{e}_{j_1} \\ \vdots \\ \mathbf{e}_{i_k}^T M \mathbf{e}_{j_k} \end{bmatrix}, \quad c := \begin{bmatrix} \mathbf{e} \\ \begin{bmatrix} I_{n-1} & 0 \end{bmatrix} \mathbf{e} \\ \mathbf{e}_{i_1}^T T \mathbf{e}_{j_1} \\ \vdots \\ \mathbf{e}_{i_k}^T T \mathbf{e}_{j_k} \end{bmatrix};$$

then problem (31) is equivalent to

$$\begin{cases} \min & f(M) \\ \text{s.t.} & \mathcal{B}(M) = c, \\ & M \in \mathcal{K}. \end{cases} \tag{32}$$

The dual problem of (32) is

$$\begin{cases} \sup & -\theta(x) \\ \text{s.t.} & x \in \mathbb{R}^{2n+k-1}, \end{cases} \tag{33}$$

where

$$\theta(x) = \frac{1}{2}\|\Pi_{\mathcal{K}}(T + \mathcal{B}^\star(x))\|_F^2 - x^T c - \frac{1}{2}\|T\|_F^2,$$

and $\mathcal{B}^\star$ is the adjoint of $\mathcal{B}$. Hence, we can extend the results that we derived for problem (1) to problem (31) and apply a Newton-type method to solve the dual problem (33) and then obtain the desired solution of the problem (31).

A SCHWARZ WAVEFORM MOVING MESH METHOD*

RONALD D. HAYNES† AND ROBERT D. RUSSELL‡

Abstract. An r-refinement (moving mesh) method is considered for solving time dependent partial differential equations (PDEs). The resulting coupled system, consisting of the physical PDE and a moving mesh PDE, is solved by a Schwarz waveform relaxation method. In particular, the computational space-time domain is decomposed into overlapping subdomains and the solution obtained by iteratively solving the system of PDEs on each subdomain. Dirichlet boundary conditions are used to pass solution information between neighboring regions. The efficacy of this approach is demonstrated for some model problems. For problems where the solutions evolve on disparate time scales in different regions of the spatial domain, this approach demonstrates the significant savings in computational time and effort which are possible.

Key words. Schwarz waveform relaxation, moving meshes, domain decomposition, dynamic iteration

1. Introduction.

The method of lines (MOL), one of the predominant approaches for solving time dependent parabolic partial differential equations (PDEs), involves discretizing spatially and then integrating in time along either fixed or moving lines. The efficacy of the method rests on that of the subsequent initial value problem (IVP) solvers. Traditional IVP solvers integrate using time steps chosen to keep an estimate of the local error below some user specified tolerance. As a consequence, the time step, largely dictated by the behavior of the fastest components locally, is used to integrate all solution components.

This global approach introduces inefficiencies by often requiring a small time step for each unknown, particularly when there are disparate scales in solution components. This occurs when solution scales along lines differ substantially, which is the case, for example, when the solution has moving interfaces or singular behavior.

A number of ways to overcome this limitation by integrating using steps locally suited to the time dynamics have been investigated. The idea appears to have originated in a paper by Rice [42] which considers split or multirate Runge–Kutta methods applied to systems of ordinary differential equations (ODEs). In the independent work of Gander and Stuart [22] and Giladi and Keller [25], the domain decomposition method is applied for solving time dependent PDEs. Splitting the problem spatially allows the solution in different parts of the spatial domain to be evolved according to local time scale. The technique, known as Schwarz waveform relaxation, is able to overcome many of the problems which exist in applying the ODE methods mentioned above to semidiscretized PDEs.

It is well accepted that the efficient solution of complex PDEs generally requires methods which are adaptive in both space and time. In this paper we are interested in

a class of spatially adaptive moving mesh PDE methods introduced in [41, 29, 30]. Our purpose is to introduce and explore a natural coupling of domain decomposition, in the Schwarz waveform context, and the spatially adaptive moving mesh PDE methods.

In the next two sections we review the relevant literature for both the ODE and PDE contexts. In section 4 we review the so-called moving mesh PDE methods. Section 5 introduces a Schwarz waveform moving mesh method. In section 6 we provide some numerical results to justify the utility of the technique. We conclude in section 7 with a summary and discussion of ongoing and future work.

2. ODE methods. There have been a number of approaches for solving systems of ODEs using decoupled integration. A decoupled integration method proceeds by identifying groups of components which evolve at similar time scales or for which it is advantageous to use particular integration formulas. Communication between the subsystems is typically handled through either interpolation or some iterative procedure. Gear [24] investigates solving a system of ODEs where the ith component is integrated using a step size function $h_i(t)$. Due to the cost of the required interpolations the method is deemed competitive only if the cost of the function evaluations is high or if f_i depends on few solution components. Hofer [28] proposes a method where the ODE is decoupled into stiff and nonstiff components. Computational efficiency is achieved by the decoupling of the integration and by restricting the number of implicit formulations to a few equations. Assuming the system has been decoupled a priori, Andrus [2] presents a method where both a different integration method and time step are used for the slow and fast subsystems. Skelboe [44, 43] investigates multirate decoupled backward differentiation formulas (BDFs) for general systems of ODEs separated into subsystems. The partitioning requires subsystems having strongly interacting components but weak couplings to the other subsystems. Deuflhard [10] suggests analyzing the Jacobian to detect groups of fast and slow components. More recently, Engstler and Lubich [11, 12] have considered a multirate technique which does dynamic decoupling using extrapolation methods.

One of the earliest techniques for decoupling the integration of systems of ODEs was waveform relaxation, where subsystems are integrated separately and communication between them handled through iteration. The theory of the method is considered in Lelarasmee, Ruehli, and Sangiovanni-Vincentelli [35] and later in Miekkala and Nevanlinna [38], which contributed to the subsequent popularization of the method.

3. PDE methods. There have been several attempts to incorporate a multirate strategy within a solution methodology for PDEs. The MOL, for example, yields a large system of ODEs for which there may be a motivation to decouple the fast and slow components. The partitioning of components can be done dynamically and automatically to adapt to temporally and spatially evolving features in the solution, although this complicates the use of the majority of the above ODE methods.

Not surprisingly the motivation to use different space-time grids in regions of the computational domain has spawned intensive research. Flaherty and Moore [14] develop integrated space-time *hp*-refinement strategies. These methods make decisions about the number of mesh points, time step size, and the order of the time integration method locally in space-time in a unified manner. In this sense these methods may be viewed as a class of multirate methods. These methods are computationally robust; however, the resulting space-time meshes are complicated and require sophisticated data structures for efficient implementation [13].

Domain decomposition methods (e.g., see [7, 40]) attempt to solve a problem over the entire spatial domain by iteratively solving on subdomains. There have been at least three general approaches for applying domain decomposition to parabolic problems in a space-time domain:

1. Discretize in time and solve the resulting elliptic problems with classical domain decomposition [5, 37, 34].
2. Discretize in space and apply waveform relaxation to the system of ODEs [36, 33, 32].
3. Subdivide the spatial domain and iteratively solve a sequence of PDEs defined on each subdomain [15, 18, 25].

The first approach is in some sense the most natural since one utilizes the extensive literature for domain decomposition applied to elliptic problems. This technique suffers from a couple of difficulties. First, since the elliptic problems arise after discretizing in time, we are forced to use the same time step on each subdomain. Second, the computed solution information must be exchanged at the end of each time step. This necessitates that identical time steps be used throughout the spatial domain and makes a natural parallel implementation difficult.

The second approach allows different time steps in different regions of the spatial domains. Information is transmitted between subdomains after solving a subset of ODEs over a time window, not after each step. Unfortunately, for Jacobi, Gauss–Seidel, and SOR waveform relaxation methods, in the case where the ODEs result from a spatial discretization of a PDE, the constants which arise in the error estimates depend negatively on the mesh parameter Δx. Sophisticated multigrid techniques have been proposed to overcome the negative dependence on the mesh parameter for these classical waveform relaxation methods; cf. [32, 36, 46].

The third class of methods, which have become known as Schwarz waveform relaxation methods, overcome the poor convergence of waveform relaxation methods. These methods were developed by Gander and colleagues [17, 22, 18, 20, 15] and independently by Giladi and Keller in [25]. The methods allow different numerical treatments (time step and integration formula) on different subdomains and have convergence independent of the mesh parameter, without the added complication of the multigrid framework. Since these methods provide the basis for the methods developed in the next section, we describe them in more detail below.

Consider a general parabolic problem

$$u_t = \mathcal{L}(u, x, t) \qquad \text{in } \Omega,$$

subject to appropriate initial and boundary conditions on $\partial\Omega$. In the case of two overlapping subdomains Ω_0 and Ω_1, the classical Schwarz waveform relaxation method can be succinctly written as follows: for $j = 0, 1$,

$$\frac{\partial u_j^{(k+1)}}{\partial t} = \mathcal{L}(u_j^{(k+1)}, x, t), \qquad (x,t) \in \Omega_j,$$

$$u_j^{(k+1)}(x,t) = \begin{cases} u_{1-j}^{(k)}(x,t), & (x,t) \in \Gamma_j = \partial\Omega_j \cap \Omega_{1-j}, \\ \text{given boundary condition} & x, t \in \partial\Omega_j - \Gamma_j. \end{cases}$$

There have been many theoretical advances towards understanding the convergence of Schwarz waveform relaxation. In [22] linear and superlinear convergence results are obtained for the one-dimensional heat equation. Convergence is shown to be independent of the mesh parameter (and hence robust with respect to mesh refinement), and the convergence rate improves by increasing the size of the overlap. Giladi

and Keller [25] prove superlinear convergence for constant coefficient convection diffusion equations. Gander [17, 18] extends these results to the one-dimensional, variable coefficient reaction diffusion case. Gander, Halpern, and Nataf [20] apply overlapping Schwarz waveform methods to the wave equation and a constant coefficient, linear convection reaction diffusion equation. The effect of the Dirichlet transmission conditions at the subdomain boundaries is studied and found to slow convergence of the algorithms. Optimal transmission conditions are then derived which lead to nonoverlapping Schwarz methods which converge in a finite number of steps [16]. Multidimensional extensions of many of these results are available [23, 19]. In a recent paper [15], Gander and Rohde provide results for one-dimensional convection-dominated conservation laws.

In the next section we describe the moving mesh PDE method and in section 5 we propose a new moving mesh Schwarz waveform method which inherits the favorable properties of the basic method and the spatial mesh resolution abilities of moving mesh PDEs.

4. Moving mesh methods. Adaptive mesh methods for PDEs typically fall into one or more of the following broad categories:

- r-refinement: moving a fixed number of mesh points to difficult regions of the physical domain,
- p-refinement: varying the order of the numerical method to adapt to local solution smoothness,
- h-refinement: mesh refinement and derefinement, depending upon the local level of resolution.

These methods may be applied in either a static or dynamic fashion. Static methods involve refining/coarsening or redistributing mesh points at fixed times during a calculation. Dynamic (or moving mesh) methods solve for the solution and mesh simultaneously. The latter, some of whose advantageous features will be explained subsequently, are the ones considered here.

To be specific, consider the solution of a PDE of the form

$$u_t = \mathcal{L}(u), \qquad 0 < x < 1, \quad t > 0,$$

subject to appropriate initial and boundary conditions, where again $\mathcal{L}$ denotes a spatial differential operator in the physical coordinate x. Our goal is basically to find, for fixed t, a one-to-one coordinate transformation

$$x = x(\xi, t) : [0,1] \to [0,1] \quad \text{with } x(0,t) = 0,\ x(1,t) = 1$$

such that $u(x(\xi,t),t)$ is sufficiently smooth that a simple mesh can be used to resolve solution features in the computational domain $\xi \in [0,1]$. Typically a uniform mesh,

$$\xi_i = \frac{i}{N}, \quad i = 0, 1, \ldots, N,$$

suffices, and the mesh in the physical coordinate x is then specified from the mesh transformation by $x_i(t) = x(\xi_i, t),\ i = 0, 1, \ldots, N$.

A standard way to perform mesh adaptation in space is to use the equidistribution principle (EP) [9]: Given some measure $M(t,x,u)$ of the error in the numerical solution, equidistribution requires that the mesh points satisfy

$$\int_{x_{i-1}}^{x_i} M(t,\tilde{x},u)\, d\tilde{x} \equiv \frac{1}{N} \int_0^1 M(t,\tilde{x},u) d\tilde{x}$$

on each subinterval $[x_{i-1}(t), x_i(t)]$ or

$$\int_0^{x(\xi_i,t)} M(t,\tilde{x},u)\,d\tilde{x} \equiv \xi_i \int_0^1 M(t,\tilde{x},u)d\tilde{x} \quad \text{for } i = 1,\ldots,N.$$

The continuous generalization of this is that

$$\int_0^{x(\xi,t)} M(t,\tilde{x},u)\,d\tilde{x} = \xi\theta(t), \tag{4.1}$$

where $\theta(t) \equiv \int_0^1 M(t,\tilde{x},u)\,d\tilde{x}$ (e.g., see [29]). It follows directly from (4.1) that

$$\frac{\partial}{\partial\xi}\left\{M(t,x(\xi,t),u)\frac{\partial}{\partial\xi}x(\xi,t)\right\} = 0. \tag{4.2}$$

Note that (4.2) does not explicitly involve the node speed $\dot{x}$. This is generally introduced by relaxing the equation to require equidistribution at time $t+\tau$. In [41, 29, 30] a number of parabolic moving mesh PDEs (MMPDEs) are developed using somewhat subtle simplifying assumptions and their correspondence to various moving mesh methods (previously motivated only by heuristic arguments) is shown. One particularly useful MMPDE is

$$\frac{\partial}{\partial\xi}\left(M(t,x(\xi,t),u)\frac{\partial\dot{x}}{\partial\xi}\right) = -\frac{1}{\tau}\frac{\partial}{\partial\xi}\left(M(t,x(\xi,t),u)\frac{\partial x}{\partial\xi}\right). \tag{MMPDE4}$$

The relaxation parameter τ is chosen in practice so that the mesh evolves at a rate commensurate with that of the solution $u(x,t)$.

A simple popular choice for $M(t,x,u)$ is the arclength-like monitor function [3, 45]

$$M(x,u,t) = \sqrt{1+\frac{1}{\alpha}|u_x|^2}. \tag{4.3}$$

This choice is based on the premise that we expect the error in the numerical solution to be largest in regions where the solution has large gradients. The choice of monitor function is often problem class dependent; e.g., monitor functions which preserve the scaling invariance of the physical PDE [4] are seen to work well for reaction diffusion problems having blow-up solutions (as opposed to the arclength monitor function, for instance, which ultimately fails to resolve the solution near the singularity in time).

As outlined in the previous section, using a moving mesh method to solve a PDE requires solving a coupled system of PDEs for the unknown mesh transformation and solution. Using the mesh transformation $x = x(\xi,t)$ to rewrite the physical PDE in quasi-Lagrangian form, we get

$$\dot{u} - u_x\dot{x} = \mathcal{L}u, \tag{4.4}$$

where the total time derivative $\dot{u}$ is given as

$$\dot{u} = u_t + u_x\dot{x}.$$

Equation (4.4) and a moving mesh equation are solved simultaneously for the mesh $x(\xi,t)$ and corresponding solution $u(x(\xi,t),t)$. Specifically, we solve the coupled PDE system

$$\begin{aligned} \dot{u} - u_x\dot{x} &= \mathcal{L}(u), \\ \left(M(x,u,t)\dot{x}_\xi\right)_\xi &= -\frac{1}{\tau}\left(M(x,u,t)x_\xi\right)_\xi \end{aligned} \tag{4.5}$$

using the moving MOL approach. Discretizing spatially with centered differences we obtain the semidiscrete approximation

(4.6)
$$\dot{u}_i - \left(\frac{u_{i+1}-u_{i-1}}{x_{i+1}-x_{i-1}}\right)\dot{x}_i = f_i,$$
$$\frac{M_{i+1}+M_i}{2(1/N)^2}\left(\dot{x}_{i+1}-\dot{x}_i\right) - \frac{M_i+M_{i-1}}{2(1/N)^2}\left(\dot{x}_i-\dot{x}_{i-1}\right) =$$
$$-\frac{1}{\tau}\left\{\frac{M_{i+1}+M_i}{2(1/N)^2}\left(x_{i+1}-x_i\right) - \frac{M_i+M_{i-1}}{2(1/N)^2}\left(x_i-x_{i-1}\right)\right\}$$

for $i = 1, \ldots, N-1$. The right-hand side of the semidiscrete physical PDE, f_i, denotes the discrete approximation to the spatial operator $\mathcal{L}$ at $\xi = \xi_i$. Centered differences are used to discretize $\mathcal{L}$. The quantity M_i denotes a centered difference approximation to the monitor function at x_i. In actual calculations, M_i is replaced by a smoothed value

$$\tilde{M}_i = \sqrt{\sum_{k=i-p}^{i+p}(M_k)^2\left(\frac{\gamma}{\gamma+1}\right)^{|k-i|} \Bigg/ \sum_{k=i-p}^{i+p}\left(\frac{\gamma}{\gamma+1}\right)^{|k-i|}},$$

where $\gamma = 2$ and $p = 2$ [29].

Initial and boundary conditions for the physical PDE come from the problem description. On a fixed interval we specify $\dot{x}_0 = \dot{x}_N = 0$ as boundary conditions for the mesh. If the initial solution $u(x,0)$ is smooth, then an initial uniform mesh for $x(\xi,0)$ is normally sufficient. If the initial solution has features which are not resolved on a uniform mesh for the chosen value of N, then an equidistributed initial mesh is required. One way used in [31] to compute an initial equidistributed mesh is to solve the PDE

$$u_t = u_0(x), \quad u(x,0) = 0,$$

coupled with a moving mesh equation. Solving this system over the time interval $0 \le t \le 1$ with a uniform initial mesh will yield the solution $u(x,1) = u_0(x)$, and the resulting mesh will approximately equidistribute the initial solution. To avoid propagating any errors from this calculation, the initial solution is reevaluated at the new initial mesh.

The semidiscrete approximation (4.6) describes a system of linearly implicit ODEs which may be written in the form

$$V(y)y' = g(y). \tag{4.7}$$

The vector y denotes the unknowns ordered as $(u_0, x_0, u_1, x_1, \ldots, u_N, x_N)^T$, and $V(y)$ is a banded matrix which depends on the unknown solution and mesh.

A typical implementation (cf. [31]) for solving (4.5) involves discretizing spatially and solving (4.7) with a stiff ODE solver such as DASSL [39]. In the next section we propose a Schwarz waveform moving mesh method to solve (4.5) and describe its implementation.

5. Schwarz waveform moving mesh method. In this section we propose a new Schwarz waveform moving mesh (or simply "moving Schwarz") method. The basic idea is to apply Schwarz waveform relaxation, as described in section 3, to the coupled system of physical and moving mesh PDEs (4.5). Specifically, we first decompose $\Omega = [0,1]$ into D nonoverlapping fixed subdomains $\tilde{\Omega}_j$, $j = 1, \ldots, D$. Each subdomain $\tilde{\Omega}_j$ is enlarged by an overlap region consisting of R mesh points, giving overlapping domains $\Omega_1, \Omega_2, \ldots, \Omega_D$. The physical PDE is then discretized along with a moving mesh equation on each subdomain. We fix the mesh points on the boundary of $\tilde{\Omega}_j$, $j = 1, \ldots, D$, but allow the mesh points to move within and on the outer boundary of the overlap regions. Algorithmically, there is no reason to keep the boundaries fixed. However, there is a tendency for moving mesh methods to emphasize the most pathological regions of the solution. Allowing the subdomain boundaries to move could potentially negate the effort to isolate difficult regions within individual subdomains. We will return to this point in the next section.

The convergence of overlapping classical Schwarz waveform relaxation is known to depend on the width of the overlap region. In this implementation we have found that having the width of the overlap in the computational domain of moderate size works well, even for somewhat pathological solution behavior in the physical domain where the width of the overlap in the physical variables varies (but the number of mesh points in this region is fixed). A priori determining an optimal width of the overlap region in the computational domain would be difficult. As in the fixed mesh case, the rate of convergence of the Schwarz iteration is improved as the size of the overlap is increased, with the faster convergence being offset by the increased computational cost. Things are further complicated by the desire to isolate difficult regions of the solution from regions where there is little activity. As the overlap is increased more subdomains become "active."

Let x_j and ξ_j denote the physical and computational meshes on each subdomain Ω_j, and denote the solution on each subdomain by u_j. The moving Schwarz method requires solving

$$\dot{u}_j^k - \frac{\partial u_j^k}{\partial x}\dot{x}_j^k = \mathcal{L}(u_j^k),$$
$$\left(M(x_j^k, u_j^k, t)\frac{\partial \dot{x}_j^k}{\partial \xi}\right)_\xi = -\frac{1}{\tau}\left(M(x_j^k, u_j^k, t)\frac{\partial x_j^k}{\partial \xi}\right)_\xi,$$

on Ω_j with $j = 1, \ldots, D$, for $k = 1, 2, \ldots$.

The boundary values for u_j^k and x_j^k come from the values $u_{j-1}^{k-1}, x_{j-1}^{k-1}$ and $u_{j+1}^{k-1}, x_{j+1}^{k-1}$ on the left and right boundaries of Ω_j, respectively, from the previous iteration. Each Schwarz waveform iteration requires the solution of D problems with (known) moving boundaries. This is illustrated in Figure 5.1 for $D = 3$.

On each subdomain the coupled system of PDEs is discretized in space as described in section 4 and the resulting ODEs are integrated over successive time windows. The time dependent boundary conditions for u_j and x_j on these time windows are obtained by cubic spline interpolation of the data from the previous iteration. Interpolation is required since in general the data from iteration $k-1$ is not computed on the same sequence of time steps as iteration k.

For efficiency, the algorithm is designed with an adaptive time windowing strategy. The algorithm begins by solving the sequence of moving boundary problems on a time window $[0, T]$. If u_j or x_j fails to reach $t = T$ in the maximum allowable time

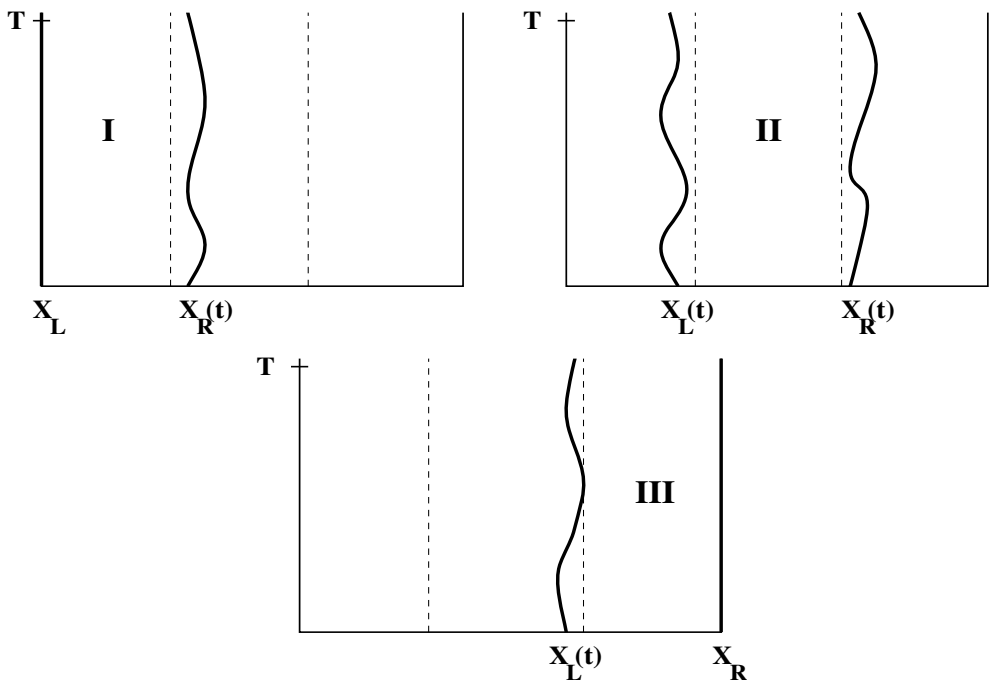

FIG. 5.1. *Sequence of moving boundary problems solved during one iteration of the Schwarz waveform moving mesh method over a time window* $[0, T]$.

steps, the iteration is restarted with a smaller time window. The window is also reduced if the Schwarz iteration fails to converge in 6 iterations and enlarged if the iteration converges in fewer than 4 iterations. These values, chosen on the basis of significant experimentation [27], provide a balance between efficiency and storage. The latter can be significant even in the one-dimensional case because in the absence of a guarantee that the maximum principle holds, we conservatively require successive approximations over subdomains to agree to within some user specified tolerance δ before the waveform iteration is terminated. A tolerance of $\delta = 1e-4$ is used in the experiments with local error control tolerance (for the time integration) of $1e-6$.

As a final note, the code provides each subdomain with an initial equidistributed mesh. That is, we solve $u_t = u_0(x)$ for $x \in \tilde{\Omega}_j$ and a moving mesh PDE subject to $u(x,0) = 0$. This provides a grid which equidistributes the initial solution to the PDE over each subdomain.

6. Numerical results. To provide some initial testing of the moving Schwarz method we first solve a straightforward test problem.

1: I Our first example is a standard test problem for adaptive methods, Burgers' equation. Specifically, we solve the one-dimensional viscous Burgers' equation

$$u_t = \epsilon u_{xx} - \frac{1}{2}(u^2)_x,$$

$$u(0,t) = 1, \quad u(1,t) = 0,$$

$$u(x,0) = c - \frac{1}{2}\tanh\left(\frac{(x-x_0)}{4\epsilon}\right),$$

where $c = 1/2$, $x_0 = 1/4$ or $1/10$, and $\epsilon \ll 1$. The solution is a traveling front of thickness $O(\epsilon)$ which moves to the right from x_0 at speed c. The initial and boundary conditions are not compatible at $t = 0$ and $x = 0, 1$, but the discrepancy is small for small ϵ. This does not pose any difficulties with the numerics.

We take $\epsilon = 1e - 4$ and use 40 mesh points in each of the three equal sized subdomains. The top row of plots in Figure 6.1 illustrates the computed solution at times $t = 0.25, 0.45$, and 1.7. The bottom plots show the corresponding pointwise error $|\tilde{u}(x_i, t^*) - u(x_i, t^*)|$, where $\tilde{u}$ is the numerical approximation to the exact solution u obtained using the Schwarz waveform moving mesh method. As expected we see a sharp front moving from left to right. The mesh trajectories as functions of time are displayed in Figure 6.2.

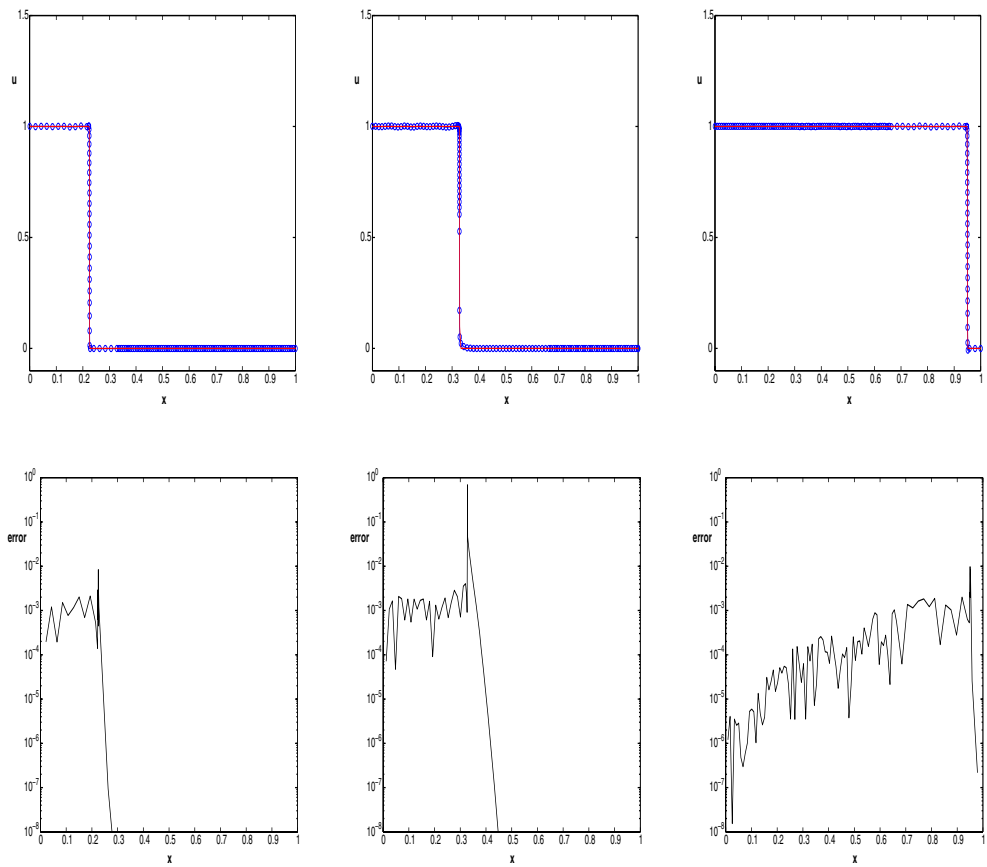

FIG. 6.1. *Solutions and pointwise errors for Burgers' equation with the Schwarz waveform moving mesh method at* $t = 0.25$ *(left),* $t = 0.45$ *(middle), and* $t = 1.7$ *(right).*

At $t = 0.25$ and $t = 1.7$, the actual errors in the solution are on the order of the tolerance controlling the convergence of the Schwarz waveform iteration. At $t = 0.45$, however, the front encounters the boundary between the first and second subdomains, and the level of communication between the solutions in these adjacent subdomains is inadequate to preserve the accuracy. A possible fix may be provided by some of the more sophisticated Schwarz waveform methods which use "higher-order" transmission conditions at the boundary [20, 21].

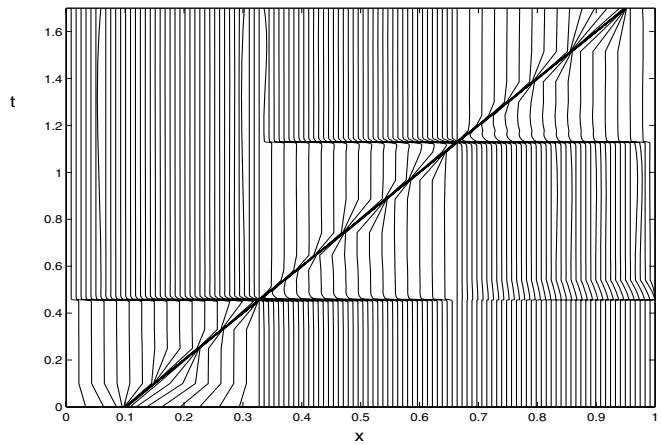

FIG. 6.2. *Mesh trajectories for Burgers' equation with* $\epsilon = 1e-4$ *and* 40 *points per domain using the Schwarz waveform moving mesh method.*

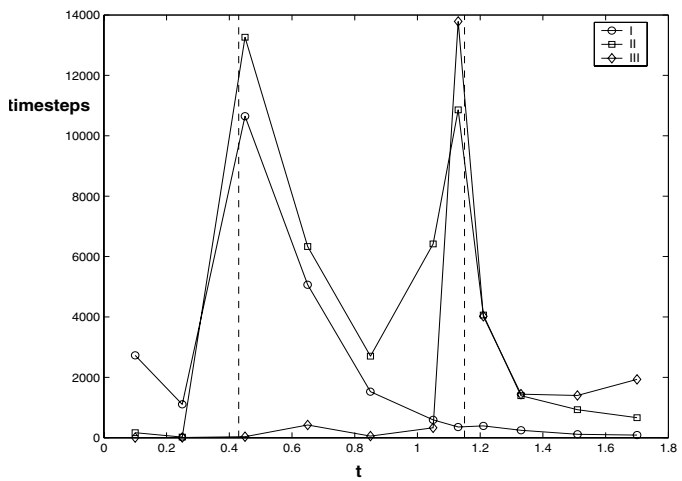

FIG. 6.3. *Number of time steps (per time window) in each subdomain.*

Both the tremendous potential and current difficulties with our basic Schwarz waveform moving mesh method are highlighted in Figure 6.3. In this plot we display the number of time steps per time window taken by implicit Euler in each subdomain, labeled I, II, and III in the legend of the plot. The dotted vertical lines specify the time at which the layer crosses the subdomain boundaries. The data shows that while the layer is completely contained in subdomain I ($0 \leq t \leq 0.4$), the work involved to integrate over subdomains II and III is negligible. As the front approaches the subdomain boundaries, the number of time steps in the adjoining domains increases dramatically, indicating the standard difficulty experienced by the classical Schwarz waveform iteration.

Another indicator of the performance of the classical Schwarz method is illustrated in Figure 6.4. The maximum number of time steps per time window is fixed, so the

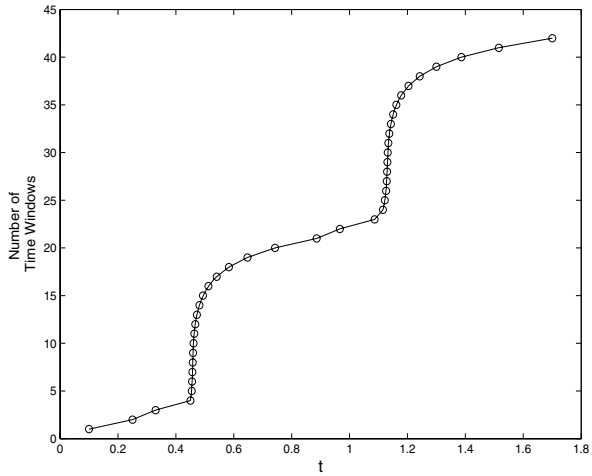

FIG. 6.4. *Number of time windows used up to time t for the Schwarz waveform moving mesh method applied to Burgers' equation with* $\epsilon = 1e-4$.

size of the time window varies over the duration of the computation. There is a dramatic decrease in the size of the time window as the moving front moves from one subregion to the next. The time window is increased or decreased based on the convergence of the Schwarz iteration. If the iteration has not converged within a user specified number of iterations, the length of the time window is decreased. We see in Figure 6.4 that the length of the time window is shortest when the front moves from one subdomain to another.

[illegible] 2: [illegible] II We now solve Burgers' equation subject to the initial condition

$$u(x,0) = \sin(2\pi x) + \frac{1}{2}\sin(\pi x)$$

and boundary conditions $u(0,t) = u(1,t) = 0$, using three overlapping subdomains. The solution develops a sharp front and moves to the right with diminishing amplitude. Mesh trajectories for this initial condition are shown in Figure 6.5. In this case, the solution evolves to a front in subdomain II. This results in a nearly uniform mesh in subdomain I for the entire computation. The grids in subdomains II and III, however, react to the evolving solution and carry the front to the boundary at $x = 1$. As with the previous example, the convergence of the Schwarz iteration deteriorates as the front moves from subdomain II to subdomain III.

[illegible] 3: [illegible] The next problem is

$$u_t = \epsilon u_{xx} + f(x,t),$$

where $f(x,t)$ is defined such that the solution has two spikes and is given by

$$u(x,t) = \frac{1}{\epsilon}\left(\max(0,\tanh(t-t_0))e^{-(x-x_0)^2/\epsilon} + \max(0,\tanh(t-t_1))e^{-(x-x_1)^2/\epsilon}\right).$$

These two spikes are centered at fixed locations x_0 and x_1 and begin to evolve at different times t_0 and t_1. We choose x_0 and x_1 to keep the spikes well separated in the spatial domain and choose $t_1 > t_0$. This allows the first spike to grow to its

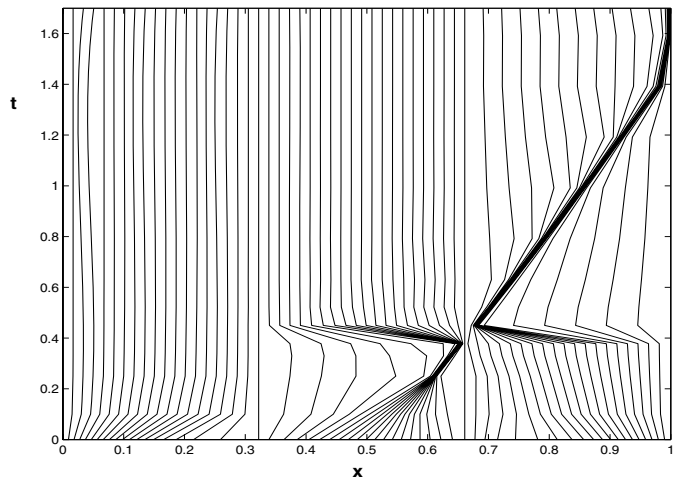

FIG. 6.5. *Mesh trajectories for Burgers' equation with* $\epsilon = 1e-3$ *and* 20 *points per domain using the Schwarz waveform moving mesh method.*

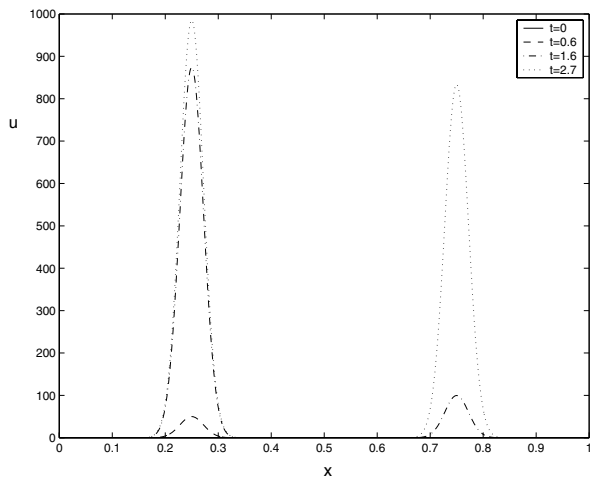

FIG. 6.6. *Exact solutions of the two-spike problem at* $t = 0, 0.6, 1.6,$ *and* 2.7.

maximum height before the second spike appears. All computations are done with $\epsilon = 1e-3$. Figure 6.6 illustrates the exact solution of the two-spike problem for times $t = 0.6$, 1.6, and 2.7. (At $t = 0$, $u(x, 0) \equiv 0$.) At $t = 0.6$ the spike centered at $x_0 = 1/4$ has appeared and continues to grow. The second spike centered at $x_1 = 3/4$ emerges at $t = 3/2$. At $t = 2.7$, both spikes have nearly reached their maximum height. This problem is chosen to show the difficulties which can occur for moving mesh methods when the solution to the PDE behaves badly in several regions, and how the Schwarz waveform moving mesh method can be used to ameliorate the situation. Solving the problem with 80 mesh points on one domain, the final solution at $t = 2.7$ and the mesh trajectories on $[0, 1]$ are shown in Figure 6.7. The computed solution is illustrated by a line with open circles indicating the location of the mesh points, and the exact solution is depicted with a thick solid line. The moving mesh method does indeed

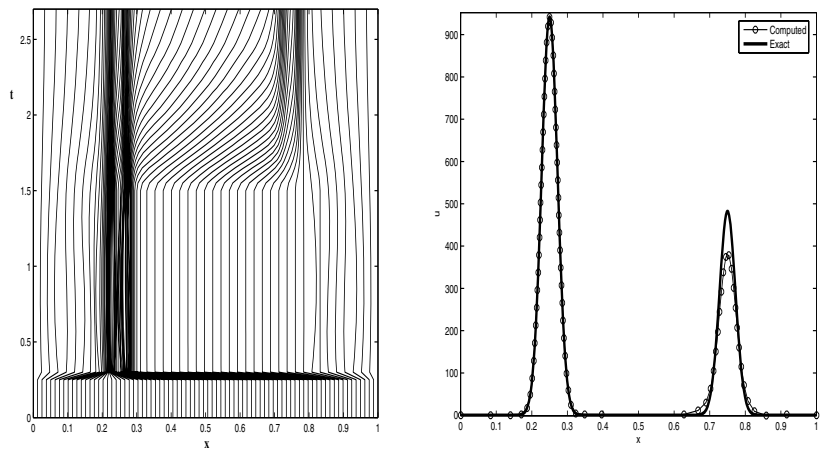

FIG. 6.7. *Mesh trajectories (left) and solutions (right) of the two-spike problem with one domain using the arclength monitor function.*

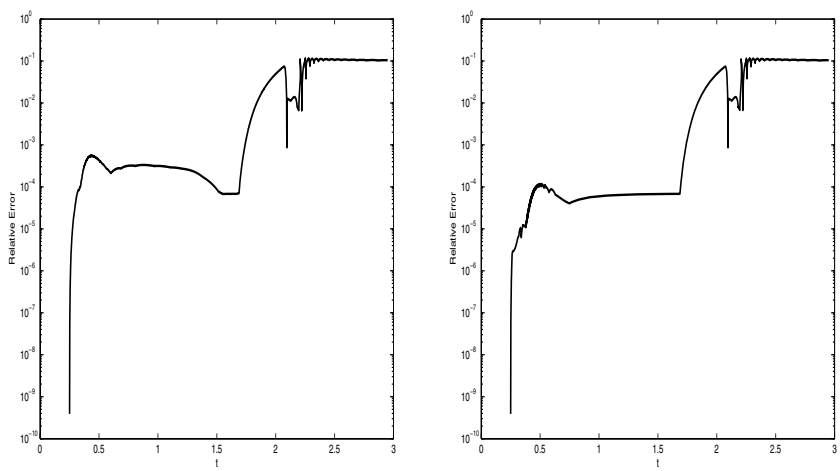

FIG. 6.8. *Relative error in the computed solution on one domain using the arclength monitor function and backward Euler (left) and variable order BDF formulation (right).*

capture both spikes; however, a loss of accuracy in the second spike is evident by the end of the computation. In fact, substantial errors arise in the computed solution for $t \geq 3/2$, corresponding to the birth of the second spike. Indeed, a moving mesh method on one domain has great difficulty achieving sufficient resolution of the second spike. The mesh trajectories indicate a relatively quick movement of mesh points from the region of the left spike towards the emerging right spike for $t > 3/2$.

Figure 6.8 illustrates the relative error in the computed solution for the two-spike problem on one domain. The plot on the left was obtained using implicit Euler to integrate forward in time, while the plot on the right was obtained using a variable order BDF implementation. The results are nearly identical. The loss of accuracy in the computed solutions arises with the birth of the second spike at $t = 1.5$. In fact, a

relatively large number of mesh points is vital to allow resolution of the second spike.

The loss of accuracy which occurs as the second spike grows is due, in part, to the time required for the mesh to adapt to new features in the solution. This may be controlled by the moving mesh parameter τ in MMPDE4. Decreasing the value of τ facilitates a quicker mesh movement and hence a quicker return to an equidistributed grid. However, this improves the accuracy of the computed solution at the expense of necessitating much smaller steps in the time integration. The situation may be improved by controlling the proportion of points outside the initial region of difficulty by an appropriate choice of α in (4.3).

This problem is ideal for a two-domain simulation with the Schwarz waveform moving mesh method. The computed and exact solutions and resulting mesh trajectories are shown in Figure 6.9.

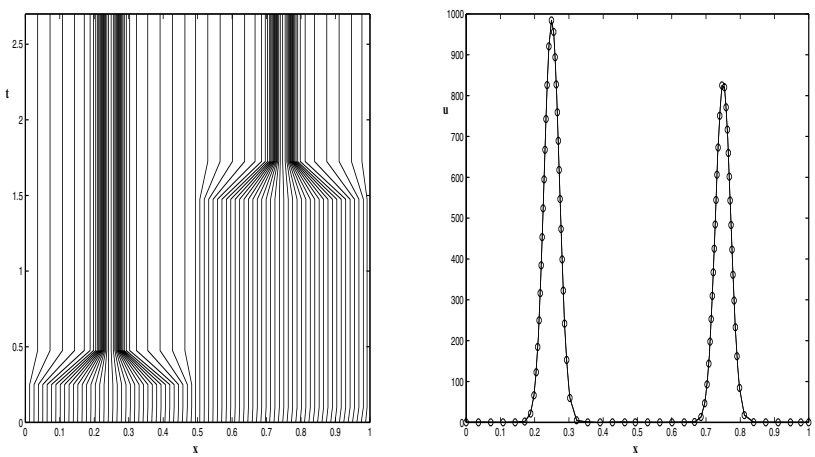

FIG. 6.9. *Mesh trajectories (left), computed and exact solutions (right) for the two-spike problem on two subdomains.*

Compared to the one-domain calculation, we see improved accuracy between the spikes and in regions of high curvature. As expected, the mesh remains uniform in each subdomain until the spike in that region is activated. At that point the mesh in the subdomain adapts well to the evolving features of the solution using a simple arclength monitor function and moderate values of τ. In fact, comparable accuracy to that for the one-domain calculation is possible with many fewer mesh points.

Figure 6.10 compares the time steps taken by the ODE solver (backward Euler) for the one-domain (left) and two-subdomain (right) simulations. In the two-subdomain case we illustrate the time steps for subdomain I (solid) and subdomain II (dashed) corresponding to the first waveform iteration. The time steps chosen for the one-domain calculation are quite large until $t = 1/4$, when the left spike begins to grow. The time steps remain relatively steady at 10^{-4} until the second spike emerges at $t = 3/2$. Immediately the time steps are reduced by an order of magnitude as the mesh points race to adjust to the emerging features in the solution.

The time steps chosen in each subdomain by the Schwarz waveform moving mesh method are controlled primarily by the local features of the solution. During the solution on subdomain I the time steps reduce to approximately 10^{-4} at $t = 1/4$. This time corresponds to the emergence of the first spike. The time steps persist at

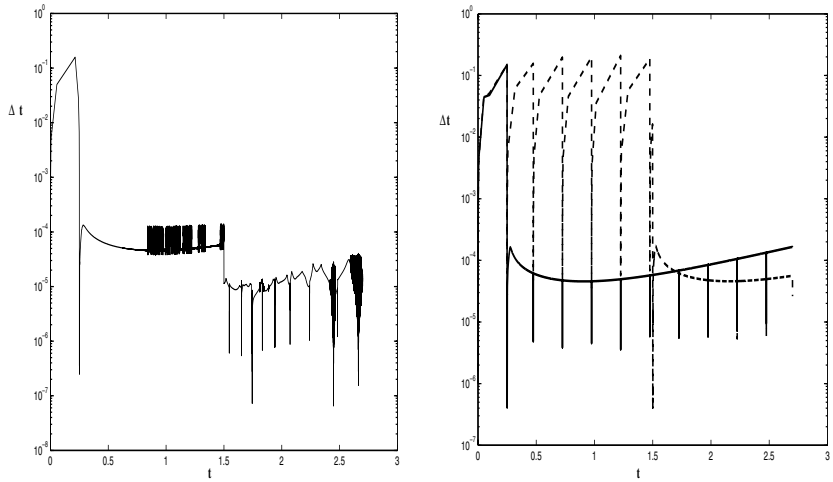

FIG. 6.10. *Time steps for the one-domain (left) and two-subdomain (right) solution of the two-spike problem.*

this level for the duration of the simulation. Little work is required to integrate the solution and mesh components in subdomain II until $t = 3/2$. At that time, the size of the acceptable time steps decreases to a level commensurate with that on subdomain I. It is important to note that the time steps in subdomain I are not affected by the development of the second spike. No mesh points move from one subdomain to another. This keeps the time steps an order of magnitude larger than for the one-domain calculation. This more than compensates for the cost of the iteration required in the Schwarz waveform moving mesh method, resulting in approximately half the run time.

7. Conclusions. The moving method of lines has proved to be an effective tool for solving a number of time dependent PDEs [31]. In this paper we propose a modification of the basic procedure—a Schwarz waveform moving mesh method. The moving mesh PDE and physical PDE are solved by a domain decomposition algorithm. The computational space-time domain is decomposed into a number of overlapping subdomains. The solution is computed iteratively by solving the system of PDEs on each subdomain with information exchange achieved through Dirichlet conditions at the subdomain boundaries. Problems with localized fast-changing solution components are shown to benefit from this approach.

Traditionally, the solution of the resulting system of ODEs in time has been obtained using standard implementations of stiff ODE system solvers with a fully implicit time stepping package, such as in [31] where DASSL [39] is used.

In the simple implementation of the Schwarz waveform method investigated here, we solve (4.7) using a backward Euler method,

$$V(y_n)(y_n - y_{n-1}) - h_n g(y_n) = 0,$$

and a crude time-stepping procedure where the local error is controlled by step doubling/halving. The nonlinear algebraic systems are solved with a modified Newton method, using the strategies of Gustafsson and Söderlind [26] and Alexander [1] to control factorizations and evaluations of the Jacobian matrix. The Jacobian is evaluated using finite differences adapted to sparse matrices [8].

There are many important aspects to consider when investigating the feasibility of the Schwarz waveform method. Classical Schwarz iteration is known to suffer from slow convergence, particularly when the solution components have substantially different time scales. The moving mesh method is specifically designed so that solution components are closer to having the same time scale than for the standard MOL approach. It remains an issue, although we have seen marked improvement in numerical results. The slow convergence can be alleviated through the use of higher-order transmission conditions at the subdomain boundaries [20]. Furthermore, to avoid fast-changing solution components crossing subdomain boundaries, a coarse grain adaptivity may be employed as well, where one dynamically determines (spatially) the number and placement of subdomains. As a front approaches a subdomain boundary, for example, domains may be collapsed or merged until the front has passed. In our implementation, the Schwarz iteration proceeds until the solutions on all subdomains agree to within some specified tolerance. This requires storage of the solution at all points in the computational space. When a maximum principle holds, it is possible to save substantially on storage by keeping boundary data only to test for convergence. Further study is certainly required to understand the role of overlap for Schwarz waveform moving mesh methods.

The issues of efficiency are even more important in higher spatial dimensions, where fast solution behavior locally comes at a much higher cost if adaptivity is not done properly or system solutions not done efficiently; cf. [47]. One major reason that moving mesh methods are ideally suited to handle certain problems with singularities is that, by choosing a suitable monitor function to incorporate scaling as proposed by Beckett and Mackenzie [3], a proper balance between adaptivity done in the inner and outer solution regions is assured. Unfortunately, for problems with multiple scales or multiple regions with fast scale behavior, using moving mesh methods alone for adaptivity can be problematic in determining the relative importance of the regions of fast solution activity. While a simple implementation of the Schwarz waveform method is not a panacea in and of itself, it can be the ideal tool for overcoming many of these difficulties. A simple Schwarz waveform relaxation has been applied directly for the mesh equation for a two-dimensional problem in [6]. We intend to investigate a more sophisticated implementation of the Schwarz waveform method, incorporating the features discussed here, in future work. An ultimate test of the method would entail a careful comparison with the other approaches of section 3.

MUSIC-TYPE ELECTROMAGNETIC IMAGING OF A COLLECTION OF SMALL THREE-DIMENSIONAL INCLUSIONS*

HABIB AMMARI†, EKATERINA IAKOVLEVA‡, DOMINIQUE LESSELIER‡, AND GAËLE PERRUSSON‡

Abstract. In this paper we consider the localization of a collection of small, three-dimensional bounded homogeneous inclusions via time-harmonic electromagnetic means, typically using arrays of electric or magnetic dipole transmitters and receivers with given polarization(s) at some distance from the collection, possibly also lying in the far field. The inclusions, somewhat apart or closely spaced, are buried within a homogeneous medium, and are of arbitrary contrast of permittivity, conductivity, and permeability vis-à-vis this embedding medium. The problem is formulated as an inverse scattering problem for the full Maxwell equations and it involves a robust asymptotic modeling of the multistatic response matrix. No specific application is studied at this stage, but characterization of obstacles in subsoils, nondestructive evaluation of man-made structures, and medical imaging are primary fields of application envisaged. The proposed approach uses a MUSIC (multiple signal classification)-type algorithm, and it yields fast numbering, accurate localization, and estimates of the electromagnetic and geometric parameters (polarization tensors) of the inclusions. The mathematical machinery is detailed first, some specific attention being given to triaxial ellipsoidal inclusions and degenerate spherical shapes (for the latter known results are retrieved). Then, the viability of this algorithm—which would be easily extended to planarly layered environments by introduction of their Green's functions—is documented by a variety of numerical results from synthetic, noiseless, and severely noisy field data.

Key words. electromagnetic inclusions, Maxwell's equations, imaging, inverse problems, MUSIC algorithm

DOI. 10.1137/050640655

1. Introduction.

The location of a collection of small three-dimensional bounded homogeneous inclusions buried within a homogeneous medium, with arbitrary contrasts of permittivity, conductivity, and permeability vis-à-vis this embedding medium, is considered herein by time-harmonic electromagnetic means.

The applications envisaged are found in military and civil engineering, and in environmental characterization, e.g., the identification of obstacles in subsoils, nondestructive testing of man-made structures, medical imaging, etc. But the proposed framework is of broad applicability and it might be tailored to many cases of practical interest, and examples given herein in what could be the microwave scattering regime do not presume of any specific situation investigated later on.

The proposed approach uses a MUSIC (multiple signal classification)-type algorithm to accurately image these small electromagnetic inclusions. The latter are of unknown finite number and they are assumed of small size with respect to the wavelength at the frequency of operation. Usually they are located somewhat far from one another (say, at distance of the order of the wavelength or more), but closer spacings

(at a fraction of the wavelength) are also modeled. The analysis is developed for arbitrarily shaped inclusions, though specific attention is given to the case of triaxial ellipsoidal shapes and their degenerate counterparts whenever it leads to useful complementary results. Notice that any three-dimensional inclusion can be represented in a canonical way by an ellipsoid with the same polarization tensor. See [7].

The collection is illuminated by an array (typically linear or planar) of electric and/or magnetic dipoles with any given polarization(s), located at some, not necessarily large, distance from it, extensions to far-field data being considered as well in straightforward fashion. The resulting electric and/or magnetic field is collected by another array, possibly but not necessarily the same as the transmitter one—in effect, one is always dealing with strongly aspect-limited data, and no full coverage is assumed. This procedure yields the multistatic data response (MSR) matrix that is characteristic of the collection of inclusions for given sets (e.g., arrays) of transmitters and receivers at the (single) frequency of operation.

Extending our previous works in two-dimensional scalar scattering situations [3, 4, 5] to full three-dimensional vector electromagnetics, we show how the eigenvalue structure of the MSR matrix can be employed within the framework of the MUSIC method in order to retrieve either dielectric inclusions or magnetic inclusions, or combinations thereof, with the limiting perfectly electric conductor (PEC) or perfectly magnetic conductor (PMC) encompassed as well.

In practice this means carrying out two steps: first, the calculation of singular values (and the corresponding eigenvectors), the number of nonzero values depending upon the number and the electromagnetic nature of the inclusions and upon the transmitters' and/or receivers' geometrical arrangement and polarization; second, the orthogonal projection of a properly built vector propagator onto the null space of the MSR matrix, coincidence with an inclusion being then associated to a peak of the inverse norm of the projection, simple forms of the indicator being used if the electromagnetic nature of the inclusions is known from prior information and is either purely dielectric or purely magnetic (e.g., all inclusions are known to be nonmagnetic dielectric ones), a slightly more complex form being used in the other situations. It is worth emphasizing that the number of nonzero singular values is computed without any knowledge of what kind of inclusion we have. Further, as will be shown in section 5, it allows us to characterize the electromagnetic nature of the inclusion.

In the case of a single triaxial ellipsoidal inclusion with arbitrary semiaxes and location with respect to the transmitter and receiver arrays, the single vectors and values are exhibited in closed form. Notice that this also enables us to retrieve as a particular case the results described earlier by Chambers and Berryman [19] for a lossless dielectric or PEC sphere with symmetric position with respect to a common transmitter/receiver array.

Numerical examples are given in this paper in order to illustrate the main features of our approach for both asymptotically exact and severely noisy data calculated for arbitrary electromagnetic and geometric configurations. A systematic discussion, however, is not attempted, being left to further studies in specific situations of practical applicability.

To put the present work in proper context, we will now emphasize some significant differences with prior work. Nearly all of the existing algorithms to solve three-dimensional inverse problems for Maxwell's equations are iterative and are then based on regularization techniques. See, for example, [28, 1, 41, 42, 23] and the many references therein. Recently, noniterative methods such as linear sampling methods and factorization methods have been developed which avoid the issue of nonlinearity

[33, 24, 30, 31, 39] but not ill-posedness. In order to handle this challenging issue it is generally advisable to incorporate all a priori knowledge about the unknown parameter and to try to determine very specific features. In this context, the method of asymptotic expansions of small volume inclusions provides a useful framework to accurately reconstruct the location and geometric features of the inclusions in a stable way, even for moderately noisy data [7]. Among the direct reconstruction methods that have been developed during the last years, MUSIC-type algorithms seem to be particularly accurate and stable [27]. In [3, 4, 5], we have designed robust numerical methods of MUSIC type for efficiently determining the locations and/or shapes of a collection of small inclusions in two-dimensional scalar scattering situations. The paper [2] points out the strong relation between MUSIC-type algorithms and linear sampling methods (cf. also [21, 32]). To the best of our knowledge, the present paper is the first attempt to design and analyze a MUSIC-type algorithm for imaging a collection of small volumetric inclusions of arbitrary shape and electromagnetic nature for fully general three-dimensional geometrical configurations and illuminations. As such, our analysis encompasses the DORT method (DORT stands for "decomposition of time-reversal operator" in French) [36] and three-dimensional time-reversal analysis [27, 29].

Let us finally emphasize again that our MUSIC-type method makes use of asymptotic expansions of the scattered electric and/or magnetic fields. Starting from application of Green's theorems to Maxwell's equations satisfied by the electromagnetic fields, we formally derive asymptotic formulations of the scattered electric and/or magnetic fields as series expansions in terms of the common order of magnitude of the diameters of the inclusions, here limiting ourselves for simplicity to the leading-order terms. Such formulations involve the polarization tensors associated to the inclusions. We refer to the closely related works [8, 6, 10, 11, 12, 15, 16, 17, 18, 35, 40] and to the monograph [7] for a systematic exposition of recent developments on the reconstruction of small inclusions.

2. Asymptotic expansions of the electric and magnetic fields.

2.1. Problem formulation. We suppose that there is a finite number m of electromagnetic inclusions in $\mathbb{R}^3$, each of the form $z_j + \alpha B_j$, where $B_j \subset \mathbb{R}^3$ is a bounded, smooth ($\mathcal{C}^\infty$) domain containing the origin. This regularity assumption could be considerably weakened. The total collection of inclusions thus takes the form $\mathcal{I}_\alpha = \bigcup_{j=1}^m z_j + \alpha B_j$. The points $z_j \in \mathbb{R}^3$, $j = 1, \ldots, m$, that determine the location of the inclusions are assumed to satisfy

$$0 < d_0 \leq |z_j - z_l| \quad \forall\, j \neq l,$$

where d_0 is a fixed positive constant. We also assume that α, the common order of magnitude of the diameters of the inclusions, is sufficiently small compared to d_0 that these inclusions are disjoint.

Let μ_0 and ε_0 denote the magnetic permeability and the electric permittivity of the free space; we shall assume that $\mu_0, \Im m(\varepsilon_0)$, and $\Re e(\varepsilon_0)$ are positive constants. Let μ_j and ε_j denote the permeability and the complex permittivity of the jth inclusion, $z_j + \alpha B_j$; these are also assumed to be constants. Using this notation, we introduce the piecewise constant magnetic permeability

$$\mu_\alpha(\mathbf{r}) := \begin{cases} \mu_j & \text{in } z_j + \alpha B_j, \qquad j = 1, \ldots, m, \\ \mu_0 & \text{in } \mathbb{R}^3 \backslash \overline{\mathcal{I}_\alpha}. \end{cases}$$

The piecewise constant electric permittivity $\varepsilon_\alpha(x)$ is defined analogously by

$$\varepsilon_\alpha(\mathbf{r}) := \begin{cases} \varepsilon_j & \text{in } z_j + \alpha B_j, \qquad j = 1, \dots, m, \\ \varepsilon_0 & \text{in } \mathbb{R}^3 \backslash \overline{\mathcal{I}_\alpha}. \end{cases}$$

Let $k = \omega\sqrt{\varepsilon_0 \mu_0} > 0$ be the wavenumber, where $\omega > 0$ is a given frequency. Positive real and imaginary parts are chosen for the square root. The conductivities of the free space and the electromagnetic inclusions are given by $\sigma_j = \omega\, \Im m(\varepsilon_j)$, $j = 0, \dots, m$. For convenience we introduce the following notation. For a vector $\mathbf{r} = (\mathbf{r}_x, \mathbf{r}_y, \mathbf{r}_z)$ in $\mathbb{R}^3$, we denote by $r = |\mathbf{r}|$ its magnitude and by $\hat{\mathbf{r}} = \mathbf{r}/r$ the dimensionless vector with a unit magnitude pointing in the direction of $\mathbf{r}$.

2.2. Lippman–Schwinger integral representation formula. We introduce the scalar function

$$g(\mathbf{r}, \mathbf{r}') = \frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|},$$

which is the outgoing fundamental solution for the Helmholtz operator $\Delta + k^2$. Using this scalar function we define the Green's function $\mathbf{G}$ by

$$\mathbf{G}(\mathbf{r}, \mathbf{r}') = \left[\mathbf{I}_3 + \frac{\nabla\nabla}{k^2}\right] g(\mathbf{r}, \mathbf{r}'),$$

where $\mathbf{I}_3$ is the 3×3 identity matrix. The function $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ is the solution of

$$\begin{cases} \nabla\times\nabla\times\mathbf{G}(\mathbf{r}, \mathbf{r}') - k^2\mathbf{G}(\mathbf{r}, \mathbf{r}') = \mathbf{I}_3\delta(\mathbf{r} - \mathbf{r}') \quad \text{in } \mathbb{R}^3, \\ \lim\limits_{r\to\infty} r\left[\nabla\times\mathbf{G}(\mathbf{r}, \mathbf{r}') - ik\hat{\mathbf{r}} \times \mathbf{G}(\mathbf{r}, \mathbf{r}')\right] = 0. \end{cases}$$

It also satisfies

$$\mathbf{G}(\mathbf{r}', \mathbf{r}) = \left[\mathbf{I}_3 + \frac{\nabla'\nabla'}{k^2}\right] g(\mathbf{r}', \mathbf{r}), \tag{1}$$

$$\left[\mathbf{G}(\mathbf{r}', \mathbf{r})\right]^T = \mathbf{G}(\mathbf{r}, \mathbf{r}'), \tag{2}$$

$$\left[\nabla'\times\mathbf{G}(\mathbf{r}', \mathbf{r})\right]^T = \nabla\times\mathbf{G}(\mathbf{r}, \mathbf{r}'). \tag{3}$$

Here ∇' denotes the differentiation with respect to the variable $\mathbf{r}'$ and T the transpose.

Suppose that the collection of inclusions $\mathcal{I}_\alpha$ is within an open subset Ω of $\mathbb{R}^3$. Let $\mathbf{r}_n \in \mathbb{R}^3 \setminus \overline{\Omega}$ be the position of the electric dipole. Then the incident electric field $\mathbf{E}_0^{(n)}$ in a homogeneous medium due to a point current density at the position $\mathbf{r}_n$ and directed in the $\overrightarrow{\beta}$ direction, $\mathbf{J}_0^{(n)}(\mathbf{r}) = \overrightarrow{\beta}\, Il\, \delta(\mathbf{r} - \mathbf{r}_n)$, is given by

$$\mathbf{E}_0^{(n)}(\mathbf{r}) = i\omega\mu_0 \left[\mathbf{I}_3 + \frac{\nabla\nabla}{k^2}\right] \cdot \overrightarrow{\beta}\, Il\, g(\mathbf{r}, \mathbf{r}_n) = i\omega\mu_0\, Il\, \mathbf{G}(\mathbf{r}, \mathbf{r}_n) \cdot \overrightarrow{\beta},$$

where the constant Il is the current moment. The magnetic field is given by

$$\mathbf{H}_0^{(n)}(\mathbf{r}) = \nabla\times Il\, \mathbf{G}(\mathbf{r}, \mathbf{r}_n) \cdot \overrightarrow{\beta} = Il\, \nabla g(\mathbf{r}, \mathbf{r}_n) \times \overrightarrow{\beta}.$$

The electromagnetic fields $(\mathbf{E}_0^{(n)}, \mathbf{H}_0^{(n)})$ are the solutions of the Maxwell's equations

$$\begin{cases} \nabla\times\mathbf{E}_0^{(n)} = \ i\omega\mu_0\mathbf{H}_0^{(n)} \quad \text{in } \mathbb{R}^3, \\ \nabla\times\mathbf{H}_0^{(n)} = \ -i\omega\varepsilon_0\mathbf{E}_0^{(n)} + \mathbf{J}_0^{(n)} \quad \text{in } \mathbb{R}^3, \\ \lim\limits_{r\to\infty} r\left[\nabla\times\mathbf{E}_0^{(n)} - ik\hat{\mathbf{r}}\times\mathbf{E}_0^{(n)}\right] = 0, \ \text{ and } \ \lim\limits_{r\to\infty} r\left[\nabla\times\mathbf{H}_0^{(n)} - ik\hat{\mathbf{r}}\times\mathbf{H}_0^{(n)}\right] = 0. \end{cases}$$

Let $(\mathbf{E}_\alpha^{(n)}, \mathbf{H}_\alpha^{(n)})$ denote the time-harmonic electromagnetic fields in the presence of the electromagnetic inclusions $\mathcal{I}_\alpha$. These time-harmonic fields are the solutions of the following Maxwell's equations:

(4)
$$\begin{cases} \nabla\times\mathbf{E}_\alpha^{(n)} = \ i\omega\mu_\alpha\mathbf{H}_\alpha^{(n)} \quad \text{in } \mathbb{R}^3, \\ \nabla\times\mathbf{H}_\alpha^{(n)} = \ -i\omega\varepsilon_\alpha\mathbf{E}_\alpha^{(n)} + \mathbf{J}_0^{(n)} \quad \text{in } \mathbb{R}^3, \\ \nu\times\mathbf{E}_\alpha^{(n)} \text{ and } \nu\times\mathbf{H}_\alpha^{(n)} \text{ are continuous across } \partial(z_j+\alpha B_j), \\ \nu\cdot\left(\varepsilon_\alpha\mathbf{E}_\alpha^{(n)}\right)^+ - \nu\cdot\left(\varepsilon_\alpha\mathbf{E}_\alpha^{(n)}\right)^- = 0 \ \text{ on } \ \partial(z_j+\alpha B_j), \\ \nu\cdot\left(\mu_\alpha\mathbf{H}_\alpha^{(n)}\right)^+ - \nu\cdot\left(\mu_\alpha\mathbf{H}_\alpha^{(n)}\right)^- = 0 \ \text{ on } \ \partial(z_j+\alpha B_j), \\ \lim\limits_{r\to\infty} r\left[\nabla\times\mathbf{E}_\alpha^{(n)} - ik\hat{\mathbf{r}}\times\mathbf{E}_\alpha^{(n)}\right] = 0, \ \text{ and } \ \lim\limits_{r\to\infty} r\left[\nabla\times\mathbf{H}_\alpha^{(n)} - ik\hat{\mathbf{r}}\times\mathbf{H}_\alpha^{(n)}\right] = 0. \end{cases}$$

Here ν denotes the outward unit normal to $\partial(z_j+\alpha B_j)$; superscript $+$ and $-$ indicate the limiting values as we approach $\partial(z_j+\alpha B_j)$ from outside $z_j+\alpha B_j$, and from inside $z_j+\alpha B_j$, respectively.

From (4), it follows that the electric field satisfies the following:

(5)
$$\begin{cases} \nabla\times\mu_\alpha^{-1}\nabla\times\mathbf{E}_\alpha^{(n)} - \omega^2\varepsilon_\alpha\mathbf{E}_\alpha^{(n)} = i\omega\mathbf{J}_0^{(n)}, \\ \nu\times\mathbf{H}_\alpha^{(n)} \ \text{ is continuous across } \ \partial(z_j+\alpha B_j), \\ \nu\cdot\left(\varepsilon_\alpha\mathbf{E}_\alpha^{(n)}\right)^+ - \nu\cdot\left(\varepsilon_\alpha\mathbf{E}_\alpha^{(n)}\right)^- = 0 \ \text{ on } \ \partial(z_j+\alpha B_j), \\ \lim\limits_{r\to\infty} r\left[\nabla\times\mathbf{E}_\alpha^{(n)} - ik\hat{\mathbf{r}}\times\mathbf{E}_\alpha^{(n)}\right] = 0. \end{cases}$$

The following Lippman–Schwinger integral representation formulae hold:

(6)
$$\mathbf{E}_\alpha^{(n)}(\mathbf{r}) - \mathbf{E}_0^{(n)}(\mathbf{r}) = \sum_{j=1}^m \int_{z_j+\alpha B_j} d\mathbf{r}' \Big[-i\omega\,(\mu_j-\mu_0)\,\nabla'\times\mathbf{G}(\mathbf{r},\mathbf{r}')\cdot\mathbf{H}_\alpha^{(n)}(\mathbf{r}') + \omega^2\mu_0\,(\varepsilon_j-\varepsilon_0)\,\mathbf{G}(\mathbf{r},\mathbf{r}')\cdot\mathbf{E}_\alpha^{(n)}(\mathbf{r}')\Big]$$

and

$$\mathbf{H}_\alpha^{(n)}(\mathbf{r}) - \mathbf{H}_0^{(n)}(\mathbf{r}) = \sum_{j=1}^m \int_{z_j+\alpha B_j} d\mathbf{r}' \Big[i\omega\,(\varepsilon_j-\varepsilon_0)\,\nabla'\times\mathbf{G}(\mathbf{r},\mathbf{r}')\cdot\mathbf{E}_\alpha^{(n)}(\mathbf{r}') + \omega^2\varepsilon_0\,(\mu_j-\mu_0)\,\mathbf{G}(\mathbf{r},\mathbf{r}')\cdot\mathbf{H}_\alpha^{(n)}(\mathbf{r}')\Big].$$

2.3. Polarization tensors. Let $\{q_j\}$ denote either the set $\{\mu_j\}$ or $\{\varepsilon_j\}$ for $1 \le j \le m$. Fix j and let q be given by

$$q(\mathbf{r}) := \begin{cases} q_0, & \mathbf{r} \in \mathbb{R}^3 \setminus \overline{B}_j, \\ q_j, & \mathbf{r} \in B_j. \end{cases}$$

By v^q, we denote the solution of

$$\begin{cases} \nabla \cdot q(\mathbf{r}) \nabla v^q(\mathbf{r}) = 0 \quad \text{in } \mathbb{R}^3, \\ v^q(\mathbf{r}) - \mathbf{r} \to 0 \quad \text{as } r \to \infty. \end{cases} \tag{7}$$

It is obvious that the function v^q depends only on the ratio q_j/q_0.

Define the polarization tensor $\mathbf{M}(q_j/q_0; B_j) \in \mathbb{R}^{3\times 3}$ associated with the inclusion B_j and the contrast q_j/q_0 by

$$\mathbf{M}\left(\frac{q_j}{q_0}; B_j\right) := \int_{B_j} \nabla v^q(\mathbf{r})\, d\mathbf{r}. \tag{8}$$

Introduce the vectors φ and ψ defined in $\mathbb{R}^3 \setminus \overline{B}_j$ and satisfying

$$\begin{cases} \Delta \varphi = 0 \quad \text{in } \mathbb{R}^3 \setminus \overline{B}_j, \\ \partial_\nu \varphi = -\nu \quad \text{on } \partial B_j, \\ \lim_{r\to+\infty} \varphi(\mathbf{r}) = 0, \end{cases}$$

and

$$\begin{cases} \Delta \psi = 0 \quad \text{in } \mathbb{R}^3 \setminus \overline{B}_j, \\ \psi = -\mathbf{r} + \mathbf{c} \quad \text{on } \partial B_j, \\ \lim_{r\to+\infty} \psi(\mathbf{r}) = 0, \end{cases}$$

where the constant vector $\mathbf{c}$ is to be chosen such that $\psi(\mathbf{r}) \to 0$ as $r \to +\infty$.

The tensor

$$\mathbf{W}(B_j) := \int_{\mathbb{R}^3\setminus\overline{B}_j} \nabla\varphi(\mathbf{r})^T \cdot \nabla\varphi(\mathbf{r})\, d\mathbf{r}$$

is the so-called virtual mass, and the tensor

$$\mathbf{Q}(B_j) := \int_{\mathbb{R}^3\setminus\overline{B}_j} \nabla\psi(\mathbf{r})^T \cdot \nabla\psi(\mathbf{r})\, d\mathbf{r}$$

is the so-called Pólya–Szegö tensor. See [38, 34, 26, 7]. Moreover, according to [18, 10], the following convergence results hold as q_j/q_0 tends towards zero or infinity:

$$\begin{aligned} &\int_{\partial B_j} \left((\partial_\nu v^q)^+\right)^T \mathbf{r}\, d\sigma \to |B_j|\mathbf{I}_3 + \mathbf{Q}(B_j) \quad \text{as } \frac{q_j}{q_0} \to +\infty, \\ &\int_{\partial B_j} \left((\partial_\nu v^q)^-\right)^T \mathbf{r}\, d\sigma \to |B_j|\mathbf{I}_3 + \mathbf{W}(B_j) \quad \text{as } \frac{q_j}{q_0} \to 0. \end{aligned} \tag{9}$$

Here ν is the outward unit normal to ∂B_j and $(\partial_\nu u)^\pm(\mathbf{r}) = \lim_{t\to 0^+} \nabla u(\mathbf{r} \pm t\nu(\mathbf{r}))$ if the limit exists.

2.4. Asymptotic formula. For any $\mathbf{r}$ away from $\mathbf{r}_n$ and $z_j, j = 1, \dots, m$, we can show that

$$\mathbf{E}_\alpha^{(n)}(\mathbf{r}) - \mathbf{E}_0^{(n)}(\mathbf{r}) = \alpha^3 \sum_{j=1}^{m} \left[-i\omega\ (\mu_j - \mu_0)\, \nabla' \times \mathbf{G}(\mathbf{r}, z_j) \cdot \mathbf{M}\left(\frac{\mu_j}{\mu_0}; B_j\right) \mathbf{H}_0^{(n)}(z_j) \right. \\ \left. + \omega^2 \mu_0\, (\varepsilon_j - \varepsilon_0)\, \mathbf{G}(\mathbf{r}, z_j) \cdot \mathbf{M}\left(\frac{\varepsilon_j}{\varepsilon_0}; B_j\right) \mathbf{E}_0^{(n)}(z_j) \right] + O(\alpha^4). \tag{10}$$

See Appendix A. If the inclusions B_j are symmetric about their centers, then we can show that the correction of order four in (10) is zero. The remainder in this case is in fact $O(\alpha^5)$. See [14].

Note that if the inclusion B_j is a ball, then its polarization tensor $\mathbf{M}(q_j/q_0; B_j)$ has the following explicit form [18]:

$$\mathbf{M}\left(\frac{q_j}{q_0}; B_j\right) = \frac{3q_0}{2q_0 + q_j} |B_j| \mathbf{I}_3, \quad q(\mathbf{r}) = \varepsilon(\mathbf{r}) \ \text{ or } \ \mu(\mathbf{r}),$$

and therefore (10) becomes

$$\mathbf{E}_\alpha^{(n)}(\mathbf{r}) - \mathbf{E}_0^{(n)}(\mathbf{r}) = \alpha^3 \sum_{j=1}^{m} \left[-i\omega\, \mu_0 \frac{3(\mu_j - \mu_0)}{2\mu_0 + \mu_j} |B_j|\, \nabla' \times \mathbf{G}(\mathbf{r}, z_j) \cdot \mathbf{H}_0^{(n)}(z_j) \right. \\ \left. + k^2 \frac{3(\varepsilon_j - \varepsilon_0)}{2\varepsilon_0 + \varepsilon_j} |B_j|\, \mathbf{G}(\mathbf{r}, z_j) \cdot \mathbf{E}_0^{(n)}(z_j) \right] + O(\alpha^4). \tag{11}$$

Formula (11) would easily extend to the case of triaxial ellipsoidal inclusions, using their standard tensors which, for inclusion B_j, read in the ellipsoidal coordinate system attached to it as

$$\mathbf{M}\left(\frac{q_j}{q_0}; B_j\right) = \begin{bmatrix} m_{j1} & 0 & 0 \\ 0 & m_{j2} & 0 \\ 0 & 0 & m_{j3} \end{bmatrix} |B_j|,$$

where the coefficients $m_{jl}, l = 1, 2, 3$, are equal to $q_0/(q_0 + L_l(q_j - q_0))$, the L_l being the well-known depolarization factors of the ellipsoid proportional to harmonic elliptic integrals of degree 1. See [34, 26, 9]. We also note that from (9) it follows that

$$\frac{\varepsilon_j}{\varepsilon_0} \mathbf{M}\left(\frac{\varepsilon_j}{\varepsilon_0}; B_j\right) \to \mathbf{Q}(B_j) \quad \text{as} \quad \left|\frac{\varepsilon_j}{\varepsilon_0}\right| \to +\infty$$

and

$$\mathbf{M}\left(\frac{\mu_j}{\mu_0}; B_j\right) \to \mathbf{W}(B_j) \quad \text{as } \frac{\mu_j}{\mu_0} \to 0,$$

which (formally) extends the validity of (10) and its specialization (11) to PEC, results being likewise obtained for PMC by duality. See [18].

2.5. Far-field pattern. Since for fixed $\mathbf{r}'$ the far-field expansions

$$g(\mathbf{r}, \mathbf{r}') = \frac{e^{ik|\mathbf{r} - \mathbf{r}'|}}{4\pi|\mathbf{r} - \mathbf{r}'|} = \frac{e^{ikr}}{4\pi r} e^{-ik\hat{\mathbf{r}} \cdot \mathbf{r}'} + O\left(\frac{1}{r^2}\right), \\ \nabla' g(\mathbf{r}, \mathbf{r}') = -ik \frac{e^{ikr}}{4\pi r} e^{-ik\hat{\mathbf{r}} \cdot \mathbf{r}'} \hat{\mathbf{r}} + O\left(\frac{1}{r^2}\right) \tag{12}$$

hold, then, using the vector identity $\nabla\times(\psi\mathbf{A}) = \nabla\psi\times\mathbf{A} + \psi\nabla\times\mathbf{A}$, we obtain that the following expansions hold uniformly in $\hat{\mathbf{r}}$ for any vector $\mathbf{a}$ and any fixed $\mathbf{r}'$:

(13)
$$\begin{aligned}\mathbf{G}(\mathbf{r},\mathbf{r}')\cdot\mathbf{a} &= -\frac{e^{ikr}}{4\pi r}e^{-ik\hat{\mathbf{r}}\cdot\mathbf{r}'}\hat{\mathbf{r}}\times(\hat{\mathbf{r}}\times\mathbf{a}) + O\left(\frac{1}{r^2}\right),\\ \nabla'\times\mathbf{G}(\mathbf{r},\mathbf{r}')\cdot\mathbf{a} &= \nabla' g(\mathbf{r},\mathbf{r}')\times\mathbf{a} = -ik\frac{e^{ikr}}{4\pi r}e^{-ik\hat{\mathbf{r}}\cdot\mathbf{r}'}\hat{\mathbf{r}}\times\mathbf{a} + O\left(\frac{1}{r^2}\right) \quad \text{as } r\to+\infty.\end{aligned}$$

Note that $-\hat{\mathbf{r}}\times(\hat{\mathbf{r}}\times\mathbf{a}) = \Delta(\mathbf{r})\cdot\mathbf{a}$, where $\Delta(\mathbf{r}) = \mathbf{I_3} - \hat{\mathbf{r}}\hat{\mathbf{r}}^T$. Moreover, $\Delta(\mathbf{r}) = \Delta^T(\mathbf{r}), \Delta^2(\mathbf{r}) = \Delta(\mathbf{r})$, and $\hat{\mathbf{r}}\times\mathbf{a} = \Lambda(\mathbf{r})\cdot\mathbf{a}$, where

$$\Lambda(\mathbf{r}) = \begin{bmatrix} 0 & -\hat{\mathbf{r}}_z & \hat{\mathbf{r}}_y \\ \hat{\mathbf{r}}_z & 0 & -\hat{\mathbf{r}}_x \\ -\hat{\mathbf{r}}_y & \hat{\mathbf{r}}_x & 0 \end{bmatrix}.$$

Here $(\hat{\mathbf{r}}_x,\hat{\mathbf{r}}_y,\hat{\mathbf{r}}_z) = (\mathbf{r}_x,\mathbf{r}_y,\mathbf{r}_z)/r$. It is easy to see that $\Lambda(\mathbf{r}) = -\Lambda^T(\mathbf{r})$, and $\Lambda(\mathbf{r})\Lambda^T(\mathbf{r}) = \Delta(\mathbf{r})$.

With this notation, since

$$\begin{aligned}&\nabla g(\mathbf{r},\mathbf{r}')\times\mathbf{a} = -\nabla' g(\mathbf{r},\mathbf{r}')\times\mathbf{a},\\ &\nabla g(\mathbf{r},\mathbf{r}')\times\mathbf{a} = ik\frac{e^{ikr}}{4\pi r}e^{-ik\hat{\mathbf{r}}\cdot\mathbf{r}'}\Lambda(\mathbf{r})\cdot\mathbf{a} + O\left(\frac{1}{r^2}\right) \quad \text{as } r\to+\infty,\end{aligned}$$

the far-field expansions in (13) become

(14)
$$\begin{aligned}&\mathbf{G}(\mathbf{r},\mathbf{r}') = \frac{e^{ikr}}{4\pi r}e^{-ik\hat{\mathbf{r}}\cdot\mathbf{r}'}\Delta(\mathbf{r}) + O\left(\frac{1}{r^2}\right),\\ &\nabla'\times\mathbf{G}(\mathbf{r},\mathbf{r}') = -ik\frac{e^{ikr}}{4\pi r}e^{-ik\hat{\mathbf{r}}\cdot\mathbf{r}'}\Lambda(\mathbf{r}) + O\left(\frac{1}{r^2}\right) \quad \text{as } r\to+\infty.\end{aligned}$$

Let $A_\alpha(\hat{\mathbf{r}},\hat{\mathbf{r}}_n)$ be the scattering amplitude of the electromagnetic inclusions $\mathcal{I}_\alpha$. The function $A_\alpha(\hat{\mathbf{r}},\hat{\mathbf{r}}_n)$ is defined to be the function which satisfies

$$\mathbf{E}_\alpha^{(n)}(\mathbf{r}) = \mathbf{E}_0^{(n)}(\mathbf{r}) + A_\alpha(\hat{\mathbf{r}},\hat{\mathbf{r}}_n)\frac{e^{ikr}}{4\pi r} + O\left(\frac{1}{r^2}\right)$$

as $r\to+\infty$, uniformly with respect to $\hat{\mathbf{r}}$ and $\hat{\mathbf{r}}_n$ on the unit sphere in $\mathbb{R}^3$, where

$$\mathbf{E}_0^{(n)}(\mathbf{r}) = -i\omega\mu_0(Il)_n\,\hat{\mathbf{r}}_n\times(\hat{\mathbf{r}}_n\times\overrightarrow{\beta})\,e^{-ik\hat{\mathbf{r}}_n\cdot\mathbf{r}}$$

is the incident field and $\mathbf{E}_\alpha^{(n)}$ is the unique solution of

(15)
$$\begin{cases}\nabla\times\dfrac{1}{\mu_\alpha}\nabla\times\mathbf{E}_\alpha^{(n)}(\mathbf{r}) - \omega^2\varepsilon_\alpha\mathbf{E}_\alpha^{(n)}(\mathbf{r}) = 0 \quad \text{in } \mathbb{R}^3,\\ \lim\limits_{r\to+\infty} r\left[\nabla\times(\mathbf{E}_\alpha^{(n)}-\mathbf{E}_0^{(n)})(\mathbf{r}) - ik\hat{\mathbf{r}}\times(\mathbf{E}_\alpha^{(n)}-\mathbf{E}_0^{(n)})(\mathbf{r})\right] = 0.\end{cases}$$

It is well known (e.g., from [25, 37]) that there exists a unique solution to (15).

By using (14), it follows from (10) that the leading-order term in the asymptotic expansion of $A_\alpha(\hat{\mathbf{r}}, \hat{\mathbf{r}}_n)$ is given by

$$A_\alpha(\hat{\mathbf{r}}, \hat{\mathbf{r}}_n) = k^2 i\omega\mu_0\, \alpha^3 \sum_{j=1}^{m} e^{-ik(\hat{\mathbf{r}}+\hat{\mathbf{r}}_n)\cdot z_j} \left[-\left(\frac{\mu_j}{\mu_0} - 1\right) \Lambda(\mathbf{r}) \cdot \mathbf{M}\left(\frac{\mu_j}{\mu_0}; B_j\right) \Lambda(\mathbf{r}_n) \right.$$
$$\left. + \left(\frac{\varepsilon_j}{\varepsilon_0} - 1\right) \Delta(\mathbf{r}) \cdot \mathbf{M}\left(\frac{\varepsilon_j}{\varepsilon_0}; B_j\right) \Delta(\mathbf{r}_n) \right] \cdot \overrightarrow{\beta}\,(Il)_n + O(\alpha^4), \tag{16}$$

where $\overrightarrow{\beta}$ is the incidence direction. See [13] for a proof. In the special case where all the inclusions are small spheres we get from (11), as shown in [20], that

$$\begin{aligned} &A_\alpha(\hat{\mathbf{r}}, \hat{\mathbf{r}}_n) \\ &= i\omega\mu_0 k^2 \alpha^3 \sum_{j=1}^{m} e^{-ik(\hat{\mathbf{r}}+\hat{\mathbf{r}}_n)\cdot z_j} \left[-\frac{3\,(\mu_j - \mu_0)}{2\mu_0 + \mu_j} |B_j|\, \Lambda(\mathbf{r})\Lambda(\mathbf{r}_n) + \frac{3(\varepsilon_j - \varepsilon_0)}{2\varepsilon_0 + \varepsilon_j} |B_j|\, \Delta(\mathbf{r})\Delta(\mathbf{r}_n) \right] \\ &\quad \cdot \overrightarrow{\beta}\,(Il)_n \\ &= i\omega\mu_0 k^2 \alpha^3 \sum_{j=1}^{m} e^{-ik(\hat{\mathbf{r}}+\hat{\mathbf{r}}_n)\cdot z_j} \left[\frac{3\,(\mu_j - \mu_0)}{2\mu_0 + \mu_j} |B_j|\, \Delta(\mathbf{r}, \mathbf{r}_n) + \frac{3(\varepsilon_j - \varepsilon_0)}{2\varepsilon_0 + \varepsilon_j} |B_j|\, \Delta(\mathbf{r})\Delta(\mathbf{r}_n) \right] \\ &\quad \cdot \overrightarrow{\beta}\,(Il)_n, \end{aligned}$$

where

$$\Delta(\mathbf{r}, \mathbf{r}_n) = \hat{\mathbf{r}} \cdot \hat{\mathbf{r}}_n \mathbf{I_3} - \hat{\mathbf{r}}_n \hat{\mathbf{r}}^T.$$

Here we have used the fact that

$$\Lambda(\mathbf{r})\Lambda(\mathbf{r}_n) \cdot \mathbf{a} = \hat{\mathbf{r}} \times (\hat{\mathbf{r}}_n \times \mathbf{a}) = -\Delta(\mathbf{r}, \mathbf{r}_n) \cdot \mathbf{a}.$$

3. The multistatic response matrix.

3.1. The multistatic response matrix for transmitter and receiver arrays. Let $\{\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z\}$ form an orthonormal basis of $\mathbb{R}^3$. Let $\{\mathbf{r}_1, \ldots, \mathbf{r}_{n_t}\} \in \mathbb{R}^3 \setminus \overline{\Omega}$ be the positions of the transmitters and $\overrightarrow{\beta}_1, \ldots, \overrightarrow{\beta}_{d_t}$ be the unit directions of incident fields due to a point current density at the position $\mathbf{r}_n$. Let $\{\mathbf{R}_1, \ldots, \mathbf{R}_{n_r}\} \in \mathbb{R}^3 \setminus \overline{\Omega}$ be the positions of the receivers and $\overrightarrow{\gamma}_1, \ldots, \overrightarrow{\gamma}_{d_r}$ be the observation directions of the fields at the position $\mathbf{R}_n$.

Recall that the incident electric and magnetic fields are given by

$$\begin{aligned} \mathbf{E}_0^{(n)}(\mathbf{r}) &= i\omega\mu_0\, \mathbf{G}(\mathbf{r}, \mathbf{r}_n) \cdot \overrightarrow{\beta}_d\, (Il)_n^d, \\ \mathbf{H}_0^{(n)}(\mathbf{r}) &= \nabla\times\, \mathbf{G}(\mathbf{r}, \mathbf{r}_n) \cdot \overrightarrow{\beta}_d\, (Il)_n^d, \quad n = 1, \ldots, n_t,\ d = 1, \ldots, d_t, \end{aligned}$$

where $(Il)_n^d$ are current moments.

The voltages induced on the pth receiving element can be expressed as

$$\begin{aligned} V_{p,n}^{1,d} &= \overrightarrow{\gamma}_1 \cdot \left(\mathbf{E}_\alpha^{(n)}(\mathbf{R}_p) - \mathbf{E}_0^{(n)}(\mathbf{R}_p) \right), \\ &\vdots \\ V_{p,n}^{d_r,d} &= \overrightarrow{\gamma}_{d_r} \cdot \left(\mathbf{E}_\alpha^{(n)}(\mathbf{R}_p) - \mathbf{E}_0^{(n)}(\mathbf{R}_p) \right), \end{aligned} \tag{17}$$

where the perturbation $\mathbf{E}_\alpha^{(n)}(\mathbf{R}_p) - \mathbf{E}_0^{(n)}(\mathbf{R}_p)$ is given by

$$\begin{aligned}\mathbf{E}_\alpha^{(n)}(\mathbf{R}_p) - \mathbf{E}_0^{(n)}(\mathbf{R}_p) = i\omega\mu_0\,\alpha^3 \sum_{j=1}^{m} \Bigg[&- \left(\frac{\mu_j}{\mu_0} - 1\right)\nabla' \times \mathbf{G}(\mathbf{R}_p, z_j) \\ &\cdot \mathbf{M}\left(\frac{\mu_j}{\mu_0}; B_j\right)\nabla \times \mathbf{G}(z_j, \mathbf{r}_n) + k^2\left(\frac{\varepsilon_j}{\varepsilon_0} - 1\right)\mathbf{G}(\mathbf{R}_p, z_j) \\ &\cdot \mathbf{M}\left(\frac{\varepsilon_j}{\varepsilon_0}; B_j\right)\mathbf{G}(z_j, \mathbf{r}_n)\Bigg] \cdot \overrightarrow{\beta}_d (Il)_n^d \end{aligned} \tag{18}$$

for $d = 1, \ldots, d_t$ and $n = 1, \ldots, n_t$. Here we have neglected the asymptotic term of order α^4 in (10).

Combining (17) and (18) yields

$$\mathbf{V} = \mathbf{A}\, J,$$

where

$$\mathbf{V} = \left[\mathbf{V}_1^1 \ldots \mathbf{V}_1^{d_t}, \ldots, \mathbf{V}_{n_t}^1 \ldots \mathbf{V}_{n_t}^{d_t}\right],$$

$$\mathbf{V}_n^d = \left(V_{1,n}^{1,d}, \ldots, V_{1,n}^{d_r,d}, \ldots, V_{n_r,n}^{1,d}, \ldots, V_{n_r,n}^{d_r,d}\right)^T, \quad d = 1, \ldots, d_t, \;\; n = 1, \ldots, n_t,$$

and

$$J = \operatorname{diag}\left((Il)_1^1, \ldots, (Il)_1^{d_t}, \ldots, (Il)_{n_t}^1, \ldots, (Il)_{n_t}^{d_t}\right).$$

The matrix $\mathbf{A} \in \mathbb{C}^{d_r n_r \times d_t n_t}$ is the so-called MSR matrix.

For $z \in \mathbb{R}^3 \backslash \{\mathbf{R}_1, \ldots, \mathbf{R}_{n_r}, \mathbf{r}_1, \ldots, \mathbf{r}_{n_t}\}$, introduce the matrices $\mathbf{g}_{r,z}^\varepsilon, \mathbf{g}_{r,z}^\mu \in \mathbb{C}^{d_r n_r \times 3}$, $\mathbf{g}_{t,z}^\varepsilon, \mathbf{g}_{t,z}^\mu \in \mathbb{C}^{d_t n_t \times 3}$:

$$\begin{cases} \mathbf{g}_{r,z}^\varepsilon = (\mathbf{G}(z, \mathbf{R}_1) \cdot \overrightarrow{\gamma}_1, \ldots, \mathbf{G}(z, \mathbf{R}_1) \cdot \overrightarrow{\gamma}_{d_r}, \ldots, \mathbf{G}(z, \mathbf{R}_{n_r}) \cdot \overrightarrow{\gamma}_1, \ldots, \\ \qquad \mathbf{G}(z, \mathbf{R}_{n_r}) \cdot \overrightarrow{\gamma}_{d_r})^T, \\ \mathbf{g}_{t,z}^\varepsilon = (\mathbf{G}(z, \mathbf{r}_1) \cdot \overrightarrow{\beta}_1, \ldots, \mathbf{G}(z, \mathbf{r}_1) \cdot \overrightarrow{\beta}_{d_t}, \ldots, \mathbf{G}(z, \mathbf{r}_{n_t}) \cdot \overrightarrow{\beta}_1, \ldots, \mathbf{G}(z, \mathbf{r}_{n_t}) \cdot \overrightarrow{\beta}_{d_t})^T, \\ \mathbf{g}_{r,z}^\mu = (\nabla g(z, \mathbf{R}_1) \times \overrightarrow{\gamma}_1, \ldots, \nabla g(z, \mathbf{R}_1) \times \overrightarrow{\gamma}_{d_r}, \ldots, \nabla g(z, \mathbf{R}_{n_r}) \times \overrightarrow{\gamma}_1, \ldots, \\ \qquad \nabla g(z, \mathbf{R}_{n_r}) \times \overrightarrow{\gamma}_{d_r})^T, \\ \mathbf{g}_{t,z}^\mu = (\nabla g(z, \mathbf{r}_1) \times \overrightarrow{\beta}_1, \ldots, \nabla g(z, \mathbf{r}_1) \times \overrightarrow{\beta}_{d_t}, \ldots, \nabla g(z, \mathbf{r}_{n_t}) \times \overrightarrow{\beta}_1, \ldots, \\ \qquad \nabla g(z, \mathbf{r}_{n_t}) \times \overrightarrow{\beta}_{d_t})^T, \end{cases} \tag{19}$$

and define the matrices $\mathbf{M}_j^\varepsilon, \mathbf{M}_j^\mu \in \mathbb{C}^{3\times 3}$, $\mathbf{M}_j^{\mu,\varepsilon} \in \mathbb{C}^{6\times 6}$ by

$$\begin{aligned} \mathbf{M}_j^\varepsilon &= i\omega\mu_0\,\alpha^3\,k^2\left(\frac{\varepsilon_j}{\varepsilon_0} - 1\right)\mathbf{M}\left(\frac{\varepsilon_j}{\varepsilon_0}; B_j\right), \\ \mathbf{M}_j^\mu &= i\omega\mu_0\,\alpha^3\left(\frac{\mu_j}{\mu_0} - 1\right)\mathbf{M}\left(\frac{\mu_j}{\mu_0}; B_j\right), \\ \mathbf{M}_j^{\mu,\varepsilon} &= \operatorname{diag}(\mathbf{M}_j^\mu, \mathbf{M}_j^\varepsilon), \quad j = 1, \ldots, m. \end{aligned}$$

Throughout this paper we consider separately the following three cases:

- case 1: $\mu_j = \mu_0$ for all $j = 1, \dots, m$,
- case 2: $\varepsilon_j = \varepsilon_0$ for all $j = 1, \dots, m$,
- case 3: $\mu_j \neq \mu_0$ and $\varepsilon_j \neq \varepsilon_0$ at least for one $j \in \{1, \dots, m\}$.

For simplicity we use the notation

$$\mathbf{g}_{p,z} := \begin{cases} \mathbf{g}^{\varepsilon}_{p,z} & \text{in case 1,} \\ \mathbf{g}^{\mu}_{p,z} & \text{in case 2,} \\ [\mathbf{g}^{\mu}_{p,z}, \mathbf{g}^{\varepsilon}_{p,z}] & \text{in case 3,} \end{cases} \tag{20}$$

$$\mathbf{M}_j := \begin{cases} \mathbf{M}^{\varepsilon}_j & \text{in case 1,} \\ \mathbf{M}^{\mu}_j & \text{in case 2,} \\ \mathbf{M}^{\mu,\varepsilon}_j & \text{in case 3,} \end{cases} \tag{21}$$

for $p = r, t$ and $j = 1, \dots, m$, to decompose the MSR matrix $\mathbf{A}$ as follows:

$$\mathbf{A} = \mathbf{g}_{r,z_1,\dots,z_m}\, \mathbf{M}\, \mathbf{g}^T_{t,z_1,\dots,z_m}, \tag{22}$$

where, for $p = r, t$,

$$\mathbf{g}_{p,z_1,\dots,z_m} = [\mathbf{g}_{p,z_1}, \dots, \mathbf{g}_{p,z_m}] \quad \text{and} \quad \mathbf{M} = \operatorname{diag}(\mathbf{M}_1, \dots, \mathbf{M}_m).$$

Note that if $d_t = d_r$, $n_t = n_r = n$, and $\{\mathbf{r}_1, \dots, \mathbf{r}_n\} = \{\mathbf{R}_1, \dots, \mathbf{R}_n\}$, then the matrix $\mathbf{A}$ is symmetric. In writing (22) we have used the fact that for any vector $\mathbf{a} \in \mathbb{R}^3$

$$\nabla \times \mathbf{G}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} = \nabla g(\mathbf{r}, \mathbf{r}') \times \mathbf{a}$$

and

$$(\nabla g(\mathbf{r}, \mathbf{r}') \times \mathbf{a})^T = (\nabla \times \mathbf{G}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a})^T = \mathbf{a} \cdot \nabla' \times \mathbf{G}(\mathbf{r}', \mathbf{r}) - \mathbf{a} \cdot \nabla \times \mathbf{G}(\mathbf{r}', \mathbf{r}).$$

Recall that the matrix $\mathbf{A}^*\mathbf{A}$, where $\mathbf{A}^* = \overline{\mathbf{A}}^T$, is called the time-reversal matrix.

3.2. The multistatic response matrix for the far-field pattern. From (16) the leading-order term in the asymptotic expansion of $A_\alpha(\hat{\mathbf{r}}, \hat{\mathbf{r}}_n)$ for any directions $\overrightarrow{\beta}$, $\overrightarrow{\gamma}$, and $\hat{\mathbf{R}}_p, \hat{\mathbf{r}}_n$ is given, after neglecting the remainder $O(\alpha^4)$, by

$$\begin{aligned} &\overrightarrow{\gamma} \cdot (A_\alpha(\hat{\mathbf{R}}_p, \hat{\mathbf{r}}_n) - A_0(\hat{\mathbf{R}}_p, \hat{\mathbf{r}}_n)) \\ &\quad = k^2 i\omega\mu_0\, \alpha^3 \sum_{j=1}^{m} e^{-ik(\hat{\mathbf{R}}_p + \hat{\mathbf{r}}_n)\cdot z_j}\, \overrightarrow{\gamma} \cdot \left[-\left(\frac{\mu_j}{\mu_0} - 1\right) \Lambda(\mathbf{R}_p) \cdot \mathbf{M} \left(\frac{\mu_j}{\mu_0}; B_j\right) \Lambda(\mathbf{r}_n) \right. \\ &\qquad \left. + \left(\frac{\varepsilon_j}{\varepsilon_0} - 1\right) \Delta(\mathbf{R}_p) \cdot \mathbf{M} \left(\frac{\varepsilon_j}{\varepsilon_0}; B_j\right) \Delta(\mathbf{r}_n) \right] \cdot \overrightarrow{\beta}\, (Il)_n, \end{aligned}$$

where $\hat{\mathbf{R}}_p = \mathbf{R}_p/|\mathbf{R}_p|, \hat{\mathbf{r}}_n = \mathbf{r}_n/|\mathbf{r}_n|$.

In this case, the vectors $\mathbf{g}^{\varepsilon}_{r,z}, \mathbf{g}^{\mu}_{r,z} \in \mathbb{C}^{d_r n_r \times 3}$, $\mathbf{g}^{\varepsilon}_{t,z}, \mathbf{g}^{\mu}_{t,z} \in \mathbb{C}^{d_t n_t \times 3}$, for $z \in \mathbb{R}^3$, are

given by

(23)
