Coulometric titrations were performed in the vessel shown in Fig. 2. It was necessary to titrate the solution in the small left-hand compartment between the discs. This titration was performed with an auxiliary platinum cathode, the current of which was also measured by the integrator. It was found that migration into this compartment corresponded to at least 0·5% of the weak acid added. Typical titration results are shown in Table IV.

TABLE IV.—COULOMETRIC TITRATION WITH A PLATINUM CATHODE AND A SEPARATE ANODE COMPARTMENT.
(Solvent: isopropanol, 50%, methylethylketone, 50%;
electrolyte: sodium perchlorate, 4 g per litre.)

Substance	Taken, *μmole*	No. of samples	Found, *μmole*	Standard deviation	Dev. from calculated, %
Salicylic acid	72·47	6	72·38	0·33	−0·12
5,5-Dimethyl-dihydroresorcinol	71·52	6	71·42	0·50	−0·14
Phenobarbital	86·26	4	86·11	0·28	+0·17
Phenobarbital	43·14	2	42·95	0·00	−0·45
Barbital	54·42	3	54·75	0·48	+0·61
Barbital	108·85	1	109·19	—	+0·31
m-Nitrobenzoic acid	100·41	2	100·34	0·35	−0·06

The uncertainty in the results is of the same order as the uncertainty in the end-point. The values are distributed evenly about the value calculated from electrical units.

In most of the titrations 4 g of $NaClO_4$ per litre were added; the current was then 10–25 mA. No influence from varying the amount of perchlorate has been observed. To prevent migration of hydrogen ions from the anode compartment, a silver anode was used, and sodium tetraphenylboron was added to the anode solution.

Chronopotentiometric reduction

If an acid undergoes reduction at the cathode, an error in the titration will follow. A reduction should cause high results because several faradays are generally required for the reduction of 1 mole of acid.

A chronopotentiometric investigation of the compounds used was made, a chronopotentiogram being taken under the same conditions as those of the titration. It was found that the acids yielded concentration-dependent single waves. These waves are caused by the discharge of the hydrogen ions.[19] The sodium salts of the acids gave no waves. There were no signs of reduction of the acids. The solvents exhibited no waves indicating side reactions.

Organic nitro compounds can be analysed by reduction with controlled potential.[20,21] However, the hydrogen overvoltage is less on platinum than on mercury. Substances which are reduced at a mercury cathode may be titrated at a platinum cathode. This is illustrated by *m*-nitrobenzoic acid, which gave two chronopotentiometric waves in water but only one in isopropanol. Table IV shows that *m*-nitrobenzoic acid can be titrated successfully, and that therefore the method may even be used with some reducible compounds.[19]

DISCUSSION

Coulometric titration in non-aqueous solvents is a very useful analytical tool, but it has several limitations. Reducible acids cannot be titrated with an internal generation technique (the reducibility can be tested by chronopotentiometry of the salts).

In the present investigation only relatively small amounts of acids have been titrated. Larger amounts of acid would permit a more accurate end-point determination. However, it has been observed that the accuracy decreases if the amount of acid is increased by an order of ten. If side reactions occur, their effect may be negligible at the concentrations employed in this investigation, but may cause an appreciable error at higher concentrations.

This effect is especially pronounced for salicylic acid. In the titration of large amounts of this acid a deposit is formed at the cathode. The infrared spectrum of this deposit shows significant differences from the spectrum of sodium salicylate and salicylaldehyde. The deposit is slightly soluble in organic solvents but soluble in water; it behaves as a very strong base; its equivalent weight is 180. This indicates that a sodium salt is formed with the hydroxide group of salicylic acid (calculated equivalent weight 182). This compound is slightly soluble and removes base from the titration reaction. Salicylic acid could be titrated quantitatively using tetra-n-butylammonium hydroxide as an electrolyte.

Most of the titrations have been performed in alcohol-ketone solvents. Some titrations have been made in pyridine, acetonitrile and dimethylformamide with 25% isopropanol added. The results indicate that these solvent combinations, too, may be used.

In this pilot investigation the solvents were purified and dried. In some experiments unpurified solvents were used, and water was added. No significant differences were observed for most solvents except that the sharpness of the end-point decreased when the water content increased. Some batches of undistilled methyl ethyl ketone contained an impurity which yielded a chronopotentiometric wave.

Zusammenfassung—Die coulometrische Erzeugung von Basen verlauft in Isopropanol und einigen isopropanolhaltigen Lösungsmittelgemischen mit hundert-prozentiger Stromausbeute. Die Bedingungen für die Titration schwacher Säuren in nichtwäßrigem Medium wurden untersucht. Die besten Resultate wurden bei Trennung der Anode von der Probelösung durch Sinterglasscheiben erhalten. 50–100 μMol Säure wurden mit einer Standardabweichung von weniger als 0,5 μMol titriert.

Résumé—La formation coulométrique de base a lieu avec une efficacité de courant de 100% en isopropanol et dans quelques mélanges de solvants contenant de l'isopropanol. On a étudié les conditions de titrage des acides faibles en milieu non aqueux. Les meilleurs résultats sont obtenus lorsque l'anode est séparée de la solution à doser par des disques de verre fritté. On a dosé 50–100 μmole d'acide avec un écart type de moins de 0,5 μmole.

Summary—A detailed study has been made of the electrolytic separation of rhodium and iridium published by MacNevin and Tuthill in 1949. By the use of carbon anodes the need to introduce hydroxylamine during the electrolysis is avoided. By the elimination of hydroxylamine a high residual current is avoided, and it is revealed that depositions of rhodium where the cathode potential is automatically controlled proceed with a periodically fluctuating current. The deposition of rhodium may be carried out in buffered solutions to avoid the onset of hydrogen evolution at the cathode; this takes precedence on occasion over rhodium plating and causes low recovery of rhodium. From buffered solutions with the pH raised to avoid hydrogen evolution the rhodium deposited appears to contain more oxide, and the separation of iridium is less effective than from solutions prepared by MacNevin's procedure. A compromise is required between working with a more acidic electrolyte from which, because of hydrogen evolution, the recovery of rhodium is incomplete, and working with a more alkaline buffered electrolyte from which the rhodium is deposited with a considerable oxide content (which can be reduced) and contaminated more by iridium. It is doubtful if the electrolytic method of separation is as reliable as other procedures.

INTRODUCTION

MACNEVIN and Tuthill[1] have published a procedure for the electrolytic determination of rhodium and the separation of rhodium from iridium. We have studied this procedure at some length to test its reliability, to try to simplify or improve it, and to try to understand the mechanisms involved.

The procedure of MacNevin and Tuthill is characterised by several unusual features:

(i) The electrolytically deposited rhodium is dark and contains oxide. Before determination of the metal the whole electrode must be heated in an atmosphere of hydrogen to reduce this oxide.

(ii) The current efficiency during the electrolysis is remarkably low. Considerable current flows throughout the duration of the electrolysis, and there is no indication by diminution of the current that the rhodium has all been removed from the solution.

(iii) The potential of the cathode is maintained at a selected value relative to a saturated calomel electrode; during the 90 min prescribed for the analysis this potential is lowered from −0·25 V to −0·40 V in three stages. Iridium is not electrolytically deposited from solutions of its chloride even when the cathode potential is as low as −1·00 V. Nevertheless, when rhodium and iridium are present together in solution and the electrodeposition of rhodium is carried out, the plated metal generally contains iridium. MacNevin and Tuthill found that special treatment of solutions containing rhodium and iridium (chlorination, addition of ammonium chloride to a molarity of 3·5) enabled rhodium to be deposited free from iridium.

These observations have been confirmed repeatedly in our experiments, except that the separation of the two metals is not always assured by the prescribed pretreatment of their chloride solution. We have also recorded a number of other observations which may shed some light on the mechanism of the deposition of rhodium and the almost unavoidable codeposition of iridium.

The chemical reduction of rhodium salts in the presence of iridium salts has been achieved by titanium^{III},[2] vanadium^{II},[3] chromium^{II},[4] antimony[5] and copper.[6] For all but the last of these, rhodium and iridium are converted to sulphates or sulphate-complexes before the reducing agent is added. A thorough study of the selective reduction of chlororhodite by copper metal, and of the separation thereby of rhodium and iridium,[6] shows that an analytically acceptable separation of these two metals is possible, although small and partially compensating amounts of rhodium remain in solution, and of iridium are deposited with the rhodium.

The standard potentials for the reduction of the tervalent chloro-salts of these metals according to Latimer[7] are:

$$e + IrCl_6^{-2} \rightarrow IrCl_6^{-3} \qquad E^\circ = 1.017\ V$$

$$3e + IrCl_6^{-3} \rightarrow Ir + 6Cl^- \qquad E^\circ = 0{\cdot}77\ V$$

$$3e + RhCl_6^{-3} \rightarrow Rh + 6Cl^- \qquad E^\circ = 0.44\ V.$$

Obviously, such thermodynamically derived standard potentials must be cautiously interpreted in relation to the actual deposition of these metals. However, if the above values are correct (they actually are based on *estimates* of entropies of the complex ions), the deposition of rhodium unaccompanied by iridium from a solution of the chloro-salts requires that the reduction of chloro-iridite be accompanied by a considerable overpotential. Expressed in another way, the reduction of chlororhodite is kinetically favoured over that of chloro-iridite, in spite of the fact that reduction of the latter is thermodynamically more favourable. Obviously, one step in the reduction of these chloro-complex ions is the rupture of the M-Cl bonds. Evidence concerning the actual stability of these complexes is lacking, but one indication that chloride is more labile in chlororhodite than in chloro-iridite is the comparatively easy hydrolysis of the former and not of the latter, at room temperature. The conditions surrounding the electrodeposition of rhodium may catalyse that of iridium, because it is only when rhodium is present that any deposition of iridium occurs. In this connection it is noteworthy that induced reduction of iridium occurs during chemical precipitation of palladium metal.[8] Alternatively, the occurrence of iridium in the deposited rhodium may be associated with the mechanism of deposition of the latter which leads to an appreciable content of oxide in the metal (often exceeding 30 atomic per cent).

EXPERIMENTAL

The experiments described here were carried out at intervals over a period of years, as a consequence of which the equipment used, and the solutions of rhodium and iridium were not the same at all times.

Solutions of rhodium and iridium

These were prepared either from very pure chloro-salts, or from spectrographically pure metal sponge. The metal content of the solutions prepared from salts was determined by gravimetric analysis; rhodium by precipitation with thiobarbituric acid,[9] and iridium by precipitation as the hydrated dioxide.[10] For the other solutions, weighed portions of metallic sponge were dissolved by the sealed-tube chlorination technique of Wichers *et al.*,[11] and the resulting solutions made up to known volumes.

Electrolysis cell

Platinum gauze cathodes of cylindrical form, 1 inch × 1 inch, with No. 18 gauge wire stems were used throughout. Platinum anodes consisted of a 0·5 inch × 1 inch helix of No. 18 gauge wire. These were secured in position in brass bushings threaded into 1/8-inch Perspex sheet, the latter serving as cover-glass for the electrolytic beaker. Carbon anodes were prepared from graphite rod of the quality used to make spectrographic electrodes. The stationary anodes consisted of 3/16-inch rod machined to 1/8-inch at the upper end to fit into the brass bushing; the rotating anodes consisted of a ¼-inch rod, machined to fit the chuck of the Fisher Electroanalyzer at the top end, and drilled transversely near the bottom end to take a 1-inch length of 1/8-inch graphite rod. When stationary electrodes were used, the electrolyte was stirred by a magnetic rotor in the solution.

A probe electrode, consisting of a saturated calomel half-cell and a saturated potassium chloride-3% agar bridge, was mounted by the electrolysis cell in such a position as to allow the tip of the salt bridge in the electrolytic solution to rest against the outer surface of the cathode.

Regulated d.c. supply

Power to the electrolysis cell was delivered to operate with controlled cathode potential from one of three sources:

(a) a manually operated supply, consisting of two parallel Cenco wire-wound rheostats in series with a multi-range ammeter and the cell, connected to the 110-V laboratory d.c. supply. The rheostats permitted fine and coarse adjustment of plating current, which was adjusted throughout the electrolysis as necessary to maintain the cathode at a selected potential relative to the probe electrode.

(b) an all-electronic potentiostat of the design proposed by Greenough *et al.*[12] Indication of the cathode potential by means of the microammeter incorporated in this unit was unsatisfactory, and accordingly this meter was removed from the circuit. All settings of this controller were based on the observed cathode potential given by an auxiliary valve voltmeter.

(c) a Fisher Electroanalyzer used in later electrolyses.

Valve voltmeter

An a.c. line-operated meter of a bridge type, very similar in design to that incorporated in the potentiostat of Diehl *et al.*,[13] was used to observe the cathode-to-probe potential difference. The full-scale reading was set, and from time to time checked, against the output of a student potentiometer which in turn was calibrated against a Weston standard cell.

Reduction chamber

A glass vessel with surrounding heating jacket, patterned after the description of MacNevin and Tuthill, but smaller because of the smaller cathodes (1·5-inch tubing, 45/50 joint), was built to permit reduction of the deposit by hydrogen gas.

All electrolyses were carried out, unless otherwise noted, with the electrolyte solution at room temperature. The cathode was weighed on a semi-micro analytical balance before each deposition, and afterwards, following reduction in hydrogen. It was observed latterly that the reduction of oxide in the deposited metal was, doubtless because of the catalytic action of the rhodium, complete in less than 5 min in the warm chamber. By accelerating the heating and cooling of the electric heating jacket and taking advantage of this rapid reduction of the oxide, the time for reducing the electrode before its final weighing was shortened to about 40 min.

DISCUSSION OF RESULTS

*Hydrogen evolution**

During electrolysis of rhodium solutions, with or without iridium added, and following the directions of MacNevin and Tuthill, hydrogen was evolved at the cathode in many cases, especially after the greater part of the rhodium had been deposited. When this occurred, a small amount of rhodium was often, though not invariably, left in solution, even if the electrolysis was prolonged to 2 hr. It appeared that the evolution of hydrogen took precedence over the plating of rhodium.

The addition of more hydroxylammonium chloride usually checked this cathodic gassing. The presence of hydroxylamine in solution was found to be responsible for the high "residual" current often amounting to 1 or 2 A (see below). This was assumed to involve oxidation and reduction of the hydroxylamine as follows:

$$\begin{array}{rl} \text{CATHODE} & 2e + NH_3OH^+ + 2H^+ \rightarrow NH_4^+ + H_2O \\ \text{ANODE} & 2NH_3OH^+ \rightarrow N_2O + H_2O + 6H^+ + 4e \\ \text{OR} & NH_3OH^+ + 2H_2O \rightarrow NO_3^- + 8H^+ + 6e \\ \text{OR} & NH_3OH^+ + H_2O \rightarrow HNO_2 + 5H^+ + 4e. \end{array}$$

Because by any of the anodic processes more hydrogen ions are produced per coulomb, the effect of prolonged discharge of hydroxylamine is to increase the hydrogen ion concentration of the solution. This was confirmed in one experiment by a decrease in pH of the electrolyte following a period of this passage of current. The onset of hydrogen evolution in the later stages of electrolysis probably results from this increased hydrogen ion concentration.

The readiness with which hydrogen is evolved at a platinum electrode is regulated in part by the hydrogen overpotential; this is commonly known to depend on the state of the surface of the platinum. We have found that the longer our cathodes were in service, the more readily hydrogen came to be evolved at them during the deposition of rhodium. We have attributed this to a roughening of the surface of the platinum resulting from the repeated removal of rhodium deposits in molten potassium pyrosulphate. After each such treatment the surface of the electrode became less lustrous and although the dark-looking surfaces could be cleaned and rendered brighter by rubbing them through the fingers with a fine-grade household scouring powder, the electrodes steadily lost weight after each immersion in pyrosulphate. Some platinum is obviously removed by each cleaning of the electrodes, and we judge that this attack of the platinum has been facilitated by a certain amount of mutual dissolution of platinum and rhodium during the repeated heating and cooling of the electrode necessitated by the reduction of oxide in the deposited rhodium.

MacNevin and Tuthill do not state that hydrogen was evolved during the deposition of rhodium, but do attribute the presence of oxide in the deposit to the "rapid discharge of hydrogen ion at the cathode, which increases the pH of the adjacent solution and causes hydrolytic precipitation of the rhodium". The validity of this supposition is questionable for two reasons. In the first place, we have carried out electrodepositions of rhodium from buffered solutions (see below) with no hydrogen

---

* Some electrolyses were tried from sulphate solutions, but complete recovery of rhodium was never obtained and in some cases there was no recovery because of cathodic evolution of hydrogen. Although Rudorff[19] plated from sulphate solutions and some commercial rhodium plating solutions are based on sulphates, the authors did not find this medium satisfactory for semi-micro work.

evolution whatever, and we have found in these cases that the proportion of oxide in the plate is as high or higher than in the case of depositions where hydrogen was evolved. Secondly, the supposed local increase in pH in the solution adjacent to the cathode would be very likely to cause hydrolytic precipitation of iridium along with rhodium. The pH at which precipitation of rhodium and iridium as hydrous oxides occurs from solutions of their chlorides is as follows:

Rhodium^{III}	6·4	(Gilchrist[14])
Iridium^{III}	4	(this investigation)
Iridium^{IV}	5–5·5	(Gilchrist; this investigation)

The values given above for iridium were determined from the point of inflection of the titration curve observed when iridium chloride solutions were titrated with sodium hydroxide. The pH was measured with a glass electrode, and the solution maintained at 95° by an immersed glass coil through which steam was passed. The value for iridium$^{(III)}$ was measured after addition of just enough hydroxylamine to decolourise the iridium$^{(IV)}$ chloride. The values were not appreciably altered by the presence of a high concentration (3*M*) of sodium chloride.

Variation in electrolytic procedure

Concerning the preliminary treatment of the solution advocated by MacNevin and Tuthill to inhibit the deposition of iridium during electrolysis, these authors state that "the temporary precipitation prior to electrolysis of much of the iridium as ammonium chloroiridate tends to minimise the co-deposition...... As the electrolysis proceeds, the ammonium chloroiridate slowly dissolves, evidently because of the electrolytic reduction of $IrCl_6^{2-}$ ion to $IrCl_6^{3-}$." Although our experiments do not conclusively prove what the function of the high concentration of ammonium chloride is, it is certain that precipitation of ammonium chloro-iridate plays no part in inhibiting the deposition of iridium. In all cases, when hydroxylammonium chloride was added as specified, the precipitate of ammonium chloro-iridate dissolved and the dark colour of the chloro-iridate ion was discharged because of reduction to chloro-iridite, and *this happened before electrolysis*. Moreover, as the results of Table I show, results of comparable validity were obtained when sodium chloride was present at the same molarity as ammonium chloride; from this solution no precipitation of iridium occurred.

These electrodepositions, the results of which are summarised in Table I, were performed in the manner described by MacNevin and Tuthill, with stepwise decrease in the cathode potential and the addition of more hydroxylammonium chloride part way through the electrolysis. The difference in our experiments was that, except as noted, the electrolyses were stopped when profuse gassing began at the cathode, and this generally resulted in shortening the duration of the electrolyses from the 90 min recommended by these authors. Among 37 electrolyses carried out in this manner, 21 gave recoveries of rhodium that were low by 2% or greater. However, when hydrogen gas was allowed to form copiously at the cathode some iridium deposited with the rhodium.

Table I.—Separation of rhodium and iridium: variations on procedure of MacNevin and Tuthill[1]

Composition of electrolyte	Rhodium taken, *mg*	Iridium taken, *mg*	Cathodic deposit, *mg*	Remarks

	15·10	20·0	14·46	No gassing allowed

Action of hydroxylamine

The relatively high extraneous current accompanying the deposition of rhodium was identified with a process involving hydroxylamine through observations such as the following. With a brand new platinum cathode in the electrolysis vessel and a solution containing hydroxylammonium chloride but no rhodium, no current flowed until the cathode potential was lowered below —0·5 V (S.C.E.), when some hydrogen evolution began at the cathode. Without stopping the electrolysis, several drops of a rhodium chloride solution (*ca.* 0·5 mg of rhodium) were added to the solution; and after a few min the current rose to 150 mA at a cathode potential of —0·3 V, and remained at this value for some time. A second solution containing a few drops of rhodium chloride solution was placed into the cell, equipped now with a used rhodium-plated platinum cathode, and again no appreciable current flowed until hydrogen evolution began at a cathode potential below —0·5 V. Several small crystals of hydroxylammonium chloride were then added, whereupon almost immediately a current of 1·5 A flowed at a potential of —0·3 V. It was concluded that some process involving hydroxylamine was occurring at one or both electrodes, and presumably both because little gassing was observed, and that this was catalysed by the presence of rhodium in the solution or on the cathode surface, or both.

The presence of too high a concentration of hydroxylamine at the beginning of an electrolysis caused incomplete recovery of rhodium. This is shown by the data of Table II, and confirms the necessity of adding the hydroxylamine in small portions as the electrolysis continues. These results suggest that a complex salt had formed, be stopped by the addition of a few drops of dilute aqueous ammonia to the solution in the cell; it was inferred that the onset of hydrogen evolution at the cathode was the consequence of a gradual increase in acidity of the solution resulting from discharge of oxygen at the anode. The results shown in Table III were obtained with a carbon anode in solutions 3·5*M* in ammonium chloride also containing 1 % w/v of ammonium sulphate. The last 4 experiments were carried out in such a way as to avoid hydrogen evolution at the cathode by the dropwise addition of dilute aqueous ammonia at the first sign of cathodic gassing.

Electrolyses from buffered solutions

The suppression of cathodic hydrogen evolution by the addition, as necessary, of aqueous ammonia to the solution in the cell, as described in the preceding paragraph, encouraged the hope that satisfactory depositions of rhodium might be accomplished if the solution were buffered against change in pH. Such electrolytic depositions were carried out by the procedure described in detail below. No gas was seen to be evolved at either electrode. The absence of any cathodic gassing did not diminish the proportion of oxide in the deposited rhodium. The absence of anodic gassing suggested that acetate from the buffer acted as a depolariser for the evolution of oxygen or chlorine.

Table IV.—Deposition of rhodium from buffered solutions

Rhodium taken, *mg*	Iridium added, *mg*	Cathodic deposit, *mg*	Duration of electrolysis, *min*
10·04	nil	10·02	90
9·95	nil	9·98	75
9·95	nil	9·95	90
10·02	nil	10·04	90
9·95[a]	nil	10·02	90
9·95[a]	nil	10·02	75
10·02[a]	nil	10·12	90
10·02[a]	nil	9·81	90
9·95	4·53	10·89	60
9·95	4·53	10·19	60
9·95	4·53	10·47	60
9·95	4·53	10·52	75
9·95	4·53	10·52	90

[a] In these 4 determinations the sample was heated for 15 min in NH_4Cl solutions, the molarities of which were, respectively, 3·5, 3·5, 5·0 and 1·0, to ensure conversion to the rose-coloured $RhCl_6^{3-}$ ion. The other samples were prepared from a brown, partially hydrolysed stock solution.

In the absence of extraneous processes occurring at the electrodes, the deposition of rhodium took place at a current efficiency of nearly 100 %. Moreover, apart from the periodicity of the plating current which is discussed in a later section, the course of the electrolysis followed more normally the behaviour described by Lingane[15] for "controlled cathode" depositions. Thus, the current in most cases began at 300 to 400 mA and declined more or less exponentially to 3 or 4 mA at the end of deposition of the metal.

The recoveries of rhodium were quantitative in many determinations, but when iridium was also present in the solution some of the latter metal was invariably included in the electrolytic deposit. Some representative results are given in Table IV.

completely or in part, from rhodium and hydroxylamine, and that from it rhodium could not be quantitatively deposited. Amounts of rhodium not accounted for in the cathode deposit were found in the plating solutions when these were tested colorimetrically after destruction of hydroxylamine. Electrodeposition of rhodium did not occur at all in an analogous experiment from the yellow-coloured solution of the complex formed in 0·5*M* thiocyanate solution; when the cathode potential was taken below −0·5 V, hydrogen was evolved but no metal was found on the cathode.

TABLE II.—EFFECT OF HYDROXYLAMINE ON DEPOSITION OF RHODIUM

Composition of electrolyte	Rhodium taken, *mg*	Rhodium recovered, *mg*
0·15*M* $HONH_2$, 3·5*M* NH_4Cl	5·03	5·02
0·40*M* $HONH_2$, 3·5*M* NH_4Cl	5·03	4·66
0·40*M* $HONH_2$, 3·5*M* NH_4Cl	5·03	4·71
0·40*M* $HONH_2$, 3·5*M* NH_4Cl	5·03	3·66[a]
1·0*M* $HONH_2$	5·03	4·19

[a] The electrolyte, containing hydroxylammonium chloride, was allowed to stand overnight before deposition of rhodium. This solution, as well as the last, was yellow instead of the usual rose or brown.

Electrolyses with carbon anodes

When electrolyses were carried out with no hydroxylamine in the solution, the gain in weight of the cathode exceeded the weight of the rhodium taken; this was traced to a corresponding loss in weight of the anode. Platinum is appreciably corroded when operating as an anode in 3·5*M* chloride solution. By substituting a very pure carbon spectrographic electrode as anode we were able to carry out rhodium depositions in the absence of hydroxylamine. The carbon rods could be used again and again provided they were allowed to soak in distilled water for some time to leach out the iridium salt, which appeared to concentrate in the porous anode during the electrolysis of solutions containing this metal.

TABLE III.—DEPOSITION OF RHODIUM WITH ANODES OF CARBON ROD

Rhodium taken, *mg*	Iridium taken, *mg*	Cathodic deposit, *mg*	Duration of electrolysis, *min*
5·03	—	5·13, 5·20	60
10·20	—	10·16	60
10·07	—	9·96, 9·97	60
10·07	—	10·09	90
15·10	—	14·88, 14·90	60
15·10	—	15·08	120
5·03	10·0	5·30, 5·11	60
20·14	20·0	20·17	120

10·07	20·0	10·25	90
5·03	20·0	4·94	50

During the early stages of these electrolyses there was considerable gassing at the anode but no significant amount at the cathode. After about 1 hr profuse gassing began at the cathode. By continuing the electrolyses with this hydrogen evolution, all or most of the rhodium was recovered on the cathode. The cathodic gassing could

Although codeposition of iridium had been noticed especially in cases where profuse cathodic gassing occurred, and was accordingly thought to be the result of localised increases in pH in the vicinity of the cathode, its occurrence in these experiments where no gas was evolved proves that the suspected mechanism cannot alone account for the presence of this metal amidst the deposited rhodium.

Because the course of the electrolysis could be followed by observing the current flowing through the cell, and therefore a satisfactory indication of complete deposition of rhodium observed, we have adopted this way of carrying out quantitative depositions of this metal. The following directions apply to chlororhodite solutions in the absence of other metals.

Recommended analytical electrodeposition of rhodium

Before electrolysis the rhodium should be dissolved as chloride in 100 ml of 3·5*M* ammonium chloride solution to which are added 5 ml of a concentrated buffer solution (3*M* acetic acid, 1*M* sodium acetate) and 1 g of ammonium sulphate. Electrolyse with a previously reduced and weighed platinum gauze cathode and an anode fabricated from spectrographic carbon, and maintain the cathode potential at −0·40 V *vs.* S.C.E. Continue the electrolysis until the current falls to zero, or to a steady small residual current (3 or 4 mA); this usually requires from 1·5 to 2 hr. Remove the cathode without interrupting the current, wash well with distilled water, dry in an oven at 100°, reduce in a hydrogen atmosphere, cool and weigh.

The pH in the buffered electrolyte is about 4. To test for completeness of deposition, evaporate the residual solution on the steam bath with concentrated nitric acid to destroy the ammonium chloride, take up the residue with hydrochloric acid and test for rhodium with tin$^{\mathrm{II}}$ chloride.

Fluctuations in plating current

It quickly becomes apparent that, when the potential of the cathode was controlled by an instrument, the deposition of rhodium from buffered solutions, especially after the first 30 min, took place in such a way as to cause a periodically fluctuating current. This phenomenon was not observed when cathode potential was maintained manually.

The electronic controller produced rather violent fluctuations. In a typical case, the current passed in pulsating bursts, suddenly reaching a maximum of 1A and falling more gradually to zero. This "saw-tooth" current was investigated as follows. With a 3·5*M* solution of sodium chloride in the cell the cathode potential was set to control at −0·45 V (S.C.E.). The cathode had been freshly stripped of rhodium by repeated immersion in molten potassium pyrosulphate, and washing in warm water. Only a very small current flowed through the cell when the e.m.f. was applied. On the addition of a small amount of chlororhodite solution (*ca.* 1 mg of rhodium), the current increased but did not oscillate. When 1 ml of an acetate buffer was added, a "saw-tooth" current was observed immediately. After 20 min of this the electrodes were removed from the cell, washed thoroughly, placed into a fresh 3·5*M* sodium chloride solution, and connected to the power supply without changing the settings of the latter. Current again flowed in the same intermittent fashion. In another similar experiment the same observations were induced by the addition of a phosphate buffer of the same pH. If no buffer was added, the onset of oscillations was delayed until after current had flowed for some min, and was in some cases obscured by the relatively greater current from hydrogen evolution.

The mechanical controller also produced a "saw-tooth" current, but of a somewhat different character. The "saw-tooth" effect was usually delayed until about half-way through the duration of the electrolysis; the rise and fall of current was much slower than that observed with the electronic controller. This slower response to whatever caused the fluctuation was undoubtedly caused by the inertia of the mechanical control system as compared with the all-electronic circuit of the former instrument. In the cycle of rise and fall of current the ammeter on the instrument recorded a slow rise to about 60 mA, followed by a slow decrease to a very small current of polarity reversed to the plating current; the latter was maintained for several sec, then the cycle was repeated. When this instrument was manually operated to hold a steady cathode potential no such variations in current were observed.

The fluctuations in current observed during the deposition of rhodium must be connected in some way with the nature of the rhodium deposit. It was observed with two different buffers in the electrolyte, and even in the absence of buffer; the fact that it had not been recorded for depositions when hydroxylamine was present is undoubtedly caused by the high residual current observed when this substance is present. An hypothesis that seems consistent with our observations, but which we were unable to prove, is that the cathode becomes slightly polarised as the result of the deposition on it of a sparingly conducting layer of oxide. This polarisation causes the controlling device to reduce the applied voltage, and the current drops. Now, while a decrease in current density would have the effect of diminishing concentration polarisation, and so would ultimately lead to restoration of the applied voltage to nearly its original value, this compensation would not be expected to occur when the polarisation is the result of a film on the surface of the metal; so once the current starts to drop in this case it will fall to zero. When the current has stopped we presume the oxide slowly dissolves from the electrode by chemical action until the plating can resume. This dissolution does not necessarily remove all of the oxide, so that a pure deposit is not

TABLE V.—EFFECTS OF CONDITIONS ON OVERWEIGHT IN RHODIUM DEPOSITION
(rhodium taken: 20·00 mg)

Rhodium recovered, *mg*	Overweight, *mg*	Temperature, °*C*	Remarks
18·56	1·20	Room (22°)	Acetate buffer, no NH_4Cl
18·89	1·60	Room	Acetate buffer, no NH_4Cl

20·02	1·80	Room	Acetate buffer, 3·5*M* NH_4Cl
19·95	1·28	Room	Acetate buffer, 3·5*M* NH_4Cl
19·70	0·74	60°	Acetate buffer, 3·5*M* NH_4Cl
19·20	0·99	60°	Acetate buffer, 3·5*M* NH_4Cl
19·37	0·80	60°	Acetate buffer, 3·5*M* NH_4Cl, manual control
13·11	0·63	60°	Acetate buffer, 3·5*M* NH_4Cl, plating for 10 min
5·76	1·98	60°	Acetate buffer, 3·5*M* NH_4Cl, gelatin added
20·57	0·97	Room	KH_2PO_4, 3·5*M* NH_4Cl
20·18	0·95	60°	KH_2PO_4, 3·5*M* NH_4Cl
20·15	0·20	60°	No buffer, 3·5*M* NH_4Cl
20·06	0·28	60°	No buffer, 3·5*M* NH_4Cl
19·95	0·44	Room	Acetate buffer, 3·5*M* NH_4Cl, hydroxylamine
19·78	0·72	Room	Acetate buffer, 3·5*M* NH_4Cl, hydroxylamine
20·02	0·82	60°	Acetate buffer, 3·5*M* NH_4Cl, hydrazine
19·59	0·54	60°	Acetate buffer, 3·5*M* NH_4Cl, hydrazine

obtained. This hypothesis is consistent with the observation that, in general, the depositions carried out in buffered solutions exhibited the "saw-tooth" fluctuations in current earlier and more consistently than those in unbuffered solutions, while the oxide content of deposits formed from buffered solutions was on the average greater than that from unbuffered solutions (see the following section and the data of Table V).

Contamination of the deposit of oxide

Electrolyses were carried out with solutions containing a fixed weight of rhodium and other constituents varied as recorded in Table V. The electrode was cleaned, dried and weighed after each deposition; it was then reduced in hydrogen and reweighed. The difference in the two weights (which we call *overweight*) was taken to be oxide. In a few cases the electrode was also heated after the first weighing without introducing any hydrogen in the small furnace, then cooled and weighed, at most only a very small loss in weight was observed in these cases, so that the overweight is apparently only removed by reduction.

TABLE VI.—DEPOSITIONS OF RHODIUM WITH IRIDIUM PRESENT
(rhodium taken: 20·00 mg; iridium taken: 14 mg)

Rhodium recovered, *mg*	Overweight, *mg*	Temperature, °*C*	Remarks
20·15	0·62	Room	Acetate buffer
20·51	0·15	60°	No buffer
20·61	0·42	Room	Acetate buffer
21·39	0·40	60°	No buffer[a]
21·68	0·43	60°	Acetate buffer
19·92	0·36	Room	KH_2PO_4
21·70	0·41	60°	KH_2PO_4
19·89	0·34	Room	KH_2PO_4

[a] pH maintained *ca.* 3 by addition of aqueous ammonia.

The results are recorded in Table V, from which the effect of the variables investigated can be seen. In general, the overweight is lower in deposits from heated solutions than from solutions at room temperature. Deposits from buffered solutions show in nearly every case a greater overweight than those from unbuffered solutions.* In view of the greater tendency to hydrogen evolution observed with unbuffered solutions, it is unlikely that the presence of oxide in the deposit can be attributed to hydrolytic precipitation resulting from localised production of alkali in the vicinity of the cathode (*cf.* molybdenum[16]). From the data of Table VI it may be noted that the overweight increases with, but not in direct proportion to the weight of rhodium deposited; the average overweights for 10, 20 and 30 mg of rhodium were, respectively, 0·82, 1·18 and 1·57 mg. Two electrolyses were performed with hydroxylamine added, following the directions of MacNevin and Tuthill, and two others in the presence of 0·05*M* hydrazine. These all proceeded with a high residual current, and the former two with considerable cathodic gassing; the overweight in these cases was somewhat lower than the average for this weight of rhodium.

To test if there was a connection between the presence of oxide in the deposit and the fluctuating current during the later stages of the deposition, we stopped one electrolysis after a few min and determined the amount of overweight in the portion of

---

* See also the data of MacNevin and Tuthill, reference 1, Table I, p. 1054.

the rhodium on the cathode. From the result it must be concluded that a substantial fraction of the overweight is laid down during the early stages of the deposition before the "saw-tooth" current becomes evident.

Further depositions of rhodium in the presence of iridium

Similar electrodepositions of rhodium were carried out with known amounts of iridium in the solutions. The results, which are summarised in Table VI, show that no connection can be traced between the amount of overweight and the codeposition of iridium. In most cases the increase in weight of the cathode was somewhat greater than the weight of rhodium taken, presumably because of the presence of iridium.

TABLE VII.—DEPOSITIONS OF RHODIUM IN WHICH PART OF THE IRIDIUM WAS REMOVED AS $(NH_4)_2IrCl_6$

Iridium taken, *mg*	Rhodium taken, *mg*	Weight of deposit, *mg*	Overweight, *mg*	Remarks or conditions

25·5	20·00	19·65	1·17	24·3

In these solutions, containing a high concentration of ammonium chloride, a black precipitate of ammonium chloro-iridate is formed. A few experiments were carried out in which this precipitate was removed by filtration before electrodeposition of the rhodium from the filtrate. The precipitation of iridium is not complete under these conditions, but its concentration is lowered considerably. It was hoped that this reduction in concentration before commencement of electrolysis might diminish the codeposition of iridium. The results of these determinations are shown in Table VII. It is seen that in these cases the gain in weight of the cathode is, on the average, within 1 % of the weight of rhodium taken. This cannot, however, be taken as proof of the completeness of separation of the two metals.

Further information concerning the separation was sought as follows. To test for coprecipitation of rhodium with the ammonium chloro-iridate, the precipitate was dissolved in water and iridium reprecipitated from this solution. The second precipitate of ammonium chloro-iridate was removed by filtration, and the filtrate tested absorptiometrically for rhodium. No more than a few μg of rhodium were found among 11 samples investigated in this way. The electrolytic solution, following deposition of the rhodium, was evaporated to dryness; ammonium chloride was destroyed by nitric acid, and the residue converted to chlorides by repeated treatment with hydrochloric acid. Absorptiometric tests revealed no more than a few μg of rhodium present. Iridium was determined in 10 cases by combining the ammonium chloro-iridate, the electrolyte solution following deposition of the rhodium, and any iridium leached out of the carbon anodes. From this combined residue ammonium chloride had to be removed by heating with nitric acid; the nitric acid and its degradation products were then removed by repeated evaporations with hydrochloric acid almost to dryness. Iridium was determined absorptiometrically in an aliquot of this residue by a procedure that could tolerate moderate amounts of rhodium.[17] The results showed complete recovery of iridium in 5 cases and low recovery in 5 others. The low recovery of iridium may be interpreted as indicating that some of this metal may have been deposited on the cathode; it could just as easily be caused by mechanical loss of iridium during the rather ebullient removal of ammonium salts, or to loss by steam distillation of iridium^{IV} chloride.

The foregoing results suggest, but cannot be taken as conclusive proof, that an acceptable separation of the two platinum metals may be achieved by precipitation and separation of most of the iridium as ammonium chloro-iridate, followed by electrodeposition to separate the rhodium from the remainder of the iridium. However, it is doubtful whether these combined operations have any advantages to recommend them over other analytical separations for rhodium and iridium.

All of the experimental evidence in this paper supports, but does not prove, the hypothesis that rhodium deposited from chloride solutions is contaminated by oxides because of prior hydrolysis of the $RhCl_6^{3-}$ ion to species such as $RhCl_5OH^{3-}$, *etc.*[18] Increased hydrolysis in buffered solutions led to increased contamination by oxide. The hydrolysis is repressed in concentrated ammonium (or sodium) chloride solution. The hydrolysis can be suppressed at lower pH, but this also leads to the onset of hydrogen evolution at the cathode, and possible incomplete recovery of rhodium. It would be interesting to see if rhodium could be recovered free from oxide by deposition from more acidic solutions into a mercury cathode. It is the authors' view that the codeposition of iridium is related to the contamination of the rhodium deposits by oxide; the best separations were obtained in moderately acidic solutions following the procedure of MacNevin and Tuthill; but in a number of these the recovery of rhodium was incomplete because of premature hydrogen evolution. The best conditions for complete deposition of rhodium (from buffered solutions) led to appreciable contamination of the rhodium by iridium when the latter was present in solution. In the absence of a detailed mechanism of deposition of the metal from the complex ions in these solutions, it is impossible to offer an explanation for the way in which contamination by iridium occurs.

CONCLUSIONS

The results of the experiments described here must be judged inconclusive in their attempts to account for the mechanism of the deposition of rhodium contaminated by oxide and by a periodically fluctuating current, and for the rarely avoidable contamination of the deposit by iridium when this element is present in the electrolyte. It would be interesting to re-examine the nature of the "saw-tooth" current with a recording potentiometer. Also it would be revealing to carry out depositions of rhodium from solutions in which the pH was systematically varied in order to test further the possible correlation between extent of oxide contamination, extent of codeposition of iridium, and hydrogen-ion content of the electrolyte. Because of the changed circumstances of the authors it has proved impossible to do this additional work. The present communication makes available our results for anyone else who might wish to study the phenomena further.

Zusammenfassung—Die von MacNevin und Tuthill 1949 publizierte elektrolytische Trennung von Rhodium und Iridium wurde in ihren Einzelheiten untersucht. Durch Verwendung von Kohleanoden wird die Zugabe von Hydroxylamin während der Elektrolyse unnötig. Dadurch wird ein hoher Reststrom vermieden, und es zeigt sich, daß die Abscheidung von Rhodium bei automatisch kontrolliertem Kathodenpotential mit periodisch sich änderendem Strom abläuft. Die Rhodiumabscheidung kann in gepufferten Lösungen vorgenommen werden, um Wasserstoffentwicklung zu vermeiden; diese überwiegt gelegentlich die Rhodiumabscheidung und bewirkt zu niedrige Rhodiumausbeute. Das aus gepufferten Lösungen, deren p_H zur Vermeidung der Wasserstoffentwicklung erhöht wurde, abgeschiedene Rhodium enthält offenbar mehr Oxyd und die Trennung von Iridium ist weniger vollständig als bei nach MacNevin bereiteten Lösungen. Man muß einen Kompromiß schließen zwischen saurerem Elektrolyten, der wegen der Wasserstoffentwicklung zu wenig Rhodium liefert, und stärker alkalischem gepuffertem Elektrolyten, aus dem Rhodium mit beträchtlichem Oxydgehalt (der reduziert werden kann) und Iridiumverunreinigung abgeschieden wird. Es ist zweifelhaft, ob die elektrolytische Trennungsmethode so zuverlässig ist wie andere Methoden.

Résumé—On a étudié en détail la méthode de séparation électrolytique du rhodium et de l'iridium publiée en 1949 par MacNevin et Tuthill. Par l'emploi d'anodes en carbone, l'introduction d'hydroxylamine au cours de l'électrolyse n'est plus nécessaire. Par l'élimination de l'hydroxylamine, on évite un courant résiduel élevé, et ceci est révélé par le fait que, lorsque le potentiel de cathode est automatiquement contrôlé, les dépôts de rhodium se développent avec un courant périodiquement variable. On peut effectuer le dépôt de rhodium en solutions tamponnées pour éviter l'apparition d'un dégagement d'hydrogène à la cathode, qui peut éventuellement prédominer sur le dépôt de rhodium et conduire à une faible récupération de celui-ci. A partir de solutions tamponnées dont le pH a été élevé de façon à éviter le dégagement d'hydrogène, le rhodium déposé se révèle contenir plus d'oxyde, et la séparation de l'iridium est moins efficace qu'à partir de solutions préparées selon la technique de MacNevin. Un compromis est nécessaire entre le travail avec un électrolyte plus acide à partir duquel, par suite du dégagement d'hydrogène, la récupération du rhodium est incomplète, et le travail avec un électrolyte tamponné plus alcalin, à partir duquel le rhodium qui se dépose a une teneur considérable en oxyde (qui peut être réduit) et est davantage contaminé par l'iridium. Il est douteux que la méthode électrolytique de séparation soit aussi sûre que d'autres techniques.

SPECTROPHOTOMETRIC DETERMINATION OF MICRO AMOUNTS OF NITROGEN WITH ORGANIC SOLVENT EXTRACTION*

APPLICATION TO METALLURGICAL ANALYSIS

MICHIKO NAMIKI, YACHIYO KAKITA and HIDEHIRO GOTÔ
Research Institute for Iron, Steel and Other Metals
Tohoku University, Sendai, Japan

(*Received* 15 *November* 1963. *Accepted* 7 *January* 1964)

Summary—Spectrophotometric determination of nitrogen, as ammonia, with organic solvent extraction has been studied. The blue coloured compound formed from ammonia, phenol and hypochlorite (chloramine-T) is completely extracted with isobutyl alcohol or isoamyl alcohol only by using a salting-out reagent, and the optimum conditions have been established. This procedure has been applied to the determination of nitrogen in iron, steel and aluminium.

VARIOUS methods have been reported for the determination of a micro quantity of nitrogen in metals, but that used in practice is the Nessler method.[1,2,3] Although the latter is simple and highly sensitive, the reaction product is colloidal in nature and the blank value is large because the reagent itself has a high absorption.

The blue coloration of ammonia with thymol and hypochlorite (chloramine-T)[4] or hypobromous acid[5] can be extracted with organic solvents, such as isoamyl alcohol,[6,9] and this has been applied to the determination of nitrogen in iron and steel.[6] Although the extraction can be effected easily, the sensitivity of this reaction is not satisfactory. The analogous blue coloration of ammonia with phenol and hypochlorite, originating with Berthelot last century, is more sensitive for nitrogen in metals[7,8] than that with thymol, but this colour is not easily extracted with an organic solvent. Consequently, only photometry using this coloration in aqueous solution has previously been reported.

An attempt was therefore made to extract the phenol reaction product, reported as indophenol,[9,10] and it was found to be easily extracted with isobutyl alcohol or isoamyl alcohol by first saturating the solution with a suitable salting-out agent. The molar absorptivity of the coloured substance extracted with isobutyl alcohol is slightly greater than that extracted with isoamyl alcohol and because this solvent is more convenient to use, optimum conditions for the determination of ammonia by the use of isobutyl alcohol were examined. Subsequently, the method was applied to the determination of nitrogen in iron, steel and aluminium, the accuracy of the results being about 2% (standard deviation).

EXPERIMENTAL

Reagents

Standard nitrogen solution. 1·9095 g of ammonium chloride, dried for about 1 hr at 110° and cooled in a desiccator, were dissolved in water to make 1 litre of solution containing 0·5 mg of

---

* Presented at XIXth International Congress of Pure and Applied Chemistry, London, July, 1963.

nitrogen/ml. 10 ml of this solution were diluted exactly to 500 ml to make a solution containing 10 μg of nitrogen/ml.

Phenol solution. 25 g of phenol dissolved in 50 ml of 40% sodium hydroxide solution was diluted with water to 100 ml.

Chloramine-T solution. 5% and 10% aqueous solutions prepared from reagent supplied by Kanto Chemical Co. (Japan).

1M Sodium hydroxide solution.

All reagents used were analytical grade.

Apparatus

An Hitachi photoelectric spectrophotometer Model EPU-2A with 1-cm cell and an Hitachi glass electrode pH-meter Model FEM-2 were used for the various measurements.

Experimental procedure

Standard nitrogen solution, containing less than 60 μg of nitrogen, was placed in a 50-ml glass-stoppered conical flask, neutralised with sodium hydroxide solution (litmus paper), then 1 ml of phenol solution and 7 ml of 5% chloramine-T solution were added to bring the whole volume to about 25 ml and the pH adjusted to 12 (pH meter). The flask was immersed in a boiling water bath for about 22 min to allow full development of the colour. After cooling the solution in water, about 9 g of sodium chloride were added and the saturated solution shaken with 10 ml of isobutyl alcohol for about 1 min. The aqueous solution was drained off, the upper isobutyl alcohol layer placed in a dry test tube and the solution lightly shaken with about 2 g of anhydrous sodium sulphate for dehydration. Part of this solution was transferred to the photometer cell and its absorbance measured at 655 mμ, from which the quantity of nitrogen present was calculated.

Selection of organic extractant

The coloured substance is extracted by isobutyl alcohol and isoamyl alcohol but not by other solvents, such as methyl isobutyl ketone, chloroform, benzene, xylene, carbon tetrachloride, amyl acetate, butyl acetate or ethyl acetate. Therefore, extractions were carried out with isobutyl alcohol and isoamyl alcohol, using 30 μg of nitrogen. The two extracts differed slightly in colour and their absorbances were measured at the wavelength of maximum absorption in each solvent (Table I).

TABLE I.—SPECTROPHOTOMETRIC DATA FOR EXTRACTION OF 30 μg OF NITROGEN

Solvent	Wavelength for maximum absorption, *m*μ	Absorbance		Molar absorptivity at maximum absorption
		Blank	Corrected for blank	
Isobutyl alcohol	655	0·020	0·320	1490
Isoamyl alcohol	645	0·020	0·305	1420

The use of isobutyl alcohol was adopted, this being the more convenient solvent. Extraction of up to 60 μg of nitrogen is complete with a single 10-ml portion of isobutyl alcohol under the experimental conditions eventually established.

Absorbance curve

The coloured solution obtained from 35 μg of nitrogen submitted to the above procedure, was extracted with isobutyl alcohol and the absorbance measured at wavelengths between 320 and 800 mμ. Below 400 mμ the blank values tended to increase towards the shorter wavelength region and no absorption of nitrogen was observed. Blank values were small in the region of 400–500 mμ, and again no absorption of nitrogen was observed. The absorbance curve above 500 mμ is shown in Fig. 1, the absorption maximum being at 655 mμ.

Effect of pH

The same procedure was carried out with 30 μg of nitrogen and with the added quantity of 1*M* sodium hydroxide solution or 1*M* hydrochloric acid varied to adjust the solution to different pH. As shown in Fig. 2, a constant absorbance is observed in the pH range 11·4–12·5. This pH corresponds to 0·05–0·15*M* in free sodium hydroxide when no other salts are present in large quantity.

Effect of amount of phenol

In the next experiments, only the amount of phenol solution added was varied, and the results are shown in Fig. 3. The absorbance becomes constant with above 0·5 ml of phenol solution present and it was, therefore, decided to add 1·0 ml of phenol.

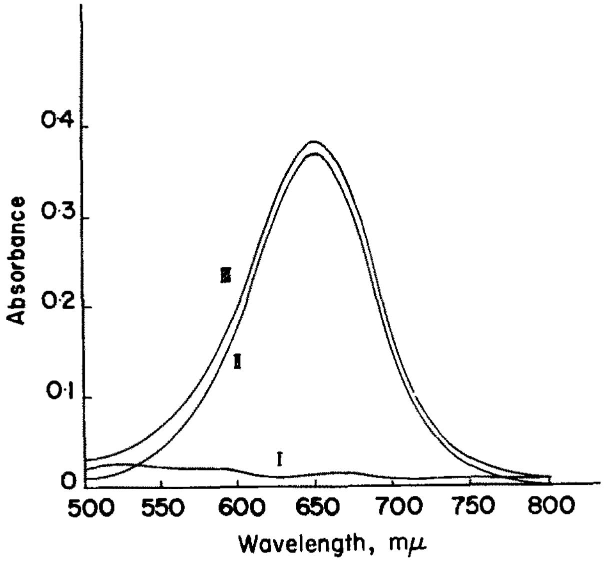

FIG. 1.—Absorbance curves using isobutyl alcohol:
I—reagent blank,
II—3·5 μg of nitrogen/ml of extract,
III—3·5 μg of nitrogen/ml of extract plus reagent blank.

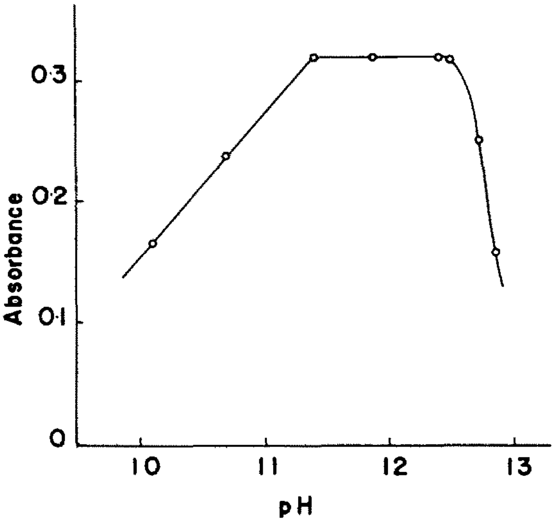

FIG. 2.—Effect of pH on absorbance (3 μg of nitrogen/ml of extract).

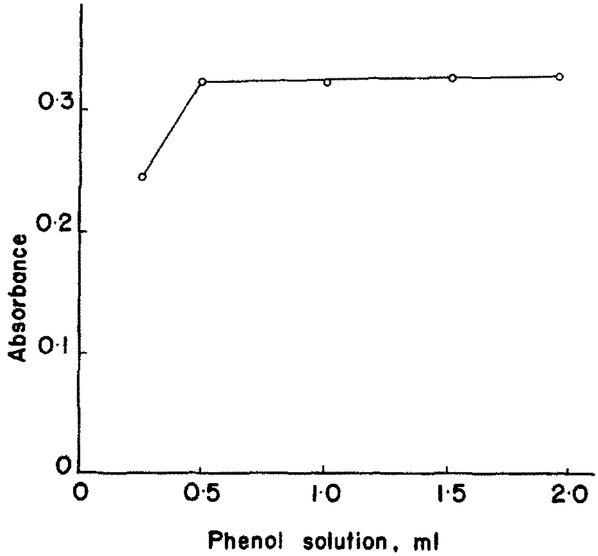

FIG. 3.—Effect of amount of phenol on absorbance (3 μg of nitrogen/ml of extract).

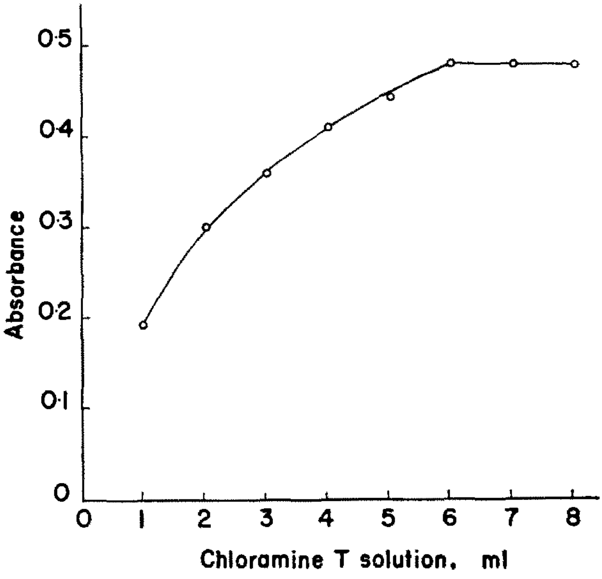

FIG. 4.—Effect of amount of chloramine-T on absorbance (4·5 μg of nitrogen/ml of extract).

Effect of amount of chloramine-T

The amount of chloramine-T solution added was varied with 45 μg of nitrogen present and keeping the other factors unchanged. From Fig. 4, a constant absorbance is obtained by the addition of over 6 ml of 5% chloramine-T solution and it was, therefore, decided to use 7 ml. There is a variation of absorbance according to the chloramine-T used and it is necessary to use a good quality product.

Effect of heating time

The same procedure was carried out as described above to ascertain the effect of the time of heating and the extraction temperature. From the experiments it was found that it is necessary to

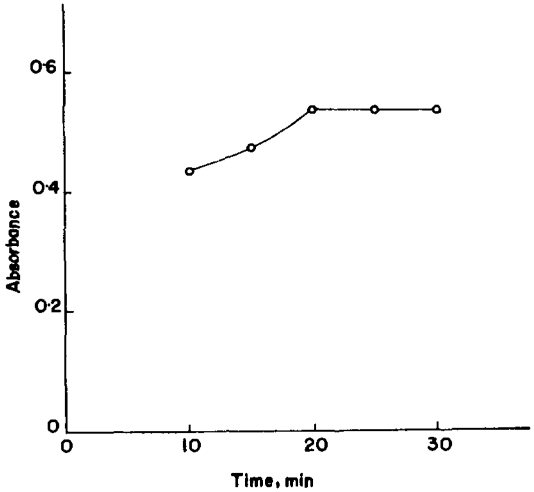

FIG. 5.—Effect of heating time on absorbance (5 μg of nitrogen/ml of extract).

heat the mixture in a boiling water bath for more than 20 min (see Fig. 5); also the absorbance of the extract solutions is constant when extracted between 10° and 25°, but it decreases when extracted at 30°.

Effect of amount of sodium chloride

Preliminary experiments (see below) with various salts as salting-out agents showed that sodium chloride was the most suitable. The same procedure as described before was carried out with 30 μg of nitrogen, but various quantities of sodium chloride were added after the cooling period. As shown in Fig. 6, it is necessary to add more than 8 g of sodium chloride. Addition of 8 g of sodium chloride brings the solution to saturation and some solid sodium chloride remains undissolved when more than 9 g of the salt is added. Because it is necessary to obtain a completely saturated solution of sodium chloride, 9 g of the salt was added henceforth.

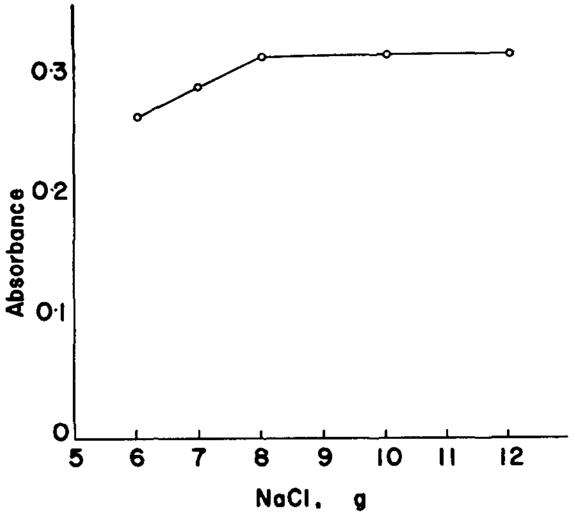

FIG. 6.—Effect of amount of sodium chloride on absorbance (3 μg of nitrogen/ml of extract).

Effect of other salting-out reagents

The same procedure as described above was employed to investigate the effects of potassium chloride, sodium sulphate, potassium sulphate, sodium nitrate and potassium nitrate as salting-out reagents. The solution was cooled to 15° after coloration, and each salt was added to more than saturation, then extraction was carried out. As indicated in Table II, the absorbance was greatest with sodium chloride and lower with all other salts.

TABLE II.—EFFECT OF VARIOUS SALTING-OUT REAGENTS ON EXTRACTION OF 30 μg OF NITROGEN

Salting-out reagent	Amount added, *g*	Absorbance	
		Blank	Corrected for blank
NaCl	9	0·035	0·320 0·322
KCl	9	0·033	0·284 0·285
Na_2SO_4	10	0·020	0·210 0·211
K_2SO_4	5	0·020	0·190 0·188
$NaNO_3$	20	0·022	0·182 0·183
KNO_3	9	0·020	0·168 0·138

Calibration curve

There is a linear relationship between the quantity of nitrogen and the absorbance over the range 0·1–60 μg of nitrogen/10-ml extract.

Effect of various ions and organic acids

Metal ions. Various metal ions were added to 30 μg of nitrogen and the same procedure carried out as above. The effect of copper is remarkable and the determination becomes impossible when 5 μg of copper is present (Table III). Other metal ions, such as 100 mg of Mo and W; 10 mg of Al, Zn, V, Ni and Sn; 2 mg of Fe; 1 mg of Co, Mg, Mn, Cd, Bi, U, Hg, Ag, Cr, Pb, Be, Se, Te, Zr and Ce; and 0·1 mg of Sb, Ti, Nb, and Ta do not affect the reaction.

Anions and organic acids. Various salts and organic acids were added to 30 μg of nitrogen and the solution was submitted to the determination of nitrogen as described above. These results are shown in Table III and Fig. 7. Organic acids which form complex salts interfere in the determination. Although sodium chloride, fluoride, nitrate and perchlorate and potassium chloride do not affect the reaction, sodium sulphate* and phosphate show characteristic effects.

Determination of Nitrogen in Iron, Steel and Aluminium

The developed procedure was applied to the determination of nitrogen in iron, steel and aluminium. Because the reaction was carried out at around pH 12, iron and most other metals will precipitate as their hydroxides. Coloration in the presence of a large amount of precipitate was not desirable because adsorption of nitrogen might occur; also, the extraction procedure was inconvenient. Consequently, steam distillation was used in the case of iron and steel to separate the ammonia before the photometric procedure. Aluminium did not precipitate under these conditions when the quantity was small, but it formed some precipitate when the quantity became larger. However, the amount of the precipitate was smaller than in the case of iron and steel samples and the number of impurities present in the metal was smaller. Therefore, the problem was only to remove copper (see above) and the determination was carried out without removal of other ions.

Determination of nitrogen in iron and steel

Procedure. The sample was placed in a beaker and heated with 40–60 ml of hydrochloric acid (1 + 1) until in solution.† The distillation apparatus (conventional type) was thoroughly steamed out, 20 ml of 0·1*M* sulphuric acid placed in the receiver and the tip of the condenser tube dipped

---

* A direct extraction procedure on a neutralised Kjeldahl digest of organic material may be possible, provided the calibration curve is produced under the same conditions.

† When it was necessary to determine acid-soluble and acid-insoluble nitrogen separately, the residue was collected by filtration through asbestos, decomposed by the usual Kjeldahl method, then submitted to distillation for separate determination of nitrogen.

TABLE III.—EFFECTS OF COPPER AND ORGANIC ACIDS ON DETERMINATION OF 30 μg OF NITROGEN

inside the solution. In the distillation flask, 50–75 ml of 12*M* sodium hydroxide solution were placed and the sample solution added from the funnel placed over it. The funnel must be thoroughly washed before use. Steam was then passed through the flask while heating the solution. When the distillate was around 90 ml, the receiver was lowered to raise the tip of the condenser tube above the solution and distillation was continued for 3–4 min. The tip of the condenser tube was washed with water, the receiver solution transferred to a 100-ml calibrated flask and diluted to the mark. From this solution a 20-ml aliquot was transferred to a glass-stoppered conical flask, 1 ml of phenol solution and 3·5 ml of 10% chloramine-T solution were added and the volume brought to 25 ml with water.

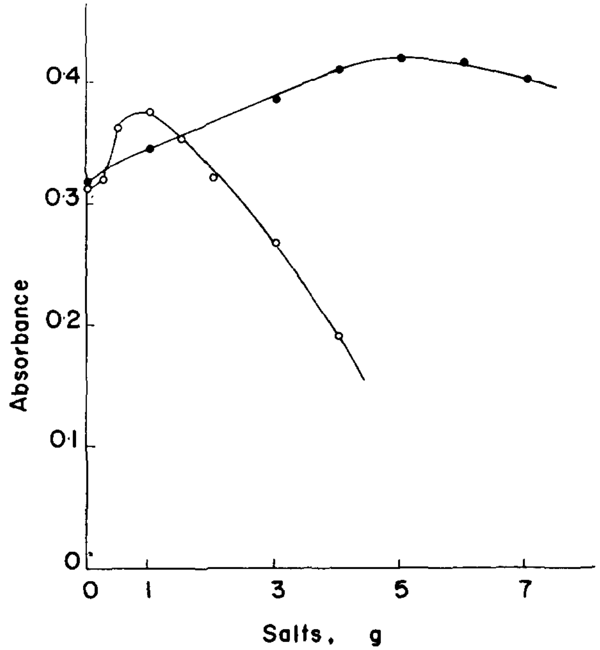

FIG. 7.—Effect of amount of sodium sulphate (●) and disodium hydrogen phosphate (○) on absorbance (3 μg of nitrogen/ml of extract).

This solution was submitted to the procedure described above and the quantity of nitrogen obtained from a calibration curve.

Examination of distillation method. Experiments were carried out to find whether nitrogen was completely recovered as ammonia by steam distillation with the apparatus used. To remove any nitrogen contained in electrolytic iron, 1 g of electrolytic iron was dissolved in 40 ml of hydrochloric acid (1 + 1), 50 ml of 12*M* sodium hydroxide solution added and the mixture boiled on a hot-plate for over 30 min. The nitrogen-free electrolytic iron solution thus obtained was transferred to a distillation flask, various amounts of standard nitrogen solution added and the mixture submitted to distillation as described above. Results of the determination of nitrogen by this procedure are shown in Table IV, and they indicate that the recovery of nitrogen is complete.

Analysis of samples. Several samples of iron and steel were submitted to determination of nitrogen by the above procedure and the results obtained are listed in Table V. Some results for the separate determination of acid-soluble and acid-insoluble nitrogen are given in Table VI.

[b] The ammonia is steam distilled into standard sulphuric acid solution, the excess of which is eventually titrated with standard sodium hydroxide using methyl red-methylene blue as indicator.

Determination of nitrogen in aluminium

Procedure. A solution of 1–2 g of the aluminium sample in a mixture of 20 ml of hydrochloric acid and 20 ml of water was diluted to about 70 ml with water and cooled to room temperature. About 10 g of granulated zinc were added and the mixture allowed to stand at room temperature with occasional shaking, when copper precipitated out on the surface of the zinc. After about 2 hr a piece of fresh zinc was added to see if its surface also blackened. When blackening no longer occurred, the solution was filtered through paper into a 100-ml calibrated flask. The filter paper and zinc were washed with water and the combined filtrate and washings diluted to the 100-ml mark with water. Ten ml of this solution were transferred to a beaker, neutralised with $3M$ sodium hydroxide solution (litmus paper), and 1 ml of phenol solution and 3·5 ml of 10% chloramine-T solution added. The pH of the solution was adjusted to about 12 (pH-meter) by the addition of $3M$ sodium hydroxide solution and the volume brought to about 25 ml with water. The total volume of $3M$ sodium hydroxide solution used in this procedure was recorded.

To a second 10-ml aliquot of the sample solution the same amount of 3*M* sodium hydroxide solution as used in the preceding experiment was added, followed by 1 ml of phenol solution and 3·5 ml of 10% chloramine-T solution. The volume was adjusted to about 25 ml and the determination of nitrogen completed as previously. The quantity of nitrogen was obtained from a calibration curve.

Examination of method for removal of copper. Only a small quantity of copper is generally present in aluminium. Preliminary experiments were carried out on its removal because copper interferes in the colour reaction (see above). The most simple method was to add zinc to the dilute hydrochloric acid solution of aluminium at room temperature to precipitate out metallic copper on the zinc.

One g of aluminium foil (0·011% of copper) was dissolved in a mixture of 20 ml each of hydrochloric acid and water, then standard nitrogen solution added. Copper was added and precipitated with zinc as described above. The solution was filtered, the filtrate diluted to 100 ml in a calibrated flask and 10 ml of this solution submitted to the determination of nitrogen.

As shown in Table VII removal of copper by the use of zinc has no effect, the added nitrogen being determined completely. Determination of nitrogen in the granulated zinc used showed that it contained $0{\cdot}001_2$% of nitrogen. The amount of zinc dissolved by this procedure was extremely small, but in any case, a blank test was always carried out at the same time.

Analysis of samples. The developed procedure was applied to the analysis of several samples of aluminium and the results obtained are shown in Table VIII.

Zusammenfassung—Die spektralphotometrische Bestimmung von Stickstoff als Ammoniak mit Extraktion in organisches Lösungsmittel wurde untersucht. Die blaue Verbindung aus Ammoniak, Phenol und Hypochlorit (Chloramin T) läßt sich durch Aussalzen völlig in Isobutyl- oder Isoamylalkohol extrahieren. Die günstigsten Bedingungen wurden ermittelt und das Verfahren auf Stickstoffbestimmungen in Eisen, Stahl und Aluminium angewandt.

Résumé—On a étudié un dosage spectrophotométrique de l'azote, à l'état d'ammoniac, par extraction avec un solvant organique. Le composé coloré en bleu que forme l'ammoniac avec le phénol et un hyperchlorite (chloramine-T) est extrait complètement à l'alcool isobutylique ou isoamylique, en utilisant seulement un réactif relargant, et on a établi les conditions optimales. Cette méthode a été appliquée au dosage de l'azote dans le fer, l'acier et l'aluminium.

A NEW OXIDIMETRIC REAGENT: POTASSIUM DICHROMATE IN A STRONG PHOSPHORIC ACID MEDIUM—III*

TITRIMETRIC DETERMINATION OF CERIUM^{III}

G. Gopala Rao, P. Kanta Rao and S. Bhanojee Rao
Department of Chemistry, Andhra University, Waltair, India

(*Received* 4 *December* 1963. *Accepted* 5 *January* 1964)

Summary—The use of potassium dichromate for the potentiometric titration of cerium^{III} in 12–13·5M phosphoric acid at room temperature has been investigated. The method, which is accurate to ±0·35% for 30–120 mg of cerium/50 ml of titration solution, has been applied to the determination of cerium in monazite sand and technical cerium carbonate. Methods have also been developed for the differential potentiometric titration of iron^{II} plus cerium^{III}, vanadium^{IV} plus cerium^{III}, and iron^{II} plus vanadium^{IV} plus cerium^{III} in the same solution.

MANY of the procedures for the titrimetric determination of cerium^{III} are indirect, involving oxidation to cerium^{IV}. Several oxidising agents have been tried, including atmospheric oxygen, potassium or ammonium persulphate, lead dioxide, bismuth tetroxide or sodium bismuthate, potassium hexacyanoferrate(III), potassium chlorate, ozone and silver^{II} oxide.

Von Knorre[1] appears to have been the earliest to apply himself to the titrimetric determination of cerium. He proposed the oxidation of cerium^{III} to cerium^{IV} with atmospheric oxygen in a basic medium. The resulting cerium^{IV} was treated in an acid medium with a known excess of hydrogen peroxide, the excess of which was back-titrated with standard potassium permanganate. Atmospheric oxidation of cerium^{III} was also resorted to by Barthauer and Pearce,[2] who reacted the cerium^{IV} formed with potassium iodide in an acid medium and titrated the liberated iodine with standard sodium thiosulphate. Lessnig[3] treated the cerium^{IV} formed with a known excess of iron^{II} and titrated the unreacted iron^{II} with standard potassium permanganate. The heterogeneous oxidation of cerium^{III} hydroxide by atmospheric oxygen in an alkaline medium must necessarily be incomplete.

The earliest investigator to employ potassium persulphate for the oxidation of cerium^{III} in sulphuric acid appears to have been Von Knorre.[4] After decomposing the excess persulphate by boiling, he determined the cerium^{IV} formed through the hydrogen peroxide-potassium permanganate method. Sterba-Boehm and Matula[5] also employed potassium persulphate for the oxidation of cerium^{III}, but they determined the resulting cerium^{IV} iodimetrically. Weiss and Sieger[6] reported that this method gives results 10–20% high. They also stated that a similar oxidation by persulphate in an alkaline medium in the presence of a nickel catalyst and titration of the cerium^{IV} with arsenite (according to the procedure of Lang and Zwerina[7]) gives low results (0–3·4%). Willard and Young[8] improved the method by using silver nitrate as a catalyst during the oxidation of cerium^{III} by persulphate.

---

* Part II: See reference 29.

Job[9] achieved the oxidation of cerium^{III} with excess of lead dioxide in a strong nitric acid medium; after the excess of oxidising agent is removed by filtration, cerium^{IV} in the filtrate is determined by the hydrogen peroxide-permanganate method. Weiss and Sieger[6] stated that the method of Job gives inaccurate results. Gordon and Feibush[10] recently employed lead dioxide for the oxidation of small amounts of cerium^{III} in sulphuric acid. The cerium^{IV} is filtered into a known excess of iron^{II}, and the unreacted iron^{II} determined by a spectrophotometric method, after complexation with 1,10-phenanthroline.

Waegner and Muller[11] oxidised cerium^{III} by treatment with excess of bismuth tetroxide in a strong nitric acid solution. The excess of bismuth tetroxide is filtered off and the cerium^{IV} in the filtrate determined by the hydrogen peroxide-permanganate method. Weiss and Sieger[6] stated that this method gives about 10% low results. Metzger[12] used sodium bismuthate in sulphuric acid solution at boiling temperature in place of bismuth tetroxide, and determined the cerium^{IV} by the iron^{II} sulphate-permanganate method. The method is not precise, giving results with an error of 2%. Moreover, the method is cumbersome, because it requires a filtration and washing.

Browning and Palmer[13] treated cerium^{III} in an alkaline medium with an excess of hexacyanoferrate(III), the hydrated cerium^{IV} oxide being filtered off and the hexacyanoferrate(IV) in the filtrate titrated in an acid medium with standard potassium permanganate. Unless every precaution is taken to exclude air during the treatment of the cerium^{III} in alkaline solution with excess potassium hexacyanoferrate (III), the results will be low because part of the cerium^{III} is oxidised by atmospheric oxygen.

Strobasch[14] employed potassium chlorate as an oxidant for cerium^{III} in sulphuric acid. The excess oxidant is decomposed by boiling and the cerium^{IV} formed determined by the hydrogen peroxide-permanganate method.

Willard and Merritt[15] used ozone as the oxidising agent. When cerium^{III} is treated with 5% ozone for 60 min in a medium containing both sulphuric and phosphoric acids, cerium^{III} phosphate is oxidised to cerium^{IV} phosphate which separates as a thick white gel, it being more insoluble than the cerium^{III} phosphate. Unless the cerium^{IV} phosphate is precipitated in this way the oxidation is reported to be incomplete. After the reaction is completed, the cerium phosphate is dissolved in sulphuric acid until a clear yellow-orange solution results. The excess of ozone is driven out from the mixture by passing carbon dioxide or nitrogen for 15 min, then the cerium^{IV} titrated with a standard solution of iron^{II} sulphate using ferroïn as indicator. It is obvious that the method is tedious, although it is reported to give precise results. All substances which are oxidised by ozone in acid solution and reduced by iron^{II} sulphate must be absent. These include manganese^{II}, cobalt^{II}, vanadium^{IV} and large amounts of chromium^{III} salt. Chlorides and large concentrations of nitrates also interfere.

Kimura and Murakimi[16] and Lingane and Davis[17] carried out the indirect titrimetric determination of cerium^{III} using silver^{II} oxide as oxidant in nitric acid at room temperature; the redox potential[18] of the silver^{II}/silver^{I} couple is very high, being 1·929 V in 4*M* nitric acid and 2·00 V in 4*M* perchloric acid. Excess oxidant is easily removed by warming for a few min. The solution is then diluted, treated with excess standard iron^{II} solution, and the unreacted iron^{II} titrated with standard cerium^{IV} sulphate or permanganate solution. Chromium^{III}, manganese^{II} and other substances which are also oxidised by silver^{II} interfere; although cobalt^{II} is also oxidised, it does not interfere because the cobalt^{III} is decomposed during the process of heating. However, it is undesirable to titrate cerium^{IV} salt or any other oxidant with iron^{II} solution in the presence of nitric acid.

Mention may also be made of the procedure developed by Lang[19] which is of considerable theoretical interest. Cerium^{III} is treated with a sufficient excess of potassium dichromate in the presence of a larger excess of arsenic^{III} in a medium containing 3–40 ml of sulphuric acid and 4–5 g of metaphosphoric acid/200 ml. The reaction between dichromate and arsenic^{III} is believed to induce the oxidation of cerium^{III} by dichromate; the resulting cerium^{IV} is determined by titration with standard iron^{II} solution using diphenylamine as indicator. Evidently the concentrations of all of the reactants should be so arranged that when all of the cerium^{III} is oxidised, there should be no dichromate left.

Recently, Issa and Allam[28] have proposed the use of potassium permanganate in an alkaline medium for the oxidation of cerium^{III}. To a known excess of standard permanganate solution, add excess of telluric acid (sufficient to keep the tellurium^{VI}/manganese^{VII} ratio greater than 5). The mixture is now treated dropwise with sodium hydroxide solution to give a concentration of 1·0–2·0*M*, followed by an aliquot of the cerium^{III} solution. After waiting for 5–10 min the excess permanganate is back-titrated with a standard solution of thallium^{I}. The permanganate is reduced only to manganese^{IV}, which is stabilised by the telluric acid present. In the direct titration of cerium^{III} in an alkaline medium with potassium permanganate in the presence of a large excess of telluric acid, the time required for equilibrium potentials is about 1 min at the beginning of the titration and 9 min near the equivalence point. The method is only of theoretical interest because the reagents involved, namely telluric acid and thallium^{I}, are expensive.

Besides the indirect methods discussed above, several direct methods have also been proposed. As early as 1916, Lenher and Meloche[20] titrated cerium^{III} nitrate solution, in the presence of an excess of zinc oxide paste, with potassium permanganate solution, first in the cold, then at the boiling temperature towards the end-point. Milk of magnesia (but no calcium carbonate) was also found suitable in place of zinc oxide. Goffart[21] has shown that cerium^{III} is oxidised to the quadrivalent state (in a neutral sodium pyrophosphate medium) by titration with standard potassium permanganate. The visual end-point is obscured by the colour of the product of the reaction, manganese^{III} pyrophosphate complex. The potentiometric end-point method is also unsatisfactory, because the potential break is very small (15–25 mV). Hence, Goffart suggested amperometric end-point detection. The reaction becomes very slow near the end-point and vigorous agitation is necessary.

Marple, Przybylowicz and Hume[22] employed photometric titration for the determination of submilligram to decigram amounts of cerium^{III} with potassium permanganate in a neutral pyrophosphate medium. Arsenic^{III}, vanadium^{IV}, antimony^{III}, thallium^{I}, mercury^{I} and iodide are reported to interfere. In the photometric method chromium^{III}, fluoride and other substances which form precipitates should also be absent.

Tomiček[23] carried out the titration of cerium^{III} with potassium hexacyanoferrate (III), in a medium containing a high concentration of potassium carbonate, under a carbon dioxide atmosphere, with a potentiometric end-point. Air must be rigorously excluded because the complex carbonates of cerium^{III} are easily oxidised by atmospheric oxygen. Moreover, the alkaline condition results in the precipitation of many metals. The position of the inflection point on the potential-concentration curve depends on the concentration of the carbonate, being shifted towards more negative potentials as the carbonate concentration increases. This indicates that the cerium^{IV} carbonates are more complex than the cerium^{III} carbonates. This method gives poor inflection points when the cerium^{IV}/cerium^{III} ratio is large.

Bricker and Loeffler[24] recommended the titration of cerium^{III} solution in 1*M* sulphuric acid with a standard cobalt^{III} solution using a photometric end-point, following the absorption at 400 mμ (where the formation of cerium^{IV} is observed) or at 610 mμ (where the excess cobalt^{III} is detected). Because the reaction between cobalt^{III} and cerium^{III} is very slow in the vicinity of the equivalence point, the addition of silver nitrate is recommended to serve as a catalyst. The authors have stated that the reproducibility of the method is about 5 parts per 1,000; the disagreement between the values obtained by the sodium bismuthate and cobalt^{III} methods is about 1·5%. Manganese^{II}, chromium^{III}, vanadium^{IV} and other elements which are oxidised by cobalt^{III} interfere. Chloride, bromide and iodide are rapidly oxidised by cobalt^{III}. Hence their presence vitiates the results, as does that of acetic acid, acetic anhydride, glycerol, *etc.*, which are also rapidly oxidised. In view of the difficulties involved in the preparation of cobalt^{III} sulphate and the very poor stability of the reagent, it is doubtful whether the reagent can attain sufficient vogue.

Recently, Doležal, Rössler and Zýka[25] reported that cerium^{III} can be titrated potentiometrically in 0·2*M* sodium carbonate under an atmosphere of nitrogen with 0·01*M* potassium periodate solution. When the equivalence point is approached, it is necessary to wait for 15–30 sec until the potential becomes constant. The end-point is indicated by a potential change of 170 mV/0·02 ml of titrant at about 0·1 V *versus* a saturated calomel electrode. It is reported that the determination of 1–10 mg and 10–50 mg of cerium gave an average deviation of ±1·8% and ±1·0%, respectively, in 50 titrations. Bismuth^{III}, cobalt^{II}, chromium^{III}, iron^{III}, nickel^{II} and zinc^{II} interfere when present in concentrations greater than 1% of the cerium. Lanthanum, europium and yttrium do not interfere. The low degree of reproducibility of the method, interference of atmospheric oxygen, large number of other interferences and high cost of the reagent are some of the disadvantages attendant on the use of potassium periodate for the determination of cerium^{III}.

From the foregoing it is evident that the only precise method for the determination of cerium^{III} now available is the indirect procedure of Willard and Young[8] involving heating of cerium^{III} with excess of persulphate in the presence of silver nitrate as catalyst.

We have now developed a direct titration method with potassium dichromate. Making use of our observation that cerium^{III} is rapidly oxidised to cerium^{IV} by potassium dichromate in 10·5–13·5*M* phosphoric acid, conditions have been established under which cerium^{III} can be titrated directly with a standard solution of potassium dichromate at room temperature with a potentiometric end-point. It has already been reported[26] that the formal redox potential of the chromium^{VI}/chromium^{III} couple increases with increasing phosphoric acid concentration, from 1·016 V in 1·0*M* phosphoric acid to 1·483 V in 12*M* phosphoric acid. The formal redox potential of the cerium^{IV}/cerium^{III} couple has now been determined in media of varying phosphoric acid concentration. From the data presented in Table I and the curves given in Fig. 1, it will be seen that the potential of the chromium^{VI}/chromium^{III} couple has a value lower than that of the cerium^{IV}/cerium^{III} couple in phosphoric acid of concentration less than 6·6*M*, but has a higher value above this concentration. In 12*M* phosphoric acid the potential of the chromium^{VI}/chromium^{III} couple is greater than that of the cerium^{IV}/cerium^{III} couple by 0·248 V. The formal redox potential of the cerium^{IV}/cerium^{III} couple could not be determined in a medium containing phosphoric acid at a concentration lower that about 6*M*, because cerium^{IV} phosphate is insoluble under such conditions.

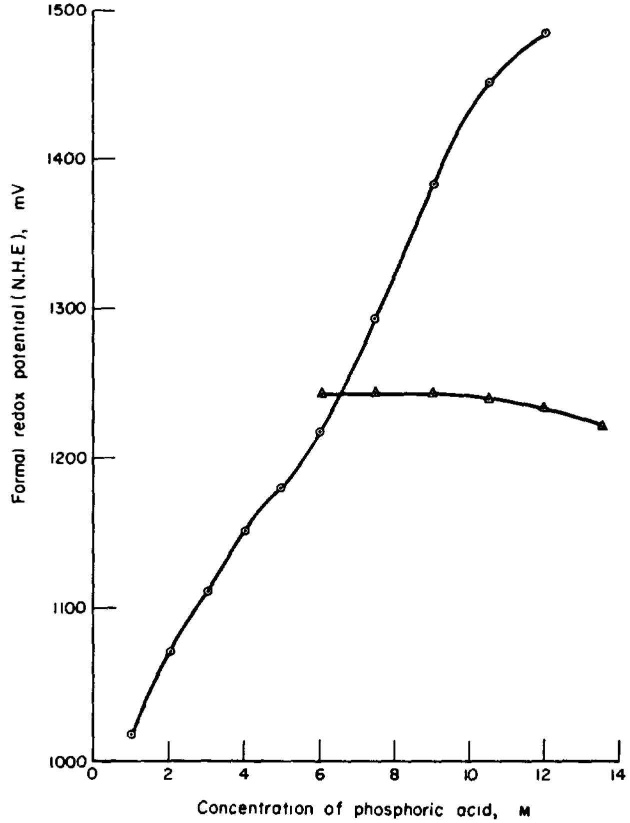

Fig. 1.—Formal redox potentials in a medium of varying phosphoric acid concentration:

○—○—chromium^{VI}/chromium^{III} couple,
△—△—cerium^{IV}/cerium^{III} couple.

In our experiments, phosphoric acid plays a two-fold role: firstly, it lowers the redox potential of the cerium^{IV}/cerium^{III} couple by complexing cerium^{IV} more strongly than cerium^{III}; secondly, it increases the potential of the chromium^{VI}/chromium^{III} couple. Thus in a suitable phosphoric acid medium cerium^{III} is oxidised to cerium^{IV} by chromium^{VI}, a reaction which is the reverse of the usual redox reaction in sulphuric or nitric acid media, namely, the oxidation of chromium^{III}

to chromium^{VI} by cerium^{IV}. Willard and Young[27] determined chromium^{III} by treatment with excess of cerium^{IV} sulphate in hot solution, followed by back-titration of the unreacted cerium^{IV} with standard sodium oxalate or sodium nitrite solution.

From the known difference in the redox couples in 12*M* phosphoric acid, the equilibrium constant of the following reaction is calculated to be $8{\cdot}318 \times 10^{24}$ at 28°:

$$6Ce^{3+} + Cr_2O_7^{2-} + 14H^+ \rightarrow 6Ce^{4+} + 2Cr^{3+} + 7H_2O.$$

EXPERIMENTAL

Determination of Formal Redox Potential of Cerium^{IV}/Cerium^{III} Couple in a Medium of Varying Phosphoric Acid Concentration

Reagents

Cerium^{IV} solution. An approximately 0·1*M* solution is prepared from "Pro Analysi" grade cerium^{IV} sulphate (E. Merck, Germany) in 1*M* sulphuric acid and standardised against sodium oxalate.

Cerium^{III} solutions. An approximately 0·1*M* solution is prepared from cerium^{IV} sulphate by reduction with hydrogen peroxide in 1*M* sulphuric acid and boiling down to crystallisation. The solution is then cooled, made up to desired volume and standardised according to the method of Willard and Young.[8]

Syrupy phosphoric acid. Syrupy phosphoric acid of "Pro Analysi" grade supplied by E. Merck, Germany, is used in this investigation. This sample of phosphoric acid is free from impurities which can react with cerium^{IV} within the time of the experiment. The strength of phosphoric acid is ascertained after suitable dilution, by titration with a standard solution of sodium hydroxide using a mixture (1:1) of phenolphthalein and α-naphtholphthalein as indicator.

Apparatus

As described before.[26]

Procedure

Volumes corresponding to 2·50 ml of 0·1*M* cerium^{IV} solution and to 2·50 ml of 0·1*M* cerium^{III} are mixed. After adding enough phosphoric acid to reach the required strength, the mixture is diluted to 50 ml. The rest of the procedure is as described before.[26] The potentials attain equilibrium values immediately.

The values of the cerium^{IV}/cerium^{III} redox potential at different phosphoric acid concentrations are given in Table I (uncorrected for liquid-liquid junction potential).

Oxidation of Cerium^{III} to Cerium^{IV} with Potassium Dichromate in a Strong Phosphoric Acid Medium

We have observed that the reaction between cerium^{III} and chromium^{VI} is so fast in 10·5–13·5*M* phosphoric acid that a direct potentiometric titration of cerium^{III} is possible with potassium dichromate at room temperature. When the concentration of phosphoric acid is 10·5*M* at the end of the titration, the reaction is somewhat slow so that near the equivalence point it is necessary to wait for about 6 min to obtain steady potentials. Hence we carried out the electrometric titration of cerium^{III} with potassium dichromate at room temperature maintaining the concentration of phosphoric acid at about 12*M* at the equivalence point.

Several experiments have shown that "Pro Analysi" grade phosphoric acid works quite satisfactorily as a titration medium. The potential break is about 50–60 mV/0·04 ml of 0·2*N* potassium dichromate when the titration solution is about 50 ml. AnalaR phosphoric acid of British Drug Houses Ltd., England, and reagent-grade acid of May and Baker, England, have also been found to give correct equivalence points, but the potential breaks are about 10 mV less.

Procedure

About 2–10 ml of solution, containing about 30–120 mg of cerium^{III}, are taken in a 150-ml Pyrex beaker and treated with the requisite volume (40–50 ml) of 90% phosphoric acid. The rest of the procedure is similar to that already described for manganese^{II}.[26] Near the equivalence point the potentials are noted after waiting for 3 min.

Because the potential break at the equivalence point is not very high, the equivalence point of the titration is best read from the curve obtained by plotting ΔE/ΔV against V. A representative curve of this type is shown in Fig. 2. A large number of determinations of cerium^{III} have been carried out in this manner and some typical results are given in Table II. The results show that the error of the determination is less than ±0·35%.

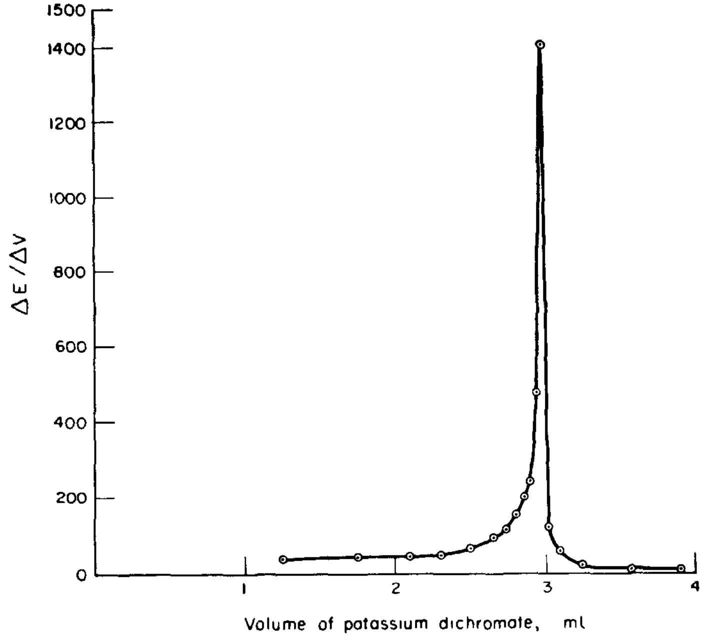

FIG. 2.—Potentiometric titration of cerium^{III} (83·50 mg) with potassium dichromate in 12*M* phosphoric acid.

Interferences

Interference from chloride and nitrate is similar to that found in the determination of manganese^{II}.[26] Fluoride interferes because it forms a precipitate with cerium^{III}, with a consequent slowing down of the reaction between cerium^{III} and chromium^{VI}. Iron^{II}, uranium^{IV}, vanadium^{IV},[29] molybdenum^{V}, arsenic^{III}, antimony^{III}, manganese^{II},[26] and lower valency states of tungsten are also oxidised by potassium dichromate under the conditions proposed for the titration of cerium^{III}. However, iron^{II} does not interfere in the determination of cerium^{III} by this method, because two different breaks in the potential *versus* volume curve are obtained, one corresponding to the oxidation of iron^{II} to iron^{III} and the other corresponding to the oxidation of cerium^{III} to cerium^{IV}. Cobalt^{II}, nickel^{II}, iron^{III}, tungsten^{VI}, molybdenum^{VI}, uranium^{VI}, chromium^{III}, cerium^{IV}, copper^{II}, zinc^{II},

thorium$^{\mathrm{IV}}$ and vanadium$^{\mathrm{V}}$ do not interfere (see Table III). Calcium, magnesium and aluminium also do not interfere. Sulphuric and perchloric acids do not interfere up to an over-all concentration of 1*N*. In the presence of thallium$^{\mathrm{I}}$ the potential break at the equivalence point is considerably reduced (from about 60 mV to about 10 mV/0·04 ml of 0·2*N* potassium dichromate solution), but the equivalence point is not affected.

Determination of Iron$^{\mathrm{II}}$ and Cerium$^{\mathrm{III}}$ in Mixtures

When a mixture of iron$^{\mathrm{II}}$ and cerium$^{\mathrm{III}}$ is titrated with potassium dichromate in 12*M* phosphoric acid under a carbon dioxide atmosphere, two breaks are obtained, the first corresponding to the oxidation of iron$^{\mathrm{II}}$ to iron$^{\mathrm{III}}$ and the second corresponding to the oxidation of cerium$^{\mathrm{III}}$ to cerium$^{\mathrm{IV}}$. At the equivalence point for iron$^{\mathrm{II}}$ one has to wait for 6 min for the attainment of stable potential, the potential break being about 500 mV/0·04 ml of 0·2*N* potassium dichromate solution. Precautions must be taken to expel even traces of oxygen from all solutions and to prevent oxygen leaking into the titration vessel during the titration, iron$^{\mathrm{II}}$ being very much more susceptible to aerial oxidation in 12*M* phosphoric acid. If there is any doubt, the result for iron$^{\mathrm{II}}$ can be checked on a separate aliquot of the mixture by titration with potassium dichromate in 0·*SM* sulphuric acid either with a potentiometric or a visual end-point using diphenylamine sulphonic acid as indicator. The determination of cerium^{III} is not affected by the presence of oxygen, unlike that of iron^{II}.

Some typical results for the determination of iron^{II} and cerium^{III} in the same aliquot of solution are presented in Table IV. These show that the error of determination of iron^{II} is not greater than −0·5% and that for cerium^{III} ±0·3%. A typical curve showing the relation between potential and volume of oxidant is shown in Fig. 3. Because the potential break for the cerium part is not high, a plot of ΔE/ΔV *versus* V is recommended (Fig. 3 inset) for the cerium part of the titration. If it is required to determine iron^{III} and cerium^{IV} in admixture, the solution can be passed through a Jones reductor and the resulting iron^{II} and cerium^{III} assayed more conveniently by the above method than by any of the existing procedures.

Determination of Vanadium^{IV} and Cerium^{III} in Mixtures

We have observed that only one break is observed in the potential *versus* volume curve when a mixture of cerium^{III} and vanadium^{IV} is titrated potentiometrically with potassium dichromate in 12*M* phosphoric acid. This break corresponds to the simultaneous oxidation of cerium^{III} and vanadium^{IV} to cerium^{IV} and vanadium^{V}, respectively. When an excess of iron^{II} (sufficient to reduce vanadium^{IV} to vanadium^{III}), is added to the mixture of cerium^{III} and vanadium^{IV} and the titration carried out in 12*M* phosphoric acid in air with potassium dichromate, however, three different breaks are obtained. The first break corresponds to the oxidation of unreacted iron^{II} to iron^{III}, the second break to the oxidation of vanadium^{III} to vanadium^{IV} and the third break to the simultaneous oxidation of vanadium^{IV} and cerium^{III} to vanadium^{V} and cerium^{IV}, respectively. From these three titres the amounts of vanadium^{IV} and cerium^{III} present in the mixture can be calculated.

Procedure

An aliquot of the mixture of vanadium^{IV} and cerium^{III} is taken in a 150-ml Pyrex beaker and an excess of approximately 0·2*M* iron^{II} solution is added. The mixture is then treated with an amount of syrupy phosphoric acid such that its concentration is 12*M* at the third potential break in the titration. The mixture is stirred by means of an electromagnetic stirrer and titrated with potassium dichromate, using the potentiometric assembly already described. The potential obtained at the first break shows considerable drift and becomes stable only after 8 min. At the second and third breaks, however, the potential attains a fairly stable value in about 3 min. The potential jump at the first break amounts to about 120 mV, at the second to about 160 mV and at the third break to about 40 mV/0·04 ml of 0·2*N* potassium dichromate solution, when the total volume of the titration solution is about 50 ml.

Some typical results given in Table V show that the method gives quite precise results for both vanadium^{IV} and cerium^{III}, the error for vanadium^{IV} being ±0·3% and that for cerium^{III} ±0·38%.

TABLE V.—DIFFERENTIAL POTENTIOMETRIC TITRATION OF VANADIUM^{IV} AND CERIUM^{III}.

11·16	11·19	43·89	44·00
31·24	31·32	28·87	28·76

Determination of Iron^{II}, Vanadium^{IV} and Cerium^{III} in Mixtures

From the foregoing it will be obvious that iron^{II}, vanadium^{IV} and cerium^{III} can be determined potentiometrically in the same solution with potassium dichromate in a strong phosphoric acid medium (12*M* at the third inflection point) at room temperature, provided an inert atmosphere is maintained during the titration and provided the amount of iron^{II} is greater than that of vanadium^{IV}. However, if the mixture contains insufficient iron,^{II} a known excess of iron^{II} may be added to the mixture before the titration is carried out. The first break in potential corresponds to the oxidation of iron^{II} to iron^{III}, the second break in potential to the oxidation of vanadium^{III} to vanadium^{IV} and the third break in potential to the simultaneous oxidation of vanadium^{IV} and cerium^{III}. From these three titres the amounts of iron^{II}, vanadium^{IV} and cerium^{III} present in the mixture can be calculated. Phosphoric acid should be added to the mixture only after it is freed from dissolved oxygen by passage of an inert gas and all necessary precautions are taken to prevent the leakage of air during titration. The potentiometric assembly and titration are the same as before.

A typical potentiometric titration curve is shown in Fig. 4. Because the third break in potential is not high, a plot of $\Delta E/\Delta v$ *versus* V is recommended (Fig. 4 inset) for the vanadium^{IV} and cerium^{III} part of the titration. Iron^{II} can be determined with an error not exceeding −0·5%, vanadium^{IV} ±0·3% and cerium^{III} ±0·38% (Table VI).

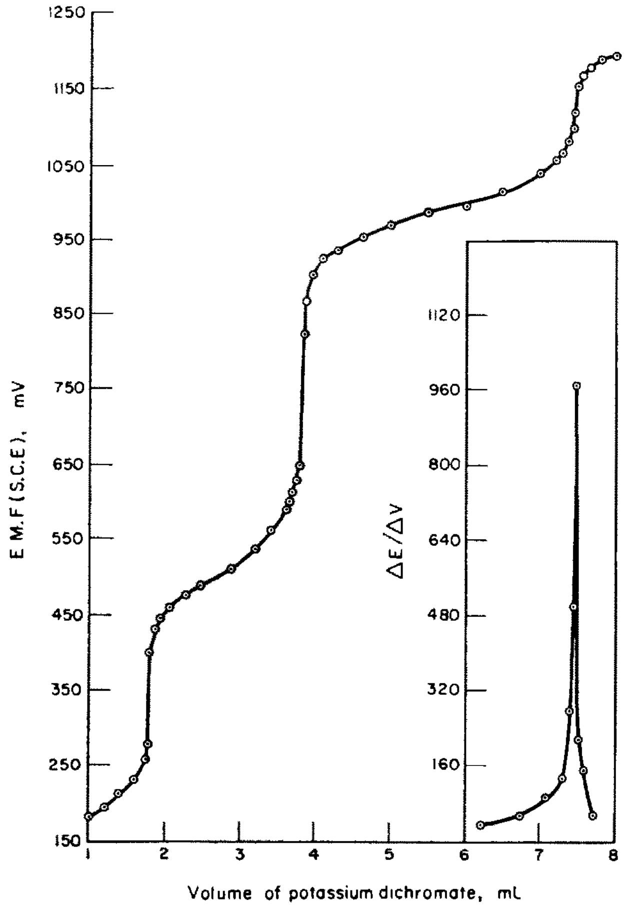

FIG. 4.—Potentiometric titration of a mixture of iron^{II} (42·74 mg), vanadium^{IV} (20·38 mg) and cerium^{III} (45·95 mg) with potassium dichromate in 12*M* phosphoric acid.

Analysis of Cerium in Minerals and Technical Products

Monazite (Travancore, India)

About 10 g of the monazite sand is digested in a porcelain evaporating basin with 25 ml of concentrated sulphuric acid on a sand bath until most of the sulphuric acid is evaporated. It is then cooled and the mass leached with 1*M* sulphuric acid, filtered and made up to 250 ml in a volumetric flask. Ten-ml portions are withdrawn and titrated by the procedure already described for the determination of cerium^{III}. None of the rare earths and thorium present in the sample interfered (Table VII).

Technical Cerium Carbonate (Indian Rare Earths Ltd., Alwaye, India)

About 6 g of sample is treated in a 600-ml Pyrex beaker with 25 ml of sulphuric acid (1 : 1). After the reaction is complete, make up to 250 ml in a volumetric flask. The solution contains mostly cerium^{III} and some cerium^{IV}. The cerium^{III} present is determined by treating 10 ml of the solution with 50 ml of syrupy phosphoric acid and titrating potentiometrically with potassium dichromate solution. The total cerium in the sample is determined by treating 10 ml of the solution with an excess of iron^{II}, then with phosphoric acid so that the over-all concentration is 12*M* at the end-point and titrating in air with potassium dichromate using a potentiometric end-point. The first break is neglected; the volume of titrant added between the first and second breaks corresponds to the cerium^{III}. Results are presented in Table VII.

Table VII

Sample	Cerium found by new method, %	Cerium found by method of Willard and Young[8], %
Monazite	24·12, 24·20, 24·12 Av. = 24·15	24·09, 24·20, 24·16 Av. = 24·15
Technical cerium carbonate	46·03, 46·15, 46·09 Av. = 46·09 (total cerium)	46·14, 46·10, 46·20 Av. = 46·15 (total cerium)
	39·96, 40·10, 39·96 Av. = 40·00 (cerium^{III} only)

Zusammenfassung—Der Gebrauch von Kaliumdichromat zur potentiometrischen Bestimmung von Cer^{III} in 12 bis 13,5 M Phosphorsäure bei Zimmertemperatur wurde untersucht. Die Methode, die bei 30–120 mg Cer in 50 ml Titrationslösung auf ±0,35% genau ist wurde auf die Bestimmung von Cer in Monazitsand und in technischem Cercarbonat angewandt. Es wurden auch Methoden zur potentiometrischen Differenzbestimmung von Eisen^{II} und Cer^{III}, Vanadium^{II} und Cer^{III} sowie von Eisen^{II}, Vanadium^{II} und Cer^{III} in derselben Lösung entwickelt.

Résumé—On a étudié l'emploi du bichromate de potassium pour le dosage potentiométrique du cérium(III) en acide phosphorique 12–13,5 M à température ambiante. La méthode, qui est précise à ±0,35% pour 30–120 mg de cérium/50 ml de solution à doser, a été appliquée au dosage du cérium dans le sable de monazite et dans le carbonate de cérium technique. On a aussi élaboré des méthodes de dosage potentiométrique différentiel de fer(II) plus cérium(III), vanadium(IV) et cérium(III), et fer(II) plus vanadium(IV) plus cérium(III) dans le même solution.

STUDIES IN THE RELATIONSHIP BETWEEN MOLECULAR STRUCTURE AND CHROMATOGRAPHIC BEHAVIOUR—I*

BEHAVIOUR OF SOME NITROPHENOLS CHROMATOGRAPHED ON ALUMINA-IMPREGNATED SURFACES

L. S. Bark and R. J. T. Graham

(*Received* 30 *September* 1963. *Accepted* 2 *February* 1964)

Summary—A series of nuclear-substituted nitrophenols has been chromatographed on various papers (cellulose, alumina-impregnated cellulose and alumina-impregnated glass fibre), using a simple non-polar developing solvent (anhydrous cyclohexane). From a consideration of the R_f values obtained, it is suggested that these compounds are mainly chromatographed by an adsorption process. As a first approximation the mechanism postulated is one of intermolecular hydrogen bonding between the nitro, phenolic and/or halogen groups of the molecule and the hydroxyl groups considered to cover the impregnation. This bonding is modified by the intramolecular hydrogen bonding of the nuclear substituents. The significance of electronic and steric effects is considered. It is suggested that because of the ease of delocalisation of electronic effects in these nuclear systems, no group or atomic chromatographic parameters can be assigned.

In the general field of chromatographic separation of phenols several techniques have been used, *viz.*, gas chromatography,[1,2] electrophoresis,[3] paper chromatography,[4,5] column chromatography with silica gel as the adsorbent,[6,7] thin-layer chromatography[8,9] and paper impregnated with polyamides[10] and formamide.[11]

Work relating structure and chromatographic behaviour has been mainly concerned with alkylated phenols chromatographed on paper,[5] although Carlton and Bradbury[6] separated alkyl phenols on silica gel and showed that the adsorption of these phenols is considerably influenced by the size and position of the alkyl group.

Very little work has previously been done on the effect of nuclear substituents, except for that of Smith[7] who investigated a small number of phenols containing halogen, nitro, amino and oxygen groups. He suggested modes of adsorption, but these could not be adequately substantiated on the relativity haphazard choice of phenols used, although there is no doubt that hydrogen bonding between the silica gel and the phenol plays a dominant role in the chromatography of these compounds.

The polyamides and formamide used to impregnate some papers studied, also bind the phenols through hydrogen bonds and using both 10% and 15% nylon-impregnated papers, Martin and Husband[10] showed that the R_f values decreased with increase in the nylon percentage when the phenols were eluted with a cyclohexane/acetic acid mixture or with dilute aqueous acetic acid.

---

* Presented in part at a Joint Meeting of the Institute of Chemistry of Ireland and the Scottish Section of the Society for Analytical Chemistry, held in Dublin, 5 September, 1963.

Both Marcinkiewicz and coworkers[5] and Martin and Husband[10] have been able to show that the number of carbon atoms in the side chain of a single unknown alkyl phenol or the several homologues of a mixture of straight chain alkyl phenols may be determined from R_f or R_M values of related compounds, because each methylene group has a definite parameter in a particular chromatographic system. Marcinkiewicz and coworkers were able to calculate ΔR_M values for branched side chains and whilst it was noted that the change in R_M or R_f caused by nuclear substitution was less than that caused by side-chain substitution, very few phenols were studied to substantiate or extend this correlation.

The present authors have investigated 38 nitrophenols with various nuclear substituents, and have chromatographed them on papers impregnated with different amounts of alumina in a standard solvent system. The effect of these various substituents on the hydrogen bonding in the system has been studied and to simplify the over-all system and minimise hydrogen bonding between the phenols and the development solvent, anhydrous cyclohexane was chosen as the solvent.

EXPERIMENTAL

The surfaces used were:

(1) cellulose paper (Whatman No. 1),
(2) cellulose paper (Whatman No. 1) impregnated with 2% of alumina,
(3) cellulose paper (Whatman No. 1) impregnated with 7·5% of alumina,
(4) glass fibre "paper" (Whatman) impregnated with 7·5% of alumina,
(5) cellulose paper (Schleicher and Schull No. 288) impregnated with 25% of alumina.

Each type of paper was from one particular manufactured batch and was supplied impregnated by the manufacturer. All papers were stored under the same conditions.

In order to obtain accurate and reproducible results, all other necessary conditions were standardised as previously discussed.[18]

Pretreatment of papers

Because the papers are hygroscopic, to ensure a standard moisture content, all papers were dried at 110° for 15 min, allowed to cool in an evacuated desiccator for 20 min, then the vacuum slowly released with dried air.

Application of phenols and development conditions

All papers were run in the "machine direction" of the fibres. To ensure that the original solvent front was a known and fixed distance from the point of application of all spots, the position of the starting point of each substance was first marked on every paper used.

2·5 μl of a 0·25% w/v solution of the chromatographically pure phenol in n-butanol were applied as quickly as possible. To prevent dispersion of the solute, a current of warm air was blown onto the paper during application. The loaded papers were then placed at a fixed position over a solvent trough in a tank thermostatted at 25° ± 0·5°. The tank atmosphere had been previously saturated with solvent vapour by keeping approximately 100 ml of solvent in two small beakers in the tank, and hanging strips of filter paper, wet with the solvent, on the inside walls of the tank. The papers were allowed to stand for 10 min to enable saturation conditions to be regained, then a standard volume (200 ml) of the anhydrous cyclohexane was placed in the solvent trough and the phenols chromatographed by an ascending technique.

The length of run from each line of application to the solvent front was 22–23 cm. The time of each run varied, depending on the amount of impregnation and the type of support fibre. The greater the amount of impregnation, the longer the time required for the solvent to move the standard distance. On the glass fibre paper, which had a noticeably more open weave than the cellulose papers, the solvent moved fairly rapidly.

Solvent

Cyclohexane (MFC grade, Hopkin and Williams Ltd., U.K.) was dried over sodium wire, then fractionally distilled. The fraction boiling at 83–4° at 760 mm of pressure was collected. This treatment ensured that the solvent was anhydrous. The purity was further assessed by gas-liquid chromatography, using a Celite column and a dinonyl phthalate stationary phase, at a column temperature of 80°. A Pye Argon chromatograph was employed. Only one peak was obtained on the record chart, indicating only cyclohexane to be present.

Phenols

All crude phenols were purified by recrystallisation from a suitable solvent until the melting point agreed with literature values and only one spot appeared on any chromatographic run.

Detection of spots

Although the nitrophenols are coloured, irradiation with ultraviolet light sharply defined the spot perimeters, enabling accurate measurement to be made.

RESULTS

The results are shown in Table I. Each result is the average of at least three runs, the difference between the R_f values of any two runs being not more than ±0·01 of an R_f unit, except where stated. In these cases (marked * in all tables) the difference is not more than ±0·02 of an R_f unit.

On untreated cellulose paper it can be seen that the number of nitro groups in the phenol has a profound effect on the chromatographic behaviour.

Mononitro compounds having the nitro group in the 2-position and one or two other substituents all travelled to the solvent front, discrete spots, slightly elongated in a direction parallel to the solvent front, being formed. Mononitro compounds with the nitro group in the 3- or 4- position and with no more than one other substituent, gave discrete spots elongated in the direction of the solvent flow. Mononitro compounds with the nitro group in the 4-position and with two other substituents may be classified into:

(a) Those having 2,6-substituents with one electronegative group. These all gave discrete spots in the solvent front.

(b) Those having 2,6-substituents with two electronegative groups. These were badly streaked, giving a distinct main spot not separated from the streak. The R_f value of these main spots was fairly high in all cases.

For dinitro compounds with a substituent in the 2-position, the spot moved, but was badly streaked. The amount of movement depended on the electronegative character of the other substituents, the more electronegative substituents giving compounds with low R_f values. The 3,5-dinitro compound had a low R_f value. The spot was small and discrete. Only one trinitro compound was chromatographed. This had a very low R_f value.

On alumina-impregnated papers the R_f values rapidly decreased with increase in the amount of impregnation; with 25% of alumina only four phenols (2-nitrophenol, 2-nitro-4-methylphenol, 2-nitro-6-methylphenol and 2-nitro-4-tert-butyl-6-methylphenol) moved and the greatest R_f recorded (for the latter two) was only 0·06 R_f unit.

There was, in general, a slightly lower R_f value for phenols chromatographed on the alumina-impregnated glass fibre paper. Slight variations are thought to be caused by variations in the texture of the glass fibre paper, which was not of as uniform an appearance as the cellulose papers.

The area of the spots diminished with increase in the amount of impregnation. Compounds which gave streaks on the untreated cellulose paper gave discrete spots on the 2% alumina-impregnated papers.

TABLE I.—R_f VALUES ON THE VARIOUS SURFACES INVESTIGATED

Phenol	R_f				
	(1)	(2)	(3)	(4)	(5)
2-Nitro-	1·00	1·00	0·28	0·28	0·04*

2-Bromo-4-nitro-6-isopropyl-	1·00	0·75	0·29	0·13	0·00
2-Bromo-4-nitro-6-sec-butyl-	1·00	0·72	0·33	0·05	0·00
2-Bromo-4-nitro-6-tert-butyl-	1·00	0·88	0·56	0·38	0·00
2-Bromo-4-nitro-6-cyclohexyl-	1·00	0·73	0·28	0·10	0·00

[a] Spots badly streaked, with streak from starting point to an area of greatest spot density at value indicated.

[b] Spot mainly reached solvent front, but also badly streaked.

[c] Spot badly streaked; all has moved from starting point.
Main spot density clearly visible with centre at value given.
There was no separation of spot and streak.

[d] Discrete spots of relatively small area, but base of spot on starting line.

DISCUSSION

It is thought that the mechanism of the chromatographic separation of the phenols studied is essentially a two-stage process:

(i) Dissolution of the phenol in the non-polar cyclohexane. This will be favoured by the formation of internal hydrogen bonds with the hydrogen of the phenolic group and an electronegative atom of a group in the 2-position, which will reduce the over-all polarity of the phenol.

(ii) Adsorption of the phenol onto the substrate by means of hydrogen bonds formed between electronegative groups or atoms of the phenol and hydrogen atoms of hydroxyl groups of the surface.

If either of these processes predominates then the spot will be discrete. If neither predominates, the spot will streak. If the polarity of the system is increased by increasing the polarity of the substrate, then the spots which previously streaked will appear as discrete spots.

Because a small increase in the amount of impregnation of the cellulose greatly decreases the R_f values of the phenols, it is suggested that in this fairly simple polar/non-polar system, the partition of the phenols between these two phases on impregnated papers, is mainly caused by the adsorption onto the alumina.

The glass fibre paper generally shows more adsorption of the phenols than does the cellulose paper with the same amount of alumina impregnation. It is, however, less uniform in texture than the cellulose paper and this may account for some non-parallelism of the results. The silica skeleton of the glass fibre paper may account for some of the increased adsorption.

For a detailed study of the mechanism of the chromatographic process it was decided to use mainly the results from the 2% and 7·5% impregnated papers (cellulose and glass fibre), but to consider for 'trend' purposes the over-all behaviour of the phenols compared.

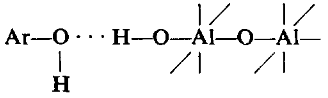
We think that the main mechanism of the process will be essentially adsorption chromatography, because it is not possible that the papers will have a sufficiently high water content to enable a surface layer of water to be obtained on the fibres. The mechanisms which are responsible for adsorption by solids from liquids are:

(i) non-polar van der Waal's forces,
(ii) formation of hydrogen bonds or operation of other non-ionic polar forces,
(iii) covalent bond formation,
(iv) ion exchange.

In any system more than one of these may operate, but we are concerned only with the forces listed under (ii); of these, hydrogen bond formation is the most important. There is little evidence that other non-ionic polar forces have much influence on adsorption processes from dilute solutions.[13] Some attempts have been made to demonstrate their operation but the evidence is equivocal.

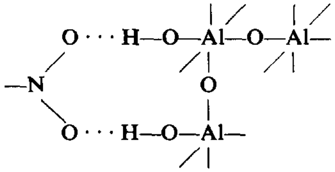
Hydrogen bonding in adsorption of phenols from solution by solids has been reasonably well established for various adsorbates, including alumina.[13] Bernal[14] has stated that many, if not all, so called oxide surfaces are effectively hydroxyl covered at ordinary temperatures, and that relatively stringent conditions of high temperatures and low pressures do not completely remove the hydroxyl groups. We consider that with the conditions used for this work, the impregnated papers must be impregnated with alumina which is wholly or substantially hydroxylated and this phenomenon will give rise to the following possible hydrogen bond systems with the phenolic group, the nitro group and probably some halogen groups:

(i)

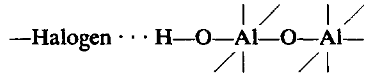


$Ar{-}O \cdots H{-}O{-}Al{-}O{-}Al{-}$

(ii)

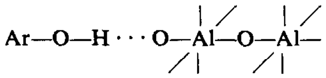


(iii)



$-Halogen \cdots H{-}O{-}Al{-}O{-}Al{-}$

(iv)



$Ar{-}O{-}H \cdots O{-}Al{-}O{-}Al{-}$

Graham and Stone[16] have shown that (iv) is unlikely and may be considered to make an insignificant contribution to the complete system.

Desorption takes place primarily as a breaking of these hydrogen bonds by the forces of dissolution of the non-polar part of the molecule in the non-polar phase (anhydrous cyclohexane) of the system.

Because each phenol has two possible points of attachment to the hydroxylated surface, it is likely that if the phenol can lie in the plane of the adsorbent surface, then the R_f value will be low because of the high probability of adsorption on the polar phase.

The factors which may affect the adsorption (and hence the R_f values) of these phenols are:

(i) Internal hydrogen bonding of the phenolic group with a nitro group, or a halogen group, in the 2-position, decreasing the probability of external hydrogen bonding by any of the groups. This internal hydrogen bonding will decrease the adsorption and hence increase the R_f value.

(ii) Electronic or steric effects altering the strength of this internal hydrogen bonding. The effect on the adsorption will depend upon the nature of the group.

(iii) Bulk effects—the effects of groups causing some of the non-polar part of the molecule to be held away from the polar surface and hence held in the non-polar phase. This effect will decrease the adsorption.

(iv) The bonding of the molecule to the polar layer by a nitro group or halogen group, not involved in internal hydrogen bonding with the phenolic group.

These factors may not always be acting alone and it is very unlikely that steric and electronic effects can be entirely separated.

Consider internal hydrogen bonding between the phenolic group and a nitro group in the 2-position. The results in Table II show that chelation of the 2-nitro group with the phenolic group greatly reduces the availability of either for bonding to the polar layer.

The effect of internal hydrogen bonding between the phenolic group and a halogen atom may be seen by a consideration of the results in Table III.

TABLE II

Phenol	$R_{f(2)}$	$R_{f(3)}$
2-Nitro-	1·00	0·28
3-Nitro-	0·04	0·02
4-Nitro-	0·04	0·02
2,4-Dinitro-	0·08	0·04

TABLE III

Phenol	$R_{f(2)}$	$R_{f(3)}$
4-Nitro-	0·04	0·02
2-Chloro-4-nitro-	0·08	0·04
2-Methyl-4-nitro-	0·05	0·01

The 2-chloro group is apparently involved in hydrogen bonding with the phenolic group, because when a methyl group replaces a chloro group there is a consequent decrease in the R_f value. A comparison of the results obtained from 4-nitrophenol and 2-methyl-4-nitrophenol indicates that a methyl group, substituted in the 2-position, has very little effect on the adsorption of the phenol.

The effect of substituents on the bonding between the phenolic group and the 2-nitro group may be seen by considering the series 2-nitro-4-(R)-phenol (see Table IV).

TABLE IV

R	$R_{f(2)}$	$R_{f(3)}$	$R_{f(4)}$
Hydrogen	1·00	0·28	0·28
Chloro	0·82*	0·21	0·14
Bromo	0·83*	0·24	0·17
Methyl	0·92	0·51	0·50

For comparison purposes, other than to show trends, R_f values above 0·80 are ignored. Hence, considering values obtained on 7·5% alumina-impregnated paper and ignoring (for simplification) any possible mutual attachment of the 4-group and the polar adsorbent, the results shown in Table IV may be explained as follows. In spite of the greater inductive effect of the 2-nitro group, the presence of a 4-halogeno substituent must slightly weaken the intramolecular hydrogen bonding, and hence slightly enhance the availability of the nitro and phenolic groups for intermolecular hydrogen bonding with the hydroxyl covered surface. The presence of a 4-methyl group will have an opposite effect.

The nitro group has a strong inductive effect, and whilst the variation in the results from the phenols shown in Table V may be considered to be partly because of the electronic effects of the substituents, it is considered that in this case the electronic effect of the methyl substituent is probably very small in comparison to the effect of the second nitro group placed in the nucleus and giving a further position of attachment to the polar surface.

A consideration of steric models indicates that substitution of a methyl group in the 6-position does not affect the ease of rotation of the phenolic group. When the phenol is attached to the polar adsorbent by the nitro and bromine groups, the

6-methyl group can lie in the plane of the organic molecule and hence the bulk effect, which may increase dissolution in the non-polar phase of the system, can be considered to be negligible.

TABLE V

Phenol	$R_{f(2)}$	$R_{f(3)}$	$R_{f(2)}$
2-Nitro-	1·00	0·28	0·28
2-Nitro-6-methyl-	1·00	0·30*	0·33
2,6-Dinitro-	0·04	0·00	0·00

Consideration of the results obtained with the series 2,4-dinitro-6-R-phenol (see Table VI), indicates that the same reasoning may be applied to slightly more complex molecules.

TABLE VI

R	$R_{f(2)}$	$R_{f(3)}$
Hydrogen	0·08	0·04
Chloro	0·04	0·00
Bromo	0·04	0·00
Iodo	0·07	0·00
Methyl	0·58	0·10

In a phenol having more than one such group, the effects may be additive, if similar, but if they are in opposition then the position of the group relative to the chelate system becomes important.

Consider groups having the same effect (Table VII).

TABLE VII

Phenol	$R_{f(2)}$	$R_{f(3)}$
2-Nitro-4-chloro-	0·82*	0·21
2-Nitro-4-chloro-6-bromo-	0·56	0·05
2-Nitro-4-bromo-	0·83*	0·24
2-Nitro-4,6-dibromo-	0·60	0·06
2-Nitro-4,6-di-iodo-	0·79	0·08

Here the effect of two halogen atoms is apparent.

With 2 alkyl groups, as in Table VIII, the large increase in R_f values with the substitution of a 4-tert-butyl group is probably caused by the bulk effect of this group. Steric models indicate that a large proportion of this hydrocarbon group is held out of the plane of the polar adsorbent, and hence in the non-polar phase of the system.

TABLE VIII

Phenol	$R_{f(2)}$	$R_{f(3)}$
2-Nitro-6-methyl-	1·00	0·30*
2-Nitro-4-tert-butyl-6-methyl-	1·00	0·77

With substituents having opposing electronic effects (Table IX), the relative positions of all groups must be considered. It is improbable that the 6-bromo group takes part in internal hydrogen bonding, so that the 2-nitro group will effectively capture the phenolic hydrogen. Although the position of the substituent plays a part in determining the total effect, each group will still give (qualitatively) the expected result.

TABLE IX

Phenol	$R_{f(2)}$	$R_{f(3)}$
2-Nitro-4-methyl-6-bromo-	0·89	0·10
2-Nitro-4-bromo-6-methyl-	0·96	0·25

The bulk effect may be both electronic and steric in origin. Whilst there is a difference in the atomic sizes of the halogen atoms, their electronic effects are very closely related to the size effect, and in nuclear-substituted phenols, because of the close proximity of the substituents to the nucleus, there is probably interaction between the nuclear π-electronic orbitals and the d-orbitals of the halogen. We suggest, therefore, that independent steric effects of the halogens cannot be considered. With alkyl substituents this electronic interaction with the benzene nucleus will be much reduced, and the steric effects are relatively more pronounced.

Consider the results (Table X) obtained from phenols held in the plane of the adsorbent by intermolecular hydrogen bonding between the hydroxyl of the polar surface and both the phenolic group and the 4-nitro group.

TABLE X

Phenol	$R_{f(2)}$	$R_{f(3)}$	$R_{f(4)}$
4-Nitro-	0·04	0·02	0·00
4-Nitro-2-methyl-	0·05	0·01	0·00
4-Nitro-2-sec-butyl-	0·08	0·02	0·00
4-Nitro-2-cyclohexyl-	0·06	0·02	0·02
4-Nitro-2-bromo-6-methyl-	0·50	0·12	0·06
4-Nitro-2-bromo-6-ethyl-	0·64	0·19	0·10
4-Nitro-2-bromo-6-isopropyl-	0·75	0·29	0·13
4-Nitro-2-bromo-6-sec-butyl-	0·72	0·33	0·05
4-Nitro-2-bromo-6-tert-butyl-	0·88	0·56	0·38
4-Nitro-2-bromo-6-cyclohexyl-	0·73	0·28	0·10

The adsorption and the amount of hydrocarbon held in the non-polar phase is generally reflected in the R_f values obtained. Models indicate that the tert-butyl group is by far the bulkiest group, but a study of models alone cannot give the complete explanation. In 2,6-dinitro-4-tert-butylphenol and 2,6-dinitro-4-methylphenol, models indicate that the tert-butylphenol should have a much greater solubility in the non-polar phase and hence a correspondingly higher R_f value than the methyl compound. The values in Table XI indicate that other effects must play a part, the R_f value of the methyl compound being higher than expected. It is suggested that the results may be explained by considering the inductive effect caused by the hyperconjugation of the 4-methyl group with the benzene nucleus. This will tend to increase the amount of internal hydrogen bonding between the 2-nitro group and the phenolic group and reduce the availability of either for intermolecular hydrogen bonding. The tert-butyl group cannot hyperconjugate with the nucleus and the main effect to be considered for this compound will be the bulk effect.

TABLE XI

Phenol	$R_{f(2)}$	$R_{f(3)}$
2,6-Dinitro-4-methyl-	0·16	0·02
2,6-Dinitro-4-tert-butyl-	0·20	0·04

The relatively large effect of an additional nitro group, the smaller effect of the halogens and the effect of variation in the polar nature of the substituent may be seen in Table XII.

TABLE XII

Phenol	$R_{f(2)}$	$R_{f(3)}$
2-Nitro-	1·00	0·28
2,4-Dinitro-	0·08	0·04
2,4,6-Trinitro-	0·00	0·00
2-Nitro-4-methyl-	0·92	0·51
2-Nitro-4-chloro-	0·82*	0·21
2-Nitro-4-bromo-	0·83*	0·24

2,4-Dinitro-6-bromo-	0·04	0·00
2,4-Dinitro-6-iodo-	0·07	0·00

CONCLUSIONS

We think that, as a first approximation, the chromatographic behaviour of the nitrophenols is dependent on the amount of internal hydrogen bonding between the phenolic group, the nitro group and/or the halogens present, and the intermolecular hydrogen bonding between these groups and the hydroxyl groups of the substrate. This intermolecular bonding may be modified by the electronic effects of substituent groups.

Whilst it may be possible to calculate chromatographic parameters (ΔR_M values) for groups or atoms in simple alkylated phenols chromatographed in relatively non-polar systems, where the system is essentially polar such parameters are not readily attainable. We suggest that because of the ease of delocalisation of electronic effects in a benzene nucleus, substitution of any group into this electronic system affects the whole molecule. The effect on the intermolecular bonding group or groups depends not only on the nature of the substituent but also on its position relative to theses bonding groups. This has been shown for other systems—phenoxyacetic acids chromatographed in butanolic systems[15]—where the effects were not so apparent because of the insulating effect of the ether oxygen. We consider that it may be possible to deduce approximate values for compounds from a knowledge of their structure and the behaviour of related compounds and so to construct a chromatographic system of solvent and support to give effective separation of closely related compounds of known structure.

Acknowledgements—The authors wish to acknowledge the gift of nitrophenols for this work from Dr. J. Gasparič (Institute for Organic Syntheses, Pardubice, Czechoslovakia) and from Dr. M. Martin-Smith (Department of Pharmaceutical Chemistry, The Royal College of Science and Technology, Glasgow, Scotland), and the Chemical Society for a grant to one of us (R. J. T. G.) for the purchase of some of the papers used in this work. We would like to thank Professor L. Hunter for affording us discussion of some of the results.

Zusamenfassung—Eine Anzahl kernsubstituierter Nitrophenole wurde an verschiedenen Trägern (Cellulose, Aluminiumoxyd auf Cellulose und Aluminiumoxyd auf Glasfaser) mit einem einfachen unpolaren Lösungsmittel (wasserfreiem Cyclohexan) zur Entwicklung chromatographiert. An Hand einer Betrachtung der R_f-Werte wird wahrscheinlich gemacht, daß diese Verbindungen im wesentlichen durch einen Adsorptionsprozeß chromatographiert werden. In erster Näherung beruht der vorgeschlagene Mechanismus darauf, daß zwischen Nitro- und Phenolgruppen und/oder Halogenen im Molekül und den Hydroxylgruppen an der Oberfläche des Adsorbens Wasserstoffbrücken ausgebildet werden. Diese Bindung wird durch innermolekulare Wasserstoffbrücken beeinflußt. Die Bedeutung elektromerer und sterischer Effekte wird betrachtet. Wegen der leichten Delokalisation elektromerer Effekte in diesen aromatischen Kernen lassen sich keine Atom- oder Gruppenparameter für das chromatographische Verhalten angeben.

Résumé—On a chromatographié une série de nitrophénols substitués au noyau sur divers supports (cellulose, cellulose imprégnéé d'alumine et fibre de verre imprégnée d'alumine) en utilisant pour le développement un solvant simple non polaire (cyclohexane anhydre). A partir des considérations sur les valeurs de R_F obtenues, on suggère que ces composés sont principalement chromatographiés par un processus d'adsorption. En première approximation, on suppose un mécanisme de liaison hydrogène intermoléculaire entre le groupe nitro, le groupe phénolique et/ou les groupes halogènes de la molécule, et les groupes hydroxylés dont on considère recouverte l'imprégnation. Cette liaison est modifiée par la liaison hydrogène intramoléculaire des substituants nucléaires. Par suite de la facilité de délocalisation des effets électroniques dans ces systèmes nucléaires, il semble qu'on ne puisse attribuer de paramètres chromatographiques de groupes ou atomiques.

PRECIPITATION OF ZINC 8-HYDROXYQUINALDATE FROM HOMOGENEOUS SOLUTION

S. HIKIME* and L. GORDON
Department of Chemistry, Case Institute of Technology, Cleveland 6, Ohio, U.S.A.

(*Received* 30 *September* 1963. *Accepted* 21 *January* 1964)

Summary—Zinc 8-hydroxyquinaldate can be precipitated quantitatively from homogeneous solution with 8-hydroxyquinaldine generated by the hydrolysis of 8-acetoxyquinaldine. Separation studies indicate the superiority of this method over the conventional procedure using 8-hydroxyquinaldine.

8-HYDROXYQUINALDINE was first reported in 1944 by Merritt and Walker[1] as an analytical reagent for the determination of several metallic ions; since then several investigators have used 8-hydroxyquinaldine in analytical applications. 8-Hydroxyquinaldine exhibits a significant difference in behaviour as compared with 8-hydroxyquinoline, *e.g.*, it will not precipitate aluminium whereas 8-hydroxyquinoline does. However, these two precipitants are similar enough chemically to have suggested the use of appropriate PFHS reagents[2,3] for the generation of 8-hydroxyquinaldine in much the same way that 8-hydroxyquinoline has been generated.[4–10] Thus, it was the purpose of this investigation to use 8-acetoxyquinaldine as a source of 8-hydroxyquinaldine in the precipitation of zinc from homogeneous solution.

EXPERIMENTAL

Reagents

Zinc: A stock solution of zinc^{II} was prepared by dissolving 2·0011 g of pure zinc sheet, 99·998%, in 20 ml of 1:1 hydrochloric acid and diluting with water to one litre. The concentration of this solution was confirmed by EDTA titration, using Eriochrome Black T indicator. Solutions containing 10·00, 25·01, and 50·03 mg of zinc per 50 ml were prepared by further dilution.

8-Acetoxyquinaldine: The reagent (Burdick and Jackson Laboratories, 1953 South Harvey St., Muskegon, Mich., U.S.A.) was stored in a desiccator, in a refrigerator, to minimise reagent hydrolysis. An acetone solution of the reagent was also kept in the refrigerator; 5 ml of this solution contained 1·5 × the theoretical quantity of reagent required to precipitate 50 mg of zinc.

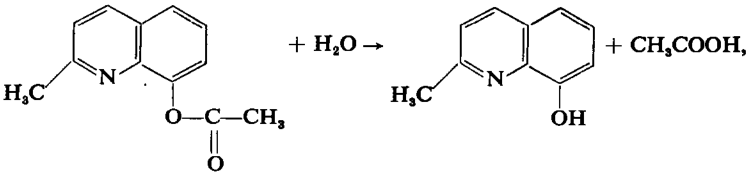
8-Hydroxyquinaldine: The stock solution was prepared by dissolving 5 g of the reagent (G. Frederick Smith Chemical Co., 867 McKinley Ave., Columbus, Ohio, U.S.A.) in 12 g of glacial acetic acid, and diluting to 100 ml with distilled water. Such a solution, kept in a refrigerator, is stable for at least 2 months.

Diverse ions: Solutions of aluminium and magnesium were prepared by dissolving their sulphates in dilute sulphuric acid. The concentration of the aluminium^{III} solution was determined by precipitation with 8-hydroxyquinoline, and that of the magnesium^{II} solution by EDTA titration.

All other chemicals used were analytical-reagent grade.

Precipitation of zinc

In the reaction



---

* Present address: Faculty of Science, Hokkaido University, Sapporo, Japan.

the rate of hydrolysis of 8-acetoxyquinaldine increases with either increasing pH or increasing temperature of the reaction mixture.

Preliminary investigations were undertaken to determine the optimum conditions of pH, concentration of reagents and temperature of reaction which would result in a precipitate with desirable physical characteristics (*cf.* Fig. 1). Precipitation was carried out in the pH range 4·5–7·0, with ammonium acetate as buffer. Below pH5·0, the precipitation of zinc^{II} was incomplete; anomalous results were obtained in the pH range 5·5–6·0; *i.e.*, some were low and some high. Desirable results were obtained at pH 6·5, with 1·5 × the theoretical quantity of 8-acetoxyquinaldine and the use of a temperature of 60–70°.

[a] 8-AQD = 8-acetoxyquinaldine; 8-HQD = 8-hydroxyquinaldine; 8-AQ = 8-acetoxyquinoline.

[b] 10 ml of 20% ammonium tartrate added to the solution before adding 8-AQD.

[c] Determined by photometric titration with 0·001*M* EDTA solution after treating the filtrate with nitric-perchloric acid.

Recommended procedure

Dilute the solution, containing 10 to 50 mg of zinc, to about 175 ml, add 10 ml of 20% ammonium acetate solution, and adjust the pH of the solution to 6·5 with either 1*M* aqueous ammonia or 1*M* acetic acid. Add slowly, with stirring, 5 ml of an acetone solution containing 0·462 g of 8-acetoxyquinaldine, and dilute to 200 ml with water. Heat the solution for 2 hr at 70°, and filter hot, using about 100 ml of hot water (*ca.* 80°) to transfer the precipitate to a medium-frit glass filter. Dry the precipitate at 130° to constant weight (~6 hr), and weigh as $Zn(C_{10}H_8ON)_2$; the gravimetric factor for zinc is 0·17125. (Note. When aluminium is present, add 10 ml of 20% ammonium tartrate solution before adjusting the pH.)

Drying of zinc 8-hydroxyquinaldate

The precipitate contains 1 molecule of water, which is removed by heating at 130°. However, it requires 5–6 hr to obtain constant weight. Attempts to reduce the drying time, *e.g.*, by drying the precipitate for 2 hr at 130° and then for 30 min periods at either 250°, 200° or 160°, were unsuccessful. Thermogravimetric study

[a] 10 ml of 20% ammonium tartrate added.

[b] Diverse metals determined or detected in the precipitate as follows: (1) Al with Alizarin S;[11] (2) Mg fluorometrically with *o*,*o*′-dihydroxyazobenzene[12] (organic material in precipitate decomposed in oxygen flask and magnesium and aluminium then separated from zinc by ion-exchange with IRA-400[13,14]).

[c] Diverse metal determined in this precipitate.

also indicated that 130° was an appropriate drying temperature for zinc 8-hydroxyquinaldate, and that it appeared to be somewhat critical. Alternatively, the determination of zinc can be concluded by titrimetric analysis.[1]

RESULTS AND DISCUSSION

Table I shows that satisfactory results could be obtained with from 1 to 100 mg of zinc using the procedure given, but modified in that 1·5 × the theoretical amount of 8-acetoxyquinaldine required was used for each precipitation. Results obtained by conventional precipitation are also shown for comparison.

As shown in Table II, satisfactory results were also obtained in the range 1–50 mg of zinc with a constant amount of 8-acetoxyquinaldine, *i.e.*, 0·462 g, which corresponds to the 1·5 × quantity for 50 mg of zinc. Because of the slightly lower results obtained with the smaller amounts of zinc, the recommended procedure is limited to 10–50 mg of zinc.

The results of the separation of zinc from aluminium and magnesium are shown in Table III. Aluminium did not coprecipitate; however, high results were obtained in the presence of magnesium. In general, more satisfactory results were obtained by PFHS than by conventional precipitation.

Acknowledgment—The authors wish to acknowledge the support in part of the United States Atomic Energy Commission under Contract AT(11-1)-582.

Zusammenfassung—Zink-8-hydroxychinaldat kann quantitativ aus homogener Lösung mit durch Hydrolyse von 8-Acetoxychinaldin erzeugtem 8-Hydroxychinaldin gefällt werden. Abtrennungsversuche zeigen die Überlegenheit dieser Methode gegenüber der gebräuchlichen mit 8-Hydroxychinaldin.

Résumé—Le 8-hydroxyquinaldinate de zinc peut être précipité quantitativement d'une solution homogène au moyen de 8-hydroxyquinaldine générée par l'hydrolyse de 8-acétoxyquinaldine. Des études de séparation montrent la supériorité de cette méthode sur le procédé habituel utilisant la 8-hydroxyquinaldine.

PRECIPITATION OF METAL 8-HYDROXYQUINOLATES FROM HOMOGENEOUS SOLUTION—VII*

INDIUM AND GALLIUM

J. P. JONES, O. E. HILEMAN, JR., A. TOWNSHEND and LOUIS GORDON
Department of Chemistry, Case Insitute of Technology
Cleveland 6, Ohio, U.S.A.

(*Received* 9 *December* 1963. *Accepted* 10 *February* 1964)

Summary—The precipitation from homogeneous solution of indium and gallium, using 8-acetoxyquinoline, has been investigated. It has been established that the method cannot be recommended for the determination of either metal, although under certain rigorously controlled conditions indium 8-hydroxyquinolate precipitates quantitatively and stoichiometrically. The conventional precipitation of indium 8-hydroxyquinolate has also been found to give erroneous analytical results.

INTRODUCTION

FROM an investigation of the precipitation from homogeneous solution of indium, using 8-acetoxyquinoline, it became evident that the experimental conditions need to be rigorously controlled in order to obtain, simultaneously, a precipitate of stoichiometric composition, and complete separation of the indium. A subsequent investigation of the conventional method[1] of precipitating indium with 8-hydroxyquinoline also indicated the difficulty of obtaining quantitative precipitation. It became the purpose of this investigation, therefore, to evaluate critically the analytical aspects of the precipitation of indium 8-hydroxyquinolate. The similar precipitation of gallium was also the subject of a brief investigation.

EXPERIMENTAL

Reagents

Indium solution: Indium metal of high purity (Indium Corp. of America, Utica, N.Y.) was dissolved in dilute hydrochloric acid, and the solution was diluted to the required volume with distilled water.

Gallium solution: High purity gallium (99·99%, Fisher Scientific Co.) was dissolved in a 1:2 mixture of 70% perchloric acid and 95% sulphuric acid, and the solution was diluted to the required volume with distilled water.

8-Acetoxyquinoline: For indium, PF/HS grade 8-acetoxyquinoline (Burdick and Jackson Laboratories, 1953 S. Harvey St., Muskegon, Mich.) was dissolved in acetone; 5 ml of this solution contained 4 times the stoichiometric quantity of reagent needed to precipitate 50 mg of indium.

For gallium, 1·0 g of 8-acetoxyquinoline was dissolved in 1:1 acetic acid (25 ml); this solution contained 2·5 times the stoichiometric quantity of reagent required to precipitate 50 mg of gallium.

All other chemicals used were reagent-grade.

RESULTS

Conventional precipitation of indium with 8-hydroxyquinoline

Geilmann and Wrigge[1] recommended a sodium acetate-acetic acid medium for the precipitation of indium with 8-hydroxyquinoline. The pH of the medium was about 4·5. Table I shows typical results obtained when this procedure was used. Low

---

	−0·08	>0·4
	−0·37	>0·4

[a] Difference = found − taken.

[b] Determined polarographically in an aqueous perchloric acid-potassium chloride medium.[8]

gravimetric results were also obtained in the mineral acid medium recommended by Geilmann and Wrigge.[1]

Conventional precipitation of gallium with 8-*hydroxyquinoline*

The method of Geilmann and Wrigge[1] and that of Moeller and Cohen[3] gave slightly low recoveries of gallium.

PFHS of indium with 8-*acetoxyquinoline*

Experiments were carried out to study the effects of (*a*) different wash solutions, (*b*) pH in the range 2·0–5·0, (*c*) various sodium acetate-acetic acid and ammonium acetate-acetic acid buffers, (*d*) absence of buffers, and (*e*) quantity of 8-acetoxyquinoline, on the PFHS of indium 8-hydroxyquinolate. Some results are shown in Table II. It became evident that indium could be precipitated quantitatively, as a stoichiometric 8-hydroxyquinolate, under closely controlled conditions.

Procedure: The starting solution should contain 15–75 mg of indium as the chloride. To this are added 2·0 ml of glacial acetic acid and 2·0 g of sodium acetate, and the resulting solution is diluted to 180 ml. The pH is adjusted to 4·5 with either hydrochloric acid or aqueous ammonia, and a two-fold excess* of 8-acetoxyquinoline is added. The solution is heated at 80° for 2 hr, and is allowed to cool to room temperature before filtering. The solution is filtered through a medium-porosity filtering crucible, and the precipitate is washed with distilled water, dried to constant weight at 130°, and weighed as $In(C_9H_6NO)_3$.

Table III shows the results obtained using this procedure. Also shown are the results obtained with smaller quantities of indium.

PFHS of gallium with 8-*acetoxyquinoline*

The procedure was similar to that used for the corresponding determination of aluminium,[4] except that the pH was adjusted to 3·7, 3·9 or 4·1. The precipitates were dried to constant weight at 112 ± 2° (*ca.* 2 hr) and weighed as $Ga(C_9H_6NO)_3$. Table IV shows the results obtained using this procedure.

---

* A two-fold excess indicates 2 times the stoichiometric amount.

DISCUSSION

Indium

The results shown in Table I clearly indicate a large solubility loss when indium is precipitated by the direct addition of 8-hydroxyquinoline. Moreover, the results shown in Table II demonstrate the difficulty of obtaining a quantitative precipitate of stoichiometric composition when PFHS is used.

Further experiments using the procedure recommended in this paper established that it was possible to precipitate the indium quantitatively as $In(C_9H_6NO)_3$ (*cf.* Table III). However, the precipitation conditions require rigorous control, *e.g.*, a two-fold excess of 8-acetoxyquinoline, which, of course, would be impractical in analysis. Furthermore, the results obtained by this procedure were satisfactory only for 15–75 mg of indium; as can be seen in Table III, unsatisfactory results were obtained in the 5–10 mg range.

To ascertain whether the non-stoichiometric composition of the precipitate resulted from the formation of a small amount of indium hydroxide, two precipitates, prepared similarly to No. 5 of Table II and No. 1 of Table III, were examined in the infrared spectral region in KBr discs carefully prepared to exclude moisture. Conclusions from the results about the presence of hydroxide were inconclusive.

It is apparent that indium can be quantitatively precipitated from homogeneous solution as a stoichiometric compound using 8-acetoxyquinoline; the experimental conditions of the method are, however, impractical for analysis, although the process is useful for preparative purposes. The conventional method of precipitating indium 8-hydroxyquinolate, as described in the existing literature, gives erroneous analytical results, and therefore it is not recommended for use. It is worthy of mention that precipitates obtained by PFHS and by direct mixing of reagents do not differ in physical appearance.

Gallium

The precipitation of gallium was also unsatisfactory. Although Hollingshead[5] suggested that the low recoveries of gallium obtained by conventional precipitation[1,3] may have resulted from the sublimation of the precipitate at 120°, the present investigation does not indicate this to be a factor. At pH 3·7 and 3·9, although apparent recoveries are slightly low, the amount of gallium in the filtrates indicates that the precipitates must contain some coprecipitated reagent to make up their weight. At pH 4·1, when the weight deficiency of the precipitate agrees with the amount of gallium found in the filtrate, the precipitate weight is low in gallium by *ca.* 0·12 mg. The low recoveries, therefore, result from the incomplete precipitation of gallium. In consequence, neither the conventional nor the PFHS methods for gallium can be recommended for use.

Acknowledgment—The authors thank N. Haberman and S. R. Smith for preliminary work on the PFHS of indium, D. B. de Oliveira for initial studies on the PFHS of gallium, and R. J. Magee for the interpretation of the infrared spectra and for his interest generally. They also acknowledge the partial assistance of the United States Atomic Energy Commision under Contract AT(II-I)-582.

Zusammenfassung—Die Fällung von Indium und Gallium aus homogener Lösung mit 8-Acetoxychinolin wurde untersucht. Es wurde festgestellt, daß die Methode für beide Metalle nicht zu empfehlen ist, obwohl unter bestimmten, scharf kontrollierten Bedingungen Indium-8-hydroxychinolat quantitativ und stöchiometrisch ausfällt. Auch die konventionelle Fällung von Indium-8-hydroxychinolat gibt falsche Analysenergebnisse.

Résumé—On a étudié la précipitation de l'indium et du gallium en solution homogène au moyen de 8-acétoxyquinoline. On a établi que la méthode ne peut être recommandée pour le dosage de ces deux métaux, bien que, dans certaines conditions rigoureusement contrôlées, le 8-hydroxyquinolinate d'indium précipite quantitativement et stoechiométriquement. On a trouvé que la précipitation ordinaire du 8-hydroxyquinolinate d'indium donne aussi des résultats analytiques erronés.

PRECIPITATION OF INDIUM 8-HYDROXYQUINALDATE FROM HOMOGENEOUS SOLUTION

J. PAUL JONES, ORVILLE E. HILEMAN, JR. and LOUIS GORDON
Department of Chemistry, Case Institute of Technology
Cleveland 6, Ohio, U.S.A.

(*Received* 9 *December* 1963. *Accepted* 10 *February* 1964)

Summary—The precipitation of indium from homogeneous solution as the 8-hydroxyquinaldate, with 8-acetoxyquinaldine as a source reagent, provides a quantitative procedure, and a satisfactory separation from lead, calcium and magnesium.

INTRODUCTION

IN a previous investigation, Jones *et al.*[1] concluded that 8-hydroxyquinoline was not a satisfactory reagent for the determination of indium. The present investigation was therefore undertaken to study the precipitation of indium from homogeneous solution (PFHS) with 8-hydroxyquinaldine, using 8-acetoxyquinaldine[2,3] as the parent reagent.

EXPERIMENTAL

Reagents

Indium: Indium metal of high purity (Indium Corp. of America, Utica, New York) was dissolved in dilute hydrochloric acid.

8-*Acetoxyquinaldine:* PF/HS grade 8-acetoxyquinaldine (Burdick and Jackson Laboratories, 1953 S. Harvey St., Muskegon, Mich.).

All other chemicals used were reagent-grade.

Procedure

To 25–50 mg of a nearly neutral solution of indium, contained in a 250-ml beaker, add 2·0 g of sodium acetate; dilute to 180 ml and adjust the pH to 4·5 with filtered aqueous ammonia (1:1). Add 10 ml of an acetone solution containing 1·0 g of 8-acetoxyquinaldine (5 times the stoichiometric quantity of reagent needed to precipitate 37·5 mg of indium). Heat the solution at 80° for 2 hr, allow it to cool to room temperature, and filter through a medium-porosity filter, transferring and washing the precipitate with water at room temperature. Dry to constant weight at 130°, and weigh as $In(C_{10}H_8NO)_3$; the gravimetric factor for indium is 0·1948.

RESULTS AND DISCUSSION

Initial investigations showed that if 1·0 g of 8-acetoxyquinaldine were used, 25–75 mg of indium could be quantitatively precipitated in the pH range 4·3–4·7; when a smaller quantity of reagent, *i.e.*, 0·33 g, was used to precipitate 25 mg of indium, the filtrate was found consistently to contain about 0·3 mg of indium. Table I shows that gravimetric results, correct to within about 0·5%, can be obtained with 25–75 mg of indium. Coprecipitation of reagent probably accounts for the slightly high results. With 5- to 10-mg samples of indium there were significant losses of indium to the filtrates. Thermogravimetric analysis of the precipitate showed 130° to be a satisfactory drying temperature. Table I also shows that indium can be satisfactorily separated from lead, calcium and magnesium, but not from aluminium; when tartaric acid was used to complex aluminium, it apparently also complexed indium, thus leading to low results.

A brief investigation of the PFHS of gallium indicated that only after about half of the gallium can be precipitated as the 8-hydroxyquinaldate by the method described.[2]

POTENTIOMETRIC DETERMINATION OF VANADIUM AS SILVER ORTHOVANADATE

RAM SAHAI SAXENA and OM PRAKASH SHARMA
Department of Chemistry, Government College, Kota (Rajasthan), India.

(*Received* 2 *January* 1964. *Accepted* 30 *January* 1964)

Summary—A rapid and accurate electrometric method for the determination of vanadium as silver orthovanadate has been investigated. It consists in titrating sodium orthovanadate solution potentiometrically at pH 11·5 against standard $AgNO_3$, using a silver indicator electrode in conjunction with S.C.E., connected by a KNO_3 bridge. Either of the reagents may be used as titrant. A marked change in e.m.f. is observed at the end-point. corresponding to the precipitation of Ag_3VO_4 in the pH range 8–9. The curves have a regular form; a pronounced maximum in dE/dV occurs at the end-point; and the accuracy and reproducibility of the electrometric results has been found to be excellent even at low concentrations ($1 \times 10^{-3}M$) of the reactants. Potentiometric titration offers a simple, rapid and accurate method for the determination of vanadium as silver orthovanadate.

BROWNING and Palmer[1] and Moser and Brandl[2] have reported an accurate gravimetric method for determining vanadium as silver vanadate. No reference has been found in the literature regarding the determination of vanadium by electrometric methods other than polarographic ones. The present investigation involves a potentiometric study of the reaction between silver nitrate and sodium orthovanadate, and has been undertaken to investigate the process as a possible analytical method for the determination of vanadium.

EXPERIMENTAL

Merck guaranteed extrapure reagents, $AgNO_3$, V_2O_5 and NaOH, were used and their solutions prepared in air-free conductivity water.

Standard solutions of sodium orthovanadate were prepared by dissolving calculated amounts of V_2O_5 in a boiling solution of NaOH of the required strength.

The pH of the sodium orthovanadate solution thus obtained was measured by means of a glass electrode and found to be about 11·5. Different concentrations of $AgNO_3$ and Na_3VO_4 were taken and a series of potentiometric titrations was carried out both by the direct and the inverse method, *i.e.*, $AgNO_3$ solution being added from a microburette to the Na_3VO_4 solution in the electrode cell, and *vice versa*. Titrations were also performed in the presence of varying concentrations of ethanol. For precise and steady measurements of e.m.f., a platinum gauze electrode was used. This was electrolytically coated with silver at a low current density (a current strength of the order of 2–10 mA) in a bath of pure silver cyanide. It was dipped in the titre solution and used as an indicator electrode in conjunction with a standard calomel electrode. The connection between the calomel half cell and the titration vessel was made with saturated KNO_3 solution. The electrode cell was immersed in an electrically maintained thermostat at 40 ± 0·1°. The e.m.f. was measured on a Cambridge (null-deflection type) pH meter. The titration solution was continuously stirred by an electrically-driven stirrer. Curves were plotted of the E (obs.) *vs.* the volume of the titrant added in ml, and from the sharp jump in potential indicated by the titration curves the equivalence point was obtained. This was further checked by calculating the maximum value of dE/dV in each case. Twenty ml of the reagent were taken in the cell each time. (See Table I.) Two typical sets of curves are illustrated (Figs. 1 and 2).

DISCUSSION

An examination of the results reveals that the reaction between $AgNO_3$ and Na_3VO_4 can be successfully followed potentiometrically using silver as an indicator

electrode with either of the reactants used as the titrant. The end-point obtained from the max. dE/dV and deflection in titration curves occurs at a point where the molecular ratio $Ag^-:VO_4^{3-}$ is 3:1, corresponding to the formation of silver orthovanadate, Ag_3VO_4, at pH range 8–9. The compound has been found to be highly insoluble, and therefore suitable for precipitation. The titration curves are symmetrical on both sides of the stoichiometric end-point, which is marked by a sharp change in e.m.f. and the results are accurate and reproducible.

In the direct titration curves (Fig. 1), when Na_3VO_4 is being titrated, the e.m.f. gradually increases with the start of the reaction and a marked upward jump is obtained at the equivalence point, after which the potential assumes a constant value. In the case of inverse titrations, when the silver electrode is dipped in $AgNO_3$ solution, the e.m.f. assumes a steady value rapidly after each addition of the alkali vanadate solution, till at the stoichiometric end-point a sharp fall in potential is observed, after which the e.m.f. becomes almost constant. Continuous stirring in the vicinity of electrode has a favourable effect on the titrations. Each titration takes about half an hour for completion. The addition of ethanol has hardly any effect on the accuracy of the end-point or on the magnitude of the break in potential.

The present investigation confirms the formation and precipitation of Ag_3VO_4 in the pH range 8–9. The potentiometric method is much more convenient than the methods currently available. It is simple because it does not require costly chemicals or complicated apparatus or procedure. Furthermore, it has the advantages of great rapidity and excellent precision. The method can therefore be recommended for the quantitative determination of even low concentrations of vanadium.

Acknowledgement—One of us (O. P. S.) is thankful to the authorities of the Council of Scientific and Industrial Research, India, for the award of Junior Fellowship.

Résumé—On a étudié une méthode électrométrique rapide et précise de dosage du vanadium à l'état d'orthovanadate d'argent. Elle consiste en un titrage potentiométrique d'une solution d'orthovanadate de sodium à pH 11,5 au moyen d'une solution titrée de $AgNO_3$, en employant une électrode indicatrice d'argent, reliée à une électrode étalon par un pont de KNO_3. Chacun des deux réactifs peut être utilisé comme agent de titrage. On observe un changement net de la f.é.m. au point final, correspondant à la précipitation de Ag_3VO_4 à pH 8–9. Les courbes ont une forme régulière, il apparaît un maximum prononcé de dE/dV au point final, et la précision et la reproductibilité des résultats électrométriques se sont révélées satisfaisantes, même aux faibles concentrations ($1 \times 10^{-3}M$) des réactifs. Les titrages potentiométriques offrent une méthode simple, rapide et précise de dosage de vanadium à l'état d'orthovanadate d'argent.

Zusammenfassung—Eine schnelle und genaue elektrometrische Method zur Vanadinbestimmung als Silber-Orthovanadat wurde erforscht. Man titriert Natrium-Orthovanadatlösung bei pH 11,5 potentiometrisch gegen eingestelltes Silbernitrat unter Verwendung einer Silber-Indikatorelektrode, Als Vegleichselektrode ist mit einer Kaliumnitratbrücke eine gesättigte Kalomelektrode angeschlossen. Beide Reagentien konnen als Titrierlösung verwendet werden. Ein ausgeprägter Sprung der EMK wird am Endpunkt beobachtet, der der Fallung von Silberorthovanadat bei pH 8–9 entspricht, Die Kurven haben die normale Form, in der differenzierten Kurve tritt am Endpunkt ein ausgeprägtes Maximum auf und die elektrometrischen

Ergebnisse sind auch bei niedrigen Konzentrationen ($1 . 10^{-}M^{3}$) der Reaktanten sehr genau und reproduzierbar. Potentiometrische Titrationen bieten eine einfache, schnelle und genaue Methode zur quantitativen Vanadinbestimmung als Silberorthovanadat.

SEPARATION OF EUROPIUM$^{\text{III}}$ AND AMERICIUM$^{\text{III}}$ BY SOLVENT EXTRACTION OF THEIR METAL CHELATE COMPLEXES

TATSUYA SEKINE* and DAVID DYRSSEN†
Department of Inorganic Chemistry, Royal Institute of Technology,
Stockholm 70, Sweden

(*Received* 7 *January* 1964. *Accepted* 30 *January* 1964)

Summary—Separation of Eu^{3+} and Am^{3+} by solvent extraction has been studied. The distribution of chelate complexes of these metal ions between $0{\cdot}1M$ sodium perchlorate and chloroform or methylisobutylketone with nineteen chelating acids has been determined. Among these acids it was observed that some extract Eu^{3+} into the organic phase better than Am^{3+}, some extract Am^{3+} better, and some extract them equally well. The separation factor, $SF = D_{Eu}/D_{Am}$, was determined for twelve of these acids by the extraction of Eu^{3+} and Am^{3+} from $0{\cdot}1M$ (H,Na)ClO_4. The values of log SF are as follows: dibutylphosphate (DBP), $+1{\cdot}36$; dioctylphosphate (DOP), $+1{\cdot}15$; 1-phenyl-3-methyl-4-acetylpyrazolone-5, $+0{\cdot}54$; 2-thenoyltrifluoracetone (TTA), $+0{\cdot}48$; neocupferron, $+0{\cdot}24$; *N*-benzoylphenylhydroxylamine, $+0{\cdot}22$; *N*-2,4-dichlorobenzoylphenylhydroxylamine, $+0{\cdot}12$; β-isopropyltropolone (IPT), $-0{\cdot}01$; 1-hydroxy-2-naphthoic acid, $+0{\cdot}03$; 2-hydroxy-1-naphthoic acid, $+0{\cdot}01$; 3-hydroxy-2-naphthoic acid, $-0{\cdot}02$; 5,7-dichloroxine, $-0{\cdot}99$. From these results it follows that dialkylhydrogenphosphates and 5,7-dichloroxine are the most suitable chelating acids for the separation of Eu^{3+} and Am^{3+} by solvent extraction.

INTRODUCTION

THE separation of tervalent lanthanide and actinide ions is usually difficult because of the similarity of these ions. Their chemical properties have been studied extensively, and various types of separations such as the group separation of gross actinide ions from lanthanide ions or the separation of an individual ion from others in the same group have been investigated. Among many separation methods, anion exchange was reported[1] to be very effective for the gross separation of tervalent actinide from tervalent lanthanide ions when concentrated hydrochloric acid or thiocyanate solution was used as the aqueous medium to form adsorbable complex ions on the anion-exchange resin.

In the present laboratory extensive work has been carried out to find out the conditions for the separation of lanthanide and actinide ions by solvent extraction, and various metal extracting ligands, organic solvents and aqueous solution systems have been investigated for this purpose.

Dyrssen and Liem[2] studied the solvent extraction of Eu^{3+} and Am^{3+} by dibutylphosphate (DBP) in different organic solvents, and they reported that the extraction of Eu^{3+} and Am^{3+} with DBP is quite different in n-hexane, carbon tetrachloride, chloroform, isopropyl ether, hexone and hexol. They showed that the distribution ratio of the metal ions between the organic phase and $0{\cdot}1M$ nitric acid, log D_{Eu},

---

* Present address: Department of Chemistry, Tokyo College of Science, Japan.
† Present address: Department of Analytical Chemistry, University of Gothenburg, Sweden.

ranges between −2·60 (in hexane) to −3·34 (in hexol) with 0·1*M* DBP; and moreover, the separation factor, log *SF*(= log D_{Eu}/D_{Am}), ranges between 1·36 (in $CHCl_3$) to 0·33 (in hexol).

The present study was made to find the most effective extracting ligand for the separation of Eu^{3+} and Am^{3+}. To fix conditions we used 0·1*M* $(H,Na)ClO_4$ and $CHCl_3$ or hexone as organic solvents. The paper gives the experimental results for the distribution of metal chelate complexes of Eu^{3+} and Am^{3+} between the organic and the aqueous phase, and presents a short discussion on the separation of these two metal ions by solvent extraction of their chelate complexes. Short reports of our results have been presented earlier.[3,4]

RESULTS

Nineteen acids were investigated, and our experimental results show that different chelating acids (HA) give different separation factors.

In the present study, only the variation of the net distribution ratio of Eu^{3+} and Am^{3+} with the hydrogen ion concentration ($-\log [H^+]$) was determined. Even though no information on the hydrolysis of tracer concentrations of tervalent lanthanide or actinide elements is available, it may be concluded from studies at higher metal concentrations[5–7] that no hydrolysis occurs below pH 5-6. All experiments were therefore carried out at a pH below 5·5. The net distribution ratio, *D*, was determined between 0·01 and 100.

Assuming that the extraction of Eu^{3+} and Am^{3+} takes place by the following reaction:

$$M^{3+}(aq) + (3 + n)HA(org) \rightleftharpoons MA_3(HA)_n(org) + 3H^+(aq)$$

and that the distribution ratio is given by

$$D = [MA_3(HA)_n]_{org}/[M^{3+}]$$

we may express the extraction constant as follows:

$$K_{ex} = D[H^+]^3[HA]_{org}^{-(3+n)}$$

Since $[HA]_{org}$ is constant for each reagent (0·05*M* for dichloroxine and 0·1*M* for the other acids) we could not determine the composition of the extracted complexes.* Therefore $D[H^+]^3$ was calculated instead of K_{ex}.

The values of $D[H^+]^3$ for Eu^{3+} and Am^{3+} with twelve ligands are listed in Table I, together with the separation factors, the acid dissociation constants, and the distribution constants of the acids between chloroform or hexone and 0·1*M* $NaClO_4$.

Table II shows the results of the extraction with three ligands, which formed aqueous complexes to such an extent that the slope of the plots log *D versus* $-\log [H^+]$ was always less than 3. Table III shows the results for four ligands which showed too small extraction to determine the net distribution ratio *D*, or the separation factor *SF*, under the experimental conditions.

DISCUSSION

As shown in Table I, the separation of Am^{3+} and Eu^{3+} is most effective with the dialkylhydrogenphosphate, which extracts Eu^{3+} better than Am^{3+}, and with

---

* For 0·1*M* IPT in chloroform, for example, we observed that EuA_3HA is the main complex in the organic phase.

2-Thenoyltrifluoroacetone (TTA)	$CHCl_3$	6·23(4·43)[c]	1·81	+0·48	11·68	12·20
Neocupferron	$CHCl_3$	(≈ 3·7)[a]	(≈ 2·8)[a]	+0·24	8·90	9·14
N-Benzoylphenylhydroxylamine	$CHCl_3$	8·15	2·33	+0·22	14·39	14·61
N-2-4-Dichlorobenzoylphenylhydroxylamine	$CHCl_3$	(≈ 8)[a]	(≈ 3·3)[a]	+0·12	- 13·92	14·04
β-Isopropyltropolone (IPT)	$CHCl_3$	7·04	3·37	- 0·01	9·90	- 9·89
1-Hydroxy-2-naphthoic acid	hexone	d	d	+0·03	13·24	13·27
2-Hydroxy-1-naphthoic acid	hexone	d	d	+0·01	12·12	12·13
3-Hydroxy-2-naphthoic acid	hexone	d	d	0·02	12·27	12·25
5,7-Dichloroxine	$CHCl_3$	7·47	3·80	0·99	13·73	12·74

* The concentration of HA is 0·1M except for 5,7-dichloroxine (0·05M).

† The constants for DBP were taken from Dyrssen and Liem.[8]

[a] Estimated value.

[b] The value of $pK_a + \log(1 + K_d)$ was determined by Jensen[10] as 7·1 ± 0·1.

[c] Enol form.

[d] cf. the values for salycylic acid; $pK_{a1} = 2{\cdot}82$, $pK_{a2} = 13$ $\log K_D = 2{\cdot}51$.

5,7-dichloroxine, which extracts Am^{3+} better than Eu^{3+}. At present it would be difficult to draw any general conclusions about the influence of the chelating acid on the separation factor. It is also difficult to predict whether a chelating acid will form extractable complexes with the rather inert tervalent lanthanide and actinide ions.

However, some conclusions may be reached on the basis of our investigation. Thus, chelating acids with the same reacting groups seem to give separation factors close to each other. Examples of such groups are =POOH (in dialkylphosphates), —COCHC(OH)— (in acetylpyrazolone and TTA), —N(OH)NO and —N(OH)CO— (in cupferron, neocupferron and the benzoylhydroxylamines), —COOH (in the hydroxynaphthoic acids). The extraction is generally poor if the chelating acid is too weak, and a substitution which increases the acid strength of a reagent will usually improve the extraction properties. Thus, dichloroxine extracts better than oxine, TTA better than acetylacetone, and 2-hydroxy-1-naphthoic acid better than 1-naphthoic acid. The extraction may also be poor because of the formation of MA_n complexes in the aqueous phase if the hydrophobic part of the chelating acid is too small in relation to the hydrophilic groups; thus, neocupferron is better than cupferron, the 2-chloromethyl derivative of kojic acid better than kojic acid itself (2-hydroxymethyl) and naphthoic acid better than benzoic acid. In the case of DBP and DOP practically no MA_n complexes are formed in the aqueous phase, because the hydrophobic groups are large enough for both acids. The difference of $D[H^+]^3$ for the two acids is rather difficult to explain.

TABLE II.—EXTRACTION OF Eu^{3+} AND Am^{3+} WITH VARIOUS CHELATING ACIDS WHICH GAVE NO CONSTANT VALUES OF $D[H^+]^3$

Chelating acid	Separation	log *SF*
1-Nitroso-2-naphthol	$D_{Eu} \ll D_{Am}$	not constant
2-Hydroxyl-1,4-naphthoquinone	$D_{Eu} > D_{Am}$	$\approx +0{\cdot}4$
2-Chloromethyl-5-hydroxyl-γ-pyrone	$D_{Eu} < D_{Am}$	$\approx -0{\cdot}4$

TABLE III.—RESULTS WITH VARIOUS CHELATING ACIDS WHICH GAVE VERY POOR EXTRACTION

Chelating acid	Approximate tendency for separation
Isatin-β-oxime	$D_{Eu} < D_{Am}$
Kojic acid (2-hydroxymethyl-5-hydroxy-γ-pyrone)	$D_{Eu} \simeq D_{Am}$
2-Methyl-5-hydroxy-γ-pyrone	$D_{Eu} \simeq D_{Am}$
1-Naphthoic acid	$D_{Eu} \simeq D_{Am}$

The separation factor of these metal ions is sometimes also influenced by the organic solvent, perhaps because of the interaction between the solvent molecule and the metal chelate MA_3.

The addition of some water-soluble ligands (masking agents like citrate) to the aqueous phase may also shift the separation factor. If $SF > 0$, a complexing ligand with a larger stability constant for Am^{3+} should increase the separation factor. If $SF < 0$ (i.e., Am^{3+} is extracted better) the stability constant of the masking agent should be larger for Eu^{3+}. Otherwise, the separation gained by the extraction is decreased by the addition of the masking agent.

There have been some reports[12–14] on the extraction of various rare earth elements with some of the ligands in the present study. Figure 1 summarises the results with IPT and DBP.

From this work we suggest in Table IV a selection of extracting ligands for the separation of the combination of ions listed below.

TABLE IV.—SUITABLE EXTRACTING LIGANDS

Separation	Extracting ligand (in $CHCl_3$)
Am^{3+} from Eu^{3+}	DOP(Eu^{3+} in the organic phase) or 5,7-dichloroxine (Am^{3+} in the organic phase)
Am^{3+} from $La^{3+} - Sm^{3+}$	5,7-dichloroxine (Am^{3+} in the organic phase) or IPT (Am^{3+} in the organic phase)
Am^{3+} from Gd^{3+}—Lu^{3+}	DOP(Gd—Lu in the organic phase).

EXPERIMENTAL

Tracers

Tracer amounts of β,γ-active $^{152}Eu + {}^{154}Eu$ and α,γ-active ^{241}Am were obtained from Harwell, England. The tracers were dissolved in 0·1*M* $HClO_4$ to prepare the stock solution. The experiments were carried out one year after the preparation and so, even if there were some short-lived radioactive impurities in the radioactive samples, they should have decayed.

Reagents

All reagents used in this study were of analytical grade. Chloroform was shaken three times with the same amount of water to remove alcohol in it. Sodium perchlorate was prepared from Na_2CO_3 and $HClO_4$ and was twice recrystallised. Dioctylphosphate was washed with dilute NaOH and 0·1*M* $HClO_4$. Other reagents were used without further purification.

Procedures

All experiments in this study were carried out in a thermostatted room at 25°. The initial volumes of the organic and the aqueous phase were each 10·0 ml. The ionic strength of the aqueous phase was always kept as 0·1*M* with 0·1*M* $NaClO_4$ and 0·1*M* $HClO_4$. The aqueous phase was prepared as follows: 0·1 ml of Eu and Am mixed tracer solution in 0·1*M* $HClO_4$, 1·0 ml of Y^{3+} carrier solution ($10^{-4}M$ Y^{3+}) in 0·01*M* $HClO_4$ + 0·09*M* $NaClO_4$ and 2·0 ml of buffer solution (0·05*M* solution of sulphanilic acid or pyridine in 0·1*M* $NaClO_4$) were added in 40-ml stoppered glass tubes. The hydrogen ion concentration of the solution was adjusted by the addition of various amount of 0·1*M* $HClO_4$ or NaOH solution into the bottles and, finally, 0·1*M* $NaClO_4$ solution was added until the volume became 10·0 ml. The organic solutions of the chelating acids were left standing overnight after the dissolution to ensure that the system was in an equilibrium state before the experiments were started. Ten ml of organic solution thus prepared were added to the aqueous solution in the bottles. The tracers were always added in the aqueous phase.

The bottles were then placed in a machine with a rotating framework, and agitation was continued until extraction equilibrium was achieved (usually, 1 hr was sufficient). In some cases, for example 1-nitroso-2-naphthol in $CHCl_3$, the system was shaken by hand for about 3 min to avoid any effects of the decomposition of the organic substance. The results for two systems which had been agitated for different intervals were always compared to check if the extraction equilibrium had been reached.

The whole system was then centrifuged, and some portion of both phases were taken to measure the radioactivities, which was done as follows: 0·2 ml of the organic phase (except for dioctylphosphate) was transferred to a stainless steel dish (2 cm in diameter). The dish was first placed under an infrared lamp to evaporate the solvent ($CHCl_3$ or hexone) gradually, and then it was placed on a hot plate at 250°. To the residue thus obtained in the dish was added a small amount of concentrated nitric acid, and it was heated on the hot plate again to complete the decomposition of the organic substance. When the organic phase contained dioctylphosphate, it was shaken with the same amount of nitric acid to back-extract the metal ion into the acid, and 0·2 ml of this nitric acid solution was transferred to the stainless steel dish and heated on the hot plate. Two ml of the aqueous phase [0·1*M* $(H,Na)ClO_4$] were transferred into another stoppered glass tube, and a small amount of ammonia was added to make the pH high enough for the extraction with β-isopropyltropolone (IPT). IPT-chloroform solution was then added, and the metal ions were extracted into the aqueous phase, agitating by hand. The organic phase thus obtained was treated as above to get samples for the radioactivity measurements.

To measure the hydrogen ion concentration, 5 ml of the aqueous phase were transferred to a small plastic vessel. The hydrogen ion concentration ($-\log[H^+]$) was measured potentiometrically using 0·0100*M* $HClO_4$ and 0·090*M* $NaClO_4$ mixture solution as the standard of $\log[H^+] = -2·00$ but when $-\log[H^+]$ was lower than 2, $[H^+]$ was calculated from the known composition of the aqueous phase.

The radioactivities of the sample in the dish (α-activity of ^{241}Am and β-activity of $^{152}Eu + ^{154}Eu$) were measured as follows: the sample on the stainless steel dish was placed in a gas-flow type proportional counter (Tracerlab SC-16). The α-activity was first measured in the proportional region (where 10^6 dpm of β-activity gives less than one cpm). Then the β-activity was measured in the Geiger region applying an aluminium foil (6 mg per cm^2) to absorb the α-particles and to count only the β-activity. The background from ^{241}Am (which may result from γ-rays), was corrected from the values obtained from samples which contained only ^{241}Am under the same experimental conditions.

Acknowledgements—We wish to thank the head of the department, Professor Lars Gunnar Sillén, for valuable discussion. The work has been supported by the Swedish Council for Atomic Research.

Zusammenfassung—Die Trennung von Europium(III) und Americium(III) durch flüssig-flüssig-Extraktion wurde untersuckt. Die Verteilung der Chelate dieser Ionen zwischen 0,1 m Natriumperchlorat und Chloroform oder Methylisobutylketon wurde mit 19 chelatbildenden, Säuren geprüft, Unter diesen Säuren extrahieren einige Eu^{3+} besser in die organische Phase als Am^{3+}, einige Am^{3+} besser als Eu^{3+}, weider andere extrahieren beide in gleichem Maße. Der Trennfaktor SF = D_{Eu}/D_{Am} wurde für 12 Säuren durch Extraktion von Eu^{3+} und Am^{3+} aus 0.1 m $(H, Na)ClO_4$ ermittelt. Die Werte von log SF sind folgende: Dibutylphosphat (DBP) +1,36, Dioctylphosphat (DOP) +1,15, 1-Phenyl-3-methyl-4-acetylpyrazolon-5 +0,54, 2-Thenoyltrifluoraceton (TTA) +0,48, Neocupferron +0,24, N-Benzoylphenylhydroxylamin +0,22, N-2,4-dichlorbenzoyl-phenylhydroxylamin +0,12, β-Isopropyltropolon (IPT) −0,01, 1-Hydroxy-2-naphthoesäure +0,03, 2-Hydroxy-1-naphthoesäure +0,01, 3-Hydroxy-2-naphthoesäure −0,02, 5,7-Dichloroxin −0,99. Hieraus folgt, daß Dialkylhydrogenphosphate und 5,7-Dichloroxin die besten Chelatbildner zur Trennung von Eu^{3+} und Am^{3+} durch flüssig-flüssig-Extraktion darstellen.

Résumé—On a étudié la séparation de Eu^{3+} et Am^{3+} par extraction aux solvants. On a déterminé la distribution des complexes chélatés de ces ions métalliques entre le perchlorate de sodium 0,1 M et le chloroforme ou la méthylisobutylcétone avec dix neuf acides chélatants. On a observé que, parmi ces acides, certains extraient mieux Eu^{3+} que Am^{3+} dans la phase organique, certains extraient mieux Am^{3+}, et d'autres extraient également ces deux ions. Le facteur de séparation, $SF = D_{Eu}/D_{Am}$, a été déterminé pour 12 de ces acides, par extraction de Eu^{3+} et Am^{3+} à partir de (H,Na) ClO_4 0,1 M. Les valeurs de log SF sont les suivantes: dibutylphosphate (DBP) +1,36; dioctylphosphate (DOP) +1,15; 1-phényl-3-méthyl-4-acétylpyrazolone-5 +0,54; 2-thénoyltrifluoracétone (TTA) +0,48; néocupferron +0,24; N-benzoylphénylhydroxylamine +0,22; N-2,4-dichlorobenzoylphénylhydroxylamine +0,12; β-isopropyltropolone (IPT) −0,01; acide 1-hydroxy-2-naphthoïque +0,03; acide 2-hydroxy-1-naphtoïque +0,01; acide 3-hydroxy-2-naphtoïque −0,02; 5,7-dichloroxine −0,99. De ces résultats, il découle que les dialkylhydrogènephosphates et la 5,7-dichloroxine sont les acides chélatants les plus convenables pour la séparation de Eu^{3+} et Am^{3+} par extraction aux solvants.

THEORETICAL CONSIDERATIONS ON THE INDIRECT DETERMINATION OF ANIONS

DETERMINATION OF SULPHATE WITH BARIUM CHLORANILATE

J. AGTERDENBOS and N. MARTINIUS
Analytisch Chemisch Laboratorium der Rijksuniversiteit Utrecht, Netherlands

(*Received* 15 *July* 1963. *Accepted* 5 *February* 1964)

Summary—Some anions (sulphate) may be determined by their reaction with a slightly dissociated or slightly soluble compound (barium chloranilate), another anion (chloranilate ion) being liberated and its extinction measured. An equation is given in this paper for the relationship between the concentration of sulphate and the extinction. For low concentrations the equation is non-linear. A calibration curve, prepared under standardised conditions, agrees well with theory. It shows a precision of about 5% at 20 μg of sulphate. At higher levels the precision is slightly better. It is proved that many interferences of foreign ions may be explained quantitatively by consideration of the activity coefficients. The scope of this method is discussed.

INTRODUCTION

FOR the quantitative determination of anions with organic reagents, indirect methods often have to be used. Many of them are based on reactions of the following type (charges have been omitted for simplicity):

$$M_pC_q + rA \rightarrow M_pA_r + qC$$

where A is the anion to be determined. C may represent any anion which can be easily determined, for example, by spectrophotometry. M_pC_q and M_pA_r are slightly soluble or slightly dissociated compounds. Several applications[1-9] of this principle have been described for the case when C represents the bivalent anion of $C_6H_2Cl_2O_4$ (H_2C), 2,5-dichloro-3,6-dihydroxybenzoquinone (chloranilic acid). In this paper the use of salts of this reagent will be discussed, but similar results may be expected for some other reagents.

The dissociation constants of H_2C are given by Schwarzenbach and Suter:[10] $pK_1 = 0{\cdot}85$ and $pK_2 = 3{\cdot}18$. Other authors give slightly different values.[11,12] The differences may arise from differences in ionic strength. The anion C is violet and has a strong absorption at 332 mμ; ε is about $27{\cdot}5 \times 10^3$ litre. mol^{-1} . cm^{-1}. Salts of the acid have been used for the determination of sulphate, [1,3,4,6,8] fluoride,[5,7] chloride,[2,3] phosphate[13] and other ions.

It seems to be generally assumed that a linear relationship exists between the concentration of A and the extinction E. In the first part of the present paper a more exact relationship between these quantities is given for the case when $p = q = r = 1$ and MC and MA are slightly soluble salts. In the second part of the paper the interference by foreign compounds (sodium chloride, potassium nitrate), not reacting *chemically* with M, C and A, is calculated from activity considerations. In the third part some results are given of experiments in which $M = Ba^{2+}$ and $A = SO_4^{2-}$, *i.e.*, in the case of the determination of sulphate with barium chloranilate.

THEORETICAL DISCUSSION

Relationship between extinction and unknown concentration

The symbol $[X]_i$ is used for the moles of component X, present in phase i, not calculated for 1 litre of solution but for 1 litre of the complete system: solid compounds (MA and MC) plus liquid. This notation simplifies the calculations, because the difference between total volume and volume of the liquid alone is neglected. The difference is so small, however, that the error made may certainly be neglected. The index t indicates the total amount of a substance present.

Furthermore, it should be noted that s_1 and s_2 have been defined in equations (6) and (8) as the products of the ionic concentrations, not of the ionic activities. The influence of this difference will be discussed in the section on the causes of error.

We define:

$$x = [C]_{sol} + [HC]_{sol} + [H_2C]_{sol} \tag{1}$$

$$y = [A]_{sol} + [HA]_{sol} + [H_2A]_{sol} + [A]_{MA} \tag{2}$$

$$A' = [A]_{sol} + [HA]_{sol} + [H_2A]_{sol} \tag{3}$$

$$\alpha = \frac{[C]_{sol}}{x} \tag{4}$$

$$\beta = \frac{[A]_{sol}}{A'} \tag{5}$$

s_1 and s_2 are the "solubility products" of MC and MA, respectively, ε is the molar extinction coefficient of C, and d is the path length of the light in the spectrophotometer cell.

From these definitions we see that, if no A is added and there is only a saturated solution of MC:

$$[M]_{sol} \cdot [C]_{sol} = s_1 \tag{6}$$

and because $x = [M]_{sol}$, substitution of equation (4) gives $\alpha x^2 = s_1$ and

$$x = \sqrt{\frac{s_1}{\alpha}} \tag{7}$$

If so much A is added that the solution is saturated with respect to MA, but no solid MA is formed, it is seen from

$$[M]_{sol} \cdot [A]_{sol} = s_2 \tag{8}$$

that

$$[A]_{sol} = \frac{s_2}{[M]_{sol}} .$$

Combination with equations (2), (4), (5), (6) and (7) gives:

$$y = \frac{s_2}{\beta} \cdot \sqrt{\frac{\alpha}{s_1}} \tag{9}$$

This value gives the amount of y which is at least necessary to give an extinction larger than the blank.

If solid MC and MA are both present, equations (10)–(14) are valid:

$$[C]_t = x + [C]_{MC} \qquad (10)$$

$$[M]_t = [M]_{sol} + [M]_{MC} + [M]_{MA} \qquad (11)$$

$$[M]_{MC} = [C]_{MC} \qquad (12)$$

$$[A]_{MA} = [M]_{MA} \qquad (13)$$

$$[M]_t = [C]_t \qquad (14)$$

Substitution of equations (10) and (11) in (12) and subtraction of (14) gives:

$$x = [M]_{sol} + [M]_{MA} \qquad (15)$$

From equations (2), (3), (5) and (13) we find:

$$[M]_{MA} = y - \frac{[A]_{sol}}{\beta} \qquad (16)$$

and from (4), (6), (8) and (16):

$$[M]_{MA} = y - \frac{s_2}{s_1} \cdot \frac{\alpha}{\beta} \cdot x \qquad (17)$$

From equations (4), (6) and (15) we see:

$$[M]_{MA} = x - \frac{s_1}{\alpha x} \qquad (18)$$

Combination of (17) and (18) gives:

$$x = y - \frac{s_2}{s_1} \cdot \frac{\alpha}{\beta} \cdot x + \frac{s_1}{x\alpha} \qquad (19)$$

After rearrangements we find the quadratic equation:

$$x^2 \left\{1 + \frac{s_2}{s_1} \cdot \frac{\alpha}{\beta}\right\} - yx - \frac{s_1}{\alpha} = 0 \qquad (20)$$

Solution of this equation gives:

$$x = \frac{y + \sqrt{y^2 + \dfrac{4 \cdot s_1}{\alpha} + \dfrac{4 \cdot s_2}{\beta}}}{2 + 2 \cdot \dfrac{s_2}{s_1} \cdot \dfrac{\alpha}{\beta}} \qquad (21)$$

For many practical cases $\frac{s_2}{\beta} \ll \frac{s_1}{\alpha}$, *i.e.*, the apparent (conditional) solubility constant of MA is much smaller than that of MC. Therefore in those cases equation (21) simplifies to:

$$x = \frac{y + \sqrt{y^2 + \dfrac{4 \cdot s_1}{\alpha}}}{2} \qquad (22)$$

The extinction measured, however, is caused by one of C, HC or H_2C, and not by their sum x. Therefore, the relation between x and this specimen should be used. In this paper the extinction of C is measured, and equation (4) gives the relation required.

From Beer's law:

$$E = \varepsilon \, . \, c \, . \, d. \tag{23}$$

and from equations (4) and (22) it now follows that

$$E = \frac{\varepsilon \, . \, d \, . \, \alpha}{2} \left(y + \sqrt{y^2 + \frac{4 \, . \, s_1}{\alpha}} \right) \tag{24}$$

where E is written for the extinction from C. We assume that the contribution of HC and H_2C to the extinction may be neglected.

It is necessary at this point to stress the fact that the values of α and s_1 may vary with the experimental conditions. The variation of α is caused especially by the pH and also by the dissociation constants, which vary with the composition (including ionic strength) of the solution. The variation of s_1 is caused especially by the composition of the solution. For these reasons the indices b and s are used below, b indicating the blank and the calibration solution, which generally will have the same over-all composition, and s indicating the sample solution.

In this way we find for the difference between the extinction of the sample solution and the blank, the value

$$\Delta E_s = \frac{\varepsilon \, . \, d \, . \, \alpha_s}{2} \left(y + \sqrt{y^2 + \frac{4 s_{1,s}}{\alpha_s}} \right) - \frac{\varepsilon \, . \, d \, . \, \alpha_b}{2} \sqrt{\frac{4 s_{1,b}}{\alpha_b}} \tag{25}$$

The difference between the extinction of the calibration solution and the blank solution is given by:

$$\Delta E_b = \frac{\varepsilon \, . \, d \, . \, \alpha_b}{2} \left(y + \sqrt{y^2 + \frac{4 s_{1,b}}{\alpha_b}} \right) - \frac{\varepsilon \, . \, d \, . \, \alpha_b}{2} \sqrt{\frac{4 s_{1,b}}{\alpha_b}} \tag{26}$$

The equations are simplified if $\alpha_s = \alpha_b = 1$.
This was the case in our experiments. The relative error:

$$F = \frac{\Delta E_s - \Delta E_b}{\Delta E_s}$$

is now given by:

$$F = \frac{\sqrt{y^2 + 4 s_{1,s}} - \sqrt{y^2 + 4 s_{1,b}}}{y + \sqrt{y^2 + 4 s_{1,s}}} \tag{27}$$

Causes of error

The main causes of error are:

(a) Errors caused by foreign compounds reacting chemically with one of the components of the solutions or absorbing at the wavelength used. They are not discussed in this paper.

(b) Photometric errors. They are discussed briefly in the discussion on the scope of the method

(c) Errors caused by different conditions and compositions in calibration and sample solutions. They are discussed below.

Errors from different conditions. It is clear that α is a function of the dissociation constants and of the pH. In the case when H_2C is chloranilic acid, with $pK_1 = 0{\cdot}85$ and $pK_2 = 3{\cdot}18$, a pH above about 5 is necessary to ensure that small differences in pH do not give large differences in α. Regarding β, a lower pH value may be used if $A = SO_4^{2-}$. In non-aqueous media the calculation of the desirable pH region is complicated by the fact that K values are not generally known in those media, and that pH values measured in the conventional way may be seriously in error because the diffusion potential between reference electrode and sample solution is often unknown. Fortunately, it is possible to find conditions, which have not to be kept rigorously constant, without danger for changes in α and β.

More serious, however, is the variation of s_1 with the experimental conditions. This is now treated in some detail.

If the symbol s is used for the product of *ionic concentrations* in the saturated solution, a for activities, c for concentrations, f for activity coefficients and ω for ionic strength, we see that

$$s_\omega = c_C \, . \, c_M = \frac{a_C \, . \, a_M}{f_C \, . \, f_M} \tag{28}$$

It should be noted that for calculations of ω, concentrations have to be expressed in moles/kg of solvent and not moles/litre of solution.
Now

$$s_{\omega=0} = a_C \, . \, a_M \tag{29}$$

and combination of equations (28) and (29) gives:

$$s_\omega = s_{\omega=0} \cdot \frac{1}{f_C \, . \, f_M} \tag{30}$$

The values of f_C and f_M are approximately equal if both ions have the same charge. Writing $f = f_C = f_M$, we find:

$$s_\omega = s_{\omega=0} \cdot \frac{1}{f^2} \tag{31}$$

The values of f are found approximately from:[14]

$$-\log f = \frac{z^2 A \sqrt{\omega}}{1 + \delta b \sqrt{\omega}} \tag{32}$$

In this equation b is the ionic radius of M^{2+} and C^{2-}; z is their charge. The values of A and δ depend on factors of which only the dielectric constant of the medium is important to us. The exact value of b is not known, but at low values of ω, $\delta b \sqrt{\omega} \ll 1$, and therefore the exact value is not very important. We used $b = 5 \times 10^{-8}$. Values of A and δ were calculated for some cases of practical importance: (1) water, (2) water-ethanol mixture containing 50 ml of 95·5% ethanol in a 100-ml total volume (*i.e.*, 43% ethanol), and (3) the same but 75 ml of 95·5% ethanol in 100 ml (*i.e.*, 69% ethanol). For water $D = 80$, and for the mixtures $D = 54$ and 40, respectively.[15] Inserting these values and $z = 2$ or -2 in the formulae for A and δ found in the literature,[14] we find:

for water:
$$-\log f = \frac{2{\cdot}00 \sqrt{\omega}}{1 + 1{\cdot}64\sqrt{\omega}} \tag{33a}$$

for 43% ethanol:
$$-\log f = \frac{3{\cdot}65 \sqrt{\omega}}{1 + 2{\cdot}00\sqrt{\omega}} \tag{33b}$$

for 69% ethanol:
$$-\log f = \frac{5{\cdot}65 \sqrt{\omega}}{1 + 2{\cdot}34\sqrt{\omega}} \tag{33c}$$

Table I gives some values of f for various values of ω. It is clear that for low values of ω, the value of f is chiefly determined by the numerator. Therefore about the same value of f is found in water and in 69% ethanol if $(2{\cdot}00\sqrt{\omega})_{\text{water}} = (5{\cdot}65\sqrt{\omega})_{69\%\ \text{ethanol}}$, *i.e.*, the ionic strength in water may be eight times as high as in the mixture to give the same effect. From this we may conclude that in this respect water is a more favourable solvent than the mixtures.

More generally, the relative influence of ionic strength in various media may be approximated by the fact that A is proportional to $D^{3/2}$.

TABLE I.—VALUES OF f FOR BIVALENT IONS

Ionic strength (ω)	Activity coefficient (f)		
	Water	43% Ethanol	69% Ethanol
10^{-5}	0·986	0·974	0·960
$1{\cdot}1 \times 10^{-5}$	0·985	0·973	0·958
10^{-4}	0·956	0·921	0·881
$1{\cdot}1 \times 10^{-4}$	0·954	0·917	0·875
10^{-3}	0·871	0·779	0·682
$1{\cdot}1 \times 10^{-3}$	0·865	0·770	0·670
10^{-2}	0·673	0·496	0·348
$1{\cdot}1 \times 10^{-2}$	0·662	0·482	0·334
10^{-1}	0·383	0·196	0·094
$1{\cdot}1 \times 10^{-1}$	0·371	0·187	0·088

CONCLUSIONS FROM THEORETICAL DISCUSSION

Calibration curve

A calibration curve was calculated from equation (26). The values used were $y = 10^{-6}$ to 3×10^{-5}, $s_1 = 6 \times 10^{-11}$, $\varepsilon = 27{\cdot}5 \times 10^3$, $d = 4$ and $\alpha = \beta = 1$. In Table II the results are given and compared with those obtained, assuming every ion of A^{2-} liberates one ion of C^{2-}. The table shows that the extinction values, calculated in the first way, are much lower, and that the deviation from linearity is large.

TABLE II.—RELATIONSHIP BETWEEN SULPHATE CONCENTRATION (y) AND EXTINCTION (E)

y	E^a	E^b
10^{-6}	0·055	0·110
3×10^{-6}	0·180	0·330
10^{-5}	0·710	1·10
3×10^{-5}	2·65	3·30

[a] Calculated from equation (26).
[b] Assuming 1 SO_4^{2-} gives 1 C^{2-}.

Consequences of variation of s_1 with ω

The error F was calculated from equation (27) for the case when $\omega = 0{\cdot}01$, both in blank and calibration solution, and $\omega = 0{\cdot}011$, $0{\cdot}013$ and $0{\cdot}020$ in the sample solution (69% ethanol). It was found from experiments that when $\omega = 0{\cdot}01$, $s_1 = 6 \times 10^{-11}$. From this value and equations (31) and (33c) the values $6{\cdot}5 \times 10^{-11}$, $7{\cdot}6 \times 10^{-11}$ and $11{\cdot}9 \times 10^{-11}$ were calculated for the solubility product at $\omega = 0{\cdot}011$, 0·013 and 0·020. Table III shows that at $\omega = 0{\cdot}01$, the ionic strength of the sample solution should not differ more than about 10 or 20% from the ionic strength of the blank and calibration solutions.

TABLE III.—ERROR (F) RESULTING FROM A DIFFERENCE IN IONIC STRENGTH (ω) BETWEEN BLANK AND SAMPLE SOLUTION AT VARIOUS SULPHATE CONCENTRATIONS (y)

y	ω_b	ω_s	F, %
10^{-6}	0·010	0·011	4
10^{-6}	0·010	0·013	11
10^{-6}	0·010	0·020	28
3×10^{-6}	0·010	0·011	3
3×10^{-6}	0·010	0·013	9
3×10^{-6}	0·010	0·020	25
10^{-5}	0·010	0·011	2
10^{-5}	0·010	0·013	6
10^{-5}	0·010	0·020	16

EXPERIMENTAL

Barium chloranilate was prepared by slowly adding, at room temperature, with stirring, a slight excess of H_2C in 4 litres of water to 250 ml of 0·04*M* barium chloride solution. A fine purple precipitate is formed. After standing overnight the liquid is decanted, and the BaC is filtered by suction through a porcelain filter. After washing with ethanol and ether, the product is dried at 100°. Some water is retained unless the product is dried for some considerable time. A less satisfactory brown product was obtained when the directions of Bertolacini and Barney[1] were followed, *i.e.* when a large excess of barium chloride was added to the H_2C solution.

For preparation of the calibration curve, the sample, containing very little free hydrogen ion, is transferred to a 100-ml calibrated flask. Five ml of 10% urotropine solution, 10 ml of 0·1*M* sodium chloride solution and 75 ml of 95·5% ethanol are added exactly, followed by water to just below the calibration mark. This causes a rise in temperature of about 5°. The flask is placed in a thermostat bath at 20° for 10 min, the volume adjusted with water, 50 mg of BaC added and the flask again placed in the thermostat bath for at least 1 hr with occasional shaking. The suspension is filtered through a G4 filter (Fig. 1) by application of gentle pressure. Part of the filtrate is collected in a spectrophotometer cell and sucked from it with a polythene tube. This filling and suction procedure is repeated twice. In this way the cell is cleaned and filled with the required solution without risk that any liquid touches the outside of the walls, and that change of the absorption results from complete purification of the walls. The blank and calibration solution were measured in the same cells. As reference an approximately 10^{-4}*M* potassium dichromate solution in 0·02*M* sulphuric acid was used.

RESULTS

Some extinction measurements were made of aqueous solutions of chloranilic acid at various pH. The results at pH 3–9 agreed with the values of pK_2 given in the literature and gave a value of 28×10^3 for ε. At pH <3 the extinction was slightly higher than expected, probably because of the extinction of H_2C or HC^-. The difference was so small, however, that no interference from H_2C and HC^- may be expected at the pH used for the measurements.

In 69% ethanol the value for ε was $27{\cdot}5 \times 10^3$. No measurement of the dissociation constant was made in this solvent, for the reason given above, but it was found that at an apparent pH of 6–6·5 (measured with the glass electrode), prepared with urotropine, small changes in pH did not influence the results. The solubility product of BaC was calculated from measurements of C^{2-} with the assumption that BaC is completely dissociated.

In 69% ethanol in 0·01*M* (0·0115 molal) solution of sodium chloride the value

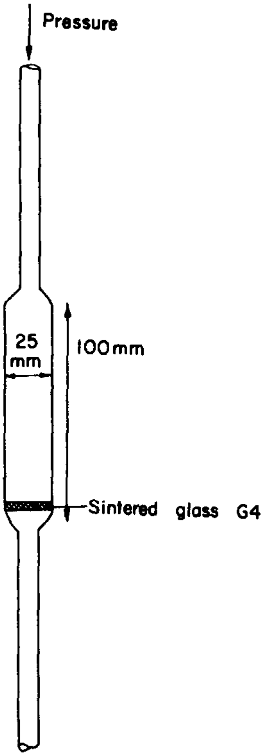

FIG. 1.—Filtration apparatus.

found was $s_1 = 6 \times 10^{-11}$. In 43% ethanol and $\omega = 0{\cdot}01$ the value was about 16×10^{-10} (20°). The large difference of these values makes it necessary for the ethanol concentration to be controlled rigorously.

The validity of equations (31) and (33c) was tested by measuring the extinction of saturated solutions of BaC to which different monovalent salts were added. The agreement of the results with theory is good (Table IV). Some experiments showed that slightly different results were found if sodium chloride was replaced by potassium nitrate in the same concentrations (the values in the presence of potassium nitrate were corrected for nitrate extinction, $\varepsilon = 0{\cdot}6$). This proves that not only the ionic strength but also the type of ion present influences the results.

A calibration curve was prepared for quantities of sulphate ranging from 18 to 108 μg in 69% ethanol and $\omega = 0{\cdot}0115$ in sodium chloride. The agreement with the theoretical curve is satisfactory. For s_2 the value 3×10^{-16} was used. It has been calculated from the value 4×10^{-17}, found by interpolation from the data given in the literature[16] and correction of this value for $\omega = 0{\cdot}0115$. The agreement with theory is very bad if it is assumed that one C^{2-} is liberated for each SO_4^{2-} added. (Fig. 2). In later experiments the curve was extended up to 400 μg of sulphate. The theoretical curve was also followed closely in this region.

For large values of y the difference between both curves corresponds to a difference in concentration of $\sqrt{s_1} = 7{\cdot}7 \times 10^{-6}$ moles/litre, *i.e.*, with 74 μg of sulphate/100 ml.

TABLE IV.—RELATIONSHIP BETWEEN IONIC STRENGTH AND EXTINCTION OF SOLUTIONS OF BARIUM CHLORANILATE IN 69% ETHANOL

Ionic strength	Salt	Extinction	
		Calculated	Found
$1·71 \times 10^{-4}$	NaCl	0·086	0·075
$3·42 \times 10^{-4}$	NaCl	0·095	0·088
$8·55 \times 10^{-4}$	NaCl	0·106	0·096
$1·71 \times 10^{-3}$	NaCl	0·122	0·108
$5·88 \times 10^{-3}$	$NaNO_3$	0·177	0·174
$8·55 \times 10^{-3}$	NaCl	0·203	0·220
$1·22 \times 10^{-2}$	$NaNO_3$	0·242	0·267
$1·72 \times 10^{-2}$	$NaNO_3$	0·280	0·339
$2·57 \times 10^{-2}$	NaCl	0·358	0·395

Therefore, a calibration curve constructed for high sulphate concentrations extrapolated to low sulphate concentrations suggests zero extinction for 47 μg of sulphate/100 ml.

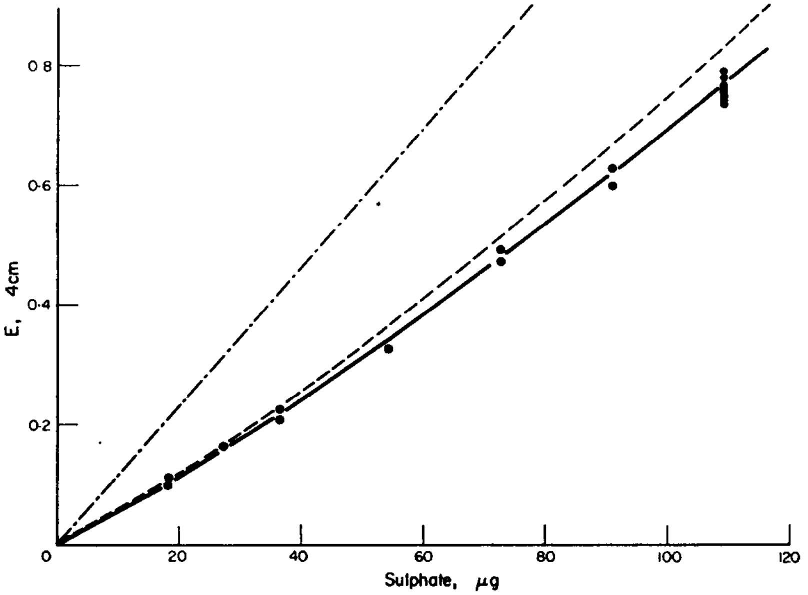

FIG. 2.—Calibration curve at 332 mμ in 100 ml of final solution (69% ethanol):
—— experimental,
– – – calculated from equation (26),
— · — · calculated by assuming 1 SO_4^{2-} gives 1 C^{2-}.

SCOPE OF METHOD

The sensitivity of a colorimetric method may be limited by two factors: chemical and instrumental. The latter factor is caused by the fact that at low extinction readings the percentage error is greatly increased. Assuming the Ringbom curve to be valid and accepting a value of 0·2% for the standard deviation in the transmission measurements, the percentage error in E from the instrument is 1% at E = 0·10, 2% at E = 0·05, 4·5% at E = 0·02 and 9% at E = 0·01.

The chemical error probably arises largely from the uncertainty in the blank (salt concentration).

The total error is found by quadratic addition of both errors. In the present example it seems that the instrumental error is of minor importance, but if the chemical error is reduced, the instrumental one may become the limiting factor.

One way to achieve this reduction seems to be a decrease in the value of the blank itself, which, probably, will give improvement in the reproducibility. In our experiments this was performed by the addition of ethanol, but the blank remained too large.

A disadvantage, however, of this change in the procedure will be that with constant sample volume the final volume will be increased considerably.

In any case, it is necessary that the ionic composition is controlled between narrow limits. It seems, therefore, that the practical application of the procedure will be limited to those problems in which good control of the ionic composition of the sample is possible.

The chloranilic acid method has also been used with other metal salts of the same anion. In some cases the solubility is less and it is an important consequence that it makes the control of the ionic composition less stringent. For the solubility product of the lead salt in 69% ethanol we found $2{\cdot}5 \times 10^{-12}$. Unfortunately, however, the solubility of lead sulphate in this medium is too large to make this favourable aspect useful for the determination of sulphate. Similar unfavourable results were obtained with 50% dioxan and 50% methylcellosolve solutions.

This consequence that a less soluble product (or a stronger complex) is required, may be a disadvantage of the use of a less soluble metal chloranilate.

Another possibility for increasing the sensitivity seems to be the replacement of the chloranilate ion by another ion giving less soluble salts. The value of ε, though theoretically limited,[17] may also be higher than in our case.

Zusammenfassung—Die Bestimmung von einigen Anionen (z.B. das Sulfat) kann durchgeführt werden durch die Reaktion mit einer wenig dissozierte oder wenig lösliche Verbindung (z.B. Bariumchloranilat). Von dieser Reaktion wird ein anderes Anion (z.B. Chloranilation) freigesetzt, dessen Extinktion gemessen wird. In dieser Arbeit ist eine Gleichung abgeleitet worden für die Beziehung zwischen der Sulfatkonzentration und der Extinktion. Für niedrige Konzentrationen ist die Beziehung nicht linear. Eine Eichkurve wurde hergestellt und zeigte gute Übereinstimmung mit der Theorie. Die Genauigkeit war ungefähr 5% bei 20 μg Sulfat, etwas besser bei grösseren Mengen. Es wird nachgewiesen dass viele Störungen erklärt werden können durch Berücksichtiging der Aktivitätskoeffizient. Die Möglichkeiten dieses Verfahrens werden erörtert.

Résumé—La détermination de certains anions (par example le sulphate) peut être exécutée a l'aide de la réaction avec une substance peu dissociée ou peu soluble (par example le chloranilate de baryum). Par cette réaction un autre anion (l'ion de chloranilate) est libéré et son extinction est mesuré. Dans notre publication une équation est derivée, exprimant la relation entre la concentration de sulphate et l'extinction mesuré. A concentrations basses la relation n'est pas linéaire. Une courbe d'étalonage est en bon rapport avec la théorie. Elle montre une précision de 5%, quand 20 μg de sulphate sont determinés. Avec des quantités plus élevées, la précision est meilleure. Nous avons demontré que beaucoup d'erreurs sont explicables, considérant les coefficients d'activité. Les possibilités de cette méthode sont discutées.

PRELIMINARY COMMUNICATION

Extractive titrations using metallochromic indicators

(*Received* 9 *March* 1964. *Accepted* 9 *March* 1964)

During recent years many new complexans as well as metallochromic indicators have been investigated to try and obtain higher selectivity, reproducibility and simplicity in the complexometric determination of various metals.

On the other hand, organic reagents forming metal chelates extractable into organic solvents, such as carbon tetrachloride and chloroform, *etc.*, have only been used as titrants to a small extent. Although such extractive titrations have been known for quite a long time,[1] they are limited to the case when the chelate formed is intensely coloured and the colour of the reagent used differs from that of the metal chelate (dithizone extraction). For this reason a great number of organic reagents forming slightly coloured or colourless metal chelates soluble in an organic solvent cannot be used as titrants, although their extraction properties are well known and systematically studied.[2] It has now been shown that the application of metallochromic indicators enables these organic reagents also to be used for extractive titrations.

It is evident that extractive titration with a metallochromic indicator can be successfully carried out only if the following conditions are fulfilled:

1. Neither the metallochromic indicator nor its metal chelate is extracted into the organic solvent.
2. The organic reagent forms extractable chelates the extraction constants of which are sufficiently high and whose solubility in organic solvents is of the order of >0·1 g/litre.
3. The extraction constant of the metal chelate is higher than the stability constant of the metallochromic indicator with the same metal.
4. The time of reaching equilibrium is not greater than 1 min.
5. The stock solution of the organic reagent is sufficiently stable.

Further discussion of these conditions, especially points 2 and 3, will be given in a subsequent paper. Although the above limitations are fairly restrictive, from among the great number of organic reagents and metallochromic indicators now available many will undoubtedly be suitable for this type of titration.

Experimental verification of extractive titrations using metallochromic indicators was made as follows. Iron^{III} was titrated at pH 3–4 using acetate buffer and 2 drops of 2% aqueous Tiron as indicator. The titrant was $1{\cdot}5 \times 10^{-2}M$ aqueous cupferron stabilised according to Kolthoff and Liberti[3] by ammonium carbonate. Chloroform was used as the organic solvent. Under these conditions Tiron forms with tiron a blue-coloured chelate soluble in water. At the equivalence point the blue colour in the aqueous phase disappears. If the equivalence point has to be observed precisely, the organic layer can be discharged and a fresh portion of chloroform added before the end of the titration. When the titrated solution is shaken in a separatory funnel, the time for reaching equilibrium is a maximum of 20–30 sec. In the case of determining milligram amounts of iron (volume: 20 ml) the precision of titration is satisfactory, the relative error being ±0·5%.

Compared with normal complexometric titration the advantage of extractive titration lies in the fact that the tested metal is not only determined but also separated from the treated solution, which remains free also from an excess of the titrant. As the extraction constants of many metals differ considerably from the stability constants of many of their chelates, new types of selective determinations may become possible. A disadvantage of this type of titration compared with normal complexometry is that stock solutions of the organic reagents involved are often less stable than those of complexans.

SHORT COMMUNICATIONS

Spectrophotometric determination of hydrogen peroxide in alkaline solution

(*Received* 11 *September* 1963. *Accepted* 6 *February* 1964)

SEVERAL methods[1-9] are available for the spectrophotometric determination of hydrogen peroxide, the situation up to 1953 having been reviewed by Duval.[10] Except for the method of Erdey and Inczédy,[9] in which hydrogen peroxide is determined at pH 12, all procedures are either for acidic or neutral solutions.

A simple spectrophotometric method for the determination of concentrations of about $10^{-4}M$ of hydrogen peroxide in $0{\cdot}1M$ potassium hydroxide solution has now been developed. It is based on the decrease in absorbance of potassium hexacyanoferrate(III) in alkaline solution:

$$2K_3Fe(CN)_6 + H_2O_2 + 2KOH \rightarrow 2K_4Fe(CN)_6 + 2H_2O + O_2 \,.$$

A similar reduction of hexacyanoferrate(III) by hydrogen peroxide in 30% alkaline solution has previously been used to determine hydrogen peroxide ($6 \times 10^{-3}M$) by potentiometric titration.[11]

EXPERIMENTAL

Reagents

Potassium hexacyanoferrate(III). Analytical-grade reagent was dried at 60° for 20 hr, then cooled in a desiccator.

Potassium hexacyanoferrate(II). Analytical-grade reagent was dehydrated by heating at 110° for 24 hr, then cooled in a desiccator.

Hydrogen peroxide. 50% H_2O_2 solution was used as received from the Food Machinery and Chemical Corporation, U.S.A.

Distilled water. Redistilled from alkaline potassium permanganate in a stream of oxygen.

Potassium hydroxide. Standard ($1M$) solution as supplied by British Drug Houses Ltd., England.

Procedure

The absorption spectra of potassium hexacyanoferrate(III) and hexacyanoferrate(II) at room temperature (29°), as measured with a Beckman DU spectrophotometer in a 1-cm silica cell, are shown in Fig. 1. Potassium hexacyanoferrate(III) shows absorption maxima at 260, 302 and 418 mμ, the absorbance being identical in aqueous and $0{\cdot}1M$ potassium hydroxide solution. Potassium hexacyanoferrate(II) has no maxima in its absorption spectrum. Its absorbance is slightly less in $0{\cdot}1M$ potassium hydroxide solution than in aqueous solution.

Aqueous solutions of potassium hexacyanoferrate(III) obey the Beer-Lambert Law up to quite high concentrations (Fig. 2).* The absorbance at 418 mμ of a mixture of potassium hexacyanoferrate(III) and hexacyanoferrate(II) (each approximately $10^{-3}M$) is a direct measure of the hexacyanoferrate(III) concentration. The absorption peaks at 260 and 302 mμ for hexacyanoferrate(III) are not useful for the analysis of mixtures of hexacyanoferrate(III) and hexacyanoferrate(II) because hexacyanoferrate(II) has an appreciable absorbance at these wavelengths.

Aqueous solutions of potassium hexacyanoferrate(II) develop a yellow colour on standing, but solutions in $0{\cdot}1M$ potassium hydroxide are stable. Therefore, determination of hydrogen peroxide by the decrease in absorbance it causes of a solution of potassium hexacyanoferrate(III) is best carried out in $0{\cdot}1M$ potassium hydroxide.

The rate of reduction of potassium hexacyanoferrate(III) by hydrogen peroxide is dependent on the hydroxyl ion concentration of the solution (see Table I). It becomes sufficiently rapid for analytical purposes in $0{\cdot}1M$ potassium hydroxide.

Various volumes (1–15 ml) of $3{\cdot}23 \times 10^{-3}M$ hydrogen peroxide solution were added to 20 ml of $5 \times 10^{-3}M$ potassium hexacyanoferrate(III) solution and 10 ml of $1M$ potassium hydroxide. The mixtures were diluted to 100 ml and allowed to stand for 25 min, then compared at 418 mμ in

---

* The results at 302 mμ are included for anyone interested in determining hexacyanoferrate(III) alone, in which case measurements at 302 mμ will be more sensitive than those at 418 mμ.

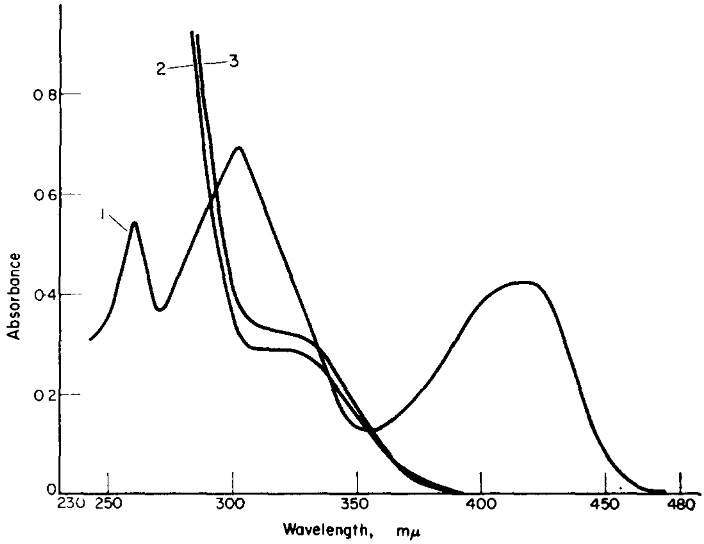

FIG. 1.—Absorption spectra:

1. 4·19 × $10^{-4}M$ $K_3Fe(CN)_6$ in water or 0·1*M* KOH.
2. 9·54 × $10^{-4}M$ $K_4Fe(CN)_6$ in 0·1*M* KOH.
3. 9·54 × $10^{-4}M$ $K_4Fe(CN)_6$ in water.

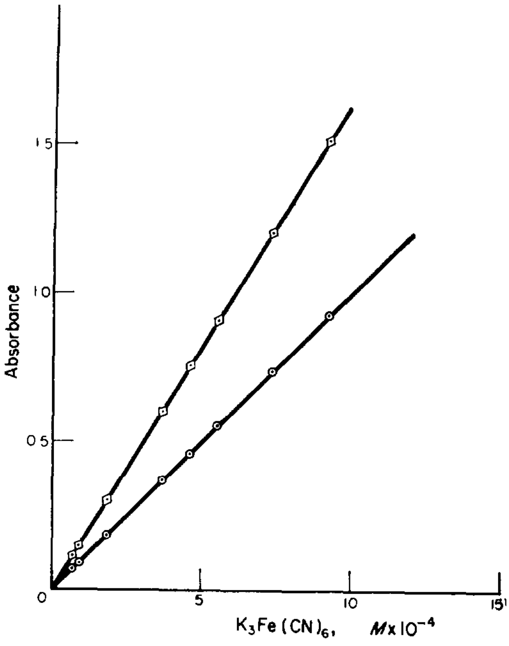

FIG. 2.—Conformity to Beer-Lambert Law of $K_3Fe(CN)_6$ at 29°:

◇ aqueous solution at 302 mμ: ϵ_{302} = 1648 mole^{-1}. cm^{-1},
○ aqueous solution at 418 mμ: ϵ_{418} = 1012 mole^{-1}. cm^{-1}.

1-cm silica cells with a blank prepared from potassium hexacyanoferrate(III) and potassium hydroxide solutions alone. The sample was placed in the "check" position and the blank in the "measure" position of the spectrophotometer. This arrangement gave absorbances which were a direct measure of the hexacyanoferrate(III) reduced by hydrogen peroxide. A comparison of the concentrations of hydrogen peroxide expected with those found on the basis of the hexacyanoferrate(III) reduced is shown in Table II. The standard deviation of the results is $\pm 2{\cdot}4\%$.

Many common ions, such as chloride, bromide, sulphate and phosphate, are stable towards hexacyanoferrate(III) and hexacyanoferrate(II); therefore they will not interfere in the determination of hydrogen peroxide. Obviously, the method will not be directly applicable in the presence of ions which react with hexacyanoferrate(III), with hexacyanoferrate(II) or with both. The authors have used the method with good results to measure hydrogen peroxide in irradiated alkaline solutions of potassium bromide in studies of aqueous radiolysis in the alkaline region.

TABLE I.—DEPENDENCE OF THE RATE OF REDUCTION OF $1{\cdot}000 \times 10^{-3}M$ POTASSIUM HEXACYANOFERRATE(III) BY $3{\cdot}336 \times 10^{-4}M$ HYDROGEN PEROXIDE ON THE HYDROXYL ION CONCENTRATION OF THE SOLUTION

Summary—A method of analysis of hydrogen peroxide in concentrations of about $10^{-4}M$, applicable to solutions which are stable towards alkaline hexacyanoferrate(III) and hexacyanoferrate(II), is suggested. The hydrogen peroxide is determined spectrophotometrically at 418 mμ from the decrease in absorbance it causes in a $1 \times 10^{-3}M$ potassium hexacyanoferrate(III) in $0{\cdot}1M$ potassium hydroxide.

Zusammenfassung—Eine Methode zur Bestimmung von Wasserstoffperoxyd in Konzentrationen von etwa 10^{-4}m wird vorgeschlagen. Sie läßt sich auf Lösungen anwenden, die gegen alkalisches Hexacyanoferrat(III) und -(II) stabil sind. Das Wasserstoffperoxyd wird spekralphotometrisch bei 418 mμ bestimmt an Hand der Extinktionsabnahme, die es an einer $1{\cdot}10^{-3}$m Kaliumhexacyanoferrat(III)-Lösung in 0,1m Kaliumhydroxyd hervorruft.

Résumé—On propose une méthode de dosage de l'eau oxygénée à des concentrations d'environ 10^{-4}M, applicable aux solutions qui sont stables vis-à-vis des hexacyanoferrate(III) et hexacyanoferrate(II) alcalins. L'eau oxygénée est dosée spectrophotométriquement à 418 mμ, par la diminution d'absorbance qu'elle apporte à une solution 1×10^{-3}M d'hexacyanoferrate(III) de potassium en potasse 0,1M.

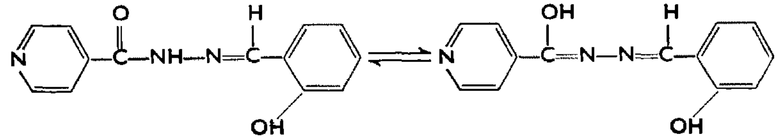
1-Isonicotinoyl-2-salicylidenehydrazine as a new chelatometric reagent

(*Received* 25 *October* 1962. *Accepted* 17 *February* 1964)

THE development of chelatometry in recent years has been responsible for the introduction of a number of organic reagents and new indicators. It has been observed in the case of certain reagents that their condensation with other compounds containing complex-forming groups (or even sometimes the self-coupling product[1]) becomes a specific reagent for some cations. In the course of development of new reagents which may exhibit specific reactions with some cations we have examined the complex-forming properties of 1-isonicotinoyl-2-salicylidenehydrazine.[2] While much work on the reagent remains to be done, the present paper briefly reports some of its possible applications for the determination and detection of cations.

The reagent was prepared by refluxing about equimolar quantities of isonicotinic acid hydrazide (isoniazid) and salicyladehyde (this being in slight excess) in 95% ethanol.[2] The product, after washing with water and ethanol to remove any unchanged reactants, had a m.p. of 265°. A 0·1% solution of the reagent in 99·9% ethanol is a very light yellow in the pH range 1–7, but deepens in the pH range 8–13. The change of colour can probably be attributed to the following two forms of the reagent



The reagent solution was investigated for metallochromic and chelatometric properties with the following 31 cations: $\mathrm{Ag^{I}}$, $\mathrm{Na^{I}}$, $\mathrm{K^{I}}$, $\mathrm{Rb^{I}}$, $\mathrm{Cs^{I}}$, $\mathrm{Hg^{II}}$, $\mathrm{Pb^{II}}$, $\mathrm{Cu^{II}}$, $\mathrm{Sn^{II}}$, $\mathrm{Fe^{II}}$, $\mathrm{Ni^{II}}$, $\mathrm{Co^{II}}$, $\mathrm{Zn^{II}}$, $\mathrm{Mn^{II}}$, $\mathrm{Ca^{II}}$, $\mathrm{Sr^{II}}$, $\mathrm{Ba^{II}}$, $\mathrm{Mg^{II}}$, $\mathrm{Pd^{II}}$, $\mathrm{TiO^{II}}$, $\mathrm{VO^{II}}$, $\mathrm{UO_2^{II}}$, $\mathrm{Sb^{III}}$, $\mathrm{Al^{III}}$, $\mathrm{Fe^{III}}$. $\mathrm{Cr^{III}}$, $\mathrm{Au^{III}}$, $\mathrm{Ce^{IV}}$, $\mathrm{Th^{IV}}$, $\mathrm{Zr^{IV}}$ and $\mathrm{Pt^{IV}}$. The experiments were carried out with 2 ml of 0·01*F* and 0·1*F* solutions of suitable salts of the cations and 10 ml of the reagent. Any colour developed and/or the appearance of a precipitate was noted. The important observations are presented in Tables I and II.

TABLE I—CATIONS FORMING PRECIPITATES WITH 1-ISONICOTINOYL-2-SALICYLIDENEHYDRAZINE

Cation	Salt used	Colour of precipitate

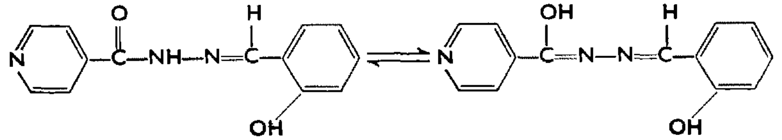
1-Isonicotinoyl-2-salicylidenehydrazine as a new chelatometric reagent

(*Received* 25 *October* 1962. *Accepted* 17 *February* 1964)

THE development of chelatometry in recent years has been responsible for the introduction of a number of organic reagents and new indicators. It has been observed in the case of certain reagents that their condensation with other compounds containing complex-forming groups (or even sometimes the self-coupling product[1]) becomes a specific reagent for some cations. In the course of development of new reagents which may exhibit specific reactions with some cations we have examined the complex-forming properties of 1-isonicotinoyl-2-salicylidenehydrazine.[2] While much work on the reagent remains to be done, the present paper briefly reports some of its possible applications for the determination and detection of cations.

The reagent was prepared by refluxing about equimolar quantities of isonicotinic acid hydrazide (isoniazid) and salicyladehyde (this being in slight excess) in 95% ethanol.[2] The product, after washing with water and ethanol to remove any unchanged reactants, had a m.p. of 265°. A 0·1% solution of the reagent in 99·9% ethanol is a very light yellow in the pH range 1–7, but deepens in the pH range 8–13. The change of colour can probably be attributed to the following two forms of the reagent



The reagent solution was investigated for metallochromic and chelatometric properties with the following 31 cations: Ag^I, Na^I, K^I, Rb^I, Cs^I, Hg^{II}, Pb^{II}, Cu^{II}, Sn^{II}, Fe^{II}, Ni^{II}, Co^{II}, Zn^{II}, Mn^{II}, Ca^{II}, Sr^{II}, Ba^{II}, Mg^{II}, Pd^{II}, TiO^{II}, VO^{II}, $UO_2{}^{II}$, Sb^{III}, Al^{III}, Fe^{III}, Cr^{III}, Au^{III}, Ce^{IV}, Th^{IV}, Zr^{IV} and Pt^{IV}. The experiments were carried out with 2 ml of 0·01*F* and 0·1*F* solutions of suitable salts of the cations and 10 ml of the reagent. Any colour developed and/or the appearance of a precipitate was noted. The important observations are presented in Tables I and II.

TABLE I—CATIONS FORMING PRECIPITATES WITH 1-ISONICOTINOYL-2-SALICYLIDENEHYDRAZINE

Cation	Salt used	Colour of precipitate
Cu^{II}	$CuSO_4{\cdot}5H_2O$	Green
Ni^{II}	$NiSO_4{\cdot}7H_2O$	Orange
Zn^{II}	$Zn(CH_3COO)_2{\cdot}2H_2O$	Bright yellow
Pd^{II}	$PdCl_2$	Deep yellow
Ce^{IV}	$2(NH_4)_2{\cdot}Ce(SO_4)_2{\cdot}2H_2O$	Light yellow

TABLE II—CATIONS FORMING SOLUBLE COMPLEXES WITH 1-ISONICOTINOYL-2-SALICYLIDENEHYDRAZINE

Cation	Salt used	Colour	Colour change on addition of excess EDTA
Pb^{II}	$Pb(NO_3)_2$	Deep yellow	Very light yellow
Fe^{II}	$FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$	Brown	Very light yellow
Co^{II}	$CoCl_2 \cdot 6H_2O$	Yellow	Very light yellow
Sn^{II}	$SnCl_2$	Deep yellow	Colourless
TiO^{II}	$K_2TiO(C_2O_4)_2 \cdot 2H_2O$	Orange-yellow	Yellow
VO^{II}	$VO(SO_4)$	Deep yellow	Greenish yellow
$UO_2{}^{II}$	$UO_2(CH_3COO)_2 \cdot 2H_2O$	Orange-yellow	Yellow
Sb^{III}	$Sb_2(SO_4)_3$	Yellow	Very light yellow
Al^{III}	$AlCl_3 \cdot 6H_2O$	Deep yellow	Very light yellow on heating
Fe^{III}	$Fe_2(SO_4)_3 \cdot (NH_4)_2SO_4 \cdot 24H_2O$	Brown	Very light yellow
Th^{IV}	$Th(NO_3)_4 \cdot 4H_2O$	Deep yellow	Very light yellow
Zr^{IV}	$Zr(NO_3)_4 \cdot 5H_2O$	Deep yellow	Yellow

It is evident from Table I that Cu^{II}, Ni^{II}, Zn^{II}, Pd^{II} and Ce^{IV} give distinctly coloured precipitates with the reagent. The precipitation of Cu^{II} is quantitative and has been utilised for its gravimetric determination. The reagent presents some difficulty in gravimetry because of its low solubility; its sodium salt serves as a better precipitant. Furthermore, because Cd^{II}, Co^{II}, Mn^{II}, Th^{IV} and Zr^{IV} are not precipitated by the reagent, its utility for the following separations seems to merit investigation:

Cu^{II} in presence of Cd^{II},

Ni^{II} in presence of Co^{II},

Zn^{II} in presence of Mn^{II},

Ce^{IV} in presence of Th^{IV} and Zr^{IV}.

These investigations are in progress and the results will be published in due course.

Acknowledgement—The authors wish to thank Professor P. K. Kelkar, Director, Indian Institute of Technology, Kanpur, for providing facilities and for his interest in the work.

Summary—1-Isonicotinoyl-2-salicylidenehydrazine, prepared by the condensation of isonicotinic acid hydrazide and salicylaldehyde, has been examined for chelatometric properties with a number of cations. It precipitates Cu^{II}, Ni^{II}, Zn^{II}, Pd^{II} and Ce^{IV}, and forms soluble complexes with Pb^{II}, Fe^{II}, Co^{II}, Sn^{II}, TiO^{II}, VO^{II}, $UO_2{}^{II}$, Sb^{III}, Al^{III}, Fe^{III}, Th^{IV} and Zr^{IV}.

Zusammenfassung—Durch Kondensation von Isonicotinsäurehydrazid und Salicylaldehyd hergestelltes 1-Isonicotinoyl-2-salicylidenhydrazin wurde mit einigen Kationen auf seine chelatometrischen Eigenschaften geprüft. Es gibt Fallungen mit Cu^{2+}, Ni^{2+}, Zn^{2+}, Pd^{2+} und Ce^{4+} und lösliche Komplexe mit Pb^{2+}, Fe^{2+}, Co^{2+}, Sn^{2+}, TiO^{2+}, VO^{2+}, UO_2^{2+}, Sb^{3+}, Al^{3+}, Fe^{3+}, Th^{4+}, und Zr^{4+}.

Résumé—La 1-isonicotinoyl 2-salicylidène hydrazine a été préparée par condensation de l'isoniazide avec le salicylaldéhyde. On a étudié ses propriétés chélatométriques avec un certain nombre de cations. Elle précipite Cu(II), Ni(II), Zn(II), Pd(II) et Ce(IV) et forme des complexes solubles avec Pb(II), Fe(II), Co(II), Sn(II), TiO(II), VO(II), UO_2(II), Sb(III), Al(III), Fe(III), Th(IV) et Zr(IV).

Determination of tetra-ethylthiuram disulphide and elemental sulphur in organic extracts using cathode-ray polarography

(*Received* 1 *November* 1963. *Accepted* 15 *February* 1964)

INTRODUCTION

A NUMBER of polarographic methods have been described previously for the determination of thiuram disulphides[1,2,3] and free sulphur[4] and in many circumstances these appear to have appreciable advantages over colorimetric or other methods, particularly for micro or semi-micro amounts. However, no methods have appeared in the literature for the determination of these compounds using the linear-sweep cathode-ray polarograph (CRP), and because organic methods are not always equally applicable to conventional polarographs and the CRP, the following are described for the latter instrument.

The method for tetra-ethylthiuram disulphide (TETDS) is based on that of Belitskaya[1], who examined the polarographic waves of TETDS in an ammoniacal, partly ethanolic, buffer. It was found that, using the CRP, the current/concentration relationship for TETDS in this buffer was very non-linear in the concentration range studied by Belitskaya (150–600 ppm), but by reducing the concentration to a level of 1·5–15·0 ppm, a linear relationship was obtained. Working in this range, it is possible to add a small aliquot of the sample solution directly to the polarographic cell containing an aliquot of partially deoxygenated base electrolyte. This procedure minimises any modification of the base electrolyte by the solvent used in the sample preparation, prevents any oxidation of the TETDS which might occur at such low concentrations, and increases the speed of the method. Depending on which solvent has been used in the extraction of the synthetic rubber and on the nature of the synthetic, the rubber itself may be more or less dissolved in the extraction solvent. On addition to the base electrolyte, the rubber will then be reprecipitated, but this does not appear to lead to entrainment of the TETDS, possibly because of the very small amounts involved. This is shown by the results given in Table I. The ethyl acetate/isopropanol solvent does not dissolve a significant proportion of the rubber which was being analysed. Therefore, no precipitation occurs when this

Determination of tetra-ethylthiuram disulphide and elemental sulphur in organic extracts using cathode-ray polarography

(*Received* 1 *November* 1963. *Accepted* 15 *February* 1964)

INTRODUCTION

A NUMBER of polarographic methods have been described previously for the determination of thiuram disulphides[1,2,3] and free sulphur[4] and in many circumstances these appear to have appreciable advantages over colorimetric or other methods, particularly for micro or semi-micro amounts. However, no methods have appeared in the literature for the determination of these compounds using the linear-sweep cathode-ray polarograph (CRP), and because organic methods are not always equally applicable to conventional polarographs and the CRP, the following are described for the latter instrument.

The method for tetra-ethylthiuram disulphide (TETDS) is based on that of Belitskaya[1], who examined the polarographic waves of TETDS in an ammoniacal, partly ethanolic, buffer. It was found that, using the CRP, the current/concentration relationship for TETDS in this buffer was very non-linear in the concentration range studied by Belitskaya (150–600 ppm), but by reducing the concentration to a level of 1·5–15·0 ppm, a linear relationship was obtained. Working in this range, it is possible to add a small aliquot of the sample solution directly to the polarographic cell containing an aliquot of partially deoxygenated base electrolyte. This procedure minimises any modification of the base electrolyte by the solvent used in the sample preparation, prevents any oxidation of the TETDS which might occur at such low concentrations, and increases the speed of the method. Depending on which solvent has been used in the extraction of the synthetic rubber and on the nature of the synthetic, the rubber itself may be more or less dissolved in the extraction solvent. On addition to the base electrolyte, the rubber will then be reprecipitated, but this does not appear to lead to entrainment of the TETDS, possibly because of the very small amounts involved. This is shown by the results given in Table I. The ethyl acetate/isopropanol solvent does not dissolve a significant proportion of the rubber which was being analysed. Therefore, no precipitation occurs when this

TABLE I—EXTRACTION OF TETDS BY DIFFERENT SOLVENT SYSTEMS

Sample	TETDS, %	
	Chloroform[a]	Ethyl acetate/isopropanol[b]
A	1·48	$1{\cdot}40_0$
B	$1{\cdot}20_0$	$1{\cdot}11_1$

[a] 0·5 g of rubber dissolved in 24·5 ml of chloroform.
[b] 1·0 g of rubber extracted with 2 × 20 ml of 3:1 v/v ethyl acetate/isopropanol mixture and the combined extracts made to 50 ml.

solvent is used. In fact, although two extractions were made with it, the result is appreciably lower than that obtained using chloroform as the solvent, probably because of incomplete extraction of the TETDS by the ethyl acetate/isopropanol mixture. A third extraction of the rubber usually contains 0·02–0·04% of TETDS.

The determination of sulphur caused rather more difficulty. A number of base electrolytes have been suggested in the literature for the conventional polarography of sulphur, *e.g*., pyridine-sodium acetate in acetic acid, pyridinium hydrochloride in methanol, and sulphuric acid in methanol. However, in all of these base electrolytes, using the CRP the wave-form from the sulphur discharge was found to be complex, with several major peaks situated close together. The relative heights of these peaks varied with sulphur concentration and also with the presence or absence of TETDS, although the latter is discharged at a more negative potential. With none of these previously mentioned base electrolytes was it possible to obtain anything approaching a linear current/concentration relationship, at least in the presence of TETDS. The sensitivity was, however, very high, as little as 0·5 ppm of sulphur giving a peak current of the order of 2 μA.

The sharp, wedge-shaped peaks obtained in the above-mentioned base electrolytes suggest that the polarographic current for sulphur using the CRP is considerably modified by an adsorption process. It was thought, therefore, that the addition of a powerful surface-active agent to the base electrolyte might cause a major alteration in the appearance of the wave-form, possibly leading to a reduction in sensitivity of the method, which would be tolerable, but also leading to a simplification of the wave-form, which was the desired effect. When a considerable quantity of cetrimide (a mixture of dodecyl-, tetradecyl- and hexadecyl-trimethylammonium bromides) was incorporated into a pyridine-pyridinium chloride in methanol base electrolyte, only one major peak was in fact observed for sulphur, and it was possible to obtain a reasonably linear current/concentration relationship, although only over a narrow range of sulphur concentration, 0·06–0·60 ppm. However, the sensitivity was enhanced, rather than decreased. The calibration was found to be still a little dependent on the TETDS concentration, but by preparing the calibration graph in the presence of TETDS at about the concentration it would be present in the solution from the sample, the effect was minimised.

RESULTS AND DISCUSSION

It is not possible to ascertain the over-all accuracy of the method as applied to synthetic rubbers, because of the uncertainty in the final amounts of sulphur and TETDS in the dry rubber, even when measured amounts have been added to the lattices. No other methods have been tried for comparison, but it is unlikely that they would give any clearer picture of the accuracy of the polarographic method. However, the reproducibilities of the methods have been determined by calculating the standard deviation of a series of replicates on the same batch of rubber. In this test, 0·5-g samples of the rubber, each cut into 10–15 pieces, were dissolved in 24·5 ml of chloroform by shaking for about 2 hr. The results were as follows:

Tetra-ethylthiuram disulphide (10 determinations): mean = 1·61% w/w,
standard deviation = 0·02;

Elemental sulphur (10 determinations): mean = 0·30% w/w,
standard deviation = 0·01.

EXPERIMENTAL

A solution or extract of the synthetic rubber is prepared using, for example, a 0·5- or 1·0-g sample and ending with a final solution volume of 25 or 50 ml. The solvent used will depend on the synthetic under investigation; we have used both chloroform and an ethyl acetate/isopropanol mixture. The solution should contain 20–1500 ppm of TETDS and 5–150 ppm of sulphur.

Polarograph. K1000 cathode-ray polarograph of Southern Analytical Ltd., Camberley, Surrey, England.

Determination of TETDS

Base electrolyte. A mixture of 30 ml of 95% ethanol, 15 ml of aqueous 1*M* ammonia:1*M* ammonium chloride buffer, and 5 ml of 10% w/v sodium sulphite solution. (This latter solution should be prepared fresh daily).

Procedure. A suitable aliquot (0·05–0·50 ml) of the sample solution is added to 5 ml of partially deoxygenated base electrolyte in the polarographic cell, so that the final concentration is in the range 3–15 ppm of TETDS. The deoxygenation is completed and the peak height of the TETDS wave read off in the usual manner, using the settings: $E_{start} = -0·40$ V versus the SCE, $E_{peak} = -0·63/-0·65$ V. The current may be referred to a calibration graph prepared by adding suitable concentrations of an ethanolic solution of pure TETDS to aliquots of base electrolyte, provided that an internal standard is used at the time of sample measurement and its value compared with the value obtained when the calibration graph was prepared. If the values are not in agreement, the sample current must be suitably adjusted before reading the TETDS concentration from the graph.

Determination of elemental sulphur

Base electrolyte. Dissolve 1 g of cetrimide (Cetavlon) in 50 ml of methanol, add 9·4 ml of analytical reagent grade pyridine and 0·6 ml of concentrated hydrochloric acid.

Procedure. Pipette 5 ml of the base electrolyte into a polarographic cell and start deoxygenation. After about 2 min, introduce a suitable aliquot (0·02–0·05 ml) of sample solution into the base electrolyte. Continue deoxygenation for a further 1–2 min, then read off the peak current at a suitable scale factor, using the instrument setting $E_{start} = -0·3$ V versus the SCE. The peak should appear on the screen at a potential of $-0·15$ to $-0·20$ V. The sulphur concentration may be obtained from a calibration graph, provided that an internal standard is used as mentioned in the TETDS procedure.

A suitable calibration graph may be obtained by weighing out 5·00 mg of micronised sulphur, dissolving in 80 ml of benzene and adjusting to 100 ml in a graduated flask. Aliquots of this solution (0·005–0·05 ml) are added with an Agla micrometer syringe (Burroughs Welcome and Co., London, England) to 5 ml of base electrolyte and the peak currents recorded as in the sample procedure. The peak current of an internal standard should also be recorded on the calibration graph.

Summary—A cathode-ray polarographic method is described for the determination of free sulphur and tetra-ethylthiuram disulphide in a synthetic rubber extract. The method appears to have a higher sensitivity and better reproducibility than is obtained by conventional polarographic methods, particularly in the case of the thiuram, although the range in which a linear current/concentration relationship is obtained is rather limited.

Zusammenfassung—Bestimmung von Tetraäthylthiuramdisulfid und elementarem Schwefel in organischen Extrakten mit dem Kathodenstrahlpolarographen. Die Arbeit beschreibt eine kathodenstrahlpolarographische Bestimmungsmethode für freien Schwefel und Tetraäthylthiuramdisulfid in einem Extrakt aus synthetischem Gummi. Die Methode ist offenbar empfindlicher und besser reproduzierbar als herkommliche polarographische Methoden, besonders im Falle des Disulfids; allerdings ist der Bereich der linearen Abhängigkeit des Stromes von der Konzentration ziemlich beschränkt.

Résumé—Le mémoire décrit une méthode oscillopolarographique de dosage du soufre libre et du disulfure de tétraéthylthiurame dans un extrait de caoutchouc synthétique. La méthode se révèle être d'une plus grande sensibilité et d'une meilleure reproductibilité que les méthodes polarographiques usuelles, particulièrement dans le cas du thiurame, bien que le domaine dans lequel une relation linéaire courant-concentration est observée soit assez limité.

LETTERS TO THE EDITOR

Correction for the separation of hydrogen isotopes during distillation in the determination of tritium

SIR:

In the determination of tritium in tritiated water, it is frequently necessary to distil the sample as a purification stage, either to separate from large amounts of interfering ions, or to separate from other β-emitters which would interfere in the liquid β-scintillation counting finish. As is well-known, the concentration of tritium in the distillate will be less than in the residue. For accurate work, it is necessary to correct for this factor. This note shows one of the many ways in which this correction can be calculated, and gives the results in a form which is of immediate use to the analyst.

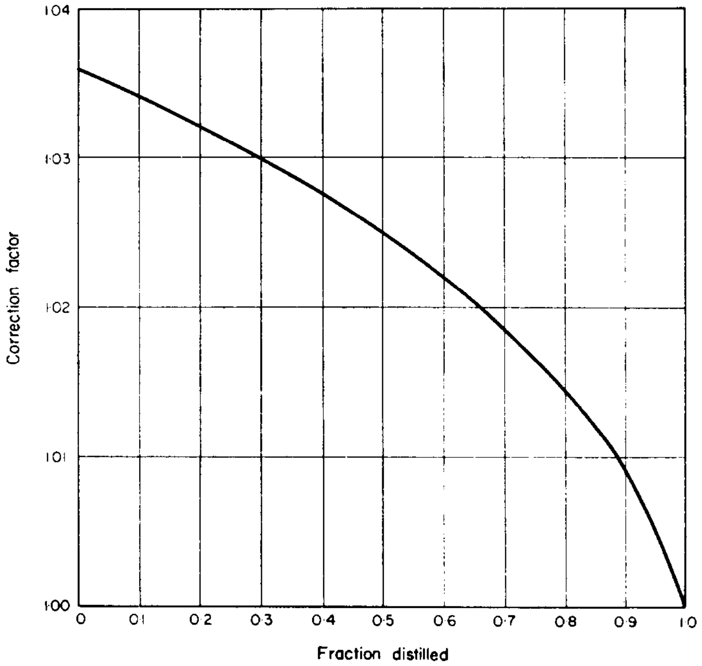

FIG. 1.—Correction factor for depletion of tritium on distillation.

The basis of the calculation is the results of Avinur and Nir;[1] they state that the ratio of the concentration of tritium, in tritiated, water in the liquid phase to that in the vapour phase at equilibrium is 1·036 ± 0.001 at 760 mm pressure.

Consider a weight of tritium, T, in a weight of water, W. T is very small in comparison with W. Distil a weight of water, δW, containing a weight of tritium, δT.

From the information of Avinur and Nir:

$$(T/W) \div (\delta T/\delta W) = 1{\cdot}036$$

$$\delta T/T = \delta W/(1{\cdot}036 W).$$

Integrating,

$$\log T = (\log W/1{\cdot}036) + \log C.$$

Hence

$$\log (T_0/T) = \log (W_0/W) \div 1{\cdot}036$$

or

$$(T_0/T) = (W_0/W)^{\frac{1}{1\cdot036}}.$$

Because W_0, T_0, are the original amounts of water and tritium, and W, T, are the amounts of water and tritium remaining, therefore $(W_0 - W)$, $(T_0 - T)$ are the amounts in the distillate.

One measures, by counting, $(T_0 - T)/(W_0 - W)$, and wishes to know (T_0/W_0).

That is,

$$\frac{(T_0 - T)}{(W_0 - W)} \times F = \frac{T_0}{W_0},$$

where F is a factor which varies with

$$\left(1 - \frac{W}{W_0}\right),$$

the fraction distilled. This factor F has been calculated, and is given in Fig. 1.

The calculation assumes that the distillation is carried out under perfect equilibrium conditions to ensure maximum isotope separation. This, in most cases, is certainly not true, but subsidiary calculations have shown that the graph is reasonably valid for non-equilibrium conditions.

The photosensitivity of the complex of iron^{III} with 1,10-phenanthroline

SIR:

Photochemical reduction of the iron^{III} complex of α,α-dipyridyl has been known for several years.[1] The corresponding iron^{III} complex with 1,10-phenanthroline might also be expected to be photosensitive. We have now confirmed this fact and used it in the study of some problems in analytical chemistry.

Photoreduction of the iron^{III}-1,10-phenanthroline complex only becomes appreciable at wavelengths shorter than 590 mμ. A very strong development of the red iron^{II}-1,10-phenathroline colour was observed after irradiation by ultraviolet rays. Practically no photoreduction occurs at pH less than 1·4. Above this value the rate increases, becoming constant between pH 4·0 and 6·0. At higher pH a decrease in photoreduction is again observed. Photoreduction is not prevented by the presence of complexing agents, such as citric, tartaric, oxalic, boric, phosphoric, acetic, iminodiacetic and nitriloacetic acids and EDTA. In fact, many of these reagents accelerate the reaction. DCyTA has a strong retarding action and fluoride completely prevents photoreduction.

Traces of iron have been determined in sodium citrate and sodium tartrate by a method based on the above findings. Chemical reduction with hydroxylamine or hydroquinone, as recommended for determination of total iron content using 1,10-phenanthroline,[2] is slow and often incomplete. It can be accelerated photochemically or complete reduction can be achieved photochemically ($>$10 min, 200 W mercury lamp) in the absence of chemical reductants.

In the determination of iron^{II} in haematite with 1,10-phenanthroline, photoreduction of any iron^{III} must be prevented. Elimination of interference from iron^{III} by addition of fluoride[3] is only possible over a very narrow range of pH, which is, moreover, very close to the lower limit of applicability of 1,10-phenathroline. Further, the slight colour from the iron^{III} increases the blank value. Reliable results have now been obtained by dissolving the haematite under non-oxidising

Integrating,

$$\log T = (\log W/1{\cdot}036) + \log C.$$

Hence

$$\log (T_0/T) = \log (W_0/W) \div 1{\cdot}036$$

or

$$(T_0/T) = (W_0/W)^{\frac{1}{1\cdot036}}.$$

Because W_0, T_0, are the original amounts of water and tritium, and W, T, are the amounts of water and tritium remaining, therefore $(W_0 - W)$, $(T_0 - T)$ are the amounts in the distillate.

One measures, by counting, $(T_0 - T)/(W_0 - W)$, and wishes to know (T_0/W_0).

That is,

$$\frac{(T_0 - T)}{(W_0 - W)} \times F = \frac{T_0}{W_0},$$

DETERMINATION OF THE METHYLOL GROUP IN PHENOLIC RESINS

(*Received* 4 *October* 1962. *Accepted* 15 *February* 1964)

Summary—An accurate and simple method for determination of the methylol group in phenolic resins is described. The phenolic hydroxyl group is determined by titration with sodium methoxide in non-aqueous solvent, and total hydroxyl group (phenolic hydroxyl plus alcoholic hydroxyl) is found by calculation of the integrated absorption intensity from the infrared spectrum observed between 3600 and 3000 cm^{-1}. The alcoholic hydroxyl group (methylol group) is calculated as the difference between the total and the phenolic hydroxyl group. In contrast to customary techniques, this method is simple, direct and provides a satisfactory precision (± 8%).

INTRODUCTION

SEVERAL techniques have recently been described for determination of the methylol group in phenolic resins, but they have not been found generally satisfactory.

Stenmark and Weiss[1] reported an accurate and simple method for determination of the methylol group in resins. Methylol groups and phenol condense in the presence of acid catalyst to form water which is titrated directly with Karl Fischer reagent. This method provided an accurate value with small samples and thus facilitated experiments on laboratory scale preparations. However, the reaction is slow, requiring as long as 3 hr for completion.

Motoyoshi[2] reported the determination of methylol groups in resins by the following method. The resin, dried in vacuum at 50°, is extracted by methanol, the phenolic hydroxyl group in the extracted resin methylated by methyl iodide-potassium hydroxide solution, and the alcoholic hydroxyl group determined by phthalic anhydride. The precision of this method was not quoted.

Somiya *et al.*[3] measured the infrared spectra of methylol derivatives of phenol, *o*-, *m*- and *p*-cresol, 2,4-dimethylphenol and 2,4-dibromophenol, and determined the intensity of the methylol group absorption at 10 μ by the potassium bromide disc process. They proved that methylol groups in novolaks can be determined with satisfactory precision by their method. However, methylol groups of phenolic alcohols absorb between 9·5 and 10·5 μ and these absorptions are not always constant in position. For this reason, methylol groups of resoles are difficult to determine with sufficient precision.

In this paper, a comparatively accurate, rapid and simple method for the determination of methylol groups in phenol-formaldehyde resins is proposed. Phenolic hydroxyl groups are titrated directly with sodium methoxide, and total hydroxyl group (phenolic hydroxyl group plus alcoholic hydroxyl group) is determined from infrared absorption spectrum between 3600 and 3000 cm^{-1}. The methylol group is calculated as the difference between the total and phenolic hydroxyl groups.

EXPERIMENTAL

Determination of Phenolic Hydroxyl Group

In 1948, Moss, Elliott and Hall[4] pointed out that phenols behave as moderately strong acids in anhydrous ethylenediamine. They were unable to find a satisfactory visual indicator, but carried out potentiometric titrations successfully using sodium aminoethoxide in ethylenediamine-ethanolamine as the titrant.

Fritz and Lisicki[5] titrated phenols potentiometrically in butylamine with sodium methoxide, but found no successful visual indicator. Later, Fritz and Keen[6] reported that phenol and alkyl-substituted phenols were somewhat weaker acids but could be titrated in ethylenediamine using *o*-nitroaniline as the indicator.

In the present work, essentially the same procedure as that of Fritz and Keen was used.

Reagents

Benzene. Extra pure (Kanto Chemical Co., Japan)

Methanol. Extra pure (Kanto Chemical Co., Japan)

Ethylenediamine (anhydrous). Guaranteed reagent (Kanto Chemical Co., Japan)

Phenol samples. Commercial samples (98–100% purity)

Benzyl alcohol. Guaranteed reagent (Daiichi Pure Chemicals Co., Japan)

o-Hydroxybenzyl alcohol (saligenine). Guaranteed reagent (Tokyo Kasei Kogyo Co., Japan)

p-Hydroxybenzyl alcohol. Prepared by hydrogenation of *p*-hydroxybenzaldehyde (Tokyo Kasei Kogyo Co., Japan) and recrystallised from water, m.p. 123°

p-Cresol dialcohol. Prepared by Auwer's Method,[9] m.p. 128·5°

o-Cresol dialcohol. Prepared by Hanus's Method,[10] m.p. 92·5°

o-Nitroaniline. Guaranteed reagent, 0·15 g dissolved in 100 ml of benzene.

Benzoic acid. Guaranteed reagent (Kanto Chemical Co., Japan)

Sodium methoxide (0·1–0·2 *M*). About 0·6 g of freshly cut sodium metal is added to 10 ml of methanol in a loosely covered flask. When the reaction is complete, 15 ml of methanol and 150 ml of benzene are added with stirring until the solution becomes homogeneous and clear. This is stored in a glass bottle protected from moisture and carbon dioxide. The titrant solution is standardised against benzoic acid.

Apparatus

The titration assembly consists of a 10-ml burette, a 50 to 100-ml titration vessel (covered to prevent absorption of carbon dioxide from the air), and a magnetic stirrer (equipped with a small stirring bar sealed in glass).

Procedure

About 25 ml of ethylenediamine, with 3–4 drops of *o*-nitroaniline as the indicator, is titrated with sodium methoxide to a red colour. The neutralised solvent is combined with the sample solution and titrated with sodium methoxide, the end-point being the change from clear yellow to orange-red. The weight of sample taken is so selected that 1–5 ml of the methoxide will be consumed.

Determination of Phenolic and Alcoholic Hydroxyl Group

From infrared studies on the association of phenol with several ketones Widom *et al.*[7] reported that the phenol-acetone complex has a great association effect. In general,[8] the intensity is greatly increased in solvents in which the association effect occurs.

In the present work, acetone was used as a solvent that not only dissolves phenols and resins but also increases the association effect, and the total hydroxyl group (phenolic hydroxyl plus alcoholic hydroxyl) was determined quantitatively by infrared absorption spectra between 3600 and 3000 cm^{-1}.

Reagents

Acetone. Extra pure (Kanto Chemical Co., Japan) distilled in an all-glass apparatus from phosphorus pentoxide immediately before use.

Phenols and phenolic alcohols. As above.

Apparatus

The absorption was measured using a Nihon Bunko Model 301 infrared spectrophotometer. Two 0·100-mm cells having sodium chloride plates were used.

Procedure

In actual measurements, a solution in which 5–30 mg of sample is dissolved in 1 ml of acetone is placed in the sample beam and acetone in the reference beam of the instrument. Examples of the spectra obtained are given for the phenol-acetone solution in Fig. 1.

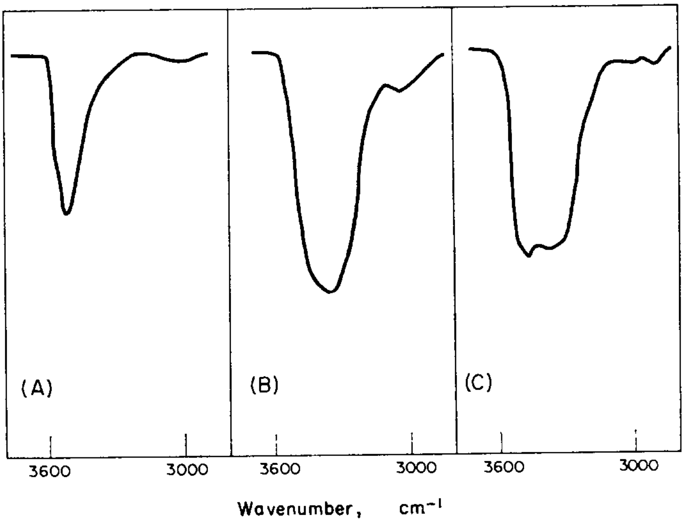

FIG. 1.—Infrared spectra of samples:
(A) benzyl alcohol,
(B) phenol,
(C) *p*-methylol phenol.

Because the phenolic and alcoholic hydroxyl absorptions occur at somewhat different wavelengths, integrated absorption intensities were calculated by dividing the range 3000 to 3600 cm^{-1} into fifteen equal parts using the following equation

$$A = 1/c, l \left(\sum_{n=1}^{15} \log (To/T)\, \Delta\nu \right)$$

where c is the concentration (mole/l.), l is the cell length (cm) and $\Delta\nu$ is the width of each part (40 cm^{-1}).

Determination of Methylol Group

The methylol content (mole/g) of the samples was calculated from the expression

$$\frac{A' - B \times D}{C}$$

where A′ = the integrated absorption intensity of total hydroxyl group/g (1/g. cm^2),
B = the mean integrated absorption intensity of phenolic hydroxyl group/molecule (1/mole. cm^2),
C = the mean integrated absorption intensity of alcoholic hydroxyl group/molecule (1/mole. cm^2),
D = phenolic hydroxyl group (mole/g).

RESULTS AND DISCUSSION

Data for determination of phenolic hydroxyl groups are given in Table I.

TABLE I.—TITRATION OF PHENOLS IN ETHYLENEDIAMINE
(Indicator: *o*-nitroaniline)

Compound	Taken, *mg*	MeONa, *ml*	MeONa, *M*	Found, %
Phenol	53·98	4·79	0·1206	100·5
o-Hydroxybenzyl alcohol	20·36	1·23	0·1331	100·0
p-Hydroxybenzyl alcohol	28·18	1·81	0·1231	97·5
p-Cresol dialcohol	23·33	1·23	0·1124	100·0
o-Cresol dialcohol	22·97	1·22	0·1124	98·5
2,6-Xylenol	40·19	2·91	0·1124	99·5
Phenol + benzyl alcohol	36·16 37·94	3·12	0·1212	98·5
Phenol + water	54·73 14·25	4·78	0·1218	100·0

This method gave satisfactory results for the titration of this type of phenolic hydroxyl group. The precision was within ±1 % and the bias was not significant. However, this method possessed the defect that high molecular weight substances precipitated in the course of titration, obscuring the end-point. The presence of a small amount of water in the sample did not interfere.

The integrated absorption intensities of phenols and phenolic alcohols are given in Table II. The intensity of aromatic CH was neglected because it was less than 1 % of the intensity of phenolic hydroxyl group in the samples.

TABLE II.—INTEGRATED ABSORPTION INTENSITY OF PHENOLIC AND ALCOHOLIC HYDROXYL GROUPS

Compound	Integrated absorption intensity, $\times 10^4$ litre. mole^{-1}. cm^{-2}
Phenol	3·35
o-Cresol	3·37
p-Cresol	3·34
2,4-Xylenol	3·35
2,6-Xylenol	2·37
Benzyl alcohol	1·35
o-Hydroxybenzyl alcohol	4·69
p-Hydroxybenzyl alcohol	4·62
o-Cresol dialcohol	5·66
p-Cresol dialcohol	6·10

The data were arranged by least squares, supposing that the following equation was applicable to them

$$A_{\mathrm{total}} = \mathrm{m}B + \mathrm{n}C$$

where A_{total} is the integrated absorption intensity of total hydroxyl/mole, B and C are as before, m is the number of phenolic hydroxyl groups/molecule, and n is the number of alcoholic hydroxyl groups/molecule.

The results were as follows: $B = 3{\cdot}35 \times 10^4$, $C = 1{\cdot}29 \times 10^4$, standard deviation $\sigma = 0{\cdot}11 \times 10^4$.

Because the hydroxyl absorption of water and alcohol occurs in the same region, the presence of small amounts of water and alcohol in the sample interferes. While the presence of lower polyoxymethylene glycols (formaldehyde polymers) is to be avoided, small amounts do not interfere.

Data of determination of methylol groups in phenolic alcohols are shown in Table III.

The precision of the method is about 8 %, with a daily error of determination of about 4 %. This is considered to be satisfactory.

Analysis of Phenol-Formaldehyde Resins

The method was applied to three phenolic resins of the resol type with the results shown in Table IV. These resins were prepared with varied concentrations of formaldehyde under alkaline conditions and were freeze-dried two or three times from benzene–methanol to eliminate water.

TABLE III.—DETERMINATION OF METHYLOL GROUPS IN PHENOLIC ALCOHOL

Compound	A′, l/g. cm^2	D, × 10^{-3} mole/g	Alcoholic OH, × 10^{-3} mole/g	
			Found	Theoretical
o-Hydroxybenzyl alcohol	378	8·01	8·5	8·1
p-Hydroxybenzyl alcohol	372	7·87	8·4	8·1
o-Cresol dialcohol	362	5·95	10·7	11·9
p-Cresol dialcohol	337	5·85	12·9	11·9

TABLE IV.—DETERMINATION OF METHYLOL GROUPS IN PHENOLIC RESINS

Resin	A′, l/g. cm^2	D, × 10^{-3} mole/g	Alcoholic OH, × 10^{-3} mole/g
1	351	7·13	8·7
2	321	5·98	9·4
3	385	5·44	15·7

The methylol content was determined under the conditions outlined above; satisfactory results were obtained.

Acknowledgement—The authors thank Professor H. Kamada of Tokyo University for advice and Vice-President T. Kikuchi of Fudow Chemical Company for permission to publish this paper.

Zusammenfassung—Eine genaue und einfache Methode zur Bestimmung der Methylolgruppe in Phenolharzen wird beschrieben. Die phenolische Hydroxylgruppe wird durch Titration mit Natriummethylat in einem nichtwäßrigen Lösungsmittel bestimmt, die Gesamtmenge an OH-Gruppen (phenolische und alkoholische) findet man aus der integrierten Absorptionsintensität im Infrarotspektrum zwischen 3600 und 3000 cm^{-1}. Der Gehalt an alkoholischen (Methylol-) Hydroxylgruppen wird als Differenz zwischen Gesamt- und phenolischen Hydroxylgruppen berechnet. Im Gegensatz zu herkömmlichen Vorschriften ist die Methode einfach und direkt und liefert zufriedens tellende Genauigkeit (±8%).

Résumé—On décrit une méthode précise et simple de sodage du groupe méthylol dans les résines phénoliques. Le groupe hydroxyle phénolique est dosé volumé-triquement au moyen de méthylate de sodium en solvant non aqueux, et l'hydroxyle total (hydroxyle phénolique plus hydroxyle alcoolique) est trouvé par calcul de l'intensité d'absorption intégrée à partir du spectre infra-rouge observé entre 3600 et 3000 cm^{-1}. Le groupe hydroxyle alcoolique (groupe méthylol) est calculé en tant que différence entre l'hydroxyle total et l'hydroxyle phénolique. Par opposition à la technique usuelle, cette méthode est simple, direct, et fournit une précision satisfaisante (±8%).

PAPER CHROMATOGRAPHY IN INORGANIC QUALITATIVE ANALYSIS

A. SCHNEER-ERDEY and T. TÓTH
Research Group for Inorganic Chemistry, Hungarian Academy of Sciences
Budapest VIII, Múzeum-körút 6-8, Hungary

(*Received* 8 *July* 1963. *Accepted* 1 *March* 1964)

Summary—A two-dimensional paper chromatographic method for the separation and identification of several metal ions is described. After preparation, the sample is run with an ethanol:hydrochloric acid:water (75 : 20 : 5) mixture, and later in a second dimension with a tetrahydrofuran: nitric acid: water (85: 5: 10) mixture. The chromatogram can be developed with a 0·2% ethanolic solution of Morin, and is examined both in sunlight and in ultraviolet light, in acidic conditions and after alkalisation with ammonia vapour. Those metal ions which migrate together in the first solvent will be separated in the second one, and can be identified reliably. The composition of the original sample can be deduced from the R_f values, colours and fluorescences of the various spots.

IN a previous paper a general method for orientative qualitative analysis has been described.[1] This was not suitable for the simultaneous detection of the following combinations: Zr-Th, Sc-Al, Co-V-Ti, Cu-U, Bi-Pd, Zn, and Sn. A further development of the method, by which any of these ions in admixture can be detected reliably, is based on the use of a solvent in a second dimension, with an appreciably lower dielectric constant than the first. Tetrahydrofuran (THF) was found to be suitable. THF has already been used chromatographically by Specker and Hartkamp.[2]

Pure THF is generally unsuitable as a chromatographic solvent, because the cations, used in the form of chlorides, sulphates or nitrates, remain at the starting point of the chromatogram. If, however, inorganic acids and water are added to the solvent, migration of the ions takes place. To find the optimal composition of the solvent mixture, thorium and zirconium, which generally show a marked difference in behaviour in this type of chromatography, were examined. If the amount of electrolyte in the solvent is increased, thorium migrates with the front, and even zirconium moves from the origin. Both ions, however, form extended spots. If the composition of the solvent is within the limits by volume of 80–85% of THF, 5–10% of nitric acid and 10–15% of water, thorium migrates exactly along with the front. In those cases where the solvent forms two fronts in the chromatographic process, thorium is found in the second front. Zirconium migrates only slightly, and although its spot may extend up to an R_f value of 0·5, it can be reliably distinguished from thorium. In addition, other metal ions, which cannot be separated with an ethanol-hydrochloric acid solvent, are separated with this solvent to such an extent that individual qualitative test can be carried out without difficulty.

Specker and Hartkamp[2] investigated the dependence of R_f values of cations on the composition of solvent mixtures. Burstall and co-workers[3] separated thorium from rare earths with 2-methyltetrahydrofuran (tetrahydrosylvan), containing 10%

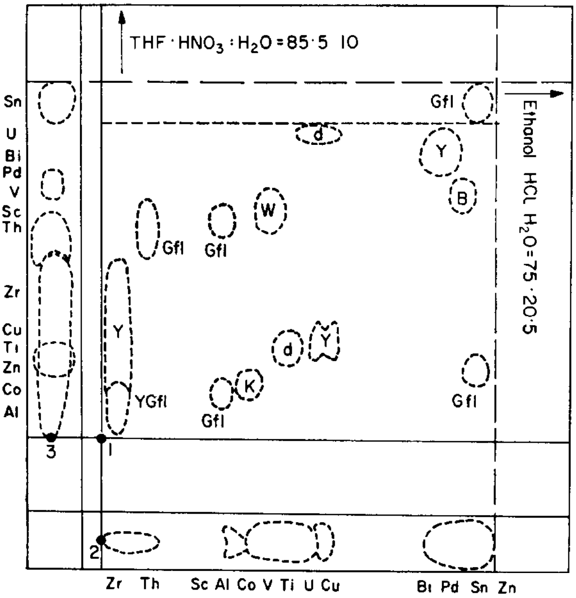

FIG. 1

by volume of nitric acid and 5% of water. For the present purpose a mixture of THF: nitric acid:water (85:5:10) is the most suitable one. Using this solvent in a second dimension, after a run with a hydrochloric acid-ethanol solvent, and drying, all those ions which were not separated by the first solvent will form clearly discernable spots in the chromatogram.

TABLE I.—R_f VALUES IN THE SOLVENT THF:HNO_3:H_2O (85:5:10)

Element	R_f value
Zr	Yellow strip extending from the origin to approximately R_f 0·5: green fluorescence at the origin.
Th	In Front 2 (R_f value in relation to Front is 1:0:9)
Al	0·14
Sc	0·65
Co	0·14
V	0·65
Ti	0·23
U	In Front 2 (R_f related to Front is 1:0:9)
Cu	0·25
Bi	0·88
Pd	0·72
Zn	0·20
Sn	0·94

If, after drying, the chromatogram is sprayed with a 0·2% ethanolic solution of Morin, the spots will appear as indicated in Fig. 1. The R_f values in the solvent mixture of the pairs and the triplet are presented in Table I.

In Table I the R_f values are related to the first Front. The distance of the two Fronts, if the first Front has migrated approximately 20 cm from the origin, is about 20 mm; the R_f value of the second Front therefore is about 0·90.

EXPERIMENTAL

Reagents

Tetrahydrofuran (THF): Puriss

Ethanol: 96%

Hydrochloric acid: S.g. = 1·19

Nitric acid: S.g. = 1·42

Morin (3,5,7,2′,4′-pentahydroxyflavone): 0·2% in ethanol

*Solvent I (ethanol:*HCl:H_2O = 75:20:5): Mix 5 ml of water with 20 ml of concentrated hydrochloric acid, and pour this solution into 75 ml of ethanol.

Solvent II (THF:HNO_3:H_2O = 85:5:10): Mix 5 ml of concentrated nitric acid with 10 ml of water and pour this with constant stirring into 85 ml of THF.

Paper: Schleicher and Schull No. 2043/A, size 58 × 60 cm.

Procedure

Prepare the solution to be analysed, using the procedure described elsewhere,[1] by boiling with H_2O_2 and HCl. Place a drop of the solution on a 29 × 30 cm (quarter) sheet of Schleicher-Schüll No. 2043/A paper. The origin must be chosen as follows (see Fig. 2). First draw two base-lines at right angles to each other, 30 mm from the original (machine-cut) edges of the paper. These lines act as the boundaries of the two test-strips which will later be cut from the chromatogram. Now ascertain the direction of the fibres of the paper; they appear in normal cases to be parallel to the longer side. Draw two starting lines at distances of 10 and 30 mm from the base-lines, one parallel and one perpendicular to the fibres. The origin is the point of intersection of these last lines (Point 1 on Fig. 2). Place a further drop of the sample at Point 2 (15 mm from the edge of the paper). Dip the paper, at right angles to the fibres, in Solvent I, and let the solvent run overnight, using ascending technique. During this time the front travels about 20 cm from the start. Dry the chromatogram under an infrared lamp, and remove traces of hydrochloric acid as completely as possible by an air stream. Cut off the 30-mm test strip (which is parallel to the shorter edge of the paper), and store for further experiments (Test strip of Solvent I).

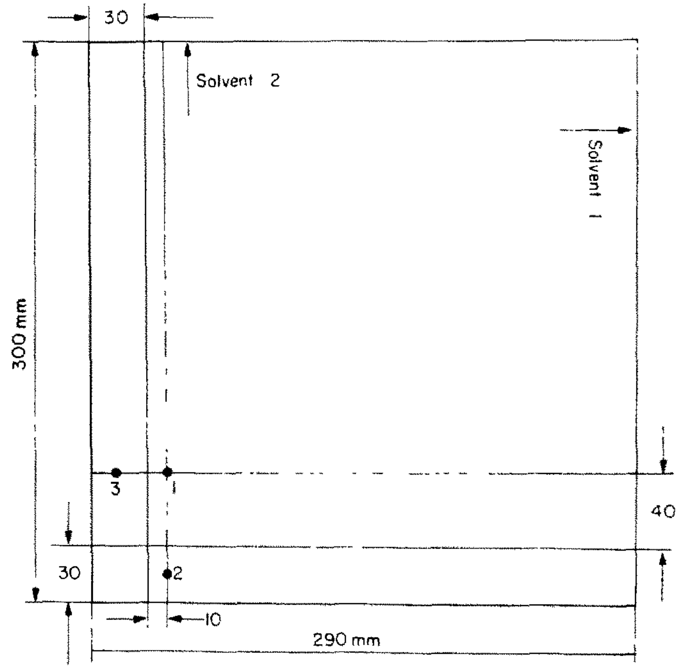

FIG. 2

Place a further drop of the original solution on Point 3 (see Fig. 3), 40 mm from the freshly-cut edge and 15 mm from the original edge of the paper. (Test strip of Solvent II). Dip the freshly-cut edge of the paper in Solvent II and let the solvent run for 4–5 hr, during which time the front migrates about 20 cm from the start. (This distance can be marked on the paper previously.) Dry the paper, remove the traces of nitric acid by an air stream, and spray the paper with a 0·2% ethanolic Morin solution.

Examine the paper in sunlight, and in transparent and reflected ultraviolet light. Mark the coloured spots and the green or yellow fluorescent ones on one side of the paper. Hold the paper over ammonia vapour and examine once more. Mark any spots on the other side of the paper. This examination shows whether spots corresponding to ions which are not separated by Solvent I contain one or more components. R_f values for Solvent II are presented in Table I, and a typical chromatogram is shown in Fig. 1. The notations are those used in an earlier paper.[1]

It is very important to remove hydrochloric acid as completely as possible from the paper after the first run by thorough drying and ventilation. Otherwise the formation of the thorium-nitrate complex (which is soluble in THF) will not be achieved. If it is not, thorium shows an R_f value of about 0·5–0·6. If the chromatographic separation is interrupted after the run with Solvent I, and the dry paper is placed over ammonia vapour, thorium will then have an R_f value higher than 0·5 in Solvent II, but it does not reach the second front. It can still, however, be reliably identified in the presence of zirconium. If only THF is used, thorium migrates along with the second Front. The R_f values for the other metal ions are not affected by previous treatment with the hydrochloric acid solvent, and therefore the same results will be obtained if only Solvent II is used for the chromatographic separation. Uranium, as opposed to thorium, will be found in either case in the second Front.

There are difficulties in identifying those ions which have high R_f values in both solvent systems (0·9 to 1·0); these will be concentrated on the diagonally opposite corner of the chromatogram from the origin. The difficulties occur because impurities dissolved from the paper (particularly iron) are concentrated on this part of the chromatogram, and the resulting dark spot will hide the spots being sought, both in sunlight and in ultraviolet radiation. However, most of these ions, *e.g.*, antimony, tin and gallium, can be identified easily in Solvent I, and of the unresolved zinc-tin pair, zinc migrates more slowly in Solvent II than does tin.

Sensitivities for the qualitative tests on the single ions are about the same as described previously;[1] if the ions are in mixtures, the sensitivities are generally lower by 1–2 magnitudes. Morin is not a very sensitive reagent for most of the metal ions. The sensitivities can be increased as follows: examine the chromatogram after the run with Solvent I, and then from the information gained in this way, apply specific reagents, after the run with Solvent II, on the spots in which any given ion is suspected.

Acknowledgement—The authors wish to express their thanks to Prof. B. Lengyel, Head of the Research Group, for having kindly permitted this work to be carried out in his Institute.

Zusammenfassung—Eine zweidimensionale papierchromatographische Methode zur Trennung und Identifikation mehrerer Metallionen wird vorgeschlagen. Nach geeigneter Vorbereitung lässt man die Probe mit einem Äthanol-Salzsäure-Wasser-Gemisch 75:20:5 laufen, anschliessend in der zweiten Dimension mit Tetrahydrofuran-Salpetersäure-Wasser 85:5:10. Das Chromatogramm kann mit einer 0·2% igen alkoholischen Morinlösung entwickelt werden und wird im Tageslicht und unter einer Ultraviolettlampe betrachtet, sowohl im sauren Zustand als auch nach Behandlung mit Ammoniakgas. Die Metallionen, die im ersten Laufmittel zusammen wandern, werden im zweiten getrennt und können zuverlässig identifiziert werden. Die Zusammensetzung der Probe kann aus R_f-Wert, Farbe und Fluoreszenz der einzelnen Flecke ermittelt werden.

Résumé—On présente une méthode de chromatographie sur papier à deux dimensions pour séparer et identifier plusieurs ions métalliques. Après une préparation convenable, l'échantillon est entraîné par un mélange éthanol—acide chlorhydrique—eau (75:20:5) puis, dans la seconde dimension, par un mélange tétrahydrofuran—acide nitrique—eau (85:5:10). Le chromatogramme peut être révélé par une solution alcoolique a 0·2% de morin, et doit être examiné à la lumière solaire et en lumière ultra-violette, tant à l'état acide qu'après alcalinisation aux vapeurs d'ammoniac. Les ions métalliques qui migrent ensemble dans le premier solvant seront séparés dans le second, et peuvent être identifiés de facon certaine. One peut estimer la composition de l'échantillon original à partir des valeurs des R_f, des couleurs et de la fluorescence des diverses taches.

THERMOANALYTICAL PROPERTIES OF ANALYTICAL-GRADE REAGENTS

AMMONIUM SALTS

L. ERDEY, S. GÁL and G. LIPTAY
Institute of General Chemistry, Technical University, Budapest XI
Gellért tér 4, Hungary

(*Received* 7 *October* 1963. *Accepted* 13 *January* 1964)

Summary—Twenty-six ammonium salts have been investigated derivatographically. The weight change, rate of weight change and enthalpy change of the salts have been measured as a function of temperature. From the results the temperatures at which the salts may be dried without decomposition are given.

DUVAL and his coworkers[1] studied nearly one thousand analytical precipitates by the method of thermal gravimetry. The intention was to establish the temperature at which the analytical precipitate is of stoichiometric composition and the temperature interval over which the precipitate is suitable for weighing. Berg[2] and Smothers and Chiang[3] introduced the method of differential thermal analysis in their books and treated in detail its most important fields of application. Few workers have used the two methods in conjunction with each other. Erdey, Paulik and Paulik combined the methods of thermal gravimetry (TG) and differential thermal analysis (DTA) with the method of derivative thermal gravimetry (DTG) elaborated by themselves.[4] TG, DTA and DTG curves were recorded automatically on an apparatus designated a derivatograph.[5,6] The derivatograph can measure simultaneously, for a single sample, change of weight (TG), rate of change of weight (DTA) and enthalpy change (DTG), as a function of temperature, at a heating rate of 1–20°/min.

Twenty-six ammonium salts have now been investigated derivatographically (Table I). We have attempted to explain the results in terms of the Lewis electron theory previously applied to acid-base reactions.[7,8] The various decomposition processes can be interpreted satisfactorily on the basis of the derivatograms. Where intermediate plateaux occur on the TG curves, they correspond to the formation of definite compounds, the formulae of which have been marked on the appropriate figures. Experimental weight losses agree well in most cases with the theoretical losses expected for the formation of such compounds. In those cases where agreement was not so good, the deviation could be attributed to two processes occurring at about the same temperature. Not all of the decomposition products were examined.

EXPERIMENTAL

The studies were carried out using a Paulik-Paulik-Erdey type 676 derivatograph manufactured by Orion-Gyem, Budapest, Hungary. The sample (100–200 mg) was weighed in the platinum crucible of the instrument. Gaseous decomposition products were pumped off from the air space of the furnace. A heating rate of 5°/min was employed. Samples were pulverised in a porcelain mortar and passed through a sieve of the same mesh-size in every case before being weighed.

The reagents used in the experiments were made available to us by E. Merck (Darmstadt, Germany), for which we would like to express our thanks.

TABLE I

Figure	Ammonium salt	Formula	DTA peaks, °C	DTG peaks, °C	Temperature of drying,[a] °C
1	Fluoride	NH_4F	Endothermic: 145, 220	145, 225	<50
2	Hydrogen fluoride	$NH_4F.HF$	Endothermic: 125, 240	235	<60
3	Chloride	NH_4Cl	Endothermic: 185, 345	345	110–120
4	Bromide	NH_4Br	Endothermic: 150, 415	410	<200
5	Iodide	NH_4I	Endothermic: 390	400	<200[b]
6	Perchlorate	NH_4ClO_4	Endothermic: 250; exothermic: 400	400	<200[c]
7	Sulphate	$(NH_4)_2SO_4$	Endothermic: 330, 410	410	<200
8	Thiosulphate	$(NH_4)_2S_2O_3$	Endothermic: 140, 225, 400; exothermic: 350	220, 245, 350, 400	<80
9	Persulphate	$(NH_4)_2S_2O_8$	Endothermic: 370; exothermic: 170	180, 365	<100[c]
10	Thiocyanate	NH_4SCN	Endothermic: 90, 115, 150, 245; exothermic: 525	245, 290, 515	<100[c]
11	Nitrate	NH_4NO_3	Endothermic: 45, 84, 130, 166; exothermic: 285	285	100–110
12	Molybdate	$(NH_4)_6Mo_7O_{24}.4H_2O$	Endothermic: 120, 235, 350	110, 230, 350	<100
13	Metavanadate	NH_4VO_3	Endothermic: 240, 375	230, 375	<100
14	Monohydrogen phosphate	$(NH_4)_2HPO_4$	Endothermic: 170; exothermic: 280	150, 170, 260, 760	<100
15	Dihydrogen phosphate	$NH_4H_2PO_4$	Endothermic: 200	230, 730	<150
16	Chromate	$(NH_4)_2CrO_4$	Endothermic: 130; exothermic: 245, 405	125, 236, 405	<40
17	Dichromate	$(NH_4)_2Cr_2O_7$	exothermic: 230, 390	230, 395	<200
18	Pentaborate	$NH_4B_5O_8.4H_2O$	Endothermic: 160, 280, 400	160, 280, 400, 430	—
19	Sulphamate	$NH_4SO_3NH_2$	Endothermic: 135, 475	225, 290, 465	
20	Carbonate	$(NH_4)_2CO_3$	Endothermic: 80	75	—
21	Acetate	NH_4OOCCH_3	Endothermic: 100, 115, 155	150	30–40
22	Oxalate	$(NH_4)_2(COO)_2.H_2O$	Endothermic: 115, 235	115, 235, 300	<150[d]
23	Citrate	$(NH_4)_2C_6H_6O_7$	Endothermic: 195	195	<100
24	Benzoate	$NH_4C_7H_5O_2$	Endothermic: 195, 250	235	<50
25	Salicylate	$NH_4C_7H_5O_3$	Endothermic: 200	190	<100
26	Tartrate	$(NH_4)_2C_4H_4O_6$	Endothermic: 185, 245	180, 245	<100

[a] Without decomposition.

[b] Sample is hygroscopic.

[c] If pure.

[d] This temperature is for anhydrous ammonium oxalate. The monohydrate can be dried at 30–40°.

RESULTS AND DISCUSSION

Ammonium fluoride

It can be seen from the derivatogram (Fig. 1) that the mechanically bound water content of the sample is lost at about 50°. The peak on the DTA and DTG curves at 145° indicates a maximal rate of removal of ammonia according to

$$2NH_4F \rightarrow NH_4F.HF + NH_3.$$

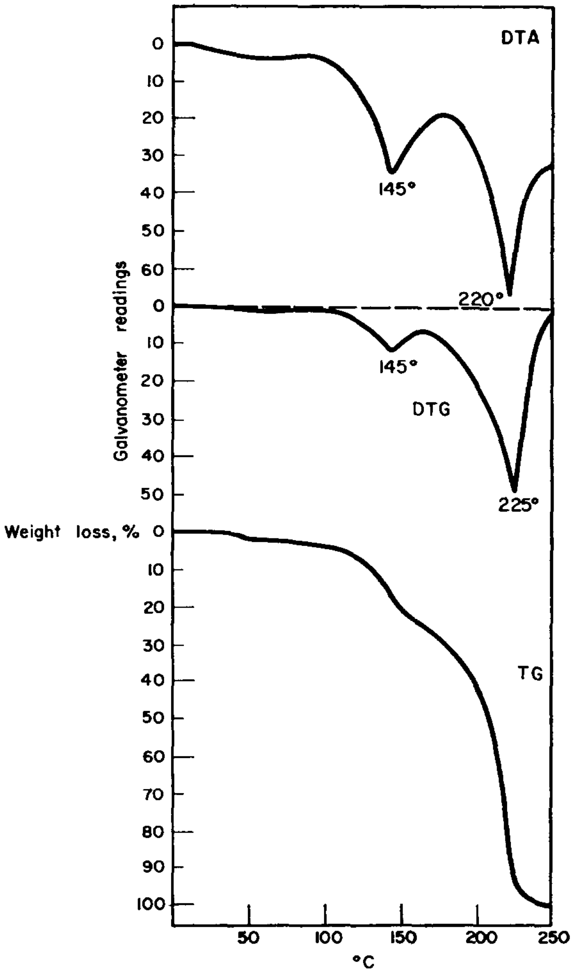

FIG. 1.—Ammonium fluoride.

The ammonium hydrogen fluoride formed begins to decompose to a small degree at this temperature. This decomposition proceeds at a maximal rate at 225°, ammonia and hydrogen fluoride being obtained.

Ammonium hydrogen fluoride

The sample melts at 125° (DTA curve in Fig. 2). The rate of decomposition—beginning at 80°—increases and the rate of weight decrease is maximal at 235°. Ammonium hydrogen fluoride is more stable than the neutral salt.

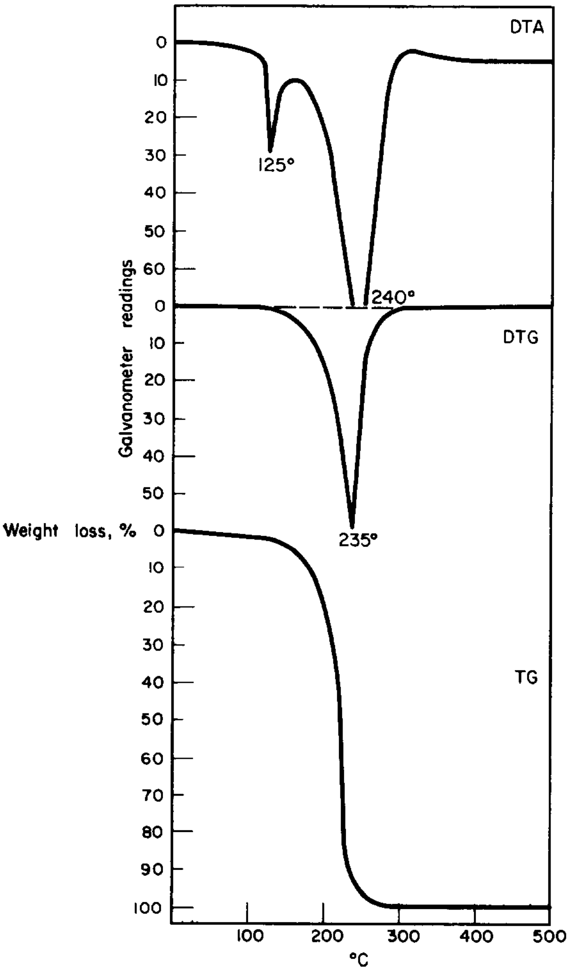

FIG. 2.—Ammonium hydrogen fluoride.

Ammonium chloride

Ammonium chloride shows little change in weight up to 200° (Fig. 3). The endothermic DTA peak at 185° indicates a change of crystal structure of ammonium chloride. Above 200° the substance sublimes, the sublimation rate being maximal at 345°. After sublimation it dissociates completely in the gaseous phase into ammonia and hydrochloric acid

$$NH_4Cl \rightleftharpoons NH_3 + HCl.$$

On cooling, the reaction is reversed and ammonium chloride condenses from the gaseous phase.

Hydrochloric acid formed during the decomposition is very active and reacts with various metal oxides or carbonates at a temperature above 300° to form chlorides, water and carbon dioxide. Thus, aluminium oxide can be fused in this way.

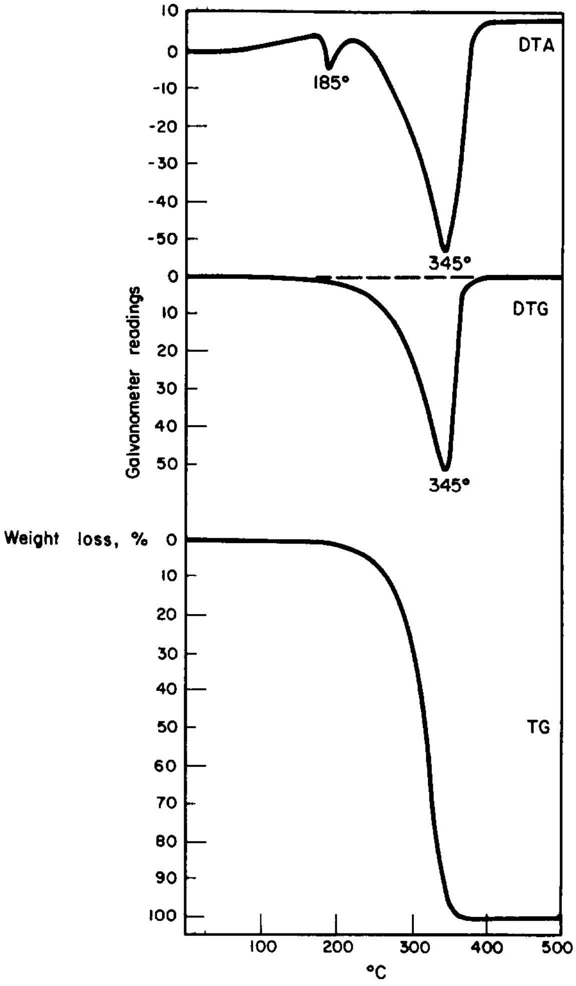

FIG. 3.—Ammonium chloride.

Ammonium bromide

Ammonium bromide shows a change in crystal structure at 150° (DTA curve in Fig. 4). Decomposition only begins to any marked extent above 250°. The salt does not melt at atmospheric pressure, but sublimes and decomposes completely in the gaseous phase to form ammonia and hydrogen bromide

$$NH_4Br \rightleftharpoons NH_3 + HBr$$

On cooling, ammonium bromide condenses, *i.e.*, the reaction is reversible. Sublimation proceeds at the highest rate at 410°.

Ammonium iodide

Sublimation of ammonium iodide proceeds over nearly the same temperature interval as that of ammonium bromide (Fig. 5). Also, the ammonium iodide sublimes and decomposes in the gaseous phase to ammonia and hydrogen iodide

$$NH_4I \rightleftharpoons NH_3 + HI.$$

On cooling, ammonium iodide condenses.

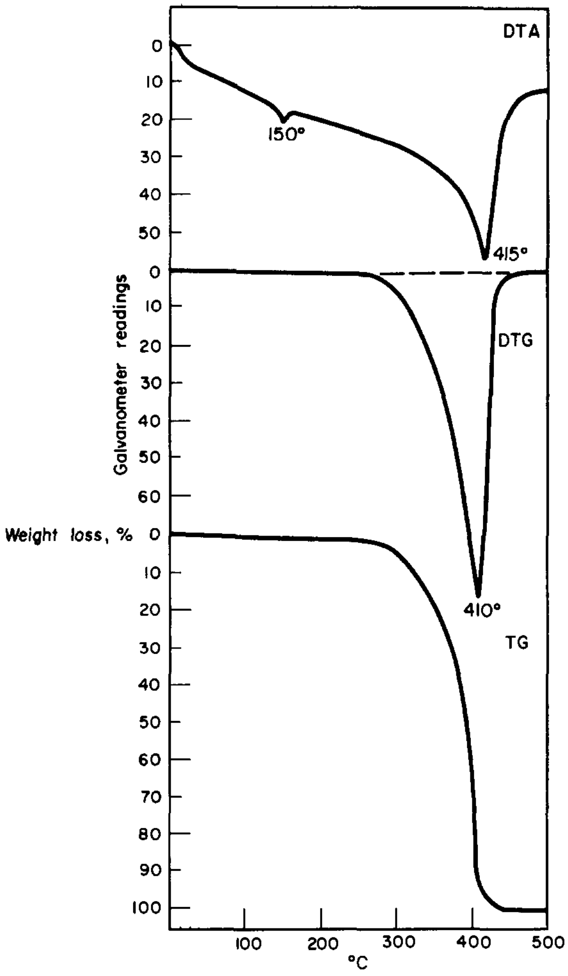

FIG. 4.—Ammonium bromide.

Ammonium perchlorate

An endothermic process can be observed on the DTA curve at 250° (Fig. 6), which accompanies a change in crystal structure of the ammonium perchlorate. Thereafter a decrease of weight begins. This decrease of weight is caused by decomposition and sublimation of the salt. Decomposition begins at a much lower temperature if there are small amounts of metal oxide or organic substance contamination. The sample studied is of analytical-grade material and is, therefore, very stable. The decomposition beginning above 250° is an exothermic process, as shown by the DTA peak at 400°. As the temperature of the sample reaches 400° decomposition proceeds explosively.

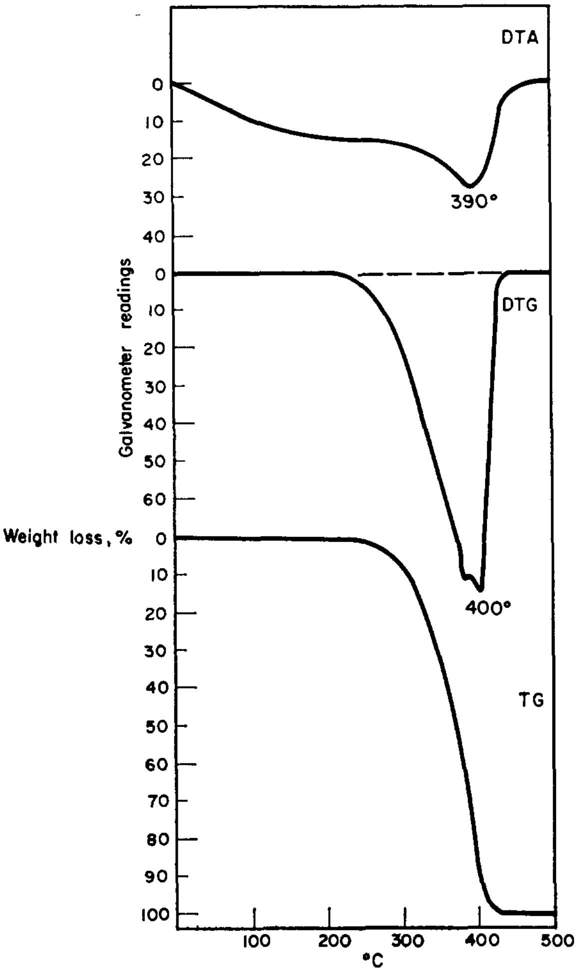

FIG. 5.—Ammonium iodide.

In the gaseous phase quite different reaction products are present depending on the temperature of decomposition. Below 300°, the reaction products are gaseous nitrogen, oxygen, chlorine and water vapour. Above 300°, various nitrogen oxides are also present besides gaseous nitrogen

$$2NH_4ClO_4 \rightarrow 2NO + O_2 + Cl_2 + 4H_2O.$$

At the temperature of the reaction the nitrogen monoxide reacts with oxygen and chlorine to form nitrogen dioxide (NO_2), dinitrogen trioxide (N_2O_3) and nitrosyl chloride (NOCl). The temperature of decomposition and composition of decomposition products varies according to the nature and amount of contaminants.

Ammonium sulphate

The ammonium sulphate sample contains neither mechanically bound nor water of crystallisation. The substance begins to decompose above 250° (Fig. 7). In the

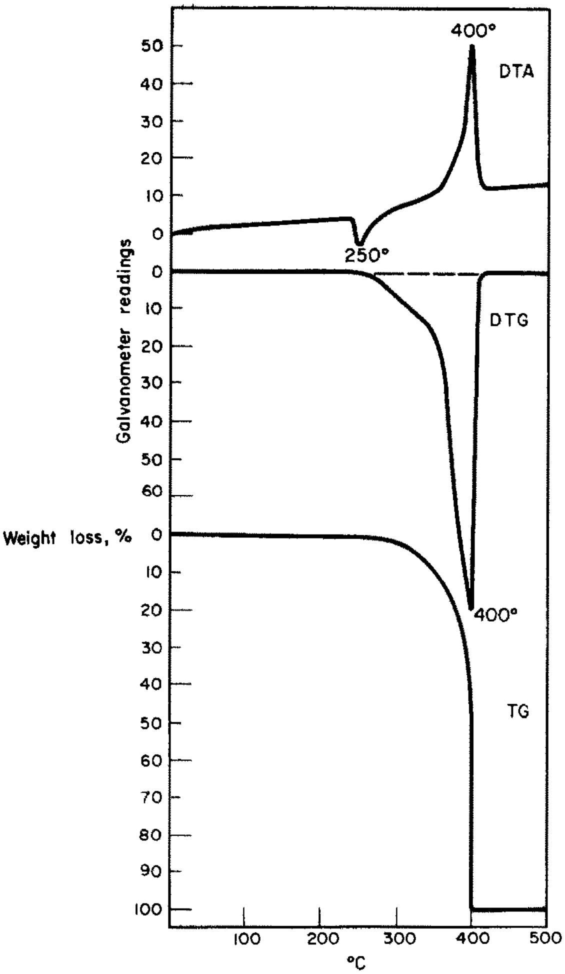

FIG. 6.—Ammonium perchlorate.

first step of the decomposition the molecule loses ammonia and ammonium hydrogen sulphate is formed

$$(NH_4)_2SO_4 \xrightarrow{230\text{-}350^\circ} NH_4HSO_4 + NH_3.$$

This reaction seems to be quantitative according to the derivatogram. The reaction is indicated by the endothermic DTA peak at 330°. Ammonium sulphate itself does not melt, although the ammonium hydrogen sulphate formed during the decomposition does. The ammonium hydrogen sulphate decomposes at 410° at a maximal rate and the process is completed at 450°

$$NH_4HSO_4 \xrightarrow{350\text{-}450^\circ} NH_3 + H_2SO_4.$$

Sulphuric acid formed during the decomposition is very active and fuses various metal oxides.

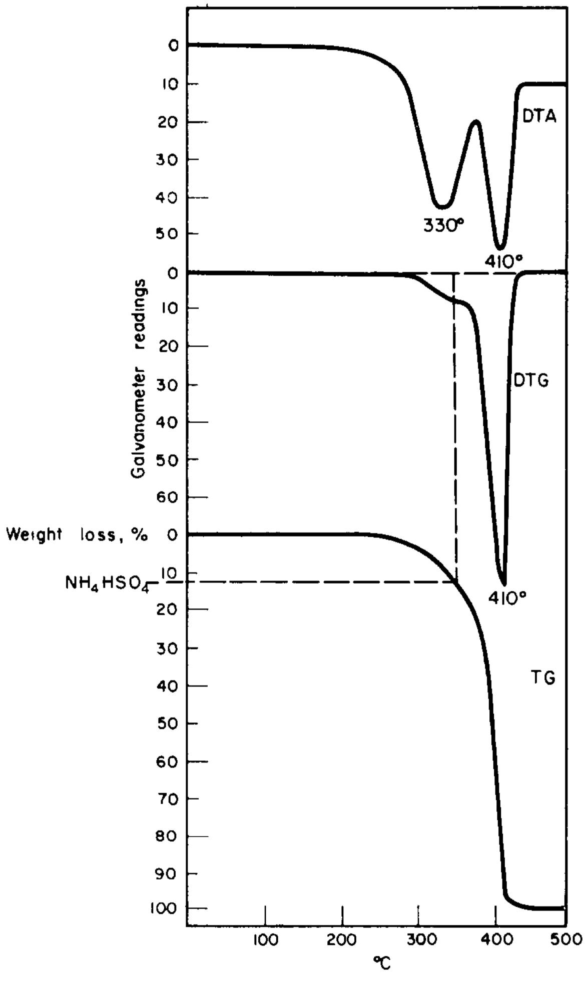

Fig. 7.—Ammonium sulphate.

Ammonium thiosulphate

The thermal decomposition of ammonium thiosulphate is complicated (Fig. 8). Up to 100° neither weight nor enthalpy change can be observed. The endothermic DTA peak at 140° indicates a change of crystal structure. Above 100° decomposition begins, ammonium sulphite and sulphur being formed

$$(NH_4)_2S_2O_3 \xrightarrow{>100^\circ} (NH_4)_2SO_3 + S.$$

Part of the ammonium sulphite immediately decomposes, the maximal rate being at 230–245°

$$(NH_4)_2SO_3 \rightarrow 2NH_3 + SO_2 + H_2O.$$

The rest of the ammonium sulphite is oxidised to ammonium sulphate. The net effect of the enthalpy changes of the two processes is endothermic. Above 275° the sulphur burns exothermically and ammonium hydrogen sulphate is formed from the ammonium sulphate. Above 360° the ammonium hydrogen sulphate decomposes, the rate being maximal at 400°.

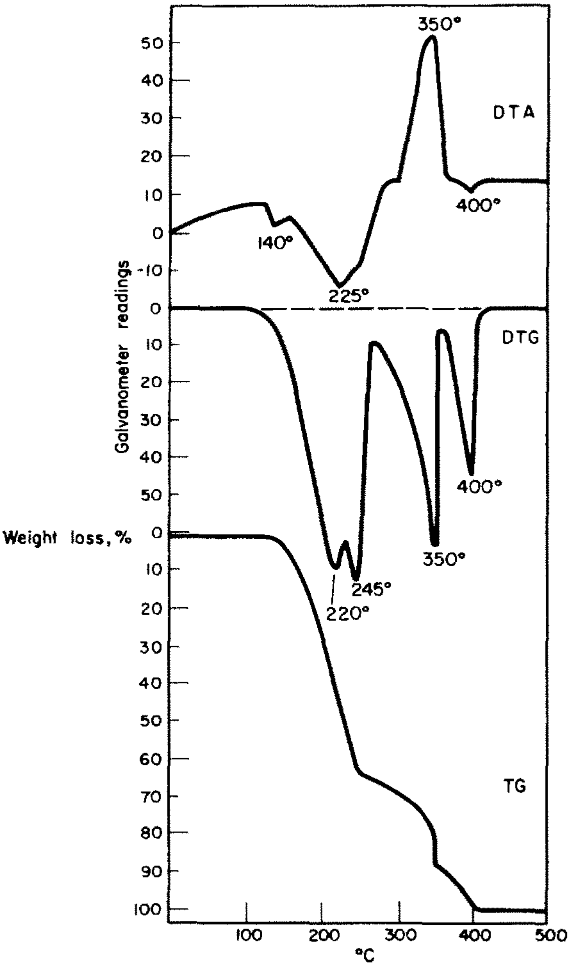

FIG. 8.—Ammonium thiosulphate.

Ammonium persulphate

Pure ammonium persulphate decomposes explosively at 180° according to the derivatographic curves (Fig. 9), ammonium pyrosulphate being formed and oxygen liberated

$$2(NH_4)_2S_2O_8 \rightarrow 2(NH_4)_2S_2O_7 + O_2.$$

As shown by the TG curve, the exothermic reaction proceeds quantitatively. If water vapour is present in the furnace air space or the sample contains any organic matter, this reaction proceeds at a lower temperature. Ammonium pyrosulphate begins to decompose above 250°, sulphur trioxide being lost and ammonium sulphate remaining

$$(NH_4)_2S_2O_7 \rightarrow (NH_4)_2SO_4 + SO_3.$$

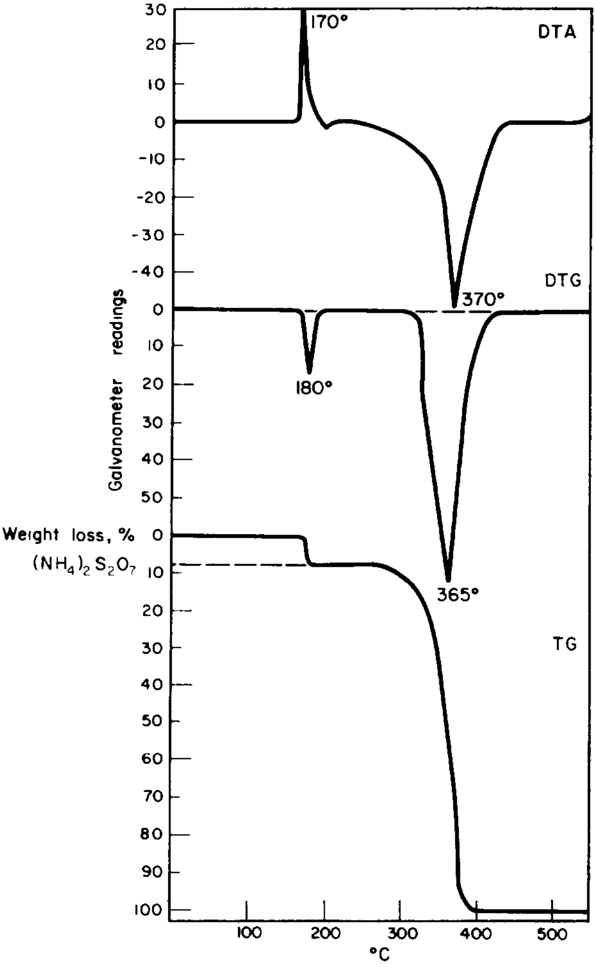

FIG. 9.—Ammonium persulphate.

This process is, however, very slow and not quantitative, because at the same time the ammonium sulphate formed decomposes to ammonium hydrogen sulphate, which in turn decomposes to ammonia and sulphuric acid

$$(NH_4)_2SO_4 \rightarrow NH_3 + NH_4HSO_4$$

$$NH_4HSO_4 \rightarrow NH_3 + H_2SO_4.$$

The above three decomposition processes proceed between 300 and 400° and are maximal in rate at 365°. All three decomposition processes are endothermic. Pure ammonium persulphate can be dried to about 100° without decomposition and heating it to 200° ammonium pyrosulphate can be obtained.

Ammonium thiocyanate

The endothermic peaks on the DTA curve (Fig. 10) of ammonium thiocyanate at 90 and 115° are characteristic of changes of crystal structure of the sample. These changes are reversible. The endothermic DTA peak at 150° is characteristic of melting of the sample; the break in the curve at about 170° shows that after the melting another process accompanied by an enthalpy change proceeds. This region of the DTA curve shows the transformation of the ammonium thiocyanate into thiourea

$$NH_4SCN \rightarrow CS(NH_2)_2.$$

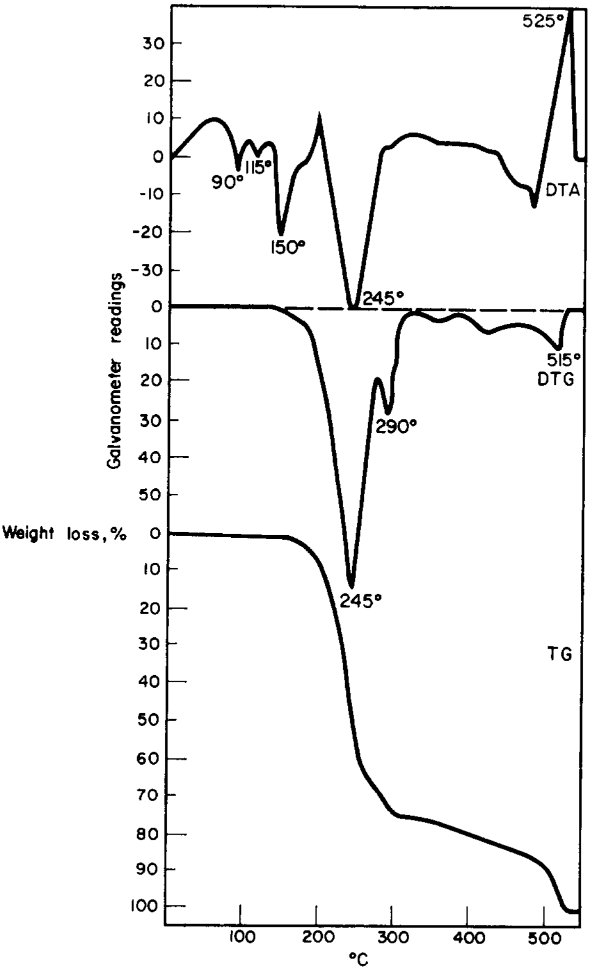

FIG. 10.—Ammonium thiocyanate.

The transformation proceeds only partially and on further increase of temperature the amount of the thiourea formed decreases. After melting and partial transformation the substance decomposes, ammonia, carbon disulphide and hydrogen sulphide being removed, while guanidine thiocyanate and melamine thiocyanate remain. The first decomposition process is complete at about 300°, while the thiocyanates formed, having a higher decomposition temperature, are removed at a maximal rate only at 515°. This process is exothermic.

Ammonium nitrate

The derivatographic curve (Fig. 11) of ammonium nitrate provides a good illustration of the advantage of a multifunctional apparatus (TG, DTG and DTA).

Ammonium nitrate has three transformation points above room temperature.

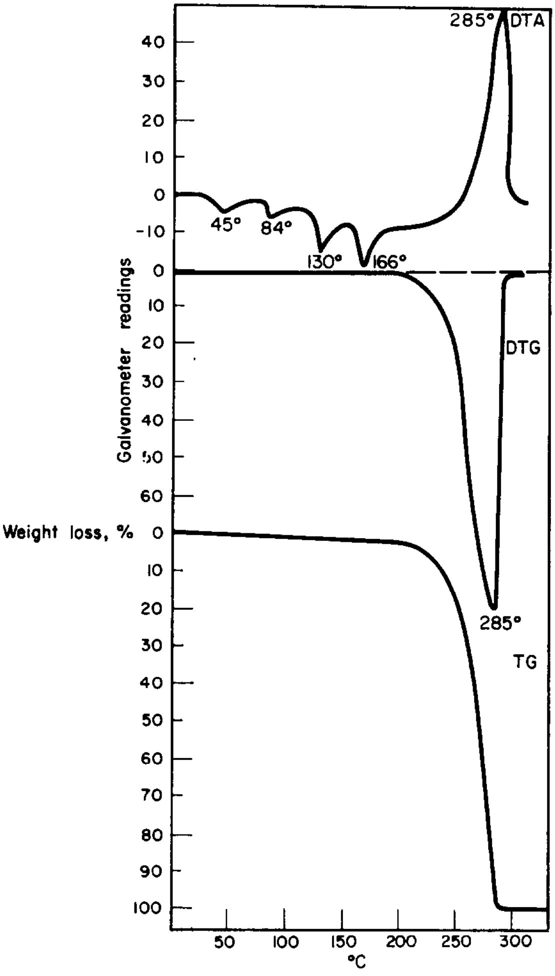

FIG. 11.—Ammonium nitrate.

The three changes of crystal structure are well shown on the DTA curve by the endothermic peaks at 45, 84 and 130°. The sample melts at 166° (DTA curve). Decomposition and decrease in weight of ammonium nitrate begin above 150°. Up to 200° the decomposition is of small extent, and above 220° it becomes exothermic. Between 220 and 260° dinitrogen oxide (N_2O) is formed in 98% yield:

$$NH_4NO_3 \xrightarrow{220\text{–}260°} 2H_2O + N_2O.$$

The decomposition proceeds explosively between 260 and 290° and on further rise in temperature the amount (previously very small) of poisonous nitrogen monoxide (NO) and nitrogen dioxide (NO_2) increases. Care should be taken in drying large amounts of ammonium nitrate not to raise the temperature above 100–110° because explosion then becomes possible.

Ammonium molybdate tetrahydrate

The sample weight begins to decrease above 40°. In the first step (Fig. 12) it loses its four molecules of water of crystallisation

$$(NH_4)_6Mo_7O_{24}.4H_2O \xrightarrow{40\text{–}170^\circ} (NH_4)_6Mo_7O_{24} + 4H_2O.$$

This process is shown by the DTG peak at 110° and the endothermic DTA peak at 120°.

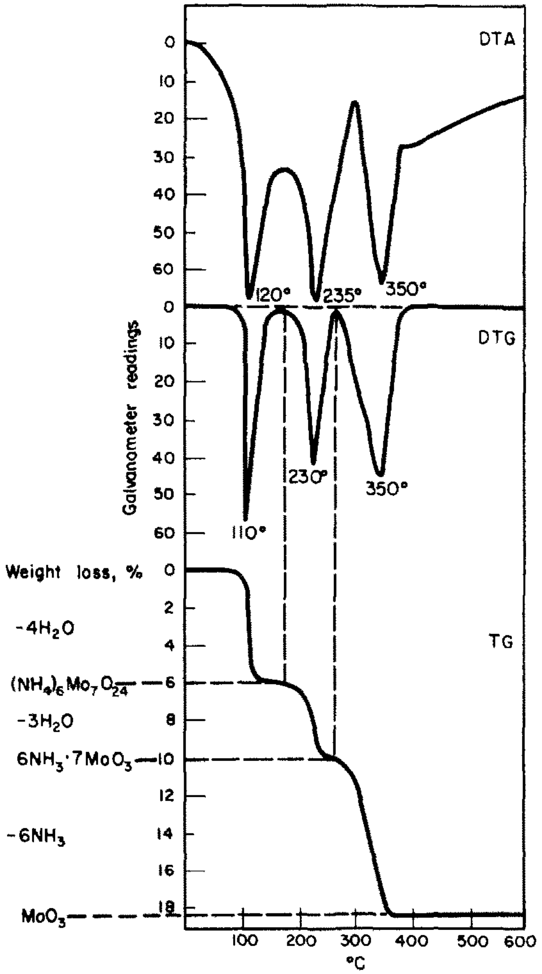

Fig. 12.—Ammonium molybdate tetrahydrate.

The sample weight then decreases further, the rate of decrease being a minimum at 170°. Above 170° the weight of the sample decreases more quickly, the weight decrease, corresponding to the removal of three molecules of water, being at a maximal rate at 230° (TG curve):

$$(NH_4)_6Mo_7O_{24} \xrightarrow{170\text{–}260^\circ} 6NH_3.7MoO_3 + 3H_2O.$$

The next decomposition process lasts from 260 to 400°, while six molecules of ammonia are removed and a residue of molybdenum trioxide remains

$$6NH_3.7MoO_3 \xrightarrow{260-400^\circ} 7MoO_3 + 6NH_3.$$

The composition of the sample, calculated on the basis of the TG curve, is exactly identical with the above formula. The weight of the molybdenum trioxide residue slowly decreased above 600°, because at this temperature molybdenum trioxide sublimes. Material free from water of crystallisation can be produced by careful drying below 100°.

Ammonium metavanadate

The sample begins to decompose above 130° (Fig. 13), the decomposition proceeding in two well separated steps. In the first step, which is indicated by the endothermic DTA peak at 240° and the DTG peak at 230°, ammonia splits off

$$NH_4NO_3 \xrightarrow{130-270^\circ} HVO_3 + NH_3.$$

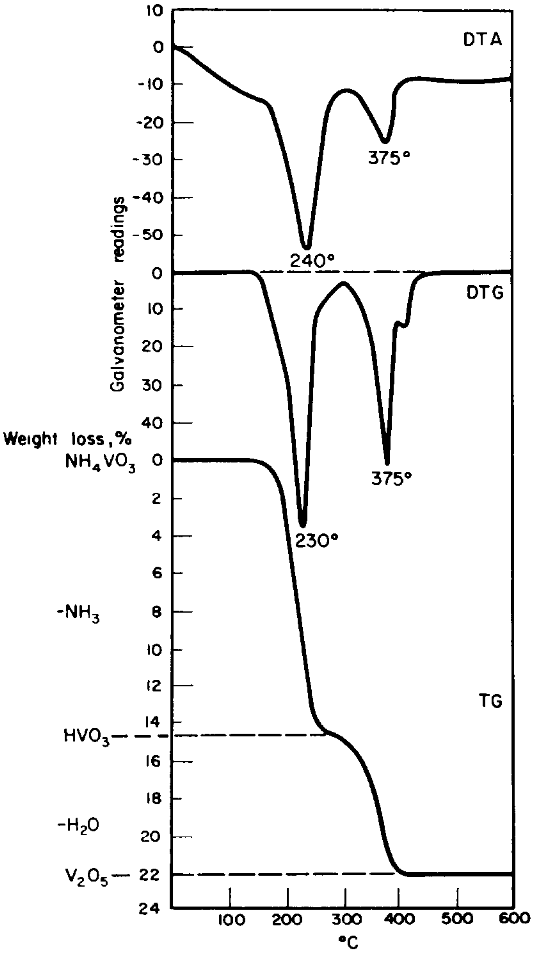

Fig. 13.—Ammonium metavanadate.

After the removal of ammonia, water starts to be lost, and above 470° only vanadium pentoxide remains

$$2HVO_3 \xrightarrow{270-470^\circ} V_2O_5 + H_2O.$$

Diammonium monohydrogen phosphate

There is no weight change up to 100° (Fig. 14). Above this temperature loss of weight begins, proceeding at 150, 170 and 260° at a maximal rate. The three peaks observed on the DTG curve indicate that several decomposition processes proceed simultaneously. In the first step ammonium dihydrogen phosphate is formed by removal of one mole of ammonia

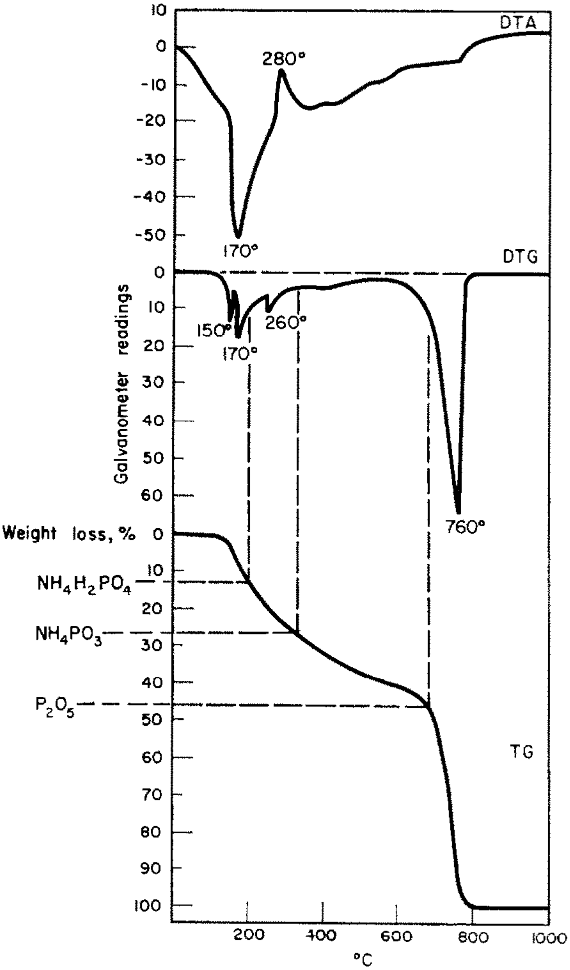

FIG. 14.—Diammonium monohydrogen phosphate.

$$(NH_4)_2HPO_4 \rightarrow NH_4H_2PO_4 + NH_3.$$

After this loss of ammonia (at about 150°), the sample melts and diammonium dihydrogen pyrophosphate is formed by removal of one mole of water

$$2NH_4H_2PO_4 \rightarrow (NH_4)_2H_2P_2O_7 + H_2O.$$

On further heating the pyrophosphate loses a further molecule of water and ammonium metaphosphate is formed

$$(NH_4)_2H_2P_2O_7 \rightarrow 2NH_4PO_3 + H_2O.$$

This ammonium metaphosphate melt is water-soluble up to 280°, then an exothermic transformation takes place and a glassy metaphosphate melt, insoluble in water, remains. Further ammonia and water are removed from the ammonium metaphosphate between 600 and 800° (maximal rate at 760°), leaving a residue of phosphorus pentoxide

$$2NH_4PO_3 \rightarrow P_2O_5 + 2NH_3 + H_2O.$$

During the experiment the various decomposition processes proceed simultaneously and may not be distinguished from each other. However, levels corresponding to the various compositions are drawn on Fig. 14, calculated on the basis of the weight of the sample, in order to make the decomposition processes clear. The various acidic pyro and metaphosphates formed from diammonium monohydrogen phosphate are very active and fuse different metal oxides, the phosphates of the metals being formed.

Monoammonium dihydrogen phosphate

It can be seen in Fig. 15 that weight loss only starts above 150°. The sample melts at 200°, which is indicated by an endothermic DTA peak. Above 200° decomposition proceeds in the same way as was described in Fig. 14 for diammonium monohydrogen phosphate. The individual decomposition processes also cannot be separated from each other here.

Ammonium chromate

The weight of the sample decreases above 50° (Fig. 16), the first decomposition process having a maximal rate at 125°. Ammonia and water are released and ammonium dichromate is formed

$$2(NH_4)_2CrO_4 \xrightarrow{50\text{–}150^\circ} (NH_4)_2Cr_2O_7 + 2NH_3 + H_2O.$$

At this temperature, however, the ammonium dichromate is unstable and it slowly decomposes above 160°. The exothermic decomposition process proceeding at about 230–240° indicates the simultaneous splitting off of water, ammonia and oxygen

$$2(NH_4)_2Cr_2O_7 \xrightarrow{160\text{–}450^\circ} 2Cr_2O_3 + 4NH_3 + 2H_2O + 3O_2.$$

The decomposition finishes at about 405°, oxygen being lost in an exothermic process. The various stages show that the decomposition proceeds explosively and this fact causes a weight loss 2% more than the theoretical value, because the gaseous decomposition products carry away solid particles.

Ammonium dichromate

Ammonium dichromate is of constant weight up to 200° in air. Above this temperature the weight of the sample slowly begins to decrease, and between 240 and 250° decomposition proceeds explosively (Fig. 17)

$$2(NH_4)_2Cr_2O_7 \xrightarrow{240\text{–}250^\circ} 2Cr_2O_3 + 4NH_3 + 2H_2O + 3O_2.$$

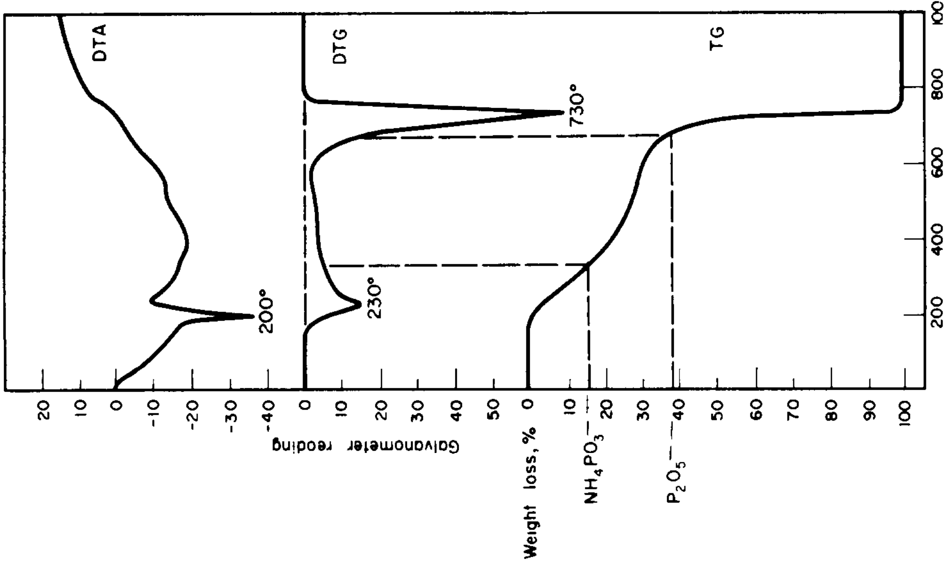

Fig. 15.—Monoammonium dihydrogen phosphate.

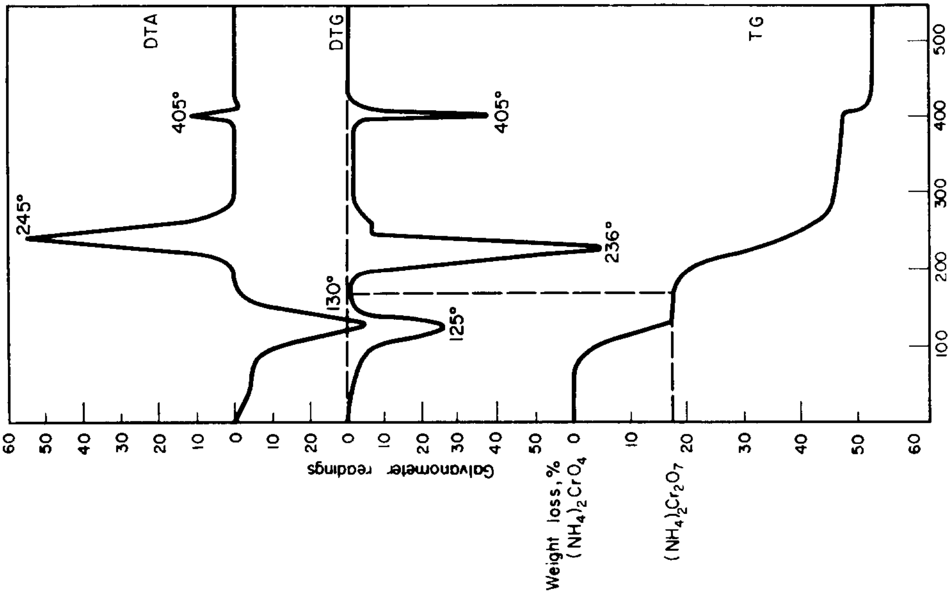

Fig. 16.—Ammonium chromate.

The decomposition proceeds in a single step when more than 100 mg of ammonium dichromate are involved (curve 1, Fig. 17). If the amount involved is decreased, decomposition proceeds in three steps. Curves 2 and 3 (Fig. 17) are thermograms of initial sample weights of 60 and 30 mg, respectively. The heating rate and other experimental conditions were the same for all three measurements. The shape of curve 1 (TG curve) agrees well with that published by Duval;[9] that of curves 2 and 3 is, however, markedly different.

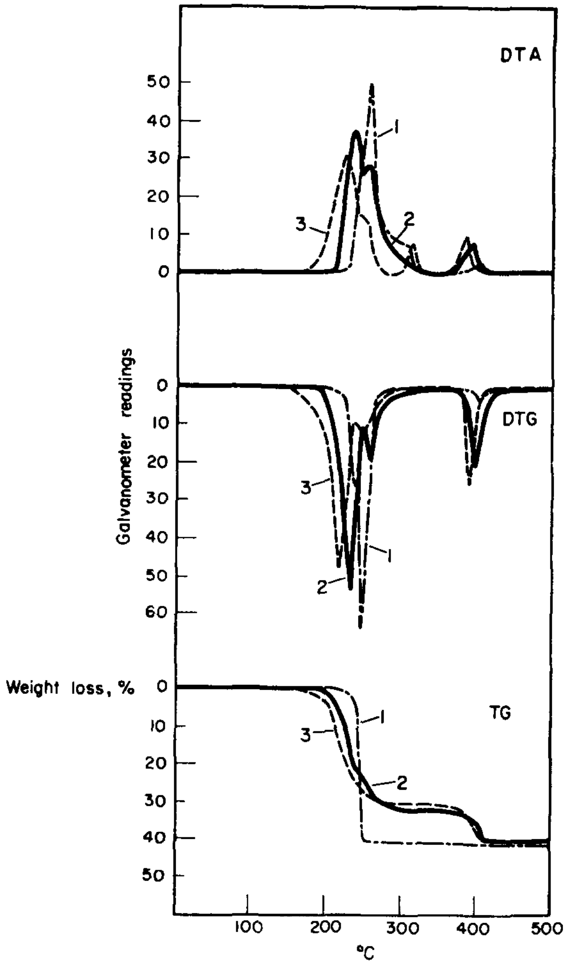

FIG. 17.—Ammonium dichromate.

Ammonium pentaborate tetrahydrate

Ammonium pentaborate tetrahydrate begins to loose weight above 100° (Fig. 18). The DTG maximum at 160° indicates a maximal rate of removal of three moles of water of crystallisation

$$NH_4B_5O_8.4H_2O \xrightarrow{100\text{-}230^\circ} NH_4B_5O_8.H_2O + 3H_2O.$$

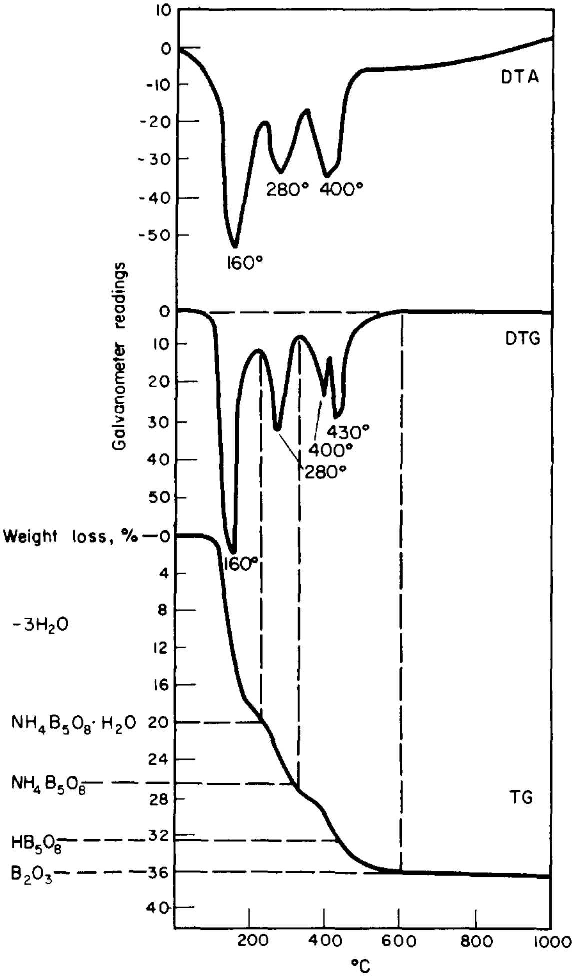

FIG. 18.—Ammonium pentaborate tetrahydrate.

Above 230° the fourth water molecule begins to be lost, the rate being maximal at 280°

$$NH_4B_5O_8.H_2O \xrightarrow{230\text{–}330^\circ} NH_4B_5O_8 + H_2O.$$

The fourth water molecule is bound more strongly than are the other three. After removal of the fourth molecule, ammonia splits off and pentaboric acid is formed

$$NH_4B_5O_8 \xrightarrow{330\text{–}440^\circ} HB_5O_8 + NH_3.$$

The pentaboric acid is, however, unstable at this temperature, immediately losing water to yield boric oxide

$$2HB_5O_8 \xrightarrow{440\text{–}460^\circ} 5B_2O_3 + H_2O.$$

On the DTG and DTA curves a peak corresponds to each of the described processes. The individual decomposition processes are more separated at a lower heating rate.

Water-free ammonium pentaborate cannot be produced by drying because loss of the fourth water molecule proceeds simultaneously with decomposition of the substance.

Ammonium sulphamate

The sample melts at 135°, as indicated by the endothermic peak on the DTA curve (Fig. 19). The weight of the sample does not change until 200°, then decomposition begins and is a maximum at 225 and 290°. Ammonia is removed and ammonium sulphamate is formed

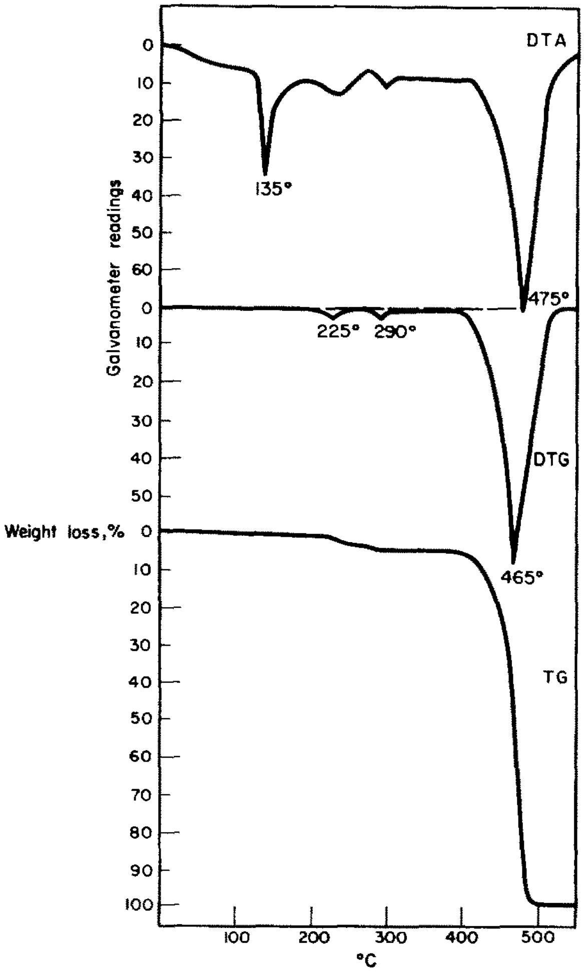

FIG. 19.—Ammonium sulphamate.

$$2NH_4SO_3NH_2 \rightarrow (NH_4SO_3)_2NH + NH_3.$$

According to our experimental conditions the reaction is not quantitative, because on raising the temperature decomposition of the ammonium sulphamate also starts. This decomposition is maximal in rate at 465° and is an endothermic process.

Ammonium carbonate

Decomposition of the sample has already begun at 20° and reaches its maximal rate at 75° (Fig. 20). Ammonia, carbon dioxide and water are formed

$$(NH_4)_2CO_3 \rightarrow 2NH_3 + CO_2 + H_2O.$$

The sample does not melt, but sublimes, and in the meantime decomposes. The endothermic peak at 80° is the enthalpy change of the decomposition. The DTG peak at 105° indicates that water remaining in the crucible during the decomposition is a little overheated and evaporated quickly. The decomposition is practically finished at 100°. By decreasing the partial pressure of the decomposition products, the decomposition can be completed at lower temperatures. According to our measurements ammonium carbonate cannot be dried without decomposition.

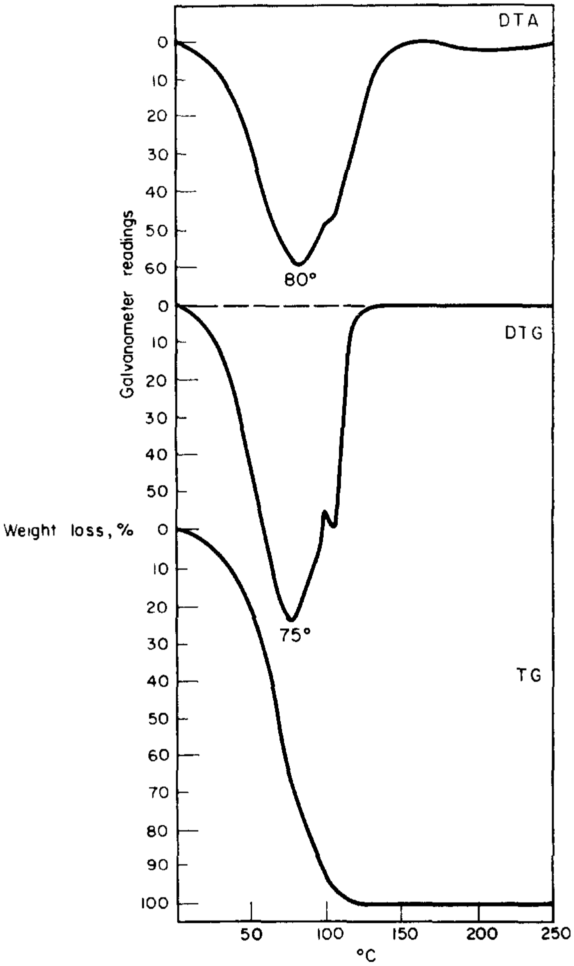

FIG. 20.—Ammonium carbonate.

Ammonium acetate

The decomposition of ammonium acetate starts above 60° (Fig. 21). The maximum on the DTA curve at 100° shows partly the decomposition and partly the onset

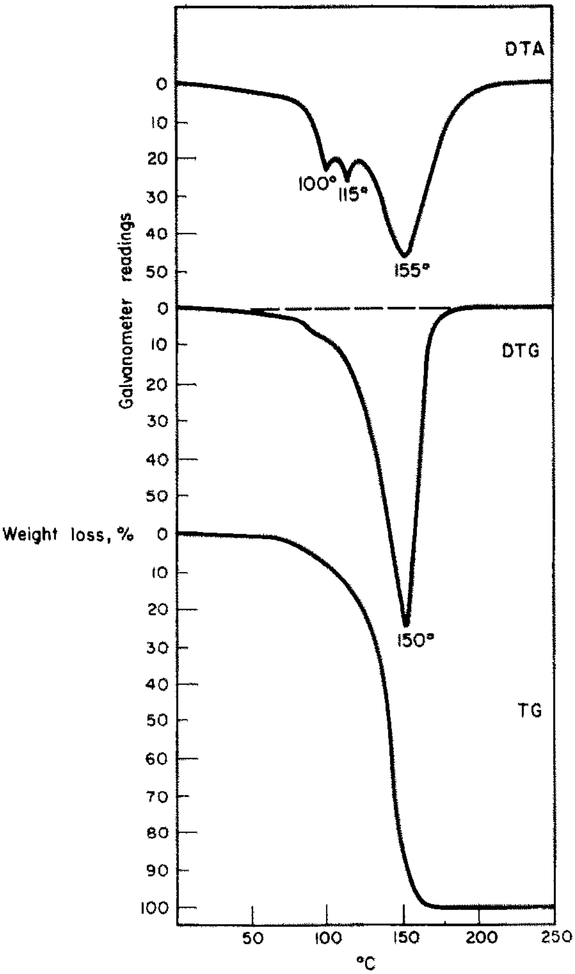

FIG. 21.—Ammonium acetate.

of melting. The sample melts at 115° (DTA curve). Ammonia is lost first during the decomposition and acetic acid is formed. On raising the temperature acetamide results and water splits off

$$NH_4OOCCH_3 \rightarrow NH_3 + CH_3COOH$$

or

$$NH_4OOCCH_3 \rightarrow H_2NOCCH_3 + H_2O.$$

The acetamide distils at about 150°. The decomposition is an endothermic process.

Ammonium oxalate monohydrate

Ammonium oxalate begins to decompose above 70° (Fig. 22). In the first stage it loses its molecule of water of crystallisation (maximal rate at 115°). The anhydrous ammonium oxalate is of constant weight between 120 and 200°, then decomposes above 200°. Decomposition proceeds in two stages. The first process is at a maximal

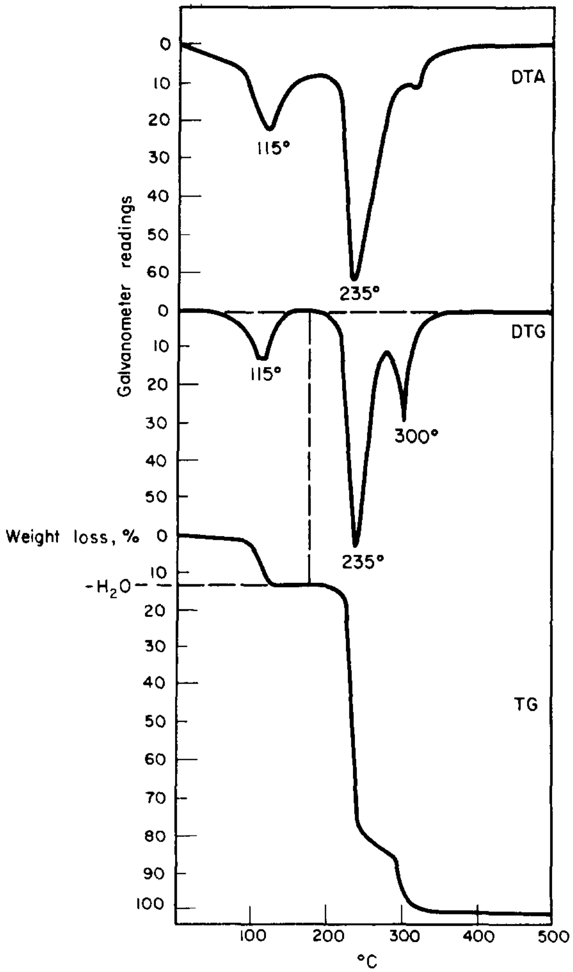

FIG. 22.—Ammonium oxalate monohydrate.

rate at 235° and the second one at 300°. The DTG peak at 235° indicates decomposition of oxalate. Carbon monoxide, carbon dioxide, ammonia, formic acid and oxamide are formed during the decomposition

$$(NH_4)_2(COO)_2 \rightarrow H_2N\text{—}CO\text{—}CO\text{—}NH_2 + H_2O.$$

The decomposition products are in the gaseous state at this temperature, except for oxamide, the composition varying according to the experimental conditions.

Ammonium citrate

The weight of the sample begins to decrease at about 150° (Fig. 23) in an endothermic process, the maximal rate being at 195°. Meanwhile, the sample cracked; the carbon residue was oxidised quantitatively only above 800°.

Ammonium benzoate

The weight of the sample scarcely changes before 100°, then it decreases and the substance sublimes. The endothermic DTA peak at 195° (Fig. 24) shows the melting

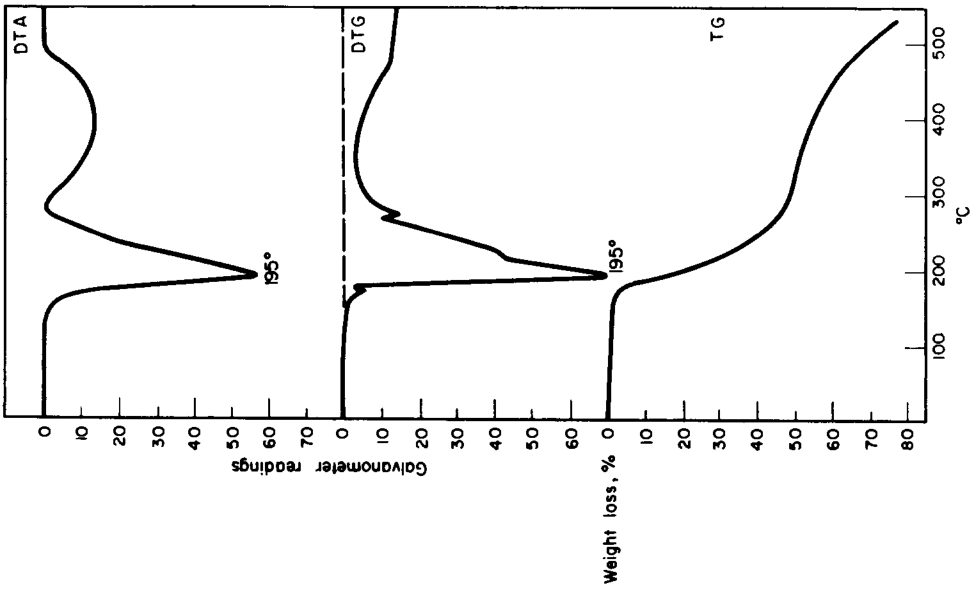

FIG. 23.—Ammonium citrate.

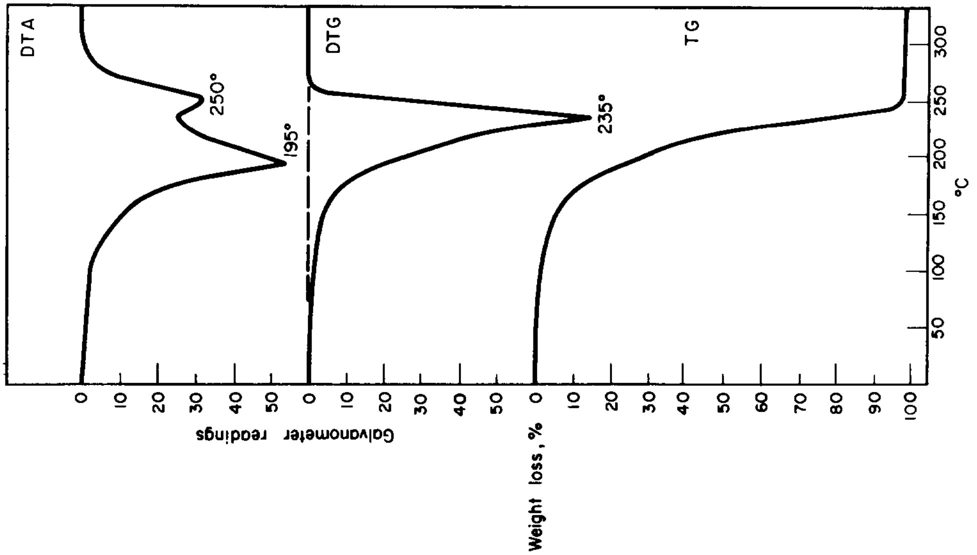

FIG. 24.—Ammonium benzoate.

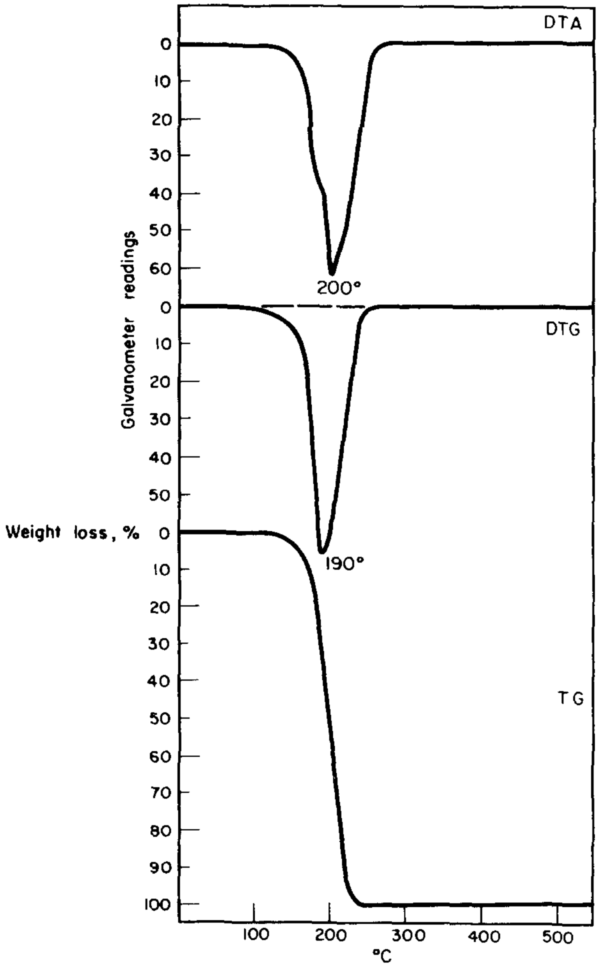

FIG. 25.—Ammonium salicylate.

of the sample (m.p.:[10] 190°). The rate of weight decrease is a maximum at 235° after the melting (DTG curve). The substance left the crucible without any change in composition. This was confirmed by the absence of any carbon residue.

Ammonium salicylate

There is no change in weight of the sample until 100°, when sublimation starts, its rate being maximal at 190°. Sublimation was complete at 250° and the crucible was empty.

Ammonium tartrate

Ammonium tartrate is of constant weight up to 100°, above which decomposition slowly starts. Ammonia is lost and ammonium hydrogen tartrate formed [maximal rate at 180° (Fig. 26)][11]

$$(NH_4)_2C_4H_4O_6 \xrightarrow{100\text{–}200^\circ} NH_4HC_4H_4O_6 + NH_3.$$

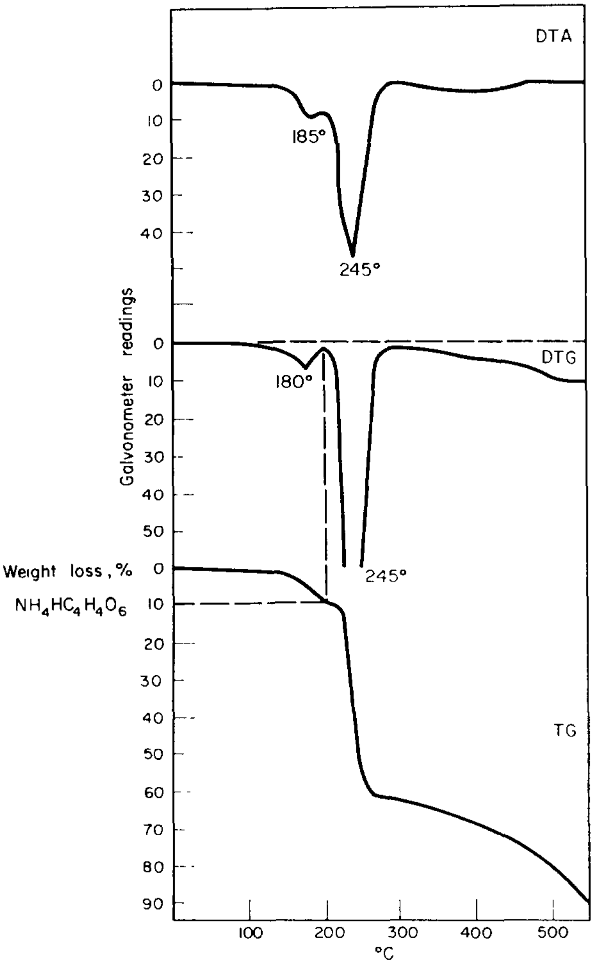

FIG. 26.—Ammonium tartrate.

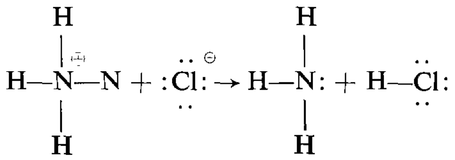
The ammonium hydrogen tartrate begins to decompose above 200°, the decomposition products varying according to the experimental conditions. They may include water, ammonium carbonate, ammonium acetate, formamide, *etc.* This process is maximal in rate at 245°. Above 300° there was a residue of decomposition products from the sample (about 30% of it).

CONCLUSIONS

It is important to follow exactly the prescribed experimental conditions. Thus, in the case of ammonium dichromate it was possible by decreasing the amount of the substance to avoid an explosive decomposition (Fig. 17). For initial amounts of 30 and 60 mg of material, the decomposition products do not carry away solid particles, so the amount of the residue is equal to the theoretical value; for 120 mg of material, however, the decomposition proceeds explosively and the weight of the residue is 2% less than the theoretical value.

The decomposition curves of ammonium salts of organic acids show well that the decomposition temperature increases with increasing molecular weight. Ammonium salicylate (Fig. 25) and ammonium benzoate (Fig. 26) sublime without decomposition.

On the basis of the high temperature acid-base theory, the decomposition of ammonium salts can be explained by the fact that the base strength of the anion increases with rise in temperature until it reaches the base strength of the ammonia molecule. At this temperature the anion base removes the proton from the ammonia.



$$\mathrm{H{-}\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{N}}{}^{\oplus}{-}N} + :\overset{..}{\underset{..}{\mathrm{Cl}}}:^{\ominus} \rightarrow \mathrm{H{-}\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{N}}}: + \mathrm{H{-}}\overset{..}{\underset{..}{\mathrm{Cl}}}:$$

The weaker the anion base, the higher the temperature of the decomposition. Comparison of decomposition curves of the various ammonium salts gives information on the base strength of the anions. According to the measurements—in agreement with the known facts—the strongest anion base is the oxygen ion. The strongly basic character of the oxygen ion is shown by the fact that ammonium oxide [$(NH_4)_2O$] has never been made because of its instability. After the oxygen ion the halide ions follow in the order of decreasing base strength: F^-, Cl^-, I^-, Br^-. Under the given conditions iodide ion is a stronger base than bromide, which is connected with its higher deformability. On the DTA curves of ammonium salts temperatures of interconversion of different crystal modifications appear. During such conversions the more closely packed crystal structure is always formed on the higher temperature side, which is in agreement with the known fact that at higher temperatures the co-ordination number generally increases.

Zusammenfassung—26 Ammoniumsalze wurden derivatographisch untersucht. Gewichtsänderung und ihre Geschwindigkeit sowie die Enthalpieänderung der Salze wurden in Abhängigkeit von der Temperatur gemessen. An Hand der Ergebnisse werden die Temperaturen angegeben, bei denen die Salze unzersetzt getrocknet werden können.

Résumé—On a étudié vingt six sels d'ammonium par dérivatographie. La variation de poids, la vitesse de variation de poids et la variation d'enthalpie ont été mesurées en fonction de la température. A partir de ces résultats, on donne les températures auxquelles les sels peuvent être séchés sans décomposition.

USE OF OXYCELLULOSE FOR COLLECTION OF TRACES OF METALS—II*

APPLICATION OF OXYCELLULOSE IN SOLVENTS AND IN SOLUTIONS OF DIFFERENT ORGANIC COMPOUNDS

E. SCHULEK, ZS. REMPORT-HORVÁTH and A. LÁSZTITY
Institute of Inorganic and Analytical Chemistry, L. Eötvös University
Budapest, Hungary

(*Received* 28 *October* 1963. *Accepted* 12 *February* 1964)

Summary—Oxycellulose has been applied as a collector for the following metal-ion contaminants of organic solvents and of different organic compounds: Cu^{2+}, Fe^{3+}, Ni^{2+}, Pb^{2+}, Zn^{2+}. From 100 ml of solvent 1–20 μg of ions have been collected with 5 mg of oxycellulose. The solutions of the organic compounds were 1–3%. The water content of the solvents has a marked effect on the collection. By repeated collection an ion can be removed quantitatively.

INTRODUCTION

EARLIER investigations[1] showed that oxycellulose is a very suitable material for the collection and removal of traces of metals from distilled water and from highly diluted inorganic salt solutions. After collection, the metal ions are identified directly on the oxycellulose. The ionic strength of the solution has a marked effect on the metal-binding capacity of oxycellulose.

The detection and the quantitative determination of the metal contaminants of organic compounds is a frequent and an important task in analysis. The metal-binding capacity of oxycellulose in the presence of organic solvents and of different organic compounds has therefore been investigated. The collection of the following metal ions was studied: Cu^{2+}, Fe^{3+}, Ni^{2+}, Pb^{2+} and Zn^{2+}. For the collection of these ions the method described previously was used.[1] The fixation of lead ion on oxycellulose was followed quantitatively by the dithizone method.[2]

EXPERIMENTAL AND RESULTS

Qualitative investigations

Table I gives the minimum detectable quantity of the ions Cu^{2+}, Fe^{3+}, Ni^{2+}, Pb^{2+} and Zn^{2+} on oxycellulose, collected from water and from different solvents. The ions were added to the purified solvent in increasing quantity, and were tested for after collection on the oxycellulose disc. In most of the organic solvents the minimum detectable quantity of the ions was greater than in water. The greater the water content of the solution, the smaller was the quantity of metal ion that could be detected. With water-immiscible solvents, *e.g.*, chloroform, carbon tetrachloride, benzene, fatty acid salts of the metals were used.

---

* Part I—See ref. 1.

TABLE I.—IONS COLLECTED ON OXYCELLULOSE FROM SOLVENTS

Solvent	Ion, μg				
	Cu^{2+}	Fe^{3+}	Ni^{2+}	Pb^{2+}	Zn^{2+}
Acetone	5	5	5	10	10
Methyl alcohol	1	1	1	10	1
Ethyl alcohol	1	1	1	10	1
n-Propyl alcohol	15	10	5	20	5
n-Butyl alcohol	10	5	1	20	5
Isobutyl alcohol	5	5	1	10	5
Dioxan	15	5	5	20	20
Dimethylformamide	1	1	5	10	10
Chloroform	2	1	2	10	5
Carbon tetrachloride	2	1	2	10	5
Benzene	10	2	10	10	5
Water	1	1	1	1	1

The following list includes the various organic compounds from which more than 50% of the Cu^{2+}, Fe^{3+}, Ni^{2+}, Pb^{2+} and Zn^{2+} ion (up to 10 μg) could be collected on oxycellulose:

Acetamide
Acetanilide
Antipyrine
Aspirin
Benzoic acid
Bromacetocarbamide
Bromovalerocarbamide
Caffeine
Carbamide
Chloral hydrate
Cholesterol
5,5-Diethylbarbituric acid
5-Ethyl-5-butylbarbituric acid
Glucose
Methyl *p*-hydroxybenzoate
Hyoscine hydrobromide
Lactose
Mannite
2-Naphthol
Phenacetin
Phenol
2-Phenylcinchoninic acid
Pyrogallol
Raffinose
Phenyl salicylate
Santonin
Terpinal hydrate
Theophylline
Thymol
Urethane

All the commercially available materials were contaminated with heavy metals. Therefore, before the experiments, these materials were purified with oxycellulose. In the case of complex-forming compounds (citric, oxalic, succinic, thiobarbituric acids, *etc.*) oxycellulose could not remove the metal ion. With alkaloid salts the collection is effective only in dilute solution. The detection of the ion is not influenced by the colour of the sample, because the organic compounds can be washed out from the oxycellulose disc by water or by another solvent. The bound metal ion is not removed by this procedure.

For an indication of the metal ions likely to be present in various solutions or solvents this qualitative process, using oxycellulose, is a very suitable rapid method. By dividing the oxycellulose disc into pieces, more than one ion can be tested for without using the ring-oven method.

Quantitative investigations

In the quantitative investigations, the fixation of Pb^{2+} ion on oxycellulose, from water, from different solvents and from solutions of organic compounds, was followed by the dithizone method.[2]

One hundred ml of the solvent, containing 1–5 μg of Pb^{2+} ion, were shaken with 5 mg of oxycellulose for 5 min and the oxycellulose fibrils were collected as usual.[1] The oxycellulose disc was put into a volumetric flask, and the lead ion was extracted by a dithizone-carbon tetrachloride solution in the presence of potassium cyanide. The colour of the solution was compared with that of a lead-dithizone standard solution.

Table II shows the result of the collection of Pb^{2+} ion from water on oxycellulose. By repeated collection, 1–5 μg of Pb^{2+} ion could be removed quantitatively.

TABLE II.—QUANTITATIVE COLLECTION OF Pb^{2+} FROM WATER WITH OXYCELLULOSE AFTER REPEATED COLLECTION

Added Pb^{2+} ion, *μg/100 ml*	Pb^{2+} ion, μg, First collection	Second collection	Third collection	Arithmetical mean of Pb^{2+} ion found, μg
1·0	0·6 0·7 0·6	0·4 0·3 0·3		1·0
2·0	1·2 1·3 1·2	0·5 0·5 0·5	0·3 0·2 0·2	2·0
3·6	1·6 1·6 1·9	0·6 0·7 0·6	0·4 0·5 0·3	2·7
4·0	2·8 3·0 2·8	0·7 0·6 0·6	0·3 0·2 0·2	3·7
5·0	3·5 3·4 3·2	0·8 0·8 1·0	0·3 0·4 0·3	4·6

Table III indicates that there may be some relation between the amount of Pb^{2+} ion removed by oxycellulose and the dielectric constant of the solvent.

As mentioned earlier, the water content of the solvent has a marked effect on the collection. Only a few per cent of the added metal ions can be removed by oxycellulose from anhydrous solvents (water content less than $10^{-2} - 10^{-3}\%$). If the oxycellulose was swollen with water before adding it to the anhydrous solvents, the quantity of the bound ion increased. This suggests that swelling of the oxycellulose is of considerable importance in binding the metal ions. (According to results in the literature,[3] water has the greatest swelling effect on oxycellulose.)

TABLE III.—EFFECT OF DIELECTRIC CONSTANT ON THE COLLECTION OF Pb^{2+} ION
(Pb^{2+} ion: 5 μg/50 ml; oxycellulose: 5 mg)

Solvent	Dielectric constant, ε	Arithmetical mean of Pb^{2+} ion found, μg
Water	78	3·8
Dimethylformamide	37	2·7
n-Butyl alcohol	18	2·0
Methyl alcohol	32	1·5
Ethyl alcohol	24	0·9
n-Propyl alcohol	20	0·8
Ethyl acetate	6·0	0·5
Ether	4·0	0·4
Dioxan	2·2	0·3
Acetone	21	0·2

The results in Table IV show the extent of removal of Pb^{2+} ion from different solvent-water mixtures.

In Table V the results of the quantitative collection of 1 μg of Pb^{2+} ion from organic compounds are summarised. The compounds were dissolved in 30 ml of water.

TABLE IV.—COLLECTION OF Pb^{2+} BY OXYCELLULOSE FROM SOLVENT WITH DIFFERENT WATER CONTENTS

(Pb^{2+} ion: 5 μg/50 ml)

Solvent	Arithmetical mean of Pb^{2+} ion found, μg			
	Water content, v/v %			
	1·5%	10%	20%	50%
Acetone	0·2	0·4	1·1	2·2

Atropine sulphate	0·1	0·6
Ephedrine hydrochloride	0·1	0·5
Hyoscine hydrobromide	0·1	0·7
Quinidine sulphate	0·1	0·5

CONCLUSIONS

From the results of experiments dealing with the collection of frequent metal contaminants of various organic solvents and organic compounds, it is apparent that oxycellulose is a suitable collector for metal ions, not only from aqueous but also from non-aqueous solutions.

Zusammenfassung—Oxycellulose wurde zur Anreicherung folgender Metallverunreinigungen in organischen Lösungsmitteln und verschiedenen organischen Verbindungen verwendet: Cu^{2+}, Fe^{3+}, Ni^{2+}, Pb^{2+} und Zn^{2+}. 1–20 μg dieser Ionen wurden aus 100 ml Lösungsmittel mit 5 mg Oxycellulose angereichert. Die Lösungen der organischen Verbindungen waren 1–3%. Der Wassergehalt der Lösungsmittel war von großem Einfluß auf die Anreicherung. Durch wiederholte Anreicherung konnte das Ion quantitativ entfernt werden.

Résumé—On a utilisé l'oxycellulose comme collecteur pour recueillir les ions métalliques suivants, contaminants de solvants organiques et de divers composés organiques: Cu^{2+}, Fe^{3+}, Ni^{2+}, Pb^{2+}, Zn^{2+}. Avec

5 mg d'oxycellulose, on recueille 1–20 μg d'ions de 100 ml de solvants. La concentration des solutions de composés organiques est de 1–3%. La teneur en eau des solvants a une grande influence sur la séparation. Par traitements répétés, l'ion peut être séparé quantitativement.

(*Received* 9 *November* 1963. *Accepted* 28 *January* 1964)

Summary—R_f values of *p'*-substituted-*p*-hydroxyazobenzenes on paper, glass-fibre "paper", and these papers impregnated with different amounts of alumina are given. Results indicate that the alumina is primarily responsible for sorption. The effect of the electrical nature of the *p'*-substituent on sorption is small. Sorption is considered to be a result of hydrogen bonding between oxygen centres in the sorbed molecule and active hydrogen centres on the hydroxylated alumina.

INTRODUCTION

THE suggested relation between R values from column adsorption chromatography and linear adsorption isotherms has been substantiated by Claesson.[1] This worker successfully constructed linear adsorption isotherms for a number of homologous series of organic compounds from results obtained by using the interferometric method of Tiselius and Claessen[2] with the techniques of frontal analysis, displacement analysis and carrier-displacement analysis.

LeRosen and his coworkers[3] related the structure of a molecule to its sorption on silicic acid. Martin[4] established a theoretical relation between the chemical potential of a molecule and its partition coefficient for a two-phase system of ideal solutions when the two phases are in equilibrium, and derived the expression

$$\Delta\mu_{(F)}A = RT \ln \left(\frac{N_A{}^M}{N_A{}^S}\right)$$

where $\Delta\mu_{(F)}A$ = the free energy required to transport 1 mole of A from phase S to phase M,

$N_A{}^M$ = the mole fraction of A in phase M,

and $N_A{}^S$ = the mole fraction of A in phase S.

He also showed that where the molecule A is composed of the several groups X, Y and Z, then the free energy required to transport A from phase S to phase M is the sum of the free energies required to transport the individual groups X, Y and Z from phase S to phase M.

---

* Presented at a joint meeting of the Institute of Chemistry of Ireland and the Scottish Section of the Society for Analytical Chemistry in Dublin, 5 September, 1963.

Later, Sporer and Trueblood[5] carried out a quantitative study of the relation between the molecular structure of a number of aromatic compounds and their adsorption affinities on silicic acid-celite columns using benzene as the eluent. These workers observed that Langmuir isotherms calculated from observed chromatographic development rates agreed with those evaluated from static adsorption studies determined for the same systems. They also suggested that the standard free energy change for a molecule on adsorption, as given by the equation

$$\Delta F^\circ = -RT \ln K$$

is, to a first approximation, the sum of the free energy changes for the component atoms which comprise the molecule. This established for adsorption chromatography a similar thermodynamic concept to that proposed by Martin[4] for partition chromatography.

Erió, Goode and Ibbitson[6] have carried out static adsorption studies of phenols from cyclohexane onto alumina, while Ibbitson, Jackson, McCarthy and Stone[7] have similarly investigated azobenzenes sorbed from benzene. In each case the free energy changes of sorption have been determined in terms of the equation

$$\Delta G^\circ = -RT \ln K.$$

Because of the foregoing we have sought to correlate data obtained from static sorption studies of hydroxyazobenzenes from benzene onto alumina by Stone,[8] with R_f values determined for the same compounds by adsorption chromatography on alumina-impregnated papers with benzene as the eluent, and with other known physical parameters. In each case the compounds were chromatographed on untreated paper of a comparable grade as control experiments. The compounds investigated were *p*-hydroxyazobenzenes with substituents of different electrical character in the *p*′-position.

EXPERIMENTAL

Five grades of paper were used in the investigation:

(a) untreated Whatman No. 1 paper,
(b) Whatman No. 1 paper impregnated with 2% of alumina,
(c) Whatman No. 1 paper impregnated with 7·5% of alumina,
(d) untreated glass-fibre paper,
(e) glass-fibre paper impregnated with 7·5% of alumina.

The papers were activated at 120° for 15 min (heating for longer periods caused yellowing of the paper), then cooled in a vacuum desiccator.

Samples (2.5 μl) of the hydroxyazobenzenes (1% w/v solutions) were applied at a point 6 cm from the base of a paper and at intervals of 2 cm from each other. The dispersing solvent was removed by a current of warm air directed at the point of application of the samples.

The eluent, M.F.C. grade benzene, was dried over sodium wire, redistilled, and the fraction boiling at 80·1° (760 mm pressure) collected. This gave a single peak when examined by gas-liquid chromatography on a dinonylphthalate column at 75°, using a Pye Argon Chromatograph.

The papers were conditioned in a tank saturated with benzene vapour for 15 min, then eluted by an ascending technique at a temperature of 25° ± 0·5°. The length of run was governed by the distance reached by the solvent front (*ca.* 22 cm from the point of application), rather than by time, because of the different rates of flow of the eluent through the different grades of paper. For both grades of glass-fibre paper the eluent rose to the desired height in 1 hr. The three grades of filter paper were slower, the solvent taking 3–5 hr to rise through the paper; the untreated paper was the fastest and the paper impregnated with 7·5% of alumina the slowest. After elution, the chromatograms were dried and viewed under an ultraviolet lamp to mark the positions of compounds.

RESULTS

The results collected in Table I represent the mean of 5 runs. The R_f values are reproducible to ±0·01 of an R_f unit.

DISCUSSION

From Table I it can be seen that on untreated glass-fibre paper the compounds travelled with the solvent front. Some sorption took place on untreated Whatman No. 1 papers but all of the compounds had high R_f values, there being little differentiation between the values for the different compounds. Impregnation of the papers with alumina resulted in a substantial increase in the degree of sorption, with R_f values ranging from 0·33 to 0·54 on the 2% alumina-impregnated paper, 0·08 to 0·15 on the 7·5% alumina-impregnated paper, and 0·03 to 0·05 on the 7·5% alumina-impregnated glass-fibre paper. Hence, it is concluded that the alumina surface is responsible for the sorption of the compounds, with the "paper" substrate playing little or no part in sorption.

TABLE I.—R_f VALUES OF *p*′-SUBSTITUTED-*p*-HYDROXYAZOBENZENES

	R_f*				
p′-Substituent	(a)	(b)	(c)	(d)	(e)

tert-Butyl	0·95	0·48	0·13	1·0	0·04
Methyl	0·95	0·46	0·12	1·0	0·05
Methoxyl	0·94	0·33	0·08	1·0	0·04

* (a) Untreated Whatman No. 1, (b) Whatman No. 1 paper impregnated with 2% of alumina, (c) Whatman No. 1 paper impregnated with 7·5% of alumina, (d) untreated glass-fibre paper, (e) glass-fibre paper impregnated with 7·5% of alumina.

Three other factors may now be considered: (a) the effect of the electrical nature of the *p*′-substituent, (b) the mechanism of sorption, and (c) the alignment of the sorbed molecule onto the surface of the adsorbent.

(*a*) *Effect of electrical nature of p*′*-substituent*

Stone,[8] from static sorption studies, has suggested that compounds of this type are adsorbed from benzene onto alumina as a result of hydrogen bonding between the hydrogen atom of the hydroxyl group of the molecule and the active oxygen centres on the alumina surface. He found that though the free energy decrease of sorption could be correlated with the electrical character of the *p*′-substituent, those compounds with electron-attracting groups being more strongly adsorbed than those with electron-releasing groups, the magnitude of the free energy change is small.

This effect has been confirmed and explained by Catchpole, Foster and Holden[9] who determined the hydroxyl stretching frequencies for hydroxyazobenzenes, including a number of the compounds investigated here. A plot of the hydroxyl stretching frequencies for these compounds against Hammett σ functions,[10] was compared with a similar plot for comparable phenols using the data of Flynn, Werner and Graham.[11] Both plots were linear, with the former having a smaller slope than the latter. Catchpole, Foster and Holden[9] suggested, therefore, that the electronic effect of the *p*′-substituent in the one benzene ring suffers a decrease in intensity when transmitted across the azo group to the *p*-hydroxyl group in the other benzene ring of the conjugated system. Catchpole and coworkers[9,12] showed that the electrical effect of the p'-substituent on the acid dissociation constants of these hydroxyazobenzenes is also small.

From Table I it can be seen that for the 2% alumina-impregnated papers and the 7·5% alumina-impregnated papers the R_f values, in general, change with the electrical nature of the group but once again the magnitude of the change is small.

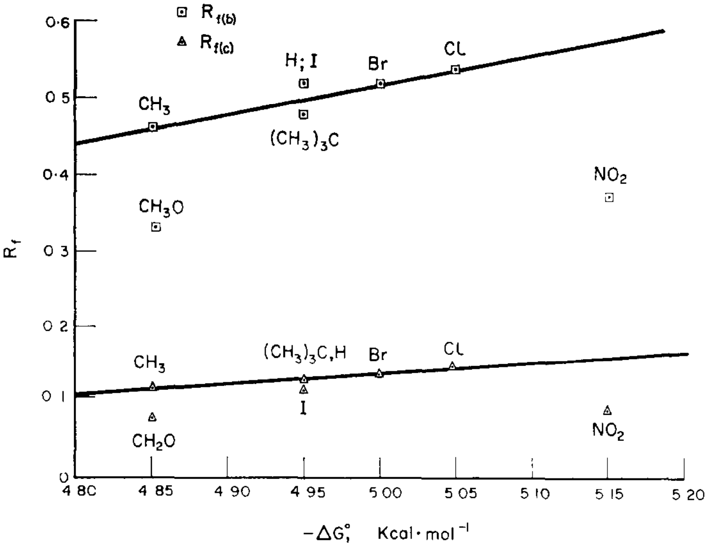

FIG. 1

(b) *Mechanism of sorption*

For the mechanism of sorption of the compounds onto alumina-impregnated paper to be the same as that proposed by Stone[8] for static sorption, one would expect that the order of R_f values would parallel the order of free energy changes of sorption and that a plot of R_f values against $-\Delta G^\circ$ values would be linear. Furthermore, one would expect plots of R_f values against hydroxyl stretching frequencies, Hammett σ functions and dissociation constants to be linear.

However, from Table I and from Fig. 1 it can be seen that the R_f values do not parallel the free energy changes. For substituents which do not contain an oxygen atom, the R_f values are lower, indicating stronger adsorption for electron-releasing groups than for electron-attracting groups, *i.e.*, the reverse of that expected from Stone's work. Those compounds in which the p'-substituent contains an oxygen atom are strongly adsorbed irrespective of whether the oxygen atom is part of the electron-attracting nitro group or of the electron-releasing methoxyl group.

Further, for compounds containing non-oxygenated substituents in the p'-position, the higher R_f values, relative to the values for the unsubstituted parent compound, in the presence of electron-attracting substituents are associated with (a) hypsochromic shifts of the hydroxyl stretching frequencies (Fig. 2), (b) positive Hammett σ functions (Fig. 3), and (c) stronger acid dissociation constants (Fig. 4), while the lower R_f values for the electron-releasing substituents are associated with (a) bathochromic shifts, (b) negative Hammett σ functions, and (c) weaker acid dissociation constants. in the case of the plot of the R_f values against $-\Delta G^\circ$ values, however, the positions of the compounds with oxygen atoms in the substituent groups are anomalous.

Because of these facts we consider that a different mechanism of bonding must operate on the alumina-impregnated papers from that on static beds of alumina.

We propose that, in accordance with the suggestion of Bernal,[13] the alumina is hydroxylated, presenting at its active sites not oxygen atoms but hydrogen atoms, and that the mechanism of sorption is hydrogen bonding *via* the phenolic oxygen and these active hydrogen sites. The electron-attracting halogen atoms decrease the electron density around the phenolic oxygen, thus resulting in a weakening of the hydrogen bond and an increase in the R_f values. The electron-releasing groups increase the electron density at the phenolic oxygen atom and hence increase the tendency to hydrogen bond with the proton-donating hydroxylated alumina. Compounds containing a nitro or methoxyl group hydrogen bond by the oxygen atoms at either end of the molecule. They are thus more strongly adsorbed, and hence have lower R_f values.

This view is substantiated by the results of other workers. Thus, Ibbitson, Jackson, McCarthy and Stone,[7] who observed an unexpectedly low free energy change for *p*-acetoxyazobenzene, proposed that the compound was sorbed by one of two mechanisms: either the carbonyl group activates a hydrogen atom of the methyl residue and this activated hydrogen atom bonds with the active oxygen of the alumina, or the acetyl group acts as an acceptor group for hydrogen bonding while the alumina acts as a proton donor. The latter of these two explanations is in accordance with our view.

Bark and Graham[14] observed that for substituted phenoxyacetic acids chromatographed on paper, those with oxygen atoms in the substituent groups had lower R_f values than the unsubstituted acid, whilst those with halogen or alkyl groups had higher R_f values. Sporer and Trueblood[5] concluded from their studies that the active sites on silicic acid were hydroxyl groups. Smith[15] observed that halogenated phenols had higher R_f values than alkyl phenols when sorbed from benzene onto silica gel. Bark and Graham[16] have similarly explained the behaviour of nitrophenols on alumina-impregnated papers.

(*c*) *Alignment of sorbed molecule onto surface of absorbent*

From column adsorption chromatography, Zechmeister,[17] Brockmann[18] and Sporer and Trueblood[5] have proposed the group anchoring site concept for attachment of the sorbed molecule to the surface. From studies of hydrocarbons and azobenzenes sorbed onto alumina-impregnated glass fibre paper, Klemm and coworkers[19] proposed a "flat-wise" π complex for the former and a partial "flat-wise" sorption through the π electrons of the benzene ring and the lone pair of electrons of the azo-nitrogen atoms.

The presence of a single spot and the absence of tailing for each compound on our chromatograms suggests the absence of the unstable cis isomers, and that the compounds migrate as the stable trans forms. Hence, for the proposed mechanism of bonding to occur, *i.e.*, the attachment of the phenolic oxygen to the substrate, the azo-skeleton is tilted slightly away from the substrate, into the organic mobile phase. Even so, the angle of the tilt is sufficiently small for the oxygen atoms of the nitro and methoxyl groups to be sufficiently close to the substrate surface for hydrogen bonding to occur.

Acknowledgement—We thank Messrs. Reeve Angel and Co. Ltd. for the gift of impregnated papers.

Zusammenfassung—R_f-Werte p'-substituierter p-Hydroxyazobenzole an Papier, Glasfasser-"papier" und mit verschiedenen Mengen Aluminiumoxyd imprägnierten Papieren werden angegeben. Di Ergebnisse zeigen, daß in erster Linie das Aluminiumoxyd für die Sorption verantwortlich ist. Der Einfluß des elektrometen Effekts des p'-Substituenten ist gering. Die Sorption wird als Ergebnis von Wassers tofibrücken zwischen Sauerstoffatomen im sorbierten Molekül und aktiven Wasserstoffatomen am hydroxylhaltigen Aluminiumoxyd angesehen.

Résumé—On donne les valeurs R_f de p-hydroxyazobenzènes p'-substitués, sur papier, papier en fibre de verre, et sur les mêmes papiers imprégnés de différentes quantités d'alumine. Les résultats indiquent que l'alumine est essentiellement responsable de la sorption. L'effect, sur la sorption, de la nature électrique du substituant en p′ est faible. On considère que la sorption est un résultat de la liaison hydrogène entre les centres oxygène dans la molécule sorbée et les centres hydrogène actif de l'alumine hydroxylée.

AMMONIUM HEXANITRATOCERATE(IV) AS AN OXIDISING AGENT—III*

PHOTOMETRIC DETERMINATION OF MANGANESE^{II} THROUGH OXIDATION TO MANGANESE^{VII}

G. Gopala Rao, K. S. Murty and P. V. Krishna Rao
Department of Chemistry, Andhra University, Waltair, India

(*Received* 6 *January* 1964. *Accepted* 6 *March* 1964)

Summary—Manganese^{II} is oxidised to permanganic acid by treatment with a slight excess of ammonium hexanitratocerate(IV) in a 0·5–2*M* nitric acid medium at room temperature. The reaction is markedly catalysed by silver nitrate, so that quantitative oxidation is possible within 1 min. Conditions have been developed for utilising the catalysed reaction for the colorimetric determination of manganese over the range 0·33–19·93 mg/litre. The new method has the advantage over those currently available in that the oxidation to manganese^{VII} is stoichiometric at room temperature. Under the conditions prescribed the permanganic acid formed is stable for at least 24 hr. Interference from sulphate and from chloride, bromide and iodide can be eliminated by treating the test solution with barium nitrate or silver nitrate, respectively, before the oxidation with cerium^{IV}. Application of the method to the determination of manganese in steel is considered.

The colorimetric determination of manganese has engaged the attention of chemists for over a century. Crum[1] appears to have been the first to observe the oxidation of manganese^{II} to permanganate by lead dioxide in nitric acid solution. Pichard[2] and a host of workers employed this reaction for the colorimetric determination of manganese. Reddrop and Ramage[3] as early as 1895 proposed the oxidation of manganese^{II} to permanganate with sodium bismuthate. The method seems to have been forgotten until Dufty[4] again drew attention to it in 1901. In the procedures employing both lead dioxide and sodium bismuthate, excess oxidising agent should be separated from the solution by filtration before the colour comparisons are made. Moreover, both methods suffer from the defect that a high temperature is necessary to complete the oxidation of manganese^{II} to permanganate. It is also possible that some of the permanganate may decompose at the high temperature and high acidities recommended. Marshall,[5] Von Knorre[6] and Walters[7] used potassium persulphate with a silver salt as catalyst in the oxidation of manganese^{II} to manganese^{VII} in the colorimetric determination of manganese. The general procedure that has been evolved as a result of the investigations of several workers is to heat the manganese^{II} in a sulphuric acid medium (containing some phosphoric acid) with excess persulphate and a trace of silver salt as catalyst. Phosphoric acid serves to prevent the precipitation of manganese dioxide. Gortner and Rost[8] and Applebaum[9] criticised the persulphate method, stating that the oxidation of manganese^{II} is often incomplete and that the permanganate colour frequently fades in a short time.

---

* Part II: *Talanta*, 1963, **10**, 657.

In view of the erratic nature of the persulphate–manganese^{II} reaction, Willard and Greathouse[10] proposed the use of potassium periodate for the oxidation of manganese^{II} to manganese^{VII} in sulphuric, phosphoric or nitric acid or in a mixture of two or more acids. Chromium^{III}, cerium^{III}, *etc.*, are also oxidised by periodate in acid solution. A disadvantage is that a large excess (about fifty to one hundred times) of periodate has to be used. Koroleff[11] proposed the use of a silver salt to speed up the reaction and this also assists in economising on the amount of periodate. Although Willard and Greathouse proposed a minimum concentration of $1{\cdot}75M$ sulphuric acid, Richards[12] found that when the concentration of manganese is low (a few μg in 10 ml), a high concentration of phosphoric acid prevents the full development of the colour. Richards recommends an acidity of $2{\cdot}0N$ in sulphuric acid. While determining manganese^{II} in caustic soda, Williams and Andes[13] add sufficient phosphoric acid to produce a pH of 2 at which the oxidation by periodate is conducted. Nydahl[14] recently stated that the colorimetric determination of manganese according to the periodate method requires rather a long period of heating for the full development of colour, especially in very dilute solution, even when it is carried out as proposed by Richards or by Koroleff. When the amount of manganese is 1 μmole/100 ml, Nydahl observed the oxidation to take place only to 49% extent in 1 hr, on a steam bath, and to 57% in 2 hr when carried out under the optimum conditions prescribed by Richards. In the presence of 0·1 mmole of silver nitrate the corresponding figures were 86 and 91%, respectively.

Strickland and Spicer[15] carried out a fairly systematic study of the important factors governing a satisfactory analytical application of the periodate oxidation. They observed that

1. The extinction obtained from a given quantity of manganese can vary in magnitude and reproducibility according to the conditions.

2. The rate of oxidation is mainly dependent upon the acidity of the solution and has a minimum value when the reaction takes place (at 100°) in a nitric or sulphuric acid medium of $1{\cdot}5M$ concentration. At lower acidities the reaction becomes very rapid, but the extinctions are rather erratic and the use of a low acidity to increase the rate is not recommended. With more strongly acid solutions there is again an increase in the rate of the reaction, but the final extinction under these conditions decreases less rapidly and the extinctions are reproducible. Nevertheless, for several reasons, the acidity must not exceed certain approximate values. It is suggested that the most satisfactory acid range to use with sulphuric acid at 100° is 3–$6M$ and the corresponding range for nitric acid at 100° is 4–$7M$.

3. With sulphuric acid concentrations greater than $6M$ the decrease of extinction becomes very rapid, largely because of the formation of permanganic anhydride. The effect with nitric acid is not so pronounced and is mainly the result of the formation of quadrivalent manganese. If the acidity becomes too great in nitric acid media, manganese dioxide may precipitate. In view of the above effects, the acidity of sample and standard solutions should be reproduced to within at least $0{\cdot}5M$ and care should be taken to ensure that concentration changes from evaporation, *etc.*, do not exceed 5–10%.

4. If solutions are boiled, the additional complication of permanganic acid volatility is encountered in the case of sulphuric acid solutions. This can lead to appreciable errors in acid solutions more concentrated than $6M$.

5. Because the rate of oxidation increases two or three times for an increase in temperature of 20°, it is obvious that as high a temperature as practicable should be used. The maximum extinction from a given quantity of manganese can vary by a few per cent, however, according to the exact temperature and the latter should be controlled to within 10°. Superheating (which is marked with sulphuric acid) may be avoided by the addition of glass beads, *etc.*

6. The reaction does not depend to any appreciable extent on the concentration of periodate, provided that this exceeds the concentration of manganese some fifty or one hundred times. It is suggested that 0·5 g of potassium periodate is used for every 100 ml of solution in which the concentration of manganese^{II} should not exceed about $5{\cdot}10 \times 10^{-4}M$.

7. The nature of the reaction is such that complete oxidation is never theoretically achieved and the extinction-time curve approaches a maximum asymptotically. Although in practice the extinction rapidly attains a maximum value within the sensitivity of measurement of the absorptiometer, the relatively slow approach to this value makes a visual estimation deceptive and it is essential to allow further time to elapse after the colour appears to be fully developed.

Tomula and Aho[16] proposed a colorimetric method for the determination of manganese^{II} through its oxidation to manganese^{III} in a sulphuric acid medium by potassium bromate, the resulting manganese^{III} being stabilised by complexation with phosphoric acid. Purdy and Hume[17] in a recent communication criticised the method and stated "in attempting to study the reproducibility and sensitivity of their method, the authors were unable to obtain consistent results". The latter authors improved the method and determined manganese as the tervalent complex in strong sulphuric acid. As much as 70 mg of manganese/100 ml could be determined. The recommended procedure was to treat the sample solution with enough concentrated sulphuric acid to give an over-all $8M$ acidity on dilution to 100 ml, followed by the addition of 2 ml of $0{\cdot}5M$ potassium cyanide and 5 ml of $0{\cdot}17M$ potassium bromate. After diluting to 100 ml, the absorbance of the solution was measured at 500 mμ in a spectrophotometer. Working at such high acid concentrations is not, however, always convenient, and the use of potassium cyanide is associated with the obvious dangers.

In view of what has been said above it was considered advantageous to possess a reagent which can oxidise manganese^{II} to permanganate quantitatively at room temperature. We have observed that ammonium hexanitratocerate(IV) does this in a dilute nitric acid medium. Silver nitrate accelerates the reaction to such an extent that the oxidation is complete within 1 min at room temperature. We have developed conditions under which the reaction can be used for the colorimetric determination of manganese over the range 0·33 to 19·93 mg/litre. Nitrate, perchlorate and borate do not interfere. Interference from chloride, bromide and iodide can be eliminated by adding sufficient silver nitrate to precipitate the silver halide, which is filtered off. Sulphate is similarly removed by the addition of barium nitrate to the hot test solution. Nickel^{II}, iron^{III}, copper^{II}, calcium^{II}, barium^{II} and molybdenum^{VI} do not interfere even when present in large quantities; when cobalt^{II} is present a correction for its own colour becomes necessary. Chromium^{III} interferes because it is oxidised along with the manganese^{II}, but curiously enough the oxidation of manganese^{II} does not go to quantitative completion at room temperature in the presence of chromium^{III}.

EXPERIMENTAL

Reagents

Ammonium hexanitratocerate(IV). An approximately $0{\cdot}05M$ stock solution of this reagent was prepared as described in Part I of this series.[18] From this a $0{\cdot}01M$ solution is prepared by suitable dilution with $1{\cdot}0M$ nitric acid which has been previously boiled out to free it from any traces of nitrous acid. No standardisation of this reagent is required because it is added in excess to the manganese^{II} solution.

Manganese^{II} solution. An approximately $0{\cdot}025M$ solution of manganese^{II} was prepared by dissolving analytical reagent grade manganese^{II} sulphate (B.D.H. Ltd., England) in doubly distilled water and diluting to 1 litre. The solution was standardised potentiometrically by the methods of Lingane and Karplus[19] and Gopala Rao and Kanta Rao.[20] This standard solution is suitably diluted as required.

Nitric acid solution. An approximately $8M$ solution of nitric acid was prepared by twice diluting analytical reagent-grade nitric acid with doubly distilled water, was boiled out to drive off any oxides of nitrogen, and was stored in an amber coloured bottle protected from light.

Silver nitrate solution. A 5% solution of analytical reagent grade silver nitrate was used as catalyst.

All other reagents employed in this investigation were of analytical reagent quality.

Apparatus

A Klett-Summerson photoelectric colorimeter with optically matched tubes was generally used for colour comparison, with a green filter transmitting at a wavelength of 525–540 mμ. A Hilger Uvispek spectrophotometer with 1-cm cells was also used whenever necessary.

Influence of time

Five ml of $0{\cdot}001510M$ manganese^{II} solution were taken in a 50-ml calibrated flask, acidified with sufficient 1:1 nitric acid to give an over-all acid concentration of $1{\cdot}0M$ when diluted to 50 ml, then treated with 10 ml of $0{\cdot}01M$ ammonium hexanitratocerate(IV) and the mixture diluted to the mark. It was immediately transferred to the colorimeter and the absorption of the solution measured against a blank of ammonium hexanitratocerate(IV) solution of equivalent concentration. The dial readings of the instrument noted at different times are recorded in Table I. In these experiments the molar ratio of manganese^{II}:cerium^{IV} was 1:10.

TABLE I

Time, *min*	1	5	15	30	45	60	120	180	240	300
Dial reading of colorimeter	26	61	101	142	161	169	179	187	194	194

The results in Table I show that about 4 hr are required for complete oxidation of manganese^{II} at room temperature.

Influence of temperature

Somewhat similar experiments to those above, but carried out at the temperature of a boiling water bath yielded the observations recorded in Table II.

TABLE II

Time of heating, *min*	1	2	5	10	15	30	60
Dial reading of colorimeter	45	61	108	122	149	193	194

It is evident that the oxidation of manganese^{II} is complete in about 30 min.

Influence of cerium^{IV} concentration

Experiments made at room temperature by varying the ratio of manganese^{II}:cerium^{IV} yielded the observations presented in Table III. In these experiments the concentration of manganese^{II} was maintained constant and that of the cerium^{IV} varied. It may be noted that 1 mole of manganese^{II} requires 5 moles of cerium^{IV} for complete oxidation to manganese^{VII}.

TABLE III

Time, *min*	Molar ratio of manganese^{II}:cerium^{IV}				
	1:5	1:10	1:15	1:20	1:40
	Dial reading of colorimeter

60	103	169	184	194	194
120	147	179	194	194	194
240	178	194	194	194	194
300	182	194	194	194	194

Manganese taken: 0·0075 mmole

From Table III the rate of oxidation of manganese^{II} at room temperature can be increased by increasing the concentration of cerium^{IV} relative to that of manganese^{II}. With a fairly large excess of cerium^{IV} (1:20) the time of reaction can be reduced to 1 hr.

Influence of catalysts

With a view to further reducing the time of reaction at room temperature the use of catalysts, such as cobalt^{II}, nickel^{II}, osmium^{VIII} and silver^{I} salts, was investigated. Of the substances tried, only silver^{I} nitrate markedly accelerated the reaction.

Experiments were made to ascertain the optimum concentration of catalyst required for rapid oxidation of manganese^{II} by cerium^{IV} in a nitric acid medium at room temperature.

Five ml of 0·001510*M* manganese^{II} solution were acidified with sufficient 1:1 nitric acid to give an over-all acid concentration of 1·0*M* on dilution to 50 ml in a calibrated flask. The mixture was treated with varying volumes of 5% silver nitrate solution followed by 10 ml of 0·01*M* ammonium hexanitratocerate(IV) solution, then diluted to 50 ml with doubly distilled water. It was immediately transferred to the colorimeter and the dial readings noted at varying intervals of time. In these experiments the molar ratio of manganese^{II} to cerium^{IV} was 1:10.

3·0	159	163	174	184	188	188	188	Development of colour very slow.
4·0	108	126	128	134	138	142	154	No pink colour; on standing a colloidal brown precipitate formed.
5·0	—	—	—	—	—	—	—	On mixing the solutions a brown precipitate formed immediately.

It is evident from Table IV that the reaction is complete in about 1 min when the silver catalyst concentration corresponds to 2·0 ml of 5% silver nitrate solution/50 ml of reaction mixture. When the concentration increases beyond that corresponding to 10 ml, the reaction is definitely retarded. When the catalyst concentration corresponds to 15 ml a brown precipitate is formed immediately the solutions are mixed, leaving a clear yellow supernate.

Influence of nitric acid concentration on silver catalysed reaction

To ascertain the optimum concentration of nitric acid required for this reaction the following experiments were carried out. Five ml of 0·001510*M* manganese^{II} solution were treated with sufficient 1:3 nitric acid to reach different over-all acidities, followed by 2 ml of 5% silver nitrate solution and 10·0 ml of 0·01*M* ammonium hexanitratocerate(IV) solution, then the mixtures diluted to 50 ml in calibrated flasks. The various solutions were measured in the colorimeter at different intervals of time. Allowance was made for the nitric acid introduced through the hexanitratocerate(IV) solution.

In view of the observations in Table V it was decided to maintain the concentration of nitric acid between 0·5 and 2·0*M* in subsequent experiments. If the concentration exceeds 2·0*M*, the reaction may be retarded and manganese dioxide may be precipitated.

Influence of cerium^{IV} concentration on silver catalysed reaction

Five ml of 0·001510*M* manganese^{II} solution were acidified with sufficient 1:1 nitric acid to give an over-all acidity of 1·0*M* when diluted to 50 ml in a calibrated flask, then 2 ml of 5% silver nitrate

Table VI

Manganese^{II}:cerium^{IV}	Time, *min* 1	2
	Dial reading of colorimeter	
1:5	140	—[a]
1:10	194	194
1:15	193	194
1:20	194	193

[a] Because added hexanitratocerate(IV) solution is in insufficient excess, a colloidal brown precipitate of manganese dioxide was obtained.

solution and sufficient 0·02M ammonium hexanitratocerate(IV) solution to give the desired molar ratio of reactants added. The final volume was made to 50 ml with doubly distilled water, and the developed color measured in the colorimeter.

From the observations in Table VI it is evident that, under the conditions employed, the reaction is complete in 1 min when the ratio of manganese^{II}:cerium^{IV} is 1:10.

Stoichiometry of reaction

In all procedures previously prescribed for the colorimetric determination of manganese^{II} based on oxidation with lead dioxide, sodium bismuthate, potassium persulphate or potassium periodate, it appears to be tacitly assumed that the product is permanganic acid, without any precise data regarding the stoichiometry of the reaction being provided. In the present case proof is provided as follows. Five ml of 0·001510M manganese^{II} solution were oxidised with excess ammonium hexanitratocerate(IV) under the conditions prescribed in the recommended procedure, then diluted to 50 ml. The solution contains nitric acid at 1·0M concentration. The developed colour of the solution was measured in the colorimeter against a blank of cerium^{IV} solution of equivalent concentration, the dial reading of the instrument being 194. A carefully standardised solution of analytical reagent grade potassium permanganate (B.D.H. Ltd., England) was suitably diluted to give a 0·001510M solution of the salt in 1·0M nitric acid. This solution gave a dial reading of 193 in the colorimeter. Furthermore, the absorption spectrum of a similarly prepared experimental solution (containing 0·0002M manganese^{II}) and that of 0·0002M permanganate were determined in 1·0M nitric acid using a Hilger Uvispek spectrophotometer and 1-cm cells in the region 480–760 mμ. The absorption of the experimental solution was measured against a blank of cerium^{IV} solution of equivalent concentration. The two absorption curves very nearly overlap (Fig. 1). The molecular extinction coefficient of the experimental solution is $2{\cdot}30 \times 10^3$ and that of the potassium permanganate $2{\cdot}275 \times 10^3$, an agreement within 1·1%, which must be considered sufficiently good considering the extreme dilution at which the absorption measurements are made.

The data presented is sufficient to show that:

(1) The product of the oxidation of manganese^{II} by ammonium hexanitratocerate(IV) in a nitric acid medium is permanganic acid.

(2) The manganese^{II} is stoichiometrically converted into permanganic acid.

Stability of permanganic acid formed

The constancy of the optical absorption of the experimental solution over a period of at least 24 hr shows that the permanganic acid is very stable. Hence the new method can be considered well suited to routine work under ordinary laboratory conditions.

Limits of applicability

Working with solutions of different concentrations of manganese^{II} it has been observed (Fig. 2) that Beer's Law is applicable for experimental solutions containing 0·0332–1·9932 mg/100 ml.

Recommended procedure

A volume of 5–10 ml of test solution, containing about 0·033 to 2 mg of manganese^{II}/100 ml, is treated with sufficient 1:1 analytical reagent grade nitric acid to give an over-all acid concentration of 0·5–2·0M on dilution to 50 ml, followed by the addition of 2 ml of 5% silver nitrate solution and an approximately ten-fold molar excess of hexanitratocerate(IV) solution. The total volume is then made to 50 ml in a calibrated flask. After allowing to stand for 2 min, the developed colour is measured in a Klett-Summerson photoelectric colorimeter, using a green filter transmitting in the wavelength region 525–540 mμ, against a blank solution containing an equivalent amount of cerium^{IV} solution to that used in the test sample.

Typical results of such determinations are presented in Table VII. The amount of manganese^{II} present in each sample is deduced from a calibration curve (Fig. 2), or alternatively the manganese content can be deduced by comparing the colour of the test solution against that of a standard permanganate solution of about the same strength in 1·0M nitric acid.

INTERFERENCES

Nitrate (as sodium or ammonium salt) does not interfere even when present up to 720 mg/50 ml. Similarly, perchlorate and borate (as their sodium salts) do not interfere even at a concentration of 150 mg/50 ml. Traces of chloride, bromide and iodide inhibit the reaction. However, the interference of these ions can be eliminated by precipitating them with silver nitrate and filtration before the oxidation with cerium^{IV} solution. Our results show that the interference of up to at least 21·6 mg

of chloride ion/50 ml can be eliminated in this way. Similar experiments have shown that the interference of up to at least 16 mg of bromide and 25·4 mg of iodide can be eliminated satisfactorily. Sulphate ion does not interfere when present below 2 mg/50 ml. The interference of larger amounts can be eliminated by initially treating the hot test solution with barium nitrate and filtering off the precipitated barium sulphate. In this way the interference of sulphate even up to a concentration of 38·4 mg/50 ml can be overcome.

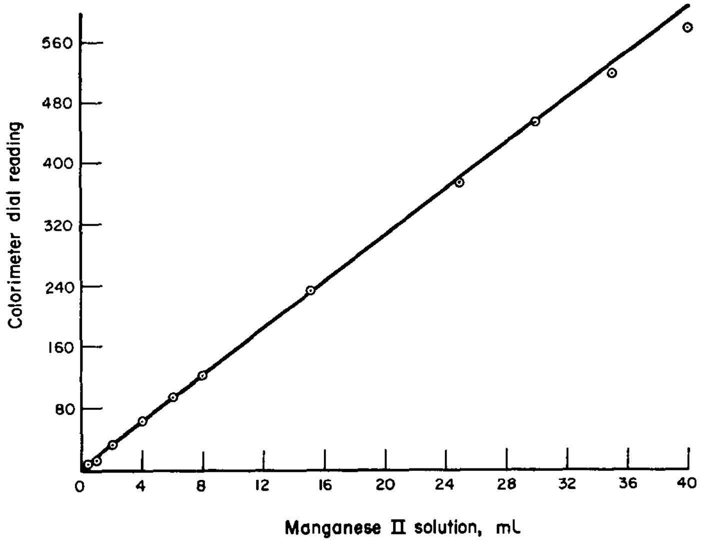

FIG. 2.—Beer's law curve for determination of manganese^{II} with hexanitratocerate(IV) ($6·04 \times 10^{-4}M$ manganese^{II} sulphate solution).

Previously published colorimetric procedures for manganese also suffer interference from chloride. In the bismuthate method the sample is usually evaporated with nitric and sulphuric acids to remove chlorides. In the persulphate method chloride is removed by adding an excess of silver nitrate. Concerning the interference of chloride in the periodate method, the statement of Willard, as quoted by Yoe,[21] is interesting: "It has been stated in various references to this method that the presence of chloride would not interfere. This is true only to a limited extent and only when the operator has taken care to add sufficient periodate to oxidise all the chloride. It is preferable to remove chloride by evaporation with nitric or sulphuric acid." Thomson and Wilson,[22] who applied the periodate method to the determination of manganese in sea water, removed the chloride by treating the evaporation residue with concentrated sulphuric acid, heating to expel the acid and fuming the salts.

The interference of sulphate constitutes a drawback for the new method as compared with the persulphate and periodate procedures. According to Yoe[23] the bismuthate method is satisfactory only when most of the sulphuric acid has been driven off. He states that this is necessary for the reason that the shade of the permanganate is not the same in sulphuric and nitric solutions.

Nickel^{II}, iron^{III}, copper^{II}, calcium^{II}, barium^{II} and molybdenum^{VI} do not interfere even when present up to 40 mg/50 ml. Cobalt^{II}, when compensated for its own colour, does not interfere even up to 100 mg/50 ml. Tungsten^{VI} interferes because of precipitation of tungstic acid in the mineral acid medium. The interference from chromium^{III} has been mentioned above (chromium^{III} also interferes in the periodate and persulphate methods).

Application of New Method to Determination of Manganese in Steel

About 1 g of silico-manganese spring steel (supplied by Messrs Globe Steels, Bombay, India) was treated with 60 ml of 1:1 nitric acid in a 600-ml Pyrex beaker, then heated on a hot-plate for 40–50 min, by which time all volatile and carbonaceous matter was completely decomposed. The resulting yellow solution contained a spongy brown mass (colloidal silicic acid with adsorbed iron^{III}) in suspension which was filtered off, after dilution to about 200 ml, through a Whatman No. 42 filter paper, the filtrate being collected in a 500-ml calibrated flask. The residue on the filter paper, after being washed twice with distilled water, was transferred along with the filter paper to a silica crucible and incinerated to a brown mass. After cooling to room temperature, it was leached with a few drops of 1:1 nitric acid and a few drops of hydrofluoric acid, and the extract transferred to a platinum dish and evaporated to dryness. The resulting mass, after twice evaporating with a mixture of 2 ml of 1:1 nitric acid and 2 ml of hydrofluoric acid, readily dissolved in dilute nitric acid. The solution obtained was transferred to the calibrated flask containing the main bulk of the solution and diluted to the mark. Three different aliquots of this solution (5, 10 and 15 ml) treated according to the new procedure gave the manganese present in the sample as 1·128, 1·127 and 1·130%, respectively, as against a value of 1·150% by the potentiometric procedure of Lingane and Karplus.[19] The agreement between the two methods is considered satisfactory.

Acknowledgement—One of us (P. V. K. R.) desires to thank the Council of Scientific and Industrial Research (India) for the award of a Junior Research Fellowship.

Zusammenfassung—Es wurde beobachtet, daß Mangan(II) durch einen schwachen Überschuß von Ammoniumhexanitratocerat(IV) in 0·5–2m HNO_3 bei Zimmertemperatur zu Permangansäure oxydiert wird. Die Reaktion wird durch Silbernitrat merklich katalysiert, sodaß die quantitative Oxydation von Mangan(II) in einer Minute beendet ist. Es wurde eine Arbeitsvorschrift entwickelt, die die katalysierte Reaktion zur kolorimetrischen Bestimmung von Mangan zwischen 0·33 und 19·93 mg/l zu verwenden gestattet. Die neue Methode hat vor den derzeit verfügbaren den Vorteil, daß die Oxydation von Mangan(II) bei Zimmertemperatur stöchiometrisch zu Ende geht. Unter den vorgeschriebenen Bedingungen ist die gebildete Permangansäure mindestens 24 Stunden beständig. Die Störung durch Sulfat und Halogenide (Chlorid, Bromid und Jodid) kann durch Behandlung der Probelösung mit Bariumnitrat beziehungsweise Sibbernitrat vor der Oxydation mit Cer(IV)-Lösung eliminiert werden. Die Anwendung der Methode auf die Manganbestimmung in Stahl wird erörtert.

Résumé—On a observé que le manganèse(II) est oxydé en acide permanganique par traitement avec un léger excès d'hexanitratocérate(IV) d'ammonium en milieu acide nitrique 0,5 à 2M à température ambiante. La réaction est nettement catalysée par le nitrate d'argent, de sorte que l'oxydation quantitative du manganèse(II) est complète en une minute. On a établi les conditions d'emploi de la réaction catalysée pour le dosage colorimétrique du manganèse entre 0·33 et 19·93 mg par litre. Par rapport aux méthodes couramment disponsibles, cette méthode est avantageuse par le fait que l'oxydation du manganèse(II) est effectuée à température ambiante, de façon stoechiométrique. Dans les conditions prescrites, l'acide permanganique formé est stable 24 hau moirs. L'interférence des sulfates et des halogénures (chlorure, bromure et iodure) peut être éliminée en traitant la solution essai au nitrate de baryum ou au nitrate d'argent, respectivement, avant oxydation par la solution de cérium(IV). On considère aussi l'application de la méthode au dosage du manganèse dans l'acier.

POLAROGRAPHIC DETERMINATION OF DISSOLVED OXYGEN IN PETROL

G. L. WOODROFFE
Research Department, Imperial Chemical Industries Ltd., Heavy Organic Chemicals Division, Organic House, Billingham, Co. Durham, England

(*Received* 24 *February* 1964. *Accepted* 5 *April* 1964)

Summary—A method is described for the determination of dissolved oxygen in petrol using a cathode ray polarograph. Oxygen produces two waves, with reduction potentials at −0·67 V and −1·25 V against a mercury pool anode, when an ethanolic solution of lithium chloride is used as supporting electrolyte. Calibrations are carried out using water of known oxygen content for the preparation of standards and the wave at −0·67 V is preferred for quantitative measurement.

INTRODUCTION

THE determination of oxygen in hydrocarbons has been carried out in these laboratories by a chemical procedure based upon that of McArthur,[1] who developed an analytical method for determination of the oxygen content of various plant gases. As applied to hydrocarbons, this method depends upon the removal of oxygen in a stream of oxygen-free nitrogen and its absorption into a 0·01*N* solution of chromium^{II} chloride. The excess chromium^{II} chloride is subsequently determined by titration with cerium^{IV} sulphate using ferroïn as indicator.

Polarography has been used for the determination of oxygen in a number of materials and it appeared an attractive alternative, having the virtues of speed and specificity.

It is well established that dissolved oxygen is reduced at the dropping mercury electrode to produce two waves.[2] The first wave results from reduction to hydrogen peroxide:

$$O_2 + 2H^+ + 2e \rightarrow H_2O_2 \text{ (acid medium)}$$

$$O_2 + 2H_2O + 2e \rightarrow H_2O_2 + 2OH^- \text{ (neutral or alkaline medium).}$$

The second wave corresponds to the reduction of the hydrogen peroxide either to water or hydroxyl ion, depending on the pH:

$$H_2O_2 + 2H^+ + 2e \rightarrow 2H_2O \text{ (acid medium)}$$

$$H_2O_2 + 2e \rightarrow 2OH^- \text{ (alkaline medium).}$$

The diffusion currents are normally well-defined and show a linear dependence on oxygen concentration. However, three main difficulties are encountered in the application of polarography to the determination in petrol: the limited solubility of petrol in aqueous or semi-aqueous electrolyte systems, the exclusion of atmospheric oxygen in handling samples and the accurate calibration of the instrument. The first difficulty was resolved by adopting a supporting electrolyte of lithium chloride in absolute alcohol and the second by the design of a special cell. Two ways of calibrating the polarograph were investigated: by using water of known dissolved oxygen content directly as a calibration standard, and by using air-saturated alcoholic electrolyte as a secondary standard, the dissolved oxygen content being determined polarographically using water as a primary standard.

EXPERIMENTAL

A 0.1*M* ethanolic solution of lithium chloride proved a suitable supporting electrolyte and gave reduction waves from dissolved oxygen at −0·67 V and −1·25 V.

In early experiments calibrations were achieved by determining the dissolved oxygen content of the supporting electrolyte and using this as a secondary standard. However, the calibration procedure given below was preferred because, under the conditions given, petrol, electrolyte and water formed a completely homogeneous system.

Apparatus

Polarograph. A Southern Analytical Differential Cathode Ray Polarograph was used, but any conventional polarograph of adequate sensitivity would be suitable.

Sampling tube. A sampling tube connected to the polarographic cell is shown in Fig. 1. It comprises a tube of about 5-ml capacity with two 3-way taps C and D, but so arranged that the sample is delivered *via* tap C to the polarographic cell. The volume of the sample tube is determined by filling it with water and weighing.

Polarographic cell. This is also illustrated in Fig. 1. A specially designed cell is so arranged that the dropping electrode, sample inlet tube and stirrer emerge through a tight-fitting bung into the cell. It contains two taps A and B, A being a 3-way tap, the inlet of which is connected to an argon supply and arranged so that the electrolyte can be degassed. Tap A can also be fitted to tap D of the sample tube and argon used to gently transfer the petrol through taps C and B into the cell, the latter being connected by means of polyvinylchloride tubing. A side arm is also provided for the anode connection, thus preventing any fouling by the stirrer.

Reagents

0.1*M* *Lithium chloride.* Prepare a 0·1*M* ethanolic solution of lithium chloride by dissolving 4·24 g of lithium chloride in absolute alcohol and diluting to 1 litre with this solvent.

Air-saturated water of known oxygen content. For most purposes a published value can be assumed for the oxygen content,[3] but for more accurate work the dissolved oxygen should be determined by the Winkler method.[4] Air-saturated water may be prepared by shaking a partially filled flask of water for several minutes, recording the temperature at which this is done.

Argon (oxygen-free). High quality nitrogen may be used as an alternative.

Procedure

Calibration of polarograph. Add 35 ml of 0.1*M* lithium chloride and 5 ml of petrol to the polarographic cell, which contains a mercury pool as anode. Fit the bung to the cell, close tap B and degas the solution by turning tap A and bubbling argon through the electrolyte for 5–10 min. Close tap A. Set the start potential at −0·2 V and measure the wave height of any remaining oxygen at −0·67 V (this should be very small; if not, continue degassing). Record this reading. Introduce 5 ml of air-saturated distilled water at a known temperature by means of a microburette through tap B and stir rapidly by switching on the electric motor after closing tap B. When a homogeneous solution is obtained, with start potential at −0·2 V, measure the height of the oxygen wave at −0·67 V. Record this reading and empty the cell.

Now take 35 ml of 0·1*M* lithium chloride, 5 ml of petrol and 1 ml of water into the polarographic cell and degas with argon *via* tap A for 5–10 min. Close tap A and measure the wave height of any residual oxygen. Introduce 4 ml of air-saturated water by means of a microburette through tap B, stir and record the wave height of the resulting polarogram.

Repeat this procedure with 35 ml of 0·1*M* lithium chloride/5 ml of petrol/2 ml of water, 35 ml of 0.1*M* lithium chloride/5 ml of petrol/3 ml of water and 35 ml of 0.1*M* lithium chloride/5 ml of petrol/4 ml of water, degas, then add 3, 2 and 1 ml of water, respectively. Convert ml of water to mg of oxygen from the tables relating temperature of water to dissolved oxygen content[3] and construct a graph relating peak height to concentration of oxygen.

Determination of dissolved oxygen in petrol. Connect the sample tube to sample point with polyvinylchloride tubing (Notes 1 and 2) and purge well with petrol. Close taps C and D so that the tube is completely filled with petrol.

Add 35 ml of 0·1*M* lithium chloride solution to the polarographic cell and 5 ml of water. Connect the rubber bung to the cell and close tap B. Degas the system by bubbling argon *via* tap A into the solution for 5–10 min. Close tap A and with start potential at −0·2 V record the polarogram of the solution. If a wave appears, continue degassing, then repeat the voltage sweep until no oxygen wave or only a small 'blank' is recorded.

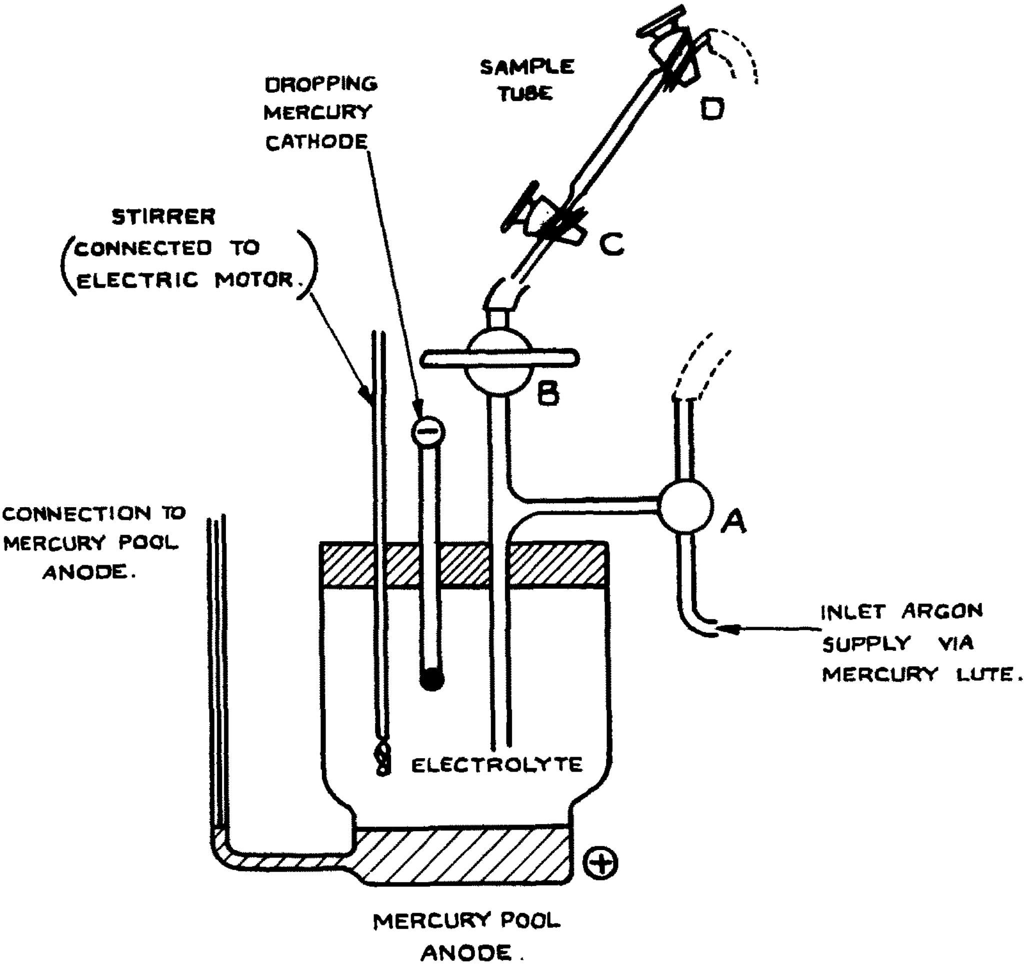

Fig. 1

Connect the sample tube to the cell with polyvinylchloride tubing between taps B and C and between taps A and D as shown in Fig. 1. Turn tap A so that argon purges through tap D for about 1 min, then close tap D and open taps B and C and purge with argon for the same period. Close taps B and C. Close tap A to the cell and turn it to the polyvinylchloride connection between A and D, opening taps D and C in that order and then tap B in such a manner that the sample is very slowly added to the cell. Close tap B after the addition of sample.

Record the polarogram from a start potential of −0·2 V at a sensitivity to give a maximum wave height. Measure the wave height of the oxygen wave and read the mg of oxygen to which this is equivalent from the calibration graph.

Notes

1. Avoid the use of rubber tubing and silicone tap grease because this interferes with the polarographic determination.
2. The amount of polyvinylchloride tubing should be kept to a minimum because it is porous to oxygen.

Calculation

Let a be the mg of oxygen from the graph and v be the volume of sample. Hence

$$(\text{ppm w/v}) = \frac{a \times 10^3}{\text{v}}.$$

RESULTS AND DISCUSSION

In all experiments the total volume and electrolyte/petrol/water ratios were maintained the same, thus providing identical backgrounds for the evaluation of the oxygen wave heights. The quantitative nature of the two oxygen waves at −0·67 V and −1·25 V was demonstrated by polarographing varying amounts of a sample of air-saturated petrol in a water and alcoholic solution of 0·1*M* lithium chloride, but maintaining the total volume and ratio of water/petrol and electrolyte the same. The linear variation of peak height with concentration is shown in Table I.

TABLE I.—MEASUREMENT OF OXYGEN WAVE AT −0·67 V AND −1·25 V

Air-saturated petrol, *ml*	Peak height at −0·67 V converted to the same scale factor	Peak height at −1·25 V converted to the same scale factor
5	186	156
3	112	96
1	35	33

It was found preferable, however, to use the oxygen wave at −0·67 V because polarographic determination in this electrolyte/petrol media caused serious streaming of the dropping mercury electrode at the higher potential.

An important feature of the polarographic method is the fact that by degassing the sample cell with argon or nitrogen, all of the dissolved oxygen is completely removed. Thus, any doubts that it is the oxygen wave being measured can be confirmed by the simple technique of degassing, when this wave will disappear. Using this technique, the calibration was easily checked by preparing standard solutions of oxygen from air-saturated water and degassed petrol and the recoveries obtained are shown in Table II.

TABLE II.—RECOVERIES OF OXYGEN ON STANDARD SOLUTIONS

Oxygen added, *ppm*	Oxygen found, *ppm*
44	43
26	25
26	26
9	10
9	7

The determination on samples taken in duplicate shows the polarographic method to be highly reproducible, a number of petrol samples being analysed which were shown to have dissolved oxygen contents between <1 ppm and 30 ppm. The fact that figures of <1 ppm could be recorded also confirmed that the special sampling and cell arrangement precluded absorption from atmospheric oxygen. The results on duplicate samples are given in Table III.

TABLE III.—DUPLICATE DETERMINATIONS OF DISSOLVED OXYGEN (ppm) IN SAMPLES OF PETROL

Detm.	Sample 1	Sample 2	Sample 3	Sample 4	Sample 5	Sample 6	Sample 7	Sample 8
1	0·8	1·3	1·6	10	14	21	23	30
2	0·8	1·4	1·8	11	16	21	25	33

Finally, by the analysis of identical samples of petrol, a comparison of the polarographic and chemical[1] methods was made. In the latter the petrol was degassed in a stream of oxygen-free nitrogen and the oxygen absorbed in an acid solution of 0·01*N* chromium^{II} chloride. The change in chromium^{II} ion concentration was then related to the amount of oxygen which the sample contained. The excess chromium^{II} ion was determined by adding the solution under test to iron^{III} alum solution and the equivalent iron^{II} ion produced titrated with a standard solution of cerium^{IV} sulphate using ferroïn as indicator. Comparison of the two techniques is shown by the results in Table IV.

TABLE IV.—COMPARISON OF RESULTS FOR DISSOLVED OXYGEN BY POLAROGRAPHIC AND CHEMICAL TECHNIQUES

By polarography, *ppm*	By chemical method, *ppm*
0·8	<1
4·5	4·0
3	2·5
6	9
15	13
10	7
15	10
36	32

These results show reasonable agreement, but the speed with which determinations can be completed by polarography compared with the chemical method and the high reproducibility on duplicate samples makes this the more attractive method for the determination of dissolved oxygen in petrol.

Acknowledgements—The author wishes to thank Mr. G. E. Penketh for his helpful advice and Mr. B. Chapman for his suggestions and valuable assistance with the experimental work.

Zusammenfassung—Eine Methode zur Bestimmung von gelöstem Saurestoff in Petroleum mit Hilfe eines Kathodenstrahlpolarographen wird beschrieben. Sauerstoff gibt zwei Stufen mit Reduktionspotentialen bei −0,67 V und −1,25 V gegen das Bodenquecksilber als Anode, wenn als Trägerelekrolyte eine äthanolische Lithiumchloridlösung benutz wird. Geeicht wird mit Wasser bekannten Sauerstoffgehalts zur Herstellung von Standardlösungen; die Stufe bei −0,67 V wird zur quantitativen Messung vorgezogen.

Resume—On décrit une méthode de dosage de l'oxygène dissous dans l'essence, au moyen d'un polarographe oscillographique. L'oxygène produit deux vagurs, avec des potentiels de réduction à −0,67 V et −1,25 V, par rapport à une anode à masse de mercure, lorsque l'électrolyte support est une solution éthanolique de chlorure de lithium. Les étalonnages sont effectués en utilisant de l'eau à teneur en oxygène connue pour la préparation des étalons et, pour les mesures quantitatives, on préfère la vague à −0,67 V.

SHORT COMMUNICATIONS

New ideas on the reaction mechanism of determinations based on decolorisation

(*Received* 1 *November* 1962. *Revised* 2 *April* 1964. *Accepted* 4 *April* 1964)

PHOTOMETRIC determinations of fluoride are mostly based on decolorisation, *i.e.*, decrease in colour intensity of a metal-dye (MD) chelate and increase in that of the free dye. *All* decolorisation determinations of fluoride have, therefore, been interpreted as being indirect methods, based on a substitution mechanism, which can be formulated as

$$M = D^{(m-d)+} + nF^- + hH^+ + \rightarrow MF_n^{(m-n)+} + H_hD^{(d-h)-} \tag{1}$$

where M^{m+} is a metal ion, D^{d-} and $H_hD^{(d-h)-}$ are different protonation forms of a dye, $=$ represents the chelate ring responsible for the colour of the metal-dye chelate, and $h \lesseqgtr 0$.

Probably the first direct colour (colorisation) reaction of fluoride was described by Feigl and Rajmann,[1,2] but today this reaction is forgotten because of its small practical use. A direct determination of fluoride which has received wide attention, is that of Belcher and coworkers:[3,4] a yellow solution of alizarin complexan gives rise to a red chelate with cerium^{III}, and this in turns yields a blue ternary complex with fluoride. When the fluoride concentration increases, the solution becomes yellow because of the rupture of all of the MD bonds according to equation (1). Belcher and coworkers' interpretation of the blue colour may be generalised as follows. The strongly electronegative fluoride ion, after reacting with a metal-dye chelate derived from the dye DOH^{d-} (which even after reacting with the metal still has a free hydroxyl group)

$$M{=}DOH^{(m-d)+} + nF^- \rightarrow F_nM{=}DOH^{(m-d-n)+} \tag{2}$$

labilises the hydrogen in the free hydroxyl group of the dye:

$$F_nM{=}DOH^{(m-d-n)+} \rightarrow F_nM{=}DO^{(m-d-n-1)+} + H^+ \tag{3}$$

This reaction is accompanied by a change of colour, which clearly indicates the formation of a ternary complex.

For reaction (3) to occur, at least two conditions must be fulfilled: (i) The dye, after having reacted with the metal, must have at least one hydroxyl (phenolic) group conjugate with the resonance system of the dye. (ii) The pH at which reaction (2) takes place must be such that (a) the dissociation of the free hydroxyl group does not take place spontaneously, and (b) the dissociation of the free hydroxyl group which is labilised by the reaction between the metal-dye chelate and fluoride must not be supressed. Alizarin complexan forms coloured binary chelates with a number of metals. Binary complexes fulfilling these conditions, which are easily identified by colour changes, are formed with cerium^{III}, lanthanum and praseodymium. Ternary complexes with other metals probably formed at a pH other than that required by condition (ii), are not easily identified.

Dyes which have one or two dicarboxymethylaminomethyl groups but no free hydroxyl group, as does alizarin complexan, can react analogously to reaction (2) in the following manner

$$M{=}D^{(m-d)+} + nF^- \rightarrow F_nM{=}D^{(m-d-n)+} \tag{2'}$$

Such dyes as Semixylenol Orange and Xylenol Orange (SXO, XO) have no superfluous hydroxyl group and therefore reaction (3), with the accompanying colour change indicating the formation of a ternary complex, cannot take place.

By generalisation of the interpretation of Belcher and coworkers, the existence of FDM complexes with the same colour as the binary metal chelate may be assumed. From the work of Přibil and Kopanica[5] ternary complexes having the same colour as the free dye is possible. They found that slight acidification caused the violet complex of copper^{II} with Xylenol Orange to turn yellow. Because copper^{II} ions could not be detected (polarographically) in this solution, the colour change could not be explained in terms of the replacement of copper^{II} in the copper-Xylenol Orange chelate by hydrogen ion. Even in this more acidic solution copper^{II} must still be bound by the dicarboxymethylaminomethyl group of Xylenol Orange. The existence of a "decolorised" binary complex that originated in accordance with the reaction

$$M{=}D^{(m-d)+} + H^{+} \rightarrow M{-}HD^{(m-d+1)+} \qquad (4)$$

has to be anticipated, by analogy with copper-Xylenol Orange. Of course, one cannot easily prove (polarographically) that zirconium has not been replaced by hydrogen ion.

The present author has shown that six coloured MD chelates which he studied, are decolorised by fluoride (and sulphate) only by a higher acidity than that pH at which these chelates mostly originate. This means that fluoride "decolorises" the system MD until the conditions are reached when the chelate is decolorised under the influence of hydrogen ions.

Fluoride that has reacted with a binary chelate in accordance with reaction (2) or (2′), labilises, of course, not only the hydrogen bound in the "remote" phenolic group but also, and preferentially, that in the "nearer" bonds between M and D. In the case when fluoride reacts with zirconium-Xylenol Orange under such acidity conditions that reaction (4) has already partially taken place, labilisation of the bond between the metal and the functional group of the resonance system of the dye (which is much weaker than the bond between the metal and the strongly complexing dicarboxymethylaminomethyl group) makes possible the reaction

$$F_nM{=}D^{(m-d-n)+} + H^{+} \rightarrow F_nM{-}HD^{(m-d-n+1)+} \qquad (4')$$

by which (already when n = 1) the "decolorised" ternary complex originates more easily than the analogous "decolorised" binary system in accordance with reaction (4). If the concentration of fluoride increases considerably, so many fluoride ions react with the metal that all of the metal-dye bonds are broken, *i.e.*, reaction (4′) passes over to reaction (1). Reaction (1), which corresponds to the existing ideas about the mechanism of decolorisation determinations of fluoride, appears as one limiting case of reactions that are probably best considered from the new point of view.

All that has been said about decolorisation methods for fluoride also applies analogously to decolorisation determinations of (or interferences from) sulphate and other anions. As long as individual decolorisation determinations are not conclusively proved experimentally to be methods with an indirect mechanism of the type of reaction (1), the possibility that the cause of decolorisation is really colorisation of a ternary complex of the same basic colour as the free dye cannot be excluded.

The only experimental data quoted here in support of the new conception of decolorisation reaction mechanisms is as follows. After having added a sufficient quantity of fluoride to the red solution of zirconium-Xylenol Orange, one obtains a yellow solution whose spectrum agrees qualitatively with that of a solution of the same amount of dye, though quantitatively it is less intense. Only after the addition of even higher amounts of fluoride do the spectra of the two solutions become identical from the quantitative point of view. It is, therefore, necessary to assume that before the limiting reaction (1)—connected with the identification of both spectra—occurs, a ternary complex is present in accordance with reaction (4′), and its colour intensity is (always slightly) lower than that of the free dye. If fluoride is added to a solution of zirconium-Xylenol Orange (or better if Semixylenol Orange is used), a polarographic curve is obtained which is intermediate between the curve of the free dye and the curve of the binary chelate (*i.e.*, after the addition of fluoride the curve with $\pi_{1/2}$ of the free dye does not appear).

The interference from sulphate, *etc.*, in the determination of fluoride with zirconium-Xylenol Orange in hydrochloric acid solution is less than in perchloric acid solution. The "protective" influence of chloride and other facts may best be explained by means of "undecolorised" ternary complexes of the type ClZrXO. By "decolorising" these complexes a quaternary complex of the type F(Cl)ZrXO presumably originates.

Other aspects of the author's ideas have already been reported,[6] and experimental data will be published elsewhere.[7]

ROMAN VALACH

Summary—The existence of fluoride-metal-dye (FDM) ternary complexes which have a different colour from that of the MD chelate and of the free dye, as well as the existence of MD binary chelates with the same colour as the free dye, is known. By analogy, the existence of FDM ternary complexes with the same colour as MD or as D

may be assumed. Such ternary complexes may be formed in some determinations based on "decolorisation", so that these determinations should not generally be considered as indirect methods.

Zusammenfassung—Ternäre Fluorid-Metall-Farbstoff-(FMD)-Komplex mit von deer des Metall-Farbstoff-(MD)-Chelats und des freien Farbstoffs verschiedener Farbe sind bekannt, desgleichen binäre Chelate MD mit derselben Farbe wie der freie Farbstoff. Analog kan die Existenz von ternären FDM-Komplexen mit derselben Farbe wie MD oder D angenommen werden. Solche ternären Komplexe Können bei einigen auf "Entfärbung" beruhenden Bestimmungen gebildet werden; daher sind diese Bestimmungen nicht allgemein als indirekte Methoden zu betrachten.

Résumé—On connaît l'existence de complexes ternaires fluorure-métal-colorant (FDM) dont la couleur diffère de celle du chélate métal-colorant (MD) et de delle du colorant libre (D), ainsi que l'existence de chélates binaires métal-colorant (MD) de même couleur que le colorant libre. Par analogie, on peut supposer l'existence de complexes ternaires FDM de même couleur que MD ou D. De tels complexes ternaires peurvent se former lors de quelques dosages basés sur la "décoloration", de sorte que ses dosages ne devraient pas en général être considéres comme des méthodes indirectes.

The determination of chlorosuccinic acid in aqueous solutions

(*Received* 27 *July* 1963. *Accepted* 10 *March* 1964)

INTRODUCTION

THE electrochemical reduction of dichloromaleic acid in buffered media has been shown to yield both chlorosuccinic and succinic acids.[1] Furthermore, the relative amounts of these products depend on the pH at which the reduction is accomplished. It was therefore necessary to develop a method for the determination of small amounts of chlorosuccinic acid ($10^{-3} - 10^{-2}M$) in the presence of succinic citric and phosphoric acids (the two last occurring as components of the buffer used in the reduction). A simple procedure has been developed which involves the dehydrohalogenation of chlorosuccinic acid followed by a polarographic determination of the fumaric acid formed.

EXPERIMENTAL

Reagents

Fumaric acid: Matheson, Coleman and Bell, technical grade (99+ %) fumaric acid was recrystallised several times from water.

Sodium hydroxide: Fisher Scientific Co., aqueous 50%, by weight.

Hydrochloric acid: Fisher Scientific Co., concentrated, reagent-grade.

may be assumed. Such ternary complexes may be formed in some determinations based on "decolorisation", so that these determinations should not generally be considered as indirect methods.

The determination of chlorosuccinic acid in aqueous solutions

(*Received* 27 *July* 1963. *Accepted* 10 *March* 1964)

INTRODUCTION

The electrochemical reduction of dichloromaleic acid in buffered media has been shown to yield both chlorosuccinic and succinic acids.[1] Furthermore, the relative amounts of these products depend on the pH at which the reduction is accomplished. It was therefore necessary to develop a method for the determination of small amounts of chlorosuccinic acid ($10^{-3} - 10^{-2}M$) in the presence of succinic citric and phosphoric acids (the two last occurring as components of the buffer used in the reduction). A simple procedure has been developed which involves the dehydrohalogenation of chlorosuccinic acid followed by a polarographic determination of the fumaric acid formed.

EXPERIMENTAL

Reagents

Fumaric acid: Matheson, Coleman and Bell, technical grade (99+ %) fumaric acid was recrystallised several times from water.

Sodium hydroxide: Fisher Scientific Co., aqueous 50%, by weight.

Hydrochloric acid: Fisher Scientific Co., concentrated, reagent-grade.

Chlorosuccinic acid: Delta Chemical Works, Inc., purified by recrystallisation from ethyl acetate and light petroleum ether and vacuum sublimation: m.p. found 146–148°, reported 146–148°.[2]

Apparatus

Polarograph, constant temperature bath, H-cell with saturated calomel electrode as reference, purified nitrogen.

Procedure

Dehydrohalogenation: The following procedure was used to analyse solutions containing $10^{-3} - 10^{-2}M$ chlorosuccinic acid. An aliquot (5–25 ml) of the solution was pipetted into a 100-ml volumetric flask, 5 ml of 50% w/w sodium hydroxide were then added, and the solution was allowed to stand for 60 min. After the addition of 10–15 ml of distilled water and 10 ml of hydrochloric acid, the solution was cooled and was diluted to the mark with distilled water.

Polarographic analysis: After removal of oxygen by passing nitrogen through the solution for 10 min, a portion of the above solution was transferred to the H-cell and polarographed. The limiting current at —0·85v *vs*. SCE was recorded and corrected for the residual current of the supporting electrolyte. A stock solution of $5\text{–}8 \times 10^{-4}M$ fumaric acid in the same supporting electrolyte was used to obtain the current-concentration ratio, i_d/c. The concentration of chlorosuccinic acid was then calculated in the following manner.

$$\frac{i_d}{K} \times \frac{100}{A} = \text{molarity of chlorosuccinic acid in the original solution}$$

i_d = corrected limiting current at —0·85v *vs*. SCE,

K = current-concentration ratio for fumaric acid,

A = aliquot of sample which was dehydrohalogenated.

RESULTS AND DISCUSSION

Effect of pH and ionic strength

The variation in current-concentration ratio with pH and ionic strength was checked to determine how closely the procedure should be standardised. It was found that the constant did not change significantly in the pH range 0·45–1·5. However, a two-fold variation in ionic strength caused deviations of 6–7% (relative), the ratio increasing with decreasing ionic strength. Thus, if a standard-addition method was used to determine the fumaric acid, a negative bias was introduced, the magnitude of which depended on the change in ionic strength which occurred upon addition of the aliquot of fumaric acid. For example, if 25 ml of the final solution were analysed and a 2-ml aliquot of fumaric acid stock solution (in water) was added to the cell, the results were consistently low by approximately 1% (relative). For highly accurate work this error was eliminated by standardising the procedure so that the ionic strength of the final solution was always the same, and the ratio was determined in this electrolyte. The accuracy and precision of the method were evaluated by analysing solutions of pure chlorosuccinic acid. The 95% confidence limits of any single determination were found to be ±3·4% (relative). The average of 10 determinations was within 0·2% of the true value.

Interferences

Although no interferences were noted in this research, a number of possible complications can be expected. Polarographically reducible material (inorganic and organic) in the original solution, which is not affected by base, need not cause any significant error even if reducible at the same potential as fumaric acid. The difference in the limiting current before and after dehydrohalogenation can be used to determine the chlorosuccinic acid. The magnitude of this difference will determine the reliability of the determination.

Material sensitive to base may be divided into compounds which are originally reducible and are transformed into other compounds on treatment with base, and compounds which are originally inactive but are transformed to active material under basic conditions. Both chloromaleic and chlorofumaric acids fall in the first category.[1] Chlorofumaric acid may be determined by polarographing at pH 9·5, where chloromaleic acid interference is minimised. Chloromaleic acid is determined at pH 7·2, where the reduction of chlorofumaric is more negative than the supporting electrolyte discharge. Both of these acids are dehydrohalogenated to acetylene dicarboxylic acid, which does not interfere if the pH is much above 3. The final solution is adjusted to pH 5·1 for the analysis of the fumaric acid, and the limiting current is recorded at —1·30v *vs*. SCE. Dichlorosuccinic acid in not reducible; it is, however, dehydrohalogenated to chlorofumaric acid, and thence to acetylene dicarboxylic acid. Again the pH of the final solution is adjusted to 5·1 for polarography of the fumaric acid. (Small amounts of chlorofumaric acid which may still be present will not interfere at this pH.)

Microtitration of plutonium^{III} and hydrogen peroxide present with plutonium^{IV} in hydrochloric acid solutions

(*Received* 12 *November* 1963. *Accepted* 3 *April* 1964)

A Method of estimation of a few tens of micrograms of plutonium^{III} and hydrogen peroxide in hydrochloric acid solutions, also containing similar amounts of plutonium^{IV}, was required for some investigations concerning redox reactions between hydrogen peroxide and plutonium ions. Such solutions are unstable because of (a) the redox reaction of hydrogen peroxide with plutonium^{IV}, and (b) the slow catalytic decomposition of hydrogen peroxide. They are, therefore, not of unique composition but time dependent. Nevertheless, it is possible to evaluate such mixtures because hydrogen peroxide is quantitatively destroyed as soon as an excess of potassium dichromate or of iron^{II} sulphate is added. For this purpose Newton and Baker's method,[1] applicable to milligram quantities in a sulphuric acid medium, has been suitably modified.

In the modified method, two aliquots of the mixture are taken separately in 1·5–2·0 ml of approximately 2·5*M* sulphuric acid. To one portion a sufficient excess of standard 0·005*N* potassium dichromate solution is added by a micropipette to oxidise both the hydrogen peroxide and plutonium^{III}, followed by addition of a known quantity of standard 0·005*N* iron^{II} sulphate solution, also in excess. The solution is titrated against standard 0·005*N* cerium^{IV} sulphate solution delivered from an Agla micrometer syringe burette, using ferroïn as internal indicator (20 μl of approximately 1·2 mM ferroïn). This titration gives a measure of the sum of plutonium^{III} and hydrogen peroxide. To the second aliquot the same quantities of dichromate and iron^{II} solutions are added, but in the reverse order, and the titration is completed as before. This gives a measure of the difference between the plutonium^{III} and hydrogen peroxide. From these measurements the concentrations of plutonium^{III} and hydrogen peroxide can easily be calculated. During a titration the solution is stirred either by a stream of nitrogen bubbles or by a suitable magnetic stirrer. The nitrogen stream did not produce any significant difference, indicating that the method is independent of the presence of dissolved air.

Microtitration of plutonium^{III} and hydrogen peroxide present with plutonium^{IV} in hydrochloric acid solutions

(*Received* 12 *November* 1963. *Accepted* 3 *April* 1964)

A Method of estimation of a few tens of micrograms of plutonium^{III} and hydrogen peroxide in hydrochloric acid solutions, also containing similar amounts of plutonium^{IV}, was required for some investigations concerning redox reactions between hydrogen peroxide and plutonium ions. Such solutions are unstable because of (a) the redox reaction of hydrogen peroxide with plutonium^{IV}, and (b) the slow catalytic decomposition of hydrogen peroxide. They are, therefore, not of unique composition but time dependent. Nevertheless, it is possible to evaluate such mixtures because hydrogen peroxide is quantitatively destroyed as soon as an excess of potassium dichromate or of iron^{II} sulphate is added. For this purpose Newton and Baker's method,[1] applicable to milligram quantities in a sulphuric acid medium, has been suitably modified.

In the modified method, two aliquots of the mixture are taken separately in 1·5–2·0 ml of approximately 2·5M sulphuric acid. To one portion a sufficient excess of standard 0·005N potassium dichromate solution is added by a micropipette to oxidise both the hydrogen peroxide and plutonium^{III}, followed by addition of a known quantity of standard 0·005N iron^{II} sulphate solution, also in excess. The solution is titrated against standard 0·005N cerium^{IV} sulphate solution delivered from an Agla micrometer syringe burette, using ferroïn as internal indicator (20 μl of approximately 1·2 mM ferroïn). This titration gives a measure of the sum of plutonium^{III} and hydrogen peroxide. To the second aliquot the same quantities of dichromate and iron^{II} solutions are added, but in the reverse order, and the titration is completed as before. This gives a measure of the difference between the plutonium^{III} and hydrogen peroxide. From these measurements the concentrations of plutonium^{III} and hydrogen peroxide can easily be calculated. During a titration the solution is stirred either by a stream of nitrogen bubbles or by a suitable magnetic stirrer. The nitrogen stream did not produce any significant difference, indicating that the method is independent of the presence of dissolved air.

Microestimations carried out by the above method in the presence of a hydrochloric acid content between 0·1 and 0·3 mmole and with known amounts of plutonium^{III} (1·5–5·2 $\times$ 10^{-4} mmole) have yielded results the error range of which lies between +3·0% and −2·0%, the mean error being +1·4%. The errors obtained in experiments with known amounts of hydrogen peroxide (0·80–7·96 $\times$ 10^{-4} mmole) lie between +3·8% and −5·5%, the mean error being −0·6%.

Typical results of estimations with mixtures of hydrogen peroxide, plutonium^{III} and plutonium^{IV}, produced by the addition of known amounts of hydrogen peroxide to known amounts of plutonium^{IV} in 2*M* and 6*M* hydrochloric acid solutions, are shown in Table I. The values in columns 3 and 4 were checked independently by spectrophotometric measurements, showing that the determination of plutonium^{III} by the present method is possible in the presence of both plutonium^{IV} and hydrogen peroxide. The data in columns 6 and 7 seem to show clearly that the equivalent of hydrogen peroxide consumed in each experiment was very close to that of plutonium^{III} formed, as expected, and thereby afford an indirect check on the estimation of hydrogen peroxide. The data in the table show a very slow rate of catalytic decomposition as compared to the reaction rate between hydrogen peroxide and plutonium^{IV}. Concentrations of plutonium^{IV} in up to about a twenty-fold excess over plutonium^{III} can be tolerated. Blank experiments confirming the stability of plutonium^{IV} through the method have been carried out.

	35	67·5	432·5	20·0	29·0	30·0

^{a} Known amount of Pu^{IV} taken initially. ^{b} Known amount of H_2O_2 taken initially.

In the method described above, dichromate and cerium^{IV} sulphate are used as oxidising agents, while potassium permanganate and dichromate, respectively, were recommended by Newton and Baker. It has been observed in the present work that the use of excess potassium permanganate or cerium^{IV} sulphate as the initial oxidising agent is unsuitable because of the presence of chloride ions, the error being as high as +80% with permanganate and +20% with cerium^{IV} sulphate. While finishing the titration potentiometrically with dichromate, as in the method of Newton and Baker, it has been found that the change in potential towards the end-point is not sharp under our experimental conditions. Further, the use of an internal indicator, *e.g.*, ferroïn is more convenient, provided a stronger oxidising agent, *viz.*, potassium permanganate or cerium^{IV} sulphate is used, which when employed for completing the titration does not seem to introduce significant error, even up to a hydrochloric acid content of 0·5 mmole. The effect of larger amounts of hydrochloric has not, however, been investigated. The method, as described, is applicable to as low as about 2 $\times$ $10^{-5}M$ plutonium^{III} and 8 $\times$ $10^{-6}M$ hydrogen peroxide in 0·3*M* hydrochloric acid. At higher hydrochloric acid concentrations the sensitivity may decrease.

Summary—A method has been developed for the estimation of a few tens of micrograms of plutonium^{III} and hydrogen peroxide in hydrochloric acid solutions containing plutonium^{IV}. The sum of plutonium^{III} and hydrogen peroxide is obtained by successive addition, in excess, of known quantities of potassium dichromate and iron^{II} sulphate to one aliquot of the mixture, then titrating with cerium^{IV} sulphate using ferroïn as indicator. Their difference is obtained by adding the same quantities of the first two reagents in reverse order to another aliquot, then completing the titration as before.

Mikrotitration von Plutonium(III) und Wasserstoffperoxyd neben Plutonium(IV) in salzsauren Lösungen.
Zusammenfassung—Eine Methode zur Bestimmung einiger Zehntel Mikrogramm Plutonium(III) und Wasserstoffperoxyd in Plutonium(IV) enthaltenden salzsauren Lösungen wurde entwickelt. Die Summe von Plutonium(III) und Wasserstoffperoxyd erhält man durch aufeinanderfolgende Zugabe bekannter überschüssiger Menger Kaliumdichromat und Eisen(II)-sulfat zu einem aliquoten Teil der Lösung und nachfolgende Titration mit Cer(IV)-sulfat und Ferroin als Indikator. Die Differenz erhält man durch Zugabe derselben Mengen der beiden ersten Reagentien in umgekehrter Reihenfolge zu einem andern aliquoten Teil der Lösung und Abachluß der Titration wie vorher.

Résumé—On a élaboré une méthode de dosage de quelques dizaines de microgrammes de plutonium (III) et d'eau oxygénée dans des solutions chlorhydriques contenant du plutonium (IV). La somme du plutonium(III)et de l'eau oxygénée est obtenue par addition successive, en excès, de quantités connues de bichromate de potassium et de sulfate de fer (II) à une partie aliquote du mélange, puis titrage au moyen de sulfate de cérium (IV) en présence de ferroïne comme indicateur. Leur différence est obtenue en ajoutant, à une autre partie aliquote, les mêmes quantités des deux premiers réactifs, dans l'ordre inverse, puis en terminant le dosage comme précédemment.

The response of cation-sensitive glass electrodes to alkali metal ions in partially aquated media

(*Received* 18 *January* 1964. *Accepted* 29 *February* 1964)

In 1957, Eisenman[1] reported on the properties of cation-sensitive glass electrodes which developed potentials proportional to the logarithm of the univalent cation activity. Improved electrodes of this type are now commercially available.

A Beckman Model 76 Expanded Scale pH Meter equipped with a 39137 cation-sensitive glass electrode and a fibre-junction saturated calomel electrode (constrained diffusion junction type) was used to measure the response of the glass electrode to $10^{-1} - 10^{-3}M$ alkali metal chlorides in mixtures of water and ethanol, ethylene glycol, acetone, and *N,N*-dimethylformamide (DMF),[2] respectively. These represent the amphiprotic (alcohols), aprotic (ketones) and protophilic (DMF) solvent types.[3] Protogenic (acids) solvents were not used owing to the response of the cation electrode to the hydrogen ion below pH = 5. Electrodes are preconditioned in the appropriate solvent, containing $0{\cdot}1M$ KCl, for approximately 18–24 hr before use, washed with solvent after each measurement, and stored in the conditioning solution between measurements. Stable, reproducible responses to alkali metal ions in 0–90 volume-% of organic solvent were obtained. The slopes of plots of mv *vs.* $-\log [M^+]$ at 25·0 ± 0·5° are summarised in Table I. Deviations from the predicted[4] Nernst slope of 55·0 mv at high concentrations of ethanol and acetone can be attributed to ion association and ion pairing.[3,5,6] The selectivity order of the cation electrode response in all solvents is found to be $K^+ > Rb^+ > Na^+ > Cs^+ > Li^+$, as would be predicted from theoretical considerations.[7]

Summary—A method has been developed for the estimation of a few tens of micrograms of plutonium^{III} and hydrogen peroxide in hydrochloric acid solutions containing plutonium^{IV}. The sum of plutonium^{III} and hydrogen peroxide is obtained by successive addition, in excess, of known quantities of potassium dichromate and iron^{II} sulphate to one aliquot of the mixture, then titrating with cerium^{IV} sulphate using ferroïn as indicator. A Beckman Model 76 Expanded Scale pH Meter equipped with a 39137 cation-sensitive glass electrode and a fibre-junction saturated calomel electrode (constrained diffusion junction type) was used to measure the response of the glass electrode to $10^{-1} - 10^{-3}M$ alkali metal chlorides in mixtures of water and ethanol, ethylene glycol, acetone, and *N,N*-dimethylformamide (DMF),[2] respectively. These represent the amphiprotic (alcohols), aprotic (ketones) and protophilic (DMF) solvent types.[3] Protogenic (acids) solvents were not used owing to the response of the cation electrode to the hydrogen ion below pH = 5. Electrodes are preconditioned in the appropriate solvent, containing 0·1*M* KCl, for approximately 18–24 hr before use, washed with solvent after each measurement, and stored in the conditioning solution between measurements. Stable, reproducible responses to alkali metal ions in 0–90 volume-% of organic solvent were obtained. The slopes of plots of mv *vs.* $-\log [M^+]$ at 25·0 ± 0·5° are summarised in Table I. Deviations from the predicted[4] Nernst slope of 55·0 mv at high concentrations of ethanol and acetone can be attributed to ion association and ion pairing.[3,5,6] The selectivity order of the cation electrode response in all solvents is found to be $K^+ > Rb^+ > Na^+ > Cs^+ > Li^+$, as would be predicted from theoretical considerations.[7]

* *vs.* ESCE † *vs.* ASCE

Increasing fractions of organic constituent in the solvent mixture yielded increasing cell e.m.f.'s for any given concentration of solute. This effect may be attributed to changes in the liquid-junction potential at the reference electrode rather than to a change in the response of the cation-sensitive electrode This view is supported by the work of Zielen,[8] Uitert[9] and Bates[5] on e.m.f. measurements in solutions of strong acids, salts, and buffers in aqueous and partially aqueous media. For experimental confirmation of this hypothesis, the following cells were constructed:

Cation glass electrode ‖y*M*KCl, X% ethanol, (100 − X)% H_2O

|KCl (satd.), 100% ethanol, Hg_2Cl_2 (satd.); Hg (I)

Cation glass electrode ‖y*M*KCl, X% ethanol, (100 − X)% H_2O

|KCl (satd., aq.), Hg_2Cl_2 (satd., aq.); Hg (II)

Hg; Hg_2Cl_2 (satd.), 100% ethanol, KCl (satd.)

|KCl (satd.), Hg_2Cl_2 (satd.), X% ethanol, (100 − X)% H_2O

|KCl (satd., aq), Hg_2Cl_2 (satd., aq.); Hg (III)

The reference electrode for cell (I), an ethanolic saturated calomel electrode (ESCE) was constructed in a typical "H" cell with a sintered-glass frit providing a constricted diffusion junction. The electrolyte solution was saturated with KCl and Hg_2Cl_2 in absolute ethanol. Preparation of the ESCE is as follows: a dry mixture of Hg_2Cl_2, KCl and Hg is intimately ground together and then placed into the prepared cell. A layer of KCl crystals is deposited on the mixture, and the cell is filled with the electrolyte solution. Contact with the mercury pool is made by means of a platinum wire sealed in soft glass. The cell is then sealed to prevent evaporation of the ethanol. The ESCE was found to be stable and gave reproducible responses in cell (III), where X = 100%, of +36·0 ± 0·5 mv after 8·67 days. An acetone-saturated calomel electrode (ASCE) was constructed in a similar manner, and gave reproducible e.m.f readings of +30·9 ± 0·5 mv after 3·5 days of aging.

If Ecell (II) − Ecell (I) = Ecell (III), the change in e.m.f. noted upon replacement of water by organic constituents in the solvent mixture cannot have arisen at the glass electrode, but must result

from effects involving the reference electrode. The confirmatory experimental results using the appropriate non-aqueous reference electrodes are summarised in Table II for both the ethanol–water and acetone–water mixtures. Table II is constructed in the following manner. Subtraction of column 2 from column 1 gives the values in column 1–2. This is equivalent to Ecell (II) − Ecell (I) = Ecell (III) (calculated). The numbers marked with asterisks and quotation marks in column 1–2 are the values of Ecell (III) obtained by direct experimental measurements. Column Δ is obtained by subtracting Ecell (III) calculated values from Ecell (III) experimental values to find apparent differences; according to our theory, Ecell (III) calculated should equal Ecell (III) experimental. The values of column Δ fall well within the range of experimental error using the high-resistance glass electrodes, and confirm our prediction. The average deviations of Δmv are +1·05 and +0·66 mv for the ethanol–water and acetone–water systems, respectively. The average deviation of the mean of Δmv is +0·24 mv for the ethanol–water mixtures and +0·15 mv for the acetone–water mixtures. Furthermore, using a knowledge of degenerate activity coefficients for single ions, Gutbezahl and Grunwald[10] have calculated liquid-junction potentials (E_L) for the hydrogen electrode *vs.* SCE (aqueous) of various acids in ethanol–water solvents, and have obtained E_L's that are dependent only on solvent compositions. These results agree well with ours for systems containing up to 87 weight-% of ethanol. Thus, the effects caused by changes in activity coefficients of salt solutions with changes in solvent composition (replacement of water with organic solvent) are small compared to the change in liquid-junction potential and may be neglected.

We conclude, therefore, that the response of the cation-sensitive glass electrode is essentially solvent-independent, but depends on the nature and concentration of the solute. The results also suggest that such electrodes might be useful as reference electrodes in solvent mixtures containing substantial concentrations of alkali metal cations.

Summary—The response of cation-sensitive glass electrodes to alkali metal ions in ethanol–water and acetone–water mixtures has been evaluated. The increase in measured potential when water is replaced with organic solvent is proved result from to the changing liquid-junction potential of the reference electrode. The response of the glass electrode is essentially solvent-independent for a given concentration and type of solute.

Zusammenfassung—Das Ansprechen der Kationenempfindliche Glaselektroden auf Alkalimetallionen in Äthanol–Wasser- und Aceton–Wasser-Gemischen wurde gemessen. Es wird gezeigt, daß das Ansteigen des gemessenen Potentials bei Ersatz von Wasser durch organisches Lösungsmitte auf der Änderung des Diffusionspotentials in der Brücke zur Referenzelektrode beruht. Die Empfindlichkeit Glaselektrode ist bei gegebener Konzentration und Art des gelösten Stoffes im wesentlichen vom Lösungsmittel unabhängig.

Résumé—On a évalué la résponse de ces électrodes aux ions métalliques alcalins dans des mélanges éthanol–eau et acétone–eau. On a démontré que l'accroissement du potentiel mesuré que l'on observe lorsqu'on remplace l'eau par un solvant organique, est dû à la variation de potentiel du liquide de jonction de l'électrode de référence. La réponse de l'électrode de verre est essentiellement indépendante du solvant, pour une concentration et un type de soluté donnés.

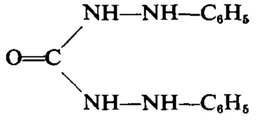
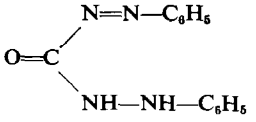
Separation of commercial diphenylcarbazone into its components

(*Received* 11 *February* 1964. *Accepted* 25 *March* 1964)

KRUMHOLZ and Krumholz verified in 1937 that "diphenylcarbazone" (1,5-diphenylcarbohydrazone), m.p. 157°, was probably an intermolecular compound of diphenylcarbazide (I) and pure diphenylcarbazone, m.p. 127° (II), which they succeeded in separating by batch extraction of alkaline solutions of the product with ethyl ether.[1] Diphenylcarbazone, being acidic, remains in solution in its anionic form, whereas diphenylcarbazide, which is not acidic, is carried into the organic solvent.



(I)



(II)

However, the commercial AnalaR grade product available nowadays is still the substance melting at 157° and catalogues do not list the existence of a different form.

In an attempt to confirm Krumholz's results we have found that commercial diphenylcarbazone could be separated into its components by thin-layer chromatography. The support used was a layer of Merck Silica-gel GF_{254}, and the eluent was a mixture of chloroform (75%) and acetone (25%). In recently-coated plates, pure diphenylcarbazone showed up as a red spot ($R_f \simeq 0{\cdot}75$) and diphenylcarbazide as a purple one ($R_f \simeq 0{\cdot}20$) after spraying with a dilute acid solution of potassium chromate. The time of elution was 15–20 min. This confirms the findings of the previous workers, but this method is not very suitable for preparing substantial amounts of the reagent. We have therefore adapted Krumholz's procedure to a continuous liquid-liquid extraction technique which gave excellent results.

An extractor similar to that used by Ashley and Murray for the extraction of $FeCl_3$ with ether[2] appeared to be best suited for the purpose and the procedure was as follows. One g of commercial diphenylcarbazone (m.p. 157°) was dissolved in 100 ml of 5% NaOH containing a few mg of KCN. The solution was transferred to the extractor, and the necessary volume of ethyl ether was added to fill the extractor up to the level of its horizontal arm. The Erlenmeyer flask containing about 100 ml of ethyl ether was connected, and the solvent was refluxed for about 36 hr.

Diphenylcarbazide was carried into the Erlenmeyer flask, where it crystallised in long colourless needles, m.p. 172–3°. The basic aqueous solution was then taken out of the extractor, filtered through a sintered-glass filter-funnel, and acidified with dilute H_2SO_4. A precipitate formed, and the suspension was allowed to settle for 1 hr when the solid was collected and dissolved in the minimum amount of hot ethanol. Twice its volume of de-ionised water was added with stirring, and the solution was allowed to crystallise. Deep orange crystals of pure diphenylcarbazone were obtained in small needles, m.p. 126–7° (rapid heating). The yield for the first crystallisation was 120 mg (~24%).

Pure diphenylcarbazone is easily soluble in ethanol, chloroform and methylene dichloride up to concentrations of the order of $10^{-3}M$; it is also soluble, but not so easily, in ether, benzene and carbon tetrachloride, among the more usual solvents.

For solutions in carbon tetrachloride, the following absorption maxima and respective molar extinction coefficients were observed:

Deep orange crystals of pure diphenylcarbazone were obtained in small needles, m.p. 126–7° (rapid heating). The yield for the first crystallisation was 120 mg (~24%).

Pure diphenylcarbazone is easily soluble in ethanol, chloroform and methylene dichloride up to concentrations of the order of $10^{-3}M$; it is also soluble, but not so easily, in ether, benzene and carbon tetrachloride, among the more usual solvents.

For solutions in carbon tetrachloride, the following absorption maxima and respective molar extinction coefficients were observed:

λ_{max}	ε_{max}
290 mμ	12,750
466 mμ	3,300
563 mμ	800

The samples we obtained using Krumholz's technique were more reddish in colour and had lower values of ε_{max} than those prepared by the method now described. Balt and van Dalen,[3] who recently started a systematic study of the metal complexes of diphenylcarbazone, and purified their reagent according to the previous authors, reported values for ε_{max} close to ours but not quite so high.

Spectra, and more detailed observations, will be published elsewhere.[4]

Summary—Confirming results of previous workers, it is shown that commercial AnalaR diphenylcarbazone can be separated into its components (diphenylcarbazide and pure diphenylcarbazone) by thin-layer chromatography or continuous liquid-liquid extraction, the latter method being preferred for preparative purposes. Some physical properties of pure diphenylcarbazone are reported.

Zusammenfassung—In Übereinstimmung mit Ergebnissen früherer Forscher wird gezeigt, daß handelsübliches analysenreines Diphenylcarbazon durch Dünnschichtchromatographie oder kontinuierliche flüssig-flüssig-Extraktion in seine Komponenten Diphenylcarbazid und reines Diphenylcarbazon aufgetrennt werden kann. Die zweite Methode ist für präparative Zwecke vorzuziehen. Einige physikalische Eigenschaften des reinen Diphenylcarbazons werden angegeben.

Résumé—On confirme des résultats d'autres chercheurs en montrant que la diphénylcarbazone p.a. commerciale peut être séparée dans ses components (diphénylcarbazide et diphénylcarbazone pure) par chromatographie sur couche mince et par extraction liquide-liquide continuelle, cette dernière méthode étant préférée pour sa préparation. On indique quelques propriétés physiques de la diphénylcarbazone purifiée.

LETTER TO THE EDITOR

The determination of phosphate in the presence of calcium by the molybdovanadate method

SIR,

THE method of Bridger *et al.*,[1] incorporating the methods of Maksimova *et al.*[2] and Misson,[3] *i.e.*, the molybdovanadate colorimetric method for the determination of phosphorus, has been applied to the determination of orthophosphate in the presence of calcium.

It has been found that grossly unreliable results are obtained when the phosphate (P_2O_5):calcium (Ca) ratio exceeds 1:10,000. Temperature effects are quite noticeable, in that if the determination is carried out at temperatures in excess of 22° the results are erratic, being approximately double the expected level. The most reliable temperature for carrying out the determination is below 14°, but even at this temperature poor results are obtained if the phosphate:calcium ratio is greater than 1:20,000. The position is not improved if the extraction finish, as described by Elwell *et al.*,[4] and by Booth *et al.*,[5] is used.

The quinoline molybdophosphate method of Wilson[6] gives satisfactory results down to a phosphate:calcium ratio of 1:50,000. The "molybdenum blue" method of Berenblum *et al.*,[7] gives satisfactory results down to a phosphate:calcium ratio of 1:200,000, provided that the determination is carried out in the temperature range 18°–24°.

NACHWEIS UND QUANTITATIVE BESTIMMUNG VON CHLORIERTEN CYCLOPENTADIENDERIVATEN DURCH GASCHROMATOGRAPHIE UND UV-SPEKTROPHOTOMETRIE

(FRAU) L. LECHNER und (FRAU) A. SOMOGYI
Forschungsinstitut für Chemische Schwerindustrie, Veszprém, Ungarn

(*Eingegange am* 24 *November* 1963. *Angenommen am* 10 *März* 1964)

Zusammenfassung—Zur qualitativen und quantitativen Bestimmung von Hexachlorcyclopentadien in Gegenwart von chlorierten Cyclopentadienderivaten wurde eine gaschromatographische und eine UV-spektrophotometrische Methode ausgearbeitet.

HEXACHLOROCYCLOPENTADIEN ist einer der Grundstoffe der Pflanzenschutzmittel vom Cyclodien-typ. Bei seiner Erzeugung durch Chlorieren von Cyclopentadien sind in dem anfallenden Produkt ausser Hexachlorocyclopentadien auch Oktachlorcyclopenten und andere Cyclopentadienderivate von verschiedenem Chlorierungsgrad anwesend.

Zur Ermittlung der optimalen Bedingungen der Chlorierung ist es erforderlich, den Hexachlorcyclopentadiengehalt des Reaktionsproduktes zu bestimmen. Zur Lösung dieser Aufgabe hielten wir unter den analytischen Bestimmungsmethoden die Gaschromatographie und die UV-Spektrophotometrie für geeignet.

In der Untersuchung der Proben bereitete der Umstand, dass das Hexachlorcyclopentadien in einem Gemisch bestimmt werden musste, das durchschnittlich 10 bis 12 chlorierte Cyclopentadienderivate von unbekannter Zusammensetzung und von stark unterschiedlichem Siedepunkt enthielt, grosse Schwierigkeiten. In Proben, die Komponenten mit höherem Chlorierungsgrad als das Hexachlorocyclopentadien enthalten, lässt sich das Hexachlorcyclopentadien mit dem Gaschromatographen qualitativ und quantitativ gut bestimmen. Die Untersuchungen zeigten, dass sich das Hexachlorocyclopentadien in Gemischen, die Verbindungen mit niedrigerem Chlorierungsgrad als die des Hexachlorcyclopentadiens enthalten, mit der gaschromatographischen Methode wegen der Anwesenheit einer Störkomponente mit nahezu gleicher Retentionszeit nicht bestimmen lässt.

Zur Untersuchung von Proben solcher Zusammensetzung wurde mit Erfolg die UV-Spektrophotometrie verwendet.

Untersuchungen mit der gaschromatographischen Methode

Die Untersuchungen wurden mit dem Gaschromatographen Fractovap B der Firma Carlo Erba durchgeführt. Die Thermostatkammer des Gerätes ist zwischen 0 und 230°C auf eine beliebige Temperatur einstellbar. Die Temperatur wird mit einem elektronischen Temperaturregler stabilisiert. Als Messgeber dient eiene Wärmeleitfähigkeitszelle. Die Strömungsgeschwindigkeit des Trägergases wird mit einem Rotameter gemessen. Zur Registrierung der Messergebnisse dient ein potentiometrisches Linienschreibgerät. Die Flächen unter den chromatographischen Spitzen werden mit einem elektronischen Integrator gemessen.

Als Standard wurden durch Destillation gereinigte Hexachlorcyclopentadien und mit Alkohol mehrmals umkristallisiertes Oktachlorcyclopenten verwendet.

Als Trennflüssigkeit diente Apiezon N Vakuumhahnfett und als Trägermittel Thermolytziegelpulver bzw. Polyäthylenpulver von 0,3 bis 0,4 mm Korngrösse. Vor dem Imprägnieren wurde das Thermolytziegelpulver bei 160°C aktiviert. Die Menge der Trennflüssigkeit betrug im Falle von Thermolytziegelpulver 10% und von Polyäthylenpulver 1%. Das Apiezonfett wurde als Lösung in Äther mit dem Trägermittel vermischt. Das Lösungsmittel wurde auf einem Wasserbad verdampft.

Bei der Bestimmung des Hexachlorcyclopentadiens aus einem Gemisch, das kein Oktachlorcyclopenten enthielt, betrug die Höhe der chromatographischen Säule 1 m und ihr Durchmesser 6 mm. Als Füllstoff wurde mit 10% Apiezon N benetztes Thermolytziegelpulver verwendet. Die Temperatur der Thermostatkammer wurde zu 165°C und die des Verdampferraumes zu 230°C ausgeregelt. Die Strömungsgeschwindigkeit des Wasserstoff-Trägergases betrug 2 l/h (Abb. 1).

Bei der Ausarbeitung der quantitativen Bestimmungsmethode bestätigten wir mit der inneren Standardmethode mit Hilfe von Proben von bekanntem Hexachlorcyclopentadiengehalt die Lineariät des Zusammenhanges zwischen der Konzentration und der Grösse der Fläche unterhalb der Spitze. Als innerer Standard wurde Cyclohexan verwendet. Die Cyclohexankonzentration betrug in jedem Fall 20 Gew. %. Die Konzentration des Hexachlorcyclopentadiens wurde zwischen 10% und 60% geändert. Als dritte Komponente wurde chloriertes Gemisch verwendet, das kein Hexachlorcyclopentadien enthielt. Die Ergebnisse wurden auf Grund der unterhalb der Spitzen ausgemessenen Flächen und der Höhen der Spitzen ausgewertet. Aus den Chromatogrammen wurden die Quotienten

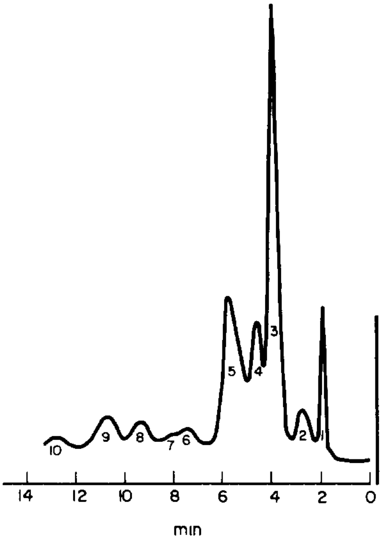

ABB. 1.—1,2,4-9: chlorierte Cyclopentadien.
3: Hexachlorcyclopentadien.
10: Oktachlorcyclopenten.

$$\frac{\text{Fläche unter der Hexachlorcyclopentadien-Spitze}}{\text{Fläche unter der Spitze des inneren Standards}} = \frac{H_T}{St_T} \text{ und}$$

$$\frac{\text{Höhe der Spitze des Hexachlorcyclopentadiens}}{\text{Höhe der Spitze des internen Standards}} = \frac{H_M}{St_M}$$

bestimmt. Die auf diese Weise erhaltenen Werte, als Funktion der Hexachlorcyclopentadien-Konzentration dargestellt, ergaben mit beiden Berechnungsmethoden Geraden.

Aus dem vorliegenden Chromatogramm wurde auch die auf die Summe der Flächen unterhalb der Spitzen bezogene prozentuelle Konzentration des Hexachlorcyclopentadiens, bestimmt. Die auf diese Weise erhaltenen quantitativen Ergebnisse stimmten mit der Einwaage ausreichend überein. Zu den weiteren Untersuchungen wurde die letztere einfachere Berechnungsmethode verwendet.

Bei Proben, die Oktachlorcyclopenten enthielten, konnte die Bestimmung des Hexachlorcyclopentadien aus der Gesamtfläche unter den oben angeführten Chromatographierungsbedingungen nicht angewendet werden; wir beobachteten nämlich, dass auf dem Chromatogramm nur ein Teil des Oktachlorcyclopenten, etwa 40 bis 50%, erschien. Es wurde vermutet, dass der negative Fehler auf die Zersetzung infolge der Temperatur sowie der katalytischen Wirkung des Kolonnenfüllstoffes zurückzuführen ist. Diese Annahme wird auch durch Beckman[1] unterstützt. Die Erhöhung der Temperatur der Thermostatkammer erschien daher nicht als zweckmässig.

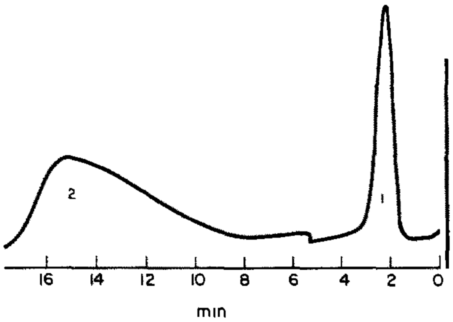

Abb. 2.—1: Hexachlorcyclopentadien.
2: Oktachlorcyclopenten.

Um auch die Bestimmung des Oktachlorcyclopentens quantitativ zu gestalten und zugleich bei der Bestimmung des Hexachlorcyclopentadiens die Anwendung der schwerfälligen internen Standardmethode zu vermeiden, wurde eine Säule von 0,25 m Länge und 4 mm Durchmesser, die mit 1% Apiezonfett benetztem polyäthylenpulver gefüllt wurde, verwendet. Die Temperatur der Thermostatkammer wurde zu 100°C, die des Verdampferraumes zu 230°C ausgeregelt. Die Strömungsgeschwindigkeit des Wasserstoffträgergases betrug 41/h (Abb. 2).

Unter diesen Umständen liess sich in entsprechender Konzentration auch das Oktachlorcyclopenten ohne Zersetzung quantitativ bestimmen; somit kann das Hexachlorcyclopentadien auch in der Gegenwart der hochsiedenden Komponente mit der einfachen und schnellen, auf die Gesamtfläche bezogenen Methode berechnet werden.

Untersuchungen mit der UV-spektrophotometrischen Methode

Die spektrophotometrischen Bestimmungen wurden mit einem Spektrophotometer Unicam Sp-700 vorgenommen. Der Messbereich des Gerätes erstreckt sich vom Ultra-violett-Gebeit bis zum nahen Infrarot-Gebiet 3·6 μ. Das Gerät registriert automatisch die auf die Referenzsubstanz bezogene Lichtabsorption der Probe.

Bei der Untersuchung der Spektren des Hexachlorcyclopentadiens und Oktachlorcyclopentens konnte festgestellt werden, dass die Absorptionsmaxima mit den in der Literatur angegebenen Werten übereinstimmen.[2,3]

Im untersuchten Ultraviolett-Gebiet weist das Specktum der Lösung des Hexachlorcyclopentadiens in Tetrachlorkohlenstoff bei 259 mμ and 318 mμ liegende zwei Absorptionsmaxima auf. Das Oktachlorcyclopenten und die übrigen chlorierten Cyclopentadienderivate ergeben nur ein Absorptionsmaximum bei 259 mμ (Abb. 3). Dadurch kann das Hexachlorcyclopentadien mit Hilfe des Absorptionsmaximums

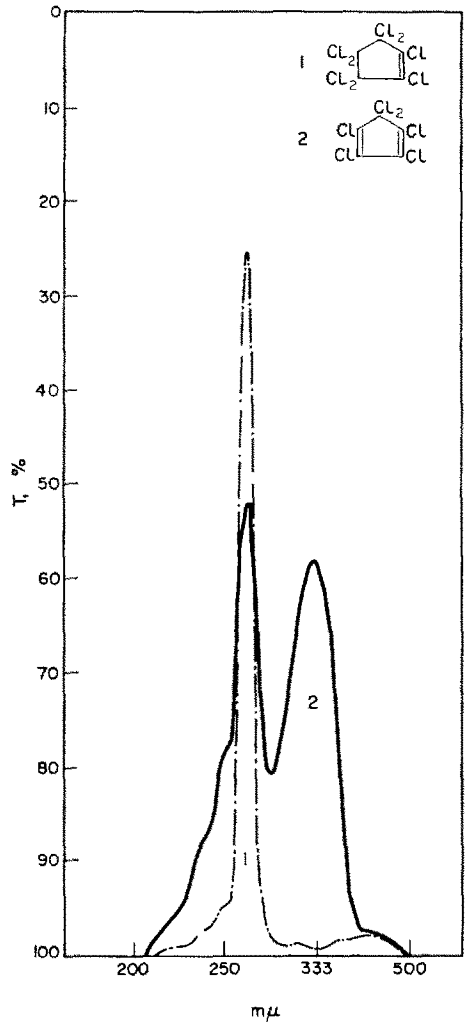

Abb. 3.—Absorptionsspektren von Hexachlorcyclopentadien und Oktachlorcyclopenten in Tetrachlorkohlenstoff als Lösungsmittel.

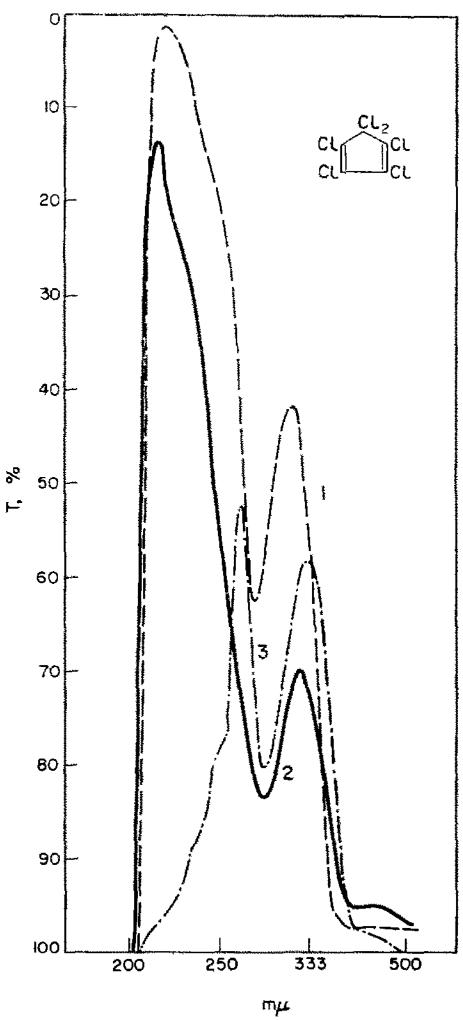

Abb. 4.—Absorptionsspektrum von Hexachlorcyclopentadien in verschiedenen Lösungsmitteln.

1: n-Hexan.
2: Äthanol.
3: Tetrachlorkohlenstoff.

bei 318 mμ auch in Gemischen, bei denen die gaschromatographische Methode nicht anwendbar ist, bestimmt werden.

Bei der Ausarbeitung der quantitativen Bestimmungsmethode wurden die Transmissionen von Hexachlorcyclopentadien-Lösungen verschiedener Konzentration bestimmt. Die geeignete Konzentration zur quantitativen Bestimmung ergab sich zu 10^{-4} mol/l. Die Messungen wurden in einer Quarzküvette von 1 cm n-Hexan, Äthanol bzw. Tetrachlorkohlenstoff als Lösungsmittel durchgeführt. Die in den verschiedenen Lösungsmitteln gemessenen Absorptionsmaxima zeigen einige mμ Abweichung (Tab. 1, Abb. 4).

TABELLE 1.—ABSORPTIONSMAXIMA IN VERSCHIEDENEN LÖSUNGSMITTELN

Verbindung	Lösungsmittel	max.,	$m\mu$
Hexachlorcyclopentadien	n-Hexan	230	310
	Äthanol	209	318
	Tetrachlorkohlenstoff	259	318
Oktachlorcyclopenten	n-Hexan	210	—
	Äthanol	230	—
	Tetrachlorkohlenstoff	259	—

Der Vergleich der mit Gaschromatographie bzw. mit UV.-Spektrophotometrie erhaltenen Ergebnisse der Hexachlorcyclopentadien Bestimmung zeigt, dass die Abweichung zwischen den beiden Methoden 1,0 abs. % nicht übertrifft (Tab. 2).

TABELLE 2.—ABWEICHUNGEN IN DER BESTIMMUNG DES HEXACHLORCYCLOPENTADIENGEHALTS

Nr.	Hexachlorcyclopentadien, Gehalt in Prozenten		Abweichung, %
	gaschromatographisch bestimmt	spektrophotometrisch bestimmt	
1	19,5	18,5	1,0
2	18,5	17,7	0,7
3	27,0	26,7	0,3
4	32,6	33,0	0,4
5	66,5	65,8	0,7

GANG DER ANALYSE

Bestimmung von Hexachlorcyclopentadien

Von der Probe werden unter den bereits beschriebenen gaschromatographischen Bedingungen mit einer Injektionsspritze 10 μl eingemessen. Aus dem Chromatogramm lässt sich die Art der Cyclopentadienderivate der Probe feststellen. Ist keine Komponente zugegen, die die gaschromatographische Bestimmung des Hexachlorcyclopentadiens stören würde, so wird das Chromatogramm mit der Berechnungsmethode der Flächensumme ausgewertet. Falls die Bestimmung in Gegenwart von Cyclopentadienderivaten niedrigeren Chlorierunggrades ausgeführt werden soll, wird das folgende Verfahren angewandt.

In einem Normalkolben wird aus der Analysenprobe auf einer analytischen Waage so viel eingewogen, dass die Konzentration der Lösung 10^{-4} Mol/Liter betrage, nachher wird der Kolben mit Tetrachlorkohlenstoff bis zur Marke aufgefüllt. Die Transmission wird in einer Quartzküvette von 1 cm gegen Tetrachlorkohlenstoff bei 318 mμ gemessen. Die Konzentration wird unter gleichen Bedingungen mit Hilfe einer unter gleichen Bedingungen mit reinem Hexachlorcyclopentadien aufgenommen Kalibrierungskurve bestimmt.

Bestimmung von Oktachlorcyclopentan

Zur gaschromatographischen Bestimmung werden 20 μl der Probe ausgemessen; bei hohem Oktachlorcyclopentengehalt ist die Probe fest, in diesen Falle wird die Probe in wenig Tetrachlorkohlenstoff gelöst. Die Auswertung erfolgt mit der Berechnungsmethode der Flächensumme.

Zur spektrophotometrischen Bestimmung wird aus der Analysenprobe dem zu erwartenden Oktachlorcyclopentengehalt entsprechend in einen Normalkolben so viel ausgemessen, dass die Konzentration der Lösung 10^{-4} Mol/Lit. betrage.

Der Kolben wird mit Tetrachlorkohlenstoff bis zur Marke aufgefüllt. Die Transmission wird in einer Quarzküvette von 1 cm gegen Tetrachlorkohlenstoff bei 259 mμ gemessen. Die Konzentration wird mit Hilfe einer Kalibrationskurve, die mit einem Oktachlorcyclopentadienstandard aufgenommen wurde, bestimmt.

Summary—A gas-chromatographic and ultraviolet-spectrophotometric method has been developed for the detection and quantitative determination of hexachlorocyclopentadiene in the presence of chlorinated derivatives of cyclopentadiene.

Résumé—On a élaboré une méthode de chromatographie en phase vapeur et de spectrophotométrie ultraviolette pour la détection et le dosage de l'hexachlorocyclopentadiène en présence de dérivés chlorés du cyclopentadiène.

RAPID DETERMINATION OF BORON IN IRON AND STEEL BY PYROHYDROLYSIS AND CONSTANT-CURRENT COULOMETRY*

TAKAYOSHI YOSHIMORI, TOMOO MIWA and TSUGIO TAKEUCHI†
Faculty of Engineering, Gifu University, Gifu-Ken, Japan

(*Received* 2 *December* 1963. *Accepted* 24 *March* 1964)

Summary—An accurate and simple method for the determination of boron in steel is proposed. A pyrohydrolytic method for separating boron has been applied to boron steel. The sample, heated in a furnace, is decomposed by water vapour, and boron in the sample is collected in a dilute sodium hydroxide solution, together with the water vapour, within 20–40 min. The boron content in the receiver is determined by constant-current coulometry using mannitol. Accurate results have been obtained within 30–50 min for several boron steels containing 0.0002–0.01% of boron.

IN spite of its very low content in steels, boron has a marked effect upon the hardening of steel. Therefore the determination of the element is very important. A methylborate separation and colorimetric determination[1–5] have been commonly applied for iron samples. These methods, however, require the treatment of acid-insoluble boron compounds, and are very complicated and time-consuming; moreover, the results obtained are not satisfactory unless the analyst is fairly skilled.

A pyrohydrolytic procedure,[6–9] as a separation method for boron or halide ions, has been adopted for the determination of these elements in those ceramic or atomic reactor samples which contain relatively large amounts of boron. This procedure has not yet, however, been applied to small amounts of boron, especially in steel samples.

According to the literature[10] and the authors' recent investigations,[11,12] 1–500 μg of boron can be determined by constant-current coulometry using mannitol, and very reliable results have been obtained. For determining microamounts of boron in steels, this coulometric method has now been combined with the pyrohydrolytic procedure already mentioned, and a more rapid and more accurate method has resulted.

EXPERIMENTAL

Apparatus for pyrohydrolysis

A schematic diagram of the apparatus for pyrohydrolysis of the sample is shown in Fig. 1. The furnace commercially available for the determination of sulphur in steel is satisfactory for this purpose, and a large combustion boat (1 cm deep, 1 cm wide and 8 cm long) is used, after pretreatment by the following procedure. It is washed by scrubbing with tap water, and is treated with 6*M* hydrochloric acid; after washing with distilled water until free from chloride, it is dried, and heated in the furnace in the same conditions as those used for the sample treatment. By this means the blank value for the boat is reduced to less than 1 μg. Steam, which is passed over the sample, is controlled by the adjustment of the voltage of the heating mantle. A 1-litre quartz flask, containing 2–3 g of sodium hydroxide in 1 litre of water, is used for steam generation. Other detailed dimensions are shown in Fig. 1.

mA: Milliammeter (1 mA or 10 mA)	Sw: Switch
VR: 25 K – 500 K Variable resistor	M: pH meter with glass electrode

Apparatus for constant-current coulometry

The coulometric titration apparatus for determining boron is shown in Fig. 2. The electrolysis cell is made from a quartz or polyethylene beaker, and the tubes for introducing nitrogen and those for salt bridge are made of polyethylene. The rotating part of the stirrer is also covered with polyethylene. Constant current is applied using an electronic constant-voltage supply and a variable resistor of high resistance.

The accuracy and the lower limit of the results obtainable by this apparatus depend largely on the accuracy of the pH meter. A pH meter, Model P, with glass electrode, made by the Hitachi-Horiba Instrument Co. is fairly satisfactory.

Reagents

"Analytical Grade" reagents and redistilled water are used. The purity of the mannitol is most important in this method. Even trace amounts of acidic materials in this reagent harms the results; the reagent with the least blank value should be chosen from several lots. The complete washing of the nitrogen introduced into the cell is also important. In order to remove alkaline materials introduced by the washing with solid sodium hydroxide it was necessary to wash at least 4 times with water.

Pyrohydrolytic separation of boron from steel

Only one example has been found in the literature[8] of the pyrohydrolytic separation of boron in steel containing a relatively large amount of boron, but the details are not given. For the determination of a small amount of boron in ordinary boron steel, no method has been described.

To obtain the optimum conditions for the separation of microamounts of boron in steel, the following method was used.

Procedure: The sample, weighed into the boat, was placed in the furnace which was above 1100°; preheated water vapour (about 900°) was then passed for 20–90 min. The rate of the flow of the steam was adjusted by controlling the voltage of the heating mantle (Fig. 1, H). The steam, containing the boron from the sample, was condensed and collected in the quartz or polyethylene beaker containing dilute sodium hydroxide solution. After passage of the steam, the distillate was evaporated, if necessary, to about 100 ml, and the boron content was determined by constant-current coulometry, as described later.

The rate and efficiency of boron recovery in the distillate is dependent on such factors as the temperature of the reaction tube, the rate of flow of the steam, the time of pyrohydrolysis, and the amount of the sample.

Rate of flow of steam

With increase in the rate of flow of the steam, the volume of the distillate becomes very large, and therefore a large amount of mannitol must be added to the electrolyte. This causes a high blank value because of the acidic matter in the reagent. If the rate is too slow, the boron compound may be condensed at the exit of the reaction tube.

TABLE I.—EFFECT OF THE RATE OF PASSAGE OF STEAM

Rate of steam, *ml/min*	Recovery of boron, %
5	98·5
4	99·4
3	100·0
2	102·2

The rate of the flow of the steam was changed from 2 to 5 ml per min (as liquid) and the other conditions were kept constant as follows: sample 1·5 g, furnace temperature 1350°, and time of pyrohydrolysis 30 min.

The results in Table I demonstrate that the rate of flow of steam had not much effect on the results within this range. Because of the considerations mentioned, however, a rate in the range 2–3 ml/min (as liquid) is preferred.

Time of pyrohydrolysis and temperature

Because the vapour pressure of boric oxide increases at high temperature, the time of pyrohydrolysis may be shortened if the furnace temperature is raised. The relation between the temperature of the furnace and the time of pyrohydrolysis is shown in Fig. 3. To obtain these results, the following conditions were kept constant: sample (NBS standard sample No. 151) 1·5 g, rate of flow of steam 2–4 ml/min. When the temperature of the furnace was kept at 1400°, the boron in the sample could be completely recovered within 20 min, and when it was kept at 1150°, 90 min pyrohydrolysis were needed to recover the element completely.

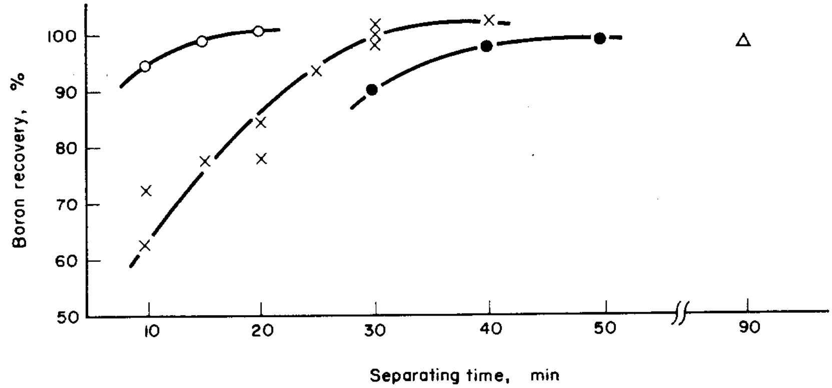

FIG. 3.—Recovery of boron as function of separating time and separating temperature;
—○— 1400°;
—×— 1350°;
—●— 1250°;
△ 1150°.

Although the time of pyrohydrolysis may change according to the amount of sample and the size of the chips, the time necessary for separation of boron from steel samples is greatly shortened if the temperature of the furnace is kept above 1300°. Moreover, evaporation of the distillate, occasionally required in colorimetric procedures, is now not necessary if the time limits described are adhered to.

Recommended procedure for pyrohydrolysis

Weigh the relatively finely divided sample (0·5–3 g) into the boat, treated as described above, and carefully charge it into the furnace, which is kept above 1350°. Connect up the apparatus as shown in Fig. 1. Use about 15 ml of water containing 3–5 drops of 0·5*M* sodium hydroxide solution to collect the distillate. Introduce the steam, preheated to about 900°, at the rate of 2–3 ml per min (as liquid), and maintain this rate for 20–40 min, according to the temperature and the size of the sample. After this time interval, remove the reservoir, and transfer the distillate to the electrolysis cell. Add about 3 g of sodium bromide and dissolve it. Adjust the volume of the solution to about 100 ml. Determine the content of boron in this solution by the constant-current coulometric method described later.

Determination of boron by constant-current coulometry

Many experiments appear in the literature[10–14] for the acidimetric determination of boron using mannitol. In these, however, the pH value when the mannitol is added and that at the end-point do not coincide. In addition, the determination has been of a relatively large amount of boron, and a titration curve for less than 1 mg of boron has not yet been described. According to the present authors' experiments, pH values and the concentration of mannitol at this level do not coincide with those in the literature.

The minimum concentration of mannitol in the electrolyte to determine such a microamount of boron was investigated, and the results obtained are illustrated in Fig. 4. These results show that it is necessary to add more than 6·0 g of mannitol to 100–120 ml of the electrolyte.

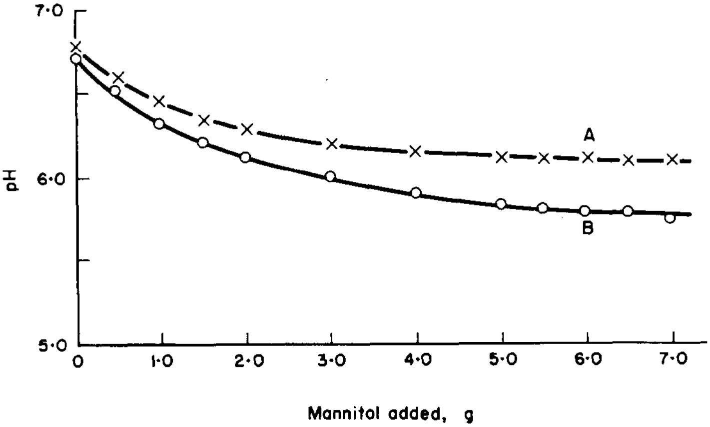

FIG. 4.—Decrease of pH of the electrolyte containing boric acid by the addition of mannitol:

A: 50 μg of boron, B: 100 μg of boron.

One hundred ml of 0·5*M* sodium bromide solution and a definite amount of sodium borate sample solution were placed in the quartz or polyethylene beaker, and it was assembled for the coulometric titration of boron as shown in Fig. 2. Nitrogen was passed through the solution to remove atmospheric carbon dioxide, and the solution was acidified with dilute hydrochloric acid (pH about 2). The solution was then neutralised to a definite pH value (pH 5·5, 6·5, or 7·5) with dilute sodium hydroxide solution, using electrical control. After addition of 6·00 g of mannitol, and a coulometric titration, using constant current, was carried out.

The results of these experiments are shown in Figs. 5–7.

When the boron content is more than 10 mg, the pH-change is sufficient for the use of an indicator such as phenolphthalein (Fig. 5, curve I; Fig. 6, curve I; Fig. 7, curve I). When the boron content is decreased to about 1·0 mg, or less, the concentration of alkaline standard solution or the current of electrolysis should be decreased, and the pH value after the end-point does not increase sufficiently for the use of phenolphthalein (Fig. 5, curves II, III; Fig. 6, curve II; and Fig. 7, curves II, III). When the boron content is decreased to 0·1 mg or less, the pH change near the end-point decreases, and therefore the pH value at the end-point should be lowered. In this case it is very difficult to obtain a clear end-point (Fig. 5, curve IV).

In any event, mannitol must be added at pH 6·5, because otherwise the results obtained are too high or too low (Figs. 5, 6 and 7).

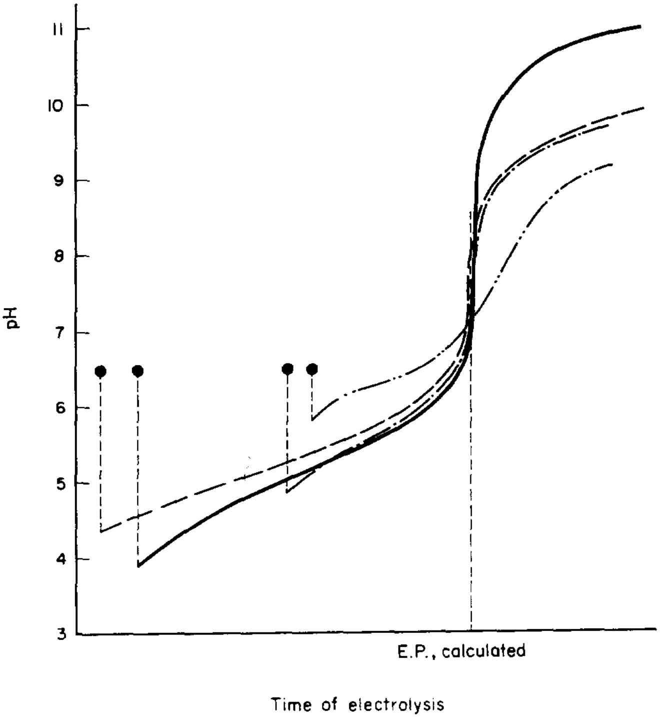

FIG. 5.—Coulometric titration curves (mannitol added at pH 6·5):

Curve I ——— 10·8 mg of boron, 216 mA, Curve III —.—. 0·50 mg of boron, 19 mA;
Curve II ——— 1·08 mg of boron, 19 mA; Curve IV —.—. 0·10 mg of boron, 4·5 mA;

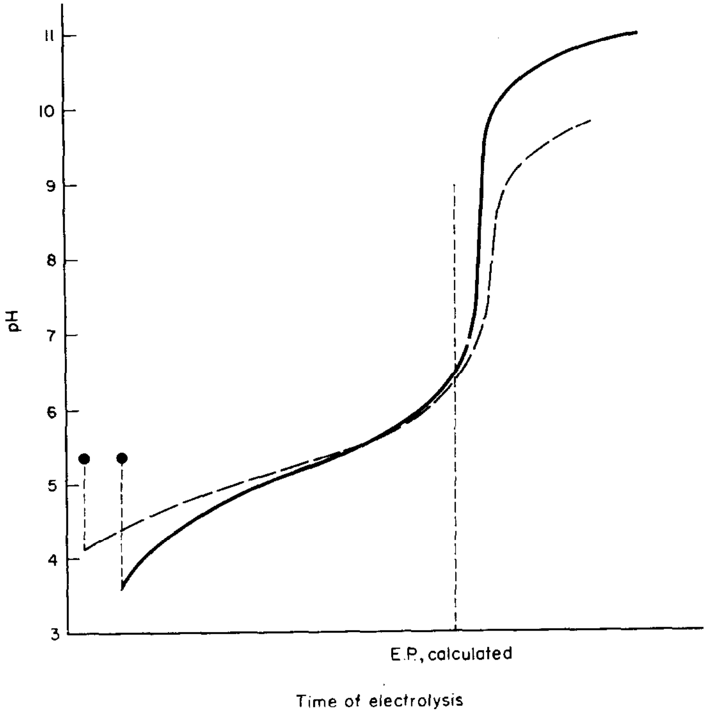

FIG. 6.—Coulometric titration curves (mannitol added at pH 5·5);

Curve I ——— 10·8 mg of boron, 216 mA; Curve II ——— 1·08 mg of boron, 19 mA.

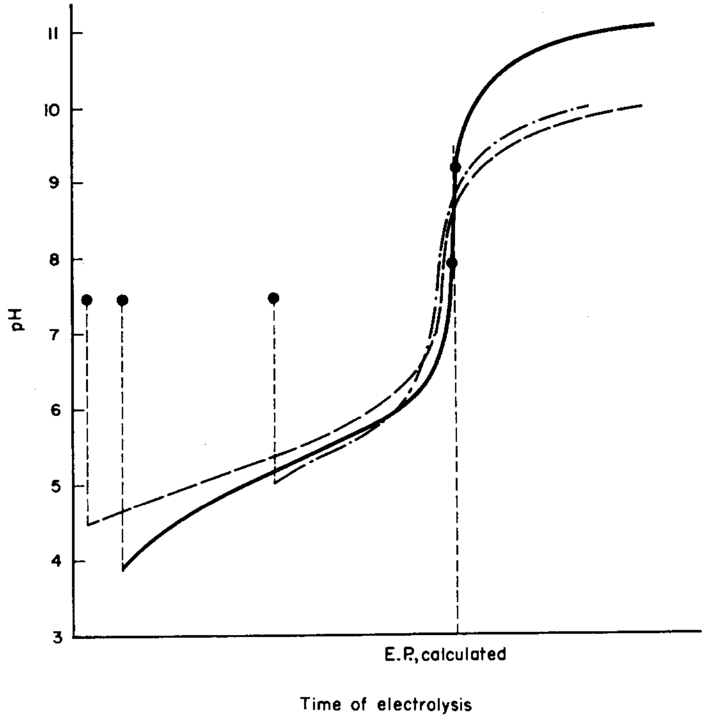

FIG. 7.—Coulometric titration curves (mannitol added at pH 7·5);
Curve I ——— 10·8 mg of boron, 216 mA;
Curve II ——— 1·08 mg of boron, 19 mA;
Curve III —.—. 0·50 mg of boron, 19 mA.

TABLE II.—EFFECT OF pH OF THE ELECTROLYTE BEFORE ADDITION OF MANNITOL AND AT THE END-POINT

pH at the end-point	Boron taken, μg	Boron found, μg	Difference	
			μg	%
5·91	50·3	44·0	−6·3	−12·5
6·31	50·3	45·8	−4·5	−8·9
6·50	50·3	50·5	+0·2	+0·4
6·80	50·3	50·2	−0·1	−0·2
6·97	50·3	48·1	−2·2	−4·4
6·05	10·1	7·5	−2·6	−25·8
6·31	10·1	8·3	−1·8	−17·8
6·50	10·1	9·2	−0·9	−8·9
6·80	10·1	9·9	−0·2	−2·0
7·00	10·1	9·7	−0·4	−4·0

For the titration of relatively high boron concentrations, the pH at the end-point is not so important because of the large pH change, and therefore pH 7, 7·5 or 8 can be chosen. For extremely low boron concentrations, however, the pH value at the end-point is very important; in this case pH 7 (or less) is advisable. For example, pH 7 is preferable for 0·1 mg or boron.

As a result of these experiments the procedure described below is recommended for the determination of the small amounts of boron occurring in ordinary boron steel. With this procedure, the pH of the electrolyte before the addition of mannitol and that at the end-point of the electrolysis coincide with each other, and this has an influence on the results. The element was determined at various pH values of the electrolyte, and the results were shown in Table II. The most satisfactory results were obtained between pH 6·5 and 6·8 for 10–50 μg of boron in the electrolyte. This pH range was nearly equal to the value mentioned elsewhere.[11]

Recommended procedure for constant-current coulometry

Acidify the sample solution in the electrolytic cell containing sodium borate with 0·5*M* hydrochloric acid till the pH is about 2, and adjust the volume to about 100 ml. Add sodium bromide until its concentration in the solution reaches about 0·5*M*. Introduce nitrogen (free from carbon dioxide), adjust the pH value to about 6·2 by adding 0·5*M* and 0·01*M* sodium hydroxide solution. Stop the nitrogen flow, and neutralise the solution with the electrolytically generated hydroxyl ion until the pH increases to 6·6–6·8. During this period adjust the electrolysis current to a convenient value. Add 6·00 g of mannitol to the solution, and pass nitrogen (free from carbon dioxide) for several min.

		1·402	0·0035
		1·401	0·0037
		1·559	0·0036

Begin the electrolysis with constant current, and at the same time start a stop-watch. Continue the electrolysis until the pH value of the electrolyte returns to the initial value, and stop the stop-watch immediately. Because the pH value shown by the pH meter is often influenced by the electrolytic current flowing through the cell, the electrolysis should be repeated at brief intervals near the end-point, including the time increment for each interval of electrolysis. At the true end-point, the pH value shown by the pH meter should coincide with the initial value when the electrolytic current has been stopped. From the value of the current and the total time of electrolysis, the amount of boron may be calculated by Faraday's equation.

Analyses of standard boron steels and commercial boron steels

Using the recommended procedure, several standard samples obtained from B.C.S. and N.B.S. were analysed, as well as some other boron steels commercially available. The results of these experiments are summarised in Tables III and IV.

According to the results in Table III, the maximum error of 16 experiments on 5 samples was 10%, and the mean values for each of these samples almost coincided with their certified values. The results for the other samples also show the good reproducibility of this method.

Zusammenfassung—Eine genaue und einfache Methode zur Bestimmung von Bor in Stahl wurde vorgeschalgen. Bor wurde durch Pyrohydrolyse abgetrennt: Die im Ofen erhitzte Probe wird durch Wasserdampf zersetzt und das Bor mit dem Wasserdampf in verdünnter Natronlauge aufgefangen. Der Borgehalt der Lösung wird dann nach Mannitzusatz durch Coulometrie bei konstanter Stromstärke bestimmt. Für verschiedene Borstähle mit Borgehalten von 0,0002 bis 0,01% ließen sich genaue Ergebnisse in 30 bis 50 Minuten erzielen.

Résumé—On propose une méthode simple et précise de dosage du bore dans l'acier. On applique la méthode pyrohydrolytique de séparation du bore à l'acier au bore. L'échantillon chauffé dans le four est décomposé à la vapeur d'eau, et le bore de l'échantillon est recueilli dans la solution diluée de soude, avec la vapeur d'eau, pendant 20 à 40 mn. La teneur en bore du condensat est déterminée par coulométrie à courant constant, avec emploi de mannitol. On a obtenu des résultats exacts pour différents aciers au bore renfermant 0,0002 à 0,01% de bore ne 30–50 mn.

THE USE OF A HIGH-FREQUENCY TESLA DISCHARGE TUBE FOR THE DETERMINATION OF NITROGEN AND OXYGEN IN HELIUM

P. EMMOTT and R. E. WILSON
Chemical Inspectorate, The War Office, Woolwich, London S.E.18, England

(*Received* 13 *December* 1963. *Accepted* 20 *March* 1964)

Summary—A study has been made of the variation in light intensity, within the wavelength range 300–700 mμ, of a high-frequency (Tesla) discharge in helium and in mixtures of this gas with nitrogen and oxygen. The increase in intensity in the presence of nitrogen and the decrease in intensity in the presence of oxygen have been related to the amounts present, and applied to the determination of up to 1% of nitrogen and up to 0·7% of oxygen (v/v). The interfering effect of nitrogen on the latter determination has been studied. The precision of the determinations and the recovery on synthetic mixtures are satisfactory.

INTRODUCTION

THE theory and practice of the high-frequency excitation of gaseous mixtures, used as an analytical tool, have been reviewed by McGrath, Magee, Pickering and Wilson.[1]

The possible applications of a Tesla discharge tube for the analysis of gaseous mixtures have been mentioned by Stemberg and Poulson,[2] and preliminary experimental work confirmed that the light intensity of such a discharge varies considerably with the impurity content. An analytical technique based on this phenomenon would have the advantages of not requiring expensive equipment and of being simple and potentially versatile. It was decided, therefore, to study the changes in the light intensity of a discharge tube containing helium on the introduction of nitrogen or oxygen, using a selenium photocell mounted on the side of the tube as a light detector. It was realised, however, that an analytical method based on such a study must be largely empirical, and that the effect of possible interfering factors, particularly pressure variations, would require careful investigation.

DISCUSSION

The important fundamental processes involved in a high-frequency discharge can be expressed as follows:

$$R + C^* \rightarrow R^+ + 2e \qquad \text{ionisation by electron impact} \qquad (1)$$

$$R + C^* \rightarrow R^* + C \qquad \text{excitation by electron impact} \qquad (2)$$

$$R^* \rightarrow R + h\nu \qquad \text{light emission} \qquad (3)$$

where R is a gas molecule or atom,
R^* is an excited molecule or atom,
R^+ is an ion,
and C^* is an electron with a high kinetic energy.

Processes (1) and (2) are often referred to as collisional processes of the first kind.[3]

Excitation and ionisation can also be effected by the impact of fast moving atoms or molecules, and by light quanta. The excitation or ionisation of a molecule or atom by an excited atom or ion is referred to as a collisional process of the second kind. The ionisation of a gas by metastable helium atoms is particularly important and is referred to as the Penning effect:

$$\mathrm{He}^* + \mathrm{R} \rightarrow \mathrm{He} + \mathrm{R}^+ + e \tag{4}$$

The energy of a metastable helium atom is about 20 *e*v, sufficient to ionise the permanent gases, most of which have an ionisation potential of about 15 *e*v. In absolutely pure helium the effective collisional process is of the first kind [processes (1) and (2)], but in the presence of traces of impurity, process (4) becomes effective, and is made use of in the present paper for the determination of nitrogen.

The principal loss of ions in a discharge is through the recombination of positive and negative ions. This is 10^5–10^8 times as probable as the recombination of a positive ion with an electron. Oxygen, the halogens and compounds of either are able to capture free electrons to form negative ions, which then combine with positive ions to decrease the number of ions present.

$$\mathrm{R}^+ + \mathrm{O_2}^- \rightarrow \mathrm{R} + \mathrm{O_2} \tag{5}$$

This recombination effect means that the presence of oxygen, in particular, can seriously interfere with the spectral examination of a gas, but it has been made use of in the present paper as a method for the determination of oxygen and by Lovelock and Lipsky[4] in the Electron-Capture Ionisation Detector.

A further process involves non-elastic collision between fast electrons and gas molecules, whereby electrons lose energy and the processes (1) to (4) are partially suppressed:

$$\mathrm{C}^* + \mathrm{R} \rightarrow \mathrm{C} + \text{energised R} \tag{6}$$

Collisions between electrons and an inert gas molecule are elastic, and the suppressing effect of the introduction of a foreign gas into an inert gas discharge is made use of by Ellis and Forrest[5] as the basis of a gas chromatographic ionisation detector. Reaction (6) is very important in high-frequency spectra work, and may outweigh the Penning Effect (4) at high impurity concentrations.

EXPERIMENTAL

Apparatus

High-frequency generator

A mains-operated Ferranti Tesvac was used, having an output frequency of four megacycles, a maximum output voltage of 30 kv and a power consumption of 30 w.

Discharge tube

High-frequency discharge tubes with internal electrodes are subject to difficulties associated with contamination from the electrode materials and adsorption on the electrode surface. Preliminary work indicated that discharge tubes without internal electrodes gave more reproducible results, and accordingly this type of tube was used in the present work.

The discharge tube (Fig. 1) consisted of a Pyrex capillary tube 1 mm i.d. and 100 mm long, fitted with external electrodes and sealed at one end. The other end was sealed to a bulb of 150-ml capacity fitted with a tap, to permit evacuation and filling. This reservoir was necessary to minimise the effect of "clean up" in the electrical discharge.

Before use, the tube was evacuated, baked at about 400° and conditioned to the sample. The gaseous mixtures were blended and introduced into the discharge tube by the use of conventional high-vacuum gas-transfer techniques.

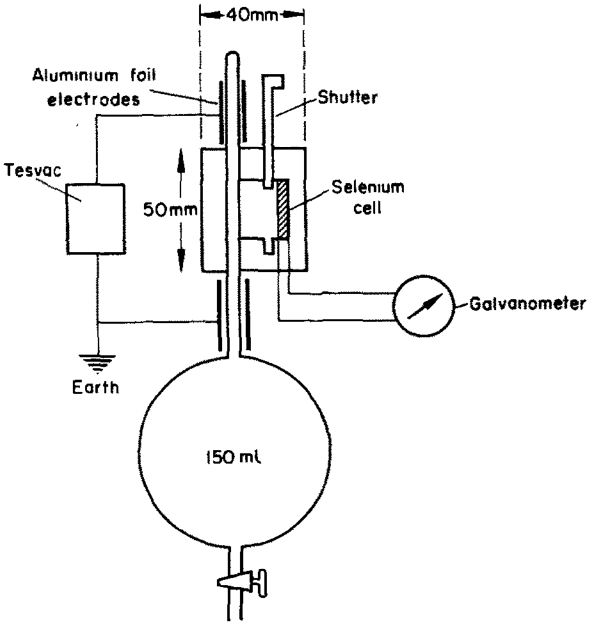

FIG. 1.—Apparatus.

Discharge tube holder and detector assembly

The holder (Fig. 1) was fabricated from Tufnol and kept the discharge tube at a fixed distance from the light detector whilst excluding extraneous light. A fixed aperture, with a shutter, allowed light from the tube to fall upon the detector, a selenium photocell (Hilger No. 633). Leads were taken from the photocell to a Pye Scalamp galvanometer (Cat. No. 7901/S) which provided a means of measurement of the light intensity in arbitrary units.

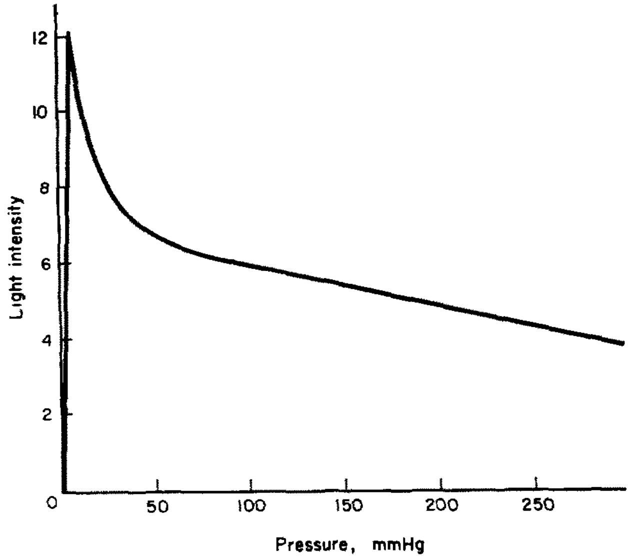

FIG. 2.—Variation of light intensity from helium with pressure.

Sampling pressure

Helium was introduced into the discharge tube, and the light intensity of the discharge was measured at different pressures. A curve was drawn (Fig. 2) relating the light intensity and the gas pressure. This indicated a maximum light intensity at a pressure of 3 mm of mercury. This condition was difficult to reproduce exactly, and it was decided to sample the helium at the more convenient pressure of 200 mm, where the pressure/light intensity curve is not steep and the intensity is still adequate for accurate measurement.

Effect of prolonged discharge

The discharge tube was filled with helium at 200 mm pressure, and was subjected to a continuous discharge. Readings of the light intensity were taken at intervals. These indicated that the light intensity did not vary with time except during the first minute of the discharge, when the readings were somewhat unsteady. In all succeeding experiments 1 min was allowed to elapse between striking the discharge and measuring the light intensity.

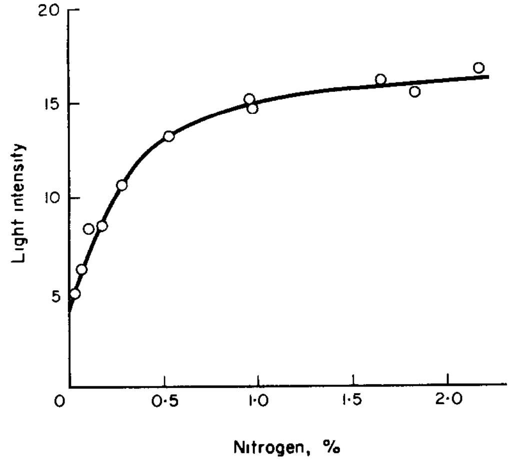

FIG. 3.—Variation of light intensity with nitrogen content, oxygen being absent.

Variation of light intensity with impurities

Mixtures containing up to 2% of nitrogen in helium were made up in a simple gas-blending rig, and were introduced at 200 mm pressure into the discharge tube. The light intensity of each mixture was measured, and a graph was drawn of nitrogen content against light intensity (Fig. 3). This curve showed an increase in light intensity with an increase in nitrogen content up to 2%. In the same way, mixtures containing up to 0·7% of oxygen in helium were prepared, and a graph was obtained (Fig. 4) showing the reduction in light intensity with increase in oxygen content up to 0·7%. It is apparent that the presence of either oxygen or nitrogen will interfere with the determination of the other.

N.B. In these and succeeding experiments the helium used in making up synthetic mixtures was purified by passing through a 5-Å molecular sieve at 77°K before use.

RESULTS AND DISCUSSION

Determination of nitrogen in helium

The light intensities of the discharges in mixtures of helium containing up to 1% of nitrogen were measured at a sampling pressure of 200 mm, and Fig. 3 was used as a calibration curve to calculate the nitrogen content. Table I compares the known nitrogen content with that found using Fig. 3, and indicates that up to 1% the error is about 0·02% of nitrogen.

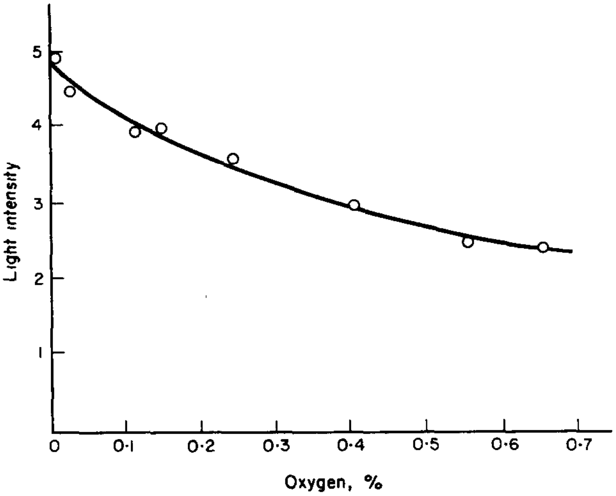

Fig. 4.—Variation of light intensity with oxygen content, nitrogen being absent.

Table I.—The determination of nitrogen in helium

Nitrogen added, %, *v*/*v*	Light intensity (arbitrary units)	Nitrogen recovered, (Fig. 3) %, *v*/*v*	Error
0	5·1		
0·04	6·1	0·04	0·00
0·10	8·4	0·14	+0·04
0·15	8·5	0·13	−0·02
0·27	10·7	0·27	0·00
0·52	13·3	0·52	0·00
0·96	15·2	1·00	+0·04
0·98	15·0	0·94	−0·04

The use of Fig. 3 as a calibration curve for the determination of nitrogen in helium required the prior removal of oxygen to eliminate interference. Commercial helium was therefore passed through a manganous oxide trap to remove any oxygen present and was then introduced into the discharge tube at 200 mm pressure. The light intensity of the discharge was measured under the same conditions as before and Fig. 3 was used as a calibration curve to calculate the nitrogen content of the helium sample. Replicate results were obtained for a sample of helium containing 0·10% of nitrogen (determined mass spectrometrically), and are recorded in Table II.

Determination of oxygen in helium

The interfering effect of nitrogen on the determination of oxygen in helium cannot be easily eliminated, because the removal of the nitrogen from the sample is difficult. It was decided to investigate this interference in more detail. Mixtures of helium and nitrogen were prepared containing up to 40% of nitrogen, and the light intensity of each was measured. Initially, the discharge colour was pink and the light intensity rose sharply with increasing nitrogen content; it remained sensibly constant between 2% and 5% of nitrogen; and it then fell rapidly throughout the rest of the range considered, where the colour of the discharge was deep purple.

TABLE II.—THE DETERMINATION OF NITROGEN IN HELIUM

Light intensity (arbitrary units)	Nitrogen found, %, *v/v* (Fig. 3)
8·8	0·15
8·4	0·14
6·5	0·06
6·3	0·05
7·2	0·09
8·0	0·12
7·8	0·11
7·7	0·10
Mean result	0·10%
Standard deviation	0·03

A series of mixtures containing up to 0·5% oxygen in helium were made up and various amounts of nitrogen were added to each. The light intensity of each mixture was measured, and Table III and Fig. 5 show the relationship between oxygen content and light intensity despite the variation in nitrogen content from 1·6% to 5·3%. Two results, for concentrations of 0·1% and 15·0% nitrogen respectively, are included in the Table to show the necessity for control of the nitrogen content.

TABLE III.—THE DETERMINATION OF OXYGEN IN HELIUM CONTAINING NITROGEN

Nitrogen added, %, *v/v*	Oxygen added, %, *v/v*	Light Intensity (arbitrary units)	Oxygen recovered, %, *v/v* (Fig. 5)	Error, %
3·0	0·00	16·0		
2·0	0·02	14·8	0·04	+0·02
3·1	0·11	13·8	0·11	0·00
2·3	0·20	12·6	0·21	+0·01
3·9	0·24	12·5	0·22	−0·02
2·1	0·30	11·6	0·30	0·00
1·6	0·34	11·4	0·32	−0·02
5·3	0·42	10·6	0·41	−0·01
1·9	0·51	9·2	0·57	+0·06
1·7	0·66	9·0	0·60	−0·06
0·1*	0·02	8·4	>0·7	
15·0*	0·12	8·5	>0·7	

* Effect of nitrogen content outside the set limits.

Fig. 5 can be used as a calibration curve for the determination of up to 0·7% of oxygen in helium. An analytical method based on this curve would first require the determination of the nitrogen and then its adjustment to between 2% and 5% by the addition of the calculated amount of pure nitrogen. Table III gives the oxygen content as determined from Fig. 5 using the observed light intensity values, and compares them with the actual oxygen figures. It can be seen that the average error is about 0·02% of oxygen.

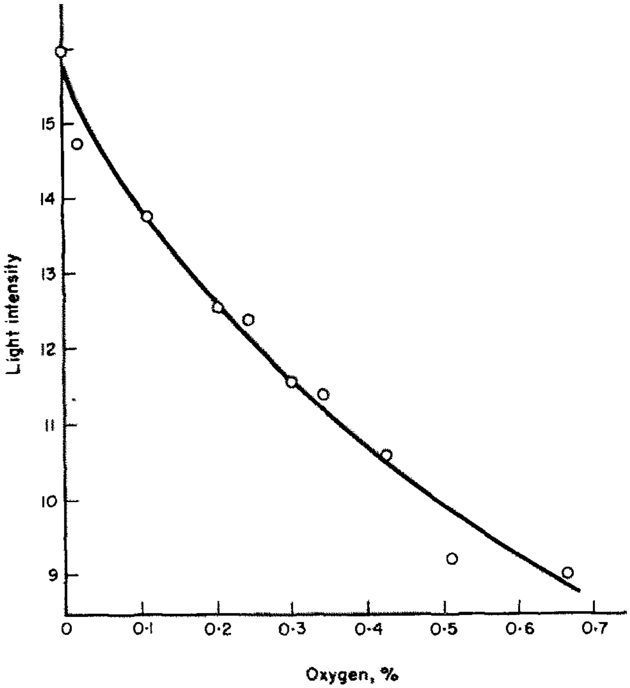

FIG. 5.—Variation of light intensity with oxygen content, nitrogen being present.

CONCLUSIONS

A selenium photocell connected directly to a galvanometer is sufficiently sensitive for the satisfactory measurement of the light intensity from a Tesla discharge tube containing helium. The light intensity from such a discharge increases on the addition of small amounts of nitrogen, and if oxygen is removed, *e.g.*, by a manganous oxide trap, it is possible to use this property to measure the nitrogen content of helium over the range 0–1 % by volume. The light intensity decreases on the addition of oxygen, and this property can be used to measure the oxygen content of helium over the range 0–0·7% by volume, provided that no nitrogen is present or that the nitrogen content can be adjusted to between 2 and 5%. The probable error involved in the determination of nitrogen or oxygen by these techniques is about ±0·03%.

The method is a rather restricted one, and liable to extreme error if indiscriminately applied to the analysis of gas mixtures in general. It is also very sensitive to physical parameters such as pressure.

Zusammenfassung—Die Änderung der Lichtintensität zwischen 300 und 700 mμ einer Hochfrequenz-(Tesla-)entladung in Helium und Gemischen von Helium mit Stickstoff und Sauerstoff wurde untersucht. Der Intensitätszuwachs in Gegenwart von Stickstoff und die Abnahme mit Sauerstoff wurde zu den anwesenden Mengen in Beziehung gesetzt und für die Bestimmung von bis zu 1% Stickstoff und 0,7% Sauerstoff (V/V) verwendet. Die Störung von Stickstoff bei der Sauerstoffbestimmung wurde ebenfalls untersucht. Die Genauigkeit der Bestimmung und die Ergebnisse an selbst hergestellten Mischungen sind zufriedenstellend.

Résumé—Dans le domaine de longueurs d'onde compris entre 300 et 700 mμ, on a étudié la variation de l'intensité de lumière d'une décharge haute fréquence (Tesla) dans l'hélium et dans des mélanges de ce gaz avec l'azote et l'oxygène. L'accroissement de l'intensité en présence d'azote, et son décroissement en présence d'oxygène ont été reliés aux quantités présentes, et appliqués aux dosages de l'azote jusqu'à 1% et de l'oxygène jusqu'à 0,7% (v/v). On a étudié l'effet perturbateur de l'azote sur le dernier dosage. La précision du dosage et la récupération, pour des mélanges synthétiques, sont satisfaisantes.

THE USE OF TESLA-LUMINESCENCE SPECTRA FOR THE DETERMINATION OF NITROGEN IN HELIUM

P. Emmott and R. E. Wilson
Chemical Inspectorate, The War Office, Woolwich, London, S.E. 18, England

(*Received* 13 *February* 1964. *Accepted* 20 *March* 1964)

Summary—The Tesla-luminescence spectra of helium containing up to 2% of nitrogen have been examined using a commercial flame photometer. The intensity of lines attributable to nitrogen have been measured relative to those of several internal-standard lines. The ratios of the intensities of these lines can be used to measure the nitrogen content over the range 0–2% with a coefficient of variation of about 3%.

INTRODUCTION

The analysis of helium for impurities is usually effected either mass spectrometrically or gas chromatographically. As an alternative or complementary method it was decided to investigate the use of luminescence spectra techniques.

There are few references in the literature to work on the analytical applications of Tesla-luminescence spectra. Chakrabarti, Magee and Wilson[1] have determined carbon dioxide in argon by high-frequency excitation, and Bochkova, Razumovskaza and Frish[2] have used the technique for the analysis of inert gases for purity. General information, and references to earlier work, are to be found in Twyman.[3]

When an enclosed gas is subjected to a high-frequency a.c. field, any free electrons present will acquire sufficient energy to excite and ionise molecules and atoms. If the field is strong enough, the rate of production of ions and electrons becomes greater than their loss (by recombination, *etc.*), and the process becomes cumulative, leading to a breakdown in the insulating properties of the gas and the production of a luminous discharge. The spectrum so obtained is characteristic of the gas present, and consists usually of both atomic and molecular band spectra.

A high-frequency discharge differs from a static d.c. discharge in that internal electrodes are not required; the high-frequency field can be applied from a remote conductor. This means that no secondary processes are required to replace electrons lost to the anode, and that lower field strengths are required than with static fields. Also, the absence of internal electrodes means that the spectra are free from lines arising from metallic conductors. The physical dimensions of the containing vessel, the pressure of the gas, and the applied field all have a marked effect on the character of the discharge, and it is essential to adhere rigidly to standardised experimental conditions in order to obtain reproducible results. The lack of reproducibility of light emission from a high-frequency discharge has been recorded in the literature,[3] and in general it is considered advisable to adopt an internal standardisation technique for quantitative analysis.

The processes of ionisation and excitation are usually achieved by a flame (as in flame photometry), or by an arc or spark (as in emission spectrography). These methods can be used for gases, but a more common technique involves the use of a discharge tube to which is applied a d.c. potential. Also, work has been carried out with high-frequency discharges in which a Tesla coil has been used as one type of source. Tesla-luminescence spectra, in common with other visible spectra, can be recorded either photographically or photoelectrically, and a conventional spectrograph or flame photometer can be used.

The present report deals with the application of luminescence spectra to the determination of nitrogen in helium, using a helium line as an internal standard. The method could also be applied to the determination of oxygen and argon in helium.

EXPERIMENTAL

Apparatus

High-frequency generator: A mains-operated Ferranti Tesvac was used, having an output frequency of 4 megacycles, a maximum output voltage of 30 kv, and a power consumption of 30 w.

Discharge tube (*Fig.* 1)*:* This consisted of a Pyrex capillary, 1 mm i.d. and 10 cm long, fitted with external electrodes and sealed at one end. The other end was sealed to a bulb of 150-ml capacity, fitted with a tap to permit evacuation and filling. This reservoir was necessary to minimise the effect of "clean up" in the electrical discharge.

Examination of spectra: A Unicam SP. 900 Flame Photometer was used to detect and examine the spectra. The discharge tube was held in a simple holder which replaced the flame unit and kept the tube at a fixed position relative to the aperture of the instrument, and which excluded extraneous light. The spectra were recorded continuously by a Bristol Pen Recorder.

RESULTS AND DISCUSSION

Sampling pressure

The total light intensity of the helium discharge from 300 to 700 mμ was measured at different pressures by means of a simple selenium photocell mounted on the side of the discharge tube. In this series of experiments, the gas was admitted into a discharge tube and the total light output measured at several different pressures. A curve was drawn (Fig. 2) relating the total light intensity to the sampling pressure; this indicated maximum light intensity for helium at a pressure of 3 mm of mercury.

Examination of spectra

Attempts to use the Hilger "Uvispek" for the examination of spectra were not entirely successful; it was difficult to screen the instrument completely from the high-frequency source. The disadvantage of using a Hilger Medium Quartz Spectrograph for this work lies principally in the time required for exposure and treatment of plates. The Unicam S.P. 900 Flame Photometer is a direct-reading instrument, easily screened from the high-frequency source, and was used for the remainder of this work. The wavelength drum of the Photometer was calibrated against standard lines from a mercury vapour discharge tube.

The gases were introduced into the sample discharge tube by the use of conventional high-vacuum gas transfer techniques. Before use, each discharge tube was conditioned by baking it under vacuum and flushing it out several times with a sample of the gas being studied.

The discharge tube was sparked continuously throughout each scan, which covered the wavelength range 300–700 mμ. The following instrument settings were used: slit width, 0·02 mm; gain, 4·0; electrical band width, 3.

The spectra of many pure inorganic gases were studied, each gas being sampled at that pressure which gave the maximum light intensity. The spectra of nitrogen and helium are discussed below.

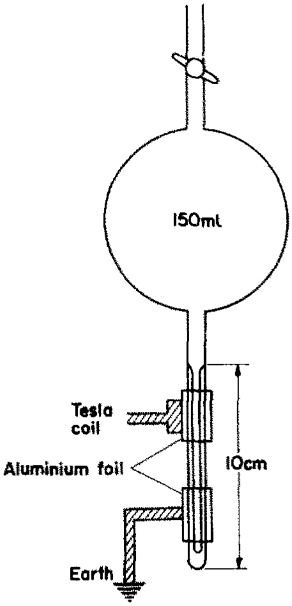

FIG. 1.—Discharge tube without electrodes.

Spectrum of nitrogen

The sample was taken at a pressure of 10 mm of mercury from a cylinder of high-purity nitrogen, and was used without further purification. The spectrum it afforded (Fig. 3) was found to be very intense, consisting of 11 main peaks. Of these, the two principal characteristic peaks were at 337 mμ and 358 mμ.

Helium

A sample of helium was taken from a cylinder at a pressure of 3 mm of mercury, and gave a spectrum (Fig. 4a) containing strong oxygen and nitrogen lines. When

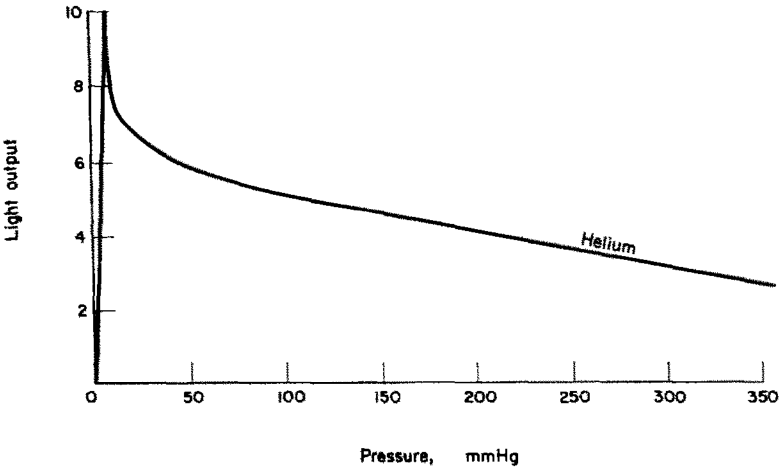

FIG. 2.—Variation of light output with pressure.

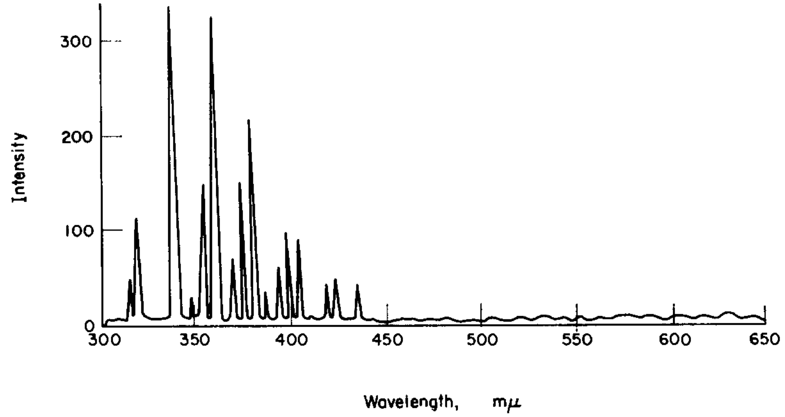

FIG. 3.—Spectrum of nitrogen.

gettered with titanium sponge at 400° for 1 hr, the resulting purified helium gave a spectrum (Fig. 4b) free from oxygen and nitrogen peaks. The spectrum consisted of nine major peaks, the three most intense being at 389 mμ, 502 mμ and 588 mμ.

A sample of helium was also taken at a pressure of 250 mm of mercury and the spectrum was recorded. The oxygen and nitrogen impurity peaks were found to be more intense relative to the helium peaks than when sampled at a pressure of 3 mm. The ratio of the peak heights are obviously dependent upon pressure, which must be standardised. For quantitative analytical work it would appear advantageous to sample the gas at the relatively high pressure of 250 mm, because this pressure would be more reproducible and less critical than the pressure of 3 mm.

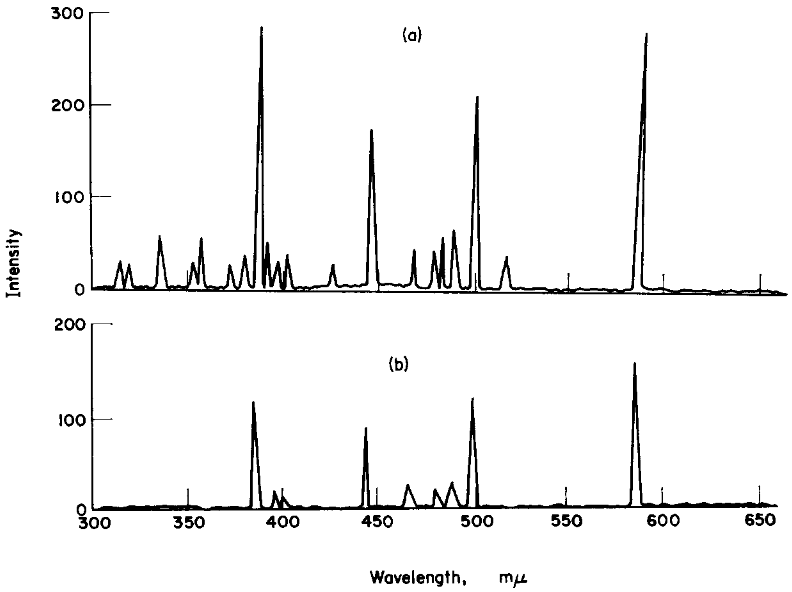

FIG. 4.—Spectrum of helium:
(*a*) Top: impure;
(*b*) Bottom: pure.

Spectra of helium-nitrogen mixtures

Mixtures containing 0–2% of nitrogen in helium were made up in a gas blending rig, small amounts of oxygen being present as an impurity (<0·04% determined mass spectrometrically). A sample was taken of each mixture at a pressure of 250 mm of mercury, and the high-frequency spectra were examined. A typical spectrum consisted of the main lines shown in Table I, identified by reference to the previously-determined spectra of the pure gases.

TABLE I.—SPECTRA OF MIXTURE OF HELIUM AND NITROGEN

Wavelength of main lines, $m\mu$	Element
558	Helium
502	Helium
469	Helium
389	Helium
358	Nitrogen
337	Nitrogen
391	Not identified

Selection of a reference line as internal standard

The helium line at 502 mμ proved to be the most satisfactory for use as an internal standard. The other three main helium lines were unsuitable for the following reasons:

(*a*) At the higher nitrogen levels (>0·05%) the 389-mμ peak existed as a shoulder on the larger peak at 391 mμ.

(*b*) The presence of numerous small peaks very close to the one at 469 mμ made accurate measurement difficult.

(*c*) The line at 588 mμ became very weak on increasing the nitrogen concentration above 0·5%.

Variation of line intensities with nitrogen content

The spectra of the mixtures of helium and nitrogen were examined and the line intensities were measured. Table II gives the intensities of the more important lines for each mixture, in arbitrary units. The intensities of the nitrogen lines at 358 mμ (I_{358}) and 337 mμ (I_{337}) were virtually identical for each mixture, hence results quoted for the line at 358 mμ will also apply to that at 337 mμ.

TABLE II.—VARIATION OF LINE INTENSITIES AND EMISSION RATIOS WITH NITROGEN CONTENT

Oxygen,* %	Nitrogen,† %	I_{358} (N_2)	I_{502} (He)	I_{358}/I_{502}
0·01	0·04	35	13	2·70
0·02	0·06	63	16	3·95
0·03	0·27	182	15·5	11·7
0·02	0·52	225	13	17·3
0·01	0·96	238	10	23·8
0·04	1·65	166	5·0	33·2
0·02	2·17	221	6·0	36·8

* Measured mass spectrometrically.

† Made up in gas blending rig and checked mass spectrometrically.

The curve showing the variation of the intensity of the nitrogen line at 358 mμ with nitrogen content (Fig. 5) is valueless as a calibration curve and illustrates the necessity for the use of an internal standard. The variation of the intensity of the helium line at 502 mμ is also shown graphically (Fig. 5).

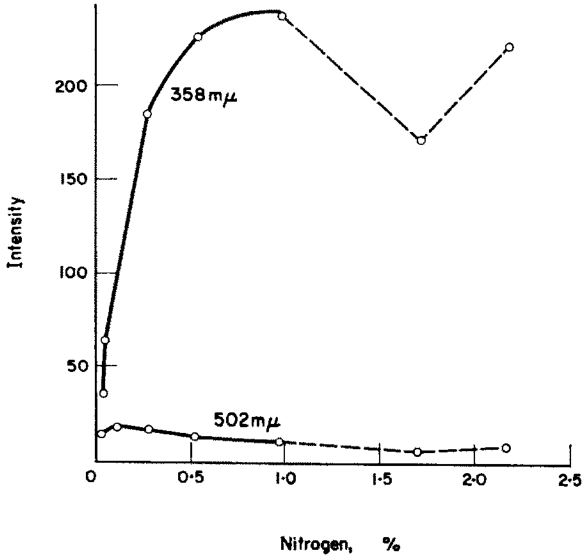

FIG. 5.—Variation of line intensities with nitrogen content.

Variation of emission ratio with nitrogen content

The emission ratio I_{358}/I_{502} for each mixture is shown in Table II. The smooth curve (Fig. 6) obtained for the variation of the ratio with nitrogen content is suitable for use as a calibration curve. The upward concavity of the curve may result from self-absorption of emitted energy by unexcited atoms. The curve appears to be parabolic, and a plot of $(I_{358}/I_{502})^2$ against nitrogen content gives a good straight line.

Precision of measurement of emission ratio

The emission ratio I_{358}/I_{502} was measured for several different samples of the mixture containing 0·06% of nitrogen in helium. The results are given in Table III, and show the coefficient of variation to be 3%.

TABLE III.—PRECISION OF MEASUREMENT OF EMISSION RATIO I_{358}/I_{502}

Nitrogen content	0·06%					
Emission ratio (I_{358}/I_{502})	3·95,	4·10,	3·90,	4·05,	4·30,	4·00
Mean ratio	4·05					
Standard deviation	0·13					
Coefficient of variation	3·2%					

Interfering effect of oxygen

The mixtures of nitrogen in helium used in these experiments contain small amounts of oxygen varying from 0% to 0·04%. Variations of oxygen content at

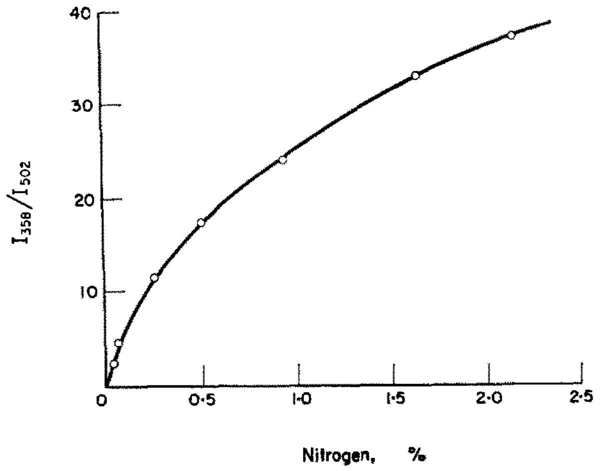

FIG. 6.—Variation of emission ratio with nitrogen content.

this level, whilst affecting the individual line intensities (see result for mixture containing 0·04% of oxygen), do not appear to affect the emission ratio (Fig. 6). However, at concentrations of oxygen in excess of 0·04% the results were somewhat unpredictable (Table IV) and it is considered advisable to reduce the oxygen content to as low a value as possible, *e.g.*, by means of a manganous oxide trap.

TABLE IV.—EFFECT OF OXYGEN

Nitrogen, %	Oxygen, %	I_{358}	I_{502}	I_{358}/I_{502}
0·06	0·02	63	16	4·0
0·06	0·10	53	14·3	3·7
0·06	0·24	39	10·9	3·6
0·06	0·65	31	6·3	4·9

Suggested analytical procedure

The calibration curve (Fig. 6) is sufficiently accurate within the range 0–2% of nitrogen to be used as the basis of an analytical method. The general procedure for such a method is outlined below.

(1) Remove oxygen from the sample, *e.g.*, by a manganous oxide trap.

(2) Sample the impure helium at a pressure of 250 mm of mercury in the discharge tube described.

(3) Excite spectrum by a Ferranti "Tesvac".

(4) Detect and measure the helium line at 502 mμ and the nitrogen line at 358 mμ.

(5) Calculate the emission ratio I_{358}/I_{502}, and read off the nitrogen content from the calibration curve.

CONCLUSIONS

(1) The spectra of helium can be excited by a Ferranti "Tesvac", and can be examined qualitatively and quantitatively by a Unicam S.P. 900 Flame Photometer.

(2) The intensity of the nitrogen lines at 358 mμ and 337 mμ, when measured relative to the helium line at 502 mμ as an internal standard, can be used to determine the nitrogen content of helium over the range 0–2%, with a coefficient of variation of 3%.

(3) The presence of oxygen in excess of 0·04% interferes with the determination, and the oxygen content must be reduced below this level.

Zusammenfassung—Die Tesla-Lumineszenzspektren von bis zu 2% Stickstoff enthaltendem Helium wurden mit einem gewöhnlichen Flammenphotometer gemessen. Die Intensität von Stickstofflinien wurde relativ zu der einiger Linien des inneren Standards gemessen. Die Intensitätsverhältnisse dieser Linien können zur Messung des Stickstoffgehalts zwischen 0 und 2% mit einer Streuung von etwa 3% verwendet werden.

Résumé—On a examiné le spectre de luminescence-Tesla de l'hélium contenant jusqu'à 2% d'azote, en utilisant un photomètre de flamme commercial. Les intensités des lignes attribuables à l'azote ont été mesurées par rapport à celles de différentes lignes étalons internes. Les rapports des intensités de ces lignes peuvent être utilisés pour mesurer la teneur en azote dans le domaine 0–2% avec un coefficient de variation d'environ 3%.

4,5-DIAMINO-6-THIOPYRIMIDINE AS AN ANALYTICAL REAGENT—I

SPECTROPHOTOMETRIC DETERMINATION OF SELENIUM*

FRANK L. CHAN
Aerospace Research Laboratories
Wright-Patterson Air Force Base, Ohio, U.S.A.

(*Received* 2 *December* 1963. *Accepted* 28 *February* 1964)

Summary—A number of organic compounds have been screened as reagents for the spectrophotometric determination of small amounts of selenium. 4,5-Diamino-6-thiopyrimidine shows promise for this determination. In ammoniacal solution, even on long standing, this reagent is colourless in the presence of quadrivalent selenium. However, at pH 1·5–2·5 or lower, 4,5-diamino-6-thiopyrimidine forms a yellow colour with quadrivalent selenium, and this has a strong absorption peak at 380 mμ when compared with a reagent blank of the same concentration. Beer's Law holds when the selenium concentration is between 0·1–2·5 μg per ml. The conditions for the quantitative determination of selenium have been investigated. When selenium in solution is in the quadrivalent state, measurement of absorption should be carried out within 30 min of the addition of the reagent. On longer standing, the reagent gives a slight yellow colour with the formation of elemental selenium. The formation of elemental selenium is slow in dilute solutions of selenium.

INTRODUCTION

THE Aerospace Research Laboratories have been actively engaged in the study of light-sensitive crystals of the elements of Groups II and IV. Not only have pure crystals, prepared from one element in each of these groups, been studied, but solid solutions in the form of single crystals prepared from three elements have also been made. These crystals of solid solutions differ in their electrical resistivity, photoconductivity, ultraviolet-excited emission and other phenomena. Crystals prepared for these studies are in the forms of minute platelets, needles and lumps, depending on the static or dynamic method of their preparation.[1] Because their physical properties and especially their photoelectric properties are affected by their chemical composition, reliable chemical methods for their analysis is of the utmost importance in correlating the various phenomena under investigation.

Physical and chemical methods for the determination of single crystals of solid solutions of cadmium sulphide and zinc sulphide have been investigated.[2] Methods for selenium determination in single crystals, of solid solution of cadmium selenide and cadmium sulphide, ranging in weight from 10 μg to 20 mg, are likewise under active investigation.

In the course of examining possible reagents for the spectrophotometric and spectrofluorimetric determination of selenium in semiconductors it has been discovered that 4,5-diamino-6-thiopyrimidine (4,5D6TP) gives a yellow colour in the

---

* Paper presented at the Eleventh Detroit Anachem Conference, October 21–23, 1963.

presence of quadrivalent selenium. Both aqueous and alcoholic solutions produce this yellow coloration at the specified pH.

In general, the spectrophotometric determination of selenium is based on two types of reaction:

(1) A reduction of its quadrivalent state to elemental selenium with the formation of a coloured substance.

(2) A reaction between the *o*-diamine fragment of an aromatic compound to form a coloured piazselenol.

In fact, a compound such as 4,5D6TP possesses functional groups capable of reacting with selenium to form a piazselenol. Its reaction can also involve a reduction of quadrivalent selenium to its elemental form. The present work has indicated that this new method is essentially of type (1), although a complex intermediate may have been produced.[3]

Spectrophotometrically, the sensitivity of this compound[4] is more than twice that of prevailing methods such as the spectrophotometric method using 3,3′-diaminobenzidine.[5]* Unlike most piazselenol methods, where the coloured products are extracted into a second solvent,[5–8] spectrophotometric determination by this method can be performed directly on the aqueous solution. After addition of 4,5D6TP and adjustment of the pH to between 1·5 and 2·5, readings can be taken after 30 min standing. The method has been used to analyse synthetic samples containing selenium and various foreign ions. It has also been successfully applied to the determination of selenium in single crystals of a solid solution of cadmium selenide and cadmium sulphide.

Elemental selenium formed from solutions containing quadrivalent selenium and 4,5D6TP has been successfully collected as thin layers, using an apparatus designed for the purpose. These thin layers can be determined by X-ray fluorescence, using a molybdenum target. This procedure has been described in a separate paper.[9]

EXPERIMENTAL

Apparatus

A Beckman spectrophotometer, Model DU, with matched 1-cm Corex cells was used. For pH determination, a Beckman pH meter, Model Zerometic, equipped with general purpose electrodes, was used.

Reagents

Standard selenium solutions: For the preparation of standard selenium solutions, several materials of high purity were employed. Two stock solutions were first prepared using entirely different procedures. In one of these procedures, a weighed amount of pure selenous acid was placed in a 2-litre volumetric flask. The quantity of selenous acid used was sufficient to give a selenium content of 1 mg per ml. The exact content of selenium was determined on an aliquot of the solution in suitable size beakers, both gravimetrically and titrimetrically. For the gravimetric method, a procedure using 4,5D6TP has been adopted as well as the one recommended by Hillebrand, Lundell, Bright and Hoffman.[10] For the titrimetric method the selenous acid was titrated iodimetrically after being treated with an iodide in the presence of nitric acid. The liberated iodine was titrated in the usual manner by sodium thiosulphate. This procedure has been recommended by Willard and Diehl.[11] The selenium contents, as determined by both methods, were in agreement.

A second stock solution was prepared by using high purity elemental selenium. The selenium used was claimed to have a purity of 99·999+%. Emission spectrographic analysis shows only

---

* *Note:* It has been reported[19] that 3,3-diaminobenzidene is suggested to have carcinogenic properties, and that it should be handled with care. Aminopyrimidine has also been stated to have growth-inhibiting properties.[20] The present author, therefore, recommends caution in handling 4,5-diamino-6-thiopyrimidine.

trace amounts of impurity. A 500-mg portion of this material was weighed out and treated with 2 ml of fuming nitric acid in a 50-ml covered beaker. After having reacted completely, the solution was evaporated to dryness on a low temperature hot plate, at 48–56°. The selenium was then converted to the quadrivalent state by evaporating twice to dryness with 2 ml of 6*M* hydrochloric acid. The dried selenous acid was transferred, and was diluted to 500 ml in a volumetric flask. The procedure was repeated three times. Diluted standard solutions containing 10 μg per ml were prepared from these stock solutions. They gave the same selenium content by the spectrophotometric method using 4,5D6TP as the reagent.

4,5-*Diamino-6-thiopyrimidine:* Five lots of the reagent purchased at different times over a period of 1 year* were colourless in appearance. (The preparation of the compound has been described in the literature.[14]) Recrystallisation of this material from absolute alcohol did not show any difference from the original material when used for the spectrophotometric determination of selenium. X-ray single crystal rotation photographs[12] as well as X-ray powder patterns appear the same for the recrystallised and the original materials.

Infrared spectra taken with this material are the same as those reported in the literature.[13] This material was found to melt at 256–258°.[14]

Chemicals for cation and anion interferences: To test for interference from foreign ions, analytical reagent chemicals were used without further purification. Solutions were usually made up to contain 3 mg per ml of the ion.

Procedures

Before the determination of selenium in a solution, a calibration curve, absorbance *vs.* concentration, was made. Appropriate quantities of the diluted standard solution, sufficient to give 0·1–2·5 μg/ml of selenium for a total final volume of 20 ml (or other designated volume), were pipetted into glass-stoppered 50-ml flasks. To each of these standard solutions were added 3·0 ml of 0·3*M* HCl and enough distilled water to make a total of 12 ml. With each of the selenium solutions a blank solution was also prepared, using the same quantity of acid and enough water to give a volume of 12 ml. Eight ml of 4,5D6TP (0·02%), freshly prepared from finely divided powder, were added to each solution and to each blank. After 30 min the absorbancy of each solution against its blank solution was taken.

Determination of an unknown solution was carried out in exactly the same manner as for the calibration solutions. For an accurate result by this method two known solutions (with blanks), having the concentration of selenium in one slightly higher and in the other slightly lower than that of the unknown,[16] were also determined.

To determine the amount of selenium in semiconductors containing solid solutions of cadmium selenide and cadmium sulphide, an amount of the semiconductor ranging from 20 μg to 1 mg was weighed out, using a Cahn electro-microbalance, and was placed in a 10-ml covered beaker. To the sample was added 2 drops of fuming nitric acid. After the disappearance of brown fumes, 6 drops of 1:1 (v/v) hydrochloric acid were added, and the mixture was allowed to evaporate to dryness on a low temperature hot plate (about 50–60°). To ensure complete conversion of all the selenium to the quadrivalent state, the mixture was evaporated again with a few drops of hydrochloric acid. The remainder of the procedure was the same as that for the preparation of standard solution.

RESULTS AND DISCUSSION

Characteristics of absorbance spectra

Two absorbance curves, A and B, are shown in Fig. 1. A_1 is the curve for quadrivalent selenium treated with 4,5D6TP, and B_1 is the curve for 4,5D6TP alone, the pH for both being 1·5. A_2 and B_2 are enlarged portions of curves A_1 and B_1. These curves were taken with water as reference. A comparison of selenium solutions treated with 4,5D6TP and a reagent blank of the same concentration, with a maximum absorbance at 380 mμ, is shown in Fig. 2. The molar absorptivity at this wavelength, based on a number of observations, was 19,200. Curve A and curve B in Fig. 2 contain, respectively, 1·5 μg and 2·5 μg selenium per ml. Although the maximum appears at 380 mμ, appreciable absorbance of the blank solution is noted at this wavelength. An inspection of curves A_1 and A_2 and of curves B_1 and B_2 in Fig. 1

None (distilled water)	0·015	0·007
0·009	0·370	0·260
0·045	0·363	0·256
3·0	0·260	0·176

* 10 ml of final solution contains 15 μg of selenium and 4 ml of 0·02% 4,5D6TP.

reveals that at 410 mμ the absorbance for the blank has been reduced two and one-half times as compared with the absorbance for the selenium solution. In one set of results the ratio of absorbance for selenium solution treated with 4,5D6TP to that of the reagent blank of the same concentration was 6·35 at 380 mμ as compared with 15·45 at 410 mμ. It is therefore recommended that two readings, one at 380 mμ and another at 410 mμ be taken for analysis by this method. Fig. 3 shows two calibration curves used for the quantitative analysis of selenium.

Effect of pH

The colour intensity of quadrivalent selenium treated with 4,5D6TP is dependent on the acidity of the solution. The solution is colourless in ammoniacal solution. The optimum pH is between 1·5 and 2·5. Table I shows the absorbance at different acidities, measured at 380 mμ and at 410 mμ. The solutions under investigation were neutral, and appropriate quantities of hydrochloric acid were added to give a pH of 1·5–2·5. For semiconductors containing solid solutions of cadmium selenide and cadmium sulphide, oxidation of the selenide and sulphide was carried out with concentrated nitric acid, *aqua regia* or fuming nitric acid, and the solutions were

subsequently treated with hydrochloric acid to convert to quadrivalent selenium. Any excess acid was removed by evaporating at slightly elevated temperature to dryness. It is essential that the pH of the solution be adjusted before making absorbance measurement. Besides hydrochloric acid, formic acid has been used successfully.

Effect of standing time

The absorbance of solutions containing 0·5–2·5 μg/ml of selenium changes but slightly between 30 min and 1·5 hr. On longer standing, especially for solutions with higher concentrations of selenium, the absorbances of the solutions decrease appreciably. For example, on 24 hr standing, solutions containing 2·5 μg/ml decreased by 6–10%. Fig. 4 shows the effect of standing time on the absorbance between 370 mμ and 410 mμ. The change in absorbance probably arises from two factors.

One of these is the air oxidation of 4,5D6TP at pH 1·5–2·5. Blanks to investigate the extent of this oxidation were allowed to stand from a few hours to 14 days. At the end of 9 days standing, the absorbance at 380 mμ was eleven-fold compared with blanks freshly prepared. At the end of 14 days the absorbance was similar to that after 9 days. When these results were plotted against the corresponding wavelengths, the shape of the curves were much the same as for those obtained using selenous acid to react with the reagent. A search of the recent literature has revealed that most reagents available for the spectrophotometric determination of selenium are subject to air oxidation to some degree[5–7,16,17] and the same has been found in this laboratory for the determination of selenium using 3,3′-diaminobenzidine as reagent, the reagent turning red after a few hours at room temperature.[5] Lott *et al.*[7] have pointed out that the air oxidation of 2,3-diaminonaphthalene is pronounced, especially when heated.

The second factor causing the change in absorbance on standing is the formation and coagulation of selenium. It can be seen on the bottom of the container, especially in solutions with 1 μg/ml or more of selenium. However, this factor is not pronounced compared with air oxidation. In a recent paper[18] the same conclusion has been reached.

The reproducibility, in terms of % standard deviation, is shown in Table II. Twenty-four observations were made using standard selenium solution, and from these the % standard deviation was calculated. Absorbance readings taken after 30 min and after 2·5 hr standing differed by a few tenths to 3%.

Effect of reagent concentration on absorbance

Fig. 5 shows that in a series of solutions containing 1·5 μg/ml of selenium the absorbance increases as the reagent is increased, up to a certain concentration. Beyond the threshold concentration the absorbance remains constant.

Effect of diverse ions

Various ions were purposely added to the solutions to ascertain their effect on the determination of selenium by this method. Table III shows some of the ions used for

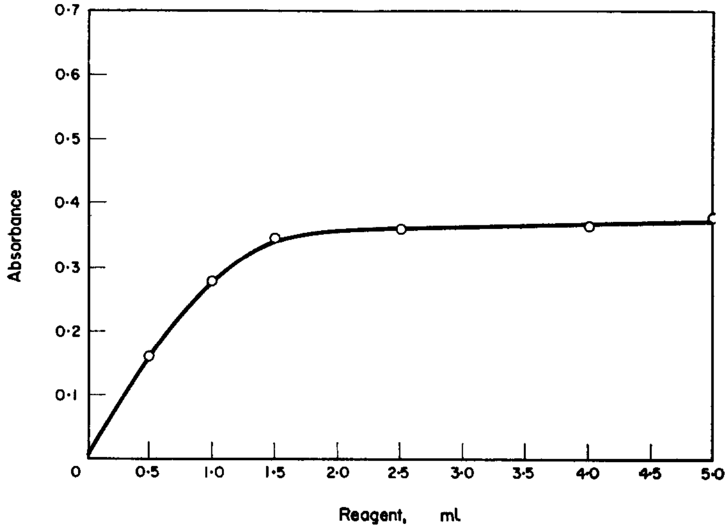

FIG. 5.—Absorbance of selenium solution containing varying amounts of 4,5D6TP. Abscissa shows ml of 0·02% reagent in 10 ml of selenium solutions and blanks. (pH 1·5; selenium 1·5 μg per ml; wavelength 380 mμ.)

this investigation. In general, the ions listed have a negligible effect on the determination of selenium by this method. These diverse ions in solutions were such that their concentration was 500-fold that of the selenium present. In Table IV is listed a number of ions commonly known to interfere with the spectrophotometric determination of selenium. Ions such as Fe^{3+}, Fe^{2+}, $S_2O_3^{2-}$, SO_3^{2-}, BrO_3^- and Cu^{2+} must be removed, or the solution must be treated with reagents for the formation of

complex ions before selenium is determined. Copper^{II} and iron^{III} can conveniently be removed by liquid-liquid extraction with chloroform, as the cupferrates. Ions such as $C_2O_4^{2-}$,ClO_4^- and I^- do not affect the quantititative determination by the present method. The presence of ClO_3^- gives a somewhat higher result, as shown in Table IV. In a recent paper[18] these ions are listed as interfering with the determination of selenium.

Determination of selenium in semiconductors

A number of solid solutions of cadmium selenide and cadmium sulphide were prepared by the vaporization method at temperatures above 1200°. These samples were analysed for their selenium content by titrimetric and gravimetric methods, as described above. A few tenths of a mg or less of these samples were weighed out and

the selenium was converted to its quadrivalent state. The selenium, in parts per million, is shown in Table IV. Appropriate quantities of these solutions were pipetted out, and the selenium determined spectrophotometrically using 4,5D6TP. The results are shown in Table IV. This method is applicable to samples in the form of small needles weighing 20–30 μg or more. An individual needle can be taken for analysis.

CONCLUSIONS

1. 4,5-Diamino-6-thiopyrimidine has been found to give a colour reaction with selenium in its quadrivalent state. Spectrophotometric determination of this element in solution can be carried out at the maximum peak of 380 mμ, using a reagent blank of the same concentration and prepared at the same time. The determination can also be made at 410 mμ, where the blank absorbance is comparatively low.

2. Because elemental selenium makes its appearance on standing, the reading of the absorbance should preferably be taken within 30 min of the addition of the reagent. However, the trace of elemental selenium does not greatly affect the result, especially in the early stage of its formation. This was confirmed by other investigators on reactions in which elemental selenium is one of the end-products. For accurate determinations, two known solutions with concentrations one slightly above and one slightly below that of the unknown should be used as controls.

3. The slow formation of elemental selenium has the added advantage of supplementing the spectrophotometric determination of this element. It further confirms the results from absorbance for determination of this element. Elemental selenium so formed can be collected in a thin layer and this layer can be determined by an X-ray fluorescence method involving no matrix effect, the procedure of which has been published in a separate paper.

4. Preliminary experiments have been carried out on the Tyndall effect and light scattering phenomena of this reaction. Both X-ray single crystal rotation photographs and X-ray powder patterns have been taken for the reagent and the treated material. Nuclear magnetic resonance spectra have also been taken during the course of the reaction for 4,5D6TP, as well as for other substances, such as *o*-phenylenediamine and 2,3-diaminonaphthalene, with and without selenium. These spectra are being studied along with infrared and ultraviolet spectra. Elemental microanalysis on the treated material are currently being made, and these results will be correlated with other results available.

Zusammenfassung—Eine Anzahl von organischen Verbindungen wurden auf ihre Eignung zur spektralphotometrischen Bestimmung von kleinen Selenmengen geprüft. 4,5-Diamino-6-thiopyrimidin verspricht dabei gute Ergebnisse. In ammoniakalischer Lösung bleibt das Reagens in Gegenwart vierwertigen Selens auch bei langem Stehen farblos. Bei pH 1,5 bis 2,5 oder niedriger bildet sich dagegen eine gelbe Lösung mit starkem Absorptionsmaximum bei 380 mμ, verglichen mit der gleichkonzentrierten Reagenslosung. Das Beersche Gesetz gilt bei Selenkonzentrationen zwischen 0,1 und 2,5 Mikrogramm pro Milliliter. Die Bedingungen für die quantitative Bestimmung von Selen wurden geprüft. Wenn Selen in der Lösung vierwertig vorliegt, sollte die Absorptionsmessung innerhalb 30 Minuten nach Zugabe des Reagens ausgeführt werden. Bei längerem Stehen gibt das Reagens eine schwach gelbe Farbe unter Bildung von elementarem Selen. In verdünnten Lösungen geht die Bildung von elementarem Selen langsam.

Résumé—Un certain nombre de composés organiques ont été examinés pour le dosage spectrophotométrique de petites quantités de sélénium. La 4,5-diamino-6-thiopyrimidine s'est révélée prometteuse pour ce dosage. En solution ammoniacale, meme après un long repos, ce réactif est incolore en présence de sélénium tétravalent. Toutefois, à pH 1,5 à 2,5, ou inférieur, la 4,5-diamino-6-thiopyrimidine développe une coloration jaune avec le sélénium tétravalent est présente un fort pic d'absorption à 380 mμ, lorsqu'on effectue la comparaison par rapport à un témoin de réactif à la meme concentration. La loi de BEER est respectée lorsque la concentration en sélénium est comprise entre 0,1 et 2,5 microgrammes par millilitre. On a étudié les conditions de dosage du sélénium. Lorsque le sélénium en solution est à l'état tétravalent, la mesure de l'absorption doit etre effectuée au plus tard trente minutes après l'addition du réactif. Par un repos plus long, le réactif présente une légère coloration jaune avec formation de sélenium élémentaire. La formation de sélénium élémentaire est lente en solutions diluées de sélénium.

A NEW OXIDIMETRIC REAGENT: POTASSIUM DICHROMATE IN A STRONG PHOSPHORIC ACID MEDIUM—IV*

TITRIMETRIC DETERMINATION OF URANIUM^{IV} ALONE AND IN MIXTURE WITH IRON^{II}, MANGANESE^{II}, CERIUM^{III} OR VANADIUM^{IV}

G. GOPALA RAO and P. KANTA RAO
Department of Chemistry, Andhra University, Waltair, India

(*Received 6 January* 1964. *Accepted 27 February* 1964)

Summary—The potentiometric titration of uranium^{IV} is possible at room temperature with potassium dichromate at all concentrations of phosphoric acid ranging from 3*M* to 12*M*. An inert atmosphere is unnecessary. The potential break at the end-point is about 70–90 mV/0·04 ml of 0·1*N* potassium dichromate in the range 3 to 9*M* of phosphoric acid, 140 mV in 10·5*M* phosphoric acid and 180 mV in 12*M* phosphoric acid. Iron^{II} and uranium^{IV} can be determined in the same solution if the concentration of phosphoric acid is maintained above 11·5*M* at the iron^{II} end-point. Under similar conditions a differential potentiometric titration of uranium^{IV} and vanadium^{IV} is possible. Uranium^{IV} and manganese^{II} can be determined in the same solution if the concentration of phosphoric acid is maintained between 3*M* and 9*M* at the uranium^{IV} end-point, then increased so that it is 12*M* at the manganese^{II} end-point. Under similar conditions the differential potentiometric titration of uranium^{IV} and cerium^{III} is possible. The application of these procedures to uranium-bearing minerals is under investigation.

EWING and Eldridge[1] were apparently the first to have attempted the titration of uranium^{IV} with potassium dichromate using an electrometric end-point. They reduced a solution of uranium^{VI}, heated to 80° in a Jones reductor, and titrated the hot solution in an inert atmosphere with potassium dichromate. The potential (E) *vs.* volume (V) showed two broad inflection points, the first corresponding to the titration of uranium^{III} and the second to the titration of uranium^{IV}. Because the curve corresponding to the second part of the titration does not clearly show the inflection point, Ewing and Eldridge[1] computed the equivalence point of the uranium^{IV} titration from the $\Delta E/\Delta V$ *vs.* V curve. When the concentration of sulphuric acid was varied from 0·36*F* to 3·6*F*, they observed that while the shape of the first part of the curve was not very much affected, the second part was greatly influenced in that the end-point could not be detected when the concentration of sulphuric acid was above 0·36*F*.

Belcher, Gibbons and West[2] investigated the reverse titration of potassium dichromate with a solution of uranium^{IV} chloride and recommended a temperature of 60° for the titration because they believed the reaction to be sluggish at room temperature. Miller and Thomason[3] also found that the electrometric titration of uranium^{IV} is not feasible at room temperature with potassium dichromate. A thermometric titration proved possible, however, and as little as 5 mg of uranium^{IV} could be

---

* Part III: see *Talanta*, 1964, **11**, 825.

determined with a relative standard error of ±1.0%. Taking this along with the observation of Rao, Murty and Gopala Rao[4] that the titration of uranium^{IV} is possible at room temperature using N-phenylanthranilic acid as redox indicator, one has to conclude that the reaction between uranium^{IV} and potassium dichromate must be very fast and not slow as believed by previous investigators. The difficulties noted in the electrometric titration must be caused by the inertness of the platinum electrode in titrations involving chromium ions[3] and uranyl ions.[5]

The difficulties encountered in the titration of uranium^{IV} with potassium dichromate using diphenylamine, barium diphenylamine sulphonate or diphenylbenzidine have been discussed by Kolthoff and Lingane.[6] The main difficulty was ascribed to the slowness of the colour development of the indicator at the end-point. They found that the uranium^{VI} salt formed retards the colour change of the diphenylbenzidine indicator, and overcame the difficulty by the addition of an excess of iron^{III} alum solution and titrating the iron^{II} formed with potassium dichromate.

In view of the difficulties experienced in the electrometric titration of uranium^{IV} with potassium dichromate in hydrochloric and sulphuric acid media at room temperature, we have now carried out investigations on the titration in a phosphoric acid medium. It has been observed that uranium^{IV} can be titrated directly with a standard solution of potassium dichromate at room temperature with a potentiometric end-point in a 3-12M phosphoric acid medium. From the previous publications[7,8] from these laboratories it will be obvious that the potentials of the chromium^{VI}/chromium^{III} and uranium^{VI}/uranium^{IV} couples are quite suitable for a chemical reaction to occur at the concentrations of phosphoric acid prescribed.

EXPERIMENTAL

Potentiometric Titration of Uranium^{IV} with Potassium Dichromate in a Phosphoric Acid Medium

Reagents

Uranium^{IV} solution. An approximately 0·1N solution of uranium^{VI} is prepared in 1M sulphuric acid from analytical-reagent grade uranyl acetate supplied by British Drug Houses Ltd., England. This is reduced in a Jones reductor and aerated to give uranium^{IV} solution, which is standardised against potassium dichromate according to the procedure of Kolthoff and Lingane[6] using diphenylamine sulphonic acid as indicator.

Phosphoric acid. "Pro Analysi" grade phosphoric acid (*ca.* 15·5M) supplied by E. Merck, Germany, is employed in this investigation.

Apparatus

The apparatus employed is as described previously.[7]

The potentiometric titration of uranium^{IV} with potassium dichromate is impossible when the concentration of phosphoric acid is less than 3M because under such conditions uranium^{IV} phosphate precipitates. Titration is possible, however, at all concentrations of phosphoric acid from 3M to 12M at the equivalence point. The time required for the attainment of steady potentials is about 1 min in the early stages and 3 min near the equivalence point. The potential break is about 70–90 mV/0·04 ml of 0·1N potassium dichromate solution when the concentration of phosphoric acid is 3–9M, at the equivalence point, and it rises to about 140 mV and 180 mV when the concentration of phosphoric acid is 10·5M and 12M, respectively. Typical results are presented graphically in Fig. 1 for titrations carried out in 3M and 12M phosphoric acid.

Procedure

From 2 to 10 ml of 0·1N uranium^{IV} solution is taken in a 150-ml Pyrex beaker and treated with sufficient phosphoric acid (10–50 ml) and water such that the concentration of phosphoric acid is 3–12M at the equivalence point. The mixture is connected to a saturated calomel electrode through a saturated sodium perchlorate bridge and a saturated sodium nitrate bridge. A bright platinum rod is used as indicator electrode. The mixture is titrated at room temperature with 0·1N potassium

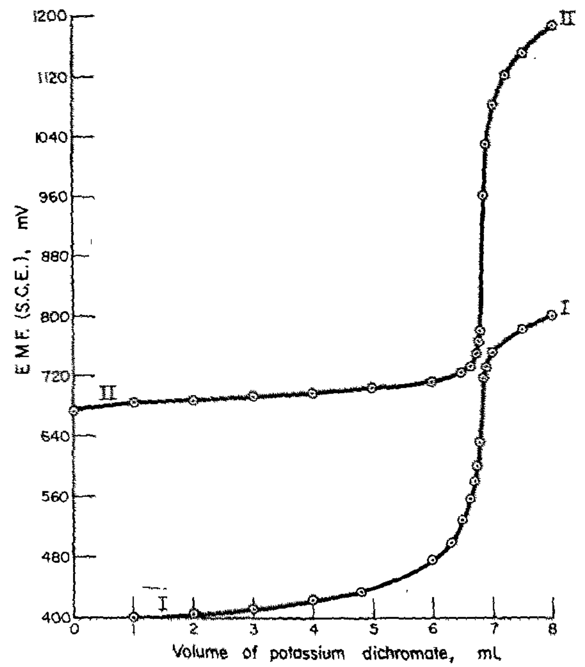

FIG. 1.—Potentiometric titration of uranium^{IV} (81·21 mg) with potassium dichromate in:
I—3*M* H_3PO_4,
II—12*M* H_3PO_4.

dichromate solution while it is stirred electromagnetically. Potentials are initially measured after waiting for 1 min following the addition of each portion of titrant, but after 3 min near the equivalence point.

Some typical results of titrations carried out in 6*M* phosphoric acid are given in Table I. The error is not greater than ±0·27%. Similar results are obtained with media containing phosphoric acid at other concentrations in the range 3 to 12*M*. The method now developed constitutes a significant improvement over the dichromate procedure of Ewing and Eldridge,[1] which requires a temperature of 80° and an inert atmosphere for the potentiometric titration. Even under these conditions, however, the potential break is poor.

91·70	91·85
110·4	110·4

Interferences

Chloride interferes, even at an over-all concentration of 0·1*M*, in the titration of uranium^{IV} with potassium dichromate when the concentration of phosphoric acid is greater than 9*M*. Steady potentials cannot be obtained and there is no break at the equivalence point. At a phosphoric acid concentration of 7·5*M*, however, chloride no longer interferes if the over-all chloride concentration is 0·1*M*, but only if it is 0·25*M*. When the concentration of phosphoric acid is 3–6*M* at the equivalence point, chloride does not interfere even at 0·25*M* concentration. However, the potential break at the inflection point is then reduced from about 90 mV to about 40 mV.

Nitrate and higher valency states of metals such as molybdenum, tungsten, vanadium, iron, *etc.*, which are also reduced in the Jones reductor, interfere. If the phosphoric acid concentration is 3–9*M*, manganese^{II} and cerium^{III} do not interfere. Above a phosphoric acid concentration of 9*M* both uranium^{IV} and manganese^{II} (or cerium^{III}) react with potassium dichromate and the reaction between uranium^{IV} with manganese^{III} or cerium^{IV} under these conditions is slow, requiring 10–30 min for the stabilisation of potentials. The interference of iron^{II} can be eliminated by carrying out the titration in phosphoric acid of concentration greater than 11·5*M*, because for such a mixture two different potential breaks are obtained (see below). Cobalt^{II}, zinc^{II} and nickel^{II} do not interfere, and neither do sulphuric and perchloric acids (in concentrations of about 1*N*).

Differential Potentiometric Titration of Iron^{II} and Uranium^{IV} in Mixture

Ewing and Eldridge[1] stated that when a mixture of uranium^{III}, uranium^{IV} and iron^{II} is titrated with potassium permagnanate at about 80° in an atmosphere of carbon dioxide, three inflections are obtained. The first corresponds to the oxidation of uranium^{III} to uranium^{IV}, the second to the oxidation of uranium^{IV} to uranium^{VI} and the third to the oxidation of iron^{II} to iron^{III}. The inflection corresponding to uranium^{IV} oxidation is not sharp, and with increasing concentration of sulphuric acid it becomes more and more indistinct. Moreover, Ewing and Eldridge did not give sufficient experimental data to ascertain the accuracy of analysis of their mixtures. According to Pappas[9], however, the potentiometric titration of uranium^{IV} with potassium permanganate does not give a sharp break in the potential *vs.* volume curve when iron^{II} is present. The difficulty is said to be overcome by the addition of some acetic acid just before the titration. Hahn and Kelley[10] also experienced difficulty in the potentiometric titration of uranium^{IV} with cerium^{IV} sulphate in the presence of iron^{II}. They proposed the micro titration of uranium^{IV} at room temperature by complexation of iron^{II} with 1,10-phenanthroline. However, the method fails for the analysis of samples containing much more than 1 mg of iron, even if a correspondingly larger amount of 1,10-phenanthroline is added.

Bricker and Sweetser[11] employed a spectrophotometric method for the differential titration of uranium^{IV} and iron^{II} with cerium^{IV} sulphate in an atmosphere of nitrogen. According to these authors, in the simultaneous titration of uranium^{IV} and iron^{II} with cerium^{IV} the rate of reaction near the uranium equivalence point is considerably slower than in the individual titration of uranium^{IV}. They believe that this is because of the slow reaction between uranium^{IV} and iron^{III} formed by the partial oxidation of iron^{II} before all of the uranium^{IV} has been titrated. However, they found that the rate of the uranium^{IV}–iron^{III} reaction can be increased by working at a low acid concentration, *e.g.*, 0·2*N*, although there is the risk of the induced oxidation of uranium^{IV} by atmospheric oxygen in the presence of iron^{II}. Thus, even the spectrophotometric titration procedure prescribed by Bricker and Sweetser[11] is attended with difficulties. Recently, Desai and Murthy[12] preferred to determine uranium^{IV} in the presence of iron^{II} by oxidising uranium^{IV} in the presence of iron^{II}, then titrating the unreacted iron^{III} iodometrically. The latter step requires the use of osmium tetroxide for accelerating the reaction between iron^{III} and hydriodic acid. In addition to the indirect nature of this procedure, it suffers from the disadvantage that it enables the determination of only one component of the mixture, namely uranium^{IV}. Iron^{II} must be obtained by determining the sum of iron^{II} plus uranium^{IV} in another aliquot of test solution and subtracting the uranium^{IV} therefrom.

From the foregoing it is evident that there is no satisfactory method for the direct titrimetric determination of both iron^{II} and uranium^{IV} in the same solution.

We have now observed that when a mixture of iron^{II} and uranium^{IV} is titrated potentiometrically at room temperature with potassium dichromate in a medium containing 11·5–13·5*M* phosphoric acid, in an atmosphere of carbon dioxide, two well-defined breaks are obtained in the potential *vs.* volume curve. The first break corresponds to the oxidation of iron^{II} to iron^{III} and the second to the oxidation of uranium^{IV} to uranium^{VI}. Until near the equivalence point for iron^{II} potentials are stabilised within 1 min, but at the equivalence point one has to wait 10–15 min for the attainment of stable values. The potential break at the equivalence point is about 190 mV/0·04 ml of 0·2*N* potassium dichromate solution. During the titration of uranium^{IV} stable potentials are attained within about 1 min in the early stages and in about 3 min at the equivalence point; the potential break is about 260 mV/0·04 ml of 0·2*N* dichromate. For an accurate determination of iron^{II} all solutions must be deaerated before the addition of phosphoric acid to the mixture containing iron^{II} and uranium^{IV} and rigorous precautions taken to prevent the leakage of atmospheric oxygen into the titration vessel, otherwise the titre for iron^{II} will be low. Unlike that of iron^{II}, the determination of uranium^{IV} is unaffected by the presence of oxygen.

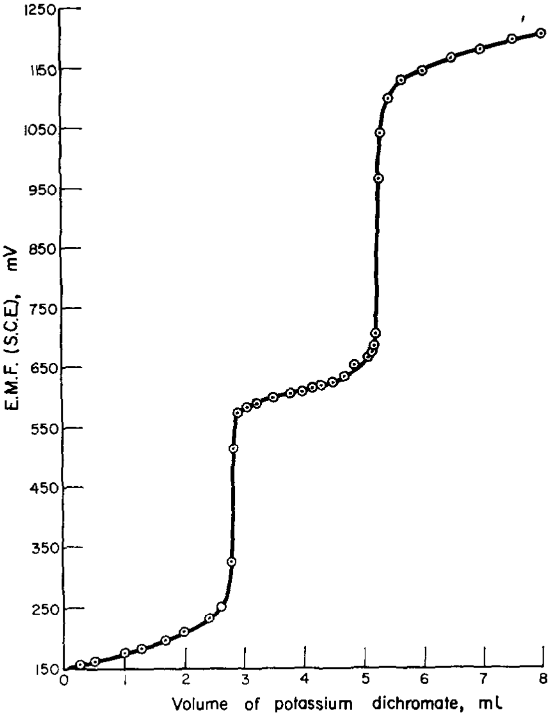

FIG. 2.—Differential potentiometric titration of a mixture of uranium^{IV} (57·59 mg) and iron^{II} (31·71 mg) with 0·2*N* potassium dichromate in a 12*M* phosphoric acid medium.

Procedure

About 10 ml of the solution containing iron^{II} and uranium^{IV} is taken in the titration vessel and the dissolved air expelled by passage of carbon dioxide for about 10 min. Sufficient deaerated phosphoric acid to give a concentration of 11·5*M* at the first equivalence point is added and an atmosphere of carbon dioxide maintained thereafter. The solution is titrated with 0·2*N* potassium dichromate solution using the potentiometric assembly already described, electromagnetic stirring being maintained during the titration.

A typical potentiometric titration curve is given in Fig. 2. Typical results of assays of iron^{II} and uranium^{IV} made by the above procedure are presented in Table II. They show that the error of determination for iron^{II} is not greater than −0·52% and that for uranium^{IV} not greater than ±0·35%. This accuracy and simplicity are not attainable with currently available procedures.

[a] The iron^{II} solution was prepared from Analar Mohrs salt and standardised against pocassium dichromate.

Differential Potentiometric Titration of Uranium^{IV} and Manganese^{II} in Mixture

When a sulphuric acid solution of uranium^{VI} and manganese^{VII} (or magnanese^{II}) is passed through a Jones reductor, a mixture containing uranium^{IV} and manganese^{II} with a little uranium^{III} is obtained. The uranium^{III} can be converted to uranium^{IV} by aeration for about 5–10 min. When such a solution is titrated with potassium dichromate in a 12*M* phosphoric acid medium two different potential breaks are obtained, the first inflection corresponding to the oxidation of uranium^{IV} and the second to that of manganese^{II}. However, this titration is rather tedious because 20–30 min are required for the establishment of stable potentials after 50% of the uranium^{IV} is oxidised and until the first break is obtained. After the first break the potentials are stabilised in about 1 min after the addition of each portion of potassium dichromate solution. The slow stabilisation of potentials for the uranium^{IV} part of the titration is probably because of the slow reaction between uranium^{IV} and manganese^{III}, formed by the oxidation of manganese^{II} before all uranium^{IV} is oxidised. We have, however, observed that when the concentration of phosphoric acid is maintained at 3–9*M* the potentials are stabilised in about 2–3 min and the break in the potential *vs.* volume curve corresponds to the stoichiometric oxidation of uranium^{IV} to uranium^{VI}. If the concentration of phosphoric acid is then raised to above 12*M* by the addition of further phosphoric acid and the titration continued, a second break is obtained which corresponds to the oxidation of manganese^{II} to manganese^{III}.

Procedure

An aliquot of the mixture of uranium^{IV} and manganese^{II} is taken in a 150-ml Pyrex beaker, treated with 12·5 ml of phosphoric acid, then sufficient water added so that the total volume is 25 ml. The mixture is titrated with 0·2*N* potassium dichromate while it is stirred electromagnetically. After the first break is obtained the titration is continued to some distance, the mixture treated with enough phosphoric acid (35–45 ml) so that the concentration of phosphoric acid is 12*M* at the second equivalence point, then the titration completed for manganese^{II}.

The first break in potential amounts to about 260 mV/0·04 ml of 0·2*N* potassium dichromate when the volume of titration solution is about 30 ml and the second break to about 25 mV/0·04 ml of 0·2*N* dichromate when the volume of titration solution is about 60 ml. A typical potentiometric titration curve is shown in Fig. 3. In view of the small break, the second inflection point is best obtained from the $\Delta E/\Delta V$ *vs.* V curve. Typical results given in Table III show that the error for uranium^{IV} does not exceed ±0·3% and that for manganese^{II} does not exceed ±0·4%.

Differential Potentiometric Titration of Uranium^{IV} and Cerium^{III} in Mixtures

When a sulphuric acid solution containing uranium^{VI} and cerium^{IV} (or cerium^{III}) is passed through a Jones reductor, a mixture containing uranium^{IV}, cerium^{III} and a little uranium^{III} is obtained. The uranium^{III} can be converted to uranium^{IV} by aeration for about 5–10 min. When such a solution is titrated potentiometrically with potassium dichromate solution in a 12*M* phosphoric acid medium, we have observed two different breaks in the potential *vs.* volume curve. More than 30 min are required for the establishment of stable potentials after 50% of the uranium^{IV} is oxidised, but even with this precaution, the end-point for uranium^{VI} is prematurely obtained. It has, however, been observed that if the concentration of phosphoric acid is 3–9*M*, the potentials are stabilised in about 2–3 min and the break in potential corresponds stoichiometrically to the

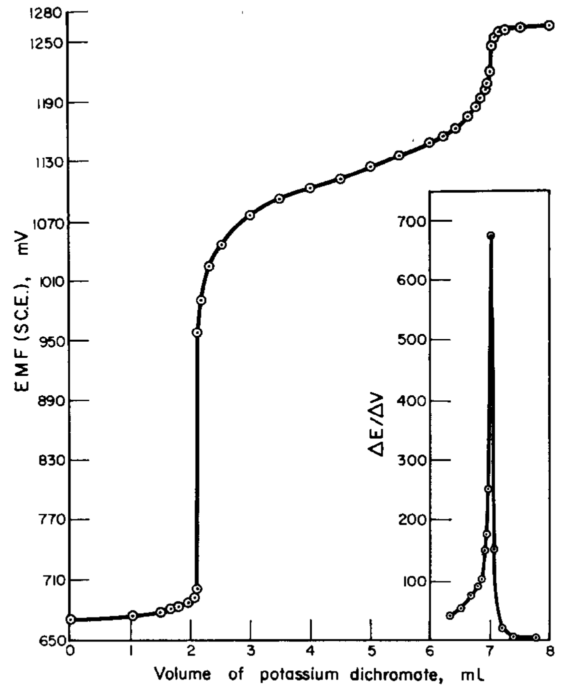

FIG. 3.—Differential potentiometric titration of a mixture of uranium$^{\mathrm{IV}}$ (50·42 mg) and manganese$^{\mathrm{II}}$ (53·95 mg) with 0·2N potassium dichromate in a phosphoric acid medium.

TABLE III.—DIFFERENTIAL POTENTIOMETRIC TITRATION OF URANIUM$^{\mathrm{IV}}$ AND MANGANESE$^{\mathrm{II}}$ IN MIXTURES

Uranium, *mg*		Manganese, *mg*[a]	
Taken	Found	Taken	Found
41·30	41·30	50·79	59·99
50·42	50·29	53·95	53·81

80·69	80·93	23·74	23·74
110·4	110·4	27·27	27·27
155·6	155·6	26·71	26·77

[a] For preparation and standardisation of manganese$^{\mathrm{II}}$ solution see G. Gopala Rao and P. Kanta Rao, *Talanta*, 1963, **10**, 1255.

oxidation of uranium$^{\mathrm{IV}}$ to uranium.$^{\mathrm{VI}}$ The concentration of phosphoric acid is then increased to above 12M by the addition of further phosphoric acid and the titration continued until the second break in potential is obtained. This corresponds to the quantitative oxidation of cerium$^{\mathrm{III}}$ to cerium$^{\mathrm{IV}}$.

Procedure

An aliquot of the mixture of uranium$^{\mathrm{IV}}$ and cerium$^{\mathrm{III}}$ is taken in a 50-ml Pyrex beaker, treated with 12·5 ml of syrupy phosphoric acid, then sufficient water added so that the total volume is 25 ml. The mixture is titrated with 0·2N potassium dichromate solution while it is stirred electromagnetically. After the first break is obtained the titration is continued to some distance, the mixture treated with sufficient phosphoric acid (35–45 ml) so that the concentration of phosphoric acid is 12M at the second equivalence point, then the titration completed for cerium$^{\mathrm{III}}$.

The first break in potential amounts to about 260 mV/0·04 ml of 0·2*N* dichromate solution when the volume of titration solution is about 30 ml and the second break to about 50 mV/0·04 ml of 0·2*N* dichromate solution when the volume of titration solution is about 60 ml. A typical potentiometric titration curve is shown in Fig. 4. Because the potential break for the cerium^{III} oxidation is not very large, the second inflection point is best obtained from the $\Delta E/\Delta V$ *vs.* V curve. Some typical results given in Table IV show that the error of determination for uranium^{IV} is not greater than ±0·33% and that for cerium^{III} not greater than ±0·3%.

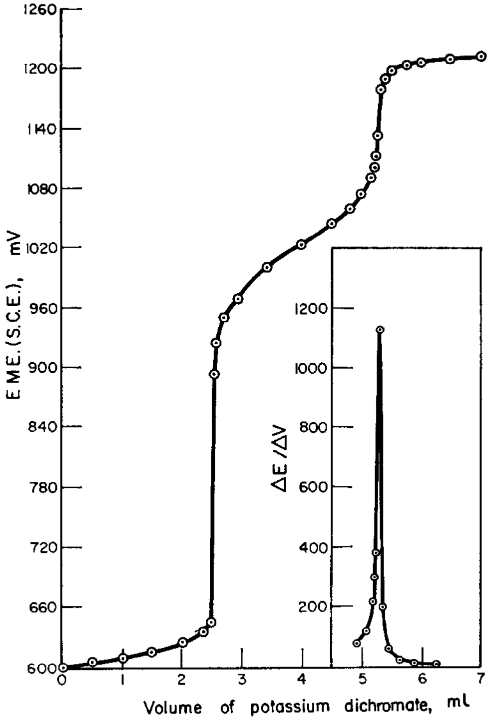

FIG. 4.—Differential potentiometric titration of a mixture of uranium^{IV} (60·32 mg) and cerium^{III} (76·83 mg) with 0·2*N* potassium dichromate in a phosphoric acid medium.

Differential Potentiometric Titration of Uranium^{IV} and Vanadium^{IV} in Mixtures

When a mixture containing uranium^{IV} and vanadium^{IV} is titrated with potassium dichromate solution in a 12*M* phosphoric acid medium two breaks are obtained in the potential *vs.* volume curve. The first break corresponds to the stoichiometric oxidation of uranium^{IV} to uranium^{VI} and the second break to the quantitative oxidation of vanadium^{IV} to vanadium^{V}.

Procedure

An aliquot of the mixture of uranium^{IV} and vanadium^{IV} (5–10 ml) is taken in a 150-ml Pyrex beaker and treated with 40–55 ml of syrupy phosphoric acid. The mixture is titrated with 0·2*N* potassium dichromate solution while it is stirred electromagnetically. The potentials are noted 2–3 min after the addition of each portion of potassium dichromate solution until the first equivalence point, then 1 min after the addition of each portion of potassium dichromate solution until the second break in potential.

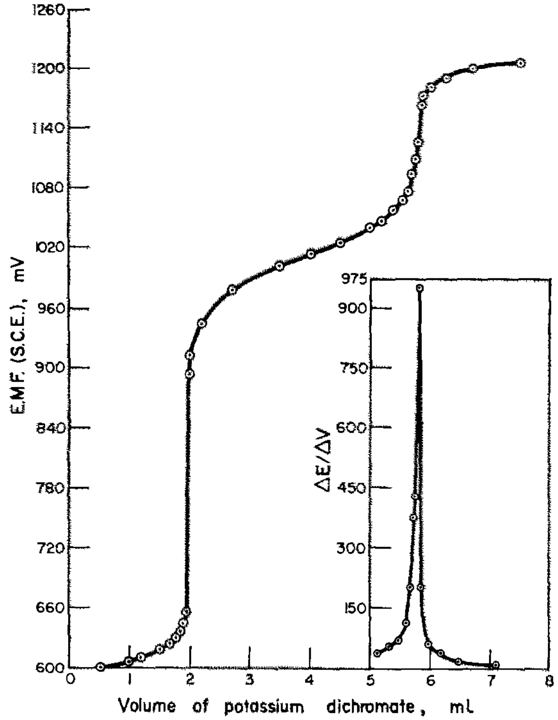

FIG. 5.—Differential potentiometric titration of a mixture of uranium^{IV} (46·46 mg) and vanadium^{IV} (39·07 mg) with 0·2*N* potassium dichromate in a phosphoric acid medium.

TABLE V.—DIFFERENTIAL POTENTIOMETRIC TITRATION OF URANIUM^{IV} AND VANADIUM^{IV} IN MIXTURES

Uranium, *mg*		Vanadium, *mg*[a]	
Taken	Found	Taken	Found
35·28	35·28	45·54	45·64
39·51	39·51	19·36	19·36
46·46	46·58	39·07	39·03
71·17	71·17	30·06	30·06
91·70	91·85	19·54	19·54
109·3	109·2	23·37	23·44

[a] For preparation and standardisation of vanadium^{IV} solution see G. Gopala Rao and P. Kanta Rao, *Talanta*, 1964, **11**, 703.

The potential jump at the first equivalence point is found to be about 260 mV/0·04 ml of titrant and at the second inflection point to about 40 mV/0·04 ml of titrant. A representative potential *vs.* volume curve is shown in Fig. 5. Because the second break in potential is not very great, the end-point is best obtained from the $\Delta E/\Delta V$ *vs.* V curve. Some typical results are given in Table V. They show that the error for uranium^{IV} is not greater than ±0·27% and that for vanadium^{IV} not greater than ±0·3%.

Zusammenfassung—Die potentiometrische Titration von Uran (IV) mit Kaliumdichromat ist bei Zimmertemperatur bei allen Konzentrationen von Phosphorsäure zwischen 3m und 12m möglich. Schutzgas ist nicht notwendig. Der Potentialsprung am Endpunkt ist für 0,04 ml 0,1 n Kaliumdichromat in 3–9 m Phosphorsäure 70–90 mV, in 10,5 m Phosphorsäure 140 mV und in 12 m Phosphorsäaur 180 mV. Eisen (II) und Uran (IV) können in derselben Lösung bestimmt werden, wenn die Phosphorsäure-konzentration beim Eisen (II)-Endpunkt über 11,5 m gehalten wird. Unter ähnlichen Bedingungen ist die potentiometrische Bestimmung von Uran (IV) und Vanadin (IV) nebeneinander möglich; Uran (IV) und Mangan (II) können in derselben Lösung bestimmt werden, wenn die Phosphorsäure-konzentration beim Uran (IV)-Endpunkt zwischen 3 m und 9 gehalten wird und dann so erhöht wird, daß sie beim Mangan (II)-Endpunkt 12 m ist. Unter ähnlichen Bedingungen kann man Uran (IV) und Cer (III) nebeneinander bestimmen. Die Anwendung dieser Vorschriften auf Uran führende Mineralien wird untersucht.

Résumé—Le dosage potentiométrique de l'uranium (IV) est possible à température ambiante, au moyen de bichromate de potassium, à toutes les concentrations en acide phosphorique comprises entre 3 M et 12 M. Une atmosphère inerte n'est pas nécessaire. Le saut de potentiel au point final est d'environ 70–90 mV/0,04 ml de bichromate de potassium 0,1 N, en acide phosphorique 3 à 9 M, de 140 mV en acide phosphorique 10,5 M et de 180 mV en acide phosphorique 12 M. Le fer (II) et l'uranium (IV) peuvent être dosés dans la même solution si la concentration de l'acide phosphorique est maintenue audessus de 11,5 M au point final du fer (II). Dans les mêmes conditions, un dosage potentiométrique différentiel de l'uranium (IV) et du vanadium (IV) est possible. L'uranium (IV) et le manganèse (II) peuvent être dosés dans la même solution si la concentration en acide en phosphorique est maintenue entre 3 M et 9 M au point final de l'uranium (IV), puis augmentée de facon à atteindre 12 M au point final de manganèse (II). Le dosage potentiométrique différentiel de l'uranium (IV) et du cérium (III) est possible dans les mêmes conditions. L'application de ces techniques aux minerais uranifères est à l'étude.

TALANTA REVIEW

RECENT DEVELOPMENTS IN THE RING OVEN TECHNIQUE

HERBERT WEISZ
Department of Chemistry, University of Freiburg in Breisgau, Federal German Republic

(*Received* 12 *February* 1964. *Accepted* 18 *March* 1964)

Summary—A review of recent developments in the ring oven technique is presented.

IN 1954 the first paper about the ring oven technique was published. This method had originally been developed as a qualitative separation technique for extremely small samples. After a short time, however, it found application in other branches of analytical chemistry, both qualitatively and semiquantitatively. Its use was extended to the analysis of radioactive substances, to electrographic analysis, to the analysis of organic substances, *etc.*

In 1961 a monograph, *Microanalysis by the Ring Oven Technique** (hereafter referred to as *monograph*), surveyed the method and its various applications. Since that time about 60 further publications dealing with this technique have appeared. It is the purpose of the present paper to review these more recent contributions.

THE APPARATUS AND SOME NEWER ACCESSORIES†

The apparatus itself has been little modified in its external appearance; all of its dimensions have proved adequate, so these have remained unchanged. Fig. 1 shows a model of the ring oven in which the variable transformer for regulating the temperature and the actual ring oven are built into a single unit.

West, Llacer and Cimerman[1] described an "auxiliary plate" of aluminium which fits into the bore hole of the ring oven and makes, *quasi*, a ring oven with a smaller bore-hole diameter (14 mm) out of the original ring oven. This makes possible ring to ring separations of substances which are first collected in the 14-mm ring zone, a procedure basically similar to that used by Ballczo in connection with the glass ring oven (see monograph, p. 30). The same authors also designed a "washing ring" which is positioned on the hot ring oven. It serves to purify filter papers for special applications (*e.g.*, selenium in air pollution studies), where commercially available filter paper does not meet the purity requirements. They also suggested a retainer ring with a heat insulated handle (instead of the usual porcelain ring) for keeping the filter paper in place on the hot ring oven.

Reynolds and Monkman[2] also reported an adapter for reducing the bore hole diameter and gave some useful details for constructing the ring oven. For use in air pollution studies, these authors suggest a drilled Teflon plug which is inserted into

the sampling head of a paper tape sampler. The small spots thus produced may then be washed into the ring zone of the usual 22-mm ring oven.

DISSOLUTION OF SAMPLE

For analysis on the microgram scale where the sample is soluble in acid, it is comparatively simple to transfer the sample drop without loss to the filter paper (*cf.* monograph, p. 34). If a fusion procedure is necessary, however, it is not so convenient to transfer quantitatively the rather greater volume of sample solution to the middle of a filter paper, to carry out spot tests or to perform an analysis with the ring oven method. For this reason, a method[3] has been worked out, in which a small drop of a saturated solution of the decomposition reagent (*e.g.*, sodium peroxide, sodium carbonate, potassium hydrogen sulphate, sodium hydroxide) is placed on a platinum foil (5 × 5 mm square, 0.03 mm thick) and a very tiny amount (several μg, 1 or 2 grains) of the solid sample is added with the aid of a glass needle.

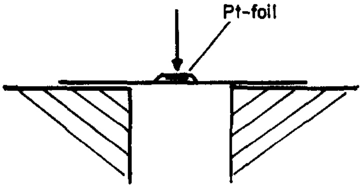

FIG. 2

The foil is then heated over the flame of a micro burner for some sec. After the decomposition, the platinum foil is placed between a filter paper and a little filter paper disk (to provide a capillary surface) and positioned on the ring oven (see Fig. 2). There, the now soluble substances are washed into the ring zone by means of a suitable solvent. In this way, the dissolved substances are concentrated in a sharply outlined ring zone where they can be identified as usual.

QUALITATIVE ANALYSIS OF METAL IONS

In the field of qualitative analysis, several spot reactions have been newly adapted for use with the ring oven method and the total number of such reactions now applicable has been considerably enlarged. Some of them will be mentioned under the present heading: others have been applied to semiquantitative analysis but can certainly be used for identification purposes. Therefore, the reactions mentioned in subsequent sections should also be regarded from the viewpoint of qualitative analysis (*e.g.*, beryllium, antimony, selenium).

Filter paper is commonly used for spot reactions only in those cases where the reaction product is either a coloured insoluble compound or has a pronounced tendency to adsorb on the fibres of the paper. Where the product of an identification reaction does not meet these conditions, it is better to carry out the tests on a spot plate or in a small tube, where the greater depth of the solution permits an easier observation of the colour. The ring oven can, however, be used to concentrate test stains which would otherwise spread badly on filter paper, so that the sensitivity of the test would be greatly diminished. This localisation of spot test colours by use of the ring oven method makes it possible to carry out reactions on filter paper which lead to soluble reaction products. The drop of the sample (for instance titanium: see Fig. 3

is placed in the centre of a filter paper. A drop of reagent (in this case hydrogen peroxide) is placed between the sample spot and the future ring zone. The sample spot is then washed with a suitable solvent (0.05*M* hydrochloric acid) into the ring zone. As the sample migrates, it "picks up" the reagent, reacts with it, and the soluble reaction product is concentrated and thus forms a coloured sector of the ring. In this way the identification limit is remarkably improved (10–100 times). Iron^{III} (with thiocyanate), chromate (with diphenylcarbazide), borate (with turmeric) and titanium (with hydrogen peroxide) can thus be identified on the paper.[4]

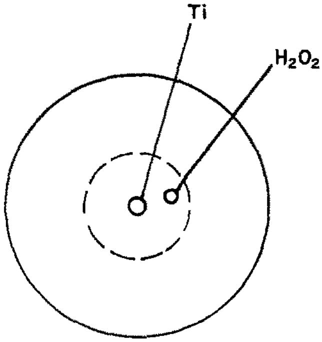

Fig. 3

Antikainen[5] reported the separation and identification of micro-amounts of mixtures of nickel and cobalt on filter paper impregnated with dimethylglyoxime. Nickel is fixed in the centre and the soluble dimethylglyoxime complex of cobalt washed to the ring zone. The inner spot bearing the nickel is punched out and placed on another paper, then the nickel transferred to the ring zone by means of an alcoholic solution of dimethylglyoxime containing bromine water as oxidant. The soluble bright red nickel^{IV} chelate is thus formed.

Matic[6] applied the ring oven technique in combination with preliminary solvent extraction to the routine analysis of technical uranium solutions. Barren solutions from 17 uranium-producing mines were analysed for the presence of 28 elements. Malissa and Ottendorfer[7] described separations of metal ions using the solubility of their diethyldithiocarbamates in pyridine. Aluminium and copper could thus be easily separated.

In connection with toxicological analysis a very sensitive test for thallium^{I} ions has been worked out.[8] A sector of the ring zone containing the thallium is treated with potassium iodide. Thallium^{I} iodide is thus precipitated, but remains invisible because of its low concentration. After the excess of iodide has been removed, the ring zone is treated with silver nitrate. The silver iodide formed by metathesis is exposed to ultraviolet light, then developed in a "physical developer".[9] A very distinct sharp black line indicates thallium (identification limit: 0.01 μg).

Biswas and Dey[10] applied the ring oven method to the separation and identification of some "less familiar" cations (uranium^{VI}, thorium^{IV}, cerium^{III}, cerium^{IV}, titanium,^{IV} zirconium^{IV}, molybdenum^{VI}, tungsten^{VI}, vanadium^{V}, beryllium^{II}, gold^{III}, platinum^{IV} and palladium^{IV}). They did this in a rather unusual way. Instead of using one of the methods for "ring to ring" separations mentioned above or one already cited in the monograph, they used the retainer ring as a heat barrier for the outer ring. They state that "in some cases, the last (outer) ring could not be obtained in a well defined form and was somewhat diffuse". This was to be expected, because the retainer ring only serves the purpose of keeping the filter in place, and certainly does not act as a heat barrier.

Singh and Dey[11] separated and identified metal ions on the ring oven, applying oxalate, tartrate or EDTA as complexing agents. Their separation technique seems nearer to paper chromatography, however, than to true ring oven technique: the various ions form rings at different distances "from the centre to the outer edge".

SEMIQUANTITATIVE DETERMINATION OF METAL IONS

Amongst semiquantitative analytical methods, spot colorimetry occupies a very outstanding place. Therefore it is not surprising that spot colorimetry in conjunction with the ring oven ("ring colorimetry") has found many new applications in the analysis of metal ions, anions and organic substances. Considerations given here are valid not only for the analysis of cations, but also for all the other semiquantitative applications.

This part of the present review could hardly be better introduced than by some statements made by Malissa.[12] "The fact that the capacity of the human eye is commonly underestimated, in conjunction with the modern trend to use precise photometers at a far too early stage in an investigation, has given rise to many unnecessary difficulties. The comparison of colours or shades, as used by Weisz and his coworkers in their contributions to spot colorimetry, brought developments back to the right level" and "It is often overlooked that the eye's capacity for integration and abstraction is something that an instrument does not easily equal."

The question has often been raised whether photometric measurements of the intensity of the rings would make the method still more accurate. Ottendorfer[13] made some density measurements on rings (in this case autoradiographs, but this does not make much difference) and was able to prove that mere visual comparison of the rings (as is usual in ring colorimetry) is at least equal if not superior to instrumental measurements.

In the following, some newer semiquantitative applications of the ring oven technique are described.

Nickel and cobalt. The previously mentioned method for the separation and identification of these two ions on filter paper impregnated with dimethylglyoxime[5] has also been evaluated quantitatively. Nickel can thus be determined in the range 0.1–100 μg, and cobalt from 0.5 to 20 μg.

Thorium. Hainberger and Sanchez[14] determined thorium with aqueous solutions of alizarin S and used this method for the analysis of monazite sand.

Beryllium. West and Mohilner[15] described a detailed study of the determination of beryllium with eriochrome cyanine R in connection with air pollution measurements. As little as 0.05 μg of beryllium can be determined. The average error is $\pm 7\%$. Magnesium, thorium, aluminium and chromium affect this method if present in a one hundred-fold excess.

Another way of determining beryllium[8] utilises the well known fluorescent reaction product of beryllium with morin. EDTA is used to mask any accompanying ions. Comparison of the test rings with a standard scale (stable for several months) is carried out under a quartz lamp. Very small amounts of beryllium (0.005 μg) can thus be determined with an accuracy of better than $\pm 10\%$.

Aluminium. Aluminium has been determined[16] by bathing the rings in methanolic morin solution and fuming them over concentrated hydrochloric acid. The dried cool papers are then compared with a standard scale (prepared in the same way) under an ultraviolet lamp. Incidently, this seems to have been the first example of a "ring-fluorometric" method.

Antimony. A method for the determination of antimony in air pollution measurements is based on the extraction of the tetra-iodo-antimony^{III} complex with a benzene-ethanol mixture (2:1) directly on the ring oven; the colour is then developed by reaction with phosphomolybdic acid (molybdenum blue). The limit of identification was found to be 0.08 μg and the accuracy is within the 5% limit.[17] Only a few ions were found to affect the determination (thallium, selenium, tellurium, tungsten and platinum metals).

Selenium. Selenium can be identified and estimated with 3,3′-diaminobenzidine, the citron yellow piazselenol being formed. The average error for this determination is ±6% in the range 0.1–0.5 μg of selenium; greater amounts of selenium give rings so intensely coloured that visual comparison becomes difficult. Because all tested varieties of filter paper were found to contain selenium, it is necessary to purify them. This is accomplished by treatment with sodium sulphide, which forms soluble seleno-sulphide complexes washable from the paper with distilled water. For this purpose, the "washing ring" mentioned above is used. Interferences were studied; the authors state[18] that the method is readily applicable to air pollution problems.

Universal standard scale

This method of semiquantitative determination (based on the fact that many metal ions can be transformed in one way or another into an equivalent amount of silver sulphide and these silver sulphide rings always compared with the same silver sulphide standard scale, irrespective of the original sample ion) has already been described in the monograph. Application of this method in paper chromatography was suggested and this has now been verified.

A mixture of metal ions is chromatographed on filter paper strips and the various parts of the paper bearing the single spots are cut out. These are ashed and made up to a certain volume (1 ml). From this solution 3 rings are made from suitable drop numbers, and the substances in these rings are transformed into equivalent amounts of silver sulphide, then compared with the silver sulphide standard scale (best derived from a copper solution). The technique has been illustrated by separating and determining mixtures of iron, cobalt and nickel and of lead, copper and cadmium.[19]

In a second approach,[20] this combination of paper chromatography with the universal standard scale has been simplified to avoid the ashing of the filter paper pieces. Varying quantities (1–10 drops) of the solution to be determined are spotted on narrow filter paper strips, then the chromatograms are run. The cut out pieces of the strips (bearing the separated substances) are rolled spirally and placed in a glass tube so that the end of the roll protrudes from the tube and makes contact with the filter paper on the ring oven. The substances are then extracted from the rolled piece of paper to the round filter and there washed into the ring zone. This has to be done with 3 pieces (derived from chromatograms of 3 different numbers of drops of sample solution) of cut out filter paper, thus yielding 3 rings necessary for comparison with the standard scale. The substances contained in the rings are again transformed into equivalent amounts of silver sulphide. It is, of course, essential that the same capillary pipette is used for applying the drops on the chromatogram and for preparing the standard rings. This very simple method, which gives results with an error of only ±5%, has been applied to the analysis of mixtures of copper and lead and of cobalt and zinc. It seems to offer the possibility of separation and determination of small amounts (a few μg) of elements in mixtures of varying composition.

The idea of using a universal standard scale for comparison in ring colorimetry is certainly not limited to the use of silver sulphide. Other compounds offer the same possibility. Ćelap and coworkers[21,22] described the application of a standard scale of copper^{II} hexacyanoferrate(II) for this purpose. Quite a number of metal ions can be precipitated as hexacyanoferrates(II) by bathing the rings in a 2% aqueous solution of potassium hexacyanoferrate(II). After thoroughly rinsing the filter paper, the difficultly soluble precipitates are converted to an equivalent amount of copper^{II} hexacyanoferrate(II) by bathing the rings in a 2% solution of copper^{II} sulphate. The rings thus obtained are then compared with a standard scale of copper hexacyanoferrate(II), prepared from a copper solution of known concentration (0.1 mg of copper/ml). As with the silver sulphide scale, conversion factors for the different ions to be determined need to be calculated. Three sample rings prepared from suitable drop numbers also need to be employed for the comparison, as in all semiquantitative applications of the ring oven method. Uranium, manganese, nickel, cobalt, zinc, cadmium, copper, lead, mercury^{I} and mercury^{II} have been determined. The results obtained deviated on average by ±3%.

ANIONS

In the field of anion analysis, 23 identification reactions were mentioned in the monograph. This number has since been enhanced only slightly. Ballczo and Hodos[23] described the use of barium rhodizonate for the detection of sulphate ions. An inner ring (12-mm diameter) bears barium rhodizonate. The sample drop is spotted at the centre of the paper and washed to this inner ring. Here the sulphate releases an equivalent amount of rhodizonate, which is then washed to the outer ring zone (22-mm diameter) where it can be made visible with barium salt. As little as 0.005 μg of sulphate can thus be detected. It is possible to use this method for semiquantitative estimation. Barney[74] published a method for the detection of submicrogram amounts of fluoride on the ring oven with thorium chloranilate.

Munshi and Dey[24] separated binary and ternary mixtures of some common anions on the ring oven. For ternary mixtures, the "retainer ring" was again used as a heat barrier for the outer ring as already mentioned (*cf.* Biswas and Dey[10]). The same objection as stated there for this type of procedure in the analysis of cations is, of course, still valid in the analysis of mixtures of anions.

Although only very little can be reported of new tests for anions carried out on the ring oven, some systematic separation schemes have been devised for various numbers of anions with this technique.

Musil, Haas and Drabner[25] reported a separation scheme for 8 common anions [bromide, iodide, thiocyanate, sulphate, chromate, phosphate, arsenate and hexacyanoferrate(II)] contained in a single drop. These anions are separated into 3 different rings, where they can be identified by suitable spot test reactions. Arsenate, phosphate and hexacyanoferrate(II) are first fixed in the original spot with zinc acetate, then the other 5 anions are transported to ring I, where they are identified on individual sectors. The precipitated zinc salts are subsequently fumed over hydrochloric acid, after which arsenate and phosphate are washed on a new filter paper into ring II. The remaining zinc hexacyanoferrate(II) is oxidised over bromine vapour, then washed with dilute hydrochloric acid into ring III on a third filter paper.

Another approach to separate anions has been described by Haba and Wilson.[26] Sulphate, chromate, vanadate, hexacyanoferrate(II), hexacyanoferrate(III), hexacyanocobaltate(III), bromide and iodide are first separated into 2 groups by means of barium nitrate. The first 3 anions listed are thus fixed in the centre of the paper, while the others are washed into the ring zone where they can be identified. One of the ions [hexacyanocobaltate(III)] is separated by a "ring to ring" separation in a single sector. The inner spot is punched out, the little disc placed on another filter and the barium salts of chromate and vanadate washed with $0.04M$ hydrochloric acid into the ring zone, whereas barium sulphate remains in the original spot. One μl of sample solution is sufficient for this scheme. The authors also briefly mention the possibility of semiquantitative determinations of the anions by their method.

A systematic scheme for the analysis of common anions on the ring oven has been worked out also by Biswas, Munshi and Dey.[27] Sulphate, sulphite, nitrate, nitrite, fluoride, chloride, bromide, iodide, hexacyanoferrate(II), hexacyanoferrate(III), thiocyanate, phosphate, sulphide, thiosulphate and borate are separated into 5 different rings and identified there. Silver ions are used to fix all of the ions except the first 5 listed here, then successive extractions with $2M$ nitric acid, with nitric acid (1:2), with ammonia solution and with sodium thiosulphate solution bring about the other separations.

Instead of actually separating all the anions into various groups, Mooney[28] employed a number of single tests in a certain sequence of application. By this "exclusion system", 12 anions can be identified (nitrate, borate, silicate, phosphate, sulphate, molybdate, fluoride, cyanide, chromate, bromide, iodide, chloride).

Apart from the semiquantitative determination of sulphate, using its reaction with barium rhodizonate as mentioned above, Huygen[29] described another method for sulphate and sulphite in connection with air pollution measurements. The rings containing the sulphate are bathed in a solution of barium chloride and potassium permanganate, dried and rinsed well with a $1M$ hydrochloric acid solution of oxalic acid. The pink rings (the permanganate is stabilised against reduction by having been included into the crystal lattice of the barium sulphate are compared with the standard scale. Sulphide is determined in the same way after it has been previously oxidised to sulphate with hydrogen peroxide.

The universal standard scale of silver sulphide rings has hitherto only been applied to the determination of metal ions, for instance in combination with paper chromatography (*viz.* above). It is, of course, also possible to determine anions in this way. Most of the anions can be precipitated as difficultly soluble metal salts; these metal salts can be transformed into sulphides and these, in turn, into an equivalent amount of silver sulphide. Obviously, the most direct way is for anions which precipitate with silver ions. A number of anions, such as chloride, bromide, iodide, thiocyanate, arsenate, dichromate and hexacyanoferrate(III), have been determined in this way. The anions are washed into the ring zone and fixed there by bathing them in silver nitrate solution. After rinsing thoroughly, the precipitates are converted into equivalent amounts of silver sulphide by bathing in hydrogen sulphide water. The resulting silver sulphide rings are compared with a standard scale, derived in the same manner from a standard solution of potassium bromide. The results of the comparison are, of course, obtained in "bromide equivalents" and must be multiplied by a suitable conversion factor, which is the quotient of the equivalent weight of the ion to be determined and that of the standard ion (*e.g.*, bromide). The accuracy of this procedure[31] is satisfactory and compares very well with that of ring colorimetry as commonly used.

ORGANIC SUBSTANCES

In the monograph it was mentioned that the ring oven method could prove useful not only in the inorganic field but also in the examination of organic substances. Since then, a number of publications have dealt with the analysis of diverse organic substances.

A sensitive spot test for nitrogen compounds in petroleum fractions and its application to semiquantitative determination seems to have been the first contribution to organic analysis with the ring oven. Tetracyanoethylene (TCNE) yields coloured reaction products with organic nitrogen compounds, such as pyridine, lutidine, pyrrole, indole, *etc.* These colours are stable on heating to 110°, in contrast to the colours produced by the reactions of TCNE with hydrocarbons, which only persist at room temperature. Peurifoy and Nager[32] suggested this method as a quick quality control test for units in which the nitrogen content is an important criterion.

Meisel, Nemeth and Erdey[33] developed a rapid micro method for the detection of several hetero-elements (nitrogen, sulphur, chlorine, bromine, iodine) in organic compounds. The organic substance is fused with metallic potassium and the resulting anions (iodide, bromide, chloride, sulphide, cyanide, thiocyanate) separated by the ring oven method and identified by suitable spot tests. The utility of the procedure has been proved by the analysis of 24 diverse organic substances.

The first published application of the ring oven technique to clinical analysis seems to have been the estimation of microgram amounts of proteins by Farr and Chaney.[34] The authors used a modified ring oven with which the substances are collected in a straight line. For developing the colours, the protein binding of bromophenol blue was employed. The samples investigated were solutions of human blood serum, containing between 0 and 100 ppm of protein. The maximum error is stated to be ±8%. This method has been used for estimation of the protein content of various biological solutions. As little as 10 μg of protein/ml can be evaluated.

Semiquantitative determination of a number of amino acids has been described by Ćelap, Janjić and Ilić.[35] A spot of copper^{II} hydroxide is prepared in the centre of a filter paper and dried. The necessary number of drops of the amino acid solution to be determined is added to this spot and part of the copper^{II} hydroxide is thus dissolved, forming a water soluble complex compound. This bluish-green compound is washed into the ring zone with water. The sample rings are then compared with standard rings in the usual manner. Glycine, alanine, asparagine, aspartic acid and glutamic acid were determined with reasonable accuracy (about ±5% relative).

Ćelap and coworkers also applied ring colorimetry to the semiquantitative determination of sugars, phenols and alkaloids. The necessary number of drops of the solution of the sugar are washed with water into the ring zone, followed by 1 drop of a hydrochloric acid–alcohol solution of resorcinol. The filter paper is then heated for 20 min to 125° in a drying oven. Stable brown-yellow rings are formed and compared in the usual manner with standard rings. Fifteen μg of sugar are sufficient for preparing the 3 rings. Glucose, mannose, galactose, fructose, sorbose, arabinose, xylose and rhamnose have thus been determined.[36]

For the determination of phenols, the sample drop is transported to the ring zone, followed by 2 drops of a $1M$ sodium hydroxide solution. The stable brown rings are developed by heating the filter papers for 1 min at 120°. Catechol, resorcinol, hydroquinone, pyrogallol, phloroglucinol and *p*-nitrophenol are cited as examples for this procedure. About 4 μg of the respective phenols are needed for the determination.[37]

Alkaloids are determined by the following reaction. The filter paper bearing the alkaloid concentrated in a ring zone, is bathed in a 1 % phosphomolybdic acid solution in nitric acid, then thoroughly rinsed in water. Subsequently, the filter is immersed in a 1 % tin^{II} chloride solution in hydrochloric acid, again washed with water and finally dried at 105°. Stable blue rings are produced which can easily be compared. The determinations were performed with 10–50 μg of nicotine, atropine, cinchonine, quinine, narcotine, morphine, codeine, aconitine, strychnine and brucine.[38]

The accuracy of the 3 methods just presented is very satisfactory; the errors are of about the same order as in the determinations of inorganic ions.

The microdetermination of caffeine has been investigated by Ordoveza and West[39] for use in air pollution studies. Solutions of acetylacetone in sodium hydroxide and of *p*-dimethylaminobenzaldehyde in hydrochloric acid are used to develop blue rings with caffeine. The standard scale is stable for about 3 days. Detailed studies have been carried out in order to establish the best conditions for the reaction and to eliminate interferences from other constituents likely to be collected from the atmosphere during the sampling procedure. As little as 0.5 μg of caffeine can be determined with an average error of 3 %.

TRACE ANALYSIS

Already some years ago Feigl and West[40] pointed out the possibility of using the ring oven method in trace analysis.

Ackermann[41] investigated heavy metals in alkali and alkaline earth salt solutions by precipitation of their hydroxides or sulphides and filtration through a specially designed filtering device, offering only a very small filtration area. The precipitate collected on the small filter paper disc is then separated and identified on another filter paper by means of the ring oven technique. As little as 10^{-3} ppm of copper and iron in salt solutions could be identified. The author mentions that by this technique it was shown that the well known autoxidation of alkali iodides is caused by traces of heavy metals.

Whereas in the method just mentioned the collection of traces of heavy metals is based on the so-called "Punktflockung", on the coagulation of the colloidal precipitate on the fibres of the paper itself (Mahr and Klamberg[42]), Schulek and coworkers[43,44,45] employed oxycellulose for the collection of traces of metals from extremely dilute solutions. The suspended oxycellulose fibrils, bearing the metals, are collected on a sintered-glass filter stick (5-mm diameter), where they form a little disc which is subsequently placed in the middle of a filter paper. On the ring oven, the various ions can be separated and identified in the usual way. About 20 ions were studied. The concentration of the ions in the original solutions was between 0.001

and 0.1 ppm. From 3 to 5 mg of oxycellulose were applied for their collection.

Two other publications can perhaps also be regarded as contributions to this field: investigations of impurities in filter paper[46] (*cf.* monograph, p. 67) and the detection of traces of lead in alloys and in prehistoric bronzes.[47] Because these two publications do not contribute basically new methods to the ring oven technique itself, no details need to be given here.

AIR POLLUTION STUDIES

During the last few years, the ring oven method has been used to study and control air pollution. The analysis of air borne particulates, including aerosols, is a very important problem of chemical analysis. Especially in industrial areas it is of significance for public health and hygiene to control the impurities in air.

Although relatively large amounts of sample can be collected over extended periods of time through the use of high volume samplers or continuous sample collecting equipment, it is desirable to handle smaller samples collected during brief sampling periods. It is likewise important that rather small amounts of certain constituents can be isolated, concentrated, identified and determined semiquantitatively in the presence of major amounts of innocuous accompanying air borne sample material.

The ring oven enables these conditions to be fulfilled and can therefore be used in this field with advantage. Its use in this context has already been suggested some years ago (*cf.* monograph, p. 66).

Samples collected by impaction or electrostatic precipitation can be taken into solution and drops of the resulting sample solution subjected to the ring oven technique in the usual way. However, samples of air borne particulates are mostly collected in air pollution studies by sucking air through special filters, membrane filters, glass fibres, nylon, rayon, *etc.* The identification and estimation reactions must be carried out on ordinary filter paper, because the surface of the other filter materials is not very suitable for colour reactions or for separations with a satisfactory degree of sensitivity. Therefore, the sample substances need to be transferred from the sampling filters to ordinary filter paper. This question of transferring substances from one filter to another could be of general interest and not only in air pollution studies.

A triangular portion (about 10 mm per side) of the filter material, having on its surface the collected particulates, is cut out for analysis. The triangle is placed on a filter paper and is fixed in place to ensure its position during subsequent operations and the quantitative transfer of the sample from the filter medium to the paper.

If membrane filters (such as "Millipore" filters), which consist of cellulose acetate, have been used for the collection of the samples, the fixation of the little triangle can be accomplished very simply by moistening the filter paper with a drop of acetone. The triangular piece of the membrane filter is placed on it (with the sample-bearing surface down) and held in position for a few sec. Enough of the cellulose acetate dissolves in the acetone to cause a cementing action.

The filter paper, together with the triangle, is placed upon the ring oven, but upside-down, so that washing can start on the surface of the paper rather than on the membrane filter (Fig. 4). Dissolution of the sample and its transfer into the ring zone is accomplished by washing with an appropriate solvent (0.1*M* hydrochloric acid, ammonia solution, *etc.*). All of the sample components are quantitatively concentrated in a sharply outlined ring zone. This ring is cut into sectors, on which the various identification tests are performed.

In the case of samples collected on other filtration media, such as linen, cotton, nylon, glass-fibre filters, or paper, again a triangular portion of the sample is cut out and must be fixed to the round filter paper using tiny dots of glue. Ordinarily, 6 spots of glue ("Duco-cement", "UHU" or a slurry of cellulose acetate in acetone) applied to the circumference of the triangle are sufficient.

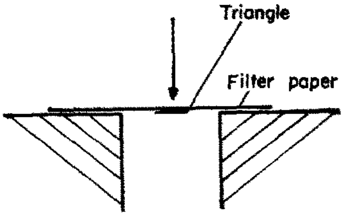

FIG. 4

These methods for transfer, concentration and analysis of collected air borne particulates have been described by West, Weisz, Gaeke and Lyles.[16] These authors also give a number of spot tests for identification of the pollutants. The quantitative determination of iron and aluminium is carried out by dissolving the sample collected on paper strips (using a low flow rate dust sampler) in a defined volume of 0.05*M* hydrochloric acid. In this sample solution, the metals are determined by ring colorimetry in the usual way. Four-hundred atmospheric samples have been analysed by this procedure. Accuracy, precision and speed were found to be satisfactory compared with conventional methods.

Methods for the estimation of antimony,[17] beryllium,[15] selenium[18] and caffeine[39] for application in air pollution studies have been worked out by West and coworkers. These methods have already been mentioned in appropriate sections of the review.

Huygen[29] described the determination of sulphate and sulphur dioxide in air. The filter paper used for the collection of sulphur dioxide is moistened with a 10% solution of potassium hydroxide or potassium carbonate and dried; sulphuric acid mist and sulphate particles in air are collected on plain filter paper (Whatman No. 1). The filter papers are clamped between circular plastic discs with centred holes in order to restrict the effective diameter to 15 mm. After the collection, the loaded filter papers are placed directly on the ring oven and the pollutants are washed to the ring zone with 0.1*M* hydrochloric acid (which contained, in the case of sulphur dioxide, 1% of hydrogen peroxide in order to oxidise it to sulphate). The reaction with barium chloride and potassium permanganate is carried out (as described above under *Anions*) to render the ring visible. The ring is then compared with standard rings for quantitative evaluation. The author obviously applied only 1 ring for comparison with the standard scale and therefore the accuracy of this method is only about ±25%. This is not surprising, because it has already been shown (*viz.* monograph) that 3 rings prepared from suitable drop numbers of sample solution have to be prepared and compared with the standard scale in order to obtain results with a degree of accuracy between ±5 and 8%.

This fact now shows the difficulty so far encountered in this type of work. One can either dissolve the collected particulates from the sampling material, such as filter papers, in a defined volume and then prepare the necessary 3 rings from varying drop numbers. Alternatively, the sample collected on the filter can be washed directly on the ring oven into the ring zone, if necessary (*e.g.*, a non-paper medium used for sampling) applying the transfer procedure described above. In this case, however, only 1 ring is available and obviously the averaging technique of ring colorimetry cannot be used; the results are not as precise as desirable in many cases.

The first technique, namely, dissolving the collected material from the sampling medium and preparing 3 sample rings, yields, of course, more precise results, but much more of the material to be determined needs to be collected than is actually used in preparing the 3 rings. Alternatively, the sample would have to be dissolved in a very small but known volume of, say, some 10 μl, which is not easily practicable.

It seems possible to overcome this difficulty by sucking the air simultaneously through at least 3 restricted areas of different but known size of the filter material. The ratio of the "sample spots" thus achieved should be such that 3 of them, after having been extracted to the ring zone and developed with suitable reagents, cover a wide range of the respective standard scale used for comparison. Thus, it would be possible to transfer the collected material directly to the ring zone without previous dissolution and to have, nevertheless, the 3 rings necessary for comparison. Only very small amounts of the pollutant need to be collected and that, on the other hand, means that only a shorter sampling period would be necessary. This could be of some importance in many practical instances.

An alternative approach might be to collect the pollutants on filter material and to cut out 3 circular or triangular pieces of different but well defined size, the areas of which should have a suitable ratio from one to the other, then to transfer the collected material from these small pieces to the ring zone of 3 separate filter papers.

Practical experiments, which we plan to carry out in the near future, will serve to evaluate these techniques.

RADIOACTIVE SUBSTANCES

In the monograph, the application of the ring oven method to the analysis of radioactive substances has already been described, but only with a few qualitative experiments. It was pointed out that autoradiography of the rings should provide a method for the semiquantitative determination of active substances. This suggestion has now been verified and two basically different methods for semiquantitative determinations are currently available and will be reviewed here.

The simpler approach to the quantitative determination is as follows. Prepare a standard scale by making rings from 1, 2, 4, 6, 8 and 10 drops of a standard solution of a radioactive isotope, expose the rings to X-ray film for sufficient time and develop the rings. Then prepare and autoradiograph under identical conditions 3 rings with varying numbers of sample drops. Compare the unknown ring autoradiographs with the standard scale and calculate the concentration of the unknown solution as in chemical ring colorimetry.

This method gives good results, but it is rather time consuming. In ring colorimetry 3 rings made from different drop numbers always have to be compared with the standard scale (*viz.* monograph).

In order to find suitable drop numbers, a ring with 1 drop is always made first and compared with the standard scale. From this preliminary result, the numbers of test drops for the other two rings are derived. In ordinary chemical ring colorimetry this is done very quickly, but in autoradiography one must first make an autoradiograph of the one-drop-ring, which takes, of course, several hr, before one can decide the drop numbers to be applied for the other two rings.

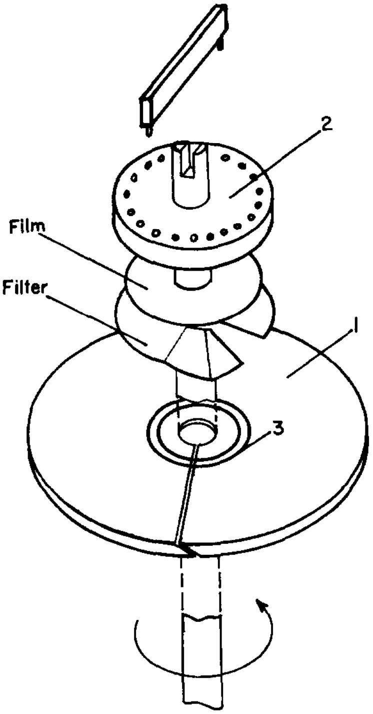

FIG. 5.—Exposure apparatus:

1—Steel plate with slit, on which the filter bearing the active ring is placed and one of the radially cut edges inserted into the slit.

2—Heavy steel plate fitted with fine steel needles on the lower side; these needles firmly fix the filter and film together.

3—Narrow groove to receive tips of the steel needles.

This has lead to another approach. In carrying out the procedure in the way mentioned above, one in fact neglects an essential possibility of autoradiography, namely, utilisation of the law of reciprocity. Two blackenings of a photographic film from radioactive substances are identical if the products of intensity and exposure time are likewise identical ($i.t$ = constant). The method to be reviewed here now makes use of this principle.[48]

The radioactive substance in the sample drop is washed into the ring zone and fixed there by a suitable precipitant. The filter paper bearing the "active ring" is provided with a central hole and cut along a radial line. It is then placed on a slit plate in an exposure apparatus (Fig. 5) and a piece of X-ray film placed on top. The paper and film are held firmly together, but during a slow rotary motion the paper gradually passes through the slit plate while the film remains above the plate. Hence the action of the active ring on the film is stopped.

One rotation takes 12 hr and the film is then developed. It shows an autoradiograph with stepwise increasing density, corresponding to exposure times from 0 to 12 hr.

The rotary motion should not be carried out linearly, for instance with the aid of a clockwork drive, because if a linearly increasing blackening of the ring autoradiograph is to be achieved, the various exposure times (for the various parts of the ring) have to follow a geometric series and not an arithmetic one. Therefore the rotary motion is carried out in 50 single steps, using a gear-wheel and a magnetic switch (not shown in Fig. 5). At different times an electrical contact gives an impulse to the magnet, which in turn moves the gear-wheel one step further. The various times are regulated by a simple additional switch apparatus, which delivers the necessary electrical contacts to the magnetic switch.

If the exposure time for the first step is t min, the time for the second step is $t.k$, for the third $t.k^2$ and so on. The exposure time for the last step, *i.e.*, for the last little segment of the ring, is therefore $t.k^{49}$ min; this is the maximum exposure time, and so also the time for a complete rotary motion of the film + filter. This total exposure time has been chosen to be 12 hr, the time for the first step t is about 10 min and k is $\sqrt[8]{2}$ (= 1.0905). This means that every eighth step has exactly double the exposure time of the first one, because $(\sqrt[8]{2})^8 = 2$. The "ring chrono-autoradiograph" is then nothing but a circular stepped grey wedge.

In this way, chrono-autoradiographs are prepared from 1, 2, 4, 8 and 10 drops of a standard solution of a radioactive isotope. From 1 drop of the unknown solution a chrono-autoradiograph is likewise prepared. Evaluation of the sample ring chrono-autoradiograph is made by comparing it with various (usually 3 or 4) standard ring chrono-autoradiographs.

The unknown autoradiograph is placed almost on top of, but separated by 1–2 mm from one of the standards and turned (clockwise or anticlockwise) until the best coincidence of blackening is observed. The number of steps (50 for the total ring) through which the sample chrono-autoradiograph had to be turned is noted. This is best done by illuminating the two rings from below and applying a simple dial, of which the circle is divided into 50 sectors (equal to the number of steps in the exposure apparatus).

As an example, suppose the unknown ring had to be turned clockwise 6 steps to give the same appearance as the standard ring. This obviously means that the activity of the sample solution is higher than that of the standard solution, because it gave at a shorter exposure time already an equal degree of blackening. The difference is 6 steps, which means the activity is $(\sqrt[8]{2})^6 = 1.495$ times that of the standard solution.

Because drop numbers can be varied and also the exposure times (one is not bound to 12 hr: 6, 24, 48 or other multiples of 12 hr could be used), the range of activities which can be measured is extremely wide. A very simple arithmetical treatment gives the ratio of the activities of the unknown and the standard solution. In the calculations the different rotation times and drop numbers have, of course, to be taken logically into account. As long as the factor k is the same, all sample rings can be compared with the same standard scale, irrespective of the rate of the rotation in the exposure apparatus. Because it would surpass the scope of this review to describe the arithmetical evaluations in detail, the reader is referred to the original publication[48] for this information.

It is also possible to compare a sample autoradiograph derived from a different active isotope than that from which the standard scale has been prepared. In this case, the result has to be multiplied by a suitable isotope conversion factor, which has been determined experimentally by a single standardisation. So far ^{59}Fe, ^{32}P, ^{235}U, ^{60}Co, ^{137}Cs, ^{95}Zr, ^{90}Sr, ^{144}Ce and ^{106}Ru have thus been determined over a wide range of concentrations, down to nano-curie and even less.

In a second publication,[49] the precision and sensitivity of this method are discussed and detailed procedures for the determination of the conversion factors are given (cobalt/caesium, cobalt/zirconium, cobalt/strontium, cobalt/cerium, cobalt/ruthenium). Chrono-autoradiography in its many aspects is summarised in a further publication.[13]

These methods have been applied to the investigation of very dilute radioactive solutions and waste waters. The dilute solutions are concentrated on the ring oven itself, using a simple glass apparatus which delivers sample solution continuously to the filter paper on the ring oven. The "active rings" are then chrono-autoradiographed as described above. The detection limits were found to be of the order of nano-curies or even less, using a total exposure time of only 6 hr.[50]

An exposure apparatus for chrono-autoradiography has also been devised which allows a continuous rotation instead of a stepwise one, as is the case in the apparatus just described. The rotation must not, of course, be linear, for reasons already mentioned. Therefore, a programme curve disk takes care of the necessary exponential rotational course.[51]

As stated above, the simplest method for the determination of radioactive substances is the direct autoradiography of sample rings, but the problem is here to ascertain suitable drop numbers of the unknown solution for preparation of the necessary 3 sample rings. A newer method has been described, in which this difficulty was overcome without any special exposure device.[52]

From a standard solution of an active isotope, standard rings with 1, 2, 4, 6, 8, 10, 13 and 20 drops are prepared and exposed to X-ray film for 20 hr. It is, of course, essential that the standard solution has a suitable activity (a_{St}) in order to obtain a well differentiated standard scale. Sample rings are prepared from the unknown solution with 1, 4, 8, 16 and 20 drops (of the same volume as the standard drops, of course) and each of them is "sandwiched" between two pieces of X-ray film and exposed (weighted with a glass-plate). After 1, 12 and 125 hr the upper film covering the sample rings made from 20, 16 and 8 drops, respectively, is developed. The upper films serve only for "piloting experiments" to ascertain the necessary exposure time. For the final comparison, the second (underlying) films are used.

The drop numbers and exposure times have been chosen so that always at least three of the 5 sample rings must fall within the standard scale, if the concentration (activity) of the unknown solution is between a fiftieth and fifty-fold that of the standard solution ($1/50\ a_{\mathrm{St}} - 50\ a_{\mathrm{St}}$). This is a limitation, but for most practical purposes a concentration range of the sample solution from 1:2500 is certainly sufficient.

The resulting ring autoradiographs are compared with the standard autoradiographs as usual. The calculation is simple:

$$\frac{a_{\mathrm{S}}}{a_{\mathrm{St}}} = \frac{\Sigma z_{\mathrm{St}}}{\Sigma z_{\mathrm{S}}} \cdot \frac{t_{\mathrm{St}}}{t_{\mathrm{S}}}$$

where a_S/a_{St} = the ratio of the activity of sample solution to standard solution,

Σz_{St} = the total number of drops of the standard rings to which the three sample rings have been aligned,

Σz_S = the total number of drops from which the 3 sample rings have been prepared,

and t_{St} and t_S = the exposure time for standard and sample ring autoradiographs, respectively.

It is also possible to chose other values for the exposure time of the standard scale as well as for the sample rings, and other drop numbers. A different range of concentration of the unknown solutions can be covered by this method.

Several radioactive isotopes have thus been determined with a satisfactory degree of accuracy ($\pm 10\%$): ^{45}Ca, ^{137}Cs, ^{110}Ag, ^{204}Tl and ^{90}Sr/Y.

If the difference of the exposure time of the standard scale and the sample rings is too great (*e.g.*, 20 — 120 hr), then the "fading" effect enhances the degree of error and the blackening of the longer exposed film becomes weaker than it should be. This can easily be avoided (or at least greatly reduced) by autoradiographing at a temperature of $-20°$ in a cool box.

Whereas all of these methods aim to determine radioactive substances themselves, in the procedure to be described next radioactive isotopes are used for the determination of inactive substances. An isotope dilution method in combination with the ring oven technique has been worked out, which allows the determination of submicrogram amounts of various ions. Only 1 drop of a rather dilute solution of the respective active isotope is needed.[53]

To the solution (2 or 3 drops) of an ion (x μg), an always constant amount (a μg) of the same ion, labelled with an active isotope of this ion, is added. With a constant amount of a suitable reagent, part (b μg) of the total amount $x + a$ is precipitated and separated on filter paper on the ring oven. The amount b is collected in the inner ring zone (14-mm diameter), whereas the rest ($x + a - b$) is transported to the outer ring zone. The separations are carried out with the aid of the auxiliary ring described above.[1] The impulses (cpm) corresponding to b and $x + a - b$, respectively, are determined by a suitable counting device (Geiger-Müller counter) after the filter paper has been cut by a pair of scissors.

It is also possible to carry out the reverse procedure: to precipitate the total $x + a$ in the inner ring and to add a certain amount of a reagent, which dissolves b μg of the precipitate. The amount b is then washed to the outer ring zone. Under identical conditions, a series of solutions of known concentrations of the ion are treated, the ratios of the two impulse rates (for b and $x + a - b$) are determined and plotted graphically *versus* the concentrations, thus giving a standard curve. The unknown solution is treated in exactly the same way, and the evaluation of the results is done graphically. It is, of course, important that the solutions are mixed as uniformly as possible. This is carried out in a blood mixing pipette.

In this way, calcium [+ EDTA, $(NH_4)_2HPO_4$], phosphate (+ $CeCl_3$, aqueous NH_3) and iron [+ $K_4Fe(CN)_6$] have been determined in the range 0·1 — 1 μg/μl with a satisfactory degree of accuracy. It should likewise be possible to carry out the measurement of the activity by autoradiography. The advantage of this method is obviously that only very small activities need to be applied, so that the technique can be used in an ordinary chemical laboratory without any danger.

Hilton and Reed[71] recently determined caesium-137 in irradiated uranium solutions using the following technique. A drop of sample solution was placed on a preformed precipitate of iron^{III} hydroxide at the centre of a filter paper. This precipitate adsorbed unwanted radioactive components. Caesium-137 was then washed, on the ring oven, with aqueous ammonia and water into the ring zone, where it was subsequently evaluated by γ-ray scintillation spectrometry. Apart from the advantages of speed, simplicity and negligible use of shielding, the method was precise and did not need any determination of the yield because a calibrated standard was always analysed under the same conditions as the sample. The authors suggested the ring oven technique in conjunction with γ-ray spectrometry should prove effective for determining many radionuclides in complex mixtures.

It seems that the ring oven method could be used also for educational purposes in the field of radiochemistry with advantage, because it allows experiments to be carried out with extremely small amounts of radioactive substances.

IN COMBINATION WITH OTHER TECHNIQUES

Several methods have already been mentioned, both in the monograph and in the present review, which are based on combinations of the ring oven method with other well established analytical procedures, *e.g.*, autoradiography, paper chromatography, electrographic sampling.

Biró[54] applied the ring oven method in connection with electrographic sampling of metallic specimens in a similar way to that already described by Stephen and by Nall (*cf.* monograph). Application of the ring oven method and especially its combination with electrographic sampling in the analysis of metals has been recently reviewed in detail by Ottendorfer.[55]

Mooney[56] described an interesting method which might be generally applicable, namely, combination of the ring oven technique with cation exchange and emission spectrography. The sample drop is spotted on a small circular disk (9-mm diameter) of cation exchange paper (Whatman CM 50) and dried. The disk is then placed on an ordinary filter paper on the ring oven and the anions washed with water to the ring zone, where they can be identified in the usual manner. Cations are either detected spectrographically by placing the disk directly in a graphite electrode for the d.c. arc method, or they are eluted from the ion-exchange paper into the ring zone of another filter paper, using $3M$ nitric acid as a solvent. In this "cation ring zone" the various metal ions are either detected by conventional chemical identification reactions or, in a sector, again spectrographically. Some of the metals which are present as anions (such as molybdate and chromate) are to be found, of course, already in the first ring zone, together with the other anions. The practical cation capacity of the ion-exchange paper and the sensitivety of the spectrographic determination for a number of metals have been studied. So far, only a rather limited number of examples for this technique has been communicated, but it is to be hoped that the author will continue with his interesting work.

CONCENTRATION OF SUBSTANCES IN THE FORM OF A STRAIGHT LINE

In the ring oven method, the concentration of the soluble substances contained in a sample drop takes place in the form of a sharply developed ring of 22-mm diameter; this causes a concentration effect of about 3–10 fold. It is obvious that a ring oven having a smaller bore hole diameter would enable a still higher concentration effect to be achieved. However, it would also give a ring with a smaller circumference. Because the ring oven method has now been developed for separations and semiquantitative determinations, too small a ring would give difficulties in this respect. With a smaller circumference of the ring, the number of sectors into which it can be cut for various identification procedures must logically decrease.

Within the last few years, several authors have described methods of concentrating substances on filter paper strips which result in short straight lines. Farr and Chaney[34] used for their method of determining proteins a modified ring oven, by which the substances are concentrated along a line. Schwarz-Bergkampf[57] described a very simple tool (gas-heated) for the accumulation procedure. Biró[58,59] published his "line oven", which consists essentially of two heating blocks, which can be pushed against each other, one serving for concentration of the sample constituents (as usual in the ring oven method) and the other, suitably positioned, serving to protect "lines" which had been previously developed, against the solvent.

Reimers[60] described a "rod oven", which does not seem to bring about any new possibilities at all.

It has been shown[61] that the ring oven in its original form can also be used advantageously for the concentration of substances along a short straight line. The sample drop is spotted on a filter paper strip of 6-mm (or even less) width. This strip is placed across the ring oven so that the spot lies between the middle and the edge of the bore hole. Using a capillary washing pipette with a suitable solvent, the soluble substances are then concentrated in the form of a short (6 mm or less, depending on the width of the paper strip) line. By suitable movement of the filter paper strip on the ring oven and by selection of the appropriate fixation reagents and solvents, the components contained in the sample drop can be separated from each other and concentrated in parallel lines on the paper strip, as with the other newer described concentration devices.

LITERATURE

The ring oven method has been frequently reviewed, and only a few of these articles need be quoted here. These reviews have, without doubt, contributed much to the growing interest in this field of microchemistry. German,[62,63] English,[64,65] Finnish,[66] Spanish[67] and Italian[68] papers have summarised the method.

In several text books and hand books of analytical chemistry, the ring oven method has been described, *e.g.*, in Feigl's *Spot Tests in Inorganic Analysis*,[72] in *Standard Methods of Chemical Analysis* edited by Welcher.[73]

Amongst the many comments on the monograph there is to be found a rather negative one.[69] The critic, who preferred to remain anonymous, was under the misapprehension that the ring oven technique was a form of paper chromatography and that it is by no means. He believed that the then limited number of publications did not justify the compilation of the monograph. It is to be hoped that a comparison of the number of publications on this subject then and at present will prove the contrary.

FUTURE DEVELOPMENTS

In order to make this present review as complete as possible, it seems to be necessary to mention studies which are currently being carried out. Only those can be quoted here, of course, which derive from the laboratories of the reviewer or of colleagues who were so kind as to communicate with him about their present work in this field.

Ring autoradiography and the isotope dilution method will be applied to more ions. A systematic qualitative separation scheme for a greater number of radioactive substances contained in one single drop is at present under investigation.

A qualitative and semiquantitative scheme for toxicological analysis will soon be available. Ring colorimetric methods for a number of dyes[70] and other organic substances and for the noble metals[70] are likewise under investigation.

Many new reactions both for organic and inorganic substances will be worked out for use with the ring oven and so contribute to the wider use of this technique. Air pollution studies are being continued. The method will be applied in the field of testing foodstuffs, especially in the dairy industry.

These few newer applications will, it is to be hoped, show that the ring oven method is being still further developed. The reviewer would be glad to learn of any information at present unknown to him and cordially invites colleagues who work in this field to communicate with him.

Zusammenfassung—Eine Übersicht über neue Entwicklungen in der Ringoftentechnik wird gegeben.

Résumé—On présente une revue des développements récents dans la technique du four annulaire.

APPLICATION OF CATION-SENSITIVE GLASS ELECTRODES TO THE STUDY OF ALKALI METAL COMPLEXES—II*

USE OF A POTENTIAL COMPARISON METHOD

G. A. RECHNITZ and S. B. ZAMOCHNICK
Department of Chemistry, University of Pennsylvania
Philadelphia, Pennsylvania, U.S.A.

(*Received* 15 *February* 1964. *Accepted* 13 *March* 1964)

Summary—Formation constants for alkali metal-citrate and -malate complexes have been evaluated by cation-sensitive glass electrodes. Use of a potential comparison method was found to be beneficial in improving the reliability and accuracy of such measurements. Formation constants for alkali metal-malate complexes agree well with the literature data; corresponding values for citrate complexes have not previously been published.

INTRODUCTION

In an earlier paper[1] we demonstrated the usefulness of cation-sensitive glass electrodes in the study of weak alkali metal complexes. The accuracy of the reported measurements for the formation constants of alkali metal-malate complexes was primarily limited by experimental problems inherent in the potentiometric procedures used. A potential comparison method has now been devised which largely eliminates sources of error, such as electrode drift and variation in solution composition, yet retains the advantages gained by the use of cation-sensitive glass electrodes. Briefly, this method involves the adjustment of the alkali metal activity of a solution containing known concentrations of complexing ligands by the incremental addition of concentrated solutions of alkali metal ions or ligands until the potential of the complex-containing solution becomes exactly equal to that of a solution containing only known concentrations of alkali metal ion. From initial concentrations and volumes of metal ion or ligand solution added, the formation constants of complexes formed can be easily calculated.

EXPERIMENTAL

Apparatus

All potentiometric and pH measurements were made using a Beckman Model 76 Expanded-Scale pH meter. A Beckman #39137 cation-sensitive glass electrode *vs.* #39170 fiber junction saturated calomel reference electrode (SCE) was employed. A #41263 pH glass electrode *vs.* SCE was used for all pH determinations.

An A. H. Thomas Co. #2457 Shohl microburette of 2-ml capacity with a hypodermic syringe needle-type delivery tip (luer lock slip hub, s.g. #25) was employed in accordance with the manufacturer's directions.

Reagents

All solutions except that of malic acid were prepared by weight from reagent-grade materials, and were used without further purification.

Alkali metal chlorides: Weigh 14·6120, 29·2240 and 43·8360 g of NaCl and bring each with water to a total volume of 0·250 litre, thus preparing 1·000, 2·000 and 3·000*M* stock solutions. Serial dilutions of 0·300, 0·200, 0·100 and 0·050*M* are made. Similar 1·000*M* stock solutions of KCl, LiCl, RbCl and CsCl, with serial dilution to 0·100*M*, were prepared.

---

* Part I: *Talanta*, 1964, **11**, 617.

Malic acid: (Purified powder, racemic). Weigh 33·5230 g and dilute to 0·250 litre with water to make a 1·000*M* stock solution, with serial dilutions of 0·300, 0·200, 0·100 and 0·050*M*. Stock solutions must be prepared fresh daily.

Citric acid: Weigh 52·5365 g and dilute to 0·250 litre with water to make a 1·000*M* stock solution; make serial dilutions as with malic acid.

Hydrochloric acid: Dilute concentrated hydrochloric acid (12·4*M*) with water to make 1·0 litre of 1·2*M* and 0·250 litre of 6·2*M* solutions.

THAM–HCl buffer solution: Weigh 145·3680 g of tris(hydroxymethyl)aminomethane (THAM), mix with 0·344 litres of 1·2*M* HCl, and dilute with water to total volume of 2·0 litre. This will give a solution of pH 8·45 ± 0·01, and is sufficient for 20 determinations.

Preconditioning solutions for cation-sensitive glass electrodes: Dilute 41·67 ml of 0·1*M* NaCl to 0·250 litre total volume with buffer solution.

Procedure

The following is a typical procedure used in the study of the sodium-citrate complex: pipette 10 m of 0·1*M* NaCl and 50 ml of buffer into a 100-ml beaker to make the standard solution, *s*. Pipette 10 ml of 0·1*M* citric acid and 50 ml of buffer into a second 100-ml beaker to make the test solution, *t*. Measure the pH of the solutions. The pH of $s >$ the pH of t, therefore adjust the standard with additions of 6·2*M* HCl until pH of $s =$ pH of t. Next, measure the potential of the standard solution, mv_s, and of the test solution, mv_t, with a cation-sensitive glass electrode *vs.* SCE, finding that $mv_s > mv_t$. Now titrate 1·0*M* NaCl into the test solution until $mv_s = mv_t$ on successive measurements. To determine the amount of NaCl complexes, *c*, by the citric acid apply the following:

$$\text{meq of NaCl}(t) - \text{meq of NaCl}(s) = \text{meq of NaCl}(c).$$

Assuming, for purposes of illustration, that a 1:1 complex is formed, the formation constant, K_f, of the complex can be calculated by the standard methods.

A back-titration of the above system can be performed as follows: the standard solution contains 10 ml of 0·1*M* NaCl and 50 ml of buffer: the test solution contains 0·1*M* NaCl in excess of 10 ml and 50 ml of buffer. Suitable pH measurements and adjustments are made. Potentiometric measurements show $mv_s < mv_t$. Titrate 1·0*M* citric acid into the test solution until $mv_s = mv_t$ as above.

All formation constant values reported are calculated from an average of 3 or 4 determinations. Magnetic stirring was used throughout, and all determinations were carried out at room temperature, 25·0 ± 0·5°. Pre-conditioning of the cation-sensitive glass electrode is essential if reproducible potentials are to be obtained. The pre-conditioning solution must be as similar as possible to the standard solutions employed; electrodes should be soaked for a minimum of 24 hr before use.

RESULTS AND DISCUSSIONS

General considerations

In order to treat the system quantitatively, the appropriate pH, ionic strength, and particular buffer system employed must all be taken into consideration. Citric acid[3] has $pK_1 = 3{\cdot}08$, $pK_2 = 4{\cdot}39$, and $pK_3 = 5{\cdot}49$. Thus, to study the system:

$$M^+ + A^{3-} \rightleftharpoons MA^{-2}, \quad K_f = \frac{[MA^{2-}]}{[M^+][A^{3-}]} \tag{1}$$

where M^+ is the alkali metal ion and A^{3-} is the citrate anion, the pH of the system must be greater than 5·49. The THAM-HCl buffer at pH 8·45 ± 0·01 was chosen for the following reasons:

(1) If pH $\leq$ 5, the potential developed by the cation-sensitive glass electrode is a function of pH and pM.[4]

(2) It is desirable to work in alkaline medium to ensure complete dissociation of the citric acid.

(3) A 1:1 complex, MA^{2-}, could not exist at pH 5·49.

(4) The THAM-HCl buffer cation, $(CH_3OH)_3CH_3N^+$, probably forms no complexes with citrate or malate anions.

(5) The cation-sensitive glass electrode does not respond to $(CH_3OH)_3CH_3N^+$.

(6) To maintain the ionic strength of the standard and test solutions equal and constant, a high buffer concentration is employed.

Malic acid has $pK_1 = 3{\cdot}62$ and $pK_2 = 4{\cdot}68$.[3] Thus, similar considerations apply to the system:

$$M^+ + A^{2-} \rightleftharpoons MA^-, \quad K_f = \frac{[MA^-]}{[M^+][A^{2-}]} \tag{2}$$

where M^+ is the alkali metal and A^{2-} is the malate anion. The same buffer was used to study the 1:1 malate complex, MA^-, which is assumed to be the predominant species formed.

Effect of pH

For the sodium-citrate system, a pH change from 8·30 to 8·01, over a concentration range of initial citrate concentrations from 0·1 to 0·3*M*, results in a change of $K_f = 1{\cdot}0$. At constant pH 8·00, a change in citrate concentrations from 0·1 to 0·3*M* results in a K_f change of only 0·2 (see Table I). This small change probably arises from unavoidable ionic strength variations as the ratio of buffer and ligand to metal ion is changed. It is clear, therefore, that while high buffer concentrations provide adequate control over ionic strength changes, rigid maintenance of constant pH values in all solutions is critical.

TABLE I.—EFFECT OF pH ON FORMATION CONSTANTS

System	Initial salt and acid concn., *M*	pH	K_f, *ml/meq*
NaCl + citric acid	0·1	8·30	5·0 ± 0·1
	0·2	8·17	4·3 ± 0·1
	0·3	8·01	4·0 ± 0·1
	0·1	8·00	4·2 ± 0·1
	0·2	8·00	4·1 ± 0·1
	0·3	8·00	4·0 ± 0·1
NaCl + malic acid	0·05	8·48	2·0 ± 0·2
	0·1	8·38	1·9 ± 0·1
	0·2	8·30	1·6 ± 0·1
	0·3	8·20	1·6 ± 0·1

Ratio of metal to ligand

The effect of changes in the ratio of metal ion to ligand concentration was tested over the range of initial sodium and citrate concentrations of 0·1 to 0·3*M*. Experiments carried out at pH 8·00 and constant ionic strength are summarised in Table II. Essentially, constant formation-constant values are obtained at equal metal ion and ligand concentrations, thus confirming the formation of a 1:1 complex.

TABLE II.—RATIO OF METAL ION TO LIGAND

NaCl + citric acid (pH 8·00 constant)

Initial salt and acid concn. *M*	K_{f_1}	K_{f_2}	K_{f_3}, *ml/meq*
0·1	4·2	10·9	16·8
0·2	4·1	7·7	10·4
0·3	4·0	6·1	7·8

Formation constants for the citrate and malate complexes

Formation constants for the alkali metal-citrate complex, MA^{2-}, at constant initial metal and salt concentration of $0{\cdot}1M$ and pH 8·30 ± 0·01, and for the malate complex, MA^{-}, at $0{\cdot}1M$ concentration and pH 8·35 ± 0·01, are summarised in Tables III and IV respectively. Both forward- and back-titration values agree for these complexes. The K_f values for malate complexes of sodium and caesium agree within ±0·05 with those obtained by Erickson and Denbo,[2] and represent considerable improvement over values reported in our first paper.[1] Formation constant values for alkali metal-citrate complexes have not been previously reported in the literature. It is interesting to note that the magnitudes of K_f-values for both citrate and malate complexes depend on the alkali metal ion involved, and follows the trend $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$ predicted by the trend in charge metal ion radius ratios.[2]

TABLE III.—FORMATION CONSTANTS OF ALKALI METAL-CITRATES

CsA^-	0·1	8·35	0·7 ± 0·1

CONCLUSION

Because the potential values measured by the glass electrodes are used only as reference points to indicate when the activities of alkali metal ion in the standard and test solutions are identical, possible errors from electrode drift or temperature effects are of no consequence. In fact, the method does not even require that the electrode shows Nernstian behaviour. Dilution errors and ionic strength changes are reduced to a minimum by the use of concentrated titrants and high buffer concentrations. The accuracy with which formation constants can be determined depends, therefore, primarily on the limitations of the titrimetric technique employed. A real limit is imposed, however, by the response of the glass electrode to hydrogen ions in regions of $pH < 5$.

The potential comparison method can be used to determine formation constants of any weak complex of alkali metal cations with organic acids, if proper precautions are taken to eliminate interfering species, control pH, and maintain ionic strength. Complexes of bivalent cations should be amenable to this method when the phosphate glass electrodes of Truesdell and Pommer[5] or similar specific-ion electrodes become more widely available.

Acknowledgement—The financial support of NIH grant GM 10086–02 is gratefully acknowledged.

Zusammenfassung—Bildungskonstanten von Alkalimetallkomplexen mit Zitronen- und Apfelsäure wurden mittels kationenempfindlicher Glaselektroden gemessen. Eine Potentialvergleichsmethode wurde als geeignet befunden, um die Zuverlässigkeit und Genauigkeit solcher Messungen zu steigern. Die Bildungskonstanten der Malatkomplexe stimmen gut mit Literaturwerten überein; entsprechende Werte für Citratkomplexe waren bisher nicht publiziert.

Résumé—Les constantes de formation de complexes métal alcalin-citrate et -malate ont été estimées au moyen d'électrodes de verre catio-sensibles. On a trouvé que l'emploi d'une méthode de comparaison de potentiel est avantageuse, car elle améliore la sûrete et la précision de telles mesures. Les constantes de formation des complexes métal alcalin-malate sont en bon accord avec les données de la littérature; les valeurs correspondantes des complexes citriques n'ont pas été publiées antérieurement.

PHOTOMETRIC TITRATIONS—IX*

DTPA TITRATION OF ZINC IN PRESENCE OF CADMIUM AND OTHER METALS

H. Flaschka and J. Butcher
School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia, U.S.A.

(*Received* 17 *February* 1964. *Accepted* 7 *April* 1964)

Summary—Zinc can be titrated in the presence of large amounts of cadmium in the following manner. The sample is neutralised and buffered to pH 5·0 with an acetate buffer. Potassium iodide (up to about 60% *w/v*, depending on cadmium concentration) and Xylenol Orange as indicator are added and the titration is performed photometrically at about 570 mμ with DTPA as titrant. Correct results have been obtained with Cd/Zn mole ratios up to 3300. Interferences and tolerable limits of concentrations of some other metal ions have been investigated.

Masking by means of the formation of soluble complexes is the most convenient and practical method of eliminating interferences in chelometric titrations. Generally, moderate concentrations of ligands which form highly stable complexes are preferred. Thus, 1:1 complexes, whose stabilities are enhanced by the chelate effect, or 1:n complexes of very high stabilities are usually employed. There are only a few exceptions where high concentrations of ligands which form rather weak 1:n complexes have been used. The most notable example is the masking of thorium *via* the formation of sulphato complexes[1] (log $K_{Th(SO_4)_2}$ = 5·6.)[2]

It seemed of interest to investigate more closely the possibilities of "low stability masking" and, as a first result, the masking of cadmium with iodide was achieved.[3] That investigation revealed that cadmium can be successfully masked by high concentrations of iodide (*ca.* 5*M*) against reaction with some chelons and metallochromic indicators. Zinc is little affected by iodide, and can be titrated at pH 5 in the presence of cadmium to a visual end-point with Xylenol Orange as indicator. The application of the method is limited, however, in that only rather small amounts of lead, copper, calcium and magnesium can be tolerated and that the deterioration of the quality of the end-point with increasing cadmium concentration sets the maximum Cd/Zn mole ratio at about 300. A photometric technique should allow end-point detection over a more extended range than the visual method and has therefore been applied to the system.

EXPERIMENTAL

The absorbance curves of Xylenol Orange and its zinc and cadmium complexes at pH 5·0 are shown in Fig. 1. In solutions containing 10 or more per cent *w/v* of potassium iodide, the cadmium-Xylenol Orange complex is essentially completely dissociated. The maximum absorbance difference between the zinc-Xylenol Orange complex and the free indicator occurs at about 572 mμ.

Some preliminary experiments indicated that zinc could be successfully titrated with EDTA to a photometric end-point in the presence of up to about a 3000-fold excess of cadmium. With much cadmium present, however, prolonged drift of the galvanometer implied that the titration reaction was quite slow. Neither addition of ethanol or acetone nor changing the concentrations of buffer,

---

* Part VIII: *Mikrochim. Ichnoanalyt. Acta*, in the press.

dye or iodide improved the situation. Other chelons were therefore investigated as titrants for the method and DTPA (diethylenetrinitrilopenta-acetic acid) was found to be satisfactory. With DTPA as titrant, the titration reaction is fast except near the end-point; there, however, because of the extrapolative nature of the method, no data are needed. It also proved possible to titrate zinc in the presence of large excesses of cadmium despite the fact that the DTPA complex of cadmium is more stable than that of zinc ($\log K_{CdY} = 19{\cdot}0$, $\log K_{ZnY} = 18{\cdot}0$),[3] a situation less favourable than in the case of EDTA ($\log K_{CdY} = \log K_{ZnY} = 16{\cdot}5$).[3]

Below pH 5, the degree of dissociation of the zinc-Xylenol Orange complex increases rapidly with decreasing pH. Only slightly above pH 5, the rate of the titration reaction slows considerably and, in high concentrations of potassium iodide, the indicator begins to change to its red form whose absorbance curve is very similar to that of the zinc Xylenol Orange complex. A pH of 5·0 was therefore selected for the titration. A Xylenol Orange concentration of 0·01 mg/ml in the titration solution was found to be satisfactory.

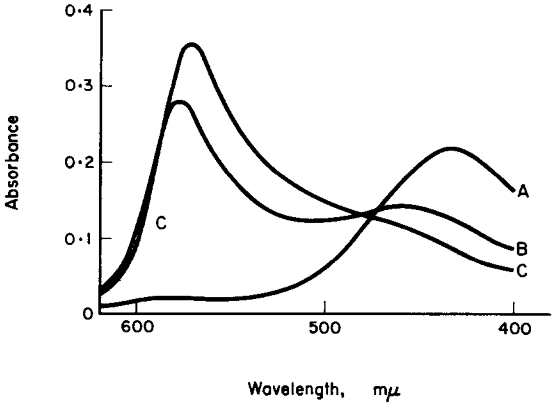

FIG. 1.—Absorbance curves of Xylenol Orange (XO) and its zinc and cadmium complexes at pH 5:

A: free XO,
B: XO + excess Cd,
C: XO + excess Zn.

Reagents

All reagents were of the highest available purity except potassium iodide, for which U.S.P. grade was found to be adequate. Only de-ionised water was used. A 0·1000*M* zinc solution was prepared by dissolving 6·358 g of zinc metal (99·99% purity) in nitric acid and diluting to 1 litre. Approximately 0·1*M* DTPA was obtained by suspending 39·3 g of the acid in water, adding sufficient sodium hydroxide to bring about dissolution and diluting to 1 litre. This solution was standardised *versus* the zinc solution at pH 5 with Xylenol Orange as indicator. $10^{-3}M$ DTPA and $5 \times 10^{-4}M$ zinc solutions were prepared by appropriate dilution of the respective stock solutions. An acetate buffer of pH 5·0 was obtained by dissolving 68 g of sodium acetate trihydrate in about 700 ml of water, adjusting the pH to 5·00 with concentrated hydrochloric acid and diluting to 1 litre. The indicator solution consisted of 50 mg of Xylenol Orange dissolved in 10 ml of water. Potassium iodide solution, 100% *w*/*v*, was prepared by dissolving 250 g of U.S.P. grade potassium iodide in sufficient hot water to make about 240 ml, filtering the hot solution, cooling and diluting to 250 ml. The indicator and DTPA solutions were stored in polyethylene bottles.

Apparatus

The phototitrator described by Flaschka and Sawyer[4] was employed with a glass heat filter mounted in the light path.[5] An interference filter with a nominal wavelength of 568 mμ was used. All titrations were performed in a glass cell of 2-cm light path and 60-ml capacity.

Procedure

Accurately measured amounts of metal solutions were delivered into the titration cell; the resulting solution was neutralised when necessary. About 5 ml of buffer and 10–25 ml of potassium iodide solution were added. The solution was then diluted to about 40 ml, the cell placed in the phototitrator and the latter adjusted to indicate a transmittance of 105–110%. Two drops of indicator solution were added and the titration was performed in the usual manner, using $10^{-3}M$ DTPA as titrant.

RESULTS AND DISCUSSION

The results of several titrations of zinc, alone and in the presence of cadmium and some other metals, are presented in Table I. The tendency to positive errors with increasing amounts of cadmium is probably because of trace impurities, most likely zinc, in the cadmium used.

With increasing amounts of cadmium present, the titration curve degenerates, as indicated in Fig. 2. Solutions with a Cd/Zn ratio of 3300 could, however, be successfully titrated in contrast to the visual method in which the maximum ratio was about 300.

With the photometric end-point, the situation with regard to other interferences also improves considerably. Calcium and lead can be tolerated in greater than a 600-fold molar excess. Magnesium was tested up to 3000-fold excess and even higher amounts should not interfere. Mercury is masked completely by iodide and does not interfere when present in any reasonable amount. A Cu/Zn mole ratio of about 200

C: Cd/Zn = 3300.

can be tolerated. Aluminium, if masked by Tiron, can be present in about 20-fold excess; chromium and bismuth can be tolerated to about the same extent. The addition of tartrate (*ca.* 0·05*M*) does not interfere, but does not materially aid in the masking of bismuth.

Cobalt, iron^{II}, manganese, nickel and vanadate interfere by complete or partial cotitration. Iron^{III} blocks the indicator. Gallium and indium appear to cotitrate, even in the presence of tartrate; the indium interference is not removed by chloride.

Acknowledgment—This work was supported by a grant from the National Science Foundation, which aid is most gratefully acknowledged.

Zusammenfassung—Zink kann in Gegenwart beträchtlicher Mengen an Kadmium in folgender Weise titriert werden. Die Probelösung wird neutralisiert und mit einem Azetatpuffer von pH 5 versetzt. Kaliumjodid (bis zu 60 g per 100 ml, je nach der Kadmium-Konzentration) und Xylenolorange-Indikator werden zugegeben und die Titration wird sodann in üblicher Art durchgeführt. Es wird bei 570 mμ gearbeitet; DTPE dient als Titrationsmittel. Korrekte Ergebnisse werden bis zu einem Cd/Zn Molverhältnis von etwa 3300 erhalten. Störungen und erlaubte Konzentrationen einiger anderer Metallionen wurden untersucht.

Résumé—On peut doser le zinc en présence de grandes quantités de cadmium de la façon suivante. L'èchantillon est neutralisé et tamponné à pH 5,0 avec un tampon à l'acétate. On ajoute de l'iodure de potassium (jusqu'à environ 60 % poids/volume, en fonction de la concentration en cadmium) et de l'indicateur xylénol orange, et le dosage est mené photométriquement, à environ 570 mμ, au moyen de DTPA. On a obtenu des résultats corrects avec des rapports molaires Cd/Zn atteignant 3300. On a étudié les interférences et les limites de concentration tolérables de quelques autres ions métalliques.

ANALYTICAL USES OF BROMANILIC ACID

R. B. HAHN, P. T. JOSEPH* and G. G. SALCICCIOLI
Department of Chemistry, Wayne State University
Detroit 2, Michigan

(*Received* 21 *February* 1964; *Accepted* 10 *March* 1964)

Summary—Bromanilic acid (2,5-dibromo-3,6-dihydroxyquinone) precipitates barium, calcium and strontium quantitatively from weakly acid solution, and forms a coloured complex with zirconyl ions in perchloric acid solution. The complex exhibits maximum absorbance at a wavelength of 335 mμ. Beer's law is obeyed in the range from 0·0 to 3·5 ppm of zirconium. Optimum results are obtained in solutions 2·8*M* in perchloric acid. The effect of various diverse ions has been investigated. Hafnium gives results identical with zirconium. Other interfering ions are Fe^{III}, Th^{IV}, UO_2^{II}, Ti^{IV}, phosphate, oxalate, fluoride and sulphate. Errors caused by varying amounts of these ions have been determined. A procedure for the determination of zirconium is given. Bromanilic acid is a more sensitive reagent than chloranilic acid for the determination of zirconium, and can be used over a slightly greater range.

INTRODUCTION

CHLORANILIC acid has been used as a reagent for the determination of calcium,[6,14,18] strontium[14] and barium.[6,17] The corresponding bromo-compound, bromanilic acid (2,5-dibromo-3,6-dihydroxy-1,4-benzoquinone), has not received much attention as an analytical reagent, and therefore has been studied in the hope of finding a reagent more sensitive and more selective than chloranilic acid.

Precipitation of barium, calcium and strontium

In the determination of calcium, strontium and barium[6,14,17] with chloranilic acid a known excess of the reagent is added. This forms a precipitate with the above ions, and the excess is then measured colorimetrically. The method is limited in usefulness because many cations interfere. The reaction of bromanilic acid with these ions has been studied.

Ultraviolet spectrophotometric determination of zirconium

Many reagents have been used for the colorimetric determination of zirconium.[2,4,5,8,13,15,16] One of the most sensitive is chloranilic acid, investigated by Thamer and Voigt,[17] who showed that low concentrations of zirconium (2×10^{-6}–$5 \times 10^{-5}M$) could be determined with accuracies within 1%. The zirconium chloranilate complex shows maximum absorbance in the ultraviolet region at 330 mμ. Frost-Jones and Yardley[6] measured the absorbance of the same complex at 525 mμ and obtained results similar to those of Thamer and Voigt, but the sensitivity was less at 525 mμ than at 330 mμ. The present investigation examined bromanilic acid to find if it could be used for the spectrophotometric determination of small amounts of zirconium.

* Present address: S. N. College, Quilon, Kerala, India.

EXPERIMENTAL

Apparatus

Absorbance measurements were made with a Beckman Model DU Spectrophotometer using 1·000-cm quartz cells.

Synthesis of reagent

Bromanilic acid was prepared from *p*-phenylenediamine, which was brominated, and oxidised with nitric acid to form bromanil. This was hydrolysed to form bromanilic acid. Procedures are given in the literature.[8,10,12]

Analysis of the purified compound gave the following: found: C, 24·07; H, 0·69; Br, 53·61; calculated for $C_6H_2O_4Br_2$: C, 24·16; H, 0·67; Br, 53·69. Bromanilic acid is a dark-red crystalline powder which dissolves to the extent of 1·5 g per litre in water to give a deep-red solution.

Solutions

Bromanilic acid: saturated aqueous and $2 \times 10^{-4}M$: 0·080 g of bromanilic acid was dissolved in 1 litre of distilled water to prepare the $2 \times 10^{-4}M$ solution.

Ammonium chloranilate: 5·0 g of bromanilic acid were dissolved in the calculated amount of dilute aqueous ammonia and diluted to 1 litre with water.

Zirconium perchlorate: 0·353 g of pure recrystallised zirconyl chloride octahydrate was dissolved in 235 ml of 72% perchloric acid (G. Frederick Smith Chemical Company) and then fumed to expel all hydrochloric acid. The product was cooled, and diluted to 1 litre with water, making a solution containing 0·1 mg of zirconium per ml. A second solution, $2 \times 10^{-4}M$ in zirconium and $2{\cdot}8M$ in perchloric acid, was prepared in a similar manner using 0·064 g of zirconyl chloride and 235 ml of 72% perchloric acid and diluting to 1 litre.

Hafnium perchlorate: 0·157 g of hafnium tetramandelate was heated to fumes with 5 ml of concentrated nitric acid and 5 ml of 72% perchloric acid. The residue was dissolved in 230 ml of 72% perchloric acid, and diluted to 1 litre with distilled water. The resulting solution was $2 \times 10^{-4}M$ in hafnium and $2{\cdot}8M$ in perchloric acid.

Other perchlorates, used in interference studies, were obtained from the G. Frederick Smith Chemical Company, U.S.A.

Procedures

Calcium, strontium and barium: Standard solutions of the nitrates were prepared by taking a known amount and diluting to 25 ml with distilled water. The solutions were heated to approximately 90°, and to each were added 40 ml of a 0·5% solution of ammonium bromanilate, dropwise, with stirring. (Ammonium bromanilate was used as precipitant because it is more soluble than the free acid.)

The precipitates were allowed to settle for about 15 min, and were then transferred to sintered-glass filters, dried for about 2 hr at 110°, and weighed.

General: A saturated aqueous solution of the reagent was added to solutions of various cations and anions.

RESULTS AND DISCUSSION

Calcium, strontium and barium: The results of the precipitations are given in Table I. In calculating the theoretical weights of the precipitates it was assumed that 1 ion of alkaline earth metal combines with 1 bromanilate ion to give compounds such as $CaC_6O_4Br_2$.

No further gravimetric studies were made, because many other cations form precipitates with the reagent (see next section), thereby limiting its usefulness.

General: In neutral or weakly acid solution precipitates were formed with the following: Ag^{I}, Hg_2^{II}, Hg^{II}, Pb^{II}, Bi^{III}, Cu^{II}, Cd^{II}, Sb^{III}, Sn^{II}, Mn^{II}, Zn^{II}, Ni^{II}, Co^{II}, Ca^{II}, Sr^{II}, Ba^{II}.

In strongly acid solution no precipitates were formed, but the following gave coloured solutions: Fe^{II}, Fe^{III}, Zr^{IV}, Hf^{IV}, Ti^{IV}, Th^{IV}, UO_2^{II}. The complexes of Ti^{IV}, Th^{IV} and UO_2^{II} were much lighter in colour than those formed with Fe, Zr and Hf.

On the basis of these tests it was decided that it would be useful to investigate

TABLE I.—PRECIPITATION OF BARIUM, STRONTIUM, AND CALCIUM BROMANILATE

further the use of the reagent for the colorimetric determination of zirconium and hafnium.

Investigation of the zirconium-bromanilate complex

Job's method[11] of continuous variations, and the subsequent study made by Vosburgh and Cooper,[19] served to determine the nature of the complex formed by zirconium and bromanilic acid. A series of solutions was prepared in which the sum

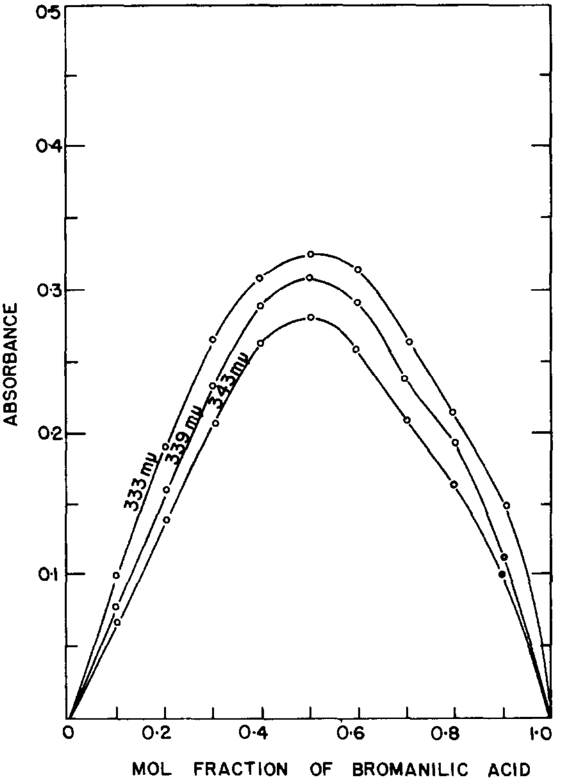

FIG. 1.—Identification of the zirconium bromanilate complex.

of the concentrations of the two reactants (zirconium perchlorate and bromanilic acid) was kept constant at 1·0 × $10^{-4}M$ but their ratio was changed. The concentration of perchloric acid was kept constant at 2·8*M*. The difference in absorbance between the measured values and those values that would have been observed at the same wavelength in case of no reaction was calculated according to the method of Vosburgh and Cooper. Fig. 1 shows this absorbance as a function of the ratio of the reactants at three selected wavelengths. Because a definite maximum was observed at $x = 5$ ($x/10$ = fraction of bromanilic acid), the formation of a 1:1 complex between zirconium and bromanilic acid was indicated. The shoulders on the right of the curves (Fig. 1) indicate that one or more higher complexes may be present to some extent, but this does not alter the usefulness of the method. Fig. 2 gives the absorption spectra of $2 \times 10^{-4}M$ bromanilic acid, and of solutions $1 \times 10^{-4}M$ in zirconium or in hafnium and $2{\cdot}8M$ in perchloric acid containing excess bromanilic acid.

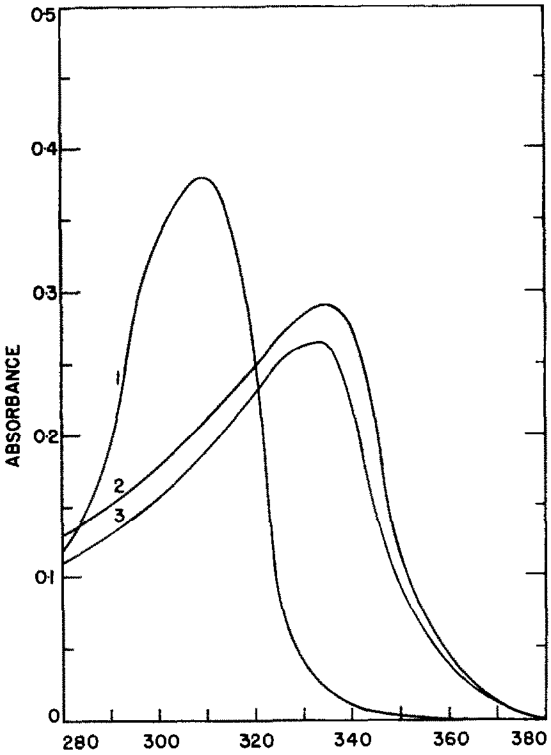

FIG. 2.—Absorption spectra:
1—bromanilic acid; 2—zirconium bromanilate complex;
3—hafnium bromanilate complex.

Solutions containing zirconium bromanilate complex at the concentrations used in the above experiments were stable, forming no precipitate even after several days. In solutions greater than $2 \times 10^{-2}M$ in zirconium a light blue precipitate formed on standing.

Hafnium perchlorate solution ($2 \times 10^{-4}M$) behaved in the same manner as the zirconium perchlorate solution. The absorbance maximum for the hafnium bromanilate complex occurred at the same wavelength as that for zirconium bromanilate complex.

Conformity to Beer's law

Bromanilic acid solution (15 ml of $2 \times 10^{-4}M$) was added to each of a number of 100-ml volumetric flasks. Standard zirconium perchlorate solution was then added in definite amounts varying from 0·05 to 0·60 mg of zirconium. Enough perchloric acid and distilled water were then added to make up 100 ml of solution which was 1*M* in perchloric acid. Absorbance measurements were made at wavelengths of 335 and 340 mμ as shown in Fig. 3. The reference solution consisted of $2 \times 10^{-4}M$ bromanilic acid in 2·8*M* perchloric acid. The wavelength of 335 mμ is recommended, because at this value the complex has its maximum absorbance and bromanilic acid has negligible absorbance.

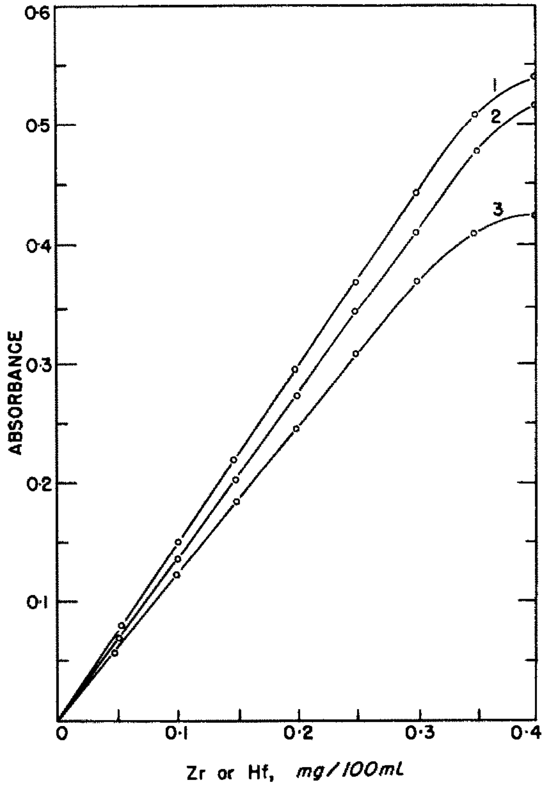

FIG. 3.—Standard curves for zirconium and hafnium:
1—zirconium at 335 mμ;
2—zirconium at 340 mμ;
3—hafnium at 335 mμ.

The standard curves shown in Fig. 3 indicate conformity to Beer's law in the concentration range 0·0–0·35 mg of zirconium in 100 ml. This covers a slightly greater range then chloranilic acid.[16]

The hafnium solutions also obeyed Beer's law (Fig. 3). Therefore, it is not possible to differentiate between zirconium and hafnium with this reagent and the method gives the sum of these two elements.

Effect of acid concentration

Bromanilic acid in water gives a purple colour which is quenched by addition of perchloric acid, hence the effect of varying the concentration of perchloric acid upon the absorbance of the complex was investigated. Consistent results were obtained in solutions 2·5*M*–3·5*M* in perchloric acid. High results are obtained in solutions less than 2*M* in acid and low results in solutions greater than 3·5*M*.

Effect of time

After mixing of the zirconium solution with the bromanilic acid reagent 15 min of standing were found to be sufficient to obtain accurate results. The absorbance did not change, even after 24 hr.

Table II.—Effect of diverse ions

		50	13·2
		100	20·2

Effect of diverse ions

To study the interference of diverse ions, absorbance measurements were made at 335 and 340 mμ on solutions containing 2 mg of zirconium per litre and varying concentrations of the diverse ion. Those ions that caused interference in the determination of zirconium are listed in Table II. Al^{III}, Ca^{II} and alkali metals showed no interference even when present in five-fold excess. Similarly, chloride, nitrate and acetate ions, added as sodium salts, showed no interference in this concentration.

Recommended general procedure

Bring the sample into solution by a suitable procedure. Add a measured excess of 72% perchloric acid, and evaporate down to copious fumes. Cool and dilute with water, then take an aliquot which does not contain more than 0·35 mg of zirconium. Transfer to a 100-ml volumetric flask, and add 15 ml of $2 \times 10^{-4}M$ bromanilic acid and sufficient 72% perchloric acid to make the final solution 2·8M in perchloric acid upon dilution. Shake and set aside for 15 min. Measure the absorbance at 335 mμ in 1·000-cm quartz cells, and determine the amount of zirconium from a standard curve.

Zusammenfassung—Bromanilsäure, 2,5-Dibromo-3,6-dihydroxychinon, fällt Barium, Calcium und Strontium quantitativ aus schwach saurer Lösung und bildet in überchlorsaurer Lösung mit Zirkonylionen einen farbigen Komplex mit einem Absorptionsmaximum bei 335 mμ. Das Beersche Gesetz gilt zwischen 0,0 und 3,5 ppm Zirkonium. Die besten Ergebnisse erzielt man in 2,8 m Überchlorsäurelösung. Der Effekt verschiedener Fremdionen wurde untersucht. Hafnium gibt dieselben Ergbnisse wie Zirkonium. Ferner stören Eisen(III), Thorium (IV), UO_2^{2+}, Ti(IV), Phosphat, Oxalat, Fluorid und Sulfat. Die durch verschiedene Mengen dieser Ionen verursachten Fehler wurden ermittelt. Eine Arbeitsvorschrift zur Zirkonbestimmung wird angegeben. Bromanilsäure ist empfindlicher bei der Zirkonbestimmung als Chloranilsäure und ist in etwas größeren Bereich anwendbar.

Résumé—L'acide bromanilique, ou 2,5-dibromo-3,6 dihydroxyquinone, précipite quantitativement le baryum, le calcium et le strontium à partir de solutions faiblement acides, et forme un complexe coloré avec les ions zirconyle en solution perchlorique. Le complexe présente un maximum d'absorption à 335 mμ. La lio de Beer est respectée entre 0,0 et 3,5 p.p.m. de zirconium. Les résultats optimaux sont obtenus dans solutions 2,8 M en acide perchlorique. L'influence de divers ions a été étudiée. Le hafnium donne des résultats identiques au zirconium. Les autres ions interférants sone Fe(III), Th(IV), UO_2(II), Ti(IV), phosphate, oxalate, fluorure et sulfate. On a déterminé les erreurs causées par des quantités variables de ces ions. On donne une technique de dosage du zirconium. Pour le dosage du zirconium, l'acide bromanilique est un réactif plus sensible que l'acide chloranilique, et il peut être utilisé dans un intervalle légèrement plus grand.

THE DETERMINATION OF ESTER GROUPS BY ETHANOLYSIS

C. HEITLER
Northampton College of Advanced Technology, St. John Street,
London E.C.1, England

(*Received* 2 *March* 1964. *Accepted* 23 *March* 1964)

Summary—Changes in boiling point, following the ethanolysis of an ester, give information about the number of ester groups present per molecule, the saponification equivalent, and, in the case of a polymeric ester, the degree of polymerisation. Methods of calculating the results are discussed and illustrative results are presented. The method is simple and rapid to apply. It yields results of only moderate accuracy, which, are however, sufficient for many purposes.

THEORY

WHEN an ester is dissolved in a large excess of boiling ethanol in the presence of a basic catalyst (*e.g.*, sodium ethoxide), ethanolysis proceeds to completion.[1-3] The examples to be considered are:

(i) $A(O{\cdot}CO{\cdot}R)_n + n\,EtOH \rightarrow A(OH)_n) + n\,RCO{\cdot}OEt$;

(ii) $R(CO{\cdot}OA)_n + n\,EtOH \rightarrow R(CO{\cdot}OEt)_n + n\,A(OH)$;

(iii) $HO(AO{\cdot}CO{\cdot}RCO{\cdot}O)_nA{\cdot}OH + 2n\,EtOH \rightarrow (n + 1)\,A(OH)_2 + n\,R(CO{\cdot}OEt)_2$.

All the solutions are considered to be sufficiently dilute to allow the change in the concentration of uncombined ethanol to be neglected.

Equations (i) and (ii) represent the ethanolysis of esters formed by the combination of a monobasic acid with an n-functional alcohol, and a polybasic acid with a monohydric alcohol, respectively. Equation (iii) is the reaction between ethanol and a polymer formed from a dihydric alcohol and a dibasic acid. Disregarding the ethanol molecules, the changes particularly attendant upon these reactions are: in cases (i) and (ii) from 1 to $n + 1$, and in the third example from 1 to $2n + 1$.

When these reactions are allowed to take place in an ebulliometer, the boiling point elevations before and after the reactions will be in the above ratios (the ethanol content may be regarded as sensibly constant). It is assumed that the original ester, the liberated alcohol and the ethyl esters are all non-volatile relative to ethanol. Thus, in principle, a method is provided for counting the number of ester groups per molecule. Because solutions of esters with molecular weights higher than *ca.* 700 are frequently non-ideal, and the elevations observed are subject to an apparent systematic zero error, the detailed calculations in individual cases are not always straightforward. These calculations are dealt with in the following sections.

RESULTS AND DISCUSSION

The symbols employed have the following meanings:

w = weight of original ester added to ebulliometer;

T_o = initial boiling point elevation;

T_f = elevation after ethanolysis;

K = ebulliometric constant for the appropriate volume of ethanol or other solvent;
M_{T_0} = molecular weight calculated from initial elevation;
M_s = molecular weight calculated from the slope of the linear part of the graph of elevation *vs.* w (in ethanol or other solvents);
M_n = molecular weight calculated by assuming that the number of ester groups per molecule is known;
n = number of ester groups per molecule;
S_e = saponification equivalent of ester found ebulliometrically;
S_h = saponification equivalent found by hydrolysis with KOH followed by back titration of the excess alkali.

Three sets of results are presented. The first two illustrate the general applicability of the method and the accuracy attainable. A number of glycerides and edible fats were investigated because methods for their characterisation are well-known and are available for comparison. Moreover, these mixtures are peculiarly subject to the errors inherent in ebulliometry. The results provide an opportunity for discussing the critical treatment of data of this kind. The third set of results illustrates the application of the method to a polymeric material, a field in which it may prove to have most usefulness.

Table I illustrates the dependence of w/T_0 on concentration, and the correction achieved by employing Kw/M_s in place of T_0. The variation of w/T_0 for the higher triglycerides arises from a number of factors, the two most important being association (which does not occur in acetone), and an error arising from their surface activity, which will be the subject of a separate publication. The fact that w/T_f is

[a] Determined in acetone. [b] Ester added to sodium ethoxide solution.

independent of concentration indicates that the low molecular weight ethyl esters and the glycerol are producing almost ideal boiling point elevations. This is also shown by the relative constancy of M_n and its agreement with M_s. In Table I the following relationships have been employed:

$$n = (T_f M_s/Kw) - 1;$$

$$M_n = (n + 1)Kw/T_f \text{ (assuming } n \text{ to be known, } e.g., \text{ 3 for the triglycerides);}$$

$$S_e = Kw/(T_f - Kw/M_s).$$

Table II contains a similar set of figures obtained for a series of edible fats. The somewhat low figures for n probably result from the presence of unsaponifiable material, including any free fatty acid; 1% of free acid would result in 0·1 units change in n. The acid and any other unsaponifiable material will increase T_0 without having a proportional effect on T_f. Because the free acids have a molecular weight about one third that of the glyceride, 1% by weight is equivalent to 3 moles %, or a 3% increase in T_0 relative to T_f, hence a 0·1-unit change in n. Figures for the free acidity are given in Column 5. The standard deviation, $\pm\sqrt{\delta/n - 1}$, between S_e and S_h for all the results in Tables I and II is ±2·0%, and in each case n provides an unambiguous count of the number of ester groups per molecule.

Hardened Palm Kernel Oil	674	2·94	229	231	1·0
Extracoa	680	2·87	237	227	0·2

In Table III are collected a number of results obtained for samples of polydiethylene adipate. The formula for these polymers was given as:

$$HO{\cdot}(CH_2)_2O{\cdot}(CH_2)_2[O{\cdot}CO{\cdot}(CH_2)_4CO\ (CH_2)_2O(CH_2)_2]_nOH$$

so that $M = 216n + 106$, and could be calculated if n (the degree of polymerisation) were known. The number of moles of product formed per mole of polymer is $2n + 1$, hence:

$$T_f/T_0 = 2n + 1 \quad \text{and} \quad (T_f - T_0)/2T_0 = n$$

Thus, it is possible to find n and M without weighing the sample. For this series of polymers the systematic error in boiling point referred to in the theoretical section amounted to 0·008° (calculated from resistance changes, which are the actual measurements made), which must be deducted from the observed values of T_0; when these are thus corrected they give the figures for n in Column 1. Column 2 lists M_n, the molecular weight calculated from the degree of polymerisation.

T_f is related to the molecular weight and n by the equation:

$$T_f = (2n + 1)Kw/M.$$

Therefore $Kw/T_f = M/(2n + 1) = (216n + 106)/(2n + 1)$. This quantity varies between 107·6 for $n = 2$ and 108 for $n = 10$; the error involved in assuming that it is constant at 108 is less than the experimental error of the method, hence:

$$K' = T_f(108)/w.$$

This quantity is found in practice to be almost constant. K' measured in this way is higher than K obtained by employing low molecular weight compounds as standards. The polymer molecular weights agree, however, with those found from n; these are listed as M_e in Column 3. In Column 4 are the molecular weights found by chemical assay of the terminal hydroxyl groups.

TABLE III.—ETHANOLYSIS OF POLYDIETHYLENE ADIPATE

n	M_n	M_e	M_{OH}
4·25	1026	1050	1005
6·35	1542	1470	1385
8·0	1830	1820	1875
8·45	1930	1950	2310
9·15	2086	2100	2750

The method is only of moderate accuracy ($r = \pm 2\%$) when compared with conventional techniques. Its principal utility arises from the circumstance that it is both rapid and simple to apply. Thus, in laboratories which are not regularly engaged in the analysis of fats and waxes it permits a quick, if admittedly rough, characterisation, and often the information thus obtained would be sufficiently accurate for many purposes. It may also be employed for the counting or detection of ester groups in substances of unknown structure. Finally, its use in the polyester field may provide alternative and additional information to that available from end-group assay, a method which itself is liable to some uncertainty.

EXPERIMENTAL

The ebulliometer was a commercially available instrument based upon that described by the author.[4] Two ebulliometers were placed in opposite arms of a Wheatstone bridge to compensate for barometric changes.

The essential precaution for obtaining consistent results is the exclusion of moisture. The ethanol used was dried by means of magnesium ethylate,[5] and stored over Hi-Drite, a form of anhydrous calcium sulphate.* The sodium ethoxide was prepared by dissolving 0·5 g of metallic sodium in 20 ml of the dry ethanol. Ten ml of ethanol were used in the ebulliometer, and 1 g of Hi-Drite was added to the solvent; this removed traces of moisture added with the sample and ensured that any water present remained at a low and constant concentration.

Up to five additions of approximately 0·1 g of ester were made and the elevations recorded. If a linear plot of T_0 versus concentration was obtained, the slope was used to calculate M_e. When curvature persisted, M_e was found in another solvent.

The ethoxide was introduced by collecting a drop on a platinum spiral attached to a glass rod, and immersing the spiral in the boiling solution. Usually 3 drops were added, and this was sufficient to bring the reaction to completion within 20 min. When the reading on the galvanometer had remained constant for 5 min it was assumed that the reaction was complete, and T was recorded. A further 3 drops of ethoxide solution were then added, and the small elevation deducted from that previously recorded. (This correction never amounted to more than 2% of the total elevation.)

Acknowledgement—The results quoted in Table II are based on results obtained by G. M. Pierce, Dip.Tech., as part of a project carried out in this department. The fats were kindly supplied by Messrs. J. S. Fry and Sons Ltd., Sommerdale, Bristol, England.

Zusammenfassung—Die Änderung des Siedepunkts nach Äthanolyse eines Esters liefert Informationen über die Anzahl von Estergruppen in einem Molekül, das Verseifungsäquivalent und im Fall eines polymeren Esters über den Polymerisationsgrad. Methoden zur Berechnung der Ergebnisse werden diskutiert und zur Illustration einige Ergebnisse angegeben.

Résumé—Les variations de point d'ébullition qui résultent de l'éthanolyse d'un ester donnent des renseignements sur le nombre de groupes ester présents dans la molécule, sur l'équivalent de saponification et, dans le cas d'un ester polymère, sur le degré de polymérisation. On discute des méthodes de calcul des résultats et on présente des résultats à titre démonstratif.

SHORT COMMUNICATION

Lead tetra-acetate in anhydrous acetic acid as an oxidising agent

(*Received* 11 *February* 1964. *Accepted* 27 *April* 1964)

EARLIER investigations[1] of oxidation-reduction titrations in acetic acid medium have been extended to an examination of reactions of lead tetra-acetate, which are described in the present communication. Lead^{IV} was first employed in the inorganic field by Tomiček *et al.*,[2] and quite recently[3] a kinetic study of the oxidation of Co^{II}, Ce^{III} and Mn^{II} acetates has been carried out.

EXPERIMENTAL

Reagents

Stock solution of Pb^{IV}: An 0·05*M* lead tetra-acetate solution was prepared by dissolving in glacial acetic acid the salt obtained by the method of Bailar.[4] The concentration was determined iodometrically in aqueous solution.

Reducing agents: Solutions in acetic acid of Na_2SO_3, $Fe(ClO_4)_2$, $AsCl_3$, $SbCl_3$, $Hg_2(ClO_4)_2$, NH_4SCN, all about 0·05*M*, were prepared from chemically pure salts. The solvent used was analytical-reagent acetic acid without further purification. Its content of water is less than 0·3%.

Apparatus

Potentiometric titrations were performed using a Metrohm model E 353 apparatus, fitted with an aqueous calomel cell as reference electrode. This electrode was connected to the titration cell through an aqueous K_2SO_4 saturated agar bridge, one arm of which terminated in an asbestos plug, and was constantly maintained immersed in glacial acetic acid.

The amperometric apparatus was that described previously.[1]

RESULTS

The results of titrations are tabulated in Table I.

Sodium sulphite is easily oxidised in the cold by lead tetra-acetate in the presence of 1*M* sodium acetate, and quantitative results which differ from the theoretical value by less than 1% are obtained. The molar ratio between oxidant and reductant is 1:1. The course of the titration can be followed potentiometrically or amperometrically. In the latter case the curve obtained is characteristic of the titration of an irreversible system with a reversible one. In the absence of sodium acetate the rate of the reaction is extremely low. The reaction does not occur in the presence of perchloric acid.

Iron^{II} perchlorate is easily oxidised by lead tetra-acetate if either sodium acetate or perchloric acid is present; the equivalence point corresponds to the molar ratio $Pb^{IV}:Fe^{II} = 1:2$. By the amperometric method, at a potential difference (ΔE) of 0·3 v, the curve obtained shows that the titration involves a reaction between two reversible systems. The equivalence point determined by either method is in agreement with the theoretical value.

In the presence of sodium acetate, although precautions are taken to avoid the oxidant action of oxygen dissolved in the solvent, the error is relatively high (3%); potentiometrically, a lowering of the oxidation-reduction potential of the system Fe^{III}/Fe^{II} is observed.

The oxidation of *arsenic trichloride* is carried out in anhydrous acetic acid in the presence of perchloric acid. During the titration a turbid solution forms because of the precipitation of lead^{II} chloride. When the molar ratio oxidant:reductant is 1:1, the equivalence point of the titration is reached, according to the equation:

$$Pb^{IV} + AsCl_3 \rightarrow PbCl_2 + As^{V} + Cl^-.$$

Further addition of Pb^{IV} causes the precipitate of $PbCl_2$ to dissolve. With $Pb^{IV}:AsCl_3 = 5:2$ the solution becomes transparent, and the potentiometric curve shows a second jump. The dissolution of $PbCl_2$ during the second part of the titration is the result of oxidation by lead tetra-acetate of Cl^- to Cl_2 according to the reaction:

$$PbCl_2 + Pb^{IV} \rightarrow 2\,Pb^{II} + Cl_2.$$

Table I.—Lead tetra-acetate in the titrimetric determination of some reducing agents

Reducing agent	CH_3COONa, *M*	$HClO_4$, *M*	Taken, *mg*	Found, *mg*	Error *mg*	Error %
SO_3^{2-}	1		8·56	8·56	—	—
	1		8·81	8·80	0·01	−0·1
	1		17·61	17·45	0·16	−0·9
	1		13·20	13·20	—	—
Fe^{2+}	0·1		10·44	10·19	0·25	−2·4
	0·1		8·71	8·48	0·23	−2·6
	0·1		4·36	4·24	0·12	−2·7
		0·7	6·59	6·63	0·04	+0·6
		0·7	13·18	13·40	0·22	+1·6
		0·9	19·77	19·88	0·11	+0·5
As^{3+}	1		4·42	4·35	0·07	−1·6
	1		3·53	3·45	0·08	−2·2
	1		6·18	6·10	0·08	−1·3
		1	2·20	2·20	—	—
		1	4·42	4·44	0·02	+0·4
		1	5·32	5·33	0·01	+0·2
SCN^-	1		18·56	18·27	0·29	−1·5
	1		37·11	36·51	0·40	+1·1
	1		55·67	54·82	0·15	+0·3

At the second equivalence point the presence of elementary chlorine in the solution has been proved by bubbling nitrogen into two containers in series, the first containing the solution under examination and the second a dilute solution of fluorescein and potassium bromide. The formation of red eosin in the latter demonstrates the presence of the molecular halogen in the former. The reaction proceeds more slowly in a warm solution of 1*M* sodium acetate, but the first equivalence point (the only one visible under such conditions) can still be easily determined.

In the amperometric titration, the corresponding curve is characteristic of an irreversible system titrated with a reversible one. During the titration the solution remains transparent on account of the solubility of $PbCl_2$ in the acetic acid added with the 1*M* sodium acetate.

Ammonium thiocyanate can be oxidised by Pb^{IV} in warm, anhydrous acetic acid solution; the reaction is extremely slow but quantitative results are obtained if 1*M* sodium acetate is present. At the equivalence point the molar ratio oxidant:reductant is 3:1. The reaction between Pb^{IV} and SCN^- leads to the formation of CN^- and SO_4^{2-} ions. The sulphate ion, reacting with Pb^{II} from reduction of the Pb^{IV}, forms an easily appreciable precipitate of $PbSO_4$.

The amperometric titration gives a curve characteristic of a titration between an irreversible and a reversible system.

In the presence of perchloric acid the reaction is very slow, and quantitative results cannot be obtained.

Mercurous perchlorate cannot be oxidised, and *antimony trichloride* is oxidised incompletely in perchloric acid solution.

Summary—A systematic study of the oxidation-reduction titration by lead tetra-acetate of various inorganic ions in anhydrous acetic acid medium is described. Na_2SO_3, $Fe(ClO_4)_2$, $AsCl_3$, $SbCl_3$, NH_4SCN and $HgClO_4$, all in the presence either of $HClO_4$ or of CH_3COONa, have been investigated. The reactions were followed by potentiometric and amperometric techniques.

Zusammenfassung—Es wird eine systematische Untersuchung der Redox Reaktion zwischen Blei tetraacetat und Na_2SO_3, $Fe(ClO_4)_2$, $AsCl_3$, $SbCl_3$, NH_4SCN und $HgClO_4$ beschrieben. Der Verlauf der jeweiligen Reaktion, mit $HClO_4$ oder CH_3COONa, wurde potentiometrisch und amperometrisch verfolgt.

Résumé—Une étude systématique a été effectuée sur les titrations redox du acétate plombique en milieu acétique anhydre, avec divers composés minéraux. Les réducteurs Na_2SO_3, $Fe(ClO_4)_2$, $AsCl_3$, $SbCl_3$, NH_4SCN et $HgClO_4$ tous en presence ou de $HClO_4$ ou CH_3 COONa, ont été etudiés. La réduction du l'acétate plombique a été suivie potentiometriquement et amperometriquement.

LETTERS TO THE EDITOR

Nucleation and precipitation of silver chloride solutions

SIR,

Klein, Gordon and Walnut,[1] studying the crystallisation of supersaturated solutions of silver chloride, suggested that de-ionised water from the ion-exchange column they used for purification in some of their experiments contained an impurity which inhibited nucleation, but which was removed, by adsorption, when their solutions were passed through a membrane filter. Nancollas and Purdie[2] have recently compared the results of Klein, Gordon and Walnut with those of Davies and Jones,[3] who used distilled water for their experiments, and they mention the different methods of water purification employed as a possible source of the difference between the critical supersaturation ratios quoted by these authors. We believe, however, that this difference is caused by the other different experimental techniques employed, because even when using distilled water, without filtration, Klein, Gordon and Walnut still find a significantly higher value for the critical supersaturation ratio. We also believe that the effects that Klein, Gordon and Walnut observed in their own experiments are more simply explained on the basis of the known absence from de-ionised water of the nucleating particles present in ordinary distilled water than on the basis of hypothetical impurity in the de-ionised water. Evidence of the difference between these two kinds of water can easily be obtained by passing a light through the two liquids in a darkened room, when no scattered light is visible to the eye from particles in water from a good quality mixed-bed ion-exchange column.[4] We have used this property for preparing particle-free solutions for work with solutions of radioisotopes of very high specific activity which adsorb on to particulate matter in solution.[5]

Klein, Gordon and Walnut[1] showed that nucleation of silver chloride was easier (*i.e.*, took place at lower supersaturation) with the use of laboratory distilled water than with de-ionised or redistilled water which had been filtered through a membrane filter, and easier with such filtered water than with de-ionised water, unfiltered. The difference between unfiltered distilled and unfiltered de-ionised water is explained simply, in our view, by the particle-free nature of the de-ionised water; we suggest that the effect of the membrane filter may have been to bring both kinds of water to the same standard of cleanliness, by removing the particulate matter originally in the distilled water, but also contributing some particles in both cases from adventitious dirt and possibly slight disintegration of the filter material. Thus, the critical supersaturation ratio is virtually the same for either kind of filtered water (1.71–1.74), being higher than the value for distilled water (1.44) and lower than that for de-ionised water (2.04). We have found that it is easy to contaminate water and solutions with particles by the use of a filtration procedure intended to clean them, and such processes should always be monitored by visual observation of scattered light to check that no particles are being introduced from the receiving vessels or the filter material.

The theory that an increased critical supersaturation ratio is an indication of higher purity, rather than of the presence of an "anti-nucleating" impurity, is consistent with other results in this field, such as those of Collins and Leinweber[6] (quoted by Nancollas and Purdie[2]) on the critical supersaturation ratio of barium sulphate.

Klein, Gordon and Walnut[1] showed in support of their theory that the presence of eosin did inhibit silver chloride precipitation in their experiments, but this is not very convincing evidence, in that (*a*) there is no supporting information on the impurity content of their de-ionised water, (*b*) the theory does not explain the difference they observed between unfiltered and filtered distilled water, and (*c*) we have found that eosin adsorbs strongly on a mixed-bed ion-exchange column.

Although it is not easy to disprove the theory that an organic impurity from the resin column caused the effects observed, it is suggested that the known facts about the filtration properties of ion-exchange columns are sufficient to explain all the phenomena observed.

An international language?

SIR,

WOULD it not be a good idea, and in keeping with the international nature of *Talanta*, to accept and encourage articles written in some international language such as Esperanto or Interlingua?

I confess that I know nothing at all about Esperanto and very little about Interlingua. However, I have seen articles written in the latter language which I have been able to read, without a dictionary, with very little difficulty. I believe that dictionaries of Interlingua are available. If this is correct, I, for one, would be very happy to spend an extra hour or two when I submit my next contribution translating it into Interlingua.

The arguments in favour of Interlingua instead of English as a universal language of science are chiefly two, in my opinion. The learning of English requires considerable effort in regard to spelling, whereas Interlingua has no irregularities either in spelling or grammar. Secondly, national pride will always cause some people to prefer their native language over English or any other living language. In contrast to this, I should hope that any scientist would take pride in presenting his work in a universal language.

It may be argued that Interlingua, which is very similar to Spanish, is helpful only to persons who know one of the languages derived from ancient Latin. This is not true. A Russian or a Japanese could learn Interlingua more easily than English, French or German because of the aforementioned irregularities in the latter languages.

COPRECIPITATION STUDIES OF SOME TERVALENT METAL IONS WITH ALUMINIUM TRIS-(8-HYDROXYQUINOLATE)

S. J. Lyle and D. L. Southern*
Londonderry Laboratory for Radiochemistry, University of Durham
South Road, Durham City, England

(*Received* 25 *March* 1964. *Accepted* 27 *May* 1964)

Summary—The coprecipitation of tracer quantities of radioactive scandium, yttrium, cerium and indium with milligram-quantities of aluminium has been studied. The aluminium was precipitated as the tris-(8-hydroxyquinolate) by slow isothermal evaporation of aqueous acetone solutions. In the presence of ammonium acetate less than 0·5% of the scandium, yttrium or cerium coprecipitates. The fraction of tracer entrained is approximately independent of the fraction of the aluminium precipitated. Surface adsorption of tracer on the glass container or on the precipitate does not occur even when all of the acetone had been removed. Milligram-quantities of yttrium and cerium give gelatinous precipitates from similar systems containing acetone (aluminium absent); the dried yttrium precipitate has the composition $Y(C_9H_6NO)_2{\cdot}OCOCH_3$. Even milligram-quantities of yttrium, when present, tend to be rejected by the aluminium precipitate. In the absence of acetate but under conditions where milligram-amounts of yttrium would precipitate, for 10–90% precipitation of the aluminium, yttrium coprecipitation ranges from 1 to 6%. Removal of all of the acetone results in considerable surface adsorption of the tracer. From acetate solutions fractional precipitation of indium as tracer in the range 10 to 90% is only slightly different (lower) than the corresponding fractional precipitation of the aluminium. D and λ, the coefficients calculated assuming a homogeneous and a logarithmic distribution, respectively, within the crystals, are approximately equal and constant. Milligram-amounts of indium give a granular precipitate by the slow evaporation procedure from acetate solutions.

Recently a method has been described for the precipitation of aluminium[1] and other metal ions[2] as 8-hydroxyquinolates by slow isothermal evaporation of solvent from a buffered aqueous acetone system containing all of the reactants. The method is claimed to give aluminium tris-(8-hydroxyquinolate) comparable in particle size and in purity to that obtained by controlled hydrolysis of 8-acetoxyquinoline[3] in solutions containing aluminium. Slow isothermal evaporation of solvent followed immediately by filtration usually results, as do homogeneous methods of precipitation,[4] in coprecipitated impurity following a logarithmic (Doerner-Hoskin's) distribution in the precipitate if isomorphous replacement of the major by minor constituent is possible or if anomalous mixed crystal formation occurs.[5]

The acetone, in the method referred to above, presumably only serves to solvate the 8-hydroxyquinolates of aluminium or other metal ions which would normally precipitate from solution in its absence. It seemed of interest, therefore, to examine

---

* Present address: Radley Research Institute, Reading, Berkshire, England.

the coprecipitation of tracer quantities of other tervalent metal ions with aluminium precipitated by this method. Accordingly, scandium, yttrium, cerium and indium were chosen for this study and their distributions between the solution and the precipitate were followed by using radioactive isotopes in conjunction with suitable counting equipment. Distributions of tracer in each system were determined for various fractions of aluminium precipitated, and the coefficients, D and λ, appropriate to a homogeneous and logarithmic distribution, respectively, were calculated from the relations

$$\left(\frac{\text{tracer}}{\text{carrier}}\right)_{\text{cryst.}} = \mathrm{D}\left(\frac{\text{tracer}}{\text{carrier}}\right)_{\text{soln.}} \tag{1}$$

and

$$\log\left(\frac{\text{total tracer}}{\text{tracer in soln.}}\right) = \lambda \log\left(\frac{\text{total carrier}}{\text{carrier in soln.}}\right) \tag{2}$$

Under the conditions employed, partial or complete precipitation of macro amounts of these elements (as 8-hydroxyquinolates) might be expected to occur (Table II).

EXPERIMENTAL

Reagents

Unless otherwise stated, reagents were of analytical reagent grade.

8-Hydroxyquinoline. A fresh 4% solution was prepared in acetone every 2 days.

Acetone. Some experiments were carried out using reagent grade acetone but most were performed with technical solvent acetone (redistilled) without any apparent effect on the results.

2M Ammonium acetate. 154 g of ammonium acetate were dissolved in 1 l. of water.

Aluminium solution. Potassium aluminium sulphate was dissolved in water to give a solution containing about 1 mg of aluminium/ml. It was standardised using 8-hydroxyquinoline.[6]

Radioactive isotopes. These were obtained from the Radiochemical Centre, Amersham, England. Yttrium-91 and cerium-144/praseodymium-144 were "carrier free" in dilute hydrochloric acid but scandium-46 and indium-114m (obtained as chlorides) contained inactive isotopes of these elements. Each stock solution was diluted with 0·1*M* hydrochloric acid to reduce the radioactivity to a level suitable for use in the procedure outlined below.

Apparatus

Yttrium-91, cerium-144/praseodymium-144 and indium-114m were counted as liquid samples in a Geiger-Müller counter of the annular type (20th Century Electronics type M6H). Scandium-46, also in a liquid form, was determined using a γ-scintillation counter consisting of a sodium iodide (thallium activated) crystal (1·5 in. diam. × 1 in. deep) in conjunction with a photomultiplier tube, a single channel pulse-height analyser and the usual scaling equipment. The photopeaks corresponding to the 0·89- and 1·12-MeV γ-rays were used together, for counting purposes.

General procedure

Ten ml of aluminium solution and 2 ml of tracer solution were pipetted into a 250-ml pyrex-glass beaker. Forty ml of ammonium acetate, 60 ml of acetone and 5 ml of 8-hydroxyquinoline solution were added in that order. The initial radioactivity was measured by counting 10 ml of such mixtures in the Geiger-Müller counter when yttrium, cerium or indium were used as tracers. A 5-ml sample was taken for counting scandium solutions with the scintillation counter.

The beakers were immersed in a thermostat at 50 ± 0·5° and the contents stirred continuously. At various stages of the precipitation a beaker was removed and the precipitated aluminium tris-(8-hydroxyquinolate) collected in a weighed sintered glass crucible (porosity No. 4), washed well with cold water, dried at 130° and weighed. A weighed portion (about 70–90%) of the precipitate was transferred to a beaker and dissolved in 4 ml of 4*M* hydrochloric acid and 15 ml of acetone. Ten ml of 2*M* ammonium acetate were then added and either 5 ml (for scandium) or 10 ml of the mixture counted.

The usual corrections for paralysis time of the counting equipment and background counting rates were made and the percentage of tracer, *W*, coprecipitated with the aluminium was calculated from the relation

$$W = \frac{x}{yz} \times \frac{29}{117} \times 100$$

where x is the final and y the initial counting rate (corrected as described) and z is the fraction of the precipitate taken for the final count.

Because the solution composition is kept almost the same for the initial and final counts, self-absorption corrections are avoided. Corrections for departures from volume additivity were also made unnecessary by following the procedure described. In experiments with scandium and indium as tracers and when inactive yttrium was added in milligram-amounts, a correction was made for the presence of the "tracer" in order to compute the fraction of the aluminium precipitated from the weight of the precipitate. This correction was always small (less than 2% of the total precipitate weight) in experiments with scandium and indium.

RESULTS AND DISCUSSION

The results presented in Table I show that the coprecipitation of scandium, yttrium and cerium (all at very low concentrations) with aluminium is very approximately constant, independent of the fraction of aluminium precipitated, and independent of the tracer element. D and λ values are not recorded because, as would be expected from the results, they both vary considerably. Table II shows pH values for the onset and completion of precipitation of macro amounts of the tracer elements used here.

[a] Molar and approximate; calculated from data in the papers quoted.

[b] The pH at which the precipitate just dissolves.

Experiment showed that evaporation of the acetone from an aqueous acetone solution of the composition described in the general procedure above gave, on removing the precipitated metal 8-hydroxyquinolate, a filtrate having a pH about 6·3. At this pH, therefore, scandium, yttrium and cerium(III) would be expected to precipitate if present in milligram-amounts and to coprecipitate readily with aluminium. However, acetate present in high concentration in the coprecipitation experiments described may prevent or partly prevent the formation of the expected 8-hydroxyquinolates of the tracer elements although not interfering with the formation of the aluminium complex. (It may be noted that the acetate-acetic acid concentration used in much of the experimental work described here is somewhat higher than that normally employed in the direct precipitation of aluminium or by Howick and Jones[1,2] in their experiments.) Accordingly, with yttrium as tracer, additional experiments were performed in which ammonium acetate was replaced by 15 ml of 0·100*M* sodium hydroxide and 25 ml of water in the procedure already outlined. Evaporation of the acetone from a solution thus prepared gave, on separating the precipated metal complexes, a filtrate having a pH of about 9·5. Table III gives the results of these experiments. It will be observed that whilst the percentage coprecipitation is higher than in the presence of acetate, it is still quite low, amounting to only about 1% for 10% of the aluminium precipitated and only 6% for over 90% precipitation of the carrier. The results suggest, therefore, that acetate alone is not responsible for the low coprecipitation observed. Table III (column 3) shows that for up to at least 95% precipitation of the aluminium the ratio of the fractions of yttrium to aluminium in the precipitate is very approximately constant. A similar result was obtained previously by Gordon, Peterson and Burtt[11] in a study of the coprecipitation of thallium(I) with silver chloride precipitated from homogeneous solution. Their results and those in Table III would suggest a homogeneous distribution of tracer within the carrier lattice; in neither series of experiments were either of the distribution laws [equations (1) and (2)] obeyed.

[a] Solutions prepared from 10 ml of aluminium + 25 ml of water + 15 ml of 0·100*M* NaOH + 5 ml of 8-hydroxyquinoline + 2 ml of ^{91}Y solution + 60 ml of acetone.

For complete precipitation of aluminium (Table III), the ratio of the fractions of yttrium to aluminium in the precipitate increases very considerably, suggesting that yttrium is deposited on the surface of the aluminium precipitate on complete removal of acetone. As might be expected, this deposition was not confined to the precipitate surface; appreciable and approximately constant losses occurred to the walls of the beaker as the results of experiments recorded in Table IV show. (There is an estimated uncertainty of about 5% in the values given in column 4.)

Losses from solutions containing acetate were negligible. It was demonstrated in preliminary experiments that adsorption of tracer from aqueous acetone solutions prepared according to the directions given in the experimental part (or with acetate replaced by sodium hydroxide), was negligible even after standing for 3 or 4 hr in glass beakers. (Polythene was found to be unsatisfactory for the work described in this paper because of the tendency of the aluminium precipitate to adhere to the surface.) It may, therefore, be concluded that tracer quantities of yttrium [and probably also scandium and cerium(III)] are prevented from undergoing surface adsorption on glass or on the precipitate by acetone or by acetate ions (expts. 5, 6 and 7, Table IV).

TABLE IV.—THE RECOVERY OF YTTRIUM FROM SYSTEMS CONTAINING ALUMINIUM TRIS-(8-HYDROXYQUINOLATE)

No.	% Total ^{91}Y Filtrate	% Total ^{91}Y Ppt.	% Total ^{91}Y accounted for	Duration of evaporation, *hr*
1	45	33	78	2·0
2	60	20	80	2·5
3	53	21	74	3·25
4	49	24	73	6·17
5	96	0·5	97	1·5
6	97	0·5	98	2·0
7	96	0·7	97	2·5

1, 2, 3, and 4 were performed according to the general procedure but with 15 ml of 0·100*M* NaOH + 25 ml of water replacing the 40 ml of 2*M* ammonium acetate. 5, 6, and 7 were performed according to the general procedure. Very little if any acetone remains after evaporation for 2·0 hr.

Coprecipitation experiments were performed in which varying amounts of inactive yttrium were present. Corresponding molar increases in 8-hydroxyquinoline were made to these mixtures which were otherwise prepared according to the *General procedure*. It was found that when yttrium was present in amounts greater than about 14 mg, it precipitated immediately or within minutes of adding the 8-hydroxyquinoline. The precipitates thus formed were not dispersed by further additions of either acetone or 8-hydroxyquinoline. Qualitative tests with cerium(III) in the absence of aluminium suggest that colloid formation followed by slow precipitation and possibly also oxidation sets in when lower amounts (≤ 5 mg) of this metal ion are present. On the other hand, 25 mg of aluminium do not precipitate. Scandium was not examined. Table V records results obtained with yttrium.

Following the same procedure as was used to obtain the results in Table V but omitting aluminium, gelatinous precipitates, difficult to filter, were obtained from solutions containing 25 mg of yttrium. Analysis of such a precipitate, collected, washed well with cold water and dried at 110° for 1·5 hr gave Y, 20·3% (as Y_2O_3); C, 55·3% and H, 3·47% [$Y(C_9H_6NO)_2.OCOCH_3$ requires Y, 20·4%; C, 55·1%; H, 3·47%.]. The dried solid had a brownish-yellow colour. In the absence of acetate a bright yellow precipitate was obtained and analysis showed that the dried substance was $Y(C_9H_6NO)_3$. In Table V, the percentage of the aluminium precipitated (column 2) was calculated on the assumption that the yttrium was coprecipitated as $Y(C_9H_6ON)_3$ in experiments 3 and 4 and present as $Y(C_9H_6NO)_2.OCOCH_3$ in 5, 6 and 7.

The results in Table V show that even when considerable relative amounts of yttrium are present in the solutions, the aluminium tris-(8-hydroxyquinolate) tends to exclude yttrium from the precipitate. Only when the concentration of the yttrium builds up relative to the concentration of the aluminium, either by deliberate addition of the former or through removal of the latter by precipitation, does the yttrium tend to precipitate significantly. Post-precipitation rather than coprecipitation may predominate when the larger amounts of yttrium are present (*cf.* results 4 and 5, Table V). The last two results recorded in Table III suggest that post-precipitation also occurs significantly with tracer yttrium in the absence of acetate.

TABLE V.—CO-PRECIPITATION OF MILLIGRAM-AMOUNTS OF YTTRIUM WITH ALUMINIUM

No.	Y added, *mg*	Al pptd., %	Y copptd., %
1	0·356	51·4	0·33
2	1·78	47·4	0·42
3	4·43	83·8	0·72
4	8·86	70·7	0·77
5	8·86	98·5	45·8
6	13·29	79·6	29·5
7	13·29	87·0	53·7

Attempts were made to obtain information on the distribution of tracer in precipitates obtained under conditions yielding the results reported in Tables I and III. The precipitates, while still on the crucible, were partly dissolved away with an aqueous acetone solvent mixture approximating in composition to that prepared initially and yielding the precipitate on evaporation except that the metal ions were absent. Typical results are recorded in Table VI.

The results suggest that in the presence of acetate the tracer may be distributed throughout the crystals or perhaps concentrated near the centres. In the absence of acetate results 4 and 5 suggest (when compared with results from Table III) that some surface adsorption may be occurring. However, these conclusions are based on the assumption that preferential leaching of one of the components does not take place, an assumption which may not be valid when the solubilities of the species involved are different and when non-equilibrium conditions exist during the dissolution process.

According to Geilmann and Wrigge,[12] indium is quantitatively precipitated as the tris-(8-hydroxyquinolate) from sodium acetate-acetic acid solutions. Moeller[10] has shown that this complex extracts completely from solutions containing some acetic acid into chloroform at a pH of approximately 3·2. Complete precipitation of milligram-amounts of indium would be expected at or above this pH and, provided acetate did not interfere, tracer quantities of indium would therefore coprecipitate readily with aluminium, precipitated according to the procedure used in investigating the other tracers. The results presented in Table VII show that coprecipitation is such that, just a slightly lower fractional precipitation of tracer occurs for a given fractional precipitation of aluminium. There is some indication (Table VII) that the fraction of indium precipitated increases relative to that of the aluminium when precipitation of the latter is nearly complete, particularly at lower acetate concentrations. The extent of coprecipitation is otherwise little affected by change in the amount of acetate present over the range investigated. (The pH may also change slightly in these experiments.) As would be expected under these circumstances if isomorphous substitution occurs in the crystal both D and λ are approximately equal and constant; these results are very different from those obtained with scandium, yttrium and cerium(III).

2·0	90·7	87·1	0·69	0·86

[a] 4·6 × 10^{-6} mole (0·53 mg) per sample.
[b] 40 ml of the concentration stated here; otherwise the procedure outlined under *Experimental* was followed.

This difference in behaviour would appear to arise from structural differences between the complexes produced in the solutions. Both aluminium and indium yield a tris-(8-hydroxyquinolate) complex from solutions containing acetate ion in the concentration range used in the work described here. It was found that milligram-amounts of indium (and incidentally also gallium) can be precipitated by isothermal evaporation of aqueous acetone solutions containing acetate with results similar to those obtained with aluminium. The other metal ions behave differently; in the presence of much acetate, mixed acetate-8-hydroxyquinolate complexes are probably formed as has been shown for milligram-amounts of yttrium. Evidence in support of this view is provided by the work of Ishimori,[13] who studied the partition of tracer quantities of yttrium between an aqueous acetate or tartrate (not specified which) phase at pH 8·6 and a chloroform phase containing 8-hydroxyquinoline. He found that the yttrium distribution depended only on the square of the reagent concentration and concluded that the species extracting had the composition $Y(C_9H_6ON)_2X$, where X is a monovalent anion.

The difference in behaviour is possibly associated with the ability or inability of the heterocyclic nitrogen atom of 8-hydroxyquinoline to act, in complex formation, as a donor in competition with oxygen from acetate ions or even water. A heterocyclic nitrogen atom acts as a strong donor for indium(III) because $[In(phen)_3]^{3+}$ can be precipitated (with a suitable anion) from aqueous solutions by *o*-phenanthroline (phen).[14] An aluminium[15] and, independently, rare-earth[16] complex ions of the form $M(phen)_3{}^{3+}$ have been isolated as perchlorate and thiocyanate salts, respectively, from ethanolic solution. Whilst the aluminium complex ion has been shown to be stable in polar solvents the rare-earth complex ions are said to break up. Only oxygen, it appears, is a satisfactory donor in chelate formation for the rare-earth(III) ions;[17] the formation (stability) constants of the complexes with 8-hydroxyquinoline are thus likely to be somewhat lower than for aluminium or indium. (Relative measurements have not been reported.) In the absence of acetate which does complex significantly with rare-earth ions, if the normal complex, $Y(C_9H_6ON)_3$, is formed, coprecipitation might be expected to occur to a greater extent than is observed (Table III). However, even assuming that a 1:3 complex is formed, it may be that the nitrogen donors failed to displace co-ordinated water readily from the hydration sphere of the metal ion, thus giving a reaction of the form

$$M(H_2O)_x{}^{3+} + 3(C_9H_6ON)^- \rightleftharpoons M(C_9H_6ON)_3(H_2O)_{x-3} + 3H_2O$$

where x, if only the primary hydration sphere is considered, is probably 6. The observation[8] that yttrium is not extracted from slightly acid aqueous solutions containing 8-hydroxyquinoline into chloroform but that $Y(C_9H_6NO)_3$, when isolated and dried, readily dissolves in the latter solvent provides support for this suggestion. For similar reasons, scandium(III) may take up an extra molecule of 8-hydroxyquinoline, giving $Sc(C_9H_6ON)_3.C_9H_7ON$ in the solid, when a sufficient concentration of this reagent is present (unlikely in the experiments described here) in such a way that only its oxygen atom co-ordinates, as has recently been shown[18] by an X-ray structural examination, to be the case for $UO_2(C_9H_6ON)_2.C_9H_7ON$.

Whatever structures these complexes assume, however, the results presented here suggest that the growing aluminium tris-(8-hydroxyquinolate) crystals are sensitive to the incorporation of more than a small fraction, even of very low levels, of impurities in the form of other tervalent-metal ions, which may exist predominantly in the solution from which the crystals are growing, in a form containing 8-hydroxyquinoline but other than $M(C_9H_6ON)_3$. (M represents the tracer metal ion.) This appears to be so notwithstanding the lower solubilities of macro amounts of the tracer ions (at least for yttrium and cerium) relative to that of aluminium in the medium from which precipitation is occurring.

Acknowledgement—We are grateful to Mr. T. F. Holmes of the Chemistry Department for performing the C and H analyses.

Zusammenfassung—Die Mitfällung von Tracermengen von radioaktivem Scandium, Yttrium, Cer und Indium mit Milligrammengen Aluminium wurde untersucht. Aluminium wurde als Tris(8-hydroxychinolat) durch langsames isothermes Abdampfen wäßriger acetonhaltiger Lösungen gefällt. In gegenwart von Ammoniumacetat wird weniger als 0,5% von Scandium, Yttrium oder Cer mitgefällt. Der Anteil mitgefallten Tracers ist von dem gefällten Aluminiumanteil ziemlich unabhängig. Oberflächenadsorption von Tracer am Glas oder am Niederschlag findet nicht statt, auch wenn alles Aceton abgedampft ist. Milligrammengen Yttrium und Cer geben aus acetonhaltigen Lösungen schleimige Niederschläge (in Abwesenheit von Aluminium); der getrocknete Yttriumniederschlag hat die Zusammensetzung $Y(C_9H_6NO)_2OCOCH_3$. Auch Milligrammengen Yttrium werden vom Aluminiumniederschlag nicht aufgenommen. In Abwesenneit von Acetat, aber unter Bedingungen, unter denen Milligrammengen Yttrium ausfallen würden, liegt die Mitfällung von Yttrium bei 10–90 prozentiger Ausfällung von Aluminium zwischen 1 und 6%. Wenn alles Aceton abgedampft wird, findet beträchtliche Oberflächenadsorption des Tracers statt. Die teilweise Ausfallung von Indium als Tracer zwischen 10 und 90% aus acetathaltigen Lösungen ist nur wenig geringer als die entsprechende teilweise Ausfällung von Aluminium. Unter der Annahme einer homogenen beziehungsweise einer logarithmischen Verteilung in den Kristallen berechnete Koeffizienten D und λ sind ungefähr gleich und konstant. Milligrammengen Indium geben bei der Abdampfmethode aus acetathaltiger Lösung eine körnige Fällung.

Résumé—On a étudié la coprécipitation des scandium, yttrium, cérium et indium radioactifs, à la concentration des traceurs, avec des quantités d'aluminium de l'ordre du mg. L'aluminium a été précipité à l'état de tris-(8-hydroxyquinolinate) par évaporation isotherme lente de solutions hydroacétoniques. En présence d'acétate d'ammonium, moins de 0,5% du scandium, de l'yttrium ou du cérium coprécipitent. La fraction de traceur entraînée est approximativement indépendante de la fraction d'aluminium précipitée. Il ne se produit pas d'adsorption en surface du traceur, ni sur le récipient en verre, ni sur le précipité, même lorsque toute l'acétone a été éliminée. Des quantités d'yttrium et de cérium de l'ordre du mg donnent des précipités gélatineux à partir de systèmes similaires contenant de l'acétone (l'aluminium étant absent); le précipité d'yttrium, sec, a la composition $Y(C_9H_6NO)_2\text{-}OCOCH_3$. Même des quantités d'yttrium de l'ordre du mg, lorsqu'elles sont présentes, tendent à être rejetées par le précipité d'aluminium. En l'absence d'acétate, mais dans des conditions où des quantités d' yttrium de l'ordre du mg précipiteraient, pour une précipitation de l'aluminium allant de 10 à 90%, la coprécipitation de l'yttrium se situe entre 1 et 6%. L'élimination de toute l'acétone a pour conséquence une adsorption en surface considérable du traceur. A partir de solutions d'acétate, la précipitation fractionnée de l'indium à l'état de traceur, dans le domaine 10 à 90%, n'est que légèrement différente (plus faible) que la précipitation fractionnée correspondante de l'aluminium. D et λ, les coefficients calculés en supposant des distributions respectivement homogène et logarithmique, à l'intérieur des cristaux, sont approximativement égaux et constants. Des quantités d'indium de l'ordre du mg donnent un précipité granulaire, par la technique d'évaporation lente, à partir des solutions renfermant de l'acétate.

DETERMINATION OF SCANDIUM, YTTRIUM, SAMARIUM AND LANTHANUM IN STANDARD SILICATE ROCKS, G–1 AND W–1, BY NEUTRON-ACTIVATION ANALYSIS*

H. B. Desai, R. Krishnamoorthy Iyer and M. Sankar Das
Analytical Division, Atomic Energy Establishment Trombay, Bombay, India

(*Received* 16 *April* 1964. *Accepted* 14 *May* 1964)

Summary—Neutron-activation analysis results for four rare earth elements in standard silicate rocks, G-1 and W-1, are reported. An anion-exchange method for the separation of scandium, yttrium, samarium and lanthanum in good radiochemical purity has been developed. The method is based on the chromatographic elution of these elements from a Dowex 1 × 8 (nitrate form) resin column using methanol-nitric acid mixtures. The results obtained by this method are compared with values already available.

INTRODUCTION

The relative abundances of the individual rare earths in terrestrial as well as meteorite samples are of geochemical interest, because they have been used as an argument for the existence of abundance rules.[1] However, the reliability of analytical data for these elements, even on "Standard Rocks," seems to be far from satisfactory as evident from the summaries of values by Ahrens and Fleischer[2] and Fleischer and Stevens.[3] The methods which have been generally used for their determinations are spectrographic. Many of the rare earth elements are well suited for neutron-activation analysis so that this technique has been used for their determination.[4–11] The present paper describes the procedure employed for the determination of scandium, yttrium, samarium and lanthanum in the standard rocks G-1 and W-1.

Nuclear data

The principles and techniques of neutron-activation analysis have been reviewed in the literature and will not be repeated here. The data[12,13] relating to the activation of the elements under consideration are given in Table I.

Based on the information shown in Table I, ^{46}Sc, ^{90}Y, ^{153}Sm and ^{140}La have been chosen as suitable isotopes for the determinations of these elements.

EXPERIMENTAL

Reagents

All reagents were of recognised analytical purity.

Carriers for lanthanum, samarium, yttrium and scandium. Oxides of purity ⩾99·9% of individual elements were ignited and dissolved in nitric acid so as to give solutions containing 10·0 mg of metal/ml.

Standards. Standards of the above elements, containing 100.0 μg/ml, were prepared by dissolving spec-pure oxides in nitric acid. In the case of scandium the purity was only 99·9%.

---

* Presented at the symposium on Nuclear and Radiation Chemistry held in Bombay between 16th and 19th March 1964, under the auspices of the Chemistry Committee of the Department of Atomic Energy.

TABLE I.—NUCLEAR DATA RELATING TO THE ACTIVATION OF SCANDIUM, YTTRIUM, SAMARIUM AND LANTHANUM

Target nuclide	Product nuclide by (n, γ) reaction	Half-life	Saturation specific activity for a flux of $1{\cdot}0 \times 10^{12}$n. cm^{-2}. sec.$^{-1}$, *dpm/μg*	Mode of decay	Gamma-ray energy, *MeV*	No. of photons per 100 disintegrations
^{45}Sc	^{46}Sc	84·0 d	9.6×10^{6}	Beta	0·885	100
				(100)	1·12	100
^{89}Y	^{90}Y	64·2 h	$4{\cdot}9 \times 10^{5}$	Beta	1·73	0·002
				(100)		
^{144}Sm	^{145}Sm	340·0 d	$<1{\cdot}5 \times 10^{4}$	EC	0.061	12·1
				(100)	0·485	0·003
^{152}Sm	^{153}Sm	47·0 h	$8{\cdot}9 \times 10^{6}$	Beta	0·069	2·3
				(100)	0·084	1·2
					0·103	33
					0·178	0·02
					0·530	0·06
^{139}La	^{140}La	40·2 h	$2{\cdot}1 \times 10^{6}$	Beta	0·328	35

Ion-exchange resin. Dowex 1 × 8 analytical grade resin of mesh size 50–100 was regenerated in nitrate form and used when required. The resin was pre-equilibrated with the proper methanol-nitric acid mixture overnight before use.

Methanol-nitric acid mixtures. Analytical reagent grade nitric acid was standardised by titrating with standard alkali and suitably diluted to give 7·0, 1·0 and 0·1*M* nitric acid. The eluants were prepared by diluting aqueous nitric acid, of the molarity indicated, with methanol to give the appropriate percentage composition. Thus, 10% 1·0*M* nitric acid-methanol is obtained by diluting 10·0 ml of 1·0*M* nitric acid to 100·0 ml with methanol. These mixtures were prepared fresh when required.

Oxalic acid. Saturated aqueous solution.

Apparatus

Ion-exchange columns. Conventional ion-exchange columns, 30·0 cm × 8·0 mm, with stopcocks to regulate flow rates were used.

Counters. Beta activities were counted using a Geiger-Müller counter. Gamma activities were measured using a single channel analyser connected to a scintillation head consisting of a 1·5″ × 1″ NaI (Tl activated) crystal coupled to a E.M.I. 9536 photo tube and cathode follower.

Irradiation

For the determination of samarium and lanthanum 50·0-mg samples were irradiated for 24–40 hr. For yttrium and scandium, 200·0 mg samples were irradiated for 24–40 hr. The samples were sealed in Polythene capsules. Standards were prepared by evaporating aliquots of the standard solution varying between 1 and 10 μg on Polythene sheets. These were sealed and irradiated with the samples, in the "Apsara" Swimming Pool Reactor of the Atomic Energy Establishment Trombay, at a flux of 1×10^{11} n. cm^{-2}. sec.$^{-1}$ A cooling of 24 hr was needed before determining yttrium, samarium and lanthanum; for scandium the cooling period was 2 weeks.

Radiochemical separation

Isolation of rare earths as a group. A weighed amount of irradiated sample (25·0 mg for lanthanum and samarium and 100·0 mg for yttrium and scandium) was treated with hydrofluoric acid in a platinum dish to expel silica. A suitable aliquot of the carrier solution, containing 10–15 mg of the element being determined, was added to the dish and evaporated to dryness. The mass was fused with potassium bisulphate and taken up in 5% sulphuric acid. The rare earth activities were isolated as a group by at least three cycles of hydroxide and fluoride separation.[14] The hydroxides were finally dissolved in nitric acid and the solution evaporated to dryness on a water bath. The residue was taken up in the appropriate methanol-nitric acid mixture for ion-exchange separation.

Ion-exchange separation. The ion-exchange separation is based on the data published by Faris and Warton.[15] Their values indicate that in these solvent mixtures scandium elutes first from the resin. The heavy earths from lutecium to terbium with yttrium move almost together, followed by gadolinium to lanthanum in that order. Eluants were prepared and their suitability was established by using the carrier for the element of interest and tracers for those from which separation was desired. The composition of the eluants used and details of the elution behaviour of the individual elements are given in Table II.

TABLE II.—COMPOSITION OF ELUANTS AND DETAILS OF SEPARATION[a]

Element	Sorption[b]	Removal of heavier rare earths	Elution of element	Elements retained on column
Scandium	10·0 ml of 2·5% 7·0*M* nitric acid–methanol	—	30·0 ml of 2·5% 7·0*M* nitric acid–methanol	All rare earths including Y
Yttrium	10·0 ml of 2·5% 7·0*M* nitric acid–methanol	30·0 ml of 2·5% 7·0*M* nitric acid–methanol (Sc)	50·0 ml Of 10·0% 1·0*M* nitric acid–acid–methanol (Lu to Tb with Y)	Elements lighter than Gd retained on column
Samarium	10·0 ml of 10% 1·0*M* nitric acid–methanol	40·0 ml of 10% 1*M* nitric acid–methanol (Lu to Tb with Y), followed by 20·0 ml of 10% 0·7*M* nitric acid–methanol (Gd to Eu)	50·0 ml of 10% 0·5*M* nitric acid–methanol (Sm)	Elements lighter than Sm retained on column
Lanthanum	10·0 ml of 10% 1·0*M* nitric acid–methanol	40 ml of 10% 1*M* nitric acid–methanol (Sc + Lu to Tb), followed by 50 ml of 10% 0·05*M* nitric acid–methanol mixture (Gd to Ce)	50 ml of 0·01*M* nitric acid (La)	

[a] Flow rates: 0·5 ml/min for sorption step and 0·5–0·8 ml/min for subsequent elutions.

[b] The residue of nitrates after chemical treatment is dissolved in the given volume of the eluant.

The solution obtained after ion-exchange separation was evaporated on a water bath, the residue dissolved in water and the oxalates of yttrium, samarium and lanthanum precipitated. Scandium was precipitated by 8-hydroxyquinoline. The precipitates were filtered using a demountable filtration unit, washed with water, dried and mounted for counting.

Counting and chemical yield

Scandium. ^{46}Sc activity was determined by counting the photopeak activities at 0·89 and 1·12 Mev.

Yttrium. ^{90}Y activity was measured through an aluminium absorber (182 mg.cm^{-2}). In the absence of an absorber, a long lived activity, possibly terbium or ytterbium was observed. Consideration of the nuclear data[12,13] of the heavy rare earths which are likely to accompany yttrium in the ion-exchange separation shows that an appreciable interference in the determination of yttrium, counted through an absorber, can only come from ^{166}Ho. The observed half-lives of the samples indicate that there is no significant contamination by an element with a shorter half-life (Fig. 2).

Samarium. ^{153}Sm activity was determined by beta counting. The radiochemical purity of samarium was established by following the half-life. The gamma spectrum of samarium isolated from the samples (Fig. 2) shows that there is no significant contamination by other nuclides.

Lanthanum. ^{140}La activity was determined by beta counting and gamma counting using the 0·487-MeV photopeak. The photopeak activity decayed with the expected half-life. The beta activity decay curve showed an impurity, presumably neodymium, which was resolved (Fig. 1).

The chemical yield was determined by igniting the precipitates as oxides.

			11·7	11			

RESULTS AND DISCUSSION

The results obtained for the four elements are given in Table III.

The mean values for lanthanum, in which both beta and gamma measurements were used, show a difference between the two procedures of 6% for G-1 and 10% for W-1. The number of measurements does not permit the assignment of any significant cause for this difference.

In Table IV, the mean values obtained by the present method are compared with those recommended and those obtained by other workers using the technique of activation analysis.

Taylor and Ahrens[16] have recommended these samples as standards for spectrographic analysis, whilst others[18,19] have expressed doubts regarding their very homogeneity.

It may be noted from Table IV that the reported values show a large spread for any given element. Hence a comparison of results becomes difficult. However, the present results are in good agreement with other results obtained by activation analysis.

While the method permits resolution of elements having close half-life values, it is not expected to separate individual members of the rare earth series, because an unusually large excess of an element modifies the elution behaviour of the adjacent elements. The advantages claimed for the method are satisfactory precision, rapidity, simplicity of operation and use of commonly available reagents. There should be few difficulties in applying the method to other minerals and ores, and work along these lines is in progress.

Acknowledgements—The authors wish to thank Dr. V. T. Athavale, Head of Analytical Division, for his interest in the work. The co-operation of the U.S. Geological Survey in supplying the samples of G-1 and W-1 is gratefully acknowledged.

Zusammenfassung—Ergebenisse der Neutronenaktivierungsanalyse für vier seltene Erden in den Standard-Silikatgesteinen G-1 und W-1 werden angegeben. Eine Anionenaustauschmethode zur Abtrennung von Sc, Y, Sm und La in guter radiochemischer Reinheit wurde entwickelt. Die Methode beruht auf der chromatographischen Elution dieser Elemente von einer Säule mit Dowex 1 × 8 (NO_3^--Form) mittels Methanol-Salpetersäure-Mischungen. Die Ergebnisse dieser Methode werden mit bereits zugänglichen Daten verglichen.

Résumé—On décrit les résultats de l'analyse par activation de neutrons pour quatre éléments des terres rares dans les roches aux silicates, étalons G-1 et W-1. On a élaboré une méthode par échange d'anions pour séparer Sc, Y, Sm et La dans un état de pureté radiochimique satisfaisant. La méthode est basée sur l'élution chromatographique de ces éléments, à partir d'une colonne de résine Dowex 1 × 8 (forme NO_3^-), au moyen de mélanges méthanol-acide nitrique. On compare les résultats obtenus par cette méthode aux données déjà existantes.

(*Received* 22 *April* 1964. *Accepted* 1 *May* 1964)

Summary—Silver in aqueous solution in the range 1–10 ppm is determined by direct atomic absorption spectroscopy in an air/propane flame at 3281 Å. Many potential interferences are examined; only thorium, iodate, tungstate and permanganate cause interference when present in 1000-fold mole-ratio excess. Silver can also be determined without interference from any known ion in the range 0·1 down to 0·01 ppm in aqueous solution following an extraction of the silver as its di-n-butylammonium salicylate into methyl isobutyl ketone. The extract is submitted directly to absorptiometry in the flame. The solvent enhancement effect is shown to be caused principally by an increase of atomisation relative to aqueous solution.

THE advent of atomic absorption spectroscopy has led not only to a simplification in the preparation of a sample for analysis, but also to the determination of traces of metals which have hitherto been very difficult to determine by their emission in flames. One such metal is silver, and methods for its analysis in trace amounts have usually been based on spectrophotometry and the use of the organic reagents dithizone,[1] *p*-dimethylaminobenzylidenerhodanine[1] and, latterly, pyrogallol red.[2] The last-mentioned reagent, used in conjunction with a selective extraction system[3,4] for silver ions, possesses the advantages of selectivity, sensitivity, stability and reproducibility. However, subsequent evaluation of the reaction mechanism,[5] together with the lack of specificity, indicates that there are some limitations to its wider application.

The use of atomic absorption spectroscopy as an analytical technique is now well established[6] and it has been reviewed by Elwell and Gidley.[7] Application of the technique to the analysis of trace amounts of silver was first described by Lockyer and Hames.[8] These workers produced calibration curves from 1·0 to 10 ppm of silver and they examined the effects of some other noble metals, *viz.*, gold, platinum, palladium and rhodium, on the determination.

Traces of silver (<10 ppm) are of vital concern in many areas, such as effluent analysis. It was, therefore, the purpose of the following investigation to examine the possibilities of applying atomic absorption spectroscopy to such complex problems.

The apparatus used by the authors was the commercially available Hilger and Watts Uvispek (H700) spectrophotometer and its atomic absorption attachment. Using the optimum instrument control settings (see *Apparatus*), it was found that down to 1 ppm of silver in an aqueous solution could be easily determined. Furthermore, a plot of absorbance against concentration of silver (in ppm) produced a straight line calibration curve from 1 to 10 ppm of silver and its extension passed through the origin (Fig. 1A). The plot above the 10-ppm level of silver curved off slowly towards the abscissa (absorbance zero).

INTERFERENCES

The absorbance depends upon the rate of atomisation or the amount of material, in the form of droplets, reaching the flame. Thus, it is necessary in such an investigation to consider those substances which could give rise to physical changes in the solution to be atomised as well as direct chemical interferences.

Cations

The effect was observed upon an aqueous solution $5 \times 10^{-5}M$ in silver nitrate (5·394 ppm of silver) of about a 1000-fold mole excess, relative to silver, of a number of metal nitrates. No interference was noted from Al, Ba, Be, Bi, Ca, Cd, Ce^{III}, Co, Cr, Cu^{II}, Fe^{III}, Hg^{II}, K, La, Li, Mg, Mn^{II}, Na, NH_4^+, Ni, Pb, Sn^{IV}, Sr, Tl^I, Zn and Zr. Other workers[8] have already shown that there is no interference from a similar excess of the noble metals Au, Pt, Pd and Rh.

Only thorium was found to interfere, causing a reduction in the absorbance of approximately 15%. This was suspected to be caused by the formation of a refractory oxide of thorium. Wilson[11] reports interference from relatively large amounts of aluminium in his determination of silver in aluminium alloys.

Inorganic anions

No interference was observed from a 1000-fold mole excess, relative to silver, of the sodium, potassium or ammonium salts of $B_4O_7^{2-}$, Br^-, Cl^-, ClO_3^-, ClO_4^-, CN^-, CO_3^{2-}, CrO_4^{2-}, $Cr_2O_7^{2-}$, $Fe(CN)_6^{3-}$, $Fe(CN)_6^{4-}$, I^-, MoO_4^{2-}, NO_2^-, NO_3^-, PO_4^{3-}, SCN^-, SO_4^{2-}, $S_2O_3^{2-}$, $S_2O_8^{2-}$ and VO_3^-.

Only iodate, permanganate and tungstate were found to interfere. Iodate decreased the absorbance by *ca.* 80%, permanganate by *ca.* 15% and tungstate by *ca.* 6%. The interferences, especially with iodate, are caused by the formation of precipitates which immediately settle out of solution. Provided that the precipitate is in an attenuated finely divided form, for example silver chloride, then there is no reduction in the expected absorbance.

Organic anions

The sodium or potassium salts of acetate, formate, oxalate, tartrate, phthalate and citrate were also investigated at a 1000-fold mole excess, but none was found to interfere.

Acids

Hydrochloric, sulphuric, nitric, phosphoric and acetic acids were examined by adding 10-ml aliquots of each concentrated acid to 5 ml of a $10^{-3}M$ solution of silver nitrate, followed by dilution to 100 ml with distilled water. The silver content of such solutions was 5·394 ppm.

There was no interference from hydrochloric and nitric acids, but sulphuric and phosphoric acid caused a reduction in absorbance, whilst acetic acid caused an increase. The reduction in absorbance (*ca.* 20% in both instances) is caused by the increased viscosity of the solution, which gives rise to a reduced rate of atomisation. The increase in absorbance (*ca.* 36%) with acetic acid is caused by what is commonly called the "organic solvent effect". This is an enhancement in absorbance observed upon the addition of an organic solvent which is miscible with the aqueous solution under investigation. The over-all effect seems to be an increased rate of atomisation. This effect is discussed below under "*The organic solvent effect*".

Organic solvents miscible with water

The absorbance of an aqueous solution $5 \times 10^{-5}M$ in silver nitrate was compared with that of solutions $5 \times 10^{-5}M$ in silver nitrate and 10% with respect to the organic solvents acetone, dioxan, ethanol, ethylene glycol, formaldehyde, glycerol, isopropyl alcohol, methanol, methyl ethyl ketone and pyridine.

Glycerol gave a reduction in absorbance because of an increase in the viscosity of the solution and a subsequent reduced rate of atomisation. All of the remaining solvents produced, however, a considerable enhancement, especially isopropyl alcohol and methyl ethyl ketone (*ca.* 43% in each instance).

Surface active agents

Gelatin was chosen as a typical surface active agent and its effect was examined in a manner similar to that of *Organic solvents miscible with water.* Although only a slight enhancement was given, it was sufficient to indicate that a lowering of surface tension can increase the rate of atomisation.

"The organic solvent effect"

The reduction or enhancement in the absorbance, from the addition of certain organic solvents miscible with an aqueous silver-containing solution, was further investigated by considering the variations in the volume of different solvents actually fed into the burner as a fine spray.

First, a known volume of distilled water was converted into a fine spray by the vapour chamber attachment under the usual optimum conditions. The total time for the complete consumption of the distilled water was recorded, together with the volume of liquid not converted into a fine spray. This latter measurement was made by attaching a measuring cylinder to the waste outlet of the spray chamber. A similar experiment was then repeated with methyl ethyl ketone and a 50% aqueous/glycerol solution. The means of a number of readings obtained are shown in Table I.

TABLE I

Solvent system	Distilled water	Methyl ethyl ketone	50% Aqueous glycerol
Volume used, *ml*	10·0	10·0	6·5
Volume recovered, *ml*	8·4	4·8	5·0
Volume atomised, *ml*	1·6	5·2	1·5
Time taken, *sec*	310	235	1200
Rate, *ml/sec* (throughput $\times 10^2$)	0·516	2·213	0·125
Throughput ratio relative to distilled water	1·00	4·29	0·24

Thus, the rate of atomisation of methyl ethyl ketone is about four times that of distilled water, whilst that of 50% aqueous glycerol is about four times less. Consequently, the differences in the absorbance produced by these systems, containing the same concentration of silver, should be in these same ratios if the rate of atomisation is the most important factor. In fact, for the systems containing 3·236 ppm of silver, distilled water gave an absorbance value of 0·080, methyl ethyl ketone a value of 0·313 and 50% aqueous glycerol a value of 0·019. This represents a ratio of 1:3·9:0·24.

It is, therefore, apparent that the increase or decrease in the absorbance observed with different solvents, provided there is no chemical interference, is mainly caused by an increased or reduced rate of atomisation. Although these results are very approximate, the conclusions reached agree well with the more elaborate experiments described by Elwell and Gidley.[7]

Extraction of Silver

The extraction of silver into an organic solvent before absorption measurements should cause an increase in the over-all sensitivity because of a concentration of silver in the organic phase and a further increase in sensitivity from the "organic solvent effect". It was, therefore, decided to examine the application of a selective extraction system (di-n-butylamine/salicylate ion-association system)[3,4] for silver ions to the determination of silver by atomic absorption spectroscopy.

Preliminary experiments showed that by extracting 1- to 5-ml aliquots of a $10^{-4}M$ silver nitrate solution with 10 ml of hexone reagent "A", it was possible to determine silver accurately down to at least 0·2 ppm. By extracting from larger volumes of an aqueous silver-containing solution with hexone reagent "B", it was possible to determine silver down to 0·01 ppm. The efficiency of this latter extraction system has been investigated and confirmed radiochemically.[4]

Fig. 1 shows the two calibration curves obtained for the range 1–10 ppm of silver in aqueous solution and after extraction with hexone reagent "A". Fig. 2 shows the calibration curve obtained over the range 0·01–0·1 ppm of silver after extraction of 1- to 10-ml aliquots of a $10^{-4}M$ silver nitrate solution in 1 litre of aqueous solution with hexone reagent "B".

The partial co-extraction of mercury^{II} with silver was also investigated and the results obtained showed that, provided a sufficient excess of anthranilic acid diacetic acid (AADA) was present to complex completely all of the mercury, there was no interference from a *ca.* 1000-fold mole excess.

The instrument control settings employed in this work were as described under *Apparatus*, but with one exception. The propane pressure was reduced slightly when organic solvents were employed so as to give a non-luminous and non-turbulent flame.

DISCUSSION

Atomic absorption spectroscopy compares very favourably with other techniques, particularly with regard to ease of operation, sensitivity, reproducibility of result and an almost complete lack of interference from extraneous cations and anions. The precision of a determination has been reported[7] to be of the order of 2% and because of its high specificity, accuracies are also high. The sensitivity obtained for silver, following extraction, is at least as high as that of any of the alternative methods

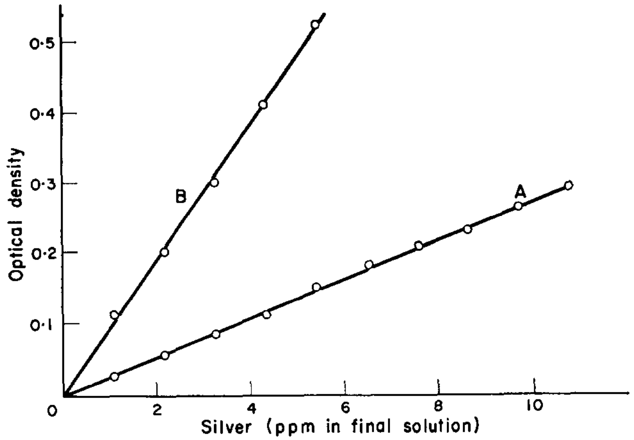

FIG. 1.—Calibration curves for silver determination:
A—normal procedure for 1–10 ppm of silver in aqueous solution;
B—procedure for 1–5 ppm of silver (in 10 ml of solution) after extraction with 10 ml of hexone reagent "A".

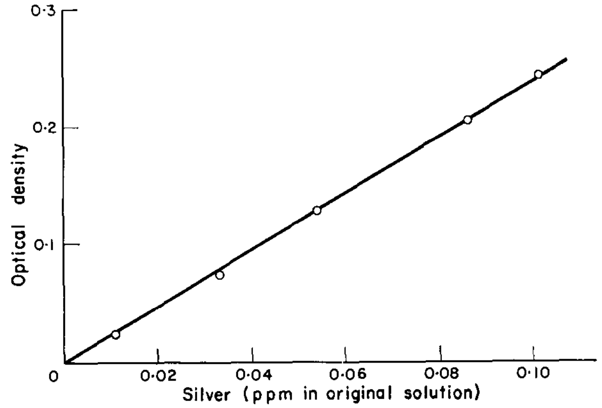

FIG. 2.—Calibration curve for extraction of silver
[normal procedure for 0·01–0·1 ppm of silver (in 1 litre of solution) after extraction with 50 ml of hexone reagent "B".]

of determination. In addition, we have observed interference from few other ions. Although the silver samples examined by the authors have all been in solution-form, it should nevertheless be possible to work directly with solid samples by employing an atomisation technique, such as cathodic sputtering.[9]

EXPERIMENTAL

Determinations in Aqueous Solutions

The working range is 1–10 ppm of silver (absorbance 0·026 to 0·270), but this can be reduced to 1–5 ppm with 50% aqueous/isopropyl alcohol solutions. Of the 27 cations and 30 anions examined, only thorium, iodate, permanganate and tungstate interfered.

Apparatus

Hilger and Watts Uvispek (H700) spectrophotometer and its atomic absorption attachment: The attachment consisted of a vapour chamber, a burner and a silver hollow-cathode lamp (FL 161), together with the appropriate power packs. The flame employed was a regulated supply of compressed air and propane.

The optimum instrument control settings were determined with a $10^{-4}M$ aqueous solution of silver nitrate (10·788 ppm of silver). The settings, listed below, were constantly checked, and were employed throughout the entire investigation:

Lamp current: 8 mA (setting 2 on power pack),
Wavelength: 3281 Å,
Slit width: 0·1 mm,
Uvispek sensitivity: setting 8, input sensitivity X5,
Air pressure to atomiser: 17·8 lb./in.^{2},
Propane pressure to burner: sufficient to give a non-luminous, non-turbulent flame.

Reagent

$10^{-3}M$ *Silver nitrate solution.* Prepared by dilution of a standard $10^{-1}M$ solution (B.D.H. Ltd.):

$$1 \text{ ml of } 10^{-3}M \text{ AgNO}_3 \equiv 107{\cdot}9\ \mu\text{g of Ag.}$$

Procedure

Calibration curve (1–10 ppm: *see Fig.* 1A). Pipette 1- to 10-ml aliquots of $10^{-3}M$ silver nitrate solution into 100-ml volumetric flasks and dilute to the mark with distilled water. Switch on the instrument and leave for about 1 hr to attain equilibrium. Next adjust the instrument control settings to their optimum or required positions, then spray distilled water through the flame for about 1 min. Set the spectrophotometer to read zero absorbance and spray the first silver solution. Measure the absorbance, then spray distilled water for a further min, resetting the spectrophotometer controls if necessary. This sequence of operations must be carried out after spraying each silver solution.

Determinations. Proceed as under *Calibration curve* if the sample is in aqueous solution. If substances are present which are likely to reduce the absorbance (*e.g.*, glycerol, sulphuric acid, *etc.*) or enhance it (*e.g.*, organic solvents), then new standard solutions must be prepared containing the same concentration of these substances and another calibration curve prepared. The concentration of silver is read from the calibration curve.

Determinations in Organic Media

The working range in organic media is normally 1–5 ppm of silver,[10] but by using the di-n-butylamine/salicylate extraction system as a means of concentration it is possible to determine silver down to 0·01 ppm in an original aqueous solution. There are no cationic interferences because of the selective nature of the ion-association extraction system, and in addition those anions compatible with silver in aqueous solution will also not interfere.

Reagents

$10^{-4}M$ *Silver nitrate solution.* Prepared as above:

$$1 \text{ ml of } 10^{-4}M \text{ AgNO}_3 \equiv 10{\cdot}79\ \mu\text{g of Ag.}$$

Hexone reagent "A". 3·2 g of salicyclic acid and 30 ml of di-n-butylamine dissolved in and diluted to 1 litre with methyl isobutyl ketone.

Hexone reagent "B". As reagent "*A*", but with 70 ml of di-n-butylamine.

$10^{-1}M$ *Anthranilic acid diacetic acid* (*AADA*) *solution.* Neutralised with sodium carbonate.

$5M$ *Sodium nitrate solution.* 42·5 g of analytical reagent grade sodium nitrate dissolved in and diluted to 100 ml with distilled water.

20% *Sodium acetate solution.* 20 g of analytical reagent grade sodium acetate trihydrate dissolved in and diluted to 100 ml with distilled water.

Procedure

Calibration Curve (0·01–0·1 ppm: *see Fig.* 2). Pipette 1- to 10-ml aliquots of the 10^{-4} silver nitrate solution into 2-litre separating funnels, treated with a protective silicone film, and make up with distilled water to *ca.* 1 litre. Add 5 ml of 20% sodium acetate solution (to give a nearly neutral solution), 5 ml of $5M$ sodium nitrate solution, 0·4 ml of $10^{-1}M$ AADA solution and 50 ml of hexone reagent "B". Shake by continuous inversion for 1 min and chill the separating funnels thoroughly in ice-water to obtain a clear solution (*ca.* 10 min). Run off the lower aqueous layer, then transfer the organic phases (now less than 40 ml) to 50-ml volumetric flasks. Wash the funnels with 5 ml of methyl isobutyl ketone and add to the volumetric flasks. Finally, make up to the mark with methyl isobutyl ketone.

Proceed with the absorbance measurements as under *Determinations in Aqueous Solutions*, but with reduction of the propane pressure to obtain a non-luminous, non-turbulent flame on spraying the hexone extract.

Hexone reagent "A" (10 ml) is used for the determination of silver in the range 1–5 ppm (Fig. 1B). A similar procedure to the above is followed with the exception that chilling of the solvent layers and subsequent dilution of the extract is no longer necessary. The volume of the aqueous phase employed was 10 ml.

Acknowledgement—We are grateful to the Department of Scientific and Industrial Research for the provision of the optical and electrical equipment used in this study.

Zusammenfassung—1–10 ppm Silber in wäßriger Lösung wird durch direkte atomare Absorptionsspektroskopie in einer Luft-Propan-Flamme bei 3281 Å bestimmt. Viele mögliche störungen werden untersucht; nur Thorium, Jodat, Wolframat und Permanganat stören in tausendfachem molarem Überschuß. 0,1–0,01 ppm Silber kann auch ohne Störung von irgendeinem Ion in wäßriger Lösung bestimmt werden, wenn es vorher als Di-n-butylammoniumsalicylat in Methylisobutylketon extrahiert wird. Der Extrakt wird direkt zur Absorptionsmessung in die Flamme gegeben. Es wird gezeigt, daß die Verbesserung durch das Lösungsmittel im wesentlichen auf besserer Zerstäubung als in wäßriger Lösung beruht.

Résumé—On dose l'argent en solution aqueuse, entre 1 et 10 ppm, par spectroscopie d'absorption atomique directe, dans une flamme air/propane, à 3281 Å. On examine de nombreuses interférences possibles; seuls, le thorium, l'iodate, le tungstate et le permanganate interfèrent, lorsqu'ils sont présents à une concentration molarie 1000 fois plus importante. On peut aussi doser l'argent sans interférence d'aucun ion connu, en solution aqueous, de 0,1 jusqu'à 0,01 ppm après extraction de l'argent, sous forme de di-n-butyl-ammonium salicylate, par la méthyl isobutyl cétone. L'extrait est soumis directement à l'absorptiométrie dans la flamme. On montre que l'effet d'exaltation du solvant est dû principalement à un accroissement de l'atomisation, par rapport à la solution aqueuse.

Absorptiometric study of ammonium aurintricarboxylate as a reagent for palladium^{II}

(*Received* 24 *December* 1963. *Accepted* 29 *March* 1964)

INTRODUCTION

AMMONIUM aurintricarboxylate (Aluminon, AAC) has been used extensively as a chromogenic reagent and as a metallochromic indicator for metal ions. In earlier papers from these laboratories, metal chelates of AAC with copper, iron, uranyl, thorium and beryllium have been described and their use in colorimetric analysis has been suggested.[1-5]

Many colour reactions and photometric methods are available for the determination of palladium.[6-11] In the present work the photometric determination of palladium^{II} and the properties of the Aluminon chelate formed have been examined. This reagent has a greater sensitivity than several others and is more tolerant of foreign metals, especially those of the platinum group.

EXPERIMENTAL

Reagents

Standard palladium solution: Prepared by dissolving an accurately weighed amount of Johnson Matthey's Specpure palladium^{II} chloride in hydrochloric acid.

Aluminon solution: Prepared by dissolving a pure preparation of the reagent (B.D.H. Indicator) in water.

Apparatus

A Unicam SP 500 spectrophotometer was used for absorbance measurements. For colorimetric measurements, a Klett-Summerson photoelectric colorimeter (test-tube model) was used. The pH was measured with a Leeds and Northrup line-operated pH meter.

Conditions of study

All experiments were performed at 25°. The total volume of the mixtures prepared for the measurements was 25 ml, and the pH was adjusted to 4·0 by the addition of sodium hydroxide or hydrochloric acid. The ionic strength of the system was maintained at $0{\cdot}1M$ with sodium perchlorate.

Palladium^{II} reacts with AAC at pH 4·0 (λ_{max} 520 mμ), giving an intense violet colour (λ_{max} 560 mμ). At relatively high concentrations of palladium and AAC a flocculent precipitate separates out. The colour intensity is stable for at least 72 hr. The ratio Pd:AAC is 1:2 by the continuous variation method (Fig. 1) and also by the slope ratio and mole ratio methods.

Effect of pH on chelate

The chelate is stable between pH 3·5 and 6·0, as shown by the constancy of λ_{max} within this range. However, the absorbance is constant only between pH 3·8 and 5·5.

Effect of temperature on colour intensity of chelate

The intensity of the colour increases with rise in temperature and decreases when the temperature is lowered. This increase in colour intensity may be attributed to AAC, whose own colour intensity increases with temperature. The colour intensity of the complex, however, remains constant for a considerable length of time at any given temperature and the readings are reproducible.

Conformity to Beer's law

Beer's law is obeyed over the range 0·14–7·7 ppm of palladium.

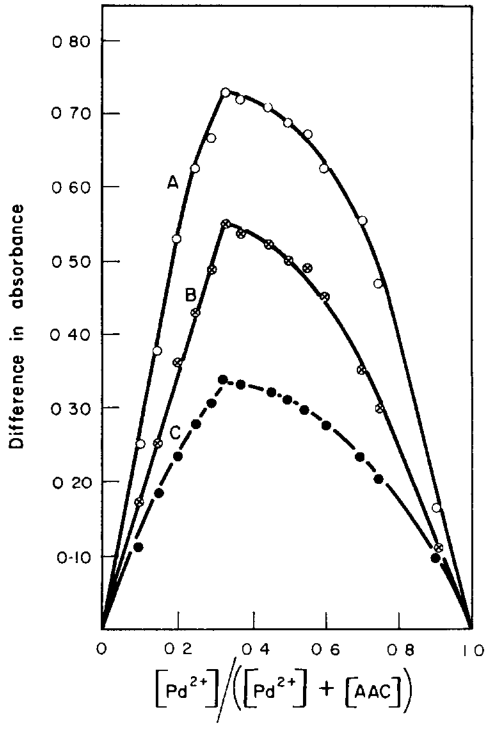

FIG. 1.—Determination of composition of complex by the method of continuous variation at 560 mμ (pH 4·0; μ 0·1*M*)
Concentrations of the interactants (equimolecular)
A: $3{\cdot}33 \times 10^{-4}M$
B: $2{\cdot}50 \times 10^{-4}M$
C: $1{\cdot}67 \times 10^{-4}M$

Sensitivity

The sensitivity of the colour is 0·026 μg. cm^{-2} for log $I_0/I = 0{\cdot}001$. The range of most accurate measurement is 1·0–5·0 ppm of palladium.

Effect of diverse ions

Various ions were tested for their influence on the colour reaction. Fe^{II}, Fe^{III}, Cu^{II}, Cr^{III}, Be^{II}, Zr^{IV}, Th^{IV}, Ga^{III}, In^{III}, Ge^{IV}, Al^{III}, Ca^{II}, Mg^{II} and UO_2^{II} interfere in all concentrations; common anions, like sulphate, nitrate, chloride, bromide, acetate, *etc.*, do not interfere in large excess. Diverse ions were added to the solutions containing 4·26 ppm of palladium and the colour was developed by adding a 3-fold concentration of AAC. The tolerance limits for the various foreign ions were taken as those concentrations which affects the absorbance by less than ±2%. The results are summarised in Table I.

Evaluation of equilibrium constant

In this procedure the equilibrium constant for the reaction $Pd^{2+} + 2H_6R \rightleftharpoons Pd(H_{6-n}R)_2 + 2nH^+$ is defined as

$$K = \frac{[Pd(H_{6-n}R)_2]}{[Pd][H_6R]}\,.$$

The effect of dissociation of the reagent is ignored, and to obtain the usual equilibrium constant this one must be multiplied by $[H]^{2n}$.

log K (K = equilibrium constant at pH 4·0, 0·1*M* ionic strength and 25°) for the reaction was determined by the method of Dey *et al.*,[1,3] as well as by the mole ratio method, and the values were found to be 9·8 and 9·6, respectively.

TABLE I.—EFFECT OF DIVERSE IONS ON THE COLOUR INTENSITY

Concentration of palladium chloride = $4\cdot00 \times 10^{-5}M$
Concentration of AAC = $1\cdot33 \times 10^{-5}M$
pH of the mixtures = $4\cdot0 \pm 0\cdot2$
Klett filter No. 54 used

Foreign ion	Added as	Tolerance limit, *ppm*
Ni^{II}	$NiSO_4$	20
Co^{II}	$Co(NO_3)_2$	58
Ru^{III}	$RuCl_3$	50
Rh^{III}	$RhCl_3$	25
Os^{VIII}	OsO_4	15
Ir^{IV}	$IrCl_4$	60
Pt^{IV}	K_2PtCl_6	20
Au^{III}	$AuCl_3$	40

Recommended procedure for the determination of palladium

The use of AAC as a reagent for the colorimetric determination of palladium^{II}, when present alone in minute quantities, may be recommended. The solution should be suitably diluted or concentrated so as to contain 1–5 ppm of palladium. Introduce a 4-fold excess of freshly prepared AAC solution and maintain at constant temperature for 0·5 hr for the development and equilibration of colour. The pH should be adjusted to 4·5. The colour intensity may then be measured either with a colorimeter using a suitable filter (Klett No. 54) or a spectrophotometer at 560 mμ, and compared with a calibration curve prepared under the same conditions.

Summary—A new colorimetric method for the determination of bivalent palladium with ammonium aurintricarboxylate (Aluminon) is described. The method involves the formation of a violet chelate of palladium-Aluminon at pH 4·0. The colour reaction has a sensitivity of 0·026 μg. cm^{-2} for log $I_0/I = 0\cdot001$, and obeys Beer's law over the range 0·14–7·7 ppm of palladium. The effects of pH, time, order of addition of the reagents, temperature, and diverse ions have been investigated, and a procedure for the microdetermination of palladium is described. The composition of the complex has been confirmed by three different methods as 1:2 (metal:reagent), and an equilibrium constant of $10^{9\cdot8}$ was found by the method of Dey *et al.* at pH 4·0, temperature 25° and ionic strength 0·1*M*.

Zusammenfassung—Eine neue kolorimetrische Methode zur Bestimmung von zweiwertigem Palladium mit Ammonium-aurintricarboxylat (Aluminon) wird beschrieben. Bei pH 4,0 bildet sich ein violettes Palladium-Aluminon-Chelat. Die Farbreaktion hat eine Empfindlichkeit von 0,026 μg. cm^{-2} für log $I_0/I = 0{,}001$, und das Beersche Gesetz wird zwischen 0,14 und 7,7 ppm Palladium befolgt. Der Einfluß von pH, Zeit, Reihenfolge der Zugabe der Reagentien, Temperatur und verschiedenen Fremdionen wurde studiert und eine allgemein anwendbare Arbeitsvorschrift für die Mikrobestimmung von Palladium mit Aluminon beschrieben. Die Zusammensetzung des Komplexes wurde mit den drei üblichen Methoden als 1:2 (Metall:Reagens) ermittelt; die nach der Methode von Dey *et al.* berechnete Stabilitätskonstante ist $10^{9{,}8}$ bei pH 4,0, 25°C und der Ionenstärke 0,1.

Résumé—On décrit une nouvelle méthode colorimétrique de dosage du palladium bivalent au moyen d'aurinetricarboxylate d'ammonium (Aluminon). La méthode met en jeu la formation d'un chélate palladium-Aluminon, coloré en violet, à pH 4,0. La réaction colorée a une sensibilité de 0,026 μg. cm^{-2} pour $\log I_0/I = 0{,}001$, et obéit à la loi de Beer entre 0,14 et 7,7 ppm de palladium. Les effets du pH, du temps, de l'ordre d'addition des réactifs, de la température, et de divers ions ont été étudiés, et on décrit une méthode générale de microdosage du palladium. La composition 1:2 (métal:réactif) du complexe a été confirmée par trois méthodes différentes et la constante de stabilité $10^{9,8}$ à pH 4,0, à la température de 25°C et à la force ionique 0,1*M*, a été calculée par la méthode de Dey *et coll.*

Direct titration of iron(III) with disodium diaminocyclohexanetetra-acetate

(*Received* 2 *April* 1964. *Accepted* 29 *May* 1964)

NUMEROUS methods have been proposed for the direct titration of iron with disodium ethylenediamine-tetra-acetate (EDTA). In most cases, Tiron, salicylic acid, sulphosalicylic acid or thiocyanate ion is used as the indicator. Each of these indicators has certain advantages and disadvantages. For example, Tiron gives an easily distinguishable end-point, but an exceptionally large concentration of the indicator is needed.[3,10] The end-point using thiocyanate indicator is sharp (and can be improved by extraction of the iron-thiocyanate complex into organic solvents),[2,6] but the competitive effect of thiocyanate ion leads to variable results for iron.[6] Chrome Azurol S also gives a good end-point, but in this case the titration results are always high by 0·5% or more.[7] Sulphosalicylic acid does not give a satisfactory colour change in the titration of milligram-amounts of iron.[4] Variamine Blue B is also a good indicator, but it cannot be used in the presence of trace amounts of copper.[5]

The best indicators for iron are those that show a large difference in the colour of the free and complexed forms, because the indicator transition must be seen over the yellow background colour of the iron(III) complex. A preliminary investigation of common indicators showed that screened thiocyanate and Chrome Azurol S gave the sharpest end-points in the titration of milligram-amounts of iron. Therefore, these two indicators were chosen for the examination of the titration of iron with disodium 1,2-diaminocyclohexanetetra-acetate (DCTA).

One would expect better results for titrations of iron in acid solutions using DCTA instead of EDTA because of a larger conditional constant for the iron-DCTA complex. Přibil[8] has reported that iron can be determined by titration with DCTA, but no indication of either the precision or accuracy of the method is given. Clearly, a more detailed investigation was necessary to show that the direct titration with DCTA gives reliable results. The purpose of this paper is to report on the precision and accuracy of the direct titration using screened thiocyanate and Chrome Azurol S as indicators. In addition, the interference of small amounts of some metals (aluminium, cobalt, nickel, manganese and copper) has been examined.

Direct titration of iron(III) with disodium diaminocyclohexanetetra-acetate

(*Received* 2 *April* 1964. *Accepted* 29 *May* 1964)

NUMEROUS methods have been proposed for the direct titration of iron with disodium ethylenediaminetetra-acetate (EDTA). In most cases, Tiron, salicylic acid, sulphosalicylic acid or thiocyanate ion is used as the indicator. Each of these indicators has certain advantages and disadvantages. For example, Tiron gives an easily distinguishable end-point, but an exceptionally large concentration of the indicator is needed.[3,10] The end-point using thiocyanate indicator is sharp (and can be improved by extraction of the iron-thiocyanate complex into organic solvents),[2,6] but the competitive effect of thiocyanate ion leads to variable results for iron.[6] Chrome Azurol S also gives a good end-point, but in this case the titration results are always high by 0·5% or more.[7] Sulphosalicylic acid does not give a satisfactory colour change in the titration of milligram-amounts of iron.[4] Variamine Blue B is also a good indicator, but it cannot be used in the presence of trace amounts of copper.[5]

The best indicators for iron are those that show a large difference in the colour of the free and complexed forms, because the indicator transition must be seen over the yellow background colour of the iron(III) complex. A preliminary investigation of common indicators showed that screened thiocyanate and Chrome Azurol S gave the sharpest end-points in the titration of milligram-amounts of iron. Therefore, these two indicators were chosen for the examination of the titration of iron with disodium 1,2-diaminocyclohexanetetra-acetate (DCTA).

One would expect better results for titrations of iron in acid solutions using DCTA instead of EDTA because of a larger conditional constant for the iron-DCTA complex. Přibil[8] has reported that iron can be determined by titration with DCTA, but no indication of either the precision or accuracy of the method is given. Clearly, a more detailed investigation was necessary to show that the direct titration with DCTA gives reliable results. The purpose of this paper is to report on the precision and accuracy of the direct titration using screened thiocyanate and Chrome Azurol S as indicators. In addition, the interference of small amounts of some metals (aluminium, cobalt, nickel, manganese and copper) has been examined.

EXPERIMENTAL

Reagents

Disodium 1,2-diaminocyclohexanetetra-acetate (DCTA). Obtained from Hach Chemical Co. and purified by treatment of a boiling solution of the salt with activated charcoal.

Iron(III) solutions. Prepared both from electrolytic iron (G. F. Smith) and reagent grade iron(III) chloride (Baker and Adamson, 99·5% min. assay). Iron solutions used in the thiocyanate method were prepared from electrolytic iron using only a very slight excess of perchloric acid. The dissolution was accomplished by using dilute perchloric acid and heating gently over a steam plate. Vigorous heating led to the formation of an intractable red residue. This problem is not encountered if a large excess of perchloric acid is used.

Erio Green. Used as the screening agent and incorporated into the DCTA titrant. A sufficient amount of the dye (G. F. Smith Co.) was present to give an absorbance of 0·50 at 575 mμ using a 1-cm cell.

Chrome Azurol S. Obtained from Hach Chemical Co. and used without further purification.

Procedure

In titrations using the thiocyanate end-point, the iron sample was mixed with the thiocyanate solution at an acid pH (*ca.* 2·6), then the mixture diluted with water to pH 3·1–3·3. Attempts to neutralise very acidic iron solutions with dilute base solutions inevitably led to low results. This is believed to be caused by the formation of hydroxy complexes in regions where local excess of base is established when the base is added dropwise. Titration with DCTA is continued until the solution becomes bright green. By incorporation of the screening agent into the titrant, the concentration of Erio Green remains constant relative to the iron content, and the colour change is less variable with iron content.

The titration of iron using Chrome Azurol S presents no particular difficulties. The pH of the sample solution is adjusted to 1·3–2·0 with perchloric acid and the solution heated to 60–70°. One drop of 0·3% indicator is added and the titrant added until the violet colour changes to green. Four or five more drops of indicator are added, and the titration continued until the solution is bright yellow-orange. It is helpful to have some estimate of the iron content, because it is possible to add the bulk of the titrant before heating, and thus the solution is in the proper temperature range when the end-point is approached.

RESULTS

Thiocyanate ion indicator

The work first centered around the effect of indicator concentration on the titration results. This was of interest in that the titration with EDTA shows a large variability with thiocyanate concentration.[6] On the basis of the difference in conditional constants for the formation of EDTA and DCTA complexes of iron, one would expect the best results at pH 3. At pH 3·5 or higher, the hydrolysis of iron would lead to unsatisfactory results.

TABLE I.—VARIATION OF TITRATION RESULTS WITH THIOCYANATE CONTENT[a]

SCN^-, *M*	0·02*M* DCTA used,[b] *ml*	Standard deviation, *ml*
0·01	11·47	0·02
0·02	11·47	0·02
0·04	11·47	0·02
0·10	11·48	0·02
0·20	11·47	0·02

[a] Each entry is the average of 6 analyses; initial pH 3·2–3·1.

[b] Iron(III) sample taken in each case is 10·02 ml and calculated amount of DCTA required is 11·47 ml.

Tables I and II summarise the results of titrations at an initial pH of 3·1–3·2. The titration is essentially independent of the concentration of thiocyanate, at least over the concentration range studied, and independent of the iron concentration over the range 0·1–0·3 mmole of iron/100-ml sample. When a correction was applied for the known amount of iron(II) in the iron(III) stock solution, the amount of iron taken for analysis and that found agreed to within 0·1%. The determination of iron using thiocyanate indicator is dependent upon the initial pH of the solution, and is

TABLE II.—VARIATION OF TITRATION RESULTS WITH AMOUNT OF IRON AT CONSTANT THIOCYANATE CONCENTRATION OF 0·04M[a]

0·02M Fe taken, *ml*	0·20M DCTA used,[b] *ml*	Standard deviation, *ml*
5·00	5·71	0·01
10·00	11·45	0·02
15·00	17·18	0·01

[a] Each entry is the average of 6 analyses.
[b] Calculated DCTA required is 11·45 ml/10·00-ml iron sample.

stoichiometric only above pH 3. Attempts to use buffers always led to low results because of complex formation of the buffer with iron(III) ion. This use of a buffer undoubtedly accounts for some of the variability of results obtained by Lydersen and Gjems.[6] Under the controlled conditions employed above, the pH change upon titration is not sufficiently large to give appreciable errors and it is not necessary to employ a buffer system. Although the method is capable of good accuracy, it is exceedingly difficult (in practice) to free the iron sample from excess acid and thus this aspect severely limits its use.

Chrome Azurol S indicator

In view of the results of the thiocyanate titrations, it was certain that titration with DCTA in the pH region 2–3 would be much more precise and accurate than that with EDTA. Hence, work was concentrated on titrations with DCTA at the lowest possible pH where good results could be obtained. Preliminary experiments indicated that this lower limit is about pH 1·25.

Table III summarises the results of the titration of iron with 0·01M DCTA. In each case, the sample was taken to fumes before titration to oxidise any residual iron(II). The agreement with the known amount of iron taken for analysis shows that the direct method gives very good results.

TABLE III.—DIRECT AND INDIRECT TITRATION OF IRON WITH DCTA AT pH 1·25–1·50 USING 0·1005-MMOLE SAMPLES

	Titrant required,[a] *ml*	
	Direct	Indirect
	10·66	10·67
	10·67	10·66
	10·64	10·67
	10·65	10·64
	10·66	
Average	10·66	10·66
Fe found, *mmole*	0·1004	0·1004

[a] 0·009421M DCTA.

The relative standard deviation for both titration methods is the same. Table IV shows the results that are obtained with 0·02M DCTA over a range of iron contents. It was found that the maximum amount of iron that can be determined with Chrome Azurol S indicator is approximately 1 mmole/100-ml sample volume because of the interfering colour of the iron-DCTA complex.

The most interesting results were those for titrations in the presence of other metal ions. In contrast to the observation of Musil and Theis,[7] milligram-amounts of aluminium react with Chrome Azurol S to give a violet colour at pH 1·3, which obscures the end-point for the iron titration. At pH 3 the molar extinction coefficient is about 30,000. Milligram-amounts of copper and nickel interfere in the titration, as would be expected from the values of the alpha function $\left(\frac{\text{free metal ion}}{\text{total metal}}\right)$ for these elements.[8] Manganese would not be expected to interfere, but the addition of 0·04 mmole

TABLE IV.—DIRECT TITRATION OF IRON AT pH 1·25–1·50 WITH 0·01959*M* DCTA

[b] Average of 6 analyses.

of manganese to 0·1 mmole of iron(III) led to results that were 0·3 % low. The cause of the interference by manganese could not be ascertained. No interference was observed for small amounts of cobalt(II). The addition of chloride ion as hydrochloric acid has no effect on the iron determination as long as the pH is greater than 1·3. Chloride ion added as sodium chloride has no effect on the titration at 0·1*M* levels. Table V shows that an increase in the ionic strength by addition of sodium nitrate does not lead to an appreciable change in stoichiometry.

TABLE V.—EFFECT OF ADDITION OF SODIUM NITRATE ON TITRATION OF IRON WITH DCTA AT pH 1·25–1·35

0·20	10·62
0·40	10·63

0·1005 mmole of iron taken in each case.

The end-point transition using Chrome Azurol S is much more easily determined than that of thiocyanate ion or sulphosalicylic acid. This and the fact that the conditions for use of the thiocyanate indicator are so restrictive, makes Chrome Azurol S the preferred indicator for the direct titration of iron.

In view of (1) the simplicity of the direct method using Chrome Azurol S, (2) the superior accuracy compared to the direct EDTA titration, and (3) a precision that is comparable to one of the best indirect titration methods, the direct titration of iron with DCTA is highly recommended.

L. W. MARPLE

Summary—The direct titration of iron(III) with disodium 1,2-diaminocyclohexanetetra-acetate using thiocyanate ion and Chrome Azurol S as indicators has been studied in detail. Good results can be obtained with thiocyanate indicator if the pH of the iron(III) solution is adjusted to 3·0–3·2 by simple dilution. The addition of a buffer or a dilute solution of a strong base to adjust the pH to the desired range always leads to low results. Chrome Azurol S is the preferred indicator because the colour transition is much more distinct and because titrations are possible in relatively acid solutions (pH 1·25). Up to 50 mg of iron/100-ml sample may be determined with a relative standard deviation of only 2 parts per thousand.

Zusammenfassung—Die direkte Titration von Eisen(III) mit Dinatrium-cyclohexadiamintetraacetat mit Rhodanid und Chromazurol S als

Indikatoren wurde in ihren Einzelheiten studiert. Gute Ergebnisse mit Rhodanid erhält man, wenn man durch einfache Verdünnung den pH der Eisenlösung auf 3·0–3·2 einstellt. Zugabe eines Puffers oder einer verdünnten Lösung einer starken Base zur pH-Einstellung gibt stets zu niedrige Ergebnisse. Chromazurol S ist als Indikator vorzuziehen, da der Farbumschlag schärfer ist und Titrationen in ziemlich sauren Lösungen (pH 1·25) möglich sind. Bis 50 mg Eisen in 100 ml Probe lassen sich mit einer relativen Standardabweichung von nur 2‰ bestimmen.

Résumé—On a étudié en détail le dosage direct de l'ion ferrique au moyen de cyclohexanediamine tétracétate disodique en utilisant, comme indicateurs, l'ion thiocyanate et le Chrome Azurol S. On peut obtenir de bons résultats avec l'indicateur au thiocyanate si le pH de la solution ferrique est ajusté entre 3·0 et 3·2 par simple dilution. L'addition d'un tampon ou d'une solution diluée de base forte pour ajuster le pH dans la zone désirée conduit toujours à des résultats faibles. On préfère l'indicateur Chrome Azurol S, car le virage de couleur est beaucoup plus net, et les dosages sont possibles en solutions relativement acides (pH 1·25). On peut doser jusqu'à 50 milligrammes de fer dans un échantillon de 100 millilitres, avec un écart type relatif de deux pour mille seulement.

The preparation of cerium–IV hydroxide from ammonium hexa-nitratocerate by employing kinetically controlled precipitation through urea hydrolysis

(*Received* 28 *April* 1964. *Accepted* 22 *May* 1964)

THE recovery of pure cerium-IV chemicals from thorium-freed monazite cerium-thorium sands involves the isolation of the cerium from the remaining rare earths by conversion to ammonium nitratocerate $(NH_4)_2Ce(NO_3)_6$.[1] A practical cerium-IV reagent which can be converted to sulphatoceric acid, $H_2Ce(SO_4)_3$, in sulphuric acid solution, for use as a standardised titrant, has previously been described.[1] The procedure involves the precipitation of $Ce(OH)_4$ by addition of a saturated aqueous solution of pure ammonium nitratocerate to a large excess of aqueous ammonia, followed by filtration of insoluble $Ce(OH)_4$, and washing this with water to eliminate ammonium salts. By this process the hydroxide is soluble in hot dilute sulphuric acid. If this $Ce(OH)_4$ is air dried, it forms a horny solid which must be ground to pass a 100-mesh sieve. The procedure here described for producing $Ce(OH)_4$ by kinetically controlled precipitation, employing urea, offers a much more practical preparation of ceric hydroxide, and avoids the difficult drying and grinding operation previously required.

Procedure

Add 1 pound of pure ammonium nitratocerate to a solution containing 1 pound of urea and 10 ml of concentrated nitric acid in a volume of 600 ml, in a 2000-ml covered Pyrex beaker, at boiling temperature. The resulting solution is dark red in colour and crystal clear. Keep the solution boiling briskly, adding water to replace that lost as vapour.

The preparation of cerium–IV hydroxide from ammonium hexa-nitratocerate by employing kinetically controlled precipitation through urea hydrolysis

(*Received* 28 *April* 1964. *Accepted* 22 *May* 1964)

THE recovery of pure cerium-IV chemicals from thorium-freed monazite cerium-thorium sands involves the isolation of the cerium from the remaining rare earths by conversion to ammonium nitratocerate $(NH_4)_2Ce(NO_3)_6$.[1] A practical cerium-IV reagent which can be converted to sulphatoceric acid, $H_2Ce(SO_4)_3$, in sulphuric acid solution, for use as a standardised titrant, has previously been described.[1] The procedure involves the precipitation of $Ce(OH)_4$ by addition of a saturated aqueous solution of pure ammonium nitratocerate to a large excess of aqueous ammonia, followed by filtration of insoluble $Ce(OH)_4$, and washing this with water to eliminate ammonium salts. By this process the hydroxide is soluble in hot dilute sulphuric acid. If this $Ce(OH)_4$ is air dried, it forms a horny solid which must be ground to pass a 100-mesh sieve. The procedure here described for producing $Ce(OH)_4$ by kinetically controlled precipitation, employing urea, offers a much more practical preparation of ceric hydroxide, and avoids the difficult drying and grinding operation previously required.

Procedure

Add 1 pound of pure ammonium nitratocerate to a solution containing 1 pound of urea and 10 ml of concentrated nitric acid in a volume of 600 ml, in a 2000-ml covered Pyrex beaker, at boiling temperature. The resulting solution is dark red in colour and crystal clear. Keep the solution boiling briskly, adding water to replace that lost as vapour.

The boiling temperature after 30 min is approximately 110° and the colour of the solution is beginning to decrease. At 40 min the colour is dark orange; foaming to the extent of 25 mm results from the evolution of carbon dioxide from the urea breakdown. At 45 min precipitation begins, the precipitate being orange in colour. At 60 min the precipitate is lemon yellow and the solution temperature is 112°. At 75 min the precipitate is still lemon yellow, and foam is still being produced. At 90 min the reaction is complete, the solution is colourless, and the precipitate is grey-white.

Allow the reaction mixture to cool, and transfer the solution and precipitate to two polyethylene wide-necked 250-ml bottles with screw caps. Place the bottles in a pair of centrifuge trunion cups, and separate the precipitate from the parent solution by 5 min rotation at 1500 rpm and 250 mm displacement from the centre of rotation. (Trunion cups #844 of a No. 2 International Instrument Company centrifuge may be employed.) Pour off supernatant solution (pH approximately 12), add 150 ml of water to each bottle, stir well and repeat this centrifugal separation 5 or 6 times until the washings no longer give an ammonia test.

Transfer the $Ce(OH)_4$ thus prepared to a sheet of polyethylene and spread it out in a thin layer. The product air-dries in a few hours to give a finely divided pulverulent product. The yield is theoretical (approximately 37·95% of the weight of hexanitratocerate taken as raw material).

The finished product is readily soluble in hot dilute sulphuric acid to give a crystal clear solution that is stable on storage, and that may be heated to boiling without decomposition. It is not soluble in cold concentrated nitric or perchloric acid except after extremely long periods of storage.

G. Frederick Smith

Summary—The preparation of cerium-IV hydroxide by kinetically controlled precipitation through use of the hydrolysis of urea and its reaction with ammonium hexanitratocerate is described. The air-dried product thus obtained is of fine-mesh particle size and is readily soluble in hot dilute sulphuric acid to form solutions of sulphatoceric acid, $H_2Ce(SO_4)_3$, for oxidimetric titrations.

Zusammenfassung—Die Darstellung von Cerhydroxyd durch kinetisch kontrollierte Fällung mittels Dissoziation von Harnstoff und Reaktion mit Ammoniumnitratocerat wird beschrieben. Das so erhaltene Produkt ist nach Trocknung an der Luft sehr feinkörnig und leicht in heißer verdünnter Schwefelsäure löslich, wobei sich als titrimetrisches Oxydationsmittel geeignete Lösungen von Sulfatocersäure $H_2Ce(SO_4)_3$ bilden.

Résumé—On décrit la préparation de l'hydroxyde cérique par précipitation contrôlée cinétiquement, en utilisant l'hydrolyse de l'urée et la réaction avec l'hexanitratocérate d'ammonium. Le produit ainsi obtenu, séché à l'air, se présente en particules fines et est aisément soluble en acide sulfurique dilué chaud, formant des solutions d'acide sulfatocérique $H_2Ce(SO_4)_3$; celles-ci sont utilisées comme oxydant pour titrages.

LETTER TO THE EDITOR

"Deionised" or "deioned"?

SIR,

In past years, the terms "deionisation" (of water, hydrogen peroxide, *etc.*) and "deionised" (of water, *etc.*)[1–7] have occurred widely in world scientific literature in connection with the extensive use of ion-exchangers in science and industry (in particular for ion-exchange water purification).

In our opinion, these expressions are not well chosen for the following reasons. In fact, the term "ionisation of water" has meant the following quite definite equilibrium for a long time:

$$H_2O \rightleftharpoons H^+ + OH^- \qquad (1)$$

Thus, the term "deionisation of water" denies ionisation, *i.e.*, denies process (1), which is incorrect: in reality, "extraction of ions" should be implied, *i.e.*, the removal of ionic impurities (*e.g.*, heavy metals) from water or hydrogen peroxide in the course of the ion-exchange purification of these substances.

This specific error occurs in the scientific literature of many languages, among them English (deionisation, deionised), German (Entionisierung, Deionisierung, entionisiertes), French (dé[s]ionisation, déionisé), Russian (деионизация, деионизированный), and also in Hungarian, Dutch, Spanish, Italian, Ukrainian, Czech, Swedish, and others. In addition to this, in English scientific literature, widespread synonyms used are "desalting", "demineralisation" (of water, *etc.*), "ion-exchange water", "demineralised water", *etc.*[1] Similar variations in this respect are observed in other languages.

It would seem more appropriate to use the expressions "deionation" and "deioned", which are shorter, and—an important point!—they express the crux of the matter more clearly and precisely. Analogous simplifications and more accurate definitions of these terms could easily be devised for other languages, and as a result of it we would find in the German language "Entionierung" and "entioniertes", in Russian "деионирование" and "деионированный" (*cf.*[8]), in Ukrainian "деіонування" and "деіонований", in French "dé(s)ionation" and "déioné", in Czech "deionace", and "deionovaný", in Swedish "avjonerat" and "avjonering", *etc.*

Surely the main thing of everything of this suggestion is not so much in the rejecting of these two unnecessary letters -is-, to which we have already become accustomed, as in terminological precision. But for precision and accuracy: *Amicus Plato, sed magis amica veritas!*

Acknowledgement—Many thanks are due to my friends Dr. A. A. Bugayevsky for his interest and helpful criticism, and Mrs. H. G. Klausnitzer for the English translation.

Summary—A review of radiometric titrations is presented.

CONTENTS

---

* For reprints of this review see publisher's announcement at the end of this issue.

1. INTRODUCTION

THE present paper aims at surveying the basis, the possibilities in, and the present state of radiometric titrations. Nearly all the papers published in this field from 1941, when this method was first developed, to the end of 1963 have been covered.

To the best of our knowledge, no review paper on this subject has so far been published in the literature. However, radiometric methods in general, and the general analytical applications of radioactive isotopes, have been discussed in quite a large number of reviews. In these only relatively small space has been devoted to radiometric titrations, and the descriptions have mainly been limited to an incomplete survey of earlier communications.

In the present review, several papers published in less readily available journals, or not available at all, have been covered in a relatively detailed manner. An attempt has been made by the present authors to discuss in a reasonably homogeneous form these less-known papers and the other better known material. This should facilitate the spread and further development of the method.

2. END-POINT DETERMINATION BY RADIOMETRY

In the course of a radiometric titration, in order to determine the end-point, the radioactivity of the solution is chosen as the "property" which is followed. Under identical conditions of measurement, changes in radioactivity are proportional to the concentration of the labelled component. Thus, on plotting the changes in the radioactivity of some of the reactants or reaction products during the titration against the quantity of titrant added, the end-point is indicated by the point of intersection of two straight lines on the titration curve.

Measurement of the radioactivity of substances, as a "property" followed during titration, can be carried out with an extreme accuracy, reliability and sensitivity, using a Geiger-Müller (GM) tube or one of the scintillation methods described in the literature. This procedure offers the particular advantage that, quite in contrast with other instrumental methods of end-point indication, the magnitude of the property being measured can be altered as desired, even when titrating extremely low concentrations. This is because the magnitude is determined exclusively by the specific activity of the radioactive isotope used for labelling.

Another important advantage of the method is the possibility of its easy automation. The technique of measuring radioactivity has been so far developed in other, non-analytical aspects to such an extent that the knowledge can also be applied in the case of radioanalytical methods without any difficulty. Although there are still only relatively few results in this field, in our opinion the process of automation would appear to represent one of the main trends in the development of radiometric titrations in the future.

In addition, it should be mentioned that end-point determination by radiometry can also be applied, without any further modification, in coloured, turbid or corroding media, because the actual measurement of radioactivity is not affected by these conditions.

3. "PHASE SEPARATION" AND ITS IMPORTANCE IN RADIOMETRIC TITRATION

As already mentioned, changes in the radioactivity of one of the reactants or reaction products are followed during radiometric titrations. This necessitates that the radioactivity of the component being followed should be measured "alone", *i.e.*, separated from that of the other partners of the system. This is one of the central problems in radiometric titrations. In effect, of all the reaction types applied in titrimetric analysis, the separation of phases only occurs in the case of titrations based on precipitate formation; in the case of other reaction types, separation can only be carried out using some auxiliary method or process.

On account of the great importance of phase separation, it will be discussed in detail in the present review, and the description of the various possibilities available in this respect will form a fundamental part of the discussion.

Phase separation is closely correlated with another problem in radiometric titration of equal importance—the continuity of the course of a titration. This must be particularly emphasised because, in order to evolve a suitable method of titration, not only must a reasonable possibility of phase separation exist, but the method chosen must be suitable for the application of continuous separation instead of merely batchwise operation.

4. RADIOMETRIC TITRATION BASED ON PRECIPITATION

Many reactions based on precipitation are known, apart from those applied in neutralisation analysis. However, with the exception of argentometric and mercurimetric titrations, reactions based on precipitate formation are rarely used in titrimetry. This is a direct result of the lack of adequate visual or instrumental methods of end-point indication.

The significance of radiometric titrations consists mainly in its capability of indicating the end-point, even in precipitation reactions of analytical importance for which no adequate visual indicators are available. A pronounced disadvantage of visual precipitation titrations against acid-base titrations, for example, is that different indicators are required for nearly every reaction. In radiometric titrations, on the other hand, it is possible to determine several substances by only one labelled titrant (which at the same time also serves as an indicator).

4.1. *Mathematical analysis of titration curves*

The theoretical problems of radiometric titrations and the mathematical analysis of the titration curves have been discussed in detail by Duncan and Thomas,[1] and by Jesenák and Tölgyessy.[2–4]

In evolving the theory of radiometric titrations based on precipitate formation, Jesenák and Tölgyessy start with the analogy between these titrations and amperometric titrations.[5]

On titrating a solution which contains cation A^+ with a titrant containing anion B^-, with the formation of a precipitate AB of poor solubility (with a solubility product L_{AB}), according to the reaction

$$A^+ + B^- \rightleftharpoons AB \qquad (1)$$

the correlation between the concentration of the ion A^+ and the amount of titrant added is expressed by the equation

$$\gamma^2 - \frac{\gamma_0 v_0 - c_0 v}{v_0 + v}\gamma - L_{AB} = 0 \qquad (2)$$

where γ_0 = the initial concentration of cation A^+ (normality),
γ = the concentration of cation A^+ during titration (normality),
c_0 = the concentration of titrant referred to B^- ion (normality),
v_0 = the initial volume of titrant (litres),
and v = the amount of titrant added (litres).

If

$$\frac{\gamma_0 v_0 - c_0 v}{v_0 + v} = Q \tag{3}$$

then

$$\gamma = \tfrac{1}{2}(Q + \sqrt{Q^2 + 4L_{AB}}) \tag{4}$$

Similarly, the concentration of B^- ion, c, is given by the equation

$$c = \tfrac{1}{2}(-Q + \sqrt{Q^2 + 4L_{AB}}) \tag{5}$$

and the sum of the concentrations of the two ions, $\gamma + c$, is given by

$$\gamma + c = \sqrt{Q^2 + 4L_{AB}} \tag{6}$$

In radiometric titrations, three types of titration curve may be obtained. The shape of the titration curve depends on whether the titrant itself, or the titrated solution, or both, are actually radioactive.

(*a*) When the solution to be titrated is active and the titrant is inactive, the activity of the supernatant solution shows a decrease during titration proportional to the formation of precipitate. At the equivalence point, the actual activity of the solution is determined by the solubility of the precipitate.

Because the radioactivity of the solution is directly proportional to the concentration, *i.e.*,

$$\gamma_0 = k \,.\, I_0$$

where I is the activity expressed by the number of impulses per minute

and $$\gamma = k \,.\, I$$

on substitution into equation (2), the equation

$$I^2 - \frac{kI_0 v_0 - c_0 v}{k(v_0 + v)} I - \frac{L_{AB}}{k^2} = 0 \tag{7}$$

is obtained.

In Fig. 1, the theoretical titration curve described by equation (7), referred to the conditions specified in the figure, is shown.

(*b*) When the solution to be titrated is inactive and the titrant is active, the activity of the solution is determined at the beginning of titration by the solubility product of the precipitate formed during titration, and the activity does not rise until the equivalence point is reached. However, on attaining this point, the activity of the solution increases markedly on the addition of further portions of active titrant.

On substituting $c = k \,.\, I$ into equation (5), the equation

$$I^2 + \frac{\gamma_0 v_0 - c_0 v}{k(v_0 + v)} I - \frac{L_{AB}}{k^2} = 0 \tag{8}$$

is obtained.

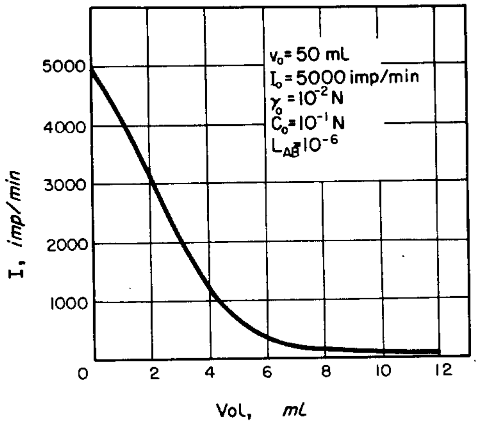

FIG. 1

The titration curve described in such conditions is shown in Fig. 2.

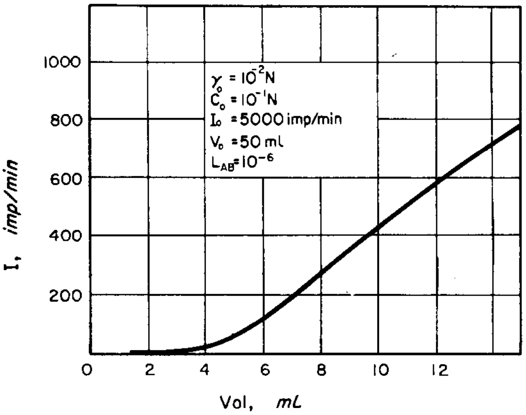

FIG. 2

(*c*) When both the titrated solution and the titrant are active, the activity of the solution decreases during titration, and subsequently rises. The equivalence point is determined by the minimum value of the curve.

If

$$\gamma_0 = k_1 I_{1,0},$$

$$\gamma = k_1 I_1,$$

and

$$c = k_2 I_2$$

the relative activity measured during the titration will be

$$I = \frac{1}{2}\left[R\left(1 - \frac{k_1}{k_2}\right) + \sqrt{R^2 + \frac{4L_{AB}}{k_1^{\,2}}} + \sqrt{\left(\frac{k_1}{k_2}R\right)^2 + \frac{4L_{AB}}{k_2^{\,2}}}\right] \tag{9}$$

where

$$R = \frac{k_1 I_{1,0} v_0 - c_0 v}{k_1(v_0 + v)} \tag{10}$$

In some cases, equation (9) can be simplified:

1. If $k_1 = k_2 = k$, *i.e.*, if the ratio of the activities of the solution to be titrated and of the titrant corresponds to the ratio of their concentrations, equation (9) can take the simplified form

$$I = \sqrt{R^2 + \frac{4L_{AB}}{k^2}} \tag{11}$$

In Fig. 3, the titration curve described by these conditions is presented.

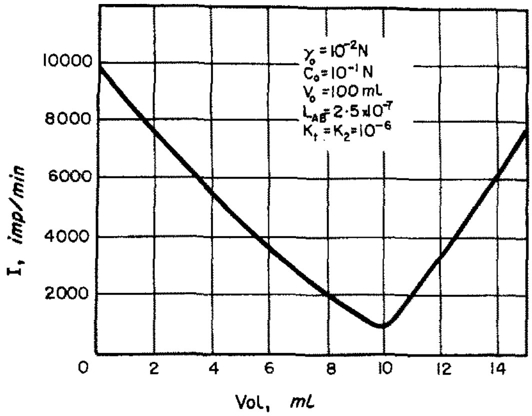

FIG. 3

2. If k_1 is negligible compared with k_2, *i.e.*, if the activity of the titrated solution markedly exceeds that of the titrant, the simplified form reads

$$I \approx \frac{1}{2}\left[R + \sqrt{R^2 + \frac{4L_{AB}}{k_1^2}}\right] \tag{12}$$

3. If, on the other hand, k_2 is negligible compared with k_1, equation (9) can be simplified to

$$I \approx \frac{1}{2}\left[-\frac{k_1}{k_2}R + \sqrt{\left(\frac{k_1}{k_2}R\right)^2 + \frac{4L_{AB}}{k_2^2}}\right] \tag{13}$$

4.2. *End-point determination by extrapolation method, and simplified techniques*

In radiometric titrations, the correlation of the activity of the solution and the quantity of titrant added is plotted as a graph. The end-point is indicated by the break in the curve.

The determination of the end-point with the aid of the titration curve (whose plotting requires 6 readings) used to last about 40–50 min. The speed of the determination depends on the nature of the precipitate formed and on the rate of its sedimentation. It is also possible to detect the end-point using only 2 points on the titration curve. In this case, the time required for the determination is reduced to 8–10 min.[6–10] Jesenák and Tölgyessy[2,3,11] have discussed in detail the mathematical analysis of end-point determination by the extrapolation method.

(*a*) *On titrating an active test solution with an inactive titrant*, the number of ml required to reach the end-point (V_{ex}) can be calculated by the formula

$$V_{ex} = \frac{I_0 \cdot V_1}{I_0 - I_1} \tag{14}$$

where V_1 is the number of ml of titrant added when the activity of the solution decreases to $I_1(V_1 < V_{ex})$, and I_0 is the initial activity of the solution (Fig. 4).

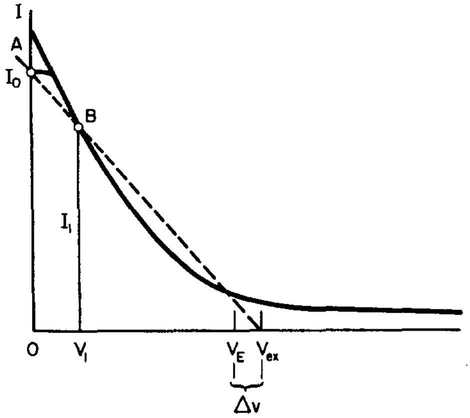

FIG. 4

When the number of ml of titrant added is given as a ratio related to the real equivalent consumption (V_E),

$$v_1 = k \, . \, V_E \quad ,$$

and the relative error of the determination by the extrapolation method, δ, is given by

$$\delta = \frac{V_E - v_{ex}}{V_E} = \left(1 - \frac{K \, . \, I_0}{I_0 - I_1}\right) \tag{15}$$

On titrating a radioactive test solution with an inactive titrant, the correlation of the concentration of the labelled ion γ with other parameters of the determination can be derived from equation (2), using values in the literature:[11]

$$\gamma^2(v_0 + v) - \gamma\gamma_0 v_0 + \gamma c_0 v - L_{AB}(v_0 + v) = 0 \tag{16}$$

and, because the radioactivity of the labelled ion is proportional to the concentration ($\gamma = k \, . \, I$), the changes in activity can be expressed by

$$\gamma_0{}^2 v_0 I^2 + \gamma_0{}^2 v I^2 - \gamma_0{}^2 v_0 I_0 I + \gamma_0 c_0 I_0 I v - L_{AB} I_0{}^2 v_0 - L_{AB} I_0{}^2 v = 0 \tag{17}$$

Because the graph of activity against the number of ml of titrant added does not give a straight line, the determination of the equivalence point by the extrapolation method is accompanied by an error which increases with an increase in the solubility product, L_{AB}, of the precipitate formed, and with an increase in the ratio v/v_0.

In order to check the validity of equation (17), Jesenák and Tölgyessy[11] titrated Tl^+ ion labelled with ^{204}Tl using $0{\cdot}1N$ Br^- solution as titrant. They also calculated the course of the titration curves under the given conditions of titration according to equation (17), using the following values: $\gamma_0 = 10^{-2}M$-$6 \times 10^{-2}M$; $v_0 = 5 \times 10^{-2}$ litre; $c_0 = 0{\cdot}1M$; $I_0 = 10^3$ imp./min; $L_{TlBr} = 2 \times 10^{-6}$ mole^2/litre^2. The titration curves obtained in this way are shown in Fig. 5. It can be seen that the experimental results are in a fair accordance with the calculated values (the experimental results are denoted by circles). Fig. 5 also shows the curves which connect the identical values of relative error of determinations by the extrapolation method, calculated using equations

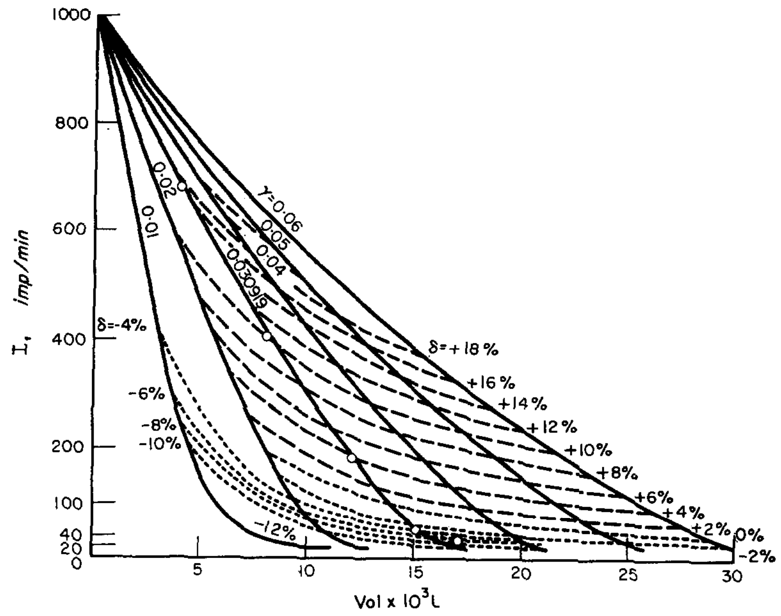

Fig. 5

(15) and (17). The dependence of the values of these errors on the volumes of titrant added and on the concentration of the test solution are shown by Fig. 6. It can be seen that relative errors may attain quite appreciable values. The errors did not show the minimum values at the ratio of $I/I_0 = 0{\cdot}5$ at which extrapolation is suggested in the literature.[7] Thus, it appears advisable in radiometric titrations to check the error of the extrapolation method or to evaluate the titration on the basis of equation (17).

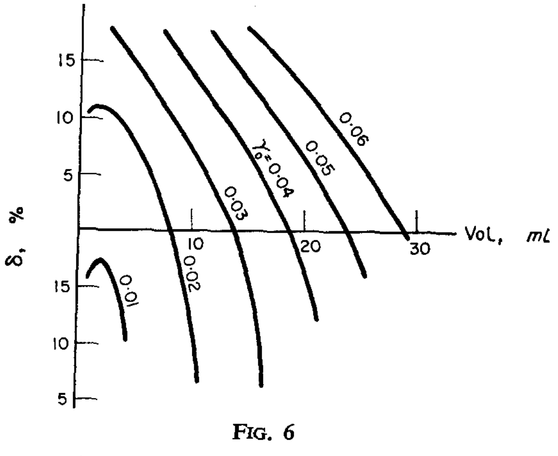

Fig. 6

Because the evaluation of equation (17) is rather cumbersome, we suggest the use of the following method. Equation (17) can also be expressed in a dimensionless form with the aid of the simplexes

$$J = \frac{I}{I_0}, \qquad V = \frac{v}{v_0}$$

and of the criteria

$$C = \frac{\gamma_0}{\sqrt{L_{AB}}}, \qquad C_c = \frac{c_0}{\sqrt{L_{AB}}}$$

leading to the equation

$$C_\gamma^2(J^2 + VJ^2 - J) + C_c VJC_\gamma - (1 + V) = 0 \tag{18}$$

Serial determinations can be carried out by maintaining, during the measurements,

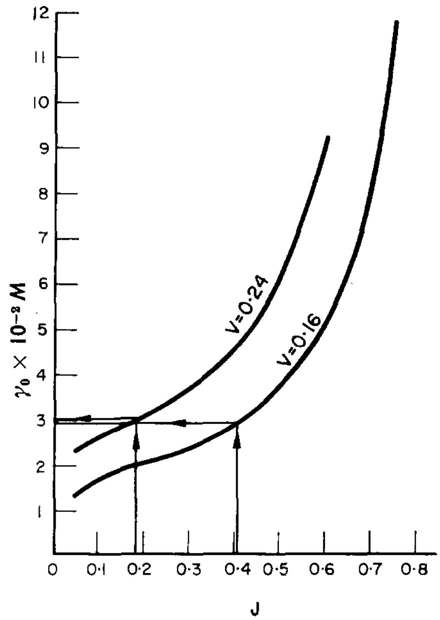

Fig. 7

constant values of V and C_c. In this case, equation (18) yields the correlation

$$C_\gamma = F(J)_{V,C_c} \tag{19}$$

or

$$\gamma_0 = G(J)_{V,C_c} = \sqrt{L_{AB}} \cdot F(J)_{V,C_c} \tag{20}$$

the application of which to the determination of Tl^+ ions, described by adding two standard volumes of titrant to the test solution, is shown in Fig. 7. The exact concentration of the test solution can be read directly from Fig. 7.

The error in the extrapolation method is

$$\delta = \frac{1 - (K - J)}{1 - J} \tag{21}$$

This method offers the advantage of maintaining c_0, v_0, v and L_{AB} at constant values in serial determinations. The value of J ($J = I/I_0$) is obtained from the activity of the test solution and from the activity measured on the supernatant liquid after forming a precipitate by addition of a standard amount of titrant. Then the concentration of the test solution is read from the graph plotted using equation (18).

(*b*) *On titrating an inactive test solution with an active titrant*, the number of ml required to attain the equilibrium point can be calculated by the formula

$$v_{\mathrm{ex}} = \frac{V_1 I_2 - V_2 I_1}{I_2 - I_1} \tag{22}$$

In this case, an excess of titrant, V_1, is first added to the test solution, and the activity of the solution, I_1, is determined. On adding a second volume of titrant, v, where $V_2 = V_1 + v$, the activity of the solution, I_2, is again measured (Fig. 8).

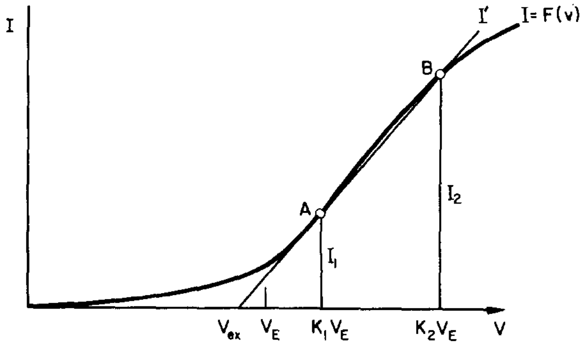

FIG. 8

In this case, according to Fig. 8, the relative error of the determination will be

$$\delta = \frac{V_{\mathrm{E}} - V_{\mathrm{ex}}}{V_{\mathrm{E}}} = \frac{I_2(1 - K_1) - I_1(1 - K_2)}{I_2 - I_1} \tag{23}$$

In addition, Jesenák and Tölgyessy[11] evaluated the derived dimensionless equations using an electronic computer, type ZRA I. Thus, the course of the curve of precipitate formation, of the dilution curve, and of the error of the linear extrapolation was calculated for a wide field of varying parameters in order to follow the effect of the single parameters in precipitation reactions of analytical importance.

4.3. *Methods of phase separation and technique of titration*

The fundamental prerequisite for the possibility of carrying out a radiometric titration is the ability to separate the initial radioactive reagents from the radioactive reaction products. This, however, as already previously mentioned, is possible only in the case when the reaction products are present in a different phase from that of the initial substances. This condition is met in precipitation reactions where the reaction product precipitates from the liquid medium in a solid form, *i.e.*, the radioactive indicator is converted from an aqueous phase into solid phase. In all such operations described in the literature, phase separation has been achieved by filtration, centrifuging or flotation.

4.3.1. *Filtration methods:* In the simplest case, the precipitate formed on titration can be separated from the solution by filtration through filter paper. This method was used, for example, by Moeller, Terril and Seal[12] to determine chloride ion in various waters.

The first apparatus applying phase separation by filtration to radiometric titration was designed by Langer.[13] This is shown in Fig. 9. On titration, after the addition of a certain amount of titrant, the supernatant liquid is sucked up by the suction device into the glass mantle, and the activity of supernatant liquid is measured by a GM counter. After returning this liquid to the bulk solution, another portion of titrant is added to the test solution, and the whole process is repeated.

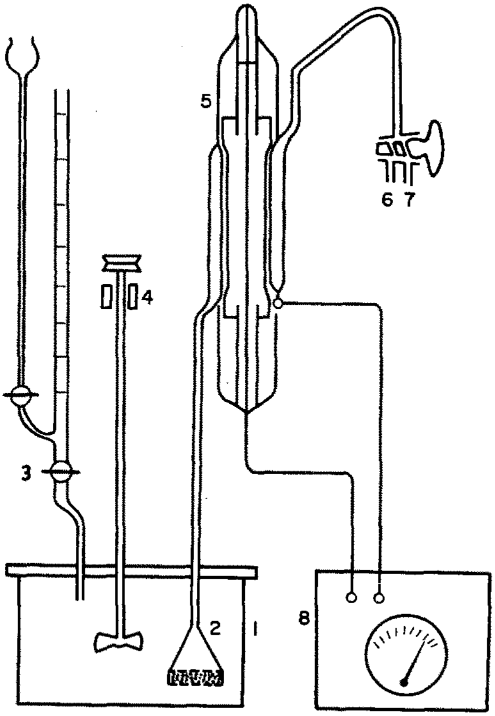

Fig. 9.—Apparatus for radiometric titrations based on precipitate formation, according to Langer.[13]

1. Titration flask	5. GM counter
2. Suction device with filter	6. To rubber bulb
3. Burette	7. To suction pump

The apparatus shown in Fig. 10 was used for radiometric titrations by Sirotina and Alimarin.[14]

The apparatus used by Tölgyessy and Schiller[15] is shown in Fig. 11.

A conventional apparatus for amperometric titration was modified and adapted to radiometric titration by Aylward and co-workers.[16] The dropping mercury electrode was removed from the original apparatus, and it was replaced by a filter tube.

During titration, volume changes take place, arising from the addition of titrant. The measured impulse values have, therefore, to be corrected for the volume change occurring during titration. The correction value is obtained by multiplying the measured impulse values by the correction factor, k', where

$$k' = \frac{V_0 + V_1}{V_0} \tag{24}$$

4. Sprayer	8. Glass tube with glass filter

V_0 being the original volume, in ml, of the test solution and V_1 the number of ml of titrant added.

4.3.2. *Centrifuging method:* A shortcoming of the filtration methods is the glass tube ending in a glass filter, which is frequently clogged by fine-grain precipitates. This drawback is, however, eliminated in the centrifuging method evolved by Korenman and co-workers.[17] In this method, identical amounts of the test solution are transferred into several centrifuge tubes, various amounts of the titrant are added, and the tubes are then filled up to the same volume with distilled water. The precipitate formed is then sedimented by centrifuging, 0·5–1·0-ml portions of the supernatant liquid are transferred by a pipette to filter paper, and, after drying the paper strips, the radioactivity of the preparations is measured. The titration curve is plotted using the values obtained. The Frieseke Hoepfner Automat apparatus, type FH 49 proved to be particularly suitable[18] for rapid determinations by the centrifuging method. In this apparatus, the circular dry filter papers are placed in the cavity of the rotating sample-exchanger disc, and their activity is automatically measured. A titration curve is plotted on the basis of the registered values of activity.

4.3.3. *Flotation method:* Flotation was used with success by Braun, Galateanu and Maxim[19,20] for phase separation in radiometric precipitation titrations. On applying flotation, solid particles suspended in water are separated from the liquid by the effect of air bubbled through the system in a vigorous flow. The particles adhere to the inner free surface of the air bubbles which, on rising, carry the solid as well. In this case the system consists of three phases: gas (air bubbles), liquid (water) and solid (solid particles of the substance). The same circumstances are also present in radiometric titrations, but, the gas phase is replaced by a liquid phase immiscible with water (organic liquid). On stirring or shaking the system, the two phases are converted to an unstable emulsion of the organic compound in water. Because of adhesive forces, the particles of the precipitate adhere to the drops of the organic compound, and finally separate at the interface of the two liquids. The measurement of activity is easier when the labelled component is present in the upper phase. Because in a titration the activity of the aqueous layer is being measured, it is desirable to use organic compounds with a specific gravity exceeding that of water.

4.3.4. *Automation of the titration:* The problem of automation of precipitation titrations is discussed in several papers.[1,21–23]

Tölgyessy and Sajter[23] evolved a procedure and an apparatus for automatic titrations which automatically adds the titrant and registers the titration curve. The titrant is added to the test solution at a steady rate, and a precipitate of low solubility is formed. The circulation of the supernatant liquid through the filter plate in the titration flask, into the glass mantle of the GM counter measuring the liquid, and back again into the titration flask, is achieved by a laboratory micropump. The GM counter is attached to a rate-meter, and the activity values indicated by this rate-meter are continuously registered by an adequate registering device. This apparatus is shown in Fig. 12.

In another paper[22] the same authors suggested a method for automatic radiometric titrations carried out to the equivalence point. This technique is particularly useful for the serial determination of substances present in approximately identical amounts. Before carrying out the actual determination it is necessary to plot the titration curve with a sample in order to obtain the radioactivity of the supernatant

liquid at the equivalence point. This method is essentially similar to the previous technique in which the titration curves are automatically registered. The only differences lie in the measurement of the radioactivity and in the determination of the equivalence point. In titrations of this type, the time from first adding the titrant to attaining the equivalence point is measured by an electric stop-watch which is automatically started and stopped by a rate-meter. The addition of titrant is also similarly controlled. If the activity of the supernatant liquid decreases to a previously set value, the addition of titrant is interrupted, and the electric stop-watch is stopped. The apparatus is shown in Fig. 13. The polyethylene tubing (4) through which the titrant is added is closed by an electromagnetic valve (3). This, in turn, is controlled through a relay (6) by a Soviet rate-meter of type TISS. With a steady rate of addition of titrant and knowing the time of addition, the volume of titrant consumed can be determined. When a burette, or another calibrated flask, is used for titration, no stop-watch is necessary because the volume of titrant consumed can be read directly.

The automatic apparatus eliminates subjective errors, and it permits an increase in the accuracy of the determination and a reduction of the time required for the titration to about 5–8 min.

4.4 *Determination of several components together*

Methods suitable for the determination of several substances in the presence of each other can be classified in five groups.[9,10,17,24,25,26]

4.4.1. *Radiometric titration of two substances by two titrations and one active titrant:* (*a*) This method lends itself to the determination of two substances in the presence of each other only when both substances yield poorly soluble precipitates with the same titrant. Two portions of identical volume of the solution to be titrated are used in this type of determination. The combined amount of both substances is first determined in a portion of the test solution by titration with active titrant. Then in another portion of the test solution of identical volume, one of the substances is precipitated by a selective reagent. The precipitate is removed by filtration (or sedimentation without filtration), and the other substance to be determined is measured by titration with the active titrant. The quantity of both substances can be calculated from the results of the two titrations. For example, to determine zinc and lead ions present together, a portion of the test solution is titrated with labelled potassium ferrocyanide solution. The amount of titrant consumed gives the combined content of zinc and lead. Subsequently, lead is precipitated from another portion of the test solution with sulphuric acid, and the zinc content of the residual solution is determined by radiometric titration. The lead content can be calculated from the difference in the two titrations.[18,25]

(*b*) As a variant of this technique, two oxidation states of the same substance can be determined in the presence of each other (*e.g.*, iodine and iodide), one of which gives with the titrant a precipitate of poor solubility. In this method, as in the previous case, two portions of identical volume of the test solution are used. In the first portion, using an active titrant, the amount of that component is determined which gives a poorly soluble precipitate with the titrant. Then, in the other portion of the test solution, by an appropriate oxidation or reduction, the second component is converted to the same oxidation state as the first, and both components are determined together. For example, to determine iodine and iodide present together, the amount of iodide ion is first measured by titration with a solution of $^{204}Tl_2SO_4$. In another portion of the test solution, iodine is reduced to iodide with sodium thiosulphate solution, and the total amount of iodide is determined.[27]

4.4.2. *Radiometric titration of two substances by two inactive titrants:* The substances to be determined are labelled by adequate radio-isotopes, and then consecutively titrated with selective titrants. For example, to determine sulphate and iodide present together, the test solution is labelled with $^{131}I^-$ and $^{35}SO_4^{2-}$ ions, *i.e.*, with the isotopes ^{131}I and ^{35}S. Then barium chloride as titrant is added to the test solution. The activity of the supernatant liquid will decrease with the precipitation of sulphate ion up to the first end-point, after which the activity will show a constant value. Silver nitrate as titrant is then added to the test solution. The activity of the supernatant liquid will then decrease with the precipitation of iodide ion. After the second end-point, the activity of the solution will be determined only by the solubility of barium sulphate and silver iodide. By plotting the course of titration, the end-points can be read from the curve obtained.[9,25]

4.4.3. *Radiometric titration of two substances by one active titrant:* Two substances can be determined together with an active titrant when the substances to be determined form precipitates with the titrant at various pH values, as in the determination of two ions by Busev and Byrko.[26,28] One of the ions is completely precipitated at pH 14, and the other ion at a lower pH value. Another example is the determination[26] of Tl^{3+} and In^{3+}, with 1-dithiocarboxy-5-phenylpyrazoline labelled with ^{35}S as titrant. The Tl^{3+} ion is first titrated at pH 14. At the end-point the activity of the supernatant liquid rises, because of the excess titrant. On adjusting the pH value of the solution to 7 the In^{3+} ion precipitates, and the activity remains constant, being determined by the solubilities of the thallium and indium complexes. After complete precipitation of the indium, the activity of the solution will again rise.

4.4.4. *Radiometric titration of two substances by one inactive titrant:* Two substances can be titrated with an inactive titrant when the substances form with the titrant poorly soluble precipitates of markedly differing solubility products. The solution is labelled with an appropriate radioisotope for the substance which gives the more soluble precipitate. The end-point can then be determined by calculation.[9,25]

The course of titration is shown in Fig. 14. Three values of activity are required for the calculation of the two end-points by equations (25) and (26):

$$V_{1_{ekV}} = (V_2 - V_1)\frac{I_0 - I_1}{I_2 - I_1} + V_1 \tag{25}$$

$$V_{2_{ekV}} = (I_0 - F)\frac{V_1 - V_2}{I_2 - I_1} \tag{26}$$

The technique of this determination is as follows. First the original activity, I_0, of the labelled test solution is measured. Then V_2 ml of titrant are added in order to precipitate quantitatively the first component, and the activity of the supernatant liquid, I_2, is measured. After adding a further amount, v ml, of titrant, where $V_1 = V_2 + v$, the activity, I_1, is measured. F is the activity of the solution at the second end-point.

For example, to determine sulphide and iodide ion the test solution is labelled with radioactive iodine (as $^{131}I^-$), and titration is carried out with a solution of silver nitrate as titrant. On adding the titrant, the activity of the solution does not change while sulphide ion is present in the solution. After the precipitation of the sulphide ion, the precipitation of iodide ions (together with ^{131}I) leads to a decrease of activity in the solution. From the values obtained a titration curve is established. The end-points can be read from this curve or can be determined by calculation.

4.4.5. *Radiometric titration of three substances by one inactive titrant:* Three substances, in fact, can be determined with an inactive titrant if the substances give with the titrant poorly soluble precipitates of markedly different solubility products.

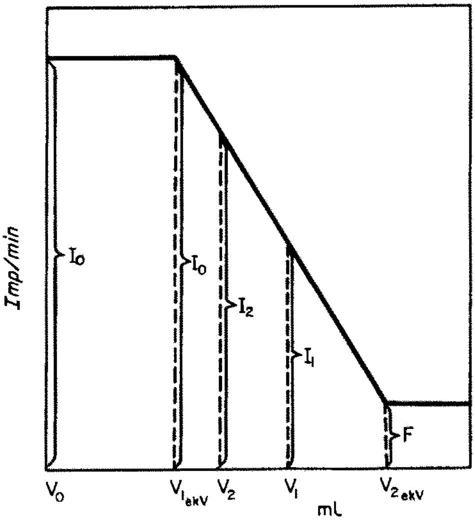

FIG. 14

In determinations of this type, radioisotopes suitable for the two components with the least and greatest solubilities, *i.e.*, those which precipitate first and last, are applied for labelling the solution.

4.5. *Practical applications*

In the field of precipitation titrations the majority of the methods are based on the precipitation reactions which are most frequently used in the normal determination of inorganic substances. In this way, the following elements and compounds have been determined: silver,[7,9,15,18,43,60] lead,[18,57] mercury,[15] copper,[15,16,18,42] cadmium,[34] zinc,[17,18,26,28,34,35,36] iron,[45] cobalt,[50] nickel,[60] calcium,[29,32] barium,[9] magnesium,[13] palladium,[15,55] thallium,[14,28,51,52,61] zirconium,[51,52,53] beryllium,[51,52,54] niobium,[56] tantalum,[56] uranium,[13] rare earth metals,[46–49] phosphates,[9,13,31] chromates,[18] carbonates,[18] sulphates,[9,12,29–32] oxalates,[18,57,59] chlorides,[7,9,12] bromides,[7,9] iodides,[9] cyanides,[9,57,59] sulphides,[18] fluorides,[18,44] ferrocyanides,[9] iodates,[18] molybdates,[31] sulphocyanides,[9] and inorganic drugs.[63] By the methods already described, several substances have also been determined in the presence of each other, such as the pairs iodide-chromate,[25] iodide-iodine,[27,29,30] sulphate-iodide,[9,25] calcium-lead,[25] zinc-cadmium,[34] zinc-copper,[17] sulphide-iodide,[25] lead-zinc[25] and thallium-indium.[26] Among organic compounds, the following can be included: quinine,[37–40] hyoscyamine,[40,41] morphine,[40,41] strychnine,[40,41] 8-hydroxyquinoline,[38,39] amidopyrine,[37,39] purines and barbiturates,[64] sulphamides,[57] alkaloids[58,62] and other organic drugs.[65]

4.6. *Increasing the sensitivity of radiometric titration based on precipitate formation*

The sensitivity of titrations based on precipitate formation is known to be of the order of magnitude of mg. This limit of sensitivity appears to follow from the basis of the method itself, being actually determined by the solubility product of the precipitate formed during titration.

Braun and Tölgyessy[69] have evolved several methods for increasing the sensitivity of titrations of this type.

4.6.1. *Radiometric titration on ion exchangers:* The radiometric titration of iodate ions by a silver nitrate solution labelled with ^{110}Ag has been carried out by Braun, Maxim and Galateanu.[70] This titration was conducted by the conventional technique. Because the solubility product of silver iodate is rather low, the titration cannot be carried out in very dilute solutions. However, when the iodate ions have previously been bound by anion exchangers added to the system, it is possible to conduct the titration even in $10^{-4}M$ solutions. The precipitate forms on the surface of the particles of ion exchanger where the ion to be titrated is present in an enriched form.

4.6.2. *Radiometric titration by separation with a collector:* The radiometric titration of zirconium by a PO_4^{3-} titrant labelled with ^{32}P was described in 1956 by Alimarin and Gibalo,[53] together with a technique suitable for the titration of mg-amounts. If, during the titration, after the addition of each new portion of titrant (PO_4^{3-}), solutions of silver nitrate and sodium iodide are added to the system from two separate burettes, the silver iodide precipitate which forms carries with it, as a collector, the traces of zirconium phosphate not still precipitated. In this way, minute amounts of zirconium can be titrated, *e.g.*, about 10 μg of zirconium can be determined with an error of about $\pm 5\%$.[71]

4.7. *Radiometric titration based on precipitation in non-aqueous media*

The radiation intensity of radioactive isotopes does not depend on the solvent used. It was proved by Chernyi, Vail and Izmailov[83] that organic acids and their salts can be titrated readily in a medium of methanol, acetone or dioxan-methanol by silver ions labelled with ^{110}Ag. The sensitivity of the method is increased by using a non-aqueous solvent in which the precipitate formed during titration is less soluble than in water. The same authors titrated calcium butyrate and sodium benzoate in a methanolic medium, valeric and caproic acid in a medium of methanol-dioxan, and halogen salts of quaternary ammonium bases in an acetone medium.

5. RADIOMETRIC TITRATION BASED ON COMPLEX FORMATION

It is known that titration methods based on complex formation (complexometry) and especially on the formation of chelate complexes (chelatometry) play an appreciable role in titrimetric analytical processes. In the past decade, this field has been extended greatly by a series of novel complex forming agents (complexones) which have made possible the simple solution of many complex analytical problems. Parallel with the development of practical methods, the theoretical basis of titrations based on complex formation has been evolved. In addition to visual methods based on colour indicators, which are doubtlessly simpler and quicker, much attention has been paid to instrumental methods of end-point indication. These latter offer possibilities, on the one hand of automating the processes, and, on the other hand of determining micro and submicro concentrations.

So far, only a relatively small number of papers have dealt with the problem of radiometric end-point indication in titrations based on complex formation. This is mainly because of the difficulties of phase separation. In this type of titration, in complete contrast to those based on precipitate formation, separation of phases does not follow from the method itself (*i.e.*, from the course of the reaction). Instead, the separate measurement of the radioactivity of the reaction partners or reaction products can only be carried out by an auxiliary but proper separation process, such as extraction of the reaction product or products by a solvent immiscible with water, separation by ion exchange or, finally, the use of solid indicators.

5.1. *Phase separation by solvent extraction*

The field of application of radiometric titrations has been appreciably extended by the use of phase separation by solvent extraction.[72–74] In general, the reaction products (chelate complexes) are extracted. The prerequisite of the application of this technique is that the complex formed during titration should be insoluble in water but readily soluble in an organic solvent. Obviously, the complex formed must meet the requirements of stability which apply to any in complexometry.[75] A considerable number of organic chelating agents have been proved to meet these requirements, *e.g.*, dithizone, 8-hydroxyquinoline, diethyldithiocarbamate, *etc.* However, the sensitivity of this method should also be considered. In the case of radiometric titrations based on precipitate formation the lower limit of sensitivity is determined by the solubility product of the precipitate, and this limit can be lowered only by special methods (*cf.* paragraph 4.6.). The sensitivity of radiometric titrations based on complex formation, with solvent extraction, however, depends only on the order of magnitude of the impurities present and on the specific activity of the radioactive isotope applied for labelling, because of the high stability of the complexes.

As has been proved by Duncan and Thomas,[73] in the radiometric titration of silver traces by extraction with dithizone, the sensitivity of the method attains that of activation analysis.

5.1.1. *Determination of equivalence point:* In general, the equivalence point is determined from graphs.[73,74] Obviously, radioactivity can be measured both in the aqueous and in the organic phase, and in consequence, the results are more accurate. In addition, the point of equivalence can be determined by calculation, although this method necessarily produces higher errors.[72] The accuracy of the result, taking into account other conditions, such as the stability of the complex, the pH value, the presence of interfering ions, and a good separation of the phases, depends, in the end, on the exact measurement of radioactivity.

From the aspect of labelling, two cases can be distinguished: either the component to be determined is labelled, according to the amount present, by larger or smaller quantities of its (possibly) carrier-free isotope; or a labelled titrant is used. The first case exists, for example, when mercury ion labelled with ^{203}Hg is titrated in the presence of carbon tetrachloride, with dithizone as titrant (dissolved in carbon tetrachloride). An example of the second case is the titration of thiocyanate ion with a solution of cobalt nitrate, labelled with ^{60}Co.

In practice, cases can occur where no radioactive isotope of the element to be determined, suitable for labelling, is available. Then the isotope of another element may be used, provided that the complex formed by this auxiliary element with the titrant possesses the same stability as that of the ion to be determined. If this is impossible, the so-called non-isotope method can be used, which is based on the following principle. When Me_1 ion is to be titrated with the complexing agent, A, this titration can be carried out with labelled Me_2 ion also present in the solution. These latter should react with A only when A has already reacted with all the Me_1 ion present. Consequently, in the titration curve the activity will be constant till the whole of the Me_1 ion is titrated, and then, when Me_2 ion enters the reaction, activity will increase or decrease depending on whether the radioactivity of the organic phase or that of the aqueous phase is followed. The volume of A consumed by Me_1 ion is indicated in the titration curve by a sharp break. This principle was first applied almost simultaneously by Korenman and co-workers[72] and by Duncan and Thomas[73] to radiometric titration by extraction.

Another possibility is utilised by the so-called indirect technique of extractive radiometric titration. This is used when the rate of the reaction between the ion to be determined and the chelating titrant is low. By adding excess of titrant, the reaction is generally speeded up. Consequently, by adding chelating titrant in excess to the solution of the ion to be titrated, and then an excess of an element which reacts instantaneously with the titrant, the excess of this last can be measured by titration with the chelating titrant using extractive radiometry, and the amount of ion originally to be determined can be calculated from the volume of titrant consumed.

5.1.2. *Theoretical basis of radiometric titration by solvent extraction:* The theoretical problems of radiometric titration by solvent extraction are discussed in detail in a paper by Duncan and Thomas.[1] On extracting metal complexes with organic solvents there occur the following equilibria:

$$\begin{aligned} \overline{\mathrm{HL}} &\rightleftharpoons \mathrm{HL} \\ \mathrm{HL} &\rightleftharpoons \mathrm{H^+} + \mathrm{L^-} \\ \mathrm{M^+} + \mathrm{L^-} &\rightleftharpoons \mathrm{ML} \\ \mathrm{ML} &\rightleftharpoons \overline{\mathrm{ML}} \end{aligned}$$

where HL represents the non-dissociated complexing agent (weak acid), and $\overline{L}$ represents the portion of component L present in the organic phase.

Denoting the partition coefficient of the complexing agent by P_{HL},

$$P_{\mathrm{HL}} = \frac{[\overline{\mathrm{HL}}]}{[\mathrm{HL}]} \tag{27}$$

the partition coefficient of the complex ML formed on titration by P_{ML},

$$P_{\mathrm{ML}} = \frac{[\overline{\mathrm{ML}}]}{[\mathrm{ML}]} \tag{28}$$

the dissociation constant of the ligand by K_a,

$$K_a = \frac{[\mathrm{H^+}][\mathrm{L^-}]}{[\mathrm{HL}]}\,. \tag{29}$$

the stability constant of the complex ML by K,

$$K = \frac{[\mathrm{ML}]}{[\mathrm{M^+}][\mathrm{L^-}]} \tag{30}$$

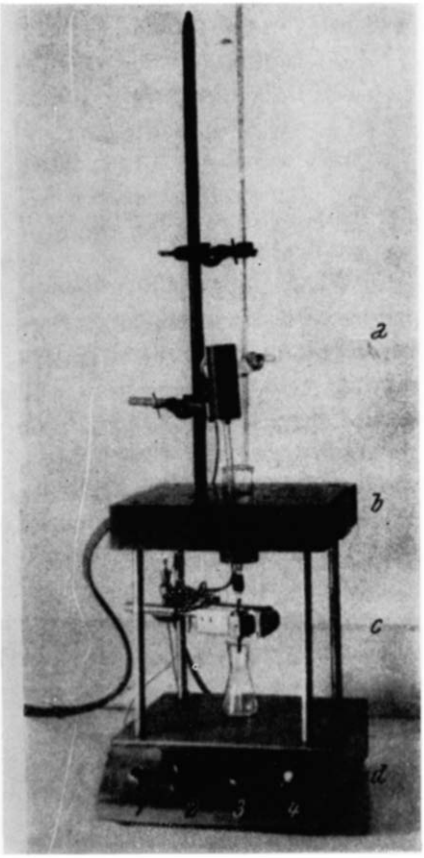

FIG. 15.—Semi-automatic apparatus for radiometric titrations based on complex formation, suitable for phase separation by solvent extraction, according to Spitzy.[74]

the volume of the solution containing the radioactive ions M^+ by v_0 (ml); the original concentration of these ions in the aqueous phase by $[M^+]_0$; and the volume of the organic solvent immiscible with water (which contains HL in the original concentration $[\overline{HL}]_0$) by v (ml); it can be derived that

$$v^2(KP_{ML}K_aR[\overline{HL}]_0) + vv_0\{K\,.\,K_aR(P_{ML}(R-1)[M^+]_0 + [\overline{HL}]_0) \\ + P_{HL}[H^+](R-1)\} + v_0^2(R-1)\{K\,.\,K_aR[M^+]_0 + [H^+] + K_a\} = 0 \quad (31)$$

where $R = (a_{M^+}/a^0_{M^+})$ is the ratio of the initial total activity of the solution to the total activity measured in a given period of titration. This relatively complicated equation can be simplified if the following conditions hold:

(*a*) the values of K and P_{ML} are relatively high;

(*b*) the values of $[\overline{HL}]_0$ and $[M^+]_0$ are low and of the same order of magnitude (dilute solutions);

(*c*) the pH of the aqueous phase remains constant so that $[H^+] \ll K\,.\,K_a[M^+]_0$, *i.e.*, on attaining equilibrium, only a negligible amount of unreacted HL remains in the aqueous phase;

(*d*) P_{ML} and P_{HL} are of the same order of magnitude.

On simplifying, the following equation is obtained:

$$v = \frac{v_0[M^+]_0(1-R)}{[\overline{HL}]_0} \quad (32)$$

which is valid for all the radiometric titrations by solvent extraction so far described in the literature.[1] When it is impossible to extract the complex ML quantitatively from the aqueous phase (the value of P_{ML} or K is low or that of $[H^+]$ is high), instead of a straight line, a curved titration graph will be obtained. With knowledge of the values of K_a, $[H^+]$ and P_{HL}, it is possible to calculate the values of K, P_{ML} and $[M^+]_0$ from three points of the graph.

5.1.3. *Titration apparatus and technique of titration:* Titrations are carried out by Korenman and co-workers[72] in glass-stoppered test-tubes carrying a volume scale. Identical volumes of the test solution are transferred to the test-tubes by pipette, the pH value of the solution is adjusted with a buffer solution, and increasing amounts of titrant are added. Then the test tubes are filled up with an organic solvent (that used for dissolving the chelating titrant) to the mark. After shaking in a shaking machine for 15 min, the test-tubes are centrifuged 1–2 min to promote separation, and the radioactivity of aliquots taken from both the aqueous and the organic phase are measured in a liquid counter. The titration curve is established from the results obtained.

Titrations are carried out by Duncan and Thomas[73] in a separatory funnel, and the activities of aliquots withdrawn from the aqueous phase are measured after each new addition of titrant and shaking. In both cases the titration is intermittent and rather cumbersome and lengthy. So far it has not been possible to evolve a continuous process for solvent extraction. In consequence the automatisation of the titration has been delayed. Spitzy[74] has developed an apparatus which automatically separates the two phases after shaking and thus markedly accelerates the course of titration (Fig. 15), but the problem of continuous titration still remains unsolved.

5.1.4. *Methods:* In the papers published so far, the applicability of the method has mainly been proved by model experiments. The advantages and drawbacks of the method can be evaluated by the published results. Duncan and Thomas[73] titrated traces of mercury labelled by ^{203}Hg at pH 1·0 and traces of cobalt labelled with ^{60}Co at pH 6·7, using a solution of dithizone as titrant. Similarly, traces of zinc[72] labelled with ^{65}Zn and traces of silver[74] labelled with ^{110}Ag can be determined by titration with dithizone. In Fig. 16 the curves of the radiometric titration of cobalt and mercury,

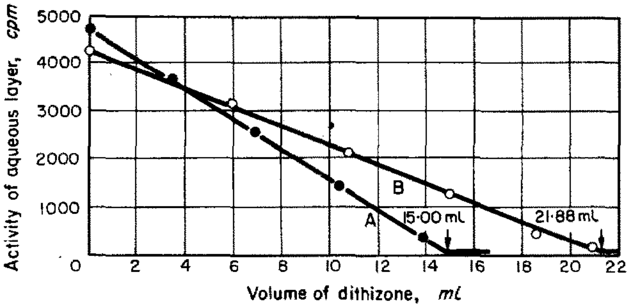

FIG. 16.—Curve of the radiometric titration of cobalt (^{60}Co, A) and mercury (^{203}Hg, B) ions with a dithizone solution in carbon tetrachloride as titrant, according to Duncan and Thomas.[73]

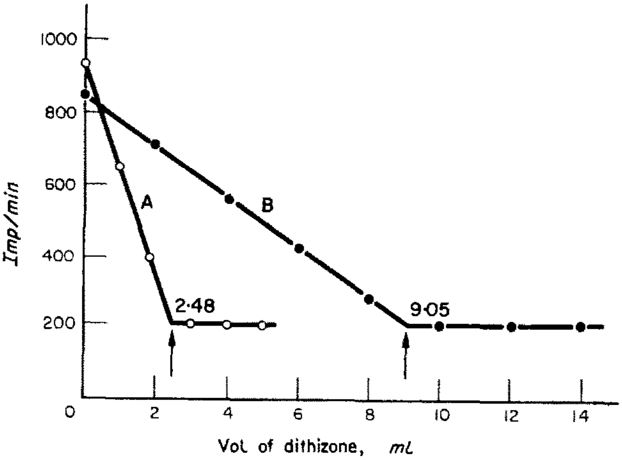

FIG. 17.—Curve of the radiometric titration of silver (^{110}Ag) and zinc (^{65}Zn) ions with a dithizone solution in carbon tetrachloride as titrant, according to Spitzy.[74]

obtained by extraction with dithizone, are shown; Fig. 17 shows the curves for the dithizone titration of silver and zinc.

5.1.5. *Determination of several components together:* The theoretical possibilities of radiometric titration by extraction, for the determination of several components together, are shown in Fig. 18, and include the use of non-isotopic methods, active titrants or different specific activities. Because Fig. 18 is prepared only as a guide, only numbers of components not exceeding three were taken into account. But similar theoretical conclusions can also be drawn for the determination of four, five or more ions. All the results published in the literature can be classified in one of the types shown in Fig. 18. However, the examples given in Fig. 18 do not include all the possibilities of simultaneous determination. For example, selective titrations can

also be carried out by varying the pH, by using auxiliary complexing or demasking agents, *etc.*

Examples of published methods include that developed by Duncan and Thomas[73] for the determination of traces of cobalt and zinc in the presence of each other, using ^{60}Co and the non-isotope method. The curve published by Duncan and Thomas is shown in Fig. 19. A similar principle was applied by Korenman and co-workers[72] to the determination of traces of mercury and zinc, and of traces of copper and zinc, using ^{65}Zn. However, the titrations must be conducted at two different pH values. Similarly, the non-isotope method and titrations at two different pH values have been applied by Spitzy[74] to the determination of traces of silver and zinc, using ^{65}Zn.

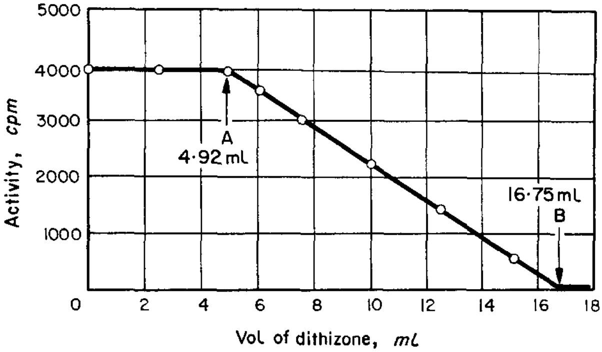

FIG. 19.—Curve of the radiometric titration of cobalt (B) and zinc (A) ions with a dithizone solution in carbon tetrachloride as titrant and with the non-isotope method, according to Duncan and Thomas.[73]

Spitzy has developed another method[74] for the titration of three components occurring together. Thus, for example, traces of mercury, silver and zinc were titrated by labelling with ^{203}Hg and ^{65}Zn, and conducting titrations at two pH values. The

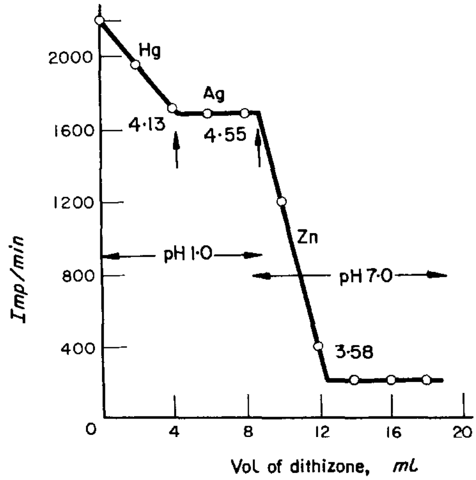

FIG. 20.—Curve of the radiometric titration of mercury, silver and zinc ions with a dithizone solution in carbon tetrachloride as titrant, and with the non-isotope method, according to Spitzy.[74]

titration curves of these three ions are shown in Fig. 20. In all the mentioned cases a carbon tetrachloride solution of dithizone served as titrant.

The application of indirect titrations has still to be mentioned. This method has been applied by Spitzy[74] for the titration of traces of palladium. The solution, containing palladium, was extracted with an excess of a dithizone solution of known concentration. The organic phase was then treated with a solution containing a known amount of ^{110}Ag. On shaking, some of the silver was bound by that part of the dithizone which did not react with the palladium. After separating the organic phase, the residual silver was titrated with dithizone. The quantity of dithizone consumed by the palladium was then calculated from the ratio of the added solutions, of known concentration and volume, to the volume of the dithizone solution consumed by the silver.

5.2. *Phase separation using solid indicators*

A novel possibility of radiometric titrations based on complex formation has been evolved by Braun, Maxim and Galateanu.[76,70] The principle of the method, based on the use of "solid indicators" is as follows. A cation, M^{2+}, is titrated with the complexing anion, A^{2-}, according to the reaction:

$$M^{2+} + A^{2-} \rightleftharpoons (MA)$$

The end-point of this titration reaction is determined with the use of the tagged cation, M_i^{*2+}, present in the system. The cation, M_i^{*2+}, is originally present as the slightly soluble precipitate, $M_i{}^*B$ (solid indicator). The prerequisite of end-point indication is that the cation, M_i^{*2+}, should react with the complexing agent, A^{2-}, only when all the M^{2+} ion (to be titrated) has already reacted. The complexing process of the cation, M_i^{*2+}, is characterised by the dissolution reaction:

$$M_i{}^*B + A^{2-} \rightleftharpoons (M_i{}^*A) + B^{2-}.$$

In order to carry out the above titration, the following conditions must be met: (*a*) the inequality

$$pK(MA) > pK(M_i{}^*A)$$

must exist between the stability constants of the complexes (MA) and $(M_i{}^*A)$;

(*b*) the ratio of the stability constant of the complex, $(M_i{}^*A)$, to the solubility product of the precipitate, $M_i{}^*B$, must be chosen in a way that the excess of the complexing agent added during titration should dissolve the precipitate.

A certain amount of labelled $M_i{}^*B$ precipitate is added to the solution of M^{2+} ion to be titrated, in a titration flask; the solution is then titrated with the complexing titrant, A^{2-}, and during titration the radioactivity of the solution separated from the precipitate is measured; the radioactivity remains low, as long as the solution contains free M^{2+} cation. When all the M^{2+} cation has been converted into complex, the excess complexing agent will react with the cation, M_i^{*2+}, and this leads to the dissolution of the precipitate, $M_i{}^*B$. Consequently, the radioactivity of the solution will increase in proportion to the amount of A^{2-} added. The titration curve is shown in Fig. 21. The sensitivity of the method is limited, on the one hand, by the stability of the complex used in the titration reaction, and, on the other hand, by the solubility and specific activity of the solid indicator. With properly chosen conditions, minute amounts can be titrated. In addition, this method appears to be suitable for automation.

These principles permit end-point indication by radiometry in complexometric titrations.[71,76,77] Methods have been evolved for the radiocomplexometric determination of calcium, strontium, magnesium, copper and zinc, using solid silver iodate labelled with ^{110}Ag as indicator.

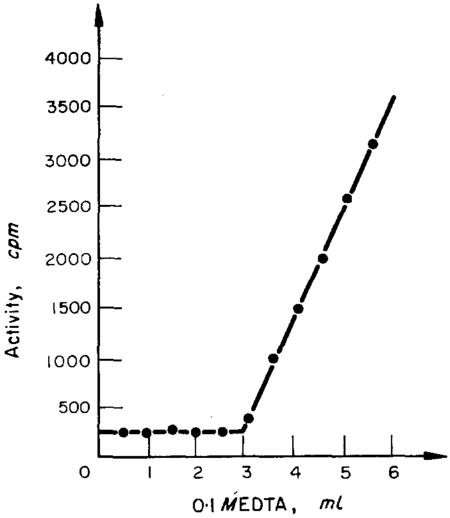

FIG. 21.—Curve of the radiocomplexometric titration of calcium ions using silver iodate as solid indicator.

5.2.1. *Possibilities of this method: direct, indirect and back-titrations:* By using solid indicators the complexometric titration of a great number of ions becomes possible. The direct titration of calcium, strontium, magnesium, copper and zinc has already been mentioned. Back-titration can be applied when, for example, the solid indicator acts only at a high pH value where the titrated ion will be hydrolysed, or when the reaction between the titrated ion and the complexing agent is slow, as in the complexometric titration of aluminium.[78] In this titration, a known excess of EDTA is added to the solution of the titrated ion at a low pH value, the system is boiled, and the pH value is adjusted to about 10. A suspension of ^{110}AgIO$_3$ as solid indicator is then added. Excess EDTA completely dissolves this indicator. Then the solution is back-titrated with a solution of calcium nitrate. The excess of EDTA is bound by the calcium ions, and the radioactivity of the solution remains constant at a high level. When the excess of EDTA is consumed, ^{110}Ag$^+$ is replaced in the $(AgY)^{3-}$ complex by Ca^{2+} because

$$\mathrm{p}K(\mathrm{AgY})^{3-} < \mathrm{p}K(\mathrm{CaY})^{2-}.$$

The displaced ^{110}Ag$^+$ ions combine with the IO_3^- ions present in the solution, and are precipitated as ^{110}AgIO$_3$. In consequence, the radioactivity of the solution gradually decreases. When the complex $(AgY)^{3-}$ is completely decomposed by Ca^{2+} ions, the radioactivity of the solution remains constant. Aluminium complexonate is not decomposed by Ca^{2+} ions because

$$\mathrm{p}K(\mathrm{AlY})^{-} > \mathrm{p}K(\mathrm{CaY})^{2-}.$$

The titration curve is shown in Fig. 22.

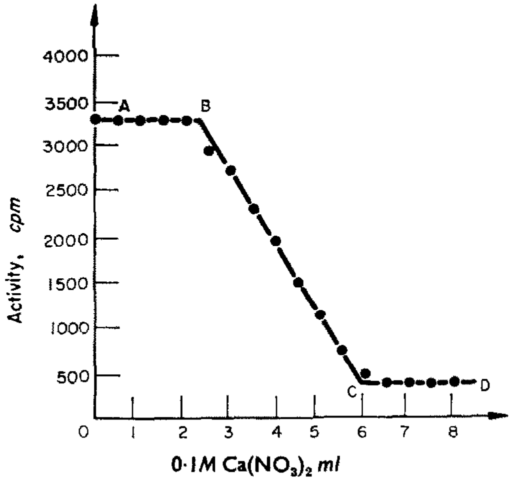

FIG. 22.—Curve of the radiocomplexometric back-titration of aluminium ions using silver iodate as solid indicator, according to Braun.[38]

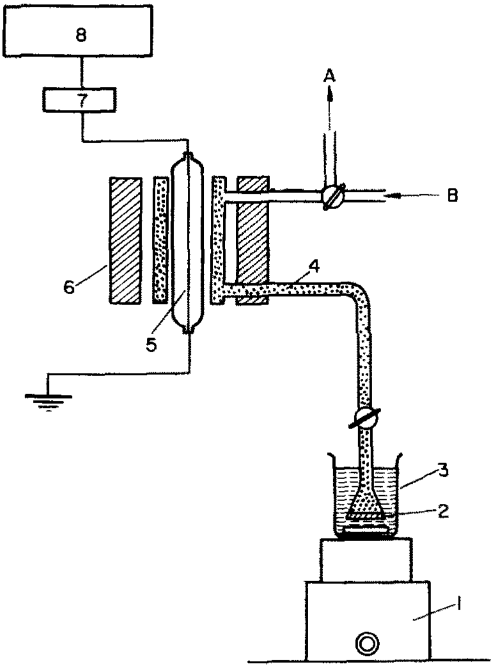

FIG. 23.—Apparatus for radiometric titration based on complex formation, carried out with a solid indicator and with phase separation by filtration, according to Braun:[82]

2. Suction tube with glass filter
3. Titration flask
4. Glass mantle
5. GM counter
6. Lead mantle
7. Pre-amplifier
8. Impulse meter

A. Air
B. Suction

In addition to these possible applications, the method also lends itself to indirect titrations, mainly for determining anions. In this case, the ion to be determined is precipitated by an excess of another ion which, by dissolving the precipitate, can be directly titrated with EDTA. This method has proved suitable, for example, for the determination of sodium through the titration of the zinc content of sodium zinc uranyl acetate, and for the determination of tungstate through the titration of the calcium content of calcium tungstate.[79]

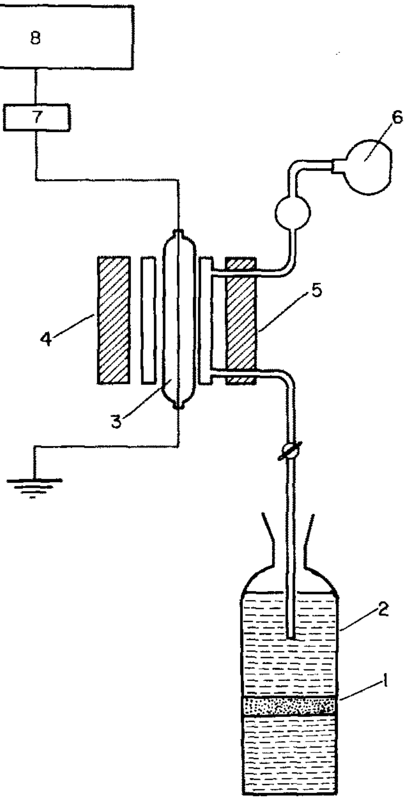

FIG. 24.—Apparatus for radiometric titrations based on complex formation, with a solid indicator and phase separation by flotation, according to Braun:[82]

1. Precipitate
2. Titration flask
3. GM counter
4, 5. Lead mantle
6. Suction device with rubber bulb
7. Pre-amplifier
8. Rate meter

5.2.2. *Titration devices and technique of titration:* Titration devices for solid indicators do not differ much from the conventional types of apparatus used in other radiometric titrations. If the solid indicator is applied during titration as a suspension, phase separation can be carried out by filtration, centrifuging or flotation. The apparatus used for phase separation by filtration is shown in Fig. 23. For the flotation method for phase separation, the equipment shown in Fig. 24 can be used.[19] Because in these cases phase separation is carried out intermittently, the titration process is not continuous. After each addition of titrant, phase separation must be carried out (filtration, centrifuging or flotation), followed by measurement of the radioactivity. The next addition of titrant can only take place after these operations. This discontinuity is a common drawback of all titration methods described, and is a hindrance to the possibility of automation. However, the method applying solid indicators can make continuous titrations possible when the indicator is introduced, in a form fixed to the fibres of filter paper instead of as a suspension, $^{110}AgIO_3$ as indicator can be precipitated within the fibres of chromatographic filter paper. This filter paper, fixed on a support, is transferred to the titrated solution during titration. No phase separation is then necessary, and titration can be carried out as a continuous operation[84] or it can be made completely automatic.

5.3. *Phase separation by ion exchangers*

Recently, Starý, Růžička and Zeman[80] showed that in radiometric titrations using EDTA, phase separation can also be carried out by ion exchangers. This method is based on the formation of negatively charged or neutral chelates which can easily be separated from the excess of unreacted metal by cation exchangers. The end-point is indicated by the measurement of the radioactivity of the eluates. As in other methods of radiometric titration, either the isotope or the non-isotope technique may be applied. The optimum pH values of this titration can be calculated on the basis of theoretical considerations suggested by Starý and Růžička.[81] According to this theory, ions forming very stable chelates, such as Co^{3+}, Zr^{4+}, Fe^{3+}, In^{4+}, Th^{4+}, *etc.*, can be titrated at pH values of 2–3, even with 10^{-6}–$10^{-7}M$ EDTA solution.

Less stable complexes can only be titrated at much higher pH values. By this technique, these authors succeeded in titrating microgram quantities of indium. By the non-isotope method it was possible to determine even 0·5 μg of cobalt by titration. The only drawback of the method is that the titration, as in other radiometric titrations, can only be conducted as an interrupted operation in the way described by these authors.

6. RADIOMETRIC TITRATION BASED ON REDOX REACTIONS

Among the methods of titrimetric analysis, redox titrations are of great importance because a great number of multivalent elements can be titrated successfully with an oxidant or a reductant.

Indication of the end-point of titrations of this nature by radioactive isotopes was until recently impossible by recognised techniques. In redox titrations all the components of the reaction remain in the same phase. Consequently, it is impossible to measure separately the radioactivity of the reactants and of the reaction products. This problem was solved by Braun[82,19] using labelled liquid amalgams. The principle can be instanced by considering bivalent Me^{2+} ion, which is titrated with a solution of the quadrivalent oxidising agent, Ox^{4+}, according to the reaction:

$$Me^{2+} + Ox^{4+} \leftrightharpoons Me^{3+} + Ox^{3+}$$

When a liquid amalgam, $Me_i{}^*Hg$, with a labelled metal atom, is also present in the system to be titrated, and this amalgam is capable of reducing the oxidising agent, Ox^{4+}, then on titration, after oxidation of all the Me^{2+} ion, the oxidising agent will react with the amalgam. During the reduction process an amount of labelled $Me_i{}^{*2+}$ ion equivalent to the amount of the oxidising agent will be liberated from the amalgam. The reduction reaction reads:

$$\downarrow Me_i{}^{*2}Hg + 2Ox^{4+} \rightleftharpoons \downarrow Hg + Me_i^{*2+} + 2Ox^{3+}.$$

The titration curve is shown in Fig. 25. At the beginning of titration radioactivity is low, and it remains constant till all the ion to be titrated is consumed (AB in Fig. 25). On adding further amounts of titrant, reaction with the amalgam follows (BC in Fig. 25), and the radioactivity of the solution shows a linear rise. The point of intersection of the two straight lines gives a readily evaluable end-point. Using this principle, Braun titrated ascorbic acid, as a model experiment, with a solution of Fe^{3+}, in the presence of zinc amalgam labelled with ^{65}Zn.

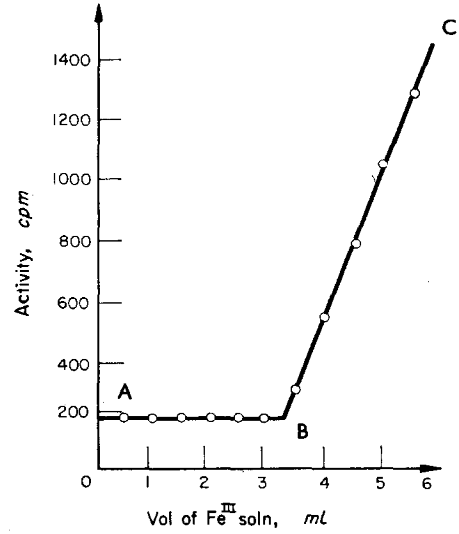

FIG. 25.—Curve of the radiometric titration in a redox reaction, with phase separation by amalgam, according to Braun.[82]

7. RADIOMETRIC TITRATION BASED ON ABSORPTION OF β-RADIATION AND ON ITS SCATTERING

β-rays, on passing through a substance, interact with it and gradually lose their energy and alter their direction. This phenomenon has been utilised for titration purposes.

7.1. *Radiometric titration based on scattering of β-rays*

An appreciable part of the scattered β-particles follow a reverse direction, *i.e.*, are back-scattered from the medium in question. The over-all effect of β-ray scattering depends on the atomic number of the examined substance, on the maximum energy of the β-radiation and on the thickness of the substance being examined (for solutions, on the concentration of the substance being examined). This phenomenon was utilised by Tölgyessy and Varga[66] to enable them to evolve a method of radiometric titration based on β-ray scattering combined with precipitate formation. In a titration of this type the titration curve shows the intensity of back-scattered β-radiation plotted against the amount of titrant added. Three alternatives are possible:

(*a*) the solution contains an element or several elements of high atomic number and the titrant has elements of low atomic number, *e.g.*, the titration of Ag^+ ions with hydrochloric acid. During titration, the intensity of β-radiation back-scattered from the solution decreases, because of the decrease in concentration of the element of higher atomic number (though precipitation of this element);

(*b*) the solution contains elements of lower atomic number and the titrant has elements of higher atomic number (*e.g.*, the titration of Cl^- ions with silver nitrate). During titration, the intensity of the back-scattered β-radiation slightly diminishes until the end-point is reached, and then increases markedly;

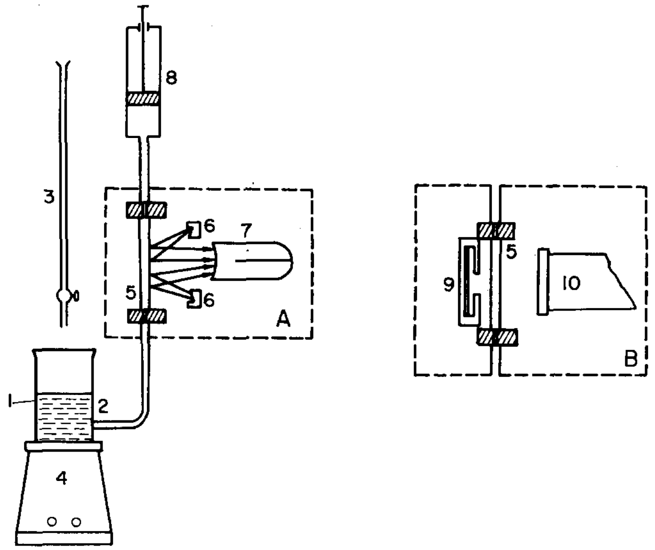

FIG. 26.—Apparatus for radiometric titrations based on β-radiation scattering (A) and β-radiation absorption (B), according to Tölgyessy, Varga, Dillinger and Braun[66,67,68]

1. Titration flask
2. Glass filter
3. Burette
4. Stirrer
5. Measuring cuvette
6. Ring-shaped radiation source
7. GM counter
8. Sprayer
9. Closed β-radiation source
10. Scintillation counter

(*c*) both the solution and the titrant contain elements of high atomic number. The intensity of the scattered β-radiation decreases until the end-point is reached, then rises.

In these titrations the conventional filtration and centrifuging methods have been applied. The experimental apparatus is shown in Fig. 26(A). The windows of the measuring cuvette (5) are of polyethylene. This cuvette is placed before the ring-shaped source of β-radiation (6), (^{204}Tl). The β-radiation back-scattered by the solution placed in the measuring cuvette is measured by a GM counter, (7), with an end window. The titration curve of Ag^+ ions with $0{\cdot}1M$ hydrochloric acid is shown in Fig. 27. Ferrocyanide ions have been titrated with $0{\cdot}1N$ lead nitrate by the same authors, using the same technique.

7.2. *Radiometric titration based on absorption of β-radiation*

The absorption of β-radiation has been utilised by Tölgyessy, Dillinger and Braun[67,68] for end-point indication in titrations based on precipitate formation and extraction. In these titrations, either the solutions to be examined, or the titrant, or

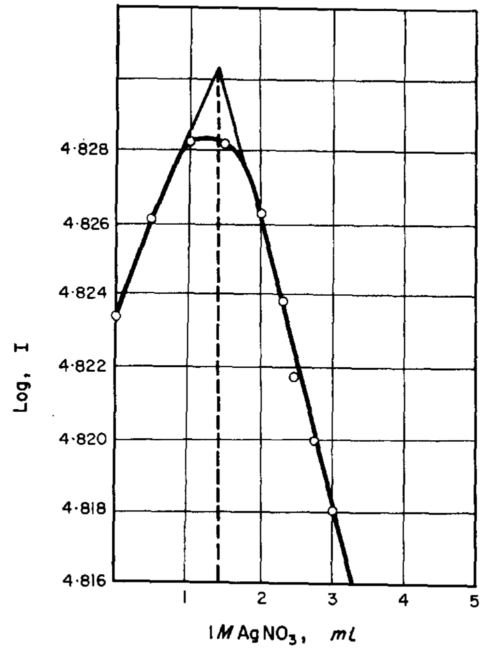

FIG. 27

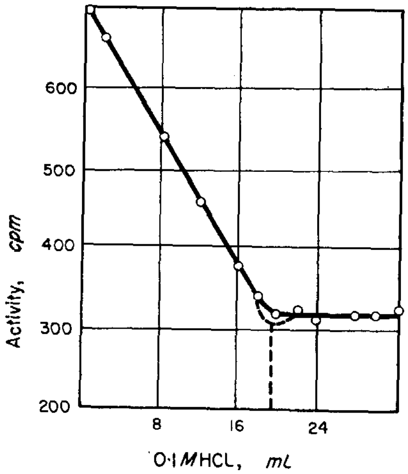

FIG. 28

both, should contain elements of high atomic number. The titration curves show the measured radiation intensities (expressed by the logarithm of the number of impulses observed in unit time) plotted against the amount of titrant. The curves show the reverse shape to that of the normal radiometric titration curves.

In titrations based on precipitate formation the usual filtration and centrifuging methods have been used; in titrations based on extraction centrifuging methods have been used. In the filtration method, the apparatus shown in Fig. 26(B) was used. On one side of the measuring cuvette (made of Plexiglass and equipped with polyethylene windows), a closed β-radiation source (^{90}Sr) of 1 mC activity was located, and on the other side a scintillation counter which was attached to an automatic measuring apparatus. Fig. 28 shows the curve obtained on titrating 25 ml of a solution containing chloride ion with 1·0*M* silver nitrate. In this determination the error was ±1·5%. These novel titration methods offer the advantage over the radiometric titration processes described earlier that a closed radiation source is used, and therefore the method is markedly freer from radiation hazards. In addition, the titration process lends itself readily to automation.

8. OTHER APPLICATIONS OF RADIOMETRIC TITRATION

Radiometric titrations have been applied with success by several authors in processes not directly analytical. Only a few papers have been published in this field, but the results attained are fairly promising and they should stimulate further experiments of this type.

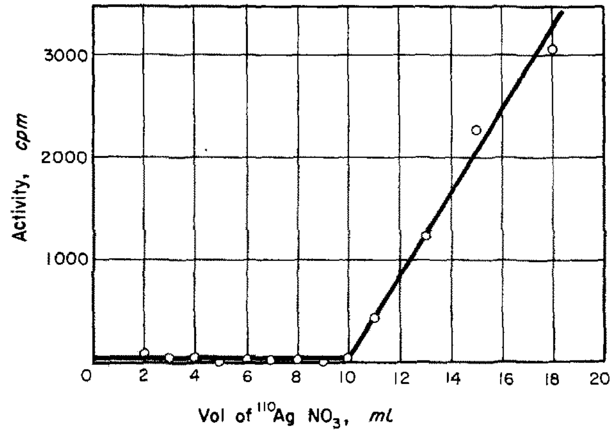

FIG. 29

8.1. *Determination of structure of compounds*

The composition of solutions of silver and cobalt tungstate has been studied by Bradhurst, Coller and Duncan[84] at various pH values, using radiometric titrations. It can be seen in Fig. 29 that on titrating a solution of sodium tungstate at pH 6·2–7·8 with a silver nitrate solution labelled with ^{110}Ag, a titration curve with a sharp break is obtained. The ratio Ag:W can easily be calculated from the end-point. The dependence on pH of the ratio Ag:W, calculated on the basis of titrations carried out at various pH values, is shown in Fig. 30, which proves that the method furnishes information on the composition of the various condensed tungstate ions present in the solution. Shinagawa, Matsuo and Yoshida[85] succeeded in establishing the composition of the complex triphenylselenonium iodobismuthite by a similar method, showing that the compound corresponds to the formula $[(C_6H_5)_3Se].[BiI_4]$.

8.2. *Investigation of coprecipitation*

Coprecipitation of various labelled compounds has been investigated, using radiometric titration, by Alimarin and Sirotina,[86] who studied in detail the coprecipitation of ^{204}Tl with AgI, AgCl, AgSCN and PbI precipitates, the titration of silver and thallium with ^{204}TlI, and that of lead and silver with CrO_4^{2-}. The results have proved, among other things that the non-isotope method lends itself to use in

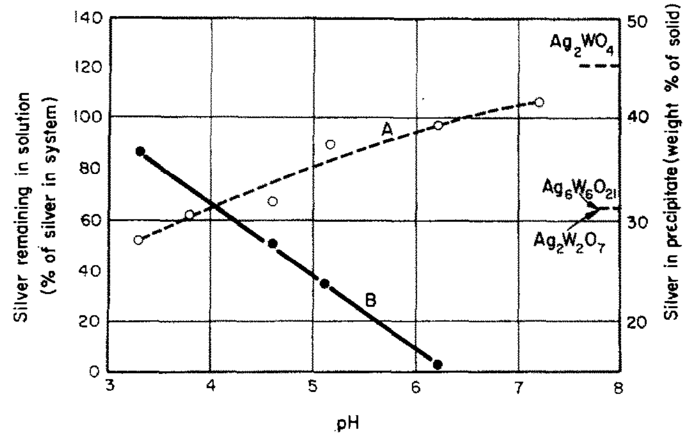

FIG. 30

radiometric titrations not only when isomorphic precipitates are formed, but also when anomalous mixed crystals develop in the solution.

8.3. *Determination of solubility product*

A method has been evolved by Duncan[87] for the determination of solubility product by radiometric titration. If a solution of volume v, which contains N^- ion at a concentration of $[N^-]_0$, is added to another solution of volume v_0, which contains the radioactive ion M^+ at a concentration of $[M^+]_0$ and which possesses a radioactivity of a_0 (impulses per minute), and if the solubility product is $S = [M^+][N^-]$, where $[M^+]$ and $[N^-]$ are the equilibrium concentrations of M^+ and N^- ion with the precipitate MN, then according to Duncan, the equation

$$Sv^2 + vv_0\{2S - [N^-]_0 \cdot [M^+]_0 R\} + v_0^2\{S + [M^+]_0^2 R(1 - R)\} = 0 \qquad (33)$$

can be derived, where $R = a/a_0$ and a is the residual activity of M ions in the solution after precipitation. The titration curve actually reflects the changes of R plotted against v. With the aid of equation (33) it is possible to calculate the value of S from any point along the curve. For details the reader is referred to the original paper.

Zusammenfassung—Eine Übersicht von radiometrischer Titration wird gegeben.

Résumé—On présente une revue de titrage radiométrique.

COLORIMETRIC DETERMINATION OF VANADIUM WITH XYLENOL ORANGE

OMORTAG BUDEVSKY* and RUDOLF PŘIBIL
Analytical Laboratory, Polarographic Institute, Czechoslovak Academy of Sciences,
Praha 1, Jilská 16, Czechoslovakia

(*Received* 24 *July* 1963. *Accepted* 19 *April* 1964)

Summary—A highly selective colorimetric method for vanadium^{V}, based on its colour reaction with Xylenol Orange, is described. In the presence of 1,2-diaminocyclohexanetetra-acetic acid (DCTA) this method is almost specific for vanadium, because other elements are screened, and do not interfere in moderate amounts.

The well-known metallochromic indicator Xylenol Orange[1,2] (XO) has also been proposed for the colorimetric determination of a number of metals, including zirconium,[3–5] hafnium,[6] uranium,[7,8] iron,[9] bismuth,[10–12] zinc,[13] cerium and rare earths,[14] niobium[15,19] and, indirectly, for fluorine.[16] It is evident that Xylenol Orange shows but slight selectivity, except for the reaction with zirconium, which occurs in acidic solutions (0·5–1·0 *M* nitric acid). For other metals it can be used only in special cases, *e.g.*, after separation of the respective metal, *etc.*

Recently, two colour reactions of Xylenol Orange with vanadium have been described. Janoušek[17] studied the reaction of vanadium^{V} at pH 4, and recommended it for the colorimetric determination of vanadium after its separation by ion exchange. Otomo[18] studied a similar reaction with vanadium^{IV} at pH 2·8 in the presence of ascorbic acid. Some elements can be masked with fluoride, but high concentrations of fluoride interfere with the colour reaction. Strong complexing agents, such as ethylenediaminetetra-acetic acid (EDTA),[19] ethyleneglycoltetra-acetic acid (EGTA), diethylenetriaminepenta-acetic acid (DTPA) and triethylenetetraminehexa-acetic acid (TTHA), completely suppress the colour reaction of vanadium with Xylenol Orange and therefore cannot be used for screening of interfering elements. We have found that 1,2-diaminocyclohexanetetra-acetic acid (DCTA) has only a very small effect on the colour reaction. Preliminary experiments have shown that conditions for a highly selective determination of vanadium^{V} in the presence of DCTA are very simple. Our experience obtained in this respect is described in the present paper.

EXPERIMENTAL

Reagents

0·001*M solution of Xylenol Orange:* Prepared by dissolving 0·83 g of about 80% reagent (Chemapol, Prague, Czechoslovakia) and diluting to 1 litre with distilled water.

0·05*M DCTA solution:* Prepared by dissolving 17·73 g of 1,2-diaminocyclohexantetra-acetic acid (Geigy, Basel, Switzerland) in 130–150 ml of hot 1*M* sodium hydroxide and diluting it, after cooling, to 1 litre.

0·05*M EDTA solution:* Prepared by dissolving 18·61 g of ethylenediaminetetra-acetic acid disodium salt (Chemapol, Prague, Czechoslovakia) in 1 litre of water.

2 × 10^{-4}*M ammonium vanadate solution:* Prepared by dissolving 0·0234 g of NH_4VO_3 (Lachema, Brno, Czechoslovakia) in 1 litre of water.

---

* Present address: Bulgarian Academy of Sciences, Institute of General and Inorganic Chemistry, Sofia 13, Bulgaria.

Buffer solution (pH about 4·5): Prepared by dissolving 200 g of ammonium acetate in 200 ml of acetic acid and diluting to 1 litre.

0·05*M solutions of salts* of Fe^{III}, Al, Th, Co^{II}, Cr^{III}, Bi, Cd, Ce^{III}, La, Ca, Sr, Ba, Mg, Mn^{II}, Sc, Pr, Nd, Cu^{II}, Tl^{III}, Ni^{II}, Hg^{II}, In, Ga, Ti^{IV}, Pb, UO_2^{2-}, CrO_4^{2-}, MoO_4^{2-}, solid tartaric acid, sodium fluoride, ammonium phosphate, citric acid and oxalic acid were used for the interference studies.

All reagents were of reagent-grade purity.

Apparatus

Spectral grating spectrophotometer: Jouan (Paris, France); 350–1100 mμ.

Pulfrich photometer with photoelectric attachement Elpho II: (VEB Carl Zeiss, Jena, E. Germany).

Recording spectrophotometer: Leres type T2D (Bagneux, Seine, France); 200–2500 mμ.

pH-meter with glass electrode: Multoscop V (Laboratorní přistroje, Prague, Czechoslovakia).

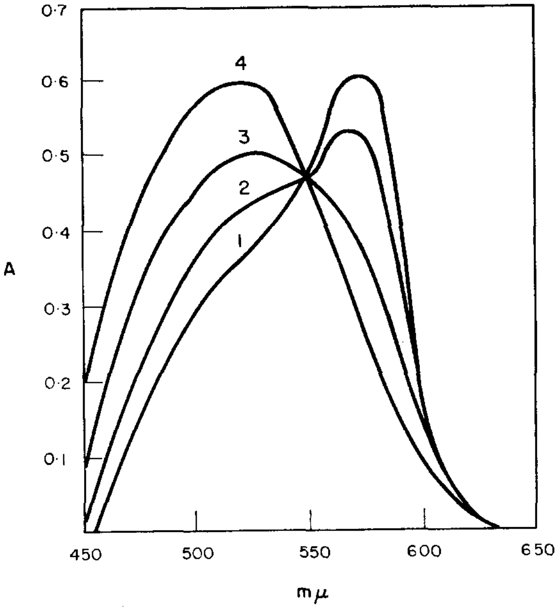

FIG. 1.—Absorption spectrum of the vanadium^V-Xylenol Orange complex for different excesses of Xylenol Orange: (1) XO:V^{5+} = 1·5:1; (2) 2:1; (3) 4:1; (4) 10:1.

RESULTS AND DISCUSSION

Structure of vanadium^V complex with Xylenol Orange

In a slightly acidic medium and with a low concentration of Xylenol Orange (up to the ratio X0:V^{5+} = 1:1) an intense violet colour is formed with vanadium^V, but with higher concentrations the coloration is red-orange (Fig. 1). From the absorption curves it is apparent that a number of complexes can be formed, their formation depending on the total concentration of Xylenol Orange. The existence of two complexes has been proved by the molar ratio method, measuring the absorbance at 520 mμ and 590 mμ (Fig. 2): one with a molar ratio of 1:1 > V:(XO), and absorption maximum at 590 mμ; and a second with a molar ratio 1:2, V:$(XO)_2$, and absorption maximum at 520 mμ.* The molecular extinction coefficients have been calculated from the above results (ε_{590} = 20,000 and ε_{520} = 13,000), classifying this coloration as

---

* A maximum at 430 mμ shows the probable existence of further complexes. This maximum disappears, however, after a few min. No other maxima have been observed in the ultraviolet region.

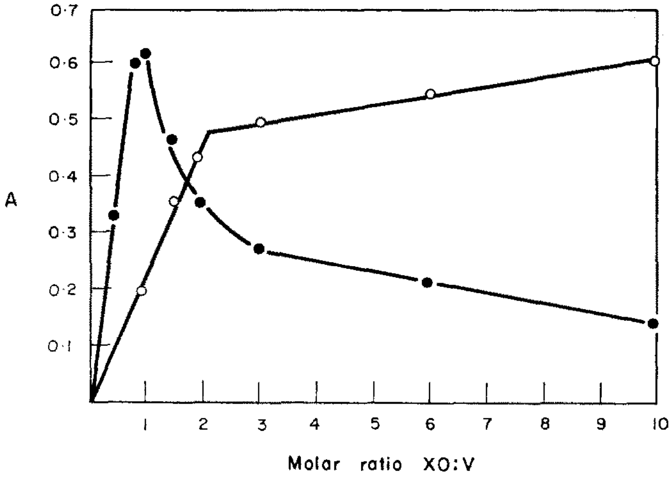

FIG. 2.—Influence of the excess of Xylenol Orange on the absorbance of the vanadium^V-Xylenol Orange complexes:
●—590 mμ,
○—520 mμ.

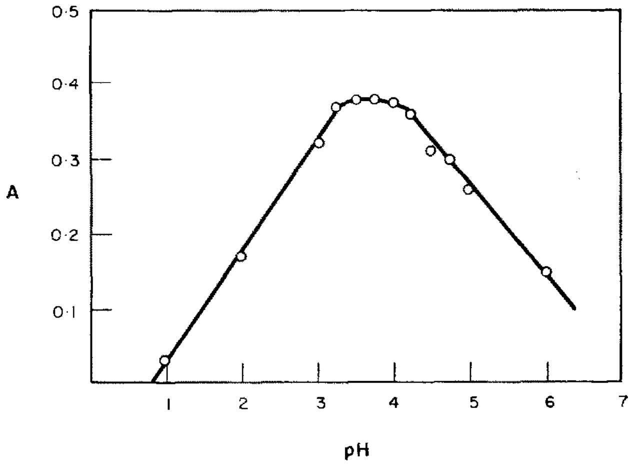

FIG. 3.—Dependence of the absorbance of the vanadium^V-Xylenol Orange complex on pH (1 μmole V^{5+}; 5 μmole XO; 550 mμ).

one of the most sensitive reactions for vanadium.[17] The coloration develops within 30 sec and remains stable for at least 24 hr. Absorbance measurements are carried out most conveniently at the isosbestic point (550 mμ): the absorbance is independent of the quantity of reagent added only at the isosbestic point. The optimum pH-range for the formation of the complex is 3–5 (Fig. 3).

Influence of DCTA on stability of the complex

From a detailed study of the colour reaction of vanadium with Xylenol Orange, it has been found that DCTA has some influence. In the presence of DCTA only one complex is formed—$V(XO)_2$ (Fig. 4). The absorbance in the presence of DCTA depends on the pH up to 4·5. Above this value however, it is effectively constant.

The coloration develops slowly, reaching a maximum within 10 min after the addition of Xylenol Orange (at room temperature). The absorbance does not attain the same value found in the absence of DCTA, but it is reproducible under identical conditions. The decrease in absorbance corresponds to the concentration of DCTA. Furthermore, even DCTA bound to other metals affects, according to the metal involved, the absorbance of the colour reaction with vanadium. This is obviously because of the equilibrium between DCTA complexes. The results for vanadium were in all cases lower. The equilibrium can, however, be shifted completely in favour of the colour reaction with vanadium by means of a considerable increase in the concentration of Xylenol Orange. With a 50-fold excess, the absorbance reaches about the same value as in the absence of DCTA (Fig. 4), and within certain limits of concentrations, it is quite independent of the nature of other metals present. It should be stressed that the absorbance at the isosbestic point (550 mμ) is less influenced by the presence of DCTA than is the maximum (520 mμ) of the absorption curve. Hence, we recommend that absorbance measurements in the presence of DCTA also be carried out at 550 mμ.

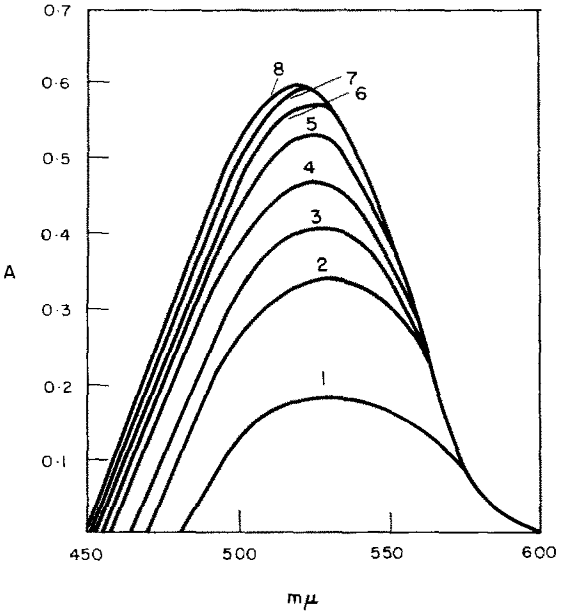

FIG. 4—Absorption spectrum of the vanadium^V-Xylenol Orange complex for different excesses of Xylenol Orange in the presence of DCTA: (1) XO:V^{5+} = 1:1; (2) 3:1; (3) 5:1; (4) 10:1; (5) 20:1; (6) 30:1; (7) 40:1; (8) 50:1.

The calibration curve must always be constructed at the same concentration of DCTA and against a blank solution containing the same concentration of Xylenol Orange. In the presence of coloured ions we prepare a blank from an aliquot of the test solution, adding EDTA, which prevents the formation of all coloured metal complexes with Xylenol Orange. The influence of foreign ions has been ascertained by the following procedure.

To 5–10 ml of slightly acidic solution, containing 5–50 μg of vanadium,$^{\mathrm{V}}$ add 5 ml of 0·05*M* DCTA solution, 5 ml of buffer solution (pH 4·5) and 5 ml of 0·001*M* Xylenol Orange solution, and dilute to 50 ml. After 10 min measure the absorbance of the solution on a spectrophotometer at 550 mμ or on a Pulfrich photometer in a 5-cm cell (filter S 53) against the same concentration of Xylenol Orange, or against an aliquot solution to which the same amount of EDTA has been added instead of DCTA. The concentration of Xylenol Orange in this blank has also to be maintained constant.

Some results of the determination of vanadium$^{\mathrm{V}}$ in the presence of common elements are given in Table I.

TABLE I.—Determination of vanadium$^{\mathrm{V}}$ in the presence of other elements

	Foreign ion, μmole	Molar ratio	Vanadium V^{5+}, μg		Differences, μg
			Taken	Found

[a] Maximum ratio of V^{5+}: Me.

[b] Measured against the same concentration of the coloured ion and 5 ml of 0·05*M* EDTA.

[c] Previously boiled at pH 0·5.

[d] In presence of 50 mg of tartaric acid.

[e] In presence of 50 mg of $(NH_4)_2HPO_4$.

Zusammenfassung—Eine hochselektive kolorimetrische Bestimmungsmethode für fünfwertiges Vanadium auf Grund der Farbreaktion mit Xylenolorange wird beschrieben. In Gegenwart von 1,2-Diaminocyclohexantetraessigsäure (DCTA) ist diese Methode für Vanadin fast spezifisch, da alle Elemente maskiert werden und in mäßigen Mengen nicht stören.

Résumé—Une méthode colorimétrique très sélective pour le dosage du vanadium pentavalent basée sur la réaction colorée qui se manifeste en présence d'orange de xylénol est décrite. En présence d'acide diamino-1,2-cyclohexane-tétracétique (DCTA) la méthode est presque spécifique du vanadium, car tous les autres éléments sont protégés et ne sont pas gênants s'ils sont en quantité modérée.

CONTRIBUTIONS TO THE BASIC PROBLEMS OF COMPLEXOMETRY—XV*

DETERMINATION OF INDIUM AND GALLIUM IN THE PRESENCE OF EACH OTHER WITHOUT THE USE OF A SCREENING AGENT

RUDOLF PŘIBIL and VLADIMÍR VESELÝ
Analytical Laboratory, Polarographic Institute, Czechoslovak Academy of Sciences
Praha 1, Jilská 16, Czechoslovakia

(*Received* 17 *February* 1964. *Accepted* 19 *April* 1964)

Summary—The different complexation reaction of indium and gallium with TTHA (triethylenetetraminehexa-acetic acid) is utilised for the complexometric determination of these elements in mixtures. With EDTA and TTHA indium forms complexes of normal composition (1:1); gallium, however, forms a 2:1 complex with TTHA. To one aliquot of test solution an excess of EDTA is added, to another the same amount of TTHA. Both solutions, after adjustment of pH to 5–5.5, are titrated with zinc solution using Xylenol Orange as indicator. From the consumption of zinc solution in the two titrations the amounts of indium and gallium are easily calculated.

WHEN systematically studying TTHA (triethylenetetraminehexa-acetic acid) as a titrimetric reagent we paid attention to the determination of indium and gallium in their mixtures. Today these elements are no longer considered as less common metals, because their practical importance in the electronic industry is steadily rising. Both elements can be easily determined by an EDTA titration, but not in the presence of each other, because with EDTA they form complexes of about the same stability ($pK_{InY} = 24{\cdot}9$, $pK_{GaY} = 20{\cdot}3$). From previous experiments[1] we concluded that indium and gallium behave differently in complex formation with TTHA. Over the whole range of pH indium forms a complex of normal composition (1:1), while gallium under the same conditions forms only a 2:1 complex (Ga_2Y). This has now been utilised as the basis of a specific determination over a wide concentration range.

EXPERIMENTAL

Reagents

0·05M TTHA solution. Prepared by dissolving 24·723 g of triethylenetetraminehexa-acetic acid (J. R. Geigy, Basel, Switzerland) in 100–120 ml of 1*M* sodium hydroxide with warming and diluting to 1 litre. The factor is controlled by titration against a weighed amount of metallic zinc (dissolved in nitric or hydrochloric acid), using Xylenol Orange as indicator. It needs to be emphasised that TTHA forms a 2:1 complex with zinc, and the consumption in the titration with zinc solution drops to one-half in comparison with that of EDTA.

Solutions of indium and gallium. Prepared by dissolving the two metals in 20 ml of hot hydrochloric acid (1:1).

Other solutions and reagents include 0·05*M* EDTA, 0·05*M* zinc chloride, 1*M* hydrochloric acid, solid urotropine and 0·5% Xylenol Orange.

Determination of Indium and Gallium with EDTA

Indium can be titrated directly with EDTA in hot solution at pH 3–5, using Xylenol Orange as indicator; under the same conditions, however, gallium blocks the indicator. The sum of the two

---

* Part XIV: *Talanta*, 1964, **11**, 1197.

metals, can, therefore, only be determined indirectly, *e.g.*, at pH 5–5·5 with an excess of EDTA and back-titration by zinc solution and Xylenol Orange.

Procedure

To the acid solution containing gallium and indium, add a sufficient amount of 0·05*M* EDTA, adjust the pH to 5–5·5 with solid urotropine and heat nearly to boiling. After the addition of Xylenol Orange, titrate with 0·05*M* zinc solution to an intense red colour.

[a] High concentration of In.

[b] In = [(EDTA − Zn) − Ga(in ml)]3·486 mg.

[c] $$\text{Ga} = 2\left[(\text{EDTA} - \text{Zn}) - \left(\text{TTHA} - \frac{\text{Zn}}{2}\right)\right] 5{\cdot}738\ \text{mg.}$$

Determination of Indium and Gallium with TTHA

Procedure

To another equal aliquot of the test solution add the same amount of 0·05*M* TTHA as EDTA used above, then carry out the back-titration with zinc solution as previously described.

Calculations

First titration. The sum of gallium- and indium-EDTA complexes corresponds to the consumption of A ml of 0·05*M* EDTA.

Second titration. Let the sum of gallium- and indium-TTHA complexes correspond to the consumption of B ml of 0·05*M* TTHA. In both cases the consumption is calculated on the basis of a back-titration of excess EDTA or TTHA with zinc solution. (In the second titration zinc forms a 2:1 complex with TTHA and its consumption is twice that compared with EDTA.)

For determination of the total consumption of TTHA to complete complexation of gallium and indium, the consumption of the zinc solution has to be divided by two. This means that the consumption of gallium in the analysed solution equals 2(A ml of 0·05*M* EDTA − B ml of 0·05*M* TTHA).

1 ml 0·05*M* EDTA (TTHA) ≡ 5·380 mg of indium or 3·486 mg of gallium.

DISCUSSION

The above method of determination of indium and gallium is given intentionally for their pure solutions, because the principle of their determination is quite new. The application of this method opens new possibilities for the determination of indium and gallium, even in the presence of other elements which may be present in different materials of practical importance (alloys, semiconductors, monocrystals of the Ga–In–As system, *etc.*). Because indium forms only a 1:1 complex with TTHA, while other heavy metals, such as zinc, cadmium, lead and copper, form 2:1 complexes, the determination of indium can be carried out in a similar way to that described in this paper. On the other hand, however, gallium can be determined by the "double titration" in the presence of all metals forming 1:1 complexes with TTHA.

Zusammenfassung—Die verschiedene Komplexbildung von Indium und Gallium mit EDTA und TTHA (Triäthylentetraminhexaessigsäure) wird zur komplexometrischen Bestimmung beider Elemente nebeneinander verwertet. Indium bildet mit EDTA und TTHA 1:1-Komplexe, Gallium jedoch mit TTHA einen 2:1-Komplex. Die Methode beruht auf folgendem: Zu einem aliquoten Teil der Lösung wird überschüssige EDTA gegeben, zu einem andern dieselbe Menge TTHA. Beide Lösungen werden nach Einstellung des p_H auf 5–5.5 mit Zinklösung und Xylenolorange als Indikator titriert. Aus dem Zinkverbrauch bei beiden Titrationen läßt sich die Menge von Indium und Gallium leicht berechnen.

Résumé—On ulitise les réactions de complexation différentes que donnent l'indium et le gallium avec l'EDTA et le TTHA (acide triéthylènetétramine hexacétique) pour le dosage complexométrique des deux éléments dans leurs mélanges. L'indium forme avec l'EDTA et le TTHA des complexes de composition normale 1:1, cependant que le gallium forme, avec le TTHA, un complexe 2:1. La méthode est basée sur le mode opératoire suivant: à une partie aliquote de la solution, on ajoute un excès d'EDTA, et à une autre la même quantité de TTHA. On dose les deux solutions, après avoir ajusté le pH à 5–5,5, au moyen d'une solution de zinc en présence de xylénol orange. On peut aisément calculer les teneurs en indium et gallium à partir des quantités de solution de zinc consommées dans les deux dosages.

SEMI-MICRO DETERMINATION OF SILICON AND PHOSPHORUS IN FLUORINATED ORGANIC MATERIALS

A. J. CHRISTOPHER, T. R. F. W. FENNELL® and J. R. WEBB
Royal Aircraft Establishment, Farnborough, Hants., England

(*Received* 4 *March* 1964. *Accepted* 16 *April* 1964)

Summary—A method for the colorimetric determination of silicon and phosphorus in fluorinated organic compounds is outlined. After mineralisation of the material by fusion with sodium peroxide, silicon is determined as silicomolybdenum blue and phosphorus as phosphovanadomolybdate. Mean recoveries of 101·3% (standard deviation 1·64) for silicon and 100·9% (standard deviation 2·02) for phosphorus were obtained.

IT was suggested in an earlier publication[1] that the interference by fluorine in the determination of silicon in organic materials could be overcome by the addition of boric acid before precipitation of silica. This was later found to be not universally applicable, especially when larger quantities of fluorine were present.

It was known that fluorine could be determined in compounds containing silicon[2] and/or phosphorus[3,4] and that phosphorus could be determined in compounds containing fluorine[5] and/or silicon.[1] Schwarzkopf and Henlein[2] proposed two procedures for the determination of silicon in fluorinated organic compounds. Neither could be used if phosphorus was also to be determined, because phosphate is precipitated with lead chlorofluoride[3] and with oxine silicomolybdate.[6] The methods for determination of silicon in the presence of fluorine proposed by Shell and Craig[7] and by Harel *et al.*[8] were considered inappropriate for adaptation.

PRELIMINARY INVESTIGATIONS

Separation of silica after complexing fluoride with aluminium[9] was moderately successful, but insufficiently reliable for the present purpose. Determination of silica after precipitation of calcium fluoride[10,11] was moderately successful but tedious. Separation of silicate from fluoride with zinc oxide[12] was found to give the required precision.

The above procedures depend on the gravimetric determination of silicon as silica, with its attendant poor gravimetric factor and tendency to produce slightly low results. Chumachenko and Burlaka[13] have suggested that an empirical factor might be used to overcome the latter defect, but this expedient is hardly justifiable. Improved gravimetric factors are achieved by precipitation of silicon as the silicomolybdate of an organic base, but such complexes are slightly soluble, and the phosphomolybdates are simultaneously precipitated. In spite of a statement to the contrary,[14] it was found that the precipitation of the quinoline-silicomolybdenum blue complex was also accompanied by quantitative precipitation of the phospho complex. In the absence of phosphate, this was found to be an excellent method for silicon determination, although an empirical factor (0·0117) had to be used.

Greenfield[15] has proposed a colorimetric method for determination of silicon in minerals containing phosphorus and fluorine. Silicomolybdate is reduced under rigorously controlled conditions without reduction of phosphomolybdate. It was confirmed that no interference was caused by the amounts of fluorine and phosphorus that might be expected to occur with the silicon in organic compounds.

A colorimetric procedure, using the phosphovanadomolybdate complex, was recommended by Dunn[16] for determination of phosphorus in organic compounds. It was established that no interference was caused by the quantities of fluorine and silicon expected (*cf.* Lew and Jakob[17]).

EXPERIMENTAL

Analysis of organic materials

Using our usual technique for peroxide bomb fusion,[6] incomplete decomposition of some organosilicon compounds has occurred, but it has been found that fusion with sodium peroxide in a nickel "fluorine" bomb[18] at 500° is effective. This technique, although possibly not essential, was used in this work.

Using triphenylsilanol as a standard compound, low recoveries of silicon were obtained if Greenfield's procedure was applied directly to the bomb leachings. Satisfactory recoveries were, however, obtained when Wilson's method[19] for complete conversion to orthosilicate was applied to the bomb leachings before determination of silicon.

Procedure

Place a little sodium peroxide in the bottom of a "fluorine" bomb, and add the weighed organic sample, containing 1–5 mg of silicon and 1–4 mg of phosphorus, followed by sufficient sodium peroxide to give a total of 1 g of peroxide. Seal the bomb, and heat it in a muffle furnace at 500° for 15 min, swirling the molten contents after 10 min and also when the bomb is removed from the furnace.

Cool and open the bomb, washing any peroxide adhering to the cap into a platinum dish. Wipe the outside of the bomb with a clean tissue, and lay it on its side in the platinum dish. Add water until the bomb is half covered, place a watch glass over the dish and heat on a hot-plate, occasionally rolling the bomb gently, until effervescence ceases and the solution comes to the boil. Remove the dish from the hot-plate and allow to cool. Rinse the underside of the watch-glass and the bomb, collecting the washings in the dish.

Run 9 ml of 4*M* hydrochloric acid into a 250-ml Polythene beaker, and pour the alkaline contents of the dish into the acid, stirring well. Rinse the dish, collecting the washings in the beaker.

Add 15 ml of 1*M* sodium hydroxide solution and allow the solution to cool. Adjust the pH back to 7 with 2*M* hydrochloric acid, using a pH meter. Add 34·0 ml of 4*M* hydrochloric acid from a burette, stir well and allow to cool. Filter the contents of the beaker through a paper-pulp pad into a 250-ml volumetric flask, rinse the beaker and pad, and dilute to the mark with water. Transfer the sample solution to a Polythene bottle.

Into each of two dry 250-ml beakers, marked "test solution" and "compensating solution", pipette 50 ml of 1% ammonium molybdate solution. Then make the additions shown in Table I after the times indicated:

TABLE I

Time, *min*	Test solution	Compensating solution
0	20 ml of sample solution	60 ml of 1 + 1 HCl (burette) followed immediately by 10 ml of 1% $SnCl_2$ (pipette) and 20 ml of sample solution (pipette)
5	60 ml of 1 + 1 HCl (burette)	—
15	10 ml of 1% $SnCl_2$ (pipette)	—
	Transfer a portion of each solution into a 5-mm spectrophotometer cell.	
20	Measure the optical density, at 800 mμ, of the "test solution", against "compensating solution" as blank.	

Compute the silicon content of the sample by reference to a calibration curve prepared from standard silicate solution* added to acidified blank bomb leachings, and put through the analytical process.

To a 100-ml volumetric flask add 20 ml of sample solution, about 20 ml of water and 5 ml of vanadomolybdate reagent†; make up to the mark with water.

Similarly, prepare a blank solution by substituting 20 ml of acidified blank bomb leachings for the sample solution.

Allow to stand for 20 min, then measure the optical density, at 420 mμ, of the sample solution against the blank in 2-cm cells.

Compute the phosphorus content of the sample by reference to a calibration curve prepared from standard phosphate solution‡ added to acidified blank bomb leachings and put through the analytical process.

RESULTS

Table II shows the results obtained for the analysis of triphenylsilanol and a selection of research compounds containing silicon and phosphorus, some also containing fluorine.

TABLE II.—ANALYSIS OF ORGANIC COMPOUNDS

DISCUSSION

Mean recoveries, calculated from the results in Table II, are: for silicon 101·3% (standard deviation 1·64, 18 determinations); for phosphorus 100·9% (standard deviation 3·02, 12 determinations). In spite of the possible existence of a positive bias in the method, and the tendency for some results to fall outside the normally

* Fuse 2 g of precipitated silica with 12 g of anhydrous sodium carbonate. Leach the cooled melt with water. Filter the resulting solution and dilute the filtrate to 1 litre. Store in a Polythene bottle. Standardise this solution gravimetrically.[22]

† *Preparation:* Dissolve 1·6 g of ammonium vanadate and 50 g of ammonium molybdate in 700 ml of water at about 60°, filter if not completely clear, and allow to cool. Add cautiously, with stirring, 150 ml of concentrated sulphuric acid, allow to cool and dilute to 1 litre with water.

‡ Dissolve 87·86 mg of KH_2PO_4, dried at 105° for 1 hr, in water, and dilute to 1 litre.

accepted limits (±0·3% absolute) for analysis of organic materials, we consider that these results are reasonable for these types of compound.

Attempts to determine fluorine, by the method of Belcher and West,[20] in a further portion of the solution obtained from the bomb leachings, met with limited success. Use of one of the methods proposed by Belcher and West[21] for larger quantities of fluorine, thus allowing larger portions of the leach solution to be taken, may be more successful.

Acknowledgements—We are grateful to Midland Silicones Ltd. for the sample of triphenylsilanol and to Mr. E. J. P. Fear and Dr. I. M. White for the other samples.

Zusammenfassung—Eine Methode zur kolorimetrischen Bestimmung von Silicium und Phosphor in fluorierten organischen Verbindungen wird skizziert. Nach Aufschluß des Materials durch Natriumperoxydschmelze wird Silicium als Silicomolybdänblau und Phosphor als Phosphovanadomolybdat bestimmt. Mittlere Ausbeuten von 101,3% (Standardabweichung 1,64) für Silicium und 100,9% (Standardabweichung 2,02) für Phosphor wurden erhalten.

Résumé—On présente une méthode de dosage colorimétrique du silicium et du phosphore dans les composés organiques fluorés. Après minéralisation du produit par fusion avec le peroxyde de sodium, on dose le silicium à l'état de bleu de silicomolybdène, et le phosphore à l'état de phosphovanadomolybdate. On retrouve en moyenne 101,3% (écart type 1,64) de silicium et 100,9% (écart type 2,02) de phosphore.

DETERMINATION OF NON-METALLIC COMPOUNDS IN STEEL—I

APPLICATION OF DIFFERENTIAL THERMAL ANALYSIS-EFFLUENT GAS ANALYSIS

W. R. BANDI, H. S. KARP, W. A. STRAUB and L. M. MELNICK
Applied Research Laboratory, United States Steel Corporation, Monroeville, Pa., U.S.A.

(*Received* 23 *March* 1964. *Accepted* 8 *June* 1964)

Summary—Differential thermal analysis can be used to identify metal carbides, nitrides and sulphides in the residues which can be chemically or electrochemically extracted from steels. Different dynamic gases can be used to produce different thermal responses, which will further aid in the identification. Monitoring changes in the thermal conductivity and/or composition of the effluent gas can also aid in this identification. Preliminary experiments in detecting changes in the composition of the effluent gas by thermal-conductivity measurement, selective absorption and coulometric titration indicate that quantitative determination of inclusion compounds extracted from steel is possible. However, the design of the sample holder must be improved to eliminate gas leaks and temperature differences between the reference and effluent gases. Future work will also be directed towards developing methods for quantitatively determining specific non-metallic compounds in mixtures extracted from steels.

INTRODUCTION

FOR many years the effect of carbide and nitride compounds on the physical and mechanical properties of steel has been recognised. For example, strain-aging, a phenomenon associated with the precipitation of iron nitride in steel, can be prevented by the addition of aluminium or vanadium, which preferentially combine with the nitrogen to form aluminium or vanadium nitride.[1,2] The precipitation of carbides is known to hinder crystal growth and thereby effect a fine microstructure and increased tensile strength.[3] Intergranular corrosion of stainless steels may be caused by depletion of chromium at the grain boundaries because of the formation of chromium carbide. To prevent this depletion, niobium or titanium is added to form a carbide in preference to that of chromium.[4] Variations in many other mechanical properties, such as hardenability, yield strength, toughness and brittleness, have been associated with the presence of compounds such as nitrides, carbides, oxides and sulphides. The analysis of steel for these compounds can, therefore, be used to aid in the development of steels with improved physical and mechanical properties.

Mixtures of compounds are isolated from steel by techniques such as electrolytic extraction,[5] acid extraction,[6] direct halogenation[7] and halogenation in an ester or alcohol medium.[8,9] Chemical analysis of these mixtures for specific compounds is difficult and sometimes impossible. Separations based on solubility in a specific reagent are not always satisfactory because the rates of solution of many of these compounds are not sufficiently different. Furthermore, reliable information on the rate of solution of many of these compounds is not available. Finally, analysis for these compounds is often complicated by their existence as very fine particles (10 mμ or less), which cannot always be isolated by normal filtration or separation techniques.[10,11,12]

The oldest method used for identification of compounds in steel is optical microscopy. Visual identification, can, however, lead to errors. Also, with this technique very fine particles cannot be seen because of insufficient resolution. In recent years more precise methods, such as X-ray diffraction, electron diffraction and electron microscopy, have been employed in conjunction with chemical-isolation and plastic-replication techniques. Although the qualitative information gained by the use of these instruments is more reliable, fine particles of titanium nitride, titanium carbide and titanium carbonitride cannot be differentiated because of their similar crystal structures. Furthermore, the methods are only semiquantitative.

Because the design of apparatus for differential thermal analysis (DTA) and effluent gas analysis (EGA) has recently been improved,[13,14,15] these techniques seemed applicable to the analysis of mixtures of compounds that are chemically extracted from steel.

In the initial work characteristic DTA curves for some of the compounds were obtained from commercially prepared synthetics, then inclusions were separated by weak-acid dissolution or anodic dissolution of the steel matrix and filtration of the residue through a 10-mμ pore size filter. The DTA-EGA results on some titanium compounds extracted from steel were compared with chemical and X-ray diffraction results.

EXPERIMENTAL

Apparatus

A Model 12BC$_2$ DTA-EGA apparatus, manufactured by the R. L. Stone Co. of Austin, Texas, U.S.A., was used for the experiments. The EGA unit was modified by replacing the conductivity cell with a Gow-Mac Model JDC-133 microvolume thermistor detector immersed in a thermally insulated oil bath. A Gow-Mac Power Supply Model 9999-D1 was used with this cell. A Pyrex Millipore filter holder, containing a 47-mm Type VF Millipore filter disk (10-mμ pore size), was used for collection of the inclusions extracted from the steels.

Reagents

Commercially prepared titanium carbide, titanium nitride, titanium carbonitride, zirconium carbide, zirconium nitride, niobium carbide and niobium nitride were used for the preliminary experiments. The identification and purity of these compounds were established by X-ray diffraction and chemical analysis.

The experimental steels used for this study contained titanium and one or more of the elements nitrogen, carbon and sulphur, as shown in Table I. The steels were prepared by vacuum melting so that very little oxygen would be present.

Procedure

DTA data were obtained by introducing 1–3 mg of sample into an R. L. Stone Model SH8A or SH9A sample holder equipped with platinum-cup thermocouples. The heating rate was 10°/min, and the thermograms of the difference in response between the reference and sample thermocouples, (ΔT, *versus* the furnace temperature) were recorded at $\frac{1}{30}$ and $\frac{1}{15}$ of the maximum sensitivity setting of the instrument for the commercial compounds and the extracted compounds, respectively. Oxygen flow rates of 5 and 40 ml/min were used for the extracted and the commercial compounds, respectively. Reagent-grade alundum, containing more than 95% of α-alumina, was used in the reference thermocouple.

EGA data were obtained by introducing a weighed sample (*ca.* 1–3 mg) to an R. L. Stone Model SH12BP sample holder equipped with platinum-cup thermocouples, and recording the difference in thermal conductivity of the effluent gases from the reference and sample sides (Δk). The attenuator was set at $\frac{1}{8}$ the maximum sensitivity for the EGA recording unless otherwise shown. The oxygen gas flow was 5 ml/min through the reference side; it varied from 5 to 8·5 ml/min in the sample side of the EGA apparatus. The heating rate was 10°/min.

Insol. Al	0·003	<0·002	0·002
N	0·002	0.001	0·019

[a] <0·005% of Cu, Mo, V, Zr, Nb or Ta; <0·0005% of B.

Titanium compounds were extracted from 5-g samples of the experimental steels by dissolving the steel matrix in 3% hydrochloric acid at 50° or by dissolving the steel anodically in a solution of 12·5% sodium citrate, 0·5% sodium thiocyanate, 1% potassium bromide and 0·01% hydrazine. The solution was filtered through a 10-mμ filter. One mg of the inclusion residue was scraped from the filter, weighed on a Cahn microbalance and introduced into the DTA apparatus. For several tests, the sample was introduced into the test apparatus with the portion of the filter on which it had been collected. One mg of residue was about $\frac{1}{10}$th of the inclusions isolated from steel samples A and B and $\frac{1}{80}$th of the inclusions isolated from sample C.

The titanium-bearing steels were also chemically analysed for titanium compounds to provide a comparison for the DTA-EGA results. Because the chemical analysis did not require filtration (see Appendix), none of the very fine inclusions of titanium compounds were lost. The chemically extracted titanium compounds were identified by standard X-ray diffraction techniques after collection on a 10-mμ filter.

RESULTS AND DISCUSSION

Thermograms of synthetic compounds

Characteristic thermograms were consistently obtained for the carbides and nitrides of titanium, zirconium and niobium (Fig. 1). Because the peak temperatures and the shapes of the thermograms are different for corresponding carbides and nitrides, these compounds can be distinguished in a residue containing these non-metallic compounds.

Often steels do not contain pure titanium carbide or pure titanium nitride, but rather titanium carbonitride (nitrogen-bearing titanium carbide or carbon-bearing titanium nitride of indefinite formula). The thermogram of a commercially prepared titanium carbonitride compound, containing 10% of nitrogen, 5% of carbon and 85% of titanium (Fig. 2), has some of the thermal characteristics of both the titanium carbide and the titanium nitride. Differences in the shapes of the titanium carbonitride thermogram permit identification of the carbonitride in the presence of either the carbide or the nitride.

Thermograms produced by different dynamic gases

In the thermograms for titanium carbide, titanium nitride and zirconium nitride in steam (Fig. 3), the peak temperatures are lower than those obtained in oxygen. The peak itself is higher for each of the two nitrides, but lower for the carbide. Substituting helium or vacuum for oxygen changes the type of reaction from combustion to decomposition and thus changes both the DTA and the EGA curves.

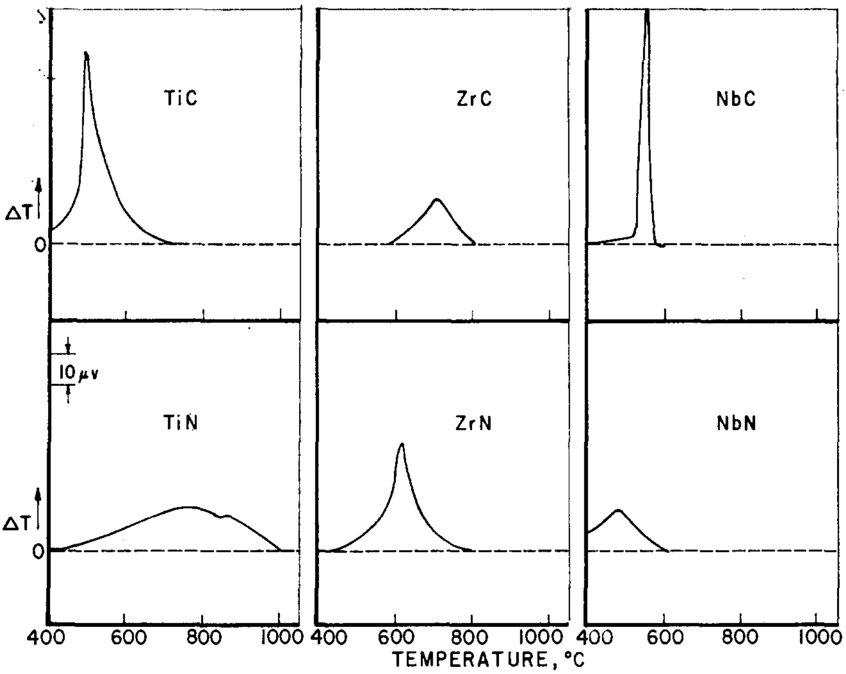

Fig. 1.—DTA recordings for carbides and nitrides of titanium, zirconium and niobium (oxygen as dynamic gas).

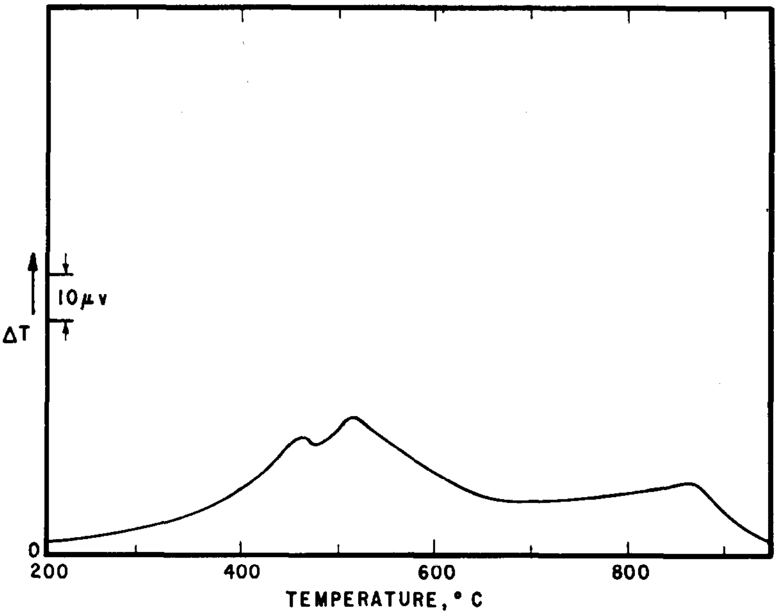

Fig. 2.—DTA recording for titanium carbonitride (85% of Ti, 5% of C, 10% of N by weight) (oxygen as dynamic gas).

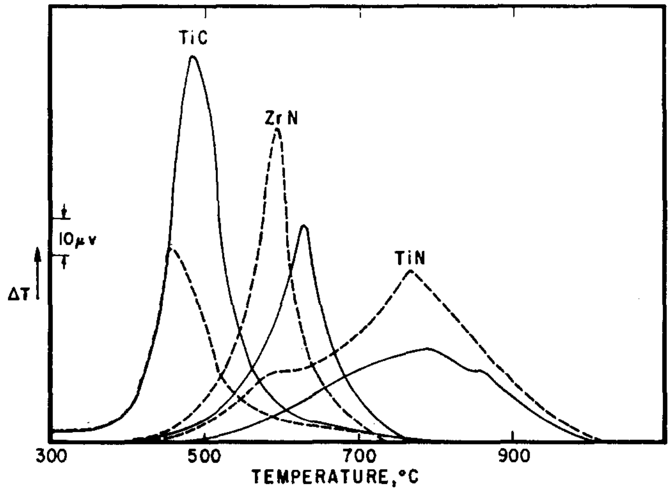

FIG. 3.—DTA recordings for titanium and zirconium nitrides and titanium carbide (oxygen or steam as dynamic gas):

—— oxygen,

– – – steam

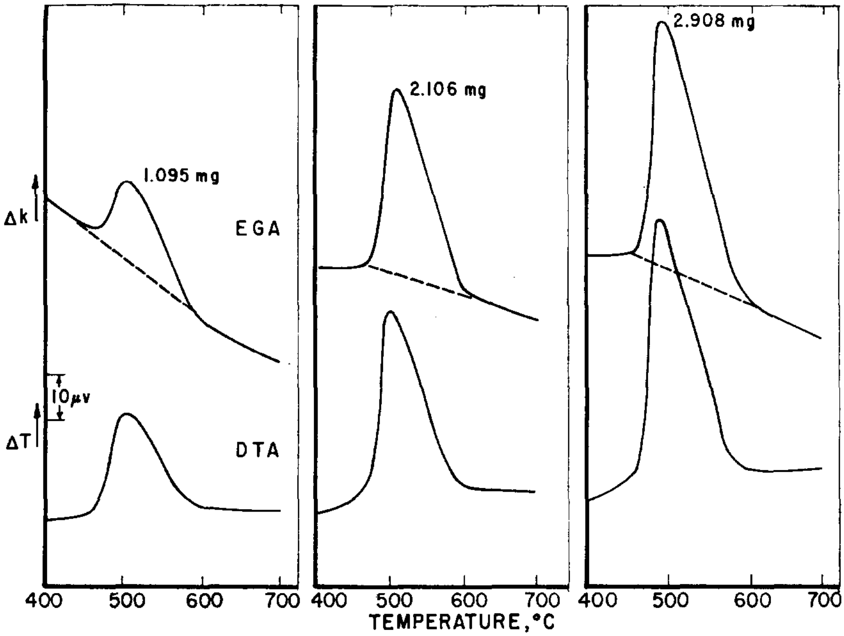

FIG. 4.—DTA-EGA recordings for different amounts of titanium carbide (oxygen as dynamic gas).

This illustrates another aid in the qualitative identification of mixtures of non-metallic compounds extracted from steel.

EGA response for titanium carbide

Fig. 4 shows the DTA and EGA curves for the combustion of 1, 2 and 3 mg of titanium carbide with oxygen as the dynamic gas in the sample and reference sides of the microvolume thermistor detector. The area above the dotted line represents the difference in thermal conductivity between oxygen containing carbon dioxide from combustion of the sample and pure oxygen from the reference side. The EGA base line drifted because of a temperature imbalance between the reference gas and the sample gas and a continuously changing gas flow rate in the sample side of the thermistor. A plot of the area representing the thermal-conductivity response against the amount of titanium carbide (Fig. 5) shows that, in spite of the base-line drift, good quantitative results are obtained. Elimination of the temperature imbalance between the reference and sample gases and the sample-holder leaks that contribute to the changing flow rates should improve the base line.

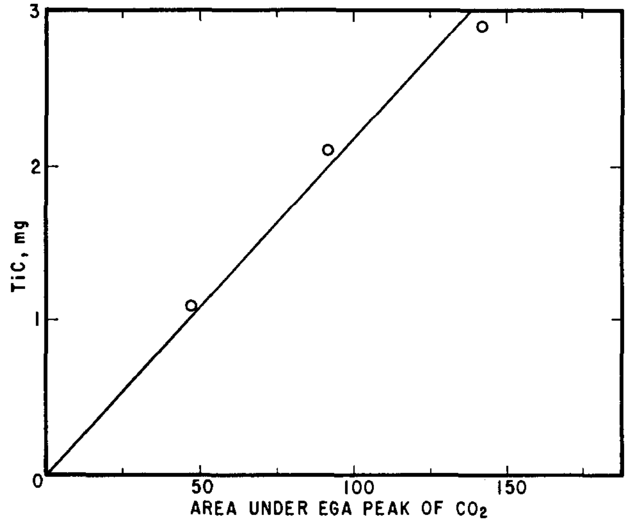

Fig. 5.—Amount of titanium carbide *versus* relative area under EGA curves (planimeter reading) for carbon dioxide (oxygen as dynamic gas).

Table II.—Analysis of inclusions

Steel sample	Chemical results, %			X-ray results		Estimated from DTA-EGA curves	
	Ti as TiN or TiC_xN_y	Ti as TiS	Ti as TiC	Major	Minor	Major	Minor
A	0·003	0·000	0·45	TiC	TiN	TiC	TiN

C	0·053	0·000	0·35	TiC	None detected	TiC	TiC_xN_y

Thermograms of inclusion residues separated from steels by acid extraction

Although the differential thermograms of the residues extracted with weak hydrochloric acid from the titanium-bearing steels are more complex than those for the commercial compounds (Figs. 6, 7 and 8), they had thermal peaks that agreed with the chemical and X-ray analyses of the residues (Table II). All three steels contained titanium carbide, and the thermogram of each steel showed a titanium-carbide peak.

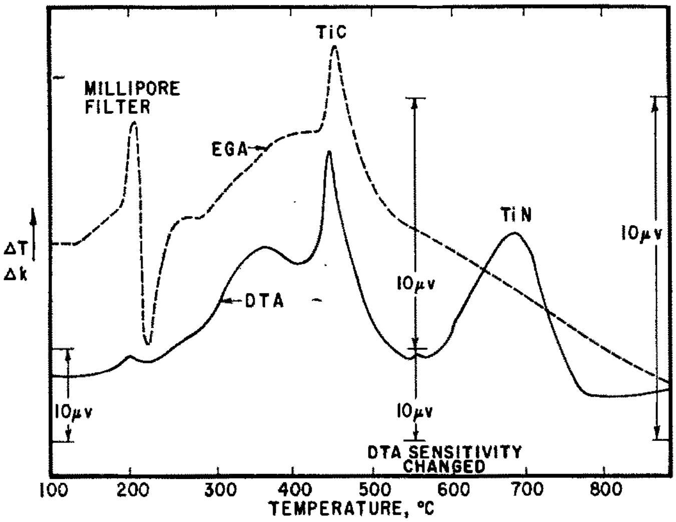

FIG. 6.—DTA-EGA recordings of membrane filter and a 1-mg sample of inclusions extracted from Steel A by weak-acid dissolution (oxygen as dynamic gas).

In addition, a thermal peak in Fig. 7 corresponds to the gamma dititanium sulphide in Steel B, and a thermal response in Fig. 8 corresponds to titanium carbonitride in Steel C. One noticeable difference in the thermograms is that the thermal peak for titanium carbide shifted from 500° for the commercial compound (Fig. 1) to 450° for the compound extracted from steel (Figs. 6–9). This shift is probably caused in part by a difference in particle size of the two titanium carbides; some of the commercial powder was 10,000 times larger than that extracted from the steel. A second possible explanation is that small amounts of other compounds in the crystal structure of the extracted titanium carbide lowered the reaction temperature. The thermal peaks for the titanium nitride in Fig. 6, for the gamma dititanium sulphide in Fig. 7 and for the titanium carbonitride plateau in Fig. 8 have also shifted.

All three differential thermograms show peaks for compounds that could not be definitely identified as titanium compounds and that might have been more complex titanium compounds or compounds containing no titanium. In addition, the doublet peaks for the titanium carbide in Figs. 7 and 8 were almost exactly reproduced on four separate thermograms of residues from two different acid extractions. Chemical tests show that carbon dioxide was evolved at each peak in the doublet. No other carbide-forming elements were present except titanium and iron. Therefore, the doublet is apparently related to the structure or the particle size of the titanium carbide.

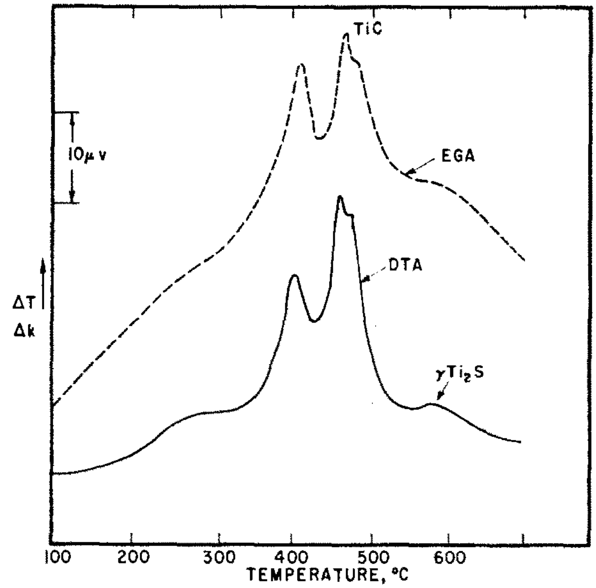

FIG. 7.—DTA-EGA recordings for 1-mg sample of inclusions extracted from Steel B by weak-acid dissolution (oxygen as dynamic gas).

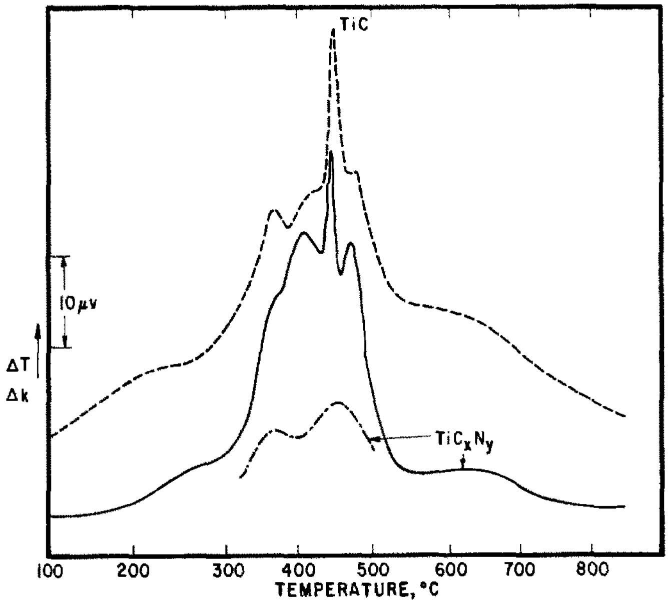

FIG. 8.—DTA-EGA recordings for 1-mg sample of inclusions extracted from Steel C by weak-acid dissolution (oxygen as dynamic gas):

--- EGA,
—— DTA,
·-·- contribution of TiC_xN_y to TiC peak.

Because the DTA-EGA response for combustion of the Millipore filter occurs below 300° (Fig. 6), the filter containing the residue can be introduced directly into the apparatus with no interference in the analysis at temperatures greater than 300°. No EGA response corresponds to the DTA peak of the titanium nitride with oxygen as the dynamic and reference gas in Fig. 6. This indicates that decomposition of the compound releases nitrogen which has a similar thermal conductivity to that of oxygen and therefore causes very little EGA response. This effect can be used to differentiate between nitrides and carbides. Because only about 0·019 mg of titanium nitride was present in the sample-holder, the DTA sensitivity was changed from $\frac{1}{15}$th to $\frac{1}{4}$th maximum at 600° so that a recognisable peak would be recorded. The sensitivity setting of only $\frac{1}{4}$ demonstrates that very small amounts of these compounds can be detected when no DTA interference is present.

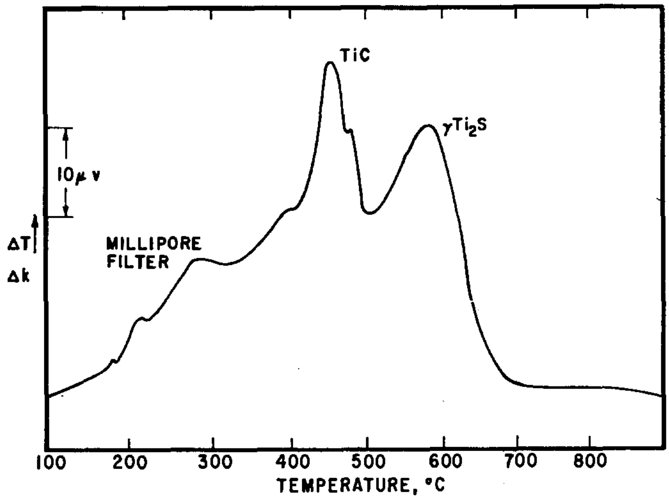

FIG. 9.—DTA recording of membrane filter and inclusions extracted from Steel B by anodic dissolution of sample (oxygen as dynamic gas).

The nitrogen found by chemical methods in the residue from Steel C was not present as TiN because the DTA peak for this compound in Fig. 6 is not present in Fig. 8. A plateau from 520 to 700° appears to fit TiC_xN_y, and a broad thermal response from 300 to 500° is characteristic of TiC_xN_y (see Fig. 2). A sharper titanium-carbide doublet peak is superimposed on the broad titanium carbonitride thermal response.

No attempt was made to calculate quantitative values for the titanium carbide in the three steels from the EGA curves because of the temperature imbalance in the gases from the sample and reference side and the gas leaks in the sample holder. However, rough estimates from assumed base lines seem to indicate that quantitative analysis of the inclusion residue can be based on the thermal conductivity of the effluent gas stream. Other methods of measuring changes in the composition of the effluent gas were also tried in a preliminary manner. Among those which seem useful are the following:

1. The removal or determination of carbon dioxide by absorption on a preweighed bulb of asbestos impregnated with sodium hydroxide.

2. The removal or determination of sulphur dioxide in the effluent stream by reaction with a solution of potassium permanganate.
3. The determination of microgram quantities of sulphur dioxide selectively and continuously by a coulometric technique wherein iodine is electrolytically generated.

In addition, these experiments and other published work indicate that selected fractions of the effluent gas could be analysed by gas chromatography and mass spectrometry.

Effect of method of extraction of inclusion compounds

Inclusions were extracted from Steel B by weak-acid dissolution and by anodic dissolution in the modified sodium citrate solution. The thermal peak for gamma dititanium sulphide is higher for the residue from the anodic extraction (Fig. 9) than for the residue from the weak-acid extraction (Fig. 7). Most of the gamma dititanium sulphide apparently dissolves under the conditions used for the acid extraction. This illustrates the importance of selecting the appropriate method of chemical isolation for specific inclusion compounds. Even low rates of solution are important because very small quantities of the fine particles, with a correspondingly large surface area, may be exposed to a dissolution medium for several days. This effect is demonstrated in Table II by the titanium sulphide results for Steel B, which were obtained from the difference in sulphur determined by the combustion and evolution methods. Very little titanium sulphide was dissolved in the few minutes necessary to evolve hydrogen sulphide in the evolution method, whereas nearly all of the gamma dititanium sulphide was dissolved in a more dilute solution of hydrochloric acid in the 2 days required to dissolve the matrix. Finally, the additional peaks and exothermic areas in Fig. 9 are from other compounds and phases in the steel, such as iron and manganese carbides and sulphides, which are chemically stable in the anodic citrate medium but not in the dilute acid medium.

APPENDIX

The following is a summary of the chemical methods used to determine the amount of the various forms of titanium in the titanium-bearing steels:

1. Dissolve a steel sample in warm 3% sulphuric acid, remove iron by mercury-cathode electrolysis, allow undissolved TiC, TiN, TiS and TiO_2 to settle, and determine the titanium in the solution by the peroxytitanic acid photometric method. The result represents the titanium in solid solution with iron in the steel (*i.e.*, titanium not combined with carbon, nitrogen, sulphur or oxygen).
2. Dissolve a second steel sample in hydrochloric acid, add perchloric acid and evaporate the solution to fumes of perchloric acid to dissolve all titanium compounds but TiO_2. Remove iron by mercury-cathode electrolysis, allow any TiO_2 to settle and determine the titanium in the solution by the peroxytitanic acid photometric method. The results represent the titanium in solid solution in the steel plus the titanium combined with carbon, nitrogen and sulphur. The difference between the titanium results obtained by procedures 1 and 2 represents the titanium combined with carbon, nitrogen and sulphur.
3. Determine sulphur by the evolution and combustion methods. The difference in the sulphur results obtained by these two methods (evolution is lower) represents the sulphur associated with the titanium and is arbitrarily calculated to TiS (the common form).
4. Dissolve a steel sample in 3% hydrochloric acid at 50° and determine the nitrogen present as iron nitride, aluminium nitride and in solid solution by the micro Kjeldahl photometric method. Dissolve another sample with potassium sulphate-sulphuric acid, heat to fumes of sulphuric acid and determine nitrogen by the same method. The difference in the nitrogen results is the nitrogen present as TiN.
5. Subtract the titanium present as TiN and TiS from the titanium value determined in procedure 2. The difference is assumed to be titanium present as TiC.

Zusammenfassung—Mit der Diferentialthermoanalyse kann man Metallcarbide, -nitride und -sulfide in den Rückständen identifizieren, die chemisch oder elektrochemisch aus Stählen gewonnen werden können. Mit verschiedenen Trägergasen lassen sich verschiedene thermische Effekte erzielen, die bei der Identifizierung weiterhelfen. Auch Messung von Veränderungen der Wärmeleitfähigkeit und/oder Zusammensetzung des ausgetriebenen Gases kann dabei von Nutzen sein. Vorläufige Experimente zur Feststellung von Änderungen der Zusammensetzung des ausgetriebenen Gases durch Wärmeleitfähigkeitsmessung, selektive Absorption und coulometrische Titration zeigen, daß die quantitative Bestimmung aus Stahl extrahierter eingeschlossener Verbindungen möglich ist. Die Konstruktion des Probenhalters jedoch muß noch verbessert werden, um Gaseinbrüche und Temperaturdifferenzen zwischen Vergleichs- und ausgetriebenem Gas zu verhindern. Weitere Arbeiten werden ferner zum Ziel haben, Methoden zur quantitativen Bestimmung bestimmter nichtmetallischer Verbindungen in aus Stahl extrahierten Mischungen zu entwickeln.

Résumé—On peut utiliser l'analyse thermique différentielle pour identifier les carbures, nitrures et sulfures métalliques dans les résidus qui peuvent être extraits chimiquement ou électrochimiquement des aciers. On peut utiliser différents gaz dynamiques pour produire différentes réponses thermiques, qui aideront ensuite à l'identification. Le contrôle de changements dans la conductivité thermique et/ou la composition du gaz effluent peut aussi aider à cette identification. Des expériences préliminaires pour détecter des variations dans la composition du gaz effluent, par mesure de conductivité thermique, absorption sélective, et dosage coulométrique, montrent que le dosage quantitatif des composés d'inclusion extraits de l'acier est possible. Toutefois, la conception du support de l'échantillon doit être améliorée pour éliminer les fuites de gaz et les différences de température entre le gaz de référence et le gaz effluent. Les travaux futurs seront également dirigés vers le développement de méthodes de dosage quantitatif de composés non métalliques spécifiques dans des mélanges extraits d'aciers.

SUCCESSIVE DETERMINATION OF THORIUM AND RARE EARTHS BY COMPLEXOMETRIC TITRATIONS*

ASIM K. GUPTA and JACK E. POWELL
Institute for Atomic Research and Department of Chemistry
Iowa State University, Ames, Iowa, U.S.A.

(*Received* 10 *April* 1964. *Accepted* 13 *June* 1964)

Summary—Thorium can be determined quantitatively by EDTA in the presence of the light rare earths but not in the presence of the heavy rare earths. The successive determination of thorium and heavy rare earths with diethylenetriaminepenta-acetic acid (DTPA) has been found to be feasible and is described. The direct successive determination of thorium and rare earths by combined titration with DTPA and *N*-hydroxyethylethylenediaminetriacetic acid (HEDTA) is also discussed.

VERY few workers[1,2] have reported methods for the successive determination of thorium and rare earths by complexometric titration, although there have been reports of the successive determination of thorium and rare earths by other complexometric methods (spectrophotometry, *etc.*). However, published complexometric titration methods have dealt only with the determination of thorium and the light rare earths (lanthanum to neodymium inclusive).

Complexometric titrations depend on the stability constants of complexes formed by interaction between a metal ion and the titrant, and sizable differences in these stability constants are responsible for the successful successive determination of different metals at controlled pH values.

It has been reported[1,2] that thorium may be determined accurately in the presence of light rare earths by titrating with EDTA at pH 2·5–3·0, using Xylenol Orange, Pyrocatechol Violet, *etc.*, but that the subsequent determination of the rare earths could not be accomplished because of a colour reaction of the thorium-EDTA complex at higher pH values. Přibil and Veselý[2] used diethylenetriaminepenta-acetic acid (DTPA) and triethylenetetraminehexa-acetic acid (TTHA) successfully for the successive determination of thorium and various light rare earths.

The present authors found that, although thorium could be determined accurately by EDTA in the presence of the light rare earths, as previously reported, it was not possible to determine thorium in the presence of the heavier rare earths (samarium to lutetium inclusive) whose EDTA complexes are much closer in stability to that of thorium-EDTA. This observation prompted the authors to examine the method of Přibil and Veselý for the successive determination of thorium and the heavy rare earths.

The DTPA method was found to be suitable for determining thorium and the heavy rare earths as well as for the determination of thorium and the light rare earths. The difference was that the end-point of the titration for determination of thorium is orange instead of clear yellow, as was reported in the case of light rare earths.

Přibil and Veselý used standard lead solution as a back-titrant for determination of rare earths. We have found that, instead of adding an excess of DTPA and

back-titrating with lead solution, rare earths may be determined directly by titrating with *N*-hydroxyethylethylenediaminetriacetic acid (HEDTA) at pH 5·0–5·5.

EXPERIMENTAL

Reagents

Diethylenetriaminepenta-acetic acid (DTPA) 0·05*M* *solution.* Dissolve 19·65 g of the free acid, obtained from Geigy, in 130–150 ml of hot 1*M* sodium hydroxide solution and dilute to 1 l. with distilled water.

N-hydroxyethylethylenediaminetriacetic acid (HEDTA) 0·05*M solution.* Dissolve 13·9 g of the free acid, obtained from Geigy, in 100 ml of hot 1*M* sodium hydroxide solution and dilute to 1 l. with distilled water.

The concentrations of the above solutions were checked by titrating with standard 0·05*M* lead nitrate solution using Xylenol Orange as an indicator.

Rare earths 0·05*M solution.* Dissolve the required amount of rare earth oxide, 99·99% pure, in concentrated hydrochloric acid (c.p.) and evaporate to incipient dryness. Dissolve the residue and dilute to 1 l. in each case with distilled water. The concentrations were checked complexometrically.

Indicator solution. Dissolve 1 g of Xylenol Orange (obtained from K & K Laboratories) in 100 ml of diluted alcohol.

Other chemicals used were all of reagent grade purity.

Successive determination of thorium and rare earths (samarium to lutetium inclusive) with DTPA

Thorium can be determined by direct titration with DTPA at pH 2·5–3·0 using Xylenol Orange, in the presence of the heavy rare earths. The colour change from red to orange is quite sharp. After the titration of thorium has been completed, more DTPA is added to complex the rare earth elements, and the excess is back-titrated with standard 0·05*M* lead nitrate solution.

Procedure. Dilute solutions containing different ratios of thorium and rare earth elements (as indicated in Table I) to 150 ml with distilled water. Adjust the pH of the solutions to 2·5–3·0, using a pH meter, with either dilute nitric acid or dilute aqueous ammonia. Titrate slowly with 0·05*M* DTPA, to an orange end-point, using Xylenol Orange as indicator. Add a further amount of DTPA (in excess to that required for complexing the rare earth element), adjust the pH of the solution to 5·0–5·5 with solid urotropine, and titrate the excess DTPA with 0·05*M* lead nitrate solution to a red-violet end-point.

Successive determination of thorium and rare earths with DTPA and HEDTA

N-Hydroxyethylethylenediaminetriacetic acid (HEDTA) behaves in a similar manner to EDTA, forming 1:1 complexes with rare earths, although the stability constants are very different. Use was made of this property of HEDTA in the determination of thorium and rare earths. After the determination of thorium with DTPA, as above, the pH was adjusted to 5·0–5·5 and the rare earth content titrated directly with HEDTA. The end-point is orange. Table II shows the results of a series of determinations.

Zusammenfassung—Die quantitative Bestimmung von Thorium mit EDTA ist in Gegenwart schwerer seltener Erden nicht möglich, dagegen neben leichten seltenen Erden genau. Die Bestimmung von Thorium und schweren seltenen Erden mit DTPA ist möglich und wird hier beschrieben. Auch die direkte Bestimmung von Thorium und seltenen Erden durch kombinierte Titration mit DTPA und HEDTA wird diskutiert.

Résumé—Le dosage du thorium à l'EDTA ne peut être mené en présence de terres rares lourdes, bien qu'il puisse l'être avec précision en présence de terres rares légères. On a trouvé que l'on peut doser successivement le thorium et les terres rares lourdes au moyen de DTPA, et l'on décrit le dosage. On discute aussi des dosages successifs directs du thorium et des terres rares par titrage combiné avec le DTPA et le HEDTA.

SPECTROPHOTOMETRIC DETERMINATION OF FLUORINE IN SILICATE ROCKS

LEE C. PECK and VERTIE C. SMITH
U.S. Geological Survey, Denver 25, Colorado, U.S.A.

(*Received* 4 *May* 1964. *Accepted* 3 *June* 1964)

Summary—The rock powder is sintered with a sodium carbonate flux containing zinc oxide and magnesium carbonate, the sinter-cake leached with water and the resulting solution filtered. Fluorine is separated from the acidified filtrate by steam distillation and determined spectrophotometrically by means of a zirconium-SPADNS reagent. If a multiple-unit distillation apparatus is used, 12 determinations can be completed per man-day.

INTRODUCTION

WILLARD and Winter's[1] method, one modification of which is described by Kolthoff and Sandell,[2] has been widely used for the determination of fluorine in silicate rocks. Although sufficiently accurate, the method is too time consuming to fulfill increased requests. Shell and Craig,[3] by the introduction of a zinc-bearing flux, have simplified the preliminary separation and greatly increased its speed. Although more rapid than the troublesome thorium nitrate titration, colorimetric methods for the determination of fluoride have defects and their use has not been favoured by silicate analysts. A simple, rapid colorimetric method based on the work of others, but having none of these defects, is described in this paper. No adjustment of pH is necessary. A stable, coloured complex is formed by the addition of a single reagent to the flask containing the distillate. A special photometric technique eliminates temperature effects. Sulphuric acid may be used in the distillation.

EXPERIMENTAL

Reagents

Flux: Thoroughly mix 7 parts of sodium carbonate, 2 parts of zinc oxide, and 1 part of magnesium carbonate. (The flux is usually fluorine-free, but a blank determination should be made on each lot.)

Stock sodium fluoride solution (1·00 mg of fluoride/ml): Dissolve 10 g of reagent-grade sodium fluoride in 225 ml of water, add a few ml of hydrofluoric acid and an equal volume of methanol. Collect the salt on paper, wash it with methanol, and air dry. Fuse 3 g of the salt, pour the melt into a platinum dish and cool. Crush the sodium fluoride and quickly weigh 1·105 g. Dissolve the weighed portion in water and filter it into a 500 ml-volumetric flask. Dilute the filtrate to the mark and mix. (A solution so prepared assayed 0·996 mg of fluoride/ml when analysed by the lead chlorofluoride method.)

Standard sodium fluoride solution (0·100 mg of fluoride/ml): Dilute the above solution ten-fold.

Zirconium sulphate-sulphuric acid solution. Dissolve 13·0 g of zirconium sulphate tetrahydrate in 1 litre of 1:1 sulphuric acid and 800 ml of water. Filter the solution through a fine-porosity paper and dilute the filtrate to 2 litres. Determine the zirconium oxide content of a 10-ml portion of the solution. (Precipitate with aqueous ammonia and weigh as zirconium oxide.)

SPADNS solution: Dissolve 32 g of SPADNS [sodium 2-(*p*-sulphenylazo)-1,8-dihydroxynaphthalene-3,6-disulphonate] in 800 ml of water. Pass the solution through a fibre-glass pre-filter and a membrane filter having 0·45-μ pores. Dilute the filtrate to 2 litres.

Zirconium-SPADNS reagent: Dilute a volume of zirconium sulphate-sulphuric acid solution containing 1·4 g of zirconium oxide to 800 ml with 1:3 sulphuric acid, add 1 litre of SPADNS solution and dilute the mixture to 4 litres. (If 12 mm × 12 mm cells are used in the colorimetry, increase the zirconium oxide content of the reagent to 1·6 g).

Procedure

Transfer 0·500 g of 100-mesh rock powder to a 25-ml platinum crucible containing 5·0 g of flux. Mix the sample and the upper part of the flux with a glass rod, then stir the mixed portion into the rest of the flux. Using an electric furnace, heat the crucible and its contents at 900° for 30 min. Allow the crucible to cool.

Add water to the contents of the crucible, loosen the cake with a stirring rod, and transfer the cake to a 50-ml beaker. Adjust the volume of the solution to 30 ml and allow the solution to stand overnight.

Crush the cake to a powder with a flat-ended stirring rod, then decant the solution through a 7-cm fine-porosity paper into a 250-ml distilling flask from the apparatus. Wash the residue twice by decantation with hot 1% sodium carbonate solution, then sluice the residue into the paper. Wash the residue 5 times with the hot sodium carbonate solution and discard the residue. Connect the flask to the condenser of the distillation apparatus.

Add 200 ml of water to the first of three 250-ml volumetric flasks (dark standard). Add 10·00 ml of standard sodium fluoride solution to the second flask, and adjust the volume to 200 ml (light standard). Place the third flask under the condenser of the distillation apparatus.

Add 250 ml of water to the steam-generating flask and bring the water to a gentle boil. Slowly add 25 ml of 1:1 sulphuric acid to the distillation flask through the steam-inlet tube. Connect the side tube of the generating flask to the steam-inlet tube of the distillation flask, and heat the solution in the distillation flask to the boil. Continue boiling at such a rate that, after 20 to 25 min, the amount of distillate is about 85 ml and the temperature of the solution is 135°. During this period, admit only enough steam to prevent bumping. Now bring the water in the generating flask to a moderate boil and adjust the flame under the distillation flask to maintain a solution temperature between 135 and 145°. Continue the steam distillation at such a rate that, in about 45 min, an additional 125 ml of distillate is collected.

Allow the distillate to stand until it attains room temperature. Add 25·00 ml of zirconium-SPADNS reagent to the distillate and to each of the standard solutions. Dilute each solution to volume and mix.

After 1 hr, measure the transmittance of the sample solution with a Beckman Model B spectrophotometer or its equivalent by the following procedure. Add light standard solution to the first of three 1 cm × 1 cm cells (Leitz), the sample solution to the second and dark standard solution to the third. Set the dark current at 0·0, then adjust the wavelength (about 585 mμ) so that the dark standard reads 25·0 ± 0·2 when the light standard reads 100·0. Adjust the dark current so that the dark standard reads 25·0 when the light standard reads 100·0 and measure the transmittance of the sample solution. Use separate portions of the standards for each measurement in a series.

If the reading is above 100·0, pipette 50 ml of the sample solution into another 250-ml volumetric flask. Dilute this portion to 200 ml and add 20·00 ml of zirconium-SPADNS reagent. Dilute the solution to the mark, mix it and measure its transmittance as before.

Prepare, in 250-ml volumetric flasks, six solutions containing from 0·00 to 10·00 ml of standard sodium fluoride solution in increments of 2·00 ml, and adjust the volume of each solution to 200 ml. Add 25·00 ml of zirconium-SPADNS reagent to each, then dilute each to volume and mix. Use the end members of the series, which are the same as the dark and light standard solutions previously mentioned, to adjust the wavelength, then measure the transmittance of the other solutions. Construct a transmittance curve from the values obtained.

To compute the fluoride content of the sample, use the transmittance curve to determine the fluoride content of the distillate and add a 3% (relative) correction.

Before re-using the distillation flask, clean it with a hot dilute solution of sodium carbonate.

DISCUSSION AND RESULTS

Silicate rocks rarely contain more than 0·2% of fluorine and almost never more than 1%. Because this method was designed for the analysis of silicate rocks, no tests were made with more than 5 mg of fluoride (1% for a 0·5-g sample); therefore statements in the following discussion may not apply to the determination of larger amounts.

It is known that the recovery of fluoride by accepted methods of steam distillation is never quite complete, and some workers have surmised that glassware adsorbs fluoride. Our experiments indicate that such adsorption occurs. If fluoride is adsorbed, the amount lost is consistent enough so that a correction can be made. Adsorbed fluoride is largely removed when the flask is cleaned with sodium carbonate solution so its effect is not cumulative. Amounts of fluoride adsorbed by or desorbed from the condenser are too small to affect the results.

The advantages of the special flux have been discussed.[4] When a sinter cake prepared with this flux is leached with water, much of the silica and alumina is retained in the residue and is removed by filtration, but enough silica and alumina are always present in the filtrate to interfere with the distillation of fluoride.

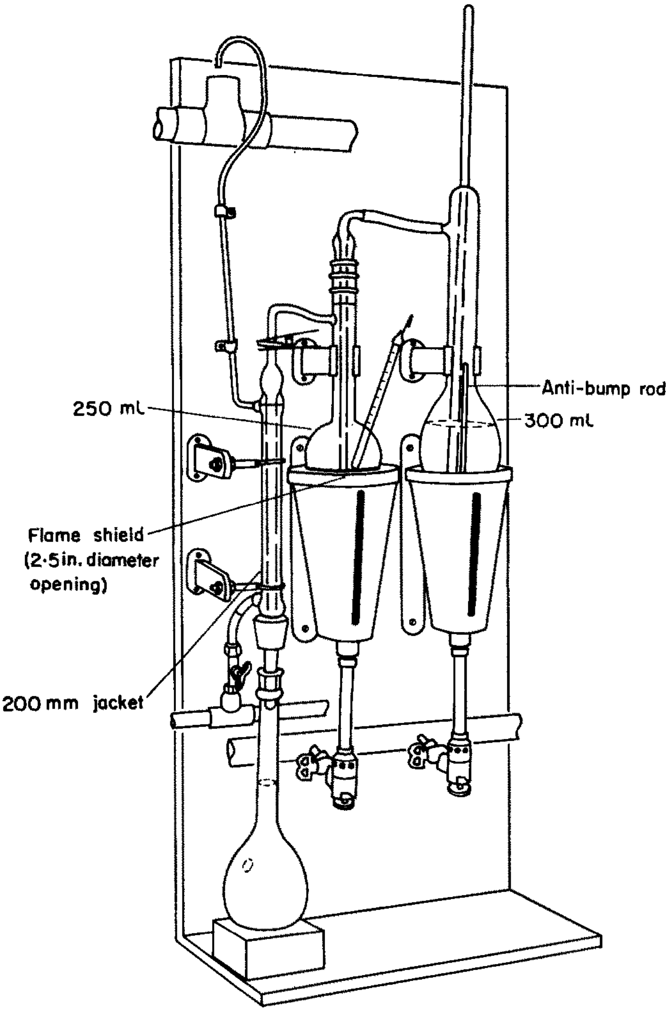

Fig. 1.—Distillation apparatus

Although limits of composition for silicate rocks cannot be defined exactly, few such rocks contain less than 35% of silica or more than 25% of alumina. Within these limits of rock composition, the alkaline filtrate never contains more than 25 mg of either silica or alumina. In the filtrate from a few uncommon samples, the amounts of either silica or alumina may be higher. Numerous experiments showed that the over-all loss caused by the presence of interfering compounds and by the adsorption of fluoride varies from about 2% to 4% (relative). If a 3% (relative) correction is applied to every analysis, the distillation error seldom exceeds 1% (relative).

Most colorimetric methods for the determination of fluoride are based upon the fading of a coloured metal-organic compound caused by the formation of a fluoride complex with the metal. Lakes of thorium or zirconium in combination with a number of organic compounds have been used for years in water analysis. The lakes we have tested are much alike: they are unstable except at low concentrations, and their use requires a close adjustment of pH.

Bellack and Shouboe[5] have described a zirconium-SPADNS chelate for use in strong hydrochloric acid solution. Our experiments confirmed their statements. If 25 ml of their combined reagent is added to the distillate, amounts of fluoride from 0·00 to 0·05% can be measured. It is desirable to extend this range so that most silicate rocks (0·0–0·2%) can be analysed without diluting the distillate. Efforts to increase the concentration of the reagent failed; precipitates always formed.

By substitution of sulphuric for hydrochloric acid, a combined reagent was prepared that gave the desired range. A plot of log transmittance against concentration is, however, slightly curved. The reagent is stable for months, perhaps indefinitely.

The transmittance of the coloured complex varies sharply with changes in temperature. Before a measurement is made, therefore, the wavelength is adjusted so that standards at the two ends of the transmittance curve have specific readings. Because of day-to-day differences in room temperature, both the slit-width and the wavelength vary, but these variations do not affect the shape of the transmittance curve. During the course of a measurement, the photometer warms the standard solutions; therefore, separate portions of the standards are used for each measurement in a series.

Sulphuric acid contained in the distillate does not interfere in the colorimetry. If the upper part of the distillation flask is shielded from the flame as shown, no more than 3 mg of sulphuric acid distil; 10 mg can be tolerated. Phosphoric acid formed from phosphates present in a rock never distils in sufficient quantity to interfere.

Table I shows the reproducibility of results obtained when 8 rock samples were analysed in triplicate. The residues from one set of samples were dried, each residue was mixed with sodium carbonate and all of the mixtures were sintered. The fluoride

contents of the sinter cakes were determined as described in the procedure. Recoveries were small (Table I).

Zusammenfassung—Das gepulverte Gestein wird mit einer Sodaschmelze gesintert, die Zinkoxyd und Magnesiumcarbonat enthält, der Sinterkuchen mit Wassen ausgelaugt und die Lösung filtriert. Aus dem angesäuerten Filtrat wird Fluor durch Wasserdampfdestillation abgetrennt und spektralphotometrisch mit Zirkonium-SPADNS bestimmt. Mit einer Mehrfachdestillationsapparatur können 12 Bestimmungen pro Mann und Tag gemacht werden.

Résumé—La poudre de roche est frittée avec un fondant au carbonate de sodium contenant de l'oxyde de zinc et du carbonate de magnesium, la masse frittée est lixiviée à l'eau, et la solution résultante est filtrée. On sépare le fluor du filtrat acidifié par distillation à la vapeur, et dose spectrophotométriquement par un réactif zirconium-SPADNS. Si l'on utilise un appareil de distillation à unités multiples, on peut effectuer 12 dosages par journée de travail.

SPECTROPHOTOMETRIC DETERMINATION OF SMALL AMOUNTS OF TELLURIUM WITH *SYM*-DIPHENYLTHIOUREA

H. YOSHIDA and S. HIKIME
Department of Chemistry, Faculty of Science
Hokkaido University, Sapporo, Japan

(*Received* 22 *April* 1964. *Accepted* 24 *May* 1964)

Summary—A spectrophotometric method of determining small amounts of tellurium in acidic media with *sym*-diphenylthiourea has been studied. Tellurium is extracted almost quantitatively from 4·5–8·0*M* hydrochloric or perchloric acid solutions with a chloroform solution of diphenylthiourea, and up to 200 μg of tellurium can be determined by measuring the absorbance of the yellow complex in the chloroform phase at a wavelength between 380 and 410 mμ. The effects of diverse ions on the determination of tellurium have also been studied. It has been found that this method, with an extraction procedure, is more simple and more sensitive than the usual thiourea method in an aqueous medium.

TELLURIUM has been determined spectrophotometrically by several investigators.[1–7] The thiourea method, proposed by Nielsch,[2] is recommended as a simple and good method for the determination of tellurium in an aqueous solution. This reaction, however, takes place in an aqueous phase and the coloured tellurium complex cannot be extracted from the aqueous solution with chloroform, carbon tetrachloride, di-ethyl ether, *etc*. Moreover, the thiourea method has not such a high sensitivity. The present authors, therefore, have attempted to find a more sensitive procedure, and one suffering from fewer interferences, by means of extraction with an organic solvent.

About sixty derivatives of thiourea were tested as complex-forming reagents with metal ions by Yoe *et al.*,[8] and some of them have been applied for the determination of osmium and ruthenium,[9] but not for tellurium-IV.

Preliminary tests showed that tellurium formed yellow complexes with phenylthiourea, *sym*-diphenylthiourea, ditolylthiourea and ethylenethiourea; and the complexes with these derivatives, except that with ethylenethiourea, were extracted almost quantitatively into chloroform. The reaction of tellurium-IV with *sym*-diphenylthiourea was the most sensitive one under the experimental conditions, and also the extraction of the complex with chloroform from 4·5–8·0*M* hydrochloric acid solution could be carried out quantitatively. It was also found that when a hydrochloric acid solution of tellurium was shaken with a chloroform solution of diphenylthiourea, the complex formed was extracted simultaneously into the organic phase. Tellurium-IV can be extracted by chloroform-diphenylthiourea from perchloric acid solution. This method proposed is more simple, more sensitive, and suffers less interference than the thiourea method in an aqueous medium.

EXPERIMENTAL

Reagents

Tellurium: A stock solution (1 g of Te/litre of hydrochloric acid solution) was prepared as described in a preceding paper.[5] A solution containing 100 μg of Te per ml was obtained by dilution of the stock solution with water.

Sym-Diphenylthiourea: A commercial reagent was purified as follows: dissolve *ca.* 8 g of the reagent in 250 ml of ethyl alcohol at 70°, and filter the solution. Cool the filtrate for recrystallisation of the reagent, filter the crystals and dry the product in a desiccator. One g of diphenylthiourea was dissolved in 100 ml of chloroform.

All other reagents used in the investigation were of analytical-reagent grade.

Apparatus

Absorbance was measured with a Hitachi spectrophotometer EPU-2A, and pH was measured using a Horiba pH-meter M-3.

Procedure

(1) *Hydrochloric acid system:* Place less than 5 ml of an acidic solution, containing 10 to 200 μg of tellurium-IV, in a 20-ml graduated test-tube with a glass stopper, add 5 ml of 12*M* hydrochloric acid solution, and dilute to 10 ml with water. Mix well, and then cool it by holding in running water for 1 min. Add exactly 10 ml of diphenylthiourea-chloroform solution, shake vigorously for 1 min, transfer the mixture to a separating funnel, and separate the organic layer from the aqueous layer. Centrifuge the organic phase for 2 min. (Anhydrous sodium sulphate may be used for dehydration instead of centrifuging.) Measure the absorbance of the organic phase at 380, 390, 400, or 410 mμ in a 1-cm cell. Calculate the concentration of tellurium using a calibration curve, prepared previously.

(2) *Perchloric acid system:* Repeat Procedure (1), but using 6 ml of 9*M* perchloric acid solution (60% $HClO_4$) instead of 5 ml of 12*M* hydrochloric acid solution.

RESULTS AND DISCUSSION

Absorption curves of tellurium complexes with derivatives of thiourea

With diphenylthiourea, phenylthiourea, ditolylthiourea, ethylenethiourea and thiourea, tellurium in a solution of hydrochloric or perchloric acid in a concentration range of 4–9*M* formed yellow complexes. The tellurium complexes with diphenylthiourea, phenylthiourea and ditolylthiourea were extracted with chloroform, but not those with thiourea and ethylenethiourea. The absorbances of the tellurium complexes with the last two reagents were measured using the aqueous phase without an extraction procedure.

To a solution containing 200 μg of tellurium, 6 ml of 9*M* perchloric acid were added and the mixture was diluted to 10 ml with water. To this solution, 200 mg of one of the reagents was added. After mixing well, the tellurium complexes of diphenylthiourea, phenylthiourea and ditolylthiourea were extracted with chloroform. Absorbances of the complexes in the chloroform phase and the complexes with thiourea and ethylenethiourea in the aqueous phase were measured 1-ml cells over the range 380–500 mμ. The results obtained are shown in Fig. 1. Each complex has similar absorption, increasing in the shorter wavelength region. The absorbances of the tellurium complexes decrease in the following order under the experimental condition described: thiourea < ethylenethiourea < phenylthiourea < ditolylthiourea < diphenylthiourea.

The absorbance of the tellurium complex with diphenylthiourea in chloroform medium was about twenty times greater than that with thiourea in aqueous medium. Therefore, diphenylthiourea was used as the spectrophotometric reagent for tellurium in the further investigation.

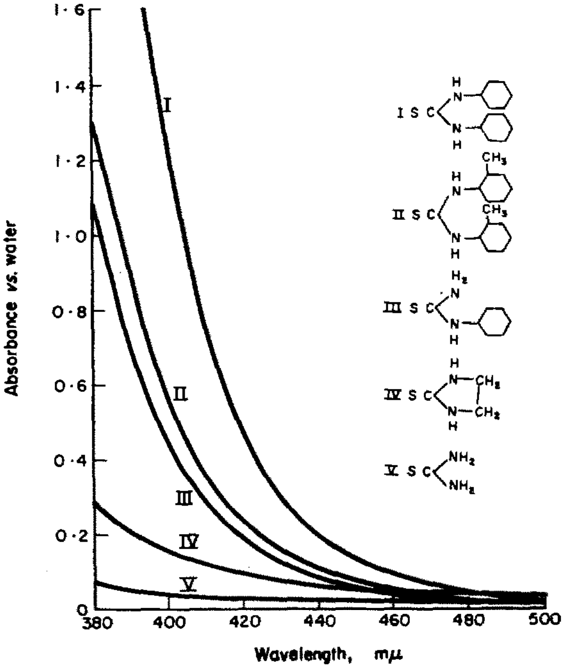

FIG. 1.—Absorption spectra of tellurium complexes with derivatives of thiourea:

I: Diphenylthiourea II: Ditolylthiourea
III: Phenylthiourea IV: Ethylenethiourea
V: Thiourea

Organic solvent

The solubility of diphenylthiourea in chloroform was several times greater than that in ethyl alcohol or in benzene; diphenylthiourea was almost insoluble in carbon tetrachloride. When an alcoholic solution of diphenylthiourea was added to a hydrochloric acid solution of tellurium, the yellow tellurium complex formed, and was extracted by chloroform. When a chloroform solution of diphenylthiourea was added to a solution of tellurium, the yellow complex formed was extracted simultaneously into the chloroform.

Effect of acid

As seen in Fig. 2, the absorbances of the tellurium complex, when extracted from 6*M* perchloric acid solution are about three times those from 6*M* hydrochloric acid solution. The effects of acid concentration on the absorbance are shown in Figs. 3 and 4. When the tellurium complex was extracted from 4·5–8·0*M* acidic solution the absorbances were always constant.

Effect of amount of reagent

Less than 0·06 g of the reagent per 10 ml of chloroform failed to produce full colour development of the complex for 100 μg of tellurium (mole ratio tellurium: diphenylthiourea *ca.* 1:330.) With more than 0·1 g of the reagent per 10 ml of chloroform the full colour development was ensured for 100 μg of tellurium. But because a solution of diphenylthiourea has absorption in the ultraviolet region (Fig. 2) a large but definite excess of the reagent should be used.

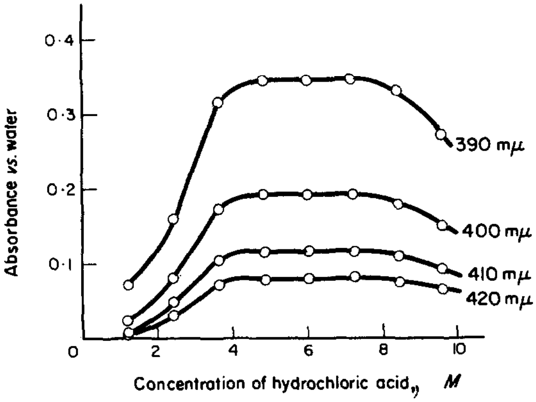

FIG. 3.—Effect of concentration of hydrochloric acid.

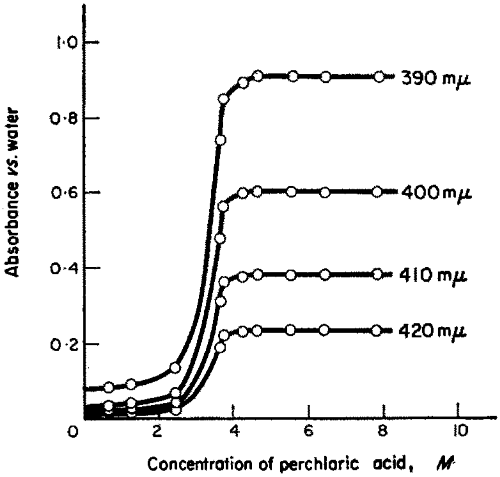

FIG. 4.—Effect of concentration of perchloric acid.

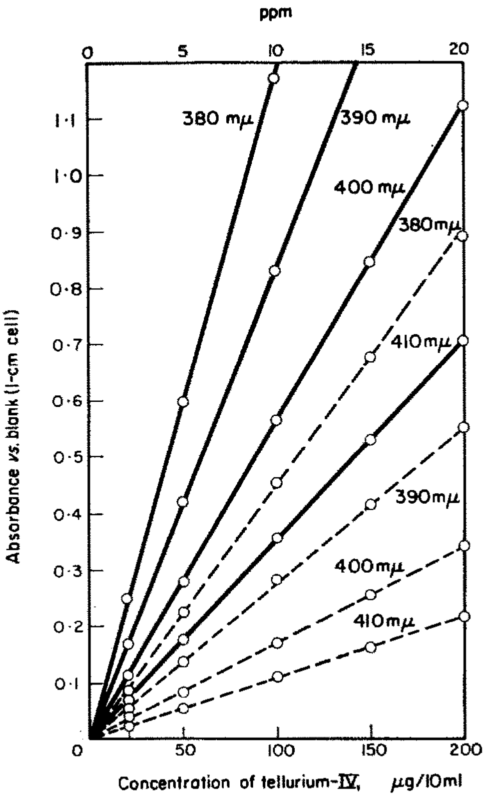

FIG. 5.—Working curves for tellurium-IV:

———— HCl system

– – – – – – $HClO_4$ system

Stability and sensitivity

The colour of the tellurium complex, developed as described, is stable for at least 90 min at room temperature, and even after 6 hr it decreases by only 3%.

Beer's law is obeyed up to 200 μg of Te/10 ml in an aqueous solution at 380, 390, 400, or 410 mμ, under the experimental conditions (Fig. 5).

The sensitivities of this reaction, by Sandell's expression,[10] are 0·022, 0·036, 0·059 and 0·09 μg of Te/cm^2 for the hydrochloric acid system; and 0·0084, 0·012, 0·018 and 0·028 μg of Te/cm^2 for the perchloric acid system.

Effect of diverse ions

The effects of a number of diverse ions on the determination of 100 μg of tellurium-IV, by Procedure (1) are summarised in Table I.

TABLE I.—EFFECT OF DIVERSE IONS
(Te 100 μg, HCl system)

Ion	Added		Te recovered, μg			
	mg	as	at 380	390	400	410 mμ
Bi^{III}	2	$BiCl_3$	101	104	107	—
Bi^{III}	1	$BiCl_3$	100	102	103	—
Cd^{II}	40	$CdCl_2$	100	100	100	101
Co^{II}	40	$CoCl_2$	102	102	102	102
Fe^{III}	0·4	$FeCl_3$	105	106	105	104
Mn^{II}	40	$MnCl_2$	100	100	101	100
Ni^{II}	40	$NiCl_2$	101	101	102	103

Large amounts of cadmium, cobalt, manganese, nickel and zinc do not interfere with the determination of tellurium. Against expectation, bismuth in an amount ten times as much as the tellurium was tolerated in the hydrochloric acid system, although in the perchloric acid system bismuth interfered with the determination. Iron-III interferes with the determination, so that it should be removed from the solution before the determination of tellurium. Because selenium-IV reacts with diphenylthiourea, no test was carried out on its interfering action.

Zusammenfassung—Die spektralphotometrische Bestimmung kleiner Tellurmengen mit Diphenylthioharnstoff in saurem Medium wurde untersucht. Tellur wird aus 4, 5–8, On salz- oder überchlorsauren Lösungen fast quantitativ mit einer Lösung von Diphenylthioharnstoff in Chloroform extrahiert. Bis 200 μg Tellur werden durch Messung der Extinktion des gelben Komplexes in der Chloroformphase zwischen 380 und 410 mμ bestimmt. Der Einfluß verschiedener Fremdionen auf die Tellurbestimmung wurde auch untersucht. Diese Extraktionsmethode ist einfacher und empfindlicher als die übliche Thioharnstoffmethode in wäßrigem Medium.

Résumé—On a étudié une méthode spectrophotométrique de dosage de petites quantités de tellurium en milieu acide, au moyen de diphénylthiourée. Le tellurium est extrait presque quantitativement, à partir de solutions 4,5 à 8,0 N en acide chlorhydrique ou acide perchlorique, au moyen d'une solution chloroformique de diphénylthiourée, et l'on peut doser jusqu'à 200 μg de tellurium en mesurant l'absorption du complexe jaune en phase chloroformique, à une longueur d'onde comprise entre 380 et 410 mμ. On a également étudié les effets de divers ions sur le dosage du tellurium. On a trouvé que cette méthode avec procédé d'extraction est plus simple et plus sensible que la méthode usuelle à la thiourée en milieu aqueux.

SPECTROPHOTOMETRIC DETERMINATION OF MANGANESE WITH THENOYLTRIFLUORACETONE

HIROSHI ONISHI and YUKIO TOITA
Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken, Japan

(*Received* 12 *May* 1964. *Accepted* 3 *June* 1964)

Summary—A new spectrophotometric method for the determination of microgram amounts of manganese with thenoyltrifluoracetone(TTA) is described. After oxidation with sodium bromate, manganese (presumably tervalent) is extracted with 0·5*M* TTA in xylene from a 0·5*M* sulphuric acid solution. The absorbance of the organic phase is measured at 440 or 450 mμ. Beer's law is followed up to 10 μg of manganese/ml of organic phase. Except for cerium, iron and chloride, small amounts of many common elements do not interfere. Iron(III) can be removed by cupferron-chloroform extraction, and cerium by washing the TTA extract with an ammonium hydrogen fluoride-nitric acid solution.

INTRODUCTION

DURING studies[1,2] on the spectrophotometric determination of cerium with thenoyltrifluoracetone (TTA), it has been found that manganese (presumably tervalent) gives a greenish-yellow colour with TTA. On the basis of this phenomenon, a new spectrophotometric method has been developed which is suitable for the determination of 10–100 μg of manganese. The proposed method is more sensitive and selective than that involving the extraction of manganese(II) with TTA at pH 6·7–8·0.[3] The elimination of interfering elements is also reported in this paper.

EXPERIMENTAL

Apparatus

Absorbance measurements were made with a Hitachi EPU-2A spectrophotometer, using 1-cm cells. A shaking machine with a time switch was used for the extractions.

Reagents

6% *w/v Cupferron solution:* Prepare fresh daily.

1*M Sodium bromate solution.*

0·5*M TTA solution:* Dissolve 45 g in 400 ml of xylene. A product of Dojindo & Co., Ltd., Kumamoto-shi, Japan, was used.

Ammonium hydrogen fluoride-nitric acid solution: 0·1*M* in ammonium hydrogen fluoride and 0·2*M* in nitric acid, stored in a polyethylene bottle.

Standard manganese solution: A standard stock solution, containing 1·00 mg of manganese/ml, was prepared by dissolving 0·100 g of pure manganese metal in 10 ml of 7*M* nitric acid and diluting to exactly 100 ml with water. Solutions of lower concentrations were prepared by diluting aliquots of the stock solution with water.

All other solutions were prepared from analytical reagent-grade compounds and metals.

Procedure: TTA-xylene extraction

Transfer the sample solution, containing 10–100 μg of manganese(II), to a small separating funnel. Add 15 mequiv of sulphuric acid and adjust the volume to 10 ml. Add 3 ml of 1*M* sodium bromate solution and allow to stand for 5–10 min. The sulphuric acid concentration should be about 0·5*M*. Add 10·0 ml of 0·5*M* TTA solution and shake the system for 10–15 min. Allow the funnel to stand for about 5 min for water droplets to separate from the organic phase. Drain off and discard the aqueous phase. Filter the organic phase through a small plug of glass wool into a 1-cm cell. Measure the absorbance of the solution at 440 or 450 mμ, using the reagent blank or xylene as the reference.

Construct a calibration curve by taking, for example, 0, 20, 40, 70 and 100 μg of manganese, adjusting the amount of sulphuric acid to 15 mequiv and the volume of the solution to 10 ml, then proceeding as described above for the TTA-xylene extraction.

Run a blank through the entire procedure.

Procedure in presence of cerium

Carry out the TTA-xylene extraction as described above. Drain off and discard the aqueous phase. To the organic phase in a separating funnel add 10 ml of ammonium hydrogen fluoride-nitric acid solution. Shake the system for 1 min. Allow the funnel to stand for about 5 min. Drain off and discard the aqueous phase. Filter the organic phase through a small plug of glass wool into a 1-cm cell. Measure the absorbance of the solution at 440 or 450 mμ against the reagent blank or xylene. The calibration curve should be prepared including the back-extraction.

Procedure in presence of iron(III): Cupferron extraction

Before the TTA-xylene extraction, transfer the sample solution, containing 10–100 μg of manganese(II), to a small (50–60 ml) separating funnel. Adjust the amount of sulphuric acid to 15 mequiv and dilute to 10 ml with water. Add 2·0 ml of cupferron solution and mix. Add 15 ml of chloroform and shake the system for 1 min. Drain off and discard the organic phase. Add 1·0 ml of cupferron solution and mix. Shake the solution with 10 ml of chloroform for 1 min. Discard the organic phase. Wash the aqueous phase by shaking it for 30 sec with 10 ml of chloroform and discard the organic phase.

Transfer the aqueous phase to a small quartz dish and evaporate to fumes of sulphuric acid. To decompose residual organic matter, add 1 ml of 30% hydrogen peroxide and heat gently. Evaporate the solution until white fumes appear. Use the residue for the TTA-xylene extraction.

RESULTS AND DISCUSSION

Absorption curve

The absorption curves are shown in Fig. 1. The manganese-TTA complex does not show a absorption maximum in the analytically-useful wavelength range. Because the absorption of the reagent blank is great below 430 mμ, a wavelength of 440 or 450 mμ has been adopted for the determination of manganese.

Effect of sulphuric acid concentration

The effect of sulphuric acid concentration on the absorbance of the extract is shown in Fig. 2. A suitable sulphuric acid concentration is 0·25–0·75*M*.

Effect of sodium bromate concentration

As indicated in Fig. 3, the absorbance of the extract remains almost constant between 0·2 and 0·4*M*. Potassium bromate was not used because of its small solubility.

Effect of TTA concentration

A suitable TTA concentration is 0·3–0·5*M* (Fig. 4). In the present work, the concentration of 0·5*M* has been adopted.

Time of extraction

It is necessary to shake the system for 10–20 min (Fig. 5).

Stability of extract

The absorbance of the manganese complex and reagent blank solutions remains constant for at least 3 hr (Fig. 6). The experiments were carried out at room temperatures within a range of 14–21°.

Calibration curve

The manganese-TTA system conforms to Beer's law with concentrations of up to 10 μg of manganese/ml of organic phase. Assuming that the extraction of manganese into the organic phase was complete, the apparent molar absorptivities were $3{\cdot}0 \times 10^3$ and $2{\cdot}5 \times 10^3$ at 440 and 450 mμ, respectively. In other words, for $\log I_0/I = 0{\cdot}001$, the sensitivities were 0·018 and 0·022 μg of manganese. cm^{-2} at 440 and 450 mμ, respectively. In this connection, it may be mentioned that the permanganate method has a sensitivity of 0·027 μg of manganese. cm^{-2} for $\log I_0/I = 0{\cdot}001$ at 522 mμ.[4]

Eight experiments with 50 μg of manganese gave an average absorbance of 0·297 and 0·245 at 440 and 450 mμ, respectively. The relative standard deviations were 1·7 and 1·3% at 440 and 450 mμ, respectively.

Nature of reaction

It has been reported that manganese(II) ion in a sulphuric acid solution is oxidised with bromate to the tripositive state.[5,6] Manganese(II) in 0·5*M* sulphuric acid does not give a coloured product with TTA. Presumably, the reaction product of TTA with manganese in the presence of bromate is manganese(III)-TTA complex. This point is being studied.

A single TTA extraction followed by a back-extraction with an equal volume (10 ml) of 7·5*M* nitric acid gave a recovery of 93% with 100 μg of manganese. The manganese was determined by the permanganate method using potassium metaperiodate as oxidising agent.[4]

Interference study

It was considered that the elements[1,2] that interfered with the photometric determination of cerium with TTA were likely to interfere with the determination of manganese. Table I summarises the results of the interference study. This study was

made by using 10 ml of aqueous solution that was 0·5*M* in sulphuric acid and 0·3*M* in sodium bromate and 10 ml of TTA in xylene.

Most of the metals used were in the forms of sulphate and nitrate. The oxidation state of metals in the table refers to that before addition of sodium bromate. Cerium, iron and chloride interfere seriously. The absorbance at 440 mμ of 50 μg of cerium is nearly the same as that of 60 μg of manganese. As a matter of fact, the optimum conditions for the determination of manganese are the same as those for cerium.[1] Chloride can be removed by fuming with sulphuric acid. If we take an error greater than ±2 μg of manganese as a limiting concentration of interference, 1 mg each of arsenic, molybdenum (at 440 mμ) and vanadium interfere. Five mg each of copper and titanium also interfere. Ammonium sulphate gives a slightly high result. In general, the present method is more selective and sensitive than the method[3] that is based on the extraction of manganese(II) with TTA at pH 6·7–8·0.

Cupferron-chloroform extraction

Iron(III), molybdenum, vanadium and some other metals are known to be extracted as cupferrates with chloroform from mineral acid solution. In the proposed procedure, the sulphuric acid concentration for the cupferron-chloroform extraction was chosen from a consideration of the sulphuric acid concentration suitable for the TTA-xylene extraction.

Results obtained in applying the proposed procedure are collected in Table II. Five determinations of 50 μg of manganese gave an average recovery of 100% and a relative standard deviation of 3·3% at 440 mμ. Iron(III), molybdenum, titanium and vanadium can be removed satisfactorily from 50 μg of manganese(II). Cerium(III) is not removed by the cupferron-chloroform extraction and remains quantitatively in the aqueous phase.[2]

Determination of manganese in presence of cerium

Cerium(III) is not separated from manganese by the cupferron-chloroform extraction. As reported previously,[2] when the TTA solution containing both cerium-(IV) and manganese is shaken with an aqueous solution that is $0{\cdot}1M$ in ammonium hydrogen fluoride and $0{\cdot}2M$ in nitric acid, cerium is selectively back-extracted.

Results obtained in applying the proposed procedure are shown in Table III. In the presence of 50–100 μg of cerium, 50 μg of manganese can be determined within an error of +10%.

Zusammenfassung—Eine neue spektralphotometrische Methode zur Bestimmung von Mikrogrammengen Mangan mit Thenoyltrifluoraceton (TTA) wird beschrieben. Nach Oxydation mit Natriumbromat wird (wahrscheinlich dreiwertiges) Mangan mit 0,5 m TTA in Xylol aus 1 n Schwefelsäure extrahiert. Die organische Phase wird bei 440 oder 450 mμ photometriert. Das Beersche Gesetz gilt bis 10 μg Mangan pro ml organischer Phase. Außer Cer, Eisen und Chlorid stören kleine Mengen vieler häufiger Elemente nicht. Eisen(III) kann durch Extraktion mit Cupferron in Chloroform und Cer durch Waschen des TTA-Extrakts mit Ammoniumhydrogenfluorid-Salpetersäurelösung entfernt werden.

Résumé—On décrit une nouvelle méthode spectrophotométrique de dosage du manganèse à l'échelle du microgramme, au moyen de thénoyltrifluoroacétone (TTA). Après oxydation au bromate de sodium, le manganèse (probablement trivalent) est extrait au moyen de TTA 0,5 M en xylène, à partir d'une solution 1 N en acide sulfurique. On mesure l'absorption de la phase organique à 440 ou 450 mμ. La loi de Beer est observée jusqu'à 10 μg de manganèse par ml de phase organique. A l'exception du cérium, du fer et des chlorures, de petites quantités de nombreux éléments communs n'interfèrent pas. Le fer (III) peut être éliminé par extraction au cupferron-chloroforme. Le cérium peut être éliminé par lavage de l'extrait TTA au moyen d'une solution fluorure acide d'ammonium-acide nitrique.

SEPARATION AND POLAROGRAPHIC DETERMINATION OF CADMIUM IN STAINLESS STEEL

H. S. KARP and G. KRAPF
Applied Research Laboratory, United States Steel Corporation, Monroeville
Pennsylvania, U.S.A.

(*Received* 14 *May* 1964. *Accepted* 27 *June* 1964)

Summary—A method has been developed for the determination of small amounts of cadmium in stainless steel. Cadmium and copper are initially separated from other elements with thioacetamide. After extraction of the copper with Neocuproïne in chloroform, cadmium is determined polarographically in an ammonium chloride–aqueous ammonia electrolyte. Over the range 0.001–0.01% of cadmium, results are accurate to within 10% of the amount present. As little as 0.0005% of cadmium may be determined, and the upper limit may be extended beyond 0.01% by using smaller samples or by aliquoting. This method may be applied to all commercial grades of stainless steel.

INTRODUCTION

CADMIUM-PLATED steel scrap and white metal may be inadvertently included in the charge of an electric furnace for the melting of stainless steel, so that cadmium may be present in the stainless steel in concentrations up to about 0·01%. Because small amounts of cadmium are detrimental to the hot-working properties of stainless steel, it is desirable to analyse for this element. Although cadmium had been previously determined in non-ferrous materials, such as zinc and aluminium, in this laboratory, no method was available for determining cadmium in steel. Therefore, the present investigation was initiated to provide standards for optical emission spectrographic analyses.

Hildebrand, Lundell, Bright and Hoffman[1] indicate that cadmium cannot be separated ordinarily except as the sulphide. In previous work in this laboratory, as little as 5 μg of cadmium were separated as the sulphide from several elements in non-ferrous materials.

The classical method of sulphide precipitation makes use of hydrogen sulphide, a noxious and toxic gas, as the precipitant. Within the last 30 years thioacetamide, a considerably less toxic chemical, has been substituted for hydrogen sulphide. According to Ivanov[2] and Flaschka and Jakobljevich,[3] thioacetamide can be used successfully for the precipitation of heavy metals. Although thioacetamide has been employed for the quantitative separation of cadmium from aluminium, molybdenum-nickel alloys and tungsten-nickel alloys,[4,5] no evidence was found in the literature that it had ever been used to separate cadmium from a steel matrix. This laboratory, therefore, investigated the use of thioacetamide to precipitate cadmium.

The determination of small concentrations of cadmium, after separation from the stainless-steel matrix, requires a sensitive technique, such as absorption spectrophotometry or polarography. The photometric determination of cadmium, as described by Sandell,[6] makes use of dithizone or di-β-naphthylthiocarbazone. Unfortunately, these photometric methods are laborious, require the use of highly toxic cyanide compounds, and are sometimes subject to error because of nickel interference.

Lingane[7] has investigated the polarographic characteristics of cadmium in various supporting electrolytes and has found that the greatest sensitivity for cadmium was obtained in an ammonium chloride–aqueous ammonia electrolyte. This electrolyte is also advantageous in that copper and nickel are the only elements common to stainless steel which exhibit half-wave potentials over the range of 0 to −1·0 V *versus* a saturated calomel electrode.

EXPERIMENTAL

Apparatus

Model XXI Sargent polarograph

Reagents

Reagent-grade chemicals are used throughout.

Citric acid: 25%w/v in water.

Formic acid mixture: Dissolve 250 g of ammonium sulphate in 300 ml of water. Add 200 ml of 90% formic acid and 30 ml of 15 M aqueous ammonia, then dilute to 1 l. with water. Store in a ground-glass stoppered bottle.

10%w/v *Thioacetamide reagent:* Prepare this solution in warm water as needed.

2% *Thioacetamide wash water:* To 500 ml of water add 4 ml of 90% formic acid and 10 ml of 10% thioacetamide reagent.

10% *Hydroxylamine hydrochloride solution*: Prepare this solution as needed.

2,9-*Dimethyl*-1,10-*phenanthroline* (*Neocuproïne*) *reagent:* This solution (0.1%w/v in 95% ethyl alcohol) should be refrigerated when not in use.

Hydrochloric acid polarographic solvent: Add 14 ml of 12M hydrochloric acid to 30 ml of water.

Ammonium chloride (1M)-*aqueous ammonia* (1M) *electrolyte:* Dissolve 53·5 g of ammonium chloride in 300 ml of water. Add 67 ml of 15M ammonia solutions and dilute to 1 l. Store in a ground-glass-stoppered bottle at 20°.

Standard cadmium solution: Dissolve exactly 0·1000 g of 99·9% cadmium in 10 ml of 1:1 nitric acid. Evaporate this solution to dryness. Add 5 ml of 12M hydrochloric acid and again evaporate to dryness. After cooling, digest the residue for 5 min in 200 ml of water containing 53·5 g of ammonium chloride. Cool again, add 67 ml of 15M ammonia solution, transfer to a 1-l. volumetric flask and dilute the mark with distilled water ($|1\text{ml}| \equiv 100$ μg of cadmium). Less concentrated standard cadmium solutions are made by dilution of appropriate aliquots of this stock solution with 1M ammonium chloride—1M aqueous ammonia electrolyte. Store in a ground-glass-stoppered bottle at about 20°.

Procedure

Transfer 1·0 g of sample to a 600-ml beaker, add 20 ml of 1:1 hydrochloric-nitric acid mixture and dissolve the sample at low heat. Add 20 ml of 12M perchloric acid, heat until dense fumes of perchloric acid are evolved, then carefully add 10 ml of 12M hydrochloric acid and heat to volatilise the chromium. Continue to heat the sample to fumes of perchloric acid, and make second and third additions of hydrochloric acid. Again heat the solution to dense fumes of perchloric acid and continue heating until less than 5 ml of perchloric acid remain in the beaker. Cool, then add 50 ml of water to dissolve the perchlorate salts. (If iron hydrolyses from solution, add 3 ml of 12M hydrochloric acid and heat until it redissolves, then add 2 ml of 12M perchloric acid and again take to fumes of perchloric acid.) Add 25 ml of 6% sulphurous acid. Heat to boiling and boil for 2 min. While boiling, add 0·5 g of hydrazine sulphate. After the latter has dissolved, remove the beaker from the hot plate and cool to room temperature. Adjust the pH to 2·0 ± 0·2 (pH meter) by carefully adding aqueous ammonia dropwise. Next, add 20 ml of 25% citric acid solution and adjust the pH to 6·0 ± 0·5 with aqueous ammonia. Add 25 ml of formic acid mixture. (A precipitate may form at this point in the procedure. It will redissolve on heating.) Dilute the sample to 300 ml and digest at low heat. Heat to boiling and add 20 ml of 10% thioacetamide reagent. Again heat to boiling, and repeat the addition of this reagent until 60 ml has been added. Digest at 90° for 1 hr. While still hot, filter the thioacetamide precipitate through a 12·5-cm Whatman No. 42 filter paper containing pulp. Wash the beaker and paper 10 times with thioacetamide wash water. Transfer the paper and precipitate to the beaker in which the precipitation was made, and add 15 ml of water, 30 ml of 16M nitric acid and 8 ml of 12M perchloric acid. Decompose the paper and precipitate by heating until dense fumes of perchloric acid are evolved. Remove the beaker from the hot plate, cool and add 100 ml of water. Add 10 ml of 10%

hydroxylamine hydrochloride solution and adjust the pH with aqueous ammonia until Congo Red paper changes from blue to red. Transfer to a 250-ml separatory funnel, and add 15 ml of Neocuproïne reagent. Shake, add 25 ml of chloroform and shake again for 30 sec. After separation of the phases, discard the organic phase. Repeat with a further 25 ml of chloroform. Make a second and third extraction with Neocuproïne and chloroform. Use one 10-ml portion of Neocuproïne and two 15-ml portions of chloroform in each of these extractions. After the final extraction, transfer the aqueous phase to the original 600-ml beaker. Add 5 ml of 12*M* hydrochloric acid and evaporate the solution to 50 ml to ensure the volatilisation of ethanol. (This precaution is necessary to prevent a violent reaction between nitric acid and hot ethanol.) Remove the beaker from the hot-plate, carefully add 30 ml of 16*M* nitric acid and heat until dense fumes of perchloric acid are evolved. Cool, add 10 ml of water and digest the solution at low heat for 5 min. Transfer the contents of the 600-ml beaker to a 150-ml beaker, rinsing the 600-ml beaker with a minimum of water. Carefully evaporate the contents of the 150-ml beaker to complete dryness at high heat. Cool, add 2 ml of hydrochloric acid polarographic solvent and digest at low heat until the residue in the beaker completely dissolves. Cool and adjust the solution to a pH of 9·6 ± 0·2 (pH meter and micro electrodes) with 1:1 aqueous ammonia (approximately 4 ml 1:1 is necessary). Carefully transfer the contents of the 150-ml beaker to a 10-ml volumetric flask. Rinse the beaker with a minimum of electrolyte. Dilute to the mark with electrolyte.

Pipette a 3-ml aliquot of the solution into a dry polarographic cell, record the polarogram for cadmium *versus* a mercury-pool electrode according to the method suggested by Meites,[8] and calculate the percentage of cadmium.

DISCUSSION

Separation of cadmium

Four elements present in stainless steel can interfere in obtaining accurate polarograms of cadmium: chromium, iron, copper and nickel. Because both chromium and iron form insoluble hydroxides in the ammonium chloride–ammonia electrolyte, they must be separated from the cadmium. The chromium was removed by volatilisation as chromyl chloride from fuming perchloric acid after dissolution of the sample, and the iron contamination of the sulphide precipitates was prevented by careful control of pH and repeated washing of the precipitates. Copper and nickel are soluble in the electrolyte and reducible at the dropping mercury electrode. It was found that a very small amount of nickel was carried along with the copper and cadmium sulphide precipitates. However, the half-wave potential of nickel, which occurred at −0·95 V, could be easily differentiated from the cadmium wave at −0·67 V. Copper exhibited a double wave with half-wave potentials of −0·25 V and −0·51 V. When present in the concentrations found in the stainless-steel matrices, it produced large polarographic waves which made the accurate determination of cadmium virtually impossible. Extreme compensation was required to obtain the cadmium wave on scale and a large residual current was produced. The copper interference was overcome by complexing the copper with Neocuproïne and extracting the complex with chloroform.

Bowersox and Swift[9] have established the conditions of pH and temperature necessary to precipitate cadmium quantitatively with thioacetamide from a solution containing no other element. In addition to these conditions, it was found necessary to reduce the iron(III) in the sample to iron(II) and also to reduce the small amount of chromium(VI), remaining after volatilisation to chromium(III), before the thioacetamide separation. Table I shows the effect of chemical reduction on the recovery of cadmium in 2 samples of stainless steel. The lack of precipitation of cadmium as a sulphide in those samples not reduced is probably caused by the consumption of thioacetamide in reducing iron(III) and chromium(VI). As can be seen in this table, the cadmium lost in the thioacetamide precipitation was recovered with hydrogen sulphide from the filtrates of the thioacetamide separation.

TABLE I.—EFFECT OF REDUCTION ON RECOVERY OF CADMIUM[a]

	Recovered, %	
	Thioacetamide separation	Subsequent H_2S separation
No reduction	0·0000 0·0000	0·0092 0·0098
With reduction	0·0098	0·0000

[a] Cadmium added to a solution of NBS 101e stainless steel to give 0·010%.

As indicated by Lundell and Hoffman,[10] copper precipitates together with cadmium during the hydrogen sulphide separation of these elements. Copper also accompanied cadmium during the thioacetamide separation of cadmium from stainless steel. Because copper interferes in the polarographic determination of cadmium, it became necessary to separate the copper from the cadmium after the sulphide precipitation.

Cadmium sulphide, after precipitation with hydrogen sulphide, is reportedly soluble in hot 1:2 hydrochloric acid.[11] After verification of this information, the solubility of copper sulphide (from a hydrogen sulphide precipitation) in the same solution was investigated. It was found that copper sulphide is only slightly soluble in hot 1:2 hydrochloric acid. This suggested a means of separating the cadmium from the bulk of the copper. However, as can be seen in Table II, when the cadmium sulphide recovered after the thioacetamide precipitation was treated with 1:2 hydrochloric acid, much of the cadmium remained in the residue. The cadmium sulphide precipitate from the thioacetamide separation was coarse and crystalline, and probably did not dissolve as rapidly as the cadmium sulphide precipitated with hydrogen sulphide. Thus, copper and cadmium sulphides precipitated with thioacetamide could not be easily separated by the preferential dissolution of cadmium sulphide with hydrochloric acid.

TABLE II.—RECOVERY OF CADMIUM BY ACID TREATMENT

	Recovered[a], %

Thioacetamide	0·0042 0·0041	0·0051 Not determined

[a] Cadmium added to NBS 101e stainless steel to give 0·010%.

There are very few methods for quantitatively separating large amounts of copper from trace amounts of cadmium. Those available involve either precipitation or electrodeposition of the copper; they are lengthy, involved and laborious. They suffer from inaccuracy because of coprecipitation or codeposition of a portion of the cadmium. It was, therefore, decided to investigate a different approach to the problem.

Smith and McCurdy[12] have proposed Neocuproïne (2,9-dimethyl-1,10-phenanthroline) as a specific reagent for copper. Luke and Campbell[13] studied the reaction of 56 metals (including cadmium) with Neocuproïne and found that only copper would form a coloured compound which was extractable into chloroform. We investigated the possibility that cadmium might form a colourless compound which was extractable. Several solutions were prepared containing either copper or cadmium in amounts similar to those expected in the stainless steels. The copper was then extracted into chloroform as its Neocuproïne complex. The aqueous layer was evaporated to dryness, the residue was dissolved in the ammonium chloride—ammonia electrolyte and polarograms of suitable aliquots were recorded. The results of these polarograms are presented in Table III. It was found that copper was completely separated from the cadmium by the Neocuproïne-chloroform extraction method, because no diffusion current for copper could be detected. The recovery of cadmium from the aqueous layer of the extractions was within ±0·0002% of the amount present.

[a] 0·0050% of cadmium added.

in Table IV show that recovery was within ±10% of the amount present, except at the 0·0005% level where recovery was within ±13% of the amount present.

Table V shows that in spite of the presence of niobium, tantalum, molybdenum and titanium, the recovery of added amounts of cadmium from National Bureau of Standards steel samples was within 10% of the amount added.

Zusammenfassung—Eine Methode für die Bestimmung von kleinen Mengen Cadmium in tostfreiem Stahl wurde entwickelt. Dabei wurden Cadmium und Kupfer zuerst mit Thioacetamid von den anderen Elementen getrennt. Nach Extraktion von Kupfer mit Neocuproin in Chloroform wurde Cadmium polarographisch in einem Ammoniumchlorid-Ammoniak-Elektrolyten bestimmt. Zwischen 0,001 und 0,01% entsprachen die Cadmiumwerte auf etwa 10% genau den anwesenden Mengen. Bis herunter zu 0,0005% Cadmium wurden bestimmt, die obere Grenze wurde durch kleinere Proben oder Teilung der Proben über 0,01% hinaus ausgedehnt. Die Methode kann auf alle handelsüblichen rostfreien Stähle angewandt werden.

Résumé—On a élaboré une méthode pour le dosage de petites quantités de cadmium dans l'acier inoxydable. Dans cette technique, on sépare d'abord le cadmium et le cuivre des autres éléments par le thioacétamide. Après extraction du cuivre à la néocuproïne en chloroforme, on dose le cadmium par polarographie, dans un électrolyte chlorure d'ammonium ammoniaque. Entre 0,001 et 0,01 p. cent, les résultats en cadmium sont précis à 10% près. On a pu doser une quantité de cadmium n, excédant pas 0,0005%, et la limite supérieure a été étendue au-delà de 0,01% en utilisant un plus petit échantillon, ou en prélevant une partie aliquote. Cette méthode peut être appliquée à toutes les qualités commerciales d'acier inoxydable.

PRELIMINARY COMMUNICATION

Purification of metal chelates by a zone-refining technique*

(*Received* 1 *June* 1964. *Accepted* 13 *June* 1964)

ZONE-refining techniques have recently been adopted as a promising method of purifying various organic compounds.[1] This communication reports on the application of this technique to the purification of metal chelate compounds.

It is well known that certain types of metal chelate compound have definite melting points without decomposition. Most of such chelate compounds belong to the inner complex type, in which the positive charge of the metal ion is neutralised by the negative charge of the ligands, and the co-ordination number of the metal ion is completed by the ligand molecules. Typical examples of this class are the metal chelates of β-diketones or α-dioximes. We have examined the zone-refining technique for the purification of various inner complex chelates in the hope that the central metal ion could be purified by this process.

For example, tris(acetylacetonato)chromium-III (m.p. 214°) was subjected to zone refining. The crude material, which was synthesised from reagent-grade chemicals, was melted in a borosilicate glass tube (8 mm in diameter, 150 mm in length) which was sealed under nitrogen. The tube was processed for zone refining, with a heater temperature of approximately 220°, and with a downward rate of 3 cm/hr. After repeating the process, the samples from the top, middle and bottom portions of the column were subjected to emission spectrographic analysis. The results are shown in Table I.

TABLE I.—ZONE REFINING OF TRIS(ACETYLACETONATO)CHROMIUM-III

Exp. no.	No. of passes	Portion of column sampled	Elements detected*						
			Al	B	Ca	Fe	Mg	Na	Si
1	17	Top	x			x	x	x	
		Middle				x	x		x
		Bottom	x			x	x		x
2	26	Top				x			x
		Middle				x	x	x	x
		Bottom	x	x	x	x	x	x	x
3	36	Top							
		Middle				x			
		Bottom	x		x	x	x		x

* Emission spectrographic analysis were carried out using a Shimadzu QL-170 Littrow type spectrograph.

It is seen from the table that, as the number of passes increases, the purity of the top portion of the column improves progressively. It is also apparent that the impurities are concentrated in the lower part of the column. With 36 passes, no element other than chromium could be detected in the top portion of the column. From these results, it is evident that the central metal ion of the chelate compounds is purified by zone refining, and the results suggest that this technique could be a useful method of obtaining ultra-pure metals which cannot or which would be very difficult to obtain by the direct zone melting of the metals, because of their high melting points or of their ease

of oxidation during the process. It would also be of interest to investigate the physico-chemical properties of the ultra-pure metal chelates. Detailed investigations are in progress, and will be published elsewhere.

Summary—Metal chelate compounds may be purified by a zone-refining technique. As an example, zone refining of tris(acetylacetonato)chromium-III is described. It has been proved that the central metal ion can be purified by this technique.

Zusammenfassung—Metallchelate lassen sich durch Zonenschmelzen reinigen. Als Beispiel wird die Reinigung von Tris(acetylacetonato)-chrom(III) beschrieben und gezeigt, daß das Zentralion auf diese Weise gereinigt werden kann.

Résumé—On purifie les chélates métalliques par la technique de raffinage par fusion de zone. A titre d'exemple, on décrit le raffinage par fusion de zone du tris (acétylacétonato)Cr^{III}, et on montre que l'ion métallique central peut être purifié par cette technique.

SHORT COMMUNICATIONS

Separation of certain cations from mixtures of various cations on ion-exchange papers—IV*: arsenic, cobalt, magnesium, manganese, mercury, nickel or vanadium

(*Received* 27 *January* 1964. *Accepted* 11 *March* 1964)

EARLIER parts of this series have reported the separation of silver or thallium;[1] antimony or arsenic;[2] and arsenic, barium, cadmium, tin, or zinc[3] from essentially all other ions by paper chromatography with complex-forming solvents on filter paper impregnated with either strongly-acidic cation-exchange resin or strongly-basic anion-exchange resin. Systems have now been found for other analytically useful separations.

EXPERIMENTAL

Standard procedures for the downward development of paper chromatograms in a commercially-available chamber were employed to test aqueous solutions of various selective reagents as developers. Details have been given in the papers cited above. Exploratory tests were performed by developing the following 26 representative ions individually with each reagent: Ag, Tl, Pb, Cu, Cd, Co, Ni, Hg^{I}, Hg^{II}, As^{III}, Fe^{III}, Sb^{III}, V^{V}, Bi, Sn^{IV}, Au^{III}, Pt^{IV}, Al, Ce^{III}, Ce^{IV}, Mg, Zn, Ba, Mn^{II}, Cr^{III} and U^{VI}. The method of preparation of each test solution at 0·050*M* was reported earlier.[4] The promising reagents were then tested with the following compatible mixture, to which were added the ions to be separated if necessary: Ag, Al, Ba, Cd, Ce^{IV}, Cr, Co, Cu, Fe, Pb, Mg, Mn, Ni, Tl and Zn. Four spray reagents, previously described,[1,2,5] served to detect all the ions listed above. These included 8-quinolinol followed by ammonia for Mn, Cr, Al, Ce, Mg, and Zn; potassium rhodizonate for Ba; potassium ferrocyanide for U; and ammonium sulphide followed by hydrochloric acid for the rest.

Some of the reagents tested were also used as background electrolytes in earlier electrochromatographic studies of these ions.[5,6] We consequently knew the sign of the charge of each ion, in each of these particular solutions, from the mode of migration of each ion. As shown earlier,[4] this did not help us to predict accurately which, if any, ion would be separated in the present paper-chromatographic studies.

RESULTS AND DISCUSSION

The separations obtained in various systems are summarised in Table I. The results given below are based upon at least four migrations of each ion in each system, with stated R_F values (measured to the front of solute zones) having a standard deviation of ±0·04 or less. The solvents were allowed to travel 30–35 cm past the origin in each case, which required about 2 hr with the cation-exchange paper and about 90 min with the anion-exchange paper, depending upon the form of the paper and the solvent used.

Arsenic was separated from all 25 other ions, and vanadium was separated from all except mercury^{I}, mercury^{II}, and antimony^{III} ions, by development with a solution of 0·010*M* sulphuric acid containing 1·0% of hydrogen peroxide, pH 2·5, on cation-exchange paper in the hydrogen form (Reeve Angel Grade SA-2, control A-7802-1,2). Arsenic migrated in a compact zone with the solvent front (R_F, 1·0), but vanadium (R_F, 0·36) formed a zone 5·4 cm in length, the tail of which was 6·2 cm from the origin. Arsenic and vanadium were separated by about 20 cm from each other. Except for antimony and the two forms of mercury, which formed diffuse zones extending from the origin and contaminated the vanadium, all other ions remained at or within 2·0 cm of the origin. Electrochromatographic studies[6] showed that vanadium, uranium and platinum were complexed by this solution to give anions. However, the latter two anionic zones had enough affinity to retain them at the origin of the cation-exchange paper. The fact that anions do not necessarily leave the origin on cation-exchange paper has been noted before.[2] Fritz and Abbink[7] found similarly that although titanium^{IV}

also formed a negative complex in this solvent, it resisted elution and remained in a tight band at the top of a column of hydrogen-form cation-exchange resin. However, columns of resin and papers impregnated with the same resin do not always yield identical chromatographic results when the same substances are developed with the same solvent. This has been demonstrated before[4] and again in this system, because Fritz and Abbink[7] were able to separate mercury-II from vanadium on a column of resin by elution with this solvent.

Arsenic was separated from all 25 other ions except vanadium and platinum, and vanadium was separated from all 25 other ions except arsenic, platinum and aluminium by development with a solution of 0·0125*M* ammonia-triacetic acid (nitrilotriacetic acid) and 2·1*M* ammonia, pH 10·9, on SA-2 paper in the sodium form. Vanadium (R_F, 0·84) migrated in a narrow zone 4·0 cm in length, and arsenic (R_F, 0·86) gave a circular zone 2·0 cm in diameter. Platinum streaked from the origin to contaminate both arsenic and vanadium, and aluminium formed a similar, less diffuse zone which contaminated vanadium but which was separated by 1·0 cm from arsenic. None of the other ions were closer than 4·0 cm (cobalt) to either arsenic or vanadium. Antimony and the two forms of mercury, which were not separated from vanadium in the previous system, remained within 3·0 cm of the origin in this system; platinum and aluminium, which were not separated from vanadium in this system, were within 2·0 cm of the origin in the previous one. Therefore, vanadium can be separated from all other ions in one or other system. Electrochromatography proved that all ions except silver (which formed the ammonia complex) were negatively charged; again, many of them did not migrate at all on cation-exchange paper.

Magnesium was separated from all 25 other ions except arsenic, barium, cobalt, manganese and nickel by development with a solution of 0·10*M* ammonium thiosulphate and 0·10*M* ammonia, pH 9·5, on anion-exchange paper in the thiosulphate form (Reeve Angel Grade SB-2, control A-10297). Magnesium (R_F, 0·99) migrated in a fairly diffuse zone (11·0 cm in length), which was clearly separated from all ions except the five mentioned above. All of these except nickel streaked from the origin for almost the entire length of the paper. Except for these, zinc was the closest zone to magnesium, and it was separated by at least 12 cm.

Nickel was separated from all 25 other ions except cobalt and zinc by development with a solution of 0·10*M* ammonium thiosulphate, 0·0050*M* sodium hydroxide and 6·0*M* ammonia, pH 11·0, on SB-2 paper in the thiosulphate form. Cationic nickel was detected spread out along the solvent front (R_F, 1·0); cobalt streaked from the origin to within 1·0 cm of the solvent front, and zinc migrated (R_F, 1·0) in a zone 4·1 cm in length. Of the other ions, aluminium was the closest, being separated by 2·5 cm from nickel. Nickel was separated from zinc in the thiosulphate system mentioned zinc immediately above; in it, nickel migrated (R_F, 0·98) in a zone 9·5 cm in length, and was always within 7·0 cm of the origin. Cobalt and nickel were not separated in that system either, but were separated in the cyanide system described below. In a previous paper[8] the separation of zinc from all ions except vanadium was reported. In the present system, vanadium (R_F, 0·68) was separated from zinc by at least 5·0 cm.

The mercury zones were separated from all 24 other ions except aluminium, vanadium and silver by development with the same solvent as described immediately above on SA-2 paper in the ammonium form. The three interfering ions all streaked from the origin to contaminate the two forms of mercury, both of which migrated in an oblong zone 1·3 cm in length and 0·80 cm wide (R_F, 1·0). Of the others only platinum and arsenic were close to mercury, being separated by 4·0 and 1·0 cm, respectively.

Manganese was separated from 22 other ions by development with a solution of 0·11*M* hydrocyanic acid and 0·10*M* tetraethylammonium hydroxide, pH 9·7, on SB-2 paper in the chloride form. Manganese migrated with the solvent front (R_F, 1·0) in an oblong zone 2·4 cm in length and 1·3 cm wide which was contaminated only by cerium^{III}, which formed a diffuse zone extending from the origin almost the entire length of the paper. The closest of the rest of the zones were those of arsenic and thallium, both of which were separated from manganese by at least 2·5 cm. Because cyanide complexed many of the ions very strongly, it was necessary to spray the papers with hydrochloric acid and to allow them to stand for several hours before the usual detection tests (above) were successful. Magnesium and barium, which are not complexed strongly by cyanide, inexplicably could not be located in this system by the usual tests or by any reagent which we could find referred to in the literature. Their position relative to manganese is therefore indeterminate. Electrochromatography showed that manganese was among the many anions in this solvent; thallium was cationic, and arsenic was uncharged.

Arsenic and cobalt were separated from all 24 other ions except mercury^{I}, mercury^{II} and aluminium, but not from each other, by development with the same cyanide-hydroxide solvent on SA-2 paper in the sodium form. Anionic cobalt migrated in a compact zone 1·5 cm in length (R_F, 0·86), and uncharged arsenic migrated (R_F, 0·90) in a zone 2·4 cm in length. The mercury and aluminium zones (all anionic) streaked from the origin almost the entire length of the paper. The closest of the other zones, vanadium, was separated from arsenic and cobalt by 4·0 cm. It was possible to locate all ions in this system by using the preliminary acid spray described above.

An investigation of fast neutron activation analysis for determination of oxygen in metals*

(*Received* 21 *February* 1964. *Accepted* 5 *April* 1964)

UNTIL a few years ago the only method which could be used for the determination of oxygen in almost all metals and alloys, was vacuum fusion. In the vacuum-fusion analysis of certain materials problems have been encountered in complete extraction of the oxygen from the sample and in gettering of the released gas by the metal vapour in the furnace. Because of the difficulties involved in preparing absolute standard samples of oxygen in metals, none are available for procedure development work. In view of the above-mentioned potential problems in applying vacuum fusion to all metals and alloys, nuclear methods of analysis[1] were considered.

EXPERIMENTAL

Apparatus

A Texas Nuclear Corporation model 150 neutron generator was used for irradiation. The generator produces 14-MeV neutrons by the ^{3}H (d, n) ^{4}He reaction. The neutron flux was of the order of 1×10^8 neutrons.cm^{-2}.sec^{-1}.

The counting of the activated sample was carried out with a Radiation Instrument Development Laboratory 200 channel pulse-height analyser in conjunction with two 3″ × 3″ NaI(Tl) scintillation crystals.

The sample transfer system used for rapidly transporting the samples from the generator to the counting position was operated by compressed nitrogen. A ⅝ × 2¼″ rabbit was generally used. The total transfer time for the 40-ft system was about 3 sec.

Samples

In order to compare effectively the results obtained by vacuum fusion analysis and fast-neutron activation, it is necessary to use samples of known analytical history. The samples used in this study were selected because of the consistency of the results, which had been obtained by vacuum fusion in several different laboratories.

Sample preparation and encapsulation

All samples for vacuum fusion and activation analysis were prepared by abrading with a clean file, then degreasing with benzene followed by an acetone rinse. Those which were intended for activation analysis were sealed in either polyethylene or aluminium capsules which were purged with dry methane before sealing. The polyethylene vials were sealed thermally and the aluminium vials were sealed by the Magneform process. The removal of both air and moisture from the vials before sealing is necessary.

The standard sample was prepared from primary standard grade arsenic trioxide mixed with graphite and contained in a polyethylene capsule. The mixture contained 100 mg of oxygen and was prepared so that it completely filled the polyvial.

Procedure

The samples and standard were loaded into the pneumatic transfer device and transferred to the irradiation position at the neutron generator. The sample was irradiated for 0·4 min, then transferred to the counting position and counted for 0·4 min. The relative neutron flux reading was taken before each irradiation so that corrections could be made for the variation of neutron flux with time.

In the case of the polyvials, after irradiation and counting the vials were cut open, the samples removed, and the vials analysed several times in order to obtain the oxygen content of the vial. In the case of the aluminium vials, the analysis was carried out on each vial before encapsulation of the sample. Only one analysis was made for each aluminium vial because of the relatively low oxygen content.

* The activation-analysis portion of this work was conducted by the author in the laboratories of the General Atomic Division of General Dynamics Corp., San Diego, California, U.S.A.

Calculations

The spectrum of the gamma radiation obtained from the ^{16}N is shown in Fig. 1. The area above the dotted line is the 6–7 MEV gamma radiation. This energy range was covered by about 25 channels of the multi-channel analyser. The area above the dotted line is proportional to the ^{16}N and therefore to the oxygen content of the sample. The area under the curve above the dotted line is compared to that of the standard to compute the amount of oxygen present in the sample. The only correction made is a normalisation of the counts for the variation in neutron flux used for irradiation of the standard and the sample. No correction is made for the decay in the ^{16}N activity during transfer from the irradiation position to the counting position because this time is essentially the same for the standard and the sample. The variation of neutron flux with time is shown in Fig. 2 and some actual data and calculations are shown in Table I.

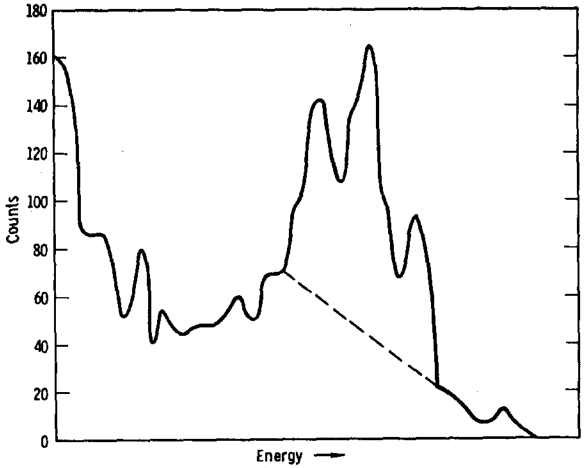

FIG. 1.—Gamma ray spectrum of ^{16}N from ^{16}O in iron.

TABLE I.—COUNTING RESULTS

Sample	Total counts	Net counts	Normalised counts	Oxygen, *mg*	Net oxygen, *mg*	Oxygen, *wt.* %

[a] Sensitivity: 114 counts/mg of oxygen.
[b] Sensitivity: 126 counts/mg of oxygen.
[c] Sensitivity: 63 counts/mg of oxygen.

RESULTS AND DISCUSSION

Table II contains a comparison of results obtained on various metals by both vacuum fusion and fast neutron activation analysis. The majority of the values obtained by both methods are in good agreement. The values marked (a) were encapsulated in aluminium and the value marked (b) was obtained without using a capsule. It was a single piece of aluminium machined to the size of a capsule. All other samples were encapsulated in polyethylene vials.

The duplicate results shown in Table II were obtained on separate duplicate specimens, and not reactivation of a sample which had been previously analysed. It can be seen from Table I that the net counts for some samples is rather small and therefore the counting statistics are poor. The statistics could be improved by rerunning the sample several times. It can also be seen that the sensitivity for oxygen in aluminium or in samples contained in aluminium capsules is much less than that in the other metals investigated. This is because of interference from the aluminium in the lower energy portion of the ^{16}N spectrum. The interference is eliminated by using only the high energy portion of the curve.

[b] No capsule.

In order to obtain good agreement between vacuum fusion and activation analysis, it is necessary to consider the possible sources of error in activation analysis and ways in which they can be eliminated or minimised. Because activation analysis is not absolute but a comparison between a standard and the unknown sample, the geometry of both counting and irradiation is extremely important. The use of the small neutron source makes this point even more important because of the relatively small neutron beam. The outside dimensions of both the standard and the unknown should be as close as possible to ensure similar irradiation and counting. It is not necessary that the density be the same, however, because almost all materials are transparent to fast neutrons and gamma rays.

When dealing with short half-life species, such as ^{16}N, it is essential that rapid transfer between neutron source and counter be effected. This can be accomplished by using a pneumatic transfer system. Most samples are, however, not of the proper shape or form to be transferred without encapsulation. Polyethylene vials are very convenient to use for this purpose; however, the oxygen and nitrogen content is usually very high and erratic. One series contained 1100 ± 150 μg of oxygen. If the value of each vial is determined separately and the oxygen value of the unknown corrected for the oxygen content of the polyvial, fairly good results can be obtained.

Other materials, such as aluminium and copper, which contain fairly low concentrations of oxygen and nitrogen, can also be used for encapsulation of the samples. Aluminium has been tried with good results, but problems exist in the sealing of the capsule. While the aluminium from which the capsules were fabricated contained about 8 ppm of oxygen, the finished capsules contained over 20 ppm. This value was not consistent between capsules and the increase was probably caused by the heat generated by the Magneforming operation which was used to seal the aluminium capsule. The use of aluminium capsules lowered the background by about a factor of 10 below that when polyvials were used. Further work on fabrication will undoubtedly lower the background of aluminium capsules by a factor of 2 or 3.

The oxygen content of the encapsulation material is not the only problem in encapsulation of samples, however. The volume of each capsule, if filled with air, contains about 2 mg of oxygen. Even though the sample occupies much of this volume, the oxygen content of the air occupying the capsule is significant and therefore must be removed. When polyvials are used this is done by purging with methane and sealing with a soldering iron. The problem is more complicated when aluminium capsules are used, because the capsule must be enclosed in a bag containing an inert atmosphere in order to have the top Magneformed on. Because the delay between sealing and irradiation can be considerable, the seal must be tight to prevent air leaks.

Obviously, the way to eliminate the problems of air contamination and capsule background is to use a transfer system in which encapsulation is unnecessary. For many materials transfer systems, both pneumatic and mechanical, can be devised which will have a negligible background.

From the data obtained in this study it appears that fast neutron activation analysis is a useful tool for the determination of oxygen in metals and compounds. While in some cases the large sample weight necessary may be a disadvantage, it is an advantage in material where an oxygen gradient exists across the specimen. The one technical advantage that fast neutron activation analysis has over vacuum fusion is that the result does not depend on recovery of the gas. Consequently, problems, such as gettering and incomplete reduction of oxides, are non-existent. Because of this, oxygen determination by activation analysis can be accomplished on materials that are a problem by vacuum fusion. Some of these are phosphorus, silicon carbide, gallium phosphide and various sulphides. The largest contribution of activation analysis to the determination of oxygen in metals is probably in the area of alloys and compounds which cannot be determined by vacuum fusion or other conventional methods.

While the combined activation and counting time for oxygen in metals is only 0·8 min, other variables tend to lengthen the actual analysis time. The surface preparation of the sample takes considerably more time for activation analysis than for vacuum fusion because of the longer time necessary to prepare the surface of the large samples properly and for the purging and encapsulation operation. While a degassing operation is unnecessary in activation analysis, accelerator maintainance time is significant. This is mainly because of deterioration of the target at an appreciable rate when the accelerator is operated at a high neutron flux. At present the life of targets operated at near full power is a matter of a few hours and the useful flux for oxygen analysis may be available for less than this because deterioration of the target is gradual.

CONCLUSION

It has been shown that fast neutron activation can give results comparable to those obtained by vacuum fusion for oxygen in metals. It is felt, however, that activation analysis should be used to compliment vacuum fusion in areas where difficulties are encountered with the vacuum fusion technique. Unfortunately, both methods have drawbacks and advantages in certain areas, and they should be used in the areas of their greatest strength.

WILLIAM F. HARRIS

Summary—A comparison has been made between results obtained for the oxygen content of metals obtained by vacuum fusion and fast neutron activation over the range 0·0008–0·1% of oxygen. The metals investigated included iron, silicon-iron, aluminium, molybdenum, niobium and niobium-base alloys. The problems encountered in the use of activation analysis for oxygen are discussed and solutions to them suggested.

Zusammenfassung—Die Ergebnisse von Sauerstoffbestimmungen in Metallen durch Vakuumschmelze und durch Aktivierung mit schnellen Neutronen wurden im Bereich von 0,0008 bis 0,1% Sauerstoff verglichen. Die untersuchten Metalle waren Eisen, Ferrosilicium, Aluminium, Molybdän, Niob und Legierungen auf Niobbasis. Die bei der Sauerstoffbestimmung durch Aktivierungsanalyse auftretenden Probleme werden diskutiert und Vorschläge zu deren Lösung gemacht.

Résumé—On compare les résultats obtenus, pour la teneur en oxygène des métaux, par la fusion sous vide et par l'activation aux neutrons rapides, dans le domaine compris entre 0,0008 et 0,1% d'oxygène. Les métaux étudiés comprennent le fer, le ferrosilicium, l'aluminium, le molybdène, le niobium et les alliages à base de niobium. On discute des problèmes rencontrés dans l'emploi de l'analyse par activation pour l'oxygène, et on suggère des solutions à ces problèmes.

Miniature magnetic stirring motor for use in teaching and analytical control laboratories

(*Received* 17 *April* 1964. *Accepted* 25 *May* 1964)

ELECTRICALLY powered magnetic stirring devices of many types are available. Although much used in research laboratories, they are too expensive for regular use by students. They are too large for convenience, they cannot be immersed in water baths, and they generate heat in operation. The stirring motor here described is free from these faults. The speed can be varied over a wide range, from slow to fast, and will remain constant at any predetermined level over a long period of use.

The parts of the motor are shown in Fig. 1. A magnet of Alnico, 45 × 20 × 8 mm, and weight 46 g, capable of lifting 150 g of iron on contact, is hermetically sealed into a plastic armature, 57 mm in diameter and 10 mm thick, with 24 driving prongs. The rotor bearings are of brass. When sealed into its plastic casing, which is 75 mm in diameter, and 20 mm thick, the assembly weighs 105 g in all.

The uses of this stirrer are illustrated in Figs. 2–6. It can be driven by water or compressed air, singly or with several units together.

Expensive Teflon-coated Alnico-cored stirring bars are not needed. A satisfactory stirring bar can be made as follows. A length of Pyrex tubing of 4-mm bore is sealed off at one end. While it is still hot, a 25-mm length cut from a carpenter's nail of slightly smaller diameter is heated just to redness and dropped into the tube. The tube is then drawn off just beyond the end of the piece of nail. For this operation, the tube can be held in forceps, or better, in a piece of spiral steel spring just small enough in diameter to grip the glass. The important thing is to heat the piece of iron before putting it into the tube; this makes it possible to achieve a closely fitting and well rounded seal.

DETERMINATION OF COBALT(II) IONS BY A DIFFERENTIAL SPECTROPHOTOMETRIC METHOD

A. PÁLL, G. SVEHLA and L. ERDEY
Institute for General Chemistry, Technical University of Budapest, XI
Gellért-tér 4, Budapest, Hungary

(*Received* 28 *January* 1964. *Accepted* 28 *February* 1964)

Summary—Cobalt(II) ions can be determined in the form of perchlorate by a differential spectrophotometric method, after evaporating the cobalt samples with perchloric acid to the production of perchloric acid fumes. From the absorption spectrum of cobalt(II) perchlorate the peak occurring at 19600 cm^{-1} (511 $m\mu$) is chosen for the determination. By the systematic investigation of optimum concentration limits it has been shown that if a solution containing 12 g/litre of cobalt is used as a reference, the concentration determination can be carried out with an error less than 1%, while the corresponding photometric error decreases to less than 0·1%. The effects of some foreign ions have been investigated; chromium, if present in the tervalent state, causes high positive errors. Other metal ions examined have no significant effect.

THE use of high-performance spectrophotometers permits of a desirable increase in the accuracy of analytical determinations. In particular, differential spectrophotometry promises the reduction of errors to such an extent that even ions which are present as main constituents in samples can be determined with adequate accuracy. Numerous differential spectrophotometric methods have already been described by various authors, among which determinations of copper,[1] nickel,[2] dichromate and permanganate,[3] titanium,[4] uranium,[5,6] vanadium[7] and phosphate[8] are the most widely used. The present investigation was to find the best experimental conditions for the determination of cobalt in the form of cobalt(II) perchlorate. From the point of view of differential spectrophotometric methods, the measurement of the optical densities of metal perchlorates are very suitable, partly because perchlorates generally do not form complexes which cause deviation from Beer's law, and partly because perchlorates can easily be prepared by simple evaporation with perchloric acid.

EXPERIMENTAL

Reagents

Cobalt(II) *perchlorate solution*, containing 50·00 mg/ml of cobalt, was prepared by dissolving 246·904 g of analytically pure cobalt(II) nitrate hexahydrate in water to which 350 ml of 60% perchloric acid were added, and cautiously evaporating the mixture to the appearance of white perchloric acid fumes. The solution was then diluted with water to exactly 1 litre. The cobalt content of the solution was checked by gravimetric methods.

This was used as a stock solution for the preparation of comparison standards. Because no marked effect on the optical densities was found if the concentration of perchloric acid was changed over a wide range, dilutions from the stock solution were simply made by water.

Apparatus

The absorption spectra of the metal perchlorates were obtained by a Unicam SP 700 spectrophotometer, equipped with a recorder presenting transmittance *vs.* wave numbers. One-cm silica cells were used, and spectra were recorded between 50×10^3 and 4×10^3 cm^{-1} wave numbers.

Optical densities were measured with a Hilger Uvispec spectrophotometer. Two 1-cm silica cells were used systematically, one always containing the reference solution, the other being the one to be measured.

RESULTS AND DISCUSSION

Absorption spectra

The transmittances of accurately prepared metal perchlorate solutions, containing 10 g of metal ion in 1 litre of solution (10 mg/ml), were measured against water. Fig. 1 shows the absorption spectrum of cobalt(II) perchlorate. The curve shows a characteristic maximum at 19600 cm^{-1} (511 mμ). This wavelength was used for the optical density measurements, where the specific absorbance of cobalt^{II} ions is $7{\cdot}9 \times 10^{-2}$ litre.g^{-1}.cm^{-1}. Similarly, the absorption spectra of the perchlorates of those metal ions which often occur with cobalt were checked carefully for interference.

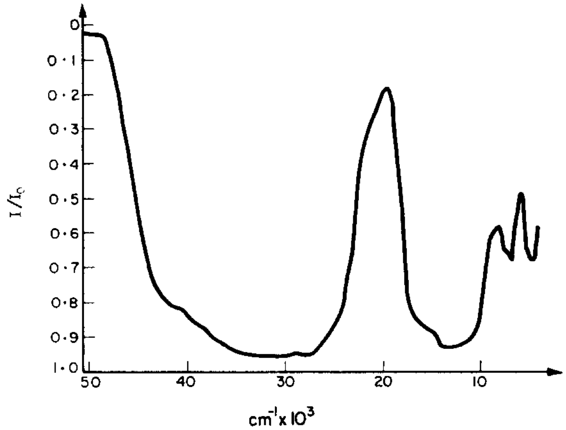

FIG. 1.—Absorption spectrum of cobalt(II) perchlorate (10 g of Co^{II}/litre)

The absorption spectra of the perchlorates of nickel(II), iron(II), copper(II) and chromium(III) are shown in Figs. 2, 3, 4 and 5 respectively.

By comparing these spectra it can be seen that the absorbances of nickel(II), iron(II) and copper(II) perchlorates at 19600 cm^{-1} are very low, and therefore there are no serious interferences to be expected in their presence. Chromium(III) perchlorate, however, shows marked absorption at this wavelength, and therefore a marked interference from chromium(III) is to be expected in determinations.

Optimum concentration limits

The determination of the optimum concentration limits was made by carrying out a series of sets of optical density measurements and calculating the corresponding percentage errors of the concentration determinations.[9] The region showing lowest errors was chosen as the most suitable one.

A set of solutions was prepared, containing 2, 4, 6, 8, 10, 12, 14, 16, 18, 20, 22, 24, 26, 28, 30, 32, 34, 36 and 38 g of cobalt per litre. Five sets of experiments were made. As reference solutions water (concentration = 0) and cobalt(II) perchlorate solutions containing 6, 12, 18 and 24 g of cobalt per litre were chosen. Optical densities were measured in all cases six times (including refilling of the cells and readjustment of the instrument). The means of six readings are presented in Table I.

In each set the optical densities, when plotted against concentrations, yield linear curves. Using the method of least squares, the equations of the best linear curves fitting the experimental points were determined, together with the standard deviations of the intercept and the slope. These equations are summarised in Table II.

For all the sets of experiments the errors were then calculated, as described elsewhere.[9] It was there pointed out that the error of concentration determination by a differential spectrophotometric method depends on the measured optical density (*i.e.*, on the concentration itself) and can be expressed by the following equation:

$$\frac{S_C}{C} \times 100 = \frac{S_E}{E - b} \times 100 + \frac{S_b}{E - b} \times 100 + \frac{S_a}{a} \times 100.$$

Simplifications arising from the use of cells of 1 cm in length are included in this expression. Here S_b and S_a are the standard deviations of the intercept and slope, respectively, while the value S_E is the standard deviation of the optical density measurements. The value $\frac{S_E}{E - b} \times 100$ is the so-called photometric error; for the details of its calculation see the earlier paper.[9] The results of the error calculations are shown in Table III. The best results can be obtained using a solution containing 12 g of cobalt per litre as a reference. In this case the total error of the method is somewhat lower than 1%, while the "photometric error," *i.e.*, the coefficient of variation of the optical density measurement, is generally lower than 0·1%. The calibration curve is shown in Fig. 6.

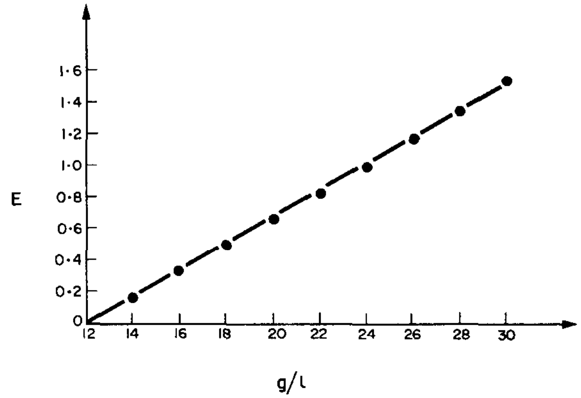

FIG. 6.—Calibration curve for cobalt determination ($E_{ref} = 0·975$)

Effect of foreign ions

Various metal ions (5, 10, 15 and 20 g per litre) were added to solutions containing 22 g of cobalt(II) per litre. The optical densities of the resulting solutions were measured against a reference solution containing 12 g per litre of cobalt.

The results of these measurements, together with the errors caused by the metal ions, are presented in Table IV. As may be seen from these results, the investigated metal ions reduce the optical density, causing about a 1% negative error in the concentration measurement. This excludes chromium which, as pointed out earlier, causes a very high positive error; this can be eliminated, however, by the oxidation of chromium to chromate. A further report will be given later on this, and on the differential spectrophotometric determination of chromium.

TABLE IV.—EFFECT OF FOREIGN ION

Ion	Concentration of foreign ion, *g/litre*	Optical density	Cobalt concentration, *g/litre*		Error caused by the ion	
			True value	Measured value	*g/litre*	%

	10	0·823	22·00	21·71	−0·29	−1·31
	15	0·812	22·00	21·59	−0·41	−1·86
	20	0·832	22·00	21·82	−0·18	−0·81

Procedure

Dissolve a sample, containing about 1·5–2·5 g of cobalt in 50 ml of perchloric acid (1:3). If this cannot be done, dissolve the sample in any other way and evaporate the solution together with 50 ml of perchloric acid (1:3) until white perchloric acid fumes appear. Allow to cool, transfer the solution to a 100-ml volumetric flask, dilute with water to the mark, mix the solution well, and measure the optical density of the solution against a reference solution containing 12 g of cobalt per litre. Prepare a calibration graph with solutions containing 14–26 g of cobalt per litre. (The calibration solutions can be prepared as described under *Reagents*.) Chromium(III) causes high positive errors.

Zusammenfassung—Kobalt(II)-ionen können als Perchlorat mit einer spektralphotométrischen Differenzmethode bestimmt werden, wenn die Kobaltproben mit Überchlorsäure bis zum Erscheinen von Überchlorsäurenebeln eingedampft werden. Aus dem Absorptionsspektrum von Kobalt(II)-perchlorat wurde die Bande bei 19,600 cm^{-1} bzw. 511 mμ zur Bestimmung ausgewählt. Durch systematische Untersuchung der optimalen Konzentrationen ließ sich zeigen, daß die Konzentrationsbestimmung auf besser als 1% genau ausgeführt werden kann, wenn als Vergleichslösung eine Lösung mit 12 g Kobalt pro Liter verwendet wird. Der photometrische Fehler wird dabei kleiner als 0,1%. Der Einfluß einiger Fremdmetalle wurde untersucht; dreiwertiges Chrom gibt hohe Plusfehler. Andere untersuchte Metallionen haben keinen nennenswerten Einfluß.

Résumé—On peut doser les ions cobalt(II) par une méthode spectrophotométrique différentielle, à l'état de perchlorate, après évaporation des échantillons de cobalt avec de l'acide perchlorique, jusqu'à apparition de fumées de cet acide. Dans le spectre d'absorption du perchlorate

de cobalt(II), on a choisi, pour ce dosage, le pic situé à 19,600 cm^{-1} (511 millimicrons). Par l'étude systématique des limites de la concentration optimale, nous pouvons établir que, si l'on emploie une solution contenant 12 grammes de cobalt par litre comme référence, la détermination de la concentration peut être effectuée avec une erreur inférieure à 1%, cependant que l'erreur photométrique correspondante est inférieure à 0,1%. On a étudié l'influence de quelques mètaux ètrangers. Parmi ceux-ci le chrome, s'il est présent à l'état trivalent, est cause d'erreurs positives élevées. D'autres ions métalliques examinés n'ont pas d'effet significatif.

THE DETERMINATION OF SODIUM, POTASSIUM, MAGNESIUM, MANGANESE AND CALCIUM IN CEMENT BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY

TSUGIO TAKEUCHI and MASAMI SUZUKI
Institute of Analytical Chemistry, Faculty of Engineering
Nagoya University, Nagoya, Japan

(*Received* 30 *January* 1964. *Accepted* 3 *July* 1964)

Summary—Various aspects of the determination of sodium, potassium, magnesium, manganese and calcium in cement by atomic-absorption spectrophotometry are described. For the determination of sodium, potassium and magnesium, both the calibration curve method and the addition method were found suitable because of the linear relationship between absorption and concentration. For the determination of manganese and calcium, the calibration curve method was found suitable. The calibration curves for sodium and potassium must be prepared to contain the same concentration of calcium as the analysed samples. The method is rapid, and no preliminary separations are necessary. The precision for the determination of sodium, potassium, magnesium and manganese is satisfactory, but is insufficient for calcium because of the large calcium content of cement.

INTRODUCTION

CURRENT methods for determining sodium, potassium, magnesium, manganese and calcium in cement include flame-emission techniques for sodium and potassium, titration with ethylenediaminetetra-acetic acid for magnesium and calcium, and a photometric technique for manganese. The phenomena of self and mutual interferences are observed in the flame-emission methods for alkalis.[1] Magnesium and manganese can also be determined by the flame-emission method. This method, however, is insufficiently sensitive.

The method of atomic-absorption spectrophotometry has been found suitable for use in routine analysis because of the marked freedom from interference, the high degree of accuracy and the simplicity of operation compared with other procedures. The aim of the work described in this paper was to examine the application of atomic-absorption spectrophotometry to the determination of sodium, potassium, magnesium, manganese and calcium in cement.

EXPERIMENTAL

Apparatus

The instrument used in this work was a Hitachi photoelectric spectrophotometer EPU-2, together with the Hitachi atomic-absorption attachment RA-1. Fig. 1 shows the optical system of the equipment. The electrical emission-compensation system was used to measure the intensity of the absorbed radiation without interference by emission from the vaporised sample.

The 7-cm fish tail burner, which could use an air-acetylene mixture, was water-cooled throughout the work. A sample solution was atomised into the spray chamber by an air stream. Acetylene was introduced directly into the burner, and mixed with the air from the spray chamber at the bottom of the burner.

Operating conditions

The optimum conditions listed in Table I were established by preliminary work with solutions of pure sodium, potassium, magnesium, manganese and calcium.

Lamp current: The lowest possible lamp current was necessary for operating the magnesium or calcium cathode lamps. The magnesium hollow-cathode lamp (Mg-Al cathode) used in this work could not be operated with a current less than 30 mA because of the low light intensity of the lamp and poor sensitivity of the detector for low light intensity. The limit of detection of magnesium in the present method is 1 μg/ml. The effect of lamp current on magnesium absorption is shown in Fig. 2. However, the manganese lamp showed an increase of sensitivity with increase in lamp current (Table II).

Acetylene pressure: After the air pressure had been set at a constant value (1·4 Kg/cm^2), an examination was made of the effect on absorbance when the acetylene pressure was varied. The position of the passage of the beam from the hollow-cathode lamp through the flame was set at 6 mm above the burner top. The top of the inner cone was 4 mm above the burner top. No incandescence in the flame was observed at 0·32 Kg/cm^2 of acetylene. The top of the inner cone varied and the incandescence increased with increase of the acetylene pressure. The incandescence was visible in the whole of the flame at 0·46 Kg/cm^2 of acetylene. The results are summarised in Fig. 3. From these results it can be seen that an acetylene pressure from 0·32 to 0·46 Kg/cm^2 seems to have no effect on absorbance of sodium, magnesium and manganese. The absorbance of calcium varied,

TABLE I.—OPTIMUM CONDITIONS FOR DETERMINATION OF SODIUM, POTASSIUM, MAGNESIUM, MANGANESE AND CALCIUM

Element	Light source	Lamp current, *m*A	Lines, *A*	Slit width, *mm*
Na	Sodium lamp (Toshiba)	—	5890	0·03
K	Potassium lamp (Hitachi)	—	7665	0·15
Mg	Hollow-cathode lamp (Mg-Al)*	30	2852	0·03
Mn	Hollow-cathode lamp (Mn-Cu)*	75	2798	0·15
Ca	Hollow-cathode lamp (Ca-Al)*	50	4225	0·035

* Hitachi hollow-cathode lamp.

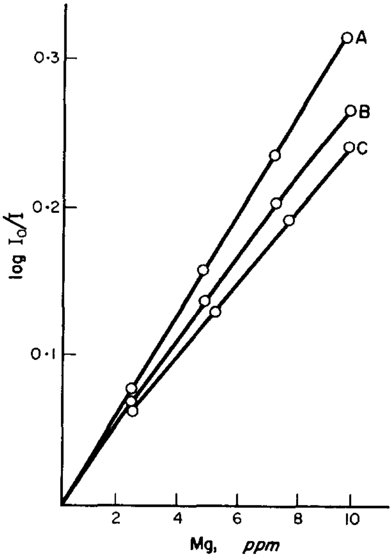

FIG. 2.—Effect of lamp current on magnesium absorption.
A: 30 mA.
B: 40 mA.
C: 50 mA.

and that of potassium varied slightly with variation in the acetylene pressure. The smallness of the region over which calcium atoms in the flame are abundant may be responsible for the variation of the absorbance with the variation of the height of the inner cone.

Slit width: Experiments were made at various slit widths. The slit widths shown in Table I were necessary to obtain satisfactory results. Because of the fluctuation of emission, the small slit width was adequate for compensating the emission from sodium. The increased absorption was obtained for manganese by opening the slit. Too wide a slit may result in unsatisfactory precision.

Relation between absorption and concentration of elements

Calibration curves were prepared for sodium, potassium, magnesium or manganese without calcium and containing calcium. The resulting curves are shown in Fig. 4. In the presence of calcium, depression of the sodium and potassium absorptions was observed. Therefore a calibration curve for the analysis of cement must be prepared by the addition of calcium. Magnesium absorption was not affected by the presence of 500 ppm of calcium. Larger amounts of calcium did affect the magnesium absorption. Sodium, potassium and magnesium can be determined by the addition method, because the curves indicate linearity, within the limits of experimental error, in the presence of calcium. Because slightly curved calibration curves were obtained for manganese and calcium,

TABLE II.—EFFECT OF LAMP CURRENT ON ABSORPTION FROM MANGANESE-COPPER HOLLOW-CATHODE LAMP

Lamp current, *m*A	Absorbance to manganese[a]
45	0·184
55	0·201
65	0·213
75	0·239
85	0·244
95	0·244

[a] 38 ppm.

the addition method was not useful for these elements in cement. The calibration curve for manganese could be prepared in the absence of calcium.

Reproducibility

Reproducibility was determined by repeatedly measuring the absorption of solutions containing sodium, potassium, magnesium, manganese or calcium. The coefficients of variation were 1·3% for a solution containing 5·8 ppm of sodium, 1·1% for a solution containing 23 ppm of potassium, 1·5% for a solution containing 7·4 ppm of magnesium, 2·3% for a solution containing 26 ppm of manganese and 1·2% for a solution containing 101 ppm of calcium.

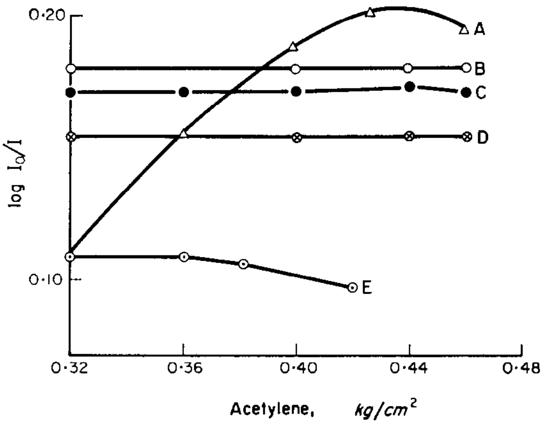

FIG. 3.—Effect of flame condition on the absorption of sodium, potassium, magnesium, manganese and calcium.

A: Calcium.
B: Sodium.
C: Manganese.
D: Magnesium.
E: Potassium.
(Air pressure kept constant at 1·4 Kg/cm^2.)

Interferences

A systematic investigation of interference effects was carried out, using various amounts of other elements. Apart from calcium, other elements, in the proportions normally found in cement, had no effect on the determination of sodium and potassium. The majority of elements did not interfere with the determination of manganese. Serious interference for magnesium in pure solution was observed in the presence of aluminium and silicon (Fig. 5). But these interference effects were not observed in the analysis of cement because of the suppression effect of calcium present in the sample on the aluminium (or silicon) interference. Phosphorus interference was observed in an air-propane flame, but not in an air-acetylene flame. Calcium absorption was interfered with in the presence of aluminium, silicon and phosphorus. The addition of large amounts of strontium was necessary to suppress the interference.

The solutions used for the analysis were about 0·24*M* in hydrochloric acid, and this was sufficient to give results lower by 20% than for solutions containing no free acid. Sulphuric or perchloric acid behaved in much the same way as hydrochloric acid.

Enhancement of absorption was obtained by the addition of acetic acid, alcohols and acetone to the solution. An increase in sensitivity of about 3-fold by the addition of 50% of propanol or about 5-fold by the addition of 50% of acetone was obtained, similar increases being obtained for the different elements.

Recommended procedure

Decompose 0·5 g of sample with 20 ml of hydrochloric acid (4*M*), heat and evaporate to dryness. Dissolve the residue in 5 ml of hydrochloric acid (4*M*) and filter through a filter paper into a 100-ml

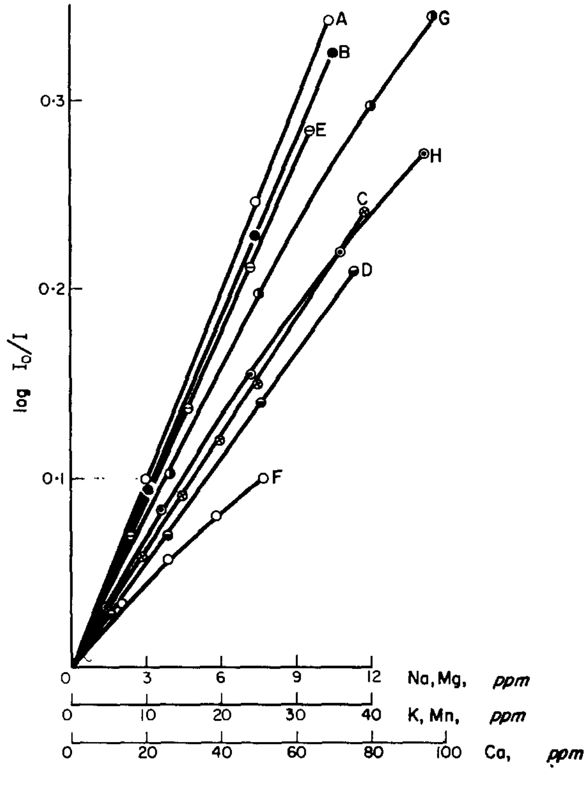

FIG. 4.—Typical calibration curves for sodium, potassium, magnesium, manganese and calcium.

A: Na without Ca.
B: Na containing 3350 ppm of Ca.
C: K without Ca
D: K containing 3350 ppm of Ca.
E: Mg without Ca and containing 503 ppm of Ca.
F: Mn without Ca and containing 3350 ppm of Ca.
G: Ca without Sr.
H: Ca containing 5000 ppm of Sr.

volumetric flask, washing with small volumes of hot water. Cool the filtrate and dilute to the mark with cold water.

Sodium: Take three 10-ml portions of the sample stock solution. Add 25 ml of solutions of sodium chloride containing 6, 12 and 18 ppm of sodium to these, and dilute each solution to 50 ml with water. Spray the solutions into the flame, and measure the absorbance. Plot the absorbance against the added amounts of sodium and read the amount of sodium in the original sample by extrapolating the linear relation curve of absorption *versus* concentration to zero absorbance.

Potassium: Take three 10-ml portions of the sample stock solution. Add 5 ml of solutions of potassium chloride containing 20, 40 and 60 ppm of potassium to these, and dilute each solution to 20 ml with water. Proceed as for sodium.

Magnesium: Take three 5-ml portions of the sample stock solution. Add 25 ml of solutions of magnesium chloride containing 4, 8 and 12 ppm of magnesium to these, and dilute each solution to 50 ml with water. Proceed as for sodium.

Manganese: Spray the sample stock solution into the flame and measure the absorbance. Obtain the manganese content of the sample by reference to a previously prepared calibration curve which was prepared from standard solutions containing the same concentration of acid as the sample solution.

Calcium: Take 5 ml of the sample stock solution. Add 50 ml of a solution of strontium chloride containing 25,000 ppm of strontium, and dilute to 250 ml with water. Proceed as for manganese.

Sodium, potassium and magnesium can also be determined using calibration curves as for manganese or calcium.

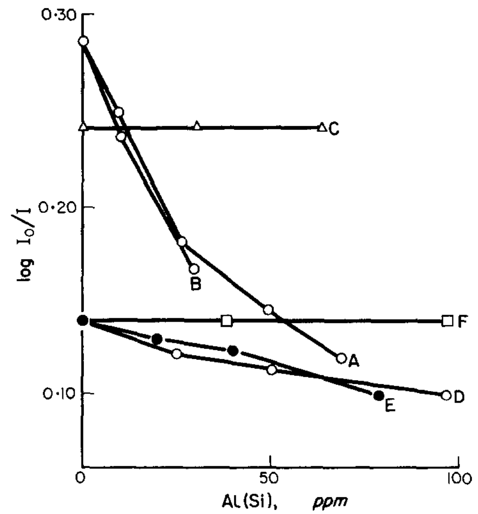

FIG. 5.—Effect of aluminium and silicon on the absorption of calcium and magnesium.

A: 76 ppm of Ca plus Al.
B: 76 ppm of Ca plus Si.
C: 76 ppm of Ca plus Al (or Si) plus 5000 ppm of Sr.
D: 4·8 ppm of Mg plus Al.
E: 4·8 ppm of Mg plus Si.
F: 4·8 ppm of Mg plus Al (or Si) plus 500 ppm of Ca.

RESULTS AND DISCUSSION

Two samples of cement were examined by the *Recommended procedure*. The results are shown in Table III.

Willis[2] has shown that the presence of sodium increases potassium absorption when using an air-coal gas flame. However, Malmstadt and Chambers[3] observed that a 20-fold excess of sodium did not interfere with potassium determination using an air-propane flame. The present authors also observed no interference of sodium on the determination of potassium.

Calcium lowered the slope of the calibration curves for sodium and potassium. The effect of calcium may be explained by assuming that the solid particles are only

TABLE III.—DETERMINATION OF SODIUM, POTASSIUM, MAGNESIUM, MANGANESE AND CALCIUM IN CEMENT

Element determined	Sample I			Sample II

[a] Na and K: flame photometric; Mn: photometric; Ca and Mg: titrimetric.

partially evaporated and so liberate only a small proportion of the sodium atoms present. The magnitude of the effect of calcium depended on the atomiser. The use of a more efficient atomiser might suppress the effect of calcium. Rubeška *et al.*[4] have also discussed the effect of calcium on the sodium absorption.

Elwell and Gidley[5] described the marked effect of silicon on magnesium absorption using an air-coal gas flame. The present authors found no interference from silicon using an air-acetylene flame.

The addition method was found to be satisfactory for the analysis of cement for sodium, potassium and magnesium, because of the linear relationship between absorption and concentration. Results obtained by both addition and calibration curve methods, in the determination of sodium and magnesium in cement, are in good agreement; but results for potassium by the addition method are lower by 10% than those by the calibration curve method.

It was found, in agreement with David,[6] that interference from aluminium, silicon and phosphorus, in the determination of calcium, was suppressed by the addition of large amounts of strontium. The results for calcium would, however, be lacking in precision because of the large calcium content of cement.

Zusammenfassung—Verschiedene Gesichtspunkte bei der Bestimmung von Natrium, Kalium, Magnesium, Mangan und Calcium in Zement durch atomare Absorptionsspektralanalyse werden untersucht. Bei der Bestimmung von Natrium, Kalium und Magnesium wurden sowohl die Eichkurvenmethode als auch die Additionsmethode für geeignet befunden, da Absorption und Konzentration linear zusammenhängen. Zur Bestimmung von Mangan und Calcium ist die Eichkurvenmethode geeignet. Die Eichkurven für Natrium und Kalium mußten in Gegenwart der selben Calciumkonzentration wie in der Probe aufgenommen werden. Die Methode geht schnell und bedarf keiner vorausgehenden Trennung. Die Genauigkeit der Bestimmung von Natrium, Kalium, Magnesium und Mangan ist befriedigend, bei Calcium ist sie wegen des hohen Calciumgehaltes von Zement unzureichend.

Résumé—On décrit l'étude de divers aspects du dosage de sodium, potassium, magnésium, manganèse et calcium dans le ciment, au moyen de la spectrophotométrie d'absorption atomique. Pour le dosage de sodium, potassium et magnésium, les méthodes par courbe d'étalonnage et par addition sont toutes deux convenables, par suite de la relation linéaire entre l'absorption et la concentration. Pour le dosage de manganèse et calcium, la méthode par courbe d'étalonnage est convenable. Les courbes d'étalonnage pour le sodium et le potassium doivent être préparées en présence d'une concentration en calcium égale à celle des échantillons analysés. La méthode est rapide, et ne nécessite pas de séparations préliminaires. La précision est satisfaisante pour le dosage de sodium, potassium, magnésium et manganèse, mais elle est insuffisante pour le calcium par suite de la forte teneur du ciment en cet élément.

CHELATING PROPERTIES OF THE CHELATING ION EXCHANGER DOWEX A-1*

H. LOEWENSCHUSS and G. SCHMUCKLER
Department of Chemistry, Technion—Israel Institute of Technology, Haifa, Israel

(*Received* 5 *March* 1964. *Accepted* 11 *June* 1964)

Summary—The properties and behaviour of the chelating ion exchanger Dowex A-1 have been studied when in contact with an aqueous solution containing metal ions complexed with aminocarboxylic ligands. The stability constants of the metal ion complexes with the resin have been determined as well as the structure of the complexes formed by the metal ions, the resin and the ligands in the solution. Dowex A-1 behaves as a solid complexing agent and forms stable 1:1 complexes with metal ions.

FUNDAMENTAL research carried out so far on Dowex A-1, a chelating ion exchanger, has dealt mainly with kinetics[1,2,3], equilibrium studies,[4] separation possibilities,[5] and the effects of the medium.[6]

In the present work an attempt is made to solve problems of a new kind, connected with the mechanism of binding metal ions to this resin and with the stability of the complexes formed. This raises a number of secondary problems, such as the structure of the resin, the ligands entering together with the metal ions, the definition of the order of affinity of the metals, the connection between the stability of the metal complexes in solution and their adsorbability, *etc.* Answers to these fundamental questions should further applied analytical research on Dowex A-1 and contribute towards an understanding of complexation mechanisms in general.

It is proposed to show how information on the structure of the complexes and their stability may be obtained with the help of simple equilibrium experiments in a solid-liquid system (the solid being Dowex A-1, the liquid being metal ions in aqueous solution bound to aminocarboxylic ligands) where chelation takes place in both phases, which are easily separable and analysable after equilibrium has been attained.

DISCUSSION

Structural considerations

Much information regarding the structure of Dowex A-1 is obtainable from elemental analysis of the sodium form of the resin. The composition of a homogeneous sample specimen of the sodium resin, when dried at 100°, is as follows:

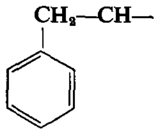
C—52·91%
H— 6·26%
N— 3·50%
O—25·63%
Na—11·7%.

---

* Part of an M.Sc. thesis to be presented by Mrs. H. Loewenschuss to the Senate of the Technion.

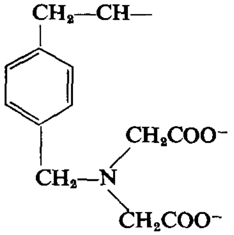
Dowex A-1 is a polymer composed of styrene-divinylbenzene rings, some of which are substituted by iminodiacetic acid (IDAA).

(a) *Calculation of number of substituted rings.* Assume that the resin is composed of two kinds of rings : A-rings, aromatic rings which have no functional group,



C_8H_8 (molecular weight 104)

and B-rings, aromatic rings substituted by IDAA.



$C_{13}H_{13}NO_4$ (molecular weight 247)

Because nitrogen is present only in the substituted rings, the number of B-rings may be calculated on the strength of the nitrogen content. The content of 3·5% of nitrogen means that each 1 g of resin contains 2·5 mmole of nitrogen or 2·5 mmole of B-rings.

One g of resin, therefore, contains 617 mg of B-rings (2·5 × 247 = 617 mg), but the balance does not give the number of A-rings, because in the substance dried at 100° water molecules are still bound as ligands to the metal ion. The required data will, however, be provided by the material balance of carbon atoms.

(b) *Carbon balance.* The carbon content being 52·91%, 1 g of resin contains 44 mmole of carbon, of which the B-rings have taken up 2·5 × 13 = 32·5 mmole of carbon. The balance (44 − 32·5 = 11·5 mmole of carbon) is available for A-rings. From this it may be inferred that of every 8 rings there are 5 substituted ones,* *i.e.*, not all rings are substituted. The chelating ligands in the resin are, therefore, well spaced, so that a metal ion is unlikely to be bound to two IDAA ligands from the resin.

(c) *Calculation of water content.*

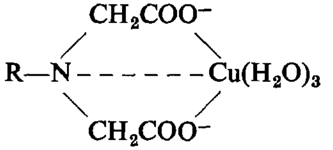
One g of resin contains 2·5 B-rings = 617 mg
1·45 A-rings = 150·8 mg
11·7% of Na = 117 mg
884·8 mg

* The basis of this inference is as follows. B-rings contain 13 carbon atoms, so that the amount taken up by them is 13 × 2·5 = 32·5 mmole of carbon. In the A-rings, on the other hand, there are only 8 carbon atoms and, because only 44 − 32·5 = 11·5 mmole are left, there can only be 11·5/8 = 1·45 A-rings. From this it is concluded that for every 8 rings in the resin there are 5 substituted ones.

giving a balance of 115 mg of water. The fact that water remains in the resin and does not evaporate at 100° is interesting in itself, because it proves the penetration of the ligands, together with the metal ions, from the solution into the resin matrix.

(d) *Oxygen balance.* Subtracting the proportion bound to water (10·2%) from the over-all percentage of oxygen (25·63%), for each mmole of nitrogen there are 4 mmole of oxygen, which corresponds to the structural considerations of the rings substituted by IDAA.

(e) *Structure of resin when containing copper.* Elemental analysis of the copper-containing resin produces results similar to the sodium-containing resin, so far as carbon, nitrogen, oxygen and hydrogen contents are concerned. The water balance shows that for each mmole of copper in the resin 3 molecules of water enter. This gives rise to the assumption that the structure of the complex formed by copper and Dowex A-1 is as follows



where R is the polymer matrix. Copper is thus seen to enter the resin in an octahedral configuration,[15] and it will be shown later that if the copper in the solution is bound to chelating ligands, it will also enter the resin with these ligands instead of with water.

Stoichiometry

In order to understand the stoichiometry of the reactions between the metal ions and Dowex A-1, measurements of the maximum capacity of the resin may be used. Experimentally, this is done by bringing a known weight of dry resin in contact with solutions of increasing concentration of the metal ion. Experiments were conducted with Cu^{2+}, Pb^{2+}, Fe^{3+} and Th^{4+} ions, and in all cases similar results were obtained, *viz.*, 2·4–2·5 mmole of metal ions/g of Dowex A-1. Because 1 g of resin contains 2·5 mmole of IDAA, it is found that metal ions are complexed by the resin in the stoichiometric ratio of 1:1, independent of valency. This is similar to the stoichiometry of the reactions of EDTA with metal ions in solution.

A marked difference in behaviour is seen to exist between IDAA in solution and in the resin matrix. In solution the metal ions combine with more than 1 molecule of IDAA, in accordance with their valency, while in the resin complexation is accomplished in a single step, from which it may be concluded that the complexes in the resin are more stable than those formed in solution.

Metal and ligand sorption

In a system consisting of a certain quantity of dry resin in contact with a solution containing a few mmole of metal ions bound to an excess of a tridentate ligand, such as IDAA, the relation between the concentration of ligands in solution and the resin's adsorptive capacity for metal ions must be established. Obviously, increasing the concentration of the ligand in the solution reduces the concentration of ions in the resin because of competing complexation. Experiments have shown two important facts:

(a) A definite quantitative relation exists between the stability constants of the metal ion complexes with the ligands in solution and their adsorbability on the resin.

(b) Stoichiometric penetration takes place of 1 IDAA molecule together with 1 metal ion.

The significant equilibria involved in this experimental system are as follows

In Solution

$$\mathrm{ML} + \mathrm{L} \rightleftharpoons \mathrm{ML_2};\ k_2 = \frac{(\mathrm{ML_2})}{(\mathrm{ML})(\mathrm{L})} \tag{1}$$

In Resin Phase

$$\mathrm{ML} + \mathrm{R} \rightleftharpoons \mathrm{MLR};\ \mathrm{K_{MLR}} = \frac{(\mathrm{MLR})}{(\mathrm{ML})(\mathrm{R})} \tag{2}$$

Over-all Reaction

$$\mathrm{ML_2} + \mathrm{R} \rightleftharpoons \mathrm{MLR} + \mathrm{L};\ \mathrm{K_{over\text{-}all}} = \frac{(\mathrm{MLR})(\mathrm{L})}{(\mathrm{ML_2})(\mathrm{R})} = \frac{\mathrm{K_{MLR}}}{k_2} \tag{3}$$

or expressed logarithmically

$$\log(\mathrm{L}) = \log\frac{(\mathrm{ML_2})(\mathrm{R})}{(\mathrm{MLR})} + \log \mathrm{K_{over\text{-}all}} \tag{3a}$$

where L represents the polydentate ligand and R represents the polymer matrix.

The quantities appearing in equation (3a) are defined as follows:

(MLR) = The quantity of metal present in the resin after the system has reached equilibrium.

(L) = The quantity of uncomplexed ligand (the quantity of ligand introduced minus the quantity of ligand bound to the metal).

$(\mathrm{ML_2})$ = The quantity of metal complex remaining in solution after phase separation; this may be calculated by subtracting the quantity of metal bound to the resin from the total quantity of metal introduced into the system.

(R) = The quantity of resin not bound to the complexing metal ion; this may be calculated by subtracting the quantity of (MLR) from the maximum capacity of the resin.

The quantities in the brackets denote the concentrations of the various species. The concentrations of the constituents in the solution ($\mathrm{ML_2}$, ML and L) are expressed in mmole/100 ml, while those in the solid phase are in mmole of metal ions (which is equivalent to the number of mmole of chelating groups in the resin) (*cf*. Table I). $\mathrm{K_{over\text{-}all}}$ is an apparent constant. It is the quotient of the stability of the mixed complex in the resin phase divided by the stability of the complex in the solution. If the proposed mechanism is correct, the graphic correlation of log (L) *vs*. log $[(\mathrm{ML_2})(\mathrm{R})]/(\mathrm{MLR})$ should be a straight line of unit slope, the intersection of which with the x-axis gives $\mathrm{K_{over\text{-}all}}$; k_2 may be found from the literature, hence $\mathrm{K_{MLR}}$

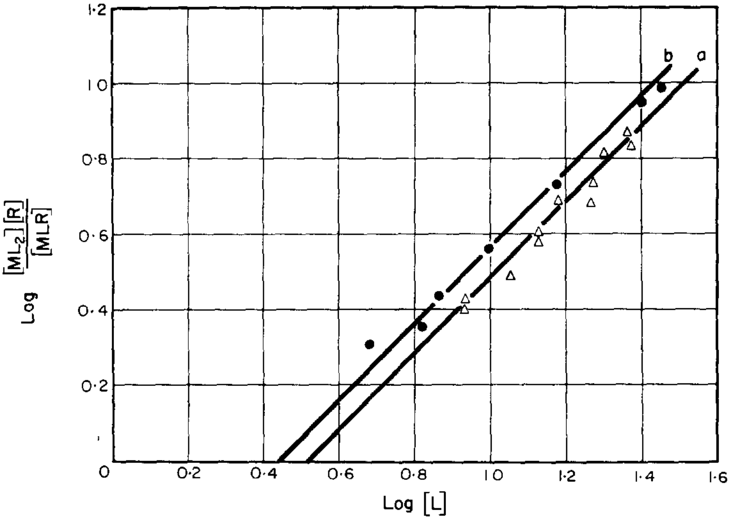


Fig. 1.—Graphical correlations from equilibrium measurements of:
(a) Cu^{2+} with IDAA in contact with 0·5-g portions of Dowex A-1.
(b) Ni^{2+} with IDAA in contact with 0·5-g portions of Dowex A-1.

may be determined. Fig. 1 shows that the results of the experiments with copper and nickel bound to IDAA confirm the above theoretical considerations.

Similar experiments were made by binding the copper ion to other ligands, such as glycine and glutamic acid. Here too, straight lines were obtained with a slope close to unity (Fig. 2). The slight deviations from unit slope are probably from neglecting the activity coefficients.

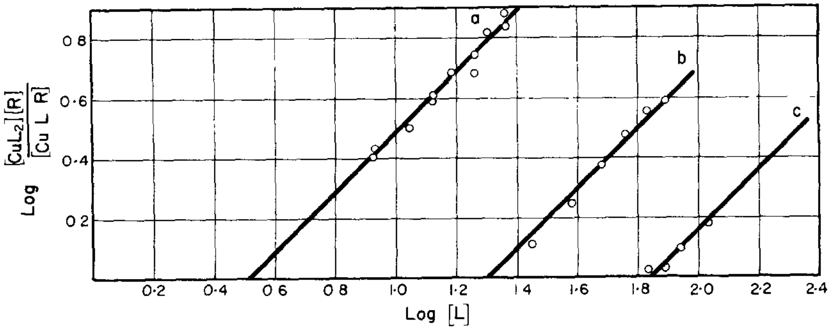

Fig. 2.—Equilibrium measurements of copper ions with various aminocarboxylic acid ligands [equation (3a)]:
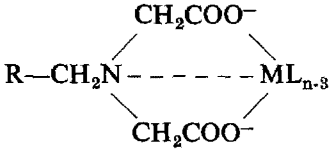
(a) IDAA,
(b) glutamic acid,
(c) glycine.

Ligand sorption in cation exchangers was first described by Stokes and Walton[7] and its theory elaborated by Helfferich,[8,9] who made use of the phenomenon for ligand exchange and separations in columns containing metal ions bound to ion exchangers.

It can now be definitely concluded that the structure of the complex formed is



L denotes the additional ligand to which the metal is bound in the resin phase. It may consist of water molecules, an anion of the salt of the metal in the solution or an aminocarboxylic ligand, as was shown before. n is the co-ordination number of the metal.

*Determination of stability constants of metal ions with Dowex A-*1

So far the formation of mixed complexes consisting of metal ions, Dowex A-1 and bi- or tridentate ligands has been discussed. Now the order of affinity of the metals to the resin must be established.

When an aqueous solution containing several metal ions is passed through a column of Dowex A-1, the ions will enter the resin according to a certain order, which depends on the stability constants of the metals with the resin. In order to determine a constant of the type K_{MR}, the resin must be brought into contact with a solution containing metal ions bound to a large polydentate ligand, such as EDTA or the like, which, because of its bulky molecules and the stereospecificity of its complexes, will not enter the resin, as did IDAA or glycine. The result will be that the hydrated metal ion alone will enter the resin.

In this system two competing complexation reactions take place

$$M + Y \rightleftharpoons MY; \;\; K_{MY} = \frac{(MY)}{(M)\,(Y)} \tag{4}$$

$$M + R \rightleftharpoons MR; \;\; K_{MR} = \frac{(MR)}{(M)\,(R)} \tag{5}$$

$$MY + R \rightleftharpoons MR + Y; \;\; K_{\text{over-all}} = \frac{(MR)\,(Y)}{(MY)\,(R)} = \frac{K_{MR}}{K_{MY}} \tag{6}$$

$$\log (R) = \log \frac{(MR)\,(Y)}{(MY)} - \log K_{\text{over-all}} \tag{6a}$$

Y denotes the large polydentate ligand to which the metal ion in the solution is bound. In the present case the ligand selected was *N*-hydroxyethylenediaminetriacetic acid (HEDTA). R again denotes the polymer matrix.

Analogously to K_{MLR}, K_{MR} may be found by graphic correlation of log (R) *vs.* log [(MR) (Y)]/(MY). In Fig. 3 the constants for nickel and copper within the resin are determined experimentally. For these equilibrium measurements HEDTA was chosen because it binds these metal ions more strongly than Dowex A-1 (log $K_{NiY} = 17{\cdot}0$; log $K_{CuY} = 17{\cdot}4$) and gives convenient distribution ratios of the ions between the resin and the solution. The lines obtained in Fig. 3 are straight

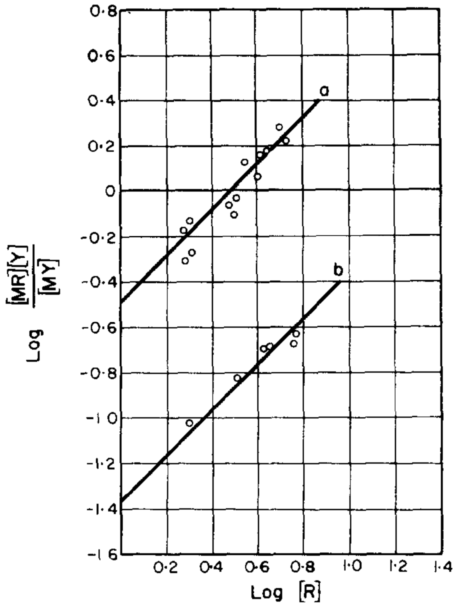


FIG. 3.—Graphical determination of stability constants [equation (6a)] of:
(a) Cu^{2+} with Dowex A-1,
(b) Ni^{2+} with Dowex A-1.

and of unit slope, which proves the correctness of the proposed mechanism [equations (4) and (5)] and also the fact that a ligand of the type HEDTA does not enter the resin. A further conclusion to be drawn is that Dowex A-1 behaves similarly to the complexation agents in the solution, and that its property to bind the metals to the solid phase makes it a convenient and effective means for the study of complexation mechanisms.

EXPERIMENTAL

Reagents

0·1*M* *Standard copper solution:* Prepared by dissolving 7·594 g of reagent-grade copper^{II} oxide in nitric acid (1 : 1), evaporating excess acid and making up to 1 litre.

0·1*M* *Standard nickel nitrate solution:* Prepared by dissolving 29·08 g of reagent grade $Ni(NO_3)_2{\cdot}6H_2O$ in distilled water and making up to 1 litre.

0·1*M* *Standard EDTA solution:* Prepared by dissolving 37·21 g of pure disodium dihydrogen ethylenediaminetetra-acetate dihydrate in distilled water and making up to 1 litre.

Complexing agents

Dowex A-1 chelating resin was prepared in the sodium form from the Dow Chemical Co. product and dried at 100°. Glycine, monosodium glutamate, iminodiacetic acid (IDAA) and *N*-hydroxyethylenediaminetriacetic acid (HEDTA) were used as analytical-grade solids.

Procedure for distribution measurements of cations from solutions containing complexing ligands (Figs. 1 *and* 2)

Weighed portions of the dried sodium form of the resin (exactly 500 mg) were placed into 250-ml beakers. To each beaker were added 100 ml of solution containing 1 mmole of copper or nickel ion and varying quantities of the complexing ligands (5–40 mmole). The pH of all solutions was adjusted to 8·5 to diminish the "pH effect" (the effect of the hydrogen ions on the stability of the complexes). The solutions were magnetically stirred for 2 hr in a water bath of 70° and for a further 2 hr at room temperature. Experience has shown that heating considerably speeds up the reaction. Without heating, equilibrium is reached after not less than 17–18 hr. After equilibrium the phases were separated at room temperature (23–27°) by means of filtration and the metal ions eluted from the resin with 6*M* nitric acid. Copper was determined polarographically with EDTA,[6] and nickel gravimetrically with dimethylglyoxime.

Knowing the general quantity of metal ions and ligand introduced into the system and the quantity of the metal ions adsorbed by the resin, all of the other quantities required for the construction of Figs. 1 and 2 may be calculated.

Procedure for determination of stability constants

The experimental set-up is identical with that described in the previous paragraph, with the exception that because log (R) appears in the abscissa of Fig. 3, different quantities of resin had to be weighed. Table I shows the concentrations of the different components with which the required data for line (a) of Fig. 3 were obtained.

RESULTS

Table II summarises the numerical results obtained for the stability constants of the mixed metal-ligand-resin complexes and of the hydrated nickel and copper ions with Dowex A-1. For comparison, stability constants of these metals with the same ligands (IDAA, glycine, glutamic acid and HEDTA) in aqueous solutions, taken from the literature, are also quoted.

The constants for reactions of the type $ML + R \rightleftharpoons MLR$ were calculated from the intercepts with the x-axis in Figs. 1 and 2, utilising equation (3a).

The constants for reactions of the type $M + L + R \rightleftharpoons MLR$ were taken as the sum of two reactions

$$M + L \rightleftharpoons ML \text{ (from the literature)}$$

$$ML + R \rightleftharpoons MLR.$$

The constants for reactions of the type $M + R \rightleftharpoons MR$ were calculated from the intercepts with the y-axis in Fig. 3.

From the numerical results shown in Table II two important conclusions may be drawn:

(1) The stability constants of mixed complexes of the type MLR are higher than the sum of the stepwise complexation constants of the metals with the ligands in the solution. This was also proved for the mixed complexes in aqueous solution of the metal chelonates with ammonia and the hydroxyl and hydrogen ions, the stability of which is greater than that of the pure metal chelonates.[14]

(2) The stability constants of complexes of the type MR are lower than those of the corresponding metals with HEDTA, but higher than the sum of the stability

constants of the metals with IDAA in aqueous solution. The reason for this is that in an aqueous solution binding to IDAA is accomplished in two steps, but in the resin in one step only.

CONCLUSION

In this work an attempt has been made to extend the general knowledge of chelating ion exchangers as regards their structure and to obtain information on the stability of the complexes formed between two transition metals and Dowex-A1. A connection has been shown to exist between complexation in solution and the adsorbability of the metal ions on the resin. The adsorption of ligands on the resin has been proved quantitatively.

The experimental results obtained in this work may be obtained by other experimental set-ups. Because the ligands used are of high molecular weight, data on ligand sorption may be inferred from measuring the increase in weight of the resin after adsorption. Another possibility is to use ligands labelled with carbon-14 and to measure their activity in the resin. Some tentative experiments were made in these two directions, but the method of graphic correlations appeared to be both the most accurate and the simplest.

Acknowledgements—The authors wish to express their grateful appreciation to Prof. E. A. Halevi for his invaluable help in interpreting the results and in clarifying theoretical aspects in the course of numerous discussions.

Zusammenfassung—Eigenschaften und Verhalten des chelatbildenden Ionenaustauschers Dowex A-1 wurden im Kontakt mit einer wäßrigen Lösung untersucht, die komplex an Aminocarbonsäuren gebundene Metallionen enthielt. Die Stabilitätskonstanten der Metallkomplexe des Harzes wurden bestimmt sowie die Struktur der Komplexe aus Metallionen, Harz und Liganden. Dowex A-1 verhält sich wie ein fester Komplexbildner und gibt mit Metallionen stabile 1:1-Komplexe.

Résumé—On a étudié les propriétés et le comportement de l'échangeur d'ions chélatant Dowex A-1, lorsqu'il est en contact avec une solution aqueuse contenant des ions métalliques fixés par coordination à des groupes aminocarboxyliques. On a déterminé les constantes de stabilité des complexes que donnent les ions métalliques avec la résine, ainsi que la structure des complexes formés par les ions métalliques, la résine et les agents coordinants dans la solution. La Dowex A-1 se comporte comme un agent complexant solide, et forme des complexes stables 1:1 avec les ions métalliques.

(*Received* 14 *April* 1964. *Accepted* 25 *May* 1964)

Summary—A study has been made of the oxidation of manganese(II) and chromium(III) solutions by silver(II) oxide in perchloric acid medium. Both the efficiency and the rate of the oxidation process were found to vary with the concentration of reductant, the amount of AgO added, the temperature, the acidity and the concentration of univalent silver ions in the solution. The inefficiency of the oxidation process can be attributed to the simultaneous formation of oxygen. The results are discussed in terms of a possible reaction mechanism, and the optimum conditions for oxidations using AgO are indicated.

INTRODUCTION

MOST titrimetric methods for the determination of manganese and chromium recommend pre-oxidation of these elements by ammonium persulphate in the presence of silver(I) ion as catalyst. The nature of the silver intermediate in these oxidations is not yet established. There is evidence to support both a bivalent and a tervalent species[1] and it has been suggested that the two higher valency silver species may be related through the equilibrium:

$$Ag^{3+} + Ag^{+} \rightleftharpoons 2Ag^{2+}.$$

The silver(II) ion in solution is a powerful oxidising agent and in the cold almost instantaneously oxidises manganous salts to permanganate[2] and chromic salts to chromate.[3] The bivalent silver ion is also reduced by water, yielding oxygen and silver(I) ion. The rate of reduction by water has been found to be dependent on the concentration and nature of the acid present.[4,5] Dissolution of silver(II) oxide in acids yields bivalent silver ions.[6]

The use of silver(II) oxide as an oxidimetric reagent for the determination of manganese, cerium and chromium has been examined by Lingane and Davis.[7] Procedures based on this reagent were found to be faster and more convenient than the classical procedures, and excellent results were obtained in determinations of manganese and chromium in aluminium and iron(II) alloys. Before this study, AgO had been used in microanalysis by Kimira and Murakim[8] for the determination of manganese and cerium, and by Tanaka[9,10] for the determination of chromium, manganese and vanadium.

These applications indicate the probable value of silver(II) oxide as an analytical reagent, but more fundamental information on oxidations by this reagent is required. This paper describes the results obtained in a study of the oxidation by silver(II) oxide of manganese(II) and chromium(III) salts in perchloric acid solution. Perchloric acid was chosen as the solvent medium to avoid complications, such as the tendency of chromium salts to form sulphato complexes in sulphuric acid solutions, and the tendency of argentic silver to form nitrate complexes in nitric acid solutions.[4]

EXPERIMENTAL

Reagents

The silver(II) oxide used was prepared according to the directions of Hammer and Kleinberg.[11] Standard manganese(II) solutions were prepared from May and Baker R-grade manganese sulphate. The solutions were standardised by oxidation to permanganate with potassium periodate, followed by spectrophotometric measurement of colour intensity.

Chromium(III) perchlorate solutions were prepared by dissolving freshly precipitated hydrated chromium(III) oxide in dilute perchloric acid solutions. The solutions were standardised colorimetrically after oxidation of the chromium by ammonium persulphate using silver ion catalyst. The excess acid present was determined by titration against standard borax solution.

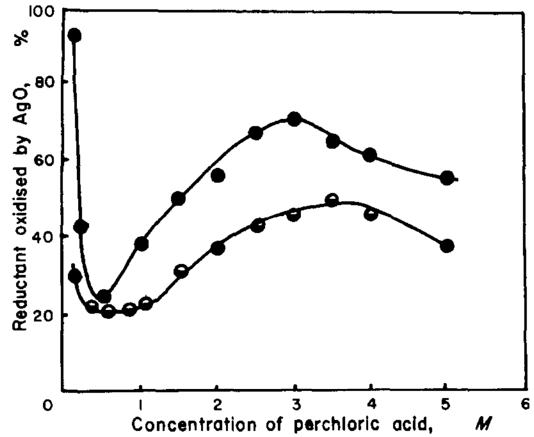

FIG. 1.—The effect of acidity on the amount of metal ion oxidised.
⊖—0·55 mg of Mn^{2+} treated with 0·021 g of AgO.
●—0·70 mg of Cr^{3+} treated with 0·032 g of AgO.

Perchloric acid solutions of differing concentrations were prepared by dilution of May and Baker 61% and 72% R-grade perchloric acid. The solutions were standardised against standard borax solution.

Apparatus

The apparatus used in the investigation was a water-jacketed reaction cell, fitted with a drain tap, and stirred by a magnetic stirrer. During the studies water was circulated around the cell from a constant temperature tank.

A Coleman Model 14 Spectrophotometer and a Unicam SP 500 Spectrophotometer were used for colorimetric measurements.

Procedure

For equilibrium studies, reaction mixtures were prepared containing varying amounts of reducing agent (0·004–0·050 mg/ml for manganese and 0·0075–0·048 mg/ml for chromium) and varying amounts of acid (0·1–5·5*M*).

Aliquots (25 ml) of these reaction mixtures were added to the thermostatted reaction cell and stirred to reach thermal equilibrium. Varying amounts of AgO (0·004–0·085 g for manganese and 0·007–0·145 g for chromium) were weighed into small plastic boats. These boats were placed on the surface of the solutions and were subsequently submerged by the stirring action. When the AgO had completely dissolved, the resulting solutions were run off into a receiving vessel and the intensity of colour was measured with a spectrophotometer. The intensity of the permanganate ion was measured at 545 mμ in the Coleman instrument and the dichromate ion was measured at 390 mμ using the Unicam SP 500 instrument. The concentrations of the oxidised products were determined from appropriate calibration graphs. The results of these studies are summarised in Figs. 1 and 2.

Varying amounts of silver(I) ion were added to a series of solutions containing a fixed amount of manganese(II) or chromium(III) salts in solutions 3·0–3·5*M* in respect of perchloric acid. The results obtained on adding a constant amount of AgO are summarised in Fig. 3.

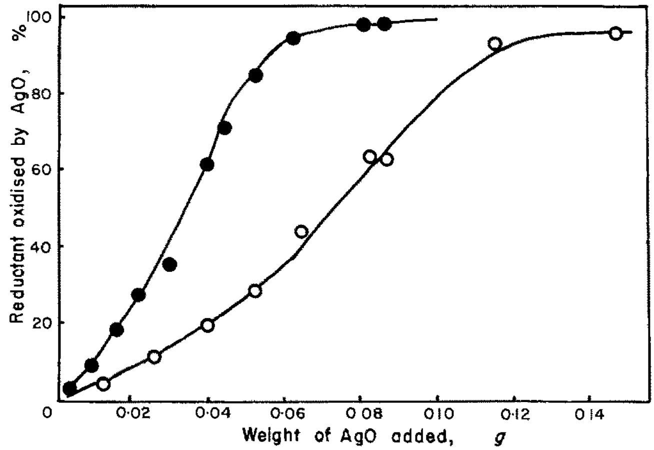

FIG. 2.—The effect of varying weights of silver(II) oxide on the percentage of metal salt oxidised.

●—0·85 mg of Mn^{2+} in 50 ml of 3·5M $HClO_4$; t = 25°; theoretical weight of AgO required for complete oxidation 0·010 g.

○—1·0 mg of Cr^{3+} in 50 ml of 3·0M $HClO_4$; t = 20°; theoretical weight of AgO required for complete oxidation 0·007 g.

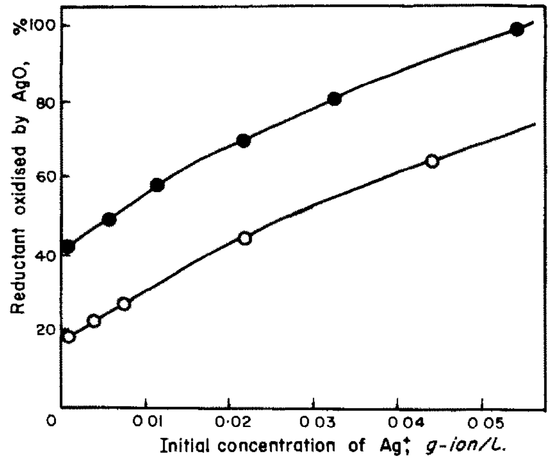

FIG. 3.—The effect of adding silver(I) ion on the percentage of metal salt oxidised.

○—0·5 mg of Mn^{2+} in 25 ml of 1M $HClO_4$ + 0·022 g of AgO; t = 25°.

●—0·7 mg of Cr^{3+} in 25 ml of 1M $HClO_4$ + 0·037 g of AgO; t = 20°.

Finally, oxidations were carried out at different temperatures and the effect of temperature is shown in Fig. 4.

Some studies of the rate of oxidation of the chromium salt at 5° were made, using solutions having acidities varying in concentration from 0·2M to 1·0M. A weighed amount of AgO was added to the solutions in the reaction cell and a sample was extracted from the cell after varying periods of time by means of a pipette fitted with a cotton wool plug to trap particles of unreacted solid. The absorbance of each sample extracted was measured at the appropriate wavelength, and the amount of metal ion oxidised was determined from the calibration graph. These kinetic results were recorded and subsequently treated as a pseudo first order reaction in order to yield the values of apparent rate constants listed in Table I.

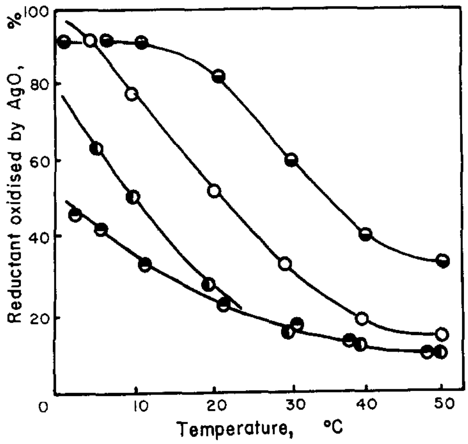

FIG. 4.—The effect of temperature on the percentage of metal salt oxidised.

0·090	5·44	0·40	4·54	11·1
0·110	5·44	0·40	4·29	14·5

RESULTS

Although, stoichiometrically, sufficient AgO was added to each solution to oxidise completely all the manganese or chromium present, complete oxidation of these species was only achieved in the presence of a large excess of reagent. To emphasise the effect, the results have been recorded in the form of percentage of the original manganese or chromium ion oxidised to permanganate or chromate.

The effect of acid concentration on the percentage conversion is shown in Fig. 1. Similar curves, displaced vertically, were obtained on adding different weights of AgO. Maximum conversion was obtained with solutions which were either 0·1–0·2*M* or 3·0–3·5*M* in respect of perchloric acid. In the former case, the rate of solution of solid was slow (5–15 min) as compared with seconds for the more concentrated solutions.

The effect of adding varying weights of AgO to a given solution is indicated by the typical results shown in Fig. 2. Total conversion was obtained if sufficient excess of oxidant was added. An interesting side effect was observed in manganese studies using sulphuric acid of equivalent strength. Where the Mn^{2+} was not fully oxidised to permanganate, there was a gradual fading of the initial purple colour, and the formation of a brown precipitate of MnO_2, indicating that the remaining Mn^{2+} in the presence of Ag^+ was reducing the oxidised species. This effect was not so marked using perchloric acid solutions.

For a given set of conditions, the percentage conversion was considerably increased by the addition of silver nitrate before oxidation, as shown by the results recorded in Fig. 3. The effect of an increase in temperature was to reduce the amount oxidised, as illustrated in Fig. 4.

In the kinetic studies, the oxidation of the chromium(III) ion approximated to a pseudo first order reaction if the ultimate amount of chromate formed was taken to represent the initial concentration of some species responsible for the formation of the chromate. On this basis, values for apparent rate constants under different conditions were calculated for comparison purposes, and these results are summarised in Table I. Initial rates of chromate formation for the varying conditions were estimated from the rate curves and these rates are shown in Table I also. The kinetic values are considered to be of limited accuracy, for it was necessary to separate the solid phase from the solution during collection of the sample, and because the time for complete reaction was only a matter of minutes, slight variations in the rate of sample collection through the filter introduced significant errors.

To obtain mathematical relationships between the results recorded in Table I, the varying sets of results were plotted against each other on log-log paper. In each case a linear relationship was obtained, and the slopes were measured to give the power dependence of the rate on the various factors. Combination of the results yielded the following expressions:

$$\text{Apparent rate constant } k = k_1 \,.\, [H^+]^{1.36} \,.\, \{AgO\}^{-0.77} \tag{1}$$

$$\text{Initial rate of formation } \left(\frac{dCrO_4}{dt}\right) k_i = k_2 \,.\, [H^+]^{1.48} \,.\, \{AgO\}^{0.74} \,.\, [Cr^{3+}]^{0.32} = k \,.\, (X)_i \tag{2}$$

where { } represents a measure of the amount of AgO added and X represents the unknown species considered to be the rate determining reactant in the pseudo first order reaction.

From equation (2) it may be suggested that

$$(X)_i = k_3 \,.\, [H^+]^{0.12} \,.\, \{AgO\}^{1.5} \,.\, [Cr^{3+}]^{0.32} \tag{3}$$

DISCUSSION

Calculations based on stoichiometric equations for the oxidation reactions indicated that only about 14% of the AgO added was used in oxidising manganese(II) to its higher valency state and only about 7% of the AgO added to the chromium solutions was responsible for chromate formation. These calculations show that most of the added AgO was reduced by some secondary process. Because the reaction mixtures effervesced greatly when the AgO was added, and solution of AgO in acid is known to liberate oxygen,[12] it can be accepted that the process responsible for the reduction of most of the added oxidant is the evolution of oxygen. Because this reaction predominates, any reduction in the rate of oxygen formation must increase the relative amount of manganese or chromium salt oxidised.

The reduction of Ag^{2+} by water to yield oxygen in perchloric acid solutions has been studied by Kirwin and co-workers.[5] The plot of apparent rate constant against acidity was found to yield a definite minimum at a perchloric acid concentration of $3{\cdot}0M$. This is the acid concentration at which oxidation of manganese and chromium salts was most efficient (Fig. 1). The rate of oxygen formation in perchloric acid solutions was found to be second order in respect of $[Ag^{2+}]$, inversely proportional to $[Ag^+][H^+]^2$ and related in a complex way to $[ClO_4^-]$. The increased yield of oxidised manganese and chromium salts observed on the addition of Ag^+ to the solutions (Fig. 3) can thus be attributed to the inhibition of the oxygen formation process. The effect of excess AgO (Fig. 2) may also be explained in part by the higher concentrations of Ag^+ formed on reduction of the excess oxidant.

The rate equation relating the evolution of oxygen to amount of AgO added is more complex than the equations obtained for solutions of silver(II) ion. Not only does dissolution of the solid in acid yield decreasing amounts of Ag^{2+}, but during the course of the reaction increasing amounts of the inhibiting species Ag^+ are formed. The mathematical expression obtained in a study of oxygen liberation on the addition of AgO to sulphuric acid solutions had the form[13]

$$dO_2/dt = K\,.\,[H^+]^{0.24}\,.\,\{AgO\}^{0.6} \tag{4}$$

The rate of oxygen formation became very slow at pH values approaching 3 and this would explain the marked increase in permanganate and chromate yields in solutions which were $0{\cdot}1$–$0{\cdot}2M$ in respect of perchloric acid. (Fig. 1).

An increase in temperature has a greater influence on the oxygen liberation process than on the other oxidation mechanisms. This is demonstrated by the effect of temperature on the amount of metal ion oxidised (Fig. 4).

The results recorded in Figs. 1–4 cannot be explained entirely on the basis of the influence of the various factors on the rate of oxygen formation, because, as indicated by equation (2), the rate of chromate formation is itself a complex function of at least three variables. The existence of the fractional terms indicates that the mechanism is complex and that each species may be involved in more than one reaction.

The oxidation of the chromium and manganese ions could occur in solution or on the surface of the solid. The production of chromate or permanganate in solution requires multiple collisions between higher valency silver ions and a hydrated chromium or manganese ion, and although this is feasible, reaction on the solid surface appears more probable. The initial rate of chromate formation was nearly linear in respect to the amount of solid added (Table I) for a given set of conditions, and this tends to support the idea of a surface reaction, because this relationship has been found to apply to heterogeneous reactions involving a species in solution and a solid catalyst.[14] A surface mechanism has previously been proposed to explain the oxidation of ammoniacal solutions by silver(II) oxide.[15]

Using the model of a heterogeneous reaction, the unknown species X can be considered to be an intermediate formed on the surface of the solid. From equation (3), the concentration of X is related to $[H^+]^{0.1}\,.\,\{AgO\}^{1.5}\,.\,[Cr^{3+}]^{0.3}$. The power in respect of Cr^{3+} can be explained in terms of an adsorption isotherm for this species on the surface of the solid; the small power term in respect of $[H^+]$ could arise from solution of Ag_2O residues on the surface or from suppression of hydrolysis of the chromium ion; and the fractional power in respect of AgO may merely reflect particle size variation in the solid. Because of the limited solubility of silver chromate, desorption of the oxidised product could be a rate-controlling step. Solution of the silver chromate would be retarded by univalent silver ions in solution and accelerated by protons. Such reactions are in agreement with the terms $[H^+]^{1.36} . \{AgO\}^{-0.77}$ found in the expression related to apparent rate constants [equation (1)].

CONCLUSIONS

Manganese and chromium salts can be quantitatively oxidised by the addition of excess silver(II) oxide, and the amount of excess required can be reduced greatly if the rate of the competing reaction, namely the liberation of oxygen, is reduced to a minimum.

The rate of oxygen liberation in nitric acid solutions is much slower than in sulphuric or perchloric acid,[4] hence the 2–5*M* nitric acid medium proposed by Lingane and Davis[7] is preferable on these grounds to the sulphuric acid solutions used by the earlier workers.[8–10] On the other hand, it is necessary to warm the nitric acid solutions to destroy excess reagent present as silver(II) nitrate complexes. It is also desirable to avoid the presence of nitric acid in oxidation-reduction titrations.

To use sulphuric or perchloric acid as the reaction medium requires alternative methods of retarding oxygen liberation. Methods available include lowering the temperature to a minimum, lowering the acidity, or adding univalent silver ion to the solution. Variation of the first two of these factors tends to increase the time required for oxidation, and therefore the preliminary addition of silver ion has much to recommend it. On the assumption that the reaction is a surface process, greater efficiency of oxidation should also result from smaller particle size for the AgO and more vigorous stirring.

It must be emphasised at this point that the efficiency of excess silver(II) oxide in oxidising manganous and chromic salts was clearly demonstrated by Lingane and Davis.[7] Because excess reagent can be destroyed by warming the solution, the method is preferable to that using sodium bismuthate, where excess has to be removed by filtration, and is preferable to the use of ammonium persulphate with silver ion as catalyst because in this case excess persulphate ion has to be destroyed by boiling.

The theoretical study described in this paper gives some information on the mechanism of the oxidation process and suggests ways in which the amount of silver(II) oxide required to give the desired excess can be reduced, but it should not deter workers from using the method of Lingane and Davis, who solved the problems described in this paper in a practical manner.

Zusammenfassung—Die Oxydation von Mangan(II)- und Chrom(III)-Lösungen durch Silber(II)-oxyd in überchlorsaurer Lösung wurde untersucht. Ausbeute und Geschwindigkeit der Oxydation ändern sich mit der Konzentration des Reduktionsmittels, der zugesetzten AgO-Menge, Temperatur, und Konzentration von Säure und einwertigen Silber in der Lösung. Schlechte Ausbeuten bei der Oxydation können der Bildung von Sauerstoff zugeschrieben werden.

Die Ergebnisse werden im Sinne eines möglichen Reaktionsmechanismus diskutiert und die besten Arbeitsbedingungen für Oxydationen mit AgO angegeben.

Résume—On a étudié l'oxydation de solutions de manganèse(II) et chrome(III) par l'oxyde d'argent(II) en milieu acide perchlorique. On a trouvé que l'efficacité, et la vitesse du processus d'oxydation, varient toutes deux avec la concentration du réducteur, la quantité d'AgO ajouté, la température, l'acidité, et la concentration en ions argent monovalent dans la solution. L'inefficacité du procédé d'oxydation peut être attribuée à la formation simultanée d'oxygène. On discute des résultats du point de vue mécanisme réactionnel possible, et indique les conditions optimales pour les oxydations utilisant AgO.

SOME PROBLEMS IN THE ANALYSIS OF GASEOUS DECOMPOSITION PRODUCTS*

A CRITICAL EVALUATION

PAUL D. GARN†
Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey, U.S.A.

(*Received* 15 *April* 1964. *Accepted* 16 *June* 1964)

Summary—Whether the analysis of effluent gases during thermal decompositions is used to elucidate the progress or the mechanism of the decompositions, or to characterise the specimen, certain problems must be dealt with. These problems, involving heating, the analysis of the products, and the compromises which must be made in simultaneous measurements, are discussed.

INTRODUCTION

THE analysis of effluent gases during thermal decompositions can be of great help in elucidating the progress or the mechanism of the decomposition. In some cases, too, the decomposition products may be used to characterise or identify the specimen. For whatever purpose the analysis is carried out, certain problems must be overcome. These problems relate to the heating, to the analysis of the products and to the compromises which must be made in simultaneous measurements.

HEATING OF SPECIMENS

The solid material being studied has been or can be heated in several ways, and for multiple-purpose studies as well as specifically for the analysis of the decomposition products. The most common of the multiple determinations would be simultaneous differential thermal analysis and effluence analysis; the effluence from a thermogravimetric analysis could also be analysed, but this will invariably be accompanied by considerable dilution. In any event, in such simultaneous determinations the heating programme and heating conditions are fairly rigidly prescribed by the requirements of the other technique. In those cases in which the sample is heated specifically for analysis of gaseous decomposition products, a fairly wide range of heating conditions can be and have been used. Examples could include slow heating of a rather massive sample to some fixed temperature or, at the other extreme, flash heating by use of a high-intensity source of visible and infrared radiation. A common technique, intermediate between these, is the practice of placing the sample on a heater (wire) or in a heater specially formed, then applying a predetermined voltage to the heater so that the specimen heats in an uncontrolled but approximately reproducible manner. In contrast to this latter, the specimen can be heated in some programmed manner, as would be typical in the simultaneous determinations.

SIMULTANEOUS DETERMINATIONS

Let us use as a starting point the present author's work with some simultaneous determinations. This has been, of late, generally concerned with some form of thermal analysis, so that simultaneous differential thermal analysis and effluence analysis would have obvious benefits. In previously reported work,[1] the author has connected a dynamic-atmosphere differential thermal analyser to various devices for detecting gaseous products and/or establishing the nature of the products.

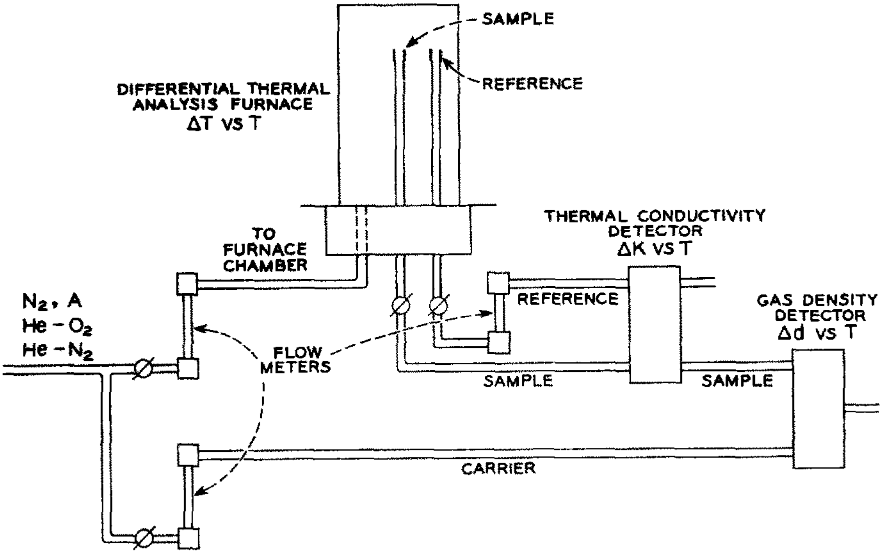

FIG. 1.—Combination differential thermal analysis and double effluence analysis. The transient changes in the sample stream are detected in chromatographic-type analysers.

One arrangement used is shown in Fig. 1. In this arrangement a gas is supplied to the furnace chamber under sufficient pressure to cause a reasonable flow—this flow varies with the type of experiment—downward through the sample and through the reference materials. The gas passing through the reference is used as the reference gas in the thermal conductivity detector, and the gas passing through the sample is compared with it. Any gaseous decomposition product whose thermal conductivity is different from that of the "chamber gas" will then produce in the thermal conductivity detector a different cooling effect from that produced by the pure chamber gas during the time that the product gas is passing through the thermal conductivity detector. The magnitude of the differential signal from the thermal conductivity detector is, at low concentrations, proportional to the quantity of the product gas passing through at the moment, so that integration of the area under a total deflection is a measure of the quantity of the gas evolved, provided that the nature of the gas is known. In this arrangement, the gas which has passed through the sample then goes into the gas density detector. The gas density detector has the advantage (over the thermal conductivity detector) that it is not only a quantitative measuring device, but is to some extent qualitative. It has a further advantage that the sensitivity of the detection can be adjusted by judicious selection of carrier gas, because the density or "apparent molecular weight" is the only property of importance in the measurement.

The gas density detector depends for its operation on the effect of minor changes of flow in the vertical column on the total flow in tubes connected to the top and bottom of a vertical column. Let us assume that in this device (Fig. 1) a steady-state flow of sample and carrier gases into their ports has been established so that we have a steady-state cooling of the detector elements. Now at some point upstream we inject a small quantity of a product gas, as we might in the normal course of a decomposition in differential thermal analysis. If this product gas is heavier than the carrier gas, the change in density, of course, will be an increase and, hence, the sample plus carrier gas will tend to flow downward to a greater extent than upward. This downward flow will decrease slightly the flow in the lower supply tube (Fig. 1 of ref. cited) and increase slightly the flow in the upper supply tube; this change in flow in the supply tubes produces a change in the cooling effect on the detector elements, an increase in the upper and a decrease on the lower. The differential flow at any moment is proportional to the difference in density of the sample plus carrier gas from that of the sample gas alone, permitting, of course, a quantitative measurement of the material passing through (assuming that it is a single gas). Note, however, that the density of the sample plus carrier gas is dependent not only on the quantity of sample but also on the nature of the sample; *i.e.*, that a gas which, pure, is only slightly heavier than the carrier gas will at a given level of concentration produce some fixed differential flow, but a gas substantially heavier than the carrier gas will at the same concentration produce a significantly greater differential flow. Because of this, qualitative as well as quantitative information can be obtained. If the sample gas is unknown, a second experiment with a carrier gas of different density will provide results for calculation of the real or apparent molecular weight of the sample. (If the sample is a mixture of gases, the apparent density will be dependent on their relative proportions and their relative densities in the pure state.) If the number of possibilities is quite limited, a simpler identification is possible by bracketing the density of the suspected gas in two runs; for example, if there is reason to believe that the specimen gives off oxygen when heated in an inert atmosphere, an experiment using nitrogen as the carrier gas will show that the sample is more dense, and a second experiment using argon will show that the sample gas is less dense; if necessary, direct comparison of the areas will show whether or not the apparent molecular weight of the gas is 32.

The present author has used this type of identification in several cases of which two may be cited. In some studies of cobalt oxalate hydrate the nature of the second step was not known with certainty. Most oxalates decompose in a non-oxidising atmosphere by loss of carbon monoxide to go to the corresponding carbonate. A cobalt oxalate resulting from the heating of the dihydrate decomposed *ca.* 400° to yield what appeared to be a finely divided metal. In closed-chamber differential thermal analysis experiments with air as the furnace atmosphere, this metal powder had, around the opening along the support tube, evidence of oxide formation. The question was resolved by differential density analysis using nitrogen as the carrier gas. If the cobalt oxalate decomposes directly to the metal, 2 moles of carbon dioxide are released and because 2 moles of water are also released the areas should be in direct relation to the density difference. The density difference between water and nitrogen, assuming ideal gas, *etc.*, is 28–18 or 10 g per mole; the difference between carbon dioxide and nitrogen would be 44–28 or 16 g per mole. The ratio of areas then should be 1·6 if the decomposition is directly to the metal. Within a few percent, attributable to experimental error, this is the result obtained. Note that in this experiment carbon monoxide, having a molecular weight of 28, would not have shown its presence at all, because its density is the same as that of nitrogen.

As part of the same work, nitrogen and argon were used to establish the evolution of oxygen during the decomposition of lanthanum oxalate hydrate. Some carbon had been found with the lanthanum oxide when the material was heated in an inert atmosphere. Above 700° a gas heavier than nitrogen, but lighter than argon, was evolved. In another experiment, reported therein but using oxygen as the dynamic gas, the arrangement shown in Fig. 1 was used to obtain simultaneous measurements of ΔT, Δd and ΔK as lanthanum oxalate hydrate was decomposed. The thermal conductivity measurements are not very useful, because carbon monoxide does not differ enough from oxygen. Carbon dioxide could be detected, but not with nearly the sensitivity obtainable in a helium or hydrogen stream.

Although these particular sets of curves were obtained during single runs with all measurements being made simultaneously, this is not by any means a necessary procedure. Separate experiments would be just as instructive, and possibly experimentally more convenient, so long as they were planned properly.

GAS CHROMATOGRAPHY

In many cases a more specific identification than described above may be needed, because at some stages in the decomposition more than one product may be given off. For such cases, the addition of gas chromatography is useful. Gas chromatography, as ordinarily practised, would be relatively ineffective; it would measure all the decomposition products up to the time of sampling. Specific identification of the product of a particular reaction requires that the sampling be made for that reaction alone; *i.e.*, any reaction products from previous decompositions should already have been removed from the site of sampling. This can be done readily by an arrangement such as that shown in Fig. 2. In this system a furnace like that shown in Fig. 1 is used to carry out the thermal decomposition. The carrier gas which passes through the sample, may, if desired, be passed through a thermal conductivity cell for a continuous and general survey of decomposition products, but, more important, it passes through a pair of sampling valves with, in some cases, an interposed water trap. These sampling valves operate at programmed intervals to withdraw samples of gas from the stream and pass them through chromatographic columns and detectors. The programming is done by trial and error. For the Fluoropak column, and separately for the split column flow, conditions were determined which gave adequate separation. An adjustable cam timer was then connected to the sampling valves so that during each revolution one sampling valve would open for 5 sec, then close. The oven temperature, the flow rates and the sampling times were chosen for each type of experiment specifically to permit rapid sampling. In effect, each sampling occurs soon after the last expected peak from the previous sampling.

The Fluoropak column, when used, permits all non-polar and not very polar materials to run through rapidly, but holds up the water long enough to give separation and permit measurement.

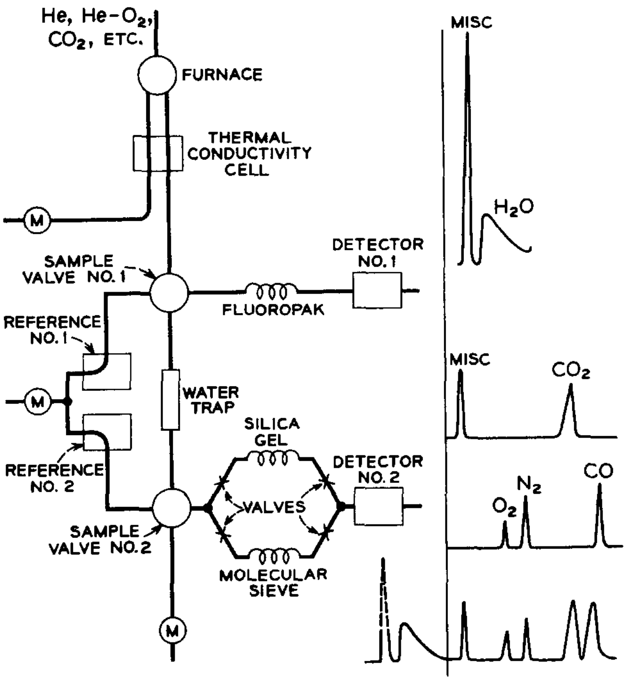

Fig. 2.—Gas train and switching for repetitive dual-sampling chromatography. Sample valve No. 1 transfers a 3-ml sample and No. 2 a 5-ml sample. Sampling interruptions have been deleted in copying (see Fig. 3.)

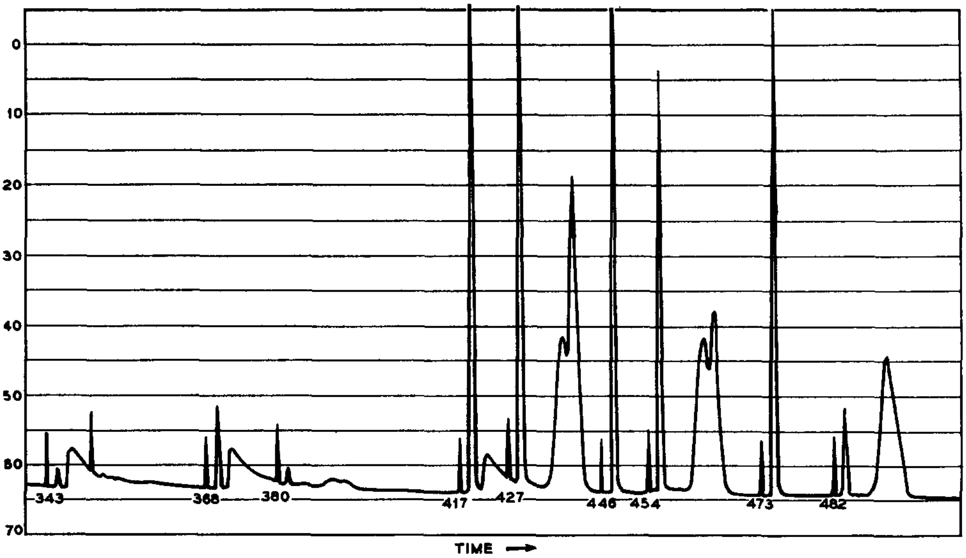

Fig. 3.—Chart section showing a number of sampling cycles and the temperature at which the sample was taken.

The temperature at the moment of sampling is measured and the reaction occurring at that temperature thus described. Alternate samplings, *e.g.*, 417° and 446°, are into the Fluoropak column; the others go through the split column.

The second sampling valve in turn withdraws a specimen from the stream and directs it through a split column to a second detector. This split column has silica gel in the one side and a molecular sieve in the other; the silica gel holds up the carbon dioxide but passes the other permanent gases through rapidly, and the molecular sieve separates the permanent gases. Proper adjustment of the relative flows permits appearance of the carbon dioxide conveniently in the interval of time between the appearance of nitrogen and of carbon monoxide from the molecular sieve. The chromatogram results from the presence of all the gases, but is shown at the right for each column and at the bottom for a complete cycle. Fig. 3 shows a chart section with a number of cycles, the appearance and disappearance of peaks reflecting the beginning and subsidence of reactions as the specimen material is heated.

Examination of several cycles of the chromatographic analysis permits, then, the following of a reaction or, more important, a series of reactions by the relative heights or areas of peaks. Fig. 4 shows such a series. The left-hand analyses are solely for water; those to their immediate right are the associated samplings for the permanent gases and those at the far right a subsequent series of analyses for the permanent gases. No water appeared in the later analyses for water so these are not shown. Note that even in the water analysis an indication of the increasing concentration of other gases was apparent from the growth of the peak just before the rather broad water peak. Similarly, even though the carbon dioxide and carbon monoxide peaks run together at high concentrations, the sharp peak shortly after the sampling, resulting from the permanent gases other than carbon dioxide passing rapidly through the silica gel column, gives an indication of the concentration of carbon monoxide even when the peak is almost obscured by the carbon dioxide. At the higher temperatures, carbon dioxide evolution ceases and carbon monoxide is the only product detected.

The results from one run are tabulated in Fig. 5 along with the differential thermal analysis and differential conductivity curves. The water is given off over a rather wide range, and the peaks are poorly defined in this dynamic atmosphere of helium; then the decomposition of oxalate occurs very sharply, and the interrupted peak on the thermal-conductivity curve can be related to the more or less continual evolution of carbon dioxide coupled with the quickly-terminated evolution of carbon monoxide. The new appearance of carbon monoxide at higher temperatures is also apparent. The high drift in the differential thermal analysis signal is a result of sintering of the specimen and consequent change in the heat transfer from the side to the centre of the specimen. One might conclude from these particular curves that ΔK is a more sensitive measurement than ΔT, and in some cases this could be justified. Consider, however, that this particular experiment used a helium atmosphere and the thermal conductivity change is at a maximum; a dynamic atmosphere of helium would seldom be picked for differential thermal analysis (*vide infra*). Further, differential thermal analysis detects changes of state which the thermal conductivity of the gas stream obviously cannot reflect.

Some of the earlier exploratory work combining chromatography with differential thermal analysis shows the hazard of vitiating results from one of the techniques. Fig. 6 shows some differential thermal analysis curves for an ocean sediment specimen obtained with air and with helium as dynamic atmospheres. While the analysis in helium was being performed, a technician took chromatographic samples by manual operation of a sampling valve at regular intervals.[2] There is no difficulty in following the appearance of carbon monoxide and the appearance and virtual disappearance of carbon dioxide in the decomposition products, but there is significant difficulty in finding any thermal effects in the helium run to which to relate the gas evolution.

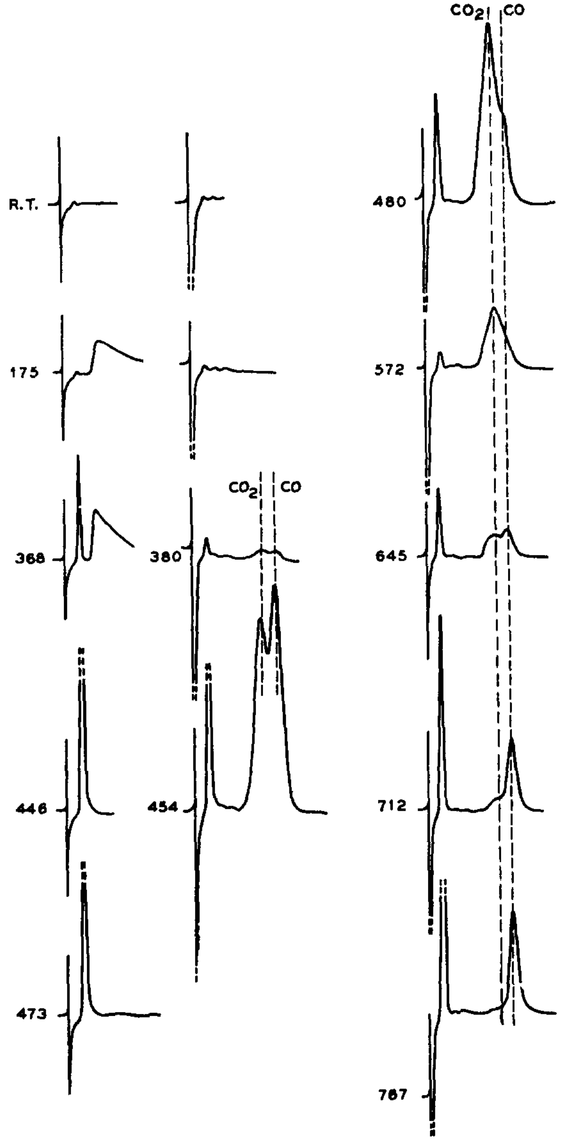

Fig. 4.—Reproduction of several chromatographic analyses from the chart of which Fig. 3 showed a part. The temperatures of sampling are indicated. The appearance and disappearance of specific products can be followed easily.

One may not conclude that combinations of techniques will necessarily be useful. Simultaneous determinations are of benefit only under those conditions in which neither technique is greatly compromised. The planning of separate experiments for each technique will often be more fruitful.

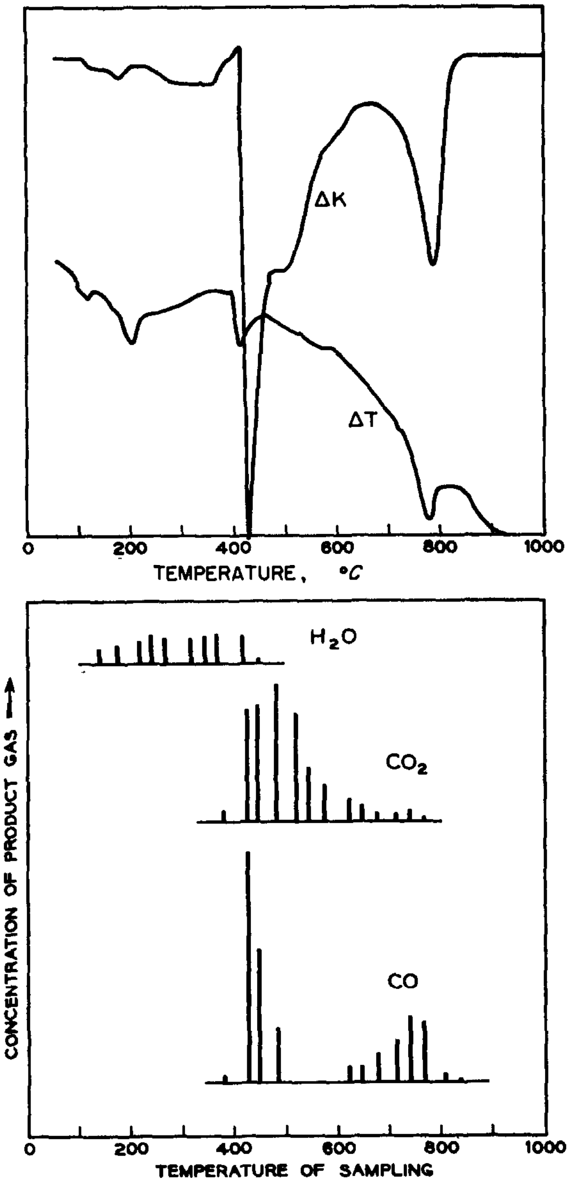

FIG. 5.—Tabulated chromatographic peak heights related to the simultaneously-obtained differential thermal analysis and thermal conductivity analysis of the effluent stream.

The sudden appearance of carbon monoxide and dioxide is indicated also by the plots. The curves, however, give no hint of the relative amounts of CO_2 and CO.

CRITIQUE

With all the problems of simultaneous analysis, and the distinct probability that separate experiments could be better or more instructive, the simultaneous-determinations technique is generally superior to point-by-point sampling for the same types of analyses. Let us consider the technique devised by Murphy, Hill and Schacher[3] in which a differential thermal analysis was performed of poly(vinyl chloride) in an evacuated vessel which had connections also to some previously evacuated sampling tubes for mass spectrometry. The object is, of course, to determine the identity of the gaseous products coming off at various stages of the heating, but consider the required procedure. One must first make a trial run in order to establish the temperatures which may be of interest. After selecting the sampling temperatures a re-run must be made with operator monitoring in order that the selected samples may be taken at the proper time; and finally, the gaseous samples taken must be conveyed to the other instrument, in this case a mass spectrometer, and analysed individually. All of this is perfectly possible, and may be justified on the basis of the need for information about a particular sample; but there immediately arises the problem of the need for an operator to make a judgment on probably inadequate results. That is, on a specimen with which the operator is not familiar, a single thermogram is seldom sufficient to establish the identity of a given reaction.

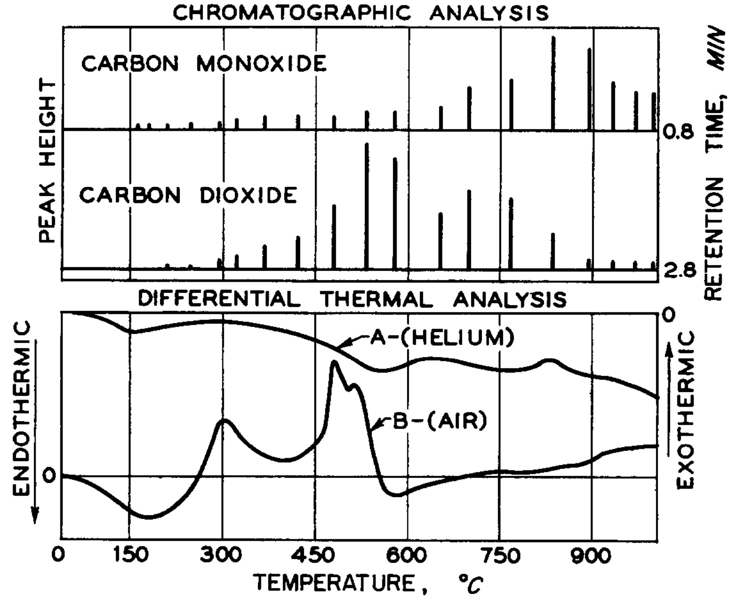

FIG. 6.—Differential thermal analyses of an ocean sediment related to the effluence analysis. The appearance and disappearance of the gases can be related to the peaks of curve *A*, but curve *B* bears no appreciable resemblance because the reactions are quite different.

In this technique the choice of sampling points is obviously extremely important, yet the example shown by Murphy *et al.*, involves what is apparently an error in choice. They sampled at 300 and 400°, the lower temperature being at the peak of an endothermic reaction and the higher temperature at what they describe as a flat exotherm. They found, as they expected, hydrogen chloride evolved at 300°; and we may infer that they had expected similar evolution at 400° for they reported that no hydrogen chloride was evolved, without specifying the presence or absence of any other material. The absence of any material evolved in the 400° region should not be a surprise; that region is almost certainly not an exotherm or caused by any reaction at all. It is far more likely a simple change in base line resulting from the change in thermal properties of the specimen. The important point here is not that their information needs re-interpretation, but that such an error is easily possible with point-by-point sampling techniques.

Let us now consider an arrangement in which the gas given off by a heated specimen is swept by a carrier gas into a thermal conductivity detector. In the arrangement described by Ayres and Bens,[4] the sample cells are test-tubes set in a metal block. A differential thermal analysis is performed on the specimen, and the plot from the thermal conductivity cell is related to the differential thermal analysis plot. The carrier gas passes through a preheater and then flows over the sample and reference specimens and thence into the detector cell; note that the gas does not pass *through* the specimen, so the atmosphere surrounding the particles will vary depending on the nature of the product gas and the depth of the particle within the total specimen. The upper layers are continually exposed to an atmosphere of essentially pure helium, but, during a decomposition, the helium will be displaced by the product gas and, especially near the bottom, the particle will experience an enrichment of the product gas concentration.

The effect of the enrichment within the bulk of the specimen will vary, depending on the nature of the sample. Reactions having any appreciable semblance of reversibility will be spread over a range of temperatures because of the atmospheric effect, but yet not to the same extent as would be the case in the absence of a moving atmosphere, because we can consider any product gas to be diffusing outward into a zero level concentration above the specimen. For a reversible reaction, then, this technique will yield differential thermal analysis curves intermediate between those obtained in static atmospheres and those in dynamic atmospheres, as cited previously. The effluent gas analysis will closely parallel the differential thermal analysis curve. Irreversible decompositions, such as the perchlorate decomposition and many organic decompositions, will be virtually unaffected by any movement of the atmosphere, because these reactions proceed rapidly when the decomposition temperature is reached, regardless of the ambient atmosphere. The detection of the effluent gas can be expected to agree less well than in the case of the reversible reactions, because a tailing off is essentially certain to follow a rapid exothermic reaction; in addition to the effect from burst of gaseous products spewed into the carrier stream, these products displace the carrier gas from the nooks and crannies within the specimen, and some reasonable interval of time will be required for this material to diffuse out of the specimen and into the gas stream. In reversible reactions, under this type of condition, there is very probably a diminution in the rate of formation of the product gases as their concentration increases and, towards the bottom of the sample vessel, material which has not reacted may yet exist after the peak temperature difference has passed. The return to the base line will be slow because of this continuing reaction, and during the same period these last portions of product gases will be diffusing out of the specimen and into the gas stream in ever-decreasing quantities; the effect in the gas detector is, then, rather similar to the differential thermal analysis peak.

Let us examine the results by Ayres and Bens using ammonium perchlorate, first reviewing the reactions of ammonium perchlorate under a small variety of conditions. Differential thermal analysis curves in various atmospheres were obtained by Stone;[5] in an ammonia atmosphere the entire decomposition occurs at one temperature, because the presence of the ammonia represses the initial decomposition. In any other gas a preliminary decomposition occurs which is slightly pressure-dependent. The final decomposition temperature remains the same. Note that this initial decomposition is not a *necessary* prelude to the exothermic decomposition. The evidence so far suggests that in the absence of ammonia this initial decomposition comprises the loss of all or part of the ammonia. We might predict either a double salt remaining at this stage or, if all the ammonia is lost, that the perchloric acid vapour pressure has not yet reached 1 atmosphere.

In vacuum the final decomposition is not exothermic at all. We may infer that the ammonium perchlorate decomposition products from the initial reaction volatilise and the material is swept out before decomposition.

In any case, the curve obtained by Ayres and Bens in helium would correspond to the third of Stone's curves, *i.e.*, the one obtained in nitrogen at 1 atmosphere. The difference in the nature of the flowing or dynamic gas between the two experiments is of no consequence, so long as the gas does not enter into any sort of reaction with the specimen. The drawn-out initial decomposition, and the tailing off of the gas evolution after the final decomposition, can be attributed to the manner of passing the gas across the sample as explained above.

Less volatile products will cause a rather different trouble, but the problem is apparently purely physical, and could be corrected by redesign of the apparatus. Ayres and Bens also show decomposition curves for nitroglycerine and a propellant. Note that at the upper extremes in temperature an evolution of gas appears to take place with no evidence of a thermal effect. This is more likely caused by the condensation of a decomposition residue in a cooler part of the glassware and subsequent vaporisation of the residue as the heating continues and that part of the glassware reaches a sufficiently high temperature.

Ayres and Bens called attention to the possible troubles from condensation; the present author's contribution is the delineation of events within the sample.

Another use of simultaneous differential thermal analysis and a form of effluence analysis was of a very special kind. Bussière and others[6] constructed an apparatus in which they could simultaneously perform differential thermal analysis, thermogravimetric analysis, and a measure of the emanation from radioactive thoron. Their work is based on the absorption of radioactive thoron along the interfaces between crystallites. The sample used was thorium oxalate hydrate. The radioactive decay of thorium produces thoron, (also radioactive), part of which escapes and part of which is trapped in the interfaces or interstices and, at best, moves slowly to the particle surface. When, however, the material undergoes a change of state, the disruption of the crystals permits more ready escape of the thoron from amongst the crystallites.

Bussière *et al.* passed a gas stream across their specimen and into a detector in which the radioactivity of this gas stream (from the thoron) was measured. Their results are not easily interpreted at first sight. The first dehydration is unambiguous; each of the measurements demonstrates an effect which we can accept as decomposition to the dehydrate, as stated by Bussière and others. The second weight loss and accompanying endotherm are clear enough, but there is no corresponding event in the emanation measurement. Further, in the final decomposition, not only does the thermogravimetric curve indicate a single, smooth-wave loss while the differential thermal analysis curve shows a pair of reactions, but the emanation curve even shows a decrease rather than the predicted increase.

The two-step final endotherm shown by the differential thermal analysis could be the decomposition of the oxalate, first to the carbonate, and subsequently to the oxide. On moderately large specimens, and with no *useful* atmosphere control, these two decompositions will (or at least can) overlap enough to give a single thermogravimetric weight loss. The present author will not attempt to explain the slow rise in the emanation between about 120 to 250°. The decrease in the region of 300° may possibly be the result of dilution; the evolution of the other gases may become such a significant part of the total gas flow that the flow through the counter is increased, and the quantity of thoron present in the counter at any moment consequently decreased. As the rapid evolution diminishes, the increased concentration is again apparent. The method is interesting, and may be particularly useful in special cases. As a general technique, it suffers from the disadvantages that it does not provide a complete and unambiguous response to events in the specimen and, further, it requires the presence of thorium or some other radioactive material producing a radioactive gas with a short half-life.

DETERMINATION ONLY OF GASEOUS PRODUCTS

Let us now consider some experiments in which the gathering of information was confined to study of the gaseous products of decompositions. These range from systems in which only the event is of interest to systems in which the products are measured quite specifically, both qualitatively and quantitatively. One of the former type is that of Rogers and others[7] in which the specimen was pyrolysed in a stream of helium. The organic vapours from the pyrolysis chamber are oxidised to water and carbon dioxide in the combustion tube, to avoid condensation as well as to enhance sensitivity. (The conversion of a molecule of some fairly complex organic material to many molecules of carbon dioxide and water will quite naturally enhance the signal obtained in passing through the thermal conductivity cell.) The pyrolysis block is heated by commercial cartridge heaters through a temperature programme. The results obtained from the thermal conductivity measurements are simple indications of decompositions without identification, except, in some cases, by the temperature at which the decomposition occurs. It has the advantage over the Ayres and Bens apparatus that the conversion to carbon dioxide and water rids the system of easily condensable materials which might later vaporise and give a false signal.

These simple indications of decompositions are useful principally in establishing temperatures of decomposition, but with known products the technique can also be used as a quantitative measure with the same confidence as gas chromatography, because the same type of detector is used. The user must know the product gases specifically, or at least know that the same material containing the same proportions of carbon and hydrogen will come off from each sample tested. If this knowledge is not available with certainty, more detailed analyses may be in order. It is necessary only to substitute a technique for analysis instead of, or as well as, detection of the gaseous products. There is no reason why programming of the temperature is not still possible. The most generally useful technique for analysis of these effluent gases is gas chromatography; in the reported work seen by the present author, these sample materials have been vaporised into the carrier gas stream, and carried immediately into the chromatographic column.

QUALITATIVE IDENTIFICATION OF DECOMPOSITION PRODUCTS

In general, direct injection of the decomposition product gases into the chromatograph is done by rapidly heating the material in the gas stream, the means of heating being usually the sample container as well. Experimenters principally interested in the chromatographic analysis can very easily overlook the importance of the manner of heating and, indeed, this is a common occurrence. The specimens are heated rapidly, so that the product gases appear in the chromatograph as a single pulse of gases; identification of the gases given off at intermediate temperatures is not attempted.

The transfer of heat from the heater wire to the sample material is a source of variation and error with specimens of appreciable thickness. Jennings and Dimick[8] avoided the heat transfer problem by evaporating the specimen on the heater wire (using aqueous phosphoric acid to supply hydrogen and oxygen for the decomposition reaction). They examined the effect of temperatures from 550 to 1100°, finding that for thymine there was no appreciable difference in the pyrolysis pattern, *i.e.*, the identities and relative quantities of products. The first composite peak in their Fig. 2 is likely to be permanent gases. These results show their reproducibility on repetition of the experiment as indicated in their table. This is not the sort of reproducibility one would expect from an ordinary chromatographic analysis, so that the deviation of irreproducibility must be related to the pyrolysis technique. The non-linearity in Jennings and Dimick's calibration values may still possibly be a heat transfer problem; the thin specimens with good exposure to the atmosphere may partly volatilise without decomposition, but the thicker specimens, being heated from the inside, may be subject only to the same absolute quantity of vaporisation, and hence a smaller percentage effect. The probability that the thicker specimens reach higher temperatures locally may also lead to some variation in the relative quantities of the several products, even though the identities of the products remain the same. Note that Jennings and Dimick were able to distinguish quite clearly between positional isomers; cytosine and isocytosine showed quite different proportions of products under similar pyrolysis conditions.

Quite different heating conditions were used by Strassburger, Brauer, Tryon and Forziati;[9] these authors used a much lower temperature pyrolysis in their studies of methyl methacrylate copolymers. They heated their pyrolysis coil to about 450° with 10–15 mg of specimen contained therein. At that temperature, and in the absence of oxygen or of hydrogen, a relatively non-volatile residue is formed. The reactions causing the formation of the residue also introduce distinct non-linearities into the calibration for quantitative measurements so that, for example, the sample weight-to-peak area ratio varies by a factor of 2 in the methyl methacrylate–ethylene dimethacrylate copolymer.

DEPENDENCE OF PRODUCTS ON CONDITIONS

Although some of the authors cited indicate that the pyrolysis products are the same over a wide range of pyrolysis conditions, to assume this happy circumstance for any given material to be studied would be exceedingly optimistic. A thin layer of material in contact with a heating element or other form of hot surface, at a temperature approximating the ultimate decomposition temperature of the material, may transmit heat rapidly enough to permit the entire film to decompose at essentially the same time, and more or less at the same temperature. The material in contact with the heated surface does not necessarily rise in temperature greatly above the surface of the film. If this heated surface were several hundred degrees, say, above the ultimate decomposition temperature, rapid decomposition of the inner portion of the film could change the conditions of heat transfer substantially. With very thin specimens the problem will arise only in the extreme cases, because the heating of the surface is not instantaneous; the heat capacity of the wire itself will cause some delay in reaching the final temperature, permitting a similar smooth rise by the specimen material.

If a thick sample is placed in contact with a heating element, and the heating element is supplied with a sudden application of an electric circuit, the relatively low thermal conductivity of the typical organic specimen will permit the establishment of a high (and not necessarily continuous) temperature gradient through the specimen. The over-all effect will depend on the nature of the sample-holding system; if the material has been deposited on a wire or other surface by evaporation of a solvent, so that there is a continuous layer on the heating surface, the material next to the heating surface may well be heated slowly enough to permit low temperature decomposition products to form; but these decomposition products cannot escape and will consequently be subject to further decomposition. If particles are laid upon the heating surface, the portion of the surface initially in contact may be heated slowly enough to undergo a low temperature decomposition, but the new layers of material subsequently touching the heated surface are coming in contact with a hotter and hotter surface, bringing about the possibility of a different decomposition mechanism.

The change in products obtained with change of pyrolysis conditions has been demonstrated by Martin and Ramstad,[10] who used flash pyrolysis to decompose cellulose in the sample chamber of a two-stage column. They separated the permanent gases on a gas-solid absorption column, using polypropylene glycol. The specimen was heated by flash photolysis; *i.e.*, intense radiation from a flash tube or arc source was directed on the specimen for a short length of time, the temperature reached depending both on the intensity and the time of exposure. They induced momentary temperatures in the sample in excess of 600°, with intense radiation of a millisecond duration, and compared the results with a slower pyrolysis in the 250–350° range, induced by less-intense radiation lasting for several seconds. The decomposition products are carried into the polypropylene glycol column, where the permanent gases are impeded only slightly. These are led from the glycol column into the activated charcoal column where the gases are separated, the columns being uncoupled immediately after passage of the permanent gases from stage 1 into stage 2. The slow pyrolysis produces only carbon monoxide and carbon dioxide among the permanent gases, but the flash pyrolysis produces significant quantities of the lighter hydrocarbons. The principal feature of the partition column curves is the greatly diminished amount of water relative to the other components in the flash pyrolysis. Although it is the major component, two of the other peaks at least surpass it in height. Note, too, that the magnitude of the carbon monoxide peak in the flash pyrolysis is more than ten times as high as the carbon dioxide peak, but in the slow pyrolysis it is somewhat smaller. Explanation of these variations would require further knowledge of the system, but a safe general conclusion can be stated: variations in the rate of heating of an organic specimen may cause different products or different relative quantities of products.

OTHER POSSIBILITIES

Now let us consider some of the extensions of effluence analysis. First of all let us consider changes in the carrier gas, made with the intention of encouraging or inhibiting some particular reaction. The use of helium-oxygen and helium-nitrogen mixtures has already been discussed in relation to determining the steps of an inorganic reaction. In this case, the helium-oxygen mixture permitted the oxidation of carbon monoxide, but the absence of oxygen brought about decomposition without oxidation. Similarly, small quantities of oxygen in the carrier gas stream would permit oxidation or partial oxidation of the specimen; or the presence of hydrogen might permit saturation of organic carbon chains. This is not being recommended as a general technique, but as a modification of procedure which might yield useful information. Repetitive sampling into the column in the manner practised by the present author (*vide supra*) would yield successive lots of decomposition products as the temperature was increased. Decompositions of specimens can be carried out directly in the sampling locations of analytical instruments other than chromatographs or chromatographic type of detectors, and similarly the decompositions can be programmed either step-wise or continuously. Two types of analyser are of particular promise, optical and mass spectrometers. Decomposition into, say, an infrared absorption spectrometer sample tube would be of particular interest if a particular compound or functional group were being monitored. Fairly high resolution would be required to obtain unambiguous results. There is the advantage, however, that the appearance of the product could be followed during the entire decomposition and if the decomposition is programmed some measure of the temperatures of appearance of various products may be obtained.

Of the mass spectrometers, the time-of-flight spectrometer would be of special interest because of the high frequency of repetitive sampling possible. Decomposition in a chamber connected to the spectrometer by an appropriate orifice would make possible the gathering of kinetic information on decompositions.

Relating the events recorded by these various techniques needs to be done with great care. Bussière *et al.*[6] compared curves obtained by their simultaneous determinations (*vide supra*) to those obtained on other (apparently single-purpose) apparatus. Bussière *et al.* conclude that it is preferable to make all the measurements simultaneously in order to obtain agreement in the interpretation of a given reaction. This is a fairly common attitude. The present author has contended[11]—and still contends—that unless the results from each technique have some real significance, attempts to relate them are seldom rewarding even when apparently successful. The agreement that is almost unavoidable in simultaneous determinations can give the observer an entirely unwarranted confidence in whatever he chooses the curves to mean. Further discussion of simultaneous determinations is presented in a forthcoming monograph.[12]

Zusammenfassung—Die Analyse der bei thermischen Zersetzungen entwickelten Gase kann dazu dienen, das Fortschreiten oder den Mechanismus der Zersetzungen zu verfolgen oder die zersetzte Probe zu charakterisieren. In jedem Fall müssen bestimmte Probleme berücksichtigt werden. Diese Probleme werden diskutiert, darunter das Vorgehen bei der Aufheizung, die Analyse der Produkte und die Kompromisse, die bei Simultanmessungen geschlossen werden müssen.

Résumé—Que l'analyse des gaz qui se dégagent lors de décompositions thermiques soit utilisée pour élucider le développement ou le mécanisme des décompositions, ou pour caractériser l'échantillon, on doit traiter de certains problèmes. On discute de ces problèmes, comprenant le chauffage, l'analyse des produits, et les compromis auxquels on doit avoir recours lors de mesures simultanées.

(*Received* 12 *May* 1964. *Accepted* 22 *June* 1964)

Summary—In this first paper of a series, a new analytical tool is introduced for the analysis of fluorescent molecules—quenchofluorescence analysis. This field of research will have far-reaching ramifications in organic trace analysis. Analytical use is made of the quenching effect in spectrophotofluorometry. Compounds such as anthracene, phenanthrene, pyrene, benz(*a*)anthracene, benzo(*a*)pyrene, perylene, *etc.*, have been found to be non-fluorescent in nitromethane solution, but hydrocarbons containing the fluoranthenic ring are fluorescent. Use has been made of this phenomenon in characterising fluoranthene and benzo(*k*) fluoranthene in airborne particulates, following column chromatography. The phenomenon has also been used in thin-layer chromatography, directly on the plate.

FLUORESCENCE quenching is a serious problem in the analysis for polynuclear aromatic hydrocarbons in airborne particulates, especially with fairly high solution concentrations of either the compound being analysed or the impurities. Primarily because of this difficulty it was believed that quenching could be a useful analytical tool. With a proper reagent it should be possible to quench part of the fluorescence excitation or emission spectra or all the fluorescence excitation and emission spectra of a molecule. In the former case the quenching could result from the direct absorption of the exciting light by the quencher; in the latter case it could result from the same phenomenon or from formation of a non-fluorescent molecule, or from both. The new molecule could be a complex or a newly formed derivative.

As a first approximation, nitro derivatives, many of which are well-known complexing agents, were selected for investigation for the following reasons. Alcoholic solutions of rhodamine B are quenched to some extent by the addition of nitrobenzene.[1] Aqueous solutions of rhodamine B are completely quenched by picric acid.[2] Complex formation is believed to cause this phenomenon. Acetone solutions of chrysene are quenched by picric acid and many other nitro compounds.[2]

Benzo(*a*)pyrene and six other polynuclear aromatic hydrocarbons have been shown to be nonfluorescent in solutions of nitromethane or nitrobenzene.[3] Of compounds of this type tetranitromethane was the most potent quencher. The fluorescence of 1 μg of benzo(*a*)pyrene in 10 ml of petroleum ether was completely inhibited by 200 μg of tetranitromethane.[3]

It is reported that in the presence of bromine, under carefully controlled conditions, the fluorescence of benzo(*a*)pyrene disappears but that of benzo(*k*)fluoranthene is unaffected.[4] By this procedure, for which details are not given, benzo(*k*)fluoranthene and benzo(*a*)pyrene were satisfactorily estimated in synthetic mixtures containing equivalent amounts of these two chemicals, perylene, and benzo(*e*)pyrene. The pure spectrum of benzo(*k*)fluoranthene could not be obtained from this mixture.

The selective use of the quenching phenomenon in the analysis for one component in a mixture has been studied in only a few isolated cases, and even in those cases the implications of the general use of quenching to increase greatly the selectivity of many fluorometric methods have not, as yet, been grasped. A thorough study is needed, because quenching reagents can greatly increase the selectivity and usefulness of spectrophotofluorometric and spectrophotophosphorometric analysis for many types of aromatic compound. It is predicted that this type of analysis will have a very wide range of application in organic analysis. It is suggested that these procedures be called *quenchofluorometric* and *quenchophosphorometric* analysis.

In the work reported in this paper, fluoranthenic hydrocarbons are characterised and determined in the presence of other types of polynuclear aromatic hydrocarbon. In subsequent papers, other types of quenchofluorometric procedures with a very high order of selectivity will be introduced.

Fluoranthenic hydrocarbons such as benzo(*b*)fluoranthene, benzo(*j*)fluoranthene, and indeno(1,3,3-*cd*)pyrene have been reported to be carcinogenic to mice.[5]

EXPERIMENTAL

Reagents and apparatus

Nitromethane was obtained from Matheson, Coleman, and Bell, Cincinnati, Ohio, and distilled before use. Alumina adsorbent was obtained from Brinkman Instruments, Inc., Great Neck, L.I., New York.

All chromatographic plates were examined for fluorescence colours in a Chromato-Vue cabinet (Kensington Scientific Corp., Berkeley, California) under a 3660-Å light source.

The following settings were used with the Aminco-Bowman spectrophotofluorometer: sensitivity 50, meter multiplier 0·01 (whenever possible), slit arrangement No. 2, and phototube RCA type 1 P 21.

Thin-layer chromatographic procedures

A. Plates were prepared and developed by procedures analogous to those described previously.[6] Where mixtures of an alkane and nitroalkane were used as developing solvents, the plate was read under the ultraviolet light as soon as it was taken out of the tank, and was then read again after it had dried (about 15–30 min).

B. *Nitromethane test for non-quenchable compounds, such as fluoranthenes*, etc. After thin-layer chromatography the line of development is treated with small bursts of nitromethane fumes, or with microdrops of the liquid. This can be done with a throwaway pipette fitted with a squeeze bulb. Any change or loss in fluorescence colour is noted.

RESULTS

Spectrophotofluorometry

In previous work the fluorescence spectra of a large variety of hydrocarbons were obtained in pentane and sulphuric acid.[7] One of the main variables in the spectra of these different hydrocarbons was their broad range of intensities. With nitromethane as the solvent most of these hydrocarbons become non-fluorescent, thus greatly increasing the selectivity of the fluorometric procedure. Thus, all non-fluoranthenic hydrocarbons are non-fluorescent in nitromethane (Table I). It must be emphasised that although all the hydrocarbons in Tables I and II are fluorescent in pentane or chloroform solution, only the fluoranthenic hydrocarbons are fluorescent in nitromethane solution.

TABLE I.—COMPOUNDS WHOSE FLUORESCENCE IS QUENCHED IN NITROMETHANE SOLUTION

Acenaphthylene
Phenanthrene
Anthracene
9-Bromoanthracene
Benz(*a*)anthracene
11-*H*-Benzo(*a*)fluorene
11-*H*-Benzo(*b*)fluorene
7-*H*-Benzo(*c*)fluorene
Benzo(*c*)phenanthrene
Chrysene
4-*H*-Cyclopenta(*def*)phenanthrene
Naphthacene
Pyrene
1-Bromopyrene
1-Methylpyrene
Triphenylene
Benzo(*b*)chrysene
Benzo(*a*)pyrene
Benzo(*e*)pyrene
Perylene
Dibenz(*ac*)anthracene
Dibenz(*ah*)anthracene
Dibenz(*aj*)anthracene
Picene
Anthanthrene
Benzo(*ghi*)perylene
Naphtho(2,1,8-*qr*)naphthacene
Dibenzo(*ae*)pyrene
Dibenzo(*gp*)chrysene
Dibenzo(*brst*)pentaphene

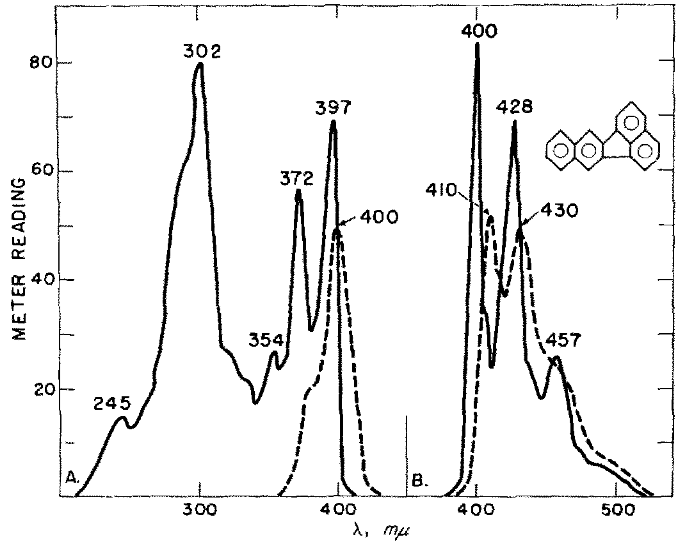

FIG. 1.—Fluorescence spectra of benzo(*k*) fluoranthene.
A. Excitation spectra: at emission λ 400 mμ, MM = 0·01 and 10^{-6} *M* in pentane (———) and at emission λ 430 mμ, MM = 0·03 and 10^{-5} *M* in nitromethane (– – –).
B. Emission spectra: at excitation λ 302 mμ, MM = 0·01 and 10^{-6} *M* in pentane (———) and at excitation λ 400 mμ, MM = 0·03 and 10^{-5} *M* in nitromethane (– – – –).

Although these latter hydrocarbons are fluorescent in nitromethane solution, their short-wavelength excitation spectral bands have been quenched (Table II). This latter effect may result from direct absorption of the short-wavelength light by the quencher. The striking effect of nitromethane on the fluorescence spectrum of benzo(*k*)fluoranthene as compared to the spectrum in pentane is shown in Fig. 1. The intensities of all bands have been decreased. The partial quenching of the short-wavelength excitation bands, which probably results to some extent from the internal filter effect of the solvent, merits further investigation. The emission spectral bands, which are present in chloroform or pentane, are present in nitromethane also, although their intensity has been decreased.

TABLE II.—FLUORESCENCE SPECTRA OF FLUORANTHENIC HYDROCARBONS IN NITROMETHANE

Compound	Det. limit, *ng/0·1 ml*	Molar concn.	Emission spectra[a]		Excitation spectra[b]	
			EM. λ, *mμ*	*MM.T*	Exc. λ, *mμ*	*MM.T*
Fluoranthene[cf]	340	10^{-4}	460	0·65	380	0·68

[a] Instrument set at most intense excitation wavelength maximum. Values *in italics* are shoulders.

[b] Instrument set at most intense emission wavelength maximum. Values *in italics* are shoulders.

[c] Band intensities in nitromethane-trifluoroacetic acid (99: 1, v: v) decreased one-half to one-third.

[d] Same intensities in acid solution.

[e] Intensity doubled in acid solution.

[f] Band intensities in nitromethane-triethylamine (99: 1, v: v) decreased one-half to one-sixth.

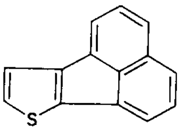
[g] Same intensity in alkaline solution.

[h] In nitromethane-trifluoroacetic acid (99: 1, v: v) at $2 \times 10^{-5}M$: excitation λ max. 400, MM.T 0·67 and emission λ max. 515, MM.T 0·67.

[i] In nitromethane-trifluoroacetic acid (99: 1, v: v) at $10^{-6}M$: excitation λ max. 423, 450 and MM.T 0·64, 0·70, respectively and emission λ max. 507.

A tentative explanation for the complete quenching of the non-fluoranthenic hydrocarbons is that these compounds form a non-fluorescent π-complex in the excited state. In line with this hypothesis is the fact that naphtho(2,1,8-*qr*)naphthacene is fluorescent in chloroform and non-fluorescent in nitromethane, but its absorption spectra in chloroform and nitromethane are essentially identical from 600 to 370 mμ (the cut-off point for nitromethane). Consequently a complex is not present in the ground state, but could be present in the excited state (all concentrations were $10^{-5}M$). This hypothesis is being investigated.

Every hydrocarbon so far investigated that is fluorescent in nitromethane solution has a fluoranthenic ring as part of its structure. Even the heterocyclic hydrocarbons appear to follow the same rule. The quinoxaline derivatives have 1 ring in the fluoranthenic part of the molecule with *para*-nitrogen atoms. In spite of these nitrogens, the compounds act like the other fluoranthenic derivatives. In the thiophene compound a true fluoranthenic ring is not present. A sulphur analogue, which is iso-π-electronic to fluoranthene, is present, however, *e.g.*,



Consequently, it appears that a fluoranthene-type ring in a molecule is necessary for a polycyclic aromatic hydrocarbon to be fluorescent in nitromethane. Exceptions to this rule are being sought.

APPLICATION

Characterisation following column chromatography

Following the column-chromatographic fractionation of organic airborne particulates, some of the fluoranthenic compounds can be readily characterised in the various fractions. When the fluorescence spectrum is obtained in nitromethane solution, the interfering aromatic hydrocarbons are eliminated. For example, the interfering spectra of all the other components in the pyrene fraction are eliminated and the fluorescence spectrum of fluoranthene is obtained (Fig. 2).

In the same way, the pure excitation and emission spectra of benzo(*k*)fluoranthene can be obtained from a nitromethane solution of the benzpyrene fraction of organic airborne particulates (Fig. 3). Thus, with a single spectral run in nitromethane, benzo(*k*)fluoranthene can be readily characterised in the benzpyrene fraction.

Characterisation following thin-layer chromatography

The use of nitromethane following a thin-layer chromatographic separation of the benzene-soluble fraction of airborne particulates is shown in Fig. 4c. The fluorescence colours obtained for a dry chromatogram following development are seen in Fig. 4b. Treatment with trifluoroacetic acid fumes gives the chromatogram as shown in Fig. 4a. The brilliant emerald green and pink fluorescent spots (marked 1 and 2) have been found in many of the benzene-soluble fractions of urban airborne

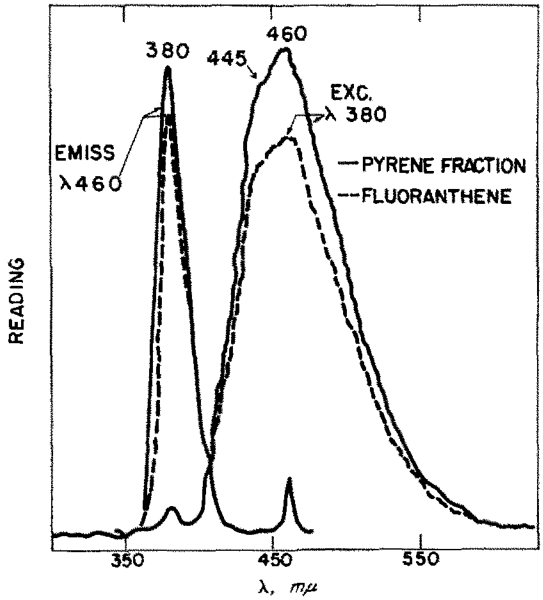


FIG. 2.—Fluorescence spectra of the pyrene fraction of airborne particulates (———) and fluoranthene (- - - - -), both in nitromethane.

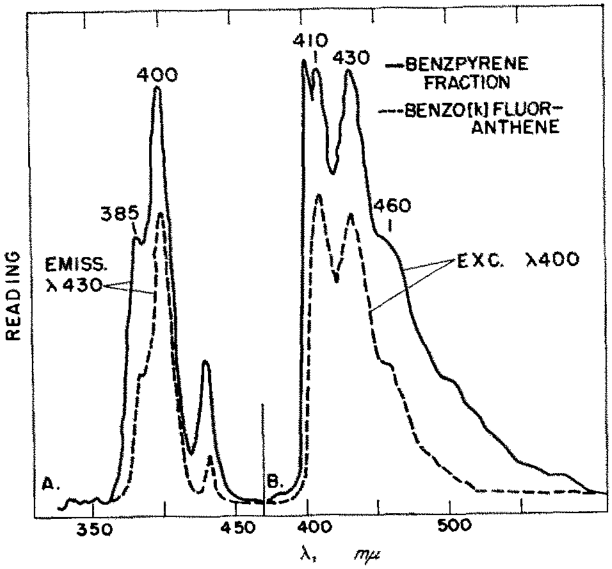

FIG. 3.—Fluorescence spectra of the benzpyrene fraction of airborne particulates (———) and benzo(*k*)fluoranthene (- - - -), both in nitromethane.

A. Excitation spectra.
B. Emission spectra.

particulates that have been examined. They serve the function of markers, in that their R_f values denote the relative activity of the alumina or the moving power of the solvent system. Treatment of the original chromatogram with nitromethane quenches the fluorescence of most of the spots, and in addition brings out new spots at 3 and the solvent front. This technique should prove useful in the eventual characterisation of the many unknown aromatic compounds in airborne particulates and other complicated mixtures. When a benzene-soluble fraction is separated on a thin layer of alumina with pentane-2-nitropropane (19 : 1, v : v), the final results differ drastically (Fig. 5a) from the pentane-ether chromatogram (Fig. 4). As the figure shows, hydrocarbons such as benzo(*a*)pyrene are invisible, while benzo(*k*)fluoranthene fluoresces with a brilliant blue colour. On standing, the fluorescence colours of most of the spots change, and new spots appear (Fig. 5b). Thus, evaporation of the nitropropane causes the compounds that are non-fluorescent in nitropropane to become fluorescent. This phenomenon is demonstrated by the benzo(*a*)pyrene spot, which is not seen in Fig. 5a, but which is shown fluorescent in Fig. 5b. Thus, these two different procedures both dependent on the quenching effect of a nitroalkane, can be used in thin-layer chromatography. In addition, either of these procedures can be followed by the treatment with trifluoroacetic acid fumes.

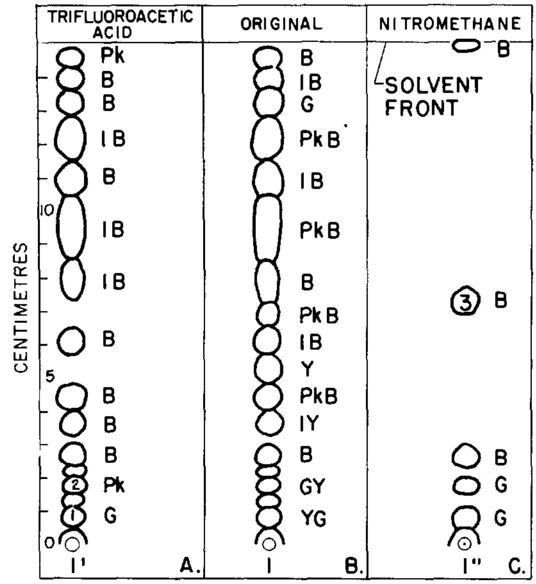

FIG. 4.—Alumina thin-layer chromatogram of a benzene-soluble fraction of airborne particulates.
A. Original treated with trifluoroacetic acid fumes.
B. After development with pentane-10% ether.
C. Original treated with nitromethane fumes.

Determination of fluoranthenes

Beer's law type relations were found to hold for fluoranthene in nitromethane from 2 to 25 μg/ml and for benzo(*k*)fluoranthene from 0·2 to 2·5 μg/ml. Fluoranthene could be readily determined in a synthetic mixture of equal amounts of pyrene, fluoranthene, chrysene, and benzo(*a*)anthracene. Similarly, benzo(*k*)fluoranthene could be readily determined in a synthetic mixture of equal amounts of benzo(*a*)pyrene benzo(*e*)pyrene, perylene and benzo(*k*)fluoranthene. The pure excitation and emission spectra of fluoranthene and benzo(*k*)fluoranthene are obtained from these synthetic mixtures. The procedure involved dissolution of the mixture in nitromethane and then reading of the meter multiplier × transmittance (MM.T) values at the most intense excitation and emission wavelength maxima of fluoranthene or benzo(*k*)fluoranthene. When this procedure was applied to the pyrene fraction obtained after column chromatography of a sample of urban airborne particulates, the values obtained for fluoranthene were 2·5 times those obtained by the ultraviolet absorption base-line method of measurement.[9,10] Similarly, high values were obtained for benzo(*k*)fluoranthene. Because fractions obtained after the fluoranthene fraction, and just before and after the benzpyrene fraction, were fluorescent in nitromethane solution, it was concluded that either additional fluoranthenic compounds or some other types of unquenched compound were present. The procedure is therefore of value for characterisation but cannot be used for the determination of individual fluoranthenic compounds until better separation is achieved and more information is obtained on any other types of compound that fluoresce in nitromethane solution.

A. Immediately after development with pentane—5 % 2-nitropropane.
B. After plate has dried about 30 min.

CONCLUSION

A simple technique is introduced that facilitates the characterisation of fluoranthenic compounds following chromatography. The method is based on the non-fluorescence of non-fluoranthenic hydrocarbons and the fluorescence of fluoranthenic hydrocarbons in nitromethane solution. By this technique the two types of compound can be differentiated on a thin-layer plate or in solution.

Zusammenfassung—In dieser Arbeit, die die erste einer Reihe weiterer Arbeiten sein soll, wird eine neue Art der Analyse fluoreszierender Moleküle eingeführt: die Fluoreszenz-Löschungs-Analyse. Diese Methode wird in der organischen Spurenanalyse einen weit verzweigten Anwendungsbereich finden. Es wird dabei analytischer Gebrauch von dem Effekt der Fluoreszenzlöschung gemacht. Verbindungen wie Anthracen, Phenanthren, Pyren, Benz(*a*)anthracen, Benzo(*a*)pyren, Perylen usw. fluoreszieren in Nitromethanlösung nicht, während Kohlenwasserstoffe mit Fluoranthenring fluoreszieren. Diese Erscheinung wurde dazu ausgenutzt, Fluoranthen und Benzo(*k*) fluoranthen in Schwebeteilchen aus der Luft nach vorhergegengener Säulenchromatographie zu identifizieren. Die Erscheinung wurde auch bei der Dünnschichtchromatographie direkt auf der Platte ausgenutzt.

Résumé—Dans ce premier mémoire d'une série, on présente une nouvelle méthode analytique pour l'analyse des molécules fluorescentes: l'analyse par extinction de fluorescence. Ce domaine de recherches aura des ramifications lointaines dans l'analyse organique de traces. On utilise analytiquement l'effet d'extinction en spectrophotofluorimétrie. On a trouvé que des composés tels que l'anthracène, le phénanthrène, le pyrène, le benzo(*a*)anthracène, le benzo(*a*)pyrène, le pérylène, etc. ne sont pas fluorescents en solution dans le nitrométhane, cependant que des hydrocarbures contenant le noyau fluoranthénique sont fluorescents. On a utilisé ce phénomène en caractérisant le fluoranthène et le benzo(*k*)fluoranthène dans les particules en suspension dans l'air, après chromatographie sur colonne. Le phénomène a été également utilisé en chromatographie sur couches minces, directement sur la plaque.

Summary—Some rather unusual chemical analyses are described. A typical example is the determination of a few μg of one element in a sample composed essentially of the elements listed in the periodic table. This somewhat bizarre sample is a solution containing 10 mg each of about seventy different elements.

INTRODUCTION

FOR the past few years, the authors and their colleagues have been concerned with developing methods for the determination of trace elements in beryllium and beryllium oxide.[1-7] Although these methods were developed primarily for application to a beryllium matrix, they were intended to have much wider usage.

It is the authors' opinion that the determination of a trace amount of an element in a matrix is rarely difficult because of the particular matrix. The real difficulty is the presence in the matrix of unknown amounts of other elements which can interfere with the method to be used. A check of the analytical literature will immediately reveal that few indeed are the methods which have been investigated comprehensively. Rarely does one know which elements of all those in the periodic table interfere, and in what amounts. Consequently, the analyst must frequently use a method whose limitations are unknown, and must apply it to a sample which might contain a number of interfering elements. Therefore, we attempted to develop, within certain limitations, specific methods of analysis. Although many tests of these methods have been made, the most critical test made is the one here described.

When measuring the effect of other elements in an analytical procedure, it is common practice to test the effect of each individual element on the determination of the constituent, in this case a trace element. However, "other elements" do not occur individually in a sample, but rather in an assorted collection of kinds and amounts. Furthermore, if there are n elements to be included in the investigation, there would be 2^n-1 combinations to be tested. This assumes that all elements would be at the same concentration level. Because the latter situation is never true, one can easily see that there is an infinite number of combinations to test. In order to make a meaningful test of the effect of other elements, it is necessary to simplify this situation. The method chosen was to measure the effect, if any, of all elements added simultaneously at one concentration level—10 mg.

The effect of 71 elements was tested (72 minus the element being determined): aluminium, antimony(III), arsenic(III), barium, beryllium, bismuth, boron, bromine (as bromide), cadmium, calcium, cerium(IV), caesium, chlorine (as chloride), chromium(III), cobalt, copper, dysprosium, erbium, europium, fluorine (as fluoride), gadolinium, gallium, germanium(IV), gold, hafnium, holmium, indium, iodine (as iodide), iridium, iron, lanthanum, lead, lithium, lutetium, magnesium, manganese(II), mercury(II), molybdenum(VI), neodymium, nickel, niobium, palladium, phosphorus (as phosphate), platinum, potassium, praseodymium, rhenium(VII), rhodium, rubidium, samarium, scandium, selenium, silicon (as silicate), silver, sodium, strontium, sulphur (as sulphate), tantalum, tellurium(IV), terbium, thallium(I), thorium, thulium, tin(II), titanium, tungsten, uranium(VI), vanadium(V), ytterbium, yttrium, zinc and zirconium. It should be noted that two valence states of an element were used for several of the tests.

All of the above elements were added (in the valence state indicated) in every test, except where noted.

The technique used to make the test was as follows. Fifty mg of each of the elements (in solution) were added to a beaker, together with the appropriate amounts of acid(s) and complexing agent, if any. If precipitation or hydrolysis occurred, the solution was filtered and the precipitate was analysed to determine what amounts of what elements were not being included in the test. This analysis is given under *Analysis of Residue*. The filtrate was then diluted to a convenient volume and divided into 5 equal parts. One part was used to make an estimate of the amount of the element being determined which was present as a trace in the elements added. Two parts, labelled B1 and B2, were carried through the procedure as blanks. In order to confirm the fact that the absorbance of the blank was caused by the element being determined, the coloured solution was analysed spectrographically. Although this measurement may not be very accurate, it is sufficiently so to confirm the fact that the absorbance measured was actually caused by the element being determined. This spectrographic analysis is listed under *Element found, spectrographic*.

The other two parts of the solution, labelled S1 and S2, were "spiked" with an appropriate amount of the element being determined and analysed by the method developed for this particular element.

EXPERIMENTAL* AND RESULTS

Determination of iron[1]

Eight hundred ml of a solution were obtained containing the elements whose effect was to be investigated. Titanium was added as Ti^{III}. Silicon was not added because of its tendency to form an emulsion during extraction. Tellurium, gallium, and uranium were not added because of their known interference effect. The solution, $6M$ with respect to hydrochloric acid, containing 5 g of citric acid and sufficient bromine to oxidise the iron, was divided as described and treated as follows.

Six extractions were made with 25 ml of $0{\cdot}01M$ tri-n-octylphosphine oxide (TOPO) in cyclohexane. The combined extracts were shaken with 35 ml, 35 ml and 10 ml of $3M$ sulphuric acid (iron reverted to the aqueous phase). The sulphuric acid phase was washed 10 times with 25-ml portions of $0{\cdot}1M$ TOPO in chloroform and the organic phases were discarded. Sixty ml of hydrochloric acid were added, and the iron was extracted with 10 ml of $0{\cdot}01M$ TOPO in cyclohexane. A 1-ml aliquot was transferred to a 25-ml volumetric flask containing 15 ml of isopropyl alcohol and sufficient hydroquinone for reduction of the iron. After addition of 1,10-phenanthroline, iron was determined as the iron(II)-phenanthroline complex. The results are shown in Table I.

---

* Because of the number of methods discussed, the reader is referred to the original publications for greater detail concerning reagents, procedures, *etc.*

The results indicate that accurate results will be obtained using this method if:

(1) the amount of silicon is reduced to a level at which it will not cause emulsification when the TOPO extraction is made;

(2) sufficient initial extractions are made to remove iron;

(3) the 1,10-phenanthroline complex solution is clear when the final absorbance measurement is made;

and (4) gallium, tellurium and uranium are below the level indicated in the published report.

TABLE I.—TEST OF IRON METHOD

B1	—	66·2	—	90
B2	—	71·7	—	—
S1	103·5	170	98	—
S2	103·5	171	98	—

Analysis of residue (on the basis of 10 mg added): 10 mg of Ba, 4 mg of Hf, 2 mg of Ta, and 1·5 mg of Zr.

Determination of copper[2]

Twelve hundred ml of a solution were obtained containing the elements whose effect was to be investigated. Iron was added as both Fe^{II} and Fe^{III} (50 mg of each), manganese as both Mn^{II} and Mn^{VII} (50 mg of each), and titanium as both Ti^{III} and Ti^{IV} (50 mg of each). Chromium and hafnium were not added. The solution, which contained 25 g of citric acid, 25 ml of hydrochloric acid, 50 ml of sulphuric acid and 5 g of hydroxylamine hydrochloride (to reduce the copper), was neutralised to a pH of 5·0, and divided as described.

Copper was determined by extraction of the neocuproïne complex using the method described[2] except that the extraction was made with 25 ml of 4-methyl-2-pentanone, and the absorbance was measured using 2-cm cells. The results are shown in Table II under B1 and S1. When the extracts were diluted in a volumetric flask (because of the varying solubility of 4-methyl-2-pentanone in the aqueous phase) the results were somewhat better, as shown by B2 and S2 in Table II.

TABLE II.—TEST OF COPPER METHOD

Soln.	Copper, μg Added	Copper, μg Found	Recovery %	Copper found (spectrographic) μg

B2	—	16·5	—	15
S2	60·9	77·4	100	—

Analysis of residue (on the basis of 10 mg added): 10 mg of Ba, 4 mg of Au, 4 mg of Pt, 4 mg of Sr, 1·6 mg of Rh, and 1·6 mg of Pb.

When the same experiment was performed in the presence of 10 mg each of Cr^{III}, Cr^{VI} and Hf, only 90% recovery of the added copper was obtained, in agreement with the published report (*loc. cit.*).

Determination of molybdenum[3]

In addition to the elements whose effect was to be investigated, the solutions to be analysed contained the proper amounts of tartaric acid, hydrochloric acid and sulphuric acid. Barium, gold, and silver were not added because of the tendency of the large amount of precipitate to clog the separatory funnel. Palladium, platinum, rhenium, selenium and tellurium were not added because of their known interference effect. Molybdenum was extracted as the thiocyanate complex with 4-methyl-2-pentanone. The results are shown in Table III.

B1	—	5·6	—	5
B2	—	5·6	—	5
S1	75	78·7	97	—
S2	75	78·7	97	—

Determination of cobalt[4]

In addition to the elements whose effect was to be investigated, the solutions to be analysed contained the proper amounts of hydrochloric acid, sulphuric acid and citric acid. Iron was added as both Fe^{II} and Fe^{III} (50 mg of each), and titanium as Ti^{III} and Ti^{IV} (50 mg of each). Chromium and manganese were not added in order to omit an ion-exchange step.

After adjustment of the pH to 4·0, the solutions were washed several times with acetylacetone. Sodium thiocyanate was added and cobalt was extracted as the thiocyanate complex with acetylacetone. The results are shown in Table IV.

TABLE IV.—TEST OF COBALT METHOD

Analysis of residue (on the basis of 10 mg added): 10 mg of Ba, 10 mg of Ag, 1·6 mg of Sr, 1·2 mg of Zr, 0·8 mg of Pd, and 0·8 mg of Rh.

Determination of cadmium[5]*

In addition to the elements whose effect was to be investigated, the solution contained the proper amounts of hydrochloric, sulphuric and citric acids. Iron was added as Fe^{III}, and titanium as Ti^{III}. Cadmium was precipitated from an ammoniacal citrate solution with benzotriazole using nickel as a collector. After treatment of the precipitate with nitric and perchloric acids, a 10% hydrochloric acid solution of the residue was passed through an anion-exchange column. Cadmium, retained by the resin and subsequently eluted with 3*M* nitric acid, was finally determined by extraction from a strongly alkaline medium with a chloroform solution of dithizone. The results are shown in Table V.

TABLE V.—TEST OF CADMIUM METHOD

Soln.	Cadmium, μg Added	Cadmium, μg Found	Recovery, %	Cadmium found (spectrographic) μg
B1	—	1·1	—	1
B2	—	1·3	—	—
S1	3	4·2	100	—
S2	5	6·0	96	—

Determination of niobium and tantalum[6]*

In addition to the elements to be investigated, the solution contained the proper amounts of sulphuric acid and hydrochloric acid. Titanium was not added. Niobium and tantalum were precipitated with cupferron using zirconium as a collector. After ignition of the precipitate and fusion with sodium bisulphate, the fused mass was dissolved in 25% hydrochloric acid-20% hydrofluoric acid and added to an anion-exchange column. Niobium and tantalum were eluted from the column separately, and again precipitated with cupferron as before. After fusion and dissolution of the precipitates, niobium was determined as the hydroquinone complex and tantalum as the pyrogallol complex. The results are shown in Tables VIA and VIB.

* Test made at Ledoux and Company by S. Kallmann *et al.*

TABLE VIA.—TEST OF NIOBIUM METHOD

Soln.	Niobium, μg Added	Niobium, μg Found	Recovery, %	Niobium found (spectrographic) μg
B1	—	142	—	—
B2	—	153	—	130
S1	700	805	94	—
S2	1400	1490	96	—

Analysis of residue (on the basis of 10 mg added): 10 mg of Ba, 10 mg of Ag, 10 mg of Sr, 10 mg of P, 2 mg of Au, 1·5 mg of Pd, 0·5 mg of Zr, 0·5 mg of Hf, and 0·5 mg of Pb.

Niobium and tantalum were determined in the same solution; consequently, the *Analysis of residue* in Table VIA applies to Table VIB also. When titanium was added with the rest of the elements, the results were high and erratic. Titanium was not completely removed from the ion-exchange column, despite the fact that it does not interfere with the determination of niobium and tantalum when it (titanium) is added by itself. This is the first indication of a "synergistic effect" in any of the methods thus far.

S1	819	877	102	—
S2	1638	1708	102	—

[a] Not detected spectrographically.

Determination of nickel[7]

In addition to the elements to be investigated, the solution contained the proper amounts of sulphuric acid, hydrochloric acid, and tartaric acid. Titanium was added both as Ti^{III} and Ti^{IV} (50 mg of each), and chromium was added both as Cr^{III} and Cr^{VI} (50 mg of each). Nickel was precipitated from an ammoniacal citrate solution with benzotriazole using cadmium as a collector. After treatment of the precipitate with nitric and perchloric acids, the residue was dissolved in a mixture of hydrochloric acid and isopropyl alcohol, and an anion-exchange separation was performed. Nickel was finally determined as the aqueous dimethylglyoxime complex. The results are shown in Table VII.

TABLE VII.—TEST OF NICKEL METHOD

S2	100	166·5	98	—

Analysis of residue (on the basis of 10 mg added): 10 mg of Ag, 10 mg of Au, 7·5 mg of Ba, 2·5 mg of In, 0·5 mg of Sr, and 2 mg of rare earths.

DISCUSSION

At one time it was hoped that the analyst's shelf would some day consist of a reagent specific for the determination of each element. Today, this idea seems to be somewhat naïve, although it may yet come to pass. However, the analyses presented here seem to indicate that specific methods can be developed. Furthermore, it is very evident that these methods are practical; *i.e.*, they can be applied to a wide variety of samples. The application of these methods will be the subject of a forthcoming paper.

It should be of interest at this time to repeat (but not in their original order) some of the remarks made by Lundell.[8]

> . . . there is an increasing tendency to devote more and more time to determinations which deal with the final act of a chemical analysis, and less time to chemical analysis itself—in other words, to consider chemical analysis as dealing with one or two variables instead of the dozen or more that are often involved . . . . Of course, there is good reason for confining analytical discussions to determinations which involve one or two variables. A system containing ten to twenty diverse components can hardly be handled on a strictly scientific basis, and any handling of it requires actual experience in analysis . . . . Methods of the type described (methods dealing with one or two variables) are about as helpful to the analyst as the method for catching a bird which the old folk used to recommend to children—namely to sprinkle salt on its tail. To do that one obviously must have the bird in hand, and in that case there is no need for the salt . . . . There is no dearth of methods that are entirely satisfactory for the determination of elements when they occur alone. The rub comes in because elements never occur alone, for nature and man both frown on celibacy. Methods of determination must therefore be judged by their "selectiveness." It is in this respect that most methods are weak and that improvements must come . . . . Because of their lack of selectivity, methods for the chemical analysis of things as they are do not stay put. Therein lies the danger of standard methods of analysis. As soon as the other group members creep in—for example, through changes in manufacture—the method must be changed.

These remarks, made over thirty years ago, are still appropriate today, with, we think, but one exception. It has been our endeavour to develop standard methods of analysis (which, of course, can be replaced or improved as new advances are made). The results of this paper indicate that specific methods can be developed, and the forthcoming paper will indicate the wide applicability of such methods.

In conclusion, it is the authors' opinion that these analyses are unique in the field of chemical analysis and should arouse the interest and thoughtful speculation of today's Lundells.

Acknowledgement.—The authors gratefully acknowledge those individuals who assisted in the development of these methods. The authors are greatly indebted to Dr. Louis Gordon who suggested this particular test.

Zusammenfassung—Enige ziemlich ungewöhnliche chemische Analysen werden beschrieben. Ein typisches Beispiel ist die Bestimmung weniger Mikrogramme eines Elements in einer Probe, die fast alle Elemente des periodischen Systems enthält. Es handelt sich um eine Lösung, die je 10 mg von etwa 70 verschiedenen Elementen enthält.

Résumé—On décrit quelques analyses chimiques un peu inhabituelles. Un exemple typique en est le dosage de quelques microgrammes d'un élément dans un échantillon essentiellement composé des éléments figurant dans le tableau périodique. Cet échantillon quelque peu bizarre est une solution contenant 10 mg de chacun d'environ soixante-dix éléments différents.

STUDIES OF THE FIRE ASSAY FOR PLATINUM METALS BY LEAD COLLECTION

K. C. AGRAWAL and F. E. BEAMISH
University of Toronto, Department of Chemistry, Toronto 5, Ontario, Canada

(*Received* 29 *May* 1964. *Accepted* 15 *June* 1964)

Summary—A fire-assay procedure for determining platinum, palladium, rhodium or iridium in the nitric acid parting solution from a lead button is described. Palladium is the only metal which is completely attacked by the parting solution; traces of platinum and rhodium are also dissolved. The presence of copper in the lead button has been found to encourage the dissolution of both platinum and iridium in the nitric acid parting solution; rhodium remains unaffected. Ion-exchange and precipitation procedures for separating palladium from lead are also included. Efforts have been made to identify the source of iridium loss which is a characteristic of classical fire assay collections.

FUNDAMENTALLY, there are two stages to the classical fire assay collection of the noble metals. The initial stage involves the accumulation by lead of the noble metals from the fusion flux prepared to provide the lead *in situ*. The result is a lead alloy containing the noble metals, called a button or regulus. The second stage involves the removal of lead from the button by volatilisation of litharge and its absorption by a cupel to form, finally, a silver alloy. A variation of this approach is a cupellation to accomplish the so-called dry assay, which is made in the absence of added silver. Traditionally, the formation of the silver alloy is followed by a series of wet separations whose character depends upon the composition of the silver collecting medium.

In recent years, the efficiency of the recovery by the silver alloy has been examined critically. In the case of iridium, it has become evident that a loss may result from mechanical processes, partly because iridium appears as intrusions on the surface of the silver bead.[1] The same phenomenon is observed with rhodium and ruthenium, except that with the latter two metals the loss is relatively small. In any case, with these three metals, there is always a considerable risk of loss except when the metals are present in microgram quantities. In the case of osmium the cupellation process can result in a complete disintegration of the silver bead, sometimes explosively. Undoubtedly this is caused by the expulsion of the readily formed volatile octavalent oxide formed with the oxygen, which is significantly soluble in silver at cupellation temperatures. On the other hand, gold, platinum and palladium silver beads can be produced and the noble metals subsequently separated by wet methods with accuracy and simplicity. In addition to the probability of cupellation losses of the more insoluble platinum metals, the subsequent wet treatments involved in separations and determinations of these metals require a high order of analytical skill.

Thus, while one must acknowledge the superiority of the cupellation process for the more common noble metals, one may hope for a more efficient method for the determination of osmium, ruthenium, iridium and rhodium immediately following a collection by lead. Recent researches with these four metals have provided evidence that the lead collection stage of the assay provides for a complete recovery of osmium and ruthenium.[2] Proof for this has been obtained by the use of perchloric acid, as a parting acid for the lead button, and simultaneously as an oxidant to form the octavalent oxides of both osmium and ruthenium. Information has also been provided to indicate a satisfactory recovery of rhodium.[3]

Because of the deficiencies of recovery of the more insoluble noble metals by cupellation to form the silver bead, and the inherent problems associated with their wet treatment, and because the lead alloy has proved to be an effective collector for the noble metals with the possible exception of iridium, it seemed profitable to examine the possibility of a wet analysis of the button, thus obviating the necessity of a cupellation.

Any effort to provide ultimately a complete wet procedure for the determination of noble metals in lead-assay buttons required first a preliminary examination of the composition of the nitric acid parting solution. The few recorded procedures for the analysis of the lead button, none of which is either proved or recorded in detail, were based on the assumption that of the noble metals, palladium was the only metal simultaneously attacked by the nitric acid parting solution. The restricted classical procedure involves the precipitation and filtration of lead sulphate, and the removal of adsorbed palladium by dissolution in ammonium acetate and reprecipitation as the sulphate. Undoubtedly, it is this cumbersome and inaccurate method which has discouraged attempts to provide complete and accurate procedures for the analysis of the lead button.

A direct lead-fusion method for the analysis of platinum-iridium alloys was developed by Gilchrist.[4] By this method the button was parted with nitric acid, and the residue was treated with *aqua regia;* iridium in the residue was determined gravimetrically. The results obtained suggest that iridium is not attacked by the parting acid used, and the small observed loss is probably the result of a slight dissolution of iridium in *aqua regia*. However, the lead button obtained by normal assay procedures differs from that obtained by Gilchrist in that appreciable amounts of copper and other base metals are often present. The influence of copper and other base metals on the dissolution of platinum metals by the nitric acid parting solution has not been recorded, although it is known that traces of copper will encourage the dissolution of precipitated platinum when the latter is leached with nitric acid.

Various techniques were applied by the present authors to determine the platinum metals content of the nitric acid solution used to part the button. The selective precipitation and ion-exchange methods described below proved of limited value. Although acceptable separations and determinations of the palladium in the parting acid could be made in the presence of other platinum metals, the techniques proved cumbersome and inaccurate. However, it seemed reasonable that an evaporation of the lead-nitric acid parting solution and a subsequent roasting to form litharge, together with the addition of flour and the usual fluxing constituents, followed by a fire assay would prove to be an applicable technique.

The fire-assay treatment described below was applied to nitric acid parting solutions derived from the dissolution of lead buttons. Initial determinations with buttons containing palladium, platinum, rhodium and iridium indicated that the parting acid contained high proportions of palladium and traces of rhodium and platinum. In the case of iridium, dissolution occurred only when copper was present in the button. Evidence was also obtained to indicate that the presence of copper in the lead button encouraged the dissolution of platinum. Because copper is a natural associate of the platinum metals, and frequently appears in small amounts in lead-assay buttons, it was necessary to determine its influence on the codissolution of the platinum metals. Methods described below allowed for the determination of each of the four platinum metals in a nitric acid parting solution. In the event that the amounts of platinum, rhodium and iridium in the parting acid are not considered significant, and a palladium separation only is required, the precipitation and ion-exchange procedures described below may also be applied.

EXPERIMENTAL

Standard solutions

Platinum: Pure platinum sponge was dissolved by *aqua regia*, and the nitric oxides were removed by repeated evaporation with hydrochloric acid. The platinum content was determined gravimetrically by thiophenol. The solution contained 1·011 mg of platinum per ml.

Palladium: Palladium chloride was dissolved in water with the addition of a little hydrochloric acid. Precipitation by the sodium salt of dimethylglyoxime yielded 0·994 mg of palladium per ml.

Rhodium: Sodium rhodium chloride was dissolved in water and standardised gravimetrically by 2-thiobarbituric acid. The solution contained 0·958 mg of rhodium per ml.

Iridium: Ammonium chloro-iridate was dissolved in water and standardised gravimetrically by 2-mercaptobenzthiazole. The solution contained 1·042 mg of iridium per ml.

The chemicals used were all of C.P. reagent grade.

Apparatus

Assay crucibles, 30-g, were supplied by A. P. Green Fire Brick Co. Ltd., Canada. The furnace used was a Williams and Wilson, 25 cycle-15 kV-amp. Globar type. For colorimetric measurements a Beckmann model B spectrophotometer was used with 10-mm glass cells.

Procedure

The following three fusion mixtures were used:

A

Litharge	125·3 g
Sodium carbonate	30·0 g
Silica	21·7 g
Flour	1·0 g

B

Litharge	124·2 g
Copper oxide	1·5 g
Sodium carbonate	30·0 g
Silica	21·9 g
Flour	1·0 g

C

Litharge	122·5 g
Copper oxide	3·0 g
Sodium carbonate	30·0 g
Silica	22·7 g
Flour	1·0 g

In each case three buttons and one blank button were prepared.

About two-thirds of the fusion mixture was transferred to a porcelain dish previously lined with an 8-in.^{2} Cellophane sheet. A small depression was made at the centre of the dish, and the mixture was salted with 5·0 ml of the standard solution (1·0 ml in the case of platinum). The mixture was dried overnight in an air oven at 70°, then 10 g of fusion mixture were carefully transferred to a 30-g assay crucible previously lined with an 8-in.^{2} Cellophane sheet. The remaining fusion mixture was added to the material in the crucible.

The crucible was transferred to the furnace at a temperature of about 1150°. The temperature was raised to 1225° over a period of 35–40 min, at which time the fusion was considered to be complete. The fused mixture was then transferred to a conical iron mould, from which a clean lead button was obtained on cooling.

Assay of the slag: The slag was crushed, pulverised to a fineness of 45-mesh and mixed with 27 g of litharge, 3 g of flour and 20 mg of silver powder. The mixture was transferred to the original assay crucible and assayed. The lead button obtained was cupelled to the silver bead, which was treated in the same manner as that obtained from the assay of the parting solution, except in the case of palladium.

Parting of the button: The button was treated with nitric acid (1:2 in case of palladium and 1:4 for other metals) and parted on a hot water bath. Subsequent to the dissolution of the button, 100 ml of water were added and the residue was allowed to settle. The latter was filtered, washed and treated as described below for the individual metals.

Treatment of the parting solution: The parting solution, including the washings, was evaporated to dryness on a hot water bath and the dried material was transferred to an assay crucible. The beaker in which the evaporation was made was washed with dilute nitric acid, and the washings were evaporated to dryness. This residue was also added to the assay crucible, and the mixture was heated for 1·5 hr in an electric furnace maintained at 750°, by which time the decomposition of lead nitrate to lead oxide was complete. The crucible was cooled, and the lead oxide was removed and weighed. Accepting this weight of the lead oxide as the weight of the sample, the required quantity of a monosilicate flux of the type $2Na_2O.SiO_2$ was prepared and mixed with the lead oxide. It has been found that a monosilicate flux of this type can be used effectively for collecting platinum and palladium along with traces of rhodium and iridium.[5]

The following typical flux composition was used: weight of lead oxide obtained = 30·1 g; sodium carbonate = 30·1 g; silica = 14·0 g; litharge = 27·0 g; flour = 3·0 g; silver = 20 mg.

The fusion mixture was transferred to the same assay crucible used for the conversion of lead nitrate to lead oxide, and was heated at 1150° for 35–40 min. The cleaned lead button was cupelled at 1000° to obtain a silver bead. The bead method was used here because it was expected, and later proved, that, of the platinum metals, only palladium would be present in appreciable proportion; platinum, rhodium and iridium would be present only in microgram quantities, in which case the silver bead method, as described earlier, could be applied successfully. The bead was parted with 1:2 nitric acid, and the residue was filtered, washed and ignited. The ignited residue in the case of platinum and palladium was dissolved in *aqua regia*, and in the case of rhodium and iridium by chlorination in the presence of sodium chloride. Silver was precipitated as chloride from the filtrate obtained after dissolving the silver bead; any adsorbed platinum metal was removed by dissolving the precipitate in aqueous ammonia and reprecipitating the silver chloride. The solutions were mixed, and the platinum metals were determined either gravimetrically or colorimetrically as described below.

TABLE I. RECOVERY OF PLATINUM BY LEAD FIRE ASSAY

Flux no.	Weight of button, *g*	Platinum in residue from parting acid, *mg*	Platinum in parting solution, *mg*	Platinum found in slag, *mg*	Total platinum recovered, *mg*	Platinum added, *mg*	Recovery, %
A	27·6	0·918	0·034	0·003	0·955	1·011	94·6
	29·8	0·944	0·031	0·003	0·978	1·011	96·5

	30·2	0·801	0·156	0·005	0·962	1·011	95·2
	25·7	0·806	0·150	0·005	0·961	1·011	95·1

Fire-assay recovery of platinum, palladium, rhodium and iridium

Lead buttons were obtained after the fusion of the fluxes A, B and C, previously salted with standard solutions of the platinum metals, and were parted with nitric acid as described above.

Platinum: The parting residue containing platinum was ignited at 600° and dissolved in *aqua regia*. The oxides of nitrogen were removed by repeated evaporation with hydrochloric acid in the presence of 4 drops of 2% sodium chloride solution. Platinum was determined colorimetrically by stannous chloride reagent.

The parting solution was assayed as described above, and platinum was determined in the silver beads colorimetrically.

In the absence of base metals, Hoffman and Beamish[6] used a nitre method, and reported a recovery of 97·3% of platinum.

Palladium: After treatment of the parting residue with *aqua regia* and then with hydrochloric acid, palladium was determined colorimetrically by *p*-nitrosodiphenylamine.

The palladium in the silver bead obtained from the parting solution was determined gravimetrically by the sodium salt of dimethylglyoxime, but in the silver bead obtained from the slag palladium was determined colorimetrically as above.

TABLE II. RECOVERY OF PALLADIUM BY LEAD FIRE ASSAY

Flux no.	Weight of button, *g*	Palladium in residue from parting acid, *mg*	Palladium in parting solution, *mg*	Palladium found in slag, *mg*	Total palladium recovered, *mg*	Palladium added, *mg*	Recovery, %
A	31·5	0·009	4·75	0·124	4·883	4·97	98·2
	30·0	0·009	4·75	0·110	4·869	4·97	98·0
	30·8	0·008	4·67	0·109	4·787	4·97	96·3
B	29·2	0·007	4·69	0·132	4·829	4·97	97·2
	27·4	0·007	4·69	0·138	4·835	4·97	97·3
	28·4	0·007	4·77	0·129	4·906	4·97	98·7

With a fusion mixture of the same silicate degree, but carrying out the analysis by a different method, Fraser and Beamish[7] reported an average recovery of 97·4% of palladium in the absence of added base metals.

Rhodium: The residue obtained after parting a lead button as described for platinum was ignited at 850° for 20 min, cooled, hydrogenated for 15 min, and then chlorinated at 600° for 8 hr in the presence of about 50 mg of sodium chloride. Rhodium was determined gravimetrically by 2-thiobarbituric acid.

Rhodium in the silver beads obtained from the parting solution and the slag was brought into a soluble form by chlorination as described above and then determined colorimetrically by stannous bromide.

TABLE III. RECOVERY OF RHODIUM BY LEAD FIRE ASSAY

Flux no.	Weight of button, *g*	Rhodium in residue from parting acid, *mg*	Rhodium from parting solution, *mg*	Rhodium found in slag, *mg*	Total rhodium recovered, *mg*	Rhodium added, *mg*	Recovery, %
A	31·2	3·32	0·820	0·010	4·150	4·79	86·6
	30·7	3·33	0·836	0·025	4·191	4·79	87·5
	32·6	3·57	0·740	0·015	4·325	4·79	90·3
B	27·4	3·96	0·579	0·031	4·570	4·79	95·4
	30·2	3·61	0·885	0·008	4·503	4·79	94·0
	29·9	3·78	0·754	0·019	4·553	4·79	95·1

In the absence of base metals, Allen and Beamish[3] have reported an average recovery of 96% of rhodium from the synthetic lead-rhodium buttons.

Iridium: The residue obtained from the parting acid in the case of iridium-lead buttons was ignited at 650° for 45 min, cooled, hydrogenated for 1 hr, and then chlorinated for 8 hr as in the case of rhodium. Iridium was obtained in soluble form and was determined gravimetrically by 2-mercaptobenzthiazole.

The lead button obtained from the parting solution was not cupelled directly, but was treated as in the case of the original button. This variation was introduced because, as noted earlier, cupellation losses of iridium are significant if the lead button contains a large amount of iridium. The parting solution obtained after parting this second button was subjected to a treatment similar to that in the case of platinum, palladium or rhodium, *e.g.*, the lead button was cupelled and then the iridium in the silver bead was determined colorimetrically by stannous bromide.

Barefoot and Beamish,[8] working with acidic fluxes, reported an average recovery of iridium of the order of 99%. Presumably the percentage recovery in the present instance is low because of the more basic fluxes used; these fluxes were used here because of their greater efficiency for platinum metals in general. With a mono-silicate flux, Barefoot and Beamish[8] found a recovery of 96% of iridium with a 0·5-mg sample of iridium.

Influence of copper on the dissolution of platinum metals in nitric acid

As stated above the lead buttons obtained from a fusion of ores from the natural deposits of the platinum metals frequently carry traces of copper. It was observed in preliminary experiments that the presence of copper in the lead button affects the distribution of the platinum metals between the parting acid and the acid insoluble. Other researches on platinum, palladium, rhodium and iridium clearly indicate that the total recovery of these precious metals by lead fire-assay collection is affected by the presence of copper in the flux or in the lead button.[3,6–8] In order to determine the influence of copper on the extent of dissolution of the platinum metals, lead buttons were prepared to contain various amounts of copper. These were parted with nitric acid, and the quantity of the platinum metal in the parting solution was determined by the procedure described above. The results are recorded in Table V.

TABLE IV. RECOVERY OF IRIDIUM BY LEAD FIRE ASSAY

Flux no.	Weight of button, *g*	Iridium in residue from parting acid, *mg*	Iridium from parting solution, *mg*	Iridium found in slag, *mg*	Total iridium recovered, *mg*	Iridium added, *mg*	Recovery, %
A	29·4	4·98	nil	nil	4·98	5·21	95·6
	28·9	4·97	nil	nil	4·97	5·21	95·4
	31·1	4·97	nil	nil	4·97	5·21	95·4
B	28·5	3·39	1·15	nil	4·54	5·21	87·2
	28·7	3·47	1·00	nil	4·47	5·21	85·8
	30·2	4·28	0·249	nil	4·529	5·21	86·9
C	27·9	2·61	1·14	nil	3·75	5·21	72·0
	28·6	2·81	1·43	nil	4·24	5·21	81·4
	29·9	2·35	1·36	nil	3·71	5·21	71·2

TABLE V. INFLUENCE OF COPPER ON THE DISSOLUTION OF PLATINUM, PALLADIUM, RHODIUM AND IRIDIUM IN NITRIC ACID

Amount of copper in button, *g*	Average quantity of noble metal found in the parting solution			
	Platinum, *mg*	Palladium, *mg*	Rhodium, *mg*	Iridium, *mg*
nil	0·031	4·72	0·799	nil
0·35	0·153	4·68	0·739	0·800
0·68				1·310

The above results indicate that the amount of platinum and iridium in the parting solution increases with an increase of copper in the button. In preliminary experiments, it was observed also that if 5 mg of iridium are collected in pure copper, and the button is parted with nitric acid, the dissolution of iridium is practically complete.

Losses of iridium in a fire assay

It may be noted from the above results that the recovery of iridium by the lead-collection method may be adversely affected by the presence of copper in the slag. Barefoot and Beamish reported that the recovery of iridium is low in the presence of both nickel and copper. Iron may, however, be tolerated. Although the sources of the loss of iridium have not been determined, it has been assumed that the losses occur to the slag or to the pot wall.

Losses to the slag

Barefoot and Beamish[8] observed that after the initial fusion the recovery by lead from the slag was not efficient, even after a number of re-assays. However, a spectrographic examination of the monosilicate and basic slags failed to show the presence of iridium.

In the present investigation an attempt was made to determine the losses to the slag by neutron activation. The procedure employed was as follows.

Representative samples (about 60 mg each) of the ground slag were wrapped in aluminium foil and subjected to neutron bombardment. After the activation was complete, the hot samples were left for 2–3 weeks to allow the decay of radioactive sodium. The samples were transferred to plastic containers, the intensities were measured in the different energy channels, and were compared with those of the blank slag salted with known amounts of iridium (about 0·1 μg). No significant amount of iridium was found to be present in the slag.

Losses to the pot wall

For the fusion of the pot wall, a basic flux is required, *i.e.*, a ratio of acid oxygen to basic oxygen of the order of 0·5. The 30-g assay crucible, in which the fire-assay collection for iridium was carried out by using flux (B) or (C), was crushed and pulverised to a fineness of 45-mesh and mixed with the following flux:

Weight of pot wall taken = 60 g
Sodium carbonate = 60 g
Calcium oxide = 37·5 g
Silica = 12·5 g
Borax = 12·5 g
Litharge = 154·0 g
Flour = 4·3 g
Silver = 20 mg

The assay was made at 1200° for 1·5–2 hr, producing a clear and homogeneous slag. The lead buttons were cupelled to obtain silver beads, which were subsequently analysed for iridium colorimetrically by the stannous bromide method.

No detectable amount of iridium was recovered from the pot wall.

A standard solution containing 1·04 mg of iridium was added to the inside walls of a new 30-g assay crucible, the crucible was then dried overnight in an air oven and subjected to the same treatment as above; the weight of iridium recovered was 0·177 mg.

It would seem that the fusion process results in some incorporation of iridium with the pot wall. Because assay pots are essentially silicates, a basic flux is required for a suitable fusion. Fluxes of this type are ineffective for the quantitative collection of iridium.[8] In any case, the sources of loss of iridium during a fire assay have not yet been determined, although by process of elimination it is not unlikely that some inclusion with the pot wall does occur.

Separation and determination of palladium in the presence of lead

By the above assay procedure evidence was obtained to indicate the presence of large amounts of palladium and only traces of platinum and rhodium in the nitric acid parting solution. In general assay practice, and particularly in those instances where assay results are obtained for the purpose of indicating the commercial value of a natural deposit, the content of platinum, palladium and gold is of primary importance, and the small traces of platinum present in the parting solution are of relatively little significance. In these instances an effective method of isolating the palladium in the parting acid is useful. Efforts were made to provide a procedure which would avoid the necessity of the cumbersome lead sulphate separation.

Ion exchange

Recently, ion-exchange procedures for the isolation of platinum metals from large amounts of base metals, such as iron, copper and nickel, have been reported.[5] The methods involve the conversion of the six platinum metals to stable anionic halides and the base metals to a cationic form. Although this method could not be applied directly to lead buttons, because of the insolubility of lead halides, it seemed probable that a cation exchanger could be used to remove lead selectively from the nitric acid parting solution. This approach was investigated by the following procedure.

The lead button, containing only palladium, was parted with 1:2 nitric acid, and the resulting solution was treated with a filtered solution containing 0·5 g of the disodium salt of 1,2-diaminocyclohexanetetra-acetic acid in 15–20 ml of water. The pH was adjusted to 0·5–1·0 by sodium hydroxide, and the solution was heated on a hot plate for 15–20 min to complex the palladium. After cooling, the solution was passed through a cation-exchange column containing 50 W × 8 cation-exchange resin sufficient in quantity to adsorb approximately 30 g of lead. To remove the palladium, 3 litres of $1M$ nitric acid were passed through the column slowly. Lead remained adsorbed, and was stripped by passing 3 litres of $3M$ nitric acid through the column.

The palladium solution was evaporated almost to dryness and then transferred to a small beaker. The palladium complex was decomposed by treating with fuming nitric acid and hydrogen peroxide alternately. Finally, the palladium was dissolved by hydrochloric acid and determined gravimetrically by the sodium salt of dimethylglyoxime. The results are recorded in Table VI.

TABLE VI. SEPARATION OF PALLADIUM FROM LEAD BY ION EXCHANGE

Palladium added, *mg*	Palladium found, *mg*	Error, *mg*
9·94	9·85	0·09
9·94	9·86	0·08
4·97	4·87	0·10

Separation of the palladium from lead by precipitation

Beamish and coworkers[9] have reported the separation of palladium from large quantities of the lead by precipitating the former with salicylaldoxime after the removal of nitric acid by evaporation of the parting solution. In the present investigation, an attempt was made to separate palladium without a prior evaporation. Preliminary experiments indicated that ascorbic acid could be employed successfully for the gravimetric determination of palladium in an acetic acid medium, and that the large quantities of nitrates did not interfere. The following procedure was applied successfully for the separation of palladium from the parting acid.

Following the dissolution of the lead button by nitric acid, sodium hydroxide was added to neutralise the solution as indicated by the appearance of a permanent precipitate, acetic acid was added to dissolve the precipitate and the resulting solution was warmed. After addition of 0·5 g of ascorbic acid, the solution was heated for a few minutes, and the precipitate was allowed to settle. The precipitate was filtered, and the residue was washed thoroughly to remove all of the lead salts. The residue was dried, ignited at 600°, dissolved by *aqua regia*, and finally treated with hydrochloric acid containing a little sodium chloride. Palladium was determined gravimetrically by the sodium salt of dimethylglyoxime. The results are listed in Table VII.

Palladium added, *mg*	Palladium found, *mg*	Error, *mg*
9·94	9·81	0·13
9·94	9·84	0·10
9·94	9·90	0·04

DISCUSSION

Irrespective of the lack of an integrated procedure for the determination of the seven noble metals in a lead button, there is value in a simple wet method for the determination of platinum, palladium, rhodium and iridium in lead buttons. By far the larger proportion of the world's supply of platinum metals is derived from deposits in which platinum and palladium predominate, with a minor proportion of the more insoluble platinum metals. The fire-assay procedure described above allows an acceptably quantitative recovery of the four metals from a lead button without the cumbersome removal of lead as the sulphate, required by the classical procedure.

One may hope for an extension of the above procedure to include consecutive determinations of osmium and ruthenium. Although these metals are collected quantitatively by lead, the only existing method for their subsequent determination involves parting with perchloric acid, followed by simultaneous isolation of both osmium and ruthenium as tetroxides. Unfortunately, there is no established procedure recorded for a nitric acid parting of the lead button and the subsequent distillation of the octavalent oxides. It would seem reasonable that the osmium in the nitric parting solution could be oxidised to remove osmium quantitatively and selectively. However, the presence of the large amounts of lead in the parting solution may well vitiate this separation as a quantitative procedure. Furthermore, no procedure has been developed for the subsequent removal of ruthenium in a lead nitrate-nitric acid parting medium. With the accomplishment of these separations a most useful assay procedure would be available.

Acknowledgement—The authors wish to acknowledge the help rendered by Professor R. E. Jervis of the Department of Chemical Engineering of the University of Toronto in the neutron-activation analysis.

Zusammenfassung—Eine Schmelzmethode wird beschrieben, bei der Platin, Palladium, Rhodium oder Iridium in der salpetersauren Scheidelösung aus dem Bleiregulus bestimmt werden. Palladium ist das einzige Metall, das von der Scheidelösung völlig gelöst wird; Spuren von Platin und Rhodium werden mit gelöst. Die Anwesenheit von Kupfer im Bleiregulus begünstigt die Auflösung von Platin und Iridium in der Scheidelösung; Rhodium wird nicht angegriffen. Auch Ionenaustausch- und Fällungsmethoden zur Palladium-Platin-Trennung werden berücksichtigt. Es wurde versucht, die Ursache der Iridiumverluste zu ergründen, die für die klassischen Schmelzproben charakteristisch sind.

Résumé—On décrit une méthode de fusion plombeuse pour doser le platine, le palladium le rhodium ou l'iridium dans la solution nitrique de séparation obtenue à partir du bouton de plomb. Le palladium est le seul métal complètement attaqué par la solution de séparation; on dissout aussi des traces de platine et de rhodium. On a trouvé que la présence de cuivre dans le bouton de plomb favourise la dissolution du platine et de l'iridium dans la solution nitrique de séparation; le rhodium reste inattaqué. On décrit également les techniques d'échange d'ions et de précipitation pour séparer le palladium du plomb. On a fait des essais en vue d'identifier la source de la perte en iridium, qui est une caractéristique des méthodes de dosage par fusion plombeuse.

SHORT COMMUNICATIONS

A new class of adsorption indicators

(*Received* 13 *January* 1964. *Accepted* 20 *March* 1964)

FAJANS[1] first suggested the use of certain luminescent dyestuffs as adsorption indicators in argentimetry. Their action is based on the disappearance of luminescence from solution at the equivalence point. This is brought about by adsorption of the dyestuff because of a change in the surface charge of the precipitate. Reversal of the charge of the precipitate causes desorption of the dyestuff and reappearance of luminescence.[2]

During investigations on the luminescence of cyanine dyes,[3] the experiment of using some of them as adsorption indicators was carried out. For this purpose the cyanometric method[4] was chosen; this can be used for the rapid determination of silver in light-sensitive precipitates of silver halides. As indicator a few drops of a saturated methanolic solution of a dyestuff were used. It was found that some of the dyestuffs were adsorbed on a precipitate of silver iodide and showed a strong fluorescence when excited with an ultraviolet lamp. This was observed with 1,1-dimethylbenzoxacyanine iodide (I), 1,1-dimethylbenzthiacyanine iodide (II) and many other oxacyanines and thiacyanines, prepared by the method of Fischer and Hamer.[5]

When using dyestuff (I) in the titration with 0·002*N* silver nitrate solution, the addition of 1 drop (0·05 ml) of titrant in excess causes the precipitation of silver iodide and the appearance of fluorescence. Titration can therefore be carried out in very dilute solution. If the titration is continued past the end-point, the intensity of fluorescence decreases as the silver iodide precipitate increases. This shows that the indicator is adsorbed on the initial precipitate and the light is scattered by the silver iodide subsequently precipitated. The addition of an excess of cyanide solution causes dissolution of the precipitate of silver iodide and disappearance of the fluorescence. After further addition of silver ions the fluorescence reappears instantly as silver iodide is again precipitated.

The fluorescence appears rapidly at the beginning of the precipitation, increases for a few sec, then remains constant. At low concentration of indicator the fluorescence is bluish-white, but with increasing indicator concentration there is a change towards green. Before the precipitation of silver iodide, the system (excited with an ultraviolet lamp) shows a violet fluorescence.

In the determination of silver in light-sensitive precipitates of silver halides in industrial laboratories, cases are sometimes encountered in which coloured or sparingly soluble compounds are also present. An accurate end-point cannot then be detected because the reprecipitated silver halide is obscured. In the presence of a fluorescent adsorption indicator, however, an accurate determination becomes possible.

The fluorescence from the adsorbed dyestuff (I) is quite selective. Precipitation of silver bromide in the presence of this indicator gives a green fluorescence, weaker than that with precipitates of silver iodide. In the case of silver chloride the precipitate shows only a trace of fluorescence.

Dyestuff (II) acts very slowly as a fluorescent indicator, apparently because of its low solubility in the system under investigation. Addition of a saturated methanolic solution of the dyestuff to an aqueous medium brings about partial precipitation of the solid dyestuff, showing a pink fluorescence. If silver iodide is precipitated in this system the pink fluorescence slowly changes to an intense yellow-green. This points to a change in form of the precipitated dyestuff to a more stable state of aggregation in the adsorbed form.

On filtering off silver iodide precipitated in the presence of dyestuff (I), it showed a strong fluorescence. The fluorescent emission curve obtained (Fig. 1) leads to the conclusion that there is a luminescence of the second type,[6] which is to be attributed to the polymeric form of the dyestuff. Such polymers are often formed in systems of monomethinecyanine dyestuffs containing water[7] and they are recognised by the Jelley adsorption band.[8]

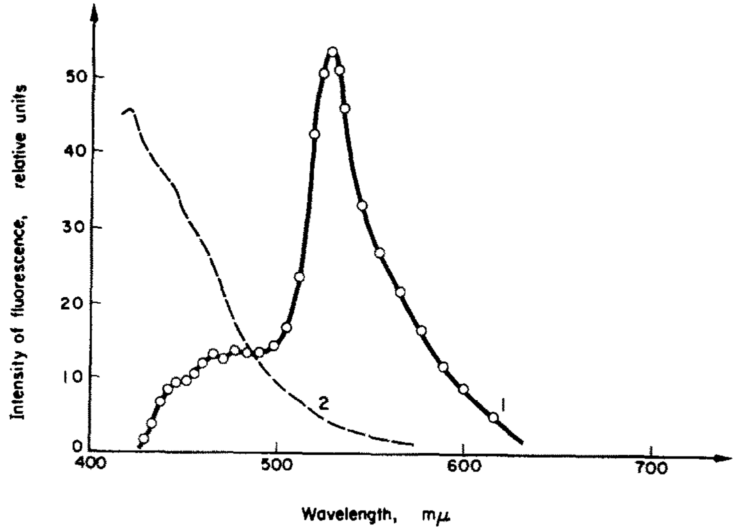

FIG. 1.—Fluorescent emission curves:
1—silver iodide precipitated in presence of dyestuff (I) (polymeric form),
2—filter paper stained with dyestuff (I) (monomeric form).

It is very interesting that cyanine dyestuffs fluoresce on silver iodide particles, *i.e.*, on a carrier which is known to absorb very easily the excitation energy of the dyestuff adsorbed on its surface. A more detailed account of the above investigations will be published in due course.

Summary—Oxacyanine and thiacyanine dyes have been found to act as fluorescent adsorption indicators in the cyanometric titration of silver halides.

Zusammenfassung—Oxacyanin- und Thiacyaninfarbstoffe wirken als fluoreszierende Adsorptionsindikatoren bei der cyanometrischen Titration von Silberhalogeniden.

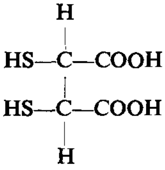
Résumé—On a trouvé que les colorants de l'oxacyanine et de la thiacyanine se comportent comme indicateurs d'adsorption fluorescents dans le dosage cyanométrique des halogénures d'argent.

Use of masking agents in chelatometric titrations—IV:* Dimercaptosuccinic acid†

(*Received* 6 *May* 1964. *Accepted* 7 *July* 1964)

In continuation of our investigations on the use of mercaptans as masking agents in chelatometric titrations, the properties of dimercaptosuccinic acid (DMS) have now been investigated. Although the antimony complex of DMS has been used as a chemotherapeutic agent for certain tropical diseases, the only paper which has discussed the chelating behaviour of DMS is that of Agren and Schwarzenbach, who investigated the chelation with zinc.[1]

DMS is a tetradentate ligand having two carboxylic acid and two mercapto groups:



$$\begin{array}{c} H \\ | \\ HS-C-COOH \\ | \\ HS-C-COOH \\ | \\ H \end{array}$$

However, all of these functional groups cannot co-ordinate with the same metal ion. As might be expected, most DMS-metal chelates are soluble in water. Although the co-ordinating groups of DMS are the same as those of thioglycolic acid or β-mercaptopropionic acid, differences in the number of co-ordinating groups and their steric arrangement will lead to a different selectivity of masking in EDTA titrations.

EXPERIMENTAL

Reagents

Dimercaptosuccinic acid (DMS):‡ This was synthesised from acetylenedicarboxylic acid and thioacetic acid according to the procedure of Gerecke, Friedheim and Brossi.[2] As is clear from the structure of DMS, four modifications (d, l, racemic and meso) are possible. However, only two of these (racemic and meso) have so far been known. The reported melting points for the pure isomers are 210–1° (meso form) and 127–8° (racemic form). The material used in this experiment has a melting point of 195–7° and is believed to consist mostly of meso form.

DMS is a white crystalline solid which is rather unstable and easily oxidised in the air. It has no objectionable odour. In the present experiments, a $0.1M$ methanolic solution of the disodium salt of DMS was employed. The methanolic solution can be stored for more than a month, if it is kept in a refrigerator in a sealed bottle. If it is used frequently in the laboratory, however, the solution should be prepared each week.

Buffer solutions: A standard composition of aqueous ammonia and ammonium chloride was used for pH 10 and hexamethylenetetramine for pH 6.

Indicator solutions: Eriochrome Black T (0.5% in methanol with an addition of hydroxylamine hydrochloride) and Xylenol Orange (0.1% aqueous) were used.

Solutions of cations and EDTA were prepared in $0.01M$ concentration from reagent-grade chemicals, and their strengths determined against primary standard metallic zinc.

Preliminary investigation

In order to estimate the selectivity of masking by DMS, the following experiments were carried out:

One ml of a $0.01M$ cation solution was diluted to 50 ml, and to this were added 1 ml of DMS solution and 1 ml of buffer solution. Tests were also carried out in the presence of Xylenol Orange or Eriochrome Black T indicator both with and without the addition of DMS. The resulting colours of the solutions were compared.

As pointed out in a previous paper,[3] this test does not always suggest the possibility of masking in the EDTA titration of certain metals. However, it can be a useful guide in the screening test of masking agents. The results are shown in Table I.

(1) Colour reaction observed after adding buffer and DMS to the metal ion solution.
(2) Colour reaction observed after adding indicator to the solution in (1).
(3) Colour reaction observed after adding buffer and indicator to the metal ion solution.
ND: Coloration of metal-DMS complex so intense that no distinct colour of indicator can be observed.

Titration of zinc in presence of cadmium or copper(II)

To a mixture of 10 ml of a 0.01*M* solution of zinc and 1–5 ml of a 0.01*M* solution of cadmium or 2–6 ml of a 0.01*M* solution of copper(II), 2–4 ml of DMS solution, about 100 mg of hexamethylenetetramine and a few drops of Xylenol Orange indicator solution were added. After diluting to 100 ml, the solution was titrated with 0.01*M* EDTA solution.

Titration of magnesium in presence of various bivalent cations

A similar procedure to that for the titration of zinc was followed, except that the pH was adjusted to 10 with 3 ml of ammoniacal buffer solution and Eriochrome Black T indicator was used as indicator.

The results of the titrations are summarised in Tables II and III.

Table II.—Titration of zinc at pH 6

Zn taken, *mg*	Metal present, *mg*	0.1*M* DMS added, *ml*	Zn found, *mg*	Error, *mg*
	Cd			
6.67	1.12	2	6.73	+0.06

RESULTS AND DISCUSSION

Use of DMS at pH 6

Zinc can be titrated selectively in the presence of cadmium, if the amount of the latter does not exceed that of the zinc. Increasing positive errors are noted with an increasing amount of cadmium. These errors may be caused by indistinct colour change near the end-point, because the pure yellow colour is only observed slightly after the equivalence point. As to the selective titration of zinc in the presence of cadmium, Přibil has proposed a method in which a selective replacement reaction of cadmium-EDTA complex with diethyldithiocarbamate is utilised.[4] The present method is simpler and can be readily adapted to practical applications.

Copper can also be masked up to one half of the amount of zinc. In this case, however, the titration errors tend to be negative, and the reason may be that the yellow coloration of the copper-DMS complex tends to give an earlier end-point with Xylenol Orange. From Table I it seems that lead can also be masked with DMS. However, the complex is insufficiently stable to be masked against EDTA titration.

Iron(III), cobalt and nickel form coloured complexes with DMS in this pH region, and their colours are so intense that no distinct end-point colour change can be observed.

Use of DMS at pH 10

Lead, copper(II), nickel, cobalt and cadmium can be masked in the presence of the alkaline earth metals. Because lead and cadmium form colourless complexes with DMS, even large amounts of them can be masked efficiently. Copper(II) forms a yellow complex at pH 10, and negative errors are noted because of the earlier end-point. Although from Table I zinc can be masked against the indicator, the zinc-DMS complex is insufficiently stable to be masked against EDTA. Nickel and cobalt form dark green and brown complexes, respectively, and they must not be present in large amount. Iron(III) forms a dark red complex even in the presence of triethanolamine and must, therefore, be absent when DMS is employed as a masking agent.

Summary—Dimercaptosuccinic acid has been examined as a masking agent in EDTA titrations. At pH 6 it is possible to determine zinc in the presence of cadmium, copper(II) and mercury(II). At pH 10 most bivalent cations except for the alkaline earth metals can be masked.

Zusammenfassung—Der Gebrauch von Dimercaptobernsteinsäure als Maskierungsmittel bei EDTA-Titrationen wurde studiert. Mit diesem Reagens kann Zink bei pH 6 neben Cadmium, Kupfer(II) und Quecksilber(II) bestimmt werden. Bei pH 10 können außer Erdalkalien die meisten zweiwertigen Kationen mit diesem Reagens maskiert werden.

Résumé—On a étudié l'acide dimercaptosuccinique en tant qu'agent de dissimulation dans les dosages à l'EDTA. En utilisant ce réactif à pH 6, on peut doser le zinc en présence de cadmium, cuivre(II) et mercure(II). A pH 10, la majeure partie des cations divalents, à l'exception des ions alcalino-terreux, peut être dissimulée par ce réactif.

A specific method for the determination of trace amounts of titanium

(*Received* 18 *May* 1964. *Accepted* 29 *July* 1964)

While attempting to devise a method for the simultaneous determination of titanium and zirconium,[1] a specific method for determining trace amounts of the former element has been developed. Titanium is precipitated from a hydrochloric-sulphuric acid medium with cupferron using zirconium as a collector. A hydrochloric-hydrofluoric acid solution, containing the titanium and other elements precipitated quantitatively or partly with cupferron, is passed through a column containing Dowex-1 × 8 anion-exchange resin.[2,3] Niobium and tantalum are retained by the resin. Titanium and the remaining elements pass unadsorbed into the eluate, from which titanium is again precipitated with cupferron. Titanium is separated from tungsten and molybdenum by precipitation with sodium hydroxide using iron as a collector. The determination is completed colorimetrically after extraction of the titanium-thiocyanate complex with a solution of tri-n-octylphosphine oxide in cyclohexane.[4] The method is accurate to within $\pm 5\%$ (relative) or $\pm 0{\cdot}75\ \mu g$ of titanium, whichever is greater.

EXPERIMENTAL

Reagents

A specific method for the determination of trace amounts of titanium

(*Received* 18 *May* 1964. *Accepted* 29 *July* 1964)

While attempting to devise a method for the simultaneous determination of titanium and zirconium,[1] a specific method for determining trace amounts of the former element has been developed. Titanium is precipitated from a hydrochloric-sulphuric acid medium with cupferron using zirconium as a collector. A hydrochloric-hydrofluoric acid solution, containing the titanium and other elements precipitated quantitatively or partly with cupferron, is passed through a column containing Dowex-1 × 8 anion-exchange resin.[2,3] Niobium and tantalum are retained by the resin. Titanium and the remaining elements pass unadsorbed into the eluate, from which titanium is again precipitated with cupferron. Titanium is separated from tungsten and molybdenum by precipitation with sodium hydroxide using iron as a collector. The determination is completed colorimetrically after extraction of the titanium-thiocyanate complex with a solution of tri-n-octylphosphine oxide in cyclohexane.[4] The method is accurate to within ±5% (relative) or ±0·75 μg of titanium, whichever is greater.

EXPERIMENTAL

Reagents

Hydrofluoric acid, 29*M*

Hydrochloric acid, 1·2*M* and 12*M*

Sulphuric acid, 3·6*M*, 6*M* and 18*M*

25% *Hydrochloric acid*-20% *hydrofluoric acid*

Filter paper, Whatman No. 40, 5·5 cm and 12·5 cm. Filter paper has been found to be the major cause of high blanks. If Whatman papers are unavailable, the papers to be used should be analysed for titanium before application of the procedure.

Filter paper pulp. Cut Whatman 40 filter paper into small (1 cm × 1 cm) pieces and shake vigorously with hot water in a stoppered Erlenmeyer flask.

Zirconium sulphate solution, 1 mg of zirconium/ml

Iron(III) chloride solution, 10 mg of iron/ml

Cupferron solution, 6% (w/v), freshly prepared

Cupferron wash solution. Add 10 ml of 6% cupferron solution to 500 ml of 1·2*M* hydrochloric acid. Prepare just before use.

Sodium bisulphate

Anion-exchange resin. Dowex 1 × 8, 100-200 mesh resin obtained from Bio-Rad Laboratories.

Sodium hydroxide, 1% and 40% solutions

Citric acid

Thioglycolic (mercaptoacetic) acid, 98% solution

Ammonium thiocyanate

Tri-n-octylphosphine oxide (TOPO), 0·01*M* in cyclohexane

Standard titanium solution. Prepare a standard titanium solution containing 5 μg of titanium/ml in 6*M* sulphuric acid.

Procedure

Dissolve the sample, preferably containing a minimum of 15 μg of titanium, and obtain it in 150 ml of solution containing 10 ml of hydrochloric acid and 25 ml of sulphuric acid. Add 10 ml of zirconium sulphate solution and 0·5 g of filter paper pulp. Cool the sample solution, the 6% cupferron solution and the cupferron wash solution to 10–15°. Add 15 ml of cupferron solution, or sufficient to obtain complete precipitation, and filter. (It is very convenient to filter through a 6·3-cm i.d. Büchner funnel using suction. A piece of 5·5-cm filter paper is first placed in the bottom of the funnel, then a piece of 12·5-cm paper is pushed down into the funnel using a 150-ml beaker. Finally, with the suction on, the paper is wetted with water.) Wash the precipitate 10 times with the cupferron wash solution. Transfer the precipitate to a platinum crucible and ignite. Fuse the residue in about 2 g of sodium bisulphate. Dissolve the melt in a polyethylene beaker with 50 ml of 25% hydrochloric-20% hydrofluoric acid, warming gently. Pass 50 ml of the hydrochloric-hydrofluoric acid solution through the anion-exchange column (12 cm × 1 cm i.d., containing 8 cm of anion-exchange resin) and discard the eluate. Pass the sample solution through the column and wash with 50 ml of the same elutrient, collecting the eluate in a platinum dish. Add 5 ml of sulphuric acid and heat to fumes of sulphuric acid. Transfer the solution to a 250-ml beaker and dilute to about 100 ml with water. Cool, add 5 ml of 12*M* hydrochloric acid, 0·5 g of filter paper pulp and 15 ml of 6% cupferron solution. Filter as described and wash the precipitate 5 times with the cupferron wash solution.

Ignite the precipitate in a platinum dish or crucible, cool and dissolve the residue with 10 ml of hydrofluoric acid. Add 2 ml of sulphuric acid and evaporate to fumes of sulphuric acid. Cool, add 15 ml of water and warm to dissolve the salts. Add 1 ml of the iron(III) chloride solution and transfer the solution to a 50 ml centrifuge tube containing 20 ml of 40% sodium hydroxide. Mix, cool and centrifuge. Decant the supernatant solution, add 30 ml of 1% sodium hydroxide, mix, centrifuge and again discard the solution. Add 15 ml of 6*M* sulphuric acid to dissolve the basic salts and transfer with 6*M* sulphuric acid to a 125-ml separatory funnel. (If the sample is known to contain more that 15 μg of titanium, transfer the solution to a volumetric flask, dilute with 6*M* sulphuric acid, and use an aliquot containing 15 μg of titanium.)

Add sufficient 6*M* sulphuric acid to the separatory funnel to obtain a volume of about 35 ml. Add 1 g of citric acid, 1 ml of thioglycolic acid and 3 g of ammonium thiocyanate. Stopper the funnel and shake for 30 sec to dissolve the salts. Add exactly 15 ml of 0·01*M* TOPO solution, stopper the funnel and shake for 5 min.* Allow the layers to separate, and draw off and discard the aqueous layer. Wash the organic phase for 1 min with 35 ml of 6*M* sulphuric acid. Discard the acid wash. Draw the organic phase into a 15-ml glass-stoppered centrifuge tube and centrifuge the extract for 1 min. Measure the absorbance of the extract in a 1-cm cell at 429 mμ using cyclohexane in the reference cell. (At this wavelength, the molar absorptivity of the complex is about 43,000, indicating an absorbance of about 0·9 for 1 μg of titanium/ml in 1-cm cells. The extracted complex is stable, within experimental error, for at least 24 hr. The absorbance is a linear function of concentration, at least from 0 to 1 μg of titanium/ml, and obeys Lambert's law when 1-, 2,- and 5-cm cells are used.) Determine the titanium concentration by reference to a standard curve obtained by carrying known amounts of titanium in 6*M* sulphuric acid through the extraction steps. (It is, of course, desirable that one determine both a reagent blank and a recovery figure for the entire procedure.)

No interference was caused by the presence of 10-mg amounts of Al, $\mathrm{Sb^{III}}$, $\mathrm{As^{III}}$, Ba, Be, Bi, B, Br (as $\mathrm{Br^-}$), Cd, Ca, $\mathrm{Ce^{IV}}$, Cs, $\mathrm{Cr^{III}}$ Co, $\mathrm{Cu^{II}}$, Dy, Er, Eu, F (as $\mathrm{F^-}$), Gd, Ga, Ge, Au, Hf, Ho, In, I (as $\mathrm{I^-}$), Ir, $\mathrm{Fe^{III}}$, La, Pb, Li, Lu, Mg, $\mathrm{Mn^{II}}$, $\mathrm{Hg^{II}}$, Mo, Nd, Ni, Nb, N (as $\mathrm{NO_3^-}$), $\mathrm{Pd^{IV}}$, P (as $\mathrm{PO_4^{3-}}$), $\mathrm{Pt^{IV}}$, K, Pr, Re, Rh, Rb, Sm, Sc, $\mathrm{Se^{IV}}$, Si, Ag, Na, Sr, Ta, $\mathrm{Te^{IV}}$, Tb, $\mathrm{Tl^{I}}$, Th, Tm, $\mathrm{Sn^{IV}}$, W, $\mathrm{U^{VI}}$, $\mathrm{V^{V}}$, Yb, Y, Zn or Zr.

---

* The extraction of titanium is discussed in considerably more detail in reference 1.

Procedure modifications

(1) If niobium and tantalum are known to be absent in interfering amounts,[1] the ion-exchange step may be omitted. After the initial precipitation of titanium, ignite the precipitate and fuse the residue in a minimum amount of sodium or potassium bisulphate. Dissolve the fused mass with 15 ml of $3{\cdot}6M$ sulphuric acid, add 1 ml of iron(III) chloride solution and transfer to a 50-ml centrifuge tube containing 20 ml of 40% sodium hydroxide. Continue with the procedure as described.

(2) If tungsten and molybdenum are known to be absent in interfering amounts,[1] the sodium hydroxide precipitation step may be omitted. Dissolve the first cupferron precipitate, after ignition, with the hydrochloric-hydrofluoric acid solution and perform the ion-exchange separation as described. Add 2 ml of sulphuric acid to the eluate and evaporate to fumes of sulphuric acid. Continue with the extraction of titanium as described.

(3) If niobium, tantalum, molybdenum and tungsten are all absent, both the ion-exchange and sodium hydroxide precipitation steps can be omitted. The precipitate can be ignited, treated with hydrofluoric and sulphuric acids, evaporated to fumes of sulphuric acid, and extracted. If barium, tin and antimony are also absent, the precipitate can be destroyed by treatment with nitric and perchloric acids as described in reference 1.

Summary—A method is presented which is specific for the determination of trace amounts of titanium. Titanium is precipitated with cupferron using zirconium as a collector. Further separation from interfering elements is made by anion exchange and precipitation with sodium hydroxide using iron as a collector. The determination is completed colorimetrically after extraction of the titanium-thiocyanate complex with a solution of tri-n-octylphosphine oxide in cyclohexane. The method is accurate to within ±5% (relative) or $\pm 0{\cdot}75$ μg of titanium, whichever is greater.

Zusammenfassung—Eine spezifische Methode zur Bestimmung von Titanspuren wird angegeben. Titan wird auf Zirkontrager mit Cupferron gefallt. Durch Anionenaustausch und Fallung mit Natriumhydroxyd auf Eisentrager werden weitere störende Elemente abgetrennt. Bestimmt wird Titan durch Extraktion seines Rhodanidkomplexes mit Tri-n-octylphosphinoxyd in Cyclohexan. Die Methode ist auf ±5% (relativ) oder bestenfalls ±0,75 μg genau.

Résumé—On présente une méthode de dosage spécifique du titane a l'état de traces. On précipitite le titane au cupferron en utilisant le zirconium comme agent collecteur. On procède ensuite à une séparation des éléments interférants par échange anionique, et précipitation a la soude, en utilisant le fer comme agent collecteur. On effectue le dosage par extraction du complexe thiocyanique du titane au moyen d'une solution d'oxyde de tri-n-octylphosphine en cyclohexane. La précision de la méthode est ±5% en valeur relative ou ±0,75 μg de titane. On prend la plus grande des deux erreurs.

Response rates of cation-sensitive glass electrodes

(*Received* 30 *May* 1964. *Accepted* 7 *July* 1964)

THE response-rate characteristics of cation-sensitive glass electrodes ultimately determine the applicability of such electrodes to dynamic concentration measurements in continuous analysis or kinetic studies. Several authors[1,2] have noted the apparently sluggish response of cation-sensitive glass electrodes to rapid concentration changes in aqueous solution; in a previous paper,[3] we also reported response times of the order of several minutes for the Beckman 78137 V experimental electrode. In the light of modern evidence[4] on the nature of the potential-determining mechanism of both pH-type and cation-sensitive glass electrodes, it seems likely that the slow response of the latter results from poor construction characteristics and pretreatment, rather than from any inherent slow steps in the response mechanism. Because considerable technical advances in the manufacture of cation-sensitive glass electrodes have been achieved since our previous report, the response characteristics of the newest commercially available electrode were re-examined to test this hypothesis.

EXPERIMENTAL

Measurements were carried out in stirred solution, using the new Beckman 39137 cationic glass electrode. Potentials (*versus* Beckman 39170 fibre-junction calomel reference electrode) were determined with a Beckman Model 76 expanded-scale pH meter; the electrode response was timed with a stopwatch. The inherent deflection time of the pH meter was found to be 0·8 ± 0·1 sec per 100 mv on the expanded scale.

Electrode-response measurements were carried out by two procedures, employing (1) a dipping and (2) a dilution method. In all cases, the glass electrode was preconditioned by a 24-hr soaking in the appropriate reference solution. Experiments were performed at room temperature because changes in ambient temperature were negligible during the times involved.

Dipping procedure: Immerse the glass-calomel electrode pair in the stirred reference solution and measure the equilibrium potential. Transfer the glass electrode to the test solution containing the metal ion in a concentration greater than, smaller than, or equal to that of the reference solution.

TABLE I.—RESPONSE OF CATION-SENSITIVE GLASS ELECTRODE TO CONCENTRATION CHANGES

(1) Dipping experiments

Metal ion	Solution concentrations, *moles/litre*	Response times, *sec*
K^+(KCl)	Reference Test Reference	
	0·5 $\xrightarrow{t}$ 0·5	1·6
	0·1 $\xrightarrow{t}$ 0·1	1·5
	0·5 $\longrightarrow$ 1·0 $\xrightarrow{t}$ 0·5	1·6
	0·5 $\longrightarrow$ 0·0 $\xrightarrow{t}$ 0·5	2·5
	0·1 $\longrightarrow$ 1·0 $\xrightarrow{t}$ 0·1	3·1
	0·1 $\longrightarrow$ 0·05 $\xrightarrow{t}$ 01	2·3
	0·1 $\longrightarrow$ 0·0 $\xrightarrow{t}$ 0·1	2·6
Na^+(NaCl)	1·0 $\xrightarrow{t}$ 1·0	1·6
	0·1 $\xrightarrow{t}$ 0·1	1·6
	1·0 $\longrightarrow$ 0·1 $\xrightarrow{t}$ 1·0	2·4
	1·0 $\longrightarrow$ 0·0 $\xrightarrow{t}$ 1·0	2·5
	0·1 $\longrightarrow$ 1·0 $\xrightarrow{t}$ 0·1	3·1
	0·1 $\longrightarrow$ 0·0 $\xrightarrow{t}$ 0·1	2·3

(2) Dilution experiments

Metal ion	Solution concentrations, *moles/litre*	Response times, *sec*
K^+(KCl)	1·0 $\xrightarrow{t}$ 0·5	2·9
	1·0 $\xrightarrow{t}$ 0·5	3·9
	0·1 $\xrightarrow{t}$ 0·05	3·1

After 30 sec return the glass electrode to the reference solution and measure the time, *t*, required for the indicated potential to return to within ±0·5 mv of the equilibrium value.

Dilution procedure: With the glass-calomel electrode pair in the stirred reference solution and at equilibrium, rapidly add an equal volume of distilled water to the cell and measure the time, *t*, required for the indicated potential to come within ±0·5 mv of the expected value (determined by prior equilibrium measurements in solutions of appropriate concentration).

RESULTS AND DISCUSSION

The results of the dipping and dilution experiments are given in the Table I. The reported response times are, in each case, the mean of at least 4 measurements, and have an experimental uncertainty of about 0·2 sec. In the dilution experiments, an added uncertainty may result from the difficulty of effectively mixing two solutions of appreciable volume (50 ml) within a fraction of a second.

The response rates determined are considerably faster than those observed with the earlier types of cation-sensitive electrodes, and approach the response limitations of the usual potentiometric measurement systems. As expected, electrode recovery times increase as the ionic environment is changed more and more drastically, but response times are compatible with the requirements of continuous analyses or kinetic studies where concentrations may change rapidly over moderate ranges. The results suggest that first-order reactions with rate constants as large as 0·4 sec^{-1} could be effectively monitored using the cation-sensitive glass electrode.

Summary—A re-evaluation of the response of cation-sensitive glass electrodes to rapid concentration changes indicates typical response times in the 1·5–4·0 sec range and suggests that such electrodes might be used for continuous analyses or for reaction rate studies.

Zusammenfassung—Eine Neubestimmung des Ansprechens kationenempfindlicher Glaselektroden auf schnelle Konzentrationsänderungen zeigt typische Ansprechzeiten in der Gegend um 1,5–4,0 Sekunden. Demnach bieten sich solche Elektroden zu kontinuierlichen Analysen oder zur Untersuchung von Reaktionsgeschwindigkeiten an.

Résumé—Une nouvelle évaluation de la réponse des électrodes de verre catio-sensibles aux variations rapides de concentration montre des temps de réponse caractéristiques entre 1,5 et 4 secondes, et suggère que de telles électrodes peuvent être employées pour des analyses en continu ou des études de vitesse de réaction.

LETTER TO THE EDITOR

The international nature of *Talanta*

SIR,

The ever increasing amount of scientific research has resulted in a constant rise in the number of journals available for its publication. One of the newer journals is *Talanta*, and on its cover is printed "An International Journal of Analytical Chemistry". It would be interesting to know if this declaration is really justified. Is it possible for you to provide data concerning the numbers of papers from different countries which have been published in *Talanta*?

R. PŘIBIL

Laboratory of Analytical Chemistry
Polarographic Institute
Czechoslovak Academy of Sciences
Praha 1, *Jilská* 16, *Czechoslovakia.*
5 *June* 1964

Dear Dr. PŘIBIL,

I hope that you will find the information for which you have asked in the Table overleaf.

CECIL L. WILSON (Editor-in-Chief)

INFLUENCE OF FOAM TEMPERATURES IN BOILING SOLUTIONS ON EBULLIOMETRIC MEASUREMENTS

C. HEITLER
Department of Applied Chemistry, Northampton College of Advanced Technology
St. John Street, London E.C.1, England

(*Received* 2 *March* 1964. *Accepted* 25 *May* 1964)

Summary—The foam, in a boiling solution, is concentrated by the transport of adsorbed solute on the bubble surfaces. The excess of boiling temperature in the foam over that in the bulk can be predicted by a mass transport equation involving the total bubble surface produced in unit time. The surface tension variation was measured in terms of the average bubble diameters in the foam at each concentration. If d and c are the bubble diameters and bulk concentration, respectively, the excess of boiling temperature is given by

$$\delta T = \left\{ B \begin{pmatrix} \mathrm{d}d/\mathrm{d}c \\ c \to 0 \end{pmatrix} + a\, \mathrm{d}d/\mathrm{d}c \right\} \left(\frac{1}{d_0} - \frac{1}{d} \right)$$

where d_0 is the bubble diameter in the pure solvent and B is a constant. This is an equation relating excess concentration in the foam with rate of change of surface tension and the area of bubble surface. Direct measurements of the difference between bulk and foam concentrations indicate a linear relation between them. The assumption that the solutes associate in the surface provides a theoretical basis for the above equation, and for the apparent departure of the adsorption from the Gibbs' equation.

A NUMBER of authors have reported that extrapolations of ebulliometric measurements do not always pass through the origin of the temperature axis.[1–3] Smith[1] suggested that adsorption of solute on the bubble surfaces and its concentration in the foam would account for the positive deviations he observed with solutions of polythene. He measured the foam concentrations and found an excess over that in the bulk. Dimbatt and Stross[4] suggested that there was a similar explanation for the increase in 'boiling noise' they observed with polymer solutions.

The present author arrived at similar conclusions following measurements of boiling temperature elevations in ethanolic solutions of triglycerides.[5] The plots of elevation *versus* concentration were decidedly non-linear (see Fig. 1, for example). These curves in ethanol are complicated by association of the solutes. However, all are inflected and, although exhibiting a subsequent curvature, have some concentration range in which the elevations are appreciably greater than is predicted by theory. When ethanolysis was induced by the addition of ethoxide,[5] the ethyl esters which were formed produced elevations which could be calculated by the Beckmann equation from the weight of triglyceride added, indicating that the ethyl esters were behaving normally under the same conditions. Similarly inflected curves were observed in ether, cyclohexane, carbon tetrachloride and acetone (Figs. 2 and 5). Other solutes were found, to varying extents, to behave in the same manner, although the deviations were in the main not large (Fig. 3).

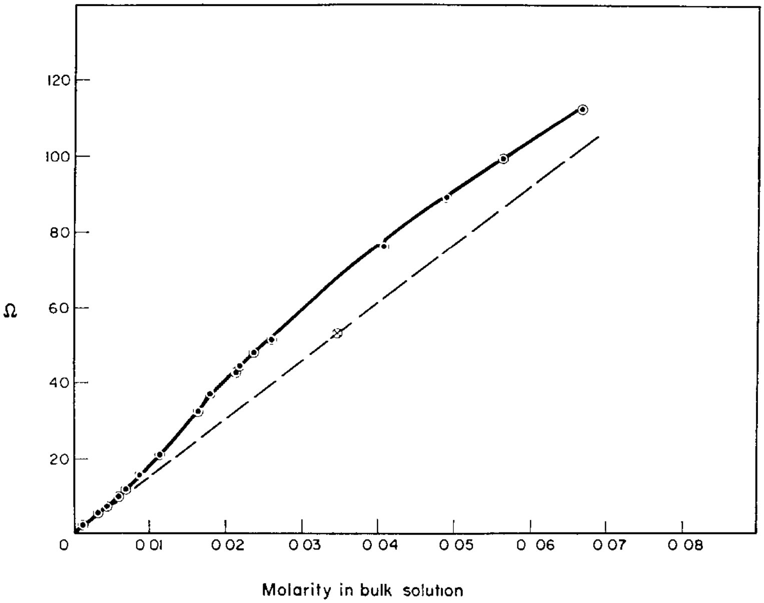

FIG. 1.—Glyceryl tripalmitate elevations in ethanol:

—— curve found in practice,

– – – line predicted by theory,

⊗ ¼-elevation after adding sodium ethoxide.

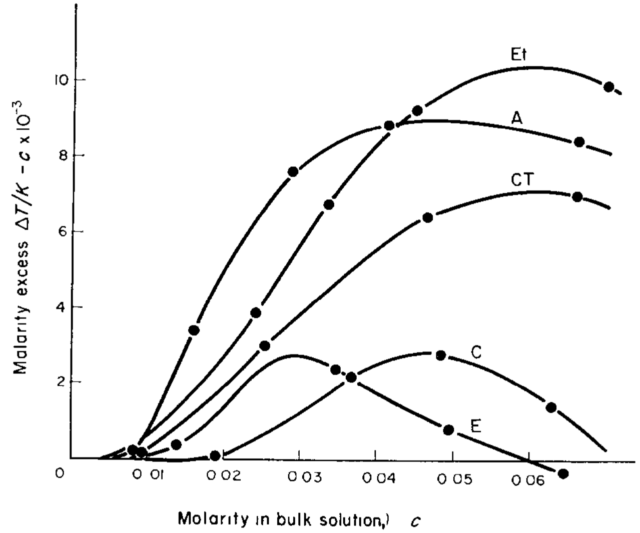

FIG. 2.—Equivalent molar excess elevations for glyceryl tribenzoate in different solvents:

Et = ethanol, CT = carbon tetrachloride,
A = acetone, C = cyclohexane, E = ether.

It was noticed that the magnitude of the excess elevation was related to the concentration at which foaming began. Also, in general, the higher the molecular weight of the solute the greater was the discrepancy. Preliminary attempts were made to measure the surface tension changes by the maximum bubble pressure method. These gave indications that the discrepancies were a function of the initial rate of change of surface tension with concentration. Measurements of the average bubble diameters with a cathetometer indicated that these were proportional to the bubble pressure measurements. In any given solvent the bubble diameters tended to almost the same minimum for all solutes, and the curves extrapolated back to the same diameter for the pure solvent (Fig. 6). These observations were sufficient to demonstrate that the excess elevations produced by different solutes were independent of the bubble diameters but bore some relation to their rate of change with concentration.

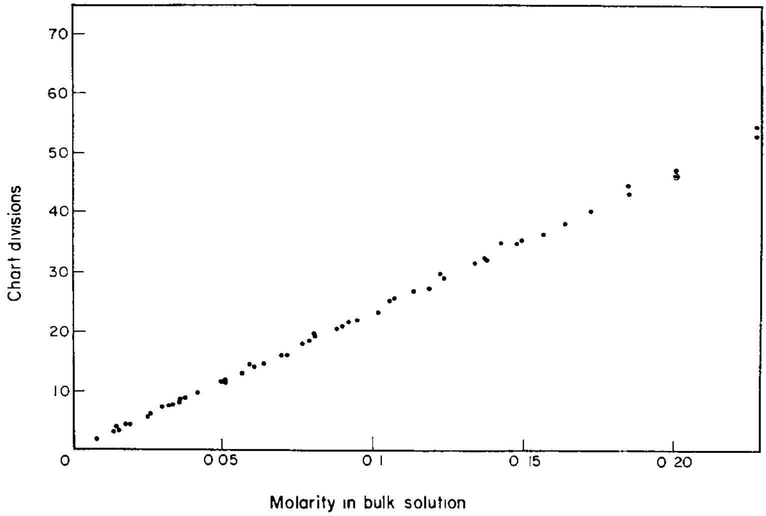

FIG. 3.—Elevations in pure acetone with the following solutes: benzophenone, benzoyl acetone, *o*-bromonitrobenzene, naphthalene, tri-n-butylphosphate, triacetone dialcohol.

The decision was taken to employ acetone as solvent for a number of solutes with widely differing foaming capacities. Acetone was chosen because it was known to have little tendency to encourage association and to lead to curves with a long linear region after the inflection.[3] Boiling temperature measurements were made of solutions in pure acetone and in acetone containing 1% of polydiethylene adipate (molecular weight *ca.* 3000: hereafter referred to as PDA). The latter foamed freely with a bubble diameter of 2·3 mm. It was expected that the additive would keep the surface tension constant for all but the most surface active solutes. The bubble diameters at each concentration were measured on high speed photographs.

DISCUSSION AND THEORETICAL TREATMENT OF EXPERIMENTAL RESULTS

The experiments in acetone confirmed the qualitative relationships noted above. With three exceptions, the curves of boiling temperature elevation (ΔT) *versus* concentration (c) could be divided into three sections. ΔT approached the theoretical line closely at the lowest concentrations; this was followed by an intermediate region in which the curve was inflected upwards, and finally by a linear section approximately parallel to, but displaced above the theoretical line (Fig. 5). For many of the solutes the inflection was small enough to have been ignored for practical purposes, or ascribed to experimental error.

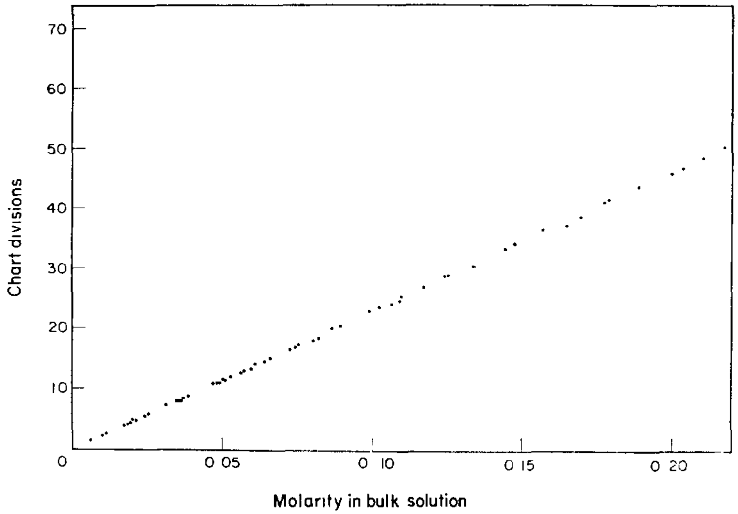

FIG. 4.—Elevations in acetone plus 1 % of PDA with the following solutes: benzophenone, benzoyl acetone, *o*-bromonitrobenzene, naphthalene, tri-n-butylphosphate, triacetone dialcohol, aspirin, glyceryl tribenzoate.

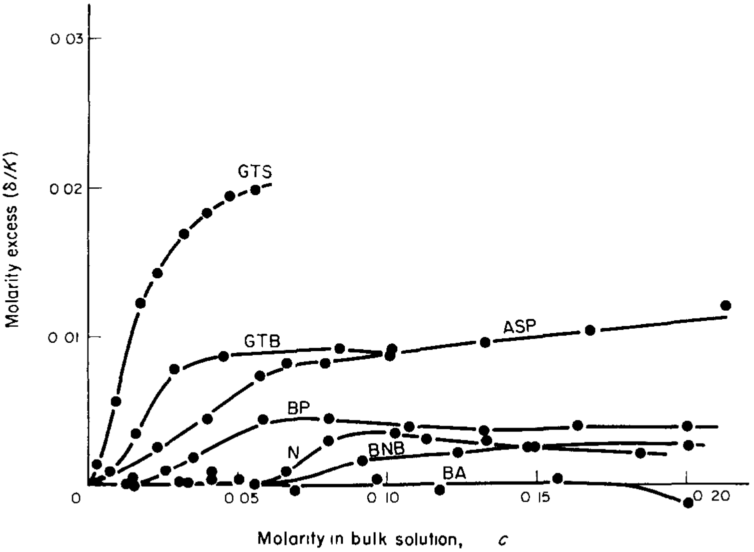

Fig. 5.—Excess elevations in pure acetone:
GTS = glyceryl tristearate, BP = benzophenone, GTB = glyceryl tribenzoate,
N = naphthalene, ASP = aspirin, BNB = *o*-bromonitrobenzene,
BA = benzoyl acetone.

All of the solutes foamed in sufficiently concentrated solution and *d*, the bubble diameter, tended to a limiting value. The curves of *d* against *c* could be extrapolated back to the zero of the concentration axis and giving the same limiting value at infinite dilution (Fig. 6). The bubbles of vapour rising to the surface of the liquid were produced on a small area of tungsten wire projecting into the base of the ebulliometer.[3] Presumably, they were generated at a constant number of asperities on the tungsten surface. The wire may be regarded as a group of minute orifices

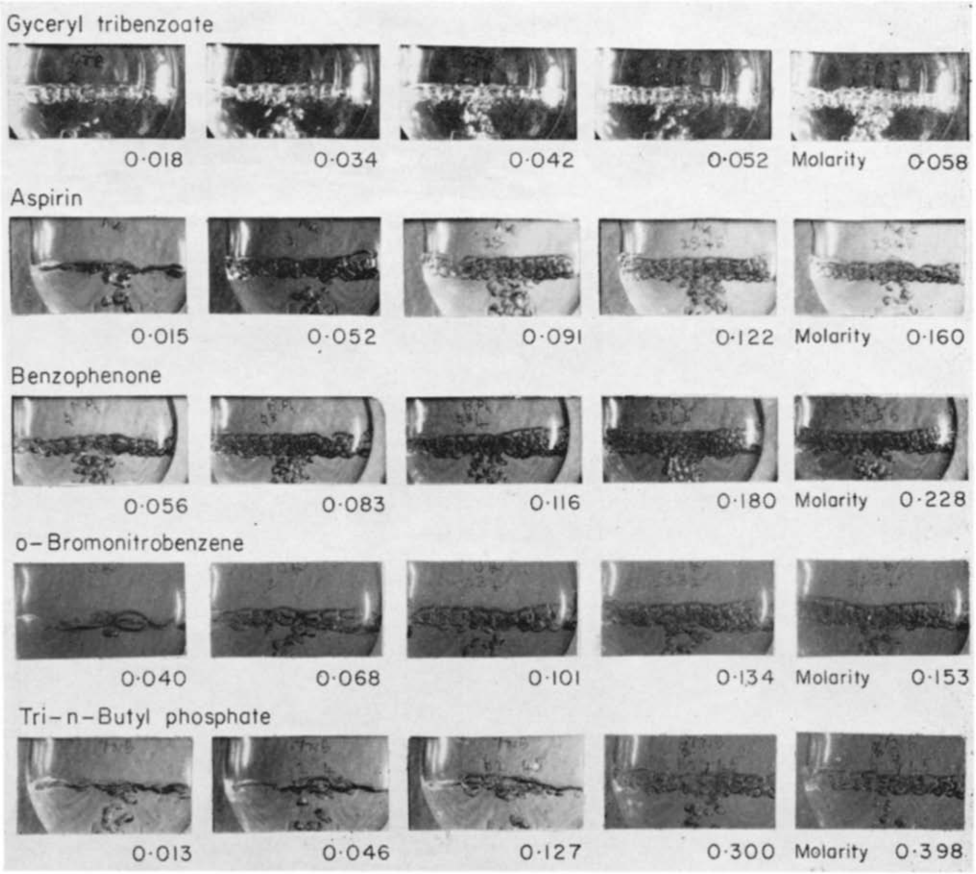

FIG. 6*a*.—Photographs of the bubbling in boiling acetone produced by various solutes at different concentrations.

through which vapour was pumped into the liquid. The heat input, which was maintained constant throughout the series of experiments, generated a constant volume of vapour in unit time (at atmospheric pressure). Bubbles detached themselves from the wire when they had achieved sufficient buoyancy. Thus, they all enclosed a similar volume of superheated vapour. The pressure within the bubbles when they left the wire was, however, governed by the surface tension of the solution. As they rose and attained equilibrium with the surrounding solution, their diameters in the short-lived foam on the surface became proportional to the surface tension.

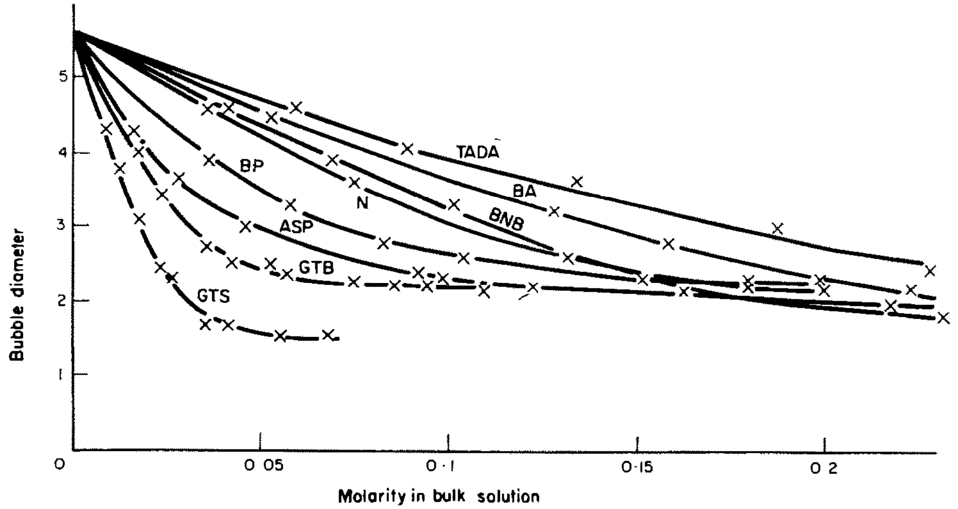

FIG. 6.—Bubble diameters in pure acetone:

TADA = triacetone dialcohol,
BA = benzoyl acetone,
BNB = *o*-bromonitrobenzene,
N = naphthalene,

BP = benzophenone,
ASP = aspirin,
GTB = glyceryl tribenzoate,
GTS = glyceryl tristearate.

Calculations. If V is the volume of vapour brought to the surface by the bubbles in unit time and n the number of bubbles containing this volume, then

$$V = \tfrac{1}{6} n\pi d^3$$

and the total surface of these bubbles is

$$S = n\pi d^2,$$

so that

$$6V/d = S.$$

The total surface transported through the solution changes with concentration from $6V/d_0$ at $c = 0$ to $6V/d$ at concentration c. Thus, the increase in the amount of solute transported on the bubble surfaces will be

$$\Delta S\mathrm{f}(c) = B(1/d - 1/d_0)\mathrm{f}(c) \qquad (1)$$

where $\mathrm{f}(c)$ is equal to the concentration of adsorbed solute per unit area of the bubble surface. $\mathrm{f}(c)$ was found to be constant beyond the inflection in the curves and

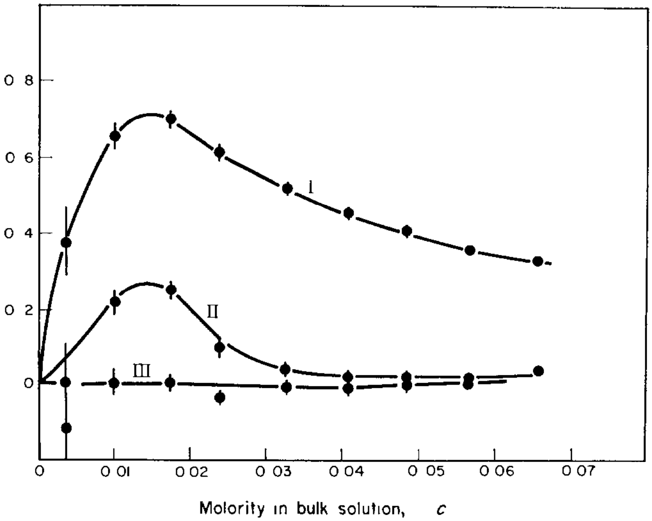

FIG. 7.—Glyceryl tristearate in pure acetone:

I. $\frac{\delta T}{Kc}$; II. $\frac{\delta T - 0\cdot08\left(\mathrm{d}d/\mathrm{d}c\right)_{c\to 0}\left(\frac{1}{d}-\frac{1}{d_0}\right)}{Kc}$;

III. $\frac{\delta T - \left\{0\cdot08\left(\mathrm{d}d/\mathrm{d}c\right)_{c\to 0} + 0\cdot05\ \mathrm{d}d/\mathrm{d}c\right\}\left(\frac{1}{d}-\frac{1_0}{d}\right)}{Kc}$

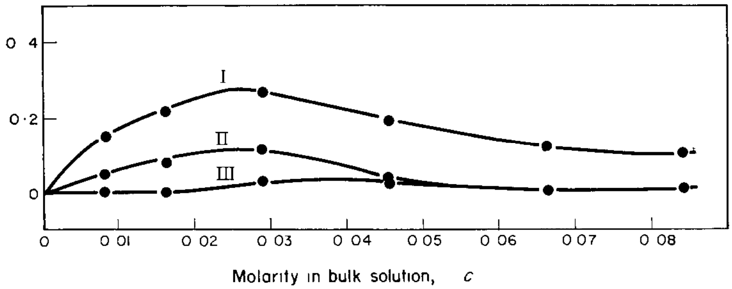

FIG. 8.—Glyceryl tribenzoate in pure acetone:

I. $\frac{\delta T}{Kc}$; II. $\frac{\delta T - 0\cdot08\left(\mathrm{d}d/\mathrm{d}c\right)_{c\to 0}\left(\frac{1}{d}-\frac{1}{d_0}\right)}{Kc}$

III. $\frac{\delta T - \left\{0\cdot08\left(\mathrm{d}d/\mathrm{d}c\right)_{c\to 0} + 0\cdot05\ \mathrm{d}d/\mathrm{d}c\right\}\left(\frac{1}{d}-\frac{1}{d_0}\right)}{Kc}$

proportional to $\underset{c\to 0}{\mathrm{d}d/\mathrm{d}c}$. When the constant B was put equal to 0·08, the final linear section of the curve was corrected to within the experimental error by deducting

$$0{\cdot}08\ \mathrm{d}d/\mathrm{d}c(1/d - 1/d_0) \qquad (2)$$

from the observed ΔT.

In the concentration range which included the inflection, the relative errors in ΔT pass through a maximum, and for glyceryl tristearate, glyceryl tribenzoate and aspirin, a maximum remained after applying the above correction (Figs. 7–9). In these graphs $(\Delta T - Kc)/Kc$ is plotted against c, where K is the ebulliometric constant, so that Kc is the theoretically expected elevation. Small errors in ΔT are accentuated at low concentration in these plots, and they illustrate the magnitude of the errors in molecular weight determinations that can result from the phenomena under discussion.

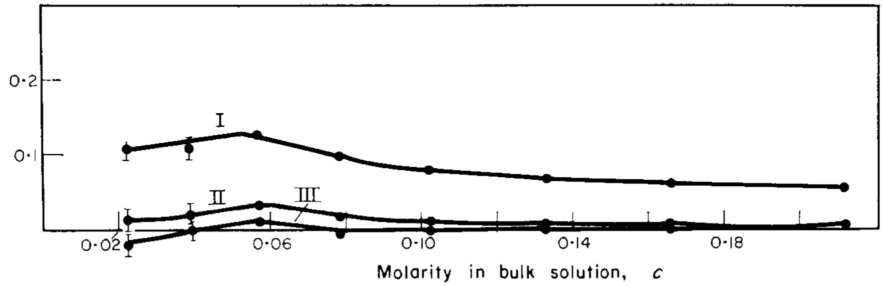

FIG. 9.—Aspirin in pure acetone:

$$\text{I.}\quad \frac{\delta T}{Kc}; \qquad \text{II.}\quad \frac{\delta T - 0{\cdot}08\left(\underset{c\to 0}{\mathrm{d}d/\mathrm{d}c}\right)\left(\frac{1}{d}-\frac{1}{d_0}\right)}{Kc};$$

$$\text{III.}\quad \frac{\delta T - \left\{0{\cdot}08\left(\underset{c\to 0}{\mathrm{d}d/\mathrm{d}c}\right) + 0{\cdot}05\mathrm{d}d/\mathrm{d}c\right\}\left(\frac{1}{d}-\frac{1}{d_0}\right)}{Kc}.$$

The fact that the excess elevation, $\delta T = \Delta T - Kc$, is almost constant and proportional to $\underset{c\to 0}{\mathrm{d}d/\mathrm{d}c}$ after the inflection, suggests that in the linear region adsorption was taking place onto aggregates or thick layers of adsorbed solute in the surface. According to Gibbs' equation:[6]

$$c_s - c_b = (c_b/RT)\,\mathrm{d}\gamma/\mathrm{d}c$$

where c_s is the concentration in the surface and c_b that in the bulk; γ, the surface tension, is proportional to d. It would appear from the above that the appropriate value of c_b to employ in the equation is that of the aggregates in the bulk solution which, if not zero, is at least always very small. Although the Gibbs' equation only strictly applies to equilibrium conditions, the adsorption here is assumed to be proportional to that at equilibrium.

Until thick layers supervene there will be areas of free solvent-vapour interface available for the adsorption of single molecules of solute, the surface becoming completely covered at concentrations beyond the inflection. Hence, a physical interpretation of the decrease of $\mathrm{d}\gamma/\mathrm{d}c$ with c in this region may be that in these cases

$\mathrm{d}\gamma/\mathrm{d}c$ is proportional to the free solvent surface available for the adsorption of solute. If S_f is the available solvent-vapour interface at each concentration, then the rate at which solute monomers enter the surface will be proportional to cS_f and also to $\mathrm{d}\gamma/\mathrm{d}c$. Hence

$$c_s - c_b\,(\text{monomers}) = bcS_f = \alpha\,\mathrm{d}\gamma/\mathrm{d}c = a\,\mathrm{d}d/\mathrm{d}c \tag{3}$$

where b, a and α are constants of proportionality. Combination with equation (2) and writing δT for the excess elevation gives

$$\delta T\,(= \Delta T - Kc) = \left\{B\left(\underset{c\to 0}{\mathrm{d}d/\mathrm{d}c}\right) + \mathrm{a}\,\mathrm{d}d/\mathrm{d}c\right\}\left\{\frac{1}{d_0} - \frac{1}{d}\right\} \tag{4}$$

The right-hand side of this equation is plotted against δT in Fig. 10, the constant B having the value 0·08 and $a = 0{\cdot}05$ when d is in cm and c in moles per litre. The excess elevations observed with glyceryl tristearate, glyceryl tribenzoate, aspirin, naphthalene, benzophenone and *o*-nitrobromobenzene were all predicted by this equation. The coefficient of correlation between the corrections and errors plotted in Fig. 10 is 0·975. In Fig. 11, δT is plotted against c for the above six solutes and for comparison the corrected points are plotted on the same figure; the standard deviation of the residual error was ±0·002°.

Of the other solutes examined, δT was within the experimental error (±0·001°) for benzoyl acetone and tri-n-butylphosphate up to 0·2*M*. The latter solute produced no persistent bubbles in this concentration range.

Triacetone dialcohol exhibited no inflection of the ΔT *versus* c curve, but the slope was 1% greater than theory predicted and this error was only partially corrected by equation (4). There was no error in the presence of PDA (see below), which implied that it was caused by adsorption. δT for this solute was approximately proportional to $c\Delta S\,\mathrm{d}d/\mathrm{d}c$, in agreement with the Gibbs' equation.

The curve of d *versus* s for *p*-dichlorobenzene was very shallow so that negligible adsorption would be expected, and the close agreement between the boiling point curves in pure acetone and in the presence of PDA supported this view. The molecular weight found was 153, instead of 147, and it appeared that the solute was associating. However, when the molecular weight in ether, acetone and ethanol are compared (see Table II), it is seen that they increase with the boiling point of the solvent rather than bearing any relation with its polarity. It is the author's opinion that the discrepancies arise from the volatility of this solute.

Boiling temperatures in acetone containing PDA

The curves in 1% PDA solutions generally included the origin to within the experimental error (Fig. 4). No point in the ΔT *versus* c curve was more than 0·002° displaced from a straight line up to a concentration of 0·1*M*, except for the solutes glyceryl tristearate and tribenzoate. These latter still gave rise to a reduced maximum in $\Delta T/Kc$ at the same concentration as in pure acetone.

An interesting result was observed when tri-n-butylphosphate was examined in this solution. The curve was linear and intercepted the origin, but the slope was 6% too high. The solute, which did not produce foam, in pure acetone, was adsorbed by the surface in the presence of PDA (Fig. 12).

A further series of measurements was carried out on six natural triglycerides in

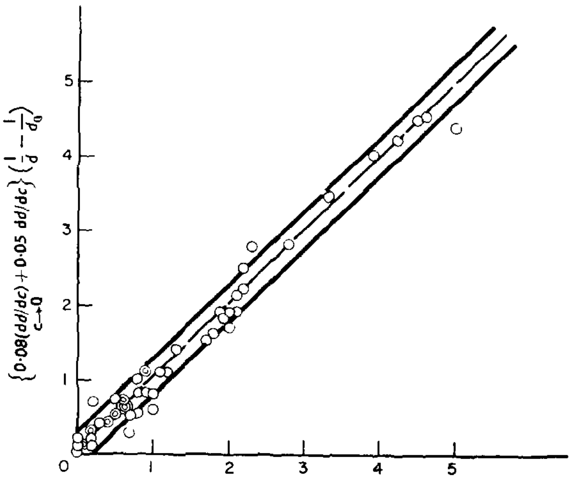

FIG. 10.—Error *versus* correction for acetone solutions of the following solutes: benzophenone, *o*-bromonitrobenzene, naphthalene, aspirin, glyceryl tribenzoate, glyceryl tristearate.

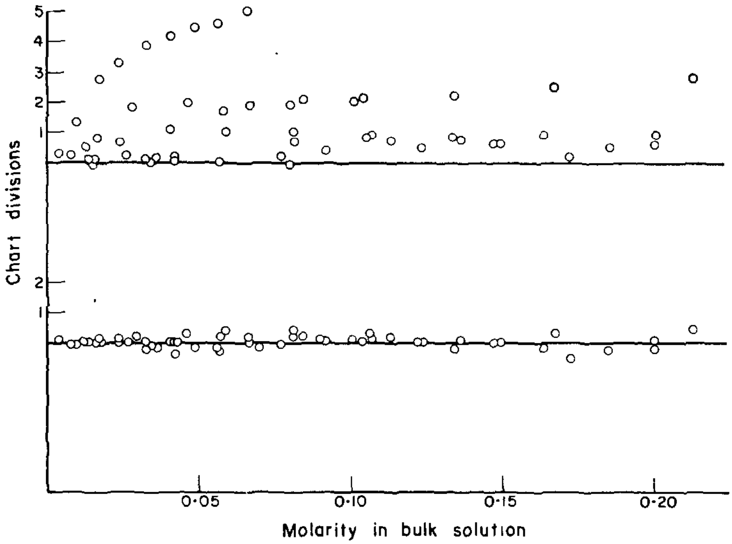

FIG. 11.—$\Delta T - K_c$ uncorrected (upper figure) and $\Delta T - (K_c + \text{correction})$ (lower figure) with the following solutes: benzophenone, *o*-bromonitrobenzene, naphthalene, aspirin, glyceryl tribenzoate, glyceryl tristearate.

acetone containing 2% of PDA. At this concentration the PDA completely suppressed the inflection and good agreement was obtained between the average molecular weights, calculated from the saponification equivalents and acid values, and those derived by ebulliometry (Table I).

It may be concluded that when the surface is saturated by an additive (preferably of high molecular weight), the phenomena observed in the pure solvent are suppressed.

Other solvents. The general occurrence of the errors from adsorption in the foam affects the choice of a suitable solvent for each class of solute. It may be impossible

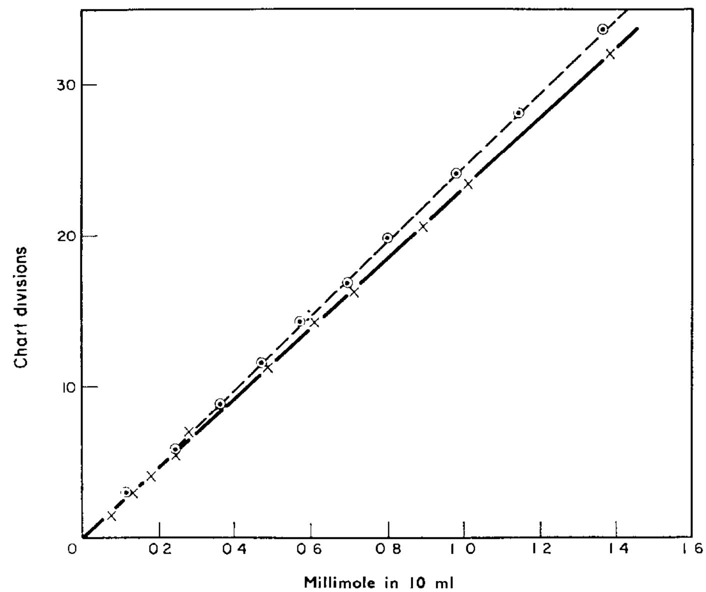

Fig. 12.—Elevations for tri-n-butyl phosphate:
×—in 10 ml of acetone, ○—in 10 ml of acetone containing 1% of PDA.
The full line is the one predicted by theory.

to reconcile the requirements of good solubility, absence of association and low adsorption. There is danger in extrapolating from the behaviour of low molecular weight materials; these can be measured at low weight concentrations. Surface phenomena are generally proportional to weight rather than molar concentration.

The ebulliometric constant, of benzene for example, apparently varies with the molecular weight when measurements are made on triglycerides. Taking *K* for naphthalene as unity, it is altered to 1·41 for diethylene glycol distearate (molecular weight 620) and to 1·50 for cacao butter (851). The ‘constant’ for diethylene glycol distearate was in good agreement with that obtained for palm kernel oil (679) and extracoa (678), while that found for cacao butter agreed with the remaining fats in Table II, which have molecular weights of the same order. No doubt both association and adsorption contributed to these results, but they indicate the caution to be exercised in drawing conclusions from ebulliometric measurements.

Table 1—Molecular weights of triglycerides in acetone plus 2% of PDA (molecular weight *ca.* 3000). The calculated weights were obtained from the saponification equivalents and corrected for free acidity

	Molecular weight	
	Calculated	Found
Cacao butter	851	845
Illipe butter	830	845
Hardened palm kernel oil	679	674
Coberine	867	854
Cacao shell butter	879	864
Extracoa	678	680

TABLE II.—THIS IS A LIST OF OBSERVED OVER EXPECTED ELEVATIONS ($\Delta T/Kc$) FOR 56 SOLVENT-SOLUTE PAIRS. FOR EACH PAIR THE VALUE OF $\Delta T/Kc$ IS GIVEN AT 0·05*M* AND FROM THE GRADIENT OF THE LINEAR PART OF THE CURVE. WHERE THERE IS NO FIGURE FOR THE ELEVATION AT 0·05*M*, THE OBSERVATION OF THE ZERO INCLUDED A SUPERHEATING ERROR. AN ASTERISK IN THE GRADIENT COLUMN INDICATES THAT THERE WAS EVIDENCE OF ASSOCIATION OF THE SOLUTE. VALUES GREATER THAN 1 INDICATE THAT THE OBSERVED MOLECULAR WEIGHT WAS TOO LOW AND *vice versa*

TABLE III.—MOLECULAR WEIGHTS IN ETHER.
THE CORRECTED MOLECULAR WEIGHTS WERE OBTAINED BY DEDUCTING $3\left(\mathrm{d}d/\mathrm{d}c\right)_{c\to 0}$
FROM THE ELEVATION (IN Ω) AT 0·05M

	$\mathrm{d}d/\mathrm{d}c_{c\to 0}$,	Molecular weight		
	cm. litre mole^{-1}	Expected	Observed	Corrected
Glyceryl tripalmitate	17·0	807	694	795
Glyceryl tribenzoate	8·0	404	378	408
o-Bromonitrobenzene	5·3	202	194	201

Very similar results were obtained when measurements were made of the molecular weights of a number of polydiethylene adipates. The constant in ethanol was approximately 1·25 that found for naphthalene,[5] despite a long linear region displaced only 0·008° above the origin. In acetone 'K' was found to be very nearly proportional to the square root of the molecular weight of these esters as determined by end-group assay.

Values of $\mathrm{d}d/\mathrm{d}c_{c\to 0}$ were measured in ether for *o*-bromonitrobenzene, tripalmitin and glyceryl tribenzoate employing a cathetometer. These measurements were not as precise as those obtainable by photography and could not be extended reliably to the smaller bubbles, which formed more than one layer on the surface. The initial rate of change was found to be approximately proportional to the maximum error, *i.e.*, $\delta T_{\max} = B\,\mathrm{d}d/\mathrm{d}c_{c\to 0}$, and when this correction was applied to the molecular weights at 0·05M the weights were in good agreement with the expected values (Table III).

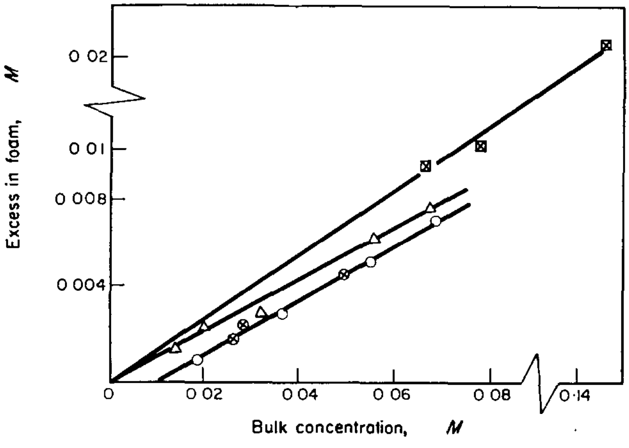

FIG. 13.—Direct measurements of foam concentration in acetone solution:
⊠—aspirin, △—glyceryl tristearate, ⊗—glyceryl tribenzoate, ○—glyceryl tripalmitate.

Maximum bubble pressure measurements in ethanol gave a more direct determination of $\mathrm{d}\gamma/\mathrm{d}c_{c\to 0}$. These measurements too, could not be extended to higher concentrations in the boiling solvent. Errors arising from adsorption of the solute on the inside of the capillary, variations in density of the solution and alterations of the mean depth of the liquid with increased foaming, became serious in all but the most dilute solutions. It was not possible to extrapolate from solutions below the boiling temperature because of the lower solubility of the solutes. Comparison of solutions of tristearin, tripalmitin and glyceryl tribenzoate showed that $\underset{c\to 0}{\mathrm{d}d/\mathrm{d}c}$ was closely proportional to $\underset{c\to 0}{\mathrm{d}\gamma/\mathrm{d}c}$. Association of the solutes precluded any attempt to correlate these figures with $\underset{\max}{\delta T}$.

Direct measurement of difference in concentration of foam and bulk

Gubbins has made measurements of foam concentrations using a specially designed flask.[9] He found that the solutes glyceryl tribenzoate, glyceryl tristearate, glyceryl tripalmitate and aspirin were all concentrated in the foam. The excess was found to increase with concentration throughout the range investigated. This result supports the view that these solutes are associated in the surface. On (Fig. 13) is plotted the relative excess against concentration for the four compounds. Because the flask was much larger and a different heating rate was applied these results cannot be compared directly with those reported above.

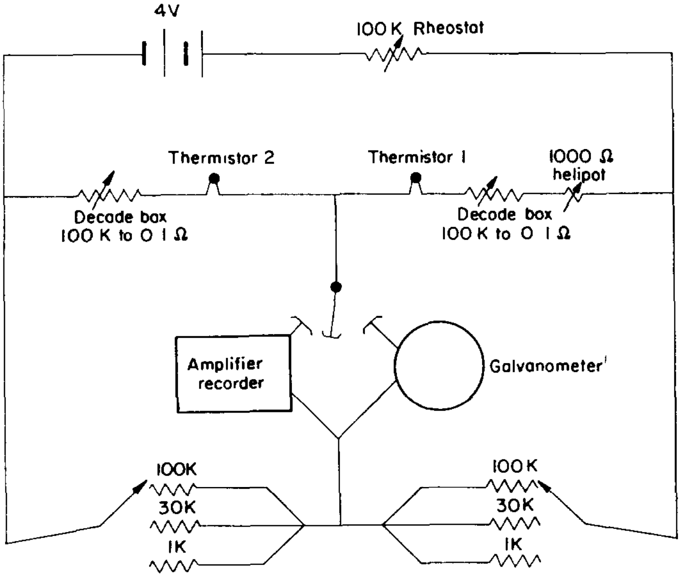

FIG. 14.—Ebulliometer circuit diagram.

CONCLUSION

It is commonly assumed that measurements which depend upon the colligative properties of solutions provide the most accurate results at the greatest dilutions. In particular, it has been the general belief that, provided the temperature changes could be assessed with sufficient accuracy, the most accurate result would be achieved at very low concentrations. This view presupposes that the only source of error, apart from superheating, is a simple departure from ideality. The work presented here indicates that the most accurate measurements of molecular weight are to be made at some intermediate concentration. The normal practice of finding the slope of the linear region of the ΔT *versus* c curve, although the line may not intercept the origin, is shown to have a theoretical as well as a pragmatic justification.

EXPERIMENTAL

Measuring circuit

The elevations were measured in a commercially available ebulliometer of the author's design which has been described elsewhere.[3] A second ebulliometer, containing a 2% solution of PDA in acetone, was employed to compensate for barometric changes.[8] The thermistors from both cells were connected in opposite arms of a Wheatstone bridge circuit (Fig. 14).

The circuit was such that the total resistance of the thermistor can be kept constant by adding resistances in series. A precision decade box was used for this purpose, having six decades and a total range of 0·1 Ω to 111,111 Ω. Thus, changes in the thermistor resistance could be measured without altering the bridge ratios or affecting the sensitivity of the detecting instrument.

The 100-KΩ rheostat in series with the accumulators was set so that the current through the thermistors was about 0·2 mA. The out-of-balance current from the bridge was amplified and recorded on a Honeywell-Brown recording amplifier, and the sensitivity was such that 1 division on the recording chart (2·8 mm) corresponded fairly closely to an 0·01° change in the thermistor resistance. The sensitivity, in Ω per division, was tested frequently by switching 100 Ω into decade box 1.

In this series of experiments all of the elevations were measured in terms of chart divisions or resistance, so that it was not necessary to have an exact temperature calibration for the thermistor.

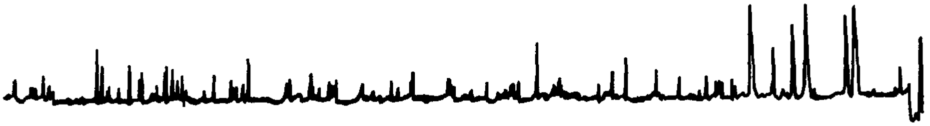

FIG. 16.—Trace of temperature *versus* time for boiling pure acetone.

Heating system (Fig. 15)

This was designed to provide good control over the boiling rate. Three 25-w miniature soldering iron elements were clamped into three grooves milled symmetrically round a 0·75-inch copper rod. The milling was continued, with decreasing depth towards the top, so that the upper face presented the appearance of Fig. 15*a*. The rod and elements were assembled inside the copper retaining tube. The device thus provided three channels up which hot air passed to flow round the ebulliometer, reducing heat losses from the main body of the flask. The tungsten wire projecting from the flask fitted into the hole in the top of the copper rod.

TABLE IV

	K, *divs./mole* × 10^{-1} . *litre*$^{-1}$	No. of observations
0·03–0·06M pure acetone	23·16 ± 0·15	11
0·03–0·06M acetone + PDA	23·20 ± 0·2	10
Gradients in pure acetone	23·24 ± 0·4	9
Gradients in acetone + PDA	23·02 ± 0·35	9

Boiling temperature of pure solvent

Fig. 16 is a facsimile of a record of the boiling temperature *versus* time for pure acetone. It is seen to have a constant baseline onto which a number of sharp peaks are superimposed. The peaks arise from splashes of superheated solvent reaching the thermistor, and if the detector were overdamped the average reading would have been too high. The boiling temperature zero was determined by taking the average of the minima in the baseline over the last inch of the chart (which ran at 300 sec per inch) before the first addition of solute. These minima varied by 0·1 division about their mean. The peaks were always reduced in the presence of solute, and for most solutes were completely absent at a low concentration.

Calculation of ebulliometer constant

For the five solutes naphthalene, triacetone dialcohol, benzoyl acetone, *o*-bromonitrobenzene and tri-n-butylphosphate, either no inflection was observed or it occurred at concentrations >0·06M. K was therefore taken as the average, for the above solutes, of $\frac{M\Delta T}{w}$ (where M is the molecular weight) between 0·03 and 0·06M, in pure acetone. A similar average was calculated for the PDA solutions, and from the gradients in both the presence of PDA and beyond the inflections in pure acetone. These averages are set out in Table IV.

The gradients of all solutes except *p*-dichlorobenzene were included in the average.

It was decided to accept 23·2 ± 0·2 as K. For the above five solutes the standard deviations of the temperature measurement of a single observation was ±0·1 chart division up to 0·05M. There was no reason to expect that this source of experimental uncertainty was greater at higher elevations.

Measurement of bubble diameters

The bubble ebulliometer is drawn full scale in (Fig. 17). It is a flattened version of the standard ebulliometer, with a similar pump, but no thermistor cavity. The pump tube ends 3 mm below the surface when the cell contains 10 ml of solvent.

The photographs were taken with a 35-mm single lens reflex camera fitted with extension tubes to provide unit magnification on the negative. Illumination was provided by a half-charged electronic flash unit (output *ca.* 20 joules), with a flash duration of 10^{-3} sec. The camera aperture was set at f22 and the cell illuminated at right-angles to the camera line-of-sight, with the flash 16 inch away. This was found to be the most efficient arrangement for delineating the bubble contours. There was little attenuation of the light across the cell.

Three techniques for obtaining the average bubble diameters were examined: (a) Outlining a magnified image of all of the bubbles in a photograph on mm graph paper and finding the total area A, then $d = \sqrt{\frac{A}{n}} \left(\text{not } \sqrt{\frac{4}{\pi}\frac{A}{n}}\text{, because the bubbles distort in contact with each other}\right)$. (b) Outlining a number of individual bubbles, measuring the longest and shortest diameters of each bubble and finally taking the average. (c) Measuring the average radius of curvature of the upper surfaces of the top layer of bubbles from the outlines of 10-fold magnified images.

There was no significant difference between the three methods, which generally agreed among themselves to within 0·2 mm. (a) was the preferred method, (c) being particularly tedious and time-consuming.

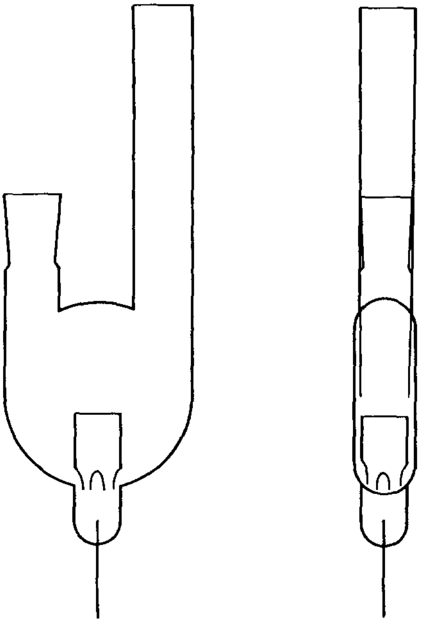

FIG. 17.—Bubble cell front view (left), side view (right).

Purification of materials

All of the solutes were purified by repeated recrystallisation from the solvent in which the measurements were to be made. This procedure could not be applied to tri-n-butylphosphate which was reprecipitated thrice from acetone by adding water. It was finally dissolved in acetone, the solution dried with Hi-Drite* and the acetone evaporated under reduced pressure. These procedures were adopted to ensure, so far as possible, that the only volatile impurity was the ebullioscopic solvent.

The glyceryl tristearate was free from acidity and had a saponification equivalent of 296, corresponding to a molecular weight of 888 (pure tristearin would be 891).

The acetone was purified by shaking first with a 30% solution of sodium hydroxide, then adding a 1% solution of silver nitrate and shaking further.[7] The acetone, now free from aldehyde, was redistilled, rejecting the first and last 25%. This distillate was dried over Hi-Drite and redistilled.

A granule of Hi-Drite (about 0·25 g) was introduced into the ebulliometer with the solvent in order to maintain a very low and constant moisture content.

Acknowledgements—I would like to thank many of my colleagues who have patiently borne with me in numerous discussions, and in particular those who have read this paper in preparation and offered much useful and constructive criticism. My thanks are also due for the project work of M. Gubbins and G. M. Pierce, who were responsible for the data in Fig. 13 and Table I, respectively.

Zusammenfassung—Der Schaum einer siedenden Lösung wird durch Transport adsorbierten gelösten Stoffes in die Blasenoberflächen konzentriert. Die Differenz der Siedetemperaturen von Schaum und Hauptmenge kann durch eine Massentransportgleichung berechnet werden, in der die pro Zeiteinheit gebildete Blasenoberfläche vorkommt. Als Maß für die Änderung der Oberflächenspannung wurde der mittlere Blasendurchmesser bei der jeweiligen Konzentration genommen. Sind d und c Blasendurchmesser und Konzentration der Hauptmerge und die Differenz der Siedetemperaturen von Schaum und Hauptmerge δT, dann ist

$$\delta T = \left\{B\left(\underset{c\to 0}{\mathrm{d}d/\mathrm{d}c}\right) + a\,\mathrm{d}d/\mathrm{d}c\right\}\left(\frac{1}{d_0}-\frac{1}{d}\right)$$

hier ist d_0 der Blasendurchmesser im reinen Lösungsmittel und B eine Konstante. Diese Gleichung setzt den Konzentrationsüberschuß im Schaum mit der Änderung der Oberflächenspannung und der Blasenoberfläche in Beziehung. Direkte Messungen der Konzentrationsdifferenz zwischen Hauptmenge und Schaum weisen auf einem linearen Zusammenang hin. Die Annahme, daß sich die gelösten Moleküle an der Oberfläche anreichern, liefert eine theoretische Grundlage für obige Gleichung und für die offenbare Abweichung der Adsorption von der Gibbsschen Gleichung.

Résumé—Dans une solution en ébullition, la mousse est plus concentrée, par le transport du corps dissous adsorbé sur les surfaces des bulles. L'élévation de la température d'ébullition de la mousse par rapport à celle de la masse du liquide peut être prévue par une équation de transport de masse mettant en jeu la surface totale des bulles produites dans l'unité de temps. La variation de tension superficielle a été mesurée en fonction du diamètre moyen des bulles dans la mousse à chaque concentration. Si d et c sont respectivement le diamètre des bulles et la concentration de la masse du liquide, l'élévation de la température d'ébulliton de la mousse par rapport à celle de la masse du liquide est donnée par

$$\delta T = \left\{B\left(\underset{c\to 0}{\mathrm{d}d/\mathrm{d}c}\right) + a\,\mathrm{d}d/\mathrm{d}c\right\}\left(\frac{1}{d_0}-\frac{1}{d}\right)$$

où d_0 est diamètre en solvant pur et B une constante. C'est une équation reliant l'excès de concentration dans la mousse à la vitesse de variation de la tension superficielle et à l'aire de la surface des bulles. Des mesures directes de la différence entre les concentrations de la masse du liquide et de la mousse montrent entre elles une relation linéaire. L'hypothèse selon laquelle le corps dissous s'associe sur la surface apporte une base théorique à l'équation ci-dessus, et au fait que l'adsorption s'écarte apparement de l'équation de Gibbs.

AMMONIUM HEXANITRATOCERATE(IV) AS AN OXIDISING AGENT—IV*

TITRATION OF HYDRAZINE AND ISONICOTINIC ACID HYDRAZIDE AT ROOM TEMPERATURE

G. GOPALA RAO and P. V. KRISHNA RAO
Department of Chemistry, Andhra University, Waltair, India

(*Received* 13 *April* 1964. *Accepted* 28 *July* 1964)

Summary—The suitability of ammonium hexanitratocerate (IV) as an oxidimetric reagent for the determination of hydrazine and isonicotinic acid hydrazide has been investigated. Conditions for a rapid titration at room temperature both with a potentiometric and visual end-point have been developed. Under the conditions prescribed the combined nitrogen in both hydrazine and isonicotinic acid hydrazide is stoichiometrically liberated as gaseous nitrogen, unlike other cerimetric methods currently available.

BENRATH and Ruland[1] studied the reaction of hydrazine with an excess of cerium(IV) sulphate in a sulphuric acid medium and reported a yield of 11·22% of nitrogen and 12·88% of ammonia. However, the following stoichiometric reaction

$$N_2H_5^+ + Ce^{4+} \rightarrow 0{\cdot}5N_2 + NH_4^+ + Ce^{3+} + H^+ \tag{1}$$

requires 10·77% of nitrogen and 13·09% of ammonia to be formed. From a consideration of these results and in view of the relatively low speed of the reaction, Benrath and Ruland concluded that hydrazine cannot be determined by direct titration with cerium(IV) sulphate.

Recently, Krishna Rao, Subramanyam and Gopala Rao[2] reported that the electrometric titration of hydrazine with cerium(IV) sulphate is possible at 50–60° using manganese(II) salt as catalyst. They stated that the experimental values for hydrazine agree with the theoretical after they are multiplied by a factor of 0·985, assuming that the reaction proceeds according to equation (1).

Jílek and Brandštetr[3] have carried out a direct titration of hydrazine at 80–90° in 4·5*M* sulphuric acid or 3·75*M* hydrochloric acid in the presence of potassium bromide with cerium(IV) sulphate and either a visual end-point (using the azo dyes Victoria Rubin and Naphthol Blue Black 10B as irreversible indicators) or a potentiometric end-point. Under these conditions the results are about 0·8% lower than the theoretical as evident from their original paper, assuming the reaction to proceed according to the equation

$$N_2H_5^+ + 4Ce^{4+} \rightarrow N_2 + 4Ce^{3+} + 5H^+$$

Bapat and Sharma[4] titrated hydrazine with cerium(IV) sulphate *via* bromide to an amperometric "dead-stop" end-point in a 2·5–3·0*M* hydrochloric acid medium containing 2–3 g of potassium bromide/100 ml, at room temperature, and reported stoichiometric results. In titrations of hydrazine sulphate with cerium(IV) sulphate

---

* Part III: *Talanta*, 1964, **11**, 955.

under the conditions prescribed by Bapat and Sharma with a potentiometric "dead stop" end-point or with a conventional potentiometric end-point, we obtained results which were about 2% lower than the theoretical. Evidently, the presence of bromide alters the course of the reaction from equation (1) to equation (2). It is interesting that the bromate method of Kurtenacker and Wagner[5] also involves the oxidation of hydrazine completely to nitrogen. The bromate method is stated to be the best available titrimetric procedure for standardisation of hydrazine solutions, and we have confirmed its accuracy using analytical reagent grade hydrazine sulphate. In a recent review on the use of hydrazine and its derivatives as reductometric reagents, Berka, Vulterin and Zýka[6] stated that "the reaction between cerium(IV) and hydrazine is not quantitative and depends upon the nature of the medium."

In view of the consistently low results obtained by us during the titration of hydrazine sulphate with cerium(IV) sulphate under the conditions prescribed either by Bapat and Sharma or by Jílek and Brandštetr, we have investigated the cause of the low results. This has been traced to the presence of sulphate ion introduced through the cerium(IV) sulphate solution and that arising from hydrazine sulphate; the exact effect of the sulphate has not been elucidated. To eliminate sulphate ion completely from the system we have worked with ammonium-hexanitratocerate(IV) in place of cerium(IV) sulphate and hydrazine dihydrochloride in place of hydrazine sulphate. It has been found that a rapid and accurate titration of hydrazine can be made in a hydrochloric acid medium with a solution of ammonium hexanitratocerate(IV) at room temperature, using potassium bromide as catalyst, either to a potentiometric end-point or to a visual end-point with α-naphthoflavone or *p*-ethoxychrysoïdine as internal indicator.

The details of our investigation are presented in this paper.

EXPERIMENTAL

Reagents

0·1M Ammonium hexanitratocerate(IV) solution. Prepared and standardised according to the procedure described in Part I[7] of this series.

0·025M Hydrazine dihydrochloride solution. The sample employed in this investigation was supplied by E. Merck, Darmstadt, Germany. It was twice recrystallised from aqueous alcohol (50% v/v) and dried at 110°. The melting point of the product was 198° as against a value of 198–199° reported in the literature,[8] thus confirming the purity of the recrystallised material. An approximately 0·025*M* aqueous solution of this material was prepared and standardised according to the bromate method of Kurtenacker and Wagner.[5]

0.025*M Isonicotinic acid hydrazide* (*isoniazid*) *solution.* Prepared from a sample, labelled "U.S.P." and supplied by Albert David (Private) Limited, Calcutta, India, by recrystallising twice from water. The 0·025*M* solution was standardised against potassium dichromate by the method recommended by Vulterin and Zýka.[9]

0·2% *Ethanolic solution of α-naphthoflavone.* Prepared from an E. Merck "guaranteed reagent" quality sample.

0·1 % *Aqueous solution of* p-*ethoxychrysoïdine.* Prepared by dissolving *p*-ethoxychrysoïdine hydrochloride supplied by E. Merck in doubly-distilled water.

Concentrated hydrochloric acid. Analytical reagent grade material (sp. gr. 1·18), supplied by Basynth Chemicals (Private) Ltd., Calcutta, India, was used.

All other reagents employed were of guaranteed reagent quality.

Apparatus

The potentiometric titration assembly employed in this investigation consists of a Junior potentiometer (W. G. Pye & Co., England), a taut suspension galvanometer (Cambridge Instrument Co., England), a saturated calomel electrode as reference electrode and a bright platinum rod (*ca.* 0·2 mm diameter) as an indicator electrode. The salt bridge consists of an inverted "U" tube with porous plate ends filled with a saturated solution of potassium chloride.

Potentiometric Titration of Hydrazine

The reaction between hydrazine sulphate and cerium(IV) sulphate was found to be very slow at room temperature in a 0·5*M* sulphuric acid medium as evidenced by the slow disappearance of the yellow colour of the cerate ion. During the early stages of the titration, when a drop of cerium(IV) sulphate is added to 50 ml of a solution of 0·1*M* hydrazine sulphate in 0·5*M* sulphuric acid, it takes about 3 min for the yellow colour to disappear and about 10 min towards the close of the titration. If the 0·5*M* sulphuric acid is replaced by 1·0*M* hydrochloric acid the time required for the disappearance of the yellow colour of the cerate ion is about 1–2 min in the early stages and 5 min towards the end. We have, therefore, avoided even the small concentration of sulphate ion introduced by cerium(IV) sulphate and hydrazine sulphate by using ammonium hexanitratocerate(IV) in place of cerium(IV) sulphate and hydrazine dihydrochloride in place of hydrazine sulphate. Even under these conditions the reaction was observed to be somewhat slow as the basis of a quick titration. Increasing the concentration of hydrochloric acid or the temperature did not bring about any improvement. Hence, we attempted the use of potassium bromide as a catalyst.

Effect of varying the concentration of potassium bromide

5·0 ml of hydrazine dihydrochloride solution (0·03140*M*) in a 150-ml Pyrex beaker were acidified with 5 ml of concentrated hydrochloric acid and varying volumes of 4*M* potassium bromide solution were added, followed by dilution to 60 ml. The reaction mixture was then titrated potentiometrically, using the assembly described above, with a solution of ammonium hexanitratocerate(IV) (0·1178*M*). The time taken for the disappearance of the yellow colour of the cerate ion or the time taken for the attainment of stable potentials after the addition of each portion of cerate solution was found to decrease with increasing concentration of potassium bromide. For example, the time taken for the attainment of stable potentials is about 40 sec and 25 sec when the concentration of potassium bromide is 0·1*M* and 0·5*M*, respectively.

Moreover, when the titration of hydrazine dihydrochloride is carried out in a 1·0*M* hydrochloric acid medium, titres lower than the theoretical are obtained when the over-all bromide concentration is lower than 0·5*M*. The results also show that the experimental titre increases as the over-all concentration of potassium bromide is increased from 0·1 to 0·5*M*, reaching the theoretical value within the limits 0·5 to 2·0*M*. The titre shows a slight decrease when the over-all concentration of potassium bromide is increased above 2·0*M*.

Effect of varying the hydrochloric acid concentration

A number of titrations have been carried out varying the concentration of hydrochloric acid but maintaining the concentration of potassium bromide constant at 1·0*M*. When the concentration of hydrochloric acid lies between 1·0 and 3·0*M*, the potentials attain stable values in about 30 sec after the addition of each portion of cerate solution, except near the equivalence point when about 1 min is necessary.

As the concentration of hydrochloric acid is decreased below 1·0*M* the time required for attainment of stable potentials increases and the titre is also less than the theoretical value (5.26 ml), being 5·14 ml and 5·20 ml in 0·10*M* and 0·25*M* acid. When the concentration of hydrochloric acid is 4·0*M* the experimental titre again becomes lower than the theoretical.

An accurate and satisfactory potentiometric titration of hydrazine dihydrochloride with ammonium hexanitratocerate(IV) at room temperature is, therefore, only possible in a 1·0–3·0*M* hydrochloric acid medium containing potassium bromide at an over-all concentration of 0·5 to 2·0*M*.

Recommended procedure

From 2·5 to 10 ml of about 0·025*M* hydrazine dihydrochloride solution (8–27·5 mg of the salt) are taken in a 150-ml Pyrex beaker and treated with 5 ml of concentrated hydrochloric acid and 15 ml of 4*M* potassium bromide solution. The mixture is then diluted with water to 60 ml and titrated potentiometrically with 0·1*M* ammonium hexanitratocerate(IV) solution. The potentials are measured 1 min after the addition of each portion of the cerate solution. The break in potential at the equivalence point is 140–170 mV/0·04 ml of 0·1*M* cerate solution. A typical E–V curve is given in Fig. 1.

Titrations of more dilute solutions of hydrazine dihydrochloride (0·0025*M*) have been carried out with about 0·01*M* cerate solution and the break in potential remains unaltered. Typical results, presented in Table I, show that the method now proposed gives values for the assay of hydrazine in agreement with those obtained by the bromate method.[5] The average error is about 0·2%(relative), assuming the bromate results to be exact.

Potentiometric Titration of Isonicotinic Acid Hydrazide

A survey of the existing literature has shown that so far cerium(IV) salts have not been employed for the direct titrimetric determination of isonicotinic acid hydrazide either at room temperature or at elevated temperatures. Vulterin and Zýka[9] state that the reaction between isonicotinic acid hydrazide and cerium(IV) depends to a large measure on the pH of the solution, but under no conditions does reaction proceed stoichiometrically. We have now found that isonicotinic acid hydrazide can be rapidly titrated to a potentiometric end-point with ammonium hexanitratocerate(IV) at room temperature under the same conditions as recommended above for hydrazine. Fig. 2 is a representative E-V curve of such titrations. The reaction may be represented by the equation:

$$C_6H_4NCONHNH_2 + 4Ce^{4+} + H_2O \rightarrow 4Ce^{3+} + C_5H_4NCOOH + N_2 + 4H^+$$

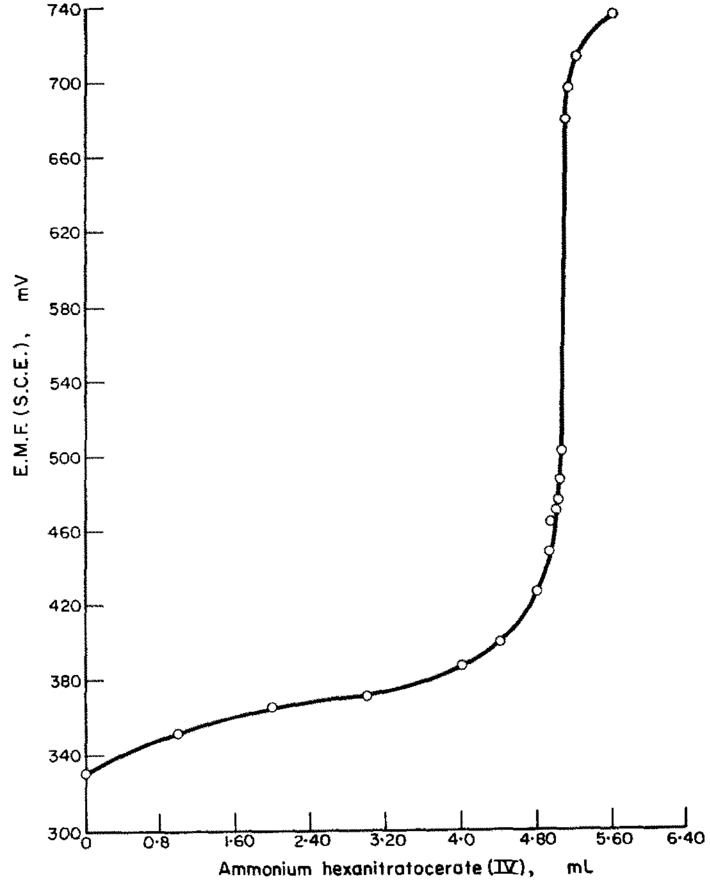

Fig. 1.—Potentiometric titration of hydrazine dihydrochloride (16·33 mg) with ammonium hexanitratocerate(IV).

Typical results on the assay of isonicotinic acid hydrazide are given in Table II, which show that the average error is 0·3%(relative), assuming the values obtained by the dichromate method to be exact.

Visual Titration of Hydrazine and Isonicotinic Acid Hydrazide

Having established conditions for a rapid potentiometric titration of hydrazine and isonicotinic acid hydrazide with ammonium hexanitratocerate(IV) at room temperature, we have attempted the use of visual indicators in these titrations with a view to providing a simple and rapid method for routine analysis. The use of the azo dyes Methyl Orange, Naphthol Blue Black 10B and Brilliant Ponceau 5R, both at room temperature and at elevated temperatures, has been investigated. In titrations at room temperature these dyes give a premature end-point, being irreversibly destroyed by the cerate solution. At higher temperatures (70–90°) Methyl Orange and Naphthol Blue Black can function as indicators provided the dye is added repeatedly, but this technique requires an appreciable indicator correction. Obviously, a procedure requiring high temperatures and repeated addition

of indicator is inconvenient. Moreover, the indicator undergoes oxidation irreversibly. However, α-naphthoflavone and *p*-ethoxychrysoïdine give an excellent indication of the end-point in titrations of 0·025*M* solutions of hydrazine and isonicotinic acid hydrazide with 0·1*M* solutions of ammonium hexanitratocerate(IV) at room temperature in a medium containing an over-all concentration of 1·0*M* hydrochloric acid and 0·5–2·0*M* potassium bromide. In titrations of 0·0025*M* solutions of hydrazine and isonicotinic acid hydrazide with a 0·01*M* solution of cerate, *p*-ethoxychrysoïdine fails to give a sharp indication of the end-point, although α-naphthoflavone still works satisfactorily.

Laszlovsky[10] has already reported the use of both of these indicators in the titration of hydrazine and isonicotinic acid hydrazide with potassium bromate in the presence of potassium bromide. *p*-Ethoxychrysoïdine has been used as an indicator by Wojahn[11] for the bromometric determination of isonicotinic acid hydrazide and by Schulek and Burger[12] for the titrimetric determination of hydrazine and its derivatives with bromine monochloride.

Domleo[13] used the same indicator for the titrimetric determination of isonicotinic acid hydrazide with 0·05*M* potassium iodate in about 7·2*M* hydrochloric acid at room temperature, the indicator being added after the addition of 90% of the iodate solution. Thereafter, the titration is continued slowly. When the indicator colour changes from scarlet to orange, the iodate was added drop by drop at an interval of 30 sec for each drop until the liquid turns from orange to yellow. A blank determination is also carried out.

Recommended procedure with α-naphthoflavone as indicator

To a test solution, containing 0·8–25 mg of hydrazine dihydrochloride or 1·1–32 mg of isonicotinic acid hydrazide, taken in a 100-ml Erlenmeyer flask, 5 ml of concentrated hydrochloric acid and 15 ml of 4*M* potassium bromide solution are added and the mixture diluted to 60 ml. 0·2 ml of 0·1% ethanolic α-naphthoflavone is then added to the mixture, which assumes, on shaking, a pale greenish-yellow opalescence. On titrating the mixture with a 0·1*M* or 0·01*M* ammonium hexanitratocerate-(IV) solution, the indicator coagulates as a greenish-yellow compound. After the equivalence point it turns orange-red on the addition of a slight excess (0·02 ml) of the cerate solution. The indicator is reversible. Under these conditions the indicator correction is 0·02 ml of 0·1*M* ammonium hexanitratocerate(IV) solution, which has to be subtracted from the total titre. Some typical results of determinations of hydrazine and isonicotinic acid hydrazide carried out in this way are presented in Table III, which indicate that the average error of such determinations is about 0·25%(relative) in the case of hydrazine and 0·45%(relative) in the case of isonicotinic acid hydrazide.

When the contents of the titration flask are stirred by shaking by hand, the coagulated indicator distributes itself throughout the titration mixture. If a magnetic paddle is used for stirring, however, the coagulated indicator collects on a small area of the surface. As the cerate solution is added this floating patch of the greenish-yellow compound momentarily assumes an orange-red colour, but soon reverts to the greenish-yellow hue. This change of colour continues until the equivalence point is reached, then, with a slight excess of the cerate solution, the floating patch assumes an orange-red colour which is stable for over 12 hr.

Recommended procedure with p*-ethoxychrysoïdine as indicator*

To the test solution, containing 7–25 mg of hydrazine dihydrochloride or 8·4–32 mg of isonicotinic acid hydrazide, taken in a 100-ml Erlenmeyer flask, 5 ml of concentrated hydrochloric acid and 15 ml of 4*M* potassium bromide solution are added and the mixture diluted to 60 ml. When 0·1 ml of 0·1% aqueous *p*-ethoxychrysoïdine is added to the mixture, it imparts a yellow colour to it. On the addition of 0·1*M* ammonium hexanitratocerate(IV) solution, the colour changes to a light orange-red, which remains so throughout the titration until the end-point is reached when it changes to a pale yellow.

As the colour transition is somewhat slow, it is necessary to wait for about 15 sec at the end-point. Under these conditions the indicator correction is 0·04 ml of 0·1*M* cerate solution, which has to be subtracted from the total titre. Some typical results are presented in Table IV: the error averages 0·15 %(relative) in the case of hydrazine and 0·2 %(relative) in the case of isonicotinic acid hydrazide.

Blank experiments have shown that in the absence of potassium bromide the indicator is irreversibly oxidised to a pale yellow compound on the addition of the first few drops of the cerate solution. Evidently, bromide greatly accelerates the reaction between the intermediate orange-red oxidation product of the dye and the reductant.

Removal of sulphate interference

Because of the interference of sulphate the new methods are inapplicable to the direct assay of hydrazine sulphate, a commonly encountered form of hydrazine. Hydrazine sulphate can be converted to the chloride by treating a hot aqueous solution of the former, containing dilute hydrochloric acid, with an excess of barium chloride and filtering off the precipitated barium sulphate.

Acknowledgements—One of us (P. V. K. R.) desires to thank the Council of Scientific and Industrial Research (India) for the award of a Junior Research Fellowship. We are also thankful to Messrs. Albert David (Private) Ltd., for the gift of a sample of isonicotinic acid hydrazide.

Zusammenfassung—Die Eignung von Ammoniumhexanitratocerat (IV) als oxydimetrisches Reagens bei der Bestimmung von Hydrazin und Isonicotinsäurehydrazid wurde untersucht. Die Bedingungen für eine schnelle Titration bei Zimmertemperatur, sowohl mit potentiometrischer als auch mit visueller Endpunktsanzeige, wurden ermittelt. Unter den angegebenen Bedingungen wird der Hydrazinstickstoff in Hydrazin und in Isoniazid stöchiometrisch als gasförmiger Stickstoff freigesetzt, im Unterschied zu den bisher üblichen Ceratverfahren.

Résumé—On a étudié la valeur de l'hexanitratocérate (IV) d'ammonium en tant que réactif oxydimétrique pour le dosage de l'hydrazine et de l'hydrazide de l'acide isonicotinique. On a mis au point les conditions d'un dosage rapide à température ambiante, avec détection potentiométrique ou visuelle du point de virage. Dans les conditions décrites, l'azote combiné, tant de l'hydrazine que de l'isoniazide, est libéré stoechiométriquement à l'état d'azote gazeux, contrairement à ce qui a lieu avec les autres méthodes cériques cériques couramment utilisées.

DETERMINATION OF TITANIUM, TANTALUM AND NIOBIUM BY PRECIPITATION FROM HOMOGENEOUS SOLUTION*

R. DAMS and J. HOSTE
Laboratory of Analytical Chemistry, Ghent University, Belgium

(*Received* 23 *May* 1964. *Accepted* 5 *July* 1964)

Summary—A method of precipitation from homogeneous solution has been developed for the gravimetric determination of titanium, by thermal decomposition of soluble peroxytitanate from either an alkaline or a slightly nitric acid medium. Recoveries are better than 99·6%. Coprecipitation of tungsten and manganese are reduced to a considerable extent. Furthermore, tantalum and niobium can be precipitated with highly satisfactory recoveries from a homogeneous nitric acid-hydrogen peroxide solution. Coprecipitation of titanium is investigated and corrections for coprecipitation calculated. The earth acids can also be precipitated from a homogeneous ammonia-hydrogen peroxide solution, the coprecipitation of tungsten being almost negligible. A study of the coprecipitation process of tungsten on tantalum and niobium shows that the distribution coefficients follow a linear pattern on both carriers. The method has been tested on a number of synthetic mixtures of the oxides, corrections for incomplete precipitation and coprecipitation being applied on the basis of the experimental values.

INTRODUCTION

THE gravimetric determination of titanium, tantalum and niobium in highly alloyed steels or in minerals and ores has always presented a rather difficult problem. The separation of the earth acids from tungsten and titanium requires particular attention because they tend to follow niobium and tantalum throughout the normal course of the analysis and appear in the final mixed oxide residue. The best method for separating the earth acids from large amounts of tungsten is probably Bedford's magnesia process.[1] However, Leliaert[2] recently showed that the precipitation of niobium is incomplete and that tungsten is coprecipitated to a considerable extent. The earth acids can be separated from titanium by Schoeller's classical separation,[3] in which the oxalates are decomposed with calcium chloride in the presence of sodium salicylate and the earth acids precipitated as salicylate complexes together with calcium oxalate. The titanium-salicylate complex is soluble, but it coprecipitates. As already shown in a previous paper,[4] tungsten can be successfully determined by precipitation from a homogeneous nitric acid-hydrogen peroxide solution. The same procedure is readily adaptable to the determination of titanium and the earth acids.[9] Radioactive tracer techniques were used to develop the proposed method.

EXPERIMENTAL

Radio-isotopes

Tantalum. ^{182}Ta, β, γ-emitter, half-life ± 111 day, produced by irradiation of tantalum pentoxide in the BR1 reactor.

---

* This work is part of the research sponsored by "Het Interuniversitair Instituut voor Kernwetenschappen".

Niobium. ^{95}Nb, β,γ-emitter, half-life ± 35·5 day, obtained from The Radiochemical Centre, Amersham, England.

Tungsten. ^{187}W, β,γ-emitter, half-life 24 hr, produced by irradiation of tungsten trioxide in the BR-1 reactor.

Manganese. ^{54}Mn, γ-emitter, half-life 324 day, obtained from The Radiochemical Centre, Amersham, England.

Apparatus

Counting techniques. Integral γ-counting was used for each isotope using a well-type NaI(Tl) detector.

Spectrophotometer. Beckman D.U. or D.K.-1 spectrophotometer with 1·000-cm Corex cuvettes.

Precipitation of Titanium from Homogeneous Solution

Fuse the dioxide with potassium bisulphate and extract the cold melt with a hot 3% solution of hydrogen peroxide to give a clear solution of the soluble peroxytitanate. Adding potassium hydroxide and dilute aqueous ammonia to bring the solution to pH 8. Heat the solution at 70° for 6 hr, after which the precipitation is complete. During the heating, the excess of hydrogen peroxide and the peroxytitanate are decomposed, causing a precipitation of metatitanic acid from a homogeneous solution.

The homogeneous precipitation can also be realised from a slightly acid medium. Preliminary experiments on the precipitation of tungsten and titanium showed that optimum results were obtained in a nitric acid medium, the solution being acidified to pH 2·5. The decomposition in an acid medium proceeds slowly, heating for 6 hr at 85° being required for complete precipitation.

In all experiments the amount of titanium left in solution was determined spectrophotometrically as the peroxide. The results are summarised in Table I.

TABLE I.—COMPLETENESS OF THE TITANIUM PRECIPITATION

Titanium taken, *mg Ti/60 ml*	Titanium left in solution, %[a]	
	NH_4OH-H_2O_2	HNO_3-H_2O_2(pH 2·5)
120·3	0·06	0·05
90·2	0·08	0·20
60·3	0·14	0·37
30·4	0·16	0·02
15·1	0·27	0·11
9·0^5	—	0·10

[a] Average of 2 experiments.

From Table I precipitation of titanium from homogeneous solution gives highly satisfactory titanium recoveries from both ammoniacal and slightly acid media. At all titanium concentrations investigated, the recovery is better than 99·6%.

Coprecipitation of tungsten and manganese

It is well known that tungstate coprecipitates with metatitanic acid. The precipitation of titanium from a homogeneous slightly alkaline medium offers the possibility of considerably reducing this coprecipitation. The coprecipitation of tungsten was investigated for tungsten/titanium ratios varying from 0·1 to 10. The absolute amount of titanium precipitated varied between 100 mg for small ratios and 35 mg for large ratios. Before melting the oxides of titanium and tungsten a known activity (*ca.* 1 × 10^6 cpm) of ^{187}W tracer was added. The percentage of tungsten coprecipitated was found by counting the activity of the precipitate. The results are summarised in Table II.

TABLE II.—COPRECIPITATION OF TUNGSTEN WITH TITANIUM DURING PRECIPITATION FROM AMMONIACAL PEROXIDE SOLUTION

W/Ti ratio	W coprecipitated, %	Error on Ti, %
0·103	0·86	0·066
0·256	0·63	0·12^1
0·51	0·30	0·11^5
1·02	0·19	0·14^8
2·55	0·23	0·44^3
5·1	0·20	0·77^0
10·2	0·26	2·0^0

At all tungsten/titanium ratios investigated less than 1% of the tungsten is coprecipitated.

The precipitation of titanium from a homogeneous nitric acid-hydrogen peroxide medium allows a separation of titanium from hydroxides insoluble in alkaline medium. Manganese, for instance, often interferes with the determination of titanium. This coprecipitation was studied for manganese/titanium ratios varying from 1 to 20. The absolute amount of titanium precipitated was varied from 35 to 10 mg. The amount of manganese coprecipitated was computed from ^{54}Mn tracer experiments. The results, summarised in Table III, show that the coprecipitation is reduced to a considerable extent. A twenty-fold excess of manganese causes an error of only 4% on the titanium determination.

TABLE III.—COPRECIPITATION OF MANGANESE WITH TITANIUM (PRECIPITATION FROM HNO_3-H_2O_2, pH 2·5)

Mn/Ti ratio	Mn coprecipitated, %	Error on Ti, %

Precipitation of Tantalum and Niobium from Homogeneous Nitric Acid-Hydrogen Peroxide

Fuse the pentoxides with potassium bisulphate and treat the cold melt by heating with a 3% solution of hydrogen peroxide. Neutralise with potassium hydroxide to give a clear solution of soluble peroxytantalates and niobates. Add nitric acid and heat to decompose the excess of hydrogen peroxide and the peroxyacids. The earth acids are precipitated homogeneously.

Preliminary experiments showed that in 5*M* nitric acid optimum results were obtained. A heating period of 10 hr at 70° was required before the decomposition was complete. In the presence of small amounts of selenous acid as a catalyst, quantitative precipitation took place after 5 hr at 85°.

In all experiments the amount left in solution was computed from tracer experiments. The tracer solutions were prepared with the same experimental conditions as the earth acid stock solutions. The results for the tantalum and niobium precipitations are summarised in Table IV.

It can be seen from Table IV that precipitation from homogeneous solution

TABLE IV.—COMPLETENESS OF THE TANTALUM AND NIOBIUM PRECIPITATIONS FROM NITRIC ACID-HYDROGEN PEROXIDE SOLUTION

Tantalum taken, *mg/60 ml*	Ta left in solution, %^{a}	Niobium taken, *mg/60 ml*	Nb left in solution, %^{a}	Niobium + tantalum taken, *mg/60 ml*	Nb left in solution, %^{a}

5·0	0·35	4·3	8·1	4·3 + 50	1·38

[a] Average of 2 experiments.

gives highly satisfactory tantalum recoveries (better than 99·6%) even at low concentrations. For niobium it is somewhat less satisfactory, although in the presence of tantalum the recoveries of niobium are usually better than 99%.

Coprecipitation of titanium

The precipitation from a homogeneous nitric acid-hydrogen peroxide medium allows a separation of the earth acids from titanium over a considerable concentration range. The coprecipitation of titanium was investigated for titanium/tantalum or niobium ratios varying from 0·008 to 8. The absolute amount of earth acids precipitated varied between 120 mg for small ratios and 15 mg for larger ratios. The amount of titanium coprecipitated was determined spectrophotometrically or gravimetrically. The results are given in Tables V and VI. The induced error is plotted in Fig. 1.

From Tables V and VI it appears that coprecipitation errors are quite low, although far from negligible in the case of large titanium/tantalum or niobium ratios. For small ratios a correction for the titanium coprecipitation can easily be made, because the values are highly reproducible.

Precipitation of Tantalum and Niobium from a Homogeneous Solution of NH_4OH-H_2O_2

Tantalum and niobium can also be precipitated from a homogeneous ammonical hydrogen peroxide solution, giving a separation of the earth acids from tungsten.

Leach the potassium bisulphate melt with hydrogen peroxide and neutralise with potassium hydroxide, carefully adjusting the pH to 7·5–8 with dilute aqueous ammonia. Heat solutions containing from 100 to 10 mg of tantalum or niobium for 20 hr at 85°, to decompose the soluble peroxytantalates and niobates. In the presence of selenous acid the heating period can be reduced to 8 hr. The decomposition causes a homogeneous precipitation of tantalum and niobium.

The completeness of the precipitations was examined by adding a known amount of ^{182}Ta or ^{95}Nb tracer and measuring the activity of the filtrate. The results are summarised in Table VII, which shows that at least 99.2% of the tantalum and niobium is precipitated.

Coprecipitation of tungsten

It might be expected that precipitation of the earth acids from a slightly alkaline medium would reduce the coprecipitation of tungsten on tantalum and niobium.

The coprecipitation of tungsten was investigated for tungsten/tantalum ratios varying from 0·01 to 10. The absolute amount of earth acids precipitated varied between 140 mg for small ratios and 20 mg for larger ratios. In all experiments the amount of tungsten coprecipitated was determined by measuring the ^{187}W activity of the filtrate or the precipitate. The results are presented in Table VIII.

TABLE VIII.—COPRECIPITATION OF TUNGSTEN WITH TANTALUM AND NIOBIUM DURING PRECIPITATION FROM HOMOGENEOUS AMMONIACAL HYDROGEN PEROXIDE

10·00	0·27	2·7^{9}	10·0	0·22^{5}	2·0^{0}

Table VIII indicates that only small amounts of tungsten are coprecipitated with tantalum and niobium. The induced error is quite small even for large tungsten/earth acid ratios. When this small correction is made for the tungsten coprecipitation, a single precipitation is sufficient for a direct gravimetric determination of the earth acids.

Analysis of Synthetic Mixtures

An analysis of a mixture of the oxides of titanium, tungsten, tantalum or niobium is possible. Precipitation from nitric acid-hydrogen peroxide separates tungsten, tantalum and niobium from titanium, whereas from an ammoniacal hydrogen peroxide solution titanium, tantalum and niobium are precipitated, tungsten being kept in solution. In the filtrates titanium and tungsten are determined by precipitations from alkaline or acid solution. The sum of the earth acids is computed twice by difference.

This procedure was tested with synthetic mixtures containing known amounts of titanium, tungsten and tantalum. The values obtained were corrected for incomplete recoveries and coprecipitation of tungsten or titanium. The corrections were computed on the basis of the experimental values described above. The results are summarised in Tables IX and X.

From Tables IX and X it appears that the results are in good agreement with the expected values, the errors being within 1 %, except for some tungsten determinations. The larger errors in these cases are obviously caused by the fact that only small amounts of tungsten were determined.

Determination of distribution coefficients

It is well known that in coprecipitation phenomena three types of distribution occur between the solid and liquid phase. If x and y represent the respective amounts

separated and a and b the initial concentrations of coprecipitant and carrier, the three distribution laws are:

homogeneous distribution law[5]

$$\frac{x}{a - x} = \mathrm{D}\frac{y}{b - y} \tag{1}$$

logarithmic distribution law[6]

$$\ln\frac{a}{a - x} = \lambda \ln\frac{b}{b - y} \tag{2}$$

proportional distribution law[7]

$$\frac{x}{y} = \mathrm{K}\frac{a}{b} \tag{3}$$

From previous work[4] it was known that the distribution of molybdenum and vanadium on tungstic acid follows the proportional distribution law. In the present work the distribution of tungsten on tantalum and niobium, from a homogeneous ammoniacal hydrogen peroxide solution, was investigated. Tracer techniques offer a relatively simple means of determining the distribution coefficients.[4] The amounts

present of carrier and of coprecipitant are computed by analysis of the composite decay curve if the half-lives are sufficiently different.

Procedure

Introduce 168·9 mg of tantalum and 1·0 mg of tungsten or 129·5 mg of niobium and 5·2 mg of tungsten into a 400-ml conical flask fitted with a reflux condenser. Add ^{182}Ta or ^{95}Nb and ^{187}W tracers, 5 ml of hydrogen peroxide (30 %) and 100 mg of selenous acid. The volume of solution should be about 250 ml. The activities of the tracer solutions are chosen to correspond to approximately 1×10^7 cpm of each tracer.

Adjust the pH of the solution to between 7·5 and 8. Heat the solutions at 85° and at regular time intervals take 5-ml portions of the solution by reverse filtration through an asbestos filter. Count 4 ml of the filtrates and analyse the composite decay curves.

The results and the values of D, λ and K, computed according to equations (1), (2) or (3), are represented in Tables XI and XII. In Figs. 2 and 3 the values of D, λ and K are plotted as a function of the percentage precipitated carrier.

From Tables XI and XII it appears that the proportional distribution law is followed in both cases, *i.e.*, the amount of coprecipitant is directly proportional to the amount of precipitated carrier, the mean values of the proportional distribution coefficient being:

$$K_{\mathrm{Ta}} = 0{\cdot}84^4 \pm 0{\cdot}03^6 \quad \text{and} \quad K_{\mathrm{Nb}} = 0{\cdot}37^2 \pm 0{\cdot}008.$$

According to the views of Hahn,[8] proportional distribution occurs when no true homogeneous mixed crystals are formed, the process being caused by surface layer crystallisation.

Distribution constants of titanium were not studied because no suitable tracer is available and spectrophotometric determinations are not accurate enough because they lack specificity.

Zusammenfassung—Eine homogene Fällungsmethode zur gravimetrischen Bestimmung von Titan wurde entwickelt, wobei lösliches Peroxytitanat entweder in alkalischen oder in schwach salpetersauren Medien mit besseren Ausbeuten als 99,6% thermisch zersetzt wird. Die Mitfällung von Wolfram und Mangan wird beträchtlich verringert. Ferner können Tantal und Niob mit sehr zufriedenstellenden Ausbeuten aus homogener Salpetersäure-Wasserstoffperoxyd-Lösung gefällt werden. Die Mitfällung von Titan wurde untersucht und Korrekturfaktoren dafür berechnet. Die Erdsäuren können auch homogen aus Ammoniak-Wasserstoffperoxyd-Lösung gefällt werden, wobei die Mitfällung von Wolfram fast vernachlässigbar ist. Die Untersuchung der Mitfällung von Wolfram mit Tantal und Niob zeigt, daß auf beiden Trägern die Verteilungskoeffizienten linear verlaufen. Die Methode wurde an einigen vorgegebenen Mischungen der Oxyde getestet, wobei auf Grund der experimentellen Werte Korrektionen für unvollständige Fällung und Mitfällung angebracht wurden.

Résumé—On a élaboré, pour le dosage gravimétrique du titane, une méthode de précipitation en milieu homogène, par décomposition thermique du peroxytitanate soluble, en milieu soit alcalin, soit légèrement nitrique, avec des récupérations supérieures à 99,6%. Les coprécipitations du tungstène et du manganèse sont considérablement réduites. En outre, le tantale et le niobium peuvent être précipités, avec des rendements très satisfaisants, à partir d'une solution homogène acide nitrique–eau oxygénée. On a étudié la coprécipitation du titane, et calculé les corrections pour cette coprécipitation. Les oxydes terreux peuvent aussi être précipités par voie homogène, à partir d'une solution ammoniaque–eau oxygénée, la coprécipitation du tungstène étant à peu près négligeable. L'étude du processus de coprécipitation du tungstène sur le tantale et le niobium montre que les coefficients de distribution suivent un diagramme linéaire sur les deux supports. On a essayé la technique avec un certain nombre de mélanges synthétiques des oxydes, les corrections pour la précipitation incomplète et pour la coprécipitation étant appliquées en se basant sur les valeurs expérimentales.

(*Received* 18 *May* 1964. *Accepted* 29 *July* 1964)

Summary—A method is described for the determination of trace amounts of zirconium and titanium. The two elements are separated from the sample matrix by precipitation with cupferron using iron as a carrier. Zirconium is determined after extraction with TOPO (tri-n-octylphosphine oxide), by colorimetric measurement of the zirconium–Pyrocatechol Violet complex. Titanium is determined by colorimetric measurement of its thiocyanate complex extracted with TOPO. The method is accurate to within ±5% (relative) or ±2·5 μg, whichever is greater, for both elements. Using the modifications suggested, the method is nearly specific for the determination of titanium (milligram amounts of niobium cause slightly high results), and only thorium and hafnium interfere with the determination of zirconium.

INTRODUCTION

By combining a number of known methods, an essentially specific determination of trace amounts of titanium and zirconium has been developed. Samples to be analysed are dissolved in the most appropriate manner and eventually obtained in a medium containing sulphuric acid, hydrochloric acid and citric acid. Iron is added as a carrier, and a cupferron precipitation is made. The precipitate is treated with nitric and perchloric acids, the solution evaporated nearly to dryness, and the residue dissolved in $8M$ nitric acid. Zirconium is extracted from an aliquot of this solution with $0{\cdot}02M$ TOPO (tri-n-octylphosphine oxide) in cyclohexane, and determined as its Pyrocatechol Violet complex.[1] Sulphuric acid is added to another aliquot of the $8M$ nitric acid solution, and this solution is evaporated to dryness. The residue is dissolved in $6M$ sulphuric acid and the titanium is extracted with $0{\cdot}02M$ TOPO in cyclohexane after the formation of the titanium-thiocyanate complex.[2]

EXPERIMENTAL

Apparatus

Cary Model 14 *Spectrophotometer*, with 2- and 5-cm cells
International Clinical Centrifuge, with 10 ml glass-stoppered centrifuge tubes
Mechanical shaker, Aloe Scientific

Reagents

Deionised water was used throughout the investigation.

Standard zirconium solutions. Dissolve 1 g of pure zirconium metal in dilute hydrofluoric acid. Add 20 ml of perchloric acid and evaporate to fumes of perchloric acid several times. Dilute to a suitable volume. Prepare two standard solutions, one containing 5 μg of zirconium/ml in $8M$

nitric acid and the other containing 1 μg of zirconium/ml in $8M$ nitric acid. Standardise the stock solution by precipitation with cupferron.

Standard titanium solutions. Dissolve 1 g of pure titanium metal in $6M$ hydrochloric acid at low heat. Oxidise the titanium with hydrogen peroxide and boil to remove the excess peroxide. Dilute to a suitable volume. Add sulphuric acid to an aliquot of this solution and heat to fumes of sulphuric acid. Dilute with $6M$ sulphuric acid to obtain two standard solutions of titanium, one containing 5 μg of titanium/ml and one containing 1 μg of titanium/ml. Standardise the stock titanium solution by precipitation with cupferron.

Ethyl alcohol, absolute

Thioglycolic acid (mercaptoacetic acid), 98% solution

Cyclohexane

Ammonium thiocyanate

Pyridine

Pyrocatechol Violet (pyrocatecholsulphonphthalein) solution, 0·05% (w/v) in absolute ethanol, prepared fresh daily.

Tri-n-octylphosphine oxide, $0{\cdot}02M$ in cyclohexane

Citric acid, 50% (w/v)

Hydrochloric acid, $12M$ and $1{\cdot}2M$

Nitric acid, $16M$ and $8M$

Perchloric acid, 70%

Sulphuric acid, $18M$, $6M$ and $1{\cdot}8M$

Hydrofluoric acid, $29M$

Cupferron, 6% (w/v), prepared just before use

Cupferron wash solution. Add 10 ml of 6% cupferron solution to 500 ml of $1{\cdot}2M$ hydrochloric acid. Prepare just before use.

Iron(III) chloride solution, 10 mg of iron/ml

Anion-exchange resin. Dowex 1X8, 100–200 mesh resin obtained from Bio-Rad Laboratories.

Filter paper, Whatman No. 40, 5·5 cm and 12·5 cm. Filter paper has been found to be the major cause of high blanks in the titanium procedure. If Whatman papers are unavailable, the papers to be used should be analysed for titanium before application of the procedure.

Filter paper pulp. Cut Whatman 40 filter paper into small (1 cm × 1 cm) pieces and shake vigorously with hot water in a stoppered Erlenmeyer flask.

Procedure

Dissolve the sample in the most appropriate manner and eventually obtain it in a volume of about 100 ml containing 5 ml each of sulphuric and hydrochloric acids and 10 g of citric acid. Add 1 ml of the iron(III) chloride solution, 0·5 g of filter paper pulp and cool to 10–15°. Also, cool an aqueous 6% solution of cupferron and the cupferron wash solution. Add an excess of cupferron to the sample solution. Filter the precipitate and wash 10 times with the cupferron wash solution. (It has been found very convenient to filter through a 6·3-cm i.d. Buchner funnel using suction. A piece of 5·5-cm filter paper is first placed in the bottom of the funnel, then a piece of 12·5-cm paper pushed down into the funnel using a 150-ml beaker. Finally, with the suction on, the paper is wetted with water.) Return the cupferrates to the original beaker, add 75 ml of nitric acid and 10 ml of perchloric acid, and evaporate using a Speedyvap cover glass. (The evaporation is continued until only a thin film of perchloric acid remains on the beaker walls. *Do not bake.*) Dissolve the residue in $8M$ nitric acid, transfer to a 50-ml volumetric flask and dilute to the mark with $8M$ nitric acid. This solution is hereafter referred to as the *prepared solution.*

Determination of Zirconium. Take an aliquot of the prepared solution, containing approximately 20 μg of zirconium, and transfer to a 125-ml separatory funnel. Add sufficient $8M$ nitric acid to give a total volume of 20 ml. Add 10 ml of $0{\cdot}02M$ TOPO solution and extract the zirconium by shaking for 10 min. Draw off and discard the aqueous phase. Wash the organic phase by shaking for 1 min with 20 ml of $8M$ nitric acid. Discard the wash solution. Transfer the extract to a glass-stoppered centrifuge tube and centrifuge for 2 min.

Add to a 25-ml volumetric flask, in the order listed, 9 ml of absolute ethanol, 5 ml of the centrifuged TOPO extract, 1 ml of Pyrocatechol Violet solution, 5 ml of pyridine, and dilute to the mark with absolute ethanol. Allow the colour of the zirconium-Pyrocatechol Violet complex to develop for 40 min and determine its absorbance at 655 mμ in 5-cm cells using absolute ethanol as a reference. The absorbance should be measured between 40 and 120 min after addition of the pyridine.

Determination of Titanium. Add a few drops of sulphuric acid to an aliquot of the prepared solution, containing 10 μg of titanium, and evaporate to dryness. Dissolve the residue by heating with 15 ml of $6M$ sulphuric acid. Cool and transfer to a 125-ml separatory funnel with $6M$ sulphuric acid. Add 5 ml of thioglycolic acid and 2 ml of 50% citric acid solution. Adjust the volume to about 60 ml with $6M$ sulphuric acid. Add 5 g of ammonium thiocyanate and, after the pink colour from the iron(III)-thiocyanate complex has faded, add 20 ml of $0{\cdot}02M$ TOPO solution. Extract the titanium by shaking for 5 min. After the phases have separated, withdraw and discard the aqueous phase. Add 30 ml of $6M$ sulphuric acid and 2 ml of thioglycolic acid to the organic phase and shake for 2 min. Discard the aqueous wash solution and transfer the extract to a 10-ml glass-stoppered centrifuge tube and centrifuge for 2 min. Measure the absorbance of the solution at 429 mμ in 2-cm cells using cyclohexane in the reference cell.

DISCUSSION

Determination of zirconium

A discussion of variables and other pertinent factors affecting the extraction and determination of zirconium is presented in the following paragraphs.

1. The efficiency of extraction will depend on both the amount of zirconium present and the TOPO concentration. The extraction coefficient is a function of nitric acid concentration and is 200, 400 and 550 when the concentration of nitric acid is $5M$, $8M$ and $10M$, respectively.[3]
2. The zirconium-Pyrocatechol Violet complex exhibits an absorbance maximum at 655 mμ. The absorbance is a linear function of concentration, at least from 0 to 0·75 μg of zirconium/ml. The effects of pyridine, ethanol, TOPO and water on the colour intensity have been discussed by Young and White.[1]
3. The colour development of the complex is concentration dependent. The higher the concentration of zirconium, the more rapidly full colour development is reached. In a solution containing 9·4 μg of zirconium/25 ml, 93% of the maximum absorbance was obtained after 2 min, 98% after 10 min and 100% after 45 min. After 2 hr, the absorbance had dropped to 99·5% of the maximum and no precipitate was visible. With 0·94 μg of zirconium/25 ml, the absorbance was 86% after 2 min, 94·5% after 10 min and 100% after 50 min. It was still 100% after 150 min, and no precipitate was visible. Nearly all solutions containing zirconium will eventually give rise to a precipitate.
4. The molar absorptivity of the zirconium complex is approximately 41,000 at 655 mμ, indicating an absorbance of about 0·8 for 0·4 μg of zirconium/ml in 5-cm cells.
5. Amounts of zirconium greater than the 20 μg referred to in the procedure can be satisfactorily extracted and determined using the procedure described. Up to 95 μg of zirconium can be extracted and determined by using a suitable aliquot. However, if the aliquot is diluted with TOPO solution and an aliquot taken of this solution, or if a measured amount of TOPO solution is added to an aliquot of the extract, low results are obtained.
6. Titanium interferes slightly with the determination of zirconium when present in a weight ratio (titanium to zirconium) of ten or greater. If the organic phase is back-washed with nitric acid, however, weight ratios (titanium to zirconium) of 100 and more are tolerated by the method.[1]
7. The extraction and absorbance measurement of the zirconium complex is quite reproducible as indicated by the fact that when 12 solutions containing 18·8 μg of zirconium were treated as described, all absorbance values were between 0·841 and 0·860.

Only a few additional remarks are necessary concerning the cupferron precipitation step and its effect on the final absorbance measurement.

1. Citric acid, between 0 and 20 g, had no effect (within experimental error) on the recovery of zirconium.
2. The recovery of 16 standards was 100 ± 5%.
3. A blank of 0·5 μg of zirconium is typical for the reagents used in the entire procedure.

Determination of titanium

A discussion of variables and other pertinent factors affecting the extraction and determination of titanium is presented in the following paragraphs.

1. The titanium-thiocyanate complex extracted in this manner exhibits an absorbance maximum at 429 mμ. At this wavelength, the molar absorptivity of the complex is about 43,000, indicating an absorbance of about 0·9 for 1 μg of titanium/ml in 1-cm cells. The extracted complex is stable (within experimental error) for at least 24 hr. The absorbance is a linear function of concentration, at least from 0 to 1 μg of titanium/ml, and obeys Lambert's law when 1-, 2- and 5-cm cells are used.
2. For quantitative extraction, the solution should be at least $6M$ with respect to sulphuric acid (mixtures of sulphuric and hydrochloric acids have no effect on the final absorbance if their total concentration is $6M$).[2]
3. Although equilibrium conditions are obtained in 3–4 min, a 5-min extraction time was used to ensure equilibrium.
4. The effect of TOPO concentration over the range 0·00002 to $0{\cdot}04M$ is slight but significant.[2] Using the procedure described, reasonable variations can be ignored.
5. The concentration of ammonium thiocyanate in the aqueous phase has no effect on the absorbance of the titanium complex provided the concentration exceeds 20 mg/ml.[2]
6. Using the procedure described, including the wash, no significant effect on the absorbance (of 10 μg of titanium in 20 ml of TOPO) was produced by 0–10 mg of iron, 0–5 g of citric acid or 0–10 ml of thioglycolic acid. Iron is present as a carrier, citric acid is added to prevent precipitation of other elements which might have been carried through the procedure, and thioglycolic acid is added to reduce iron and moderate or strong oxidants which might interfere in the determination.
7. There was no measurable effect on the absorbance of the titanium complex when the time between the addition of ammonium thiocyanate and the extraction of the complex was varied between 3 and 60 min, even though the iron(III)-thiocyanate colour was still visible after the shorter time period.
8. Up to 1 mg of titanium can be extracted using the procedure described, diluted appropriately with cyclohexane, and determined within experimental error.
9. The extraction and determination of titanium, if present in the tervalent state, is quantitative (within experimental error).
10. The extraction and absorbance measurement of the titanium complex is quite reproducible as indicated by the fact that when 10 solutions containing 10 μg of titanium were treated as described, all absorbance values were between 0·875 and 0·884.

Only a few additional remarks are necessary concerning the cupferron precipitation step and its effect on the final absorbance measurement.

1. Citric acid, between 0 and 20 g, had no effect, within experimental error, on the recovery of titanium.
2. The recovery of 50 μg of titanium(III) was quantitative within experimental error.
3. The recovery of 8 standards varied from 98·2 to 102·2%.
4. A blank of 2–3 μg of titanium is typical for the reagents used in the entire procedure.

Cupferron precipitation step

1. Quantitative recovery of 50 μg each of titanium and zirconium was obtained from:—
   (a) 100 ml of solution containing:
      i. 20 ml of 6*M* sulphuric acid, 5 ml of hydrochloric acid and 10 g of citric acid.
      ii. 50 ml of 6*M* sulphuric acid, 5 ml of hydrochloric acid and 10 g of citric acid.
      iii. No sulphuric acid, 10 ml of hydrochloric acid and 10 g of citric acid.
   (b) 250 ml of solution containing 60 ml of 6*M* sulphuric acid, 12·5 ml of hydrochloric acid and 10 g of citric acid.
2. Quantitative recovery of 3 mg each of titanium and zirconium was obtained using the procedure described. The 8*M* nitric acid solution was appropriately diluted before the determination of the two elements.

RESULTS

Effects of other elements

Table I indicates the results obtained in the study of the effect of other elements on the procedure described. The table also indicates whether the cupferron precipitation is necessary or sufficient to eliminate interference by an element.

The behaviour of hafnium (in the zirconium procedure) parallels that of zirconium. The absorbance spectrum and wavelength of maximum absorbance are apparently identical. The molar absorptivity of the hafnium complex is about 40,000 at 655 mμ. The absorbance of the hafnium complex is a linear function of concentration, at least from 0 to 1 μg of hafnium/ml.

Sulphate has an adverse effect on the extraction and determination of zirconium. The recovery of 18·8 μg of zirconium was 96·8, 95·4 and 94·2%, respectively, for 38, 384 and 676 mg of sulphate, present as sulphuric acid.

Both thorium and uranium interfere with the determination of zirconium if present when the zirconium is extracted. Results are within the accuracy limits described if less than 100 μg of uranium or 50 μg of thorium are present. The interference of uranium and thorium is shown in greater detail in Table II.

A discussion of the interferences indicated in Tables I and II is presented in the following paragraphs.

1. Barium interferes by precipitating as barium sulphate, which is insoluble in 8*M* nitric acid. To eliminate interference from barium, it would be necessary to make the cupferron precipitation from a hydrochloric acid solution.
2. Antimony(III) is carried to some extent with the cupferron precipitate and yields a residue insoluble in 8*M* nitric acid. Antimony must, therefore, be oxidised to antimony(V), which does not interfere.
3. Tin is partially carried and also yields a residue insoluble in 8*M* nitric acid. An anion-exchange separation is discussed in the following pages in which a 4% hydrofluoric acid solution is added to the column, and titanium and zirconium eluted

Elements with numbered superscript were added with other elements with same number.

[a] Except as indicated.

[b] 10 μg of Ti and 18·8 μg of Zr added.

[c] 50 μg of Ti and 47 μg of Zr added.

[d] 1 g added.

[e] 100 mg added.

[f] Precipitated in extraction medium

[g] Added as chloride.

[h] Irreproducible high results.

[i] Precipitation occurred. When W was added before Zr, so as not to occlude Zr, 98% recovery was obtained.

[j] Oxidised to I_2, which oxidised the reagent and prevented colour formation

[k] Same effect as I (see j).

[m] Precipitated on addition of thioglycolic acid.

[n] Oxidised the reagent.

[p] 2 ml of 72% $HClO_4$.

[q] See discussion regarding interference of Hf.

[r] 0·5 ml of 30% H_2O_2.

[s] 101 and 100% recovery of Zr was obtained in the presence of 1 g of $\mathrm{U^{VI}}$ after a double pptn.

[t] Precipitated as $BaSO_4$. Results shown were obtained by filtering the solution before spiking.

[u] After cupferron pptn., residue insoluble in HNO_3 (1 + 1).

[v] AgCl ppt. soluble in HNO_3 (1 + 1).

[w] See Table II regarding interference of thorium and uranium.

with 9*M* hydrochloric acid. Faris[4] has shown that tin(IV) is very strongly adsorbed on an anion-exchange column from a dilute hydrofluoric acid solution. Also, Kraus and Nelson[5] indicate that tin(IV) in 9*M* hydrochloric acid solution would be strongly retained on such a column. Therefore, the determination of titanium and zirconium in the presence of tin should be no significant problem.

Table II.—The effect of uranium and thorium on the determination of 18·8 μg of zirconium (extraction only)

Element	Added, μg	Error,[a] %
U	50	2,3
U	100	5
U	250	11
U	500	22
Th	50	4,5
Th	100	35
Th	250	100

[a] All errors positive.

4. Ten mg of thorium interferes with the determination of zirconium even with a prior cupferron precipitation. This element is not felt to be especially significant or important in the analysis of most samples because of its scarcity. However, when it is present, several ways of separating it from zirconium are apparently available, among which are:
   (a) Anion exchange–Thorium is strongly adsorbed on an anion-exchange column from a solution 9*M* with respect to nitric acid, whereas zirconium is only very slightly adsorbed.[6] Also, zirconium is strongly adsorbed on an anion-exchange column from a solution 12*M* with respect to hydrochloric acid, whereas thorium is not adsorbed.
   (b) Moore,[7] using radioactive tracers, states that zirconium can be extracted from 2*M* (or higher) solutions of nitric or hydrochloric acids with 0·5*M* TTA (thenoyltrifluoracetone) in xylene. Among those elements he lists as not extracting are thorium and uranium(VI). Zirconium can be stripped from the organic phase either with 0·5*M* nitric acid-0·5*M* hydrofluoric acid, or by diluting with xylene to a TTA concentration of 0·05*M* and extracting for 10 min with an equal volume of 8*M* nitric acid (90% of the zirconium-95 removed).
5. Hafnium interferes with the determination of zirconium and can be separated from the latter by ion exchange according to:
   (a) Hague and Machlan,[8] who used a 3·5% sulphuric acid medium, and a Dowex-1X8 column.
   (b) Kolosova *et al.*,[9] who used the cation-exchange resin KU-2X12, and a 0·35*M* sulphuric acid medium.
6. Niobium, tantalum, molybdenum and tungsten give rise to interference for two reasons. Firstly, because of their insolubility in the nitric acid medium used to dissolve the cupferrate residues, and secondly, molybdenum, tungsten and niobium interfere markedly if present during the extraction and determination of titanium. Table III indicates the behaviour of these elements in the extraction procedure used for the determination of titanium.

Kallmann has reported[11] that 50 μg each of titanium and zirconium can be quantitatively separated and determined in the presence of 1-g amounts of niobium, tantalum, molybdenum or tungsten as follows.

From niobium and tantalum: Separation by anion exchange (Dowex 1X8) using 25% hydrochloric acid-20% hydrofluoric acid. Titanium and zirconium are eluted, whereas niobium and tantalum remain on the column.

From molybdenum: Precipitation with aqueous ammonia using 10 mg of iron as a carrier.

From tungsten: Precipitation with cupferron from a 50% tartaric acid solution using iron as a carrier.

TABLE III.—BEHAVIOUR OF MOLYBDENUM, TUNGSTEN, NIOBIUM AND TANTALUM IN TITANIUM EXTRACTION PROCEDURE

Element	λ_{max}, *mμ*	Present, *μg/ml*	A_{429}, *mμ*	Titanium equivalent (at 429 mμ)
Mo	473	1	0·030	1 μg of Mo = 0·017 μg of Ti
W	409	5	0·190	1 μg of W = 0·022 μg of Ti
Nb	384	5	0·410	1 μg of Nb = 0·046 μg of Ti
Ta	—	5	0·000	—

On the basis of information in the literature, in particular the work of Faris,[6] Kraus and Nelson[5] and Wilkins,[10] it was believed that if a solution of the seven elements (titanium, zirconium, iron, molybdenum, tungsten, niobium and tantalum) in 4% hydrofluoric acid was added to an anion-exchange column, iron would not be retained on the column. After removal of the residual hydrofluoric acid by washing with ethanol, the titanium and zirconium could be eluted with 9*M* hydrochloric acid, presumably free from the other refractory elements. The procedure used is as follows.

The sample solution, in 4% hydrofluoric acid, containing the elements mentioned, is added to the ion-exchange column (12 × 1·5 cm of anion-exchange resin), *ca.* 50–75 ml of acid being used for the transfer. The column is washed twice with 10 ml portions of 4% hydrofluoric acid and then with 70 ml of the same solution (to remove iron). Finally, the column is washed with 35 ml of ethanol to remove the 4% hydrofluoric acid. Titanium and zirconium are eluted with 100 ml of 9*M* hydrochloric acid, the eluate being caught in a 600-ml beaker containing 2 g of boric acid and 10 mg of iron(III) in 250 ml of water. A cupferron precipitation is performed as previously described, and the precipitate is filtered and treated with nitric and perchloric acids. (Plastic columns, beakers and stirring rods are used for all steps before the wet oxidation.)

It was found that both titanium and zirconium were quantitatively recovered using this procedure. Zirconium could be determined accurately in a solution originally containing 50 μg of titanium, 47 μg of zirconium and 10 mg each of iron, molybdenum, tungsten, niobium and tantalum. However, some niobium did "dribble' through the column as shown by a spectrum of the titanium extract. Results for titanium indicated that about 100 μg of niobium had not been retained on the column. This caused an error in the determination of 50 μg of titanium of about 10%.

Although this separation is not as satisfactory as could be desired, it indicates that samples containing a more favourable ratio of niobium to titanium could be accurately analysed in this manner.

Application of method

A number of samples have been analysed using the procedure described, or modifications thereof. The results obtained are shown in Tables IV and V.

[1] S. Kallmann found 0·038 and 0·040% of Zr using 4% HF-ethanol-9*M* HCl modification.

[2] O. Kriege found 0·038, 0·035, 0·039, 0·039% of Zr using his X-ray fluorescence technique.[12]

[3] Direct extraction of zirconium failed, presumably because of the chromium content.

[4] Results obtained by S. Kallmann at Ledoux and Company.

[5] Anion-exchange modification used.

Acknowledgement—This paper is derived from work performed under the auspices of United States Atomic Energy Commission Contract AT(11-1)-171.

Zusammenfassung—Eine Methode zur Bestimmung von Spuren Zirkonium und Titan wird beschrieben. Die beiden Elemente werden vom Hauptteil der Probe durch Fällung mit Cupferron auf Eisenträger abgetrennt. Zirkonium wird mit TOPO (Tri-n-octylphosphinoxyd) extrahiert und kolorimetrisch als Zirkonium-Brenzkatechinviolett-Komplex bestimmt. Titan wird kolorimetrisch als Rhodanidkomplex bestimmt, der mit TOPO extrahiert wird. Die Methode ist für beide Elemente auf ±5% (relativ) oder höchstens auf ±2,5 μg genau. Mit den vorgeschlagenen Änderungen ist die Methode fast spezifisch für die Bestimmung von Titan (Milligrammengen Niob geben Plusfehler); nur Thorium und Hafnium stören die Zirkon-bestimmung.

Résumé—On décrit une méthode de dosage du titane et du zirconium. Les deux éléments sont séparés de la gangue échantillon par précipitation au cupferron, en utilisant le fer comme entraîneur. On dose le titane par mesure de son complexe thiocyanique extrait à l'oxyde de tri-n-octylphosphine (TOPO). Le zirconium est dosé après extraction au TOPO de la solution 8 M en acide nitrique, par mesure du complexe zirconium-violet de pyrocatéchol. Pour les deux éléments, la méthode est précise à ±5% ou 2,5 μg près. On prend la plus grande de ces deux valeurs. En utilisant les modifications suggérées, la méthode est spécifique pour le dosage du titane, et seuls le thorium et le hafnium interfèrent dans le dosage du zirconium.

THE PRECIPITATION OF CADMIUM SULPHIDE BY THIOACETAMIDE FROM ACID CHLORIDE SOLUTIONS

DAVID V. OWENS, ERNEST H. SWIFT and DWIGHT M. SMITH*
Department of Chemistry, California Institute of Technology, Pasadena,
California, U.S.A.†

(*Received* 25 *May* 1964. *Accepted* 30 *June* 1964)

Summary—The rate of precipitation of cadmium(II) by thioacetamide from 0·030 *VF* to 0·040 *VF* chloride solutions has been found to conform to the expression

$$\frac{-\mathrm{d}[\mathrm{Cd^{II}}]}{\mathrm{dt}} = k\,\frac{[\mathrm{Cd^{2+}}][\mathrm{CH_3CSNH_2}]}{[\mathrm{H^+}]^{1/2}} + k'\,\frac{[\mathrm{CdCl^+}][\mathrm{CH_3CSNH_2}]}{[\mathrm{H^+}]^{3/4}}$$

where k and k' are $8{\cdot}1 \times 10^{-4}$ litre$^{1/2}$ mole$^{-1/2}$ min^{-1} and $1{\cdot}55 \times 10^{-4}$ litre$^{1/4}$ mole$^{-1/4}$ min^{-1}, respectively, at 90°. This rate expression applies to solutions having pH values above 3, where the so-called direct reaction between cadmium species and thioacetamide is predominant. At the above chloride concentrations, the observed rate of precipitation is greater than that which should have been observed if all of the cadmium(II) were present as aquated cadmium ion, Cd^{2+}. Rate measurements at 0·15 and 1 *VF* chloride have shown that the higher chloride complexes of cadmium(II), $CdCl_2$ and $CdCl_3^-$, react at a very much slower rate than does $CdCl^+$ or Cd^{2+}. The value of the dissociation constant for the monochlorocadmium ion,

$$K_{\mathrm{diss}} = \frac{[\mathrm{Cd^{2+}}][\mathrm{Cl^-}]}{[\mathrm{CdCl^+}]},$$

has been found to be $(2{\cdot}18 \pm 0{\cdot}07) \times 10^{-2}$ at 90° by means of a concentration cell with cadmium amalgam electrodes.

INTRODUCTION

BOWERSOX and Swift[1] found that in the pH region from 3·3 to 6·3 the rate of precipitation of cadmium sulphide by thioacetamide (TAA) from formic acid-formate buffered solutions conformed to the expression

$$\frac{-\mathrm{d}[\mathrm{Cd^{II}}]}{\mathrm{dt}} = 8{\cdot}1 \times 10^{-4}\,\frac{[\mathrm{Cd^{II}}][\mathrm{CH_3CSNH_2}]}{[\mathrm{H^+}]^{1/2}} \tag{1}$$

They also observed that chloride ion decreased the rate of precipitation, and this decrease was attributed to the formation of chloride complexes of cadmium. It was hoped that a quantitative investigation of this inhibition would provide information regarding the effect of complexing ligands on the rates and mechanisms of the direct reactions of hydrated metal ions with TAA. In addition, the analytical implications were of interest.

I. THE DISSOCIATION CONSTANT OF MONOCHLOROCADMIUM ION

The rate measurements on the reaction of cadmium with thioacetamide in chloride solutions were carried out at 90°. Therefore a reliable value for the dissociation constant of the monochlorocadmium ion at this temperature was needed for quantitative interpretation of the results. A sufficiently accurate value could not be obtained by extrapolation of published values at other temperatures;[6,7,9] therefore, a concentration cell utilising cadmium amalgam electrodes was used for gathering the results required to calculate the desired dissociation constant at 90°. Approximate calculations from limited available values, indicated that at 90°, and the prevailing pH values, less than 0·0003 % of the cadmium would be present as $CdOH^+$.

EXPERIMENTAL

Reagents

Reagent-grade chemicals were used.

Cadmium perchlorate solution: 0·10*VF* (volume formal), prepared by dissolving cadmium carbonate in a measured volume of 9*VF* perchloric acid and diluting to volume.

Cadmium amalgam: 5%, made by mixing 15 g of cadmium metal turnings with 285 g of triply distilled mercury and warming the mixture in an atmosphere of nitrogen.

Sodium chloride solution: 0·50*VF* prepared by weight.

Sodium perchlorate solution: (chloride-free) 1·00*VF*, used to provide a constant ionic strength of 0·23.

Apparatus

A thermoregulated constant temperature bath was used to maintain the system at 90°. A Leeds and Northrup K-2 potentiometer was used for the potential measurements. The cell was a conventional polarographic H-cell with a sintered glass disc separating the two compartments. The cadmium amalgam was placed in the lower end of J-shaped 6-mm glass tubing having a length of platinum wire sealed in to maintain electrical contact with the cadmium amalgam in the cup. This apparatus was similar in nature to that used by Vanderzee and Rhodes[10] for the study of stannous chloride complexes.

Procedure

The method consisted of measuring the potential difference between two identical cadmium amalgam electrodes, one in a reference cadmium perchlorate solution of known concentration, the other in a solution of known cadmium and chloride concentrations and having the same ionic strength and pH as the reference solution. Fresh cadmium amalgam electrode surfaces were prepared for each experiment.

The empty H-cell was preheated in the constant temperature bath. The two cadmium solutions were deaerated with nitrogen, heated quickly to about 90°, and rapidly poured into the appropriate compartments of the cell, and the compartments were closed. An atmosphere of nitrogen was maintained over the solutions throughout each experiment. The electrodes were inserted, and potential difference readings were taken as soon as the temperature of the solutions stabilised at 90°. A series of readings was taken at approximately 3-min intervals for about 20 min; after this time the potential differences began to decrease because of the migration of chloride ion through the sintered glass disc. The values obtained during a given run agreed to within 0·3 mV; the average value of multiplicate runs agreed to within 0·2 mV. The reference solution in all measurements was a standard cadmium perchlorate solution, about 0·01 *VF* in cadmium and adjusted to ionic strength 0·23 with sodium perchlorate. The chloride-containing solutions were of the same ionic strength and same formal cadmium concentration.

RESULTS AND DISCUSSION

The reversible e.m.f. of the cell

$$Cd(Hg) \mid Cd^{2+}(C_1) \parallel Cd^{2+}(C_2) \mid Cd(Hg)$$

is given by

$$E_{cell} = \frac{RT}{2F} \ln c_2/c_1 \tag{2}$$

where c_2 represents the cadmium ion concentration of the standard solution and c_1 the cadmium ion concentration of the chloride-containing solution. In this work the junction potential has been neglected because the solutions are nearly identical in composition and of equal ionic strength; only the chloride and cadmium ion concentrations differ. There was no evidence of significant concentration changes caused by evaporation during the course of the measurements.

Checks on the experimental reliability of the method were made as follows:

1. The asymmetry potential resulting when the two cadmium amalgam electrodes were placed in identical solutions was measured at 25° and 90°, and in all cases, was within approximately ±0·5 mv.

2. The reversibility of the cadmium amalgam electrodes in these solutions at 90° was checked by measuring the potential difference between two solutions of the same ionic strength having a cadmium concentration ratio of 10:1 and comparing the value obtained with that predicted by equation (2); the calculated value was 36·4 mv, and the observed value 37·4 mv.

3. The dissociation constant of the monochlorocadmium ion at 25° was determined over a range of cadmium–chloride ratios and the value obtained compared with literature values. King[6] and Vanderzee and Dawson,[9] among others, have shown that a chloride concentration range exists in which cadmium and monochlorocadmium ions are the predominant species, and the results of Vanderzee and Dawson on the variation of the dissociation constant with ionic strength were used to calculate an approximate value for

$$K_{\text{diss}} = \frac{[Cd^{2+}][Cl^-]}{[CdCl^+]} \tag{3}$$

at 25° and $\mu = 0{\cdot}23$. (This ionic strength was used so that later comparison of the rate values with those of Bowersox and Swift[1] on the cadmium ion-TAA reaction

TABLE I.—DISSOCIATION CONSTANT OF MONOCHLOROCADMIUM ION AT 90° CALCULATED FROM CONCENTRATION CELL VALUES.

$K_{\text{diss}} = (2{\cdot}18 \pm 0{\cdot}07) \times 10^{-2}$

[a] Calculated from the expression

$$K_{\text{diss}} = \frac{[Cd^{2+}][Cl^-]}{[CdCl^+]}$$

could be made.) The mean of the experimental values found for K_{diss} at 25° was $3{\cdot}2 \times 10^{-2}$; the value calculated from the results of Vanderzee and Dawson[9] was $3{\cdot}5 \times 10^{-2}$.

Dissociation constant of monochlorocadmium ion at 90°

Table I presents the results of two independent series of measurements of the e.m.f. of cadmium ion concentration cells at 90° and the resulting values for the dissociation constant at each chloride concentration. The average value of the dissociation constant, $2{\cdot}18 \times 10^{-2}$, was used during the rate study described below for calculating equilibrium concentrations of cadmium and monochlorocadmium ions under the conditions specified.

II. REACTION RATES OF CHLOROCADMIUM SPECIES WITH THIOACETAMIDE

EXPERIMENTAL

Reagents

Thioacetamide (*TAA*) *solutions:* 1·00*VF*, prepared by weight from Arapahoe thioacetamide.* These solutions were clear and were used for not longer than 3 weeks.

Disodium ethylenediaminetetra-acetate (EDTA): 0·011*VF*, prepared by weight and standardised with a standard zinc chloride solution. Eriochrome Black T in 1:1 ethanolamine-isopropanol was used as indicator.

Formic acid–formate buffer systems were used; the concentration of formate ion in the reaction solution was 0·15*VF*.

Buffer solution, pH 10: made by diluting a solution of 67·5 g of ammonium chloride and 570 ml of concentrated aqueous ammonia (stock reagent) to 1 litre, was used in the EDTA titrations.

Apparatus

The reaction vessel was a 38-mm × 200-mm Pyrex test-tube fitted with a three-hole stopper. Inserted in the stopper were a 6-mm siphon tube, a 6-mm outlet tube with a pressure bulb, and a thermometer. The vessel was immersed in the constant temperature bath and the temperature of the entire system was maintained at 90 ± 1°. In one experiment an additional 6-mm tube was inserted in the reaction vessel to allow nitrogen to bubble through the vessel.

Procedure

The cadmium perchlorate, sodium perchlorate, sodium chloride and buffer solutions were mixed in the reaction vessel at a temperature slightly above 90°. The TAA solution was heated quickly to about the same temperature and then added rapidly to the system. The initial concentration of cadmium(II) was 0·010*VF*, the chloride was 0·031–1·0*VF*, and the TAA concentration was varied from 0·100*VF* to 0·445*VF*. After temperature equilibration, samples of the reaction mixture were removed at timed intervals, quenched in an ice bath, and centrifuged to separate the cadmium sulphide. Duplicate 5·00-ml portions of each sample solution were pipetted into 15-mm × 125-mm test-tubes. An excess of ammonia was added to precipitate the cadmium sulphide, and the tubes were placed in hot water to coagulate the precipitate. Then the mixture was centrifuged, and the cadmium sulphide was transferred quantitatively to a flask. About 4 ml of 6*VF* hydrochloric acid were added, the solution was boiled to expel hydrogen sulphide, and was then partially neutralised with 6*VF* potassium hydroxide. The solution was cooled, and 10 ml of the pH 10 buffer solution and a few drops of Eriochrome Black T indicator were added. The solution was then titrated with 0·011*VF* EDTA to a blue-green end-point.

DISCUSSION AND RESULTS

The rate measurements were made with solutions, 0·030–0·040*VF* in chloride, which had approximately equal concentrations of cadmium and monochlorocadmium ions; the dissociation constant of $CdCl_2$, estimated from the results of Vanderzee and Dawson[9] at 25° and 45°, indicated that less than 5% of the total cadmium existed

---

* Arapahoe Chemicals, Inc, Boulder, Colorado, U.S.A.

as this species. Evidence is presented later that $CdCl_2$ does not react with thioacetamide at a significant rate under the conditions prevailing.

A semi-logarithmic plot of the total or volume formal cadmium concentration *versus* time was made for each experiment, and as shown in Fig. 1 linear plots were obtained in all cases. The rate of decrease of the formal cadmium concentration under the conditions studied can be expressed in the form.

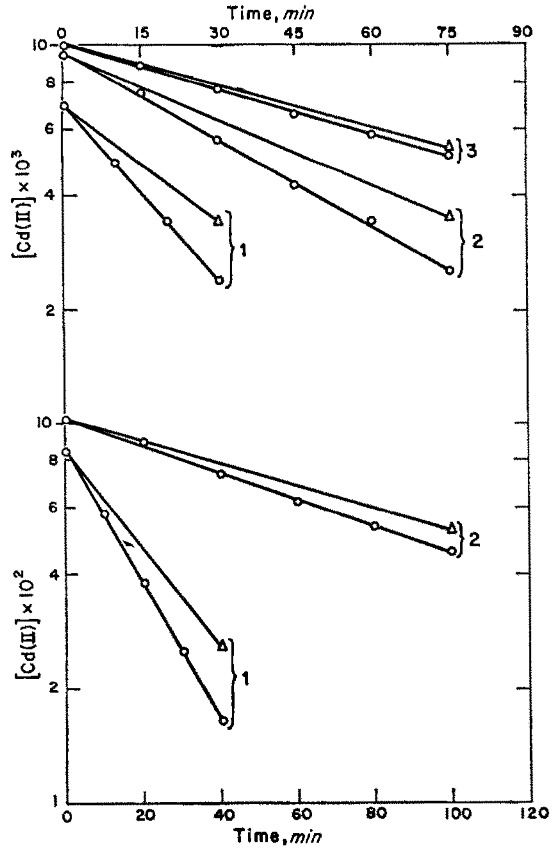

FIG. 1.—Effect of cadmium(II), thioacetamide and pH on the rate of precipitation of cadmium from chloride solutions by thioacetamide.

○ Experimental measurements.

Δ Calculated using equation (1), assuming no chlorocadmium(II) complexes formed.

A. CH_3CSNH_2 0·200*VF*; chloride 0·030*VF*; 90°
  (1) pH 4·30
  (2) pH 3·80
  (3) pH 3·30; chloride 0·040*VF*
B. pH 3·80; chloride 0·030*VF*; 90°
  (1) CH_3CSNH_2 0·445*VF*
  (2) CH_3CSNH_2 0·100*VF*

$$\frac{-d[Cd^{II}]}{dt} = K\,[Cd{-}II] \qquad (4)$$

Because essentially all of the cadmium exists as cadmium and monochlorocadmium ions under these conditions, the rate may be expressed also as

$$\frac{-\mathrm{d}[\mathrm{Cd^{II}}]}{\mathrm{dt}} = -\left[\frac{\mathrm{d}[\mathrm{Cd^{2+}}]}{\mathrm{dt}} + \frac{\mathrm{d}[\mathrm{CdCl^{+}}]}{\mathrm{dt}}\right] \tag{5}$$

where $[\mathrm{Cd^{2+}}]$ and $[\mathrm{CdCl^{+}}]$ designate the concentrations of aquated cadmium and monochlorocadmium ions, respectively.

Bowersox and Swift[1] have shown that the rate of reaction of cadmium ion with thioacetamide in acid solution at 90°, in the pH region where the so-called direct reaction predominates, conforms to equation (1). Nearly exact reproducibility of the rate constant, $8{\cdot}1 \times 10^{-4}$ litre$^{1/2}$ mole$^{-1/2}$ min^{-1} at 90°, reported by these investigators, was confirmed in separate experiments during the course of the present work. Therefore, the over-all reaction rate under these conditions becomes

$$\frac{-\mathrm{d}[\mathrm{Cd^{II}}]}{\mathrm{dt}} = 8{\cdot}1 \times 10^{-4}\,\frac{[\mathrm{Cd^{2+}}][\mathrm{CH_3CSNH_2}]}{[\mathrm{H^+}]^{1/2}} + k_d[\mathrm{CdCl^+}]^n \tag{6}$$

where k_d is a constant for any given thioacetamide and hydrogen ion concentration.

If $\mathrm{CdCl^+}$ does not react with TAA at a measurable rate, the second term in equations (5) and (6) disappears, and the observed rate should conform closely to the rate calculated using the equilibrium concentrations of cadmium ion. The results presented in Table II show that the observed rate cannot be explained on this basis. Equilibrium concentrations of cadmium and monochlorocadmium ions were calculated at each experimental point, using the dissociation constant for $\mathrm{CdCl^+}$ previously determined. Cadmium(II) complexes are highly labile and there is no evidence for delay in establishing equilibrium.[8] The total observed rate of cadmium(II) precipitation and calculated rates of reaction of cadmium ion are tabulated for one representative set of conditions (Table II), and indicate that the monochlorocadmium ion reacts with TAA at a greater rate under these conditions than does the simple (aquated) cadmium ion. A similar representation of the relative reaction rates observed in all other experiments leads to the same conclusion.

TABLE II.—COMPARISON OF OBSERVED CADMIUM(II) PRECIPITATION RATE WITH PRECIPITATION RATE OF CADMIUM ION ($\mathrm{Cd^{2+}}$).

$$\frac{[\mathrm{Cd^{2+}}][\mathrm{Cl^-}]}{[\mathrm{CdCl^+}]} = 2{\cdot}18 \times 10^{-2} \quad (90°)$$

[b] Calculated from the expression

$$\frac{-\mathrm{d}[\mathrm{Cd^{II}}]}{\mathrm{dt}} = K[\mathrm{Cd{-}II}]$$

[c] Calculated from the expression (1)

$$\frac{-\mathrm{d}[\mathrm{Cd^{2+}}]}{\mathrm{dt}} = 8{\cdot}1 \times 10^{-4}\,\frac{[\mathrm{Cd^{2+}}][\mathrm{CH_3CSNH_2}]}{[\mathrm{H^+}]^{1/2}}$$

Fig. 1 shows the relationships between the experimentally determined reaction rates of cadmium and TAA under the conditions specified [equation (4)], and the rate calculated using the Bowersox–Swift expression [equation (1)] assuming no complex formation. In every case, under the experimental conditions studied, the observed rate is greater than that calculated assuming that all cadmium in the system was present in the form of the aquated cadmium ion, represented as Cd^{2+}. The calculated plots were made by determining a rate constant, K, of the form in equation (4). These plots are consistent with the example results shown in Table II.

Rates of monochlorocadmium ion-thioacetamide reaction

Effect of monochlorocadmium ion: Because the term dependent on cadmium ion in equation (6) can be calculated, the results obtained from rate measurements at constant TAA and hydrogen ion concentrations can be used to determine the value of n in this equation. From equations (4), (5) and (6) it is seen that

$$\frac{-\mathrm{d}[\mathrm{CdCl}^+]}{\mathrm{dt}} = K[\mathrm{Cd^{II}}] - 8{\cdot}1 \times 10^{-4}\frac{[\mathrm{Cd}^{2+}][\mathrm{CH_3CSNH_2}]}{[\mathrm{H}^+]^{1/2}} = k_d[\mathrm{CdCl}^+]^n \qquad (7)$$

The results were plotted as the term

$$K[\mathrm{Cd^{II}}] - 8{\cdot}1 \times 10^{-4}\frac{[\mathrm{Cd}^{2+}][\mathrm{CH_3CSNH_2}]}{[\mathrm{H}^+]^{1/2}}$$

versus the equilibrium concentration of $CdCl^+$ at each experimental point.

The linearity of these plots (*cf.* Fig. 2) establishes a first order rate dependence on the concentration of monochlorocadmium ion. The value of n in equation (7), which has been calculated from the results is 1·01 ± 0·01.

Effect of thioacetamide: Experiments at three different TAA concentrations and at constant pH, permitted the calculation of the corresponding rate constants, K and k_d, in equation (7). The value of m in the expression

$$\frac{-\mathrm{d}[\mathrm{CdCl}^+]}{\mathrm{dt}} = k_d'[\mathrm{CdCl}^+][\mathrm{CH_3CSNH_2}]^m \qquad (8)$$

was then calculated as 1·03 ± 0·05.

TABLE III.—EFFECT OF THIOACETAMIDE CONCENTRATION ON THE MONOCHLOROCADMIUM ION—THIOACETAMIDE REACTION.
(Chloride 0·0300*VF*; pH 3·80; 90°)

$[CH_3CSNH_2]$, *VF*	$k \times 10^2$, sec^{-1} [a]	$k' \times 10$, $M^{-1}\,sec^{-1}$ [b]
0·100	1·04 ± 0·00	1·04
0·200	2·23 ± 0·01	1·11
0·445	4·93 ± 0·00	1·11

$k'_{\text{average}} = (1{\cdot}09 \pm 0{\cdot}03) \times 10^{-1}\,M^{-1}\,\mathrm{sec}^{-1}$

[a] Calculated from the expression

$$\frac{-\mathrm{d}[\mathrm{CdCl}^+]}{\mathrm{dt}} = k[\mathrm{CdCl}^+]$$

[b] Calculated from the expression

$$\frac{-\mathrm{d}[\mathrm{CdCl}^+]}{\mathrm{dt}} = k'[\mathrm{CdCl}^+][\mathrm{CH_3CSNH_2}]$$

In Table III the information on the effect of TAA is summarised, and shows that the rate of reaction of monochlorocadmium ion with TAA is first order with respect to the TAA concentration.

Effect of hydrogen ion: In order to establish the dependence on pH of the rate of the reaction of $CdCl^+$ with TAA, measurements were carried out in solutions varying from $5{\cdot}0 \times 10^{-4}$ to $5{\cdot}0 \times 10^{-5}$ *VM* in hydrogen ion. The measurements were not made over a wider range because at lower pH values precipitation by TAA hydrolysis becomes significant,[1] and at higher pH values the formate buffer system is inefficient.

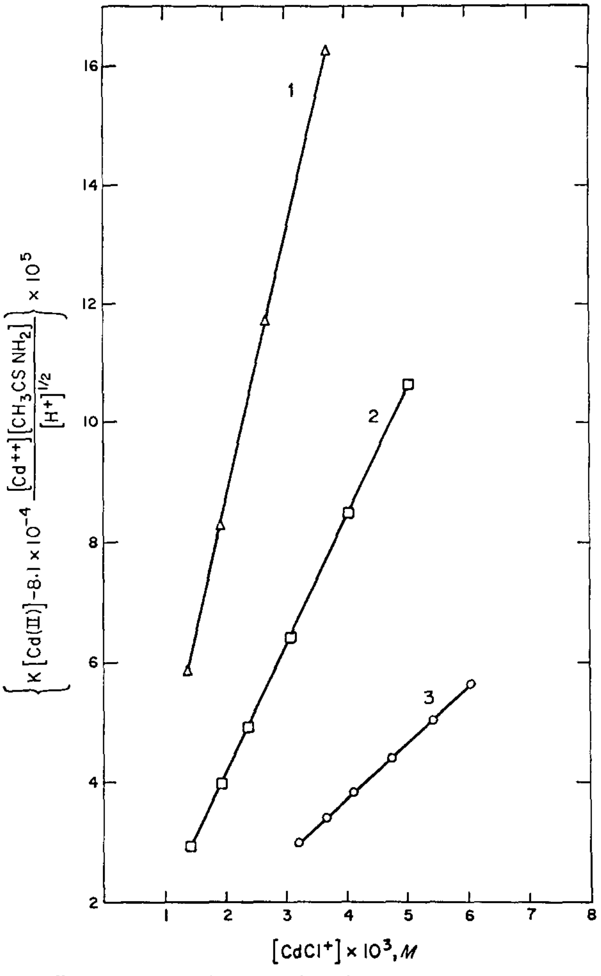

FIG. 2.—Effect of monochlorocadmium ion and pH on the rate of precipitation of monochlorocadmium ion by thioacetamide.

(CH_3CSNH_2 0·200*VF*; chloride 0·0300*VF*; 90°)
(1) pH 4·30
(2) pH 3·80
(3) pH 3·30; chloride 0·0400*VF*

It was desirable to retain the formate buffer system in order to utilise the information previously reported by Bowersox and Swift.[1] In this and similar work done in these laboratories the pH values reported were determined at 25° rather than at 90°.

Accurate and reproducible measurements at 90° are difficult to make, and reliable standards are not readily available. In some experiments, relative measurements of pH were made at 90° and gave essentially the same rate dependence. The measurements show that the reaction of monochlorocadmium ion with TAA is inhibited by hydrogen ion (Fig. 2) and that this inhibition is significantly different from the half-order inhibition observed in the direct reaction of the aquated cadmium ion.[1] The dependence observed in this case is inverse three-fourths order under the conditions shown in Table IV. The exact order calculated from the results is (—0·75 ± 0·00).

TABLE IV.—EFFECT OF pH ON THE MONOCHLOROCADMIUM ION—THIOACETAMIDE REACTION.
(Chloride 0·0300*VF*; CH_3CSNH_2 0·200*VF*; 90°)

pH	$k_1 \times 10^5$ [a]	$k_2 \times 10^3$ [b]	$k' \times 10^4$ [c]
3·30[d]	2·33	1·04	1·56
3·80	1·72	1·37	1·54
4·30	1·32	1·86	1·57

$k' = (1{\cdot}55 \pm 0{\cdot}01) \times 10^{-4}$ litre$^{1/4}$ mole$^{-1/4}$ min^{-1}.

[a] Calculated from the expression

$$\frac{-d[CdCl^+]}{dt} = k_1 \frac{[CdCl^+][CH_3CSNH_2]}{[H^+]}$$

[b] Calculated from the expression

$$\frac{-d[CdCl^+]}{dt} = k_2 \frac{[CdCl^+][CH_3CSNH_2]}{[H^+]^{1/2}}$$

[c] Calculated from the expression

$$\frac{-d[CdCl^+]}{dt} = k' \frac{[CdCl^+][CH_3CSNH_2]}{[H^+]^{3/4}}$$

[d] Nitrogen bubbled briefly through reaction vessel.

Rate expression: The experiments discussed above have shown that the rate of precipitation of cadmium by TAA from dilute chloride solutions having pH values from 3·3 to 6·3 follows the expression

$$\frac{-d[Cd^{II}]}{dt} = k \frac{[Cd^{2+}][CH_3CSNH_2]}{[H^+]^{1/2}} + k' \frac{[CdCl^+][CH_3CSNH_2]}{[H^+]^{3/4}} \tag{9}$$

where k and k' are $8{\cdot}1 \times 10^{-4}$ litre$^{1/2}$ mole$^{-1/2}$ min^{-1} and $1{\cdot}55 \times 10^{-4}$ litre$^{1/4}$ mole$^{-1/4}$ min^{-1}, respectively, at 90°. This expression indicates that, as with the aquated cadmium ion, there is a direct reaction between the monochlorocadmium complex and the TAA.

Rates at higher chloride concentrations: It was of interest to determine the effect of increasing the chloride concentration on the precipitation rate. Especially of interest would be the rates of precipitation in chloride concentration regions where the higher chloride complexes of cadmium, $CdCl_2$ and $CdCl_3^-$, were present in significant quantities. Butler and Swift[5] have shown that arsenic(III) does not undergo a direct reaction with TAA in the same pH region as lead,[4] cadmium,[1] nickel[2] or zinc,[3] the reaction apparently being hydrolysis-controlled even at pH 6. In this pH region arsenic(III) exists in the form of a neutral complex species; thus more information on the reaction of neutral and negatively charged species was of interest.

Rate measurements were carried out in solutions 0·15*VF* and 1·0*VF* in chloride, where significant concentrations of $CdCl_2$ and $CdCl_3^-$, respectively, should be present. The results of King[6] show that at 25° the distribution of species should be approximately one-fifth total cadmium as $CdCl_2$ in a 0·15*VF* chloride solution: and one-third as $CdCl_2$, and one-half as $CdCl_3^-$ in a 1·0*VF* chloride solution.

The results are summarised in Fig. 3, where the rates at the higher concentrations are compared with one of the experiments at 0·0300*VF* chloride under the same conditions. The over-all rate of reaction of cadmium with TAA is greatly diminished as the chloride concentration increases. Also, it is to be seen that the rate of the reaction is still first order with respect to the volume formal cadmium concentration. This information indicates that the uncharged and negatively charged species, $CdCl_2$ and $CdCl_3^-$, react at a very much slower rate than does $CdCl^+$.

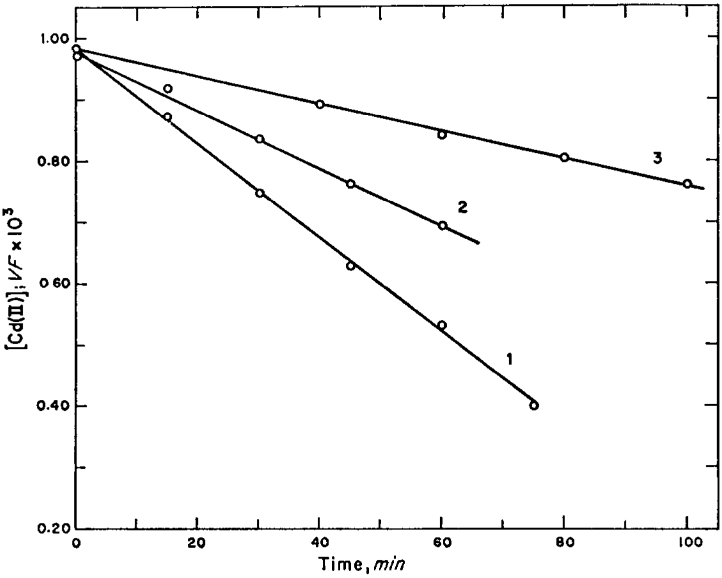

Fig. 3.—Effect of chloride concentration on the rate of precipitation of cadmium(II) by thioacetamide.

(pH 3·80; CH_3CSNH_2 0·200*VF*; 90°)
(1) chloride 0·0300*VF*
(2) chloride 0·146*VF*
(3) chloride 1·00*VF*

No quantitative conclusions can be drawn, because only very approximate values for the dissociation constants of $CdCl_2$ and $CdCl_3^-$ are available. In addition, the ionic strength of these more concentrated chloride solutions exerts a significant effect on the value of the individual dissociation constants. Nevertheless, attempts were made to calculate approximately the ionic strength and temperature effects on the available dissociation constants of $CdCl_2$ and $CdCl_3^-$ at lower temperatures and different ionic strengths.[6,9] These resulting approximate constants were applied in the calculation of the equilibrium distribution of the various cadmium species in the reaction solutions of chloride concentration 0·15*VF* and 1·0*VF*. Calculations made in this way indicate that $CdCl_2$ and $CdCl_3^-$ do not react with thioacetamide at a measurable rate under the conditions specified.

Comments on reaction rates of various species

As the results in Table II and Fig. 1 show, the rate of reaction of the monochlorocadmium ion with thioacetamide is greater than that of the aquated cadmium ion. A direct comparison of rate constants is not meaningful, because the rate constant of the $CdCl^+$—CH_3CSNH_2 reaction has different dimensions from that of the Cd^{2+}—CH_3CSNH_2 reaction because of the different hydrogen ion dependences of these reactions. If the Cd^{2+} and $CdCl^+$ rates had the same hydrogen ion dependence, the rate constant of the $CdCl^+$ reaction would be much greater than that of the Cd^{2+} reaction (Table IV); at pH 3·80, for example, k_2 would have been $1{\cdot}37 \times 10^{-3}$ litre$^{1/2}$ mole$^{-1/2}$ min^{-1}. As indicated by Fig. 3, and by the approximate calculations described in connection with the rate measurements in 0·146 and 1·00 *VF* chloride solutions, the $CdCl_2$ and $CdCl_3^-$ species react very slowly, if at all, under the conditions described. No information appears to be available by which one can explain these apparent relative rates by direct analogy with similar reactions.

Subsequent experiments in these laboratories[11] have indicated that nucleation and crystal growth phenomena can exert striking effects on precipitations by the direct reaction, and that under certain conditions reactions taking place at the surface of the precipitate particles constitute the rate-controlling step. These effects are being investigated further.

This investigation again shows the variety of effects which may occur when TAA is substituted for hydrogen sulphide as a precipitant, and the necessity for careful experimental verification of proposed analytical procedures based on this substitution.

Acknowledgement—We are indebted to David F. Bowersox for preliminary measurements which established that the aquated cadmium ion and the monochlorocadmium ion reacted with TAA at different rates. We have received valuable suggestions and comments from Fred C. Anson, Robert L. Causey, and David H. Klein. Financial support from the National Science Foundation is gratefully acknowledged.

Zusammenfassung—Die Fällungsgeschwindigkeit von Cadmium(II) mit Thioacetamid aus 0,03–0,04-molaren Chloridlösungen läßt sich durch die Gleichung

$$\frac{-d[Cd(II)]}{dt} = k\,\frac{[Cd^{2+}][CH_3CSNH_2]}{[H^+]^{1/2}} + k'\,\frac{[CdCl^+][CH_3CSNH_2]}{[H^+]^{3/4}}$$

darstellen, mit $k = 8{,}1 \cdot 10^{-4}\ l^{1/2}\ mol^{-1/2}\ min^{-1}$ und $k' = 1{,}55 \cdot 10^{-4}\ l^{1/4}\ mol^{-1/4}\ min^{-1}$ bei 90°C. Diese Geschwindigkeitsgleichung gilt für Lösungen mit pH-Werten über 3, wo die sogenannte direkte Reaktion zwischen Cadmium und Thioacetamid überwiegt. Bei den gennanten Chlorid-konzentrationen ist die beobachtete Fällungsgeschwindigkeit größer als die, die man erwarten würde, wenn alles Cadmium(II) als hydratisiertes Cadmiumion Cd^{2+} vorläge. Geschwindigkeitsmessungen bei 0,15 und 1-molarer Chloridkonzentration zeigten, daß die stärker chloridhaltigen Komplexe $CdCl_2$ und $CdCl_3^-$ viel langsamer reagieren als $CdCl^+$ und Cd^{2+}. Die Dissoziationskonstante des Monochlorocadmiumions

$$K_{diss} = \frac{[Cd^{2+}][Cl^-]}{[CdCl^+]}$$

wurde mit Hilfe einer Konzentrationszelle mit Cadmiumamalgamelektroden zu $(2{,}18 \pm 0{,}07) \cdot 10^{-2}$ bei 90°C gefunden.

Résumé—On a trouvé que la vitesse de précipitation du cadmium(II) par le thioacétamide, à partir de solutions de chlorure $0{,}030 VF$ à $0{,}040 VF$, est en accord avec l'équation:

$$\frac{-\mathrm{d}[\mathrm{Cd(II)}]}{\mathrm{d}t} = k\,\frac{[\mathrm{Cd}^{2+}][\mathrm{CH_3CSNH_2}]}{[\mathrm{H}^+]^{1/2}} + k'\,\frac{[\mathrm{CdCl}^+][\mathrm{CH_3CSNH_2}]}{[\mathrm{H}^+]^{3/4}}$$

où k et k' sont respectivement, à 90°C, $8{,}1 \times 10^{-4}$ litre$^{1/2}$ mole$^{-1/2}$ min^{-1} et $1{,}55 \times 10^{-4}$ litre$^{1/4}$ mole$^{-1/4}$ min^{-1}. Cette équation de la vitesse s'applique aux solutions dont le pH est supérieur à 3, et où prédomine la réaction dite directe entre le cadmium et le thioacétamide. Aux plus grandes concentrations en chlorure, la vitesse de précipitation observée est supérieure à celle que l'on devrait noter si tout le cadmium(II) était présent à l'état d'ion cadmium hydraté, Cd^{2+}. Les mesures de vitesse pour les valeurs 0,15 et 1F en chlorure ont montré que les complexes chlorés supérieurs du cadmium(II), $\mathrm{CdCl_2}$ et $\mathrm{CdCl_3}^-$, réagissent à des vitesses beaucoup plus lentes que CdCl^+ ou Cd^{2+}. On a trouvé, au moyen d'une cellule de concentration avec électrodes à amalgame de cadmium, que la valeur de la constante de dissociation pour l'ion monochlorocadmium,

$$K_{\mathrm{diss}} = \frac{[\mathrm{Cd}^{2+}][\mathrm{Cl}^-]}{[\mathrm{CdCl}^+]}$$

est de $(2{,}18 \pm 0{,}07) \times 10^{-2}$ à 90°C.

A SELECTIVE AND SENSITIVE COLOUR REACTION FOR SILVER

R. M. DAGNALL* and T. S. WEST*Ⓡ

Birmingham 15, England

(*Received* 20 *June* 1964. *Accepted* 16 *July* 1964)

Summary—Bromopyrogallol red (BPR) and 1,10-phenanthroline (phen) may be used as a reagent system for the spectrophotometric determination of silver ions in aqueous solution in the range 0.02–0·20 ppm. Photometric and potentiometric methods have shown that the blue coloured ternary complex, which absorbs at 635 mμ, is most probably an ion-association system $[(\text{phen-Ag-phen})^+]_2\text{BPR}^{2-}$. The colour reaction, using EDTA, fluoride and hydrogen peroxide as masking agents, is free from interference of a 100-fold g ion excess over silver of some 24 cations and 11 anions investigated. Only gold(III), cyanide and thiosulphate were found to interfere. With a molar extinction coefficient of 51,000, the colour reaction is probably the most sensitive of all known colorimetric methods for silver.

FROM an examination of the literature it is apparent that there is considerable need for a selective colorimetric reagent for silver without the disadvantages of the existing organic reagents, dithizone and the rhodanine derivatives.[1] We felt it was unlikely that much success could be gained by designing similarly constituted reagents and have pursued a rather different approach to the problem.

We have previously described the use of pyrogallol red as a spectrophotometric reagent for silver ions.[2] This reagent forms a yellow complex [$\lambda_{\max} = 390$ mμ, $\epsilon_{390\text{ m}\mu} = 10{,}000$] with silver, but the colour development is protracted. The bromo-substituted reagent, bromopyrogallol red, behaves similarly and also forms a yellow colour. Subsequently, in the course of examining the use of 1,10-phenanthroline as a masking agent, we discovered that the presence of the latter caused a dramatic change in the course of the reaction between silver ions and the reagent. Instead of the slow removal of the red colour of the pyrogallol red, with the formation of a yellow colour of much lower intensity, we observed an instantaneous formation of a blue coloured solution of very high intensity. Because the colour formation was very rapid, sensitive and unaffected by the mass masking agent, EDTA, it was decided to investigate the reaction and develop it for the determination of trace amounts of silver.

The blue colour may be produced by the addition of a silver nitrate solution to an aqueous solution of 1,10-phenanthroline and pyrogallol red, buffered to pH 7 with ammonium acetate. The use of bromopyrogallol red increases the sensitivity of the reaction, which can be obtained over the pH range 3–10, although the optimum pH appears to be *ca.* 7. At pH values greater than 7 there is a risk of reagent oxidation, which becomes appreciable at pH > 9. The absorption of the bromopyrogallol red and 1,10-phenanthroline system at 560 mμ decreases with increasing amounts of

---

silver and at the same time, another absorption peak builds up at 635 mμ. The ratio of silver:bromopyrogallol red, as deduced from this experiment at the position of maximum colour development, is 2:1 (*cf.* Fig. 1). It is worthy of note that the reaction is instantaneous. With more concentrated solutions of silver nitrate (*ca.* $10^{-3}M$) a blue gelatinous precipitate settles out on standing, but with lower concentrations of silver (*ca.* $10^{-5}M$) there is no obvious precipitation over a period of 2–3 days. Lastly, a considerable excess of 1,10-phenanthroline (*ca.* a 10-fold mole excess over silver) is required to give maximum colour formation.

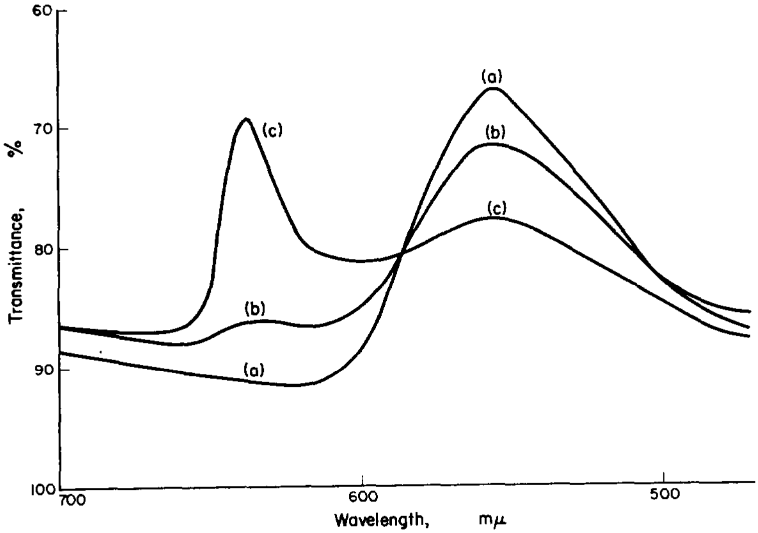

Fig. 1.—Transmission spectra:

(a) 5 ml of $10^{-5}M$ bromopyrogallol red plus 1 ml of $10^{-3}M$ 1,10-phenanthroline + 1 ml of 20% ammonium acetate diluted to 50 ml with distilled water.
(b) As (a) plus 5 ml of 10^{-5} M silver nitrate.
(c) As (a) plus 10 ml of 10^{-5} M silver nitrate.
(Measurements made at 635 mμ in 4-cm cuvettes with Beckman D.B. spectrophotometer.)

Preliminary calibration curves for silver in the range 1–10 μg (0·02–0·2 ppm) gave linearity only for 4–10 μg of silver. This appeared to indicate either the presence of a weak complex or the existence of a precipitate, the solubility product of which had not been reached with very small amounts of silver. There was no excess bromopyrogallol red at the upper silver limit (10 μg) in these experiments. The calibration curve was repeated using a 2-fold mole excess of bromopyrogallol red together with a 10-fold mole excess of 1,10-phenanthroline (both relative to silver). EDTA (1000-fold mole excess over silver) was also incorporated into the solution as a convenient masking agent for cations which would interfere by reacting with bromopyrogallol red [*e.g.*, lead(II)], with 1,10-phenanthroline [*e.g.*, iron(II)] or both [*e.g.*, mercury(II)]. By measuring the absorbance at 635 mμ in 4-cm cuvettes against a blank containing no silver, linearity was obtained from 1–10 μg (0·02–0·2 ppm) of silver. The solution colours slowly faded on standing, but were quite stable for 0·5 hr after preparation and subsequent dilution to 50 ml. The order of addition of reagents was unimportant.

Interferences

The permissible level of cation concentration, other than silver, depends largely on the concentration of EDTA employed, because it is intended that EDTA should function as the principal masking agent. Solutions were prepared, therefore, containing *ca.* 10 μg of silver (*ca.* 0·2 ppm), under the normal optimum conditions necessary for the preparation of a calibration curve. Each solution contained, in addition, varying concentrations of EDTA from a 100- to 10,000-fold mole excess over silver. It was found that there was no significant change in the absorbance of any of the solutions at 635 mμ. It should, therefore, be possible to determine silver in the presence of very large excesses of extraneous cations provided that they form reasonably stable EDTA complexes at pH 7, and that these complexes do not absorb appreciably at 635 mμ. Table I shows the effect of *ca.* a 100-fold (g ion) excess of various cations over silver in the presence of a 1,000-fold (mole) excess of EDTA.

TABLE I

[a] In a 100-fold g ion excess over silver.
[b] At 635 mμ in 4-cm cuvettes.

Except for gold(III), iron(II), niobium(V), thorium(IV) and uranium(VI), the deviation from the expected results is not greater than ± 0·006 absorbance unit, *i.e.*, $\not>$ 1·6% at a silver level of 0·18 ppm.

The red coloured tris-1,10-phenanthrolinium iron(II) complex was produced with iron(II) and 1,10-phenanthroline but its effect could be overcome by the addition of a sufficiently large excess of 1,10-phenanthroline to complex all of the iron(II) and to react with the silver-bromopyrogallol red. It does not absorb at 635 mμ. Uranium(VI), thorium(IV) and niobium(V) interfere because they all form blue-coloured complexes with bromopyrogallol red. However, these interferences could be eliminated completely at moderate concentrations of these cations [10-fold (g ion) excess over silver], by the addition of excess of fluoride for uranium and thorium, and of hydrogen peroxide for niobium. Only gold(III) continued to cause interference by producing a green-blue coloured precipitate.

It is obvious from this investigation that only silver and gold(III), of those ions examined, give, with 1,10-phenanthroline and bromopyrogallol red, ternary complexes which absorb at 635 mμ. Other complexes produced are complexes of either bromopyrogallol red or 1,10-phenanthroline.

Several anions were also examined at a level of a 10- to 100-fold mole excess over silver. There was no interference from acetate, bromide, carbonate, chloride, citrate, fluoride, nitrate, oxalate, sulphate, sulphite or phosphate. In addition, there was no interference from an appreciable excess of hydrogen peroxide, which is used to mask niobium(V). Only cyanide and thiosulphate were observed to interfere. Both of these ions completely inhibited formation of the blue ternary complex between silver and the reagents.

Reaction mechanism

The nature of this reaction in aqueous solution suggests that the colour is dependent on the formation of a precipitate. This is further indicated by its inability to extract into organic solvents; a blue precipitate normally settles out at the interface.

The composition of the complex was investigated by the following methods.

(a) *Photometric titration*

(i) *Bromopyrogallol red vs. silver nitrate (in excess 1,10-phenanthroline).* The ratio of *reagent:silver* at the end-point of the titration was 1:1·95 (*i.e.*, 1:2).

(ii) *Bromopyrogallol red plus silver nitrate (1:2 ratio) vs. 1,10-phenanthroline.* The ratio of *reagent plus silver:1,10-phenanthroline* at the end-point of the titration was 1:5·25. There was no excess of any one reagent throughout this titration. The actual amount of 1,10-phenanthroline will probably be less than the above because of the amount necessary to form and stabilise the precipitate.

(b) *Job plots*

(i) *Bromopyrogallol red:silver ratio (in excess 1,10-phenanthroline).* A continuous variation plot indicated a *reagent:silver* ratio of 1:2·16 (*i.e.*, 1:2) [Fig. 2(a)].

(ii) *Bromopyrogallol red: 1,10-phenanthroline ratio (in excess silver nitrate).* In this instance a *reagent:1,10-phenanthroline* ratio of 4:16 was given (*i.e.*, 1:4) [Fig. 2(b)].

(iii) *1,10-phenanthroline:silver ratio (in excess bromopyrogallol red).* Here the 1,10-*phenanthroline:silver* ratio was 13·85:6·15 (*i.e.*, 2:1) [Fig. 2(c)].

Thus, the over-all ratio of the reagents employed is $(\text{silver})_2$:$(\text{phen})_4$:$(\text{BPR})_1$.

(c) *Potentiometric measurements*

Potentiometric titration was investigated in order to show up differences in the reaction between Ag^+/BPR on the one hand and Ag^+/phen/BPR on the other. Silver is well known to form a co-ordinately-bound complex with 1,10-phenanthroline. It was felt possible that the BPR was reacting in some way with a $[\text{phen-Ag-phen}]^+$ complex or that the 1,10-phenanthroline was reacting with an Ag^+/BPR chelate by

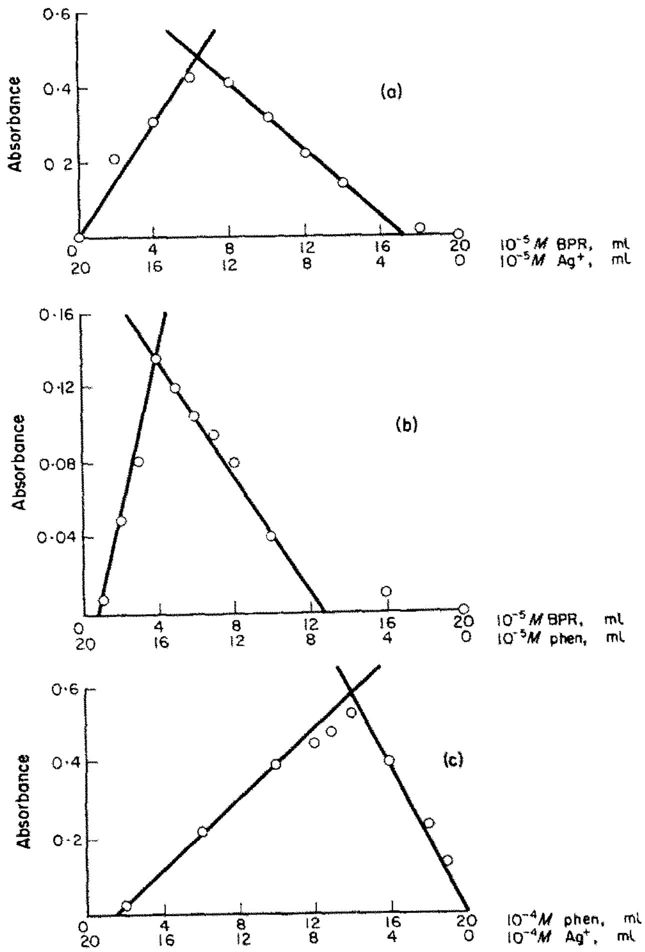

FIG. 2—Job plots:

(a) Bromopyrogallol red–silver (in excess 1,10-phenanthroline): Varying ratios of 10^{-5} M bromopyrogallol red and silver nitrate plus 1 ml of 20% ammonium acetate and 1 ml of $10^{-3}M$ 1,10-phenanthroline diluted to 50 ml with distilled water. Absorbance measured at 635 mμ in 4-cm cuvettes.

(b) Bromopyrogallol red-1,10-phenanthroline (in excess silver nitrate): Varying ratios of 10^{-5} M bromopyrogallol red and 1,10-phenanthroline plus 1 ml of 20% ammonium acetate and 5 ml of $10^{-4}M$ silver nitrate diluted to 50 ml with distilled water. Absorbance measured at 635 mμ in 4-cm cuvettes.

(c) 1,10-Phenanthroline–silver (in excess bromopyrogallol red): Varying ratios of 10^{-4} M 1,10-phenanthroline and silver nitrate plus 1 ml of 20% ammonium acetate and 20 ml of $10^{-4}M$ bromopyrogallol red diluted to 50 ml with distilled water. Absorbance measured at 635 mμ in 1-cm cuvettes. (Bromopyrogallol red solution prepared in 1% ammonium acetate.)

taking up co-ordination sites on the chelated silver ions. In the first instance the mechanism of colour production was likely only to involve ion-association or surface adsorption of the BPR on a colloidal [phen-Ag-phen]$^+$ salt, whilst in the second instance chelate formation with concomitant release of H^+ would be involved. Accordingly, this study was made to try and resolve which mechanism was the more probable.

Three types of curve were constructed:

1. titration of BPR with alkali,
2. titration of BPR + Ag^+ with alkali,
3. titration of BPR + 1,10-phenanthroline + Ag^+ with alkali.

It is obvious from the shape of the titration curves obtained that the silver:1,10-phenanthroline:bromopyrogallol red reaction is in no way related to the bromopyrogallol red-silver reaction. The half-wave pH for the titration of bromopyrogallol red with standard alkali occurs at *ca.* pH 8 and at 2 moles of base to 1 mole of reagent, *i.e.*, liberation of 2 hydrogen ions (*cf.* Fig. 3). This is, in fact, very similar to the titration of bromopyrogallol red plus silver nitrate plus 1,10-phenanthroline with standard alkali (*cf.* Fig. 4). However, the titrations of bromopyrogallol red and silver (*cf.* Fig. 5) give, not only more than one inflection, but also a considerably lower half-wave pH for the first inflection (*ca.* pH 5·0–5·5). Consequently, only in this latter instance is direct chelate formation indicated. Because the liberation of 2 hydrogen ions in the former titrations corresponds to the ionisation of the sulphonic acid and 1 hydroxyl group of bromopyrogallol red, the resulting silver/1,10-phenanthroline/bromopyrogallol red product is likely to be an ion-association system $[(\text{phen-Ag-phen})^+]_2\ \text{BPR}^{2-}$.

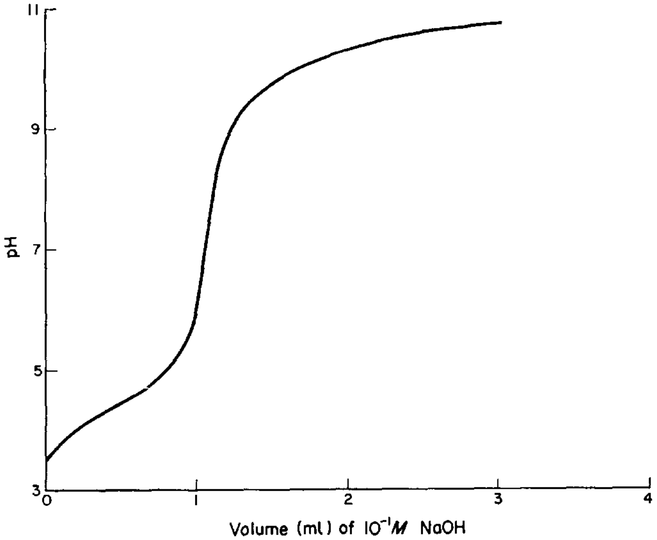

FIG. 3—Potentiometric titration of bromopyrogallol red (50 ml of $10^{-3}M$ reagent *vs.* $10^{-1}M$ sodium hydroxide).

DISCUSSION

The colour reaction described, using EDTA as masking agent, is reliably and virtually completely free from all cationic interference. In addition, with a molar, extinction coefficient of 51,000 (*cf.* Table II), it is the most sensitive of all colorimetric silver reagents known to us.

The system 1,10-phenanthroline/bromopyrogallol red has some useful indicator properties, *e.g.*, in silver cyanide titrations, *etc.*, although this has yet to be put on a more firm basis. The use of bromopyrogallol red as an adsorption indicator has been recently described.[3]

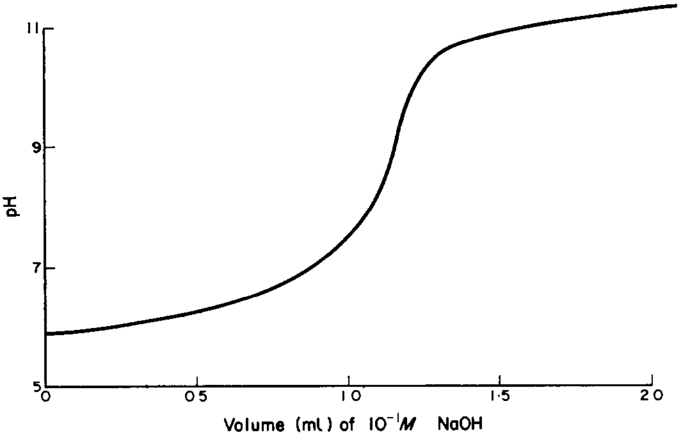

FIG. 4—Potentiometric titration of bromopyrogallol red/1,10-phenanthroline/silver (ratio of reagents was 1:10:2 with 50 ml of $10^{-3}M$ bromopyrogallol red).

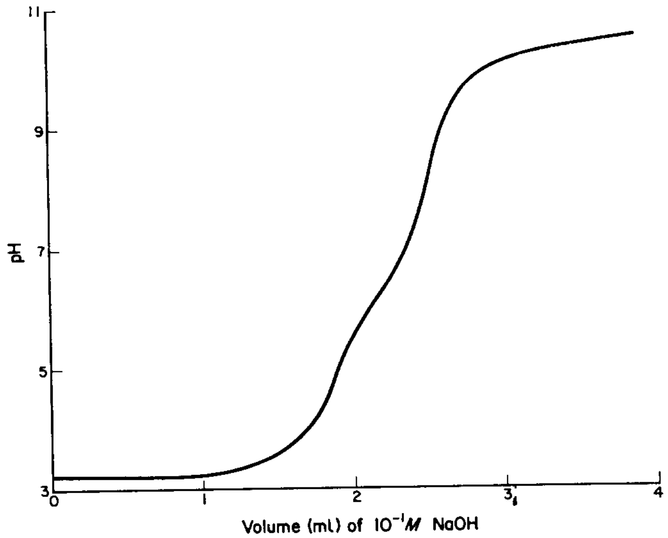

FIG. 5—Potentiometric titration of bromopyrogallol red/silver (ratio of reagents was 1:2 with 50 ml of $10^{-3}M$ bromopyrogallol red).

TABLE II

Method	Molar extinction coefficient (ϵ)
Phen/BPR	51,000 (635 mμ)
Dithizone	30,500 (462–465 mμ)
p-Dimethylamino-benzylidenerhodanine	23,200 (595 mμ)
$\alpha\beta\gamma\delta$-Tetraphenylporphine	39,000 (425 mμ)

The evidence obtained so far indicates either that we are dealing with an ion-association system between BPR^{2-} and [phen-Ag-phen]$^+$ or that the dyestuff BPR is physically adsorbed on the surface of a colloidal bis-1,10-phenanthrolinium-silver(I) salt. On currently accepted theories which explain the mechanism of the indicator action of adsorption indicators, it is readily possible thus to explain the formation of the blue colour-body in these experiments. Also, such an explanation is consistent with the destruction of the colour system by fairly large excesses of indifferent electrolytes, such as potassium nitrate. On the other hand, the stoichiometric ratios observed in the reaction between BPR^{2-} and [phen-Ag-phen]$^+$ tend to support the hypothesis that a stoichiometric compound is formed between the two rather than simple adsorption. It is also possible to explain the breakdown of the colour body by potassium nitrate, for example, on the basis of competition between the anions, NO_3^- and BPR^{2-}, in setting up the ion-association complex. It remains to be explained, however, why the blue colour of the ion-association system is different from that of the yellow-white $Ag(phen)_2^+$ ion and the red BPR^{2-} ion. A possible explanation is that a charge-transfer occurs between the oxidisable silver(I) ion in the [phen-Ag-phen]$^+$ part of the system and the reducible quinoid group in the associated BPR^{2-} molecule. Certainly, the intensity and sharpness of the adsorption band (c) at 630 mμ (Fig. 1) is consistent with this hypothesis.

This argument also raises the interesting speculation that the colour action of many adsorption indicator systems may be explained similarly on the basis of charge transfer mechanisms rather than on the currently accepted adsorption/electronic distortion theory. These matters are being further investigated and will be reported at a later date.

We also propose to continue this investigation with the aim of replacing bromopyrogallol red with alternative dyestuffs, which may offer an increase in sensitivity and may also eliminate the use of masking agents. This may be realised with dyestuffs which do not contain complexing centres, but nevertheless undergo this type of reaction. Work on an extraction system based upon this reaction will be described in a subsequent paper.

EXPERIMENTAL

Preparation of Calibration Curve

Reagents

10^{-5} *M Silver nitrate.* Prepared by dilution of standard 0·1*M* silver nitrate solution.

10^{-3} *M 1,10-Phenanthroline.* 49·56 mg of analytical reagent grade 1,10-phenanthroline dissolved in and diluted to 250 ml with distilled water.

10^{-4} *M Bromopyrogallol red.* 13·96 mg of bromopyrogallol red plus 2·5 g of analytical reagent grade ammonium acetate dissolved in and diluted to 250 ml with distilled water. This solution should be discarded after 5 days.

20% *Ammonium acetate.* 20 g of analytical reagent grade ammonium acetate dissolved in and diluted to 100 ml with distilled water.

10^{-1} *M* EDTA. 3·7225 g of analytical reagent grade disodium salt dissolved in and diluted to 100 ml with distilled water.

Apparatus

Unicam SP 600 spectrophotometer with 4-cm cuvettes.

Procedure

Pipette 1–10 ml of the 10^{-5} *M* silver nitrate solution into 50-ml volumetric flasks containing 1 ml of 10^{-1} *M* EDTA solution, 1 ml of 10^{-3} *M* 1,10-phenanthroline solution, 1 ml of 20% ammonium acetate solution and 2 ml of 10^{-4} *M* bromopyrogallol red solution. Dilute the solutions to 50 ml with distilled water and measure the absorbance immediately, or within 30 min, in 4-cm cuvettes at 635 mμ against a blank, containing all of the reagents except silver.

A plot of absorbance against concentration of silver gives a straight line graph over the range 1–10 μg of silver:

$$1 \text{ ml of } 10^{-5}\, M \text{ AgNO}_3 \equiv 1{\cdot}0787\ \mu\text{g of Ag.}$$

Determinations

Take an aliquot of the silver test solution (1–10 μg of silver in not more than 30–40 ml of solution) through the above procedure. If iron(II) is present, add sufficient 1,10-phenanthroline to complex it completely and to react with the silver and bromopyrogallol red. When uranium(VI), thorium(IV) or niobium(V) is present, add sufficient fluoride (for the first two) or hydrogen peroxide (for the last) to complex it before developing the colour with silver. The silver content is obtained from the calibration curve.

Acknowledgment—We wish to express our thanks to Professor R. Belcher for his interest in and support of this work.

Zusammenfassung—Brompyrogallolrot (BPR) und 1,10-Phenanthrolin (phen) können als Reagentien zur spektralphotometrischen Bestimmung von Silberionen in waßriger Lösung von 0,02–0,20 ppm verwendet werden. Photometrisch und potentiometrisch wurde gezeigt, daß der blaue ternäre Komplex, der bei 635 mμ absorbiert, höchstwahrscheinlich ein Ionenassoziat $[(\text{phen-Ag-phen}^+]_2\ \text{BPR}^{2-}$ ist. Wenn man mit EDTA, Fluorid und Wasserstoffperoxyd maskiert, ist die Farbreaktion auch bei hundertfachem Übershuß von Fremdionen über Silber (24 Kationen und 11 Anionen wurden untersucht) störungsfrei. Nur Gold(III), Cyanid und Thiosulfat störten. Mit einem molaren Extinktionskoeffizienten von 51,000 ist die Farbreaktion wahrscheinlich die empfindlichste aller bekannten kolorimetrischen Silberbestimmungsmethoden.

Résumé—On peut utiliser le rouge de bromopyrogallol (BPR) et la 1,10-phénanthroline (phen) comme système réactif pour le dosage spectrophotométrique des ions argent en solution aqueuse, aux concentrations comprises entre 0,02 et 0,20 p.p.m. Les méthodes photométrique et potentiométrique montrent que le complexe ternaire coloré en bleu, qui absorbe à 635 mμ, est très probablement une association ionique $[(\text{phen-Ag-phen})^+]_2\ \text{BPR}^{2-}$. A des concentrations en ionsgramme 100 fois supérieures à celle de l'argent, 24 cations et 11 anions étudiés n'interfèrent pas dans la réactions colorée, l'EDTA, le fluorure et l'eau oxygénée étant utilisés comme agents dissimulants. On a trouvé que seuls l'or(III), le cyanure et l'hyposulfite interfèrent. Avec un coefficient d'absorption moléculaire de 51,000 cette réaction colorée est probablement la plus sensible de toutes les méthodes colorimétriques connues pour l'argent.

PRELIMINARY COMMUNICATION

Applications of precipitate membranes in analytical chemistry

(*Received* 18 *August* 1964. *Accepted* 18 *August* 1964)

RECENTLY, several analytical procedures have been introduced which are based in some manner on the solubility of precipitates, on exchange reactions taking place with precipitates or on some other properties of precipitates. These include, for example, indirect colorimetric determination of anions with the aid of sparingly soluble metal chloranilates,[1] radiometric titrations using solid precipitate indicators,[2] and procedures involving radioactive precipitate exchange.[3]

However, all of these processes have the common drawback of requiring the separation of a precipitate from solid-liquid (aqueous) phases after the relevant reaction has reached equilibrium. In general, separation is carried out by filtration or centrifuging and the time required for the determination is thereby appreciably lengthened. Furthermore, in attempting to evolve automated techniques, difficulties are encountered when filtration or centrifuging is necessary.

These drawbacks can be eliminated when, instead of transferring the precipitate (which serves as the basis of the conventional method) in the form of a suspension to the solution containing the component to be determined, a precipitate fixed to a carrier is utilised. According to our experiments, chromatographic filter paper lends itself excellently to use as a carrier in that the precipitate is formed between the fibres of the paper. A precipitate membrane prepared in this way is fixed to a suitable framework, then immersed in the solution containing the component to be determined. Membranes of this type can be readily stored in the dry state, and when immersed in a solution, they behave exactly as freshly prepared precipitates. Suitably prepared membranes can be used for a great number of determinations, provided they are rinsed with water after each separate determination. Of the filter papers Whatman 1, Whatman 3, Whatman 4, Schleicher & Schüll 2043 b and Nagel 62 so far tested, Whatman 1 and Schleicher & Schüll 2043 b have proved best suited for the preparation of membranes. On applying such membranes, filtration or separation by centrifuging of the solid-liquid phases becomes superfluous.

In practice, the method is carried out as follows. The precipitate membrane, attached to a suitable framework, is immersed in a solution containing a component to be determined, then the solution is stirred or circulated until the equilibrium of the analytical reaction in question is set up. Subsequently, the extinction or radioactivity of the pure solution is measured.

In our preliminary experiments, the following determinations have been carried out with the aid of precipitate membranes:-

1. Indirect colorimetric determination of sulphate ions with the aid of a precipitate membrane of barium chloranilate.
2. Radiometric titration of calcium ions with EDTA solution as titrant, using a precipitate membrane of $^{110}AgIO_3$.
3. Determination of cyanide ions by radioactive precipitate exchange, using a precipitate membrane of $^{203}Hg(IO_3)_2$.

In all three cases, the results were in good agreement with those obtained by the more conventional techniques. Work is in progress to extend the fields of application of precipitate membranes and to design automatic analysing devices based on the use of precipitate membranes.

Summary—The need for separation of a precipitate in the indirect colorimetric determination of anions with the aid of sparingly soluble metal chloranilates, in radiometric titrations using solid precipitate indicators and in procedures involving radioactive precipitate exchange, has been eliminated by the use of precipitate membranes.

Zusammenfassung—Bei der indirekten kolorimetrischen Bestimmung von Anionen mittels schwerlöslichen Metall-Chloranilaten, bei radiometrischen Titrationen mit festen gefällten Indikatoren und bei Verfahren mit radioaktivem Austausch in Fällungen wurde die Notwendigkeit, den Niederschlag abzutrennen, durch Gebrauch gefällter Membranen beseitigt.

Résumé—Par l'emploi de membranes de précipité, on a éliminé la nécessité de séparer un précipité lors du dosage colorimétrique indirect d'anions à l'aide de chloranilates métalliques faiblement solubles, lors de dosages radiométriques utilisant des indicateurs à l'état de précipité solide, et lors d'emploi de techniques comprenant un échange radioactif dans un précipité.

SHORT COMMUNICATIONS

Contributions to the basic problems of complexometry—XVI:* Determination of thorium and scandium in the presence of each other

(*Received* 7 *January* 1964. *Accepted* 27 *July* 1964)

Recently we have described the determination of zirconium, thorium and titanium in the presence of each other[1] and the successive determination of thorium, rare earths and some other elements.[2] However, the determination of thorium and scandium in their mixtures has not yet been solved. With EDTA these elements form complexes of the same strength ($pK_{ThY} = 23{\cdot}2$, $pK_{ScY} = 23{\cdot}1$) and their sum can be readily determined. *e.g.*, by direct titration with EDTA at pH 2·5-4 using Xylenol Orange as indicator. Obviously, their separate determination in the same solution is impossible unless a highly selective masking agent for one or the other element can be found and this is unlikely.

During some preliminary experiments we observed an interesting phenomenon in the behaviour of the Th- and Sc-EDTA complexes. Both complexes are quite stable in acidic media (pH 2–4). In solutions of pH higher than 5, however, the Th-EDTA complex again reacts with Xylenol Orange and forms a red-violet colour; the Sc-EDTA complex remains unchanged under these conditions. We deduced that, under given conditions of acidity and in the presence of another complexing agent X, it would be possible to shift the following equilibrium completely to the right

$$\mathrm{ThY} + \mathrm{X} \rightleftharpoons \mathrm{ThX} + \mathrm{Y} \qquad (1)$$

and liberate all of the EDTA bound to the thorium. Our previous experience[2] with the reaction between thorium and TTHA (triethylenetetraminehexa-acetic acid) and DTPA (diethylenetriaminepenta-acetic acid) is in accordance with these findings. The Th-TTHA and Th-DTPA complexes do not undergo a colour reaction with Xylenol Orange at pH 2-6. The use of DTPA cannot be considered for the displacement reaction (1) because, like EDTA, it forms 1:1 complexes and the equilibrium cannot be followed complexometrically by titration of the free X and Y. The situation is quite different if one uses TTHA, which forms 2:1 complexes with bivalent cations in a slightly acidic medium and has already been proposed with advantage as a complexometric reagent.[3] Reaction (1) can then be followed very simply by titration with zinc solution at pH 5-5·5 using Xylenol Orange as indicator. Determination of the liberated EDTA and of the excess TTHA occurs smoothly according to the reactions:

$$\mathrm{EDTA} + \mathrm{Zn} \rightarrow \mathrm{ZnEDTA} \qquad (2)$$

$$\mathrm{TTHA} + 2\mathrm{Zn} \rightarrow \mathrm{Zn_2TTHA} \qquad (3)$$

Suppose that an equivalent amount of TTHA is added to a solution of the Th-EDTA complex. The equilibrium is given by

$$\text{Th-EDTA} + \mathrm{TTHA} \rightarrow \text{Th-TTHA} + \mathrm{EDTA} \qquad (4)$$

If this reaction does not occur at all, the consumption of zinc corresponds to reaction (3); if it occurs quantitatively the consumption of zinc corresponds to reaction (2) and is halved. In the same way one should be able to test the following reaction of scandium

$$\text{Sc-EDTA} + \mathrm{TTHA} \rightarrow \text{Sc-TTHA} + \mathrm{EDTA} \qquad (5)$$

We have now shown experimentally that reaction (5) for scandium does not take place at all, and that reaction (4) for thorium proceeds quantitatively. This difference in behaviour of thorium and scandium enables their complexometric determination to be made in mixtures over a wide range of concentration ratios.

EXPERIMENTAL

Reagents

0·05*M EDTA solution.* Prepared by dissolution of 18·61 g of Chelaton (Lachema, Brno, Czechoslovakia) in 1 litre of redistilled water and standardisation by titration against lead nitrate using Xylenol Orange as indicator.

---

* Part XV; see *Talanta*, 1964, **11**, 1319.

0·05*M TTHA solution.* Prepared by dissolution of 24·723 g of the free acid (J. R. Geigy, Basel, Switzerland) in 100–200 ml of 1*M* sodium hydroxide, with warming, then diluting to 1 litre. This solution was also standardised complexometrically.

0·05*M Zinc nitrate solution.* Prepared by dissolution of 14·874 g of $Zn(NO_3)_2 \cdot 6H_2O$ in 1 litre of water.

0·05*M Thorium nitrate solution.* Prepared by dissolution of 27·656 g of $Th(NO_3)_4 \cdot 4H_2O$ in 70 ml of nitric acid (1 + 1) and dilution to 1 litre (1 ml of solution = 11·6025 mg of thorium).

0·05*M Scandium nitrate solution.* Prepared by dissolution of 3·45 g of Sc_2O_3 in 70 ml of nitric acid (1 + 1) and dilution to 1 litre (1 ml of solution = 2·248 mg of scandium).

Buffer solution (pH 3). Prepared by neutralisation of 2*M* monochloracetic acid with aqueous ammonia (1 + 1) under potentiometric control with a glass electrode.

Other reagents include: 1*M* nitric acid, solid urotropine, 0·5% Xylenol Orange.

Procedure

Determination of sum of thorium and scandium. Thorium is readily determined by the well known direct titration with 0·05*M* EDTA at pH 2·5–4 using Xylenol Orange as indicator.[4] Titration of scandium under these conditions gives a somewhat sluggish end-point at room temperature. Therefore, the combined titration of the two elements should be carried out in hot solution (50°). The colour change of the indicator from red-violet to lemon yellow is very sharp.

Determination of thorium. After the above titration with EDTA, add to the hot solution an excess of 0·05*M* TTHA and adjust the pH to 5–5·5 with solid urotropine. Stand for 5 min, stirring occasionally. During this time reaction (4) proceeds quantitatively (even if a large amount of thorium is present). Titrate the excess of TTHA and the liberated EDTA with zinc solution [reactions (2) and (3)].

Calculations

Second titration: 2(ml of 0·05*M* TTHA) − ml of 0·05*M* Zn = ml of 0·05*M* Th.

First titration: ml of 0·05*M* EDTA − ml of 0·05*M* Th = ml of 0·05*M* Sc.

DISCUSSION

Table I shows a number of results using the above procedure for different concentration ratios of thorium and scandium (100:1 and 1:4). The last ratio can hardly be raised. Because of the atomic weights of thorium and scandium the ratio 1:4 appears as 1:20 in the consumption of EDTA. The method can only be applied to pure solutions of thorium and scandium, but these can easily

Summary—The first titrimetric determination of thorium and scandium in the presence of each other is described. It is based on complexometric determination of their sum with EDTA at pH 2·5–3·5 using Xylenol Orange as indicator. After the addition of an excess of TTHA (triethylenetetraminehexa-acetic acid) and adjustment of the pH to 5–5·5, the following displacement reaction then takes place:

$$\text{Th-EDTA} + \text{TTHA} \rightarrow \text{Th-TTHA} + \text{EDTA}$$

while the Sc-EDTA complex remains unchanged. The liberated EDTA and excess of TTHA are determined by titration with a solution of zinc, which forms 1:1 and 2:1 complexes with EDTA and TTHA, respectively. From the consumption of zinc solution the amount of thorium is calculated.

Zusammenfassung—Die erste Methode zur volumetrischen Bestimmung von Thorium und Scandium wird beschrieben. Zuerst wird die Summe beider komplexometrisch mit EDTA und Xylenolorange bei pH 2,5–3,5 bestimmt. Nach Zugabe eines Überschusses TTHA (Triäthylenstetraminhexaessigsaure) und Einstellung auf pH 5,0–5,5 findet folgende Verdrängungsreaktion statt:

$$\text{Th-EDTA} + \text{TTHA} \rightarrow \text{Th-TTHA} + \text{EDTA}.$$

Der Scandium-EDTA-Komplex reagiert nicht mit TTHA. Die freigesetzte EDTA und der Überschuss von TTHA wird dann mit Zinklösung bestimmt; Zink bildet mit EDTA bzw. TTHA einen 1:1- bzw. 2:1-Komplex. Aus dem Zinkverbrauch wird die Thoriummenge berechnet.

Résumé—On décrit la première méthode de dosage volumétrique du thorium et du scandium. Elle est basée sur le dosage complexométrique de la somme au moyen d·EDTA et de Xylenol Orange á pH 2,5–3,5. Après addition d'un excès de TTHA (acide triéthylènetétramine-*N*, *N*, *N'*, *N"*, *N'''*, *N"*-hexacétique) et adjustment du pH à 5,0–5,5, la réaction de déplacement suivante se produit:

$$\text{Th-EDTA} + \text{TTHA} \rightarrow \text{Th-TTHA} + \text{EDTA}$$

(cependant que le complexe Sc-EDTA ne réagit pas avec TTHA). L'EDTA libéré et l'excès de TTHA sont alors déterminés par dosage avec une solution de zinc, qui forme avec l·EDTA et le TTHA des complexes 1:1 et 2:1 respectivement. On calcule la teneur en thorium à partir de la quantité de solution de zinc consommée.

The spectrophotometric determination of mercury in selenium

(*Received* 7 *May* 1964. *Accepted* 16 *August* 1964)

In the determination of high purity selenium, mercury is an important impurity. At the level of 1 ppm, the precision of the blanks becomes most important. This paper discusses a dithizone[1–5] procedure with low consistent blanks, in which the other impurities, normally found in selenium, are non-interfering.

EXPERIMENTAL

Reagents

Standard mercury solution: 1 μg per ml in 0·5*M* sulphuric acid. Dissolve 0·1354 g of $HgCl_2$ in exactly 1000 ml of 0·5*M* sulphuric acid. Dilute 5 ml of this solution to exactly 500 ml with 0·5*M* sulphuric acid.

Selenium: 99·999% purity.

Dithizone: Chloroform solution (8·0 mg per 500 ml of chloroform). Dissolve 0·160 g of dithizone in 200 ml of chloroform. Dilute a 10-ml aliquot to 500 ml with chloroform.

Buffering and complexing solution: Dissolve 100 g of sodium acetate, 10 g of EDTA and 20 g of sodium thiocyanate in 500 ml of water.

Sulphuric acid: 0·5*M*

Aqueous ammonia:

Procedure

Sample dissolution procedure: Dissolve the sample of selenium in a minimum amount of nitric acid (1 : 1).[6] Transfer the solution to a volumetric flask such that aliquots containing 0·5 g of selenium will be contained in 25 ml or less. If the volume is less than 25 ml, adjust it with water.

To the aliquot of sample, add 20 ml of buffering solution and immediately adjust the pH to 4·5–5·0 with sulphuric acid (0·5*M*). Transfer the solution to separatory funnel *A*, and add 10 ml of the dithizone-chloroform solution. Shake for 2 min and allow the layers to separate. Reserve the lower layer in a second separatory funnel, *B*. Add 10 ml of chloroform to the aqueous layer of separatory funnel *A*, and shake for 0·5 min. Drain the lower layer into separatory funnel *B*. Discard the aqueous layer. To separatory funnel *B* add 50–60 ml of water and 13–15 drops of aqueous ammonia. Extract for 30 sec, allow the layers to separate, and drain the chloroform layer into separatory funnel *A*. Discard the aqueous layer. To separatory funnel *A* add 50–60 ml of water and 13–15 drops of aqueous ammonia. Extract for 30 sec and reserve the chloroform layer in a dry 25-ml volumetric flask. Make to volume with absolute ethanol. Determine the absorbance in a Beckman DU Spectrophotometer in 5-cm cells at a wavelength of 495 mμ.

Radiochemical separation of cobalt by isotopic exchange

(*Received* 29 *May* 1964. *Accepted* 26 *August* 1964)

LANGER[1] in 1942 studied the exchange of silver ions between freshly precipitated silver chloride and an aqueous solution of silver nitrate, using radioactive silver tracer. He found that rapid isotopic exchange takes place between the silver atoms in the precipitate and the silver atoms in the solution. Sunderman and Meinke[2] made use of this fact to develop a rapid single-step, high-decontamination procedure for the separation of trace amounts of radioactive silver from solutions containing other activities. They also applied this technique for the separation of iodine-131[3] and for the preparation of β-ray sources of silver-III.[4]

By the use of isotopic exchange it is possible to devise simple separation procedures, and to shorten the existing radiochemical procedures, without sacrificing specificity or yield. In the present paper, the technique of isotopic exchange has been applied to develop a rapid procedure for the separation of trace amounts of cobalt from aqueous solutions.

If freshly precipitated cobalt(II) oxalate is agitated with an aqueous solution containing radioisotopes of cobalt, a high percentage of radioactive cobalt will, in a short time, exchange with the inactive cobalt in the precipitate. The necessary conditions of the exchange are that the concentration of inactive atoms in the precipitate should be much greater than that in the solution, and that the precipitate should have a low solubility.

CONCLUSIONS

This procedure seems suitable for the determination of mercury in the low ppm in selenium. There is no interference from the presence of up to 25 μg each of silver, lead, or copper.

LANGER[1] in 1942 studied the exchange of silver ions between freshly precipitated silver chloride and an aqueous solution of silver nitrate, using radioactive silver tracer. He found that rapid isotopic exchange takes place between the silver atoms in the precipitate and the silver atoms in the solution. Sunderman and Meinke[2] made use of this fact to develop a rapid single-step, high-decontamination procedure for the separation of trace amounts of radioactive silver from solutions containing other activities. They also applied this technique for the separation of iodine-131[3] and for the preparation of β-ray sources of silver-III.[4]

By the use of isotopic exchange it is possible to devise simple separation procedures, and to shorten the existing radiochemical procedures, without sacrificing specificity or yield. In the present paper, the technique of isotopic exchange has been applied to develop a rapid procedure for the separation of trace amounts of cobalt from aqueous solutions.

If freshly precipitated cobalt(II) oxalate is agitated with an aqueous solution containing radioisotopes of cobalt, a high percentage of radioactive cobalt will, in a short time, exchange with the inactive cobalt in the precipitate. The necessary conditions of the exchange are that the concentration of inactive atoms in the precipitate should be much greater than that in the solution, and that the precipitate should have a low solubility.

The separation technique involves a single isotopic exchange step, and can be represented by the following reaction:

$$CoC_2O_4 + Co^{*2+} \rightleftharpoons Co^{*}C_2O_4 + Co^{2+}$$

where the asterisk denotes the radio-isotope of cobalt.

EXPERIMENTAL

Apparatus

International Clinical Centrifuge

Centrifuge cones: Borosilicate glass, graduated, with cone point, 15 ml.

Planchets: 1-inch diameter cupped stainless steel.

Bottles: One-ounce, flint glass, square narrow mouth bottles with polyethylene screw caps were used for agitating the precipitate during separation. They were clamped in a *mechanical shaker* (Wrist-Action Shaker, Burrell Corp., Pittsburgh, Pa., U.S.A.), to which an extension arm of 9 inches was connected to give additional radial action.

Counters: The γ-ray measurements were made with a Baird-Atomic Model 810B Scintillation well-counter. The β-radioactivity was measured with a Tracerlab Geiger tube TGC-1.

Reagents

Cobalt chloride: May and Baker, analytical-reagent grade.

Oxalic acid: Baker analysed reagent.

Potassium chloride: Baker analysed reagent.

Sodium nitrate: Baker analysed reagent.

All other non-radioactive reagents used in this work were of C.P. or analysed-reagent grade.

All radio-isotopes used as tracers were obtained from The Radiochemical Centre, Amersham, England.

Preparation of cobalt(II) oxalate

Add an excess of 1% oxalic acid solution to a 1% solution of cobalt chloride. Digest the precipitate for 30 min at room temperature, with occasional stirring. Filter, and wash thoroughly with deionised water. Wash with acetone, and dry the precipitate in an oven at 90° for about 30 min.

Isotopic-exchange procedure

Place in a bottle 10 ml of 0·5*M* aqueous oxalic acid solution. Add cobalt-60 tracer (10^4–10^5 cpm), and agitate well to ensure thorough mixing. For contamination studies, add radioactive tracers (10^5–10^6 cpm) of the contaminating ions together with 1 μg of cobalt. Remove a 500-μl aliquot for counting. Add 200 mg of freshly prepared cobalt(II) oxalate precipitate, and shake mechanically for 3 min. Transfer the precipitate to a centrifuge cone. Centrifuge at top speed for a few sec, and remove the supernate. Wash the precipitate thoroughly twice with 1% oxalic acid solution and then with acetone. Count in the scintillation well-counter to determine the chemical yield. The total time for separation is about 6 min.

DISCUSSION AND RESULTS

To investigate the isotopic-exchange behaviour of cobalt, a number of insoluble compounds, *e.g.*, cobalt(II) sulphide, cobalt(II) ammonium phosphate, cobalt(II) oxalate, were agitated in different exchange media containing radioactive cobalt tracer. Yields of 21%, 98% and 85% were obtained for cobalt(II) sulphide, cobalt(II) ammonium phosphate and cobalt(II) oxalate, respectively, when 200 mg of their precipitates were agitated for 5 min in 0·5*M* sodium nitrate solution. Although cobalt(II) ammonium phosphate showed a high exchange, it did not exhibit good selectivity, probably because of the instability of the precipitate. Therefore cobalt(II) oxalate was used in the standard precedure.

To develop an optimum separation procedure, several experiments were performed, in which the agitation time, the amount of the precipitate, and the exchange medium were varied.

Of the various exchange media tried, 0·5*M* oxalic acid, 0·5*M* sodium nitrate, 0·5*M* potassium chloride and 0·5*M* ammonium chloride appeared to be favourable for the exchange, and gave yields of 83·6%, 81·3%, 80·5% and 80·2%, respectively, when 200 mg of the precipitate were agitated for 3 min.

The exchange yield is also dependent on the duration of agitation. A regular increase in exchange yield was observed during a 3-min agitation; after that, the rate of increase was considerably slowed down. Therefore a 3-min agitation was used in the separation. Using 200 mg of the precipitate in 0·5*M* oxalic acid solution, yields of 68·7%, 76·2%, 83·6%, 86·1% and 89·3% were obtained for 1-min, 2-min, 3-min, 5-min and 10-min agitations, respectively.

The recovery of cobalt tracer was studied by using different amounts of cobalt(II) oxalate precipitate. With increase in the amount of the precipitate from 50 mg to 100 mg, 200 mg and 300 mg, the yields were 34·1%, 65%, 83·6% and 85·2%, respectively. Therefore 200 mg of precipitate was chosen as the optimum quantity. A considerable decrease in the yield was observed when the precipitate was kept overnight and then used for the exchange. The best results are obtained with a freshly prepared precipitate but the mode of preparing the precipitate has no effect on the exchange properties.

The optimum separation procedure has been described above; this requires about 6 min for the entire separation, and gives an average yield of 83·6%.

In the interference studies it was observed that the presence of mineral acids or of aqueous ammonia significantly decreases the yield, because they dissolve the precipitate. It is, therefore, necessary that these reagents should be neutralised before the exchange step. Sodium hydroxide and potassium hydroxide, in concentrations below 0·1*M*, do not affect the exchange.

Decontamination

The extent of the separation of cobalt that can be obtained with this procedure was checked by making decontamination studies with tracers of 11 representative elements. (Unfortunately, tracers of Fe, Mn, Ni, and Zr-Nb were not available for this study.) The daughters of the tracers were tested with the parents, because no attempt was made to separate daughters from parents. The results are shown in Table I. Silver and mercury show high contamination, probably because of adsorption of their ions on the cobalt(II) oxalate precipitate. The contaminations from silver, mercury and thallium were reduced considerably when 1 mg of carrier for each of these elements was added to each of the exchange medium; this probably acts as a hold-back carrier, and reduces the adsorption of these ions on the precipitate. Similarly, contamination of other elements may be further reduced by adding mg-amounts of the corresponding carriers. Many elements, however, form insoluble oxalates; precipitation may, therefore, occur when the carrier is added to the exchange medium. In such cases, 0·5*M* sodium nitrate may be used in place of 0·5*M* oxalic acid as the exchange medium.

TABLE I.—SEPARATION OF COBALT AND CONTAMINANTS (ISOTOPIC EXCHANGE PROCEDURE)[a]

Tracer	Weight, μg[b]	Separated, %
Ra-DEF	0·9	0·09

^{204}Tl	1000	0·66
^{203}Hg	11·4	13·2
^{203}Hg	1000	4·1
^{110m}Ag	0·3	20·3
^{110m}Ag	1000	4·9
^{60}Co	0·1	83·6 ± 2·3

[a] Average of at least duplicate runs. Cobalt is average of 7 runs. "Error" is standard deviation.

[b] Weight of inactive element present before separation.

[c] Iodine in its lowest reduced state.

The rapidity of the method makes it suitable for the separation of short-lived isotopes of cobalt. It may be applied to the activation analysis of cobalt, using the short-lived cobalt-60m. The simplicity of the operation involved in this procedure allows it to be adapted to the remote handling of high-radiation levels.

Summary—The radiochemical separation of cobalt by an isotopic exchange technique has been evaluated for an aqueous $0.5M$ oxalic acid system. The optimised procedure requires 6 min for the entire separation and gives cobalt yields of more than 83%. The specificity of this method was checked with the available tracers of 11 different elements. Mineral acids and aqueous ammonia interfere in the separation. This procedure may find useful applications in the separation of short-lived isotopes of cobalt and is adaptable to remote handling.

Zusammenfassung—Die radiochemische Abtrennung von Kobalt durch Isotopenaustausch wurde für ein wäßriges System mit 0,5 m Oxalsäure untersucht. Unter optimalen Bedingungen dauert die ganze Abtrennung 6 Minuten und gibt Kobaltausbeuten über 83%. Die Spezifität der Methode wurde mit 11 verschiedenen Elementen als Trägern geprüft. Mineralsäuren und Ammoniumhydroxyd stören bei der Trennung. Die Arbeitsvorschrift kann bei der Abtrennung kurzlebiger Kobaltisotope nützliche Anwendungen finden und kann auf Fernbedienung eingerichtet werden.

Résumé—On a étudié la séparation radiochimique du cobalt par une technique d'échange isotopique, dans le cas d'un système aqueux $0{,}5M$ en acide oxalique. La technique mise au point nécessite 6 min pour la séparation totale, et donne des rendements en cobalt supérieurs à 83%. La spécificité de cette méthode a été vérifiée avec 11 éléments traceurs différents. Les acides minéraux et l'ammoniaque interfèrent dans la séparation. Cette technique peut trouver des applications utiles dans la séparation des isotopes du cobalt à courte durée de vie, et elle est adaptable aux manipulations à distance.

Observations on the atomic absorption spectroscopy of lead in aqueous solution, in organic extracts and in gasoline

(*Received* 27 *July* 1964. *Accepted* 10 *August* 1964)

In theory, atomic absorption spectroscopy affords a simple and rapid method for the analysis of lead in commercially available products such as gasoline.[1] However, our efforts to carry out this determination, using an air-propane flame, produced unaccountable results in this instance. In general, the lead standards (as nitrate and 8-hydroxyquinolate) prepared by us and diluted with the same solvent as tetra-ethyl lead standards were in good agreement with each other, but gave low results for tetra-ethyl lead in gasoline. This observation led us to undertake a detailed investigation of this phenomenon. The effects of extraneous ions, extraction procedures and solvents on the determination of lead by atomic absorption spectroscopy were also investigated.

EXPERIMENTAL

The equipment used in this work was the Hilger and Watts "Uvispek" and atomic absorption attachments.

A calibration curve for lead in aqueous solution in the range 20–145 ppm (absorbance: 0·053–0·372) was prepared using the following instrument conditions: slit width: 0·1 mm; wavelength: 2833 Å; lamp current: *ca.* 18 mA; air pressure: 25 lb/in.^{2}; propane pressure: just insufficient to give a luminous flame. The effective dimensions of the burner head (perforated plate) were 10 cm long by 1·5 cm wide.

The following aspects of the atomic absorption spectroscopy of lead were then examined.

Lead in aqueous solution

Extraneous ions

Cations. Of those cations investigated at *ca.* a 1000-fold mole excess over lead, *viz.*, Ag^+, Al^{3+}, Ba^{2+}, Be^{2+}, Bi^{3+}, Cd^{2+}, Ce^{3+}, Co^{2+}, Cr^{3+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, K^+, La^{3+}, Li^+, Mg^{2+}, Mn^{2+}, Na^+, Ni^{2+}, Sn^{2+}, Sr^{2+}, Tl^+, Th^{4+}, Zn^{2+} and Zr^{4+}, only Al^{3+}, Be^{2+}, Th^{4+} and Zr^{4+} interfered by giving a reduction in absorbance. Be^{2+} interfered because of precipitate formation. The interference of Al^{3+}, Th^{4+} and Zr^{4+} is probably caused by the formation of refractory compounds in the flame with mechanical sequestration of the lead in the solid matrices.

Anions. A similar excess to that for cations was also investigated for the following anions: $B_4O_7^{2-}$, Br^-, Cl^-, ClO_3^-, ClO_4^-, CN^-, SCN^-, CO_3^{2-}, CrO_4^{2-}, $Cr_2O_7^{2-}$, F^-, $Fe(CN)_6^{3-}$, $Fe(CN)_6^{4-}$, I^-, IO_3^-, MoO_4^{2-}, NO_2^-, NO_3^-, PO_4^{3-}, S^{2-}, SO_4^{2-}, $S_2O_3^{2-}$, $S_2O_8^{2-}$, VO_3^- and WO_4^{2-}. Those anions which produced precipitates with lead interfered, but the addition of EDTA eliminated this and the subsequent interference. Only PO_4^{3-} and $S_2O_8^{2-}$ continued to interfere by slightly reducing the absorbance.

Organic anions. Of those anions examined at *ca.* a 1000-fold mole excess over lead, *viz.*, acetate, citrate, formate, oxalate, phthalate and tartrate, only formate and phthalate interfered because of the production of precipitates and a subsequent lowering of the absorbance.

Organic solvents (water-miscible). Solutions were examined containing 100 ppm of lead and 10% with respect to the following solvents: acetone, acetic acid, dioxan, ethanol, ethylene glycol, glycerol, methanol, methyl ethyl ketone and isopropyl alcohol. All increased the absorbance because of an increased efficiency of vaporisation, except for ethylene glycol and glycerol which decreased the absorbances because of an increase in the viscosity of the solutions (*cf.* Table I).

Determination of Lead in Organic Media Following Solvent Extraction

Extraction experiments were carried out with the following systems:

Lead 8-hydroxyquinolate in chloroform and isobutyl methyl ketone. Chloroform as a solvent was soon discarded because noxious gases were produced during the combustion and, furthermore, the vaporisation chamber quickly became clogged with solid 8-hydroxyquinoline because of rapid evaporation of chloroform. A far more suitable solvent for atomic absorption work was found to be isobutyl methyl ketone. Lead could be determined over the range 2 to 20 ppm (in the organic phase) by extracting with a 1% solution of 8-hydroxyquinoline in isobutyl methyl ketone (absorbance: 0·014–0·137) over the range pH 7–11. This represents *ca.* a 3-fold increase in sensitivity relative to aqueous solution.

TABLE I.—EFFECT OF 10% CONCENTRATIONS OF WATER-MISCIBLE ORGANIC SOLVENTS ON THE ABSORBANCE OF A 100-ppm SOLUTION OF LEAD

Solvent	Absorbance (2833 Å)
—	0·238
Isopropyl alcohol	0·366
Methyl ethyl ketone	0·352
Acetone	0·328
Acetic acid	0·307
Dioxan	0·294
Ethanol	0·291
Methanol	0·291
Ethylene glycol	0·212
Glycerol	0·190

Lead diethyldithiocarbamate in ethyl acetate. Lead was extracted at pH 7 into ethyl acetate as its diethyldithiocarbamate complex using 1 ml of a 2% aqueous solution of the disodium salt of the reagent. The calibration curve obtained was a straight line, passing through the origin, over the range 1–10 ppm of lead (in the organic phase). This gave *ca.* a 3-fold increase in sensitivity over the extraction system using 8-hydroxyquinoline as reagent in isobutyl methyl ketone. The sensitivities of these two methods are compared with that for aqueous solution in Fig. 1.

These extraction systems were subsequently employed to separate and concentrate lead for its determination in some commercially available products, *e.g.*, analytical reagent grade chemicals, chocolate samples and canned beer, by atomic absorption spectroscopy.

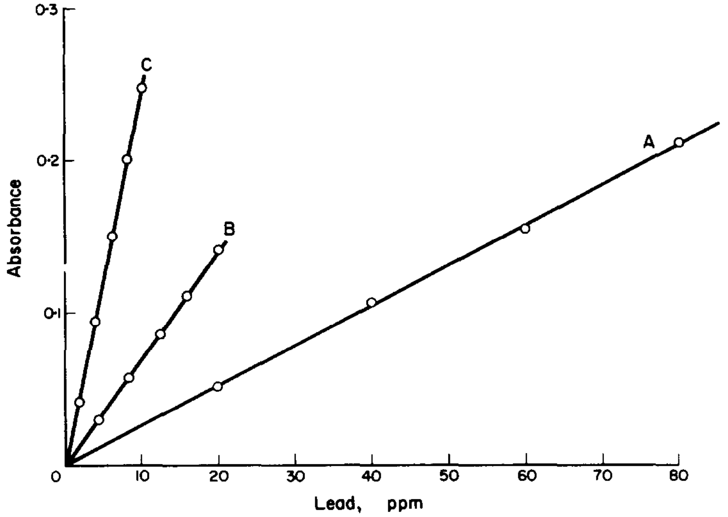

FIG. 1.—Comparative sensitivities of extraction systems at 2833 Å (calibration curves):
(A) lead nitrate in water;
(B) lead 8-hydroxyquinolate in isobutyl methyl ketone;
(C) lead diethyldithiocarbamate in ethyl acetate.

Determination of Lead in Gasoline

Following the success obtained in determining lead in non-aqueous extracts using reagents such as 8-hydroxyquinoline and disodium diethyldithiocarbamate, little difficulty was anticipated in dealing with the determination of lead as tetra-ethyl lead in gasoline. However, this did not prove to be the case.

The first difficulty encountered was the choice of solvent required to dilute the gasoline (iso-octane) samples. Several of these were examined, *e.g.*, ethanol, methyl ethyl ketone, isopropyl alcohol, isobutyl methyl ketone, hexane, iso-octane, but mostly they were either too volatile (hexane and iso-octane), or slowly increasing readings were obtained upon spraying the tetra-ethyl lead samples (tetra-ethyl lead was very difficult to wash out from the burner head with many solvents). The best solvent appeared to be methyl ethyl ketone.

Calibration curves were prepared subsequently from two standard substances, lead nitrate and lead 8-hydroxyquinolate dissolved in methyl ethyl ketone. In each instance 5·18–25·9 ppm of lead gave absorbances of 0·092–0·455. Tetra-ethyl lead diluted with the same solvent gave a straight line calibration curve, but with a 3-fold decrease in absorbance for the same lead content (11·2–67·7 ppm of lead gave absorbances of 0·067–0·402).

A similar series of results was obtained using ethyl acetate as solvent. Standard additions of lead as its nitrate were also made, but the same conclusions were reached, *i.e.*, disagreement between lead nitrate and lead 8-hydroxyquinolate on the one hand and tetra-ethyl lead on the other.

Subsequent experiments revealed that the position of measurement in the flame was a vital factor. When the absorbance measurements were made at progressively higher positions in the flame relative to its base, the absorbance from lead nitrate or 8-hydroxyquinolate in methyl ethyl ketone slowly increased. However, under the same conditions, the absorbance from tetra-ethyl lead in methyl ethyl ketone decreased significantly (Table II).

The lead contents of the lead nitrate and tetra-ethyl lead solutions used in this experiment were the same, *i.e.*, 21 ppm.

Similar results were obtained using other solvents, *e.g.*, isopropyl alcohol.

TABLE II.—EFFECT OF POSITION OF ABSORBANCE PATH IN FLAME IN RELATION TO ABSORBANCE BY LEAD NITRATE AND TETRA-ETHYL LEAD(TEL)
(Pb ≡ 21 ppm)

Position of absorption path in flame	Absorbance (2833 Å) in methyl ethyl ketone	
	$Pb(NO_3)_2$	$(C_2H_5)_4Pb$
Top [most suitable for $Pb(NO_3)_2$ and $Pb(C_9H_6ON)_2$]	0·350	0·130
Middle	0·326	0·156
Base (most suitable for TEL)	0·289	0·203

CONCLUSIONS

The determination of tetra-ethyl lead in gasoline by atomic absorption spectroscopy must be treated with caution. Satisfactory results will only be obtained if the standard solutions are prepared from tetra-ethyl lead. Our experiments on the position of the absorption path in the air-propane flame used in these experiments suggest that this is caused by a different "burn-off" rate or easier atomisation of tetra-ethyl lead compared with lead nitrate or 8-hydroxyquinolate. Consequently, the population of ground state atoms is highest at the base of the flame when tetra-ethyl lead is involved and measurements are best made at this point. The maximum population of ground state atoms of lead is obtained higher up in the flame when less readily atomised compounds of lead are present. It is probable that for the majority of lead compounds the upper regions of an air-propane flame may be preferable for absorption measurements.

In a previously reported method for the determination of lead in gasoline it may be noted that Robinson[1] has used tetra-ethyl lead rather than more conventional lead standards. He used an oxy-hydrogen flame and did not comment on the position of the absorbance path in the flame.

Obviously, there is no reason why this phenomenon should only apply to this particular compound. The so-called "organic solvent" effect[2] may be caused not only by an increase in the throughput of cation-solution vapour,[3] but also by a conversion of the particular cation into a more easily atomised species.

Summary—The effects of extraneous ions, solvents and flame height on the determination of lead by atomic absorption spectroscopy at 2833 Å have been examined. In order to obtain satisfactory results for lead in gasoline, the standard solutions used in the preparation of the calibration curve must also be prepared from tetra-ethyl lead and the absorbance should be measured near the base of the air-propane flame. There are differences in atomisation efficiency of tetra-ethyl lead compared with lead nitrate or lead 8-hydroxyquinolate dissolved in the same solvent.

Zusammenfassung—Der Einfluß von Fremdionen, Lösungsmitteln und der Flammenhöhe auf die Bleibestimmung durch atomare Absorptionsspektroskopie bei 2833 Å wurde untersucht. Um zufriedenstellende Bleiwerte in Benzin zu erhalten, müssen die Standardlösungen zur Aufstellung der Eichkurve ebenfalls aus Tetraäthylblei hergestellt und die Extinktion nahe bei der Basis der Luft-Propan-Flamme gemessen werden. Es bestehen Unterschiede in der Ausbeute an Bleiatomen zwischen Tetraäthylblei und Bleinitrat oder Blei-8-hydroxychinolat, auch im selben Lösungsmittel.

Résumé—On a examiné les influences d'ions étrangers, des solvants et de la hauteur de flamme sur le dosage du plomb par spectroscopie d'absorption atomique à 2833 Å. Afin d'obtenir des résultats satisfaisants pour le plomb dans l'essence, les solutions titrées utilisées pour la préparation de la courbe d'étalonnage doivent aussi être préparées à partir de plomb-tétraéthyle, et l'absorption doit être mesurée près de la base de la flamme air-propane. Il y a des différences dans l'efficacité d'atomisation du plomb tétraéthyle, par comparaison avec le nitrate de plomb ou le 8-hydroxyquinolate de plomb dissous dans le même solvant.

LETTER TO THE EDITOR

The analytical importance of the methoxyl content of *Acacia* gum exudates

SIR,

Methoxyl groups occur frequently in plant gums as 4-methoxyglucuronic acid (*e.g.*, in *Albizzia*[1] and *Khaya*[2] species) or as ester groups (*e.g.*, in *Sterculia*[3] and *Astragalus*[4] gums). To date, however, the possibility of the presence of methoxyl groups in *Acacia* gum exudates appears largely to have been ignored, *e.g.*, in studies of *A. senegal*,[5] *A. pycnantha*,[6] *A. karroo*,[7] *A. cyanophylla*[8] and *A. sundra*,[9] although Stephen reported (without comment) a value of 0·35% for *A. mollissima*,[10] and Hulyalkar *et al.* found no methoxyl content in *A. catechu*.[11]

Recently, Anderson and Herbich observed[12] that the methoxyl content of a number of nodules of the gum from *A. seyal* ranged from 0·7–1·3%, and this has led us to analyse specimens of the gum from 12 further *Acacia* species, not hitherto studied chemically. We have also re-investigated three different specimens of *A. senegal syn. Verek* (gum arabic) and a sample of *A. karroo*. An infrared method,[13] specific for methoxyl groups, was used to analyse purified samples, prepared from authenticated single nodules of each species by electrodialysis so that artifacts arising from solvent retention[14] could not occur (*cf.* ref. 1).

The results shown in Table I indicate that the presence of methoxyl groups in *Acacia* gums is a more general occurrence than hitherto believed. In addition, the range of values found (0·75 to 1·44%) for 9 nodules of *A. nilotica* substantiates recent evidence[12,15] for inter-nodule variation in the composition of plant gums.

The viscosity of samples of gum tragacanth and of pectins is known[16] to be related to their methoxyl content. The limiting flow-time numbers for some of our *Acacia* samples, determined under standardised conditions, are also shown in the Table: a plot of methoxyl content *versus* limiting flow-time number gives a smooth curve.

TABLE I

Acacia species	Methoxyl, %*	Limiting flow-time number†
A. giraffae Burch	2·40	
A. nilotica (L.) Willd. ex Del.	1·14[a]	10·4

* Electro-dialysed, freeze-dried samples, corrected for trace residual moisture and ash content.

† In aq. 4% NaCl solution at 25°.

[a] Average of results for 9 nodules (range 0·75–1·44%).

[b] Average of results for 6 nodules (range 0·70–1·30%).

[c] Average of results for 3 nodules (range 0·34–0·37%).

It is therefore suggested that the methoxyl content of *Acacia* gums has some structural significance, and that greater analytical attention should be given to this in future studies. We do not subscribe to the view, recently expressed[17] in a study of gum Jeol, that a methoxyl content of 0·51 % can readily be dismissed as being very low and not structurally significant.

It is of interest that our re-examination of *A. senegal* and *A. karroo* has revealed the presence of methoxyl groups. Re-examination of other species, *e.g.*, *A. pycnantha*, may well provide an explanation for the complex behaviour observed[6] during examination of the aldobiuronic acid fraction.

Acknowledgements—We thank Professor Sir Edmund Hirst, F.R.S. for his interest, and record our indebtedness to (the late) Mr. M. P. Vidal-Hall, Gum Research Officer, El Obeid, and to Dr. Dyer, Botanical Research Institute, Pretoria, for collecting authenticated specimens of *Acacia* gums for our studies. We thank Samuel Jones and Co., Ltd. (Camberwell); James Laing, Son and Co., Ltd. (Manchester); Rowntree and Co., Ltd. (York); and the Director of Forests, Sudanese Government, for financial support.

PUBLISHER'S NOTICE

Owing to pressure of other work, Professor C. L. WILSON is relinquishing his office as Editor-in-Chief of *Talanta* at the end of 1964. We owe him a great debt of gratitude for his work over seven years, especially in establishing the journal. Fortunately, it has been possible to maintain Professor Wilson's association with Talanta, for he is to continue as a Consulting Editor. His successor as Editor-in-Chief will be the current Associate Editor, Dr. M. WILLIAMS. Papers not normally submitted through a Regional Editor should now be sent to Dr. M. WILLIAMS, Department of Chemistry, College of Advanced Technology, Gosta Green, Birmingham 4, England.

TALANTA REVIEW*

RECENT USES OF LIQUID ION EXCHANGERS IN INORGANIC ANALYSIS

H. Green
British Cast Iron Research Association, Bordesley Hall, Alvechurch
Birmingham, England

(*Received* 27 *June* 1964. *Accepted* 20 *August* 1964)

Summary—A review of recent uses of liquid ion exchangers in inorganic analysis is presented.

INTRODUCTION

Separations using liquid ion exchange may be said to date from the publication, in 1948, of a paper by Smith and Page[1] entitled "The Acid-Binding Properties of Long-Chain Aliphatic Amines". Since then, increasing interest has been shown in the use, as extractants, of those high molecular weight acids and bases which possess low solubility in water and high solubility in water-immiscible solvents.

The operation of liquid ion exchangers involves selective transfer of solute between two immiscible phases, an aqueous phase and an organic phase containing the liquid exchanger. The technique for liquid ion exchange separation is, therefore, identical to that employed in general solvent extraction separations. From the very first, liquid ion exchange has been compared with resinous ion-exchange because the behaviour of analogous functional groups in the two systems is frequently similar. From this similarity, by reference to available data on extractions with ion-exchange resins, it is possible to make a reasonable prediction of the likely course of the corresponding liquid ion-exchange extractions. Liquid ion exchangers may be employed in a similar manner to resinous exchangers except that, although the course of the reaction may involve 'salt-splitting', the ultimate products will not be acids or bases, as may be obtained with solid resins. They may be employed for the extraction of acids and bases, when the extraction from aqueous solution is by a neutralisation process to form a salt which is soluble in the organic solvent but insoluble in water, *e.g.*, $RNH + HX \rightarrow RNH_2X$. Alternatively, the same liquid exchangers may be used in the salt form when ions may be exchanged with those in the aqueous solution, *e.g.*, $RNH_2Cl + NaNO_3 \rightleftharpoons RNH_2NO_3 + NaCl$. This is, of course, a reversible reaction and when the organic phase contains the amine chloride a strong solution of sodium nitrate will strip the amine of chloride ions, while if amine nitrate in the organic phase is treated with a strong solution of sodium chloride the amine is stripped of nitrate ions. Regeneration of the appropriate amine salt is accomplished in these cases, and if the amine salt is treated with an alkaline solution, such as aqueous ammonia, sodium hydroxide or sodium carbonate, the free amine is obtained. Similar considerations apply in the case of cation exchangers, where regeneration can be achieved using suitable acid solutions. Selectivity is obtained when using liquid ion-exchangers by the usual means—control of pH and salt concentration, adjustment of valency, addition of complexing agents and probably most important of all choice of organic diluent.

---

* For reprints of this Review see Publisher's Announcement at the end of this issue.

It will be seen that liquid ion exchangers combine many of the advantages of both solvent extraction and ion exchange. There are, however, a number of difficulties and disadvantages associated with their use, and an appreciation of these is essential if the full advantage of the combination of solvent extraction and ion exchange is to be obtained. The major difficulty is associated with the formation of emulsions between the organic and aqueous phases, making separation difficult and on some occasions impossible. The relative viscosities and densities of the two phases are of major importance here and, because liquid exchangers usually possess some surface activity, it is necessary to select those having a low activity and to use those conditions which will minimise the formation of stable emulsions. Such conditions are control of temperature, choice of acid and amount of free acid in the aqueous phase, organic diluent for the exchanger, relative volumes of organic and aqueous phases and concentration of the exchanger in the organic phase; the addition of 2–3% of a higher alcohol to the organic phase has proved effective in preventing emulsion formation in some cases.

The expense associated with the use of organic liquids for solvent extractions is not usually of major importance in laboratory applications, but organic solvents can be dangerous if care is not taken in handling and storage, and the exchangers themselves may constitute a certain hazard. For example, in the case of the aliphatic amines used as anion exchangers, the manufacturers point out that although the volatility is low, it is very important, particularly before dilution, to provide adequate ventilation to prevent inhalation of the vapours. Every precaution should be taken to avoid contact with the eyes or prolonged contact with the skin.

It is advisable to keep apparatus used for liquid ion-exchange extractions separate from that used for normal solvent extraction because separating funnels, in particular, are difficult to render completely free from the exchangers. If this is not possible, treatment with a solution containing 5 g of ammonium fluoride and 5 ml of hydrochloric acid in 100 ml of water followed by 10% sodium carbonate solution is usually an effective method of cleaning the glassware.

Another disadvantage in the use of liquid ion exchangers is the fact that, unlike many of the common solvent extraction separations, it is usually necessary to back-extract the required species from the organic phase to complete the determination. It is sometimes possible to use the organic phase directly for determination of the extracted ion or ions, *e.g.*, by aspirating directly into a flame and measuring by means of flame photometry or atomic absorption spectroscopy;[17] by employing a cellulose column impregnated with the liquid exchanger,[2] when metal ions may be recovered on ashing the cellulose and exchanger. If radioactive materials are under investigation, direct measurement of the activity present in the organic phase is possible. Back-extraction procedures can be very tedious where successive extractions are involved, because the organic layer is usually chosen to be the lower layer, when the extraction is being made, for ease of separation; if this layer has to be back-extracted manipulation is much more difficult. Before liquid ion exchange becomes as popular a method of separation as solvent extraction procedures have become, it will be necessary for simple techniques to be devised which utilise the organic phase directly. This is one of the great assets when employing normal solvent extraction methods.

Compared with resinous ion exchange the use of liquid ion exchangers offers a much more rapid method of separation of the required ionic species. In its normal method of use a liquid exchanger is closely similar to a solid resinous exchanger used in the 'batch analysis' technique. It does not, as yet, offer the same range of potential separations. For example, it is not possible to employ the technique of 'frontal analysis' in the same way as with solid resins except by the use of cellulose columns impregnated with the liquid exchanger referred to earlier. This does make possible the use of selected elution and it is claimed that the elution peaks are very narrow, but the preparation of the column appears to be a much longer process than the preparation of resin columns and the advantages accruing are rather marginal.

A comprehensive list of liquid ion exchangers has been given by Coleman, Blake and Brown,[3] but many of those listed have not been extensively used in analysis, and the exchangers mentioned here are those which have become generally accepted as the major materials for carrying out liquid ion exchange. Attention is also directed to a paper by Kunin and Winger.[4] Because of these authors' association with the Rohm and Haas Company, who manufacture Amberlite ion-exchange materials, the information given is invaluable as an introduction to the use of liquid ion-exchange materials.

Much of the earlier work up to 1960, covering extraction with liquid anion exchangers, has been reported by Moore.[5] The section in the present review dealing with liquid anion-exchangers is intended to cover the more important published work since then, with particular reference to the analysis of the more commonly encountered inorganic materials.

In order to prevent this review from becoming excessive in length, work carried out on the transuranic elements has not been included. Papers presented at the 1962 Conference on Solvent Extraction at Gatlinburg, U.S.A., many of which are now in the open literature,[6] effectively review the position regarding these elements.

LIQUID ANION EXCHANGERS

Liquid anion exchangers, at present available, are based on primary, secondary and tertiary aliphatic amines. They are of high molecular weight, water insoluble but soluble in many organic solvents, such as petroleum distillates, aliphatic and aromatic hydrocarbons, high molecular weight alcohols and chlorinated hydrocarbons. For laboratory separations only a small number of the amines which are commercially available have so far been examined and recommended for particular applications and of these the Amberlite exchangers have received by far the greatest attention. The important relevant properties of Amberlite LA.1 [*N*-dodecenyl(trialkylmethyl)amine] and Amberlite LA.2 [*N*-lauryl(trialkylmethyl)amine], both secondary amines, are summarised in Table I.

TABLE I.—SUMMARY OF RELEVANT PROPERTIES OF AMBERLITE EXCHANGERS LA.1 AND LA.2

Property	Amberlite LA.1	Amberlite LA.2
Molecular weight	351–393	353–395
Neutral equivalent	380–410	360–380
Acid binding capacity,		
mequiv/g	2·5–2·7	2·6–2·8

Viscosity (25°), *cp*	72	18
Flash point, *°C*	*ca.* 105°	*ca.* 180°

These exchangers are usually employed at solution strengths varying from 2 to 20% in an inert organic solvent and, as may be expected, the capacity for ion exchange of a particular exchanger, for the same anion, is directly proportional to its concentration in the organic phase. Figures given by the manufacturers for Amberlite LA.1 show that, using kerosene as diluent, 1 litre of 0·05*M* amine has a capacity for $U_3O_8^{2-}$ ions of 1·78 g, while a 0·1*M* solution of amine has a capacity of 3·56 g and a 0·25*M* solution a capacity of 8·88 g/litre. A difference in capacity for ion exchange is exhibited for different ions. Table II shows how this capacity varies with the anion in question for Amberlite LA.1 and LA.2 when 0·1*M* solutions of the exchanger in kerosene are equilibrated with an equal volume of 0·1*M* acid in water. These extraction figures can be improved upon by the addition of a salt, such as sodium chloride, nitrate, sulphate, acetate or tartrate as appropriate, to increase the anion concentration.

TABLE II.—EXTRACTION OF ANIONS[a] BY AMBERLITE LA.1 AND LA.2

Acid	Extraction, %	
	Amberlite LA.1	Amberlite LA.2
Hydrochloric	77·3	88·6
Nitric	85·3	94·4
Sulphuric	74·5	88·0
Acetic	2·7	8·9
Tartaric	1	44

[a] In the form of the free acid.

Several metals form anionic complexes in solutions of mineral acids and it is possible to extract many of these complexes using anion exchangers. Such metals include niobium, tantalum, chromium, zirconium, zinc, uranium, titanium, vanadium and tin, while the anionic complexes may contain radicals such as sulphate, nitrate, oxalate, chloride or fluoride. Figure 1 shows the effect of variation in free sulphuric acid

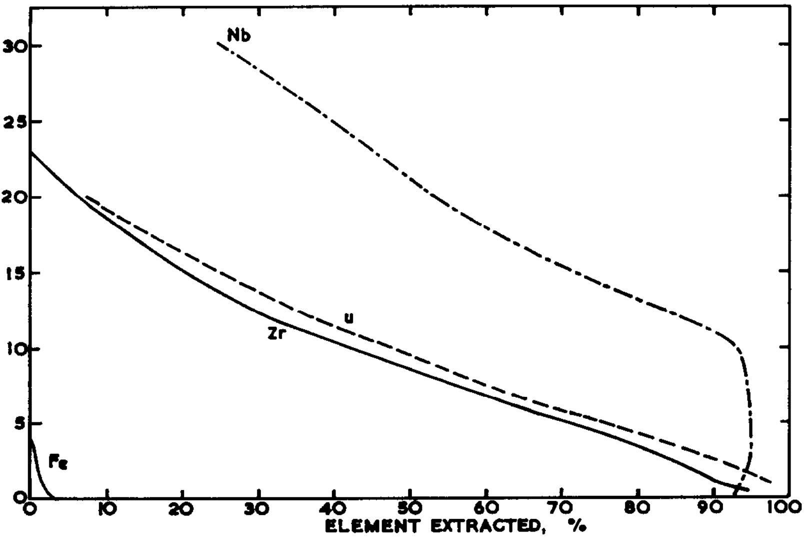

FIG. 1.—Typical curves for liquid ion-exchange extractions.
(Extractions made from sulphuric acid media using a 2:1 ratio of aqueous/organic phases and 4% of Amberlite LA.1 in chloroform[7,8,9].)

content of solution on degree of extraction of some metals as anionic sulphate complexes. Each extraction was made from a 100-ml volume of solution containing 0·02 g of the element and sulphuric acid only, except in the case of niobium when 0·1 g of oxalic acid was also present to prevent hydrolysis and precipitation of the hydrated pentoxide. Only one extraction was made in each case using 50 ml of 4% Amberlite LA.1 in chloroform. Iron(III) is seen to extract only slightly using sulphuric acid media and even then only at very low free acid contents. Zirconium and uranium give very similar extractions to one another, the degree of extraction increasing as the acid concentration decreases. Two extractions with 50-ml volumes of the exchanger at the 1–2% of free sulphuric acid level will then give virtually 100% extraction of both metals. Niobium extraction is appreciable even at the 30% of free sulphuric acid concentration, and from a 5% acid solution two extractions again give a virtual 100% removal.

Under similar conditions, Green[8] has shown that titanium and vanadium do not extract from sulphuric acid solutions alone using Amberlite LA.1. In fact, at the lower sulphuric acid concentrations titanium is hydrolysed. If sufficient fluoride ion is added to the solution of titanium containing 5% of free sulphuric acid to convert the titanium sulphate to titanium fluoride, then 95% of the titanium may be extracted with one 50-ml volume of the exchanger and virtually 100% using two 50-ml volumes. Vanadium gives only a partial and variable extraction in the presence of fluoride. When hydrogen peroxide is used in conjunction with the 5% sulphuric acid solution, 65–70% of the titanium is extracted with one 50-ml volume and 90–95% with two volumes of exchanger. Vanadium extraction is about 30% with one 50-ml volume of exchanger and about 50% with two volumes.

Conditions for the extraction of a number of metal ions from hydrochloric acid solutions, using a 10% solution of Amberlite LA.1 in xylene, have been investigated by Nakagawa.[10,11] A summary of his results is given in Table III. The range of

TABLE III.—EXTRACTIONS USING 10% AMBERLITE LA.1 IN XYLENE

Element	Optimum HCl range, *M*	Extent of extraction,[a] %
Cadmium(II)	2–6	95
Chromium(VI)	1–6	Almost quantitative[b]
Chromium(III)	—	Negligible
Copper(II)	7	35
Gallium(III)	>4	Quantitative
Germanium(IV)	8–11	Almost quantitative
Indium(III)	7	86
Iron(III)	6	Quantitative
Lead(II)	1·5	40
Manganese(II)	1–10	<12
Mercury(II)	1–8	Quantitative

Titanium(IV)	—	No extraction
Vanadium(V)	6–8	90[b]
Vanadium(IV)	—	No extraction

[a] One extraction.

[b] Reduction of V^{5+} to V^{4+} and of Cr^{6+} to Cr^{3+} occurs in solutions more than 6*M* in HCl.

hydrochloric acid concentration given in the table for each element is that over which maximum extraction occurs; outside this optimum range, extraction for any particular element may still be appreciable. Cadmium can be extracted from hydrochloric acid solutions as low as 0·1*M*, with maximum extraction at 2–6*M* and decreasing extraction with increased acid concentration to become 23% in concentrated acid. Tervalent chromium shows negligible extraction but sexivalent chromium gives almost quantitative extraction from solutions 1–6*M* in hydrochloric acid. More concentrated acid tends to reduce the chromium and lower the amount extracted. Back-extraction of the chromium from the organic phase only required that the aqueous phase contained a reducing agent, such as iron(II) sulphate or hydroxylamine hydrochloride.

Copper extracts from hydrochloric acid solutions greater than 3*M* with a maximum extraction of 35% from 7*M* acid. Extraction of germanium commences from 4*M* acid, becoming almost quantitative between 8 and 11*M*. The extraction of indium increases from 12% in 1*M* hydrochloric acid to 86% in 7*M*, decreasing again with increase in acid concentration to 20% in concentrated acid. Lead shows maximum extraction from 1·5*M* acid, decreasing to nothing at 10*M*. Tellurium is quantitatively extracted from hydrochloric acid solutions between 4 and 6*M* and was readily back-extracted with 0·5*M* acid. The extraction of tin commences at 0·5*M* hydrochloric and increases with increase in acid concentration, reaching a maximum between 5 and 6*M*, then decreasing above 6*M* acid; back-extraction using 1*M* nitric acid is recommended, dilute hydrochloric and sulphuric acids being stated as unsuitable. Quadrivalent vanadium does not extract from hydrochloric acid solutions, whereas up to 90% of quinquevalent vanadium may be extracted from 6*M* acid. When the acid concentration is greater than 6*M*, reduction of the vanadium occurs and extraction decreases.

Using Amberlite LA.1 as a 10% solution in kerosene, Nakagawa[12,13] has investigated the extraction of iron(III), nickel, cobalt, zinc, aluminium, titanium, arsenic, antimony and bismuth from hydrochloric acid solution. A summary of his results is given in Table IV.

TABLE IV.—EXTRACTIONS USING 10% AMBERLITE LA.1 IN KEROSENE

Element	Optimum HCl range, *M*	Extent of extraction, %
Aluminium(III)	—	Negligible
Arsenic(III)	8–11	92
Arsenic(V)	—	No extraction
Antimony(III)	1–4	Almost quantitative
Antimony(V)	>6	Quantitative
Bismuth(III)	0·3	Quantitative
Cobalt(II)	8	35
Iron(III)	6–10	Quantitative
Nickel(II)	—	No extraction
Titanium(IV)	12	10
Zinc(II)	2–3	90

Tervalent arsenic extracts from solutions greater than 4*M* in hydrochloric acid, a maximum extraction of 92% occurring in 8–11*M* acid. Tervalent antimony is almost quantitatively extracted from 1–4*M* acid solutions, extraction decreasing with increase in hydrochloric acid concentration. The extraction of quinquevalent antimony is, however, facilitated by an increase in acid concentration and only becomes quantitative from solutions greater than 6*M*. Bismuth extraction is complete from 0·3*M* acid; increasing the hydrochloric acid concentration results in decreasing extraction until at $10M$ acid no extraction occurs. It is recommended that tervalent antimony and bismuth be back-extracted using $0{\cdot}5M$ citric acid, and quinquevalent antimony with $1M$ sodium hydroxide, but not with mineral acids. Cobalt extraction starts from solutions more than $5M$ in acid, but maximum extraction at $8M$ acid is only about 35% complete. No extraction of titanium occurs from solutions below $8M$ in acid and only about 10% from concentrated hydrochloric acid solutions. Zinc extraction is maximum at 2–$3M$ acid, decreasing with increase in acid concentration.

The extraction data given by Nakagawa provide an excellent example of the parallelism which exists between liquid and resinous ion exchangers. The reader can qualitatively extend the data given in Tables III and IV by reference to the more comprehensive work on anion exchange in chloride media by Kraus and coworkers.[56]

Amberlite LA.1 has been used by Ishibashi and Komaki[14] for the determination of zinc in aluminium alloys. The zinc, present at about the 5-mg level, is extracted into a 15% solution of Amberlite LA.1 in kerosene from $6M$ hydrochloric acid. The procedure is to dissolve the sample in $6M$ hydrochloric acid and hydrogen peroxide, then extract the zinc with Amberlite LA.1/kerosene. The zinc is back-extracted into the aqueous phase using $0{\cdot}3M$ nitric acid, the solution made ammoniacal and triethanolamine and potassium cyanide added to mask iron and copper. Finally, the zinc is demasked using formaldehyde and titrated with standard EDTA.

For the determination of zirconium in cast iron, Green[15] employed a 4% solution of Amberlite LA.1 in chloroform. The precedure here is to dissolve the sample in sulphuric acid in the presence of a small amount of sodium fluoride. After mercury cathode separation, hydrogen peroxide is added and zirconium extracted with Amberlite LA.1/chloroform. The zirconium is back-extracted with hydrochloric acid and finally reacted with Pyrocatechol Violet for spectrophotometric measurement. Titanium and vanadium will be partially extracted by the exchanger under these conditions and a correction has to be applied if either or both are present.

Using the same exchanger, 4% of Amberlite LA.1 in chloroform, Green[16] has determined uranium in cast iron. The sample is dissolved in sulphuric acid solution and extracted directly with the ion exchanger. Under the conditions used, apart from the uranium, any niobium, tantalum and zirconium present will be extracted, along with a small quantity of iron. Back-extraction of the organic phase with sodium carbonate results in precipitation of these elements, while the uranium is extracted as the water-soluble uranyl-carbonate complex, $UO_2(CO_3)_3^{4-}$. After filtration, the uranium in the filtrate is reacted with hydrogen peroxide to yield the yellow peroxy complex, which is measured spectrophotometrically.

The use of Amberlite LA.1 has been described for the determination of zinc in bauxite.[17] Fifty ml of a 25% solution of the exchanger in xylene can be used to extract up to 5 mg of zinc from 1-g samples of bauxite. Despite the high concentration of exchanger, the organic phase can be fed directly to the burner of a Perkin-Elmer 214 atomic absorption spectrophotometer to complete the determination.

In an investigation into the separation and determination of chromium sesquioxide in chrome ores and refractories, Bennett and Marshall[18] used both Amberlite LA.1 and LA.2. The extraction of chromium from sulphuric acid solution, as the dichromate ion, increased with increasing acid concentration. However, at higher acid concentrations, increasing reduction of the sexivalent chromium took place. Because

Amberlite LA.2 is the more basic of the two exchangers and shows less tendency to emulsify, it was chosen for use in the final method. For decomposition of the sample a fusion is made using 7 g of anhydrous sodium carbonate and 2·5 g of boric acid with 0·5 g of sample. The cooled melt is extracted with dilute sulphuric acid and dilute aqueous ammonia added until a faint permanent precipitate forms. This precipitate is just dissolved by addition of dilute sulphuric acid and the solution extracted using a 10% solution of Amberlite LA.2 in chloroform. After two 25-ml extractions with the exchanger, further sulphuric acid is added to the aqueous phase and a third extraction made with 25 ml of exchanger. The extracts are combined and back-extracted using $1M$ potassium hydroxide. After acidification and reduction with sulphite, the chromium is reacted with EDTA and the determination completed by spectrophotometric measurement of the violet complex at 550 mμ. Under these conditions, other constituents of chrome ores and refractories, such as iron, titanium, manganese and silicon, are in no way affected by the ion-exchange separation and the aqueous phase can be used for their determination after being washed with chloroform.

The behaviour of tin(IV) and lead ions in extraction from hydrochloric acid solutions with a xylene solution of Amberlite LA.2 has been studied by Nakagawa.[19] Tin(IV) can be extracted from hydrochloric acid solutions between 5 and $9M$ up to 98%; lead extraction is about 40% from $2M$ acid, decreasing rapidly with increasing acid concentration to become negligible at concentrations above $8M$. A method for the separation of tin and lead was suggested in which the solution of the metal ions is adjusted to between 7 and $8M$ in hydrochloric acid. Two extractions are made using a 10% solution of Amberlite LA.2. The combined organic phases are then washed with fresh 7–$8M$ hydrochloric acid to remove traces of lead, and the tin returned to the aqueous phase by stripping with three consecutive volumes of $0{\cdot}5M$ nitric acid.

Hirano, Mizuike and Iida[20] have employed Amberlite LA.2 as a 10% solution in xylene for the determination of traces of cadmium in thorium compounds. The sample, containing about 10 g of thorium, is dissolved in hydrochloric acid and sodium fluoride solution, evaporated almost to dryness after addition of nitric acid, then taken up with 5 ml of concentrated hydrochloric acid and 35 ml of water. The cadmium in the solution is extracted with two 10-ml volumes of the exchanger. The combined extracts are washed twice with small volumes of $1M$ hydrochloric acid to remove iron and the cadmium back-extracted using two 5-ml volumes of $2M$ nitric acid. The cadmium in the extract is then determined polarographically. It is claimed that the separation can be applied to cadmium determinations as low as 0·01 ppm with a relative error of less than 10%.

Unpublished work, reported to the author,[59] shows that macro quantities of lead may be extracted using a 20% solution of Amberlite LA.2 in hexone. From a 100-ml volume of solution containing the equivalent of 0·13 g of PbO, 5 ml of concentrated hydrochloric acid and 1·5 g of potassium iodide, two extractions with the exchanger followed by one extraction with hexone alone will achieve a lead extraction of over 99%. The concentration of acid and iodide appears to be rather critical. Presumably, other metal iodides, such as those of tin, antimony, bismuth and cadmium, could be extracted under similar conditions.

Although the Amberlite exchangers have received the widest attention, other amines have proved of great value for certain separations. It has been shown by

Baeckmann and Glemser,[21] using a solution of a tertiary amine such as tribenzylamine (TBA) in chloroform, that it is possible to separate iron(III) chloride from elements which do not form anionic chloro complexes, such as aluminium, silicon, zirconium, titanium, hafnium, thorium, niobium, tantalum, nickel and alkali and alkaline earth metal ions. The extraction is made from 5*M* hydrochloric acid solution using a 0·2*M* solution of TBA in chloroform, when a quantitative separation can be achieved. The iron may be back-extracted into the aqueous phase using hydrochloric acid solutions less than 0·5*M*.

The separation of niobium and tantalum has been achieved by Ellenburg, Leddicotte and Moore,[22] using TBA in chloroform. Niobium can be extracted easily with equal volumes of aqueous and organic phases, whereas tantalum extraction was minimal. The extraction of niobium is dependent on the concentration of TBA in the organic phase—the distribution coefficient rising from 0·20 using 1·25% TBA to 74·4 using 8% TBA. The corresponding values for tantalum are 0·003 and 0·002, respectively. The concentration of acid is quite critical. Using 8% TBA in chloroform, practically no extraction occurs below 8*M* hydrochloric acid. At 9*M* acid the Kd value is 5·05 for niobium and 0·0013 for tantalum; from 11*M* hydrochloric acid the Kd values are 74·4 and 0·0025, respectively. When methylene chloride is used instead of chloroform the extraction is even better, niobium giving a Kd of 80·5 and tantalum 0·0023 from 11*M* hydrochloric acid. The reason for the success of the separation achieved under these conditions is explained by 'the extraction of niobium as an oxychloride complex of the type $H(NbOCl_4)$ or $H_2(NbOCl_5)$, while neither chlorotantalates nor oxychloride complexes of tantalum are presumed to exist in aqueous solution'. The investigation was extended to extraction from sulphuric acid solutions. Quantitative separation of tantalum and niobium is possible from 4·5*M* acid solution. The acid concentration is stated to be very critical. Both niobium and tantalum are extracted from oxalic acid solutions using TBA in chloroform and methylene chloride; on the other hand, if the solvent is changed to benzene, toluene, xylene or carbon tetrachloride, no extraction of either metal takes place.

Using a 5% solution of methyldioctylamine (MDOA) in xylene, Leddicotte and Moore[23] showed that niobium and tantalum could be separated satisfactorily. The radioactive isotopes ^{95}Nb and ^{182}Ta were used in the investigation. From hydrochloric acid solutions the extraction of tantalum is only 0·25% at 3*M* acid concentration, rising to only 1·4% in concentrated acid. With niobium, on the other hand, extraction is 2·4% at 3*M* hydrochloric acid with the percentage extraction increasing rapidly above 6*M* acid to reach over 99% at 8*M*. From nitric acid solutions neither niobium nor tantalum extracts appreciably up to 10·6*M*; from sulphuric acid solution up to 12*M* very little niobium extracts, but tantalum extraction is appreciable at 2*M* sulphuric acid, decreasing with increase in acid concentration.

Following the investigation into these separations for tantalum and niobium using MDOA and TBA, Mahlman, Leddicotte and Moore[24] examined the extraction of chromium, manganese, iron, nickel, copper, zinc and cobalt. In each case the course of the extraction was followed by using radioactive materials. From aqueous hydrochloric acid solutions using an 8% solution of MDOA in trichloroethylene, chromium extraction is only about 2%, and nickel less than 1%, irrespective of the acid concentration from 0·1 to 10*M*. Very little manganese is extracted below 5*M* hydrochloric acid and only 32% from 10*M*. Iron extraction becomes appreciable above about

0·5*M* and reaches a maximum at 94/95% between 4 and 5*M* acid, remaining at more than 90% even in 10*M* hydrochloric acid. Cobalt extraction is less than 2% in 3*M* acid, rising rapidly to 85% in 10*M* acid. Zinc, on the other hand, extracts readily from 0·5*M* acid, with quantitative extraction occurring from 2 to 10*M* acid. When chloroform is substituted for the trichloroethylene, cobalt does not extract until 8*M* acid, while zinc gives a maximum extraction of 85% at 3*M* acid. When the organic diluent is changed to xylene, cobalt extraction does not reach 2% until 4*M* hydrochloric acid, and is only 21% in 10*M* acid. Zinc again shows maximum extraction in 3*M* acid—over 99%, with over 95% extraction taking place from all solutions between 1 and 10*M*. When TBA is used in place of MDOA, maximum zinc extraction of 72% again occurs at 3*M* acid with negligible cobalt extraction occurring below 6*M* acid.

Other amines which have been used by a number of workers are tri-iso-octylamine and tri-n-octylamine. Marchart and Hecht[25] have examined the extraction behaviour of tantalum and niobium with tri-iso-octylamine from various acids and acid mixtures. The distribution coefficient is dependent on the acid concentration and on the nature of the complexing agent used. A method is given for the separation of the two metals from nitric/hydrofluoric acid solution.

The distribution of septivalent rhenium between nitric acid solutions and tri-iso-octylamine has been investigated by Kertes and Beck.[26] Variation in the rhenium molarity in the organic phase shows that the species extracted is free perrhenic acid, $HReO_4$.

Using tri-iso-octylamine hydrochloride, Lorenzini, Stoppa and Barbieri[27] separated gram-quantities of uranium from solutions of 8*M* hydrochloric acid before the spectrographic determination of the rare earth elements. A 6-g sample of uranium metal is dissolved in 50 ml of 8*M* hydrochloric acid and extracted with five 100-ml portions of 0·3*M* tri-iso-octylamine hydrochloride in a xylene/octanol mixture (19:1). Any iron present is extracted with the uranium.

White, Kelly and Li[28] have converted tri-n-octylamine (TOA) to its hydrochloric and perchloric salts before an investigation into the chloride complexes of iron(III) and indium(III). The tertiary amine is dissolved in benzene and equilibrated with equal volumes of 1*M* hydrochloric and perchloric acid to convert it to the appropriate salt. The amine itself is a light yellow colour; its hydrochloride and perchlorate salts in benzene are light yellow and slightly pink, respectively. The investigation was made using the radioactive materials ^{59}Fe and ^{114}In; the aqueous phase contained the metal ion in a concentration of the order of $10^{-7}M$ and varying concentrations of hydrochloric acid and/or perchloric acid. The organic phase contained the TOA salt in benzene and in each case was equilibrated with an equal volume of the aqueous phase to be used, without the radioisotope. Equal volumes of aqueous and organic phases were shaken for a number of hours at 25 ± 0·5°, then allowed to settle for 1 hr before measurement of the radioactivity of each phase. No extraction of iron or indium occurs from perchloric acid solutions less than 2*M* with no chloride present, indicating that the perchlorate ion does not form anionic complexes with either iron or indium in the organic phase. The distribution coefficient (defined as the concentration of metal ions in the organic phase divided by the concentration of metal ions in the aqueous phase) for both iron and indium are second power dependent on the

TOA/hydrochloric acid concentration in the benzene phase, indicating that the negatively charged complexes $FeCl_5^{2-}$ and $InCl_5^{2-}$ are formed in the organic phase.

The distribution of sulphuric acid between water and a benzene solution of TOA and tri-n-hexylamine (THA) has been investigated by Verstegen and Ketelaar.[29] Assuming that the organic activities of the amine salts, $(TOAH)_2SO_4$ and $(THAH)_2SO_4$, are equal to concentrations, then the law of mass action describes the equilibrium until the amine salt exceeds a certain value. The heat and entropy of the formation of $(TOAH)_2SO_4$ have been calculated and the equilibrium leading to the formation of $(THAH)_2SO_4$ studied at 25°. Finally, the relative basic strengths of tertiary amines, on the basis of infrared measurements of the proton-accepting properties, are discussed. It is emphasised by the authors that the results obtained using infrared measurements may only be interpreted as showing a certain trend because of small variation in the proton-accepting property. Furthermore, it is certainly not the only point governing the relative basicity of the amines.

An extensive investigation[30] has been made into the extraction of uranium from aqueous sulphate solutions by long-chain aliphatic primary, secondary and tertiary amines in various organic diluents. Tertiary amines have a remarkable preference for uranium over the other elements normally found in uranium leach liquors. Only molybdenum is extracted to any great extent. The extraction coefficients for uranium from sulphate solutions at a pH of about 1 are directly proportional to the concentration of the amine in the organic phase (see figures quoted earlier for Amberlite LA.1). At the same time, the extraction coefficients are dependent on temperature, pH, sulphate concentration and concentration of other anions in the aqueous phase. The back-extraction of uranium can be accomplished using dilute hydrochloric acid, sodium carbonate, sodium hydroxide or aqueous solutions. Using aqueous ammonia, the uranium is precipitated as it is returned to the aqueous phase. Again, there is a close parallel with the studies on ion exchange, such as those reported by Burstall *et al.*[58]

The tertiary amine didodecenyl-n-butylamine (Amberlite XE-204) has not been investigated to a great extent. However, Dono, Nakagawa and Wada[31] have employed it for the separation of micro amounts of nickel in cobalt. Approximately 95% of the cobalt can be extracted from an 8*M* hydrochloric acid solution, but nickel does not extract from hydrochloric solutions of any concentration.

Direct spectrophotometric determinations after liquid anion-exchange

Using a 1% solution of TBA in chloroform, Fasolo, Malvano and Massaglia[32] have extracted chromium(VI) from 1*M* hydrochloric acid solutions. The chloroform extracts can be measured spectrophotometrically to obtain the chromium content. Maximum absorption occurs at 355 and 458 $m\mu$. Only gold (100%), antimony (>90%) and mercury (>95%) give appreciable extraction under the conditions used. Negligible extraction (<1%) occurs for copper, cobalt, nickel, zinc, iron, chromium, manganese, cadmium, arsenic, uranium, cerium, molybdenum, rare earths and alkaline earths.

Direct spectrophotometric determination of the green cobalt complex in the organic phase, after extraction of cobalt thiocyanate using a 20% of TOA in carbon tetrachloride, is reported by Selmer-Olsen.[33] The absorption curve shows two maxima (340 and 627·5 $m\mu$). Bivalent manganese, nickel and zinc give no colour in the organic layer and do not interfere, while iron gives an absorption maximum at 475 mμ and practically no absorption at 627·5 mμ. It is, therefore, possible to determine small amounts of iron and cobalt in the presence of each other.

LIQUID CATION EXCHANGERS

Coleman, Blake and Brown[3] listed 24 liquid cation-exchange materials, but to-date only two of these have been used to any extent. These are di-(2-ethylhexyl)orthophosphoric acid (D2EHPA, DEHPA or HDEHP) and dinonylnaphthalene sulphonic acid (DNS).

DNS is obtained from the manufacturers as an approximately 48% solution in n-heptane, and is a mixture of isomers resulting from the sulphonation of dinonylnaphthalene, the dinonylnaphthalene being made by controlled alkylation of naphthalene with nonene. It is a monobasic acid with only slight solubility in water but readily soluble in many organic solvents. White, Tang and Li[34] analysed the material by extraction of a known volume of the solution in heptane with standard potassium hydroxide solution, followed by titration of the aqueous phase with standard hydrochloric acid. Kaufman and Singleterry[35] have demonstrated micelle formation by DNS in moist benzene, and White *et al.*[34] inferred from this 'that DNS in moist heptane may also exist as the polymer, $(\mathrm{DNS})_x$.'

The behaviour of DNS as a liquid cation exchanger has been examined by White, Tang and Li.[34] Using ^{60}Co, ^{54}Mn, ^{59}Fe, ^{114}In and ^{65}Zn as radioactive tracers, extractions were made from an aqueous phase, containing the metal radioisotope at a concentration of $10^{-6}M$, into a heptane solution of DNS in concentrations of the order of 10^{-3} to $10^{-4}F$. The heptane/DNS reagent was shaken for a number of hours with an equal volume of $0{\cdot}1M$ perchloric acid before use. Extractions were made using equal volumes of aqueous and organic phases of Co^{2+}, Zn^{2+}, Mn^{2+}, Fe^{3+} and In^{3+} as the perchlorates with a varying concentration of perchloric acid to obtain the desired pH, at a temperature of 25 ± 0·5°. After shaking for a number of hours, the two phases were allowed to settle for 1 hr and the activity of the metal ion in each phase measured.

The results show that the distribution coefficients of the bivalent and tervalent ions are inversely second power and third power, respectively, dependent on the pH of the aqueous phase and first power dependent on the DNS concentration of the heptane phase. At the same time, experiments were made to determine the formation constants of the indium(III) complexes of glycolate and bioxalate and the cobalt(II) complex of bioxalate. The formation constants obtained using DNS agree with the values obtained using a resinous cation exchanger.

The stability constants of the iron(III) and indium(III) chloride complexes were investigated by White, Kelly and Li[28] using DNS and radioisotopes ^{59}Fe and ^{114}In. Using metal ion concentrations of about $10^{-7}M$ and varying concentrations of hydrochloric and/or perchloric acid, extractions were carried out using equal volumes of aqueous and organic phases. In each case the organic phase was pre-equilibrated with an equal volume of the aqueous phase to be used, without the radioisotope. The total hydrogen ion concentration in each experiment was kept constant while the ratio of hydrochloric and perchloric acids varied. The solutions were shaken at 25 ± 0·5° for a number of hours, then allowed to settle for 1 hr before measuring the radioactivity of each phase.

A table is given showing the decrease in distribution coefficient for iron(III) with increase in hydrochloric acid concentration and corresponding decrease in perchloric acid concentration to maintain the total acid at 1*M*. The Kd value at 1*M* perchloric acid is 3·01 and on subsequent substitution of hydrochloric acid for the perchloric acid the Kd value becomes 0·65 at 0·8*M* hydrochloric acid/0·2*M* perchloric acid. By assuming that there is no complexing of M^{3+} and ClO_4^-, the stability constant for the reaction $M^{3+} + Cl^- \rightarrow MCl^{2+}$ was calculated by the method of White *et al.*[34] Good agreement was found for iron between the stability constants determined using DNS and the values in the literature obtained spectrophotometrically. The stability constant of the $FeCl^{2+}$ complex at ionic strengths varying from 0·2 to 1·0 is independent of whether H^+ or Na^+ is the cation associated with the perchlorate ion. With the indium(III) complex, the substitution of Na^+ for H^+ as the cation associated with the perchlorate ion decreases the value of the stability constant.

D2EHPA has been employed by McHenry and Posey[36] for the separation of strontium-90 and calcium. Calcium is extracted into the organic phase while the strontium remains in the aqueous phase to an extent greater than 95%. The effects of the addition of acetic acid, alcohol and 2-ethylhexanol on the recovery of calcium and strontium and on their distribution coefficients were investigated.

Using the same reagent, Butler and Ketchen[37] separated cerium-144 and yttrium-91 from other rare earth fission products, producing a highly pure ^{144}Ce in good yield. The extractions were made from nitric acid solution containing citric acid and the cerium was oxidised to the quadrivalent state with permanganate before extraction.

Using a D2EHPA solution in toluene, Peppard *et al.*[38] employed fractionation extraction of the lanthanides and yttrium from solutions containing various anions—nitrate, chloride and sulphate. The extracted lanthanide species do not contain any of the anion associated with the lanthanide in the original solution. Once this was established the rest of the investigations were carried out from hydrochloric acid solutions. Using radioisotopes it was found that, under the experimental conditions used, the distribution coefficients are directly third power dependent on the concentration of D2EHPA in the organic phase and inversely third power dependent on the hydrogen ion concentration of the aqueous phase. A further paper by Peppard *et al.*[39] examined the relative effectiveness of mono- and di-orthophosphoric esters for the extraction of the rare earths.

Using a 4% solution of D2EHPA in toluene, Arden[40] has determined the radioisotope ^{95}Zr in fission products. These products are allowed to cool for a minimum period of 15 days, then taken into solution with mineral acids, such as nitric, hydrochloric and sulphuric. A suitable aliquot of the solution is taken, such that the activity will not be less than 200 cpm. Niobium, iron and iodine carriers are added, together with hydrogen peroxide, and the solution is extracted with carbon tetrachloride. The organic phase containing any radio-iodine is discarded and the aqueous phase extracted with the toluene/D2EHPA. The aqueous phase is then discarded and the organic phase is extracted with potassium thiocyanate solution to remove any radio-iron. The organic phase, which contains the radio-zirconium, is then counted using a γ-scintillation counter.

The determination of total radio-strontium in milk using D2EHPA in toluene has been described by Butler.[41] The major problem in the analysis of milk for total radio-strontium is the removal of the large quantities of calcium that are present before counting. Using a 20% solution of D2EHPA in toluene, calcium is removed from hydrochloric acid solution by one extraction at pH 3·6–3·8, followed by a second extraction at pH 2·6–2·8, using equal volumes of aqueous and organic phases. These extracts are discarded and the strontium extracted at pH 4·8–5·0. The strontium is then back-extracted from the organic phase using 3*M* nitric acid and after suitable treatment the β-count of the strontium determined.

At a Symposium on Solvent Extraction Chemistry held at Gatlinburg, U.S.A., in 1962, a series of papers covering the theory and use of D2EHPA as an ion-exchanger was presented. A number of these papers have now been published in the open literature.[6] The reader who is about to use this reagent for the first time is recommended to consult these papers in view of the valuable information they contain.

At the same Symposium a paper on extraction with sulphur-containing organophosphorus compounds was presented by Handley.[42] Both mono- and di-substituted sulphur derivatives of the alkylphosphoric acids were investigated. In general, these new reagents extract from mineral acid solutions those metal ions which form insoluble sulphides. Because of their stability and wide range of acid tolerance it may be possible to use these reagents for many purposes where at the present time xanthates and diethyldithiocarbamates are employed.

CHROMATOGRAPHIC SEPARATIONS USING LIQUID ION EXCHANGERS

Chromatographic separations of a number of cations by means of paper treated with liquid ion exchangers have been reported by Testa and Cerrai. In the first report[43] the paper was treated with a 0·2*M* solution of TOA. Paper treated with TOA behaves very much like a film of anionic resin: it retains the chloride, nitrate and sulphate complexes of the various elements in accordance with the strength of the complex itself. The cations were used in concentrations of 20–50 μg in hydrochloric acid solution for each spot and development was carried out with appropriate reagents, such as potassium thiocyanate for iron(III), dimethylglyoxime for nickel and 8-hydroxyquinoline for cobalt. Using circular chromatography and 4*M* hydrochloric acid for elution, these three ions can be separated satisfactorily. Nickel follows the solvent front (R_f 0·97) because it is not complexed by hydrochloric acid and hence not retained by the amine. Cobalt is partially complexed and gives an R_f value of 0·50, while iron is completely complexed (R_f 0) and is retained in the original spot by the amine. Similarly, using 10*M* hydrochloric acid, uranium (R_f 0), zirconium (R_f 0·35) and thorium (R_f 0·95) can be separated or uranium, zirconium and titanium (R_f 0·85). Many other separations are possible using hydrochloric acid of suitable strengths. These include iron(III), copper and aluminium using 1*M* acid; uranium, vanadium and titanium using 3*M* acid; zinc and manganese using 3*M* acid; zinc, cobalt and manganese using 4*M* acid; zinc, manganese and nickel using 10*M* acid. Separation of zirconium (R_f 0·25) and hafnium (R_f 0·80) is made using 8*M* hydrochloric acid plus 5% concentrated nitric acid. When a 0·2*M* sulphuric acid solution is used, uranium and nickel can be separated from iron and copper, and using 0·5*M* sulphuric acid separation of molybdenum from iron, copper and nickel is possible.

Descending chromatography was used for the separation of some cation mixtures, such as zinc, cobalt and manganese, uranium, zirconium, thorium, vanadium and titanium. By judical selection of the strength of hydrochloric acid for elution, satisfactory separations were made of these mixtures.

The second report[44] dealt with the separation of uranium, thorium and lanthanum. In this case the chromatographic paper was treated with benzene solutions of various concentrations of TOA and elution was made using nitric acid, lithium nitrate, sodium nitrate, ammonium nitrate, calcium nitrate and aluminium nitrate. Lanthanum is not retained by the amine and so moved with the solvent front, while thorium and uranium form well defined spots. Lowering the TOA concentration on the paper effects a considerable increase in the R_f values of both thorium and uranium. Increasing the strength of the nitrate solution for elution decreases the R_f values for all three cations.

A third report[2] examined the use of TOA-cellulose in chemical separations. Whatman No. 1 cellulose powder was impregnated with $0{\cdot}1M$ TOA in benzene and then heated for 2 hr at 85° to volatilise the benzene solvent. The treated cellulose was crushed in a mortar, then packed into a column, fitted at the bottom with a fritted glass disc. This column was then used in a similar manner to a column of ion-exchange resin. Nickel, cobalt and iron can be separated by elution with hydrochloric acid, similarly, thorium, zirconium and uranium. The authors admit that the exchange capacity of this type of column is only 25–30% of that of the common resin but claim a number of advantages:

(1) Because of the white colour of the column the position and movement of coloured zones can be easily followed.
(2) Because the active functional groups are concentrated at the surface of the powder grains and the grain size is very small, the column has a high ability to fix large molecules, which often cannot penetrate the complex structure of anionic resins.
(3) Very narrow elution peaks are obtained.
(4) When working with radioactive tracers the column can be easily burned and the residue conveniently obtained for radioactive counting; the resins are less easily burned.

The chromatographic separation of the rare earths using paper treated with TOA and elution with lithium nitrate has been studied by Testa.[45] Previously reported work suggested that the rare earth elements formed anionic complexes in a concentrated solution of an alkaline nitrate. Based on this, Testa determined the R_f values for a number of rare earth elements, for various concentrations of lithium nitrate as eluting solution, using chromatographic paper treated with $0{\cdot}2M$ TOA in benzene. From these R_f values a number of separations of the rare earth elements was shown to be possible. The R_f values obtained increase on adding nitric acid to the lithium nitrate for elution, indicating that the presence of free nitric acid lowers the formation of the complex. The spots from the various elements were developed by means of a 1% solution of 8-hydroxyquinoline in 1:1 water/alcohol. On exposure of the paper strips to ammonia vapour the spots became clearly visible.

A further study of Cerrai and Testa[46] involved the separation of the rare earth elements on chromatographic paper treated with a $0{\cdot}1M$ solution of D2EHPA in cyclohexane. The R_f values for 9 rare earths (lanthanum, cerium, praseodymium, samarium, europium, gadolinium, dysprosium, erbium, ytterbium) and 7 additional elements (yttrium, scandium, thorium, uranium, zirconium, iron, aluminium) as functions of the molarity of the hydrochloric acid elutriant are given. The spots were developed using a 1% solution of 8-hydroxyquinoline in 1:1 water/alcohol solution. A relationship was established between the quantity log $(1/R_f - 1)$ and (1) the atomic number of the element, (2) the molarity of the acid used as elutriant, (3) the molarity of the solution with which the paper is treated; and (4) the operating temperatures. Under the same conditions, the R_f values increase as the atomic number decreases. For a given element, the R_f value increases with the strength of the acid used for elution and with the operating temperature, and it decreases with the concentration of D2EHPA on the paper. Examples are given of the chromatographic separation of the rare earth elements from each other and from the other 7 elements mentioned previously.

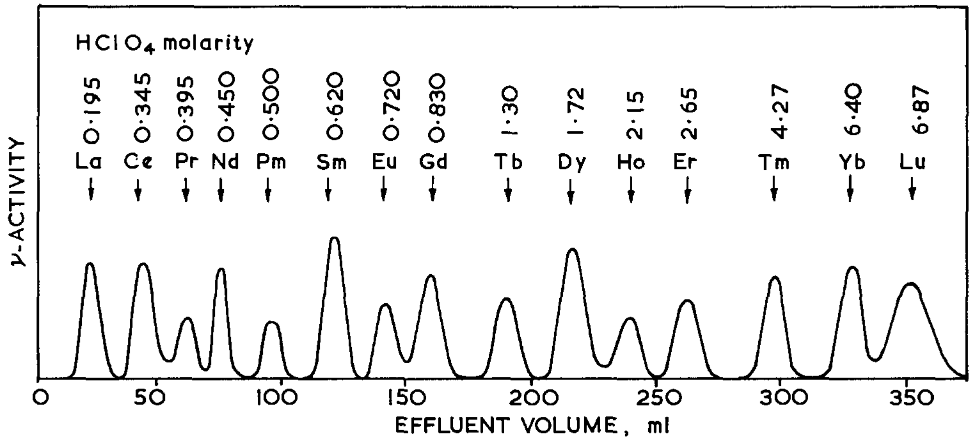

FIG. 2.—Separation of the rare earths by gradient elution from a Corvic/HDEHP column.[47]
(Reproduced by courtesy of Macmillan & Co. Ltd.)

The chromatographic separation of the rare earth elements using D2EHPA and reverse-phase partition chromatography has been described by Pierce *et al.*[47,48,49] A chromatographic column impregnated with D2EHPA was prepared using poly-(vinyl chloride/vinyl acetate) copolymer ('Corvic', Imperial Chemical Industries Ltd.) as supporting medium. Ten g of the copolymer (100–150 mesh) were mixed with 10 ml of solution containing 5 ml of chloroform plus 3 ml of toluene plus 2 ml of D2EHPA. The organic solvent was evaporated off and the resulting powder slurried in 0·002*M* perchloric acid and made into a column of the required size. The temperature of the column was thermostatically controlled at 60° and a flow rate of 2·0 ml.cm^{-2}.min^{-1} used throughout the experiments. It was shown that the separation of the rare earth element is possible using elution with perchloric acid. Separation of certain combinations of the rare earths, such as cerium with praseodymium and europium with gadolinium, proved difficult when perchloric acid of constant strength was employed for elution. Gradient elution using perchloric acid of gradually increasing strength is very successful in separating the rare earth series, the elements being eluted successively in the order of increasing atomic number. In order to check the separations, radioactive earths were used in dilute perchloric acid solution and the effluent from the column was passed through a γ-scintillation flow counter. The elution peaks were identified using a γ-spectroscope and the acidity of the eluate at the peak maxima was determined by titration with standard alkali. Fig. 2 illustrates the results obtained using gradient elution for separation of the rare earths on a Corvic/D2EHPA column.

Sastri and Rao[50] have described the use of paper impregnated with DNS for chromatographic separations. The paper was treated with a $0{\cdot}1M$ solution of DNS in n-heptane and the solvent removed by blowing hot air. The chromatograms were obtained using the ascending technique and the solvent front was allowed to move through a distance of 18 cm. More than 20 metal ions were examined using nitric and hydrochloric acids as elutriants at strengths between 0·1 and $1{\cdot}0M$. The R_f values increase with increase in the strength of the acid used to elute, and the R_f values for hydrochloric acid are somewhat greater than for nitric acid. The values obtained are in agreement with those expected from the cation-exchange mechanism. A number of separations were shown to be possible, *e.g.*, aluminium and beryllium; copper and cadmium; iron, titanium and vanadium; indium, gallium and zinc; calcium, barium and magnesium; in each case using $0{\cdot}25M$ hydrochloric acid.

NEUTRAL CO-REAGENTS

Reagents such as tri-n-butylphosphate and tri-n-octylphosphine oxide have been classed as 'neutral co-reagents' by Coleman *et al.*[3] They are frequently used for extraction of metal ions from aqueous solution. It is not the intention of this review to cover the use of these extractants. The reader is referred to the summary of much of the earlier work carried out with neutral co-reagents by Morrison and Freiser[51] and a more recent review by White and Ross.[52]

MISCELLANEOUS

The determination of amines and alkylphosphates in kerosene solutions, used for the extraction of uranium, has been reported by Ashbrook.[53] For the determination of an amine the kerosene is shaken with calcium hydroxide, when the sulphuric acid present is precipitated as calcium sulphate and the uranium absorbed on the calcium hydroxide. The solids are then removed by filtration and the amine determined in the filtrate by titration. If alkylphosphates are present it is necessary to extract the uranium first with 20% sulphuric acid, then to shake the kerosene with calcium acetate. The amine is titrated in chloroform solution with a dioxan solution of perchloric acid using Thymol Blue as indicator. For the determination of an alkylphosphate the kerosene is shaken with sodium methoxide. This precipitates the sulphuric acid as sodium sulphate, which is insoluble in chloroform. Excess methoxide is back-titrated with perchloric acid to the blue/yellow end-point (pH 8·9) of Thymol Blue. The titration with perchloric acid is then continued to the yellow/red end-point of the indicator (pH 1·7). At this stage both amine and alkylphosphate are titrated, and the difference between this volume of perchloric acid and that used to titrate the amine alone is equivalent to the amount of alkylphosphoric acid.

Damodaran[54] has recently found that a chloroform solution of tetra-n-hexylammonium iodide will extract the highly coloured anion $[Co(NH_3)_2(NO_2)_4]^-$ of Erdmann's salt, to give a deeply coloured liquid anion exchanger. Such a solution had been used to study exchange equilibria for a number of anions. Typical results are

(a) $F^- < Cl^- < Br^- < I^-$,

(b) $Cl^- < ClO_3^- < ClO_4^-$,

(c) $BF_4^- < ClO_4^- < IO_4^- < ReO_4^- < MnO_4^-$.

Anions such as SO_4^{2-} and PO_4^{2-}, which carried more than unit charge, are not extracted at all. The concentration of erdmannate ion displaced into the aqueous phase by the competing anion can be determined spectrophotometrically and so used for indirect determination of the anion in question.

The determination of perchlorate ion using this indirect technique with the erdmannate ion has been described by Clifford and Irving.[55] Interference of many other ions is overcome by pretreatment of the solution with silver sulphate. The interference of chlorate can be serious; when the ratio of ClO_3^- to ClO_4^- is 10:1 the error is 5%, and at a ratio of 100:1 it is about 35%. The error can be reduced by reduction of the chlorate ion to chloride using sulphurous acid or iron(II) sulphate. If the necessary constants are known a suitable correction for the chlorate ion can be calculated.

The use of reagents of the Erdmann or Morland $[Co(NH_3)_2(SCN)_4]^-$ type opens up some interesting possibilities and will undoubtedly extend the use of liquid anion exchange.

FUTURE OF LIQUID ION EXCHANGERS

It is not because of low potentiality that liquid ion exchangers have not been accorded the attention of other extraction systems. As already pointed out, the use of liquid ion-exchange extraction dates from 1948, compared to, say, resinous ion exchange, which may be said to have started in 1935 with the discovery by Adams and Holmes of the ion-exchange properties of certain synthetic resins.[57]

The reasons for the lack of attention to liquid ion exchangers are not easily defined. Partly the cause may be lack of knowledge of the fundamental principles of the technique, and partly the belief that extractions with such materials are only an extension of normal solvent extraction processes and not a separate technique at all. The tendency for emulsion formation between the aqueous and organic phases may be a contributory cause, again because of lack of basic knowledge to enable this to be avoided. In most cases the need for stripping the organic extract to complete the analysis, compared with the ease with which the extracts from chelate extractions may be utilised directly for spectrophotometric measurement, has undoubtedly contributed to lack of interest in their use. On the other hand, the rapidity with which the ion-exchange process is completed using liquid exchangers, instead of resinous exchangers, does not appear to have been of such wide interest to the users of ion exchange as might have been expected. This is probably because many analytical separations using resinous exchangers are made by the techniques of 'selective elution' or 'frontal analysis'.

What then is needed to make the technique of liquid ion exchange acceptable to more analysts?

1. Greater basic knowledge of the principles involved.
2. Some means of assessing the relative 'strengths' of the exchangers.
3. Investigations into the change in extraction properties of the exchangers which occurs when the organic diluent is changed.
4. Greater selectivity in separations, *e.g.*, by choice of a suitable exchanger for the particular separation or by a suitable selective back-extraction technique.
5. Easier ways of employing the organic phase directly for determination of the extracted ions.

The possibilities of liquid ion exchangers are slowly becoming apparent as analytical methods employing these materials are published. Bennett and Marshall[18] pointed out the tedious nature of the current methods for the analysis of chrome ores and chrome-bearing materials and the discrepancies which can occur between laboratories analysing these materials. By employing liquid ion exchange the time taken in analysis was reduced appreciably and reproducibility improved.

Green[16] showed that liquid ion exchange could be made to work directly for the separation of uranium in cast iron without prior separation stages other than removal of the graphitic carbon. Selectivity was achieved without the use of complexing agents or close control of pH.

In their work on chromatographic separations, Cerrai and Testa[2,43,44] and Pierce *et al.*[47,48,49] have demonstrated that the often difficult separation of rare earth mixtures can be achieved quite readily using paper cellulose treated with liquid ion exchangers, while Damodaran,[54] Clifford and Irving[55] and Handley[42] have shown that the field of liquid ion exchange separations may become very much wider.

In radiochemical analysis, the fact that the activity of the organic phase may be measured directly shows a distinct advantage over the use of resin exchangers, where the particular isotopes have first to be eluted, then their activity measured.

Zusammenfassung—Eine Übersicht über neuere Anwendungen flüssiger Ionenaustauscher in der anorganischen Analyse wird vorgelegt.

Résumé—On présente une revue sur les emplois récents des échangeurs d'ions liquides en analyse inorganique.

DETERMINATION OF LOW CONCENTRATIONS OF ACETALDEHYDE IN ETHYLENE OXIDE

HERMAN HAGLUND
Research Laboratory, Mo och Domsjö AB, Örnsköldsvik, Sweden

(*Received* 22 *March* 1964. *Accepted* 8 *September* 1964)

Summary—The method is based on a qualitative test for acetaldehyde in which the reagents sodium nitroprusside and piperidine react with acetaldehyde to form a coloured substance that can be determined photometrically. This substance is unstable, however, and after reaching a maximum value in about 25 sec the absorbance decreases. Ethylene oxide also reacts with sodium nitroprusside to form brownish substances, but this reaction is slower, the colour not developing for 100–120 sec. If, therefore, the absorbance is measured about 25 sec after adding the reagents, any disturbance from the ethylene oxide is avoided.

INTRODUCTION

THE determination of impurities in ethylene oxide is complicated by its low boiling point and by its reactivity with a large number of substances, there being few reagents that do not produce disturbing side reactions. Gas chromatography and direct spectrophotometry can be applied for acetaldehyde concentrations down to about 20 μmole/ml, but it is necessary to be able to determine concentrations as low as 0.2 μmole/ml. The following photometric method has been worked out for this purpose.

PRINCIPLES

Sodium nitroprusside reacts with a number of substances to form coloured compounds. It also reacts with an aqueous solution of acetaldehyde in the presence of an organic base such as piperidine.[1,2] The mechanism of the reaction of sodium nitroprusside with acetaldehyde has been discussed by Williams.[3] The reaction was described for the first time by Simon,[4] and its use has since been reported in several papers.[5-9] The base used was piperazine. The reaction has been used as a qualitative test for acetaldehyde in water.[4] The resulting colour, which is bluish-red, attains its maximum intensity after 20–30 sec, and then quickly decreases, to be replaced after about 1 min by the same golden brown colour as is obtained from a blank. A method based on the sodium nitroprusside reaction with an aqueous solution of acetaldehyde has recently been published.[10]

When added to ethylene oxide, which reacts with amines, and consequently with piperidine, sodium nitroprusside and piperidine give a brownish colour after 100–120 sec. By mixing sample and reagents in the cell of a direct reading spectrophotometer the development of the colour may be followed. A maximum at 575 nm results from the reaction of acetaldehyde, and the absorbance reaches its highest value after about 25 sec and then decreases. After 90–120 sec the absorbance increases again, now because of the reaction of ethylene oxide with the reagents: the substances formed absorb all visible radiation strongly.

The procedure described below enables the absorbance maximum from the acetaldehyde reaction to be read off easily on the instrument. A calibration curve based on such readings obeys Beer's law, and gives a molar absorptivity of 2000–3500 litre.cm^{-1}.$mole^{-1}$, depending on the dilution of the sample. Experiments have shown that the logarithm of the absorbance is a linear function of the ethylene oxide concentration at a given acetaldehyde concentration, and that the absorbance increases with a decreasing ethylene oxide concentration. This means that a nomogram can be constructed in such a way that only one calibration curve is necessary to cover any dilution of the sample.

The reaction may be disturbed by a number of substances (*e.g.*, organic sulphides and mercaptans) but not by the impurities normally present in ethylene oxide made from ethanol or ethylene. Formaldehyde does not interfere with the reaction, because only aldehydes capable of forming aldoles, *i.e.*, compounds with at least two carbon atoms, react with sodium nitroprusside.[3]

EXPERIMENTAL

Reagents

Piperidine: Puriss.

Sodium nitroprusside: In aqueous solution, 10% w/w; dissolve 10 g of $Na_2[Fe(CN)_5NO]2H_2O$ in 90 ml of distilled water.

Apparatus

Beckman B spectrophotometer: Setting: wavelength, 575 nm; photomultiplier, position A; sensitivity, 2; slit width, *ca.* 0·11–0·12 mm.

Standard solutions

A calibration curve has to be drawn for a suitable dilution of freshly distilled ethylene oxide with distilled water. Two dilutions of the ethylene oxide samples may be used, one of 5% v/v (dilution A) for concentrations of acetaldehyde in the sample exceeding $2{\cdot}3 \times 10^{-6}$ mole/ml (0·01% w/v), and one of 20% v/v (dilution B) for lower concentrations. At room temperature it is difficult to obtain good results with samples of a higher ethylene oxide concentration than 20% because of the low boiling point of ethylene oxide.

If the dilutions A and B are chosen, prepare two series of standard solutions as follows: make stock solutions of dilutions A and B, each containing 0·005% of acetaldehyde w/v. Transfer known volumes of the stock solution to volumetric flasks, and make up to the mark to give the appropriate dilution A or B. Prepare at least 4 solutions in each series, with the acetaldehyde concentrations evenly distributed over the range of measurement.

Blanks

Prepare blanks for the adjustment of the instrument as follows (three blanks are recommended to ensure reliable adjustment): pipette 0·30 ml of sodium nitroprusside solution into a 1-cm cell. (Experiments, in which the volume of nitroprusside solution was varied from 0·1 to 0·4 ml, indicated that the optimum volume was 0·3 ml.) Pipette 2·00 ml of dilution A or B (without acetaldehyde) and 0·20 ml of piperidine into a 5-ml test-tube, and shake carefully for 10–15 sec to obtain a homogeneous mixture. To avoid the formation of bubbles do not invert the test-tube when mixing, but effect the mixing by small rapid lateral movements of the tube. Nor should the mixture be shaken too long, (at most 10–15 sec), because the heat of reaction may produce vapour bubbles. After shaking, transfer the solution to the cell by means of a pipette. To ensure complete mixing in the cell use a 2-ml pipette provided with a rubber bulb, or use a syringe. To avoid the formation of bubbles, direct the solution along the wall of the cell. Within the next 25 sec set the absorbance scale of the spectrophotometer at zero with the slit, because after this time the solution may turn brown. Repeat the procedure for 3 blanks. Only 1 zero adjustment is necessary for each test series.

Calibration curve

Treat the prepared standard solutions as described above under *Blanks*. Pipette 0·30 ml of sodium nitroprusside solution into a 1-cm cell. Pipette 0·20 ml of piperidine and 2·00 ml of the standard solution into a 5-ml test-tube, mix, and transfer the mixture to the cell. Perform the measurement at once and at room temperature. After the sample and reagents are mixed the absorbance increases to reach a maximum after *ca.* 25 sec: this lasts a few seconds, after which the absorbance decreases again. Read off the maximum value, and use this for drawing the calibration curve.

Dilution A gives a linear calibration curve in the concentration range of $0 - 2 \times 10^{-6}$ mole of acetaldehyde per ml of undiluted ethylene oxide ($0 - 9 \times 10^{-3}$% w/v; absorbance 0–0·6) and dilution B gives a linear curve in the range of $0 - 4{\cdot}5 \times 10^{-6}$ mole of acetaldehyde per ml of undiluted ethylene oxide ($0 - 20 \times 10^{-3}$% w/v; absorbance 0–0·6).

Measurements of samples

Dilute the unknown ethylene oxide sample with distilled water to 5% (dilution A) or 20% (dilution B), the dilution depending on the expected concentration of acetaldehyde. Set the spectrophotometer at zero as described under *Blanks*. Perform the measurements as described under *Calibration curve*, with the standard solution replaced by 2·00 ml of the diluted sample solution. As mentioned under *Principles*, there is a linear relationship between the logarithm of the absorbance and the degree of dilution of the ethylene oxide sample. Therefore a nomogram can be constructed where the calibration curve for a chosen dilution of ethylene oxide can be used for any dilution of the sample.

DISCUSSION

To obtain good results the determinations must be made with great care. Routine measurements have, however, been carried out at our laboratory for more than a year without difficulties.

The standard deviations are $1{\cdot}5 \times 10^{-8}$ and $2{\cdot}4 \times 10^{-8}$ mole per ml of ethylene oxide (original sample) for dilutions of 5 and 20 times, respectively, of the sample. Because the accuracy of the final results is dependent on the purity of the ethylene oxide used for making the calibration curve, it is important that this should be freshly and carefully distilled. We have used a Podbielniak column (120 theoretical plates) for the distillation.

The method is applicable to ethylene oxide samples diluted at least 4:1; otherwise bubbles appear which make it impossible to measure the samples in a spectrophotometer at room temperature. Large amounts of propionaldehyde or acrolein ($>0{\cdot}1$%) react with the sodium nitroprusside to increase the absorbance. The presence of formaldehyde does not affect the determination.

In most of the experiments piperazine has been used as the base. Lewin[1] describes experiments in which piperidine was used. A comparison between piperidine and piperazine that we carried out on samples with different concentrations of acetaldehyde showed that piperidine gives a 10 times higher absorptivity.

Acknowledgement—The author is very indebted to Mr. Jan Söderberg, who has carried out most of the experimental work and to Mrs. Margareta Carlson for translating the manuscript and for many valuable suggestions.

Zusammenfassung—Bei einer qualitativen Probe auf Acetaldehyd reagiert dieser mit Nitroprussidnatrium und Piperidin zu einer photometrisch bestimmbaren farbigen Substanz. Die Substanz ist jedoch instabil; die Extinktion sinkt von einem nach etwa 25 Sekunden erreichten Maximalwert wieder ab. Äthylenoxyd readiert auch mit Nitroprussidnatrium zu bräunlichen Produkten; diese Reaktion ist langsamer, die Farbe tritt erst nach 100–120-Sekunden auf. Wird daher die Extinktion etwa 25 Sekunden nach Zugabe der Reagentien gemessen, so wird die Störung durch Äthylenoxyd vermieden.

Résumé—La méthode est basée sur un essai qualitatif de l'acétaldéhyde dans lequel le réactif: nitroprussiate de sodium et pipéridine, réagit avec l'acétaldéhyde pour donner une substance colorée, qui peut être dosée photométriquement. Cette substance est toutefois instable, et après avoir atteint une valeur maximale en 25 secondes environ, l'absorption décroît. L'oxyde d'éthylène réagit aussi avec le nitroprussiate de sodium pour former des substances brunâtres, mais cette réaction est plus lente, la couleur ne se développant pas pendant 100–120 secondes. Si, par conséquent, l'absorption est mesurée environ 25 secondes après l'addition des réactifs, toute perturbation dûe à l'oxyde d'éthylène est évitée.

SEPARATION OF BISMUTH FROM LEAD, COPPER AND OTHER ELEMENTS BY MEANS OF ANION EXCHANGE

F. FEIK and J. KORKISCH
Analytical Institute, University of Vienna, IX, Währingerstrasse 38, Austria

(*Received* 30 *April* 1964. *Accepted* 15 *August* 1964)

Summary—The anion-exchange behaviour of bismuth and various other elements has been investigated in media consisting of methyl glycol and nitric acid. Through the determination of the distribution coefficients in such mixtures, a method for the anion-exchange separation of bismuth from many metal ions has been developed. A mixture of 90% methyl glycol and 10% 5*M* nitric acid is a suitable medium for this separation on the strongly-basic anion exchanger Dowex 1, X8. Only bismuth, thorium and lanthanum are strongly retained on the resin in these conditions. All other elements investigated, such as lead, copper, iron, *etc.*, are either only weakly adsorbed or are not absorbed. By means of this ion-exchange procedure, a series of analyses of copper-base alloys for bismuth has been carried out. The results show that this method can be used successfully for the quantitative isolation of bismuth from such materials. The final determination of bismuth in the eluates is performed by complexometric titration.

INTRODUCTION

THE anion-exchange behaviour of bismuth in pure aqueous nitric acid solutions has been investigated in detail by Buchanan and Faris,[1] who found that this element is rather weakly adsorbed on strongly basic anion-exchange resins, even at high concentrations of nitric acid; its adsorption is, however, markedly enhanced in the presence of ammonium nitrate. A similar increase has also been observed by Korkisch and Tera[2] in a 90% methanol–10% 5*M* nitric acid system, and Fritz and Greene[3] noted a similar phenomenon when they determined the distribution of bismuth in 1·5*M* nitric acid–85% isopropanol.

Because the adsorption of lead is comparatively high in both these organic solvent-nitric acid media, and also in 90% acetic acid–10% 5*M* nitric acid, as shown by Korkisch and Arrhenius,[4] a separation of these two elements from each other cannot easily be effected. Recent investigations by Korkisch and Feik[5] have shown that in a mixture consisting of 90% tetrahydrofuran and 10% 5*M* nitric acid the adsorption behaviour of bismuth and lead is such that a separation of these two elements can easily be carried out. Because bismuth is, however, accompanied by practically all other elements, its separation from metal ions such as copper, iron, nickel, zinc, *etc.*, is not feasible, and therefore a determination of bismuth in presence of all these elements is complicated by interferences. In order to overcome these difficulties several organic solvent-nitric acid mixtures have been studied. As a result of these investigations a medium consisting of methyl glycol and nitric acid has been found to be most suitable, not only for the separation of bismuth from lead, but also from practically all other elements usually present in copper-base alloys. The method described here can therefore be applied to the isolation and determination of bismuth in such alloys.

Because uranium can also easily be separated from bismuth, which is used in reactor cooling systems, this method might prove of importance in the field of reactor chemistry.

EXPERIMENTAL

Reagents

Ion-exchange resin: The strongly-basic anion exchanger Dowex 1, X8 (100–200 mesh, nitrate form) was used.

Standard solutions of bismuth and other elements: Solutions in $5M$ nitric acid, of precisely known element content, were employed.

Organic solvent: Methyl glycol of reagent-grade purity.

Wash solution: 90% (vol) of methyl glycol + 10% (vol) of $5M$ nitric acid.

Apparatus

The column operations were carried out in columns of the type and dimensions described earlier.[6] The height of the resin bed was 10 cm and its diameter 0·6 cm.

Quantitative determination of elements investigated

The determinations of bismuth and all other elements except uranium, which was determined fluorimetrically,[7] were performed by titration with $0{\cdot}01M$ or $0{\cdot}001M$ EDTA, using suitable indicators, *e.g.*, Xylenol Orange.

Determination of distribution coefficients

The distribution coefficients of all elements were determined in the manner described earlier.[8]

Column operations

All separations on resin columns were performed by the following working procedure.

Pretreatment of resin bed: Before passage of the sorption solution the resin was treated with 50 ml of the wash solution.

Sorption step: The sorption solution was prepared by diluting 2 ml of $5M$ nitric acid, containing the metal ions in question, with methyl glycol to 20 ml. This solution was passed through the column at a flow rate of 0·5 ml/min. During this operation, bismuth, thorium and lanthanum were strongly adsorbed, and lead to some extent; the other elements, such as copper, zinc, *etc.*, passed into the effluent.

Washing step: To remove lead completely from the column the resin bed was washed with 150 ml of the wash solution used in small portions.

Elution: The bismuth was eluted with 100 ml of $1M$ nitric acid. After evaporation of the eluate, bismuth was determined by titration with EDTA using Xylenol Orange as indicator.

In the analysis of copper-base alloys, 2 g of the sample were dissolved in nitric acid and the residue obtained after evaporation of the solution was dissolved in 10 ml of $5M$ nitric acid. To 1-ml aliquot of this solution 1 ml of a bismuth standard solution was added, and after dilution to 20 ml with methyl glycol the solution was passed through the column as described above. In blank runs, 1 ml of $5M$ nitric acid was used instead of the bismuth standard solution.

RESULTS

Investigation of the effect of methyl glycol concentration on the adsorption of bismuth at a constant over-all nitric acid concentration of $0{\cdot}5M$ (10% of $5M$ nitric acid) showed a linear decrease of the distribution coefficient with decreasing concentration of organic solvent.

An increase of the nitric acid concentration in solutions consisting of 90% methyl glycol caused the distribution coefficient of bismuth to increase linearly from 115 (in the presence of 10% of $2{\cdot}5M$ nitric acid) to 460 (in presence of 10% of $10M$ nitric acid). Although better adsorption can evidently be achieved in the latter case, mixtures with 10% of $5M$ nitric acid were invariably used for all other experiments, such as the separations, because the solubility of the nitrates of the investigated metal ions is still high enough in these media, whereas at much higher concentrations of nitric acid the solubility is low.

Loading experiments showed that the distribution coefficient of bismuth decreases with increasing load from 230 to 185, when equilibrating 5–30 mg of bismuth with 1 g of the resin.

Investigation of the adsorption of various other elements in 90% methyl glycol–10% 5*M* nitric acid media showed that besides bismuth only lanthanum and thorium are strongly retained on the resin. The results of these experiments are recorded in Table I.

TABLE I.—DISTRIBUTION COEFFICIENTS IN 90% METHYL GLYCOL–10% 5*M* NITRIC ACID ON DOWEX 1, X8

La^{III}	9,000·
Yb^{III}	4·
UO_2^{II}	6·6

It is seen that bismuth can easily be separated from most of the elements listed in Table I. Fractions of micrograms of the element can be separated from milligram quantities of other metals. For the quantitative separation from lead, however, a prolonged treatment with the wash solution is necessary (see *Experimental*).

Based on all these investigations several samples of copper-base alloys to which known amounts of bismuth were added have been analysed using the working procedure described above. From the results of these experiments, which are shown in Table II, it is seen that in all cases a quantitative separation of bismuth from the elements present in the samples was achieved, the error being within small limits. From a number of experiments with varying amounts of the elements, a relative standard deviation of ±1·65% was calculated.

In order to demonstrate the effectiveness of the separation method more clearly, a typical separation of lead from bismuth is shown in Fig. 1 from which it is seen that even when washing with 260 ml of the wash solution no trace of bismuth appears in the effluent. Because practically all other elements investigated except lanthanum

Zusammenfassung—Das Anionenaustauschverhalten von Wismuth und verschiedener anderer Elemente wurde in Medien bestehend aus Methyl-Glykol und Salpetersäure untersucht. Auf Grund von Bestimmungen der Verteilungskoeffizienten in solchen Mischungen wurde eine Methode zur Anionenaustauschtrennung des Wismuts von vielen Metallionen entwickelt. Eine Mischung bestehend aus 90% Methyl-Glycol und 10% $5M$ Salpetersäure erwies sich als am besten geeignet zur Trennung am stark basischen Anionenaustauscher Dowex 1, X8. Unter diesen Bedingungen werden nur Wismut, Thorium und Lanthan stark am Harz adsorbiert während alle anderen Elemente wie z.B. Blei, Kupfer, Eisen etc. überhaupt nicht oder nur schwach festgehalten werden. Mittels dieses Verfahrens wurde Wismut in einer Anzahl von Kupferlegierungen bestimmt. Die Ergebnisse dieser Untersuchungen zeigten, daß diese Methode erfolgreich zur quantitativen Abtrennung des Wismuts aus solchen Materialien angewendet werden kann. Die Endbestimmung des Wismuts in den Eluaten erfolgte durch komplexometrische Titration.

Résumé—On a étudié le comportement, au point de vue échange anionique, du bismuth et de divers autres éléments dans des milieux propylèneglycol-acide nitrique. Par la détermination des coefficients de distribution dans de tels mélanges, on a élaboré une méthode de séparation par échange anionique du bismuth de nombreux autres ions métalliques. Un mélange composé de 90% de propylèneglycol et 10% d'acide nitrique $5M$ s'est révélé être le milieu le plus convenable pour cette séparation, sur l'échangeur anionique fortement basique Dowex 1, X8. Seuls, le bismuth, le thorium et le lanthane sont fortement retenus sur la résine dans ces conditions, cependant que tous les autres éléments étudiés, tels le plomb, le cuivre, le fer, etc . . . , ne subissent qu'une adsorption faible ou nulle. Au moyen de cette méthode d'échange d'ions, on a effectué une série d'analyses, concernant le bismuth, sur des alliages à base de cuivre. Les résultats de ces recherches ont montré que cette méthode peut être utilisée avec succès pour l'isolement quantitatif du bismuth de tels matériaux. Le dosage final du bismuth dans les éluats a été effectué par titrage complexométrique.

NUCLEATION OF LEAD CHROMATE FROM HOMOGENEOUS SOLUTION

NORTON HABERMAN* and LOUIS GORDON
Department of Chemistry, Case Institute of Technology, Cleveland 6, Ohio, U.S.A.

(*Received* 13 *May* 1964. *Accepted* 10 *August* 1964)

Summary—On the basis of the Christiansen-Nielsen model for nucleation, the nucleus of lead chromate precipitated from homogeneous solution has been found to consist of about five ions. The critical supersaturation values of solutions of lead chromate are dependent upon the method of filtration; however, a change in supersaturation of about 25% is without effect on the size of the critical nucleus.

THE nucleation of sparingly soluble salts may be considered to take place in two steps, the first being the production of supersaturation within the system and the second the formation of the nucleus within the supersaturated system.[1,2] In the present investigation an attempt is made to elucidate the mechanism of nucleation of lead chromate, to determine the degree of supersaturation which must be attained for nucleation to occur, and to learn the effect of the degree of supersaturation on the size of the critical nucleus.

Christiansen and Nielsen[3] proposed that the mechanism of nucleation proceeds by a series of bimolecular collisions between precipitating ions and subcritical embryos. Klein, Gordon and Walnut[4] modified the Christiansen-Nielsen approach to make it applicable to the determination of the critical nucleus size in precipitations from homogeneous solution. In their modification, they obtained

$$N = k\int[\mathrm{I.P.}]^n\,dt \tag{1}$$

where N = number of nuclei and hence number of particles found,
k = a constant,
I.P. = ion product,
n = nucleus size,
and t = time.

Thus, by determining N, the number of particles formed, and evaluating the variation of the ion product with time, one can determine n, a measure of the number of ions in the critical nucleus. Klein *et al.*[4] studied the precipitation of silver chloride from homogeneous solution and determined that the critical nucleus consisted of five ions.

The present investigation was undertaken to study the nucleation of lead chromate from homogeneous solution. The chromate ion was generated by the reaction[5] of chromium(III) with bromate in the presence of lead ion, the stoichiometry of the reaction being:

$$10Cr^{3+} + 6BrO_3^- + 22H_2O \rightarrow 10CrO_4^{2-} + 3Br_2 + 44H^+.$$

---

EXPERIMENTAL

Reagents

All stock solutions were prepared from reagent-grade chemicals. All solutions, except lead and chromium(III) nitrates, were prepared by weighing the dry reagent and diluting to volume. The necessary dilutions were made with distilled water previously filtered through a Millipore HA filter. There was no further standardisation of these solutions.

The stock solution of lead was standardised gravimetrically by precipitation of the sulphate. The chromium(III) solution was standardised by oxidation to chromate with sodium peroxydisulphate, followed by addition of a known amount of iron(II) sulphate and titration with standard potassium permanganate.[6]

Apparatus

Spectrophotometric measurements were performed with a Beckman DU spectrophotometer fitted with a dual thermospacer set, which permitted circulation of water around the cell housing compartment to maintain constant temperature in the cells. Fused 10-mm silica cells were used.

Turbidimetric measurements were made using a Phoenix-Brice light scattering instrument equipped with a thermostatted jacket which encircled a cylindrical cell; a 430-mμ filter was used.

Procedure

Appropriate amounts of stock solutions of lead nitrate, potassium bromate, potassium nitrate and equimolar acetic acid-sodium acetate buffer were drawn through a Millipore filter into a 500-ml volumetric flask; potassium nitrate was used to vary the ionic strength of the medium. The resulting solution was diluted to approximately 400 ml with pre-filtered distilled water. A solution of chromium(III) ions was then introduced into the reaction mixture through the Millipore filter and the contents were diluted to volume with water. The time was measured from the moment of addition of chromium(III) ions to the other reagents. Portions of the solution were transferred to optical cells for spectrophotometric and turbidimetric measurements and to Erlenmeyer flasks for later use in sampling studies. All reaction vessels were maintained at 25° ± 0·2°.

Spectrophotometric determination of chromate. The photometer was used to determine the concentrations of chromate ion in the solution up to the onset of precipitation. The wavelength used was 340 mμ, at which the molar extinction coefficient for chromate ion is $1{\cdot}51 \times 10^6$ cm^2.mole^{-1}. Because the precipitate particles acted as light scattering centres, thus introducing an uncertainty in the absorbance readings, it was necessary to extrapolate the absorbance-time curve in order to determine the total chromate ion produced.

Titrimetric determination of lead. To determine the amount of lead ion precipitated and therefore the concentration of lead ion remaining in solution, it was necessary to pipette 50-ml portions of the reacting solution and transfer these into 50-ml Erlenmeyer flasks suspended in the constant temperature bath. Then, approximately 40 min after the start of precipitation and every 20 min thereafter, one of the samples was filtered through a Millipore VC filter. The precipitate particles on the walls of the flask and on the filter were dissolved in concentrated potassium hydroxide, the solution transferred to a 100-ml volumetric flask and analysed for chromate; the amount of lead ion precipitated was determined from this measurement.

Turbidimetric determination of onset of precipitation. Turbidimetric measurements were made to determine the time at which precipitation began. The relative turbidity was plotted as a function of time and the inception of precipitation taken to be the time at which there was a sharp increase in the slope of the turbidity-time curve.

RESULTS AND DISCUSSION

Size of nucleus

The solution concentrations of lead and chromate ions were determined from the analytical results; a typical plot of the variation of the ion product ($[Pb^{2+}].[CrO_4^{2-}]$) with time is shown in Fig. 1. The lead concentration in solution was considered to be that remaining uncomplexed by acetate.[7] According to equation (1), when the variation of the ion product with time and the quantity of nuclei, *i.e.*, the particle count, is known, it is possible to determine the number of ions in the critical nucleus. (The particle count was determined microscopically.)

For each experiment, the *ion product* was plotted as a function of *time*. If the ion product, raised to a power x (selected integral values), is plotted *versus* time the area under the curve is the value $\int(\mathrm{I.P.})^x\,dt$. If this value is divided by the particle count N, a value of $1/k$ is obtained. For each selected value of x, $1/k$ for each run was plotted *versus* $\int(\mathrm{I.P.})^x\,dt$. Where $d(1/k)/d\int(\mathrm{I.P.})^x\,dt$ *versus* x was zero, the term $1/k$ was taken as constant and x to be equal to n, where $2n - 1$ represents the number of ions in the critical nucleus. The limits for the integration of $(\mathrm{I.P.})^x$ *versus* time were chosen to include essentially all ion products at which nucleation was occurring. For these experiments the limiting ion product chosen was $1{\cdot}70 \times 10^{-9}$ mole^2.l.$^{-2}$.

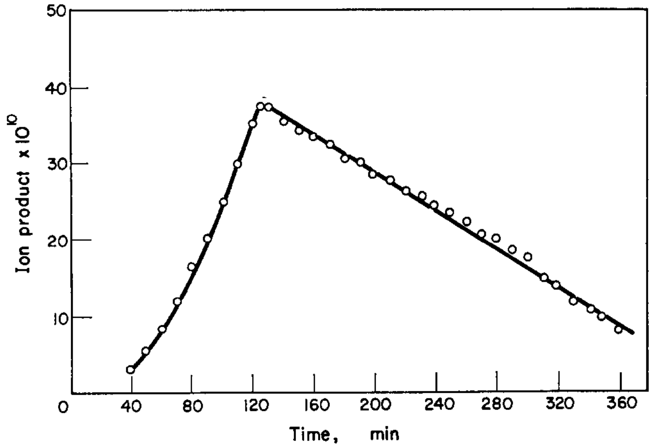

FIG. 1.—Ion product of lead chromate as a function of time during the precipitation.

Table I summarises the values used in the determination of the critical nucleus size. The results indicate n to be three; therefore, the number of ions in the critical nucleus is five.

[a] Millipore HA filter used.

The values presented in Table I are for experiments conducted with Millipore HA filters (pore size = 0·45 μ). In order to determine whether the filtration process has any effect on the nucleus size, an analysis of the results from experiments using Millipore VC filters (pore size = 0·1 μ) was made. These results are shown in Table II. Again, n was found to be three, showing the number of ions in the critical nucleus to be independent of the filter pore size.

This part of the study demonstrates the use of kinetic methods to determine the size of the critical nucleus of lead chromate, thus supporting the model for nucleation proposed by Christiansen and Nielsen. Although the critical nucleus of lead chromate consists of five ions, the significance of this number is its order of magnitude. Christiansen and Nielsen's induction time experiments, used to determine the nucleus size, have been criticised because the use of direct mixing of reactants may possibly cause nucleation to occur during the mixing process rather than having it occur after the system becomes homogeneous. The present work eliminates the effect of direct mixing by using the technique of precipitation from homogeneous solution, with, however, the results still in agreement with the model for nucleation as proposed by Christiansen and Nielsen.

[a] Millipore VC filter used.

Effect of supersaturation

This phase of the investigation involved a study of the effect of filtration, the rate of generation of the chromate ion and the variation of the ionic strength of the medium upon the supersaturation ratios which were reached before precipitation was first observed. The "critical"* supersaturation ratio, S_{crit}, is defined as $[(I.P.)/K_{sp}]^{\frac{1}{2}}$, where K_{sp} is the equilibrium solubility product. The turbidimetric measurements were used to determine the time of inception of precipitation. The concentration of chromate ion used for the ion product was taken from the absorbance-time curve and the lead ion concentration was taken as the uncomplexed ion initially present.

Effect of filtration on S_{crit}. Two filters of different pore size were used in the preparation of the reacting solutions; these were Millipore HA filters with a nominal pore size of 0·45 μ and Millipore VC filters with a nominal pore size of 0·1 μ. The results of these experiments are shown in Table III, S_{crit} being calculated on the basis of concentration. The supersaturation ratios varied inversely with the pore size of the filter. With the HA filter, S_{crit} is 104 ± 3; with the VC filter, it is 128 ± 8, *i.e.*, a 25% change for the four-fold variation in filter pore size.

If nucleation occurs by a heterogeneous process involving a foreign body, then the finer filter must remove some of the larger (or more active) nucleation sites so that the

---

* A purely critical value does not exist (*cf.* Nielsen[13]). It appears to be critical only because the rate of formation of nuclei changes drastically with supersaturation. As a result, the experimental range, within which the rate of nuclei formation can be followed, is quite restricted.

system can become more supersaturated before nucleation occurs. Thus the first step in the nucleation mechanism, rather than being a reaction between the two ions comprising the precipitate, is a "reaction" between either one or other of their ions (or both) and a foreign site M, as follows:

$$\mathrm{M} + \mathrm{Pb}^{2+} = \mathrm{MPb}^{2+}$$

or

$$\mathrm{M} + \mathrm{CrO_4}^{2-} = \mathrm{MCrO_4}^{2-}$$

Effect of rate of generation of chromate ion. The rate was altered by varying the concentration of chromium(III) and bromate ions in the reacting solutions. The results of these experiments are shown in Table IV; the times indicated are those at which precipitation was first detected turbidimetrically. It was noted, although the times varied considerably (45–157 min), that there was no change in S_{crit}. If the value of the supersaturation ratio were not critical, but merely dependent upon the time required for the system to reach a particular supersaturation,[8] one might expect that the value of the supersaturation ratio atwhich precipitation is first detected should change. This result was not observed for the nucleation of lead chromate. Thus, the supersaturation ratio is truly "critical" at least for the particular set of experimental conditions utilised here.

Effect of ionic strength of reacting solution. The ionic strength was varied by adding known quantities of potassium nitrate; the mean activity coefficient for lead chromate was calculated from the Debye-Hückel equation. The results of these experiments are shown in Table V. The critical supersaturations show no apparent variation with change in ionic environment. This is a surprising result, for if the mechanism for nucleation involves an ionic dependence, then a large concentration of foreign ions would decrease the electrostatic attraction between the ions which can form the precipitate. Possible explanations for the results obtained are either (1) that the range over which the ionic strength was varied was insufficient or (2) that these experiments were conducted above a limiting value of the ionic strength. If the latter were the case, any further increase in the ionic strength would be without effect upon nucleation. Further, the values used for the mean activity coefficient for lead chromate may be inaccurate; LaMer and Dinegar[10] comment in a similar manner in their study of the precipitation of barium sulphate.

Relation between nucleus size and supersaturation

It is informative to examine the relationship between supersaturation and nucleus size according to the Ostwald-Freundlich equation:[11]

$$r = \frac{2\sigma M}{RT\rho \ln S}$$

where r = radius of the nucleus,
σ = interfacial tension,
M = molecular weight,
ρ = density,
S = supersaturation,
and R and T have their usual meanings.

When this equation is used to calculate the size of the nucleus of lead chromate, using values of 40 for the supersaturation and of 150 dynes/cm² for the interfacial tension,[11] the radius is found to be 40 Å. This radius is considerably greater than that of the Christiansen-Nielsen model, for which the rather small nucleus size of five ions is found. Furthermore, there is no interdependence of nucleus size and supersaturation as with the Ostwald-Freundlich equation. A homogeneous 40-Å radius nucleus would contain hundreds of ions. It seems improbable that a nucleus of such size could be built up either by a kinetic process or by concentration fluctuations. One possibility is that the bulk of such a nucleus might consist of a heterogeneous site (solvent or foreign impurity) with the ions contributing little volume to its actual size. Thus, it has been suggested that the Ostwald-Freundlich nucleus consists of the ions and the foreign site while the Christiansen-Nielsen nucleus is the ion aggregate only.[12]

Acknowledgment—The authors acknowledge the partial assistance of the United States Atomic Energy Commission in supporting the investigation described herein under contract AT(11-1)-582.

Zusammenfassung—Auf Grund des Keimbildungsmodells von Christiansen-Nielsen wurde gefunden, daß der Keim für die Fällung von Bleichromat aus homogener Lösung aus etwa 5 Ionen besteht. Die Werte für die kritische Übersättigung von Bleichromatlösungen hingen von der Filtrationsmethode ab; eine Änderung der Übersättigung um etwa 25% wirkte sich aber auf die Größe des kritischen Keimes nicht aus.

Résumé—Sur la base dur modèle Christiansen-Nielsen pour l'amorçage on a trouvé que le germe de chromate de plomb précipité d'une solution homogène est constitué par environ cinq ions. Les valeurs critiques de sursaturation des solutions de chromate de plomb dépendent de la méthode de filtration; toutefois, un changement d'environ 25% dans la sursaturation est sans effet sur la dimension du germe critique.

SEPARATION AND DETERMINATION OF TANTALUM AND NIOBIUM BY PRECIPITATION FROM HOMOGENEOUS SOLUTION*

R. DAMS and J. HOSTE
Laboratory of Analytical Chemistry, Ghent University, Belgium

(*Received* 23 *May* 1964. *Accepted* 27 *July* 1964)

Summary—An attempt to separate niobium and tantalum by precipitation from homogeneous solution by thermal decomposition of their peroxy complexes, in the presence of tannin and oxalate, has been only moderately successful. A more satisfactory separation of tantalum and niobium for ratios from 50:1 to 1:30 is obtained by extracting the bisulphate melt with ammonium oxalate before adding hydrogen peroxide, hydrochloric acid and tannin. For a tantalum/niobium ratio of 1:1 the niobium coprecipitation is reduced to 5%. Furthermore, two alternative possibilities are presented: (1) a quantitative recovery of a tantalum precipitate at small oxalate and high tannin concentration, leaving 90% of the tantalum-free niobium in solution; (2) an 85% recovery of niobium-free tantalum at high oxalate and small tannin concentration. A study of the coprecipitation process of niobium shows that the distribution coefficients follow a logarithmic pattern, true homogeneous mixed crystals being formed.

INTRODUCTION

BECAUSE of the similarity of their chemical properties, the gravimetric separation of tantalum and niobium from each other has always presented a very difficult problem in analytical chemistry. Probably the most reliable, but tedious, procedure for the separation is a fractional tannin precipitation. This procedure, developed by Powell and Schoeller,[1] is based on the difference in the stability of the oxalato-complexes. Precipitation from homogeneous solution was recently proposed by the present authors for the separation and determination of tungsten,[2] titanium, tantalum and niobium,[3] based on the thermal decomposition of soluble peroxy complexes from a hydrogen peroxide medium. An analogous procedure can readily be adapted for the separation and determination of niobium and tantalum. Radioactive tracer techniques were used to develop the proposed method.

EXPERIMENTAL

Radioisotopes

Tantalum. ^{182}Ta, β,γ-emitter, half-life ± 111 days, produced by irradiation of Ta_2O_5 in the BR-1 reactor.

Niobium. ^{95}Nb, β,γ-emitter, half-life ± 35·5 days, obtained from the Radiochemical Centre, Amersham, England.

Counting techniques. Integral γ-counting was performed for ^{182}Ta and ^{95}Nb using a standard scintillation counter with a well-type sodium iodide (thallium activated) crystal. In the presence of each other they were measured by differential γ-counting, using a 3″ × 3″ sodium iodide (thallium activated) crystal connected to a 400-channel analyser.

---

* This work is part of the research sponsored by "Het Interuniversitair Institut voor Kernwetenschappen".

Procedure

Precipitation of tantalum. Fuse the mixture of the oxides with potassium bisulphate and remove the cold melt from the crucible by warming with 5% ammonium oxalate. Rinse the contents of the crucible into a beaker and heat with water until a clear solution is obtained. Add 2 ml of 30% hydrogen peroxide, an adequate amount of 12*M* hydrochloric acid and an amount of tannin corresponding to 20 times the weight of the acids. Dilute the solution with water to obtain a final concentration of earth acid oxides of 0·02%, an ammonium oxalate concentration of 1% and an acidity of 2·5*M* hydrochloric acid. Decompose the peroxides by heating at 85° for 7–8 hr, and collect the dense precipitate. Some results are summarised in Table III.

Precipitation of niobium. Evaporate the filtrate from the tantalum precipitation to about 200 ml, and add 5–10 ml of nitric acid (sp. gr. 1·4) to clarify the dark-coloured solution. Oxidise the excess of oxalate with an adequate amount of sodium bromate, added dropwise. Neutralise with aqueous ammonia and precipitate the niobium with a ten-fold excess of tannin. Heat the solution to boiling over 5 min.

Precipitation of Tantalum from Homogeneous Solution

Tantalum is incompletely precipitated (95%) by the thermal decomposition of soluble peroxy-tantalate and -niobate in a homogeneous ammonia-hydrogen peroxide solution at pH 10 or 11; niobium is coprecipitated (at least 40%). Thermal decomposition of peroxytantalate in an acetate, citrate or tartrate solution, in the presence of tannin, results in an incomplete and voluminous precipitation. In an acid oxalate-tannin solution, however, a dense and readily filterable precipitate was obtained. Preliminary experiments showed that optimum results were obtained in an acidic medium (5*M* nitric acid); recoveries of 99·8% were achieved.

Separation of tantalum and niobium

In the present case, γ-spectrometric measurements offer a relatively simple means of determining the amounts of coprecipitated niobium as a function of the amount of precipitated tantalum. The gamma rays at 1·12, 1·15, 1·19, 1·22 and 1·23 *MeV* of ^{182}Ta can be measured independently from the activity of ^{95}Nb. The ^{95}Nb content can be computed from the activity under the 0·776 *MeV* peak, after subtraction of the Compton continuum of ^{182}Ta. For ^{182}Ta, the ratio of the activity under the peaks at about 1·2 *MeV* to the activity in the energy range about 0·776 *MeV* is, under standard conditions, a constant.

It appears that for the precipitation of tantalum from the homogeneous peroxide solution, optimum results are obtained in the presence of 1200 mg of oxalic acid, together with tannin and selenous acid. The respective amounts of the latter should correspond to 7 and 0·5 times the weight of the pentoxides. Different amounts of tantalum were precipitated from 200 ml of solution. The results are given in Table I.

TABLE I.—PRECIPITATION OF THE EARTH ACIDS AS A FUNCTION OF THEIR CONCENTRATION

50·1	50·0	10	0·9	19
75·2	75·1	5	1·3	34

From Table I it appears that from the most dilute solution 99·4% of the tantalum was recovered, the niobium coprecipitation being reduced to 10·5%.

A decrease of the coprecipitation was observed by extracting the bisulphate melt of 20 mg of tantalum pentoxide and 20 mg of niobium pentoxide with ammonium oxalate before adding the hydrogen peroxide. The precipitations were also carried out in the presence of different amounts of nitric, hydrochloric and selenous acids, ammonium oxalate and tannin, the volume of the solution being 200 ml.

Typical results are given in Table II.

TABLE II.—SEPARATION OF THE EARTH ACIDS IN THE PRESENCE OF AMMONIUM OXALATE

$(NH_4)_2Ox$, %	Acid	Ratio to the oxides (w/w)		Heating period, *hr*	Ta left in solution, %	Nb coprecipitated, %
		H_2SeO_3	Tannin			
1	4·5*M* HNO_3	1	10	20	1·5	7·2
1	3*M* HNO_3	1	10	10	4·9	6·4
1	1·5*M* HCl	1	10	10	26·5	1·1
1	2·5*M* HCl	1	10	20	3·3	2·7
1	3·5*M* HCl	1	25	12	5·1	2·9
1	2·5*M* HCl	0	25	7	0·3	8·4
0·75	2·5*M* HCl	0	25	7	1·7	7·0
0·50	2·5*M* HCl	0	25	12	0·5	12·5
0·50	2·5*M* HCl	2	25	14	0·1	11·5
1·25	2*M* HCl	0	7	7	15·0	<0·5

From Table II it appears that, from a 0·5% ammonium oxalate solution and in the presence of a large amount of selenous acid, tantalum can be precipitated homogeneously with recoveries of 99·9%. From the γ-ray spectrum of the solution before and after precipitation, it is clear that the ^{182}Ta activity in the filtrate is undetectable. The last result given in Table II shows that it is possible to precipitate 85% of practically niobium-free tantalum. In the γ-ray spectrum of the precipitate, the niobium-peak at 0·776 *MeV* can barely be seen, although in the original solution it was as important as in the standard. These precipitations are interesting for preparative purposes. For a rapid analysis, however, optimum results were obtained by following the procedure, as shown in Table III.

TABLE III.—PRECIPITATION OF TANTALUM FROM HYDROGEN PEROXIDE OXALATE SOLUTION

Ta_2O_5 taken, *mg*	Ta left in solution, %
140·1	0·60
109·8	0·49
79·9	0·71
57·3	0·64
42·1	0·65
33·4	0·81
20·7	0·87
16·6	1·5^3
10·0	1·9^0
8·0	2·1^8

From Table III it appears that precipitation of tantalum from a homogeneous hydrogen peroxide-oxalate solution gives satisfactory tantalum recoveries.

Coprecipitation of niobium

The coprecipitation of niobium was investigated for niobium/tantalum ratios varying from 2 × 10^{-2} to 30. The absolute amount of tantalum precipitated varied from 100 mg for small ratios to 5 mg for larger ratios. The results are given in Fig. 1.

From Fig. 1 it appears that for a Nb_2O_5/Ta_2O_5 ratio equal to one the error on the tantalum determination is 5·5 %. If the precipitation is repeated, the error is reduced to 1 %. A correction can be made after a single precipitation if this ratio is higher than unity.

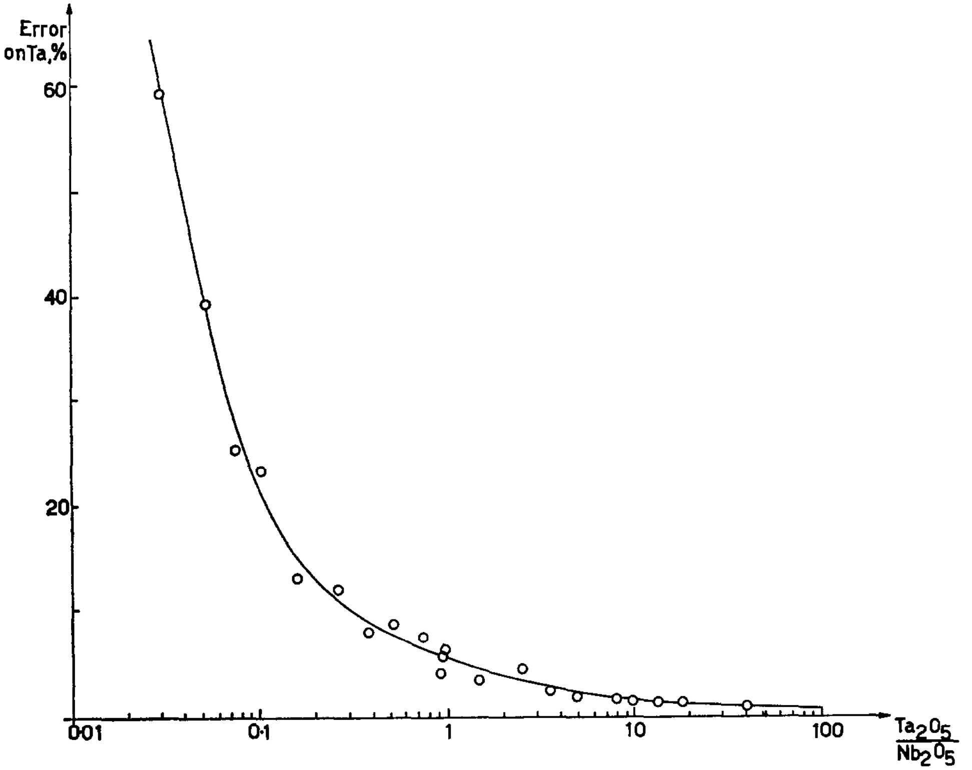

FIG. 1.—Coprecipitation of niobium with tantalum.

Precipitation of niobium from the filtrate after precipitation of tantalum

The amount of niobium left in solution was computed by adding, before the fusion, an adequate amount of ^{95}Nb of known activity (*ca.* 1 × 10^6 cpm) and counting an aliquot of the filtrate. The results are summarised in Table IV. It appears that this precipitation gives highly satisfactory niobium recoveries. The small amounts of tantalum and titanium present are coprecipitated quantitatively.

Determination of Distribution Coefficient

A coprecipitant can be distributed between solid and liquid phase according to an homogeneous,[4] logarithmic[5] or proportional distribution law.[6] As was shown in previous papers,[2,3] the coprecipitation process of molybdenum and vanadium with tungstic acid and of tungsten with the earth acids follows a linear pattern. In the present case, measurements of the radioactive isotopes offer a relatively simple means of determining the amount of coprecipitant as a function of the amount of precipitated carrier. To effect this, a small quantity of solution was removed at regular time intervals. The amount of each element present was then computed by γ-ray spectrometric analysis.

TABLE IV.—PRECIPITATION OF NIOBIUM IN THE FILTRATE

Taken, *mg*		Nb left in solution, %
Ta_2O_5	Nb_2O_5	
19·7	100·4	0·05
20·6	80·0	0·10
20·5	60·3	0·09
20·2	40·1	0·13
20·7	20·8	0·13
20·5	10·6	0·07
40·5	10·4	0·12
60·1	10·1	0·14
80·2	10·2	0·07

Procedure

Extract with 50 ml of 5% ammonium oxalate after bisulphate fusion of 43·8 mg of tantalum, and 5·6 mg of niobium, labelled with ^{182}Ta and ^{95}Nb, and transfer to a 400-ml conical flask fitted with a reflux condenser. Add 2 ml of 30% hydrogen peroxide, 50 ml of 12*M* hydrochloric acid and 1·5 g of tannin. Make the volume up to 300 ml. The activities of the tracer solutions are chosen to correspond respectively to *ca.* 3×10^6 and 5×10^6 cpm of ^{182}Ta and ^{95}Nb. Heat the solution for 7 hr at 85° and remove 5-ml portions by reverse filtration through an asbestos filter. Count 4-ml portions of these filtrates in standard vials with a multichannel analyser. The values of D, λ and K, corresponding to the different distribution constants, are presented in Table V.

From Table V it appears that the logarithmic distribution law is followed, the mean value being $\lambda = 0{\cdot}030_4 \pm 0{\cdot}001_3$.

TABLE V.—COPRECIPITATION OF NIOBIUM WITH TANTALUM

Ta pptd., %	Nb copptd., %	Distribution coefficients		
		D	λ	K
$42{\cdot}5_1$	$1{\cdot}7_4$	$0{\cdot}023_9$	$0{\cdot}031_8$	$0{\cdot}040_9$
$72{\cdot}6_3$	$4{\cdot}3_8$	$0{\cdot}017_4$	$0{\cdot}034_6$	$0{\cdot}060_3$
$83{\cdot}7_8$	$6{\cdot}3_6$	$0{\cdot}013_1$	$0{\cdot}036_1$	$0{\cdot}075_9$
96·38	$9{\cdot}9_7$	$0{\cdot}0041_6$	$0{\cdot}031_6$	$0{\cdot}10_3$
97·56	$10{\cdot}4_9$	$0{\cdot}0029_3$	$0{\cdot}029_8$	$0{\cdot}10_7$
$98{\cdot}82_5$	$11{\cdot}3_6$	$0{\cdot}0015_2$	$0{\cdot}027_1$	$0{\cdot}11_5$
$99{\cdot}17_6$	$11{\cdot}6_7$	$0{\cdot}0011_0$	$0{\cdot}025_8$	$0{\cdot}11_8$
$99{\cdot}25_9$	$12{\cdot}2_3$	$0{\cdot}0010_4$	$0{\cdot}026_5$	$0{\cdot}12_3$
			$\bar{\lambda} = 0{\cdot}030_4 \pm 0{\cdot}001_3$	

Furthermore, the experiments showed that the coprecipitation of niobium on tantalum also follows a logarithmic distribution if the bisulphate melt of the earth acids is extracted with hydrogen peroxide, the mean value of the distribution coefficient being $\lambda = 0{\cdot}067 \pm 0{\cdot}005$.

In this case, 61·5 mg of tantalum were precipitated in the presence of 5·25 mg of niobium. The concentration of oxalic acid was 1·5%; the solution contained 50 ml of 14*M* nitric acid and the precipitation was carried out with 0·75 g of tannin for a volume of *ca.* 200 ml. The results are presented in Table VI.

TABLE VI.—COPRECIPITATION OF NIOBIUM WITH TANTALUM (MELT EXTRACTED WITH HYDROGEN PEROXIDE)

Zusammenfassung—Einem Versuch zur Niob-Tantal-Trennung durch homogene Fällung in Gegenwart von Tannin und Oxalat durch thermische Zersetzung der Peroxykomplexe war nur mäßiger Erfolg beschieden. Eine bessere Tantal-Niob-Trennung in Verhältnissen von 50 : 1 bis 1 : 30 wurde jedoch erzielt durch Extraktion des Bisulfataufschlusses mit $(NH_4)_2Ox$ vor der Zugabe von H_2O_2, HCl und Tannin. Beim Niob-Tantal-Verhältnis 1 : 1 wird die Mitfällung von Niob auf 5% gedrückt. Darüber hinaus werden zwei Alternativen vorgeschlagen: 1) quantitative Tantalausbeute im Niederschlag bei kleiner Oxalat- und großer Tanninkonzentration, wobei 90% des Tantal-freien Niob in Lösung bleiben; 2) 85%-ige Ausbeute von Niob-freiem Tantal bei hoher Oxalat- und niedriger Tanninkonzentration. Die Verteilungskoeffizienten der Mitfällung von Niob verlaufen logarithmisch; es werden homogene wahre Mischkristalle gebildet.

Résumé—Un essai de séparation du niobium et du tantale par précipitation en milieu homogène en présence de tanin et d'oxalate, en effectuant la décomposition thermique des peroxy complexes, n'a été que moyennement satisfaisant. On a toutefois obtenu une séparation plus satisfaisante du tantale et du niobium, pour des rapports allant de 50 : 1 à 1 : 30, en extrayant la masse de fusion au bisulfate avec $(NH_4)_2Ox$ avant addition de H_2O_2, HCl et tanin. Pour un rapport tantale/niobium 1 : 1, la coprécipitation du niobium est réduite à 5%. En outre, on présente deux possibilités: 1) une récupération quantitative d'un précipité de tantale à faible concentration en oxalate et forte concentration en tannin, laissant 90% du niobium exempt de tantale en solution; 2) une récupération de 85% en tantale exempt de niobium, à forte concentration en oxalate et faible concentration en tanin. L'étude du processus de coprécipitation du niobium montre que les coefficients de distribution suivent un diagramme logarithmique; il se forme un vrai cristal mixte homogène.

GRAVIMETRIC ANALYSIS OF TANTALOCOLUMBITES BY PRECIPITATION FROM HOMOGENEOUS SOLUTION*

R. DAMS and J. HOSTE
Laboratory of Analytical Chemistry, Ghent University, Belgium

(*Received* 23 *May* 1964. *Accepted* 27 *July* 1964)

Summary—An analysis of complex tantalocolumbites has been carried out by precipitation from homogeneous solutions. A homogeneous precipitation of tungsten, titanium, tantalum and niobium by thermal decomposition of the soluble peroxytungstates, described in previous papers, is used. Corrections for incomplete precipitation and coprecipitation phenomena are applied on the basis of the experimentally found values. Silicon and tin are separated by volatilisation as fluoride and iodide, respectively. Iron is extracted by means of isopropyl ether and the rare earth metals are precipitated homogeneously from an oxalate solution. Manganese is precipitated as the ammonium phosphate. The results are in good agreement with an independent method, the standard deviations being within 1% for the major constituents.

INTRODUCTION

As shown in previous papers,[1-3] tungsten, titanium, tantalum and niobium can be separated and determined by precipitation from a homogeneous hydrogen peroxide solution. In the present work the method is tested on a number of synthetic and natural minerals, containing tantalum and niobium.

Qualitative analysis

Before carrying out the quantitative determination of three natural minerals, a spectrochemical qualitative analysis by means of a d.c. arc was effected. A quartz-prism spectrograph was used in the wavelength range of 2600–3950 Å and 2750–4200 Å. The results are given in Table I.

TABLE I.—Spectrochemical analysis of the minerals

Mineral	I	II	III
Major constituents	Nb, Ta, Fe, Mn	Nb, Ta, Fe, Mn, Ti	Nb, Ta, Fe, Mn, Ti, Cr, rare earths
Minor constituents	Ti, Si, Sn, W	W, Si, Sn, Mn	W, Sn, Si, Mg, Mo, Th
Traces	Cr, Zr, Al, Mo, Mg	Cr, Zr, Al, Mo, Pb	As, Zr, Al, Pb

Discussion of method

Because tin(IV) oxide and silica are only slightly attacked by a bisulphate fusion, and because the melt is only extracted with hydrogen peroxide-nitric acid, tin(IV) oxide and silica are found almost quantitatively in the residue. They are volatilised as the tetra-iodide and tetrafluoride, respectively; the content of silicon and tin is then computed by difference.

Tantalum, niobium and tungsten are separated by precipitation from a homogeneous hydrogen peroxide-nitric acid solution. They are separated and determined by homogeneous precipitation from a slightly alkaline hydrogen peroxide and from an oxalate-tannin-hydrogen peroxide medium. From the filtrate of the earth acids

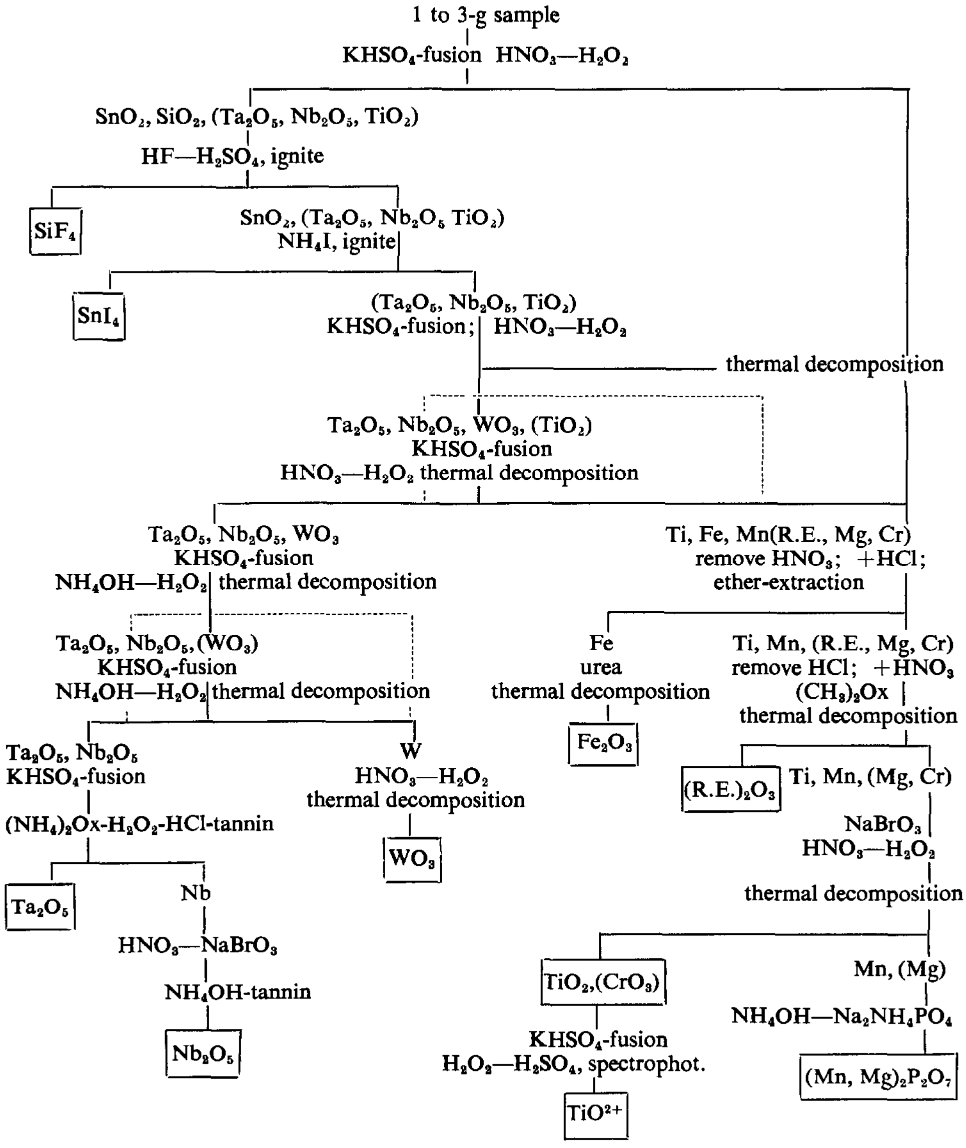
---

* This work is part of the research sponsored by "Het Interuniversitair Instituut voor Kernwetenschappen".

precipitation, iron is extracted with isopropyl ether, without manganese and titanium interference.[4] From a homogeneous hydrogen peroxide-nitric acid solution (pH 2·5) titanium precipitates practically quantitatively.[2] Manganese is obtained as manganese ammonium phosphate,[5] contaminated with small amounts of magnesium. The rare earths present in Mineral III are separated and determined as oxalates by a homogeneous precipitation with dimethyl oxalate.[6] In the presence of chromium (Mineral III), the precipitate of titanium is contaminated and was determined colorimetrically as peroxide in this precipitate.

An outline of the general scheme of the analysis is given in Fig. 1.

FIG. 1.—General scheme of analysis



Procedure. Fuse 1–3 g of finely powdered mineral with 5–15 g of bisulphate and dissolve the melt in hot 3% hydrogen peroxide. After neutralising with aqueous ammonia, acidify the solution to obtain 5*M* nitric acid. Filter the solution into an 800-ml beaker and transfer the precipitate to a platinum crucible. Add 4 ml of concentrated hydrofluoric acid and 1 ml of sulphuric acid and volatilise the silicon as silicon tetrafluoride. Take the residue twice to dryness with 2–3 ml of 14*M* nitric acid. Ignite the residue to constant weight at 950° to convert the sulphates and nitrates into the oxides. The silica content is found by difference. Add a ten-fold excess of ammonium iodide and 1 ml of hydriodic acid and stannictetriodide and heat at 475°. Repeat the process to ensure complete removal of tin. The loss in weight represents the amount of tin(IV) oxide. Fuse the residue with bisulphate and dissolve the melt in a few ml of 3% hydrogen peroxide and transfer the solution to the original filtrate. Heat at *ca.* 85° for 7 hr, in the presence of 0·1 g of selenous acid. Filter the hot solution and wash the precipitate with hot 1% nitric acid until free from sulphate. Incinerate and ignite the precipitate at 950° for 1 hr to constant weight. Fuse the mixed oxide residue with bisulphate in a silica crucible and leach the melt with 3% hydrogen peroxide and with dilute aqueous ammonia. Carefully adjust the pH of the solution to 7·5–8. After adding 0·1 g of selenous acid, heat the solution at 85° for 8 hr; tantalum and niobium are precipitated from this homogeneous solution. Collect the precipitate on a filter paper and wash with hot 2% alkaline ammonium nitrate until free from sulphate. Ignite the precipitate at 950° to constant weight as $(Ta, Nb)_2O_5$. For the determination of small amounts of titanium and tungsten repeat the precipitation steps from nitric acid and from slightly alkaline solution to reduce the coprecipitation of the latter. Evaporate the filtrate from the precipitation from alkaline medium, containing the bulk of the tungsten to *ca.* 150 ml and add 2 ml of 3% hydrogen peroxide and 75 ml of 14*M* nitric acid. Heat the solution at 60° for 2 hr. As soon as the precipitate has settled, filter from the hot solution, wash with hot 1% nitric acid, incinerate and ignite to constant weight at 900°. Weigh as WO_3. Fuse another two fractions, of *ca.* 125 mg, of the mixed oxides with bisulphate and transfer the crucible to an 800-ml beaker. Dissolve the melt in 120 ml of hot 5% ammonium oxalate solution. Add 120 ml of 12*M* hydrochloric acid, 2 ml of hydrogen peroxide (30%) and 2·5 g of tannin, dilute the solution to 600 ml. Heat for 7 hr at 85°. Filter the precipitate from the hot solution, wash with hot 2% ammonium chloride and ignite at 950° for 1 hr to constant weight. Weigh as Ta_2O_5. Evaporate the filtrate to *ca.* 200 ml. Remove the oxalate by adding a few ml of 14*M* nitric acid and a suitable amount of sodium bromate (3 g). Neutralise the solution with aqueous ammonia and add a ten-fold excess of tannin to the boiling solution. Boil for a few minutes until the precipitate settles. Filter and wash with hot 2% ammonium nitrate. Ignite the residue at 950° for 1 hr to constant weight as Nb_2O_5.

The filtrate from the earth acids precipitations contains titanium, iron, manganese and, in the case of Mineral III, chromium, rare earths and magnesium. Take almost to dryness and treat the residue with 50 ml of 12*M* hydrochloric acid. Repeat the operation to ensure complete removal of the nitric acid. Dissolve the residue in 300–800 ml of 8*M* hydrochloric acid and extract the iron repeatedly with isopropyl ether. Test for complete iron removal with thiocyanate. Shake the ether-phase three times with water to back-extract the iron. Neutralise the solution with aqueous ammonia and reacidify with dilute hydrochloric acid. Add 10 g of urea and boil the solution until neutrality is obtained; allow the precipitate to settle. To ensure complete precipitation of the iron, add a few ml of aqueous ammonia. Filter, wash and ignite the precipitate to constant weight as Fe_2O_3. For the determination of titanium, manganese and the rare earths, hydrochloric acid must be removed by the addition of 14*M* nitric acid and evaporation. Repeat the process twice. If rare earths are present, neutralise the solution with aqueous ammonia to pH 0·2, add 2 ml of 30% hydrogen peroxide and 30 ml of dimethyloxalate reagent solution (40 g of dehydrated oxalic acid dissolved in 100 ml methanol) to the solution and boil gently for 1 hr. Add an excess of 4 g of oxalic acid and boil for 0·5 hr. Filter the precipitate, wash with hot 2% oxalic acid and ignite at 950° to constant weight. Cover the crucible during cooling, and weigh quickly without removing the cover because the oxides absorb moisture and carbon dioxide from the air. Oxidise the excess of oxalate in the filtrate with sodium bromate in a nitric acid medium. Add 1 ml of hydrogen peroxide (30%), neutralise the solution to pH 2·5 and subject the peroxytitanates to thermal decomposition at 85° for 6 hr. Collect the precipitate and wash with hot 2% ammonium nitrate. Ignite the precipitate to TiO_2 at 950°. In presence of much chromium fuse the precipitate and extract with sulphuric acid. Add a few ml of hydrogen peroxide (30%) and determine the titanium by spectrophotometry at 410 mμ. To the filtrate from the titanium precipitation add aqueous ammonia and disodium ammonium phosphate. Collect the precipitate on a Gooch crucible and redissolve with sulphuric acid. Reprecipitate manganese and magnesium, if present, as ammonium phosphates. Collect the precipitate and ignite to constant weight at 650° as $(Mn, Mg)_2P_2O_7$. The tantalum, niobium, tungsten and titanium precipitates are filtered on SS 589^3 and the iron precipitate on SS 589^1 filter papers.

The results for tantalum, niobium, tungsten, titanium and manganese were corrected for incomplete recovery and for coprecipitation, corrections being applied according to the experimentally found values.[1–3]

[b] Titanium content determined colorimetrically, the difference between the colorimetric and gravimetric determination being given as chromium.

[c] Analysis by Société Genérale Métallurgique de Hoboken.

The double precipitation used for the analysis of the 3-g samples reduces the coprecipitation of titanium and tungsten to a considerable extent. When calculating the weighed mean values and the standard deviations for the titanium and tungsten, a three-fold weight was given to these results.

Before carrying out the analyses of the 3 minerals, the tantalum, niobium, tungsten, titanium, silicon and tin contents of a synthetic mixture were determined following the same procedure. The results are given in Tables II, III, IV and V.

From Tables III–V it appears that the results are mostly in good agreement with the results of an analysis performed elsewhere by an independent procedure. The deviation of the results of the major elements (tantalum, niobium, iron and manganese) are within 1 %. The larger deviation in the case of tungsten and titanium is obviously caused by the fact that the contents are only small in the presence of large amounts of earth acids. Chromium interferes with the gravimetric determination of titanium.

Acknowledgments—Thanks are due to the "Société Générale Métallurgique de Hoboken" for providing the samples of tantalocolombites. The technical assistance of Miss M. Helsen is gratefully acknowledged.

Zusammenfassung—Eine Analyse komplizierter Tantalocolumbite wurde mittels Fällungen aus homogener Lösung ausgeführt. Homogene Fällung von Wolfram, Titan, Tantal und Niob durch thermische Zersetzung der löslichen Peroxywolframate wird verwendet, wie in den vorhergehenden Arbeiten beschrieben. Korrekturen für unvollständige Fällung und Mitfällung werden auf Grund der experimentell gefundenen Werte angebracht. Silicium und Zinn werden durch Abdestillieren als Fluorid bzw. Jodid abgetrennt. Eisen wird mit Isopropyläther extrahiert, die seltenen Erden homogen aus Oxalatlösung gefällt und Mangan als Ammoniumphosphat niedergeschlagen. Die Ergebnisse stimmen gut mit einer unabhängigen Methode überein, die Standardabweichungen für die Hauptbestandteile liegen unter 1 %.

Résumé—On a effectué une analyse de tantalocolumbites complexes par précipitation à partir de solutions homogènes. On emploie une précipitation homogène des tungstène, titane, tantale et niobium par décomposition thermique des peroxytungstates solubles, qui a été décrite dans des mémoires antérieurs. Sur la base des valeurs trouvées expérimentalement, on applique des corrections pour la précipitation incomplète et pour les phénomènes de coprécipitation. Le silicium et l'étain sont séparés par volatilisation à l'état de fluorure et d'iodure. Le fer est extrait au moyen d'éther isopropylique et les métaux des terres rares sont précipités en milieu homogène à partir d'une solution oxalique. On précipite le manganèse avec le phosphate d'ammonium. Les résultats sont en bon accord avec une méthode indépendante, les écarts types étant à 1 % près pour les principaux constituants.

DETERMINATION OF ZINC AND CADMIUM IN THE PRESENCE OF EACH OTHER

RUDOLF PŘIBIL and VLADIMÍR VESELÝ
Analytical Laboratory, Polarographic Institute of J. Heyrovský
Czechoslovak Academy of Sciences, Prague 1, Jilská 16
Czechoslavokia

(*Received* 27 *May* 1964. *Accepted* 15 *September* 1964)

Summary—A new method for separating cadmium from zinc by precipitation as $Cd(phen)_2I_2$ is reported. Even very small amounts of zinc can be determined complexometrically in highly ammoniacal media by back-titration of an added excess of DCTA with calcium(II) using Methylthymol Blue as indicator.

CADMIUM and zinc form complexes with EDTA of almost identical stability ($\log K_{CdY} = 16{\cdot}46$, $\log K_{ZnY} = 16{\cdot}50$), so it is necessary to separate them for their complexometric determination in mixtures. Some years ago Přibil[1] proposed diethyldithiocarbamate for precipitation of cadmium after the complexometric determination of the sum of zinc and cadmium in slightly ammoniacal solutions. Kinnunen and Wennestrand[2] removed small amounts of cadmium by precipitation with thiourea. The adsorbed zinc was then removed by extracting its thiocyanate complex into an ether-amyl alcohol mixture. Recently, Fabregas, Prieto and Garcia[3] masked cadmium with a lead-EDTA complex. The displaced equivalent amount of lead was then precipitated as sulphate and removed from the solution by filtration. In the filtrate zinc was determined by EDTA titration with Eriochrome Black T as indicator. The results are satisfactory up to the weight ratio Zn:Cd = 1:17. Only one method for the determination of cadmium in the presence of zinc without previous separation is known; Flaschka and Ganchoff[4] titrated cadmium with ethyleneglycol-bis-(β-aminoethylether)-*N*,*N*-tetra-acetic acid (EGTA) solution, using copper sulphate as indicator. The end-point was detected spectrophotometrically by the appearance of the first traces of a blue copper-EGTA complex. With this method cadmium can be determined up to a 1:500 ratio of Cd:Zn.

None of the mentioned methods is, however, suitable for the determination of zinc in the presence of high concentrations of cadmium. Because one can hardly expect to find a specific masking agent for cadmium, we have searched for a new method for its separation from zinc. From preliminary experiments it was ascertained that cadmium precipitates quantitatively in a well filtrable form as $Cd(phen)_2I_2$. We have now found simple conditions where no adsorption of zinc occurs. The precipitation of cadmium as a phenanthroline-iodide complex is much more selective than the analogous precipitation as a phenanthroline-thiocyanate complex which has been used for the gravimetric determination not only of cadmium but also of copper, manganese, nickel and cobalt.[5]

---

* Part XVI: *Talanta*, 1964, **11**, 1545.

The last three elements do not precipitate at all in the presence of iodide with phenanthroline. Amounts of cadmium even smaller then 5 mg can be separated by the proposed method.

EXPERIMENTAL

Reagents:

0·1*M o-Phenanthroline solution:* Add 1·8 g of solid *o*-phenanthroline to 50 ml of water, dissolve by dropwise addition of 1*M* hydrochloric acid, then dilute to 100 ml.

0·05*M DCTA solution:* Dissolve 17·72 g of 1,2-diaminocyclohexanetetra-acetic acid (J. R. Geigy, Basel, Switzerland) in hot water by adding 130 ml of 1*M* sodium hydroxide. Dilute to 1 litre. The pH of the solution should be *ca.* 5. Standardise by a complexometric titration with lead nitrate using Xylenol Orange as the indicator.

Other reagents: 0·05*M* cadmium nitrate, 0·05*M* zinc nitrate (prepared by dissolving metallic zinc in nitric acid), 0·05*M* calcium chloride (prepared by dissolving calcium carbonate in hydrochloric acid), solid potassium iodide, solid urotropine, Methylthymol Blue (1:100 with solid potassium nitrate).

Precipitation of cadmium as Cd(phen)$_2$I$_2$

To precipitate cadmium in a well defined crystalline form without adsorption of zinc great care has to be taken. The original pH of the solution must be 2·5–3·5, otherwise a voluminous precipitate adsorbing zinc is formed; also, the washing out of the precipitate on the filter is very important. The following procedure is considered to be most advantageous. Adjust the pH of the solution containing cadmium and zinc to 2·5–3·5, add 0·5–1·0 g of potassium iodide and heat to boiling. Add, dropwise, 0·1*M o*-phenanthroline solution until no further precipitate is formed. Cease boiling the solution and adjust the pH to 4·5–5 with solid urotropine. Intense stirring with a glass rod speeds up the formation of a crystalline precipitate, which settles easily. With small amounts of cadmium (< 5 mg) let the solution stand for 1 hr in a water-bath. Filter the precipitate through a paper filter (Black or White ribbon) and wash out the precipitate on the filter 8–10 times with a warm (50–60°) wash solution.[*] All of the zinc is in the filtrate.

Determination of zinc

In slightly acidic media zinc is completely complexed by *o*-phenanthroline,[6] but in strongly ammoniacal media the Zn(phen)$_2^{2+}$ complex is broken down. An ammonia-ammonium chloride buffer of pH 9–10, suitable for titrations with Eriochrome Black T, is not sufficiently concentrated and aqueous ammonia is required. Under these conditions the titration with EDTA does not have a sufficiently sharp change of pZn^{2+} at the equivalence point and it is better to use an indirect determination with DCTA solution.

Procedure. To the filtrate from the separation of cadmium add an excess of 0·05*M* DCTA (at least 30%) and 20–30 ml of concentrated aqueous ammonia. Add Methylthymol Blue and back-titrate with a solution of 0·05*M* calcium chloride to an intense blue coloration. The end-point is very sharp and reversible. A greater excess of aqueous ammonia than that given has no influence on the titration.

A number of determinations of zinc in the presence of small and high concentrations of cadmium have been made following the procedure. The results are shown in Table I.

TABLE I.—DETERMINATION OF ZINC AND CADMIUM

[*] 10 ml 0·1*M o*-phenanthroline in 500 ml of water.

DISCUSSION

The separation of cadmium as $Cd(phen)_2I_2$ is rather selective. Manganese, nickel and cobalt are not precipitated, but copper and lead must be absent. This offers a further possibility of determining cadmium gravimetrically as $Cd(phen)_2I_2$. In this case, iron(III), lead, *etc.*, could be screened with EDTA. This enables some simplified analyses of alloys containing cadmium, zinc and other elements to be made. These practical applications will be discussed elsewhere.

Zusammenfassung—Eine neue Methode zur Trennung von Cadmium und Zink durch Fällung von Cadmium als Cd-Phenanthrolin-Jodid $Cd(phen)_2J_2$ wird angegeben. Auch sehr kleine Zinkmengen werden in stark ammoniakalischem Medium komplexometrisch durch Rücktitration von DCTA mit Calciumsalz bestimmt. Methylthymolblau wird als Indikator verwendet.

Résumé—On décrit une nouvelle méthode pour séparer le cadmium du zinc, par précipitation à l'état d'iodure de cadmium-phénanthroline, $Cd(Phen)_2I_2$. Même de très petites quantités de zinc sont dosées par complexométrie en milieu fortement ammoniacal, par titrage en retour du DCTA au moyen d'un sel de calcium. On prend pour indicateur le bleu de méthylthymol.

THE DETERMINATION OF ACETONE IN BUTANONE-2 BY PHASE SEPARATION

D. W. ROGERS*
Chemistry Department, Long Island University
Brooklyn 1, New York, U.S.A.

(*Received* 1 *June* 1964. *Accepted* 2 *July* 1964)

Summary—Binary solutions of acetone in butanone-2 have been analysed by adding a constant amount of water and determining the temperature at which phase separation takes place. Because butanone-2 and water have a lower critical solution temperature, solutions are clear at lower temperatures and opalescent at higher temperatures. The weight percent of acetone in the original binary solution of ketones is a function of the phase-separation temperature, enabling the analyst to construct a calibration curve and determine unknown solutions directly. The error is about 0·1 absolute %.

MANY binary solutions exhibit a miscibility gap and, at certain concentrations, separate into two phases. Each phase is, itself, a binary solution. As the temperature of the system is increased, the composition of each phase usually approaches that of the other. Normally, at some temperature, the compositions of the phases become the same and the components become miscible in all proportions. This temperature is called the upper critical solution temperature. Less commonly, the liquid components become more soluble in each other as the temperature decreases and are completely miscible in all proportions below a temperature minimum. Such a temperature minimum is called a lower critical solution temperature. Some systems have both lower and upper critical solution temperatures.

Small amounts of impurities have a profound effect on the solubility curves of partially miscible binary solutions.[1] As long ago as 1914, Findlay suggested the critical solution temperatures as a criterion of purity,[2] and phase separation is the basis of a number of analytical methods, including the cloud-point method of determining water[3–7] and binary mixtures,[8–9] and the cloud- and aniline-point methods of characterising petroleum products[10] and fats.[11]

Because many binary solutions have miscibility gaps which are displaced by any one of an indefinite number of impurities, the phenomenon of phase separation should be capable of much wider analytical application than it now enjoys. This work is an example of the application of the phenomenon of phase separation to the subtle analytical problem of the accurate determination of the ratio of acetone to butanone-2 in binary solutions. It is novel in the application of the lower critical solution temperature to an analytical problem.

THEORY

Butanone-2 and water have an upper and a lower critical solution temperature. Because the lower critical solution temperature is more readily accessible, we will consider it in the following discussion. Acetone, being completely miscible with both

---

* Address for 1964–65: American School of Madrid, Apartado 80, Madrid, Spain.

butanone-2 and water, increases their mutual solubility and increases the lower critical solution temperature. If a calibration curve were constructed of the critical solution temperature of butanone-2 in ternary solutions with water and acetone, as a function of the ratio of acetone to butanone-2, unknowns could be determined by comparison. Critical solution temperatures would be determined by varying the amount of water in combination with a given ratio of acetone to butanone-2 and recording the minimum temperature of phase separation. The method would not be useful for determining the amount of water in any ternary solution because the temperature of phase separation is not very sensitive to small changes in composition of the system with respect to water.

Because the shape of the solubility curve is flat over a wide composition range in the region of the critical solution temperature, a considerable experimental simplification can be achieved. A convenient composition near the critical solution composition is selected, keeping the amount of water constant throughout, and the temperature of phase separation is determined. This avoids the necessity of determining the entire lower part of the solubility curve. The exact critical solution composition is not selected because it is not accurately known and it may change with increasing amounts of acetone.

EXPERIMENTAL

Reagents

Reagent-grade acetone and butanone-2 and distilled water were used throughout.

Procedure

Ten ml of a binary solution of acetone in butanone-2 are put in a test-tube with an equal amount of water. After cooling the solution below the temperature at which it becomes homogeneous and clear, it is allowed to warm slowly and, at the appearance of the first slight haze, the temperature is recorded to the nearest 0·1°. To prevent separation into two layers, the solution is stirred using a magnetic stirrer and a short stirring bar rotating at low speed. If turbidity occurs above room temperature, a water bath is used. In all cases, the rate of heating is less than 1° per min.

RESULTS

Fig. 1 is the calibration curve of the solution temperature of ternary solutions of acetone, butanone-2 and water at constant water composition. The temperature is plotted as a function of the weight percent of acetone in the original binary solution to which the water was added. The lower limitation of the curve is the point at which ice begins to separate from the water-rich phase and the upper limit is the boiling point of the organic rich phase. These are about −6 and 60°, respectively. The calibration curve has not been taken to these extremes because at the lower temperature, bubbles, arising from stirring, interfere with the observation of turbidity. They do not float out because of the increased viscosity of the solution at low temperatures. The upper extreme was avoided to prevent slight changes in composition from vaporisation. Any solution outside the useful composition range can be adjusted by standard addition of one of its components.

Observation of phase separation

Because the refractive indices of the phases are not very different, the turbidity which appears as the system goes from one to two phases is light. Viewed against a black background with cross illumination, phase separation produces a slight haze which, despite its unspectacular nature, is unmistakable and occurs within 0·1°. Stirring should be slow and intermittent up to the point of phase separation to prevent interference by bubbles.

The solution temperatures were approached from both lower and higher temperatures. Agreement was within 0·4°, indicating little kinetic lag. For maximum reproducibility, only those solution temperatures observed on increasing the temperature were used for analytical purposes.

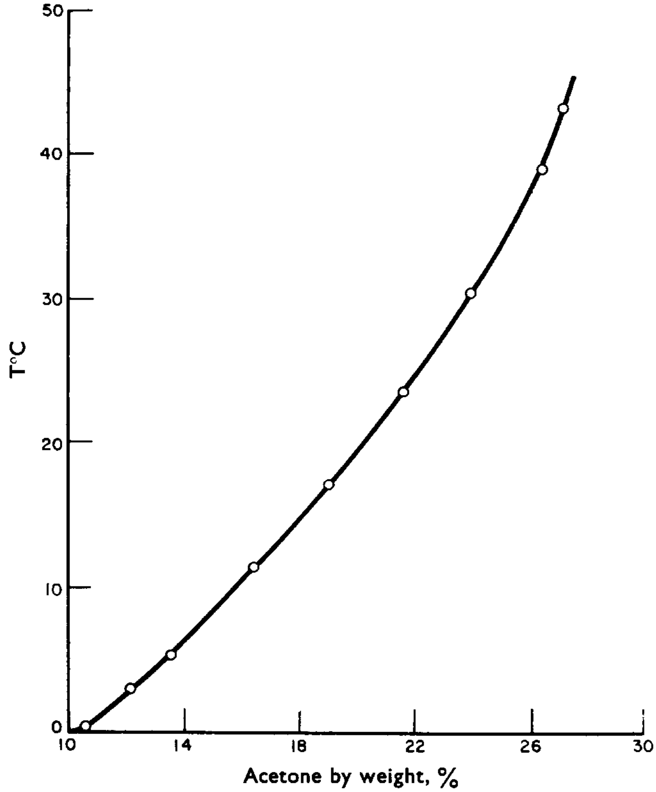

FIG. 1.—The temperature above which phase separation takes place for solutions of acetone, butanone-2 and water. The composition is constant with respect to water.

Potential accuracy of the method

The phase separation temperature can be determined with an error of less than 0·2° for replicate samples. The minimum slope of the calibration curve is 0·65% per degree and its maximum slope is 0·21% per degree at higher temperatures. Therefore, the minimum error should be about 0·13% at lower temperatures and 0·04% at higher temperatures. The extreme sensitivity of the solubility of butanone-2 in water to the presence of acetone makes this method one of high potential accuracy.

Comparable methods of analysing binary solutions are by density and refractive index measurements. The difference in density between acetone and butanone-2 is 0·0140 g/ml.[12] Assuming a minimum error of 0·0002 g/ml in density measurements, the error is about 1·4%.

The difference in refractive index between acetone and butanone-2 is 0·0216.[12] Assuming a minimum error of 0·0002 in refractive index measurement, the resulting analytical error is slightly less than 1%.

Interferences

All foreign substances interfere with analysis by phase separation. Like the comparable physical methods of density and refractive index, analysis by phase separation is strictly applicable only to binary solutions or solutions in which the amount of interfering substance is absolutely constant from one sample to the next.

One common impurity, water, does not interfere to a serious extent if its concentration is low. Because of the flat shape of the solubility minimum, small variations in the ratio of water to the organic components do not cause large changes in the solution temperature. The addition of 0·1 ml of water in excess of the usual amount increases the solution temperature by 0·1° for a solution showing phase separation at 30·4°. The addition of 0·1 ml of ethanol to the same system raised the solution temperature by more than 6°.

If the amount of water, the most common impurity, is less than 1% there will be no noticeable effect on the solution temperature. The amount of water which may be tolerated varies with the composition of the solution being analysed because the shape of the solubility curve varies with composition.

Applications

Like density and refractive index, phase separation will usually be useful only when the solutions being analysed are known to be binary solutions. An example is in the determination of the theoretical plates of a distilling column by analysis of the distillate and residue of a solution which is known to be binary.

Routine analysis is most convenient by phase separation when acceptable limits of concentration have been set. One constant temperature bath can be set to the temperature of the lower limit of concentration and another to the temperature of phase separation of the upper limit. Duplicate samples can be allowed to come to temperature equilibrium, one in each bath. If one is turbid and the other is not, the sample is within the concentration limits specified.

Phase separation is a method of cross checking other methods applicable to binary solutions. If a solution is assumed to be binary but is contaminated by a third substance, density, refractive index or phase separation measurements, taken singly, will give false results. If analysis by all three methods gives results which check with each other, the original solution was binary.

CONCLUSION

Analysis of binary solutions by phase separation at a lower consolute temperature has been illustrated by the system acetone in butanone-2. The method has the advantages of accuracy, simplicity and generality. It has the disadvantage of great susceptibility to interference.

Zusammenfassung—Binäre Lösungen von Aceton in Butanon-2 wurden analysiert durch Zusatz einer konstanten Wassermenge und Bestimmung der Temperatur, bei der Phasentrennung eintritt. Da Butanon-2 und Wasser eine untere kritische Lösungstemperatur haben, sind die Lösungen bei tiefen Temperaturen klar und bei höheren trübe. Der

Gewichtsprozentsatz von Aceton in der binären Ketonlösung ist eine Funktion der Trübungstemperatur. Damit kann man eine Eichkurve aufstellen und unbekannte Lösungen direkt bestimmen. Der Fehler beträgt etwa 0,1% absolut.

Résumé—On a analysé des solutions binaires d'acétone et de butanone-2, par addition d'une quantité constante d'eau et détermination de la température à laquelle on observe une séparation de phases. La butanone-2 et l'eau ayant une température critique inférieure de miscibilité, les solutions sont claires aux plus basses températures, et opalescentes aux températures plus élevées. Le pourcentage en poids de l'acétone dans la solution binaire initiale des cétones est une fonction de la température de séparation des phases. L'analyste peut ainsi construire une courbe d'étalonnage et doser directement des solutions inconnues. L'erreur est d'environ 0,1% absolu.

ANION-EXCHANGE SEPARATION OF BERYLLIUM, VANADIUM AND OTHER ELEMENTS FROM LARGE AMOUNTS OF URANIUM

J. KORKISCH and S. S. AHLUWALIA
Analytical Institute of the University of Vienna, IX
Wahringerstrasse 38, Austria

(*Received* 22 *June* 1964. *Accepted* 9 *September* 1964)

Summary—A method is described for the anion-exchange separation of small quantities of beryllium, vanadium, magnesium, calcium, aluminium, gallium and indium from gram-amounts of uranium. For this purpose, a medium consisting of 95% methanol and 5% $5M$ nitric acid is passed through a resin bed of Dowex 1, X8. By subsequent washing of the resin with a methanol-nitric acid mixture of the same composition, these metal ions are preferentially eluted from the column, whereas uranium is still retained by the anion exchanger. In the eluates the elements are determined by means of spectrophotometric or titrimetric procedures.

INTRODUCTION

RESEARCH work carried out by Buchanan and Faris[1] has shown that uranium is only weakly adsorbed on strongly basic resins from aqueous nitric acid solutions. This fact has been employed to separate uranium, together with other weakly adsorbed elements, from those which are strongly adsorbed, such as thorium and bismuth.

When the nitrate concentration of such solutions is increased, as, for instance, by adding the nitrates of ammonium,[2] aluminium[3,4] or nickel,[4] the uptake of uranium by these resins is considerably enhanced, and quantitative adsorption can be achieved. These methods, however, suffer from the disadvantage that large amounts of salts will be present in the effluent in which the non-adsorbable elements have to be determined. In addition, gross quantities of vanadate and other anions would compete with uranium for resin sites, thus limiting the quantitative retention of uranium.

In mixed aqueous-organic solvent systems, in which the distribution coefficients of most elements are considerably higher than in pure aqueous nitric acid solutions, uranium is also more strongly adsorbed, as has been shown in detail by Korkisch and coworkers.[5,6]

Based on these observations an attempt has been made to find a means of separating large amounts of uranium as the nitrate from milligram or microgram quantities of other metal ions, such as beryllium and vanadium, which might be present in uranium used as a reactor fuel, or in uranium compounds obtained after the processing of uraniferous materials such as carnotite ores.

EXPERIMENTAL

Reagents

Ion-exchange resin: The strongly basic anion exchanger Dowex 1, X8 (100–200 mesh; nitrite form) was used.

Standard solutions of uranium and other elements: $5M$ nitric acid solutions of the nitrates, of exactly known element content, were employed.

Organic solvent: Reagent-grade methanol.

Wash solution: 95% (v/v) methanol- 5% (v/v) 5*M* nitric acid.

Apparatus

Ion-exchange columns: The column operations were carried out in resin columns of 75 cm length and a diameter of 1 cm.

Spectrophotometer: For the spectrophotometric determination of all elements investigated, with the exception of uranium which was determined fluorimetrically, the Beckman Model B spectrophotometer was employed.

Fluorimeter: The photoelectric fluorimeter employed was a Galvanek Morrison Fluorimeter, Mark V.

Quantitative determinations

Determination of uranium: The quantitative determination of uranium in the effluents was performed fluorimetrically by means of a procedure described by Schönfeld, El Garhi, Friedmann and Veselsky.[7]

Determination of other elements: The convenient and accurate photometric procedures described by Sandell[8] and by Snell and Snell[9] were used to determine microgram amounts of all metal ions investigated except beryllium, for the assay of which the following method was developed:

To 1 ml of 5*M* nitric acid, containing not more than 20 μg of beryllium, are added 1 ml of a 1% solution of Neothoron in methanol and 1 ml of 0.1*M* EDTA solution (disodium salt), and the solution is diluted to 10 ml with 2*M* sodium acetate solution. Spectrophotometric measurement is carried out at 570 mμ.

Under these experimental conditions, Beer's law is obeyed from 0 to 20 μg of beryllium/10 ml of measured solution. The addition of EDTA reduces the number of interfering elements considerably, so that in practice only appreciable amounts of aluminium and iron interfere slightly. Uranyl ions would cause strong interference when present, but they are removed by the ion-exchange step.

The determination of milligram quantities of the elements investigated was performed by using suitable titrimetric methods, mostly employing titration with 0.01 or 0.001*M* solutions of EDTA.

Column operations

Through the resin bed, pretreated with 100 ml of the wash-solution, were passed 20 ml of a mixture consisting of 1 ml of 5*M* nitric acid (containing uranium and the other element to be separated from uranium) and 19 ml of methanol, at a flow rate of 0.5 ml/min. The column was washed at the same rate with the wash solution, effecting the preferential elution of the second element; uranium passes only slowly down the column. When performing the test runs, each 5-ml portion of the effluent was collected and analysed for the metal ion in question and for uranium. After complete elution of the element, uranium is removed from the column by washing with a mixture consisting of 50% methanol–45% water–5% 5*M* nitric acid. The composition of this mixture is not critical, but after elution the resin can be regenerated better than if aqueous nitric acid only were used. In addition, excessive bubble formation is prevented.

RESULTS AND DISCUSSION

In Table I, the results of a series of separation experiments, carried out according to the ion-exchange procedure described above, are recorded. In all cases quantitative separation can be achieved, even when 10 g of uranium are present in the sorption solution. To demonstrate the effectiveness of this separation procedure the break-through volumes of uranium and the elution volumes of the other elements have been included in the table. As the elution volume, the ml of wash solution necessary to elute completely the element in question was taken. The break-through volumes of uranium are the ml of effluent in which uranium is detectable by means of the fluorimetric procedure.[7] Because the elution and break-through volumes are always more or less distinct, quantitative separation can thus be ensured.

Attempts to separate cadmium or strontium from uranium were unsuccessful.

Investigations carried out using other aliphatic alcohols in place of methanol have shown that in these solvents the separation of uranium from the metal ions investigated here is less advantageous, because of stronger adsorption by the resin.

TABLE I.—SEPARATION OF BERYLLIUM, VANADIUM(V), MAGNESIUM, CALCIUM, ALUMINIUM, GALLIUM AND INDIUM FROM URANIUM

Zusammenfassung—Es wird eine Methode beschrieben mittels der geringe Mengen an Beryllium, Vanadium, Magnesium, Calcium, Aluminium, Gallium und Indium von Grammengen Uran durch Anionenaustausch getrennt werden können. Zu diesem Zweck wird eine Lösung bestehend aus 95% Methanol und 5% 5*M* Salpetersäure durch ein Harzbett aus Dowex 1, X8 fließen gelassen. Beim darauffolgenden Waschen des Harzes mit einer Methanol-Salpetersäuremischung derselben Zusammensetzung werden diese Metallionen bevorzugt von der Säule eluiert während Uran weiterhin vom Anionenaustauscher festgehalten wird. In den Eluaten werden dann die Elemente mittels spektrophotometrischer oder titrimetrischer Verfahren quantitativ bestimmt.

Résumé—On décrit une méthode de séparation, par échange anionique, de petites quantités de beryllium, vanadium, magnésium, calcium, aluminium, gallium et indium, à partir de quantités d'uranium de l'ordre du gramme. Dans ce but on fait passer, à travers une couche de résine Dowex 1, X8, un milieu constitué de 95% de méthanol et 5% d'acide nitrique 5*M*. Par lavage ultérieur de la résine avec un mélange méthanol-acide nitrique de même composition, on élue préférentiellement ces ions métalliques de la colonne, cependant que l'uranium reste retenu par l'échangeur anionique. Dans les éluats, les éléments sont dosés par des techniques spectrophotométriques ou volumétriques.

A SELECTIVE EXTRACTION SYSTEM FOR TRACE AMOUNTS OF SILVER

R. M. DAGNALL* and T. S. WEST*®
Department of Chemistry, University, Edgbaston, Birmingham 15, England

(*Received* 23 *July* 1964. *Accepted* 10 *August* 1964)

Summary—Silver can be extracted from near-neutral aqueous solution into nitrobenzene as the ion-association system formed between its 1,10-phenanthroline complex and bromopyrogallol red. In the presence of EDTA, mercury(II) and bromide ions as masking agents, the extraction system is highly selective. Of 42 ions examined, only thiosulphate and large amounts of gold interfere. The colour system is very sensitive ($\epsilon = 32{,}000$). Also, it can readily be applied to the indirect determination of concentrations of cyanide down to 0·026 ppm by determination of an added excess of silver.

THE few extraction systems that exist for silver are, in the main, dependent on chelation and are, as a consequence, somewhat unselective in action. Notable exceptions are the ion-association systems developed by Betteridge and West[1] and by Ziegler *et al.*[2] However, even these systems have some limitations, especially with anions which form strong silver complexes. In addition, some cations interfere,[1] among the more prominent being mercury(II).

In our examination of the very sensitive and selective silver/1,10-phenanthroline/bromopyrogallol red method,[3] it was noted that very large amounts of anions completely prevented the development of the colour system. Even nitrate, when present in greater than a 1000-fold mole excess over silver, completely prevented all colour development. This is, of course, in keeping with the behaviour of ion association systems of which the above is an example. In addition, with large amounts of silver ($10^{-4}M$ solutions) there is danger of precipitation. Thus, although this reaction is extremely sensitive in aqueous solution ($\epsilon = 51{,}000$), its usefulness is limited by interference from anions and it cannot be used for the determination of amounts of silver larger than 10 μg.

With these restrictions in mind, the possibilities of extracting the blue ternary complex, produced between silver, 1,10-phenanthroline and bromopyrogallol red, from near-neutral solution were investigated.

Water-immiscible solvents, such as ether, benzene, carbon tetrachloride, chloroform, methyl isobutyl ketone, amines, higher alcohols, *etc.*, all caused the blue complex to collect at the interface of the two phases. In addition, water-miscible solvents prevented or completely destroyed the colour. Only nitrobenzene was found to be capable of extracting the complex. In this medium the maximum absorption peak was at 590 mμ (*cf.* 635 mμ in aqueous solution) when compared with a blank of distilled water or nitrobenzene. Although the colour slowly faded to brown after several days, there was no sign of any precipitation at any time. The colour

could also be developed directly in the nitrobenzene phase by first extracting an aqueous solution of silver nitrate and 1,10-phenanthroline at pH *ca.* 7 with nitrobenzene, followed by an equilibration with an aqueous solution of bromopyrogallol red in 1% ammonium acetate. The dyestuff itself is not extracted by nitrobenzene.

Procedures were subsequently developed along these lines for the determination of 10-50 μg of silver directly in the nitrobenzene phase. The molar extinction coefficient was calculated to be 32,000, which is equal to that of the standard dithizone and *p*-dimethylaminobenzalrhodanine methods. In addition, amounts of silver down to 1 μg, can be determined with but slight alteration in the recommended procedure. Small concentrations of silver can be determined by using the extraction system as a means of concentration.

The major difficulty encountered in this investigation was the slowness of the phase separation, following the final extraction with an aqueous solution of bromopyrogallol red. An ice-water treatment of the separating funnels was unsuccessful and the addition of a very large excess of electrolyte merely destroyed the colour of the final complex in the nitrobenzene phase.

The turbidity of the organic phase could be removed, without prolonged standing, by running it into a beaker containing a few pellets (*ca.* 5) of sodium hydroxide. Upon swirling, the turbidity disappeared in about 1 min. However, under these conditions the stability of the solutions was somewhat reduced and the absorbance measurements had to be made within 0·5 hr of this treatment. Other drying agents, such as calcium chloride, oxide and sulphate, *etc.*, merely adsorbed the blue complex, *cf.* however Note 1.

The effect of the 1,10-phenanthroline concentration on the efficiency of the extraction system was determined. It was concluded that, provided a 5-fold mole excess over silver was present, there was no significant increase or decrease in the expected absorbances. The effect of EDTA was similarly investigated, but once again it had no pronounced effect, even with amounts such as 10 ml of a $10^{-1}M$ solution. Furthermore, the order of addition of reagents was found to be equally unimportant.

Interferences

Because of the anionic interference in aqueous solution, this examination was restricted, in the first instance, to about a 1000-fold g ion excess over silver of the following anions: sulphate, phosphate, carbonate, chloride, bromide, iodide, fluoride, cyanide, thiocyanate, chlorate, thiosulphate, nitrate, acetate, oxalate and citrate. Provided that the aqueous phase is removed after the initial extraction of the silver/1,10-phenanthroline with nitrobenzene, and before the final extraction with an aqueous solution of bromopyrogallol red, only cyanide, thiocyanate, iodide and thiosulphate interfere. With the aid of a *double masking action* with mercury(II) ions, only thiosulphate continued to interfere. A sufficient excess of mercury(II) ions is added to the solution containing silver and 1,10-phenanthroline to complex cyanide, thiocyanate and iodide. Excess EDTA is then added to complex the excess mercury(II). Under these conditions only silver and 1,10-phenanthroline are extracted and the colour can be developed in the usual way.

Only mercury(II) and copper(II), of those cations previously investigated[3] and found not to interfere in aqueous solution in the presence of excess EDTA, were re-investigated in the extraction procedure. Neither was, however, found to interfere in the recommended procedure, which incorporates, once again, the use of EDTA as a general masking agent.

The cation examination was confined primarily to those ions which were found to interfere in aqueous solution, *i.e.*, niobium(V), gold(III), thorium(IV) and uranium(VI).[3] To these antimony(V) was added because it had been found to give, with bromopyrogallol red, a blue coloured complex, which was stable to EDTA. Under those conditions outlined in the recommended procedure only gold(III) continued to interfere. In addition, it was now unnecessary to add further masking agents, such as hydrogen peroxide or fluoride.

Gold(III), when present in a 5-fold excess over silver, no longer interfered if a sufficient amount of bromide ions was added to form the $AuBr_4^-$ complex before the initial extraction. Alternatively, the extraction can be carried out from ammoniacal solution at pH 10. The ammine complex of gold now prevents its extraction, but a decrease in sensitivity (*ca.* 4-fold) is obtained because of the less efficient extraction of silver/1,10-phenanthroline at this elevated pH.

Thus, the proposed extraction is completely free from the interference of the 26 cations and 14 anions examined, *viz.*, aluminium(III), ammonium, antimony(V), barium(II), bismuth(III), cadmium(II), calcium(II), cerium(III), chromium(III), cobalt(II), copper(II), iron(II), iron(III), lanthanum(III), lead(II), magnesium(II), manganese(II), mercury(II), niobium(V), nickel(II), palladium(II), thallium(I), thorium(IV), titanium(IV), uranium(VI), zinc(II) and acetate, bromide, carbonate, chloride, chlorate, citrate, cyanide, fluoride, iodide, nitrate, phosphate, sulphate, tartrate and thiocyanate. Only thiosulphate and large amounts of gold(III) caused interference.

EXPERIMENTAL

Reagents

$10^{-4}M$ *Silver nitrate solution.* Prepare by dilution of standard $10^{-1}M$ silver nitrate solution.

$10^{-3}M$ *1,10-Phenanthroline solution.* Dissolve 49·56 mg of analytical reagent grade 1,10-phenanthroline in distilled water and dilute to 250 ml.

20% *Ammonium acetate solution.* Dissolve 20 g of analytical reagent grade ammonium acetate in distilled water and dilute to 100 ml.

$10^{-4}M$ *Bromopyrogallol red solution.* Dissolve 13·96 mg of bromopyrogallol red plus 2·5 g of analytical reagent grade ammonium acetate in distilled water and dilute to 250 ml. This solution should be discarded after 5 days.

$10^{-1}M$ *EDTA solution.* Dissolve 3·7225 g of the analytical reagent grade disodium salt in distilled water and dilute to 100 ml.

$1M$ *Sodium nitrate solution.* Dissolve 8·5 g of analytical reagent grade sodium nitrate in distilled water and dilute to 100 ml.

Nitrobenzene, Reagent grade

Sodium hydroxide, Reagent grade pellets

Apparatus

A Unicam SP 600 spectrophotometer was used for the absorbance measurements.

Procedure

Calibration curve. Pipette 1–5 ml of $10^{-4}M$ silver nitrate solution, 1 ml of 20% ammonium acetate solution, 5 ml of $10^{-3}M$ 1,10-phenanthroline solution, 1 ml of $10^{-1}M$ EDTA solution and 1 ml of $1M$ sodium nitrate solution into 100-ml separating funnels. Add sufficient distilled water to give a constant volume of solution in each funnel, then add 20 ml of nitrobenzene and shake by continuous inversion for 1 min. Allow about 10 min for the layers to separate, then transfer the lower organic layers to different 100-ml separating funnels and add to the latter 25 ml of $10^{-4}M$ bromopyrogallol red solution. Again shake by continuous inversion for 1 min and allow about 30 min for the layers to separate. Run the lower nitrobenzene layers into 100-ml beakers, each containing about 5 pellets of sodium hydroxide (*Note 1*) and swirl each beaker until all cloudiness disappears (*ca.* 1 min). Finally, transfer the solutions to 1-cm cuvettes and, as soon as possible (within 0·5 hr), measure the absorbance at 590 mμ against a blank carried through the same procedure, but containing no silver:

$$1 \text{ ml of } 10^{-4}M \text{ AgNO}_3 \equiv 10{\cdot}788\ \mu\text{g of Ag}.$$

The graph of absorbance *vs.* micrograms of silver is a straight line from 10 to 50 μg of silver and passes through the origin.

Determinations. Take an aliquot of the silver test solution, containing between 10 and 50 μg of silver, and add sufficient EDTA to complex all those cations present which form an EDTA complex. If gold is present (<250 μg), add, in addition, sufficient bromide ion to form the $AuBr_4^-$ complex. If cyanide, thiocyanate or iodide is present, add sufficient mercury(II) ions to complex these anions followed by sufficient EDTA to complex any excess mercury(II). Add 1 ml of 20% ammonium acetate solution, *etc.*, and proceed as under *Calibration Curve*. Only thiosulphate interferes in this determination.

The determination of smaller amounts of silver can be carried out in a similar manner by using 4-cm cuvettes (for 1–10 μg of silver) or by using the extraction system as a means of concentration.

DISCUSSION

The proposed method is, in most respects, superior to the existing spectrophotometric procedures for the determination of silver. It is simple and quick in operation; there is no need for a special purification of reagents and the usual disadvantages associated with the dithizone and rhodanine methods are, therefore, eliminated. The method is equally as sensitive ($\epsilon = 32{,}000$) as the hitherto most sensitive silver reagent *p*-dimethylaminobenzalrhodanine. In addition, because of the use of masking agents and the selectivity of the nitrobenzene extraction system, only thiosulphate was found to interfere. The solution colours are stable for 0·5 hr after complete colour development and, provided the bromopyrogallol red reagent solution is not kept for longer than about 5 days, reproducible results can be obtained. With large amounts of silver (10–50 μg) there is no danger of precipitation, and smaller amounts of silver can readily be determined with the minimum of alteration in the recommended procedure.

Furthermore, the method can be readily applied to the indirect determination of trace amounts of cyanide by determination of an added excess of silver. Thus, by employing 10 ml of a $10^{-4}M$ silver nitrate solution and extracting into 40 ml of nitrobenzene in the recommended procedure, 2·602–13·01 μg of cyanide (1–5 ml of $10^{-4}M$ potassium cyanide solution) can be determined. Smaller concentrations of cyanide can be determined by using the extraction system as a means of concentration. Cyanide, in the range 0·026–2·6 ppm, has been determined in this way. The advantages of this method are that, of the common anions, only thiocyanate, iodide and thiosulphate interfere; in addition, only those cations which form a more stable complex with cyanide than silver (*e.g.*, Hg^{2+}), will interfere.

The complex produced in aqueous solution between silver, 1,10-phenanthroline and bromopyrogallol red is an ion-association system, $([\text{Phen-Ag-Phen}]^+)_2 \cdot \text{BPR}^{2-}$. This accounts for the selectivity and sensitivity of the method and for the instability towards anions in aqueous solution. However, there is still some doubt as to the mechanism of the extraction into nitrobenzene. Preliminary experiments suggest the existence of a differently constituted species in this solvent, probably $[\text{Phen-Ag-Phen}]^+ \cdot \text{BPR}^{2-}$, which would account for the decrease in the value of the molecular extinction coefficient and for the shift in wavelength of maximum absorption. Work is now proceeding on this aspect and on the possibility of using chromogens which do not contain chelating groups. Ligand bases other than 1,10-phenanthroline are also being investigated.

Note 1. The sodium hydroxide is the source of instability of the colour system, which is otherwise as stable as that of the aqueous one.[3] We have found more recently that the use of sodium hydroxide is unnecessary. Effective clarification of the nitrobenzene extract can be obtained by swirling a portion of it in a clean dry beaker before transference to the cuvette.

Zusammenfassung—Silber kann aus fast neutraler wäßriger Lösung als Ionenassoziat zwischen seinem 1,10-Phenanthrolinkomplex und Brompyrogallolrot mit Nitrobenzol extrahiert werden. In Gegenwart von EDTA, Quecksilber(II) und Bromid zur Maskierung ist das Extraktionssystem hochselektiv. Unter 42 untersuchten Ionen störten nur Thiosulfat und große Mengen Gold. Die Farbreaktion ist sehr empfindlich (ϵ = 32 000). In gleicher Weise kann die Methode zur indirekten Bestimmung von Cyanid bis herunter zu 0,026 ppm verwendet werden durch Bestimmung eines zugesetzten Silberüberschusses.

Résumé—On peut extraire l'argent au nitrobenzène, à partir de solutions aqueuses voisines de la neutralité, à l'état de système d'association ionique formé entre son complexe 1,10-phénanthrolinique et le rouge de bromopyrogallol. En présence d'EDTA, et d'ions mercure (II) et bromure comme agents dissimulants, le système d'extraction est hautement sélectif. Parmi 42 ions examinés, seuls l'hyposulfite et de fortes quantités d'or interfèrent. Le système coloré est très sensible (E = 32 000). On peut aussi appliquer aisément cette méthode au dosage indirect de concentrations en cyanure aussi faibles que 0,026 p.p.m. par dosage d'un excès d'argent ajouté.

DETERMINATION OF BERYLLIUM BY MEANS OF HEXAMMINECOBALT(III) CARBONATOBERYLLATE—I

COMPOSITION OF THE PRECIPITATE AND ITS SUITABILITY AS A WEIGHING FORM FOR BERYLLIUM

R. G. MONK and K. A. EXELBY
Atomic Weapons Research Establishment, U.K.A.E.A.,
Aldermaston, Berks., England

(*Received* 3 *August* 1964. *Accepted* 24 *August* 1964)

Summary—The precipitate obtained when hexamminecobalt(III) chloride is added to a solution of beryllium in excess ammonium carbonate has been analysed and its behaviour under different humidity conditions examined. The composition is that of hexamminecobalt(III) hexacarbonato-oxo-tetraberyllate $[Co(NH_3)_6]_2[Be_4O(CO_3)_6]\cdot xH_2O$, as suggested by Sen Gupta, rather than that of Pirtea $[Co(NH_3)_6][(H_2O)_2Be_2(CO_3)_2(OH)_3]\cdot 3H_2O$. x depends on the humidity of conditioning, varying between 10·8 and 11·1 at relative humidities between 32 and 80%. Drying the precipitate *in vacuo* over anhydrous magnesium perchlorate or phosphorus pentoxide results in 3 molecules of water being retained. The compound as normally precipitated may be a mixture of the deca- and dodecahydrates that Sen Gupta prepared. After conditioning at a definite humidity and if an empirical factor is used, the precipitate may be suitable as a gravimetric form for determining beryllium where precision requirements are not too exacting.

OVER the past few years the development of beryllium metallurgy has resulted in the production of increasingly pure metal and consequently in heavier demands on the analytical chemist. The purest metal now available has a total impurity content of not more than 0·05%, most of which is oxygen, and it is desirable to have a highly accurate and precise beryllium assay method to supplement other analytical information.

The accurate determination of beryllium is a matter of some difficulty because the element does not readily form complexes or insoluble compounds of definite stoichiometric composition. The oxide has, perhaps, been most used for the gravimetric determination of beryllium, the hydroxide being precipitated in the presence of ethylenediaminetetra-acetate (EDTA) ion, which complexes a wide range of other cations. Unfortunately, this is not completely successful in preventing coprecipitation of impurities and it is usually necessary to carry out a spectrographic analysis of the oxide to enable suitable corrections to be made. This method also suffers from the usual difficulties associated with the high temperature ignition and weighing of a hygroscopic oxide. The determination as pyrophosphate suffers from similar disadvantages.

A number of organic precipitants have been proposed for the determination of beryllium, including 8-hydroxyquinaldine, β-hydroxy-α-naphthaldehyde and dimethylhexandione, but none of the resulting procedures is of a sufficiently high order of precision for the present purpose.

A method based on the potentiometric titration of the hydroxyl ion liberated in the reaction

$$Be(OH)_2 + 4F^- \rightarrow BeF_4^{2-} + 2OH^-$$

has been described by McClure and Banks[1] and has been used quite widely. This is an empirical procedure and the acid titrant must be standardised against beryllium. It was used routinely in this Establishment for some time, for moderately pure beryllium metal, giving results reproducible to 0·1–0·2 %. However, on occasions the method broke down completely and a more reliable procedure was required.

A number of papers by Pirtea[2–4] and coworkers describe a gravimetric method for determining beryllium in which the element is precipitated as a hexamminecobalt(III) compound of a carbonatoberyllate anion. Good results were obtained with quantities of beryllium between 0·9 and 72 mg, the reproducibility being about 0·1 % of the beryllium added at the higher levels; a micro-adaptation was shown to be satisfactory for quantities of beryllium between 70 and 350 μg. In this procedure the beryllium solution is neutralised and a large excess of ammonium carbonate added, forming the basic carbonatoberyllate anion. Any precipitated beryllium hydroxide or carbonate dissolves fairly readily in ammonium carbonate and a clear solution is obtained. Excess saturated hexamminecobalt(III) chloride is then added. After standing for some time the precipitate is collected on a sintered glass crucible, washed successively with 0·2 % hexamminecobalt(III) chloride solution, 60 % alcohol, absolute alcohol and ether. The precipitate is first dried by suction, then left in a vacuum desiccator for 15 min and weighed. The method was shown to be highly selective for beryllium if carried out in the presence of a suitable complexing agent, such as tartrate or EDTA, to prevent the precipitation of metals giving insoluble hydroxides or carbonates.

The above method appeared to be the most promising of available procedures from which a highly precise beryllium assay method might be developed and it was decided to investigate it further. The composition assigned to the complex by Pirtea disagrees with the results of other workers on carbonatoberyllates, although these are not entirely consistent with each other, as is shown below.

Compounds of basic beryllium carbonate were first prepared in 1855 by Debray,[5] who dissolved beryllium hydroxide in aqueous potassium carbonate solution. From this solution he isolated the potassium salt to which he assigned the formula $3K_2Be(CO_3)_2 \cdot Be(OH)_2$; he and Klatzo[5] prepared the corresponding ammonium salt. More recently, Sen Gupta[6] dissolved beryllium hydroxide in aqueous potassium bicarbonate and from the resulting solution he isolated a hygroscopic compound which he considers to be a hydrated form of $K_6[Be_4O(CO_3)_6]$; he similarly obtained the corresponding sodium salt. Ignoring the water content, Debray's and Sen Gupta's products are identical in composition. The formula proposed by Sen Gupta contains the anion $[Be_4O(CO_3)_6]^{6-}$, which has the typical basic beryllium carboxylate structure as found in the basic acetate $Be_4O(CH_3COO)_6$.

In contrast with the above observations, Humpidge,[5] in 1886, prepared an ammonium carbonatoberyllate whose formula he gave as $2(NH_4)_2Be(CO_3)_2 \cdot Be(OH)_2$. As regards the hexamminecobalt(III) compound, Pirtea gives it the formula $[Co(NH_3)_6][(H_2O)_2Be_2(CO_3)_2(OH)_3] \cdot 3H_2O$, whereas Sen Gupta considers it to have the same anion as the other salts and writes the formula as $[Co(NH_3)_6]_2[Be_4O(CO_3)_6]$. Sen Gupta finds it to contain 10 or 12 molecules of water "according to the amounts of ammonium carbonate or alkali bicarbonate utilised for complexing beryllium". The $10H_2O$ compound gives tetrahedral and octahedral crystals, while the crystals of the $12H_2O$ are said to be feather-like. He states that the latter can be used for the gravimetric determination of beryllium, but gives no details as to how each hydrate can be produced or how he dried his precipitates.

The formulae given by Sen Gupta for his compounds are all supported by analytical results for N, Be, C and H. However, no such evidence is given by Pirtea and it is difficult to see on what grounds he arrives at his rather odd formula. The only statement made in its justification, literally translated from the Rumanian, is as follows: "Given the high molecular weight of the compound obtained, 440, corresponding to an empirical formula $[(H_2O)_2Be_2(CO_3)_2(OH)_3][Co(NH_3)_6]\cdot 3H_2O$ and the small atomic weight of beryllium, 9·02, beryllium enters into this compound in the proportion of only 4·10%." The experimental results obtained by Pirtea, using 4·10% as the beryllium content of the precipitate, appear to be good, in-so-far as the weight of beryllium found agrees with the amount added, but here the paper is obscure in another respect. It appears that the beryllium was added as a standard solution of $Be(NO_3)_2\cdot 4H_2O$ but it is not stated how the solution was standardised.

From the foregoing it was evident that it would first be necessary to establish the composition of the precipitate and experiments for this purpose are described below.

EXPERIMENTAL

Preliminary experiments showed that vacuum desiccation of hexamminecobalt(III) carbonatoberyllate over anhydrous magnesium perchlorate or phosphorus pentoxide resulted in continuous weight loss over a period of a day or two before constant weight was reached. The short drying period of 15 min in a vacuum desiccator as recommended by Pirtea could not, therefore, be regarded as a satisfactory procedure. Experiments were therefore performed to determine whether a suitable conditioning procedure at a definite humidity would give a product of sufficiently stable composition for weighing.

Stability of Compound at Various Humidities

Reagents

Standard beryllium solution (about 2% by weight). Prepared by dissolving beryllium metal flake of 99·8% purity (based on impurity analysis) in hydrochloric acid in a tared flask, diluting and weighing. Portions of the solution were weighed out as required from a polythene ampoule drawn out to a fine jet.

25% Ammonium carbonate solution (containing EDTA). 250 g of ammonium carbonate and 4 g of disodium ethylenediaminetetra-acetate were dissolved by stirring with 500 ml of water containing 120 ml of concentrated aqueous ammonia, and the solution diluted to 1 litre.

Hexamminecobalt(III) chloride. 5% aqueous solution

Wash solutions. 0·2% aqueous hexamminecobalt(III) chloride
60% v/v ethanol and water

Procedure

A weighed portion of beryllium solution was diluted to about 25 ml, 1*M* aqueous ammonia added until a permanent precipitate was formed and the latter dissolved by the addition of 1*M* hydrochloric acid. 20 ml of ammonium carbonate solution were added and the solution heated to about 60° for a few minutes until it became completely clear. An excess (20–50%) of 5% hexamminecobalt(III) chloride solution was then added and the solution allowed to cool to room temperature. The precipitate was collected on a tared X4 sintered glass crucible and washed successively with 0·2% hexamminecobalt(III) chloride solution and 60% v/v ethanol. It was then dried by suction (about 15–20 min). Washing with absolute ethanol was avoided to prevent possible dehydration of the compound.

The crucible and contents were weighed and transferred to a desiccator in which an atmosphere of controlled humidity was maintained. The humidifying agents used were moistened crystals of ammonium chloride (about 80% R.H. at 20°), magnesium nitrate (about 55% R.H. at 20°) and calcium chloride (about 32% R.H. at 20°). When constant in weight the sample was transferred to a vacuum desiccator containing anhydrous magnesium perchlorate or, in one experiment, phosphorus pentoxide.

Constant weight, reproducible to about 0·03%, was reached in 10–20 hr at relative humidities of 30–80%. However, dehydration took much longer and the reproducibility was only about 0·3% in these experiments because the desiccated material was very hygroscopic.

The results are shown in Table I.

TABLE I.—EFFECT OF HUMIDITY ON HEXAMMINECOBALT(III) CARBONATOBERYLLATE

^{a} Dried over phosphorus pentoxide.

^{b} Ratios were calculated from the minimum weights observed.

Analysis for Elementary Constituents

Early experiments showed that conditioning at 30–80% R.H. gave a product sufficiently stable to handle in the ordinary laboratory atmosphere without the occurrence of sudden weight changes. Further experiments were carried out in which the complex was conditioned for 24 hr at 32% R.H., then analysed for cobalt, carbon, hydrogen and nitrogen. Four precipitations were carried out and cobalt determined on all four precipitates by the method to be described in Part II. Duplicate determinations of carbon, hydrogen and nitrogen by micro-combustion were made on two of the precipitates. The beryllium content of the precipitate was calculated from the known amounts added on the assumption of complete precipitation.

These results are shown in Table II.

DISCUSSION

It is clear, from the atomic ratios of carbon to the other elements shown in Table II, that the precipitate has the composition stated by Sen Gupta and not that of Pirtea. The compound should, therefore, be termed hexamminecobalt(III) hexacarbonato-oxo-tetraberyllate and has the formula $[Co(NH_3)_6]_2[Be_4O(CO_3)_6]\cdot xH_2O$. The value of x may be calculated from the cobalt content, which was the most accurate of the determinations carried out. The mean value of the cobalt content of the compound conditioned at 32% R.H. was 12·696 ± 0·003%, corresponding to a molecular weight of 928·4 and giving x the value of 10·8. From the results in Table I, x has the value of 11·0 and 11·1 for the material conditioned at 55% and 80% R.H., respectively. 3·0 molecules of water are retained by the precipitate after drying *in vacuo* over magnesium perchlorate. In view of Sen Gupta's identification of the deca- and dodecahydrates it is possible that these species are of very similar

TABLE II.—COMPOSITION OF HEXAMMINECOBALT(III) CARBONATOBERYLLATE

stability and that the precipitates normally obtained are mixtures of the two. It is difficult to account for the continuous change in composition between 32 and 80% R.H. that we observed, but equilibrium is certainly reached quite rapidly at any humidity in the range. The loss in weight *in vacuo* over magnesium perchlorate also took place rapidly in the initial stages, and in Experiments 1 and 2 over 80% of the total water lost came off in the first 2 hr. Drying the precipitate in a vacuum desiccator for 15 min as recommended by Pirtea would, therefore, be expected to give a large loss in weight and a product of variable composition.

Since completing the above work we have seen the paper of Vinogradov[7] *et al.* on the same subject. They used Pirtea's method for precipitating beryllium and after determining the cobalt, carbonate and water contents of the precipitate, also concluded that it has the Sen Gupta formula. However, they find the beryllium content to be 3·95%, corresponding to 10 molecules of water. Because they followed Pirtea it is presumed that they also dried the precipitate for 15 min *in vacuo* over an unspecified desiccant. Because Pirtea and Vinogradov obtained results of reasonable reproducibility it is presumed that whatever desiccant was used was relatively slow in action. However, even in this case, the system cannot have been in equilibrium and the compound must have been losing weight continuously, if slowly. Vinogradov also measured the rate of decomposition of the compound on heating. He showed that it begins to lose weight at 30° and decomposition proceeds rapidly up to 60°. After a short halt there is another sharp increase in the decomposition rate at 75–85°. The results were rather variable and inconclusive, but about half of the water was lost on drying for 2 hr at 60°.

The rather variable and non-stoichiometric water content of the precipitate renders it unsuitable for the gravimetric determination of beryllium for work of the highest precision. However, as reasonably good reproducibility of composition is attainable by conditioning at a definite humidity it is considered that the method, used empirically, could find application in circumstances where a precision of 0·1–0·2% is adequate. The beryllium content of the precipitate conditioned at 32% R.H. is 3·883%. It should be noted that precipitation conditions in our experiments were not quite optimum. From the Be/Co ratios in Table II it may be calculated that only 99·5–99·8% of the beryllium was precipitated and this is attributed to insufficient dilution of the solution after adding the hexamminecobalt(III) chloride. This point will be dealt with in Part II in which a highly precise method for determining beryllium will be described, based on the determination of the cobalt in the hexamminecobalt(III) hexacarbonato-oxo-tetraberyllate precipitate.

Acknowledgements—Our thanks are due to Mr. J. B. Hornsby for experimental assistance in the early stages of the investigation, to Mr. H. Swift for carrying out the carbon, hydrogen and nitrogen determinations, and to Mr. F. E. Wallwork for translations from the Russian and Rumanian.

Zusammenfassung—Der beim Zusatz von Hexamminkobalt(III)-chlorid zu einer Lösung von Beryllium in überschüssigem Ammoniumcarbonat entstehende Niederschlag wurde analysiert und sein Verhalten bei verschiedenen Feuchtigkeiten untersucht. Die Zusammensetzung entspricht Hexamminkobalt(III)-hexacarbonato-oxo-tetraberyllat $[Co(NH_3)_6]_2[Be_4O(CO_3)_6].xH_2O$, wie von Sen Gupta vorgeschlagen, besser als der Formel von Pirtea

$$[Co(NH_3)_6][(H_2O)_2Be_2(CO_3)_2(OH)_3]\cdot 3\ H_2O$$

x hängt von der Feuchtigkeit bei der Aufbewahrung ab, es variiert bei

relativen Feuchtigkeiten von 32 bis 80% zwischen 10,8 und 11,1. Beim Trocknen im Vakuum über wasserfreiem Magnesiumperchlorat oder Phosphorpentoxyd werden 3 Moleküle Wasser zurückgehalten. Die normalerweise gefällte Verbindung ist vielleicht eine Mischung der von Sen Gupta hergestellten Deka- und Dodekahydrate. Nach Aufbewahrung bei einer definierten Feuchtigkeit und bei Gebrauch eines empirischen Faktors kann sich der Niederschlag als Wägeform bei der Beryllium-bestimmung eignen, wenn die Genauigkeitsansprüche nicht zu streng sind.

Résumé—On a analysé le précipité obtenu par addition de chlorure de cobaltihexammine à une solution de beryllium dans un excès de carbonate d'ammonium, et étudié son comportement dans différentes conditions d'humidité. La composition est celle de l'hexacarbonate-oxo-tétraberyllate de cobaltihexammine $[Co(NH_3)_6]_2[Be_4O(CO_3)_6],xH_2O$, ainsi que l'a suggéré Sen Gupta, plutôt que celle de Pirtea $[Co(NH_3)_6][(H_2O_2)Be_2(CO_3)_2(OH)_3],3H_2O$. x dépend de l'humidité ambiante, variant entre 10,8 et 11,1 pour des humidités relatives comprises entre 32 et 80%. Après séchage sous vide sur perchlorate de magnésium anhydre ou sur anhydride phosphorique, 3 molécules d'eau sont retenues. Le composé normalement précipité peut être un mélange des déca- et dodécahydrates que Sen Gupta a préparés. Après traitement sous une humidité définie, et par emploi d'un facteur empirique, le précipité peut convenir au dosage gravimétrique du béryllium, lorsque les exigences quant à la précision ne sont pas trop grandes.

PRECIPITATION OF COPPER 8-HYDROXYQUINALDATE FROM HOMOGENEOUS SOLUTION

R. P. GRAHAM,® E. J. BILLO and J. A. THOMSON
Burke Chemical Laboratories, McMaster University, Hamilton
Ontario, Canada

(*Received* 10 *August* 1964. *Accepted* 19 *September* 1964)

Summary—Copper can be precipitated quantitatively, over a wide range of pH, by 8-hydroxyquinaldine produced from the hydrolysis of 8-acetoxyquinaldine. The copper 8-hydroxyquinaldate can be weighed as either the monohydrate or the anhydrous dichelate. Differences in the appropriate pH conditions, between the PFHS and conventional precipitation methods, and between thorium and copper precipitations from homogeneous solution, are accounted for.

ALTHOUGH precipitation from homogeneous solution (PFHS) has been extensively investigated and used for about twenty-five years, the generation of organic precipitants *in situ* received little attention until three or four years ago. Interest in this field is increasing, as a recent survey[1] of the literature shows. Since that review, studies[2,3] have revealed advantages, for the precipitation of zinc and of indium, of 8-acetoxyquinaldine as a source reagent for the precipitant 8-hydroxyquinaldine.

A study[4] of the precipitation of thorium 8-hydroxyquinaldate [thorium 2-methyloxinate, $Th(C_{10}H_8ON)_4$] *via* the hydrolysis of 8-acetoxyquinaldine disclosed a disadvantage of the PFHS method: the pH conditions for the quantitative precipitation of the pure chelate can be much more restrictive than in the conventional method. It was anticipated that, with regard to the pH conditions for successful precipitation, the difference between the conventional and PFHS methods would be much less with copper than with thorium. The present work demonstrates that this is so, and that copper can be determined with high precision and accuracy through the agency of 8-acetoxyquinaldine.

EXPERIMENTAL

Reagents and procedures

Copper(II) solution: Copper foil (AnalaR) was dissolved in nitric acid, and the solution was diluted with water to a concentration ~1·0 mg of Cu/ml. Standardisation was done iodometrically, using procedures recommended by Hammock and Swift.[5]

8-Acetoxyquinaldine (8-AQD): The sources of, and method of storing, this reagent were the same as in an earlier study.[4] The infrared spectra (in Nujol) of the commercial and synthesised products were the same; in neither was the hydroxyl stretching band at about 3400 cm^{-1} detected. Solutions were made by dissolving in 2·0 ml of glacial acetic acid the amount of 8-AQD required to give 20% or 200% excess of reagent, and diluting with water to 10 ml (100 mg of 8-AQD are equivalent to 15·8 mg of copper, for the 1:2 chelate).

All other chemicals were reagent-grade. Weights and volumetric ware were calibrated. The thermobalance has been described previously.[4]

The pH values of precipitation were determined by measurements on the filtrates at room temperature; the meter was standardised before use by an appropriate buffer solution, and readings of pH >10 were corrected for sodium-ion error.

Precipitation of copper 8-hydroxyquinaldate

Twenty-five ml of copper(II) solution (1 mg/ml) were diluted with water to 225 ml and 10 ml of a freshly prepared solution of 8-AQD (*vide supra*) were added. The pH was adjusted using 1·5–3*M* aqueous ammonia (or, for precipitations at pH values >10, using 2–5*M* sodium hydroxide), added drop by drop with vigorous stirring. (To allow for drift during precipitation, the pH was brought to a value higher than that desired after precipitation: about 0·1 unit higher at pH 5; about 1 unit at pH 7.) The solution was warmed for 2 hr at ~80°, filtered (medium porosity frit), and the precipitate washed, using for the transferring and washing about 100 ml of hot water. The precipitate was dried for 2 hr at 105–110° or for 1 hr at 125–130°, cooled over phosphorus pentoxide, and weighed as $Cu(C_{10}H_8ON)_2$.

RESULTS AND DISCUSSION

Character and composition of the precipitate

Precipitation began after some minutes of heating. The delay at pH 5.2 was less than half that at pH 4·0: this is a consequence of a sharp increase in the rate of hydrolysis of 8-AQD with increasing pH in the range 3·0 to 5·5.[6] The precipitate was distinctly crystalline, consisting of large, well-formed, thin, brown plates that were readily washed.

On being heated at 105–130°, the precipitate became dark green. That this reflects the dehydration of $Cu(C_{10}H_8ON)_2{\cdot}H_2O$ was established by the following (all precipitations at pH 4·5–9·5): weights of the brown product, dried at 60° for 16 hr, corresponded to quantitative recovery of the copper as the dichelate monohydrate; weights of the green product, dried for 2 hr at 105–110° or 1 hr at 125–130°, corresponded to quantitative recovery as the anhydrous dichelate; the green compound had a copper content (by ignition) of $16{\cdot}7_1$% with an average deviation of $0{\cdot}0_2$% (theoretical, for $Cu(C_{10}H_8ON)_2$, 16·73%); and thermogravimetric curves for precipitates previously dried at room temperature for 72 hr showed a break beginning at 102° followed by another plateau from about 130° to 230°, the decrease in weight corresponding to the loss of the hydrate water. (These temperatures are reasonably close to those found by Borrel and Pâris,[7] and we agree that the oxide level is reached at about 600°.)

pH Range for quantitative precipitation

The recommended procedure, even with an excess of reagent of only 20%, permits the quantitative recovery of copper (from solutions of concentration ~90 mg of Cu/litre or $1{\cdot}4 \times 10^{-3}M$) as the dichelate, with high precision, over a wide range of pH. Sixteen determinations in the pH range 4·5–9·5 had an average deviation, from the 100·0% recovery value, of only 0·1%.

The pH range for quantitative precipitation can, of course, be extended by increasing the excess of reagent (Fig. 1). The pH values for both "incipient" and quantitative precipitation of a metal chelate depend on several factors, including the concentration of any complexing anions in the solution; in spite of such differences, our values (pH 3·2 and 4·5 for 20% excess reagent; pH 2·9 and 3·9 for 200% excess) are in good agreement with other results[8,9] obtained using 8-hydroxyquinaldine directly.

No work bearing on the upper limit of pH for the quantitative precipitation of copper 8-hydroxyquinaldate is known to us. With 20% excess reagent, we found that precipitation—calculated as the dichelate—beyond pH 10 began to fall below 100%, decreasing to 94% at pH 13·9. In this same range, the copper contents of the precipitates (dried at 105–130°) rose from $16{\cdot}7_1$% (proper for the anhydrous dichelate) to $16{\cdot}8_6$%. These results indicate that precipitation beyond pH 10 occurs as an hydroxychelate or a mixture of the normal chelate and hydrous copper oxide. Moreover, more than one kind of experiment showed that (regardless of the composition of the precipitate), at least at and beyond pH 12·8, copper was not quantitatively precipitated; this, too, is likely due to hydroxo complexing.

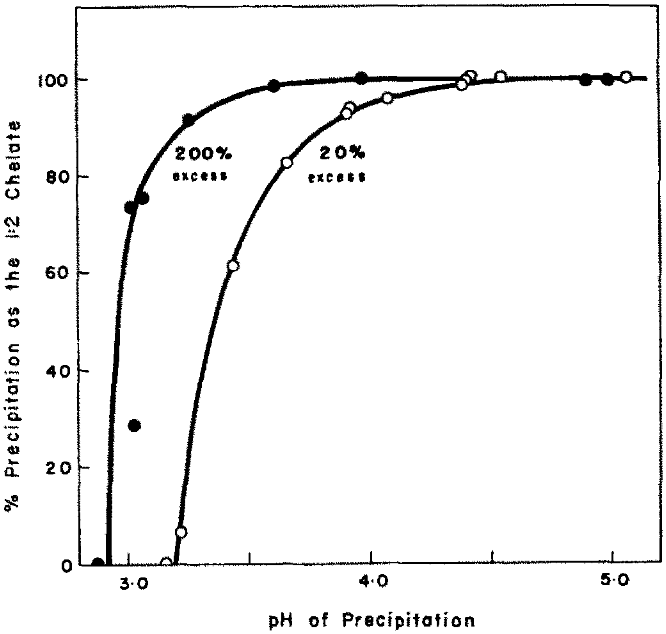

FIG. 1.—Precipitation of copper 8-hydroxyquinaldate from homogeneous solution in relation to pH of precipitation and excess of reagent.
(Copper in original solution = 0·1 mg/ml.)

Comparison of PFHS and conventional methods

With 20% excess reagent, precipitation of copper, by this PFHS method ceased to be quantitative (100·0 ± 0·1%) *as the dichelate* at pH 10; recovery of copper in this form was 99·5% in the pH range 10–12, thereafter decreasing more sharply with increasing pH, to 94% at pH 13·9 as has been mentioned. In contrast, in precipitations in which 8-hydroxyquinaldine was used directly, but which otherwise were comparable, quantitative precipitation of copper as the dichelate was obtained at pH values up to 12.

This wider pH range for successful precipitation using the conventional precipitation method is consistent with what was found with thorium,[4] although the effect is much less pronounced with copper. The differences in the useful pH range of the two methods likely arise from the different concentrations of the chelating quinaldate anion during adjustment of the pH and the consequences of this, as elaborated in the earlier paper.[4] That copper shows this effect in much lesser degree than thorium is to be expected. The effect stems from a competition between hydroxyl-ion and chelating anion for the metal-ion, and thorium-ion is, of course, relatively very prone to hydrolysis. Of the bivalent metal-ions of the first transition period, copper may have the widest pH range for successful precipitation of the 8-hydroxyquinaldate, because of the high stability of copper chelates. Another relevant factor, though, is the intrinsic solubility[10] of the chelate, and the intrinsic solubilities of these metal chelates may differ appreciably. In fact, pronounced differences in the intrinsic solubilities of the 8-hydroxyquinolates of cobalt, copper and zinc have recently been reported[11] and, moreover, the intrinsic solubilities of these chelates do not follow their stability order.

In any event, copper can be quantitatively precipitated as the 8-hydroxyquinaldate over a wide pH range: 6 to 8 or more pH units, depending on the excess of reagent and whether 8-acetoxyquinaldine or 8-hydroxyquinaldine directly is used.

Acknowledgement—We gratefully acknowledge financial support from the National Research Council of Canada.

Zusammenfassung—Kupfer kann quantitativ in einem weiten pH-Bereich mit 8-Hydroxychinaldin gefällt werden, das durch Hydrolyse von 8-Acetoxychinaldin erzeugt wird. Das Kupfer-8-hydroxychinaldinat kann entweder als Monohydrat oder als wasserfreies Dichelat gewogen werden. Unterschiede in den geeigneten pH-Werten zwischen der Fällung aus homogener Lösung und konventionellen Fällungsmethoden und zwischen Thorium- und Kupferfällungen aus homogener Lösung werden berücksichtigt.

Résumé—On peut précipiter quantitativement le cuivre, dans un large domaine de pH, au moyen de 8-hydroxyquinaldine produite par hydrolyse de la 8-acétoxyquinaldine. Le 8-hydroxyquinaldinate de cuivre peut être pesé à l'état de monohydrate ou de dichélate anhydre. On interprète les différences observées, dans des conditions de pH appropriées, entre la méthode de précipitation en milieu homogène et les méthodes de précipitation usuelles, et entre les précipitations du thorium et du cuivre en milieu homogène.

SPECTROPHOTOMETRIC INVESTIGATION OF THE NATURE AND STABILITY OF SILVER(II) IN ACIDIC SULPHATE MEDIA

G. A. RECHNITZ and S. B. ZAMOCHNICK
Department of Chemistry, University of Pennsylvania
Philadelphia, Pennsylvania, U.S.A.

(*Received* 17 *August* 1964. *Accepted* 15 *September* 1964)

Summary—A spectrophotometric study of silver(II) in sulphuric acid solution indicates the formation of two sulphato complexes, in the range 4–18*M* H_2SO_4, with absorbance peak maxima at 361 and 260 mμ, respectively. In 15*M* H_2SO_4 the molar absorptivity of silver(II) is $3{\cdot}11 \times 10^4$ at 361 mμ. Kinetic studies of the reduction of silver(II) by the solvent suggest a rate-determining step first order in silver(II) and yield a pseudo first-order rate constant of $1{\cdot}9 \times 10^{-1}$ min^{-1}. Further studies as a function of H_2SO_4 concentration show that the specific decomposition rate of the two complexes is identical and that changes in H_2SO_4 concentration only serve to shift the concentration equilibrium between the two complexes.

INTRODUCTION

IN a previous paper[1] we reported preliminary observations concerning the powerful oxidising agent, silver(II), in aqueous solution at low pH values. Silver(II) was found to be complexed even in perchlorate media and to undergo reduction by the solvent at rates proportional to the square of the silver(II) concentration and inversely proportional to the silver(I) concentration with an over-all activation energy of 11·6 kcal. mole^{-1}.

The present paper describes the results of systematic experiments aimed at elucidating the nature of silver(II) in sulphuric acid media and the details of the reduction of such species by the solvent. In particular, we were interested in establishing the effect of sulphate complexation on the stability of silver(II) with regard to its decomposition to silver(I) to learn whether or not the rate determining step of the over-all oxidation-reduction process involves a change in co-ordination number.

Because of uncertainties in the actual nature of solid silver(II)oxide,[2] employed as starting material in our preliminary experiments, we used an electrolytic generation method, similar to that of Davis and Lingane,[3] to prepare homogeneous solutions of silver(II). Previously unknown data on the nature and optical properties of sulphate-silver(II) complexes are reported in detail.

EXPERIMENTAL

Reagents

All solutions were prepared from reagent-grade materials, except where noted, and used without further purification.

Silver(II) oxide. AgO of 98·5% minimum purity was obtained from Handy & Harmon Company, New York, U.S.A., and was weighed as needed.

Silver(II) sulphate. $AgClO_4{\cdot}H_2O$ (G. F. Smith Chemical Co., Columbus, Ohio, U.S.A.) was used to produce silver(II) sulphate complexes in sulphuric acid media by electrolysis. Best results were obtained by making serial dilutions from 0·2400*M* $AgClO_4{\cdot}H_2O$ in 15*M* H_2SO_4 stock solutions to a final concentration of 0·0024*M* in 15*M* H_2SO_4.

Cerium(IV) sulphate. Pipette 10 ml of 0·1021*M* cerium(IV) sulphate (G. F. Smith Chemical Co.) in 0·5*M* sulphuric acid solvent and dilute with 15*M* sulphuric acid solvent to a total volume of 100 ml. Make further serial dilutions of $5{\cdot}0 \times 10^{-3}$, $1{\cdot}0 \times 10^{-3}$, $5{\cdot}0 \times 10^{-4}$, $1{\cdot}0 \times 10^{-4}$, $5{\cdot}0 \times 10^{-5}$, and $1{\cdot}0 \times 10^{-5}M$ in 15*M* sulphuric acid.

Cerium(III) sulphate. Weigh 0·3250 g of $Ce_2(SO_4)_3{\cdot}8H_2O$ (G. F. Smith Chemical Co.), dissolve in water and dilute with 18*M* sulphuric acid to a final concentration of $2{\cdot}04 \times 10^{-3}M$ in 15*M* sulphuric acid.

Apparatus

Spectra. Spectra and decomposition curves were recorded using a Beckman Model DB ultraviolet-visible spectrophotometer equipped with 1·00-cm matched silica cuvettes. Temperature of both the spectrophotometer and electrolysis cells was held at 25·0° ± 0·15° by a Wilkins-Anderson Co. Lo-Temp Bath system. An E. H. Sargent Model SRL recorder was employed for all absorbance measurements.

Electrolysis. The electrolysis current was provided by a Heathkit Model EUW-17 transistorised power supply. The current and voltage were monitored by Simpson Model 269 and 260 meters, respectively. A cylindrical platinum gauze cathode, 1·40 cm by 3·80 cm, and anode, 2·70 cm by 5·10 cm, were employed to provide proper cell geometry. The cathode was isolated from the anode by a glass cylinder 2·50 cm by 6·20 cm, closed at the bottom by either an "A" or a "C" sintered glass frit. The electrodes, isolation cylinder and electrolysis solution were contained in a thermostatted double-walled glass cell.

Procedure

Silver(II) in sulphuric acid solution was obtained both by dissolution of silver(II) oxide and by electrogeneration at constant current from silver(I). Dissolution was carried out by weighing the desired amount of silver(II) oxide into a 125-ml Erlenmeyer flask and adding 25 ml of sulphuric acid solvent. The flask was swirled until all the silver(II) oxide was dissolved and spectra or decomposition curves were recorded in the usual manner, with correction for initial decomposition time effects where necessary.

Electrolytic production of silver(II) complexes in sulphuric acid. Place 70 ml of silver(I) perchlorate in 15*M* H_2SO_4 into the electrolysis cell and stir vigorously. Adjust the power supply to furnish currents of 87–90 *mA*, which cause the voltage to be greater than the minimum 1·98 *V* needed with the cell used.[3] After rapid initial production of silver(II), a steady-state concentration of silver(II) is reached because the rate of silver(II) decomposition approaches the electrolysis rate. Because silver(I) inhibits the decomposition of silver(II), the steady-state concentration of the latter can be adjusted by changing the initial silver(I) concentration.

Withdraw samples by pipette and record spectra or decomposition curves in the usual manner, correcting for the time elapsed during sample withdrawal and transfer.

Beer's law was checked for the silver(II) complexes in sulphuric acid by allowing silver(I) to oxidise cerium(III) to cerium(IV) and measuring the absorbance of the stable cerium(IV) complex produced. A typical procedure is given for the determination of the molar absorptivity for the silver(II)-sulphate complex in 15*M* sulphuric acid at 361 mμ. Spectra of cerium(IV) sulphate in 15*M* sulphuric acid solvent were obtained in the $1{\cdot}0 \times 10^{-2}$–$1{\cdot}0 \times 10^{-5}M$ range, yielding $\epsilon_{380} = 2{\cdot}36 \times 10^3$ and $\epsilon_{360} = 3{\cdot}86 \times 10^3$, respectively.

Electrolytically generate silver(II)-sulphate complexes from 0·0024*M* silver(I) perchlorate in 15*M* sulphuric acid. Withdraw aliquots of the electrolysis solution and follow its decomposition as A_λ *vs. t*, at $\lambda = 361$ mμ. When suitable absorbance readings are reached, rapidly empty the cuvette into a beaker containing 10 ml of $2{\cdot}04 \times 10^{-3}M$ cerium(III) sulphate in 15*M* sulphuric acid, which provides a large excess of cerium(III). After the redox reaction has taken place, record the spectra of the stable cerium(IV) complex formed. Record the spectra of silver(I) perchlorate and cerium(III) sulphate in 15*M* sulphuric acid and of 15*M* sulphuric acid so that wavelengths can be chosen where silver(II) will not be interfered with by cerium(IV), cerium(III), silver(I) or sulphuric acid.

Calculate the actual concentrations of silver(II) corresponding to the measured absorbances at the appropriate wavelength from the amount of cerium(IV) produced by oxidation of cerium(III) by silver(II). Finally, plot A_λ (at $\lambda = 361$ mμ) of the silver(II)-sulphate complex (from decomposition curves) *vs.* the calculated silver(II) concentration. Beer's law is obeyed and the molar absorptivity, ϵ_λ, is calculated.

A further test of the applicability of Beer's law can be obtained using silver(II) from silver(II) oxide. Weigh 0·0023–0·0100 g of silver(II) oxide into 125-ml Erlenmeyer flasks. Add 10 ml of $2{\cdot}0 \times 10^{-3}M$ cerium(III) sulphate in 15*M* sulphuric acid. When all silver(II) has been reduced to silver(I), record the spectra of the cerium(IV) complex produced. Beer's law plots of A_λ [cerium(IV) produced] *vs.* initial concentration of silver oxide are obtained at $\lambda = 460$, 440, 420 and 410 mμ, all producing excellent straight lines.

RESULTS AND DISCUSSION

Spectra of silver(II) as a function of sulphuric acid concentration

Ultraviolet and visible spectra of an initial concentration of 0·0065 g of silver(II)-oxide in 25 ml of sulphuric acid solvent at 25·0° ± 0·15° suggest that two sulphate complexes of silver(II) are predominant in the range 4–18*M* sulphuric acid. One complex predominates in 10–18*M* acid with absorption maxima between 368 and 343 mμ (visible complex); the second complex predominates between 4 and 9*M* acid with absorption maxima between 262 and 245 mμ (ultraviolet complex). An isosbestic point, occurring in 12 and 18*M* acid at 310 mμ, further confirms the fact that significant concentrations of only two complexes in equilibrium are present in these media. Absorbances, at the respective maxima for the two complexes, are equal in 10*M* sulphuric acid.

The visible complex appears only as a shoulder between 339 and 332 mμ on spectra of the ultraviolet complex in the range 4–9*M* sulphuric acid. In the range 0·25–2·5*M* acid no measurable peak of either complex can be distinguished; undissolved particles of silver(II) oxide colour the solutions pale grey initially. Between 4 and 18*M* sulphuric acid, the solutions initially are brownish-yellow and decompose first to pale yellow and then, within a few hours, to water white. The highest absorbance for a given silver(II) concentration is obtained in 15*M* sulphuric acid at 356 mμ and in 5*M* acid at 250 mμ for the visible and ultraviolet complexes, respectively. Spectra of silver(I) perchlorate in sulphuric acid and of sulphuric acid showed no interference at the above wavelengths.

Definite shifts in location of the maxima occur for both complexes and are probably the result of several effects. Spectra taken at various times during the silver(II) decomposition process, but at constant sulphuric acid concentration, show small (3 mμ or less) wavelength shifts; changes in the acid concentration result in substantial changes in peak heights described above. All the above results are summarised in Table I.

Molar absorptivity of silver(II) in sulphuric acid

Beer's law was tested for the visible complex of silver(II) sulphate at 15*M* sulphuric acid at 361 mμ. This acid concentration and wavelength correspond to conditions where the absorbance of the visible complex reaches its maximum value for any given silver(II) concentration. A molar absorptivity of $3{\cdot}11 \times 10^4$ at 361 mμ was calculated for the silver(II) complex. No interference by perchlorate could be noted in the electrogeneration experiments where silver(I) perchlorate was used as a starting material.

Decomposition kinetics of silver(II) complexes in sulphuric acid media

The decomposition of silver(II)-sulphate complexes obtained by dissolution of 0·0050 and 0·0100 g of silver(II) oxide in 15*M* sulphuric acid was followed at 356 mμ (visible complex), 310 mμ (isosbestic point) and 260 mμ (ultraviolet complex), respectively, at 25·0 ± 0·15°. Plots of log absorbance *vs.* time yielded pseudo first-order rate constants of $8{\cdot}44 \times 10^{-2}$, $8{\cdot}79 \times 10^{-2}$ and $9{\cdot}43 \times 10^{-2}$ min^{-1}, respectively. Reliable values are difficult to obtain in such experiments, however, because silver(II) oxide does not instantly dissolve in these media and rate constants are not obtainable from initial slopes. All decomposition experiments were carried out in triplicate.

Silver(II)-sulphate complexes were also obtained by electrogeneration of 0·0024*M* silver(I) perchlorate in 15*M* sulphuric acid and their decomposition followed at 361 mμ at 25·0 ± 0·15°. Good straight lines were obtained for the early portions of log absorbance *vs.* time plots and yielded calculated pseudo first-order rate constants of 1·98 × 10^{-1} and 1·85 × 10^{-1} min^{-1} for electrolysis currents of 90 *mA* and values of 1·85 × 10^{-1} and 1·90 × 10^{-1} min^{-1} at 87 *mA*.

13	0·936	4	1·001
12	0·997		

In order to establish whether or not the extent of complexation of silver(II) by sulphate has any influence on the kinetics of silver(II) decomposition to silver(I), the absorbance *vs.* time behaviour of the visible and ultraviolet complexes was compared by a ratio method. For each acid concentration (see Table II) complete spectra were recorded at preselected intervals. From these absorbance *vs.* wavelength scans, absorbance *vs.* time data for each of the two complexes could be derived and corrected for any shifts in location of peak maxima and for decomposition during the time required to record each spectrum. A comparison of the specific decomposition rates can be obtained from the slopes, m, of the resulting plots as follows:

$$\frac{A_1 - A_{11}}{t_{11} - t_1} = m_1\,, \qquad \text{for } \lambda_1 \tag{1}$$

$$\frac{A_2 - A_{21}}{t_{21} - t_2} = m_2\,, \qquad \text{for } \lambda_2 \tag{2}$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$\frac{A_{m(n)} - A_{m(n+1)}}{t_{m(n+1)} - t_{m(n)}} = m_n\,, \qquad \text{for } \lambda_m \tag{3}$$

The standard rate expression, with concentration, C, pseudo-rate constant, k^1, and and reaction order, n^1, is

$$\frac{dC}{dt} = k^1[C]^{n^1} \tag{4}$$

and if $n^1 = 1$, then

$$\frac{dC}{dt} = k^1[C] \tag{5}$$

Substituting absorbance for concentration with $A_1 - A_{11} = \Delta A_{1-11}$, $A_2 - A_{21} = \Delta A_{2-21}, \ldots A_{m(n)} - A_{m(n+1)}$ and $t_{11} - t_1 = \Delta t_{11-1}, t_{21} - t_2 = \Delta t_{21-2}, \ldots t_{m(n+1)} - t_{m(n)}$, then combining (3) with (5)

$$\frac{\Delta A_{m(n)-m(n+1)}}{\Delta t_{m(n+1)-m(n)}} = k_m{}^1 A_{m(n+1)} \tag{6}$$

Divide $k_1{}^1$ by $k_2{}^1$ and let $\Delta t_{11-1} = \Delta t_{21-2}$, then

$$\frac{\dfrac{\Delta A_{1-11}}{A_1}}{\dfrac{\Delta A_{2+21}}{A_2}} = \frac{k_1{}^1}{k_2{}^1} = K \tag{7}$$

where K is the ratio of rate constants.

In the system under present consideration, it is experimentally observed that in the ranges of 4–18*M* sulphuric acid at constant initial silver(II) oxide concentration, K, the ratio of pseudo-rate constants, is a constant. Furthermore, the ratio of the pseudo-rate constants for the decomposition of the visible and ultraviolet silver(II)-sulphate complexes is 1·000 ± 0·015 (see Table II). Because the relative concentrations of the two complexes vary widely over the range of acid concentrations studied, one can conclude from the fact that the ratio of rate constants is a constant, that the rate determining step in the silver(II) decomposition is independent of both sulphate and hydrogen ion concentrations. Also, the decomposition reaction must indeed be pseudo first-order, in the range studied, in order to yield a rate constant ratio of unity.

Acknowledgement—This investigation was supported, in part, by the Laboratory for Research on the Structure of Matter, University of Pennsylvania.

Zusammenfassung—Eine spektralphotometrische Untersuchung von Silber(II) in schwefelsaurer Lösung zeigt die Bildung zweier Sulfatokomplexe im Bereich von 8–36*n* H_2SO_4 mit Absorptionsmaxima bei 361 mμ und 260 mμ. In 30*n* H_2SO_4 ist der molare Extinktionskoeffizient von Silber(II) 3,11 × 10^4 bei 361 mμ. Kinetische Untersuchungen der Reduktion von Silber(II) durch das Lösungsmittel deuten auf einen geschwindigkeitsbestimmenden Schritt erster Ordnung bezüglich Silber(II) und liefern eine scheinbare Geschwindigkeitskonstante erster Ordnung von 1,9 × 10^{-1} min^{-1}. Weitere Untersuchungen, bei denen die H_2SO_4-Konzentration variiert wurde, zeigen, daß die spezifische Zersetzungsgeschwindigkeit der beiden Komplexe gleich ist und Änderungen in der H_2SO_4-Konzentration nur das Konzentrationsgleichgewicht zwischen den beiden Komplexen verschieben.

Résumé—Une étude spectrophotométrique de l'argent (II) dans l'acide sulfurique montre, dans le domaine 8–36*N* en SO_4H_2, la formation de deux complexes sulfato, avec des pics d'absorption maximale à 361 et 260 mμ respectivement. En SO_4H_2 30*N*, l'absorption molaire de l'argent (II) est de 3,11 × 10^4 à 361 mμ. Des études cinétiques sur la réduction de l'argent (II) par le solvant suggèrent un stade déterminant la vitesse d'ordre un en argent (II), et donnent une constante de vitesse d'ordre pseudo-un de 1,9 × 10^{-1} min^{-1}. Des études ultérieures en fonction de la concentration en SO_4H_2 montrent que la vitesse spécifique de décomposition est identique pour les deux complexes et que les variations dans la concentration de SO_4H_2 servent seulement à déplacer l'équilibre de concentration entre les deux complexes.

PHOTOMETRIC TITRATIONS—X*

THE EDTA TITRATION OF IRON(III) IN THE PRESENCE OF HIGH CONCENTRATIONS OF BISMUTH

H. FLASCHKA and J. GARRETT
School of Chemistry, Georgia Institute of Technology
Atlanta, Georgia, U.S.A.

(*Received* 15 *September* 1964. *Accepted* 25 *September* 1964)

Summary—In solutions containing a high concentration of ammonium chloride, bismuth is masked as the chloro complex, and iron(III) can be titrated with EDTA to a photometric end-point using sulphosalicylic acid as the indicator. Up to a mole ratio Bi:Fe of about 2,000, good results are obtained. At higher ratios slightly high results are obtained for the iron. The influence of some other metal ions on the titration has been studied.

THE direct chelometric titration of bismuth when present as the chloride is usually difficult, because of the formation of the insoluble oxychloride. It is known that high chloride concentrations prevent the formation of the oxychloride, or redissolve it once it has formed, provided that the pH is lower than about 3. It was thought that addition of high concentrations of chloride might offer a possibility for the direct titration of bismuth because, in such a solution, no precipitate would form. However, under these conditions bismuth gave only a faint colour or no colour at all with several metal indicators tried, and the rate of reaction of bismuth with EDTA was, from all indications, slow. These experimental findings suggested the possibility of using chloride for the "low stability masking" of bismuth. Masking by complex formation is commonly accomplished by employing low concentrations of complexing agents which form fairly stable complexes. However, a few cases are known where high concentrations of complexing agents which form weak complexes are employed. Notable examples are the masking of thorium with sulphate[1] and, recently, of cadmium with iodide.[2] Thus the term "low stability masking" was coined,[3] and investigations indicated that this approach offers further interesting possibilities.

To test this idea an attempt was made to titrate iron in the presence of bismuth, masking the latter by chloride. The stabilities of the EDTA complexes of iron and bismuth are of nearly the same order. Consequently the metals mutually interfere in titration. Although it is not difficult to titrate bismuth in the presence of iron when the latter is masked by reduction to iron(II) with ascorbic acid, the determination of iron in the presence of bismuth is possible only by difference methods. The sum iron + bismuth is titrated in one aliquot and the bismuth is titrated in a second aliquot, after the iron is masked by reduction; the iron is obtained by difference. This procedure yields good results for iron only if the Bi:Fe ratio is close to or below unity. With bismuth present in increasing excess, the results for iron rapidly become less accurate.

---

* Part IX: *Talanta*, 1964, **11**, 1067.

Sulphosalicylic acid was employed as the indicator for the titration of iron at pH 2–3. Preliminary experiments revealed that the colour of the iron-sulphosalicylic acid complex is discharged only slowly after the addition of excess EDTA, when the amount of ammonium chloride added is not higher than that required to redissolve the bismuth oxychloride initially formed. But with the solution nearly saturated with ammonium chloride, the colour disappeares rapidly and with seemingly equivalent amounts of EDTA. However, the disappearance of the red colour at the end-point was only gradual, especially with a large excess of bismuth present. Thus, in this particular case, no visual end-point could be obtained and a photometric titration was used.

EXPERIMENTAL

Apparatus

The phototitrator described by Flaschka and Sawyer[5] was employed with a heat filter mounted in the light path.[6] An interference filter with the nominal wavelength of 508 mμ was used. All titrations were performed in a glass cell with a 2-cm path length and a 200-ml capacity.

Reagents

All solutions were prepared from reagent-grade materials. Deionised water was used exclusively.

An approximately 0·1*M EDTA solution* was prepared by dissolving 37 g of the disodium salt dihydrate and making the volume to 1 litre.

An approximately 0·1*M iron solution* was prepared by dissolving 40 g of iron(III) nitrate in 1 litre.

A 0·6*M bismuth solution* was prepared by dissolving 290 g of bismuth nitrate in water to which several ml of concentrated nitric acid had been added, and diluting to 1 litre.

The EDTA solution was standardised against 0·10000*M* zinc solution which had been prepared by dissolving 6·538 g of zinc metal (99·99% purity) in the minimum amount of dilute nitric acid, and diluting to 1 litre. The standardisation was performed by titration at pH 5, using Xylenol Orange as indicator. This EDTA solution was used as the reference in the standardisation of the iron(III) solution, using sulphosalicylic acid as indicator at pH 2–3 in a photometric titration. Appropriate dilutions of the stock solutions were performed in order to obtain 0·01*M* iron and EDTA solutions.

Ammonium chloride was used as the solid and as a saturated aqueous solution.

The *indicator solution* was prepared by dissolving 1 g of sulphosalicylic acid in 10 ml of water.

Procedure

An accurately measured amount of the metal ion solution was transferred to the titration cell and enough hot water was added to make the solution volume 75–100 ml. Then 20–30 g of solid ammonium chloride were added in 5-g portions, with vigorous stirring, until no more solid was observed to dissolve readily. The remaining solid was dissolved by adding small amounts of hot water, and the solution volume was then brought to about 150 ml with a saturated ammonium chloride solution. The solution was cooled to room temperature, and the pH was adjusted to between 2 and 3 by dropwise addition of dilute sodium hydroxide, with vigorous stirring to minimise the local precipitation of bismuth salts. The cell was positioned in the phototitrator, which was then adjusted to indicate a transmittance of 85–90%. Finally, 4–5 drops of indicator were added and the titration was carried out at 508 mμ in the usual manner, with 0·01–0·1*M* EDTA.

RESULTS AND DISCUSSION

The results of several titrations of iron(III), alone and in the presence of bismuth and other metals, are presented in Table I. Using the procedure presented above, solutions with a molar ratio of Bi:Fe of 2,100 were titrated, and showed the precision and accuracy to be expected with the apparatus and technique employed. When the ratio was increased to 3,000 and slightly above, a tendency towards increasing positive errors was observed. Impurities of iron or other titratable metals in the bismuth salt may be responsible for this trend, but it is more likely that at this high ratio some bismuth is also titrated.

The rate of fading of the colour of the iron-sulphosalicylic acid complex upon the addition of an increment of titrant solution decreases considerably for Bi:Fe ratios above 1,000, and it becomes necessary to wait 4–5 min for the reaction to go to virtual completion after each addition of titrant. However because only a few points are required for locating the end-point graphically, this delay is not too serious. A reasonable explanation for the delayed reaction may be suggested. As the EDTA is added to the solution containing such a high concentration of bismuth, complex formation first occurs with that metal; then the iron exchanges with the bismuth, and this exchange reaction takes place slowly.

A mole ratio, Bi:Fe, of 3,000 is equivalent to a weight ratio of approximately 11,200. Thus the situation in the artificial solutions parallels the determination of about 0·01% of Fe in a bismuth metal sample of which 12 g were taken. The determinations at this ratio were precise to about 4% relative. At these levels of amounts and ratios, the success of a titrimetric determination is rather unusual. It must, of course, be considered that in an actual analysis less favourable results may be obtained because of the presence of interfering impurities.

For the titration of iron at the high Bi:Fe ratios it is necessary to obtain the maximum amount of dissolved chloride. In order to incorporate as much ammonium chloride as possible, it is helpful to warm the saturated ammonium chloride solution in contact with excess solid salt, before using it to raise the volume of the solution in the titration cell to 150 ml.

Predictions about elements that may interfere with the iron titration may be made cautiously from a comparison of the stability constants, and from knowledge of the situation in the absence of extreme chloride concentrations. Because iron(III) is known to form chloro complexes, the effective stability constant of the iron(III)-EDTA complex may be lowered to such an extent that the metals which are of no influence under normal conditions may interfere at high chloride concentrations. Several metals were added in order to see if there was a noticeable effect on the position and quality of the end-point. No effects were observed with calcium, magnesium, mercury, indium, lead, manganese or zinc in solutions containing the ratios of metal:Fe indicated in Table I. No attempt was made to establish limiting ratios. Cobalt slowed the rate of reaction considerably at a ratio of 250. Nickel and copper could only be tolerated in concentrations up to about that of iron(III). As expected, aluminium interfered and high results were obtained, implying that this metal is partially titrated. Zirconium and hafnium were fully titrated under these conditions. Gallium, in contrast to indium, was not completely masked by the chloride and high results for iron were obtained at a ratio Ga:Fe as low as 1. Titanium slowed the reaction between iron and EDTA to such an extent that the titration became impracticable, even with equal concentrations of titanium and iron.

The interference studies reported are only exploratory in nature, because the main concern of the present investigation was masking of bismuth and the determination of iron. A study of the application of low stability masking with chloride, and of the exclusion of some interfering metals by addition of further masking agents is under way on a broader basis, and any results of interest will be published at a later date.

Acknowledgement—The presented work was conducted under a grant of the National Science Foundation, Washington, D.C. This aid is most gratefully appreciated.

Zusammenfassung—In Lösungen, die hohe Konzentrationen an Ammoniumchlorid enthalten, wird Wismut als Chlorokomplex maskiert; Eisen(III) kann dann mit AeDTE gegen Sulfosalicylsäure als Indicator photometrisch titriert werden. Bis zu einem Molverhältnis Bi/Fe von etwa 2000 werden gute Resultate erhalten. Bei höheren Verhältnissen ergeben sich leichte Überwerte. Der Einfluss einiger anderer Metall wird studiert.

Résumé—Dans les solutions à forte concentration en chlorure d' ammonium, le bismuth est dissimulé à l'état de chloro-complexe, et l'on peut doser le fer (III) au moyen d'EDTA, avec virage final photométrique, en utilisant comme indicateur l'acide sulfosalicylique. On obtient de bons résultats jusqu'à un rapport molaire Bi/Fe de 2000 environ. Pour des rapports plus grands, on obtient, pour le fer, des résultats légèrement trop élevés. On étudie l'influence de quelques autres ions métalliques sur le dosage.

Summary—The reaction of quadrivalent osmium and iridium with antipyrine and some of its derivatives has been studied, and it has been shown that in acidic solutions the compounds $(R.H)_2MeX_6$ are formed. The extraction of the halide complexes of osmium, iridium, ruthenium, rhodium, platinum and palladium with diantipyrylpropylmethane by dichloroethane has been investigated. An extraction–photometric method is proposed for determining 2–20 μg/ml of osmium in the presence of 40 mg of ruthenium and for determining 4–40 μg/ml of iridium in the presence of 4 mg of rhodium. The error of the determination is ±10%. A gravimetric method is proposed for determining 5–13 mg of osmium and iridium with diantipyrylpropylmethane and diantipyrylmethane. The error of the determination is ±3%. The possibility is shown of the extractive separation of small amounts of iridium and rhodium, platinum and rhodium, and palladium and rhodium, using diantipyrylpropylmethane.

THE platinum metals form stable complex anions with a number of monodentate inorganic ligands. During the analysis of the platinum metals, they frequently pass into solution in the form of anionic chloride and bromide complexes: $Me^{IV}X_6^{2-}$ and $Me^{II}X_4^{2-}$. where X is Cl^- or Br^- and Me is a platinum metal. These anions form compounds with many organic bases. Some of the organic bases (strychnine,[1–3] brucine,[4] acridine,[5,6] tetraphenylarsonium chloride,[7–10] fatty amines[15]), and tributyl phosphate,[11–14] have been used for the gravimetric and photometric determination or extractive separation of the platinum metals.

We have made a detailed study of the reaction of the halide complexes of the platinum metals with antipyrine and its derivatives (diantipyrylmethane, diantipyrylpropylmethane and diantipyrylphenylmethane) in order to develop new and improved analytical methods for the determination and separation of the platinum metals. These reagents are widely used in analytical chemistry at the present time. In acid solutions they are present in the form of cations, and these react with the anionic metal complexes:

$$[Me^{m}X_{n}]^{-(m-n)} + (m + n)RH^{+} \rightleftharpoons (RH)_{(m-n)}[Me^{m}X_{n}] \qquad (1)$$

It was found that quadrivalent osmium, iridium and platinum, and also bivalent platinum and palladium, are precipitated from hydrochloric acid solutions (0·5–2M) and hydrobromic acid solutions by antipyrine, diantipyrylmethane, diantipyrylpropylmethane and diantipyrylphenylmethane. The compounds formed possess valuable analytical properties—a high molecular weight, low water solubility, the capacity for being extracted with organic solvents, a characteristic coloration, *etc.* We have used these properties to develop extraction-photometric and gravimetric methods for the determination of osmium and iridium and for the extractive separation of rhodium from platinum, palladium and iridium.

EXPERIMENTAL

Reagents

Osmium, ruthenium, iridium and platinum were used in the form of the following salts: $(NH_4)_2OsCl_6$, $(NH_4)_2OsBr_6$;[16] $(NH_4)_2RuOHCl_5$;[17] $(NH_4)_2RuOHBr_5$;[18] $(NH_4)_2IrCl_6$;[19] $(NH_4)_2IrBr_6$;[20] $(NH_4)_2PtCl_6$;[21] $(NH_4)_2PtBr_6$.[22]

The content of metal in the products was determined by calcining a weighed sample in a current of hydrogen (in air in the case of the platinum preparation) to constant weight of metallic osmium, ruthenium, iridium or platinum. Standard solutions were prepared by dissolving weighed amounts of the salts.

The hydrochloric and hydrobromic acid solutions of the rhodium and palladium salts were prepared from metallic rhodium and palladium by known methods.[23-25] The contents of rhodium and palladium in the prepared solutions were determined gravimetrically by means of thionalide[26] and dimethylglyoxime,[27] respectively.

The antipyrine was a commercial preparation with a melting point of 113·5–114·5°. The diantipyrylmethane,[28] diantipyrylpropylmethane[29] and diantipyrylphenylmethane[30] were synthesised from antipyrine by condensing it with the corresponding aldehydes. The materials obtained were purified by recrystallisation from ethanol.

Preparation and Composition of Compounds of Osmium(IV) and Iridium(IV) with Antipyrine and Its Derivatives

When acidic solutions of $(NH_4)_2OsCl_6$, $(NH_4)_2OsBr_6$, $(NH_4)_2IrCl_6$ or $(NH_4)_2IrBr_6$ and of the various antipyrine derivatives were mixed, curdy precipitates of low water-solubility immediately separated. To study the composition and properties of these precipitates, they were obtained in a pure state by the following method.

A hydrochloric (or hydrobromic) acid solution, containing 20–30 mg of osmium or iridium in the form of $(NH_4)_2OsCl_6$, $(NH_4)_2OsBr_6$, $(NH_4)_2IrCl_6$ or $(NH_4)_2IrBr_6$, was treated with 5–8 ml of a 2% solution of diantipyrylmethane, diantipyrylpropylmethane or diantipyrylphenylmethane in acetic acid (1:1).* The curdy precipitates which separated were filtered off and washed three or four times with water acidified with hydrochloric acid (or hydrobromic acid) and then three or four times with water alone.

The materials obtained were purified by recrystallisation from a 1:1 mixture of methanol and acetone and were analysed for their contents of osmium and iridium by calcining a weighed sample in a current of hydrogen to constant weight of metallic osmium or iridium.

Table I gives the formulae of the compounds (from the results of chemical analysis) and also some of their properties.

To elucidate the structure of the compounds, their infrared spectra were recorded in the crystalline state. The spectra were taken on a IKS-14 spectrophotometer in Nujol over the frequency range 4000—700 cm^{-1}.

As can be seen from Table II (Fig. 1), the band of carbonyl absorption at 1650–1660 cm^{-1}, present in antipyrine, diantipyrylmethane and diantipyrylpropylmethane,

---

* Because of their high solubility in water, the compounds with antipyrine were isolated by adding dry antipyrine to a solution of the osmium or iridium salt.

TABLE I.—COMPOSITION AND PROPERTIES OF THE COMPOUNDS OF OSMIUM (IV) AND IRIDIUM (IV) WITH ANTIPYRINE AND ITS DERIVATIVES OBTAINED

m = medium-intensity, s = strong, w = weak.

disappears and bands of comparatively low intensity appear in the region of 1500–1560 cm^{-1}. In the region of absorption of the O—H and $\overset{+}{N}$—H groups, broad intense bands appear (3500–3000 cm^{-1}), the intensity of these bands in the antipyrine complexes being considerably higher than in the diantipyrylmethane and diantipyrylpropylmethane complexes. A number of the spectra are characterised by intense absorption in the region of 3500–1800 cm^{-1}.

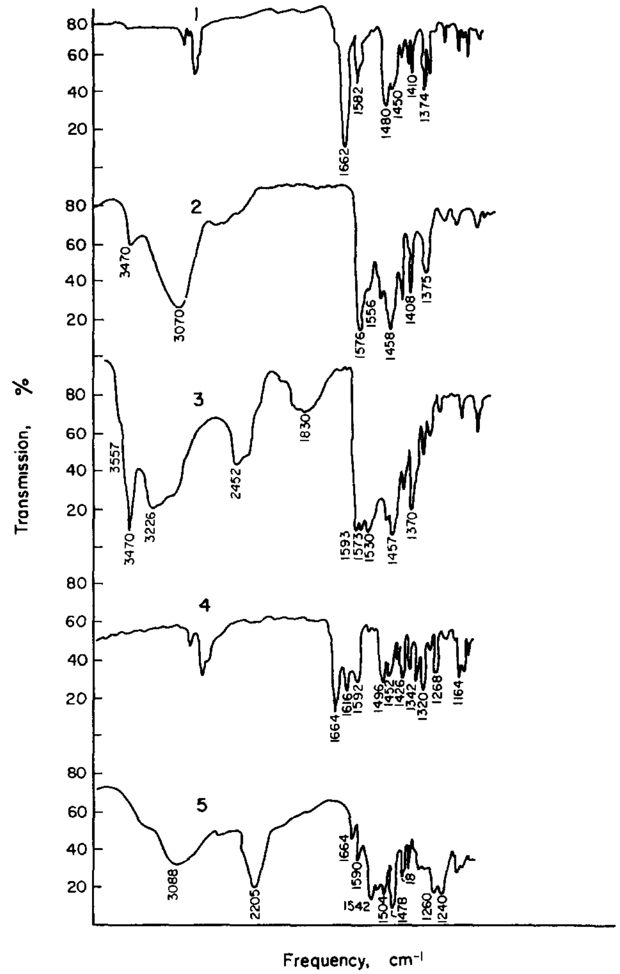

FIG. 1.—Infrared spectra of compounds in the crystalline state (in Nujol):

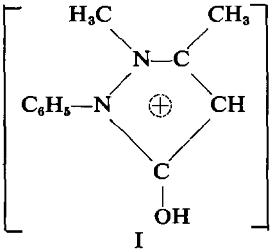
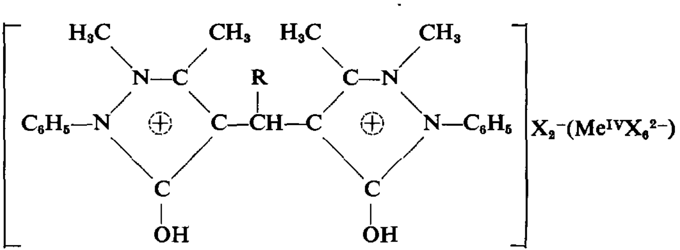
1. antipyrine,	4. diantipyrylmethane,
2. antipyrine hexachloro-osmate,	5. diantipyrylmethane hydrochloride.
3. antipyrine hexabromo-osmate,	

The assignment of the absorption bands, in the complexes investigated, in the region of 3500—3000 cm^{-1} to the stretching vibrations of the $\overset{+}{N}$—H bond does not agree with the behaviour of the carbonyl band. In fact, the interaction of the protons with the N_1 or N_2 nitrogen atoms must lead to a displacement of the C=O band to the high-frequency region, *i.e.*, under these conditions, the conjugation of the C=O bond with the unshared pair of electrons of the nitrogen atom will decrease and their electronegativity will increase.[31]

Thus, the appearance of bands in the region of 3500–3000 cm^{-1} in compounds of antipyrine and its derivatives with acids is connected with the addition of a proton to the carbonyl oxygen atom with subsequent opening of the carbonyl bond and formation of a hydroxyl group, which leads to the formation of onium salts of types I and Ia.



I



Ia

However, the appearance in the spectra of the compounds studied (Fig. 1, Table II) of absorption bands in the region of 2500–1800 cm^{-1} evidently shows an interaction of the antipyrine cation with the anions not only through electrostatic forces but also as a consequence of the formation of hydrogen bonds:

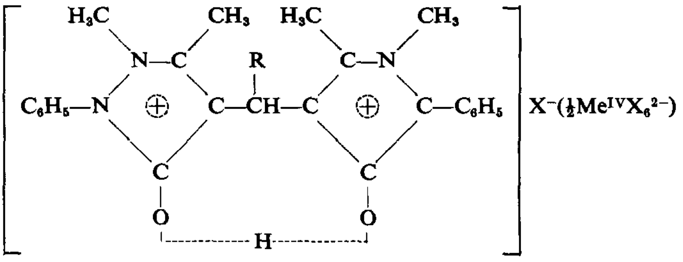
$$>\mathrm{C—O—H}\cdots\mathrm{X}\,(\mathrm{H_2MeX_6}) \rightleftharpoons\ >\mathrm{C}\overset{\cdots}{-}\mathrm{O}\cdots\mathrm{HX}\,(\mathrm{H_2MeX_6}).$$

The bands in the region of 1500–1560 cm^{-1} are apparently connected with the absorption of the strongly polarised $\mathrm{C}\overset{\cdots}{-}\mathrm{O}$ bond in the complexes

$$>\mathrm{C}\overset{\cdots}{-}\mathrm{O}\cdots\mathrm{HX}\,(\mathrm{H_2MeX_6}).$$

The considerably increased intensity of the hydroxyl absorption bands in the compounds of diantipyrylmethane and diantipyrylpropylmethane with osmium(IV) and iridium(IV) is probably connected with the formation of strong intramolecular hydrogen bonds between one proton and two carbonyl oxygen atoms (see formula II below). This is in agreement with the aromatic nature of antipyrine. In actual fact, in the formation of complex II (see below), the proton evidently adds first to one of the two carbonyl oxygen atoms in the diantipyrylmethane (or diantipyrylpropylmethane) with subsequent formation of a strong intramolecular hydrogen bond in which the proton is attached to the two carbonyl oxygen atoms to the same extent. The intensity of the absorption of such hydroxyl groups is particularly strongly reduced.[32]

The results obtained on the structure of the compounds of antipyrine and its derivatives with quadrivalent osmium and iridium are in good agreement with the fact that in all of the compounds formed in an acidic medium antipyrine and its



II

derivatives participate as singly charged cations (see I above). This fact is difficult to explain if the basicity of antipyrine and its derivatives is connected with the basicity of the heterocyclic nitrogen atoms. In actual fact, in the case of antipyrine, the formation of a singly charged cation can be connected formally with a weakening of the basic properties of the nitrogen present in the α-position to the C═O group. In the case of diantipyrylmethane, diantipyrylpropylmethane and other derivatives having two nitrogen atoms of equivalent basicity in the molecule, however, it is difficult to see why protonation takes place only in respect of one of them.

Thus, the compounds of antipyrine and its derivatives that have been obtained with quadrivalent osmium and iridium are, in the crystalline state, salts of the cations of antipyrine, diantipyrylmethane and diantipyrylpropylmethane with the anions $OsCl_6^{2-}$, $OsBr_6^{2-}$, $IrCl_6^{2-}$ and $IrBr_6^{2-}$. The formation of these compounds may be expressed by the equation:

$$2R + Me^{IV}X_6^{2-} + 2H^+ \rightleftharpoons (R\cdot H)_2MeX_6.$$

Solubility of Compounds of Osmium(IV) and Iridium(IV) with Antipyrine and Its Derivatives in Aqueous Solution

The hexachloro- and hexabromo-osmates and the hexachloro- and hexabromo-iridates of diantipyrylmethane, diantipyrylpropylmethane and diantipyrylphenylmethane are sparingly soluble in water, but readily soluble in certain organic solvents—dichloroethane and chloroform. The compounds of osmium(IV) and iridium(IV) with antipyrine, on the other hand, are readily soluble in water and sparingly soluble in organic solvents. As a rule, the bromine-containing complexes are less soluble in water than the corresponding chlorine-containing complexes (see Table I).

The influence of the concentrations of the acid, the reagent and alkali-metal chlorides on the solubility of diantipyrylpropylmethane hexachloro-osmate and -iridate and of diantipyrylmethane hexabromo-osmate has been studied. The procedure used was as follows.

A freshly produced precipitate, carefully washed with water, was placed in a bottle containing 50 ml of hydrochloric acid (or hydrobromic acid) of the appropriate concentration and shaken in a thermostat at 25° for 2–3 hr (it was established by preliminary experiments that this time was sufficient for saturation). The resulting saturated solution was rapidly filtered through filter paper, the first portion of the filtrate being rejected. The content of metal in an aliquot of the clear filtrate was determined: osmium with thiourea[33] or with diantipyrylpropylmethane (for the method, see below), and iridium with diantipyrylpropylmethane (for the method, see below).

The results obtained are given in Figs. 2–4. In the presence of sodium chloride, the solubility of the iridium compound diminishes somewhat; the solubility of the osmium compound remains practically unchanged.

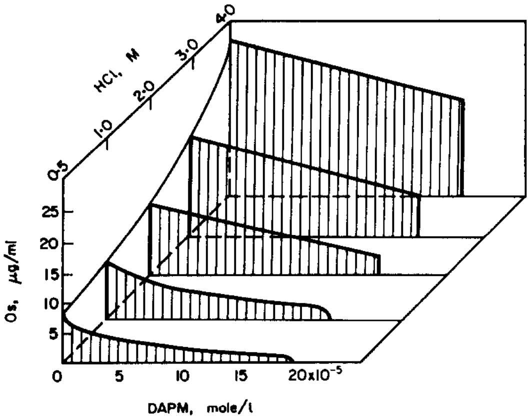


FIG. 2.—Influence on the solubility of $(C_{26}H_{30}O_2N_4{\cdot}H)_2OsCl_6$ of the concentration of hydrochloric acid and diantipyrylpropylmethane (DAPM).

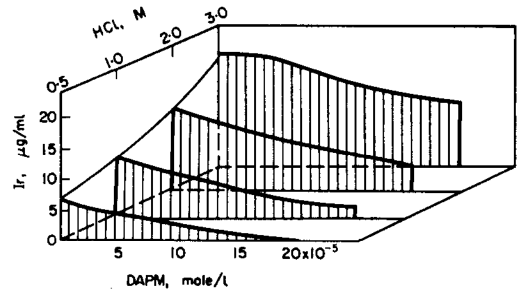

FIG. 3.—Influence on the solubility of $(C_{26}H_{30}O_2N_4{\cdot}H)_2IrCl_6$ of the concentration of hydrochloric acid and diantipyrylpropylmethane (DAPM).

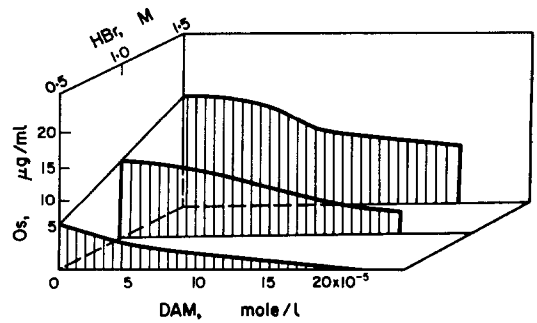

FIG. 4.—Influence on the solubility of $(C_{23}H_{24}O_2N_4{\cdot}H)_2OsBr_6$ of the concentration of hydrobromic acid and diantipyrylmethane (DAN).

Extractability of Osmium and Iridium, and also of Platinum, Palladium, Ruthenium and Rhodium with Dichloroethane in Presence of Diantipyrylpropylmethane

In the presence of diantipyrylpropylmethane, quadrivalent osmium, iridium, platinum and ruthenium, and also bivalent palladium, are well extracted by dichloroethane from hydrochloric and hydrobromic acid solutions.

Tervalent ruthenium, rhodium and iridium are extracted considerably less well.

TABLE III.—EXTRACTABILITY OF CHLORIDES OF COMPLEXES OF PLATINUM, PALLADIUM, IRIDIUM AND RHODIUM FROM HYDROCHLORIC ACID SOLUTIONS (1*M*) WITH DICHLOROETHANE IN PRESENCE OF DIANTIPYRYLPROPYLMETHANE[a]

Metal	Metal taken, *mg*	Metal found, *mg*		Percentage extraction, E	Distribution coefficient, D[b]
		Aqueous phase	Organic phase

	10·23	8·80	2·50	14·7	0·34
	10·23	8·80	1·54	15·0	0·35

[a] Extraction carried out with 10 ml of a 1% solution of diantipyrylpropylmethane in dichloroethane. Contents of platinum, palladium, iridium and rhodium in each of the phases determined by means of tin(II) chloride.[34–37]

[b] $D = \frac{\text{mg/ml of metal in organic phase}}{\text{mg/ml of metal in aqueous phase}}$.

The greatest difference in extractability is found with hydrochloric acid solutions. Thus, the extractability of osmium is 94–96%, of iridium 98·5%, of platinum > 99%, of palladium > 99%, of ruthenium(IV) 96·5%, of ruthenium(III) 1·5% and of rhodium(III) 15%, in extraction from solutions 1*M* with respect to hydrochloric acid by a 1% solution of the reagent in dichloroethane (Tables III and IV).

The extractability of the platinum metals depends on the acidity of the aqueous solution and on the excess of reagent.

A 6- to 10-fold excess of diantipyrylpropylmethane is sufficient for the complete extraction of osmium(IV), iridium(IV), platinum(IV) and palladium(II) (Fig. 5; the study was carried out spectrophotometrically from the optical density of the extracts).

TABLE IV.—EXTRACTABILITY OF CHLORIDES OF COMPLEXES OF RUTHENIUM AND OSMIUM FROM HYDROCHLORIC ACID SOLUTIONS (1*M*) WITH DICHLOROETHANE IN PRESENCE OF DIANTIPYRYLPROPYLMETHANE[a]

3·0	95·0	3·6	—
4·0	96·5	5·6	—

[a] Extraction carried out with 10 ml of a solution of the given concentration of the reagent in dichloroethane (volume of aqueous phase: 20 ml). Extraction of osmium and ruthenium studied by means of the radioactive isotopes ^{191}Os and $^{106}Ru + ^{106}Rh$.

Ruthenium(IV) requires a 150-fold excess of the reagent (Table IV). The percentage extraction of tervalent ruthenium and of rhodium, even with a large excess of diantipyrylpropylmethane, did not exceed 6% and 15%, respectively (Tables IV and V).

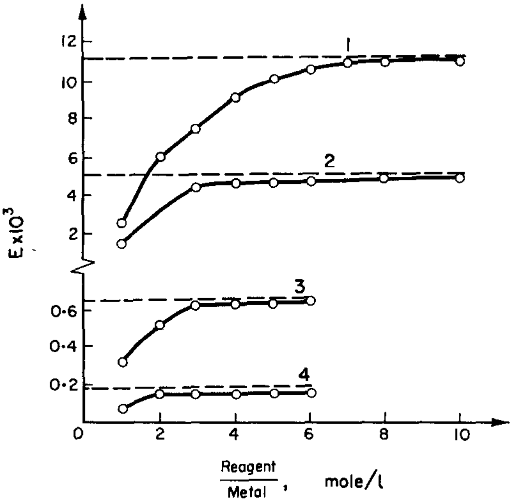

FIG. 5.—Influence of an excess of diantipyrylpropylmethane on the extraction of:
1. osmium, 3. platinum,
2. iridium, 4. palladium.

The extractability of osmium(IV), iridium(IV), platinum(IV) and palladium(II) remains practically constant over a wide range of concentrations of acid (0.5–5*M* hydrochloric acid) (Fig. 6). The percentage extraction of ruthenium and rhodium (Table VI) decreases with an increase in the concentration of the hydrochloric acid.

Photometric Method for Determination of Osmium(IV) and Iridium(IV) by Means of Antipyrine Derivatives

The dichloroethane extracts of quadrivalent osmium and iridium are intensely coloured. The absorption curves (Fig. 7) for all three complexes of osmium and

1. osmium, 4. platinum,
2. ruthenium(IV) 5. palladium.
3. iridium,

iridium with diantipyrylmethane, diantipyrylpropylmethane and diantipyrylphenylmethane are identical with one another, and the coefficients of molar absorption are practically the same. Curves 2 and 4 (Fig. 7) show the light absorption of solutions of ammonium hexachloro-osmate and -iridate in 1*M* hydrochloric acid, respectively. By comparing curves 1 and 2 with 3 and 4, the light absorption of the extracts arises from the absorption of the $OsCl_6^{2-}$ and $IrCl_6^{2-}$ anions. A slight displacement of the absorption curves of the extracts to the long-wave region of the spectrum and an increase in the intensity of the absorption are connected with the replacement of the ammonium cation in the compounds $(NH_4)_2MeX_6$ by the large organic cations $(C_{23}H_{24}O_2N_4{\cdot}H)^+$, $(C_{26}H_{30}O_2N_4{\cdot}H)^+$ and $(C_{29}H_{28}O_2N_4{\cdot}H)^+$ and with the change of solvent. Analogous phenomena are found in the case of the bromine-containing compounds. The light-absorption curves of solutions of the pure materials in dichloroethane proved to be identical with the absorption curves of the extracts.

It was found by the method of isomolar series that the ratio of metal to reagent in the extracted compounds was 1:2, *i.e.*, the extracted compounds had the same composition as those isolated in the crystalline state.

The optical density of the extracts is proportional to the concentration in the range 2–20 μg/ml of osmium and 4–40 μg/ml of iridium. This has permitted the development of simple photometric methods for determining osmium and iridium.

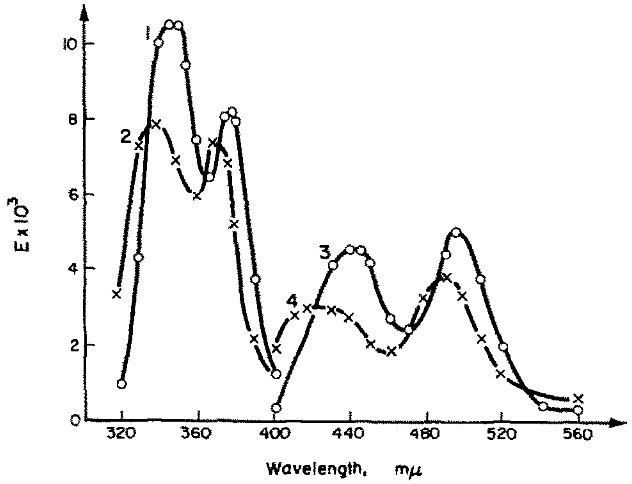

Fig. 7.—Absorption curves of the chlorides of complexes of osmium (1) and iridium (3) with antipyrine derivatives, and of ammonium hexachloro-osmate (2) and ammonium hexachloro-iridate (4).

The most suitable reagent for the extraction and subsequent photometric determination of osmium and iridium is diantipyrylpropylmethane and the most suitable organic solvent is dichloroethane.

Ruthenium does not interfere with the determination of osmium if it is first converted to the tervalent state. As mentioned above, in the presence of a small excess of reagent (10 ml of a 0·1 % solution in dichloroethane for 0·8 mg of osmium) it is not appreciably extracted.

Rhodium does not interfere with the determination of iridium if the content of the former in the initial solution does not exceed 4 mg. In this case, the amount of rhodium passing into the organic phase does not exceed 0·2 mg (on extraction with a 0·2 % solution of the reagent). The light absorption of an extract containing 0·2 mg of rhodium at 498 mμ (maximum of the light absorption of the iridium complex) is insignificant.

After a detailed study of the reaction of osmium and iridium tetrachlorides with the antipyrine derivatives and an investigation of the behaviour of the other platinum metals under the conditions of the formation of the osmium and iridium complexes, extraction-photometric methods were developed for the determination of osmium in the presence of ruthenium and of iridium in the presence of rhodium. The methods are simple to carry out and are as follows.

Determination of osmium in presence of ruthenium. A hydrochloric acid solution (3–6*M* with respect to this acid), containing osmium in the form of $OsCl_6^{2-}$ and ruthenium, is heated with hydrazine hydrochloride or hydrazine sulphate for 10–15 min until the dark red colour of the solution changes to pale yellow. Under these conditions, the ruthenium is reduced to the tervalent state while the osmium remains in the quadrivalent state.

After cooling, the solution is transferred to a separating funnel and the osmium tetrachloride extracted with 10 ml of a 0·1 % solution of diantipyrylpropylmethane in dichloroethane. The optical density of the extract is measured at 346 mμ or 378 mμ and the osmium content found from a calibration curve. The method permits the determination of 2–20 μg of osmium/ml in the presence of 40 mg of ruthenium (Table VII).

TABLE VII.—SPECTROPHOTOMETRIC DETERMINATION OF OSMIUM AND IRIDIUM WITH DIANTIPYRYLPROPYLMETHANE

Amount taken, μg		Amount added, mg		Found, μg		Error, %	
Os	Ir	Ru	Rh	Os	Ir	Os	Ir
19·0	—	6·10	—	19·0	—	0·0	—
38·0	—	30·52	—	39·7	—	+4·5	—
57·0	—	27·46	—	62·5	—	+9·6	—
171·2	—	18·30	—	163·0	—	−4·8	—
152·1	—	36·61	—	150·0	—	−1·3	—
133·1	—	45·76	—	141·0	—	+5·9	—
114·1	—	18·30	—	110·0	—	−3·6	—
—	38·6	—	0·988	—	40·5	—	+4·9
—	77·2	—	4·09	—	75·3	—	−2·5
—	347·6	—	4·09	—	351·4	—	+1·1
—	38·6	—	2·04	—	36·7	—	−4·9
—	154·5	—	3·952	—	152·5	—	−1·2
—	77·2	—	1·976	—	81·1	—	+5·0
—	231·7	—	1·02	—	237·5	—	+2·5

The error of the above determination is ±10%. Thus, the extraction-photometric method for determining osmium by means of diantipyrylpropylmethane is not inferior in sensitivity to the widely used thiourea method,[33] but its selectivity is superior to that of all known photometric methods of determining osmium.

The method may be used for the analysis of hydrochloric acid distillates and other solutions of osmium after this had been converted to $OsCl_6^{2-}$.

Determination of iridium in presence of rhodium. A solution, containing iridium and not more than 4 mg of rhodium, is twice evaporated on a water-bath with concentrated hydrochloric acid, in the presence of sodium chloride and hydrogen peroxide, to the state of moist salts to convert the iridium to $IrCl_6^{2-}$. The residue is dissolved in water, the solution transferred to a separating funnel and the iridium extracted with 10 ml of a 0·2 % solution of diantipyrylpropylmethane in dichloroethane. The optical density of the extract is measured at 490 mμ and the content of iridium found from a calibration curve. The method permits the determination of 4–40 μg of iridium/ml in the presence of up to 4 mg of rhodium with an accuracy of ±10% (Table VII).

The extraction-photometric method for determining iridium by means of diantipyrylpropylmethane is equal in sensitivity to the method used in practice,[38–40] being inferior in this respect to the majority of other photometric methods for determining iridium. However, it is favourably distinguished from them in respect of selectivity, permitting the determination of up to 4 μg/ml in the presence of 100-fold amounts of rhodium. In our opinion, the method can be used for the analysis of any solution of iridium after its conversion to $IrCl_6^{2-}$.

The extraction-photometric determination of osmium and iridium in the form of the bromide complexes is not selective, *i.e.*, all platinum metals, including tervalent ruthenium and rhodium, are extracted well from hydrobromic acid solutions with the formation of coloured extracts.

Gravimetric Methods for Determination of Osmium and Iridium by means of Antipyrine Derivatives

Because the development of gravimetric methods for osmium and iridium is of practical importance, we have studied the possibility of using for this purpose the compounds of quadrivalent osmium and iridium with antipyrine derivatives that we have obtained.

Diantipyrylmethane (with precipitation from hydrobromic acid solution) and diantipyrylpropylmethane (with precipitation from hydrochloric acid solution) must be considered the most suitable reagents for the gravimetric determination of osmium and iridium. Diantipyrylphenylmethane is unsuitable because of the low solubility of its hydrochloride and hydrobromide. For the same reason, it is also undesirable to use diantipyrylpropylmethane in precipitation from hydrobromic acid solutions.

In the presence of a small excess of the reagent, quadrivalent osmium and iridium are precipitated practically completely from hydrochloric acid solutions by diantipyrylpropylmethane; quadrivalent osmium is also precipitated quantitatively from hydrobromic acid solutions by diantipyrylmethane (Figs. 2–4). Thus, in a solution $0{\cdot}5M$ with respect to hydrochloric acid and containing 20×10^{-5} mole/l. of reagent in excess, osmium cannot be detected with thiourea[33] nor iridium with a mixture of acids (H_2SO_4—H_3PO_4—$HClO_4$). From the results obtained, a gravimetric method for the determination of osmium and iridium has been developed.

Determination of osmium and iridium. A 2% solution of diantipyrylpropylmethane (or diantipyrylmethane in precipitation from hydrobromic acid solutions) in acetic acid (1:1) is added slowly with stirring to 60–70 ml of hydrochloric acid solution ($0{\cdot}1$–$0{\cdot}5M$) or a corresponding hydrobromic acid solution, containing osmium in the form of $OsCl_6^{2-}$ or $OsBr_6^{2-}$ or iridium in the form of $IrCl_6^{2-}$, until the addition of a fresh portion of the reagent causes no further precipitation. A further 1 ml of the reagent solution is then added and the solution containing the precipitate is allowed to stand for 2–3 hr. The resulting precipitate is filtered off through a No. 4 filter crucible, washed 4–5 times with a 0·05–0·1% solution of the reagent in $0{\cdot}5M$ hydrochloric acid, dried to constant weight at 100–110° and weighed. As can be seen from Table VIII, using diantipyrylmethane and diantipyrylpropylmethane it is possible to determine 5–13 mg of osmium and iridium by precipitation and weighing in the form of $(C_{26}H_{30}O_2N_4{\cdot}H)_2OsCl_6$, $(C_{23}H_{24}O_2N_4{\cdot}H)_2OsBr_6$ or $(C_{26}H_{30}O_2N_4{\cdot}H)_2IrCl_6$.

The error of the above determination is ±3%. Platinum and palladium interfere with the determination, forming sparingly soluble compounds with the antipyrine derivatives. Ruthenium and rhodium, although they do not give sparingly soluble compounds, nevertheless undergo considerable coprecipitation with the osmium and iridium precipitates. Thus, they precipitate to the extent of 2–3% from hydrochloric acid solutions of quadrivalent and tervalent ruthenium, as was found by means of the $^{106}Ru + {}^{106}Rh$ isotope. On precipitation from hydrobromic acid solutions, the amount of quadrivalent ruthenium coprecipitated increases to 20% and that of tervalent ruthenium to 7%.

The gravimetric methods for the determination of osmium and iridium by means of diantipyrylmethane and diantipyrylpropylmethane are favourably distinguished from many other gravimetric methods, firstly, because they do not require calcination of the precipitate to the metal and, secondly, because they permit the determination of milligram-amounts of osmium and iridium with great accuracy because of the small conversion factor to the metal. The disadvantage of these methods is their low selectivity: all platinum metals interfere with the determination.

Extractive Separation of Iridium and Rhodium, Platinum and Rhodium, and Palladium and Rhodium by means of Diantipyrylpropylmethane

The difference in extractability of iridium(IV), platinum(IV), palladium(II) and rhodium(III) has permitted the development of an extraction method for separating small amounts (6–10 mg) of rhodium and iridium, rhodium and platinum, and rhodium and palladium with the aid of diantipyrylpropylmethane.

Before separation, the solution containing the platinum metals was evaporated three times with concentrated hydrochloric acid, sodium chloride and hydrogen peroxide, to convert the platinum metals to the chloride complexes. During the extraction, part of the quadrivalent iridium may be reduced to the tervalent state, so that this operation of evaporating the solution must be repeated before each successive extraction. Moreover, it has been found that the extraction of the chloride complex of rhodium is irreversible, *i.e.*, when the extract is shaken with 1*M* hydrochloric acid no appreciable amounts of rhodium pass into the aqueous phase. To re-extract the rhodium from the organic phase, the extract was shaken with a 25% solution of nitric acid (under these conditions, platinum, palladium and iridium are also re-extracted). The re-extract was then treated with concentrated hydrochloric acid and sodium chloride to reconvert the platinum metals to the chlorides.

The separation was carried out in separating funnels by Bush and Densen's scheme (Fig. 8).[41] A 1% solution of diantipyrylpropylmethane in dichloroethane was used for the extraction. The volume of the organic phase was 10 ml and that of the aqueous phase 20 ml, and the over-all concentration of hydrochloric acid in the aqueous phase was 1*M*. The results obtained are given in Table IX.

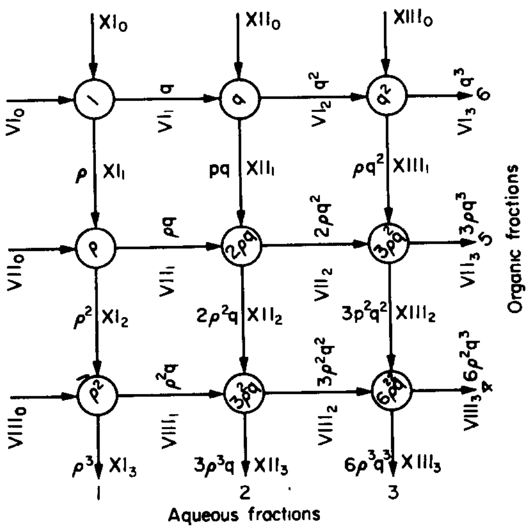

FIG. 8—Scheme of extractive separation.

TABLE IX.—SEPARATION OF RHODIUM AND IRIDIUM, RHODIUM AND PLATINUM, AND RHODIUM AND PALLADIUM

Fraction no.	Metal found,[a] *mg*					
	Rh	Ir	Rh	Pt	Rh	Pd
1	7·60	0·00	7·60	0·00	7·70	0·00
2	2·11	0·00	2·18	0·00	2·12	0·00
3	0·30	0·00	0·18	0·00	0·22	0·00
4	traces	0·000	traces	0·00	traces	0·00
5	0·00	0·33	0·00	traces	0·00	0·32
6	0·00	6·22	0·00	6·50	0·00	7·45

[a] Amounts taken were 9·88 mg of Rh, 6·55 mg of Ir, 6·60 mg of Pt and 7·80 mg of Pd.

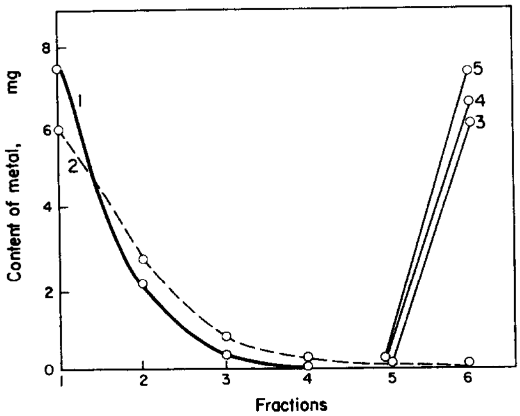

FIG. 9.—Experimental curves of the distribution of rhodium (1), iridium (3), platinum (4) and palladium (5), and theoretical curves of the separation of rhodium (2) and iridium (practically coinciding with the experimental curve).

The experimental distribution curves (Fig. 9) of rhodium and iridium proved to be close to those calculated from the formula

$$p = \frac{K.V_x}{K.V_x + V_y}$$

where p is the fraction of the metal remaining in the aqueous phase after the first extraction, V_x and V_y are the volumes of the aqueous and organic phases, respectively, and $K = \frac{1}{D}$ where D is the distribution coefficient. After a 9-stage extraction separation, about 80% of the original amount of rhodium taken was obtained in the first fraction, which was spectroscopically free from iridium, platinum and palladium. However, to obtain samples of iridium, platinum and palladium spectroscopically free from rhodium it was necessary to carry out the separation with a greater number of extraction stages.

The method developed has been used to purify metallic rhodium from trace amounts of platinum, iridium and palladium.

It is also possible to use diantipyrylpropylmethane for the extractive separation of platinum, palladium, iridium, osmium and ruthenium from other elements, *e.g.* from nickel and selenium, which are not extracted by dichloroethane in the presence of diantipyrylpropylmethane.

Zusammenfassung—Die Reaktion von vierwertigem Osmium und Iridium mit Antipyrin und einigen seiner Derivate wurde untersucht und es wurde gezeigt, daß in sauren Lösungen Verbindugnen vom Typ $(RH)_2MeX_6$ gebildet werden. Die Extraktion von Halogenokomplexen von Osmium, Iridium, Ruthenium, Rhodium, Platin und Palladium mittels Diantipyryl-propylmethan in Dichloräthan wurde geprüft. Eine extraktiv-photometrische Methode wird vorgeschlagen für die Bestimmung von 2–20 μg/ml Osmium neben 50 mg Ruthenium und von 4–40 μg/ml Iridium neben 4 mg Rhodium mittels Diantipyryl-propylmethan. Der Fehler der Bestimmung ist ±10%. Eine gravimetrische Methode zur Osmium- und Iridiumbestimmung, in Mengen von 5–13 mg, mittels Diantipyryl-propylmethan und Diantipyryl-methan wird vorgeschlagen. Die Möglichkeit selektiver Extraktion kleiner Mengen Iridium und Rhodium, Platin und Rhodium und Palladium und Rhodium mittels Diantipyryl-propylmethan wird gezeigt.

Résumé—On a étudié la réaction de l'osmium tétravalent et de l'iridium avec l'antipyrine et quelques-une de ses dérivés, et l'on a montré qu'en solutions acides, il se forme des composés $(RH)_2MeX_6$. On a examiné l'extraction des complexes halogénés d'osmium, iridium, ruthénium, rhodium, platine et palladium au moyen de diantipyryl-propylméthane en dichloréthane. On propose une méthode photométrique par extraction pour le dosage de 2–20 μg/ml d'osmium en présence de 40 mg de ruthénium, et de 4–40 μg/ml d'iridium en présence de 4 mg de rhodium, au moyen de diantipyrylpropyl méthane. L'erreur du dosage est ±10%. On propose une méthode gravimétrique pour le dosage de 5–13 mg d'osmium et d'iridium au moyen de diantipyrylpropylméthane et diantipyrylméthane. L'erreur du dosage est ±3%. On montre la possibilité d'extraire séparément des petites quantités d'iridium et rhodium, platine et rhodium, et palladium et rhodium, à l'aide du diantipyrylpropylméthane.

OBITUARY

ELEMÉR SCHULEK

It is with regret that we announce the sudden death on Wednesday, 14th October, 1964, at the age of 71, of ELEMÉR SCHULEK. Professor Schulek, Member of the Hungarian Academy of Sciences and Head of the Institute of Inorganic and Analytical Chemistry of the L. Eötvös University of Budapest, had been a Member of the Advisory Board of *Talanta* since its inception in 1958. A review of his career and his scientific work was published in *Talanta*, 1963, **10**, 429.

Talanta, 1964, Vol. 11, pp. i to iii. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

(Material for this section should be sent directly to the Associate Editor)

BUNDESREPUBLIK DEUTSCHLAND

1.–2. *April* 1964: *GDCh-Fachgruppe "Kern-, Radio und Strahlenchemie"*: Symposium über *Methoden zur Messung weicher β-Strahler:* Karlsruhe.

CZECHOSLOVAKIA

Tuesday 29 *September–Friday* 2 *October* 1964: **Third National Radiochemical Conference:** *Czechoslovak Chemical Society, Nuclear Chemistry Section:* Scientific House, Liblice by Praha.

The following topics are proposed for the Conference:

1. Separation methods in radiochemistry.
2. Radioisotopes in chemical analysis.
3. Hot atom chemistry.
4. Radioisotopes in chemistry and industrial research.
5. Production of radioisotopes.

Original papers are invited. Two copies of a brief abstract (150 words) with names of authors and their address should be sent, not later than 1 May, 1964, to Jaremír Růžička C. Sc., Faculty of Technical and Nuclear Physics, Praha 1, Břehovà 7. Other correspondence and the full text of papers should be sent to Miroslav Křivànek C. Sc., Institute of Nuclear Research ČSAV, Rež by Praha.

DEUTSCHE DEMEKRATISCHE REPUBLIK

14.–17. *April* 1964: **Moderne elektrochemische Analysenmethoden:** Eisenach (Die Hauptvorträge sind in *Talanta*, 1963, **10**, December, i, schon angedeutet worden).

SWEDEN

Monday–Saturday 14–19 *September* 1964: **Third International Measurement Conference and Sixth International Instruments and Measurements Conference:** The Congress halls at *Felkets Hus*, Stockholm.

Approximately 120 papers have been submitted by scientific and technical societies participating in the organisation of the Conference. Topics of general character will be discussed in the Plenary Sessions and in Sections, whereas new methods for measuring specific physical or chemical quantities are to be handled in the Specialised Sections. New developments in the border fields of measurement and automation will again be discussed in a Section organised jointly with the Technical Committee on Components of the International Federation for Automatic Control. The number of papers has been limited so as to secure time for personal discussions, visits to institutes and plants, excursions, etc.

Correspondence regarding registration, accommodation, *etc.*, should be addressed to RESO Congress Service, Stockholm 1, Sweden. Enquiries regarding the scientific programme should be directed to IMEKO Secretariat, Budapest 5, P.O.B. 3, Hungary. Information regarding the Commercial Exhibition may be obtained from the Exhibition Management, AB Anders Beckman, Birger Jarlsgatan 13, Stockholm C, Sweden.

UNITED KINGDOM

Thursday 2 *April* 1964: Contributions from Research Workers in Universities and Colleges of Advanced Technology: *Society for Analytical Chemistry:* University College, Gower Street, London W.C.1.

Monday–Thursday 6–9 *April* 1964: **Anniversary Meetings:** *Chemical Society:* University, Edgbaston, Birmingham 15.

This will include a Symposium on **New Methods of Organic Analysis** the programme for which is as follows:

Wednesday 8 April, Afternoon	
Qualitative organic analysis.	F. Feigl
Determination of organic functional groups.	F. E. Critchfield
Some instrumental methods in organic anlaysis.	J. R. Majer
Thursday 9 April, Afternoon	
General developments in organic analysis.	R. Belcher
Analysis of organic compounds by titration in non-aqueous media.	E. A. M. F. Dahmen
Organic polarography.	P. Zuman

Further information may be obtained from The Chemical Society, Burlington House, London W.1.

Friday 17 *April* 1964: **Fluorine and Teeth Decay** G. N. JENKINS: **Chemical Additives in Foods** J. MARKLAND: *Society for Analytical Chemistry, North of England Section* and *Scottish Section*: Central Hotel, Victoria Viaduct, Carlisle. 7.15 p.m.

Wednesday 22 *April* 1964: **Analytical Chemistry, Chemical Analysis and the Analyst,** R. C. CHIRNSIDE: *Society for Analytical Chemistry, Midlands Section* and *Royal Institute of Chemistry, Lea Valley Section:* Luton.

Wednesday 29 *April* 1964: Meeting on **Immunological Assay of Hormones:** P. G. H. GELL and A. J. FULTHORPE: *Society for Analytical Chemistry, Biological Methods Group:* Burlington House, London W.1. 7.00 p.m.

Sunday–Saturday 6–12 *September* 1964: **Summer School in Organic Spectroscopy:** *Royal Institute of Chemistry* in collaboration with *Society for Analytical Chemistry:* School of Pharmacy, Brunswick Square, London W.C.1.

The Summer School will provide an organised and concise presentation of infrared and nuclear magnetic resonance spectroscopy in terms of organic structures. Emphasis will be placed on fundamental principles and basic techniques. There will be morning lectures and small seminar discussion groups each afternoon. Laboratory sessions will also be provided.

Further information may be obtained from the Summer School Secretary: Mr. G. D. CHISMAN, Royal Institute of Chemistry, 30 Russell Square, London W.C.1.

At the **Ninth Annual General Meeting** of the *Western Section* of the *Society for Analytical Chemistry* held on *Friday*, 10 *January*, 1964, the following Officers were elected for the forthcoming year:

Chairman: E. A. HONTOIR
Vice-Chairman: L. E. COLES
Secretary/Treasurer: T. G. MORRIS, Brockleigh, Clevedon Avenue, Sully, Glamorgan.

At the **Twenty-Ninth Annual General Meeting** of the *Scottish Section* of the *Society for Analytical Chemistry* held on *Friday*, 24 *January*, 1964, the following Officers were elected for the forthcoming year:

Chairman: R. A. CHALMERS
Vice-Chariman: J. K. McLELLAN
Secretary/Treasurer: J. W. MURFIN, Boots Pure Drug Co. Ltd., Motherwell Street, Aidrie, Lanarkshire.

UNITED STATES OF AMERICA

Sunday–Friday 5–10 *April* 1964: **147th National Meeting:** *American Chemical Society:* Philadelphia. This includes Symposia on *Chromatography and Electrophoresis* and on *Chemical Analysis through Systems Control.*

Tuesday 7 *April* 1964: **Applications of High Resolution NMR to Determination of Organic Structures** J. L. HOLCOMB: *Society for Applied Spectroscopy, New York Section:* Hotel Manhattan, 8th and 44th Street.

Thursday–Saturday 16–18 *April* 1964: Course on **Evaluation and Interpretation of Physical and Chemical Testing Methods:** *American Society for Quality Control* and *American Chemical Society, Joliet Section:* Kankakee, Ill.

Sunday–Tuesday 19–21 *April* 1964: **Second Annual Oak Ridge Radioisotope Conference:** Gatlinburg, Tenn.

Wednesday–Saturday 22–25 *April* 1964: **Fourth Rare Earth Research Conference:** Camelback Inn, Pheonix, Ariz.

Wednesday–Friday 11–13 *November* 1964: **Sixth Eastern Analytical Symposium:** *Analytical Groups* of *New York and North Jersey Sections* of *American Chemical Society, American Microchemical Society,* and *Baltimore-Washington, Delaware Valley, New England* and *New York Sections* of *Society for Applied Spectroscopy:* Statler-Hilton Hotel, New York.

Following the successful pattern of previous years, the technical programme will consist of selected invited papers on topics of current interest in chemical analysis and closely related fields. Suggestions for programme topics and speakers are invited from all interested persons, These should be submitted to the Programme Chairman: Dr. LEO SAFRANSKI, E. I. du PONT de Nemours and Co., Plastics Department, Experimental Station, Wilmington 98, Delaware.

American Society for Testing and Materials has announced that the following publications in the field of spectroscopy are now available:
First Supplement to the Molecular Formula List of Compounds, Names and References to Published Infrared Spectra: STP 331-A (Price $4.50; $3.15 to ASTM members).
Index of Mass Spectral Data: STP 356 (Price $18.50; $13.00 to ASTM members).
Molecular Formula List of Compound Names and References to Published Ultraviolet and Visible Spectra: STP 357 (Price $6.00; $4.20 to ASTM members).
Serial Number List of Compound Names and References to Published Infrared Spectra: STP 358 (Price $12.00; $8.40 to ASTM members).

Copies may be obtained from ASTM, 1916 Race Street, Philadelphia, Pa.

ERRATUM—Volume 11

Page 2, *line* 7: this should read *Methods have previously been described . . .*

Page 16, *line* 2 *above formula* XIX: this should read *In order to study the formation of complexes by arsenazo . . . .*

Page 18, *line* 4 *of Synthesis:* this should read *excess of nitrous acid . . .*

Page 5, *insert after Zusammenfassung*

Résumé—L'utilité analytique particulière de l'Arsenazo-III est due à sa capacité de former des complexes spécialement stables avec certains elements. Ceci permet le dosage en milieu acide fort (HCl, 10 M ou SO_4H_2) des éléments penta- ou quadrivalents: Pa, Np^{IV}, Th, Zr, Hf, U^{IV}; la reproductibilité est bonne, la manipulation facile et l'on ne note que de petites interférences dûes aux anions. La grande sensibilité (0,1–0,01 μg/ml, coefficient d'absorption molaire 50–150 × 10^3) est due au grand effet de contraste de la réaction (changement de coloration durose au vert émeraude, déplacement du maximum d'absorption de 125 mμ), nature de spectre, et enfin possibilité d'atteindre des dilutions extremes sans dissociation des complexes.

Page 41, *insert after Zusammenfassung*

Résumé—Les mélanges formés d'orthophosphate, de ses polymères linéaires supérieurs jusqu'au tridécaphosphate compris et trois polymères cycliques ont pu être séparés par chromatographie d'échange ionique. L'un des polymères cycliques (recontré dans les verres de polyphosphate . . . est probablement le pentamétaphosphate. Sa nature cyclique a été démontrée par dosage des groupes terminaux et chromatographie sur papier, mais les tentatives de dénombrement des atomes de phosphore du noyau ont échouées à cause de la très faible quantité de produit disponible. Évidence est presentée a l'appui de la supposition courante que les phosphates linéaires supérieurs sont élués suivant leur degré de polymérisation.

Page 46, *insert after Zusammenfassung*

Résumé—Une méthode pour le dosage des trimétaphosphates en présence d'oligophosphates linéaires supérieurs au trimère est developpée. Il a été démontré que l'ortho-, lt pyro-, at le triphosphate ne sent pas complètement précipitéspar l'ion baryum, tandis que les phosphates oligomères linéaires de type supérieur sont précipités quantitativement. Ces derniers sont isolés des mélanges de phosphates par chromatographie d'échange d'anions, mélangés avec des quantités connues de phosphates cycliques, at précipités par l'ion baryum. Une erreur moyenne de +0,8 et un écart standard de ±3 micromoles de phosphore de l'ion cyclique a été mise en évidence dans les mélanges contenant de 0 à 203 micromoles de phosphore sous forme de trimétaphosphate en présence de 0 à 81 micromoles de phosphare sous forme de polymères linéaires,

Page 49, *line* 1: this should read *using barium diphenylamine . . .*

Page 57, *line* 1: this should read *between ammonium ion and chloramine-T . . .*

Page 57, *insert after Zusammenfassung*

Résumé—La chloramine-T oxyde quantitativement la thiourée en urée et l'ion sulfate en milieu neutre et en milieu basique. L'oxydation est totale en 2 minutes même en présence d'un léger excès d'oxydant. L'uree et l'ion ammonium ne sont pas gênants si l'oxydation est effectuée en milieu alcalin.

Talanta, 1964, Vol. 11, pp. i to iii. Pergamon Press Ltd. Printed in Northern Ireland

CZECHOSLOVAKIA

At the **National Meeting on Activation Analysis** at Modrá from 4 to 7 November, 1963, 20 papers were presented. The subjects included instrumental activation analysis, neutron sources, methods of counting and gamma spectrometry. Substoichiometry, especially its use for determination of traces of elements by activation analysis, was discussed. The meeting was sponsored by the Scientific and Technical Society in collaboration with the Department of Radiochemistry and Radiation Chemistry, Faculty of Chemistry Bratislava Kollárovo nám. 2. Abstracts of the papers are available from the above address.

III. Internationaler Polarographischer Kursus

In der Zeit vom 31.8. bis 12.9.1964 veranstaltet das Institut für Physikalische Chemie der Karls Universität und das Polarographische Institut der Tschechoslowakischen Akademie der Wissenschaften einen Lehrgang in Polarographie. Dieser Kursus besteht aus Vorlesungen über die Grundlagen der Polarographie, die in deutscher Sprache abgehalten werden, und einen entsprechenden Praktikum. Der Lehrgang ist für Hochschulabsolventen gedacht, spezielle Vorkenntnisse der Polarographie sind jedoch nicht Bedingung. Die Zahl der Teilnehmer wird auf 20 begrenzt. Dieser Lehrgang wird vorbereitet unter Schirmherrschaft von Professor Dr. J. HEYROVSKÝ, die Vorlesungen und das Praktikum liegen in den Händen von Fachkräften der Karls-Universität und des Polarographischen Instituts. Die Teilnahmegebühr beträgt Kčs 300.-einschliesslich eines Ausfluges in die Umgebung Prags und eines gemeinsamen Abendessens am Abschlusstage des Lehrganges. Eine Unterbringung in Studentenheimen zu mässigen Preisen bzw. auf besonderen Wunsch im Hotel, wird gewährleistet.

Vorläufige Anmeldungen mit Angabe von Titel, Name und Adresse sind an das Institut für Physikalische Chemie der Karls-Universität, Prag 2, Albertov 2030, bis spätestens 15. Mai 1964 zu richten.

UNITED KINGDOM

Wednesday 5 *February* 1964: Brains Trust Evening entitled **High Purity Chemicals**: E. F. HERSANT, B. ILLINGWORTH and F. H. LEVER: *Society for Analytical Chemistry, Midlands Section:* University, Edgbaston, Birmingham 15: 6.30 p.m.

Friday 14 *February* 1964: **Hydrolytic Studies of Phosphorus Compounds using Chromatographic Methods**: F. H. POLLARD: *Society for Analytical Chemistry, North of England Section* and *Leeds University Chemical Society:* University, Leeds: 6.00 p.m.

Friday 21 *February* 1964: **Annual General Meeting** followed by **Ordinary Meeting**: *Society for Analytical Chemistry, Microchemistry Group:* Burlington House, London W.1.

Tuesday 25 *February* 1964: Meeting on **Atomic Absorption Spectroscopy**: **Chemistry of Flames,** T. M. SUGDEN: **Review of Progress in Field of Atomic Absorption Spectroscopy**: J. B. DAWSON: *Society for Analytical Chemistry, Midlands Section* and *Physical Methods Group* with *Royal Institute of Chemistry, East Midlands Section* and *Leicester University Chemical Society:* University, Leicester: 7.00 p.m.

Friday 28 *February* 1964: Meeting on **Qualitative Analysis**: W. MOSER and E. H. REID: *Society for Analytical Chemistry, Scottish Section:* Paisley College of Technology: 7.15 p.m.

A **Conference of the Society for Analytical Chemistry** will be held at Nottingham University between 19 and 23 July, 1965.

The scientific programme, which will consist of original papers on all aspects of analytical chemistry, is to be organised by the Programmes Committee of the Society, and the responsibility for refereeing of papers will be in the hands of *The Analyst* Editorial Committee. A Trade Exhibition (Secretary, Mr. N. Mix, Standards Department, Boots Pure Drug Co. Ltd., Nottingham) and a programme of social functions will also be arranged.

Preliminary enquiries should be addressed to Mr. C. A. Johnson, Honorary Secretary, SAC Conference 1965, 14 Belgrave Square, London S.W.1.

At the **Nineteenth Annual General Meeting** of the *Physical Methods Group* of the *Society for Analytical Chemistry* held on Tuesday, 26 November, 1963, the following Officers were elected for the forthcoming year:

Chairman: L. Brealey
Vice-Chairman: G. F. Reynolds
Secretary and Treasurer: T. L. Parkinson, Product Research Department, Beecham Food and Drink Division Ltd., Harpenden Rise, Harpenden, Herts.

At the **Nineteenth Annual General Meeting** of the *Biological Methods Group* of the *Society for Analytical Chemistry* held on Thursday, 12 December, 1963, the following Officers were elected for the forthcoming year:

Chairman: W. A. Broom
Vice-Chairman: M. W. Parkes
Secretary and Treasurer: K. L. Smith, Standards Department, Boots Pure Drug Co. Ltd., Pennyfoot Street, Nottingham.

UNITED STATES OF AMERICA

Monday–Tuesday 3–4 *February* 1964: Research Conference on **Progress in Gas Chromatography:** University of California, Los Angeles, Calif.

The programme is as follows:

Monday, February, 3

Preparative Gas Chromatography	J. Howard
Mixed Bed Columns	C. N. Reilley

Tuesday, February 4

Improvements in Detectors and Readout	J. C. Sternberg
Gas Chromatography of Steroids and Related Substances	E. C. Horning

The Conference will be followed by an intensive basic **Three-Day Chromatography Course** (5–7 February) of lectures and laboratory work for those with a limited amount of experience in gas chromatography, as well as those who are new to the field.

Monday–Thursday 3–6 *February* 1964: **International Conference on Materials:** *American Society for Testing and Materials:* Sheraton Hotel, Philadelphia, Pa.

The following items from the programme may be of interest to analytical chemists:

Monday, 3 *February: Application of Advanced and Nuclear Physics to Testing Materials*

Application of Microwave Spectroscopy in Non-destructive Testing	A. Watson
X-Ray Fluorescence Analysis of Materials	B. L. Bean and W. Mulligan
Use of Neutron Diffraction in Study of Properties of Matter	E. Ligrand
Non-destructive Estimation of Cement Content of Finished Concrete	E. Yaltkaya, S. Urkan, S. Sentürk, K. Köksal and B. V. Enüstün.
Impact of Nuclear Technology on Highway Engineering	P. L. Blackwell
Measurement of Moisture Content in Brick Walls by a Neutron-Scattering Technique	B. Rossinski, T. Przedecki and Z. Stacmonwicz

Tuesday, 4 *February*

Influences of Modern Physics on Properties of Wood and their Evaluation	R. L. Youngs
Applications of Centimetric Radio Waves in Non-destructive Testing	R. W. Nurse
Microwave and X-Ray Diffraction Studies of Swelling of Baked Clays by Radioisotope Techniques	J. Brocard, C. DaWance, R. LaChaud and J. Paquet

Wednesday, 5 February: Impact of Physics on Analysis and Testing of Materials

Electron Beam Microprobe as a Tool in Materials Engineering	F. P. Landis, R. W. Merchant and P. D. Zemany
Progress in Field Ion Microscopy	E. W. Mueller
Nuclear Magnetic Resonance in Materials Analysis and Testing	C. M. Huggins
Modern Solid-State Mass Spectroscopy as a Tool for Standardisation in Analysis of Nuclear Materials	T. L. Collins, Jr.

Thursday, 6 February: Modern Physics and New Materials

Lasers and Laser Materials	K. Nassau

Monday–Friday 3–7 *February* 1964: **Winter Gordon Research Conference on Electrochemistry: Electrode Reactions:** Miramar Hotel, Santa Barbara, California [see *Talanta*, 1963, **10** (December), Notices p. ii].

Tuesday 4 *February* 1964: Panel Discussion on **Emission Spectroscopy Techniques:** E. Jaycox, T. Sheehy and C. Albright: *Society for Applied Spectroscopy, New York Section:* Hotel Manhattan, 8th Avenue and 44th Street, New York: 8.00 p.m.

Thursday–Saturday 27–29 *February* 1964: **Fifth Omnibus Conference on Experimental Aspects of Nuclear Magnetic Resonance Spectroscopy:** Mellon Institute, Pittsburgh, Pa.

National Bureau of Standards has announced the availability of a new nitrogen-bearing and two new precipitation-hardening stainless steel standards. NBS Standard Sample No. 343 is intended for calibrating procedures for determining nitrogen and the precipitation-hardening standards, Nos. 344 and 345, for controlling the composition of these stainless steels.

In addition, nine other standard materials, previously available but recently out of stock, have been renewed. Of these, No. 158a is a standard copper alloy (silicon bronze), No. 3a is a standard white iron in chip form, Nos. 83c and 84g are standards of purity (arsenious oxide and acid potassium phthalate, respectively) and the remaining five are rubber or rubber-compounding standards (sulphur: 371d; stearic acid: 372e; benzothiazyl disulphide: 373e; oil furnace black: 378a; styrene-butadiene, type 1500: 386d).

Talanta, 1964, Vol. 11, pp. i to iv. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

BUNDESREPUBLIK DEUTSCHLAND

6. *Juni* bis 2 *Juli* 1964: **Deutschsprachige Spektrometer-Tagung:** Frankfurt/Main.

Die Fachgruppe "Analytische" der Geselleschaft Deutscher Chemicker, der Deutsche Arbeitskreis für Spektroskopie, die Arbeitsgruppe Massenspektrometrie der Deutschen Physikalischen Gesellschaft und die Chemikerausschüsse der Gesellschaft Deutscher Metallhütten- und Bergleute, des Steinkohlenbergbauvereins und des Vereins Deutscher Eisenhüttenleute veranstalten gemeinsamam eine Tagung über "Moderne Methoden der anorganischen Analyse". Diese Tagung soll vom 5. –7. Oktober 1964 in Düsseldorf stattfinden.

Es sind folgende Hauptthemen für die Tagung vorgesehen:

1. Nichtmetalle in Metallen.
2. Analyse von Verbindungsformen und ihre Verteilung im festen Zustand
3. Probenahme
4. Erfassen und Verwerten analyrischen Zahlenmaterials.

Zu diesen Themen werden Hauptvorträge von folgenden Kollegen gehalten:

Prof. Dr. J. FISCHER, Frankfurt (Gruppe 1)
Prof. Dr. W. KOCH, Duisburg (Gruppe 2)
Dr. ZETTLER, Hamburg, und
Dipl.-Ing. SPORBECK, Essen (Gruppe 3)
N.N. Gruppe 4)

FRANCE

La **Commission Internationale d'Essais** "C.I.E." du **COMITE INTERNATIONAL DE LA DETERGENCE** (C.I.D.) a tenu, sous la présidence du Dr. GÖTTE (Allemagne), sa session annuelle les 23 et 24 Mars 1964 à Düsseldorf, sur aimable invitation du Deutscher Ausschuss für Grenzflächenaktive Stoffe.

C'est la 7ème fois que les pays membres de cette Commission sont appelés ainsi à se réunir depuis sa fondation, et 10 pays ont répondu à cette invitation: Allemagne, Autriche, Belgique, Espagne, France, Italie, Pays-Bas, Portugal, Royaume Uni et Suisse. L'INTERNATIONAL ORGANIZATION FOR STANDARDIZATION "I.S.O.", qui suit tous les travaux du C.I.D., avait délégué un de ses collaborateurs.

Les travaux de la C.I.E. étant considérés comme suffisamment avancés sur un certain numbre de sujets, il a été décidé que 5 projets de normes pouvaient être adoptés définitivement et seraient présentés dans le courant de l'année au Comité Technique ISO/TC-91 "Agents de Surface" pour homologation sur le plan international. Il s'agit des normes suivantes:

Stabilité des agents de surface à l'eau dure,
Eau distillée (conditions requises pour essais physicochimiques relatifs aux agents de surface),
Eau dure (définition et propriétés),
Masse volumique apparente des pâtes,
Point de trouble des agents de surface non-ioniques selon la méthode au butyldiglycol.

Le nombre des travaux soumis à l'ISO/TC-91 par la C.I.E. se trouvera ainsi porté à 9.

Par ailleurs, les membres de la C.I.E. effectueront des essais inter-laboratoires dans leurs pays, pour améliorer ou vérifier certaines études actuellement au stade expérimental:

Solubilité des agents de surface,
Pouvoir protecteur vis-à-vis des savons calcaires, en utilisant un savon préparé à l'avance,
Tension superficielle selon une méthode dite "de la bulle par pression", pur laquelle un appareil nouveau a été mis au point en Allemagne. Les mesures seront comparées à celles du pouvoir mouillant sur coton.
Viscosité des agents de surface sur appareils Roto-Visco et Rhéomat,
Stabilité des solutions d'agents de surface, en utilisant la chromatographie par couche mince,
Mesure de la couleur par comparaison de différentes échelles colorimétriques,
Contrôle du lessivage à l'aide de bandes-témoins non souillées; un groupe de travail a été spécialement créé à cet effet et fait appel au concours de techniciens du lavage.

Enfin, un travail bibliographique et documentaire sera entrepris pour différentes questions nécessitant encore de longues études, telles que les pouvoirs détergent, dispersant, émulsionnant et la stabilité des émulsions, la concentration critique de micelles, l'action des oxydants et leur influence sur les taches, la préparation des détergents en pastille, le dish washing test et al tension d'adhésion.

Ce programme de travail est important et nécessite, de la part des laboratoires, de longues et patientes recherches mais leurs efforts s'avèrent, de par les résultats déjà obtenus, particulièrement fructueux et appréciés sur le plan international.

Rappelons que le but de la Commission Internationale d'Essais est de mettre au point des méthodes d'essais facilement reproductibles et utilisables de par le monde. C'est pourquoi elles sont établies selon un schéma uniformisé et recommandent des appareillages connus de tous les techniciens.

La prochaine session de la C.I.E. aura lieu en Mars 1965, sur invitation du British National Committee on Surface Active Agents, et elle se déroulera à Londres.

UNITED KINGDOM

Thursday-Saturday 2–4 *July* 1964: **Symposium on Pollution:** *Society for Analytical Chemistry, Western Section:* University College, Singleton Park, Swansea.

The programme is as follows:

Thursday, 2 July: Morning	
Opening Address—Environmental pollution.	D. T. Lewis
The effects on industry of recent legislation on the discharge of trade effluent.	A. I. Biggs
Thursday, 2 July: Afternoon	
Water pollution with respect to sewage.	S. H. Jenkins
Water pollution of all kinds.	L. Klein
Friday, 3 July: Morning	
Atmospheric pollution.	S. G. Burgess
Effects of pollution on vegetation.	J. Webber
Friday, 3 July: Afternoon	
Lecture and visit to the Lower Swansea Valley Project.	
Saturday, 4 July: Morning	
Biological effects of pollution.	R. D. Brinkhurst
Tidal pollution.	P. N. J. Chipperfield

Further information may be obtained from Dr. T. G. Morris, Brockleigh, Clevedon Avenue, Sully, Glamorgan.

Thursday-Friday 2–3 July 1964: Summer Meeting on **Limitations of Detection in Spectrochemical Analysis:** *Institute of Physics and Physical Society, Spectroscopic Group:* University of Exeter (see *Talanta*, 1964, **11,** April, vi).

Sunday-Saturday 19–25 *July* 1964: **Third International Congress for Polarography:** *Polarographic Society:* University of Southampton.

Tuesday 28 *July* 1964: Lecture by W. Kemula: *Society for Analytical Chemistry* and *Polarographic Society:* Burlington House, London W.1.

British Standards Institution has announced the following *New British Standard:*
B.S. 1728: *Methods for the analysis of aluminium and aluminium alloys: Part* 13: 1964: *Method for the determination of titanium in aluminium and aluminium alloys (absorptiometric chromtropic acid method).* This specifies reagents required, recommended methods of sampling and analytical procedure for the determination of titanium in alloys having a titanium content between 0·005 and 0·3%. (*Price* 4s.)

The following *Amendment Slip* has also been announced:
B.S. 1016: *Methods for the analysis and testing of coal and coke: Part* 1: 1957: *Total moisture of coal. Amendment No.* 1: *PD* 5146.

UNITED STATES OF AMERICA

Tuesday–Thursday 6–8 *October* 1964: **Eighth Conference on Analytical Chemistry in Nuclear Technology:** *Analytical Chemistry Division of Oak Ridge National Laboratory:* Mountain View Hotel, Gatlinburg, Tennessee.

The subject will be **Determination of Interstitials and Trace Constituents in Reactor Materials and Products.** The Conference will be composed of six sessions embracing the following subtitles:

1. *Spectrochemical and X-ray Methods of Analysis.*
2. *Mass Spectrometric Methods of Analysis.*
3. *Nuclear Methods of Analysis.*
4. *Gas Chromatographic Methods of Analysis.*
5. *Determination of Carbon, Hydrogen, Oxygen and Nitrogen in Metals.*
6. *Determination of Trace Constituents by Diverse Methods.*

Participation in the Conference will be on the basis of invited contributions. However, a limited number of papers, up to 25 min in length, are solicited and will be accepted provided the subject matter of such contributions fits in with the over-all objectives of the Conference and meets with the approval of the Programme Committee.

Those who wish to make contributions are requested to submit an abstract of 200–500 words not later than 10 July, giving the name of the intended speaker and the amount of time that will be required for the presentation. Abstracts of papers and any enquiries concerning the Conference should be directed to C. D. SUSANO, Oak Ridge National Laboratory, P.O. Box X, Oak Ridge, Tennessee.

Monday–Thursday 19–22 *October* 1964: **78th Annual Meeting of Association of Official Agricultural Chemists:** Marriott Motor Hotel, Twin Bridges, Washington D.C. 20044.

The programme will have almost 300 scientific papers on analysis of foods, drugs, cosmetics, food and colour additives, beverages, pesticides, extraneous materials in foods and drugs, fertilisers, feeds, and many other commodities important to agriculture and public health. In addition, six outstanding European scientists will present key addresses to general sessions on such topics as drugs, pesticides, food laws, chromatography detectors, food additives and fish composition. The six invited speakers are: J. A. LOVERN (Scotland); J. F. REITH (Netherlands); D. C. GARRATT, A. T. JAMES (England); H. CHEFTEL (France) and FINN BRO-RASMUSSEN (Denmark). Dr. D. T. LEWIS, Head, Laboratory of the Government Chemist, England, will keynote the Monday evening banquet with his address, *The Changing Environment of Mankind.* Another feature of the banquet will be honoring the winner of the Harvey W. Wiley Award for notable contributions to analytical methodology.

The meeting will include about 30 exhibits of the latest equipment and supplies for analytical chemists. Other information is available from LUTHER G. ENSMINGER, Association of Official Agricultural Chemists, Box 540, Benjamin Franklin Station, Washington, D.C. 20044, U.S.A.

The **ORNL Master Analysis Manual** is a collection of the analytical methods developed and used in the Analytical Chemistry Division of Oak Ridge National Laboratory. The manual was begun in 1963, but includes methods used earlier. In 1957, the Office of Technical Services of the U.S. Department of Commerce reprinted the unclassified sections of the manual for public sale and since then has issued annual supplements that contain reprints of new or revised methods. These reprinted parts are designated TID-7015.

The Oak Ridge National Laboratory has now published a paperbound volume which consists of a key word index composed from method titles, a bibliographic index that is equivalent to a table of contents for the manual, an author index, and method-number cross indexes. The bibliographic index gives the complete history and current status of every method. The titles entered in this publication are those of all unclassified methods included in the manual from 1953 through 1962.

The indexes will be brought up-to-date annually. This publication, TID-7015 (Indexes), is available from the U.S. Department of Commerce, Office of Technical Services, Washington, D.C. 20230 ($2.50).

The publication of **Nuclear Magnetic Resonance Abstracts** has been announced. This is intended to include the total world literature on all aspects of nuclear magnetic resonance; theoretical and applied papers in both high resolution and broad line areas, techniques, apparatus, *etc.*, will be covered. The abstracts will be in English. Further information is available from Preston Technical Abstracts Co., 1718 Sherman Avenue, Evanston, Ill. 60201.

The **American Society for Testing and Materials** has announced the publication of *Report on Available Standard Samples, Reference Samples, and High-Purity Materials for Spectrochemical Analysis* (1963): STP 58-E. This provides an up-to-date reference to the availability and sources of 5050 samples and materials. The introduction presents the scope and form of the report and a discussion of definitions and nomenclature.

The following parts of the 1964 *Book of ASTM Standards* are now available: *Part* 30: *General Testing Methods; Quality Control; Appearance Tests; Temperature Measurements; Effects of Temperature* (Price $11.00; $7.70 to ASTM members).
Part 31: *Metallurgy; Nondestructive Testing; Radioisotopes and Radiation Effects; Industrial Chemicals; Emission, Absorption and Mass Spectrometry* (Price $12.00; $8.40 to ASTM members).
Part 32: *Chemical Analysis of Metals* (Price $14.00; $9.80 to ASTM members).

Talanta, 1964, Vol. 11, pp. i to iv. Pergamon Press Ltd.

NOTICES

(Material for this section should be sent directly to the Associate Editor)

The **Fifth Report on Reagents and Reactions for Qualitative Inorganic Analysis,** prepared by the *Commission on Analytical Reactions* of the *Analytical Chemistry Division of I.U.P.A.C.* has now been published (*Pure and Applied Chemistry*, 1964, **8,** No. 1).

CANADA

Monday–Wednesday 1–3 *June* 1964: **47th Annual Meeting of Chemical Institute of Canada:** Kingston, Ontario.

The programme for the **Analytical Chemistry Division** is as follows. It should be noted that Sessions I and II on 1 June will be concurrent.

Monday, 1 *June Morning—Professional development seminar statistics*

Statistics applied to production.	R. Vance Ward
Designed experiments.	N. Sawyer
Evolutionary operation.	B. Bonner

Monday, 1 *June, Afternoon*

Session I

A definition of the chemical sampling and smoothing problem.	G. A. Coulman
Statistical evaluation of routine test methods.	A. G. Wood and M. L. Yeo
Using statistical inference in development of analytical methods	C. G. Miller
Qualitative aspects of surface chemistry in polarographic maxima suppression.	R. G. Barradas and F. M. Kimmerle

Session II

Process analysers: Philosophy and experiences.	R. O. Clark
Conductometric determination of salt in crude oils.	R. E. Borup
Some analytical applications of vacuum spark mass spectrography.	E. R. Blosser
Analytical instruments in Shell's Oakville refinery.	L. Korchinski
Carboxyl group response in flame ionisation detectors.	R. G. Ackman
Determination of ethanol and some other volatiles in blood, urine and tissue by gas-liquid chromatography.	B. B. Coldwell and G. L. Grant

Tuesday, 2 *June, Morning—Quality control and laboratory administration*

Quality control and laboratory administration.	S. Siggia
Minimising the risk concept in laboratory safety.	E. A. Crockett
A format for writing analytical test methods.	J. Russel
Administration of a modern centralised petrochemical analytical laboratory.	W. H. Webster
Use of spectrophotometry in inspection services.	M. T. Antoniades

Tuesday, 2 *June, Afternoon—Panel discussion: Management assays the image of the analytical chemist*

Personnel director: D. S. Kirkbridge
Management consultant: G. M. Currie
Industrialist: J. C. Langford
Director of quality control: D. S. Jackson

Wednesday 3 *June, Morning—Panel discussion: Application of instruments to analytical chemistry*

Mass spectrometry: R. T. Moir
Spectrophotometry: M. M. Antoniades
Emission spectroscopy: D. Bender
High resolution NMR: J. F. Hanlan
Infrared spectroscopy: R. M. B. Small

FEDERAL GERMAN REPUBLIC

Friday–Saturday 19–27 *June* 1964: **European Convention of Chemical Engineering 1964,** including **1964 ACHEMA Congress:** Frankfurt am Main (see *Talanta*, 1964, **11**, February, i).

UNITED KINGDOM

Tuesday, 9 *June* 1964: **Galvanic Analysis:** P. HERSCH: *Society for Analytical Chemistry, Midlands Section* with *Royal Institute of Chemistry, Birmingham and Midlands Section* and *Polarographic Society* and *Guild of Associates of Birmingham College of Advanced Technology:* University, Edgbaston, Birmingham 15: 6.30 p.m.

Wednesday 17 *June* 1964: **Discussion Meeting:** *Society for Analytical Chemistry, Microchemistry Group: The Feathers*, Tudor Street, London E.C.4: 6.30 p.m.

Thursday–Friday 27–28 *August* 1964: **Conference on Recent Advances in Activation Analysis:** University of Glasgow.

The Conference will be conducted under the following general themes:

(a) *Instrumentation and techniques*
(b) *Biological and medical applications*
(c) *Industrial applications*
(d) *Future trends.*

Further information can be obtained from Dr. J. M. A. LENIHAN, Regional Physics Department, Western Regional Hospital Board, 9–13 Graham Street, Glasgow C.4.

Monday–Tuesday 14–15 *September* 1964: **First European Colloquium on Electron-Probe X-Ray Microanalysis:** *Institute of Physics and Physical Society, Electron Microscopy and Analysis Group* and *Sous-Commission Microsonde of France:* Delft, Holland.

The Colloquium will be divided into three main sessions: instrumentation, quantitative microanalysis and applications. An invited survey will precede each of the main sessions. Advance registration is necessary and application forms and further details are available from Administration Assistant, Institute of Physics and Physical Society, 47 Belgtave Square, London S.W.1, England.

British Standards Institution has announced the following *New British Standard: B.S.* 1748*: Methods for the analysis of copper alloys: Parts* 11–12*:* 1964: *The determination of copper and lead in leaded-bronze alloys.* Part 11 specifies reagents required, recommended methods of sampling and test procedure for the determination of copper in copper alloys containing lead in the range 7–25%. The method is applicable to copper contents in the range 70–90%. Part 12 specifies reagents required, recommended methods of sampling and test procedure for the determination of lead in copper alloys containing lead in the range 7–25%. (*Price* 4s.)

UNITED STATES OF AMERICA

Monday–Wednesday 1–3 *June* 1964: **10th National ISA Analysis Instrumentation Symposium;** *Instrument Society of America, N. California Section:* Sheraton-Palace Hotel, San Francisco, California.

The advance programme is as follows:

Monday morning, June 1	
A systematic review of the research programme for Instrumental Analysis at the Technical University in Eindhoven, Holland.	A. I. M. KEULEMANS
Analysis instrumentation in the petrochemical industry.	THEODORE W. EVANS
Monday afternoon, June 1: *AIR POLLUTION*	
The phenomena of light scattering by fine particles in relation to air-pollution instruments.	J. RAYMOND HODKINSON
Exhaust inspection instrumentation.	CHARLES HEINEN
Collecting representative exhaust gas samples.	RICHARD W. HURN, JAMES O. CHASE and RALPH D. FLEMING
Instrumental measurement of contamination in clean rooms for proposed federal standard 209.	PAUL L. MAGILL

Monday afternoon, June 1: ELECTROCHEMICAL AND CHEMICAL METHODS OF ANALYSIS

Electrochemical transducers for water quality.	Curtis E. Borchers, R. W. Raible M. K. Testerman and R. W. Romine
Analogue simulation design of a highly-dynamic pH control system.	Robert M. Green
Membraneless potentiometric analysis of dissolved oxygen in process streams.	Kenneth K. Konrad
Process polarograph for measuring PPM H_2S.	Bernard L. Connelly
A new process analyser for hydrogen.	James J. McKinley and Edward A. Hinkle

Tuesday morning, June 2: LABORATORY METHODS OF ANALYSIS—I

Determination of molecular weights of high melting point polymers.	Harry C. Ehrmantraut and Leon E. Hiam
Role of EPR in free radical chemistry.	Lawrence H. Piette
Present status of high resolution NMR spectroscopy.	James N. Shoolery and Leroy F. Johnson

Tuesday morning, June 2: RADIATION METHODS OF ANALYSIS

Radiation gauging breakthrough.	Charles O. Badgett
Application of actuation analysis in the petroleum and chemical industries.	Frank A. Iddings

Tuesday morning, June 2

Maintenance Workshop (morning session)
Discussion of Plant Analysers

Tuesday afternoon, June 2: LABORATORY METHODS OF ANALYSIS—II

Preparative GC for analytical purposes.	Roy Teranishi
Modern electroanalytical techniques.	Richard Pierson Buck
A mathematical procedure for referral of day-to-day analytical data to an original working curve, with emphasis on X-ray emission techniques.	William F. Loranger

Tuesday afternoon, June 2: PHYSICAL PROPERTIES ANALYSIS

Automatic pour point testers.	W. V. Cropper and G. L. Hammond
Haze point analyser.	D. J. Geniesse
Design and performance of the piezoelectric sorption hygrometer.	W. H. King, Jr., H. M. Crawford T. J. Mesh and J. J. Heigl

Tuesday afternoon, June 2

Maintenance Workshop (afternoon session)
Panel on instrument maintenance

Wednesday morning, June 3: GAS CHROMATOGRAPHY—I: PROCESS

Simultaneous analysis and BTU determination of natural gas.	Bryan Thompson and Richard C. Cavenah
New detectors for gas chromatography.	D. M. Coulson
Liquid chromatography.	L. E. Maley

Wednesday morning, June 3: OPTICAL METHODS OF ANALYSIS

A versatile process polarimeter.	Robert S. Saltzman
Flame photometry instrumentation at Indian Point nuclear power plant.	W. A. Crandall
Film coating monitoring by non-dispersive infrared.	Robert L. Chapman and William P. Houben

Wednesday morning, June 3: LABORATORY METHODS OF ANALYSIS—III

A closed-loop laboratory liquid feeder.	Lewis Fowler and Walter N. Trump

Advances in analytical emission flame spectrophotometry.	PAUL T. GILBERT, JR.
Atomic absorption spectrophotometry.	WALTER SLAVIN

Wednesday afternoon, June 3: *GAS CHROMATOGRAPHY—II: LABORATORY*

A programmed attenuator for laboratory gas chromatography.	LEWIS FOWLER, R. L. MCKINLEY and W. N. TRUMP
Generalisations of gas chromatography to study vapour—solid and vapour liquid equilibrium in multicomponent mixtures at elevated pressures.	R. KOBAYASHI
A simple apparatus for reproducibly packing gas chromatographic columns.	R. VILLALOBOS and G. R. NUSS
Application of switching valves in laboratory gas chromatography.	C. B. MCKINNEY and D. CARLE

Wednesday afternoon, June 3: *USE OF PROCESS STREAM ANALYSERS IN ON-LINE COMPUTER SYSTEMS*

Instream analysers aid in computer control.	J. C. RHODES and B. A. RITZENTHALER
Gas stream analysers in computer process control.	JOSEPH C. LANDWEHR, LLOYD J. BOESCH and EVERETT M. WOLVERTON
Chromatographs mated to digital computer implement process Studies.	W. H. WILLIAMS and M. C. BURK

Tuesday–Friday 2–5 *June* 1964: **15th Annual Mid-America Symposium on Spectroscopy:** Sheraton-Chicago Hotel, Chicago, Illinois.

Sunday–Friday 7–12 *June* 1964: **12th Annual Conference on Mass Spectrometry and Allied Topics:** *ASTM Committee E*-14: Sheraton-Mt. Royal Hotel, Montreal, Canada.

Monday–Friday 15–19 *June* 1964: **Symposium on Molecular Structure and Spectroscopy:** Department pf Physics, Ohio State University.

Sunday–Friday 21–26 *June* 1964: **Annual Meeting of ASTM and 16th Materials Testing Exhibit:** Conrad Hilton Hotel, Chicago, Illinois.

Wednesday–Friday 24–26 *June* 1964: Summer Symposium on **Recent Developments in Structure Determination:** *American Chemical Society, Division of Analytical Chemistry:* Cornell University, Ithaca, N.Y.: (see *Talanta*, 1964, 11, April vii).

Wednesday 30 *September–Thursday* 2 *October* 1964: **11th National Vacuum Symposium:** *American Vacuum Society:* Pick Congress Hotel, Chicago, Illinois.

The Programme Committee solicits the submission of contributed papers from those who have new and original work to report. Abstracts (150 words, in triplicate) should be submitted by 1st July to G. H. BANCROFT, Bendix-Balzers Vacuum, Inc., 1645 St. Paul Street, Rochester, New York.

Wednesday–Friday 21–23 *October* 1964: **12th Anachem Conference and Instrument Exhibit:** *Association of Analytical Chemists* (an affiliate of *ACS Detroit Section*) in collaboration with *Optical Society of America, Detroit Section:* McGregor Memorial Conference Center, Wayne State University, Detroit, Michigan.

It will feature symposia in many fields of interest, including thermal methods of analysis, organic functional group analysis, micro analysis, spectroscopy (emission, absorption, X-ray), *etc.*, and automation in analytical chemistry.

Further information can be obtained from C. M. GAMBRILL, Co-Chairman of the Publicity Committee, Ethyl Corporation, 1600 West 8 Mile Road, Detroit 20, Michigan.

Talanta, 1964, Vol. 11, pp. i to ix. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

(*Material for this section should be sent directly to the Associate Editor*)

INTERNATIONAL UNION OF PURE AND APPLIED CHEMISTRY

Division of Analytical Chemistry
Commission on Microchemical Techniques

International Investigation into Errors in Elementary Organic Microanalysis

The deadline for this investigation (see *Talanta*, 1964, **11**, April, i) has been extended until 1st September, 1964.

BELGIUM

Monday–Saturday 7–12 *September* 1964: **Fourth International Congress on Surface-Active Substances**; *Comité International de la Détergence*: Université Libre de Bruxelles, 48 Avenue Franklin Roosevelt, Bruxelles 5.

The scientific meetings are divided into three sections, of which Section A is on *Chemistry of Surface-Active Substances.* The provisional papers in Group A/IV, *Analytical Methods*, are as follows:

Analysis of fatty alcohol and alkyl phenol ethylene oxide condensation products.	P. Voogt
Direct determination of anionics in the anionics-ampholytics-nonionics ternary system.	Y. Izawa, Y. Ogata and W. Kimura
Separation and determination of nonionics in anionics-ampholytics-nonionics ternary mixtures.	W. Kimura and Y. Izawa
Development of an analytical method for determination of alkyl benzenesulphonate in surface waters and sewage.	Y. Dessouky
Determination of alkyl napthalenesulphonate in tomato products.	Y. Dessouky
Méthodes d'analyse des esters de saccharose et des sucroglycérides.	M. Roussos
Contribution à l'analyse des Polyéthylèneglycols et de leurs monoéthers, par chromatographie sur papier de leurs esters 3,5-*dinitrobenzoïques.*	H. Gauthier et M. G. Mangeney
Analyse des poloxyéthylèneglycols commerciaux par chromatographie en phase gazeuse de leurs dérivés diméthylés et dichlorés.	R. Celades et C. Paquot
Novel methods of isolation and identification of odiferous compounds in polypropylenebenzenesulphonate.	W. K. Seifert
Etude sur l'application de la technique chromatographique sur couches minces à l'analyse des mélanges des agents de surface (note III° des recherches sur la chimie analytique des agents de surface).	A. Arpino et V. De Rosa
Recherches sur le fractionnement et la composition de la fraction non sulphonée dans une pâte alkylarene-sulfonates.	A. Arpino, V. De Rosa et G. Jacini
Untersuchungen der in der Textilindustrie angewendeten Makromolekularen oberflächenaktiver Stoffe mittels der polarographischen Maximadämpfungen bzw. der oszillo-polarographischen kapazitiven Ströme.	A. Gergely
Estimation of alkyl phenol ethylene oxide adducts in soil.	B. Weibull

Verteilung zwischen Wasser und Chllroform von den Verbindungen aus n-Nonylbenzolsulfonat und einige n-Alkyltrimethylammoniumbromiden.	M. Hellsten

Further information is available from the General Secretariat of the Congress, 49 Square Marie-Louise, Bruxelles 4.

Monday–Tuesday 14–15 *September* 1964: **Third International Symposium on Chromatography;** *Belgian Society of Pharmaceutical Sciences*: Universite Libre de Bruxelles, Faculte de Medecine, 115 boulevard de Waterloo, Bruxelles 1.

Papers will be presented on theoretical aspects and practical applications in the following fields: *Biological Analytical Chemistry, Photochemistry, Analysis of Medicaments, Food Chemistry, Toxicology Industrial Chemistry and Synthetic Products, Radioisotopes—Tracers, Techniques, Apparatus, Solvents, Reagents.* The following Plenary Lectures will be given:

Détermination de la nature de la liaison mucopolyoside-protéine dans les glucoprotéides.	J. Montreuil
Chromatography in toxicological analysis.	A. S. Curry
Sur l'identification des composés dans la chromatographie en phase gazeuse.	A. I. Keulemans
Neue techniken und fortschrifte auf dem gebiet der dunnschikt-Chromatographie.	E. Stahl

Further information is available from the Secretariat of the Belgian Society for Pharmaceutical Sciences, 11 rue Archimede, Brussels 4.

CZECHOSLOVAKIA

Wednesday 26 *August–Friday* 4 *September* 1964: **Third European Regional Conference on Electron Microscopy;** Prague.

FRANCE

Monday–Friday 14–18 *September* 1964: **International Conference on Mass Spectrometry;** *Committee E-*14 *American Society for Testing and Materials, Groupement pour l'Avancement des Méthodes Spectrographiques, Institute of Petroleum:* Salle La Rochefoucauld-Liancourt, 9 bis, Avenue d'Iéna, Paris 16^e.

The programme is as follows:

Monday, 14 *September, Morning*

Détermination précise des masses atomiques.	J. Mattauch

Instrumentation and Advanced Techniques

Production of field ionisation mass spectra with a sharp edge.	A. J. B. Robertson and B. W. Viney
Progress of experimental techniques, applications and theory of field ion mass spectrometry.	H. D. Beckey
Mass spectrometric studies of the species of particles leaving a monocrystalline target in a charged or uncharged state under high-energy ion bombardment.	M. Kaminskny
Microanalyse par émission ionique secondaire.	R. Castaing et G. Slodzian

Monday, 14 *September, Afternoon—Analysis of Solids*

Analysis of solids by mass spectrometry.	R. E. Honig
Essai d'analyse absolue par spectrométrie de masse à étincelles.	M. Desjardins, R. Stefani, R. Bourguillot et A. Cornu
Qualitative analysis by spark source mass spectrometry.	J. S. Halliday, P. Swift and W. A. Wolstenholme
Contribution to the investigation of background effects in spark source mass spectrography.	H. Mai

Tuesday, 15 *September, Morning—Ion Collisions*

Ion-molecular reactions.	V. Talrose
Ionisation efficiency measurements by the retarding potential difference method.	S. Tsuda and W. H. Hamill
Appearance potentials obtained from a study of organic chlorides.	M. Baldwin, A. Maccoll and S. I. Miller

Positive and negative ion mass spectra of phosphorus compounds.	H. Halmann and Y. Klein
Ionisation cross-section measurements for 0·5–20 keV *electrons in atomic and molecular gases.*	B. L. Schram, A. J. H. Boerboom, M. J. v.d. Wiel and F. J. de Heer
A new type of formation of secondary negative ions in a mass spectrometer.	A. Henglein and G. Jacobs
Studies of atomic impact phenomena on metal surfaces with a pulsed molecular-beam mass spectrometer.	M. Kaminsky

Tuesday, 15 *September*, *Afternoon*

Ion molecular reaction cross sections.	C. F. Giese
The "stripping" and "inelastic complex" model in ion-molecule reactions.	A. Henglein, K. Lachmann and G. Jacobs
Réactions molecule-ion dans le cyanogène et l'acide cyanhydrique.	M. Inoue et M. Cottin
A high pressure mass spectrometric study of neopentane.	M. J. Henchman, H. T. Othwinowska and F. H. Field
Study of unimolecular and bimolecular reactions of ions using a pulsed ion source.	A. G. Harrison, T. W. Shannon and F. Meyer
Charge transfer collisions by ground state ions.	J. T. Scott and J. B. Hasted
Effect of excitation energy on charge transfer reactions.	F. W. Lampe
Charge transfer and atom transfer in ion-molecule interactions studied by a time-of-flight mass spectrometer.	J. B. Homer, R. S. Lehrle, J. C. Robb and D. W. Thomas

Wednesday, 16 *September*, *Morning—Theory of Mass Spectra*

Mass spectra theory of small molecules.	H. M. Rosenstock
Structure électronique des alkanes ionisés.	J. C. Lorquet
Unimolecular ion decompositions.	F. W. McLafferty
Etude par la méthode de déviation des distributions d'énergie cinétique d'ions formés par impact électrique.	J. Durup, J. Appell et F. Heitz
Mass spectrometric study of photoionisation of small molecules.	V. H. Dibeler and R. M. Reese
Effets isotopiques dans la dissociation par impact électronique des molécules triatomiques deutérées.	F. Fiquet-Fayard et P. M. Guyon
Study of fragment-ions formation in mass spectra of 1-*butyne*, 1-*pentyne*, 1-*hexyne*, 1-*heptine*, 1-*octyne*.	Z. Dolejsek, V. Hanus and K. Vokac

Thursday, 17 *September*, *Morning—Measurements of Isotopic Abundances*

Precise atomic abundance measurements.	H. Hintenberger
Mesure de l'abondance relative et absolue des isotopes de lithium produits dans des réactions nucléaires à haute énergie sur des cibles métalliques.	E. Alorent, R. Klapisch, E. Gradsztajn, F. Yiou, M. Épherre et R. Bernas
Tandem mass spectrometer for precise analysis.	L. G. Ridley
Abundance of vanadium isotopes in well-characterised sources of geochemical interest.	G. D. Flesch, J. Capellen and H. J. Svec
Preliminary report on half-life of tellurium-130 *double β-decay.*	K. Ogata, J. Okano and N. Takaoka
Etude par spectrométrie de masse des réactions du type La(p, 3p × n)Cs.	Nguyen Long-Den
Analyse de bore par dilution isotopique au spectromètre de masse.	M. Chemla et M. Périe
Isotopic analysis of boron as trimethyl borate by mass spectrometry.	H. Sanz Garcia

Thursday, 17 *September*, *Afternoon—High Resolution Mass Spectrometry*

Use of mass spectrometry in conjunction with other analytical techniques.	H. Powell
Distinction entre pics moléculaires et pics de fragmentation du spectre de masse d'un mélange complexe.	J. Champy et A. Cornu

Mass spectrometric investigation of di- and oligosaccharides and acylated peptides containing trifunctional amino acids.	H. Scharmann, K. Heyns and H. Fr. Gutzmacher
Mass spectrometry in natural product chemistry.	M. Barber, T. Bryce, E. Clayton, H. C. Hill, A. McCormick and R. I. Reed
Mass spectra of saturated cyclic nitrogen compounds.	A. E. Williams
Application of high-resolution mass spectrometry in molecular structure studies.	A. L. Burlingame
High resolution mass spectrometry of some large molecules.	M. Barber, R. M. Elliott and T. O. Merren
Combination of high resolution and low ionising voltages in determination of hydrocarbon and sulphur compound types in petroleum fractions using mass spectrometry.	W. K. Reid, W. L. Mead and K. M. Bowen

Friday, 18 *September, Morning—Instrumentation and Advanced Techniques*

Some problems relating to thermal emission of ions in mass spectrometric determination of isotopic abundances for neutron cross section measurements.	R. Baldock
Influence of oxygen on surface ionisation of some rare earth metals on tungsten and rhenium.	W. Weierhausen
Thermal ionisation of elements of high ionisation potential.	D. A. Crouch
Problèmes liés a l'obtention de réponses rapides em spectrométrie de masse.	J. Vastrel et J. Duroux
Sector-type double focussing mass spectrometer.	M. Sakai and M. Goto
Application à grande échelle d'analyse chimique industrielle par spectrométrie de masse: Digitalisation des informations en spectrométrie de masse.	P. Dard, J. Guiborg, J. C. Merlivat et G. Bernard
Results of a new time-of-flight mass spectrometer developed at the reactor centre Seibersdorf.	M. J. Higatsberger, F. Rudenauer, F. P. Viehbock and F. Butschbeck
Mass spectrometric sampling and detection of intermediates for gaseous reactions.	J. Cuthbert
Mass spectrometric sampling of high pressure high temperature sources.	F. T. Greene and T. A. Milne

Friday, 18 *September, Afternoon—Mass Spectrometry in General Chemical Research and in the Field of High Temperature Chemistry*

Review paper.	P. Le Goff et P. Goldfinger
Etude de l'oxydation du tantale et du tungstène: Etude thermodynamique du système uranium-dioxyde.	J. Drowart, F. De Greve, D. Detry et A. Pattoret
Equilibres thermodynamiques dans le système Sb–O *déterminés avec le spectromètre de masse.*	A. J. H. Boerboom et J. Kistemaker
Etude thermodynamique de l'hémioxyde de soufre (S_2O) *par spectrométrie de masse.*	R. Hagemann, R. Botter, G. Nief et E. Roth
A new-type of flow reactor for measurements of fast thermal reactions.	I. P. Fischer, J. B. Homer, B. Roberts and F. P. Lossing
Etude par spectrométrie de masse de la pyrolyse de quelques composés organiques.	E. Collin
Mass spectrometric investigation of reactions involving free radicals.	V. Talrose
Application of high temperature mass spectrometry to study of composition function of thermodynamic properties in non-stoichiometric compounds.	K. A. Gingerich

Further information may be obtained from Secretariat du G.A.M.S., 1 rue Gaston-Boissier, Paris 15^{e}, France.

UNITED KINGDOM

Sunday–Saturday 19–25 *July* 1964: **Third International Congress of Polarography;** *Polarographic Society*: University of Southampton.

The following papers will be presented:

Polarography in organic solvents (Presidential Address).	I. M. Kolthoff

SECTION 1.—*Theory, Methods and Instrumentation*

Role of polarography in study of rapid electrode processes.	G. C. Barker
Prospective developments in d.c. polarography and tensammetry.	B. Breyer
Determination of fast reaction processes at the dropping mercury electrode.	M. Fleischmann
Temperature coefficients of the electric tension (electrode potential) of individual electrodes.	G. Milazzo
Recent developments in d.c. polarography.	D. J. Fisher, W. L. Belew and M. T. Kelley
Complex plane analysis of cell impedances.	M. Sluyters-Rehback, D. J. Kooijman and J. H. Sluyters
Determination of rate constants for dissociation and recombination of weak acids by High Level Faradaic Rectification.	H. W. Nurnberg
Shielding effect of the capillary tip and its influence on RF current distribution.	A. W. Gardner
Recent studies in high-resistance polarography.	W. B. Schaap and P. S. McKinney
Diffusion-controlled electrolysis with gas injection through the porous electrode.	D. B. Spalding and P. L. Duffield
Multi-sweep oscillographic polarography: Theory, instrumentation and applications in analytical chemistry.	H. A. Glastonbury
Square wave d.c. bridge polarograph.	E. Niki
Alternating current polarography at stationary electrodes.	Yu. S. Lyalikov, V. I. Bodyu and L. G. Madan
Studies in subtractive and continuous polarography.	K. G. Powell and G. F. Reynolds
An oscillopolarography using a magnetic deflecting cathode-ray tube.	Y. Yasumori
Application of transistors to polarographic instrumentation.	C. L. Roughton
Graphite indicating electrodes: Theory, methodology and applicability.	P. J. Elving and I. Fried
Moglichkeiten und Grenzen einer Strömungsapparatur mit Polarographischer Registrierung.	E. Bauer and H. Berg
Influence of salting-out effect on polarographic behaviour of pyridine.	C. Pécasee and L. Gierst
Study of return of polarographic maxima in the function of the base electrolyte.	I. Rusznak, A. Gergely, I. Kralik and V. Komiszar
Reduction of hydrogen ions at the dropping mercury electrode.	O. H. Müller
An interpretation of differential electrolytic potentiometers as a linear diffusion process.	E. Bishop and G. D. Short
Auto-inhibition phenomena in polarography.	E. Laviron and Ch. Degrand
Kapazitäts und Inhibitions-Untersuchungen mit der Wechselstrompolarographie.	H. Jehring
Investigation of adsorption phenomena occurring at the dropping mercury electrode.	F. Peter
Application of cyclic chronopotentiometry to study of electrode reaction mechanisms.	A. J. Bard and H. B. Herman
Study of chronopotentiometric curves in current scanning polarography.	E. Laviron
Fortschritte der Photo-polarographie.	H. Berg

SECTION 2.—*Study and Analysis of Inorganic Systems*

Polarography and mechanism of electroreduction of carbon dioxide.	P. T. Smith

Polarographic studies of carbonate complexes of some metal ions.	S. Misume and Y. Masuda
Reduction, oxidation and disproportionation of uranium ions in sodium carbonate solutions.	M. Branica and V. Pravdić
Influence of pH and of the double layer on rate constants of reduction of oxygen on the dropping mercury electrode.	J. Kuta and J. Koryta
A study of the polarographic behaviour of the system O_2Pb^{II}.	A. Arevalo and A. Bazo
Polarography of sulphide-ion.	S. Zhdanov and B. Kiselev
Polarographic determination of sulphur in organic compounds.	G. Russell
La polarographie de la réaction de l'activation de quelques ions complexes diacidotétrammino Co^{III}.	R. Ralea, G. Burlacu et D. Giurgiu
La radio-polarographie des maximas obtenues par la réduction de l'arsenic cataliseé par le cobalt et le fer.	R. Ralea et A. Cecal
Polarographic investigation of metal acetylacetones—II: Cupric acetylacetonates.	M. Petek, L. Jeftić and M. Brancia
Polarography of pentacyano-, tetracyano- and dicyano-cobalt(III) complexes: Electron-transfer mechanism of the electrode reaction.	N. Maki
Polarographic studies of zirconium with Solochrome Violet RS in various supporting electrolytes.	D. S. Turnham
Polarographic behaviour of tervalent lanthanide ions in aquo-alcoholic media.	V. A. Huertas, J. A. Huertas and J. S. Gomez
Polarographic study of dibromotetraquochromium(III) ion hydrolysis.	J. Ibarz, A. M. Calvo and J. M. Costa
Determination of composition and stability constants of mercury(II)—thioacetamide complexes.	T. D. Seth and R. C. Kapoor
Polarographic behaviour of metal ions in aged KOH solutions.	P. Bersier and F. V. Sturm
Polarographic studies of ion binding: Zinc Polystyrene Sulphonate.	S. Lapanje and S. Oman
Polarographic determination of traces of molybdenum.	H. Woggon
Polarographic determination of mercury distribution in mercuric chloride catalyst supported by activated carbon granules.	F. Zilio-Grandi, A. M. Perazzolo and L. Fornasiero
Determination of trace metal impurities in zinc oxide and zinc salts.	R. J. Browning and G. F. Reynolds
Polarographic investigations in acidic fluoride solutions.	J. B. Headridge, A. G. Hamza, D. P. Hubbard and M. S. Taylor
Some uses of solvent extraction in polarographic analysis.	R. C. Rooney and D. L. Jones
Application of single-sweep polarography to analysis of trace elements in sea-water.	G. Whitnack
Continuous multipotential polarography in strong gamma-radiation field.	Z. P. Zagórski

SECTION 3.—*Study and Analysis of Organic Systems*

Recent trends in organic polarography.	P. Zuman
Oscillopolarographic study of reductions at high negative potentials.	R. Kalvoda
Formation of surface film by cyclohexane on mercury cathode.	K. Tsuji
Effect of composition of aqueous-organic solvents on polarographic behaviour of organic compounds.	S. Mairanovskii
*Polarographic investigation of indandione-*1,3 *and related compounds.*	J. Stradins, I. Tutane and G. Vanags
Some observations about the connection between structure and adsorption at the DME of some aromatic sulphonic acids.	G. Palyi
Polarography of sulphilimines.	M. Vajda and F. Ruff

Polarography of some α-halogen substituted aldehydes in dimethylformamide.	N. Moe
Polarographische untersuchung und Bestimmung von Krotonaldehyd im Technischen n-butylalkohol.	J. Pasciak
Polarography of tropon and 2,3-*dimethyl*-7-*benzotropon.*	A. Pozdeeva and S. Zhdanov
Controlled potential electrolytic reduction of polycyclic aromatic hydrocarbons, and concurrent polarography and spectrophotometry of the reduction products.	I. Bergman
Contribution a l'etude polarographique de quelques aci-reductones.	P. Souchay, M. Fleury and D. Fleury
Polarographie et electrolyse a potentiel controlé de derives aliphatiques gem-halogenonitres, gem-halogenonitrosés et gemnitrosonitrés.	P. Souchay, J. Armand and S. Deswarte
Role of surface active cations in electrode reaction mechanism of catalytic currents caused by organic compounds containing nitrogen.	E. Pungor
Über reversibilität und reversibilitätsgrenzen von Azo-/Hydrazo-Redoxreaktionen an der Hg-Tropfelektrode.	L. Holleck
Polarographic reversibility of the azobenzene-hydrazobenzene system with special reference to an absorption mechanism.	B. Nygård
Properties electrochimiques de l'hydrazo-9 *acridine et de l'azo*-9 *acridine en milieu non-aqueux*: *Deux radicaux libres intermediares.*	C. Cauquis and G. Fauvelot
Polarographic reduction of 4-*methylimidazol*-2-*ylthiosulphuric acid.*	R. A. F. Bullerwell
Polarographische Untersuchungen der Kinetik und Mechanismus der Azomethinreaktionen.	M. Deželić
Polarographic behaviour of 1-*oxy*-1,2,3,4-*tetrahydroisoquinoline.*	K. Gyorbiro
Development of polarographic activity in some cyostatic agents containing nitrogen.	T. Horvath and J. K. Pauncz
Determination of residual fumaric and maleic esters in copolymer emulsions.	J. S. Double, C. E. R. Jones and G. E. J. Reynolds

SECTION 4.—*Study and Analysis of Biological Systems*

New contributions to palladium polarography and their application to carbon monoxide determination in blood.	R. Portillo, P. Sanz Pedrero and P. Ramos
Polarographische Sauerstoffmessungen mit der Quecksilbertropfelektrode and Festelektroden in Mikrobenkulturen und ihr Vergleich mit Redoxpotentialmessungen.	G. Horn and H. E. Jacob
Tissue pO_2 *measurement with a miniaturized Clark-type electrode.*	R. Penneys
Controlled potential electrolytic reduction of diphosphopyridine nucleotide and a number of model compounds: *Polarography of oxidised and reduced forms.*	I. Bergman
The Brdicka serum filtrate reaction applied to normal and cancerous menstrual fluids.	R. Rappolt
Polarographic study of effect of gamma radiation on 1-*ascorbic acid.*	R. P. Lansky

SECTION 5.—*Study of Non-aqueous Systems*

Die polarographische Bestimmung kleinster Mehgun von Wasser und Stoffen mit aktivem Wasserstoff.	H. Dehn, V. Gutmann and G. Schober
Complex formation in polarography of aromatic compounds in organic solvents.	M. E. Peover and J. D. Davies

Voltammetric oxidation of aromatic compounds in acetonitrile.	T. A. Gough and M. E. Peover
Polarographic studies in acetonitrile and dimethylformamide: Behaviour of triphenylphosphine and related compounds.	S. Wawzonek and J. H. Wagenknecht
A simple quasi reference electrode: Applications in controlled potential polarography and voltammetry and in chronopotentiometry.	D. J. Fisher, W. L. Belew and M. T. Kelley
A reference electrode for polarography in organic solvents.	G. P. Kumar and D. A. Pantony
Electrochemistry in acetic anhydride: Behaviour of silver, mercury, gold and platinum electrodes and oxidation-reduction systems of iodine.	V. Plichon and J. Badoz-Lambling
Etude des domaines d'electroactivité a une electrode de platine poli de quelques ammoniacates liquids.	J Badoz-Lambling and M. Herlem
Polarography in the eutectic aluminium chloride-sodium chloride potassium chloride.	R. M. de Fremont, R. Rosset and M. Leroy
Polarography in molten fluorides.	D. L. Manning and J. W. Dale
Oscillographic polarography in molten nitrates II° Association constants determination.	M. F. Francini and S. Martini

Further information may be obtained from Dr. D. A. Pantony, Department of Metallurgy, Royal School of Mines, London S.W. 7, England.

Thursday–Friday 27–28 *August* 1964: **Conference on Recent Advances in Activation Analysis;** University of Glasgow (see *Talanta*, 1964, **11**, May, ii)

Tuesday–Wednesday 13–14 *April* 1965: **Symposium on Thermal Analysis;** Northern Polytechnic, London

The programme will include main lectures on various aspects of thermogravimetric and differential thermal analysis to be given by distinguished visitors from Europe and U.S.A. Contributed papers are also invited. Further information is available from Dr. B. R. Currell, Northern Polytechnic, Holoway Road, London N.7.

British Standards Institution has announced the following *New British Standard*:

B.S. 3727: *Methods for the analysis of nickel for use in electronic tubes and valves* (Price of Parts: 3s. each).

Part 4: 1964: *Determination of chromium*, 0·002–0·010% (*photometric method*).
Part 5: 1964: *Determination of cobalt*, 0·01–1·0% (*photometric method*).
Part 6: 1964: *Determination of copper*, 0·002–0·20% (*photometric method*).
Part 7: 1964: *Determination of iron*, 0·03–0·25% (*photometric method*).
Part 8: 1964: *Determination of manganese*, 0·005–0·025% (*photometric method*).
Part 10: 1964: *Determination of silicon*, 0·020–0·25% (*photometric method*).
Part 14: 1964: *Determination of tungsten, up to* 5% (*gravimetric method*).

UNITED STATES OF AMERICA

Monday–Tuesday 10–11 *August* 1964: **Seventh Annual Rocky Mountain Spectroscopy Conference;** *Society for Applied Spectroscopy, Rocky Mountain Section*: Albany Hotel, Denver, Colorado.

Wednesday–Friday 12–14 *August* 1964: **Thirteenth Annual Conference on Application of X-Ray Analysis;** Albany Hotel, Denver, Colorado.

Monday–Thursday 17–20 *August* 1964: **Sixteenth Annual Meeting of American Association of Clinical Chemists;** Hotel Statler-Hilton, Boston, Mass.

Monday–Friday 17–21 *August* 1964: **Gordon Research Conference on Analytical Chemistry;** New Hampton School, New Hampton, New Hampshire (see *Talanta*, 1964, **11**, April, viii).

Sunday 30 *August–Friday* 4 *September* 1964: **148th National Meeting of American Chemical Society;** Chicago, Ill.

Monday–Thursday 19–22 *April* 1965: **International Conference on Modern Trends in Activation Analysis;** *International Atomic Energy Agency, Division of Isotopes Development of U.S. Atomic Energy Commission* and *Activation Analysis Research Laboratory of Texas A and M University*: Texas A and M University, College Station, Texas.

Reports of new activation analysis developments in the following categories are invited:

1. *Radiochemical Methods*
2. *Instrumental Methods*
3. *Data Processing*
4. *Detector Developments*
5. *Sources*
6. *Nuclear Reactions*
7. *Statistical Considerations*
8. *Applications*

A technical abstract (250–500 words) should be submitted, not later than 1 August, 1964, to Dr. R. E. WAINERDI, Activation Analysis Research Laboratory, Texas A and M University, College Station, Texas, U.S.A. Authors will be notified of the decisions of the selection committee before 1 October, 1964. Abstracts should describe new, unpublished work of substantial interest. Those papers which indicate trends and new approaches are especially encouraged. Abstracts and papers should be submitted in English, which will be the official language of the Conference.

Sunday–Friday 22–27 *August* 1965: **International Symposium on Microchemical Techniques**—1965; *American Microchemical Society* with sponsorship of *I.U.P.A.C.*: Pennsylvania State University, Pa.

A call is now being made for research papers directed towards small-scale operations, techniques and methods in all phases of chemistry, including clinical chemistry and biochemistry. Papers centered on history, speculation or review will not be considered. It is hoped to have sessions on the following subjects:

1. *Micro methods in structural elucidation.*
2. *Micro techniques in peptide studies.*
3. *Clinical and forensic analysis.*
4. *Novel micro and ultramicro approaches in organic elemental analysis.*
5. *Micro techniques with high-energy materials.*
6. *Novel micro separation methods.*
7. *Inorganic microanalysis and trace analysis.*
8. *Micro methods in air and water pollution studies.*
9. *Determination of physical properties with small samples.*
10. *Education for instrumentation.*
11. *General papers.*

Further information, including regulations governing papers, may be obtained from Mr. H. FRANCIS, JR., Vice-Chairman, Intern. Sym. Microchem. Techniques—1965, c/o Pennsalt Chemicals Corp., 900 First Ave., King of Prussia, Pennsylvania, U.S.A. A descriptive title and abstract for a paper must be received by 31 January, 1965, and the text of the paper by 31 April, 1965.

American Society for Testing and Materials has announced the availability of the following publication:

ASTM Standards on Methods for Emission Spectrochemical Analysis (1963): E-2 (Price $16.00; $11.20 to ASTM members). This compilation, now in its fourth edition, contains all spectrochemical practices and methods published by the Society, as well as excerpts from ASTM methods or practices. The scope, limitations, precision and accuracy of the methods have been recorded to the extent of data available so that the methods can be compared and evaluated with respect to other analytical methods. The table of contents lists those methods and practices which have been discontinued or replaced since the previous edition.

Talanta, 1964, Vol. 11, pp. i to v. Pergamon Press Ltd. Printed in Northern Ireland

UNITED KINGDOM

Wednesday 4 *November* 1964: Afternoon and evening meeting on **Toxic Substances in Air:** Society for Analytical Chemistry. Wellcome Building, Euston Road, London N.W.1, 3.00 p.m.

Friday–Saturday 12–13 *November* 1964: Conference on **Accuracy in X-Ray Analysis:** *Institute of Physics and Physical Society, X-Ray Analysis Group.* Institution of Mechanical Engineers, London S.W.1 (see *Talanta*, 1964, **11**, August, ii).

Thursday 19 *November* 1964: **Photometric Titrations:** J. B. HEADRIDGE: *Society for Analytical Chemistry, Midlands Section.* Lanchester College of Technology, Priory Street, Coventry, 7.00 p.m.

Friday 20 *November* 1964: **High Resolution Mass Spectrometry:** W. SNEDDON: *Society for Analytical Chemistry, North of England Section* and *Special Techniques Group.* The Blossoms Hotel, Chester, 6.00 p.m.

Tuesday 24 *November* 1964: **Annual General Meeting** followed by Film Show: *Society for Analytical Chemistry, Special Techniques Group.* Burlington House, London W.1, 7.00 p.m.

Friday 27 *November* 1964: **Some Aspects of Chemical Toxicological Analysis:** H. V. STREET: *Society for Analytical Chemistry, Scottish Section.* University of Strathclyde, Glasgow, 7.15 p.m.

Friday 27 *November* 1964: **Recent Advances in Analytical Chemistry:** T. S. WEST: *Society for Analytical Chemistry, Western Section* and *Royal Institute of Chemistry, Cardiff and District Section.* College of Technology, Newport, 6.30 p.m.

British Standards Institution has announced the following **New British Standards:**

B.S. 3599/6–15: 1964: *Organic pigments for paints.* C.I. Pigment Red 12 (Bordeaux F2R), C.I Pigment Red 112 (Red FGR), C.I. Pigment Red 10 (Red FRL), C.I. Pigment Red 7 (Red F4RH), C.I. Pigment Red 9 (Red FRLL), C.I. Pigment 5 (Carmine FB), C.I. Pigment Green 7 (Polychlorocopper phthalocyanine), C.I. Pigment Blue 15 (Copper phthalocyanine), C.I. Pigment Green 10 (Nickel azo yellow), C.I. Pigment Yellow 12 (Benzidine yellow).

Residue on sieve, sulphated ash, matter volatile at 100°, matter soluble in water and pH of aqueous extract, oil absorption value, colour, staining power and colour on reduction, fastness to light, bleeding, heat stability and resistance to acids and alkalis, determination of copper content. Stability of C.I. Pigment Blue 15. (*Price:* 17s. 6d.)

B.S. 3762: 1964: *Methods of sampling and testing detergents.*

Part 1, two sampling methods for powders from packets;
Part 2, analytical methods in four sections; A: two qualitative test methods; B: seventeen methods for schematic examination of active matter; C: nine other methods for analysis of active matter; D: fourteen methods for determination of constituents other than active matter.
Part 3, nine test methods for physical properties and performance.
Appendices: special reagents, three methods of preparation and one specification. (*Price* £2. 2s.)

The following *Revised British Standards* have been announced:

B.S. 903: *Methods of testing vulcanized rubber: Part B*14: 1964: *Determination of carbon black* (*replacing Part* 7 *of B.S.* 903: 1950). This covers three methods of determining carbon black with details of reagents, apparatus and procedure. (*Price:* 10s.)

B.S. 2690: *Methods of testing water used in industry: Part* 1: 1964: *Copper and iron. This details three methods for copper and two methods for iron.* (*Price:* 6s.)

The following *Amendment Slips* have been announced:

B.S. 1728: *Methods for the analysis of aluminium and aluminium alloys: Part* 5: 1953: *Copper (absorptiometric method). Amendment No.* 1: *PD* 5267.

B.S. 2782: *Methods of testing plastics. Part* 4: *Analytical methods and viscosity in solution. Amendment No.* 10: *Methods* 405 and 406: *PD* 5283. (*Price:* 10s.)

UNITED STATES OF AMERICA

Wednesday–Friday 21–23 *October* 1964: **Twelfth Detroit Anachem Conference.** McGregor Memorial Conference Centre, Wayne State University, Detroit, Michigan.

The programme is as follows:

Wednesday Morning, October 21: *Significance of Spectroscopic Methods to Clinical and Biological Research*

Interpretation of analytical data in clinical and biological research.	H. MITCHELL PERRY, JR.
Standardisation problems in analysis of biological samples for trace elements.	C. L. GRANT
Spectrographic determination of beryllium in air, biological materials and ores using the sustaining a.c. arc.	R. G. KEENAN and J. L. HOLTZ
The place of atomic absorption in tissue analysis.	C. FELDMAN
Lasers in emission for clinical research.	F. BRECH
Light-induced absorption changes in photosynthetic bacterial preparations.	H. E. BALES

Symposium on Thermal Methods of Analysis

New developments in "solution enthalpimetry".	J. JORDAN and P. T-S PEI
A critical evaluation of experimental variables in DTA.	J. R. SCHEMPF, F. M. ANGELONI and F. E. FREEBERG
Evaluation of solid state phase transformations by DTA and dilatometry.	S. GORDON
Improved resolution of differential thermal analyses through use of pressure effects.	P. D. GARN
A thermoanalytical study of pyrotechnic coloured smoke compositions.	C. CAMPBELL, G. WEINGARTEN and D. ANDERSON
Thermoparticulate analysis.	F. W. VAN LUIK, JR. and C. B. MURPHY
Thermal analysis in phase purifications of polymorphic solids.	A. R. GLASGOW, JR.
Product control by differential scanning calorimetry.	J. L. JUSTIN and N. BRENNER

Wednesday Afternoon, October 21: *Significance of Spectroscopic Methods in Clinical and Biological Research*

The analytical problems in biology and medicine.	W. B. MASON
Chemical enrichment methods in spectrographic analysis.	E. E. PICKETT
X-Ray methods of elemental analysis.	T. HALL
Breath analysis: Key to diagnosis of vapour exposure.	R. D. STEWART

Symposium on Microanalysis

Microchemistry: Implications and current trends.	T. S. MA
A rapid Pregl combustion carbon-hydrogen determination.	C. E. CHILDS and E. E. MEYER
Chemical analysis of thin films.	K. L. CHENG
Role of the electron probe microanalyser in microanalytical chemistry.	A. C. OTTOLINI and T. P. SCHREIBER

Analytical Chemistry—General

Determination of trace amounts of vanadium in steels and cast irons by amperometric titration.	F. P. VALENTE and G. H. CAREY
Cumulative coulographic titrimetry—I: Principles—II: Some new light on mercury catalysis in halogenation of unsaturated compounds: Titrations with electrogenerated bromine monochloride.	S. T. HIROZAWA

Reactions in concentrated lithium chloride solutions: Determination of free acid and hydrolysable metal.	H. Kubota
Radio-release methods for evaluation of atmospheric pollution.	H. H. Ross

Thursday Morning, October 22: Symposium on Polarography

Recent developments in stripping analysis.	I. Shain
Application of derivative techniques to anodic stripping voltametry.	S. P. Perone and J. R. Birk
Stripping and voltammetric determination of manganese via manganese dioxide.	C. Huber
Second derivative d.c.-polarography as a technique in quantitative polarographic measurements.	W. L. Belew, J. D. Fisher and M. T. Kelley
Pulse polarography.	E. P. Parry, R. A. Osteryoung and H. Schlein
Recent developments in lanthanide ion polarography.	A. Timnick, R. F. Large and R. O'Donnell
Polarographic reduction of pyridinium ion in pyridine: Application to determination of Bronsted and Lewis acids.	M. S. Spritzer, J. M. Coste and P. J. Elving
Electro-oxidation of tetraphenylborate ion at the pyrolytic graphite electrode.	W. R. Turner and P. J. Elving
Polarographic behaviour of molybdenum(VI) in acidic chloride media.	G. A. Rechnitz and J. Wittick

Symposium on Organic Functional Group Analysis

New dimensions in organic functional group analysis.	S. Siggia
Recent advances in redox methods.	K. G. Stone
Reagents for hyroxyl group analysis.	G. H. Schenk
Potentiometric determination of acid groups in acrylic polymers and fibers.	J. R. Kirby and A. J. Baldwin
Colorimetric determination of tertiary aromatic amines in primary and secondary amines using tetracyanoethylene.	P. O. Warner and G. H. Schenk
Determination of 18 *to* 22 *mole ethoxymers in* 9 *mole ethylene oxide adduct of p-nonylphenol.*	N. E. Skelly and W. B. Commett

Thursday Afternoon, October 22: Anachem Award Symposium

Anachem Address: *The challenge of analytical chemistry.*	L. T. Hallet
Trends and problems in the literature of analytical chemistry.	W. D. Cooke
The information explosion myth.	H. S. Nutting

Thursday Evening, October 22: Conference Address

Alpha particle analysis of surfaces: Plans for lunar missions.	A. Turkevich

Friday Morning, October 23: Clinical and Biochemistry Symposium

A study of determination of phosphorus in blood serum and urine.	R. E. Mosher
Colorimetric estimation of urinary iron by a non-ashing technique.	J. F. Goodwin
Spectrophotometric determination of p-hydroxyphenylpyruvic acid in human urine.	I. J. Holcomb and A. J. Boyle
Photosynthetic nucleotide coenzyme analyses.	W. L. Ogren
A study of the Liberman colorimetric determination of serum cholesterol.	J. Caruso and G. H. Schenk
Measurement of serum cholesterol synthesis employing deuterium.	C. B. Taylor, B. Mikkelson, J. A. Anderson and D. T. Forman
Nature of lactic dehydrogenase isoenzymes.	N. Ressler, U. Cook, E. Olivero and R. Joseph
New applications of Starch gel electrophoresis to study of complex molecules.	A. L. Koen
Determination of acid mucopolysaccharides in tissue culture.	Y. Shimizu and D. Francis

Chromatography

Application of gas chromatography to determination of carbonate carbon in sodium metal.	H. Bradley, J. Ferguson and S. A. Meacham

A modified high temperature combustion technique for determination of carbon in sodium.	E. J. Havlena and H. V. Myers Jr.
Separation of methyl and propyl esters of p-hydroxybenzoic acid by gas chromatography and their determination by ultraviolet spectroscopy.	S. J. Donato
New correlations between physical properties and gas chromatographic retention times for members of various homologous series of organic compounds.	B. J. Gudzinowicz
Identification of polymeric materials using two new instrument attachments.	K. A. Hutchinson
Rapid quantitative determination of long chain tertiary amines by thin layer chromatography.	J. R. Pelka and L. D. Metcalfe
Column, paper and thin-layer chromatographic characterisation methods for aromatic compounds and their application to air pollution.	E. Sawicki, H. Johnson and T. W. Stanley
Column chromatographic separation of basic polynuclear aromatic compounds from complex mixtures.	E. Sawicki, J. E. Meeker and M. Morgan

Spectrophotometry

Precision analysis of high purity gallium by indirect spectrophotometry.	R. Bastian, R. S. Kelly and E. W. Lanning
Simultaneous determination of trace amounts of titanium and zirconium.	J. O. Hibbits, A. F. Rosenburg and R. T. Williams
Improved spectrophotometric method for determination of organo aluminium compounds.	S. R. Henderson, T. G. Mungall and J. H. Mitchen
Indirect spectrophotometric determination of chlorine dioxide.	J. A. Howell, G. E. Linnington and D. F. Boltz
Spectrophotometric determination of antimony.	J. C. Guyon and R. M. Matulis
Determination of oxides of nitrogen in effluent of an inert gas generator.	D. M. Zall
Method for sampling and analysis of nitrogen in potassium.	H. Kirtchik
Determination of fluorine in organic compounds.	M. Brandt and D. G. Cobb

Friday Afternoon, October 23: Symposium on Automation in Analytical Chemistry

Automation in analytical chemistry.	B. Klein
Automated determination of proteins.	E. S. Baginski and B. Zak
Automated determination of iron.	B. Zak
Kinetic measurements in the clinical laboratory.	D. G. Remp
Automatic, real time digital integration of amino acid peaks.	D. W. Spence and H. J. Jones
Automatic potentiometric EDTA and redox titrations of nonstoichiometric compounds.	M. C. Gardels and J. C. Cornwell
Automated system for rapid and precise neutron activation analysis.	J. R. Vogt and W. D. Ehmann

Industrial Application of Optical Methods of Analysis

Refinement of spectrochemical procedures.	J. K. Hurwitz
Spectrographic determination of impurities in beryllium.	E. S. Melick, L. Bunck and E. Peterson
Industrial applications of atomic absorption spectroscopy.	R. E. Mansell
Vacuum ultraviolet instrumentation and development and manufacture of a double beam monochromator for ultraviolet region.	P. M. McPherson
Vacuum ultraviolet and soft X-radiation detection.	C. F. Hendee
A precise recording absolute spectroflurometer.	G. K. Turner and R. E. Phillips
Optical emission spectrographic method for determination of chloride ion in chromium plating baths.	W. Edgar and N. B. Parseghian
Spectrochemical determination of microgram amounts of tantalum, niobium, titanium and hafnium in U_3O_8.	J. E. Scott and E. R. Shuster, Jr.

Wednesday–Friday 4–6 *November* 1964: **Annual Pittsburgh Diffraction Conference.** Mellon Institute, Pittsburgh, Pa.

Monday 30 *November-Friday* 4 *December* 1964: **Short Course on Gas Chromatography:** *Instrument Society of America.* Carnegie Institute of Technology, Pittsburgh, Pa. (see *Talanta*, 1964, **11**, August iii).

New standard samples for four groups of copper-base alloys have been issued by the **National Bureau of Standards Institute for Materials Research**. Several samples, which vary in composition, are available for each of the alloys—free-cutting brass, gilding metal, commercial bronze and aluminium brass. These standards have been prepared primarily for optical-emission and X-ray spectrochemical analysis calibrations and are in a form convenient for such use.

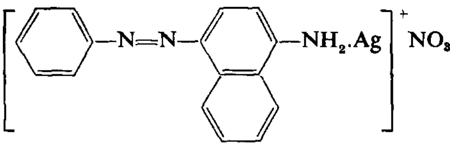
American Society for Testing and Materials has compiled the *Wyandotte-ASTM Punched Card Index* for finding and correlating infrared spectral absorption data using programmed tapes for computers. These tapes are used in connection with the Codes and Instructions for the Wyandotte-ASTM Punched Card System. This system facilitates the sorting of spectral data in matching spectrograms in qualitative analysis. Further information is available from Dr. L. E. KUENTZEL, ASTM, 1916 Race Street, Philadelphia, Pa. 19103.

American Society for Testing and Materials has announced the availability of the following publication:

ASTM Standards for Industrial Water and Atmospheric Analysis: Part 23 *of* 1964 *Book of ASTM Standards* (*Price* $13.00; $9.10 *to ASTM members*). This contains 98 standards of which 58 are new or have been revised since the publication of the 1960 edition of *Manual on Industrial Water-D*-19, which it replaces. The contents include industrial water—sampling and analytical methods, corros-tests, methods of reporting; atmospheric analysis.

ERRATA—Volume 11

Page 1098: The structural formula for compound III should be



Page 1121: The title should read *Colorimetric determination of cobalt*[11]
Page 1136, Table I: the second entry in the last column should read 0·511 *MeV*
Page 1137, Table II: The entries in the third column should read 0·511 *MeV* and 1·04 *MeV*
Page 1177: This paper should read *Eingegangen am* 15. *Februar* 1964

BUNDESREPUBLIK DEUTSCHLAND

"Moderne Methoden der anorganischen Analyse": Vortragstagung veranstaltet von der Fachgruppe "Analytische Chemie" in der Gesellschaft Deutscher Chemiker in Zusammenarbeit mit den Chemikerausschüssen der Gesellschaft Deutscher Metallhütten- und Bergleute des Steinkohlenbergbauvereins und des Vereins Deutscher Eisenhüttenleute sowie dem Deutschen Arbeitskreis für Spektroskopie und der Deutschen Arbeitsgruppe Massenspektrometrie der Deutschen Physikalischen Gesellschaft: Düsseldorf 5.-7. Oktober 1964.

Vortragsprogramm

Montag, 5. Oktober: Nichtmetalle in Metallen

Nichtmetalle in Metallen.	J. Fischer
Die Bestimmung kleiner Gehalte Selen in Kupfer mit Röntgenfluoreszenz-Spektralanalyse	G. Maassen
Nachweis und Analyse kleinster Gasmengen in Metallen mit Massenfilter.	H. Böhm, K. G. Günther und W. Kuhl
Eine γ.γ-Koinzidenz-Anordnung zur aktivierungsanalytischen Bestimmung der Spurenghalte Ir, Se etc. in Platinmetallen und in Nickeleisen.	W. Herr und R. Wolfle
Massenspektroskopische Analyse von Nichtmetallen in Metallen.	H. Hintenberger
Bestimmung von Sauerstoff in Kupfer und Blei.	A. Olofsson
Nichtdispersive Spektralanalyse der Gase aus der Hekissextraktion.	W. Baum und S. Eckhard
Schnellbestimmung des Stickstoffs in Stahl nach dem Schmelzextraktionsverfahren in Trägergasstrom. Weiterentwicklung und statische Bewertung.	H. Lemm
Gefügeuntersuchungen von Erzen und Schlacken mit dem Mikroanalysator.	P. Dickens, P. König und P. Jaensch
Die Sauerstoffbestimmung in Urancarbiden durch Heissextraktion.	H. Nickel und J. Rottmann
Fortschritte bei der Bestimmung des Sauerstoffs, Wasserstoffs und Stickstoffs in Metallen.	Th. Krays
Beitrag zur Bestimmung von Spurenverunreinigungen in hochreinem Germanium(IV)-chlorid und Germanium(IV)-oxid.	E. Wunderlich

Mitgliederversammlung des Chemikerausschusses der Gesellschaft Deutscher Metallhütten- und Bergleute

Dienstag, 6. Oktober: Erfassen und Verwerten analytischen Zahlenmaterials

Mathematisch-statische Grundlagen des Auswertens von analytischem Zahlenmaterial.	R. Wartmann
Erfassen und Verwerten chemischer Daten.	F. A. Pohl
Zur Problematik der Nachweisgrenzen.	H. Kaiser
Die Anwendung des Streudiagramms am Beispiel der Spektralanalyse.	G. Holdt

Probenahme

Probenahme.	H. Zettler
Technische Hilfsmittel der Probenahme und Probenvorbereitung.	H. Sporbeck

Ein Metall-Aufschluss und -Umschmelzverfahren zur Herstellung von Proben für die Spektralanalyse.	P. Holler
Zur Probenahme von Schwefelkiesabbränden.	H. Spitzer
Probenahme von Fe- und Mn-Erzen, gegenwärtrige Situation bei der ISO-Normung.	K. E. Stumpf
Auswirkungen theoretischer Überlegungen bei der Probenahme von Kohlen.	F. Finze

Mitgliederversammlung der GDCh-Fachruppe "Analytische Chemie"
Mitgliederversammlung des Deutschen Arbeitskreises für Spektroskopie

Mittwock, 7 Oktober: Analyse von Verbindungsformen und ihre Verteilung im festen Zustand

Analyse von Verbindungsformen und ihre Verteilung im festen Zustand.	W. Koch
Die Reaktionen des Mangans in Kohlenstoffstählen, untersucht durch electrolytisches Isolieren.	W. Koch und H. Keller
Bestimmung von metallischem und Oxidischem Nickel in Hüttenprodukten.	G. Kraft
Strukturen und chemische Eigenschaften verschiedener Nitride in ternären Eisenlegierungen.	W. Koch und K.-H. Sauer
Zusammenhänge zwischen Raumgewicht, Grobkorntitration und chemischer Analyse bei gebranntem kalk.	S. Eckhard
Einsatz der Autoradiographie zur Untersuchung der Verteilung von Verunreinigungen in Elektrolytniederschlägen.	Ch. Fischer-Bartelk

Spektrochemische Analyse

Lösungsspektralanalyse von Edelmetallen.	W. Diehl
Quantitative Analyse von Metallspuren mit Hilfe der Flammenphotometrie (Atom-Absorption).	(G. Nonnenmacher und F. H. Schleser
Untersuchungen zur Anwendung des Eichzusatzverfahrens.	G. Ehrlich und R. Gerbatsch
Die Verwendung radioaktiver Nuklide zur Untersuchung physikalisch-chemischer Vorgange in Graphitelektroden bei Lichtbogenanregung.	H. Nickel
Die röntgenspektrometrische Bestimmung von Metallspuren mit Hilfe einer speziellen Methode des inneren Standards	E. Bankmann
Fällungsoperationen durch Dekomplexierungen.	Sw. Pajakoff

Das 3. **International Fluorsymposium** findet vom. 30. August bis 2. September 1965 in München statt und wird von der Gesellschaft Deutscher Chemiker organisiert. Der wissenschaftlische Teil wird von Herrn. Prof. Dr. F. Weygand, Technische Hochschule München, bearbeitet.

Anmeldeformulare für die Teilnahme und zur Vorankündigung von Diskussionsvorträgen können bei der

GDCh-Geschäftsstelle
6000 Frankfurt/Main, Postfach 9075

angefordert werden. Dabie ist zu bemerken, daß diese Voranmeldungen bis zum 30. September 1964 bei der GDCh-Geschäftsstelle eingegangen sein müssen.

CZECHOSLOVAKIA

Tuesday 29 *September-Friday* 2 *October* 1964: **Third National Radiochemical Conference:** *Czechoslovak Chemical Society, Nuclear Chemistry Section:* Scientific House, Liblice by Prague (see *Talanta*, 1964, **11**, March, i).

UNITED KINGDOM

Friday-Saturday 25–26 *September* 1964: Meeting on **Automatic Methods of Analysis:** *Society for Analytical Chemistry, Microchemistry Group and Scottish Section:* University of Aberdeen, Old Aberdeen.

The following papers will be presented and discussed on the Friday evening:

Nomenclature.	T. R. Fennel
Process gas chromatography.	C. S. F. Pine
Automation in clinical chemistry.	C. F. M. Rose
Differential thermal analysis.	R. C. MacKenzie

On the Saturday evening there will be a discussion meeting on *Automatic Techniques.*

Thursday 1 *October* 1964: **Solvent Extraction,** D. Betteridge: *Society for Analytical Chemistry, Midlands Section: Spread Eagle Hotel,* Shakespeare Street, Nottingham. 7.00 p.m.

Monday-Wednesday 12–14 *October* 1964: **Technicon 26th Anniversary International Symposium on Automated Analytical Chemistry:** Royal College of Surgeons, Lincoln's Inn Fields, London W.C.2.

Papers will be presented under the following headings:

Monday, 12 *October:* Pollution Analyses; Power Station Chemistry; Chemical Process Control; Soils, Rocks and Fertilisers; Pharmaceutical Assays; Food Chemistry; New Methods.

Tuesday, 13 *October:* Chromatography; Lipid Analyses; Enzyme Analyses; Cell Physiology; Electrophoresis; Elemental Analysis; Haematology; Haemagglutination Procedures; New Methods.

Wednesday, 14 *October:* Multiple Analytical Techniques and Health Screening Procedures; Gynaecological Cancer; *In Vivo* Techniques; Electrophoresis; New Methods.

Wednesday 14 *October* 1964: Symposium on **Thin-Layer Chromatography:** *Society for Analytical Chemistry, Midlands Section and Thin-Layer Chromatography Panel* with *Royal Institute of Chemistry, Birmingham and Midlands Section:* University, Edgbaston, Birmingham 15 (see *Talanta*, 1964, 11, August): 1.30 p.m.

British Standards Institution has announced the following *New British Standards:*

B.S. 1428: *Microchemical apparatus: Part B*3: 1964: *Nitrogen determination apparatus (non-transference micro-Kjeldahl).* This includes the components for the digestion apparatus and distillation apparatus used in the micro-determination of nitrogen by the Kjeldahl method without transference of the digestion mixture; alternative types of components where appropriate; notes on the method of use of the apparatus; and dimensioned drawings. (*Price:* 5s)

B.S. 1673: *Methods of testing raw rubber and unvulcanized compounded rubber: Part* 5/5.2-4: 1964: *Analysis of styrene butadiene copolymers (SBR).* This gives methods for determination of moisture, solvent extraction and total ash. (*Price:* 4s. 6d.)

The following *Revised British Standards* have also been announced:

B.S. 1428: *Microchemical apparatus: Part B*1: 1964: *Nitrogen determination apparatus (micro-Kjeldahl).* This includes components for the digestion apparatus and Parnar-Wagner type distillation apparatus used in the micro-Kjeldahl method; alternative types of components where appropriate; notes on method of use of the apparatus; and dimensioned drawings. (*Price:* 5s.)

B.S. 1902: *Methods of testing refractory materials: Part* 2*A*: 1964: *Chemical analysis of high silica and aluminosilicate materials.* This details the reagents required for analysis, determination of blanks; preparation of sample, loss on ignition. For high silica materials: determination of silica, ferric oxide, titania, phosphorus pentoxide, alumina, lime, magnesia and alkali metals. For aluminosilicates: determination of manganese oxide plus above-mentioned constituents. Method for the direct determination of alumina. (*Price:* 10s.)

UNITED STATES OF AMERICA

Monday 28 *September-Friday* 2 *October* 1964: **Third National Meeting:** *Society for Applied Spectroscopy:* Sheraton-Cleveland Hotel, Cleveland, Ohio.

Monday-Thursday 5–8 *October* 1964: **Fourteenth Annual Instrument Symposium and Research Equipment Exhibit:** National Institutes of Health, Bethesda, Md.

Tuesday-Thursday 6–8 *October* 1964: **Eighth Conference on Analytical Chemistry in Nuclear Technology:** *Analytical Chemistry Division of Oak Ridge National Laboratory:* Mountain View Hotel, Gatlinburg, Tennessee (see *Talanta*, 1964, 11, **June**, iii).

The preliminary programme is a follows:

Tuesday Morning, 6 October: Nuclear Methods of Analysis

Application of a Potentiostatic Electrodeposition Technique to Ultra-trace Analysis by Neutron-Activation Methods.	Harry B. Mark, Jr. and Francis J. Berlandi
Determination of Trace Elements in Wool	L. C. Bates and W. B. Healy
Photon Activation Analysis of Caesium.	Jacob Spira, Robert Bastian and Carmine Persiani
Precision of Activation Analysis of Short-Lived Nuclides.	F. F. Dyer and J. F. Emery
Determination of Attogram Quantities of ^{3}H *and* ^{3}He *Produced by Photonuclear Reactions.*	L. A. Currie
Reactions Observed with 14-*MeV Neutrons.*	W. J. Ross and J. E. Strain

Determination of Trace Constituents in Alkali Metals

Rapid Determination of Low Concentrations of Oxygen and Hydrogen in Alkali Metals by a Modified Amalgamation Technique.	Gerald Goldberg
Precise Determination of Oxygen in Alkali Metals by Neutron-Activation Analysis.	E. L. Steele
Determination of Oxygen in Metallic Sodium.	K. S. Bergstresser, G. R. Waterbury and C. F. Metz
Determination of Oxygen in Rubidium and Caesium.	Sheridan Rogers and Fred Tepper
Determination of Total Carbon in Sodium Metal by High-Temperature Combustion.	Harold Bradley and S. A. Meacham
Determination of Total Carbon in Sodium.	D. Dutina, W. W. Sabol, D. E. Rey and J. L. Simpson
Methods of Analysing Sodium Metal at Culcheth Laboratory, U.K.A.E.A.	W. T. Edwards

Tuesday Afternoon, 6 October: Burnup Analysis

Technetium-99 *as a Burnup Monitor for Fast and Thermal Reactors.*	R. J. Meyer, R. D. Oldham, R. J. Popek and R. P. Larsen
Lanthanum-139 *as a Burnup Monitor- a Mass Spectrometric Method.*	E. R. Ebersole, R. P. Larsen, M. T. Laug and J. J. McCown
Uranium-235 *Thermal Fission Yields of Caesium*-133 *and* -137.	R. P. Larsen, R. J. Meyer, M. T. Laug and G. W. Smith
Determination of Nuclear Fuel Burnup: Status of Development Programme.	James E. Rein
Proposed Determination of Nuclear Fuel Burnup Based on Ratio of two Stable Fission Products of same Element.	William J. Maeck
Flame Photometric Determination of Lithium Produced by B-10(*N, a*)*Li*-7 *Reaction to Measure Boron*-10 *Burnup in Reactors Utilising Chemical Shim Control.*	B. D. LaMont and W. D. Fletcher

Determination of Carbon, Hydrogen, Oxygen and Nitrogen in Metals

Determination of Gases in Plutonium Nitride and Carbide, and in Plutonium Metal.	Manley W. Mallett
Manometric Measurement of Nitrogen, Oxygen, and Hydrogen Extracted from Plutonium Materials by Inert Gas Fusion.	Ben D. Holt and Harvey T. Goodspeed
Determination of Oxygen in Pyrolytic-Carbon-Coated Uranium Dicarbide Beads.	M. E. Smith, J. M. Hansel and G. R. Waterbury
Oxygen and Nitrogen Determination in Columbium and Tantalum by Inert Gas Fusion Employing Chromatographic Detection.	W. C. Gannon and F. T. Coyle
An Automatic Spectrographic Method for Determination of Oxygen in Steel.	M. S. W. Webb and R. J. Webb
Comparative Studies on Determination of Oxygen, Nitrogen and Hydrogen in Rare-Earth Metals, and of Oxygen in Thorium.	Wayne E. Dallman, Velmer A. Fassell, C. Clifton Hill and Royce K. Winge
Analysis of Zirconium Metal and Alloys for Hydrogen, Carbon and Oxygen.	H. R. Weiler, Jr.

Spectrochemical and X-ray Methods of Analysis

Wednesday Morning, 7 October:

Influence of Interaction of Plasma Components on Spectroscopic Analysis.	Wilhelm H. Tappe
Spectrographic Determination of Chlorine in Refractory Materials.	G. Baudin
Effect of Electrode Dimensions in Carrier Distillation Procedure for Spectrochemical Analysis.	H. R. Mullins and R. L. Graff
Determination of Uranium Isotopes by Atomic Absorption Spectrophotometry.	Joseph A. Goleb
Use of Computers in Spectrochemical Analysis	Isabel H. Tipton, Fred W. Roberts and Jane J. Shafer
Far Ultraviolet Flame Emission Lines of Cobalt	John A. Dean and J. E. Adkins
Chemical Isolation and Flame Photometric Determination of Barium.	Cyrus Feldham, T. C. Rains and N. Marion Ferguson

Mass Spectrometric Methods of Analysis

Commentary on Spark Source Mass Spectrograph.	W. Fletcher
Commentary on O.R.N.L., Double-Magnet Mass Spectrometer.	A. E. Cameron
Determination of Hydrogen in Zirconium Alloys by Isotopic Equilibration.	R. W. Ashley and A. S. Denovan

Gas Chromatographic Methods of Analysis

Adaptation of the Chromatograph for Analysis of Corrosive Gases.	E. L. Williamson
Determination of Trace Impurities in Helium.	E. G. H. Romberg

Special Methods of Separation and Determination

Wednesday Afternoon, 7 October:

A Specific Method for Determination of Titanium.	J. O. Hibbits and Silve Kallmann, William Giustetti and Hans K. Oberthin
Microdetermination of Ruthenium in Uranium Compounds.	O. A. Vita and C. F. Trivisonno
An Infrared Method for Determining Variations in Deuterium Content of Natural Water.	W. H. Stevens, J. G. Bayly and W. M. Thurston
Separation of Americium from Lower Transuranics: Extraction with Quaternary Ammonium Salts.	William J. Maeck, Maxine E. Kussy and James E. Rein
Separation of Europium from Fission Product Samples by Reduction with Lithium Amalgam.	J. Bubernak, M. Lew and G. M. Matlack
Reversed-Phase Partition Chromatographic Separation of the Lanthanides with Paper Impregnated with Bis-(Di-N-Hexylphosphinyl) Methane.	George J. Kamin, Jerome W. O'Laughlin and Charles V. Banks
Analysis of High Purity Materials in Nuclear Energy Research: A Short General Survey of Methods.	A. A. Smales

Thursday Morning, 8 October: Radiochemistry

Radiochemical Techniques in Fission Gas Mobility Studies of Hydride Systems.	Alfred J. Moses
Analytical Determination of Uranium-232 and Uranium-233 in Irradiated Thorium.	M. R. Weiler and W. Y. Matsumoto
Non-Destructive Determination of Uranium-232 and Thorium-228 by Gamma Spectrometry.	S. A. Reynolds
Determination of Nuclide Concentrations in Solutions Containing Low Levels of Radioactivity by Least-Squares Resolution of Gamma-Ray Spectra.	Ernest Schonfeld, Arlene H. Kibbey and Wallace Davis, Jr.

Liquid Scintillation Counting

Determination of Radioactive Noble Gases with a Liquid Scintillator.	Donald L. Horrocks and Martin H. Studier

Liquid Alpha-Gamma Counter for Simultaneous Determination of Plutonium and Americium.	K. I. Hawkins and C. R. Forrey
Absolute Counting of Beta-Emitters by Liquid Scintillation Method.	Gerald Goldstein

Spectrochemical and X-Ray Methods of Analysis

Application of Anion Exchange-Partition Chromatography to Trace Impurity Analysis of Thorium-Uranium and Plutonium-Thorium-Uranium Alloys.	Edmund A. Huff
Determination of Plutonium in Irradiated Uranium Dioxide Fuel Pellets by X-Ray Fluorescence Spectrometry.	B. D. LaMont, J. D. Johnson and J. A. McSorley
Applications of Electron Probe Microanalyzer to the Determination of Trace Constituents in Reactor Materials.	E. A. Hakkila, G. R. Waterbury and C. F. Metz

---

Monday-Thursday 12–15 *October* 1964: **Ninteenth Annual Instrument-Automation Conference and Exhibit:** *Instrument Society of America:* New York City.

The following lectures may be of interest to analytical chemists:

Monday, 12 *October: Primary Elements (Transducers)I*

Design of pH Control Systems.	H. S. Wilson and W. J. Wylupek

Tuesday, 13 *October: Process Simulation by Analogue Method*

A pH Control System Implemented from a Simulated Design.	William B. Field and Robert M. Green

Tuesday 13 *October: Fluorescence Instrumentation*

A Precision Recording Absolute Spectrofluorometer.	G. K. Turner and R. E. Phillips
Design of a Fluorescence Spectrometer.	John U. White
Construction and Calibration of a Spectro-radiometer-Fluorimeter for Fluorescence Quantum Yield Studies.	B. G. Roberts and R. C. Hirt
Modifications of Existing Instruments for Fluorescence Measurements.	L. A. Hurlbut and E. F. Gillette

Tuesday, 13 *October: Laboratory Instrumentation*

Internal Reflection Spectroscopy.	N. J. Harrick

Wednesday, 14 *October: Radiation Methods of Analysis*

Moisture Measurement with Radio-Frequency Techniques.	Fred W. Truxall
Computer-Integrated Activation Analyses.	John W. Nostrand, Jr. and Henry H. Kramer

Thursday, 15 *October: Chemical and Instrumental Methods of Analysis*

Spectroscopic Methods to Detect Water in Salts (Alkali Halides).	J. Greenberg
Preparation of Mercury/Mercurous Sulphate Reference Electrode for Halide Titrations.	Richard A. Murie and A. C. Eckert
An Improved Cell for Analysis of Impurities in Liquid Chlorine Using Infrared Spectroscopy.	David L. Hammitt
Continuous Process Stream Analyser for Determination of Aluminium Alkyl Concentration.	R. J. Fanning
A Recording Electrolytic Titrator.	Dr. Austin

Thursday, 15 *October: Introduction to Thermoanalysis: Methods and Applications*

Differential Thermal Analysis-Principles and Applications.	Saul Gordon
Automatic Recording Thermo Balances.	H. Vaughan
DTA Variables.	I. M. Sarasohn
Theory and Application of Thermogravimetry.	A. E. Newkirk
Quantative Dynamic Calorimeter.	E. L. Dosch

Tuesday-Friday 13–16 *October* 1964: **Annual Meeting:** *Electron Microscopy Society of America:* Detroit Hilton Hotel, Detroit, Mich.

Wednesday-Friday 14–16 *October* 1964: **Third Annual Gas Chromatography Symposium:** *A.S.T.M. Committee E*-19: Sheraton-Lincoln Hotel, Houston, Texas.

Thursday-Saturday 15–17 *October* 1964: **South-East Regional Meeting:** *American Chemical Society:* Charleston, W. Va.

Monday-Thursday 19–22 *October* 1964: **78th Annual Meeting:** *Association of Official Agricultural Chemists:* Marriott Motor Hotel, Twin Bridges, Washington D.C. 20044 (see *Talanta,* 1964, **11,** June, iii).

Wednesday-Friday 21–23 *October* 1964: **Twelfth Anachem Conference and Instrument Exhibit:** *Association of Analytical Chemists* in collaboration with *Optical Society of America, Detroit Section:* McGreggor Memorial Conference Center, Wayne State University, Detroit, Mich. (see *Talanta,* 1964, **11,** May, iv).

Wednesday-Friday 21–23 *October* 1964: **Conference on Spectroscopy, Instrumentation and Chemistry:** Jack Tar Hotel, San Francisco, Calif.

INTERNATIONAL UNION OF PURE AND APPLIED CHEMISTRY

Division of Analytical Chemistry
Commission on Microchemical Techniques

International Investigation into Errors in Elementary Organic Microanalysis*

The obsrevations, findings and effects governing the microanalytical errors encountered by every microanalyst in the course of his daily work only add to his special knowledge or that of his close collaborators. In order to go beyond the limits of the individual laboratory, the Commission on Microchemical Techniques has set up a Study Group on Errors in Elementary Organic Microanalysis, which is intended to centralise, classify and publish these findings in generally workable form for the benefit of all.

The study Group on Errors in Elementary Organic Microanalysis invites microanalysts of all countries, either personally or as representatives of their laboratories, to collaborate in this collective international task by communicating in the form of a report the results of their experiences.

In practice, it is desriable that each report conform to the outlines given below:

1. It must be drafted in either German, English, French or Russian.
2. It must be divided into as many separate parts as the errors under examination.
3. Each part must follow the headings of the following outline.

Outline

1. Element(s), amount(s)
2. Microanalytical range (milligram, decimilligram, centrmilligram)
3. Microanalytical balance employed (principle, model, installation, with or without air-conditioning *etc.*); standard deviation of weights
4. Method employed—principle of mineralisation (combustion), principle of the determination, apparatus, reagents, method of operation, *etc.*
5. Type of error studied—systematic or uncertain errors affecting the accuracy or precision of the results
6. Order of algebraic magnitude of the systematic error, standard deviation or possible limits of the uncertain errors (errors of chance)
7. Sources of error, real or apparent. All of the factors of error must be retained, especially those which appear in the following unlimited list:
    Order of magnitude of the contents to be determined
    Physical properties of the compounds analysed (condition, vapour pressure, hygroscopicity, triboelectricity (static electricity) *etc.*)
    Structures of the compounds analysed
    Presence of interfering elements
    Presence of interfering functional groups
    Principle of the method of mineralisation (combustion) employed
    Principle of determining the end product
    Reagents employed (nature, degree of purity, source)
    Other chemical products employed
    Small apparatus and various material employed (joints, stoppers, glass, silica, plastic materials, metals, *etc.*)
    Manual or automatic apparatus employed for the mineralisation (combustion)
    Apparatus employed for the measurements (balances, burettes, colorimeters, spectrophotometers, potentiometers, coulometric, conductometeric, or thermal-conductometric set-ups, recorders, integrators, *etc.*). Possible influence of automation

---

* The present investigation does not include trace analysis.

Operative parameters (temperature, rate of gas flow, pressure, *etc.*)
Environment parameters (temperature, relative humidity, atmospheric pressure, air pollution, vibrations, situation and exposure of the laboratory, place or position of installation in the laboratory, *etc.*)
Subject parameters (manipulations, lectures, observations)
Operative methods and techniques

8. Means employed for characterising the source of error (if possible)
9. Modifications eventually used with the intention of diminishing or eliminating the error
10. Suggestions
11. Specific questions

The preceding outline must be considered as a simple, helpful memorandum. The errors reported need not necessarily be "originals"; they may have been cited in publications from which they have been noted.

The present investigation is already in progress; consequently, the reports, depending upon the geographic location or the language used, can be addressed without delay to the following members of the Study Group on Errors in Elementary Organic Analysis:

a. American reports in the English language (U.S.A., Canada, *etc.*) to:

Dr. Al Steyermark, Chairman
Commission on Microchemical Techniques
Hoffmann-La Roche Inc.
Nutley 10, New Jersey
U.S.A.

b. European reports in the German or Slavic languages (with the exception of Russian) to:

Dr. Wolfgang Schöniger, Secretary
Commission on Microchemical Techniques
Department of Pharmaceutical Chemistry
Sandoz, Ltd.
Basle 13, Switzerland

c. Reports originating in Russia to:

Dr. N. E. Gel'man, Associate Member
Commission on Microchemical Techniques
Institute on Elemental Organic Compounds
Academy of Sciences
Moscow, Russia

c. Reports in the English, French, or German languages which originate in coutries other than those listed in a, b, and c, to:

Dr. Roger Lévy, Titular Member
Commission on Microchemical Techniques
Chairman, Study Group on Errors in
Elementary Organic Analysis
Central Department of Microanalysis
of the National Center of Scientific Research
39 bis, rue de Dantzig
Paris 15, France

In order to speed up the study, the Study Group would like to receive reports on errors which will eventually be part of a published report, even though the main portion is not ready for publication.

The deadline for this material will be 1st, July 1964.

BUNDESREPUBLIK DEUTSCHLAND

1. *und* 2. *April* 1964: Symposium **Methoden zur Messung weicher β-Strahler** veranstaltet von der *Fachgruppe Kern-, Radio- und Strahlenchemie* der *Gesellschaft Deutscher Chemiker* und der *Gesellschaft fur Kernforschung mbH*, Karlsruhe-Leopoldshafen.

Programm

Mittwoch, 1. *April*

Hauptvortrag

Übersicht über die Methoden zur Messung weicher β-Strahler — H. KIEFER

Diskussionsvorträge

Erfahrungen mit einen Gaszählrohr für die Serienmessung von Kohlendioxyd. — E. BRODA und B. KALAB

Nominierung der Meßbedingungen bei der Routinebestimmung von Tritium und ^{14}C im Proportionalzählrohr.	P. Jordan
Bestimmung niederer spezifischer Aktivitäten von ^{45}Ca durch flüssige Szintillationszählung	H. Vemmer und J. O. Gütte
Donnerstag, 2. April	
Hauptvortrag	
Gas Radio Chromatography.	A. T. James
Diskussionsvorträge	
Einige Ergahrungen über Radiogaschromatographie ^{14}C- oder T-markierter Verbindungen mit Proportional-Gaszählrohren und Ionisationskammern.	H. Simon und R. Medina
Neuere Anwendungen der Radio-Dünnschicht-Chromatographie.	M. Wenzel P. E. Schulze
Messung niederenergetischer β-Strahler in heterogener Phase mit Flüssigszintillatoren.	W. Hoffmann
Kontinuierliche Messung von ^{14}C-markeirten Aminosäuregemischen nach der Trennung an Ionenautasschersäulen mit Hilfe von Szintillatorschlauch.	H.-J. Stan

NETHERLANDS

Wednesday–Saturday 20–23 *May* 1964: Symposium on **Modern Methods of Analysis of Organic Compounds:** *Fachgruppe Analytische Chemie* of *Gesellschaft Deutscher Chemiker* and *Sectie voor Analytische Chemie* of *Koninklijke Nederlandse Chemische Vereniging:* Eindhoven.

The Symposium represents a continuation of the meeting on the same subject at Munich in 1960 and has the following programme:

Wednesday, 20 *May*

Plenary Lectures:	
Die Bedeutung der Analyse für die Organische Chemie	J. F. Arens
Derzeitiger Stand der organischen Mikroelementaranalyse.	W. Schöniger
Gruppenreaktionen in der organischen Analyse.	S. Veibel
Discussion Lectures:	
I. *Elemental Analysis*	
A six minute C—H-determination with titrimetric finish.	L. Blom
Ein Schnellverbrennungsapparat mit elektrischer Endpunktsanzeige zur Bestimmung von Kohlenstoff und Wasserstoff in organischen Substanzen.	F. Salzer
Three Decimal Place Hydrogen and Carbon Determination in Mineral Oil Samples.	P. Gouverneur
Zweijährige Erfahrungen in der Routine-analyse mit einem CNH-Automaten,	H. Weitkamp
Ultramikroelementaranalyse organischer Stoffe mit Substanzmengen von 1–20 µg.	G. Tölg
A Colorimetric Method for the Sub-micro Determination of Bromine in Organic Compounds.	T. R. F. W. Fennell
II. *Massspectrometry*	
Jetziger Stand der Massenspektrometrie in der organischen Analyse.	E. Stenhagen
Anwendung eines hochauflösenden Massenspektrometers in der organischen Analyse.	D. Henneberg
III. *X-ray Analysis*	
Structure Determination of Organic Compounds by X-ray Analysis.	J. D. Dunitz
Wege zur automatisierten Strukturanalyse.	W. Hoppe
Über ein neues Gerät zur automatischen Messung der Intensität von Einkristallreflexen.	E. Mayer

Thursday, 21 *May*

Plenary Lectures:	
Moderne Analysenverfahren, besonders Gaschromatographie, bei stereoisomeren alicyclischen Verbindungen.	W. Hückel
Spektrochemische Verfahren zur Konstitutionsermittlung.	G. Kresze
Analytical Separation Techniques.	A. J. P. Martin

Discussion Lectures:	
IV. *Constitution determination via mol spectrometry*	
Applications of Proton Magnetic Resonance to Functional Group Analysis.	N. van Meurs
Die Kernresonanzspektren von Steroiden in polaren Lösungsmitteln.	B. Hampel
Konformationsanalyse von Nitrosteroiden mit Hilfe des Circulardichroismus.	G. Snatzke
Präzisionsanalyse von Mehrkomponentengemischen in Quarzspektrophotometergebiet.	I. S. Herschberg
Bestimmung der Geschwindigkeitskonstanten der Dissoziation und Rekombination organischer Säuren mit der Methode der "High Level Faradaic Rectification."	H. W. Nürnberg
V. *Separation Techniques, part I*	
Über ein neues Verfahren der Flüssigkeits-Chromatographie.	E. Bayer
Die Anwendung einer neuen Arbeitsweise in der Flüssig-fest- bzw. Flüssig-flüssig-Chromatographie.	D. Jentzsch
Permanente Kolonnen für Flüssigkeitsverteilungschromatographie.	R. Dijkstra
Automatische Kopplung der Dünnschicht-Chromatographie an temperaturprogrammierten Gas-Chromatographen als stoffspezifische Detektion und Analysenkontrolle.	R. Kaiser
Möglichkeiten und Grenzen der Identifizierung von Stoffen aus ihrem Verhalten bei der isothermen Eluierungsgaschromatographie.	J. F. K. Huber
Some Rapid Identification Methods in Gas Chromatography.	F. H. Huyten
Friday, 22 May	
Plenary Lectures:	
Analysis in Polymer Research.	P. W. D. Wijga
Aminosäuren und Peptide.	F. Weygand
New Developments in Clinical Analysis.	E. J. van Kampen
Discussion Lectures:	
VI. *Separation techniques, part II*	
Auswahl der stationären Phase für die Dünnschicht-Chromatographie.	P. J. Schorn
The Mechanism of Peak Broadening in Paper Chromatography.	C. L. de Ligny
Quantitative Analyse von Polyphenylgemischen mit der Dünnschichtchromatographie.	F. J. Ritter
Verwendung Silbernitrat-imprägnierter Silicagel-Dünnschichten.	F. C. den Boer
Separation of Sterol Acetates by Thin-layer Chromatography in Reversed-phase Systems and on Silicagel G-silver Nitrate Plates.	J. W. Copius Peereboom
R_f-Werte und Annellierung kondensierter polycyclischer aromatischer Kohlenwasserstoffe.	S. Laufer
VII. *Analysis of high polymers*	
Pyrolysis Gas Chromatography with Programmed Temperature and Capillary Columns.	L. S. Ettre
Infrared Determination of Unsaturation in Polyethylene.	R. J. de Kock
Saturday, 23 May	
Discussion Lectures:	
VIII. *Clinical Analysis, Analysis of Natural products*	
Präparative dünnschichtchromatographische Trennung von Phosphatiden und dünnschichtchromatographischer Nachweis ihrer Hydrolyseprodukte.	O. W. Thiele
Eine verbesserte Methode zur quantitativen Elektrophorese in Agar-Agar-Schichten.	K. Dose
Über die Reaktion von Diazoniumsalzen mit Nukleotiden und Nukleinsäuren und ihre mögliche Anwendung zur Sequenzanalyse.	H. Kössel

Acetessigsäurebestimmung in 0,1 *ml Blut. Die Abtrennung des Acetons durch wärmebeschleunigte Mikrodiffusion und seine Bestimmung mit Salicylaldehyd.*	F. Bahner
Die Bestimmung von Aminosäuren durch Messung der elektrischen Leitfähigkeit.	A. Niemann
Verbesserung und Automation der Kreatininbestimmung.	K. Beyermann
Ein Beitrag zur Analytik der Tropan-Alkaloide.	H. Frauendorf
Die Analyse von Arzneistoffen in biologischen Flüssigkeiten mit der Tropäolinmethode.	P. Hajdu

Further information can be obtained from the GDCh-Geschäftstelle, 6000 Frankfurt (Main), Postfach 9075.

ÖSTERREICH

Tagung der Österr. Gesellschaft für Mikrochemie und Analtyische Chemie in Bad Hall

Die Österr. Gesellschaft für Mikrochemie und analytische Chemie im Verein der österr. Chemiker hielt am 28. und 29. Februar 1964 in Bad Hall, 0.Ö., seine 17. ordentliche Jahreshauptversammlung ab.

Vor etwa 80 Fachkollegen aus Industrie und Wissenschaft aus Österreich, Deutschland und der Schweiz wurde zunächst im Rahmen der Geschäftssitzungen der Fritz-Feigl-Preis 1964 an den Oberass. der Techn. Hochschule Wien, Dr. L. J. Ottendorfer, für seine Arbeiten auf dem Gebiet der Mikrochemie, insbesondere über den Nachweis kleinster Mengen radioaktiver Stoffe verliehen.

Im wissenschaftlichen Teil dieser Tagung wurde eine Reihe von Fragen über moderne Analysenmethoden besprochen, die für die Industrie und das Hüttenwesen von besonderem Interesse sind.

Im ersten Vortrag sprach Univ.-Prof. Dr. W. Leithe (Österr. Stickstoffwerke, Linz) über Gaschromatographie in der Industrie, wobei er die wichtigsten Anwendungsmöglichkeiten dieser vielseitigen Methode erläuterte.

Anschließend berichtete Frau Dpl. Ing. H. Selzer (Österr. Mineralöl-verwaltung, Raffinerie Schwechat) über die speziellen Probleme der Gaschromatographie in der Mineralölindustrie und anschließend berichtete Herr Dr. Bayzer (Österr. Stickstoffwerke, Linz) über Trennung und Nachweis der Aminosäuren.

Ein gemeinsamenes Abendessen im Kurhotel Landes-Sanatorium gab den Teilnehmern Gelegenheit, bei zwanglosem Beisammensein über ihre Erfahrungen zu diskutieren.

Am Samstag, 29. Februar, vormittags, fanden Vorträge von Herrn Doz. Dr. Zitter (Gebr. Böhler AG., Kapfenberg) über die derzeit aktuellen Fragen der Gasbestimmung in Eisenlegierungen und Dr. E. Lassner (Metallwerke Plansee, Reutte/Tirol) über die Bestimmung von Sauerstoff in hochschmelzenden Metallen wie Molybdän und Wolfram statt. Der letzte Vortrag der Tagung wurde von Dr. Breit (Vereinigte Metallwerke, Ranshofen-Berndorf) beigesteuert, der über die analytischen Fragen bei der Erzeugung und Verarbeitung von Aluminium berichtete.

UNITED KINGDOM

Wednesday 29 *April* 1964: Meeting on **Immunoassay of Hormones**: *Society for Analytical Chemistry, Biological Methods Group*: Burlington House, Piccadilly, London W.1: 7.00 p.m.

The programme is as follows:

Outline of principles and methods available.	P. G. H. Gell
Immunoassay of chorionic conadotrophin.	A. J. Fulthorpe
Immunoassay of insulin.	C. N. Hales

Thursday 2 *April* 1964: Meeting consisting of **Contributions from Research Workers in Universities and Colleges of Advanced Technology**: *Society for Analytical Chemistry*: University College, Gower Street, London W.C.1.

Afternoon Session—2.30 p.m.

The automation of anion-exchange chromatography of phosphorous anions.	G. Nickless and D. Rogers
Kinetic studies in bromate titrimetry.	J. M. Ottaway
Use of liquid anion exhangers in analytical chemistry.	A. D. Damodaran

Evening Session—5.15 p.m.

Some applications of thermogravimetric analysis.	A. W. Coats
Spectrographic determination of beryllium in fluorite minerals.	D. N. Waters
Gravimetric determination of iron by the homogeneous precipitation of tris(2-thiopyridine-N-oxide)iron^{III}.	J. A. W. Dalzeil and M. Thompson

Friday 1 *May* 1964: **Physical Methods of Moisture Determination:** *Society for Analytical Chemistry, Physical Methods Group* and *Midlands Section,* and *Royal Institute of Chemistry, East Anglia Section*: Levington Research Station, Ipswich, Suffolk: 6.00 p.m.

Review of methods determining moisture in paper.	L. A. Kirk
An introduction to microwaves moisture measurement.	H. B. Taylor
Application of nuclear magnetic resonance to measurement of mositure content of coals and cokes.	W. R. Ladner

---

Friday 8 *May* 1964: Meeting of *Microchemistry Group, Society for Analytical Chemistry*: Royal College of Advanced Technology, Salford 5, Lancs.

Thursday–Friday 2–3 *July* 1964: Summer Meeting on **Limitations of Detection in Spectrochemical Analysis.** *Institute of Physics and Physical Society, Spectroscopy Group*: University of Exeter.

The main subjects and speakers are as follows:

Introduction and principles.	F. W. J. Garton and R. J. Webb
Emission spectroscopy	
(*a*) *Instrumental factors*	A. C. Menzies
(*b*) *Metallurgical samples*	W. Ramsden
(*c*) *Non-metallurgical samples, e.g., silicates and plant residues.*	R. L. Mitchell and R. O. Scott
X-ray fluorescence.	R. Jenkins
Atomic absorption.	J. A. F. Gidley
Mass spectroscopy.	R. A. Saunders
Comparison of emission, X-ray and mass spectroscopy.	N. W. H. Addink

Further details can be obtained from the Spectroscopy Group Secretary: Dr. L. Bovey, Building 329, A.E.R.E. Harwell, Nr. Didcott, Berks.

Monday–Saturday 12–17 *July* 1965: **XII International Spectroscopy Colloquium:** British *Spectroscopist Co-ordinating Committee* in collaboration with *Institute of Physics and Physical Society*: University of Exeter.

The subjects to be dealt with are concerned primarily with analytical applications of spectroscopy. The principal topics will be optical emission, absorption, X-ray and mass spectroscopy and special attention will be given to chemical, metallurgical, medical and biological applications. Continuous process control, the detection of non-metallic impurities in metals and a study of the limitations to detection in analysis will be some of the subjects of discussion. The official languages of the Colloquium will be English, French, German and Russian: simultaneous interpretation will be available. Some 6 invited papers are being arranged on leading topics of interest in the field of spectroscopy and also some open discussions on current trends. There will also be an opportunity for about 70 original contributed papers which should be submitted for consideration before the end of this year.

All enquiries should be addressed to the Colliquium Secretary: Mrs. C. E. Arregger, 1 Lowther Gardens, Prince Consort Road, London S.W.7.

At the **Annual General Meeting** of the *Society for Analytical Chemistry*, held on Wednesday, 4 March, 1964, the following were ellected Officers and Members of Council for the forthcoming year:

President: D. C. Garratt

Past Presidents serving on Council: A. J. Amos, R. C. Chirnside, J. H. Hamence, K. A. Williams.

Vice-Presidents: S. G. Burgess, A. A. Smales, R. E. Stuckey.

Hon. Treasurer: D. T. Lewis

Hon. Secretary: S. A. Price

Hon. Assistant Sectetaries: B. S. Cooper, D. W. Wilson.

Ordinary Members of Council: A. S. Beidas, E. Bishop, L. Brealey, H. J. Cluley, C. A. Johnston, A. G. Jones, E. Q. Laws, G. W. C. Milner, F. H. Pollard, F. C. J. Poulton, S. G. E. Stevens, C. Whalley.

Ex-Offico Members of Council: C. J. House, R. A. Chalmers, E. A. Hontoir, W. H. Stephenson, D. W. Wilson, L. Brealey, W. A. Broom.

At the **Twentieth Annual General Meeting** of the *Microchemistry Group* of the *Society for Analytical Chemistry*, held on Friday, 21 February, 1964, the following Officers were elected for the forthcoming year:

Chairman: D. W. Wilson
Vice-Chariman: R. Goulden
Treasurer: G. Ingram
Secretary: Mrs. D. E. Butterworth, National Chemical Laboratory, Teddington Middlesex.

At the **Ninth Annual General Meeting** of the *Midlands Section* of the *Society for Analytical Chemistry*, held on Wednesday, 11 March, 1964, the following Officers were elected for the forthcoming year:

Chariman: W. H. Stepenson
Vice-Chariman: W. T. Elwell
Treasurer: J. Blenkin
Secretary: M. L. Richardson, John and E. Sturge Ltd., Lifford Lane, Kings Norton, Birmingham 30.
Asst. Sectetary: R. Adkins

British Standards Institution has announced the following new *British Standard*: *B.S.* 3703: 1964: *Method for the quantitative chemical analysis of binary mixtures of wool and certain regenerated protein fibres.* This provides a method for determining the proportions of fibre in binary mixtures of wool and certain proprietary regenerated protein fibres. It is suitable for application to fibres in any textile form with the exception of high density felts. (*Price* 3*s*.)

UNITED STATES OF AMERICA

Thursday–Friday 7–8 *May* 1964: **Fourth Informal Conference on Vacuum Microbalance Techniques:** Mellon Institute Auditorium, 4400 Fifth Avenue, Pittsburgh, Pennsylvania (see *Talanta*, 1963, **10**, *October*, iii).

Tuesday 12 *May* 1964: **Spectroscopic measurements from above the atmosphere:** D. Morton: *Society for Applied Spectroscopy, New York Section*: Hotel Manhattan, 8th Avenue and 44th Street: 8.00 p.m.

Wednesday–Friday 24–26 *June* 1964: Summer Symposium on **Recent Developments in Structure Determination:** *American Chemical Society, Division of Analytical Chemistry*: Cornell University, Ithaca, N.Y.

The programme is as follows.

Wednesday, 24 *June*

NMR of heavier nucleii and structure determination.	W. G. Schneider
Application of NMR to problems in stereochemistry.	A. D. Cross
Homonuclear and heteronuclear spin-decoupling: Application to high-resolution NMR	H. Agahigian
Electron paramagentic resonance.	W. Landgraf
Electron spin resonance of randomly orientated triplets.	E. Wasserman

Thurdsay, 25 *June*

Mass spectrometry.	F. W. McLafferty
High resolution mass spectra of organic compounds.	K. Biemann
Combining separation and instrumental techniques.	W. R. Moore
Chemical exploitation of the Mössbauer effect.	R. H. Herber
X-ray diffraction.	R. F. Bryan

Friday, 26 *June*

Molecular structure determinations by microwave spectroscopy.	R. D. Lide, Jr.
Raman spectroscopy.	J. C. Evans
Opitcal rotatory dispersion and circular dichroism.	U. Weiss
Microscopy.	W. C. McCrone

Further infromation may be obtained from Dr. F. W. McLafferty, The Dow Chemical Company, Eastern Research Laboratory, Framingham, Massachussetts, U.S.A.

Wednesday–Friday 12–14 *August* 1964: **Thirteenth Annual Conference on Applications of X-ray Analysis:** *Metallurgy Division, Denver Research Institute, University of Denver*: Albany Hotel Denver, Colorado.

There will be sessions on X-ray diffraction, emission spectroscopy, microprobe, absorption and microscopy, and instrumentation.

Monday–Friday 17–21 *August* 1964: **Gordon Research Conference on Analytical Chemistry:** New Hampton School, New Hampton, New Hampshire.

The programme is as follows:

Monday, 17 *August*	
Thermochemical titrations.	J. JORDON
pH measurements in amphiprotic solvents.	R. F. BATES
Problems in potentiometric measurements: pH, pNa and pM.	J. E. LEONARD
Tuesday, 18 *August*	
Principles and applications of spectrofluorimetry.	D. M. HERCULES
Laser principles and materials.	R. PASTOR
Laser excited emission spectroscopy: Current and potential capabilities.	F. BRECH
Wednesday, 19 *August*	
Photoluminescence and the triplet state.	C. A. PARKER
Modern methods of microanalysis.	G. SLODZIAN
Thursday, 20 *August*	
Nuclear magnetic resonance studies of metal chelates.	D. T. SAWYER
(to be announced)	C. N. REILLEY
Open discussion	
Friday, 21 *August*	
Recent advances in gas chromatography and their practical significance.	B. O. AYRES.

Further information may be obtained from Dr. W. GEORGE PARKS, Director of Gordon Research Conferences, University of Rhode Island, Kingston, Rhode Island.

April 1965: **1965 International Conference on Modern Trends in Activation Analysis:** *International Atomic Energy Commission*, and *Activation Analysis Research Laboratory, Texas A and M University*: Texas A and M University, College Station, Texas.

For information contact either Dr. RICHARD E. WAINERDI, Activation Analysis Research Laboratory, Texas A and M University, College Station, Texas, U.S.A., or Dr. DEREK GIBBONS, Wantage Research Laboratory, U.K.A.E.A., Wantage, Berkshire, England.

Talanta, 1964, Vol 11 pp i to xiv Pergamon Press Ltd

NOTICES

(*Material for this section should be sent directly to the Associate Editor*)

FEDERAL GERMAN REPUBLIC

Friday–Saturday 19–27 *June* 1964: **European Convention of Chemical Engineering 1964:** Frankfurt am Main

This will include the **1964 ACHEMA Congress**, of which the following parts of the programme may be of interest to analytical chemists

Friday, 19 *June Measurement and measured-value transformation in chemical technology*

Intermittierende elektrochemische Sauerstoffmessungen in verungreinigten Gewässern.	F. Tödt
Neue elektrochemische Meßanordnungen zur Kontrole von Spurenkonzentrationen reduzierender Stoffe in Gasen und Flussigkeiten	G. Teske
Volltransistorisierter Gleichspannungsverstarker fur pH-Messungen.	P. Wunderer
Durchflußmessung von aggressiven und mit Festoffen versetzten Flüssigkeiten.	H. Engelhardt
Ein neuer Meßplatz zur Bestimmung der Stoffkonstanten E_r und tan δ von Proben mit weitgehend beliebigen Formen bei 3000 *MHz.*	G. Schilling
Emploi du chromatographe automatique à l'usine de Lacq	R. Caboz
Die Flammenionisation zur kontinuierlichen Bestimmung von Qualitätsgrößen	G Steinmuller

Saturday, 20 *June*

Szintillationsspektrometrie von α und β-Strahlung mit Cäsiumjodid.	K. H. König
Neuere Entwicklung bei der Meßwertgebung mit Radioisotopen.	A. Trost
Isotopenanwendung in der chemischen Industrie	K. Czeija
Kontinuierliche Dichtemessung in Industriebetrieben	H. Krech
Überwachung der Äthylenproduktion mit dem Massenspektrometer.	H. G Lossau
The infrared analyser—a powerful analytical tool for on-line chemical analysis.	E. G. Meyer
Neue Erfahrungen bei der kontinuierlichen Überwachung der Viskositat.	H. Kühlewein

Tuesday, 23 *June: New physical methods of chemical analysis, especially methods of trace analysis*

Brennstoffzellen als Spurenmeßgerate.	P. Hersch
Fortschritte in der Entwicklung der Analyse mit Hochfrequenz.	K. Cruse
Impurity analysis in high polymers by the pulse dielectric method	P. Hedvig
Ein neues Gerat für Elektronenbeugung im Ultravakuum.	M. Gribi und L. Wegmann
Neuere Entwicklungstendenzen in der EPR-Spektrometrie.	H. G. Thom
Ein Universalgerät fur Kernresonanzuntersuchungen.	F. Furrer
High precision comparative polarography	H. M Davis
Some analytical applications of differential cathode ray polarography.	R. C. Rooney
Coulo-Halometrie mit galvanischen Zellen	P. Hersch

Wednesday, 24 *June*

Dreidimensionale Dünnschicht-Chromatographie bei tieferen Temperaturen	E. Stahl
New developments in column technology in gas chromatography	L. S Ettre

Arbeitsmethoden der Gaschromatographie	E Rodel
Erfahrungen auf dem Gebiet der gaschromatographischen Spurenanalyse mit neuen hochempfindlichen Detektoren.	E. Thom
Separation of multicomponent mixtures by continuous gas-liquid chromatography	P E Barker
Applications of duel channel gas chromatography	J Amy, K P Dimick and T Z Chu
Thermische Fragmentierung und Strukturbestimmung organischer Verbindungen	W. Simon
Versuche zur Spurenanalyse von Kohlenwasserstoffgasen	M Freund, L Szepesy und F Simon
Die Anwendung der Gas-Chromatographie in der CHN-Analyse.	K. Derge

Thursday, 25 *June*

Die Bedeutung einer Erweiterung des Spektralbereiches in der Infrarot-Spektroskopie.	G. Kemmner und F Brunner
Automatisierte Röntgenfluoreszenz-Analyse.	H Neff
Röntgenmikroanalyse elektronenmikroskopischer Praparate.	K.-H. Herrmann und H Neff
Ölverschmutzung in Wasser und Gewässern. Nachweis und quantitative Bestimmung mit dem IR-Spektrophotometer	W Fastabend
Eine neue Apparatur zur Prüfung der Lichtund Wetterechtheit von Farbungen auf dem Textilgebeit, von Kunststoffen, Lackanstrichen und Gumm.	E O Seitz
Flammenspektrometrische Möglichkeiten zur Bestimmung von Phosphor in phosphororganischen Verbindungen.	W Schmidt
Strahlenquellen für die atomare Absorptionsspektroskopie.	K Osterhammel
A new instrument for analytical atomic absorption spectrophotometry.	W J Price
Eine neue Geräteserie selbstkompensierender Analysenautomaten fur die Spurenmessung.	H Fuhrmann
Kontinuierliches Meßverfahren zur Überwachung von MAK-Werten	W Gey und K Schuster

Friday, 26 *June*

Submicro methods of organic analysis.	R Belcher
Eine neue Vakuumthermowaage.	H G. Wiedemann
Eine neue Dosierungsmethode zur Durchfuhrung von Mikroreaktionen.	H. Straubel
Neue Verfahren auf dem Gebiet der thermometrischen Titration	H Knauer
Polymer molecular weight analysis by gel permeation chromatography.	L. E Maley
Neue Anwendungsgebeite des Verfahrens der Gel-Filtration durch die Entwicklung neuer Dextrangele	B Gelotte
Die Endpunktbestimmung in der analytischen Chemie.	H Jucker
Neue Laborwaagen mit Vorrichtungen zur Bedienungserleichterung.	H Hartwig
Gravimetrische Sondergeräte für physikalischchemische Untersuchungen.	B. Kassner

The **Deutsches Atomforum e. V.** is organising for the first time a series of lectures within the framework of the Convention on 25 June, entitled *Nuclear Radiations in Science and Industry*. The following of the lectures may be of interest to analytical chemists

Aktivierungsanalyse und Erzeugung kurzlebiger Isotope in Chemie und Technik in kleinen Reaktoren.	A. Thiel
Das kontinuierliche Beta-Gamma-Photometer als Hilfsmittel bei der Uberwachung und seine Grenzen.	K. H. Waechter
Sunnschichtmelzen mit radioaktiven Stoffen. Dünnschichtchromatographie mittels Radionukliden	G. Boucke
Zonenschmelzen mit radioaktiven Stoffen	H. Schildknecht
Bremsstrahlen-Fluoreszenzanalyse.	W. Kuhn
Verweilzeit-Messungen mittels radioaktiver Indikatoren	D. Schulz-Pillot

Further information can be obtained from DECHEMA, 6 Frankfurt (Main) 7, Postfach 7746, Bundesrepublik Deutschland.

FRANCE

La **Commission Internationale d'Analyse "C I A."** du **Comité Internationale de la Détergence** "C.I D" a tenu sa 7ème session les 24 et 25 Octobre 1963 à Saint-Gall, sur invitation du Comité Suisse de la Détergence, sous la présidence du Prof JACINI (Italie)

Apres avoir entendu un rapport sur l'activite generale, depuis un an, du C.I.D par son Secrétaire Géneral, M. DE WIT et sur l'organisation du 4eme *Congres International de la Détergence* qui doit avoir lieu a Bruxelles du 7 au 12 Septembre 1964, les membres de la C I A discutèrent les résultats des differentes analyses circulaires effectuees en 1963, concernant notamment

—analyse des alkylsulfonates de sodium,
—analyse de melanges d'alkylsulfates primaires et d'alkylarènesulfonates,
—analyse de mélanges de non-ioniques, d'alkylarènesulfonates et de savon,

toutes réalisées a l'aide de méthodes récemment mises au point par les pays appartenant à la Commission et basees sur l'emploi des échangeurs d'ions Ces travaux seront repris au cours de l'année prochaine en vue de leur apporter certaines améliorations avant de les faire homolguer sur le plan international

Les discussions sur l'analyse des non-ioniques ont occupé une grande partie de la session. L'étude de méthodes reproductibles a été confiee, il y a deux ans, à un Groupe de Travail, dont les travaux avancent rapidement puisqu'il a pu soumettre à ses collègues de la C.I.A , qui les ont acceptées, des propositions pour les déterminations titrimétriques et celles de l'eau et des cendres, qui seront presentées incessamment, pour homologation, à l'Organisation Internationale de Normalisation "I S.O."

Le programme futur de ce Groupe de Travail comprendra la poursuite des recherches sur la détermination de l'oxyde d'éthylène, de l'indice d'hydroxyle, des polyglycols libres, et des alkylphénols libres dans les alkylphénols oxyéthylenes D'autres Commissions devant s'attacher plus particulièrement à la séparation des hydrocarbures non sulfonés et à la détermination des polyoxyéthyles sulfatés

Il est à noter que les méthodes d'analyse déjà soumises a l'I.S O. semblent devoir être adoptées sans difficulté par les membres de cette Organisation, ce qui est un grand encouragement pour la C.I.A

POLAND

Tuesday–Saturday 15–19 *September* 1964· **XXXVth International Congress of Industrial Chemistry:** Varsovie.

Among the many sections of the Congress, one is devoted to *Analytical Chemistry*. Further information can be obtained from the Scientific Committee of the XXXVth International Congress of Industrial Chemistry, Warsaw 86, skr. poczt 26, Poland

UNITED KINGDOM

Wednesday 4 *March* 1964: **Annual General Meeting** followed by **Bernard Dyer Memorial Lecture:** *Society for Analytical Chemistry.* Burlington House, London W 1: 3.00 p m

Wednesday 11 *March* 1964. **Annual General Meeting** followed by **Analysis of Peroxygen Compounds:** C. WHALLEY: *Society for Analytical Chemistry, Midlands Section* University, Edgbaston, Birmingham 15: 6.30 p.m

Saturday 14 *March* 1964: **Biochemistry of Quinones:** R. A MORTON: *Society for Analytical Chemistry, North of England Section* City Laboratories, Mount Pleasant, Liverpool: 2.15 p m

Wednesday 18 *March* 1964· **Discussion Meeting:** *Society for Analytical Chemistry, Microchemistry Group· The Feathers,* Tudor Street, London E C 4· 6 30 p m

Friday 20 *March* 1964· **Organic Analytical Reagents—A Survey of Some New Work:** W. I. STEPHEN· *Society for Analytical Chemistry, Scottish Section* Queen's College, Dundee· 7.15 p.m.

Tuesday 24 *March* 1964: **The Work of a Public Analyst:** R A DALLEY· *Society for Analytical Chemistry, Midlands Section·* Nottingham and District Technical College: 7 00 p m.

Tuesday 24 *March* 1964: **Physical Methods Applied to Examination of Archaeological Remains:** E. T. HALL and A. E. A WERNER: *Society for Analytical Chemistry, Physical Methods Group* Burlington House, London W.1· 6.30 p.m

---

Wednesday 14 *October* 1964: Symposium on **Thin-Layer Chromatography:** *Society for Analytical Chemistry, Thin-Layer Chromatography Panel* and *Midlands Section* with *Royal Institute of Chemistry, Birmingham and Midlands Section* University, Edgbaston, Birmingham 15.

The programme will consist of a Plenary Lecture by Professor Dr. E. STAHL and the following lectures:

Thin-Layer Chromatography in Biosynthetic Studies	T. W GOODWIN
Recent Developments in Thin-Layer Chromatographic Equipment	R. P. HIRSCH

Thin-layer Chromatography on Ion-Exchange Media. C. S KNIGHT
Thin-Layer Chromatography in Clinical Chemistry. J G. LINES
Exploitation of Thin-Layer Chromatography in Plant Chemistry. E J SHELLARD

Further information can be obtained from Mr. M L. RICHARDSON, John and E. Sturge, Lifford Lane, Kings Norton, Birmingham 30.

At the **First Annual General Meeting** of the *Atomic Absorption Spectroscopy Discussion Panel* of the *Physical Methods Group* of the *Society for Analytical Chemistry*, held on Tuesday, 3 December, 1963, the following Officers were elected for the forthcoming year —

Chairman· W T ELWELL

Secretary: D. MOORE, 98 St. Pancras Way, Camden Road, London N W.1

British Standards Institution has announced the following *New British Standards*:—

B S 2649: *Methods for the analysis of glass: Part* 4: 1963: *Recommended procedure for the analysis of fluoride-opal glasses.* This recommends detailed analytical procedures for determining all of the important constituents of the so-called 'fluoride-opal' glasses based on investigations carried out by the Society of Glass Technology. (*Price* 6s.)

B S 3406: *Methods for the determination of particle size of powders. Part* 2: 1963: *Liquid sedimentation methods.* This describes methods of determination of the size distribution of particles in those fractions of powders which pass a 75 μ British Standard test sieve, using the principle of liquid sedimentation Four methods are described, *viz.* the fixed depth pipette, the fixed position pipette, the liquid column method with sedimentation accumulation and the liquid column method with sediment extraction. The basic principle (Stokes's law) is described in the foreward. An appendix advises on liquid suspended media and dispersing agents, providing a list of suitable suspended media for many materials. Other appendices describe methods of evaluating a size analysis instrument and the correlation of results from different methods of size determination. (*Price* 15s.)

Part 4: *Optical microscope method* This describes a method of determination of the size distribution of particles in those fractions of powders which pass through a 75 μ British Standard test sieve A representative sample of powder to be sized is dispersed and placed on a glass slide and the particles are viewed through a microscope by means of transmitted light. The areas of the magnified images of the particles are compared with the areas of reference circles of known size inscribed on a graticule and simultaneously visible The relative numbers of particles in each of a series of size classes are determined. These numbers, expressed as percentages, constitute the size distribution by number From the relative numbers in the size classes it is possible to calculate the size distribution by weight, provided it is assumed that particles of all sizes have the same shape in the sense that the square root of the projected area of a particle stands in a constant ratio to the cube root of the volume of the particle, and that all of the particles have the same density. (*Price* 20s.)

B.S 3681: 1963. *Methods for the sampling and testing of lightweight aggregates for concrete* This describes methods for sampling and testing of lightweight aggregates for concrete. The tests cover bulk density, sieve analysis, apparent specific gravity, sulphate content, volatile matter, loss-on-ignition, carbon content and soundness. (*Price* 7s. 6d.)

The following *Revised British Standards* have also been announced:—

B S 1428: *Microchemical apparatus. Part* 11: 1963: *Combustion boats and sheath for microchemical analysis.* This specifies the following apparatus designed to fit the microcombustion tubes specified in other parts of B.S 1428: one size of platinum combustion boat and a sheath to fit it and three sizes of porcelain combustion boat It includes dimensional drawings as well as appropriate requirements for material, weight and marking, and for constancy of weight of the platinum boat or sheath or ignition It also gives desirable limits for constancy of weight of porcelain boats on ignition or heating with acid, but these are not a mandatory part of the specification. (*Price* 4s 6d)

B S 1747 *Methods for the measurement of air pollution Part* 4: 1963: *The lead dioxide method* This covers the construction and use of apparatus for the lead dioxide method of measuring the reactivity of atmospheric sulphur compounds. (*Price* 5s)

B S 1016: *Methods for the analysis and testing of coal and coke Part* 14: 1963: *Analysis of coal ash and coke ash* This deals with the determination by chemical analysis of the major constituents in samples of coal ash or coke ash An appendix describes a spectrographic method by which certain constituents can be determined speedily and with sufficient precision for most purposes. (*Price* 10s)

B S 1715: 1963· *Methods of analysis of soaps and soap powders.* This describes methods of sampling and the preparation of the sample for analysis, and the following determinations: total fatty matter, alkali combined as soap, total alkali, titre, matter insoluble in ethanol, matter insoluble in water, free alkali, free fatty acids, unsaponifiable matter and unsaponified fat, chlorides, silica, phosphate, per-salts, rosin, glycerol, loss on drying at 100–105° and water. (*Price* 16s.)

B.S. 1756: *Methods for the sampling and analysis of flue gases. Part* 5: 1963: *Semi-routine analyses.* This describes semi-routine methods for the determination of carbon dioxide, carbon monoxide and total oxides of sulphur, mainly employed for the assessment of the combustion performance of domestic gas appliances. (*Price* 6s.)

UNITED STATES OF AMERICA

Monday–Friday 2–6 *March* 1964: **15th Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy:** *Analytical Chemistry Group, Pittsburgh Section ACS and Spectroscopy Society of Pittsburgh.* Penn-Sheraton Hotel, Pittsburgh, Pa.

The programme is as follows.—

Monday, 2 March. Morning

Gas Chromatography—Detectors

Characteristics of a sensitive and absolute ultrasonic detector for gas chromatography.	F. W. Noble and K. Abel
Response of hotwire thermal conductivity cell.	D. W Robinson and D. M. Rosie
Electron drift-velocity detector for gas chromatography.	V. N. Smith and J. F. Fidiam
Piezoelectric sorption detector.	W. H. King, Jr
A high temperature hydrogen flame ionisation detector. A critical evaluation of design and operating characteristics.	A C Seibel
A rapid-scan far UV spectrophotometer for monitoring gas chromatograph effluent	W. Kaye and F Waska
A preliminary study of the characteristics of a photoionisation detector for gas chromatography.	J F Roesler

Instruments for Analysis

A fully automated analytical balance.	L Cahn and H. Schultz
A versatile sorption hygrometer	J. Kertzman
Electrodeless conductance measurements	D. E. Burge and T A. Olson
Galvanic determination of strong acids.	P. Hersch and C. Sambucett
Electronic potentiometer defines new standard in pH instrumentation	D. C. Douglass and E. F. Blondfield
A convenient solution calorimeter	E M Arnett, J. J. Burke and L. V. Guild
Oxygen gauge.	W. M Hickam
Instrument cloud point determinations.	J. L. Williams and N Stein

Symposium on High Resolution NMR of Oriented Molecules

NMR in liquid crystals: PMR spectrum of benzene in a nematic solution.	A. Saupe
PMR investigations on oriented molecules.	G Englert
Some studies of ordered nematic phases from highly resolved dipole-dipole splittings	W. D. Phillips, J C. Rowell and L R. Melby
NMR spectra in single crystals.	P. C Lauterbur

Monday, 2 March: Afternoon

Gas Chromatography—General

GLC studies of bile acid esters.	L I. Braddock, J. J Kelly and L. V Hook
Analyses of chloraniline isomers by gas chromatography.	K J. Bombaugh
Gas chromatography of water in hygroscopic liquids	S Ahuja, G D. Chase and J G Nikelly
Analysis of diluted auto exhaust with a multi-columned gas chromatograph.	T. A. Bellar, M. L. Bellar and E. Sigsby, Jr
Use of polymers as liquid phase in gas chromatographic analysis of high boiling-point compounds.	P Shapras and G. C Claver
Behaviour of phosphate pesticides in electron affinity detectors.	G E. Cook, C W. Stanley and J. E. Barney II

A microvapour-phase hydrogenation accessory for gas chromatographic analysis of glyceride oils.	T. L. Mounts and H. J. Dutton
Correlations between electron capturing ability and structure.	W. E. Baitinger and J. W. Amy

Spectrophotometric Methods of Analysis

Determination of microgram quantities of non-radioactive caesium in uranium and its compounds.	L. Silverman and R. S. Dunn
Determination of phosphorus in alloy steels.	G. A. Bauer
Automated procedures for spectrophotometric determination of silicon, phosphorus and manganese in steel.	P. H. Scholes and C. Thulbourne
Spectrophotometric determination of antimony in gold.	B. Yurash
Simultaneous spectrophotometric determination of calcium and magnesium with chlorophosphonazo III.	J. W. Ferguson, J. J. Richard J. W. O'Laughlin and C. V. Banks
Use of the molybdenum blue reaction in spectrophotometric determination of thallium.	L. Hargis and D. F. Boltz
An improved chloanilate method for determination of boron.	D. R. Peterson and J. R. Hayes
Precision analysis of highly pure bismuth telluride by differential spectrophotometry.	A. Eldridge, R. S. Kelly and R. Bastian
Indirect UV spectrophotometric determination of ammonia.	J. Howell and D. F. Boltz
New technique for study of photometric precision.	D. C. Nelson and R. C. Hawes
A study of a new spectrophotometric data acquisition system.	R. N. Rand and B. Helm

Symposium on High Resolution NMR of Oriented Molecules

NMR of polar molecules in an external electric field.	J. S. Waugh and J. D. Macomber
High resolution NMR spectra of molecules in an applied electric field	K. A. McLauchlan

NMR and ESR Spectroscopy

Conformation of sugars and glucose polymers by PMR.	C. A. Glass
A nuclear resonance study of equilibria in the system boron trifluoride-methanol.	S. Brownstein
NMR study of isomeric pentadienes.	P. W. Flanagan and H. F. Smith
Proton and carbon-13 NMR of coal derivatives and other carbonaceous materials	H. L. Retcofsky and R. A. Friedel
End-group analysis and number average MW determination of some polyalkylene glycols and their esters using NMR spectroscopy	T. F. Page, Jr. and W. E. Bresler
A new type of spectrometer.	M. Takeuchi and T. Miyamae
ESR observations of oxidation-reduction process in some viscera.	T. Okabe and P. Y. Sakagishi

Tuesday, 3 March Morning

Analysis of Inserstitial Elements in Metals

Co-operative testing programmes on gases in metals.	T. D. McKinley
Separation and identification of impurities in hydrided uranium-zirconium alloy.	L. Silverman and D. J Klein
Rapid determination of nitrogen in refractory borides and nitrides.	J. W. Tereshko
Simultaneous determination of oxygen and nitrogen in refractory metals by d.c. carbon arc-gas chromatographic technique.	R. K. Winge and V. A. Fassel
Rapid determination of low concentrations of oxygen in potassium and NaK by a modified amalgamation technique.	G. Goldberg
Determination of carbon and carbon compounds in alkali metals.	J. C. Gerken, S. J. Rodgers and J. W. Mausteller
Rapid method for determination of micro amounts of sulphur in selenium.	L. Acs and S. Barabas
A recording linear-response gauge for vacuum fusion analysis.	H. F. Waldron

Liquid and Gas Chromatography

Improved techniques in liquid column chromatography.	L E. Maley and J. L. Waters
Advantages and limitations of gel permeation chromatography.	L. E. Maley, G. E. Stackhouse and J. L. Waters
Thin-layer chromatography of organic phosphorus compounds.	C. W. Stanley
Quantitative analysis of mixtures separated on thin-layer chromatographic plates.	R D. Spencer and B H. Beggs
A method for recording elution curves on liquid column chromatography.	T. Naono
Effect of column shape on efficiency in gas chromatography preparative separations.	E. M. Taft, J. E. Booker and K. P. Dimick
Effect of injection port temperature on peak broadening in gas chromatography.	T. Haruki, T. Morii and K. Sato
Injection and vapourisation of samples in gas chromatography.	T. Johns and B. Thompson
Polymer analysis by pyrolysis-gas chromatography.	B. Groten

Polarography and Coulometric Analysis

A versatile polarographic analyser incorporating facilities for conventional d.c., rapid d.c., anodic stripping and a.c. polarography	R. Kopp
Polarographic determination of mercury, tellurium and cadmium in HgTe and CdTe alloys.	M. C. Gardels and J. C. Cornwell
Polarographic determination of cadmium in stainless steel.	H. S. Karp and G. Krapf
Dissolved oxygen measurement by constant-potential continuous coulometry.	E. L. Eckfeldt and E. W. Shaffer
Chromatographic separation and coulometric determination of magnesium, calcium and strontium.	J. W. O'Laughlin, G. J. Kamin and C. V. Banks
Controlled potential coulometric studies of oxidation state ratios of trace elements.	B. W. Conroy and O Menis
Application of controlled-potential coulometry to study of redox reactions in solution. The iridium^{III} *chlorate system.*	J. McClure and G A Rechnitz
A continuous automatic coulometric titrator.	P. Johnson, J K. Jacobsen and R. J. Drago
An advanced automatic microcoulometer for trace sulphur and halogen analysis.	J. A. McNulty and A. R Myers

Tuesday, 3 *March: Afternoon*

Symposium on Analysis of Gases and Non-Metallic Inclusions in Metals

Basic concepts of quantitative separation of alloy phases.	W. Koch
Neutron-activation analysis of metals for nitrogen, oxygen, silicon, phosphorus and sulphur.	V. P. Guinn
Analysis for non-metallic elements in metals by vacuum spark mass spectrography.	W. M. Henry and E. Blosser
Separation of oxide inclusions and nitrides.	W. Koch

Gas Chromatography—General

An ultra pure hydrogen generator for gas chromatography.	J. K. Jacobsen
Construction and performance of an IR chromatographic fraction analyser.	R. Brown and P. A. Wilks, Jr.
Design and performance of a portable ionisation chromatograph.	B. H. Andreen and D. V. Kniebes
Design considerations for an over-all high performance gas chromatograph.	M. R. Burnell
Pyrolysis gas chromatography with programmed temperature and capillary columns.	E. W. Cieplinski and L S. Ettre
A continuous extractor for analysis of trace gases in liquids.	H. L. Ashmead, B. D. Crouch and J. A. Schmit
Minimising the time for the chromatographic analysis of complex mixtures.	T. B. Rooney and W. Aznavourian

An analogue bleed line compensation system	E J Levy, D G Paul and L Mikkelson
Multiple column compensation in process gas chromatographs	E L Szonntagh and T A Gray

General Analytical Methods

Radio-release determination of vanadium	A S Gillespie, Jr. and H G Richter
Rapid radiochemical determination of americium^{III}	M H Campbell
Determination of nickel by magnetic susceptibility	J F Reed
A rapid and simple mass spectrometric procedure for detection and determination of boron	K F Sporek and R A Duvall
Indirect determination of fluorides by EDTA titration of samarium	H F. Combs and E L. Grove
Determination of ferrous oxide in ferrites	K L Cheng
Analysis of vanadium-gallium alloys based on displacement of vanadium^{V} *from its EDTA complex*	M C Gardels
Determination of silica in presence of phosphate and fluoride	F W Czech, T P Hrycyshyn and R J Fuchs
Determination of nitrate plus nitrite with special reference to air pollution	N A Huey, C C Golden and R E Boone
Precise method for assay of potassium iodate by comparison with (primary standard) arsenic trioxide	S M Tuthill, R S Sprague and W C Stoecker
Very accurately defined gas mixtures for use as primary standards	H G Guillaume and G Kanter
Use of cylinder gas mixtures to check moisture analysis instruments	H G Guillaume

Wednesday, 4 March Morning

Symposium on Chemical Applications of Far Infrared Spectroscopy

Recent developments in far infrared spectroscopy	R C Lord
Interferometrics spectrometers Their use as a practical laboratory tool	A Maki, L R Blaine and R Nelson
Far infrared interferometer for the region 20–1000 micron	J Tadayon and J N. A Ridyard
Torsional vibrations in the far infrared spectrum	W G Fateley, R K Harris, F A Miller and R E Witkowski
Hydrogen bond studies in the far infrared	R J Jacobsen and J W Brasch
On the lattice spectrum of HI	D W Robinson
Some infrared absorption studies in the 350–100 cm^{-1} *region*	F F Bentley, N T McDevitt and A Rozek

Analysis of Organic and Biological Material

Polymer MW determination by high temperature vapour pressure osmometry	J P Burger
Ion-exchange separation of acetamide from ammonium acetate and its determination	P King and J R Simmler
Polarographic determination of aldehydes and acetals in alcohols	C C Budke, D K Banerjee and F J. Miller
Polarographic determination of microgram amounts of selenium in biological material	G D. Christian and W C Purdy
Determination of dl and meso dibromosuccinic acids in aqueous solutions	R Annino and D. J Manzo
A new spectrofluorophotometer and its application to determination of biological substances	K Iwai, S. Kazawa and T Haruki
Determination of phenyl-β-naphthylamine in polyurethane	D W. Chambers, D. M. Knight and J L Myers
A study of the pi complexes of trinitrofluorenone Determination of amines, phenols and aromatic hydrocarbons	G H. Schenk, P. Wines and C Mojzis
A new automated apparatus for determination of oxygen in organic compounds	M. E Ebeling and D W Marcinkus

Thermal Analysis and Potentiometric Analysis

Differential thermal analysis using self-generated atmospheres at supra-ambient pressures	P D Garn
Application of differential thermal analysis to quantitative analysis	J Justin and N Brenner
A semi-micro thermogravimetric analyser	R W Tabeling
Determination of fluosulphonic acid in solutions containing large amounts of hydrofluoric, sulphuric and fluosulphonic acids	W E Skillmann and S A Ashworth
Differential potentiometric determination of palladium in presence of platinum	S Barabas and J Vinaric
Comparison of methanol with water as solvent in potentiometric titration of halides	H T Havacek and W B Swann

Symposium on Chemical Applications of Far Infrared Spectroscopy

The cooled germanium bolometer as a far infrared detector	C E Jones, Jr, R Hilton, J B Damrel Jr, and C C Helms
A comparison of the Golay cell and the thermocouple as far infrared detectors	G L Carlson
Far-infrared instrumentation Second generation	G T Keahl, H J Sloane and M Lu
Special sampling system for far infrared	A J Russo and E H Siegler, Jr
Low frequency infrared spectrum and vibrational assignment of glyoxal	R K Harris
Infrared absorption study of some metal oxides in the region 350 to 70 cm^{-1}	N T McDevitt, W L Baun and F F Bentley
Far infrared spectra of DL-leucine and DL-2-methylleucine	L May and M St L Eaton

Infrared Sampling and ATR

Arsenic trichloride as a solvent for NMR and IR spectroscopy	H Szymanski, A Bluemle, D Bakalik and J LaFanora
Design and application of a high temperature IR gas cell	R W Rinehart, G E Bronson and A W Crowley
Soldering non-metals to metals for construction of improved IR absorption cells	J S Ard
New IR absorption cells for macro to ultramicro quantities, utilising soldered seals of windows to metals	J S Ard
Microsampling techniques in the IR	R C Gore
ATR and specular reflectance measurements in the IR	D E McCarthy
Evaluation of some factors affecting reproducibility of ATR spectra	R L Harris
Analysis of suspended particulates with membrane filters and ATR	R W Hannah and J L Dwyer
ATR analysis of the non-volatile vehicle in unseparated paint	R J McGowan

Apparatus and Equipment for X-Ray Spectrographic Analysis

Effects of X-ray tube parameters on fluoresence analysis	H T Dryer
Effect of excitation on X-ray emission intensities	F Bernstein
Description of an automatic "twin path" X-ray fluorescent spectrometer and its applications to process control	C C Pyne
Multilayer soap films as analysing crystals in X-ray spectrometry	A J Mabis and K T Knapp
Components for X-fluorescence spectroscopy in the 5–65 Å wavelength region	J A Dunne
X-radiation analysers Some advantages and disadvantages of various operating techniques	R Torkildsen
Automatic analysis of X-ray spectrographic data	R. W Deichert
A new simultaneous spectrometer for analysis of the light and heavy elements in static and dynamic samples	J F Croke and W J Pfoser

Thursday, 5 March Morning

Instrumentation for Molecular Spectroscopy

A new routine spectrophotometer	J. J J Staunton and R. E Boostrom
An across-the-counter double beam microscope spectrophotometer	H C Duecker and E R Lippincott

Performance of the model 350 recording spectrophotometer in the far UV region.	T. J. Porro, H. T. Morse and E. S. Gillette
An improved method for measuring optical rotatory dispersion	G. R Thiel and D. C. Demoth
A precision recording absolute spectrofluorimeter.	G. K. Turner
Raman spectra of small solid samples including lattice vibrations.	D. C. Nelson and W. N. Mitchell
A near IR spectrophotometer for physical measurements.	R. C. Hawes, J. R. Eno and K. A. Wickersheim
Design development of a new filter-grating IR spectrophotometer.	C. W. Warren, A. E Chapple and R. P. Bauman
Construction and performance of a frustrated multiple internal reflectance IR spectrophotometer.	P. A. Wilks, Jr
Continuous IR instrumentation in packaging converting operations	I. L. Brazier

Emission Spectroscopy—Excitation Techniques

New studies with gas-controlled arc sources	M. Margoshes
The hollow cathode tube as a source for optical emission spectroscopy.	J. E. Paterson
A year of progress in laser excited spectroscopy	F. Brech
Characteristics of the laser source for spectral excitation	S. D. Rasberry, B. F. Scribner and M. Margoshes
The laser as a direct excitation source in analytical emission spectroscopy.	R. L. Rupp and R. Bastian
On the spectral excitation mechanism and properties of high frequency plasma-flames and d.c. plasma-jets	J. van Calker and W. Tappe

Infrared

Vibrational spectra of hexafluoroacetone.	C. V. Berney
Infrared and Raman spectrum of methyl isocyanate	R. E. Witkowski and W. G. Fateley
Asymmetric rotor band contours.	S. C. Wait
Infrared stretching frequency of Si—F bond	G. W. Miller, R. Gagne and J. Vanek
Infrared spectral studies of sulphones in the 2000–250 cm^{-1} *region.*	W. R. Feairheller, J. E. Katon and F. F. Bentley
Infrared spectra of organophosphate and organophosphorothioate pesticides.	L. Kahn and C. H. Wayman
Infrared studies of water of hydration in inorganic acetates.	S. E. Wiberley and K. J. Eisentraut
Infrared spectra of condensed thiophenes and their alkyl derivatives.	F. R. McDonald and G. L Cook

Thursday, 5 March: Afternoon

Coblentz Memorial Symposium

Coblentz memorial lecture.	G. B. B. M. Sutherland
Development of vibrational spectroscopy of high polymers	S. Krimm
Electronic spectra of polyatomic molecules.	D. A. Ramsay

Emission and Mass Spectroscopy—Instrumentation

Sensitivity and accuracy of analysis by spark source mass spectrometry.	J. S. Halliday, W. A. Wolstenholme and J. D. Waldron
Discussion of an interference spectrometer with resolution in excess of 10^6	J. O. Crote and D. C. Damoth
The lazyprobe, a device for sampling large objects non-destructively for emission spectrochemical analysis	A. Arrak, G. Chaplenko and D. O. Landon
A new visual spectroscope and its application to metal analyses.	Y. Tachibana and K. Kobayashi

Minimisation of spectral background influence and results of its automatic removal in direct reading instrumentation for stainless steels.	W. R. Kennedy
Multichannel spectrophotometer	C. Iida, K. Fuwa and B. L. Vallee
Automatic readout system for a spectrometer.	H. R. Gram, Jr.

Atomic Absorption Spectroscopy

Simultaneous multi-channel analysis by atomic absorption spectroscopy.	A. Strasheim and L. R. P. Butler
Hollow cathode lamps for atomic absorption spectroscopy.	C. Sebens, D. C. Manning and W. Slavin
Relation between the Ca-resonance line profile of the hollow cathode lamp or flame and absorption intensity in atomic absorption.	K. Yasudo and S. Matsudaira
Determination of selenium and tellurium in copper by atomic absorption spectrophotometry.	S. Sprague, D. C. Manning and W. Slavin

Friday, 6 March Morning

Symposium on Application and Instrumentation for Electron Probe Analysis

Application of electron probe to determination of concentration gradients and dispersed phase compositions.	D. M. Koffman
Electron probe and metallographic characterisation of an NBS spectrometric low alloy steel standard.	R. E. Michaelis, H. Yakowitz and G. A. Moore
Recent advances in application and instrumentation of electron probe microanalysis.	D. A. Melford
Application of the Zeibold-Ogilvie empirical quantitative calculation method to electron beam microanalysis.	S. H. Moll
Quantitative microanalysis using the A.E.I. scanning electron probe microanalyser.	P. W. Wright
Progress in design of equipment for electron probe analysis.	E. Davidson, W. E. Fowler, H. Neuhaus and W. G. Shequen
On the backscattered electron image by silicon P-N junction through the electron probe X-ray microanalyser.	S. Kimoto and H Hashimoto

Symposium on Spectra of Adsorbed Molecules

Application of ESR to study of heterogeneous catalysis.	R. J. Kokes
IR spectroscopy in study of adsorption at non-metallic surfaces.	R. S. McDonald
Application of IR spectroscopy to study of adsorption on metal surfaces.	J. W. Ward
Electronic spectra of adsorbed molecules.	H. P. Leftin
Hydrogen chemisorbed in silicon	W. A. Pliskin

Emission Spectroscopy—Applications

Spectrographic determination of silicon, phosphorus and nickel in copper-germanium alloys.	A M. Liebman, R J. Carver, L A. Tissot and J. R. Zuber
Quantitative analysis of major and minor constituents of silicate rocks and minerals by means of direct reading spectroscopy.	H. Schwander and J. B. Marling
Element calibrations by plasma jet solution spectrography.	E. H. Sirois
Methanol as a diluent for gas stabilised arc sources.	J. D. Nohe
Use of a nitrogen atmosphere to reduce matrix effects in analysis of aluminium alloys using point-to-plane spark excitation.	C. K. Matocha, J Petit and W. H. Tingle
Spectrochemical determination of cobalt, nickel, aluminium and boron in commercial acid gold baths by solution technique.	E. F. McLain and W H Wade
A direct reading spectrochemical procedure for measurement of 19 minor elements in natural water.	J. F. Kopp and R C. Kroner
Spectrochemical determination of microgram amounts of tantalum, niobium, titanium and hafnium in U_3O_8.	J. E. Scott and E. R. Shuster, Jr
Multi-element spectrographic impurity analysis of graphite.	O. V. Coble and F. V. Fair

Friday 6 March Afternoon

Electron Diffraction and Applied X-Ray Spectrography

A new high vacuum unit for electron diffraction combined with surface electron microscopy	M GRIBI, L WEGMANN and L M MOUNTFORD
X-ray fluorescent determination of cobalt, zinc and iron in organic matrices	S A BARTKIEWICZ and E A HAMMATT
Internal standard X-ray spectrographic procedure for determination of calcium, barium, zinc and lead in hydrocarbons	W E BURKE L S HINDS, G E DEODATO, E D SAGER, JR and R E BORUP
X-ray spectrographic determination of trace thorium in U_3O_8	J E. SCOTT and E R SHUSTER, JR
X-ray emission analysis of solders by solution technique	W T BARNES and D E WILSON
Combined X-ray spectrometric and IR method for determining sulphonate and sulphate concentration of detergent range alkylbenzene solutions	S D. KULLBOM, W K POLLARD and H F SMITH
Digital programming applied to steel analysis	P BRECKHEIMER and W E FOWLER

Analyses by Microwave and Infrared, Fluoresence

Microwave spectroscopy for compound identification	W O SWAN, G F CRABLE and J C WAHR
Quantitative analysis by microwave spectroscopy	G. F. CRABLE, W O. SWAN J C WAHR
Analytical applications of IR spectroscopy with gratings	G KEMMNER
Analysis of detergents in aqueous solutions using IR spectrometry	G JENKINS and D ELLIS
Chemical nature of plastic film surfaces	M W LONG, JR. and J G COBLER
Butadiene-styrene copolymer ratio by IR spectrometry	A. S WEXLER
Quantitative determination of polychloroprene microstructures by IR and NMR spectroscopy	R. C FERGUSON
Fluorescence of aromatic hydrocarbon-1,3,7,9-*tetramethyluric acid complexes in the solid state*	B L VAN DUUREN and C. E BARDI
Polarization of steroid fluoresence	H S STRICKLER and R C. GRAUER

Infrared-Spectra and Miscellaneous

Computor handling of spectra—III —Programmes for evaluation of spectrophotometer performance	A SAVITZKY and J M ROCHE
Identification of IR spectra by computor techniques	P SADTLER and J BIRKENSTOCK
A computor analysis of carbon-hydrogen stretching bands in the IR spectra of hydrocarbons.	A S. ROSENBERG and H F. SMITH
Vibrational and NMR spectra of some methyl derivatives of the guanidinium ion.	J U. LOWE, A S TOMPA and G B WILMOT
IR study of the asymmetric methylene stretching band of alkanes, alkenes, alcohols, phenylalkanes and chloro-, bromo- and iodo-alkanes	A S. ROSENBERG and H. F SMITH
New group frequency assignments	H. SZYMANSKI
An IR study of keto-enol tautomerism as a function of sample preparation.	R T CONLEY and J A CORRIGAN
Low frequency O—H . . O bond vibrations in hydrogen bonded crystals	V ANANTHANARAYANAN

Further information can be obtained from R. B. FRICIONI, Allegheny Ludlum Steel Corporation, Brackenbridge Works, River Road, Brackenbridge, Pa , U S.A

Monday-Thursday 23–26 *March* 1964. **Second International Symposium on Advances in Gas Chromatography**: Sheraton-Lincoln Hotel, Houston, Texas

The programme is as follows —

Monday, 23 *March*. *Morning*

Cross-section ionization	J. E. LOVELOCK
Concentration and mass flow sensitive detectors in gas chromatography	I. HALASZ
Specific detection of halogens by flame ionisation	A. KARMEN

Monday, 23 March Afternoon

How to obtain maximum information from a chromatogram Identification in particular	A I M Keulemans
Gas chromatographic characterisation of organic substances in the retention index system	E Kovats
The specific retentions of monofunctional organic solutes in monofunctional hexadecyl derivatives.	A B Littlewood
Pressure volume changes in a gas chromatographic column	R P W Scott

Tuesday, 24 March Morning

Gas chromatographic analysis of urinary oestrogens.	H H. Wotiz
Gas-liquid chromatography of carbohydrates and related compounds	C C Sweeley
Characterisation and estimation of organic amines of biological interest	E C. Horning
Gas Chromatographic analysis of catechol amines	C J W Brooks
A new type of liquid–liquid and liquid–solid chromatography	E Bayer

Tuesday, 24 March Afternoon

Performance of argon detectors in the field intensified current region	J Z. Knapp
Measurement and interpretation of the C terms of gas chromatography	J C Giddings
Temperature limitations of stationary phases in gas chromatography	S. J. Hawkes
A new method of measuring the diffusivity in the gas phase and the obstruction factor	J. H Knox
Effect of particle-to-column diameter ratio on band spreading.	J. C Sternberg

Wednesday, 25 March Morning

Analysis of flavours by gas chromatography	A I M. Keulemans
Analysis of sulphur compounds with electron capture/flame dual channel gas chromatography.	K. P Dimick
Thermoramic programmed gas chromatography in the separation of very complex mixtures	C Merritt, Jr
Capillary column gas chromatography Mass spectral analyses of volatiles from orange oil	R. Teranishi

Wednesday, 25 March Afternoon

Preparative columns	C. Y. Sacodynsky
Simulated distillation by gas chromatography.	L E. Green
Automatic capillary gas chromatography and sampling of distillation products	D. W. Grant
Air pollution measurements by gas chromatography and flame ionisation detection	J. L. Monkman

Thursday, 26 March Morning

Gas chromatographic study of influence of geometry and chemistry of silica surfaces on their separating and adsorption properties	A V. Kiselev
Gas chromatography using solid adsorbents	L B. Rogers
Applications of isotopic exchange in gas chromatography.	J Tadmor
Some properties of graphited black and stationary phases in gas chromatography	I. Halasz

Further information and registration forms are available from Dr A. Zlatkis, Chemistry Department, University of Houston, Houston, Texas, U.S.A.

Monday-Thursday 12-15 *October* 1964 **19th Annual International Instrument-Automation and Exhibit of Instrument Society of America:** New York City

Papers are now invited for the above meeting Individuals active in all major areas of instrumentation, including measurement, information processing and automatic control, should submit abstracts to H TYLER MARCY, Vice President-Development, General Products Division, International Business Machines Corporation, White Plains, New York, U S A (deadline 31 March) The theme of the meeting is **World Frontiers in Instrumentation.**

The **American Society for Testing and Materials** has announced the availability of the 32-volume 1964 *Book of ASTM Standards* This reflects the entire span of today's knowledge of materials and materials testing Each volume covers a specific field of interest and includes a detailed index, table of contents and numeric list of standards. Beginning with the 1964 edition, the book will be brought up to date and published annually with the various parts available on the same scheduled date each year There will no longer be supplements

PAPERS RECEIVED

Chelating radiometric titrations by ion exchange for determination of traces of metals: JIŘI STARY JAROMÍR RŮŽIČKA and ADOLF ZEMAN (29 *July* 1963).

Chromatography of p'-substituted-p-hydroxyazobenzenes on alumina-impregnated papers: R J T GRAHAM and C W STONE (9 *November* 1963)

4,5-Diamino-6-thiopyrimidine as a reagent for the spectrophotometric determination of selenium: FRANK L. CHAN (2 *December* 1963)

Rapid determination of boron in iron and steel by pyrohydrolysis and constant-current coulometry: TAKAYOSHI YOSHIMORI, TOMOO MIWA and TSUGIO TAKEUCHI. (2 *December* 1963)

Contributions to the basic problems of complexometry—XIV: Determination of zirconium, thorium and titanium in the presence of each other: RUDOLF PŘIBIL and VLADIMÍR VESELÝ. (2 *December* 1963)

New trace analysis using radioactive isotope: NOBUO SUZUKI (2 *December* 1963)

A new oxidimetric reagent: Potassium dichromate in a strong phosphoric acid medium—III: Titrimetric determination of cerium: G GOPALA RAO, P KANTA RAO and S BHANOJEE RAO (4 *December* 1963)

Precipitation of metal 8-hydroxyquinolates from homogeneous solution—VII: Indium and gallium· J P JONES, O E. HILEMAN, JR., A. TOWNSHEND and LOUIS GORDON (9 *December* 1963)

Precipitation of indium 8-hydroxyquinaldate from homogeneous solution: J PAUL JONES, ORVILLE E HILEMAN, JR , and LOUIS GORDON (9 *December* 1963)

Use of "dead stop" indication of the end-point in chelometric titrations: F VYDRA and J VORLICEK. (10 *December* 1963).

The use of a high frequency Tesla discharge tube for the determination of nitrogen and oxygen in helium: P ELMOTT and R E. WILSON. (13 *December* 1963)

Silver^{II} in aqueous perchlorate solutions: GARRY A RECHNITZ and SIDNEY B ZAMOCHNICK (24 *December* 1963)

Absorptiometric study of ammonium aurintricarboxylate as a reagent for palladium^{II}: KAILASH N MUNSHI and ARUN K. DEY (24 *December* 1963)

Colorimetric determination of cobalt^{II} by a specific spot reaction: M H HASHMI, A A AYAZ and ABDUR RASHID. (30 *December* 1963)

PUBLISHER'S ANNOUNCEMENT

REPRINTS OF REVIEW PAPERS

Reprints of the following review published in Talanta are available from Journals Department, Pergamon Press Ltd , Headington Hill Hall, Oxford, England, at 7s or $1 per copy, on a cash with order basis only

"Precipitation of Metal Chelates from Homogeneous Solution" by F. H Firsching

Talanta, 1964, Vol. 11, p. ii. Pergamon Press Ltd Printed in Northern Ireland

PAPERS RECEIVED

Zur Entmischung der Lösungsmittel bei der chromatographischen Trennung-III: Einfluss des Alkohol-Wasser-Verhaltnisses auf den Sorptionsvorgang: Jan Michal und Gerhard Ackermann. (7 *September* 1964)

A method for increasing the reproducibility of chromatographic parameters in thin-layer chromatography: L. S. Bark, R. J. T. Graham and D. McCormick. (8 *September* 1964)

The determination of beryllium by means of hexamminecobalt(III) carbonatoberyllate: R. G. Monk and K. A. Exelby. (8 *September* 1964).

Determination of sulphite and sulphurous acid by permanganate using iodine monochloride: H. G. S. Sengar and Y. K. Gupta. (8 *September* 1964).

New analytical methods based on the principle of quantitative isotope dilution and their application to radioactivation analysis: Nobuo Suzuki. (8 *September* 1964).

A coulometric titrator using potentiometric end-point determination: Gillis Johansson. (9 *September* 1964).

The EDTA titration of iron(III) in the presence of high concentrations of bismuth: H. Flaschka and J. Garrett. (15 *September* 1964).

Tetraethylenepentamine-$N,N,N',N'',N''',N'''',N''''$-hepta-acetic acid as a titrimetric reagent: Rudolf Přibil and Vladimir Veselý. (16 *September* 1964).

Amperometry with two polarisable electrodes-III: Chelometric determination of iron(III) using the indication system of two carbon electrodes: J. Vorlíček and F. Vydra. (21 *September* 1964).

Precipitation of zirconium tetramandelate from homogeneous solution: John C. Rowe, Louis Gordon and William G. Jackson. (22 *September* 1964).

Analytical applications of Solochrome Azurine B.S: New method for the specific detection of copper: Uma Tandon, S. N. Tandon and S. S. Katiyar. (26 *September* 1964).

The reflectance spectra of two solvated uranium 8-hydroxyquinolates: R. J. Magee and Louis Gordon. (26 *September* 1964).

The infrared spectra of chelate compounds-IV: A study of the uranyl chelates of 8-hydroxyquinoline in the region 5000 cm^{-1} to 250 cm^{-1}: R. J. Magee and Louis Gordon. (26 *September* 1964).

Study of zirconium reaction with arsenazo-III by means of zirconium radioactive tracer: P. Pištěk, J. Rais and M. Kyrš. (28 *September* 1964).

Talanta, 1964, Vol. 11, pp. i to iii. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

CANADA

Monday 8 *February* 1965: **First Toronto Symposium on Thermal Analysis.** Seaway Towers Hotel, Toronto, Ontario.

The programme will include a technical session, instrument exhibit, dinner and an evening panel discussion between speakers and audience. Papers to be presented will be

Experimental practices and considerations in differential thermal analysis.	P. D. Garn
Dynamic thermogravimetry.	A. E. Newkirk
Quantitative information from DTA.	R. L. Bohon
Making decomposition rate measurements on simple inorganic chemical powders by TGA.	T. R. Ingraham
Simultaneous thermal methods.	W. W. Wendlandt
Applications of thermal analysis to the study of polymers.	H. W. Holden
Application of DTA to evaluation and testing of catalysts.	W. M. Keely
Applications of DTA to petroleum chemistry.	L. Weber

Further details and registration forms may be obtained from Dr. H. G. McAdie, Ontario Research Foundation, 43 Queen's Park Cresent East, Toronto 5, Ontario.

DEUTSCHE DEMOKRATISCHE REPUBLIK

Die Unterkommission für Gas-Chromatographie bei der Sektion Chemie der Deutschen Akademie der Wissenschaften zu Berlin (Sekretariat, Leipzig 0 5, Permoserstraße 15) veranstaltet

vom 11. bis 14. *Mai* 1965 in Berlin
das
V. Symposium über Gas-Chromatographie
in der Deutschen Demokratischen Republik

Es sind Vorträge zur Methodik und Theorie der Gas-Chromatographie, zu vielfältigen anwendungstechnischen und zu apparativen Fragen vorgesehen. In den Nebenräumen des Konferenzsaales wird eine Ausstellung mit kommerziellen Geräten und Zubehör für die Gas-Chromatographie gezeigt werden.

FRANCE

Vendredi 15-1-1965: **Les développements récents de l'électrochimie organique,** par M. G. Cauquis, à 17 h 30, à l'Ecole Nationale Supérieure de Chimie de Paris, 11 rue Pierre Curie, Paris 5^{e}.

UNITED KINGDOM

Friday 8 *January* 1965: **Annual General Meeting** followed by **Editing a Scientific Journal,** J. B. Attrill: *Society for Analytical Chemistry, Western Section.* College of Advanced Technology, Bristol, 6.30 p.m.

Tuesday 19 *January* 1965: Discussion Meeting on **Analysis of Polyester Resins,** C. H. Hughes: *Society for Analytical Chemistry, Midlands Section.* University of Birmingham, Edgbaston, Birmingham 15, 7.00 p.m.

Friday 22 *January* 1965: **Annual General Meeting:** *Society for Analytical Chemistry, Scottish Section. More's Hotel,* Glasgow, 1.45 p.m.

Wednesday 27 *January* 1965: **Discussion Meeting:** *Society for Analytical Chemistry, Microchemical Methods Group. The Feathers,* Tudor Street, London E.C.4, 6.30 p.m.

Saturday 30 *January* 1965: **Annual General Meeting** followed by address of Retiring Chairman, C. J. House: *Society for Analytical Chemistry, North of England Section. Old Nags Head Hotel,* Lloyd Street, Manchester, 2.15 p.m.

At the *Twentieth Annual General Meeting* of the **Special Techniques Group** of the **Society for Analytical Chemistry** held on Tuesday, 24 November, 1964, the following Officers were elected for the forthcoming year:

Chairman: L. Brealey
Vice-Chairman: G. F. Reynolds
Secretary and Treasurer: T. L. Parkinson, Product Research Department, Beecham Food and Drink Division Ltd., Harpenden Rise, Harpenden, Herts.

British Standards Institution has announced the following *New British Standard: B.S. 1747: Methods for the measurement of air pollution: Part 2: 1964: Determination of concentration of suspended matter.* This covers the construction and use of apparatus for the determination of fine suspended particles (smoke) in the atmosphere, both by comparison with an arbitrary standard and by an absolute (weighing) method. (*Price:* 6s.)

UNITED STATES OF AMERICA

Friday-Saturday 22–23 *January* 1965: **Symposium on Hydrocarbon Analysis—Future Development and Applications:** *American Society for Testing and Materials, Committee D-2 on Petroleum Products and Lubricants.* Sheraton-Lincoln Hotel, Houston, Texas.

The following papers will be presented:

Friday Afternoon, 22 January—Where we are and a look ahead

The basis for future developments of hydrocarbon analysis.	S. S. Kurtz, Jr.
Current and future applications of hydrocarbon analysis in quality control.	L. C. Dawson

Potential analytical developments

Mass spectrometric analysis of hydrocarbons.	R. A. Brown and R. F. Stubbeman
NMR analysis of hydrocarbons and related molecules.	J. R. Zimmerman
Absorption spectroscopy of hydrocarbons.	R. L. LeTourneau
Applications of gas chromatography to hydrocarbon analysis.	J. M. Dietz

Saturday Morning, 23 January—Integrated methods approach

Gasoline and blended fuels.	D. M. G. Lawrey
Analysis of kerosine and gas-oil fractions.	R. E. Farrell, A. J. Ehrler, I. M. Nawrocka and N. M. Ingber
Aromatic hydrocarbons in high-boiling fractions.	B. J. Mair
The molecular complex comprising heavy petroleum fractions.	J. G. Erdman

Hydrocarbon and non-hydrocarbon impurities

Trace impurities in hydrocarbons used as raw materials.	R. A. Klett, L. R. Korous, R. W. King and R. W. Warren
Sulphur compounds in petroleum.	C. J. Thompson, H. J. Coleman, R. L. Hopkins and H. T. Hall
Basic nitrogen compounds in petroleum.	D. M. Jewell, R. E. Snyder and J. P. Yevich
Non-basic nitrogen compounds in petroleum.	D. R. Latham, I. Okuno and W. E. Haines
Aspects of linear elution adsorption chromatography for extraneous materials.	L. R. Snyder
Research Division IV of Committee D-2 leadership: Past, present and future	J. F. Hickerson

Further information may be obtained from R. R. Wright, A.S.T.M., 1916 Race Street, Philadelphia, Pa. 19103.

Sunday-Friday 16–21 *May* 1965: **13th Annual Conference on Mass Spectrometry and Allied Topics:** *American Society for Testing and Materials, Committee E-14 on Mass Spectrometry.* Sheraton-Jefferson Hotel, St. Louis, Missouri.

In addition to contributed papers, the Conference will include four one-half day symposia in which invited speakers will discuss particular topics. It is expected that over 100 technical papers will be presented during the five day Conference. The general subjects to be covered by the symposia, together with those individuals responsible for their arrangement, are as follows:

Photoionisation and electron impact phenomena:	V. H. Diebler
Isotope abundance and atomic weights:	A. E. Cameron
High resolution mass spectroscopy in organic analysis:	F. W. Lafferty
Instrumentation developments:	W. M. Brubaker

Contributed papers are solicited in research and development topics pertinent to mass spectrometry and ionisation phenomena. The deadline for submitted abstracts is 15 February, 1965. Contributed papers and correspondence should be sent to Dr. H. M. Rosenstock, National Bureau of Standards, Washington, D.C. 20234.

ERRATA—Volume 11

Page 438: The equations should be numbered (1) and (2) and not (2) and (3).
Page 438: In equation (2) [incorrectly numbered (3)] the term $2OH^{-}$ is unnecessary.
Page 1498, line 2 of the procedure: This should read ..... *peroxytitanate, Add potassium*.......
Page 1550, line 10 from bottom of page: For *silver-III* read *silver*-111.

American Society for Testing and Materials has announced that the following publications in the field of spectroscopy are now available:
First Supplement to the Molecular Formula List of Compounds, Names and References to Published Infrared Spectra: STP 331-A (Price $4.50; $3.15 to ASTM members).
Index of Mass Spectral Data: STP 356 (Price $18.50; $13.00 to ASTM members).
Molecular Formula List of Compound Names and References to Published Ultraviolet and Visible Spectra: STP 357 (Price $6.00; $4.20 to ASTM members).
Serial Number List of Compound Names and References to Published Infrared Spectra: STP 358 (Price $12.00; $8.40 to ASTM members).

Copies may be obtained from ASTM, 1916 Race Street, Philadelphia, Pa.

ERRATUM—Volume 11

Page 2, *line* 7: this should read *Methods have previously been described . . .*

Page 16, *line* 2 *above formula* XIX: this should read *In order to study the formation of complexes by arsenazo . . . .*

Page 18, *line* 4 *of Synthesis:* this should read *excess of nitrous acid . . .*

Page 5, *insert after Zusammenfassung*

Résumé—L'utilité analytique particulière de l'Arsenazo-III est due à sa capacité de former des complexes spécialement stables avec certains elements. Ceci permet le dosage en milieu acide fort (HCl, 10 M ou SO_4H_2) des éléments penta- ou quadrivalents: Pa, Np^{IV}, Th, Zr, Hf, U^{IV}; la reproductibilité est bonne, la manipulation facile et l'on ne note que de petites interférences dûes aux anions. La grande sensibilité (0,1–0,01 μg/ml, coefficient d'absorption molaire 50–150 × 10^3) est due au grand effet de contraste de la réaction (changement de coloration durose au vert émeraude, déplacement du maximum d'absorption de 125 mμ), nature de spectre, et enfin possibilité d'atteindre des dilutions extremes sans dissociation des complexes.

Page 41, *insert after Zusammenfassung*

Résumé—Les mélanges formés d'orthophosphate, de ses polymères linéaires supérieurs jusqu'au tridécaphosphate compris et trois polymères cycliques ont pu être séparés par chromatographie d'échange ionique. L'un des polymères cycliques (recontré dans les verres de polyphosphate . . . est probablement le pentamétaphosphate. Sa nature cyclique a été démontrée par dosage des groupes terminaux et chromatographie sur papier, mais les tentatives de dénombrement des atomes de phosphore du noyau ont échouées à cause de la très faible quantité de produit disponible. Évidence est presentée a l'appui de la supposition courante que les phosphates linéaires supérieurs sont élués suivant leur degré de polymérisation.

Page 46, *insert after Zusammenfassung*

Résumé—Une méthode pour le dosage des trimétaphosphates en présence d'oligophosphates linéaires supérieurs au trimère est developpée. Il a été démontré que l'ortho-, lt pyro-, at le triphosphate ne sent pas complètement précipitéspar l'ion baryum, tandis que les phosphates oligomères linéaires de type supérieur sont précipités quantitativement. Ces derniers sont isolés des mélanges de phosphates par chromatographie d'échange d'anions, mélangés avec des quantités connues de phosphates cycliques, at précipités par l'ion baryum. Une erreur moyenne de +0,8 et un écart standard de ±3 micromoles de phosphore de l'ion cyclique a été mise en évidence dans les mélanges contenant de 0 à 203 micromoles de phosphore sous forme de trimétaphosphate en présence de 0 à 81 micromoles de phosphare sous forme de polymères linéaires,

Page 49, *line* 1: this should read *using barium diphenylamine . . .*

Page 57, *line* 1: this should read *between ammonium ion and chloramine-T . . .*

Page 57, *insert after Zusammenfassung*

Résumé—La chloramine-T oxyde quantitativement la thiourée en urée et l'ion sulfate en milieu neutre et en milieu basique. L'oxydation est totale en 2 minutes même en présence d'un léger excès d'oxydant. L'uree et l'ion ammonium ne sont pas gênants si l'oxydation est effectuée en milieu alcalin.

PAPERS RECEIVED

Application of the measurement of thermoelectric tension in chemical analysis—I: Determination of silicon in cast iron: A. Krajina and J. Dolezal. (19 *December* 1963)

Rapid chemical analysis of silicate rocks: C. O. Ingamells. (20 *December* 1963).

The identification of metavanadate anion by infrared spectroscopy: Ileana Lukács, Constanta Strusievici and Erika Hamburg. (1 *January* 1964).

Correction for the separation of hydrogen isotopes during distillation in the determination of tritium: C. J. Riley and H. Brooks. (2 *January* 1964).

A new spot test for titanium with resacetophenone-oxime: S. G. Kadarmandalgi. (2 *January* 1964).

Potentiometric determination of vanadium as silver orthovanadate: Ram Sahai Saxena and Om Prakash Sharma. (2 *January* 1964).

Separation of Eu^{3+} and Am^{3+} by solvent extraction of their metal-chelate complexes: Tatsuya Sekine and David Dyrssen. (6 *January* 1964).

Ammonium hexanitratocerate-(IV) as an oxidising agent—III: Photometric determination of manganese^{II} through oxidation to manganese^{VII}: G. Gopala Rao, K. S. Murty and P. V. Krishna Rao. (6 *January* 1964).

A new oxidimetric reagent: Potassium dichromate in a strong phosphoric acid medium—IV: Titrimetric determination of uranium^{IV} alone and in mixtures with iron^{II}, manganese^{II}, cerium^{III} or vanadium^{IV}: G. Gopala Rao and P. Kanta Rao. (6 *January* 1964).

Contribution to the basic problems of complexometry—XV: Determination of thorium and scandium in the presence of each other: Rudolf Přibil and Vladimír Veselý. (6 *January* 1964).

Über eine neue Klasse von Adsorptionsfluoreszenzindikatoren: Antoni Basiński and Kazimierz Kiciak. (13 *January* 1964).

The feasibility of fast neutron-activation analysis for copper content determination in low silesian copper deposits: Ludwik Górski, Włodzimierz Kusch and Jolanta Wojtkowska. (13 *January* 1964).

The photosensitivity of 1,10-phenanthroline complexes with tervalent iron: J. Novák and H. Arend. (17 *January* 1964).

Cation-sensitive glass electrodes: Response to alkali metal ions in partially aquated media: G. A. Rechnitz and S. B. Zamochnick. (18 *January* 1964).

Spectrophotometric determination of anthraquinone disulphonic acid sodium salt and its reduced form: J. Dubik and J. Gallus-Olender. (20 *January* 1964).

Separation of certain cations from mixtures of various cations on ion-exchange papers—IV: Arsenic, cobalt, magnesium, manganese, mercury, nickel and vanadium: Joseph Sherma. (27 *January* 1964).

The conductimetric determination of fluorides: A. de Sousa, A. R. Nana and G. E. Cameron. (28 *January* 1964).

Determination of cobalt ions by a differential spectrophotometric method: A. Páll, G. Svehla and L. Erdey. (28 *January* 1964).

A new principle of activation-analysis separations—VII: Substoichiometric determination of traces of arsenic: A. Zeman, J. Růžička, J. Starý and E. Klečková. (28 *January* 1964).

A new principle of activation-analysis separations—VIII: Substoichiometric determination of traces of arsenic: J. Růžička, J. Starý and A. Zeman. (28 *January* 1964).

Talanta, 1964, Vol. 11, p. iv. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

The electrolytic determination of rhodium and its separation from iridium: W. A. E. McBRYDE and N. A. GRAHAM. (1 *November* 1963)

The determination of tetraethylthiuram disulphide and elemental sulphur in organic extracts using the cathode-ray polarogram: A. F. TAYLOR. (1 *November* 1963)

Substoichiometric determination of traces of metals: J. STARÝ and J. RŮŽIČKA. (4 *November* 1963)

Ultrasonic study of the complex formed by chrome azurol S with tervalent aluminium: SATYA PRAKASH, ALAKH DHARI PANDEY and JATA DHARI PANDEY. (12 *November* 1963)

A new oxidimetric reagent: Potassium dichromate in a strong phosphoric acid medium: II—Titrimetric determination of vanadium^{IV}: G. GOPALA RAO and P. KANTA RAO. (12 *November* 1963)

Microtitrimetric estimation of plutonium^{III} and hydrogen peroxide present with plutonium^{IV} in hydrochloric acid solutions: P. V. BALAKRISHNAN, A. S. GHOSH MAZUMDAR and B. N. SINGH. (12 *November* 1963)

Zur Kenntnis der Gibbs'schen Farbreaktion auf Phenole: F. FEIGL, V. ANGER and H. MITTERMANN. (13 *November* 1963)

Spectrophotometric determination of microamounts of nitrogen with organic solvent extraction: MICHIKO NAMIKI, YACHIYO KAKITA and HIDEHIRO GOTO. (15 *November* 1963)

Spot tests for chlorate, bromate and iodate: ERVIN JUNGREIS and LINA BEN-DOR. (18 *November* 1963)

Nachweis und quantitative Bestimmung von chlorierten Cyclopentadienderivaten durch Gaschromatographie und UV-Spektrophotometrie: L. LECHNER and A. SOMOGYI. (22 *November* 1963)

The Determination of Sterols: Society for Analytical Chemistry Monograph No. 2. The Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1, 1964, pp. 72, 15s: \$2.00.

Six papers originally presented at a Meeting of the Society held on May 2nd 1962.

G. S. Boyd: Determination of cholesterol for clinical purposes. J. Glover: Determination of cholesterol and 7-dehydrosterols. C. J. W. Brooks: Gas-chromatographic examination of sterols. J. H. Recourt and R. K. Beerthus: The detection of animal fats in vegetable fats by gas-chromatographic analysis. W. E. Davies, T. W. Goodwin and E. I. Mercer: The identification and determination of plant sterols. E. V. Truter and B. Bush: Determination of sterols (of wool wax) by the Liebermann-Burchardt reaction. Discussion.

Monday 30 *November–Friday* 4 *December* 1964: **Short Course on Gas Chromatography:** *Instrument Society of America.* Carnegie Institute of Technology, Pittsburgh, Pa. (see *Talanta*, 1964, **11,** August iii).

New standard samples for four groups of copper-base alloys have been issued by the **National Bureau of Standards Institute for Materials Research.** Several samples, which vary in composition, are available for each of the alloys—free-cutting brass, gilding metal, commercial bronze and aluminium brass. These standards have been prepared primarily for optical-emission and X-ray spectrochemical analysis calibrations and are in a form convenient for such use.

American Society for Testing and Materials has compiled the *Wyandotte-ASTM Punched Card Index* for finding and correlating infrared spectral absorption data using programmed tapes for computers. These tapes are used in connection with the Codes and Instructions for the Wyandotte-ASTM Punched Card System. This system facilitates the sorting of spectral data in matching spectrograms in qualitative analysis. Further information is available from Dr. L. E. KUENTZEL, ASTM, 1916 Race Street, Philadelphia, Pa. 19103.

American Society for Testing and Materials has announced the availability of the following publication:

ASTM Standards for Industrial Water and Atmospheric Analysis: Part 23 *of* 1964 *Book of ASTM Standards* (*Price* $13.00; $9.10 *to ASTM members*). This contains 98 standards of which 58 are new or have been revised since the publication of the 1960 edition of *Manual on Industrial Water-D*-19, which it replaces. The contents include industrial water—sampling and analytical methods, corrostests, methods of reporting; atmospheric analysis.

PAPERS RECEIVED

Direct titrimetric determination of iron with disodium cyclohexanediamine tetra-acetate: L. W. Marple, (2 *April* 1964).

Extraction and spectrophotometric determination of microamounts of aluminium, chromium, copper, iron, manganese, molybdenum and nickel in pure water: Use of 8-hydroxyquinaldine and dimethylglyoxime as reagents: Kenji Motojima znd Nasumi Ishiwatari. (3 *April* 1964).

Determination of scandium, yttrium, samarium and lanthanium in standard silicate rocks G-1 and W-1 by neutron-activation analysis: H. B. Desai, R. Krishnamoorthy Iyer and M. Sankar Das. (9 *April* 1964).

The determination of phosphate in the presence of calcium by the vanadomolybdate method: M. L. Richardson. (9 *April* 1964).

Successive determination of thorium and rare earths by complexometric titrations: Asim K. Gupta and Jack E. Powell. (10 *April* 1964).

Ammonium hexanitratocerate(IV) as an oxidising agent-IV: Titration of hydrazine and isonicotinic acid hydrazide at room temperature: G. Gopala Rao and P. V. Krishna Rao. (13 *April* 1964).

A study of the oxidation of manganese(II) and chromium(III) ions by silver(II) oxide: C. P. Lloyd and W. F. Pickering. (14 *April* 1964).

Some problems in the analysis of gaseous decomposition products: Pauz D. Garn. (15 *April* 1964).

Miniature magnetic stirring motor for student or analytical-control laboratories: G. Frederick Smith and A. H. Smith. (17 *April* 1964).

Ultraviolet spectra of piaselenol derivatives: Masako Toto and Kyoji Toei. (17 *April* 1964).

Mesityl oxide as an extracting agent: S. M. Khopkar. (21 *April* 1964).

Spectrophotometric determination of small amounts of tellurium with diphenylthiourea: H. Yoshida and S. Hikime. (22 *April* 1964).

An examination of the atomic absorption spectroscopy of silver: R. Belcher, R. M. Dagnall and T. S. West. (22 *April* 1964).

Systematic titration errors I: General considerations and neutralisation titrations: U. A. Th. Brinkman. (24 *April* 1964).

Rapid iodometric determination of copper in alloys with tin, antimony and other metals: J. Agterdenbos. (28 *April* 1964).

The preparation of ceric hydroxide from ammonium hexa-nitratocerate (IV) by employing kinetically controlled precipitation through urea dissociation: G. Frederick Smith. (28 *April* 1964).

Separation of bismuth from lead, copper and other elements by means of anion exchange: F. Feik and J. Korkisch. (30 *April* 1964).

A Spectrophotometric study of the complexes formed between uranyl and oxalate ions in water and water-dioxan solvents: Carz L. Griffis, Nirmal K. Shastri and Edward S. Amis. (1 *May* 1964).

A thermogravimetric pyrolysis study of the interaction of di(1,2,3-benzotriazolatium) hexacyanoosamat (IV) with certain organic amines: Ray F. Wilson and Phillip Merchant, Jr. (5 *May* 1964).

Extraction and spectrophotometric determination of rhenium(VIII) with 2-thenoyltrifluoroacetone: Anil K. De and M. Syedur Rahaman. (6 *May* 1964).

Use of masking agents in chelatometric titrations-IV: Dimercaptosuccinic acid: Tôru Mekada, Kôichi Yamaguchi and Keihei Ueno. (6 *May* 1964).

ADVISORY BOARD OF TALANTA

The Editorial Board and Publishers of TALANTA take pleasure in welcoming the following new members to the Advisory Board of the journal:

A. I. Busev	N. Tanaka
L. B. Rogers	D. W. Wilson

Also, they would like to record their sincere thanks for the help given by

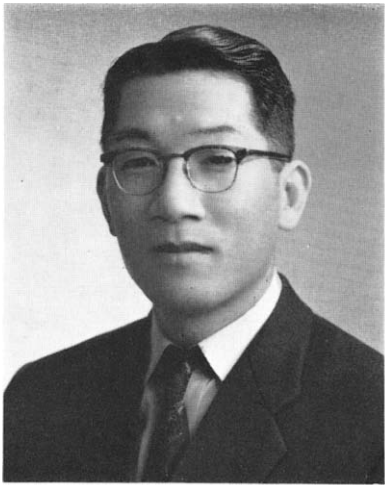
C. E. Crouthamel

who retires from the Advisory Board.

Aleksei Ivanovich Busev (U.S.S.R.) was born in 1919. He defended a thesis for the degree of Candidate in Chemistry in 1946 and a thesis for the degree of Doctor in Chemistry in 1952. From 1953 to 1955 he worked as Lecturer and subsequently as Professor in the Chair of Analytical Chemistry, M.V. Lomonosov State University, Moscow. Since 1953 he has been a member of the Commission on Analytical Chemistry of the Academy of Sciences of the U.S.S.R. Professor Busev's most important work has been on organic analytical reagents and the analytical chemistry of the rarer metals. He has published a number of monographs on these metals.

Born in 1917, LOCKHART B. ROGERS (U.S.A.) studied at Wesleyan University for his B.A. (1939) and Princeton University for his Ph.D. (1942). Thereafter he held various positions before moving to Massachusetts Institute of Technology in 1948. In 1961 he was appointed Professor and Head of the Analytical Chemistry Division at Purdue University. He is a past Secretary-Treasurer and past Chairman of the Division of Analytical Chemistry of the American Chemical Society. His main research interests are in analytical separations (electroanalytical, gas chromatographic) and trace analysis (polarography, coulometry and fluorimetry).

NOBUYUKI TANAKA (Japan) was born in 1920 and educated at University of Tokyo, where he received his B.S. (1941). He was appointed Assistant Professor at University of Tokyo in 1947 and obtained his Dr.S. there in 1948. From 1952 to 1954 he worked as a Research Fellow with Professor I. M. Kolthoff at University of Minnesota (U.S.A.). Since 1955 he has been Professor of the Department of Chemistry at Tohoku University, Sendai. His fields of research include co-ordination chemistry, electrode kinetics and electroanalytical chemistry.



DAVID W. WILSON (U.K.) graduated at Queen's University of Belfast, and obtained his M.Sc. there, having been on the Lecturing Staff for a short time before World War II. After a period in the Armaments Research Department of the Ministry of Supply, followed by a year on the Staff of the Northampton Polytechnic in London, he moved to Sir John Cass College where he eventually became Head of the Chemistry Department in 1962. He is associated with his brother, the Editor-in-Chief of TALANTA, as joint editor of the multi-volume work *Comprehensive Analytical Chemistry*. He is closely connected with the Society for Analytical Chemistry, being a past Secretary and now Chairman of its Microchemistry Group, and also an Assistant Secretary of the Society.

PUBLISHER'S ANNOUNCEMENT

REPRINTS OF REVIEW PAPERS

Reprints of the following reviews published in Talanta are available from Journals Department, Pergamon Press Ltd., Headington Hill Hall, Oxford, England, at 7s. or $1 per copy, on a cash with order basis only:

"**Precipitation of Metal Chelates from Homogeneous Solution**" by F. H. Firsching.

"**Recent Developments in the Ring Oven Technique**" by H. Weisz.

"**Absorption Indicators in Precipitation Titrations**" by R. C. Mehrotra and K. N. Tandon.

"**Radiometric Titrations**" by T. Braun and J. Tölgyessy.

"**Recent Uses of Liquid Ion Exchanges in Inorganic Analysis**" by H. Green.

Talanta, 1964, Vol. 11, p. vi. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

Analysis of ores containing lead, copper and zinc by anion-exchange chromatography and complexometry: D. Sen Gupta and R. N. Sen Sarma. (7 *August* 1964)

Remote simultaneous titration of free acid and metal ions in irradiated fuel re-processing solutions: H. H. Ph. Moeken, H. Keese and W. Heinz. (10 *August* 1964)

The methoxyl content of *Acacia* gum exudates: D. M. W. Anderson, G. M. Cree, M. A. Herbich, K. A. Karmalla and J. F. Stoddart. (10 *August* 1964)

Precipitation of copper 8-hydroxyquinaldate from homogeneous solution: R. P. Graham, E. J. Billo and J. A. Thomson. (14 *August* 1964)

Selektive Trennung von Selen(IV) durch Extraktion mit Methyläthylketon: N. Jordanov und L. Futekov. (17 *August* 1964)

Spectrophotometric investigation of the nature and stability of silver(II) in acidic sulphate media: G. A. Rechnitz and S. B. Zamochnick. (17 *August* 1964)

Applications of precipitate membranes in analytical chemistry: T. Braun and J. Tölgyessy. (18 *August* 1964)

Complexes of 3-methylgalangin with uranyl and thorium ions: Mohan Katyal and R. P. Singh. (19 *August* 1964)

Theoretical considerations in the zone melting of organic substances: Paul J. Jannke and Robert Friedenberg. (21 *August* 1964)

Selective retention of alkali metals on cation-exchange resin: Rapid separation of alkali metals from other metals: Eugene D. Olsen and Harold R. Sobel. (17 *August* 1964)

Relation between the shapes of titration curves of a dibasic acid and of a mixture of two monobasic acids with equal concentrations: A. A. Bugaevsky. (22 *August* 1964)

Spectrophotometric study of the iron(III) reaction with 3,5-di-iodine-salicylic acid and its utilisation in iron determination: I. C. Ciurea, Gr. Popa and C. Lazar. (1 *September* 1964)

Selective spot tests for glyoxal, pyruvic and lactic acid: F. Feigl and S. Yariv. (2 *September* 1964)

Application of steady-state controlled-potential coulometry to the study of homogeneous solution reactions: G. A. Rechnitz and J. E. McClure. (2 *September* 1964)

Eine Analysemethode des nichtwassrigen Medium: Die Bestimmung von aromatischen Aminen: László Légrâdi. (2 *September* 1964)

Talanta, 1964, Vol. 11, p. vi. Pergamon Press Ltd.

PAPERS RECEIVED

Radiometric titrations—I: Automatic titrimeter for titrations based on precipitate formation: J. Tölgyessy, V. Jeszenák, T. Braun and M. Hradil. (4 *March* 1964)

A new oxidimetric reagent: Potassium dichromate in a strong phosphoric acid medium—V: Potentiometric determination of uranium^{VI}: Reduction with excess of iron^{II} in a strong phosphoric acid medium and titration with potassium dichromate: G. Gopala Rao, P. Kanta Rao and M. A. Rahman. (10 *March* 1964).

Determination of rare earths by neutron activation with the aid of ion-exchange chromatography: Analysis of spectrally pure erbium oxide: Jerzy Minczewski and Rajmund Dybczynski. (14 *March* 1964)

Adsorption indicators in precipitation titrations: R. C. Mehrota and K. N. Tandon. (15 *March* 1964)

Co-precipitation studies of some tervalent metal ions with aluminium tris-(8-hydroxy-quinolate): S. J. Lyle and D. L. Southern. (18 *March* 1964).

Automatic amperometric titrations using a mercury cathode: Samuel A. Myers, Jr., and William B. Swann. (4 *March* 1964)

Determination of low concentrations of acetaldehyde in ethylene oxide: Herman Haglund. (23 *March* 1964)

Determination of nonmetallic compounds in steel—I: Application of differential thermal analysis-effluent gas analysis: W. R. Bandi, H. S. Karp, W. A. Straub and L. M. Melnick. (23 *March* 1964)

β-Absorption radiometric titration: J. Tölgyessy, P. Dillinger and T. Braun. (25 *March* 1964)

"Deionized" or "deioned": Rudolph Alexander Geitz. (26 *March* 1964)

Extraction and spectrophotometric determination of micro amounts of aluminium, chromium, copper, iron, manganese, molybdenum and nickel in pure water: Use of 8-quinolinol, 8-hydroxyquinaldine and dimethylglyoxime as reagents: Kenji Motojima and Masumi Ishiwatari. (3 *April* 1964)

Chromatographie Symposium II, 1962: Société Belge des Sciences Pharmaceutiques, Rue Archimède, 11, Bruxelles 4, Belgium. 1963, pp. 310. 150 B.F.

Papers presented at the Second Symposium on Chromatography, held in Brussels 14–15 September, 1962 by the Belgian Society of Pharmaceutical Sciences.

Conferences: Chromatographie sur papier et en couche mince des alcaloïdes et des flavonoïdes: Récentes acquisitions sur l'identification chromatographique des oses et oligosaccharides: Polyamidchromatographie: Gas-liquid chromatography: a compact gas-radio chromatogram.

Communications: Les procédés d'étude de la structure des glycoprotéides: Sur la séparation chromatographique sur papier des ions; magnésium, calcium, sodium et potassium; applications aux eaux minérales: Dünnschicht-verteilungschromatographie der Plastidenpigmente: Concernant la séparation des amino-acides par chromatographie en phase gazense: Chromatographie des acides désoxyribonucléiques sur papier de diéthylaminoéthyl-cellulose: Chromatography and electrochromatography of gastric and duodenal extracts: The detection of lipoproteins after electrochromatography: Étude chromatographique de dérivés substitués du lysozyme: Étude comparative des hémoglobines humaine, de lapin et de poule: Fractionnement des protéines soluble du jaune d'oeuf de poule: Dünnschichtchromatographie von Tricarbonsäurezyklus-substraten mit Autoradiographie: Radiochromatographie sur Dowex des acides aminés iodés du sérum: Chromatographic separation of the components of staphylomycin: Considérations sur l'analyse chromatographique des sulphamides: Papierchromatographische Trennung der gebraüchlichen Kationen: Chromatography of Doriden (α-phenyl-α-ethyl glutarimide) in postmortem material on coated glass sheets: Die Dünnschicht-Chromatographie als Analysenmethode zur Untersuchung lipophiler sekundärer Pflanzeninhaltsstoffe unter besonderer Berücksichtigung der Harze und Balsame: Récherches chromatographiques sur les acides aminés libres des vins naturels: Chromatographie de flavonoïdes sur échangeurs d'ions: Dünnschichtchromatographie von Phosphatiden, Glykolipiden und Ubicenonen: Chromatographie sur verre sablé et muni de couches minces: Utilisation de la poudre de verre en chromatographie sur couche mince: The Unikit: an apparatus and Manual for the teaching of chromatography and electrophoresis on paper: The adsorption system in column and thin-layer chromatography; recent results: Les applications de l'automation à la séparaton chromatographique et au dosage des acides aminés, peptides et protéines: Spectrofluorimetric identification of chromatographically separated plastid pigments: Les cétoses de l'urine: Chromatographie des protéines urinaires: Fractionnement chromatographique des hétérosaccharides du colostrum humain: The biosynthesis of unsaturated fatty acids in plant systems: Dünnschichtchromatographie von Phloroglucinbutanonen:

Immunochemistry: Vol. I, No. 1, April 1964. Regional Editors: Dan H. Campbell, Alain Bussard, Henri Isliker, Fred Karush. Pergamon Press, Oxford, London, New York, Paris, quarterly, pp. 63. Annual subscription rates: (A) For libraries, government establishments, research institutions, *etc.*, £15 ($40.00): (B) For individuals who place their orders directly with the publisher and certify that the Journal is for their personal use, £5 ($15.00).

J. F. Gerstein, L. Levine and H. Van Vunakis: Altered antigenicity of pepsinogen and pepsin as an index of conformational change: effect of urea and reducing agents. S. J. Singer: On the heterogeneity of anti-hapten antibodies. M. Eichlin, M. Hoy and L. Levine: Antibodies to human A_1 hemoglobin and their reaction with A_2, S, C, and H hemoglobins. J. L. Groff and F. Haurowitz: Comparison of the peptide maps of antibodies against an acidic and basic determinant group. P. J. Lachmann and C. B. Richards: Some molecular parameters of borine conglutinin. L. Gyenes and A. H. Sehon: The use of toly-lene-2,4-diisocyanate as a coupling reagent in the passive hemagglutination reaction. F. Franěk and I. Řiha: Purification and structural characterization of 5 S γ-globulin in new-born pigs.

Application of Distillation Techniques to Radiochemical Separations: James R. DeVoe, National Academy of Sciences, National Research Council, Nuclear Science Series, Radiochemical Techniques. NAS-NS 3108, Aug., 1962. Pp. 29, $0.50. (Available from the Office of Technical Services, Department of Commerce, Washington, 25, D.C., U.S.A.)

Introduction: The Distillation Process for Radiochemical Separations: Radiochemical Distillation Procedures; Hydrogen; Rare Gases; Carbon, Nitrogen and Oxygen; Halogens; Alkali Metals; Silicon; Phosphorus; Sulfur; Alkaline Earths, Rare Earths and Yttrium; Vanadium; Chromium; Manganese; Germanium, Arsenic, Antimony and Tin; Selenium and Tellurium; Ruthenium, Osmium, Technetium, Rhenium; Rhodium and Silver; Cadmium; Indium; Gold; Mercury; Lead; Bismuth; Polonium; Astatine; Uranium: References (66).

Interpretation of Mass Spectra of Organic Compounds: HERBERT BUDZIKIEWICZ, CARL DJERASSI and DUDLEY H. WILLIAMS. Holden-Day, Inc., San Francisco, U.S.A., pp. xiii + 271, 1964, $8.75.
Aliphatic and monocyclic carbonyl compounds: Alcohols: Ethers, thioethers and mercaptans: Amines and amides: Cyclic amines: Aliphatic cyanides and isothiocyanates: Alkyl halides: Bicyclic ketones: Aromatic hydrocarbons and functional derivatives: Tropones and tropolones: Aromatic heterocyclics: Index.

Controlled Potential Analysis: GARRY A. RECHNITZ. International Series of Monographs on Analytical Chemistry, Volume 13. Pergamon Press. Ltd., Oxford, London, New York, 1963, pp. 85, 35s.
Introduction: Theory: Apparatus and Techniques: Analytical Applications: Author Index: Subject Index.

Titrimetric Organic Analysis, Part I: Direct Methods. M. R. F. ASHWORTH. (Chemical Analysis, Volume 15, Editors, P. J. ELVING and I. M. KOLTHOFF.) Interscience Publishers (John Wiley and Sons) New York, London, Sydney, Pp. xx + 501, 132s.
Introduction: *Section* 1; Titration Procedure; Physical properties and measurements in end-point determination: (A) Light absorption, (B) Electrical properties, (C) Temperature, (D) Other physical properties; Automatic titration; Reactions used in the direct titration of organic compounds; Examples of direct titration of organic compounds: *Section* 2; Reagents (117 categories) used in direct titration of organic compounds: *Section* 3; Index to functional groups and compound classes (105 entries): Indexes.

Handbuch der Kolorimetrie, Band II: Kolorimetrie in der Pharmazie: BOHUMIL KAKÀČ and ZDENĚK J. VEJDĚLEK. Übersetz von E. HACHOVÁ. VEB Gustav Fischer Verlag, Jena, DDR., 1963, pp. xv + 1128, £7 1s. 0d.
I. Synthetische Verbindungen: *Acyclische Verbindungen*; Kohlenwasserstoffe und Derivate, Oxyverbindungen, Oxoverbingungen, Säuren und ihre Funktionsderivate, Amine, Aminoalkohole: *Isocyclische Verbindungen*; Oxyverbindungen, Oxoverbindungen, Säuren und ihre Funktionsderivate, Sulfonsäuren und ihre Funktionsderivate, Amine, C-As und C-Hg-Verbindungen: *Heterocyclische Verbindungen*; 10, 1N, 2N, 3 und mehr N, 10(S) + 1N, 10(S) + 2N.

III. Steroïde
IV. Einige anorganische anionen.
Monographienverzeichniss (1 S.): Autorenregister (41 S.): Synonymregister (34 S.): Sachregister (48 S).

Radioactive Isotope Dilution Analysis: The Radiochemical Centre, Amersham, Buckinghamshire, England, 1964, pp. 12, free on application.
Introduction: Laboratory and material requirements: Principle: Developments in dilution analysis; derivative dilution; saturation analysis: Inorganic applications: Conclusion: References (25).

Practical Optical Crystallography: N. H. HARTSHORNE and A. STUART. Edward Arnold (Publishers) Ltd., London, England, 1964, pp. vii + 326, 40s.
The morphology of crystals: The optical properties of crystals: The polarising microscope: The microscopic examination of crystals; A. Orthoscopic observations ("parallel" light); B. Conoscopic observations ("convergent" light): The stereographic projection: Preparation, mounting and manipulation of material: Determining optical crystallographic properties; some practical examples: Appendix I; Books recommended for further reading: Appendix II; Tables and collection of optical crystallographic data: Appendix III; Sources of certain material mentioned in the text: Index: Folding chart; nomogram for determination of refractive indices.

Talanta, 1964, Vol. 11, p. x. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

A review of recent uses of liquid ion exchangers in inorganic analysis: H. GREEN. (27 *June* 1964).

Coprecipitation kinetics—I: Coprecipitation of lead with barium sulphate; DAVID H. KLEIN and BERNARDO FONTAL. (6 *July* 1964).

5,5′-Thiodisalicyclic acid as an analytical reagent: MARY L. GOOD and SURESH C. SRIVASTAVA. (16 *July* 1964).

Reaction of boric acid with pyrocatecholphthalein: VENCESLAV PATROVSKY. (20 *July* 1964).

The determination of copper in sea water by atomic-absorption spectroscopy: ROBERT J. MAGEE and A. K. MATIOR RAHMAN. (21 *July* 1964).

An investigation of complex formation reactions and their analytical applicability—I: Evaluation of constants of equilibria involved in sparingly soluble complex formation: A. DUTTA AHMED. (22 *July* 1964).

Precipitation of zinc sulphide from ammoniacal solutions by thioacetamide: DAVID H. KLEIN and ERNEST H. SWIFT. (23 *July* 1964).

Precipitation of nickel sulphide from ammoniacal solutions by thioacetamide: DAVID H. KLEIN, DENNIS G. PETERS and ERNEST H. SWIFT. (23 *July* 1964).

Effect of nucleation on the rate of precipitation of metal sulphides by thioacetamide: DAVID H. KLEIN and ERNEST H. SWIFT. (23 *July* 1964).

A selective extraction system for trace amounts of silver: R. M. DAGNALL and T. S. WEST. (23 *July* 1964).

Determination of cobalt in cobalt-doped sodium chloride crystals: MARIAN E. HILLS and GERALD C. WHITNACK. (24 *July* 1964).

Direct determination of oxygen in organic compounds: Studies of various modifications: R. BELCHER, D. H. DAVIES and T. S. WEST. (25 *July* 1964).

Observations on the atomic-absorption spectroscopy of lead in aqueous solution in organic extracts and in gasoline: R. M. DAGNALL and T. S. WEST. (27 *July* 1964).

The composition of the manganese complex with thenoyltrifluoroacetone: HIROYUKI YOSHIDA, HITOSHI NAGAI and HIROSHI ONISHI. (27 *July* 1964).

Analytical applications of cacotheline—II: Determination of formal redox potentials of cacotheline-reduced cacotheline couple: G. GOPALA RAO, N. KRISHNA MURTY and V. NARAYANA RAO. (28 *July* 1964).

L'étude de l'échange ionique en présence des solvents organiques—III: L'influence du solvent organique sur le coéfficient de distribution des ions de Cs^+, de Ba^{2+} et de Zn^{2+}: CARMEN SABAU et STEFANIA SPIRIDON. (30 *July* 1964).

Ein qualitativer Trennungsgang für Uranspaltprodukte mittlerer bis langer Halbwertszeit mit Hilfe der Ringofenmethode: H. WEISZ und D. KLOCKOW. (30 *July* 1964).

The oximation of biacetyl: ORVILLE E. HILEMAN, JR. and LOUIS GORDON. (31 *July* 1964).

Une nouvelle methode pour le dosage gravimetrique de l'uranium: RALUCA RIPAN et V. SACELEAN. (31 *July* 1964).

Le titrage enthalpimetrique de quelques diamines: E. POPPER, L. ROMAN et P. MARCU. (3 *August* 1964).

Determination of beryllium by means of hexamminecobalt (III) carbonatoberyllate—I: The composition of the precipitate and its suitability as a weighing form for beryllium: R. G. MONK and K. A. EXELBY. (3 *August* 1964).

Jodgravimetrische Methoden in der organischen Elementaranalyse—I: Ein neues Reagenz zur quantitativen Umsetzung von Chlor und Brom in Jod im Verbrennungsrohr: E. KOZLOWSKI. (5 *August* 1964).

Thermoanalytical properties of analytically pure chemicals—II: Caesium salts: L. ERDEY, G. LIPTAY and S. GAL. (5 *August* 1964).

Aktivierungsanalytische Bestimmung von Molybdän in Wolfram: H. GROSSE-RUYKEN und H. G. DÖGE. (5 *August* 1964).

Talanta, 1964, Vol. 11, p. x. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

Spectrophotometric determination of fluorine in silicate rocks: LEE C. PECK and VERTIE C. SMITH. (4 *May* 1964).

Spectrophotometric determinations of mercury in selenium: EUGENE N. POLLOCK. (7 *May* 1964).

Gravimetric determination of rubidium and caesium with *N,N*-dimethylethanolammonium orotate: NAZHAT Z. BABBIE and WALTER WAGNER. (11 *May* 1964).

Quenchofluorometric analysis for fluoranthrenic hydrocarbons in the presence of other types of aromatic hydrocarbons: E. SAWICKI, T. W. STANLEY and W. C. ELBERT. (12 *May* 1964).

Some rather unusual chemical analyses: JAMES O. HIBBITS and SILVE KALLMANN. (12 *May* 1964).

Spectrophotometric determination of manganese with thenoyltrifluoroacetone: HIROSHI ONISHI and YUKIO TOITA. (12 *May* 1964).

The nucleation of lead chromate from homogeneous solution: NORTON HABERMAN and LOUIS GORDON. (13 *May* 1964).

The separation and polarographic determination of cadmium in stainless steel: HOWARD S. KARP and GEORGE KRAPE. (14 *May* 1964).

Nucleation and precipitation of silver chloride solutions: C. E. MELLISH. (14 *May* 1964).

Determination of combined carbon in aluminium nitride: V. T. ATHAVALE, S. P. AWASTHI and M. SUNDARESAN. (16 *May* 1964).

An international language?: WM. RIEMAN III. (18 *May* 1964).

The simultaneous determination of trace amounts of titanium and zirconium: J. O. HIBBITS, A. F. ROSENBERG, R. T. WILLIAMS and SILVE KALLMAN. (18 *May* 1964).

A specific method for the determination of titanium: JAMES O. HIBBITS, SILVE KALLMAN, WILLIAM GIUSTETTI and HANS K. OBERTHIN: (18 *May* 1964).

Colorimetric determination of vanadium with 4-(2-pyridylazo)-resorcinol (PAR): OMORTAG BUDEVSKY and LIDIA JOHNOVA. (18 *May* 1964).

The accuracy of gold determination by atomic absorption methods: H. KHALIFA, L. ERDEY and G. SVEHLA. (19 *May* 1964).

The accuracy of copper determinations by atomic absorption methods: H. KHALIFA, L. ERDEY and G. SVEHLA. (19 *May* 1964).

The determination of titanium, tantalum and niobium by precipitation from homogeneous solution: R. DAMS and J. HOSTE. (23 *May* 1964).

The separation and determination of tantalum and niobium by precipitation from homogeneous solution: R. DAMS and J. HOSTE. (23 *May* 1964).

The use of certain derivatives of antipyrine in the analytical chemistry of platinum metals: A. I. BUSEV and V. K. AKIMOV. (23 *May* 1964).

Gravimetric analysis of tantalocolumbites by precipitation from homogeneous solution: R. DAMS and J. HOSTE. (23 *May* 1964).

The precipitation of cadmium sulphide by thioacetamide from acid chloride solutions: DAVID V. OWENS, ERNEST H. SWIFT and DWIGHT M. SMITH. (25 *May* 1964).

Studies of the fire assay for platinum metals by lead collection: K. C. AGRAWAL, and F. E. BEAMISH. (25 *May* 1964).

Contribution to the basic problems of complexometry—XVII: Determination of zinc and cadmium in the presence of each other: RUDOLF PŘIBIL and VLADIMÍR VESDLÝ. (27 *May* 1964).

Radiochemical separation of cobalt by isotropic exchange: IQBAL H. QURESHI. (29 *May* 1964).

Response rates of cation-sensitive glass electrodes: G. A. RECHNITZ. (30 *May* 1964).

Purification of metal chelates by a zone-refining technique: KEIHEI UENO, HISAMITSU KANEKO and NORIKI FUJIMOTO. (1 *June* 1964).

Some 4-substituted *o*-phenylenediamines as reagents for selenium: MOTOHARU TANAKA and TAKUJI KAWASHIMA. (2 *June* 1964).

Chromogenic reactions of titanium, zirconium and hafnium with sulphodichlorohydroxydimethyl fuchson dicarboxylic acid (chrome azurol S) and their application to analysis: SHIB DAS BISWAS, ROSHAN LAL SETH and ARUN K. DEY. (3 *June* 1964).

Colour reagents for the spectrophotometric determination of rare earth elements in the presence of traces of thorium: SHIGERU KATSUMATA. (4 *June* 1964).

Talanta, 1964, Vol. 11, pp. xi to xii. Pergamon Press Ltd. Printed in Northern Ireland

AUTHOR INDEX

PUBLISHER'S ANNOUNCEMENT

REPRINTS OF REVIEW PAPERS

Reprints of the following reviews published in Talanta are available from Journals Department, Pergamon Press Ltd., Headington Hill Hall, Oxford, England, at 7s. or $1 per copy, on a cash with order basis only:

"Precipitation of Metal Chelates from Homogeneous Solution" by F. H. Firsching.

"Recent Developments in the Ring oven Technique" by H. Weisz.

Monday-Thursday 12-15 *October* 1964 **19th Annual International Instrument-Automation and Exhibit of Instrument Society of America:** New York City

Papers are now invited for the above meeting Individuals active in all major areas of instrumentation, including measurement, information processing and automatic control, should submit abstracts to H TYLER MARCY, Vice President-Development, General Products Division, International Business Machines Corporation, White Plains, New York, U S A (deadline 31 March) The theme of the meeting is **World Frontiers in Instrumentation.**

The **American Society for Testing and Materials** has announced the availability of the 32-volume 1964 *Book of ASTM Standards* This reflects the entire span of today's knowledge of materials and materials testing Each volume covers a specific field of interest and includes a detailed index, table of contents and numeric list of standards. Beginning with the 1964 edition, the book will be brought up to date and published annually with the various parts available on the same scheduled date each year There will no longer be supplements

---

PAPERS RECEIVED

Chelating radiometric titrations by ion exchange for determination of traces of metals: JIŘI STARY JAROMÍR RŮŽIČKA and ADOLF ZEMAN (29 *July* 1963).

Chromatography of p'-substituted-p-hydroxyazobenzenes on alumina-impregnated papers: R J T GRAHAM and C W STONE (9 *November* 1963)

4,5-Diamino-6-thiopyrimidine as a reagent for the spectrophotometric determination of selenium: FRANK L. CHAN (2 *December* 1963)

Rapid determination of boron in iron and steel by pyrohydrolysis and constant-current coulometry: TAKAYOSHI YOSHIMORI, TOMOO MIWA and TSUGIO TAKEUCHI. (2 *December* 1963)

Contributions to the basic problems of complexometry—XIV: Determination of zirconium, thorium and titanium in the presence of each other: RUDOLF PŘIBIL and VLADIMÍR VESELÝ. (2 *December* 1963)

New trace analysis using radioactive isotope: NOBUO SUZUKI (2 *December* 1963)

A new oxidimetric reagent: Potassium dichromate in a strong phosphoric acid medium—III: Titrimetric determination of cerium: G GOPALA RAO, P KANTA RAO and S BHANOJEE RAO (4 *December* 1963)

Precipitation of metal 8-hydroxyquinolates from homogeneous solution—VII: Indium and gallium· J P JONES, O E. HILEMAN, JR., A. TOWNSHEND and LOUIS GORDON (9 *December* 1963)

Precipitation of indium 8-hydroxyquinaldate from homogeneous solution: J PAUL JONES, ORVILLE E HILEMAN, JR , and LOUIS GORDON (9 *December* 1963)

Use of "dead stop" indication of the end-point in chelometric titrations: F VYDRA and J VORLICEK. (10 *December* 1963).

The use of a high frequency Tesla discharge tube for the determination of nitrogen and oxygen in helium: P ELMOTT and R E. WILSON. (13 *December* 1963)

Silver^{II} in aqueous perchlorate solutions: GARRY A RECHNITZ and SIDNEY B ZAMOCHNICK (24 *December* 1963)

Absorptiometric study of ammonium aurintricarboxylate as a reagent for palladium^{II}: KAILASH N MUNSHI and ARUN K. DEY (24 *December* 1963)

Colorimetric determination of cobalt^{II} by a specific spot reaction: M H HASHMI, A A AYAZ and ABDUR RASHID. (30 *December* 1963)

Volume 10

Page 1088, Table I: For Compound XIII, under the heading *Ar* for *3-Me-4-OH-*C_6H_3 read *3-MeO-4-OH-*C_6H_3.
Page 1088, Table I: For compound *XIII* read *XIV*; for compound *XIV* read *XV*; for compound *XV* read *XIII.*

Volume 11

Page 2, line 7: This should read *Methods have previously been described . . .*
Page 5: Insert after Zusammenfassung

Résumé—L'utilité analytique particulière de l'Arsenazo-III est due à sa capacité de former des complexes spécialement stables avec certains éléments. Ceci permet le dosage en milieu acide fort (HCl, 10 M ou SO_4H_2) des éléments penta- ou quadrivalents: Pa, Np^{IV}, Th, Zr, Hf, U^{IV}; la reproductibilité est bonne, la manipulation facile et l'on ne note que de petites interférence dûes aux anions. La grande sensibilité (0,1–0,01 μg/ml, coefficient d'absorption molaire 50–150 × 10^3) est due au grand effet de contraste de la réaction (changement de coloration du rose au vert émeraude, déplacement du maximum d'absorption de 125 mμ), nature de spectre, et enfin possibilité d'atteindre des dilutions extremes sans dissociation des complexes.

Page 7, line 2 from bottom: For *TR* read *rare earths.*
Page 16, line 2 above formula XIX: This should read *In order to study the formation of complexes by arsenazo III . . . .*
Page 18, line 4 of Synthesis: This should read *excess of nitrous acid . . .*
Page 41: Insert after Zusammenfassung

Résumé—Les mélanges formés d'orthophosphate, de ses polymères linéares supérieurs jusqu'au tridécaphosphate compris et trois polymères cycliques ont pu être séparés par chromatographie d'échange ionique. L'un des polymères cycliques (recontré dans les verres de polyphosphate . . . est probablement le pentamétaphosphate. Sa nature cyclique a été démontrée par dosage des groupes terminaux et chromatographie sur papier, mais les tentatives de dénombrement des atomes de phosphore du noyau ont échouées à cause de la très faible quantité de produit disponsible. Évidence est presentée a l'appui de la supposition courante que les phosphates linéaries supérieurs sont élués suivant leur degré de polymérisation.

Page 46: Insert after Zusammenfassung

Résumé—Une méthode pour le dosage des trimétaphosphates en présence d'oligophosphates linéares supérieurs au trimère est developpée. Il a été démontré que l'ortho-, le pyro-, at le triphosphate ne sont pas complètement précipités par l'ion baryum, tandis que les phosphates oligomères linéares de type supérieur sont précipités quantitativement. Ces derniers sont isolés des mélanges de phosphates par chromatographie d'échange d'anions, mélangés avec des quantités connues de phosphates cycliques, et précipités par l'ion baryum. Une erreur moyenne de + 0,8 et un écart standard de ±3 micromoles de phosphore de l'ion cyclique a été mise en évidence dans les mélanges contenant de 0 à 203 micromoles de phosphore sous forme de trimétaphosphate en présence de 0 à 81 micromoles de phosphore sous forme de polymères linéares,

Page 49, line 1: This should read *using barium diphenylamine . . .*
Page 57, line 1: This should read *between ammonium ion and chloramine-T . . .*
Page 57: Insert after Zusammenfassung

Résumé—La chloramine-T oxyde quantitativement la thiourée en urée et l'ion sulfate en milieu neutre et en millieu basique. L'oxydation est totale en 2 minutes même en présence d'un léger excès d'oxydant. L'urée et l'ion ammonium ne sont pas gênants si l'oxydation est effectuée en milieu alcalin.

Page 340, Table III: The units in the headings to columns 6, 7 and 8 should read *V* and not *v.*

Page 421, line 21: For *molydbenum* read *molybdenum.*

Page 438: The equations should be numbered (*1*) and (*2*) and not (*2*) and (*3*).

Page 438: In equation (2) [incorrectly numbered (3)] the term $2OH^-$ is unnecessary.

Page 474, line 18 from bottom: This should read (*4-aminophenyl*)*morpholine and N*-(*4-aminophenyl*)-*piperazine.*

Page 474, line 12 from bottom: This should read . . . *and* (*vi*) *2·0 μg of* CN^-/*ml of the final solution tested.*

Page 474, line 10 from bottom: For *0·2 ml of saturated bromine water* read *2·0 ml of saturated bromine water.*

Page 474, line 9 from bottom: For *0·2 ml of arsenious acid* read *2·0 ml of arsenious acid.*

Page 474, line 7 from bottom: This should read . . . *and a 5·0-ml aliquot* . . . .

Page 475, line 9: This should read . . . *for amines Nos. 1, 5, 6, 7 and 10* (*Table III*).

Page 479, reference 15: This should read . . . *Carcinogenic and Chronic Toxic Hazards of Aromatic Amines* . . . .

Page 499, line 17: This should read . . . *by a 130-ml fraction* . . . .

Page 534, line 12 from bottom: This should read

$$\ldots K = \frac{C_{\text{solid phase}}}{C_{\text{solution}}}\Big).$$

Page 553, caption to Fig. 4: For *390°* read *340°*.

Page 563, line 2 under Fig. 11: For *450°* read *540°*.

Page 563, line 3 under Fig. 11: For *140°* read *150°*.

Page 581, line 4 under Apparatus: For *precede* read *preceed.*

Page 595, line 17: this should read *Weisse*,[26] . . . .

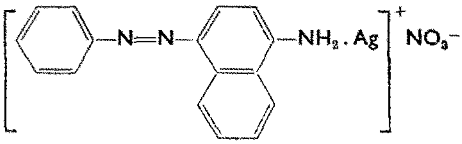
Page 599, reference 18: This should read *F. Haber u. Z. Klemensiewicz*, ...

Page 599, reference 23: This should read *F. Crotogino*, ...

Page 618, Table I: For *mv* in heading to column 3 read *mV.*

Page 623, Table II: For *0·065* absorbance in bromine water (1.0 ppm of cyanide, 30 min after mixing) read *1·065.*

Page 625, Fig. 2: For (*c*) both in the figure and caption read (*d*).
Page 740, line 16 from bottom: For *nagatively* read *negatively.*
Page 760, reference 5: This should read . . . *ibid., 1964, 11, 667.*
Page 801, line 14: For *iridium*^{IV} read *iridium*^{III}.
Page 801, line 15: For *iridium*^{III} read *iridium*^{IV}.
Page 807, line under Table VI: This should read . . . *then cooled and weighed. At most* . . .
Page 837, reference 29: This should read . . . *Talanta, 1964, 11, 703.*
Page 842, Table I: The second and third entries in column (1) of the R_f values should read $0{\cdot}13^d$ and $0{\cdot}08^d$.
Page 871, Fig. 1: The second line of the caption should read . . . *Duyckaerts, Drèze and Simon.*[14]
Page 887, line 30 of main text: This should read . . . Tiron forms with iron . . .
Page 891, The first author of the paper should read *Farhataziz.*
Page 905, line 1 of Résumé: For *sodage* read *dosage.*
Page 905, line 3 of Résumé: For *volumé-triquement* read *volumétriquement.*
Page 905, last line of Résumé: For *direct* read *directe.*
Page 908, Table I: The R_f value for Th should read *In Front 2* (*R_f value in relation to Front I is 0·9*).
Page 908, Table I: The R_f value for U should read *In Front 2* (*R_f value in relation to Front I is 0·9*).
Page 927, equation above Fig. 13: For NH_4NO_3 read NH_4VO_3.
Page 948, line 13: For *Erió* read *Erić.*
Page 953, line 4 of Résumé: For *effect* read *effet.*
Page 964, line 12 of Résumé: For *24 hau moirs* read *24 h au moins.*
Page 972, line 3 of Résumé: For *vagurs* read *vagues.*
Page 973, last line: For *ternary* read *binary.*
Page 973, last line: For *is* read *are.*
Page 975, line 3 of Résumé: For *delle* read *celle.*
Page 975, line 7 of Résumé: For *peurvent* read *peuvent.*
Page 975, line 8 of Résumé: For *ses* read *ces.*
Page 982, line 4 of Summary: This should read *is proved to result from* . . .
Page 982, line 1 of Résumé: For *résponse* read *réponse.*
Page 997, line 13 from bottom of page: This should read *mannitol, a coulometric titration* . . . .
Page 998, Fig. 5: This should read
Curve I ———— 10·8 mg of boron, 216 mA;
Curve II - - - - - - - 1·08 mg of boron, 19 mA;
Curve III — · — · — 0·50 mg of boron, 19 mA;
Curve IV — ·· — ·· — 0·10 mg of boron, 4·5 mA.
Page 998, Fig. 6: This should read
Curve I ———— 10·8 mg of boron, 216 mA;
Curve II - - - - - - - 1·08 mg of boron, 19 mA.
Page 999, Fig. 7: This should read
Curve I ———— 10·8 mg of boron, 216 mA;
Curve II - - - - - - - 1·08 mg of boron, 19 mA;
Curve III — · — · — 0·50 mg of boron, 19 mA.
Page 999, line 5 under Table II: This should read . . . *0·1 mg of boron.*
Page 1026, caption to Table III: This should read *Effect of diverse ions on the determination of selenium*[a] (*20 ml of final solution contains 30 μg of selenium*^{IV}).
Page 1036, footnote to Table II: For *Mohrs* read *Mohr's.*
Page 1036, footnote to Table II: For *pocassium* read *potassium.*
Page 1060, reference 74: The author should read *J. E. Barney, II.*
Page 1064, line above Conclusion: This should read . . . *charge:metal ion radius.*[2]
Page 1098: The structural formula for compound III should be



Page 1121: The title should read *Colorimetric determination of cobalt*^{II} . . .
Page 1136, Table I: the first entry in the last column should read *0·511 MeV.*
Page 1137, Table II: The entries in the third column should read *0·511 MeV* and *1·04 MeV.*
Page 1141, line 13: This should read *The investment cost is estimated to be $20,000 for each fully automatic measuring device. The requirement of a generator* . . .
Page 1177: This paper should read *Eingegangen am 15. Februar 1964.*
Page 1200, Table III: The heading to the fifth column should read *Found, 0·05M, ml.*
Page 1203: This paper should read *Received 10 February 1964.*

Page 1239: This paper should read *Received 18 March 1964.*
Page 1249: This paper should read *Received 9 April 1964.*
Page 1275: This letter should be dated *26 March 1964.*
Page 1284, Fig. 5: This should read $\gamma_0 = 0{\cdot}06$, *etc.*
Page 1307, line 2: For *though* read *through.*
Page 1311, reference 46: This should read . . . *1963,* ***18****, 18.*
Page 1313, line 4 of Experimental: This should read . . . *1,2-diaminocyclohexanetetra-acetic.*
Page 1314, line 2 of Apparatus: This should read . . . *photoelectric attachment* . . .
Page 1314, line 4: For UO_2^{2-} read UO_2^{2+}.
Page 1314, line 8 under Results and Discussion: This should read . . . *a molar ratio of 1:1, V:(XO)*, . . .
Page 1317, Table I: In the first column read UO_2^{2+} for UO_2^{2-}.
Page 1325, second footnote to page: Delete *Preparation*:
Page 1329: For *Table 1* read *Table I.*
Page 1350, line 14 of Results and Discussion: This should read . . . *measured in 1-ml cells* . . .
Page 1355, reference 5: The journal should read simply *Japan Analyst.*
Page 1366, line 3 above Procedure: This should read *(1 ml ≡ 100 μg of cadmium).*
Page 1367, line 7 from bottom of page: This should read . . . *chromium(VI), remaining after volatilisation, to chromium(III)* . . . .
Page 1377, line 2 under Calculations: For *MEV* read *MeV.*
Page 1406, Table I: The headings for columns two, three and four should read

Cu^{2+} taken, *mmole/100 ml*	HEDTA taken, *mmole/100 ml*	Resin, *g*

Page 1498, line 2 under the heading *Precipitation of Titanium from Homogeneous Solution:* This should read . . . *peroxytitanate. Add potassium* . . . .
Page 1550, line 10 from bottom of page: For *silver-III* read *silver-111.*
Page 1607, line 8: This should read *hydriodic acid and stannic tetra-iodide* . . . .
